Rupture of the common digital extensor tendon occurs in foals, and may be present at birth, or develops within the first few weeks of life. This condition may be primary or secondary to flexural deformities of the carpus or metacarpophalangeal joint that result in increased tension in the common digital extensor tendon.[13] It has been suggested that rupture of the common digital extensor tendon may be an inheritable condition,[14] because Arabians and Quarter Horses were overrepresented in one retrospective study.[15]

Because rupture of the common digital extensor tendon always occurs within the synovial sheath,[13] affected foals have a characteristic fluctuant swelling over the dorsolateral aspect of the carpus at the level of the distal carpal joints (Fig. 78-1).

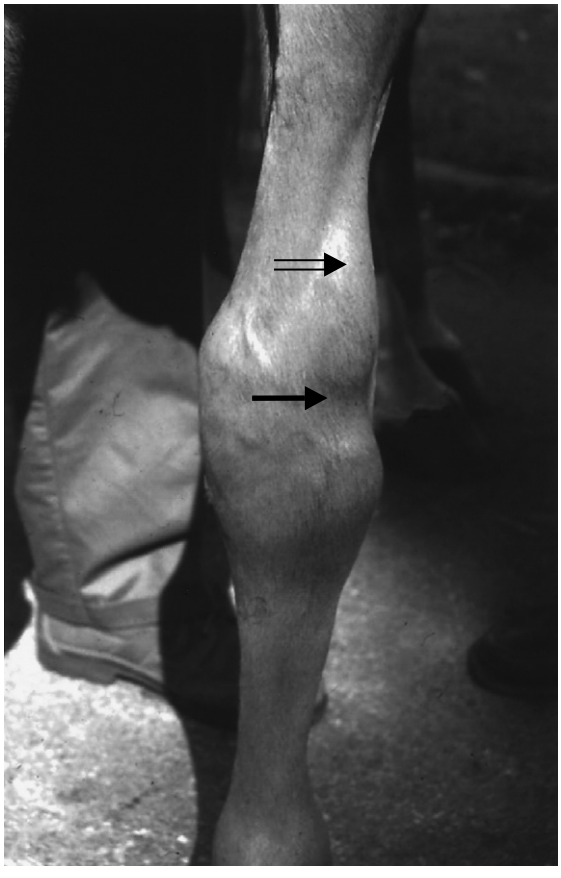

Fig. 78-1 Fluctuant swelling over the dorsolateral aspect of the carpus in a foal with rupture of the common digital extensor tendon. The injury shows the typical transverse depression in the sheath where the common digital extensor tendon has ruptured *(solid arrow)* and the bulge in the sheath where the transected distal part of the tendon is situated *(open arrow)*.

Palpation reveals fluid distention of the tendon sheath, and the ruptured ends of the common digital extensor tendon can usually be identified. Affected foals may have a normal stance, but often stand with the carpus slightly flexed (over-at-the-knee appearance), and may frequently knuckle forward on the fetlock. Most affected foals, however, quickly accommodate the gait and learn to flip the distal limb during the swing phase of the stride.

Diagnosis of rupture of the common digital extensor tendon is based on careful palpation and is confirmed by ultrasonography. Radiography of the carpus should be performed to rule out cuboidal bone malformation.

In foals with primary injuries, those without associated flexural deformities, treatment usually involves box rest and the application of well-padded bandages to support the carpus and prevent abrasion of the dorsum of the fetlock. For foals that exhibit frequent knuckling over on the fetlock, or foals with concurrent flexural deformities of the carpus, a PVC splint should be applied to the palmar aspect of the limb extending from the elbow to the fetlock. For foals with concurrent cuboidal bone malformation, tube casts from the elbow to the fetlock should be used to provide carpal support. Foals with splints usually walk comfortably, and sufficient fibrosis usually has developed after 2 to 4 weeks to allow removal of the splints. However, the foal should be maintained in padded bandages for several more weeks to maintain pressure on the area of tendon rupture to minimize the resulting blemish.

It has been suggested that the ruptured ends of the common digital extensor tendon are unlikely to reunite but adhere to the tendon sheath and that the lateral digital extensor tendon assumes the function of the common digital extensor tendon.[14] However, anecdotal evidence indicates that the tendon ends may rejoin in some horses.[16] Consequently, foals with primary rupture of the common digital extensor tendon, without concurrent cuboidal bone malformation, usually have an excellent prognosis for athletic performance with minimal blemish. Foals with concurrent cuboidal bone malformation or flexural deformities have a more guarded prognosis for athletic performance.[17]

Rupture of Extensor Carpi Radialis Tendon

Rupture of the extensor carpi radialis tendon is a rare condition of adult horses.[14] Partial rupture also may occur rarely, particularly in horses that are used for jumping.[18] Complete and partial rupture of the tendon usually occurs within the synovial sheath on the dorsal aspect of the carpus. The injury is believed to result from trauma associated with repeated overflexion of the carpus.[14] Partial rupture of the tendon has been reported to be a consequence of tendon damage caused by exostoses on the distal radius.[18]

Acute rupture of the extensor carpi radialis tendon is characterized by pain and distention of the tendon sheath. Extension and flexion of the carpus are limited, which may result in dragging of the toe.[19] With chronic injuries of the extensor carpi radialis tendon, distention of the tendon sheath persists, but this condition is usually painless unless an associated inflammatory tenosynovitis occurs.

Complete rupture of the extensor carpi radialis tendon results in excessive carpal flexion during limb protraction and consequently a higher arc of foot flight in the affected limb. Limb extension may be characterized by a double movement as the carpus suddenly snaps into extension.[20,21] Atrophy of the extensor carpi radialis muscle may be evident in chronic injuries. Partial rupture of the extensor carpi radialis tendon may be associated with mild lameness and restricted carpal flexion.[18]

Diagnosis of rupture of the extensor carpi radialis tendon may be confirmed by careful palpation, ultrasonography, and

contrast radiography.[6,7] Plain radiography should be used to evaluate associated osseous lesions.

However, horses with acute, complete rupture of the extensor carpi radialis tendon may be treated surgically. Tenosynovotomy and primary suturing of the tendon ends, or substitution of the extensor carpi obliquus tendon by tendon anastomosis, has been described.[14] However, other authors believe that surgical apposition of the tendon ends is unnecessary and advocate tenoscopy that allows characterization of the extent of the injury, debridement of the damaged tendon ends, tenolysis, and lavage of the sheath. Postoperatively the limb should be immobilized in a tube cast or splint for 2 to 4 weeks. Once the cast and sutures have been removed, passive range of movement exercises should be instituted to prevent the formation of intrathecal adhesions and to reduce carpal joint capsule fibrosis that result in a limited range of carpal flexion. The prognosis for return to athletic performance for horses with complete rupture of the extensor carpi radialis tendon is unfavorable. The prognosis for return to athletic performance for horses with partial rupture of the extensor carpi radialis tendon is also guarded to fair, but tenolysis and partial tenosynovectomy may benefit some horses.[14,19]

Enthesopathy of the Insertion of the Extensor Carpi Radialis Tendon

In the racing Standardbred, tearing of the extensor carpi radialis tendon attachment at its insertion on the proximodorsal aspect of the third metacarpal bone can cause lameness, and these tears may play a role in the cause of fractures of the dorsomedial aspect of the proximal end of the third metacarpal bone (see Chapter 38).[22]

CONDITIONS AFFECTING THE EXTENSOR TENDON SHEATHS

Tenosynovitis

Idiopathic Tenosynovitis

Idiopathic tenosynovitis may be defined as tenosynovitis with synovial effusion, but without inflammation, pain, or lameness.[14] Idiopathic tenosynovitis of the extensor tendon sheaths has been reported in foals at birth[23]; in adults the condition tends to develop insidiously. The pathogenesis in newborn foals is unknown, but in adult horses the pathogenesis is presumed to be caused by chronic trauma.[14] However, distention of the long digital extensor sheath in hindlimbs often occurs bilaterally, unassociated with any history of trauma, and is of unknown cause.

Ultrasonographic examination usually reveals anechoic fluid within the sheath. Occasionally, hypoechoic lesions are identified within the enclosed tendon, the significance of which is unknown, because lameness is rarely present.

Because idiopathic tenosynovitis usually is not associated with pain or lameness, treatment is unnecessary unless the owner is concerned about cosmesis. Treatment by injection of corticosteroids (10 to 20 mg triamcinolone acetonide, or 40 to 100 mg methylprednisolone acetate) and pressure bandaging often only provide a temporary resolution of tendon sheath effusion.[14] Anecdotal reports suggest that intrathecal injection of 4 to 15 mg of atropine sulfate, alone or with corticosteroids and hyaluronan, may cause permanent resolution of the effusion. Atropine sulfate is purported to reduce the production of synovial fluid from synoviocytes; however, its anticholinergic effects means its use has been associated with transient signs of mild colic and depression.

Acute Traumatic Tenosynovitis

Acute tenosynovitis is characterized by a rapidly developing effusion of the tendon sheath, accompanied by heat, pain, and variable lameness. Acute tenosynovitis of the extensor tendon sheaths is often caused by trauma, such as a fall, or hitting a jump with the carpus.[18] The injury is common in event horses, in which it often is not associated with lameness.[16]

Diagnosis of acute tenosynovitis is based on clinical signs and ultrasonography. Ultrasonography is useful to evaluate concurrent tendonitis of the extensor tendons and to differentiate acute tenosynovitis from other conditions that are associated with soft tissue swelling over the dorsal aspect of the carpus, including hygroma, cellulitis, synovial hernia, and effusion of the carpal joints (see Chapter 39).

Horses with acute tenosynovitis of an extensor tendon sheath are treated by rest, cold hydrotherapy, and nonsteroidal anti-inflammatory drugs. Aspiration of fluid and injection of corticosteroids is reserved for horses that do not respond to more than 1 week of conservative treatment.[24]

Infectious Tenosynovitis

Infectious tenosynovitis is characterized by dramatic synovial effusion, heat, pain, swelling, and severe lameness. Contamination from a penetrating wound is the most common cause of infectious tenosynovitis, but infection also may arise from hematogenous spread of bacteria and iatrogenic infection.[25] Infection of the common digital extensor tendon sheath also has been reported as a complication of hemicircumferential periosteal transaction.[26] After penetration of a tendon sheath, severe lameness does not become evident unless infection becomes established. As long as the tendon sheath is open and draining, then the lameness may be less severe.[27]

Once infection is established, rapid and aggressive treatment is necessary to prevent synovial membrane hyperplasia, fibrosis of the tendon sheath, intrathecal adhesion formation, and damage to the extensor tendons. Prompt recognition of infectious tenosynovitis is essential for a successful outcome. Diagnosis of infectious tenosynovitis is based on clinical signs and must be confirmed by synovial fluid aspiration and analysis. Infected synovial fluid is typically turbid and has a low viscosity, an elevated total nucleated cell count ($>30 \times 10^9$/L, with more than 90% neutrophils), and a total protein concentration of more than 40 g/L. Contrast radiography (Fig. 78-2) or ultrasonography may be useful to confirm communication between a penetrating wound and the tendon sheath, especially if horses are presented soon after injury.

The primary aim of treatment of horses with infectious tenosynovitis is the rapid elimination of bacteria and rapid return of the normal synovial environment. This is best achieved by wound debridement, lavage of the tendon sheath with copious amounts of sterile isotonic fluids, and the provision of bactericidal levels of appropriate antibiotics within the sheath.

Appropriate systemic and intra-thecal antibiotic therapy should be initiated immediately. The presence of Enterobacteriaceae most commonly is associated with tendon sheath infection caused by a penetrating wound, whereas staphylococci are most commonly identified as the cause of iatrogenic infections of the tendon sheath.[25] The most effective combination of antibiotics for the treatment of infectious tenosynovitis is amikacin and cephalosporin (>85% effective).[28] However, the cost of these drugs may be prohibitive, and other drug combinations, such as penicillin and gentamicin, may be considered. The initial selection of antibiotic may be altered according to bacterial sensitivity, if a positive culture is obtained from the synovial fluid.

Wound debridement and lavage of the affected tendon sheath with copious amounts of sterile isotonic fluids is important to reduce concentrations of bacteria and inflammatory mediators. Early in the infection, effective lavage maybe achieved by through-and-through lavage using 16-gauge needles or arthroscopic egress cannulae. In more established infectious tenosynovitis, leukocytes and fibrin accumulate

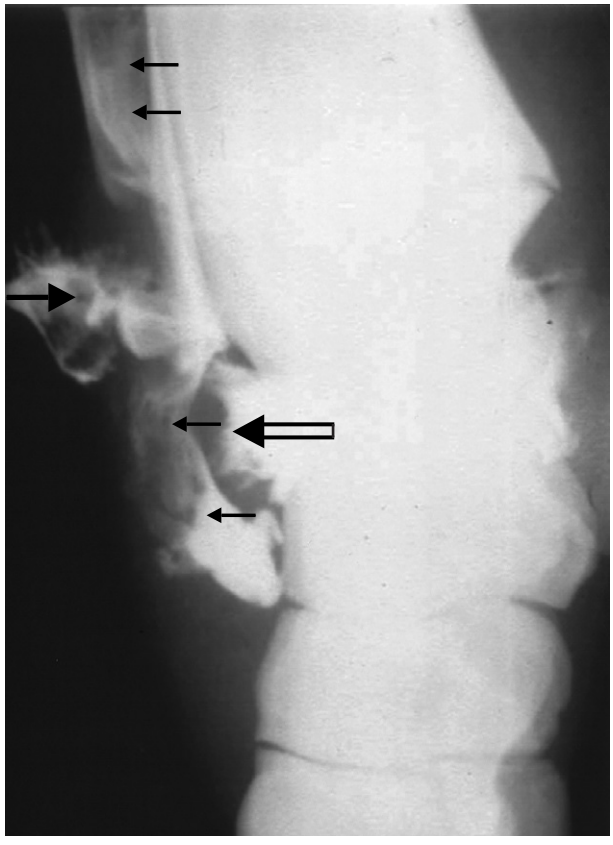

Fig. 78-2 Lateromedial radiographic view of a carpus. Dorsal is to the left. Positive-contrast medium has been injected into the extensor carpi radialis tendon sheath and antebrachiocarpal joint in a horse that had sustained a deep puncture wound over the dorsal aspect of the carpus. Radiopaque contrast agent is near the skin surface *(solid arrow)*, outside the tendon sheath *(small arrows)*, confirming penetration of the extensor carpi radialis sheath. The antebrachiocarpal joint *(open arrow)* was not involved.

within the sheath, necessitating tenoscopic debridement. If satisfactory debridement and lavage have been achieved, primary closure of the sheath may be performed. The horse should be monitored closely for lameness, and repeated synovial fluid samples should be taken at 2- to 3-day intervals to monitor for return of infection. Alternatively the sheath may be left open, or a closed suction drain system may be inserted into the sheath for further elimination of inflammatory mediators and fibrin. The drain should be left in place for 3 to 5 days, but careful management is important to prevent ascending suprainfection.

Systemic antibiotic therapy should be continued for at least 2 weeks after the resolution of clinical signs. Once the infection has been eliminated, intrathecal injection of corticosteroids or hyaluronan may be used, with physiotherapy, to reduce adhesion formation and restore the normal gliding movement of the tendon within its sheath. However, both drugs may cause immunosuppression within the sheath and may potentiate dormant infection. Early return to controlled exercise is also important to reduce intrathecal adhesion formation.

If chronic infectious tenosynovitis becomes established, exploration of the tendon sheath and radical synovectomy may be required (see the following discussion). Successful outcome has been reported after complete resection of the intrasynovial part of the common digital extensor tendon in a horse with chronic infectious tenosynovitis and tendonitis.[29]

Fig. 78-3 Chronic distention of the tendon sheath of the extensor carpi radialis in a horse with chronic tenosynovitis.

The prognosis for return to soundness after infectious extensor tenosynovitis appears to be more favorable than for infectious flexor tenosynovitis,[25,27] possibly because extensor tendons are non–weight bearing compared with flexor tendons. The prognosis for return to soundness is generally good after early surgical intervention and appropriate antibiotic therapy for horses with infectious extensor tenosynovitis.

Chronic Tenosynovitis

Chronic tenosynovitis of the extensor tendon sheaths is characterized by persistent synovial effusion, fibrous thickening of the sheath, and subcutaneous edema.[30,31] Chronic tenosynovitis results in variable, sometimes severe, lameness; restricted carpal flexion; and a gait characterized by circumduction of the affected limb during protraction.[31] However, in some horses there is no gait abnormality.

Chronic tenosynovitis commonly arises after penetrating injuries to the carpal extensor sheaths, which may result in the inoculation of foreign material or bacteria into the synovial cavity, and establishment of an infectious or non-infectious chronic tenosynovitis. The condition commonly occurs in horses jumping natural fences, because of penetration of the sheath by thorns.[31] Chronic tenosynovitis also may occur after acute tenosynovitis and may be associated with partial tendon rupture.[21,30] Chronic inflammation of the tendon sheath causes granulomatous proliferation of the synovial membrane, connective tissue deposition in the fibrous capsule, and fibrous adhesion formation between the tendon and its sheath, resulting in restriction of movement and pain on carpal flexion.[30,31]

Diagnosis of chronic tenosynovitis is based on clinical signs of effusion and thickening of the affected sheath (Fig. 78-3)

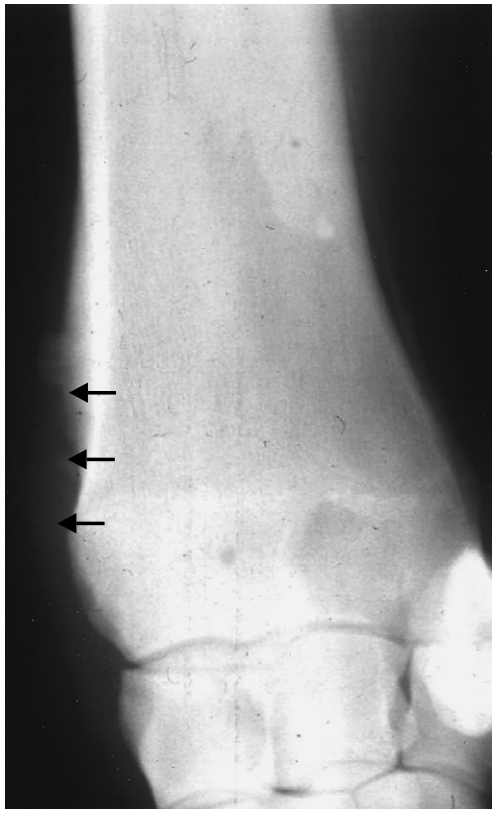

Fig. 78-4 A craniolateral-caudomedial oblique radiographic view of the distal radius in a horse with chronic tenosynovitis of the extensor carpi radialis tendon sheath. There is palisading new bone formation *(arrows)* on the craniomediodistal ridge of the radius adjacent to the tendon sheath.

and restricted carpal flexion. Radiography of the carpus often reveals palisading new bone formation on the craniodistal ridges of the radius adjacent to the affected sheaths (Fig. 78-4) and entheseous new bone formation on the dorsal aspect of the carpal bones.[31] Synovial fluid aspirates vary from serosanguineous to turbid, with an increased nucleated cell count and total protein concentration. Ultrasonography may demonstrate tendon damage, synovial membrane hypertrophy, foreign bodies, and intrathecal adhesions.

Conservative treatment with antibiotics, analgesics, intrathecal corticosteroids, and symptomatic physiotherapeutic procedures such as bandaging, cold hosing, massage, and forced exercise is usually unrewarding.[18,21,30,31] The results of surgical treatment have been good, however. Surgical treatment involves exposing the entire length of the tendon within its sheath, radical synovectomy of the hyperplastic synovial membrane, removal of intrathecal adhesions, debridement of damaged tendon, and primary closure of the fibrous layer of the tendon sheath and skin. Postoperatively the carpus should be kept bandaged and the horse confined to its box for 10 days. After suture removal on the fourteenth post-operative day, an intensive program of physiotherapy involving manual flexion and extension of the carpus and an ascending program of in-hand walking exercise should be initiated. Early passive motion to stimulate cavitation and reformation of the synovial lining and prevent adhesion formation is considered an essential part of the treatment.[31] Initially, carpal flexion is resented and administration of non-steroidal anti-inflammatory drugs and sedatives may be required. Full flexion of the carpus should be achieved by 30 days after surgery.

The prognosis for soundness after surgical exploration and radical synovectomy is excellent, but the resultant scar may cause a substantial blemish. In a retrospective study of 15 horses with chronic tenosynovitis treated by surgical exploration and radical synovectomy, all were sound and all but one horse returned to the former use.[31]

Osteochondromatosis

Synovial osteochondromatosis of the extensor carpi radialis tendon sheath has been reported. Synovial osteochondromatosis is characterized by the formation of multiple small osseous bodies within a synovial-lined structure. The cause is unclear, but it may be associated with trauma. Clinical signs include swelling on the dorsal surface of the carpus characterized by multiple, firm subcutaneous nodules and crepitus during joint movement, and lameness is usually evident. Diagnosis is confirmed by radiography and ultrasonography.[32] Although no information is available for the surgical treatment of osteochondromatosis of the extensor tendon sheaths in horses, partial synovectomy and arthroscopic removal of the osteochondral bodies has been used successfully in other synovial cavities in horses and other species.[33]

Intersynovial Fistulae

Intersynovial fistulae are uncommon, but they have been documented between the common digital extensor tendon sheath and antebrachiocarpal joint,[34] the common digital extensor tendon sheath and middle carpal joint,[14] and the extensor carpi radialis tendon sheath and middle carpal joint.[5] The cause of these fistulae is unclear, but they are considered to be traumatic in origin and may occur with carpitis or carpal fractures.[5,34] Typically, horses with intersynovial fistulae have chronic lameness and distention of the affected tendon sheath. Synovial fluid can be massaged from the joint to the tendon sheath. Diagnosis may be confirmed by contrast radiography[6] and intrasynovial analgesia. Surgical treatment is advocated in the management of intersynovial fistulae,[14] but little information concerning the prognosis of affected horses is available, because reports of this condition are rare. Surgical treatment involves exposure of the fistula, removal of redundant synovial membrane, and closure of the fibrous layers of the joint and tendon sheath.

Infectious Bursitis

Infectious bursitis may occur in any of the bursae associated with the extensor tendons over the dorsal aspect of the fetlock. The condition is seen most commonly in horses that jump natural obstacles (e.g., eventers and National Hunt horses). Typically these horses have swelling of the dorsal aspect of the fetlock (Fig. 78-5) and mild to severe lameness. Infectious bursitis may affect the subtendonous bursae or more commonly affects an acquired subcutaneous (supratendonous) bursa on the dorsal aspect of the long digital extensor tendon in the fetlock region.[35] Occasionally both bursae may communicate around the lateral or medial aspect of the long digital extensor tendon. Some horses have a severe, non–weight-bearing lameness, and this condition frequently is confused with infectious arthritis of the metacarpophalangeal or metatarsophalangeal joints. Diagnosis is confirmed by ultrasonographic examination or contrast radiography[6] and synoviocentesis. Synoviocentesis from the palmar or plantar pouch of the adjacent metacarpophalangeal or metatarsophalangeal joint should be used to rule out joint infection. Treatment consists of surgical drainage and debridement and appropriate antibiotic therapy. The prognosis for return to soundness is good.

Fig. 78-5 Prominent soft tissue swelling over the dorsal aspect of the fetlock region in the hindlimb of a horse with severe lameness. This is a supratendonous infectious bursitis and should not be confused with infectious arthritis of the metatarsophalangeal joint. Arthrocentesis of the metatarsophalangeal joint through a dorsal approach may result in iatrogenic infectious arthritis.

CHAPTER • 79

Curb

Mike W. Ross and Ronald L. Genovese

The historical definition of curb is enlargement on the plantar aspect of the fibular tarsal bone (calcaneus), caused by inflammation and thickening of the (long) plantar ligament.[1] However, by ultrasonographic evaluation, we have redefined curb as a complex of soft tissue injuries that occurs on the distal plantar aspect of the tarsus. Long plantar desmitis is only one of many injuries that causes curb. However, the term *curb* is useful to describe swelling of the distal, plantar aspect of the tarsus (excluding the calcaneal bursa and proximal aspect of the calcaneus). In the rest of this chapter, curb is used specifically to mean soft tissue swelling of the plantar aspect of the tarsus. Conformational abnormalities or bony exostoses can mimic or contribute eventually to formation of curb.

CLINICAL APPEARANCE OF CURB

The convex profile typical of curb is best seen from the side (Fig. 79-1). Careful evaluation of swelling from all perspectives, palpation, and thorough lameness examination are critical. Curb must be differentiated from other swellings of the hock, including capped hock, effusion, edema and fibrosis of the calcaneal bursa (see Chapter 80), tarsal tenosynovitis (see Chapter 77), thoroughpin (with or without involvement of the tarsal sheath), and bony enlargements of the distal hock region (see Chapter 45). Injuries of the deep digital flexor tendon (DDFT) as it courses along the plantaromedial aspect of the hock within the tarsal sheath can produce typical signs of curb, but they account for only a small percentage injuries in horses with curb.

Horses with sickle-hock conformation are said to be curby (see Chapter 4). Sickle-hock and in-at-the-hock conformation lead directly to curb, a finding most common in the Standardbred (STB) and Thoroughbred (TB) racehorse. Prognosis for STB racehorses with sickle-hock conformation and curb is worse in the trotter than in the pacer. Trotters with sickle-hock conformation are usually fast early in training and racing, but this conformation is often career limiting. Sickle-hock conformation is also undesirable in the TB racehorse. Horses with sickle-hock conformation often develop curb first, but they then independently or concomitantly develop other lameness associated with the distal hock joints. Tarsal region lameness begins with curb in 2- and 3-year-olds and progresses to osteoarthritis of the centrodistal and tarsometatarsal joints or fractures of the central tarsal bone, or more commonly the third tarsal bone.

Horses can have curby conformation without developing curb, and horses with normal hindlimb conformation can develop curb. The proximal aspect of the fourth metatarsal bone (MtIV) is often prominent in horses with sickle-hock conformation. The most dramatic example of altered joint morphology occurs in young foals with tarsal crush syndrome, the result of delayed or incomplete ossification of the tarsal cuboidal bones (see Chapter 45).

Fig. 79-1 A Standardbred racehorse with typically appearing curb. Swelling associated with the distal, plantar tarsus is centered over the centrodistal and tarsometatarsal joints. In this horse swelling was caused by superficial digital flexor tendonitis.

CLINICAL APPEARANCE OF CURB

The convex profile typical of curb is best seen from the side (Fig. 79-1). Careful evaluation of swelling from all perspectives, palpation, and thorough lameness examination are critical. Curb must be differentiated from other swellings of the hock, including capped hock, effusion, edema and fibrosis of the calcaneal bursa (see Chapter 80), tarsal tenosynovitis (see Chapter 77), thoroughpin (with or without involvement of the tarsal sheath), and bony enlargements of the distal hock region (see Chapter 45). Injuries of the deep digital flexor tendon (DDFT) as it courses along the plantaromedial aspect of the hock within the tarsal sheath can produce typical signs of curb, but they account for only a small percentage injuries in horses with curb.

Horses with sickle-hock conformation are said to be curby (see Chapter 4). Sickle-hock and in-at-the-hock conformation lead directly to curb, a finding most common in the Standardbred (STB) and Thoroughbred (TB) racehorse. Prognosis for STB racehorses with sickle-hock conformation and curb is worse in the trotter than in the pacer. Trotters with sickle-hock conformation are usually fast early in training and racing, but this conformation is often career limiting. Sickle-hock conformation is also undesirable in the TB racehorse. Horses with sickle-hock conformation often develop curb first, but they then independently or concomitantly develop other lameness associated with the distal hock joints. Tarsal region lameness begins with curb in 2- and 3-year-olds and progresses to osteoarthritis of the centrodistal and tarsometatarsal joints or fractures of the central tarsal bone, or more commonly the third tarsal bone.

Horses can have curby conformation without developing curb, and horses with normal hindlimb conformation can develop curb. The proximal aspect of the fourth metatarsal bone (MtIV) is often prominent in horses with sickle-hock conformation. The most dramatic example of altered joint morphology occurs in young foals with tarsal crush syndrome, the result of delayed or incomplete ossification of the tarsal cuboidal bones (see Chapter 45).

Fig. 79-1 A Standardbred racehorse with typically appearing curb. Swelling associated with the distal, plantar tarsus is centered over the centrodistal and tarsometatarsal joints. In this horse swelling was caused by superficial digital flexor tendonitis.

Firm, fibrous soft tissue swelling can develop just proximal to MtIV as a sequela to injection or local analgesia of the tarsometatarsal joint, presumably from local trauma, hemorrhage, or leakage into the subcutaneous tissues. Mild bony proliferation or fragmentation of proximal MtIV, or of the fourth tarsal bone, can cause focal swelling easily mistaken for curb.

Considerable variation in clinical signs occurs, and the injury cannot be categorized, or a management program and prognosis established, without thorough clinical and ultrasonographic examinations. Historically, owners and trainers consider curb to be an annoying, self-limiting problem that rarely causes lameness or poor performance, that responds to a single treatment that is uniformly effective, and that is cured once curb is treated. Most racehorse trainers are opposed to resting a horse with curb unless lameness is performance limiting, so veterinarians often are faced with management decisions without an option for even short-term rest or a reduction in training intensity. Many traditional therapies have no data to support efficacy.

Lameness ranges from none, mild, or severe depending on the structure involved and extent of injury. Lameness tends to be worse if the soft tissue structure involved is located dorsal to the superficial digital flexor tendon (SDFT) in the plantar tarsus (DDFT, long plantar ligament), if SDFT injury is diffuse, or if a mixed injury involves more than one structure. Diagnosis is straightforward in horses with obvious lameness seen at a trot in hand and painful swelling, but lameness may be evident only as a slight loss of performance or unlevelness when performing at maximum and may be perceived only by trainers, drivers, or riders. A horse with chronic curb may not exhibit signs of pain during palpation, or lameness at a trot in hand, but can show lameness at speed, and convincing a trainer that the long-term swelling is a source of pain may be difficult. The area should be palpated carefully with the limb bearing weight and flexed. Swelling may be firm and fibrous, with few signs of active inflammation, or may be warm, painful, and edematous. Acute, compliant or mushy swelling is associated with hemorrhage or other subcutaneous fluid accumulation and sometimes deeper soft tissue injury. Horses with this form of curb usually have acute, moderate to severe lameness. Horses with distal hock joint pain often exhibit a painful response when direct pressure is placed on plantar hock structures, including the SDFT, proximal aspect of MtIV, second metatarsal bone, and proximal aspect of the suspensory ligament. Often swelling is not detected in these horses. Response to upper limb flexion varies and is non-specific. Direct digital palpation followed by trotting is useful, because horses with active curbs show increased lameness.

Because horses with curb can have concomitant osteoarthritis or other problems of the lower hock joints, differentiation of the source of pain is important but difficult. Diagnostic analgesia is useful but not foolproof. If horses are lame at a trot in hand, local infiltration of local anesthetic solution subcutaneously over the curb is effective. A minimum of 20 to 30 ml of local anesthetic solution should be infiltrated along the lateral, plantar, and medial aspects of the curb. Small-gauge needles should be avoided (to avoid needle breakage), and the injection should be performed with the limb in flexion, because horses may object to several injections. If horses are not visibly lame at a trot in hand, examination at the track or under saddle should be performed. Selective intra-articular analgesia of the lower hock joint and sequential perineural analgesia to rule out the lower limb are essential. A tibial nerve block alleviates pain with curb, but it is seldom done because other common sources of pain are abolished similarly.

Radiography and scintigraphy help differentiate other sources of pain, but ultrasonography is the imaging method of choice to determine which structures are involved and the extent of damage.

APPLIED ANATOMY AND NORMAL ULTRASONOGRAPHIC EXAMINATION OF THE PLANTAR TARSUS

Plantar to the calcaneus are skin, subcutaneous tissues, a thin fibrous tissue layer, the SDFT, and the long plantar ligament. Medially the DDFT courses distally over the sustentaculum tali, within the tarsal sheath. Normally the tarsal sheath has a small amount of fluid that can be seen during ultrasonographic examination, but it is not felt. The long plantar ligament originates from the calcaneus, closely adheres to this bone, and inserts distally on the plantar surface of the fourth tarsal bone and MtIV. The plantar tarsus can be divided into zones to classify findings (Fig. 79-2) or the distance measured from the proximal aspect of the calcaneus (point of hock). Transverse and longitudinal images of both limbs should be obtained from the plantar midline, plantaromedial (to evaluate the DDFT), and slightly plantarolateral (to evaluate the distal aspect of the long plantar ligament). Measurement of cross-sectional area (CSA) is important to confirm lesions in which enlargement has occurred but with no overt fiber damage. Precise placement of the ultrasound transducer is important since the long plantar ligament changes size and shape as it courses distally. Knowledge of normal ultrasonographic anatomy is crucial (Figs. 79-3 to 79-6).

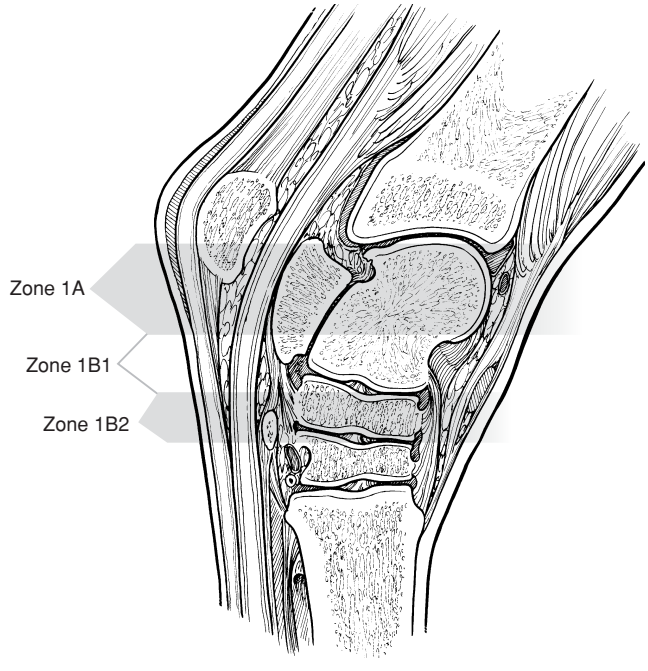

Fig. 79-2 The plantar aspect of the tarsus is divided into zones lA and lB. Because zone lB is rather large and important, the zone is sometimes subdivided into 1B1 and 1B2. An alternative technique for recording level of injury is to measure distally from the proximal aspect of the calcaneus.

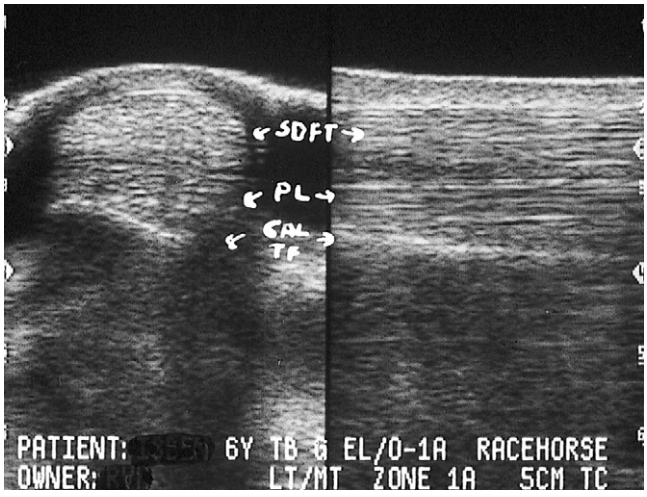

Fig. 79-3 Transverse (*left*) and longitudinal (*right*) midline ultrasonographic images at 5 cm distal to the point of the hock. A thin subcutaneous fibrous tissue layer runs along the plantar surface of the superficial digital flexor tendon. The superficial digital flexor tendon (*SDFT,* crescent shape) is narrower in a medial to lateral direction and somewhat thickened from that seen proximally. In the longitudinal scan the normal SDFT has a dense parallel fiber pattern. Deep to the SDFT the long plantar ligament *(PL)* is at full thickness (plantar to dorsal direction), is rectangular in shape, and is attached firmly to the calcaneus *(CAL)*. At this level the deep digital flexor tendon is out of view medially and must be evaluated by placing the transducer plantaromedially.

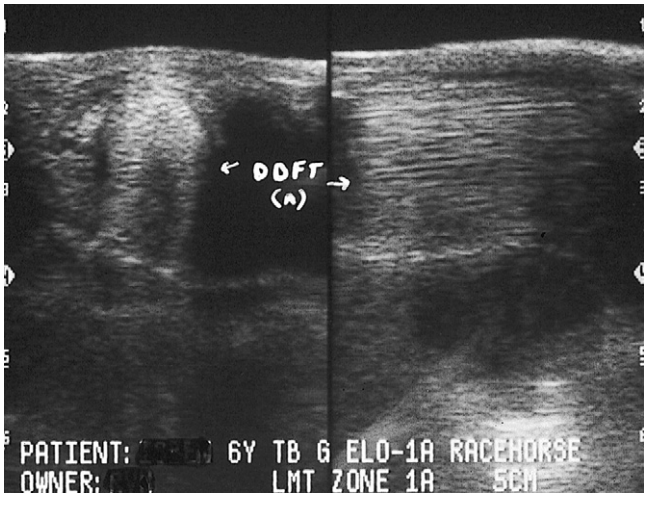

Fig. 79-4 Transverse (*left*) and longitudinal (*right*) ultrasonographic images from the plantaromedial aspect of the left hock 5 cm distal to the point of the hock. In the transverse image the tarsal sheath surrounds the deep digital flexor tendon *(DDFT)*. The tendon is oval and has a large eccentric hypoechoic region composed of residual muscle tissue, but this defect could be caused by incident angle artifact.

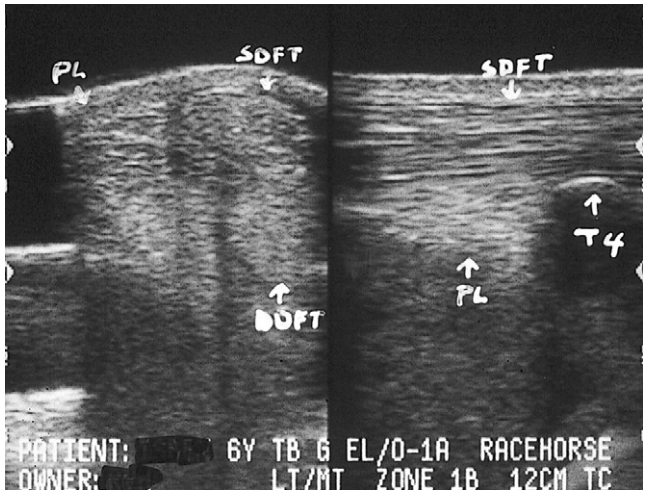

Fig. 79-5 Transverse (*left*) (medial is to the right) and longitudinal (proximal is to the left) (*right*) plantarolateral ultrasonographic images 9 cm distal to the point of the hock at the level of the fourth tarsal bone (*T4*). The long plantar ligament *(PL)* is a multi-septated ligamentous structure, and large plantar fiber bundles are not normally perfectly aligned with dorsal bundles. In transverse images the long plantar ligament normally may appear to lack echogenicity, and the size and shape changes at the insertion on the fourth tarsal bone. The long plantar ligament is wide at the insertion on the fourth tarsal bone (longitudinal scan).

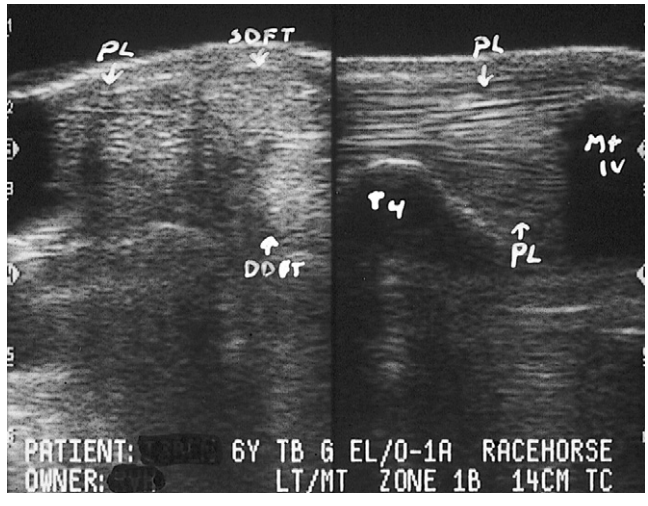

Fig. 79-6 Transverse (*left*) (medial is to the right) and longitudinal (*right*) (proximal is to the left) plantarolateral ultrasonographic images 14 cm distal to the point of the hock, just distal to the insertion of the long plantar ligament *(PL)* on the fourth tarsal bone *(T4)*. The long plantar ligament is thick in the plantar to dorsal direction. A midline image would show the superficial digital flexor tendon *(SDFT)* and deep digital flexor tendon *(DDFT)*, but at this level a plantarolateral transducer placement is needed to assess the long plantar ligament. In the longitudinal image the long plantar ligament is seen attaching to the fourth tarsal bone proximally and fourth metatarsal bone *(MtIV)* distally.

CURB: A COLLECTION OF SOFT TISSUE INJURIES

Seventy-three horses with a curb were examined using ultrasonography, comprising 58 (80%) racehorses (48 STB and 10 TB) and 15 non-racehorse sport horses (hunters, jumpers, Tennessee walking horses, reining horses, Three-Day Event horses, barrel racing, and general-use horses).[2] Twenty-two horses (30%) had thickening, inflammation, swelling, or fluid accumulation in peritendonous and periligamentous tissues, without obvious injury of the SDFT, DDFT, and long plantar ligament. Eighteen horses (25%) had a combination of fluid accumulation of peri-tendonous and periligamentous tissues with superficial digital flexor tendonitis, and 25 (34%) had a combination of fluid accumulation of peritendonous and periligamentous tissue and long plantar ligament desmitis. Six horses (8%) had fluid accumulation of peritendonous and periligamentous tissues and DDFT injury, and two horses (3%) had peritendonous and periligamentous tissue infection. This incidence of injury is considered typical.

Curb is primarily an injury of racehorses, especially STBs. Gait, speed, and training methods differ between racing breeds, and STB racehorses have a higher prevalence of conformational abnormalities, such as sickle hock and in at the hock. Weight and load distribution are considerably different. Curb develops frequently in STB racehorses that train and race on a thin, near-hard surface, contrary to many soft tissue injuries that result from work on deep surfaces. Many curbs develop in young STB racehorses early in training. In some instances track surfaces are inconsistent and perhaps slippery, since early training is done in the winter months. Non-racehorse sport horses develop curb, but only sporadically, and lameness is often moderate to severe and most commonly is associated with peritendonous and periligamentous tissue swelling, although other structures are sometimes involved.

Peritendonous and Periligamentous Inflammation

Peritendonous and periligamentous tissue swelling occurs alone or with abnormalities of one or more of the SDFT, DDFT, or long plantar ligament. Peritendonous and periligamentous tissue injury can occur secondary to direct trauma from horses kicking a wall or trailer door, or rarely from a direct kick or interference injury from another horse, resulting in acute, large, painful swelling. Ultrasonographic examination most often reveals frank hemorrhage and edema. More commonly the horse has neither history of trauma nor clinical findings suggesting trauma. We suspect that peritendonous and periligamentous tissue injury reflects excess loading or strain of the plantar tarsal soft tissue structures from race training. Extensive jogging of young STBs early in training may cause dramatic increase in hock loading, and tension and overstretching of thin peritendonous and periligamentous tissue occurs. Peritendonous and periligamentous tissue injury may be an accumulated overload injury and may develop secondarily to other lameness. The peritendonous and periligamentous tissue is most plantar in location, is thin, may be most vulnerable to injury from abnormal strain, and may be the first tissue in progression to be injured. Conformational abnormalities may predispose the horse to such injuries. The cause of such soft tissue injury in mature non-racehorses is unknown, and although swelling can develop with relatively mild lameness, more often lameness is moderate to severe.

Clinical examination reveals localized soft tissue swelling, often with heat and pain on palpation, with or without lameness. Previous application of liniments or blisters, or pin firing may create sore skin and considerable soft tissue swelling. Ultrasonographic findings depend on the duration of the injury. Acute lesions have an accumulation of anechoic fluid subcutaneously; in more chronic injuries, swelling is from subcutaneous echogenic material (Figs. 79-7 to 79-9). The SDFT, DDFT, and long plantar ligament should be inspected carefully, but they are frequently normal.

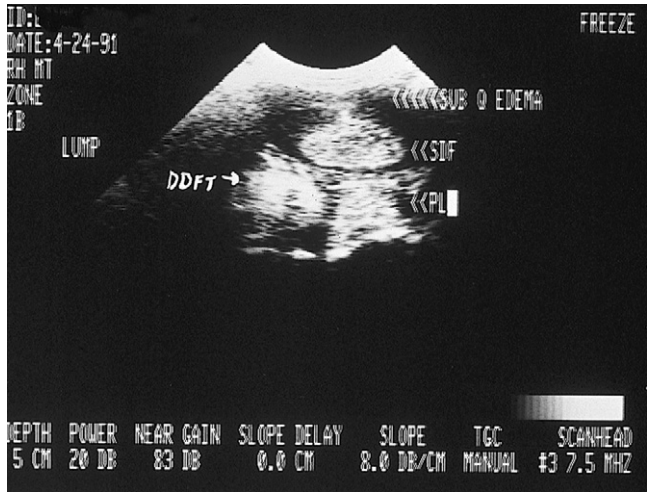

Fig. 79-7 Transverse midline ultrasonographic image (medial is to the left) of the plantar aspect of the hock of 2-year-old Standardbred gelding obtained in zone lB. There is subcutaneous edema *(arrows)* and thickening. The superficial digital flexor tendon *(SDFT)*, deep digital flexor tendon *(DDFT)*, and long plantar ligament *(PL)* were normal. This horse was managed using a peritendonous injection of corticosteroids.

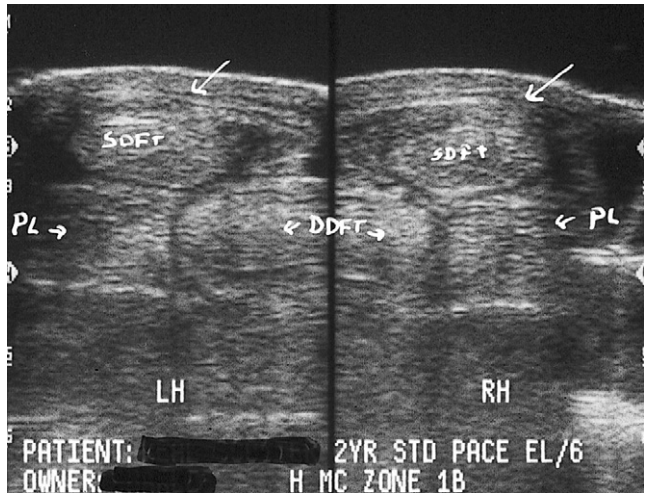

Fig. 79-8 Transverse midline ultrasonographic images of the left hindlimb (*left*) and right hindlimb taken in zone lB in 2-year-old Standardbred colt pacer with bilateral curb showing subcutaneous fibrosis *(arrows)* (*LH*, *RH*) and mild fluid accumulation (*RH*) typical of that seen in curb from peritendonous and periligamentous tissue injury.

Management depends on the degree of lameness, the stage of training, the race or competition schedule and the owner's or trainer's wishes. Blistering is used widely, but we question its value. Although not supported by scientific evidence, thermocautery (pin firing) appears to be an effective management tool, perhaps because it enforces rest. However, prolonged rest is rarely necessary in racehorses, and many horses can be managed by local injection of corticosteroids (triamcinolone acetonide, 9 mg) without significant interruption of training. More than one treatment may be required if the swelling and

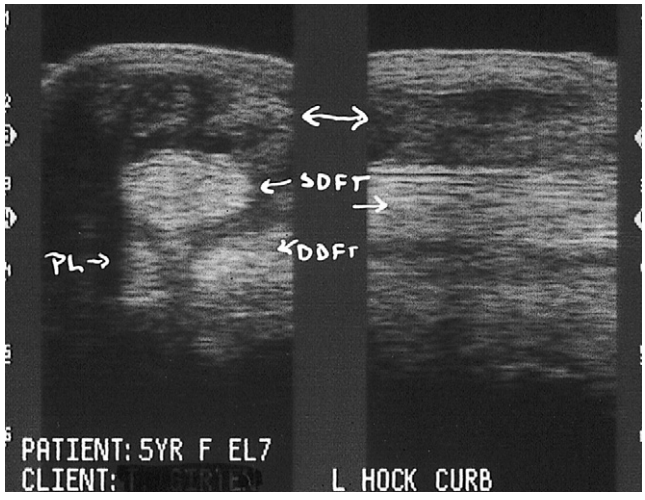

Fig. 79-9 Transverse (*left*) (medial is to the right) and longitudinal midline ultrasonographic images of the hock in zone lB in a 5-year-old Thoroughbred racehorse. There is soft tissue swelling of heterogeneous echogenicity of the peritendonous and periligamentous tissues and fibrous adhesion *(double-headed arrow)* plantaromedial to the superficial digital flexor tendon *(SDFT)*. The SDFT, deep digital flexor tendon *(DDFT)*, and long plantar ligament *(PL)* are normal.

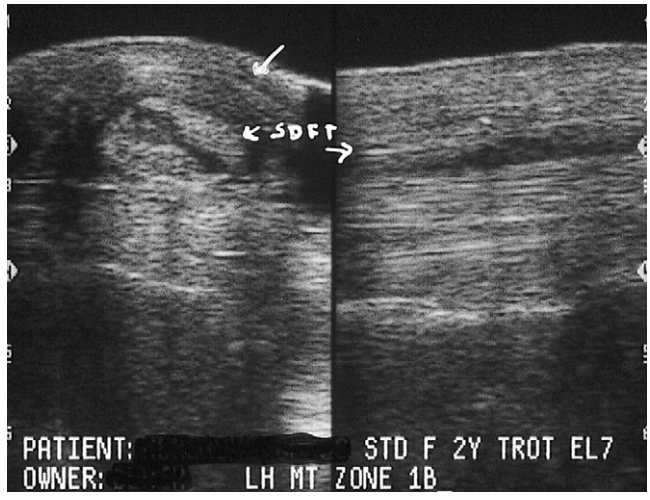

Fig. 79-10 Transverse (*left*) and longitudinal midline ultrasonographic images of the plantar aspect of the hock of 2-year-old Standardbred racehorse with curb resulting from peri-tendonous and peri-ligamentous tissue injury and superficial digital flexor tendonitis. Subcutaneous fibrous tissue accumulation *(top arrow)* plantar to the superficial digital flexor tendon *(SDFT)* and a central anechoic lesion of the SDFT can be seen, findings verified in the longitudinal view. Cross-sectional area of the affected superficial digital flexor tendon was 33% greater than the normal tendon.

lameness do not resolve. A lame horse must be rested to prevent injury to deeper structures. In non-racehorses with moderate to severe lameness, lameness may take several weeks to resolve. If the swelling becomes firm, fibrous, and pain free but lameness recurs, further investigation is warranted, because other causes of tarsal pain often develop in STB and TB racehorses with curb.

Infection can occur from direct trauma with skin penetration, previous injection, or severe topical counterirritation. If infection is suspected, cytological examination and culture are indicated. If a hematoma resulting from trauma is large or recurrent, or the curb is infected, establishing drainage is often necessary. A distal incision is made to provide drainage and fibrin and debris are removed. Care must be taken to avoid penetration of the tarsal sheath when creating the incision. A drain is inserted if necessary and the hock is bandaged. Culture usually reveals *Staphylococcus* species and appropriate antimicrobial and non-steroidal anti-inflammatory drug (NSAID) therapy is instituted. Horses are rested for 2 to 3 weeks to allow the tissues to heal, even though lameness from peritendonous and periligamentous tissue injury was not present before infection developed. Prognosis in horses with infection of peritendonous and periligamentous tissues is excellent but is far worse in those with infection of the SDFT, DDFT, or tarsal sheath.

Superficial Digital Flexor Tendonitis

A common finding in horses with curb is superficial digital flexor tendonitis. Sickle-hock conformation may predispose the horse to tendonitis, which can occur alone, but rarely is seen without concomitant inflammation of the peritendonous and periligamentous tissues. Pathogenesis likely involves progressive or accumulated overload injury of first the thin, fragile peritendonous and periligamentous tissues and later the SDFT.

Previous peritendonous and periligamentous tissue injury appears to predispose to subsequent superficial digital flexor tendonitis if the training level is increased quickly. Peritendonous and periligamentous injury may simply be an early stage of a progressive legion that eventually involves the SDFT or long plantar ligament. Progressive injury occurs frequently if horses with peritendonous and periligamentous tissues injury are treated with cryotherapy, internal blisters, or corticosteroids, and training intensity is accelerated before mature fibrous tissue can form. In horses with peritendonous and periligamentous tissue injury and superficial digital flexor tendonitis lameness varies, but it is much more likely to be observed than in horses with only peritendonous and periligamentous tissue injury. Lameness may be acute in onset and often is seen at fast speeds, but it can be seen in some horses at a trot in hand. Superficial digital flexor tendonitis occurs commonly in young STB racehorses but usually at a later stage of training than peritendonous and periligamentous tissue injury. Ultrasonographic examination reveals enlargement of the CSA of the SDFT, with a variable change in echogenicity and fiber pattern, depending on the severity of the injury (Fig. 79-10). Often subcutaneous edema or fibrosis occur, depending on the chronicity of the injury.

In horses with superficial digital flexor tendonitis, rest is an important part of management. Lesions usually are localized to the plantar tarsus, and those extending farther distally are associated with more severe lameness and horses have a poorer prognosis. Horses with localized lesions have a fair prognosis, although the prognosis is worse in trotters than in pacers. Horses with mild acute superficial digital flexor tendonitis, with enlargement of the tendon without fiber tearing, should be rested for 3 to 4 weeks. Without rest, progressive fiber damage may occur, resulting in prolonged recovery. Horses with more severe injuries may require up to 4 months of stall rest and controlled walking exercise.

In some STB racehorses, superficial digital flexor tendonitis in horses actively racing can be managed symptomatically, without giving rest, if the lesion is well localized and mild. Mild lameness may be observed at speed or while the horse is trotting in hand, but severe lameness should not be evident. Ultrasonographic examination often reveals peritendonous and periligamentous tissue injury with enlargement of the SDFT, but core lesions are not present. In most horses local

therapy using cold water hosing and poultice application, NSAID therapy, and subcutaneous injection of a corticosteroid preparation is successful. Subcutaneous injection of methylprednisolone acetate (200 mg) and Sarapin (25 ml) medial, plantar, and lateral to the SDFT is often done by practitioners with apparent success. Horses are given 10 to 14 days of jogging and light training before racing again. Non-racehorses with localized lesions usually respond well to rest for up to 3 months and have a favorable prognosis.

Horses with severe superficial digital flexor tendonitis have severe mushy swelling. If not given rest, these horses develop progressive tearing of the SDFT distal to the hock in the metatarsal region and lose support of the hock. Long-term rest (9 to 12 months) is recommended, but prognosis for return to previous race class is poor and in trotters, grave.

Deep Digital Flexor Tendonitis

Deep digital flexor tendonitis is a rare cause of curb. Horses with curb resulting from deep digital flexor tendonitis are usually acutely lame and have substantial swelling. Mixed injury with deep digital flexor tendonitis accompanying superficial digital flexor tendonitis and long plantar ligament desmitis occurs, but it is unusual. Horses with deep digital flexor tendonitis have concomitant peritendonous and periligamentous tissue inflammation and effusion of the tarsal sheath (tenosynovitis). The DDFT simply can be enlarged compared with the contralateral limb or have anechoic or hypoechoic core lesions. During ultrasonographic examination, the DDFT should be evaluated carefully from the midline and plantaromedial aspects. Lameness often is pronounced, and rest is recommended for a minimum of 4 to 6 months, but prognosis is guarded because lameness can recur. Serial ultrasonographic examination, corrective shoeing, and controlled exercise are given.

Long Plantar Desmitis

Long plantar ligament injury usually causes acute lameness, but chronic soft tissue swelling and progressive lameness can occur. Soft tissue swelling often is pronounced. Although long plantar desmitis can occur in racehorses, this form of curb appears to be equally common in other types of horses, such as Western performance horses. Long plantar desmitis can be well localized or diffuse. Cross-sectional measurements of the long plantar ligament are critical, because desmitis typically is often manifested as ligament enlargement rather than overt fiber tearing. Subtle thickening of the long plantar ligament may cause high-speed lameness, and evaluation of the cross-sectional area may be the only method to identify early lesions in these horses. Lesions can occur at any level within zones 1A and 1B, and injury may involve the insertion of the long plantar ligament on MtIV (Fig. 79-11).

Conservative management is best for horses with long plantar desmitis, because lameness and swelling often are pronounced. Owners and trainers of non-racehorses are often open to a conservative approach involving ample rest (3 months) to rehabilitate horses with curb properly. Intervening with therapy to enforce rest is not necessary. Controlled return to exercise is straightforward in this type of horse, because walking and trotting under saddle can be given easily. Graded exercise programs are not administered as easily or desired in the STB racehorse compared with non-racehorse sport horses. Lunging and walking and trotting under saddle are usually not practical,

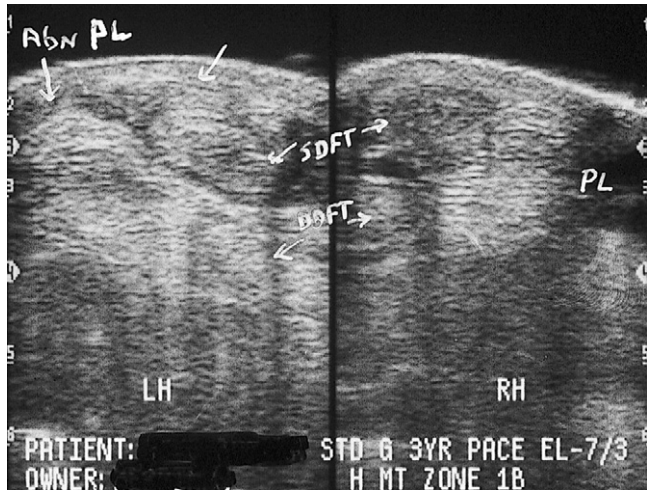

Fig. 79-11 Transverse plantarolateral ultrasonographic images of the left hindlimb *(LH)* (abnormal) and right hindlimb *(RH)* (normal) plantar tarsi in zone lB of 3-year-old Standardbred pacer. The left long plantar ligament *(PL)* is enlarged, with an indistinct central hypoechoic lesion. *SDFT,* Superficial digital flexor tendon; *DDFT,* deep digital flexor tendon.

although riding trotters is popular among trainers originally from Europe. Walking and light jogging in the jog cart is the best way to give graded exercise in the STB racehorse. We do not recommend turnout exercise in any horse with soft tissue injury, because we feel strongly this prolongs recovery and may lead to re-injury, but we realize our recommendations may not be followed. Cryotherapy, topical counterirritants, subcutaneous injections, and thermocautery are less likely to influence inflammation and healing of the long plantar ligament than more superficial causes of curb, but these treatments are sometimes requested.

Curb can result from long plantar desmitis at its insertion on MtIV. These horses do not have extensive swelling but focal thickening just proximal to MtIV. Mild soft tissue swelling must be differentiated from a prominent but normal MtIV seen in yearlings with sickle-hock conformation. Horses with curb resulting from distally located long plantar desmitis show lameness and mild, focal swelling and are managed with rest.

Mixed Soft Tissue Injuries

Ultrasonographic examination of curb nearly always identifies peritendonous and periligamentous tissue inflammation and in many horses an abnormality of the SDFT, DDFT, or the long plantar ligament. Occasionally, however, simultaneous injury of the SDFT and long plantar ligament occurs in addition to peritendonous and periligamentous tissue inflammation. This is most common in non-racehorse sport horses, in which lameness and swelling are severe.

CHAPTER • 80

Bursae and Other Soft Tissue Swellings

Sue J. Dyson

A bursa is a flattened, closed sac interposed between structures subject to friction or at points of unusual pressure, such as bony prominences and tendons. Bursae are lined with a cellular membrane resembling synovium and are classified according to position (subcutaneous, subligamentous, submuscular, and subtendonous) and according to the method of formation (congenital or acquired).

Acquired bursae develop because of pressure and friction over bony prominences. Tearing of the subcutaneous tissues results in accumulation of transudative fluid, which becomes encapsulated by a fibrous tissue. In chronic injuries fibrous bands may develop within the capsule.

SUPRASPINOUS BURSA

The supraspinous bursa overlies the summits of the dorsal spinous process of the second to fifth thoracic vertebrae, under the funicular part of the nuchal ligament. Inflammation of the supraspinous bursa and surrounding soft tissues, so-called fistulous withers, is usually infectious in origin and may be a sequel to trauma. *Streptococcus* and *Staphylococcus* species, *Brucella abortus,* and *Onchocerca cervicalis* have been considered important causative agents.[1-3]

Clinical signs of supraspinous bursitis are generalized soft tissue swelling, heat and pain, and often draining tract(s). Osteitis or osteomyelitis of the dorsal spinous processes of the cranial thoracic vertebrae may be concurrent. Care must be taken not to misinterpret the normal granular radiopaque appearance of normal, incompletely ossified summits of the dorsal spinous processes.[4] Diagnostic ultrasonography and radiography are useful for determining the extent of the infection, for identifying a foreign body, and for evaluating signs of osteitis or osteomyelitis.

Treatment is by aggressive surgical debridement of all infected tissue and establishment of adequate drainage, taking care not to penetrate the dorsoscapular ligament. Several surgical procedures may be required to resolve the infection successfully.[1-3]

INTERTUBERCULAR (BICIPITAL) BURSA

The intertubercular (bicipital) bursa is discussed in Chapter 41.

HYGROMA

Hygroma is discussed in Chapters 39 and 68.

NAVICULAR BURSA

The navicular bursa is discussed in Chapters 24 and 30.

TROCHANTERIC BURSA

The Editors have no clinical experience of trochanteric bursitis. This condition is discussed further in Chapter 48.

CALCANEAL BURSA

The calcaneal bursa lies between the tendons of the gastrocnemius and the superficial digital flexor muscles, proximal to the hock, and extends distally on the plantar aspect of the calcaneus to the distal aspect of the hock (Fig. 80-1). In some horses a communication exists between the calcaneal bursa and the gastrocnemius bursa.

Injuries of the calcaneal bursa are not common and are usually the result of trauma. However, mild distention of the calcaneal bursa often is seen with gastrocnemius tendonitis (see page 709). Mild distention also may be seen unilaterally or bilaterally, as an incidental finding unassociated with lameness.[5] Primary inflammation of the bursa results in acute onset lameness associated with distention of the bursa. Hemorrhage into the bursa also may occur. Conservative management by rest, with or without injection of short-acting corticosteroids, usually results in resolution of lameness, although enlargement of the bursa may persist.

More commonly infection of the bursa is caused by a penetrating injury or is secondary to infectious osteitis of the calcaneus[6] (see Chapter 45).

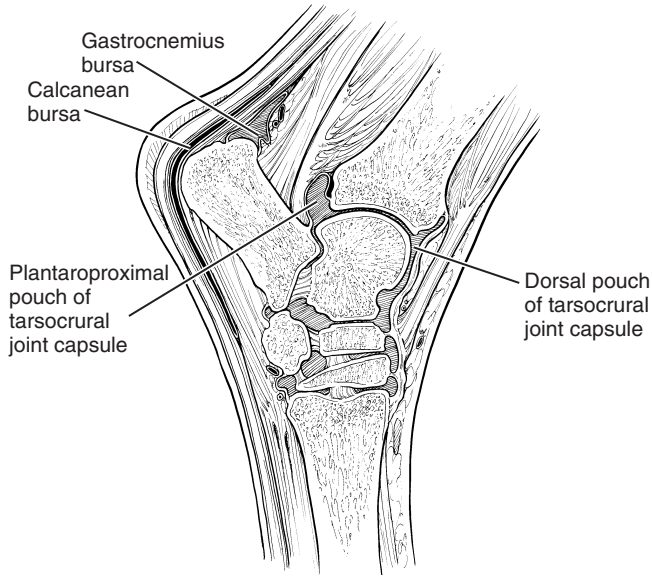

Fig. 80-1 Diagram of sagittal section of the hock region showing the relative positions of the calcaneal and gastrocnemius bursae.

Chronic distention of the calcaneal bursa also has been seen with well-circumscribed osteolytic lesions on the tuber calcanei, which were thought to represent enthesopathy at the insertion of gastrocnemius.[7]

Further investigation should include diagnostic ultrasonography, radiography of the calcaneus, and synoviocentesis. Radiographic examination should include a flexed skyline view of the calcaneus.[8] The internal structure of the bursa may be evaluated endoscopically,[9] but some underlying bony lesions may not be visible if the insertion of gastrocnemius is intact.[7] Endoscopy has been used diagnostically and therapeutically in horses with infectious osteitis, or bursitis, and in those with osteolytic lesions.

Horses with primary infection of the calcaneal bursa should be treated by debridement and lavage of the bursa and broad-spectrum antimicrobial therapy. Horses with infectious and non-infectious lesions of the calcaneus have been managed conservatively and surgically, with rather disappointing results.[6,7] A substantial number of treated horses have persistent lameness.

GASTROCNEMIUS BURSA

The gastrocnemius bursa lies between the superficial digital flexor tendon and the tuber calcanei. Mild distention may be present, unassociated with lameness. Primary injuries of the gastrocnemius bursa are rare. The bursa may be distended in association with gastrocnemius tendonitis, resulting in a capped hock appearance (see page 709). Occasionally, infection may occur because of a puncture wound or extension of infection from the calcaneal bursa.

CUNEAN BURSA

The cunean bursa lies underneath the cunean tendon on the medial aspect of the hock. Inadvertently penetrating the bursa is easy if one is inexperienced in injecting the centrodistal joint. Although the potential for primary bursitis exists, neither of the Editors of this text recognizes primary bursitis as a cause of lameness in racehorses or other sports horses. Gabel recognized a syndrome, "cunean tendonitis and bursitis-distal tarsitis syndrome of harness racehorses," but appreciated that horses showed substantially better improvement in gait after local analgesia of the distal hock joints than after infiltration of the cunean bursa alone.[10] Nonetheless, a component of peri-articular soft tissue pain may occur in Standardbred trotters and pacers with distal hock joint pain, and treatment of the cunean bursa with cortiscosteroids frequently is used as part of management. Cunean tenectomy is practiced by some, but it has largely fallen from favor. Subcutaneous injection of corticosteroids and Sarapin over the proximal aspect of the second metatarsal bone may yield better results than medication of the cunean bursa.[11]

CAPPED ELBOW

A capped elbow is an acquired bursa that develops over the olecranon of the ulna. The bursa results from repeated trauma from the heel of the shoe on the ipsilateral forelimb when the horse is lying down. The condition generally is not associated with lameness and is merely a cosmetic blemish. The use of a sausage boot around the pastern prevents trauma from the shoe, and usually the swelling diminishes significantly and rapidly in size. Chronic injuries have been treated by injection of corticosteroids, orgotein, or dysprosium-165, with disappointing results, or surgically, with better cosmetic results.[12]

CAPPED HOCK

A capped hock appearance may be caused by distention of the gastrocnemius bursa or by development of an acquired bursa over the tuber calcanei. An acquired bursa develops because of repetitive trauma, such as the horse kicking the stable walls or leaning backward on its hindlimbs when traveling. Capped hock usually has no associated lameness. Protection of the hocks with hock boots may help to prevent deterioration.

ACQUIRED BURSA ON THE DORSAL ASPECT OF A HIND FETLOCK

Firm swelling on the dorsal aspect of the hind fetlocks of horses that jump fixed fences is common. These lesions are false bursae that overlie the extensor tendon and are usually of no consequence, except cosmetically. However, a puncture wound may result in infection, resulting in enlargement of the bursa and surrounding soft tissue swelling, localized heat, and pain on palpation.[5] In contrast to infection in a joint or tendon sheath, lameness is usually only mild to moderate. Ultrasonography is useful to identify better the causes of the soft tissue swelling, and diagnosis is confirmed by synoviocentesis and identification of many nucleated cells. Surgical treatment is required and the prognosis is good.

FALSE THOROUGHPIN

A thoroughpin is the colloquial name for distention of the tarsal sheath, but more commonly the term is misused to describe a variety of swellings that may develop in the distal crus cranial to the gastrocnemius tendon. These conditions are otherwise called *false thoroughpins* and should be differentiated from distention of the tarsal sheath, tarsocrural joint capsule (see Chapter 45), or calcaneal bursa (see page 705). A false thoroughpin occurs laterally more commonly than medially and may develop unilaterally or bilaterally. A false thoroughpin varies in size from small to large. In contrast to distention of the tarsal sheath or the plantar outpouching of the tarsocrural joint capsule, these swellings cannot be balloted from laterally to medially and do not extend distal to the hock (Fig. 80-2). They may be sudden or insidious in onset and may or may not be associated with lameness.

The causes vary and are poorly understood. False thoroughpins are usually solitary, fluid-filled sacs (Fig. 80-3), unilocular or multilocular, with a wall of variable thickness, with or without large echogenic fibrous bands traversing them (Fig. 80-4). They may develop secondary to local hemorrhage or because of herniation of the tarsal sheath or the calcaneal or gastrocnemius bursae.[13-15]

Diagnostic ultrasonography is useful to identify the nature and extent of the swelling (Fig. 80-4). Unlike the tarsal sheath, no tendon is within the cavity. Positive-contrast radiography can be used to demonstrate whether any communication exists between adjacent structures (Fig. 80-3).

A false thoroughpin may be an incidental clinical finding unassociated with lameness. They are seen commonly in horses with a base-narrow hindlimb conformation.[5] Other causes should be excluded before one concludes that a false thoroughpin is the cause of lameness. Even if the swelling is acute in onset, in the absence of lameness I have maintained horses in work with no deleterious effects. Sometimes such swellings spontaneously reduce in size, but some swelling is likely to persist.

Long-term lameness associated with a false thoroughpin has been seen in a number of horses with chronic hindlimb

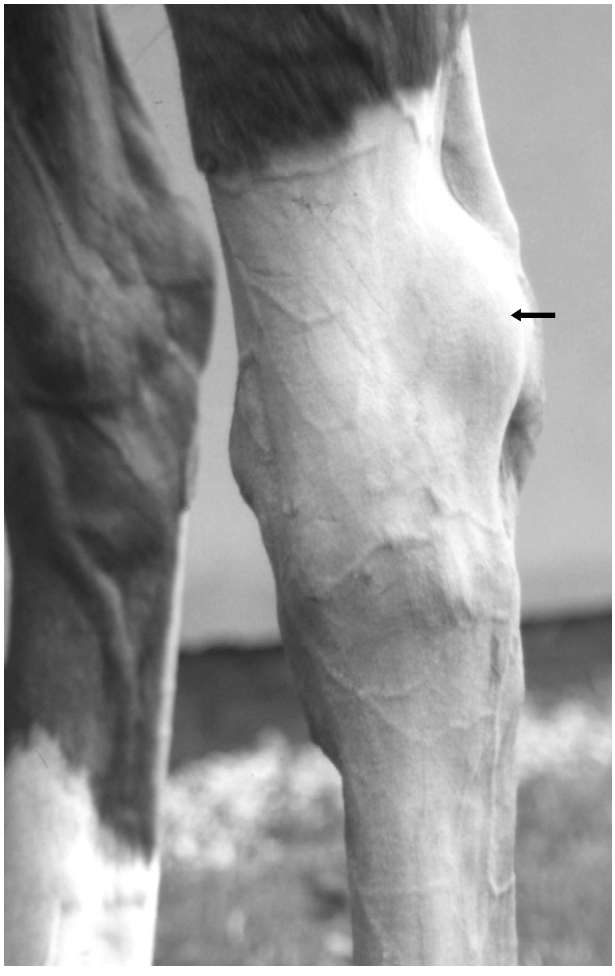

Fig. 80-2 A false thoroughpin (*arrow*). The swelling in this horse was acute in onset, but it was unassociated with lameness. The horse was maintained in full work, and despite this the swelling reduced in size. Ultrasonographic evaluation revealed a unilocular fluid-filled cavity.

Fig. 80-3 Dorsolateral-plantaromedial oblique radiographic view of a hock. A positive-contrast radiographic study of false thoroughpin. This fluid-filled cavity did not communicate with the tarsal sheath.

Fig. 80-4 Longitudinal ultrasonographic image of false thoroughpin. Proximal is left. There is a thick-walled fluid-filled cavity with some echogenic bands.

lameness that has not responded to conservative management. Surgical excision of large multiloculated cyst-like lesions has resolved lameness successfully in some horses,[5] although cosmetic results may be disappointing.

Other Soft Tissue Injuries

Sue J. Dyson

RUPTURE OF FIBULARIS (PERONEUS) TERTIUS

Anatomy

Fibularis (peroneus) tertius is an entirely tendonous muscle that lies in the craniolateral muscle group of the crus, between the subcutaneous long digital extensor and the cranialis tibialis, which cover the craniolateral aspect of the tibia. The muscle originates from the extensor fossa of the femur. Distally the fibularis tertius divides into branches that enfold the tendon of insertion of tibialis cranialis and insert on the dorsoproximal aspect of the third metatarsal bone, the calcaneus, and the third and fourth tarsal bones. The tendon is an important part of the reciprocal apparatus of the hindlimb, which coordinates flexion of the stifle and hock.

Fibularis tertius is the most echogenic structure on the craniolateral aspect of the crus and is identified readily by ultrasonography as a well-demarcated hyperechoic structure relative to the surrounding muscles (Fig. 81-1).

History and Clinical Signs

Rupture of fibularis tertius invariably is caused by trauma resulting in hyperextension of the limb; for example, a horse trying to jump out of a stable and getting one hindlimb caught on the top of the stable door. This usually results in rupture of the tendon in the middle of the crus but occasionally farther distally. Alternatively, rupture may be caused by a laceration on the dorsal aspect of the tarsus, resulting in transection of the tendon. Occasionally, partial tearing of the tendon occurs, usually at the level of the tarsocurual joint, with prominent swelling. Occasionally the reciprocal apparatus is partially but not totally disrupted. Avulsion injuries of the origin of the tendon rarely occur in young foals.

The clinical signs are pathognomonic, because rupture of this tendon allows the hock to extend while the stifle is flexed. When standing at rest, the horse may appear clinically normal, although with acute injury careful palpation may reveal some muscle swelling on the craniolateral aspect of the crus or further distally. When the horse walks, it should be viewed carefully from behind and from the side. The hock may extend more than usual. The tendons of gastrocnemius and the superficial digital flexor tendon may appear unusually flaccid, and a dimple is seen on the caudal aspect of the crus about one hand's breadth proximal to the tuber calcanei. At the trot the horse appears severely lame, with apparent delayed protraction of the limb because of over-extension of the hock.

If the limb is picked up and pulled backward, the hock can be extended gradually and "clunks" into complete extension while the stifle remains flexed. A characteristic dimple appears in the contour of the caudal distal aspect of the crus (Fig. 81-2). If rupture is only partial, or if lameness is chronic and some repair has taken place, clinical signs may be less severe and the diagnosis less obvious.

Presumably, strain of this tendon can occur, resulting in lameness, but I have no experience of this, and to my knowledge this condition has not been documented.

Diagnosis

The diagnosis of rupture of fibularis tertius is based on the pathognomonic clinical signs. The site of rupture can be iden-

lameness that has not responded to conservative management. Surgical excision of large multiloculated cyst-like lesions has resolved lameness successfully in some horses,[5] although cosmetic results may be disappointing.

Other Soft Tissue Injuries

Sue J. Dyson

RUPTURE OF FIBULARIS (PERONEUS) TERTIUS

Anatomy

Fibularis (peroneus) tertius is an entirely tendonous muscle that lies in the craniolateral muscle group of the crus, between the subcutaneous long digital extensor and the cranialis tibialis, which cover the craniolateral aspect of the tibia. The muscle originates from the extensor fossa of the femur. Distally the fibularis tertius divides into branches that enfold the tendon of insertion of tibialis cranialis and insert on the dorsoproximal aspect of the third metatarsal bone, the calcaneus, and the third and fourth tarsal bones. The tendon is an important part of the reciprocal apparatus of the hindlimb, which coordinates flexion of the stifle and hock.

Fibularis tertius is the most echogenic structure on the craniolateral aspect of the crus and is identified readily by ultrasonography as a well-demarcated hyperechoic structure relative to the surrounding muscles (Fig. 81-1).

History and Clinical Signs

Rupture of fibularis tertius invariably is caused by trauma resulting in hyperextension of the limb; for example, a horse trying to jump out of a stable and getting one hindlimb caught on the top of the stable door. This usually results in rupture of the tendon in the middle of the crus but occasionally farther distally. Alternatively, rupture may be caused by a laceration on the dorsal aspect of the tarsus, resulting in transection of the tendon. Occasionally, partial tearing of the tendon occurs, usually at the level of the tarsocurual joint, with prominent swelling. Occasionally the reciprocal apparatus is partially but not totally disrupted. Avulsion injuries of the origin of the tendon rarely occur in young foals.

The clinical signs are pathognomonic, because rupture of this tendon allows the hock to extend while the stifle is flexed. When standing at rest, the horse may appear clinically normal, although with acute injury careful palpation may reveal some muscle swelling on the craniolateral aspect of the crus or further distally. When the horse walks, it should be viewed carefully from behind and from the side. The hock may extend more than usual. The tendons of gastrocnemius and the superficial digital flexor tendon may appear unusually flaccid, and a dimple is seen on the caudal aspect of the crus about one hand's breadth proximal to the tuber calcanei. At the trot the horse appears severely lame, with apparent delayed protraction of the limb because of over-extension of the hock.

If the limb is picked up and pulled backward, the hock can be extended gradually and "clunks" into complete extension while the stifle remains flexed. A characteristic dimple appears in the contour of the caudal distal aspect of the crus (Fig. 81-2). If rupture is only partial, or if lameness is chronic and some repair has taken place, clinical signs may be less severe and the diagnosis less obvious.

Presumably, strain of this tendon can occur, resulting in lameness, but I have no experience of this, and to my knowledge this condition has not been documented.

Diagnosis

The diagnosis of rupture of fibularis tertius is based on the pathognomonic clinical signs. The site of rupture can be iden-

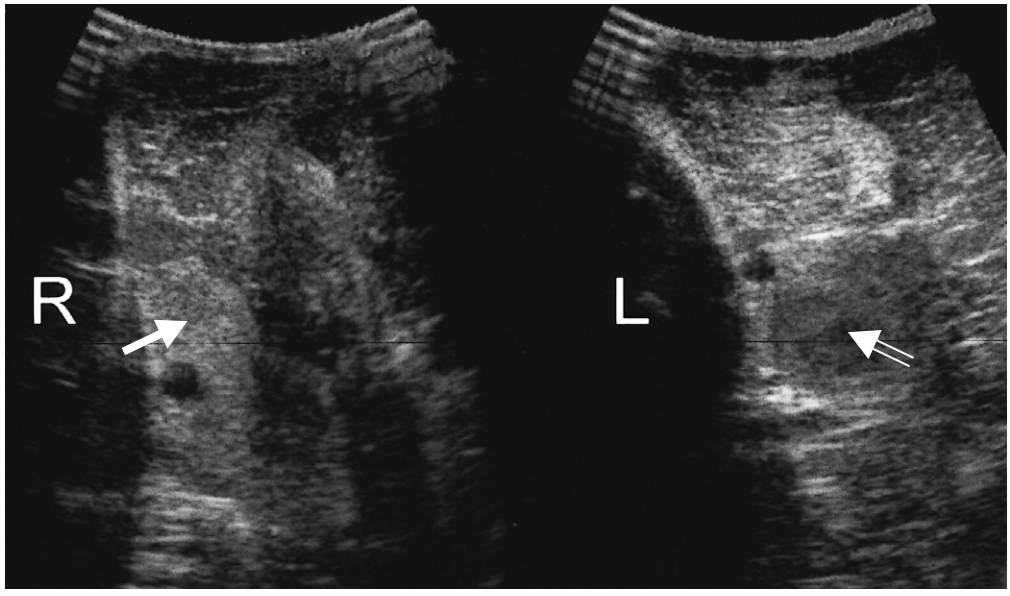

Fig. 81-1 Transverse ultrasonographic images of the craniolateral aspect of the mid-crus of 7-year-old horse with left hindlimb lameness of 2 months' duration. Fibularis tertius is the most echogenic structure in the center of the image of the right (*R*) hindlimb *(solid arrow)*. Compare this with the image of the left (*L*) hindlimb in which fibularis tertius is markedly hypoechoic *(open arrow)*. Note also that the overlying muscle is increased in echogenicity compared with the right hindlimb.

Fig. 81-2 A horse with rupture of the fibularis tertius. The hock can be extended while the stifle is flexed. Note also the characteristic dimple in the contour of the caudodistal aspect of the crus. Clinical signs developed after the horse had attempted to jump out of its stable and had got hung up on the door. The horse made a complete recovery.

tified with ultrasonography (Fig. 81-1). The normally echogenic structure is not clearly identifiable and may be replaced by a region hypoechoic relative to the surrounding muscles. In chronic injuries the surrounding muscles may become hypertrophied. Usually no associated radiological abnormalities are apparent in adult horses, although avulsion fracture of the origin has been described in foals.

Treatment

Confinement to box rest for 3 months, followed by a slow resumption of work usually results in total resolution of clinical signs. Most horses are able to return to full athletic function without recurrence of clinical signs. However, delayed recognition of the clinical signs and failure to confine the horse may result in a chronic lesion, which fails to heal satisfactorily. However, compensatory hypertrophy and or fibrosis of surrounding muscles may permit functional recovery.[1]

COMMON CALCANEAL TENDONITIS

The common calcaneal tendon comprises components from the superficial digital flexor and gastrocnemius tendons and from biceps femoris, soleus, semimembranosus, and semitendinosus muscles. Contributions from the latter two muscles are called the axial and medial tarsal tendons. So-called common calcaneal tendonitis has been described as resulting from a kick in the hock region.[2] Unfortunately the horse was not examined with ultrasonography until 5 months after injury, at which time soft tissue swelling was marked. Ultrasonographic examination revealed that the superficial digital flexor and gastrocnemius tendons appeared normal, but the axial and medial tarsal tendons were enlarged. The horse made a complete functional recovery.

GASTROCNEMIUS TENDONITIS

Tendonitis of gastrocnemius is a relatively unusual cause of hindlimb lameness in the horse.[3-5]

Anatomy

The gastrocnemius muscle arises from two heads that terminate in the mid-crus in a common tendon. Proximally the tendon lies caudal to the superficial digital flexor tendon (SDFT); farther distally the tendon lies laterally and is ultimately cranial, inserting on the tuber calcanei. The SDFT and gastrocnemius tendons are separated by a bursa, the calcaneal bursa, that extends to the mid-tarsal region. A small bursa, the gastrocnemius bursa, also lies cranial to the insertion of the gastrocnemius tendon on the tuber calcanei. A communication may exist between these bursae.

The tendon of gastrocnemius may still contain some muscular tissue as far distally as the level at which it lies lateral to the SDFT. This results in hypoechoic regions within the tendon.

Gastrocnemius tendonitis usually occurs distally, distal to the musculotendonous junction. Rarely, damage occurs at the musculotendonous junction.[6] Occasionally, injuries occur at the origin of the gastrocnemius on the femur.[7]

History and Clinical Signs

Lameness may be acute or gradual in onset and varies from mild to severe. Distention of the calcaneal bursa frequently is associated with gastrocnemius tendonitis, and the horse often develops a capped-hock appearance also because of distention of the gastrocnemius bursa (Fig. 81-3). However, these swellings can occur without lameness or detectable pathological conditions of the gastrocnemius or SDFT (see page 706). Mild enlargement of the gastrocnemius tendon may occur, but this can be difficult to appreciate. Eliciting pain by palpation usually is not possible.

Severe lameness is characterized by a reduced height of arc of foot flight, shortened cranial phase of the stride, and a tendency to hop off the caudal phase of the stride. Horses with less severe lameness have no specific gait characteristics. Lameness often is accentuated by proximal or distal limb flexion. Two of four horses with injury to the origin of the gastrocnemius muscle had an unusual gait characterized by internal rotation of the affected limb (outward movement of the calcaneus).[7]

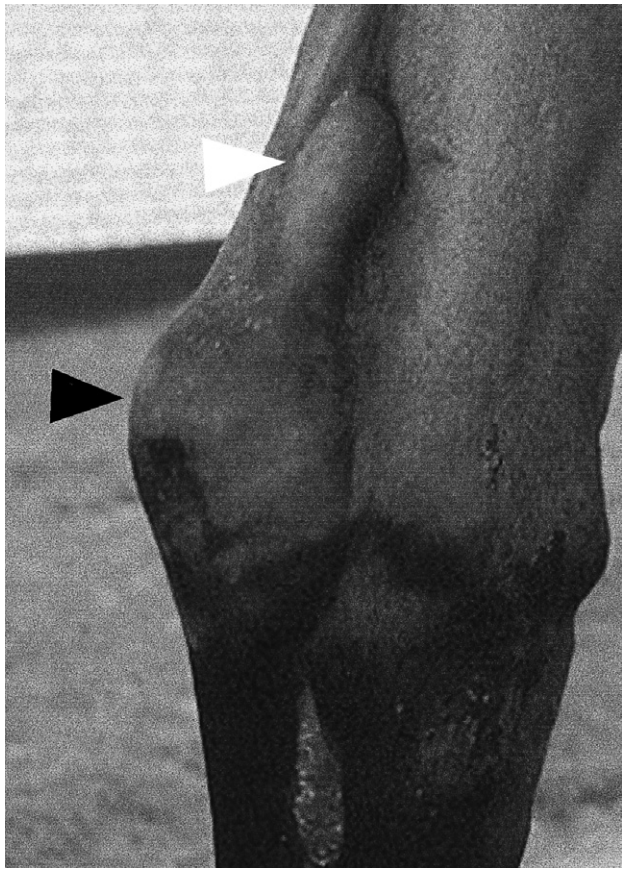

Fig. 81-3 Medial view of the left hock of 7-year-old Thoroughbred with acute-onset lameness associated with gastrocnemius tendonitis. Note the capped-hock appearance (*black arrowhead*) and the distention of the calcaneal bursa (*white arrowhead*).

Diagnosis

Lameness is improved substantially by perineural analgesia of the tibial nerve, possibly because of local diffusion of the local anesthetic solution, unless the injury is at the origin. Diagnosis is confirmed by ultrasonographic examination. Comparison with the contralateral limb is useful.

The tendon usually is damaged in the distal aspect of the crus, where it lies cranial to the SDFT. Ultrasonographic abnormalities include enlargement of the tendon, poor definition of the margins, and focal or diffuse hypoechoic or anechoic regions (Fig. 81-4). Usually no detectable radiographic abnormalities are apparent. Radiographic (proliferative changes) and scintigraphic (increased radiopharmaceutical uptake) abnormalities may exist in horses with chronic injury at the origin of the gastrocnemius muscle on the caudal femur.[7]

Treatment and Prognosis

Conservative treatment with box rest and controlled exercise for up to 12 months generally has resulted in progressive improvement in lameness and improvement in the ultrasonographic appearance of the tendon. Horses with mild lesions have been able to return to full athletic function without recurrent lameness, but more severe lesions have a more guarded prognosis.[4,5] Three of four horses with injury of the origin returned to athletic use, but recurrent injury occurred in the fourth horse.[7]

SUBLUXATION AND LUXATION OF THE SUPERFICIAL DIGITAL FLEXOR TENDON FROM THE TUBER CALCANEI

Lateral (see Fig. 6-29), or less commonly medial, luxation or subluxation of the SDFT from the point of hock may occur along with damage to or rupture of the tendonous bands that insert medially and laterally on the tuber calcanei. Although usually a unilateral injury, the condition can occur bilaterally.

Lateral displacement of the SDFT occasionally occurs secondarily to hyperextension of the hind fetlock associated with

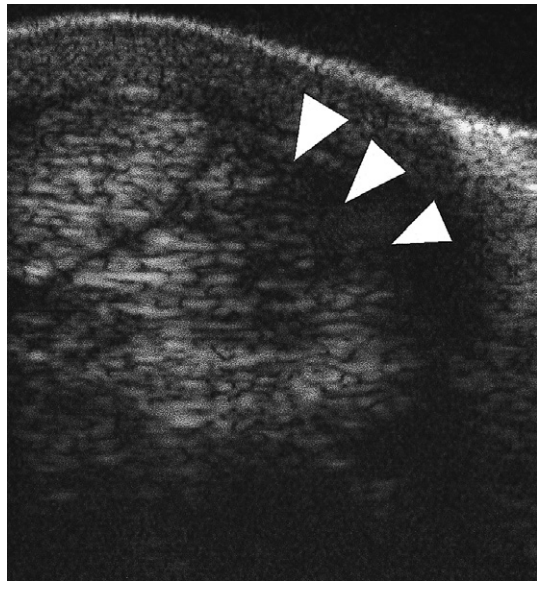

Fig. 81-4 Transverse ultrasonographic image of the caudal aspect of the distal crus of 6-year-old mare with left hindlimb lameness that was alleviated by perineural analgesia of the tibial nerve. Medial is to the left. The gastrocnemius tendon is enlarged, its plantar lateral aspect is poorly defined (*arrowheads*), and there is a large hypoechoic region consistent with gastrocnemius tendonitis.

progressive breakdown of the suspensory apparatus (see Fig. 73-24 and page 671).

Anatomy

The SDFT lies caudally in the distal crus and broadens to form a cap over the tuber calcanei. At this level, broad tendonous bands extend medially and laterally to insert on the tuber calcanei. The calcaneal bursa is interposed between the SDFT and the tendon of gastrocnemius.

History and Clinical Signs

Partial or complete disruption of one of the retinacular bands that attach the SDFT to the tuber calcanei can result in subluxation, or more commonly, luxation of the SDFT laterally or medially. Lameness is usually sudden in onset and severe, although occasionally mild lameness precedes this, associated with soft tissue swelling in the region of the point of hock. Frequently no history of trauma is apparent, and the injury often occurs as the horse is being worked. The horse may suddenly stop and may become extremely distressed, especially if the tendon repeatedly moves on and off the tuber calcanei. The horse may kick out repeatedly with the limb. The tendon may return to its normal position when the horse bears weight. Soft tissue swelling rapidly ensues, making accurate palpation difficult. If the horse is kicking repeatedly when moving, one may conclude wrongly that the soft tissue swelling developed as the result of trauma caused by kicking.

With subluxation of the SDFT, the tendon is usually positioned normally at rest. Careful observation of the tendon as the horse moves may reveal instability. With luxation it may be possible to see that the SDFT has been displaced laterally or, less commonly, medially. If the tendon remains luxated, then the horse tends to be less agitated, although obviously in pain in the acute stage. Careful palpation may reveal instability of the tendon or its displacement to an abnormal position.

In horses in which lateral displacement occurs secondary to hyperextension of the fetlock, the condition may be insidious in onset and slowly progressive and unassociated with acute lameness.[8]

Diagnosis

Ultrasonographic examination is helpful if the tendon is displaced by confirming its abnormal position, but such examination can add to confusion if the tendon is in the normal position when the horse stands still.

Treatment

In the acute stage pain relief is essential and tranquilization may be necessary to calm the horse. If the SDFT is unstable and is moving constantly on and off the tuber calcanei, management in the acute and chronic phases may be difficult. If the tendon is permanently dislocated laterally or medially, the distress usually resolves rapidly. Anti-inflammatory drugs are best avoided, because the surrounding soft tissue swelling helps stabilize the tendon. If the tendon has luxated laterally, prolonged rest (6 months) usually results in resolution of pain, although a mechanical lameness may persist. This limits the horse's function for dressage, but these horses may be able to race or show jump at a high level. The prognosis associated with medial luxation is more guarded and tends to be associated with a greater degree of mechanical lameness.

If the SDFT is unstable initially, the tendon may with time and progressive further disruption of the attaching retinacular bands become more stable in a luxated position. Peritendonous injection of a sclerosing agent, P2G (Martindale Pharmaceuticals, Romford, Essex, England), has been helpful in stabilizing the luxated tendon in a limited number of horses.[8] Surgical transection of a partially torn band has helped in chronic subluxation.[9] Attempts at surgical stabilization of the SDFT in its normal position often have been disappointing, although successful results have been reported.[10,11] Surgical stabilization is only worth considering if the horse is temperamentally suited to a full-limb cast. Prognosis is influenced by the ease of reconstruction of the torn retinaculum, which depends on the site of the tear (close to the tendon, close to the bone, or mid-way) and its age. Only four of nine horses were sound.[12]

BICEPS BRACHII TENDONITIS

Biceps brachii tendonitis is discussed in Chapter 41.

CHAPTER • 82

Tendon Lacerations

Sue J. Dyson and Alicia L. Bertone

Tendon lacerations are serious injuries in horses because of the loss of the biomechanical function of the tendon, the slow return of tendon strength, the immediate strenuous loading demanded by the equine patient, and the complications of scarring. Nonetheless, early diagnosis, wound management, limb support, and long-term surgical and medical management have resulted in a good prognosis for most extensor tendon lacerations and a fair prognosis for most flexor tendon lacerations.[1,2] The extensor (dorsal) aspect of the limb is often damaged by wire or a sharp object over which the horse has jumped. The flexor (palmar or plantar) aspect of the limb may be traumatized by circumferential wire injuries, landing on a sharp object, or being struck. The latter may be self-inflicted or from another horse.

DIAGNOSIS

Gross Appearance of the Wound

Any laceration over the dorsal or palmar/plantar surface of the limb distal to the stifle or elbow, especially across the dorsal tarsus, distal dorsal tarsus, dorsal metatarsal region, distal radius, dorsal metacarpal region, and dorsal fetlock region may involve a tendon (Fig. 82-1). Extensor tendons and the superficial digital flexor tendon (SDFT) are positioned directly under the skin; therefore minor-appearing wounds can transect these tendons completely. Direct visual inspection may reveal transected tendon fibers protruding from the wound. However, injuries sustained at the gallop may result in a skin wound removed from the site of tendon damage, because of the movement of the skin during exercise. The position of the wound relative to synovial structures should be evaluated with care, because concurrent synovial contamination or sepsis reduces the prognosis and necessitates specific emergency treatment.

Evaluation of Gait

Each tendon serves a biomechanical function. Complete severance of a tendon results in a posture or gait change, which may be pathognomonic for disruption of the tendon integrity.

Extensor Tendons

Transection of an extensor tendon below the carpus produces a reduced ability to extend the digit, which is detected as an exaggerated, rapid (uncontrolled) dorsal flip of the hoof at the walk. This subtle change is easiest to detect if the lateral and common (or long) digital extensor tendons are transected completely. Intermittently the horse knuckles at the fetlock joint and places the digit on the dorsal surface of the pastern and fetlock joint. The gait abnormality is more obvious in the hindlimb and with lacerations in close proximity to the fetlock. Remaining peritendonous fascial attachments provide some support in the more proximal injuries. Horses with extensor tendon lacerations fully bear weight in a normal posture, unless other aspects of the wound create lameness and pain.

Transection of extensor tendons proximal to the carpus and at, or just proximal to, the tarsus also commonly occurs. Proximal to the carpus, transection of the extensor carpi radialis and common digital extensor tendons is most frequent. Flexion of the carpus may cause pain. The tendon sheath often is often involved.

Proximal or dorsal to the tarsus, transection of the long digital extensor, cranial tibialis, and fibularis (peroneus) tertius tendons is most frequent. If the fibularis tertius is disrupted, the hock can be extended while the stifle is flexed, indicating loss of the reciprocal apparatus. The gastrocnemius tendon develops a characteristic wrinkle in this extended position (see Fig. 81-2 and page 708). The degree of gait abnormality may be mild. Transection of all the extensors over the tarsus still allows full weight bearing with the foot flat on the ground. A greater tarsal extension during the swing phase of the stride and intermittent knuckling of the digit can be detected.

Flexor Tendons

Transection of flexor tendons below the carpus or tarsus produces pain on weight bearing and therefore lameness and gait abnormality. Transection of the SDFT is most common, because it has the most superficial position of the two flexor tendons. The suspensory ligament (SL) is deep to the deep digital flexor tendon (DDFT) and is therefore least commonly injured with lacerations. A horse with complete transection of the SDFT may stand normally, or it may bear weight on the toe of the hoof to minimize movement of the tendon ends with fetlock joint extension. Administration of phenylbutazone for pain may eliminate lameness, and a gait abnormality may become hard to detect. The DDFT and SL support the fetlock joint together with the SDFT. Therefore slight hyperextension of the fetlock because of disruption of the SDFT may be difficult to detect unless the contralateral limb is picked up. The greater the number of structures transected, the less support to the fetlock and other distal joints and the greater the likelihood of vessel and nerve transection. Elevation of the toe is pathognomonic for transection of the DDFT.

Digital Palpation of the Wound

Digital palpation is a simple and direct way to determine the extent of damage to structures below the skin. Integrity of the tendons is readily determined by feel. Partial tears can be distinguished from complete tears, and this affects treatment (see "Partial Tendon Lacerations"). The tendon ends are often palpable beneath the skin proximal and distal to the wound, but they may be removed from the wound if the injury was sustained while the horse was galloping. The muscular attachment to the proximal end pulls the proximal tendon end farther from the wound. The wound should be shaved around the edges and cleansed thoroughly with a dilute antiseptic solution such as chlorhexidine before exploration. Gross debris can be debrided manually from the wound. Sterile gloves should be worn for the digital exploration after the wound is clean. Digital palpation may reveal involvement of a tendon sheath or joint capsule; however, small tears of these synovial structures may not be palpable. Sterile preparation of the skin and injection of a balanced electrolyte solution into the synovial structure in question at a site distant from the

wound may demonstrate communication if solution exits the wound. Synovial fluid also can be obtained and submitted for cytological evaluation. Hemorrhage or inflammation is usually present in the synovial fluid if the sheath has been penetrated. Mild inflammatory changes can be seen in synovial structures adjacent to tendon injuries, even if no actual communication with the wound occurs.

Ultrasonographic Evaluation

Ultrasonographic evaluation of the tendons can quantitate the degree of tendon damage, particularly in horses with partial tears. Ultrasonographic examination is not necessary for diagnosing complete tears and therefore is performed rarely.

Ultrasonographic evaluation can be useful during the healing phases of horses with partial or complete tendon lacerations.[3] The amount of repair tissue should increase early in repair and then decrease as the tissue matures and gains strength. In flexor tendons, about 6 weeks are required for the tendon to gain the strength to support 450 kg, and the strength of the repair tissue is largely because of an increase in tissue mass. The repair tissue cross-sectional area is greater than the original tendon area, but the strength of that tissue per unit area is reduced.[4] The quality of the repair tissue can be monitored with ultrasonography. Ultrasonographic examinations should show progressively increased homogeneity of echogenicity, reduction in the hypoechoic areas of damaged tendon or early immature repair tissue, and appearance of parallel arrangements of fibers.

EMERGENCY MANAGEMENT

Treatment of Shock

Trauma is often severe in horses with lacerated tendons, particularly flexor tendons. Some horses may be trapped for hours in wire or entangled in equipment. Blood loss may be extensive if major arteries to the distal limbs have been transected. The loss of the function of a limb is painful and stressful. Initial management of these horses can be lifesaving. If possible, the horse should be caught and brought into a warm, clean area for examination and further treatment. If the horse has severe tachycardia (>100 beats/min), with pale mucous membranes and is reluctant to move, initial treatment should be performed on site. If the wound is still bleeding, a clean pressure bandage should be applied to stop the bleeding and provide some support to the limb. If the function of the limb is impaired mechanically, a splint should be applied over the bandage to minimize further damage with movement. Use of tranquilizers and sedatives should be kept to a minimum until the degree of blood loss and shock can be assessed and treated. Most sedatives are peripheral vasodilators and may produce significant hypotension in a hypovolemic patient. Some horses may be in stress-induced shock from pain, with extreme catecholamine release. The effect of tranquilizers may be unpredictable and potentially worsen the bleeding. Securing the horse in a familiar, warm, clean environment and stabilizing the injured limb may resolve the stress-related shock and allow assessment of hemorrhagic shock by evaluating peripheral pulse strength and quality, heart rate, and mucous membrane color. If hemorrhagic shock is severe, the most important treatment is intravenous fluid volume replacement, which can be in the form of high-volume isotonic fluids (20 to 60 L minimum per 450 kg of horse), or hypertonic saline (9% NaCl; 1 L per 450 kg of horse), followed by isotonic fluid replacement. Hypertonic fluid therapy can be effective for rapid expansion of the vascular space in hemorrhagic shock, but hypertonic solutions dehydrate the interstitium and induce a profound renal diuresis. Therefore it is critical that isotonic fluid therapy begins within 30 minutes to 1 hour after hypertonic fluid administration. Hypertonic fluid therapy is practical because of the convenience of the small volumes necessary and works well if the horse is referred or transported to a facility that has access for fluid administration.

Transportation

For transportation the injured limb should be placed toward the back of the trailer. The horse's weight shifts to the front of the trailer during braking, which is often less controlled than acceleration. The horse's head should not be tied tightly, so the head and neck can be used for balance. The limb should be supported with a padded pressure bandage and a splint for transport.

MEDICAL MANAGEMENT

All horses with tendon lacerations need medical therapy, whether surgery to re-appose tendon ends is elected or not. If tendon laceration, partial or complete, is diagnosed, a more thorough aseptic preparation of the wound should be performed. These procedures require sedation, restraint of the patient, and local or regional analgesia.

Wound Cleansing and Debridement

The hair should be clipped circumferentially around the limb from above the wound (to the estimated top of the bandage) and the entire limb distal to the wound. Drainage of serum and exudate from the wound is often voluminous, and removal of the hair makes subsequent cleaning of the limb easier and more thorough, thereby minimizing bacterial growth and contamination. A 10-minute scrub of the wound with an antiseptic solution should be performed. If bone and tendon are exposed, care must be taken to minimize trauma to these tissues. A minor sterile instrument pack may be helpful in trimming heavily contaminated tissues, macerated tendon ends and removing hair and debris from deep in the wound. Lacerated tendons should be trimmed at the edges to remove traumatized tissue that is expected to become necrotic. Debridement of tendon ends should be most conservative in horses with flexor tendon lacerations, for which apposition of tendon ends with suture is recommended.

Systemic and Local Medications

Tetanus toxoid should be administered to any horse with a tendon laceration, and tetanus antitoxin if no vaccination history exists. Because all wounds are contaminated at injury and compound wounds have extensive soft tissue injury, broad-spectrum antimicrobial drugs should be administered systemically for a minimum of 3 days. Metronidazole should be considered in horses with grossly contaminated distal extremity wounds. The duration of antimicrobial therapy may be longer in horses with heavily contaminated wounds, wounds healing by second intention, infected wounds, wounds involving a tendon sheath, or wounds with delayed treatment (>24 hours). Wound lavage should be copious, usually with a minimum of 5 L of a balanced electrolyte solution.

SURGICAL TREATMENT

Surgery in the form of wound closure is performed in most horses with compound wounds involving tendons. Primary closure is preferred, if possible, to provide the best success of obtaining primary wound healing, minimal scar formation, and the fewest complications associated with the transected tendon. However, wounds that are heavily contaminated, older than 24 hours, or heavily traumatized should have a delayed closure (1- to 3-day delay) performed to reduce the contamination and necrotic debris before closure. The decision to close a wound older than 24 hours must be made based on the condition of the wound and surrounding structures. Wounds in horses that have been managed appropriately from the time of injury until surgery can be closed at any time, if tissue loss is minimal and infection is not present.

Extensor Tendons

Transected extensor tendons heal well without primary suturing of the tendon, even if a large gap has formed between the tendon ends. Serial ultrasonographic evaluations show fibrosis occurring between the tendon ends that eventually becomes more organized and regains the linear arrangement of collagen along the pattern of the original tendon. This fibrous tissue seems to provide a mechanical link between the tendon ends, because extensor function of the digit returns in most horses. In our experience, a palpable thinning of the new tendon and an enlargement at the old tendon ends usually remains, even after 1 year.

Horses with lacerated extensor tendons have a good prognosis, with 73% of injured horses returning to athletic soundness and 18% to pasture soundness.[2] In that study, 62% of the affected limbs were treated with a 3-layer cotton bandage, 23% with a splint and bandage, and 10% with fiberglass casts.

It is important that the horse is confined to box rest for at least 6 weeks so that lameness does not ensue. With lameness the hoof may be positioned on the toe, and the force of the flexor tendons maintains this position, particularly without the counter-force of the extensor tendon. Chronic flexor pull may result in permanent flexor deformity and lameness. If flexor dominance is noted, a splint or cast should be applied (see Chapter 87).

In our experience, the best cosmetic outcome, and chances of achieving primary wound closure, occur with using a fiberglass cast for 3 to 6 weeks. The cast provides the most immobility to the limb and the lacerated tendon ends. Early fibrosis matures more quickly, without disruption of the early granulation tissue.

Flexor Tendons

Horses with complete laceration of one or more flexor tendons are best treated with tendon suturing, wound closure, and post-operative immobilization for about 6 weeks. Flexor tendons support the weight of the horse on loading. Thus healing and return to full strength is a slow process, one that does not return to normal for at least 6 months. In studies investigating methods of tendon repair, immobilization of the limb in a cast without suturing produced a significantly weaker repair that resulted in the clinical sequela of a hyperextended fetlock joint.[4,5] The amount of scar tissue filling the tendon gap was significantly less in this group compared with the sutured groups and was the reason for the reduced strength. Suturing of flexor tendon injuries is therefore recommended. Monofilament suture (nylon or polyglyconate) produced the greatest strength of repair compared with carbon fiber suture, when placed in a double-locking loop pattern (nylon) or three-loop pulley pattern (polyglyconate) for apposition of tendon ends, or for spanning tendon gaps.[4-6] The limb should be cast for at least 6 weeks, with the fetlock joint in mild flexion, by building a heel support with casting tape or plaster to provide a level weight-bearing surface with the ground.

Repairs of flexor tendon lacerations above the hock (i.e., gastrocnemius tendon, DDFT, or SDFT) should follow the same principles, but the prognosis is decreased because of the greater difficulty in maintaining a full-limb cast, larger size of the tendons at this location, and greater biomechanical stresses to support the hock with weight bearing.

Partial Tendon Lacerations

Tendons that are partially transected can be treated successfully without suturing but with wound closure and limb immobilization in most horses. Partial transection of flexor tendons usually involves the SDFT only or the axial margin (medial or lateral) of the SDFT and DDFT. If the limb is immobilized, the remaining fibers of tendon provide the stability for the torn tendon ends to remain in apposition and

provide the strength to prevent further tendon tearing during healing. Anecdotally, if greater than 75% of the SDFT is lacerated, tendon suturing may provide a reduced gap and faster healing and improve the repair. If the SDFT is completely transected along with a partial laceration of the DDFT, the SDFT should be treated with suturing as previously described and the DDFT left unsutured.

Lacerations in Tendon Sheaths

If a laceration enters a tendon sheath, then therapy is altered to include aggressive lavage of the sheath and wound, intrathecal administration of antibiotics, close monitoring of sheath fluid cytological condition, longer use of systemic antibiotics, and limb immobilization. If tissue loss is minimal, wounds entering tendon sheaths should be closed primarily. Primary closure and fiberglass cast application offer the best chance of early healing and minimize the potential for the complications of ascending infection, chronic drainage and fistulae formation, and fibrosis.

CONVALESCENT THERAPY

Shoeing

After removal of a cast or splint for extensor tendon lacerations, a gradual return to full weight bearing is recommended. Shoeing recommendations are simple and include trimming or shoeing level, without toe extensions that may catch and produce knuckling. For flexor tendon lacerations, an elevated and extended heel shoe can be applied and the heel lowered sequentially over the next 6 weeks to a flat position. For severe lacerations involving the DDFT, SDFT, or SL, an extended heel shoe may always be required for additional flexor support.[7]

Graduated Exercise

Horses with extensor tendon injuries have not been evaluated as closely during the healing process to assess tissue maturation and return of strength as those with flexor tendons injuries Because the function of the extensor tendon is to extend the digit and not endure a load on weight bearing, return to full strength may occur sooner than for flexor tendons. Horses should remain in a box stall or a confined area during the wound healing phases and early fibroblastic repair phases of tendon healing (3 to 6 weeks). After this time, hand walking and controlled exercise such as swimming can begin to strengthen the tendon and improve gliding function. After 10 to 12 weeks of controlled exercise, and if no signs of knuckling or flexor dominance are present, gradual return to athletic use can begin.

Horses with flexor tendon lacerations require a more gradual convalescent period. After the first 6 weeks of immobilization, the next 6 weeks should be spent in confinement and regaining a normal foot posture and full weight bearing. Heel support shoes are applied during this time. After 12 weeks, hand walking can begin and gradually increase in frequency and duration over the next 3 to 6 weeks. Controlled exercise with walking, lunging, swimming, or ponying (leading from another horse) is preferred to turnout. Turnout can be given after the horse is sound at the walk and trot and ultrasonographic examination demonstrates extensive fibrosis and mature scar tissue. Heavy athletic use should not begin until 8 to 12 months after the injury.

PROGNOSIS

Successful outcome (soundness) occurs in about 75% of horses with extensor tendon lacerations and up to 54% of horses with flexor tendon lacerations.[1,2,8] The prognosis for horses with partial disruption of the SDFT, or the DDFT, or both is better than those with complete lacerations.[8] Long-term failures are attributable to continued pain from extensive adhesions, joint pain, other injury at the time of laceration, tendon sheath adhesions, tendon contracture, annular ligament constriction, re-injury, and failure of the repair to regain adequate strength to support the joint, leading to breakdown. Re-injury to a damaged tendon may occur during healing, but such a tendon can heal successfully, although convalescence is prolonged. In general the prognosis is better for pleasure riding horses than for sports horses, but especially with injuries involving the flexor tendons of a hindlimb, complete function may be restored. An association exists between lacerations of either or both the long and lateral digital extensor tendons in the proximal part of the metatarsal region and the subsequent development of stringhalt several months later.[9]

CHAPTER • 83

Soft Tissue Injuries of the Pastern

Virginia B. Reef and Ronald L. Genovese

Injuries to the flexor tendons and ligaments in the pastern are a common cause of lameness in horses.[1-6] Injuries to the collateral ligaments or the palmar or plantar ligaments of the proximal interphalangeal joint are a less frequent cause of lameness.[1,7-9] Swelling, heat, and sensitivity of the affected tendon or ligament to palpation often accompany lameness. Ultrasonographic evaluation of the pastern is indicated when local swelling, heat, and sensitivity are detected, or when effusion occurs in the digital flexor tendon sheath (DFTS). The cause of the swelling can be determined by ultrasonography, and the severity of the injury can be characterized. If injury occurs to the superficial or deep digital flexor tendons (SDFT, DDFT) in the metacarpal or metatarsal region, ultrasonographic examination should include an evaluation of these structures in the pastern. Lameness associated with soft tissue injuries of the pastern also can occur without localized soft tissue swelling, and ultrasonographic examination is indicated if pain is localized to the region using diagnostic analgesia and no radiographic abnormality is detected, or entheseous new bone is seen. The clinician should bear in mind that intra-articular analgesia of the metacarpophalangeal or metatarsophalangeal joints and the proximal interphalangeal joint is not necessarily specific and may influence closely related structures such as the distal sesamoidean ligaments and the palmar ligaments of the proximal interphalangeal joint. It also may be important to use diagnostic analgesia to determine whether any injury causing soft tissue swelling in the pastern region is the source of pain causing lameness. Perineural analgesia of the palmar nerves at the level of the base of the proximal sesamoid bones (PSBs) should remove lameness if the soft tissue swelling is the sole cause of lameness. Nuclear scintigraphy may help to determine if entheseous new bone is active, and magnetic resonance imaging has the potential to provide additional information.

ANATOMY

Most of the soft tissue structures in the pastern are on the palmar or plantar aspects and are similar in the forelimbs and hindlimbs. The following describes the forelimb but applies equally to the hindlimb. The SDFT forms a thin ring around the DDFT at the ergot and in the proximal most portion of the pastern and then bifurcates into medial and lateral branches. The origin of the branches have a teardrop shape. The cross-sectional area (CSA) of each SDFT branch gradually enlarges as the branch extends distally along the palmarolateral and palmaromedial aspects of the pastern, until the branches insert on the distal aspect of the proximal phalanx and on the proximal aspect of the middle phalanx. The DDFT lies immediately dorsal to the SDFT and extends along the midline to its insertion on the distal phalanx.[1-6,10-14] The DDFT has a bilobed shape in the pastern and is surrounded by the DFTS. The oblique (middle) distal sesamoidean ligaments originate from the base of the lateral and medial PSBs as two large, round to oval branches. These branches become smaller in CSA as they extend distally. The branches join in the proximal to mid aspect of the proximal phalanx and insert as a broad band on the palmar aspect of the middle of the proximal phalanx. The straight distal sesamoidean ligament also has its origin at the base of the PSBs and the palmar ligament and extends distally in the midline, palmar to the oblique distal sesamoidean ligament, to insert on the scutum medium of the middle phalanx.[1-6,10-12] The straight distal sesamoidean ligament lies dorsal to the DDFT and has an hourglass shape, larger proximally and distally, and narrowest in the middle.

The DFTS surrounds the SDFT and DDFT throughout the proximal aspect of the proximal phalanx to the bifurcation of the SDFT.[1-6,10-15] The entire length of the DDFT is included in the DFTS, except for a small area in the distal palmar pastern, just proximal to the bulbs of the heel. The dorsal aspect of the DFTS extends farther distally than its palmar aspect. The proximal digital annular ligament is adhered closely to the palmar aspect of the SDFT in the proximal pastern.[1,3-5,16] The distal digital annular ligament forms a sling over the distal part of the DDFT. These two structures are thin in normal horses.

The palmar ligaments of the proximal interphalangeal joint originate in pairs from the medial and lateral aspects of the proximal phalanx, medial or lateral (respectively) to the SDFT branches, and insert on the scutum medium between the straight distal sesamoidean ligament and the branches of the SDFT. These are large, round to oval ligaments that extend in a diagonal direction from the origin to the insertion. The collateral ligaments of the proximal interphalangeal joint originate from a small eminence on the lateral and medial aspects of the proximal phalanx, distal to the origin of the palmar ligaments, and arc across the joint to insert on a small eminence on the lateral and medial aspects, respectively, of the proximal aspect of the middle phalanx.[1,3,7,10] The proximal interphalangeal joint has a closely adhered joint capsule.

The common digital extensor tendon is located on the dorsal aspect of the pastern.[1] The extensor branch of the suspensory ligament (SL) joins the common digital extensor tendon in the distal part of the proximal phalanx. The main insertion of the common digital extensor tendon is on the extensor process of the distal phalanx, but there are also areas of insertion onto the proximal and middle phalanges. A bursa is present between the tendon and the proximal interphalangeal joint.

ULTRASONOGRAPHIC ANATOMY

The pastern has been divided into five zones: three zones for the proximal phalanx and two zones for the shorter middle phalanx [1-6,11-14] (see Chapter16).

Superficial Digital Flexor Tendon

In the proximal pastern (zone PlA) the SDFT is imaged from the palmar aspect and is homogeneously echogenic and has a

thin, half-moon shape in the transverse plane.[1-6,11-13] In longitudinal images the SDFT has a parallel fiber pattern and a triangular shape along the midline in zone PlA, because its thickness decreases distally. In normal horses, distinguishing the proximal digital annular ligament from the DFTS and the palmar border of the SDFT is difficult. The body of the SDFT ranges in thickness (palmar to dorsal) from 2 to 6 mm in PlA to 1 to 4 mm over the middle of the proximal phalanx.[3] The teardrop-shaped branches in the proximal to mid-pastern region (at the junction of zones PlA and P1B) are imaged from the palmaromedial and palmarolateral aspects and are followed individually to their triangular-shaped insertions. The SDFT branches are similarly homogeneously echogenic, with a parallel fiber pattern throughout. The branches of the SDFT range in thickness from 4 to 7 mm in the proximal pastern to 7 to 12 mm distally.[14] The CSA of the two SDFT branches ranges from 0.3 to 0.4 cm^2 in the distal portion of zone PlA where the branch begins, increases to 0.4 to 0.6 cm^2 in zone PlB, and further enlarges to 0.6 to 0.8 cm^2 near the insertion.

Deep Digital Flexor Tendon

The DDFT has an oval to bilobed appearance in the pastern and is imaged on the palmar midline of the pastern until the DDFT is lost from view distally.[1-6,11-14] The two lobes are symmetrical. The fibers of the DDFT extend obliquely from a deeper to a more superficial position in the more distal portion of the pastern and are separated from the straight distal sesamoidean ligament by an anechogenic space. The dorsopalmar thickness and lateral to medial width of the DDFT decrease in the mid-pastern and increase again in the distal pastern. The DDFT measures 5 to 10 mm (palmar to dorsal) in the proximal pastern, slightly less in the mid-pastern, and 7 to 12 mm in the distal pastern region. The width of the DDFT in a lateral-to-medial direction ranges from 18 to 33 mm in the proximal pastern, decreasing to 15 to 23 mm in the mid-pastern, and increasing in the distal pastern to 23 to 32 mm.[3] Along the dorsal aspect of the DDFT in the mid-pastern region is a synovial fold of the DFTS that is imaged readily, surrounded by a small amount of anechogenic synovial fluid. In the distal pastern region the palmar aspect of the DDFT adheres to the synovial membrane of the DFTS.

Oblique Distal Sesamoidean Ligaments

The origin of the medial or lateral branch of the oblique distal sesamoidean ligament is best found by placing the ultrasound transducer over the medial or lateral PSB and scanning distally over the bone to its base.[1-6,11,12] Alternatively, the origin of the oblique distal sesamoidean ligament can be found by following the SL branches distally over the respective PSBs to the base. Immediately distal to the base of the PSB is the origin of the oblique distal sesamoidean ligament, best located initially in its transverse section as a large, round to oval structure. The branches of the oblique distal sesamoidean ligament merge in the distal part of zone PlA into a broad, rectangular band dorsal to the DDFT. The oblique distal sesamoidean ligament then inserts on the palmar or plantar aspect of the proximal phalanx in zone P1B. The oblique distal sesamoidean ligament is the most difficult to follow to its insertion, because the ligament extends diagonally from its origin to its insertion. Following the medial or lateral branch from its origin to the main body of the oblique distal sesamoidean ligament requires a transducer angle of about 45° from the base of the PSBs to the palmar midline of the proximal phalanx. Properly aligning the transducer and eliminating off-normal incidence artifact is difficult. The oblique distal sesamoidean ligament branches may appear less echogenic because of an oblique orientation. The branches are thickest in the medial to lateral direction proximally. The oblique distal sesamoidean ligament branches measure 12 to 20 mm (lateral to medial) in proximal PlA, decreasing to 9 to 17 mm just before their convergence, and 0 to 9mm (one side only) at their insertion. The palmar to dorsal thickness of the oblique distal sesamoidean ligament branches is 5 to 12 mm in PlA, decreasing to 2 to 6 mm just proximal to the convergence, and decreasing again to 0 to 3 mm at the insertion.

Straight Distal Sesamoidean Ligament

The origin of the straight distal sesamoidean ligament is found by angling the transducer in a proximal and dorsal direction from the proximal most aspect of the pastern, just underneath the ergot, to image the ligament and the base of the PSBs. The straight distal sesamoidean ligament becomes a more oval-shaped structure and is palmar to the oblique distal sesamoidean ligament in zone P1B. The straight distal sesamoidean ligament remains dorsal to the DDFT as it inserts on the scutum medium.

The dorsal-to-palmar thickness of the straight distal sesamoidean ligament gradually increases as the medial to lateral width decreases. The straight distal sesamoidean ligament measures 5 to 9 mm (palmar to dorsal) proximally, increasing slightly over the distal aspect of the proximal phalanx to 6 to 12 mm, and increasing again to 8 to 14 mm at the scutum medium. The medial-to-lateral thickness of the straight distal sesamoidean ligament ranges from 17 to 30 mm in zone P1A, decreases to 10 to 15 mm, and then widens over the scutum medium to 45 to 65 mm.[3] The straight distal sesamoidean ligament is echogenic with normal parallel fiber alignment throughout. Care must be taken to be sure that lesions are not created at the insertion of the straight distal sesamoidean ligament because of the difficulty in aligning the transducer perpendicular to the ligamentous fibers because of the horse's heel. A hypoechoic area of dropout is detected at this location with most ultrasound transducers, because the shape of the heel bulbs precludes obtaining a 90° angle between the transducer and the ligament. If proper angulation of the transducer can be achieved, however, this off-incidence artifact is not imaged.

Cruciate Distal Sesamoidean Ligaments

The cruciate distal sesamoidean ligaments are imaged only in the proximal most portion of the pastern and measure 2 to 4 mm in a palmar to dorsal direction.[3]

Collateral Ligaments

The collateral ligaments of the proximal interphalangeal joint are easiest to examine by imaging them longitudinally and then evaluating them in the transverse plane. The collateral ligaments of the proximal interphalangeal joint are homogeneously echogenic structures, with a parallel fiber pattern from their origin on the distal aspect of the proximal phalanx to their insertion on the proximal half of the middle phalanx.[1,2]

Proximal Interphalangeal Joint

The proximal interphalangeal joint is easiest to image initially in longitudinal plane by identifying the joint space, and then a transverse evaluation of the joint can be made.[7] Fluid normally is not imaged in the proximal interphalangeal joint.

Palmar/Plantar Ligaments of the Proximal Interphalangeal Joint

The palmar ligaments of the proximal interphalangeal joint can be imaged from the origin on the middle of the proximal phalanx to the insertion on the proximal palmar aspect of the middle phalanx. These ligaments are paired on the medial and lateral aspects of the pastern and are located by placing the

transducer dorsal to the branch of the SDFT. The more abaxial branch originates first and is easier to follow than the more axial branch. Each branch has a round to oval shape, is homogeneously echogenic with a parallel fiber pattern, and must be followed individually from origin to insertion.

Digital Nerves

The digital nerves are located dorsal to the lateral and medial aspects of the SDFT, adjacent to the lateral or medial palmar digital arteries.[1] The nerves are found most easily by identifying the digital vein and artery, looking immediately adjacent to the digital vein and the adjacent SDFT. The nerves are tiny, homogeneously echogenic circular structures. The normal thickness of the palmar or plantar digital nerves is 2 to 3 mm, with a CSA of 0.5 to 1 mm^2.[1]

TENDON AND LIGAMENT INJURIES

In the fore pastern the SDFT is the most frequently injured tendon or ligament in all performance horses. The oblique distal sesamoidean ligament is the second most commonly injured structure in the fore pastern, followed by injuries to the DDFT and straight distal sesamoidean ligament.[1-6] In the hind pastern, injuries to the DDFT are most common, with a low incidence of injuries to the other tendonous and ligamentous structures.[1-5] Injuries to the DDFT are accompanied most often by tenosynovitis of the DFTS.[1-6] Injuries to the collateral ligaments of the proximal interphalangeal joint occur infrequently and are more common in the forelimb.[1,3,7] Injuries to the palmar/plantar ligaments of the proximal interphalangeal joint are also uncommon and occur in forelimbs (most common) and hindlimbs. The tendonous and ligamentous structures in the pastern have little covering, and thus they are vulnerable to injury with puncture wounds and lacerations. Ultrasonographic evaluation of the pastern in a horse with an acute laceration or puncture wound to the pastern should be performed aseptically and is an integral part of the evaluation of these soft tissue structures to determine if injury occurred and the severity of the injury.

Superficial Digital Flexor Tendonitis

Injuries to the branches of the SDFT are more common in the forelimb.[1-6] Injury in the pastern may occur in isolation, without an injury to the SDFT in the metacarpal or metatarsal region, or may be an extension of a more proximal tendon injury. Extension of the SDFT injury into the proximal pastern region, and less frequently into the mid- and distal pastern, is more common in the forelimb. Abnormal conformation such as a long pastern, an underrun heel, or an axially displaced heel may predispose the horse to injury of an SDFT branch.

Lameness usually occurs at the onset of injury, is more common with SDFT injuries in the pastern than with those in the metacarpal or metatarsal region, and may persist longer, lasting for 1 to 4 weeks. Longitudinal swelling that extends in a proximal-to-distal direction along the lateral or medial aspect of the pastern throughout its length is often characteristic.[1,2] Focal heat and sensitivity usually accompany this swelling. However, in horses with acute injuries, no localizing clinical signs may be apparent, but lameness is alleviated by palmar (abaxial sesamoid) nerve blocks. Generally, swelling develops within 3 to 4 days. Ultrasonographic examination in the absence of swelling may result in false-negative results. Subluxation of the proximal interphalangeal joint can occur in horses with severe injury to or complete rupture of the SDFT in the pastern. Severe dropping of the fetlock joint with weight bearing can occur in horses with severe SDFT injury.

Core injuries are the most common detected by ultrasonography (Fig. 83-1), followed by diffuse injury to the affected branch.[1,2] Complete ruptures or near complete ruptures of the branches do occur, but they are less frequent. These injuries can be unilateral or bilateral and uniaxial or biaxial, although uniaxial injuries are most common. The medial SDFT branch appears to be more frequently injured than the lateral branch. Peritendonous soft tissue swelling is common. Avulsion fracture of the insertion of the SDFT branch occurs infrequently. Ultrasonographic evaluation of the more proximal SDFT in the metacarpal or metatarsal region is indicated to determine if the injury is an extension of a more proximal injury (see Chapter 70) (Fig. 83-2). Ultrasonographic evaluation of the contralateral fore- or hindpastern is recommended, because bilateral disease may be present, more frequently in the forelimb. Radiographic evaluation of the pastern is indicated for all horses with subluxation of the proximal interphalangeal joint, avulsion fractures at the insertion of the SDFT branch, or a ruptured SDFT branch.

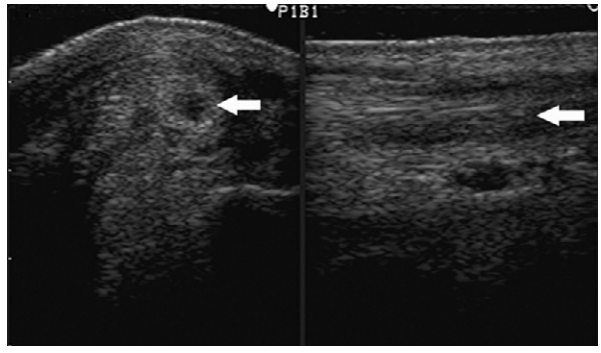

Fig. 83-1 Ultrasonographic images of the left fore lateral branch of the superficial digital flexor tendon obtained in the proximal part of zone P1B in a horse with acute injury. The anechoic to hypoechoic core lesion is apparent within the branch (*arrows*) in the transverse (*left image*) and longitudinal (*right image*) views. Fiber disruption and short linear fibers are imaged within the lesion in the longitudinal view, consistent with a recent injury and early healing. The horse was 1 out of 5 degrees lame, with focal swelling, heat, and sensitivity.

Treatment for horses with acute superficial digital flexor tendonitis in the pastern is similar to that in the metacarpal or metatarsal region.[1,2] Horses with SDFT injuries in the pastern may have a poorer prognosis for returning to racing than those with injuries in the metacarpal region, with a more frequent recurrence of injury.[1,2,17] However, successful return to performance does occur for horses with SDFT branch injuries. Rare horses are able to continue to compete with SDFT branch injuries, without a period of rest, but these are the exceptions rather than the rule. Healing of the SDFT occurs similarly to that in the metacarpal region, with an increase in the echogenicity of the lesion and the subsequent appearance of short, usually randomly aligned linear echoes. Rehabilitation of horses with injuries to the SDFT is similar to that described for bowed tendons and is based on the injury severity (see Chapter 70). A minimum of 6 months in a controlled exercise program is needed for horses with mild SDFT branch injury, whereas 12 months or more are indicated for those with severe injury to the SDFT branch to maximize the horse's chance of returning to its previous level of competition. Ultrasonographic monitoring of tendon healing is an important part of the rehabilitation program. A central echogenic scar surrounded by a hypoechoic halo may be detected in the SDFT branch with a healed core lesion (Fig. 83-3). Peritendonous echogenic tissue representing immature and maturing fibrous tissue often is imaged adjacent to the injured SDFT branch and can result in adhesions between the branch and the surrounding tendonous and peri-

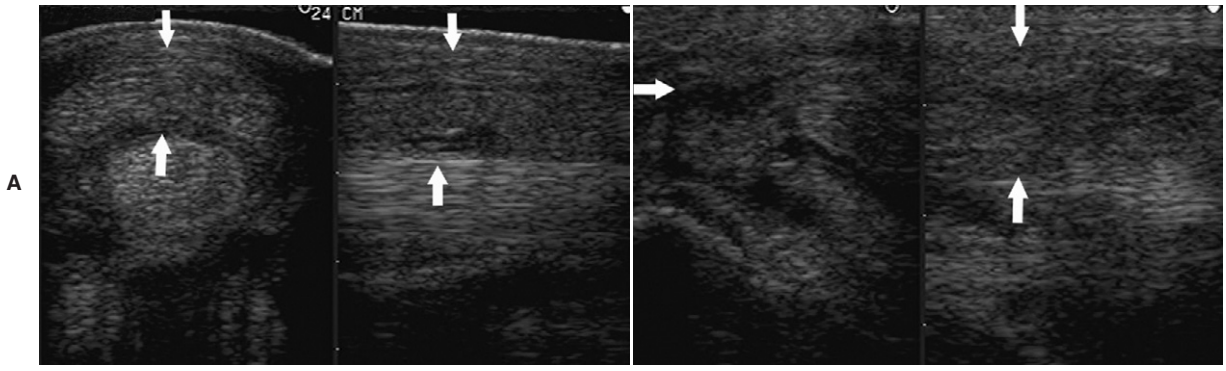

Fig. 83-2 Ultrasonographic images of the right superficial digital flexor tendon in the metacarpal region (**A**) and pastern (**B**) obtained from a horse with an acute severe injury to that tendon. This horse was lame at the walk, with substantial swelling of the superficial digital flexor tendon in the metacarpal and pastern regions and heat and sensitivity of the tendon on palpation. The metacarpophalageal joint dropped on weight bearing, and mild subluxation of the proximal interphalangeal joint was apparent. The transverse images are on the left, and the longitudinal images are on the right. **A,** The superficial digital flexor tendon is enlarged and slightly hypoechoic and was injured from 5 to 32 cm distal to the accessory carpal bone. The superficial digital flexor tendon in zone 3A is surrounded by a thickened hypoechoic digital flexor tendon sheath at the proximal reflection of the sheath (*arrows*). Although the superficial digital flexor tendon still appears relatively echogenic in the transverse image, moderate fiber disruption is visible in the longitudinal image (*arrows*). **B,** The medial branch of the superficial digital flexor tendon in the distal portion of zone P1A is hypoechoic with an abaxially located anechoic lesion *(arrow)* in the branching portion of the tendon in the transverse view (on the left). The surrounding digital sheath and peritendonous tissues are greatly thickened and hypoechoic, and the distinction between the abaxial margin of the superficial digital flexor tendon branch and the peritendonous structures is difficult to discern, particularly in the longitudinal image (on the right). The medial branch of the superficial digital flexor tendon (outlined by *arrows*) has nearly complete fiber disruption in the longitudinal image.

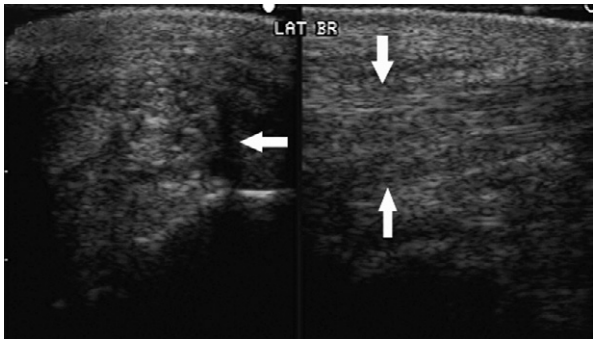

Fig. 83-3 Ultrasonographic images of the left fore lateral branch of the superficial digital flexor tendon obtained in zone P1B of a horse with a chronic healed core injury. The horse had sustained the original injury more than 5 years earlier, and after a long, controlled exercise program the horse had raced successfully several times a year, although some small areas of re-injury were detected periodically, necessitating short periods of downtime from race training. The original central core lesion is still visible in this branch as an echogenic central area, with a thin hypoechoic rim (*arrow*) in the transverse view (*left image*) and longitudinal *(right image)* views. In the longitudinal view the central area of the tendon has a more random fiber pattern than the periphery.

tendonous structures. New areas of fiber disruption often occur adjacent to the previously healed area (see Fig. 83-2) or are associated with adhesions to the surrounding tendonous or peri-tendonous structures.

Deep Digital Flexor Tendonitis

Deep digital flexor tendonitis is discussed in Chapter 71.

Distal Sesamoidean Desmitis

Oblique Distal Sesamoidean Desmitis

Desmitis of the oblique distal sesamoidean ligament is most common and has been seen in all types of performance horses.[1-6] Horses with a valgus or varus limb conformation or a long sloping pastern may be at increased risk for oblique distal sesamoidean ligament injuries. Swelling in the pastern region in horses with oblique distal sesamoidean ligament injuries is characteristic, because this ligament runs diagonally across the proximal to mid-pastern and swelling of the pastern usually occurs in this direction. Most horses have local swelling, heat, and pain detected on palpation of the affected ligament and lameness in the affected leg. Subluxation of the proximal interphalangeal joint can occur in horses with complete rupture of the oblique distal sesamoidean ligaments. Complete biaxial rupture of the oblique distal sesamoidean ligaments is more common in Thoroughbreds and can have catastrophic implications. Distal sesamoidean ligament injury involving the medial branch of the oblique distal sesamoidean ligament is more common than injury involving the lateral branch and is more common in the forelimb than in the hindlimb.[3] Hindlimb oblique distal sesamoidean ligament injuries are more common in horses that are not used for racing. Horses with SL injury are also at increased risk of injuring the oblique distal sesamoidean ligaments. Therefore ultrasonographic evaluation of the SL is recommended for all horses with oblique distal sesamoidean desmitis.

Discrete core lesions often are seen in the medial and lateral branches of the oblique distal sesamoidean ligament, although diffuse areas of fiber damage and splits also occur (Fig. 83-4). Injuries to the insertion of the oblique distal sesamoidean ligament are usually diffuse (Fig. 83-5). Periligamentous soft tissue thickening is often seen. Comparison of the ultrasonographic findings in the affected limb with the

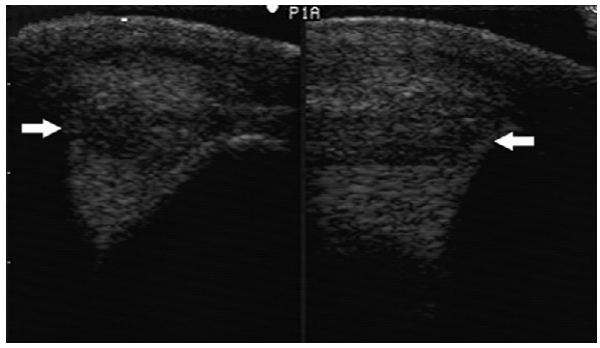

Fig. 83-4 Ultrasonographic images of the origin of the left fore medial branch of the oblique distal sesamoidean ligament obtained in zone PlA. The abaxial portion of the oblique distal sesamoidean ligament is diffusely hypoechoic (*arrow*) in the transverse (*left image*) and longitudinal (*right image*) views. Substantial fiber disruption is visible in the longitudinal view, beginning at the base of the proximal sesamoid bone *(arrow)*. Some periligamentous echogenic soft tissue thickening surrounds the branch. The stallion was sound, but had local heat, swelling, and mild sensitivity of the medial oblique distal sesamoidean ligament.

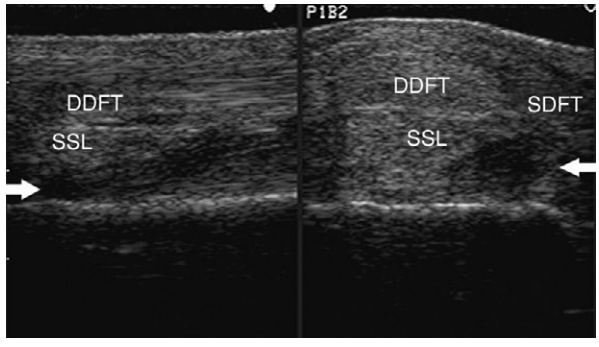

Fig. 83-5 Transverse *(on the right)* and longitudinal *(on the left)* ultrasonographic images of the lateral branch of the right fore oblique distal sesamoidean ligament obtained where the two branches join. The lateral aspect of the transverse view is on the right side of the image. This horse had sustained an acute injury to the lateral branch of the oblique distal sesamoidean ligament from the base of the lateral proximal sesamoid bone to its insertion. A large anechoic to hypoechoic core lesion (*arrows*) is visible. The horse was lame at the walk, with mild subluxation of the proximal interphalangeal joint and local swelling, heat, and sensitivity along the entire lateral branch of the oblique distal sesamoidean ligament. *DDFT,* Deep digital flexor tendon; *SSL,* straight sesamoidean ligament; *SDFT,* superficial digital flexor tendon.

contralateral limb is recommended to be sure that subtle or early injuries are not missed. The origin and insertion of the oblique distal sesamoidean ligaments should be carefully evaluated for avulsion fractures.[1,2] Avulsion fractures usually occur in association with fiber tearing in the distal sesamoidean ligaments and occur from the base of the PSBs (Fig. 83-6) and the insertion on the proximal phalanx. Avulsion fractures remain visible for years after the original injury, long after the associated desmitis in the distal sesamoidean ligament has resolved. Radiographs of the fetlock (particularly the PSBs) and the pastern regions should be obtained in all horses with oblique distal sesamoidean desmitis, paying careful attention to the base of the PSBs. However, it is important to recognize that entheseous new bone on the base of one or both of the

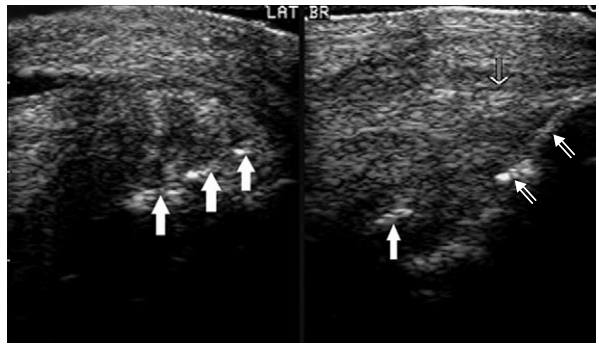

Fig. 83-6 Ultrasonographic images of the lateral branch of the oblique distal sesamoidean ligament obtained in zone PlA of the left forelimb in a horse with chronic active desmitis of the oblique distal sesamoidean ligament and small basilar sesamoid fractures. The hyperechoic bony fragments *(arrows)* are distracted away from the base of the proximal sesamoid bone in the transverse view (*left image*) and the longitudinal view (*right image*). Hypoechoic to anechoic areas are visible in the transverse view, abaxial to the fracture fragments, and areas of amorphous and random fiber pattern are imaged in the longitudinal view, distal to the fracture fragments (to the left of the image). The basilar surface of the lateral proximal sesamoid bone is irregular *(open arrows)*. The horse was 1 out of 5 degrees lame, with thickening of the base of the lateral proximal sesamoid bone, but no heat or local sensitivity.

PSBs or on the mid-palmar aspect of the proximal phalanx can be seen as incidental radiographic abnormalities, unassociated with lameness or active desmitis. Homogeneously radiopaque mineralized bodies are also sometimes seen distal to the PSBs as incidental findings.

Horses with acute injuries to the oblique distal sesamoidean ligament should be managed in the same way as those with other tendon and ligament injuries, with initial anti-inflammatory therapy and exercise restriction.[1,2] A controlled exercise program with incremental increases in the exercise level should be based on ultrasonographic monitoring. As the injury heals, the CSA of the ligament usually decreases, the echogenicity of the lesion increases, and linear echoes are imaged in the area of previous fiber tearing (Fig. 83-7). A long recuperative period usually is indicated for horses with oblique distal sesamoidean desmitis to maximize the chance of return to athletic function.

Prognosis for horses with oblique distal sesamoidean ligament injury is guarded to grave for returning successfully to racing and other competitive athletic activities and depends on the severity of the injury. Horses with coexisting suspensory desmitis, basilar fractures of the PSBs, or subchondral palmar third metacarpal or plantar third metatarsal bone disease have a poorer prognosis for return to athletic function. The incidence of recurrence of oblique distal sesamoidean ligament injury is high. Prognosis is grave for athletic horses with subluxation of the proximal interphalangeal joint associated with distal sesamoidean desmitis.

Straight Distal Sesamoidean Desmitis

Injuries to the straight distal sesamoidean ligament occur infrequently and may occur alone or with other soft tissue injuries.[1-6] These injuries usually are associated with lameness, but focal heat, swelling, and sensitivity are not always detected. Lameness is usually acute in onset and may be severe. Some horses, especially those with proximal lesions, never develop localizing soft tissue swelling, and diagnosis depends on localizing pain to the pastern region by diagnostic analgesia and subsequent ultrasonographic identification of a

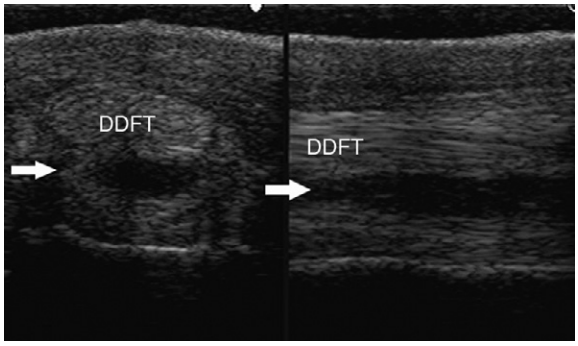

Fig. 83-7 Ultrasonographic images of the right fore pastern obtained in zone P1B from a horse with an acute injury to the straight distal sesamoidean ligament. The horse was lame at the walk, with swelling of the palmar aspect of the pastern and local heat and sensitivity. The large anechoic core lesion (*arrows*) in the palmar aspect of the straight distal sesamoidean ligament is visible in the transverse view (*left image*), with complete fiber disruption in this region that is best imaged on the longitudinal view (*right image*). The straight distal sesamoidean ligament is enlarged in dorsal to palmar and medial to lateral directions. Note also the thickened subcutaneous tissues. *DDFT,* Deep digital flexor tendon.

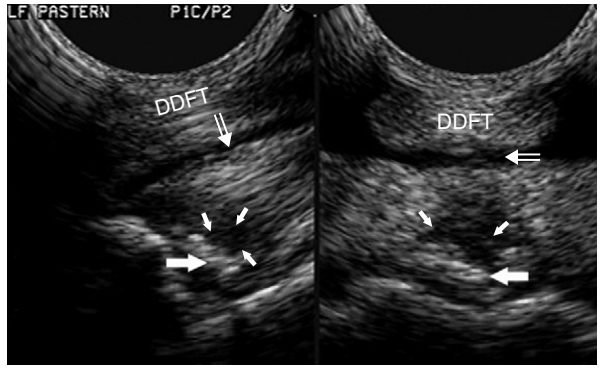

Fig. 83-8 Ultrasonographic images of the left fore straight distal sesamoidean ligament obtained in zone PlC-P2A from a horse with an acute severe injury to the straight distal sesamoidean ligament and an avulsion of its insertion onto the scutum medium. The horse was lame at the walk, with subluxation of the proximal interphalangeal joint and substantial soft tissue swelling of the palmar pastern, with local heat and pain on palpation of the oblique distal sesamoidean ligament and straight distal sesamoidean ligament. The hypoechoic lesion (*small arrows*) in the distal most portion of the oblique distal sesamoidean ligament and the hyperechoic fragment distracted away from the middle phalanx (*large arrows*) are visible in the transverse (*right image*) and longitudinal (*left image*) views. There is anechogenic effusion *(open arrows)* in the digital flexor tendon sheath. *DDFT,* Deep digital flexor tendon.

lesion. The ease with which the most proximal aspect of the ligament can be seen depends on the conformation of the horse and the position of the ergot. Ultrasonographic viewing of the straight distal sesamoidean ligament is most difficult in horse with short pasterns and easiest in those with relatively long, upright pasterns.

Small splits or core lesions may be seen in the straight distal sesamoidean ligament.[1-6] Large areas of fiber disruption in the straight distal sesamoidean ligament are uncommon (Fig. 83-7). Areas of periosteal proliferative change or avulsion fractures at the insertion of the straight distal sesamoidean ligament on the proximal aspect of the middle phalanx may be seen (Fig. 83-8). Avulsion fractures of the origin of the straight distal sesamoidean ligament are less common than with oblique distal sesamoidean ligament desmitis, but the base of the PSBs should be evaluated carefully.

Treatment for horses with desmitis of the straight distal sesamoidean desmitis is similar to that recommended for horses with oblique distal sesamoidean desmitis.[1-6] Horses with mild injuries have returned successfully to racing, but the prognosis for horses with more severe lesions is guarded for any form of competitive athletic function, because recurrent injury is common. Horses with multiple tendonous or ligamentous injuries in the pastern have a guarded to grave prognosis for returning to full athletic function.

Cruciate Distal Sesamoidean Desmitis

Desmitis of the cruciate distal sesamoidean ligament is rare and difficult to diagnose by ultrasonography because of the location of these ligaments.[1,2]

Proximal Digital Annular Desmitis

Desmitis of the proximal digital annular ligament or proximal digital annular ligament constriction occurs infrequently.[1,3] Affected horses usually have chronic moderate to severe lameness. Distention of the palmar pouch of the DFTS is usually present, in addition to subtle distention proximal to the palmar annular ligament of the fetlock. Thickening of the proximal digital annular ligament and skin usually is substantial, with a combined thickness of 4 to 5 mm (normal thickness is 1 to 2 mm) and distention of the DFTS.[17]

SOFT TISSUE SWELLING

Soft tissue swelling in the pastern, without tendonous or ligamentous injury, can result from skin irritation caused by liniments, blisters, local therapeutic ultrasound or cold laser treatment, local trauma from a blow, bandaging, or bell boots, or from a skin infection. Ultrasonographic findings of thickened anechogenic to echogenic subcutaneous tissues, with normal tendonous and ligamentous structures, are typical for injury or inflammation to the skin and subcutaneous tissues. Thickening of the skin also may be seen in horses with skin irritation or infection. These horses usually respond well to local or systemic anti-inflammatory therapy.

TENOSYNOVITIS OF THE DIGITAL FLEXOR TENDON SHEATH

Tenosynovitis of the digital flexor tendon sheath is discussed in Chapter 75.

ABNORMALITIES OF THE PASTERN JOINT

Lameness and local swelling are two common findings in horses with injuries of the collateral or palmar ligaments of the proximal interphalangeal joint.[1,3-5,7-9] Swelling is usually primarily medial and lateral, although it can be circumferential. Acute desmitis of the collateral ligaments may be confirmed by ultrasonography, with decreased echogenicity and loss of fiber pattern, with or without an associated avulsion fracture (Fig. 83-9).[1,3-5,7] In horses with more chronic injuries enthesophyte formation at the origin and the insertion of the collateral ligaments usually is detected. A smoothing of these areas of insertional injury occurs as the desmitis becomes inactive. Similar ultrasonographic findings may be detected in horses with acute (Fig. 83-10) and chronic injury (Fig. 83-11) to the palmar ligaments of the pastern. These

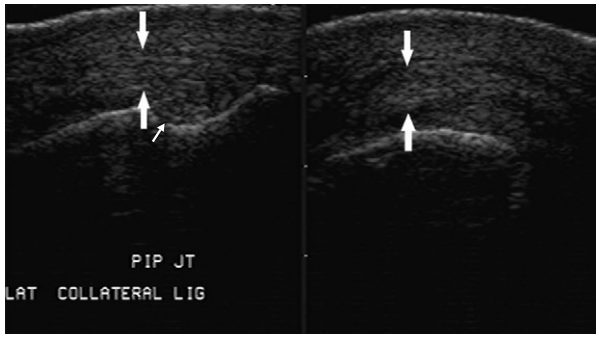

Fig. 83-9 Ultrasonographic images of the lateral collateral ligament of the proximal interphalangeal joint of the right forelimb of horse with moderate lameness and localized swelling. The thickening of the lateral collateral ligament (*arrows*) and the short random fiber pattern seen in the longitudinal view (*left image*) are consistent with desmitis. The distal portion of the proximal phalanx is on the right side of the longitudinal view. The small anechoic slit between the proximal and middle phalanges represents the joint space (*small arrow*). Some echogenic subcutaneous thickening is viewed best superficial to the collateral ligament in the transverse view (*right image*).

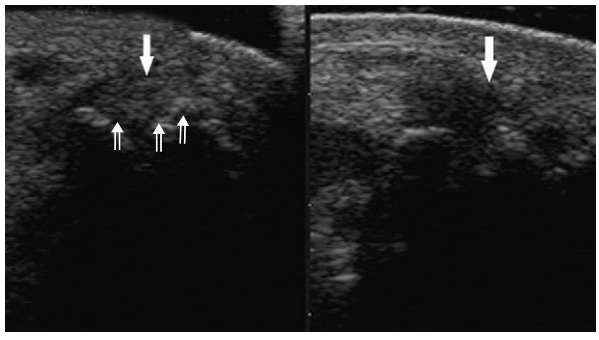

Fig. 83-11 Ultrasonographic images of the lateral palmar ligament of the proximal interphalangeal joint in a horse with chronic severe desmitis and severe enthesopathy. The bony proliferative changes of the proximal phalanx in the transverse (*left image*) and longitudinal views (*right image*) make imaging the ligament in its entirety in the longitudinal plane impossible. The visible portion of the ligament appears homogeneously echogenic in the transverse image (*arrows*), but there is a hypoechoic area within the ligament adjacent to the bony proliferative change in the longitudinal view (*arrow*). The mare was 2 out of 5 degrees lame, with thickening over the lateral and medial aspects of the proximal phalanx, but no heat or local sensitivity was detected.

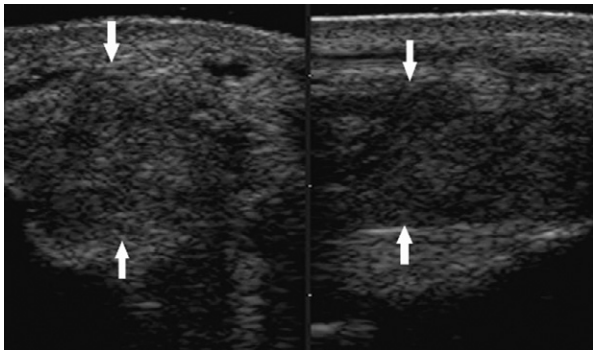

Fig. 83-10 Ultrasonographic images of the left abaxial plantar ligament of the proximal interphalangeal joint in a horse with severe desmitis associated with mild lameness and localized swelling. There is enlargement of the ligament. It is hypoechoic and circular to oval in the transverse view (*left image*), and has a random fiber pattern in the longitudinal view (*right image*). The *arrows* outline the margins of the ligament. A small amount of echogenic peritendonous subcutaneous tissue is visible.

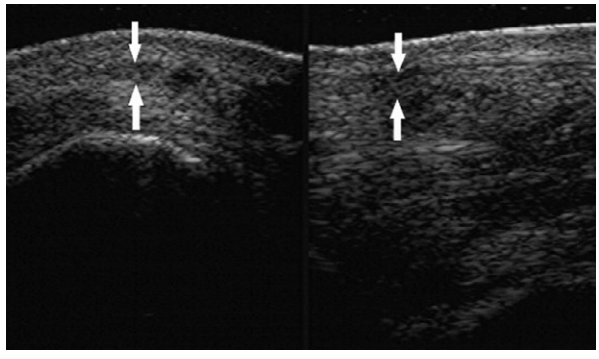

Fig. 83-12 Ultrasonographic images of the left hind lateral plantar digital nerve obtained from a horse with neuritis resulting in acute onset of moderate lameness with local swelling, heat, and exquisite sensitivity to palpation. The enlarged nerve *(arrows)*, oval to circular shape, is located plantar to the digital artery in the transverse view (*left image*). The cross-sectional area of the nerve is increased to 0.17 cm^2. A hypoechoic area disrupts part of the nerve (*arrows*) in the longitudinal view (*right image*).

horses have a guarded prognosis for return to full athletic function.

NEURITIS/NEUROMA

Neuritis of the palmar (plantar) digital nerves results in acute lameness associated with exquisite pain on palpation of the nerves and localized heat and swelling. Ultrasonography shows swelling and decreased echogenicity of the nerve (Fig. 83-12). Neuromas following palmar digital neurectomy initially appear as focal painful swellings over the stump of the digital nerve. With ultrasonography the nerve appears enlarged and hypoechoic, with perineural soft tissue swelling in horses with an acute neuroma. The neuroma becomes more echogenic and heterogeneous with increasing chronicity of injury. A large amount of perineural echogenic tissue may be present in horses with chronic neuromas.

CHAPTER • 84

Skeletal Muscle and Lameness

Stephanie J. Valberg and Sue J. Dyson

DIAGNOSIS OF SPECIFIC MUSCLE DISORDERS

Diagnosis of a particular muscle disorder is accomplished best with a thorough neuromuscular examination. The key components of the examination include the items mentioned in this section.

History

A history of stiffness, muscle cramping, pain, muscle fasciculations, exercise intolerance, weakness, or muscle atrophy may indicate a muscle disorder. Further characterization requires a detailed account of the horse's exercise schedule; diet; vaccination history; signs of respiratory disease; duration, severity, and frequency of muscle problems; any factors that initiate the muscle problem; and all medications with which the horse is being treated.

Physical Examination

A detailed evaluation of the muscular system includes inspection of the horse while standing with the forelimbs and hindlimbs exactly square to assess symmetry of muscle mass. Any evidence of fine tremors or fasciculations should be noted before palpating the horse. The entire muscle mass of the horse should be palpated for heat, pain, swelling, or atrophy, comparing contralateral muscle groups. Firm, deep palpation of the lumbar, gluteal, and semimembranosus and semitendinosus muscles may reveal pain, cramps, or fibrosis. The triceps, pectoral, gluteal, and semitendinosus muscles should be tapped with a fist or percussion hammer and observed for a prolonged contracture suggestive of myotonia. Running a blunt instrument, such as artery forceps, a needle cap, or a pen, over the lumbar and gluteal muscles should illicit extension (swayback), followed by flexion (hogback), in healthy animals. Guarding against movement may reflect abnormalities in the pelvic or thoracolumbar muscles or pain associated with the thoracolumbar spine (see Chapter 54) or sacroiliac joints (see Chapters 52 and 53). The horse should be observed at a walk or trot for any gait abnormalities and some horses should be ridden.

Ancillary Diagnostic Tests

Muscle Enzymes

Skeletal muscle necrosis may be identified by determining the activity in blood of serum enzymes or proteins that are normally present in high concentration within intact muscle cells but leak out into the blood stream following cell damage.[1,2] Three enzymes are used routinely to assess muscle necrosis: creatine kinase (CK), aspartate aminotransferase (AST), and lactate dehydrogenase (LDH). Carbonic anhydrase III and serum myoglobin also have been suggested as markers of equine muscle necrosis.[3,4] The permeability of the muscle cell membrane, rate of enzyme production, alternate tissue sources of the enzyme, and rate of enzyme excretion and degradation also may influence serum enzyme activities.[1]

Serum creatine kinase. Isoforms of CK are found in skeletal muscle, cardiac muscle, and nervous tissue. CK is a relatively low molecular weight protein (80,000 d) that is involved intimately in energy production within the cell cytoplasm. CK is liberated within hours of muscle damage or increased cell membrane permeability into the extracellular fluid and usually peaks at 4 to 6 hours after muscle injury (half-life [$t_{1/2}$] is 108 minutes).[5] A threefold to fivefold increase in serum CK from normal values is believed to represent necrosis of about 20 g of muscle tissue.[6] Rhabdomyolysis results in a proportionately greater increase in the skeletal muscle isoform than the cardiac muscle isoform, although some studies disagree with the tissue

Skeletal Muscle and Lameness

Stephanie J. Valberg and Sue J. Dyson

DIAGNOSIS OF SPECIFIC MUSCLE DISORDERS

Diagnosis of a particular muscle disorder is accomplished best with a thorough neuromuscular examination. The key components of the examination include the items mentioned in this section.

History

A history of stiffness, muscle cramping, pain, muscle fasciculations, exercise intolerance, weakness, or muscle atrophy may indicate a muscle disorder. Further characterization requires a detailed account of the horse's exercise schedule; diet; vaccination history; signs of respiratory disease; duration, severity, and frequency of muscle problems; any factors that initiate the muscle problem; and all medications with which the horse is being treated.

Physical Examination

A detailed evaluation of the muscular system includes inspection of the horse while standing with the forelimbs and hindlimbs exactly square to assess symmetry of muscle mass. Any evidence of fine tremors or fasciculations should be noted before palpating the horse. The entire muscle mass of the horse should be palpated for heat, pain, swelling, or atrophy, comparing contralateral muscle groups. Firm, deep palpation of the lumbar, gluteal, and semimembranosus and semitendinosus muscles may reveal pain, cramps, or fibrosis. The triceps, pectoral, gluteal, and semitendinosus muscles should be tapped with a fist or percussion hammer and observed for a prolonged contracture suggestive of myotonia. Running a blunt instrument, such as artery forceps, a needle cap, or a pen, over the lumbar and gluteal muscles should illicit extension (swayback), followed by flexion (hogback), in healthy animals. Guarding against movement may reflect abnormalities in the pelvic or thoracolumbar muscles or pain associated with the thoracolumbar spine (see Chapter 54) or sacroiliac joints (see Chapters 52 and 53). The horse should be observed at a walk or trot for any gait abnormalities and some horses should be ridden.

Ancillary Diagnostic Tests

Muscle Enzymes

Skeletal muscle necrosis may be identified by determining the activity in blood of serum enzymes or proteins that are normally present in high concentration within intact muscle cells but leak out into the blood stream following cell damage.[1,2] Three enzymes are used routinely to assess muscle necrosis: creatine kinase (CK), aspartate aminotransferase (AST), and lactate dehydrogenase (LDH). Carbonic anhydrase III and serum myoglobin also have been suggested as markers of equine muscle necrosis.[3,4] The permeability of the muscle cell membrane, rate of enzyme production, alternate tissue sources of the enzyme, and rate of enzyme excretion and degradation also may influence serum enzyme activities.[1]

Serum creatine kinase. Isoforms of CK are found in skeletal muscle, cardiac muscle, and nervous tissue. CK is a relatively low molecular weight protein (80,000 d) that is involved intimately in energy production within the cell cytoplasm. CK is liberated within hours of muscle damage or increased cell membrane permeability into the extracellular fluid and usually peaks at 4 to 6 hours after muscle injury (half-life [$t_{1/2}$] is 108 minutes).[5] A threefold to fivefold increase in serum CK from normal values is believed to represent necrosis of about 20 g of muscle tissue.[6] Rhabdomyolysis results in a proportionately greater increase in the skeletal muscle isoform than the cardiac muscle isoform, although some studies disagree with the tissue

specificity of serum CK isoforms in the horse.[7] Limited elevations in CK (<1000 U/L) may accompany training or transport.[8] Extreme fatiguing exercise (e.g., endurance rides, or the cross country phase of a Three Day Event) may result in CK activities being increased to more than 1000 U/L, but usually less than 5000 U/L. Under these circumstances, serum CK activities rapidly return to baseline (i.e., <350 U/L in 24 to 48 hours). Recumbent animals also may have slightly elevated CK activities that are usually less than 3000 U/L. In contrast, more substantial elevations (from several thousand to hundreds of thousands of units per liter) in the activity of this enzyme may occur with rhabdomyolysis.[9]

Serum aspartate aminotransferase Serum AST, previously known as serum glutamic-oxaloacetic transaminase, is a larger molecular weight protein that has high activity in skeletal and cardiac muscle and liver, red blood cells, and other tissues.[1] Elevations in AST are not specific for myonecrosis and increases could result from hemolysis and muscle, liver, or other organ damage. AST activity rises more slowly in response to myonecrosis than does CK, often peaking between 12 to 24 hours after the insult. In addition, AST is cleared slowly by the reticuloendothelial system and may persist for 2 to 3 weeks after rhabdomyolysis ($t_{½}$ is 7 to 10 days).[5]

By comparing serial activities of CK and AST, information concerning the progression of myonecrosis or muscle cell membrane permeability may be derived. Elevations in CK and AST reflect relatively recent or active myonecrosis or muscle cell stress. Persistently elevated serum CK indicates that myonecrosis or muscle stress is likely to be continuing. Elevated AST activity accompanied by decreasing or normal CK activity indicates that myonecrosis has ceased. The degree of elevation of CK and AST does not necessarily reflect the severity of clinical signs.

Serum lactate dehydrogenase LDH is a tetramer made of combinations of the M (muscle) and H (heart) subunits, with five isoenzyme forms found in various organs within the body. Electrophoretic separation suggests that the M_4 (LDH_5) and M_3H (LDH_4) isoforms are found predominantly in skeletal muscle. Elevations in LDH may be detected in horses with rhabdomyolysis, myocardial necrosis, or hepatic necrosis.[8] Therefore concurrent measurement of serum CK is necessary to establish that rhabdomyolysis is present.

Myoglobin Elevation in plasma and serum myoglobin concentrations indicate acute muscle damage. Myoglobin is a low molecular weight protein (16,500 MW) that leaks into plasma immediately after muscle damage and is rapidly cleared in the urine by the kidney. About 200 g of muscle or more must be damaged before myoglobin is detectable in the urine in people.[10] Normal serum concentrations in resting horses have been determined by nephelometry (range 0 to 9 μg/L), with measured concentrations with rhabdomyolysis ranging from 10,000 to 800,000 μg/L.[3,11]

Exercise Response Test

Diagnosing chronic exertional rhabdomyolysis may be problematic in horses that do not have acute clinical signs and have normal serum AST and CK concentrations at rest. In such horses, an exercise challenge can be helpful in detecting subclinical exertional rhabdomyolysis. In addition, quantifying the extent of rhabdomyolysis during mild exercise is helpful in deciding how rapidly to put a horse back into training. Blood samples should be taken before exercise and about 4 to 6 hours after exercise to evaluate peak changes in CK level. Serum CK activity measured immediately after exercise will not reflect the amount of damage occurring during the exercise test. Small fluctuations in serum CK activity may occur with exercise because of enhanced muscle membrane permeability, particularly if exercise is prolonged or strenuous and the horse is untrained.[12] A submaximal exercise test is often valuable for detecting rhabdomyolysis because it provides more consistent evidence of subclinical rhabdomyolysis than maximal exercise tests.[9,13] Fifteen minutes of trotting is often sufficient to produce subclinical muscle damage in horses prone to exertional myopathies.[13] If signs of stiffness develop before this, exercise should be concluded. A normal response would be less than a three- to fourfold increase from basal CK concentration.

Thermography

Thermography (see Chapter 25) may be useful for identifying superficial abnormal temperature changes caused by muscle damage, but it has little value in horses with deeper injuries. However, there are many potentially confusing issues, such as recent removal of a rug or tack. Careful comparisons of the left and right sides should be made. Muscle inflammation is seen as an area of increased temperature in the skin directly overlying the affected muscle. The most common sites of muscle strain identified thermographically include the longissimus dorsi, the origin or body of the middle gluteal, the insertion of the gluteals on the greater and third trochanters of the femur, biceps femoris, semitendinosus, semimembranosus, and adductor.[14]

Nuclear Scintigraphy

Nuclear scintigraphy is useful for identifying some forms of muscle damage and may alert the clinician to an area of deep muscle damage that had not been suspected based on clinical examination. In human athletes ^{99m}Tc stannous pyrophosphate has been used to assess the degree of skeletal muscle damage and to delineate areas of damage.[15,16] It is thought that abnormal radiopharmaceutical uptake reflects an early stage of muscle damage caused by episodic ischemia, which is reversible in some fibers, but may lead to muscle necrosis in others.[15]

^{99m}Tc methylene diphosphonate is taken up in some damaged muscle in the horse and is best seen in bone-phase images, that is, 3 hours after radiopharmaceutical injection. Scintigraphy has been used most commonly in horses with a history of poor performance, with or without stiffness after exercise, to confirm a diagnosis of exertional rhabdomyolysis.[17] Some, but not all, horses with recurrent exertional rhabdomyolis have abnormal radiopharmaceutical uptake into the affected muscles. The mechanism of ^{99m}Tc-MDP binding is unknown, but the release of large amounts of calcium from damaged muscle or the exposure of calcium binding sites on protein macromolecules in the damaged muscle may be responsible.

The use of scintigraphy for diagnosing other muscle injuries has not been documented in the horse, but in one author's experience (S.J.D.) can be helpful in some horses with proximal forelimb or hindlimb muscle injury. Radiopharmaceutical uptake tends to be much more focal and much less intense than in horses with exertional rhabdomyolysis. In some, but not all, horses the region of increased radiopharmaceutical uptake has correlated with a region of increased echogenicity identified by ultrasonography.

Ultrasonography

Diagnostic ultrasonography is potentially useful for identifying muscle trauma and fibrosis, provided that physical disruption of the muscle occurs and assuming that one knows where to look. Muscles have a rather typical striated echogenic pattern,[18,19] but this varies by muscle group, and careful comparisons must be made between similar sites in contralateral limbs in transverse and longitudinal images. The appearance of muscle is also sensitive to how the horse is standing and whether the muscle is under tension, so it is important that the horse is standing squarely and bearing weight evenly. Muscle fascia appears as well-defined, relatively echogenic bands. Care must be taken in identifying large vessels and artifacts created by them.

In an acute injury, muscle fiber disruption is seen as relatively hypoechoic areas within muscle, with loss of the normal muscle fiber striation. The jagged edge of the margin of the torn muscle may be increased in echogenicity. Tears in

the muscle fascia may be identified. The defect in the muscle may be filled by a loculated hematoma, which is slowly replaced by granulation tissue that is hypoechogenic. As the muscle fiber repairs, echogenicity progressively increases. Relatively hyperechoic regions may develop because of fibrous scarring, which may result in long-term gait abnormalities. Hyperechoic regions causing shadowing artifacts reflect mineralization.

Muscle Biopsy

The routine examination of muscle biopsies from horses with various myopathies has resulted in identification of a number of specific equine myopathies. To characterize fully a neuromuscular disorder and its rate of progression, muscle fiber sizes and shapes, fiber type distribution, mitochondrial distribution, polysaccharide staining pattern, neuromuscular junctions, nerve branches, connective tissue, and blood vessels should be examined in frozen sections using a battery of tinctorial and histochemical stains.[20]

A number of basic pathological responses of muscle can be identified in formalin-fixed, paraffin-embedded sections. These include inflammation, muscle fiber necrosis, muscle fiber regeneration, variations in muscle fiber sizes and shapes, vacuolar change, and proliferation of connective tissue. However, many pathological alterations cannot be detected in formalin-fixed tissue, but they can be seen readily in histochemical stains of fresh-frozen biopsy samples.[21] These alterations include muscle fiber types and the respective pattern of distribution to differentiate neurogenic atrophy from myogenic atrophy, characterization of vacuolar storage material, characterization of inclusion bodies, assessment of mitochondrial density, and biochemical analysis of substrate concentrations and enzyme activities.

When considering collection of muscle biopsy specimens, some general guidelines are applicable. Samples preferably should be collected from what is considered abnormal or diseased muscle. A 6-mm outer diameter (Carl Mortensen, Baerskov, Denmark) percutaneous needle biopsy technique can be used to obtain small muscle samples through a 1.5-cm skin incision using subcutaneous local analgesia. If this technique is used, at least 1.5 cm^2 of tissue should be obtained. These samples do not tolerate transport well to an outside laboratory. The optimum biopsy for transport of histopathological tissues to a laboratory is collected using surgical or open techniques, performed with the horse under local analgesia. Care must be exercised to infiltrate only the subcutaneous tissues, not the muscle, with the local anesthetic agent. The objective is to obtain about a 2-cm cube of tissue, and a suitably long skin incision is required. Subsequently two parallel incisions 2 cm apart should be made with a scalpel longitudinal to the muscle fibers. The muscle should only be handled in one corner using forceps. The muscle sample is then excised by transverse incisions 2 cm apart, and the tissue is fixed appropriately.

Routine histopathological samples can be placed in formalin. Samples for histochemical analysis require fixation in isopentane (methylbutane), chilled in liquid nitrogen to ensure rapid freezing and minimization of freeze artifact. In the field, where freezing is not possible, fresh samples wrapped in gauze moistened with saline solution can be shipped in a watertight hard container on ice-packs to specialized laboratories. Samples that potentially may be used for biochemical analysis should be frozen immediately in liquid nitrogen. Samples for electron microscopy (EM) require appropriate fixation in glutaraldehyde preparations. Ideally, thin sections of muscle for electron microscopy should be clamped in vivo to maintain fibers at a resting length before they are excised. However, if pathological conditions other than the alignment of thick and thin myofilaments are to be investigated, small muscle pieces can be excised and placed directly in appropriate EM fixative.

Responses of strips of fresh muscle to stimuli such as caffeine, halothane, and a variety of other agents can be performed on site by specialized laboratories.[22,23]

Electromyography

A specific diagnosis of the cause of muscle atrophy, muscle fasciculations, or myotonic dimpling after tapping the muscle can be aided by performing electromyography. Electromyography of normal skeletal muscle shows a brief burst of electrical activity when the needle is inserted in muscle and then quiescence, unless motor units are recruited (motor unit action potentials) or the needle is close to a motor end plate (miniature end plate potentials). Normal muscle shows little spontaneous electrical activity, unless the muscle contracts or the horse moves. Horses with abnormalities in the electrical conduction system of muscle, or denervation of motor units, show abnormal spontaneous electrical activity in the form of fibrillation potentials, positive sharp waves, myotonic discharges, or complex repetitive discharges.[24]

Classification of Muscle Disease

Based on the information obtained on neuromuscular examination and muscle biopsy a diagnosis usually can be obtained. The following classification system may be helpful in narrowing down causes of muscle disease in horses:

I. Non-exercise associated rhabdomyolysis
  A. Inflammatory myopathies
    1. Clostridial myositis
    2. Influenza myositis
    3. Sarcocystis myositis
    4. Immune-mediated myopathy
  B. Nutritional myopathy
    1. Vitamin E and selenium deficiency
  C. Toxic myopathy
    1. Ionophore toxicity
    2. Pasture myopathies
      a. Rayless golden rod or white snake root
      b. *Cassia occidentalis*
      c. Atypical myoglobinuria
  D. Traumatic myopathy
    1. Compressive anesthetic myopathy
    2. Trauma
  E. Metabolic myopathy
    1. Glycogen branching enzyme deficiency in Quarter Horses
    2. Polysaccharide storage myopathy

II. Exertional rhabdomyolysis
  A. Focal muscle strain
  B. Sporadic tying-up (historically first episode; normal AST)
  C. Chronic tying-up
    1. Dietary imbalances, vitamins, minerals, electrolytes
    2. Polysaccharide storage myopathy (biopsy diagnosis)
    3. Recurrent exertional rhabdomyolysis (biopsy diagnosis)
    4. Idiopathic chronic exertional rhabdomyolysis

III. Exertional myopathy with normal CK
  A. Mitochondrial myopathy

IV. Muscle atrophy
  A. Myogenic atrophy
    1. Severe rhabdomyolysis
    2. Disuse
    3. Cushing's disease
    4. Immune-mediated myositis (rapid atrophy)
  B. Neurogenic atrophy
    1. Equine protozoal myelitis
    2. Local nerve trauma
    3. Equine motor neuron disease

V. Muscle fasciculations
  A. Pain, fear

B. Electrolyte abnormalities
C. Hyperkalemic periodic paralysis
D. *Otobius megnini* ear tick infestation
E. Myotonic dystrophy
F. Stiff horse syndrome

MUSCULAR PAIN, STRAIN, AND TEARS

The role of muscle pain and injury in lameness and poor performance in the horse is poorly recognized. In human athletes muscle fatigue, muscle stiffness, and muscle soreness are well recognized entities, although the pathological processes in the absence of detectable structural abnormalities are not understood completely. Raised intramuscular pressure may be associated with muscle pain after prolonged vigorous exercise in human athletes.[15]

Delayed-onset muscular stiffness or soreness is recognized in people as pain that develops 24 to 48 hours after unaccustomed use of certain muscles and usually resolves spontaneously, assuming the muscles are not overworked again.[25] Continued overstress may result in structural muscle damage. However, specific training involving the activity that provoked the original delayed-onset muscular stiffness or soreness decreases the amount of soreness associated with that condition.

Muscle soreness in the pectoral region after repeated jumping efforts is commonly recognized, especially in event horses several hours after completing the cross country phase of a Three Day Event (S.J.D.).[26] Massage seems to improve the soreness.

Muscle fiber tearing and hemorrhage can result in acute muscular pain in human athletes. A palpable defect or swelling can be detected in superficial muscles. For deeper muscles ultrasonography is required for accurate diagnosis.[27,28]

Muscle fibrosis and mineralization have been well documented in the horse after tearing of the semimembranosus and semitendinosus muscles (see Fibrotic Myopathy, Chapter 81), but acute lesions elsewhere in the limbs have been documented

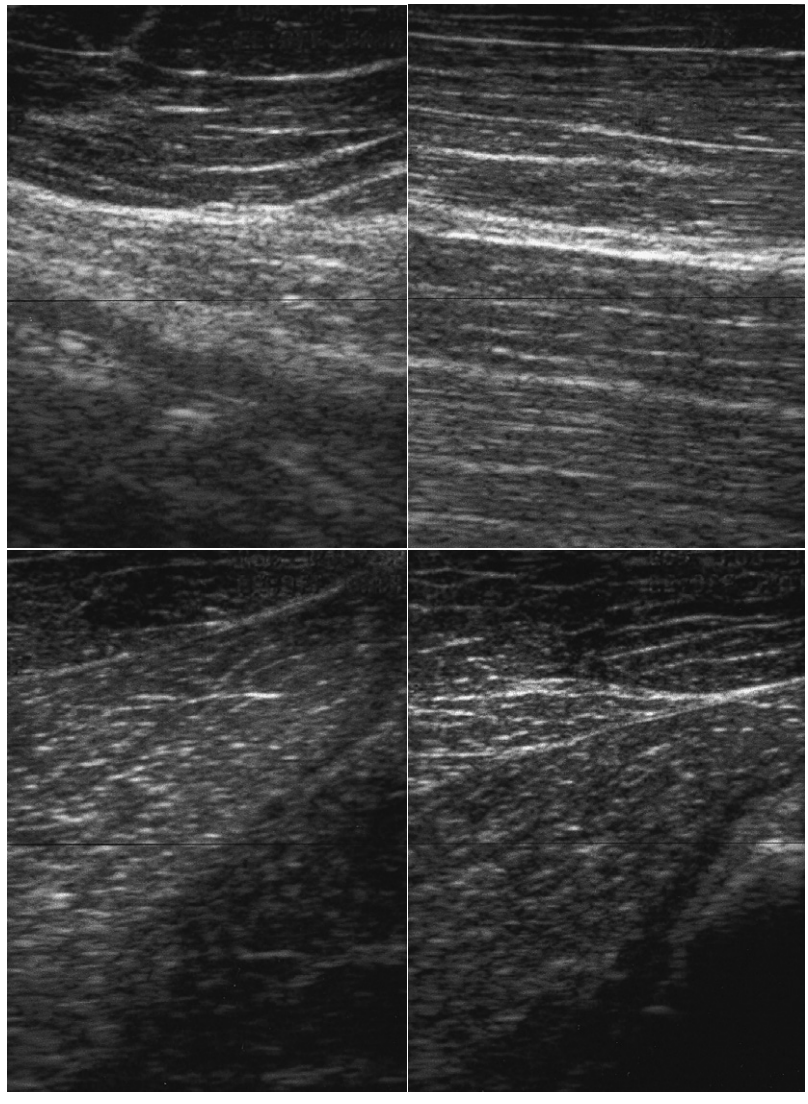

Fig. 84-1 A and B, Longitudinal ultrasonographic images of the muscles at the base of the neck on the left and right sides of an advanced-level event horse with restricted forelimb gait (*left* images indicate left side; *right* images indicate right side). Caudal is to the left. The horse had severe pain and tension in the strap muscles at the base of the neck on the left side and slight muscle atrophy. Note the increased echogenicity of the deeper muscle on the left side compared with the right. The horse was treated by H-wave stimulation that resulted in progressive relief of the muscle spasm and significant improvement in gait and ability to jump.

poorly.[25,29,30] Diagnostic ultrasonography[18,19] has helped in the diagnosis of acute and more chronic muscle lesions, but diagnosis often remains a challenge because of the deep location of some affected muscles and the lack of localizing clinical signs.

In one author's (S.J.D.) experience the most commonly recognized muscle injury sites in the forelimb include biceps brachii, braciocephalicus, the pectorals, and the musculotendonous junction of the superficial digital flexor muscle (Figs. 84-1 to 84-4). In the hindlimb, semimembranosus and semitendinosus, adductor, gluteal, and gastrocnemius muscle injuries have been recognized most frequently.

Muscle tension and spasm in the thoracolumbar region are well documented as sources of pain contributing to poor performance in association with a primary hindlimb lameness, but primary muscle pain in this region often has tended to be overlooked by many clinicians but recognized by physiotherapists. Localized muscle soreness and the interpretation of abnormal sensitivity of acupuncture points are potentially confusing. Protective muscle spasm also may develop secondary to a primary lesion of the thoracolumbar spine or sacroiliac region (see Chapters 52 through 54).

Jeffcott et al.[31] demonstrated that injection of lactic acid into the left longissimus dorsi muscles could significantly diminish performance of Standardbred (STB) trotters worked at speed on a treadmill, although changes in gait were subtle.

One of the authors (S.J.D.) has seen a number of horses that suddenly had lost performance during competition or training, after a particularly extravagant jump or after an awkward jump. The horses had subsequently become reluctant to jump or to gallop downhill. Clinical examination revealed intense muscle spasm in the caudal thoracic and lumbar regions with associated pain. Manipulation to release muscle spasm resulted in relief of pain and rapid restoration of normal performance. Acute back muscle pain also may be induced by a fall.

Localized back muscle soreness is induced readily by a poorly fitting saddle and also may be caused by a rider who sits crookedly or is unable to ride completely in balance with the horse. Poor riding may be due to the ineptitude of the rider, or to the shape of the saddle and the way in which it sits on a particular horse and so positions the rider. Such muscle pain usually is localized to the saddle area and may be associated with slight soft tissue swelling. Thermographic examination may be helpful to demonstrate to an owner the associated

Fig. 84-2 Longitudinal ultrasonographic image of the right semitendinosus muscle of 6-year-old Thoroughbred with acute-onset right hindlimb lameness, with slight swelling of the muscle and pain on palpation. A focal region of increased echogenicity is caused by muscle fiber tearing and hemorrhage.

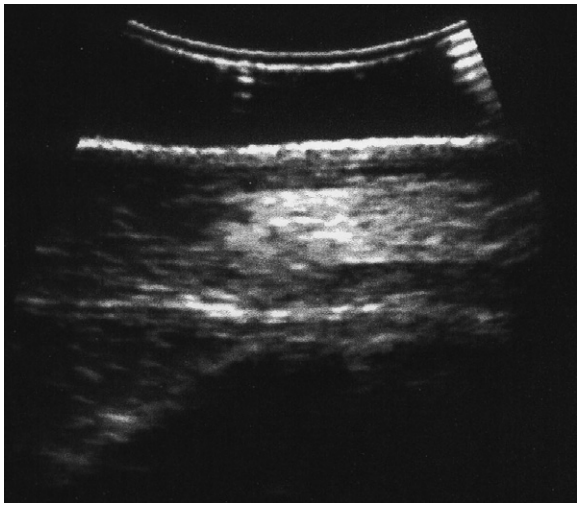

Fig. 84-3 Longitudinal ultrasonographic image of the left brachiocephalicus muscle of a Grand Prix dressage horse that showed left forelimb lameness only when performing lateral movements, such as half pass. The lameness was not altered by any local analgesic technique. There is a focal area of increased echogenicity, caused by muscle fibrosis.

Fig. 84-4 Longitudinal ultrasonographic image of the cranial aspect of the antebrachium of 7-year-old hunter. The horse had developed acute-onset lameness 3 months previously, associated with substantial soft tissue swelling on the cranial aspect of the antebrachium. The extensor carpi radialis muscle is enlarged greatly and has hypoechoic and hyperechoic regions, with little normal muscle architecture.

localized inflammation. Pressure measurements can also be used (see Fig. 118-6).

Diagnosis

History and Clinical Examination

It is important to establish whether the horse has a history of a fall or other traumatic event, the duration of clinical signs, whether swelling had been noted, and whether the horse had exhibited lameness or had performed poorly.

The detection of muscle swelling caused by recent trauma, or loss of muscle bulk caused by either fibrosis associated with a chronic injury or atrophy, often requires the horse to stand completely squarely, bearing weight evenly on all limbs and looking straight ahead. The horse should be appraised visually and by careful, systematic palpation, looking for defects in the muscle, muscle swelling, areas of abnormal muscle firmness caused by fibrosis, muscle tension or spasm, and areas of pain.

In an acute injury resulting in muscle tearing or rupture, in the early stages palpating a defect may be possible, but the defect will become filled with hemorrhage, inflammatory exudates, and edema. Careful palpation should enable detection of most acute superficial muscle injuries, but localization of deeper muscle injury may be more difficult. Identification of chronic muscle strain is more challenging, because the clinical signs are more subtle. The horse must be as relaxed as possible to assess properly the response to firm and deep palpation. If the muscle is sore, the horse may react by increasing tension in anticipation of pain or by pulling away. The area of damaged muscle may have knots.

The neck, limbs, and thoracolumbar region should be moved passively to detect any limitations in movement or pain induced by movement. The horse should be observed moving at the walk and trot to identify any characteristic gait abnormalities such as an abnormal hind foot placement caused by fibrotic myopathy (see Chapter 81) or sinking of a front fetlock because of rupture at the musculotendonous junction of the superficial digital flexor tendon (see Chapter 13). However, one must bear in mind that muscle soreness resulting in compromise of performance may not result in overt lameness, because pain may be induced only when the muscle contracts strongly or is stretched maximally. Pain associated with a braciocephalicus muscle in a dressage horse may be evident only in particular movements such as half pass (Fig. 84-3). A show jumper with sore gluteal muscles may not push off as strongly with the affected limb, resulting in the hindquarters drifting toward the ipsilateral side as the horse jumps.

Muscle Stimulation

Muscle-stimulating machines can be helpful in identifying superficial muscle injuries. Intermittent electrical stimulation of focal areas within a muscle results in muscle contraction and relaxation. The strength of stimulus can be varied. Horses vary in the sensitivity and tolerance of the procedure, so careful comparisons must be made between the left and right sides. Damaged muscle tends to respond greater to a lower stimulus strength, and contraction and relaxation are less smooth and may induce pain.

Thermography, Nuclear Scintigraphy, and Ultrasonography

Thermography, nuclear scintigraphy, and ultrasonography are discussed on page 724.

Muscle Enzymes

Determination of serum muscle enzyme concentrations is rarely of value in identifying muscle soreness or trauma, but it is useful for detecting horses with rhabdomyolysis (see page 723).

Treatment

The aims of treatment include healing of damaged muscle, relief of muscle spasm and pain, restoration of normal circulation, minimization of fibrous scar formation, and remobilization of muscles. The precise mode of treatment depends on the type of muscle injury and the stage of injury and repair. Treatment modalities include laser,[32] therapeutic ultrasound,[33] H wave, transcutaneous electrical stimulation, electromagnetic therapy,[34] massage[26] or passive stretching, combined with box rest, and a graduated, controlled exercise program. Relief of acute muscle spasm may require chiropractic manipulation. During return to work the exercise program must be moderated carefully according to the site of the injury to avoid over-stress in the early stages of repair but encourage a progressive increase in strength. These subjects are discussed more fully elsewhere (see Chapters 94 through 97).

Prevention

Because of the poor recognition of muscle injury in the horse, little work has been done on its prevention. Recently, however, evidence documenting the beneficial effects of warm-up before strenuous exercise has become available.[35-37] Warm-up enhances blood flow to active muscle and increases muscle temperature, which results in better oxygen delivery to exercising muscle, improved enzyme function, and increased range of motion. The best warm-up program for each type of exercise remains poorly defined. However, warm-up should aim to prepare the physiological systems, without contributing to excessive heat generation or fatigue.

EXERTIONAL RHABDOMYOLYSIS

Exertional rhabdomyolysis (ER), literally the dissolution of muscle with exercise, is a common muscle disorder in horses and is a frequent cause of poor performance in a variety of breeds, including Draft breeds, Warmbloods, Thoroughbreds (TBs), STBs, Arabians, Morgans, Quarter Horses, Appaloosas, and American Paint horses.[38] ER was common in Draft horses before the advent of the automotive engine and was called *Monday morning disease, azoturia*, or *paralytic myoglobinuria*.[39,40] Horses often died from myonecrosis or subsequent renal failure. A milder syndrome was noted in lighter breeds and the terms *tying up, set fast, myositis,* and *chronic intermittent rhabdomyolysis* have been used to describe muscle necrosis or muscle cell stress after any form of exercise in the lighter horse breeds.[41,42]

In the past the tendency has been to assume a common cause for all exercise-related myopathies in horses. However, over the past decade it has become apparent that ER is a complex syndrome that has numerous causes. Dietary imbalances, concurrent respiratory infections, and inappropriate training regimens all may produce a sporadic episode of rhabdomyolysis in otherwise successful athletic horses.[40,43-45] ER may occur as a single event in a horse, triggered by a specific event with no tendency for recurrence, or may be a recurrent problem.

Sporadic Exertional Rhabdomyolysis

The most common cause of sporadic ER is exercise that exceeds the horse's underlying state of training.[42] Horses that are advanced too quickly in training, horses that are only ridden sporadically while being fed full rations continually, and horses performing strenuous exercise such as racing or endurance riding without sufficient conditioning commonly develop rhabdomyolysis. In addition, rhabdomyolysis may be more common in horses exercising during an outbreak of respiratory disease. Equine herpes virus I and equine influenza virus have been implicated as causative agents.[29,35]

Clinical Signs

Classically, horses loose impulsion during exercise and develop a stiff, stilted gait, particularly involving the hindquarters. Horses sweat excessively and have a high respiratory rate

because of pain. The horse may be unable to walk forward after resting because of firm, painful muscle contractures involving the back and hindquarters. Signs are most commonly seen after 15 to 30 minutes of light exercise. A horse with severe rhabdomyolysis may show signs of colic, become recumbent, and develop occult myoglobinuria. The urine may be discolored and have an abnormal smell. Attempts to move more severely affected animals may result in extreme pain, obvious anxiety, and exacerbation of the condition.

ER is often symmetrical, involving gluteal, biceps femoris, semitendinosus, and semimembranosus muscles.[46] ER may accompany the exhaustion syndrome in endurance horses, with concurrent evidence of a rapid heart rate, dehydration, hyperthermia, synchronous diaphragmatic flutter, and collapse.[37] Muscle contractures are not always consistent in endurance horses with ER.

Diagnosis is usually obvious based on the clinical signs, but in equivocal situations measurement of serum muscle enzyme concentrations is useful. The degree of elevation of muscle enzyme concentrations does not reflect necessarily the severity of clinical signs.

Treatment of Acute Rhabdomyolysis

If the attack has occurred during exercise some distance from where the horse normally is stabled, the horse should not be made to walk home, but it should be transported back home or left in a nearby stable. If an attack has occurred at a competition, the horse should be treated there and should not be transported home over a long distance until at least 24 to 48 hours later.

The objectives of treatment are to relieve anxiety and muscle pain and to correct fluid and acid-base deficits. Acetylpromazine (0.04 to 0.07 mg/kg), an α-adrenergic antagonist, is helpful in relieving anxiety and may increase muscle blood flow. Its use is contraindicated in dehydrated horses. In horses with extreme pain, detomidine (0.02 to 0.04 μg/kg) combined with butorphanol (0.01 to 0.04 mg/kg) provides excellent sedation and analgesia. Non-steroidal anti-inflammatory drugs (NSAIDs) such as ketoprofen (2.2 mg/kg), phenylbutazone (2.2 to 4.4. mg/kg), or flunixin meglumine (1.1 mg/kg) successfully resolve pain in less severely affected horses. Analgesic treatment is continued to effect, but most horses are relatively free of pain within 18 to 24 hours.

Intravenous or intragastric dimethylsulfoxide (as a <20% solution) can be used as an antioxidant, anti-inflammatory, and osmotic diuretic in severely affected horses. Corticosteroid administration has been advocated by some clinicians in the acute stage. If the horse is recumbent methylprednisolone succinate (2 to 4 mg/kg IV) should be given once. Muscle relaxants such as methocarbamol (5 to 22 mg/kg, IV slowly) seem to produce variable results, possibly depending on the dosage used. The administration of dantrolene sodium (2 to 4 mg/kg PO) in severely affected horses may decrease muscle contractures and possibly prevent further activation of muscle necrosis.

Severe rhabdomyolysis can lead to renal compromise because of the ischemic and combined nephrotoxic effects of myoglobinuria, dehydration, and NSAIDs. The first priority in horses with hemoconcentration or myoglobinuria is to re-establish fluid balance and induce diuresis. In horses with mild rhabdomyolysis administration of fluids via a nasogastric tube may be adequate, but generally fluids are best given intravenously. Balanced polyionic electrolyte solutions are best. If severe rhabdomyolysis is present, then isotonic saline solution or 2.5% dextrose in 0.45% saline solution may be necessary, because horses often have hyponatremia, hypochloremia, and hyperkalemia. If hypocalcemia is present, then supplementing intravenous fluids with 100 to 200 ml of 24% calcium borogluconate is recommended, but serum calcium should not exceed a low normal range. Affected animals are usually alkalotic, making bicarbonate therapy inappropriate.[47]

Ten liters of fluids may be given rapidly. The total fluid replacement is based on an estimation of the degree of dehydration and the clinical response. If the horse is mildly dehydrated (5%), 10 L may be given fast and then 15 L over the next 4 to 6 hours. If dehydration is severe (20%), 10 L may be given fast and then 50 L at 4 L/hr. If the horse is recumbent, the veterinarian should consider using at least two intravenous lines and infusing into the jugular and cephalic veins. The catheters should be sutured in place.

Ideally, reassessment of the packed cell volume, total plasma protein, and serum electrolytes after the initial period of therapy should provide a successful guide for the therapeutic regimen. However, in the practical situation the clinical response to therapy is usually an adequate indicator. In severely affected animals, regular monitoring of blood urea nitrogen and serum creatinine is advised to assess the extent of renal damage. Diuretics usually are contraindicated unless the horse is in oliguric renal failure.

Horses should be rested in a stall on a hay diet for a few days. Small paddock turnout in a quiet area for a few hours twice a day is then helpful. Horses may be hand walked at this time, but not for more than 5 to 10 minutes at a time. Rest with regular access to a paddock should continue until serum muscle enzyme concentrations are normal. Training should be resumed gradually and a regular exercise schedule that matches the degree of exertion to the horse's underlying state of training should be established. Lunging exercise should be avoided until the horse is back in normal work. If the horse has a day or several days off, the dietary energy concentrations should be reduced accordingly.

Chronic Exertional Rhabdomyolysis

Horses that have repeated episodes of ER from a young age, from the time of purchase, or when they are put back into training after a long period of rest may have an underlying abnormality of muscle function. Many of these horses have repeated episodes of rhabdomyolysis with minimal exercise, even when the dietary and training recommendations for sporadic ER are followed. Forms of chronic ER are seen in many breeds of horses including Draft horses, Warmbloods, Quarter Horses, American Paint horses, Appaloosas, TBs, Arabians, STBs, and Morgans.[41,42,45,48,49] Inclement weather has been cited as a trigger of ER, and rhabdomyolysis is reported more commonly in the autumn and winter in the United Kingdom.[50,51] Two specific heritable causes of ER have been identified to date: recurrent ER and polysaccharide storage myopathy.[52-54] Possibly other specific causes exist that have yet to be identified (idiopathic chronic ER). In all of these forms of chronic rhabdomyolysis, apparently specific environmental stimuli are necessary to trigger muscle necrosis in genetically susceptible animals.[54] Animals cannot be cured of the susceptibility to this condition, but if the specific disease is identified, changes in management can be implemented to minimize episodes of rhabdomyolysis.

About 5% of TB racehorses develop ER during a racing season, and 75% of these horses have more than 4 episodes in 4 months.[55] Horses with a nervous disposition, especially fillies, are highly predisposed. Recent research suggests that a subset of these horses has a specific form of ER denoted as recurrent exertional rhabdomyolysis (RER).[23] RER appears to be an inherited, intermittent, stress-induced defect in the regulation of muscle contraction.[52,55] Analysis of pedigrees of TB horses from across the United States suggests that RER is an autosomal dominant trait.[52] Small breeding trials using TB horses with RER confirm that the characteristic abnormality in muscle contracture is inherited in an autosomal dominant fashion (S.V.). Recurrent episodes of rhabdomyolysis in STBs and Arabian horses may be caused by a similar abnormality. A heritable basis for RER in STBs was supported by equine lymphocyte antigen profiles in affected horses.[56]

Factors that trigger rhabdomyolysis in susceptible horses include gender, temperament, excitement, stress, dietary starch, exercise duration and intensity, season, and lameness.[50,51,55] Females are most commonly afflicted with RER (67% female; 33% male), particularly those that are 2 years of age and in race training. Nervous horses are five times more likely to develop RER, and horses with lameness are four times more likely to develop rhabdomyolysis. Susceptible horses receiving more than 5 kg of concentrate feed (oats, corn, and molasses mix) are more likely to develop rhabdomyolysis than those receiving 2.5 kg of concentrate feed per day.[57]

Electrolyte depletion in horses can occur because of dietary deficiency and losses in sweat with strenuous exercise.[46] Sodium, potassium, magnesium, and calcium play key roles in muscle fiber contractility. With severe, acute electrolyte depletion, such as that after endurance exercise, serum electrolytes may be below normal ranges.[46] With chronic dietary depletion, however, serum concentrations may not reflect total body electrolyte imbalances.[44,58] Work by Harris and Colles established renal fractional excretions as a technique to evaluate electrolyte concentrations in horses with chronic ER.[44,58] Blood and urine samples are obtained concurrently, and creatinine and electrolyte concentrations measured in both. Serum creatinine concentration divided by urine creatinine concentration, multiplied by the reciprocal for urine and serum electrolyte concentrations, multiplied by 100 provides the fractional excretion of a particular electrolyte. In the United Kingdom a number of horses with chronic ER had low fractional excretions of sodium, and daily dietary supplementation of 60 g (2 oz) of NaCl resulted in abatement of clinical signs. Other horses had high phosphorus excretion suggesting a dietary calcium/phosphorus imbalance, and decreasing bran while providing a daily calcium supplement (60 g of $CaCO_3$) was helpful in reducing clinical signs of ER.[44] Hypokalemia also has been suggested to play a role in chronic ER, although it is not a common finding in horses consuming adequate quantities of forage.[59,60] Supplementation with good quality forage, or 30 g of KCl per day is recommended for horses with low renal fraction excretion of potassium.

The increased oxidative metabolism associated with exercise results in the generation of free radicals. Selenium, acting through the enzyme glutathione peroxidase, and vitamin E, acting within the lipid component of cell membranes, scavenge free radicals and prevent lipid peroxidation of cell membranes. Primary selenium or vitamin E deficiency is common in young animals living in areas with selenium-deficient soil (see page 736); however, such deficiency rarely has been demonstrated as a cause of ER.[51] In fact, many horses with chronic ER have higher concentrations of selenium and vitamin E because of zealous dietary supplementation by the owner.[61] Whether horses that experience repeated episodes of ER may generate more free radicals than normal horses is not known. A higher generation of free radicals in horses with chronic ER may explain the perceived benefit of repeated administration of selenium and vitamin E in TB horses with RER.[43] Adequate values for blood selenium are greater than 0.07 μg/ml and for serum vitamin E greater than 1.1 μg/ml.

Horses consuming a high-grain diet appear to be more likely to develop ER than horses fed a low-grain or low-fat diet.[57,62,63] The reason for this is unclear and may differ between different forms of chronic ER. For example, in horses with polysaccharide storage myopathy, high soluble carbohydrate diets may enhance glycogen storage. In horses with recurrent ER, however, glycogen storage does not increase substantially even though serum CK activities are highest on high-grain diets.[63] Dietary effects in RER may in part be related to the psychogenic effects of grain on excitability.

A contribution of reproductive hormones to triggering ER has been postulated, because the incidence of chronic ER appears to be highest in mares.[51,55,63,64] Many owners report that episodes of rhabdomyolysis occur most commonly during estrus, but in one study of racehorses no direct correlation was shown between progesterone fluctuations and serum CK activity.[65] The estrus cycle is likely one of many factors that combine to trigger ER in susceptible horses. In some mares where episodes of ER coincide with estrus, suppression of estrus using progesterone implants or injections may be helpful. This should be done with dietary and training alterations. Hypothyroidism and lactic acidosis also have been suggested as a cause of ER but never truly substantiated.[45,49,63,66]

Clinical Signs

Horses with RER have intermittent elevations in serum CK activity.[67,68] Episodes of muscle stiffness, sweating, and firm muscle contractures often occur in horses once they become fit and are frequently associated with excitement at the time of exercise. In TBs, rhabdomyolysis occurs most frequently during training when horses are held to a slow gallop.[55] In STBs, rhabdomyolysis often occurs 15 to 30 minutes into jogging (slow trotting).[67] Obvious clinical signs are rare after racing. A history of poor performance and elevated serum AST and CK may be the only presenting complaints in some horses. Older TBs used as riding horses may have intermittent episodes of rhabdomyolysis associated with lay up of fit horses. Event horses often develop clinical signs after the steeplechase phase of a Three Day Event, or in the 10-minute box, or less commonly during the cross country phase. Muscle stiffness and reluctance to collect may be present on a continual basis between episodes in some of these older horses. Arabian horses often develop clinical signs with little exertion, frequently in association with excitement.

In some riding horses the clinical signs of a mild attack may be subtle and are missed easily by the rider. The horse is maintained in work and actually may be experiencing daily episodes resulting in cumulative muscle damage (Fig. 84-5).

Diagnosis

A submaximal exercise test (see page 724) is useful for identifying RER in a horse that has a history of poor performance unrelated to signs typical of tying-up. Nuclear scintigraphy (see page 724) may demonstrate increased uptake of radiopharmaceutical in the affected muscles of some, but not all, affected horses.

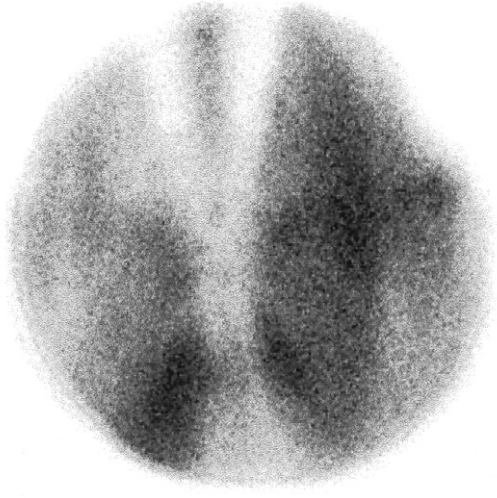

Fig. 84-5 Dorsal scintigraphic image of the pelvic region of an 8-year-old hunter mare with a history of poor performance and reluctance to work. There is intense radiopharmaceutical uptake in the muscles, associated with chronic, repetitive exertional rhabdomyolysis.

Muscle biopsies from horses with RER that are in training have a characteristic histological appearance. These horses have increased numbers of centrally located nuclei in mature muscle fibers (Fig. 84-6). They may have evidence of varying stages of muscle degeneration and regeneration and normal to slightly increased muscle glycogen staining.[68] In addition, RER is characterized by abnormal sensitivity of intact muscle bundles to contractures induced by the addition of caffeine or halothane to a muscle bath.[22,23] Elevated myoplasmic calcium concentration has been reported with ER.[69] Physiological similarities exist between the contracture results of RER and contractures tests for malignant hyperthermia. Biochemical studies of isolated muscle cell membranes have not identified, however, the same defect in the function of the calcium release channel in horses with RER.[70] The increased halothane sensitivity of the muscles in RER horses may explain why many TBs with RER develop rhabdomyolysis under halothane anesthesia.[71]

Management

In the past, horses have been rested in box stalls for several weeks after an episode of RER. Our opinion is that this is counterproductive and increases the likelihood that the horse will develop rhabdomyolysis when put back into training. The initial muscle pain usually subsides within 24 hours of acute RER and daily turnout in a small paddock can be provided at this time. Subsequently a gradual return to performance is recommended once serum CK is within the normal range.

Prevention

Prevention of further episodes of RER in susceptible horses includes standardized daily routines and providing an environment that minimizes stress. This should include desensitizing horses to stressful situations, moving to a quiet area of the barn, regular turnout, and positioning near compatible horses. Daily exercise is essential, whether in the form of turnout, walking on a horse walker, lunging, or riding. The horse should have a long, slow warm-up period.

The diet should be adjusted to include a balanced vitamin and mineral supplements, high-quality hay (but not alfalfa), and a minimum of carbohydrates (<3 to 5 kg). Post-exercise serum CK activity in horses with RER is influenced by the amount of energy horses are fed on a daily basis and the composition of the diet. When 500-kg TBs with RER were fed 88 MJ (21 Mcal) of energy and exercised for 30 minutes a day, serum CK activity after exercise was within the normal range. No measurable effect of feeding a starch-based (2.5 kg of an oat, corn, and molasses mix) or a fat-based (2.3 kg of rice bran; 20% digestible energy from fat) supplement with hay was found on muscle necrosis.[66] However, when the energy level was increased to a level that was closer to that which is normally fed to racehorses (117 MJ or 28 MCal) the source of energy had a significant effect on post-exercise CK activity. Horses fed a high proportion of energy in the form of starch (5 kg of oat, corn, and molasses mix) had significantly higher CK levels after exercise than horses fed 25% of total digestible energy as fat (Releve, Hallway Feeds, Lexington, KY).[72] Apparently, therefore, TBs susceptible to RER that are in moderate- to high-intensity training should be fed concentrate feeds that are relatively low in starch (<20% digestible energy) and high in fat (20% digestible energy or a feed that is 10% to 12.5% fat by weight) to minimize post-exercise muscle damage. Achieving this level of fat supplementation without additional starch can be done by adding corn oil to the diet (a maximum of 600 ml per day, with 800 U of vitamin E), adding rice bran (up to 2.5 kg combined with grains), or purchasing specially designed diets such as Releve. Corn and barley should be avoided because they are particularly high in starch. No more than half of the total of forage should be fed as alfalfa; lower starch hays such as grass or meadow, timothy, brome, or oat hay are preferable.

The use of low doses of acetylpromazine tranquilizers (0.005 to 0.01 mg/kg) 30 minutes before exercise in excitable horses is believed to help some horses. Dantrolene (2 to 4 mg/kg PO) given 1 hour before exercise may be effective in preventing RER in some horses.[73] Dantrolene is used to prevent malignant hyperthermia in people and swine by decreasing the release of calcium from the calcium release channel. Phenytoin also has been advocated as a treatment for horses with RER.[48] Dosages are adjusted in horses to maintain serum levels of 8 to 10 μg/ml. Initial doses begin at 6 to 8 mg/kg orally for 3 to 5 days. Doses can be increased by 1-mg/kg increments every 3 days until rhabdomyolysis is prevented, but they should be cut back if horses appear drowsy. If possible, serum phenytoin concentrations should be assessed regularly at the initiation of treatment. Phenytoin acts on a number of ion channels in muscle and nerves, including sodium and calcium channels. Unfortunately, long-term treatment with dantrolene or phenytoin is expensive, and efficacy has not been established.

The described management is effective in reducing episodes of rhabdomyolysis in many horses, but some remain intractable. Nervous young racing fillies and older riding horses, especially event horses, present the greatest challenge in management.

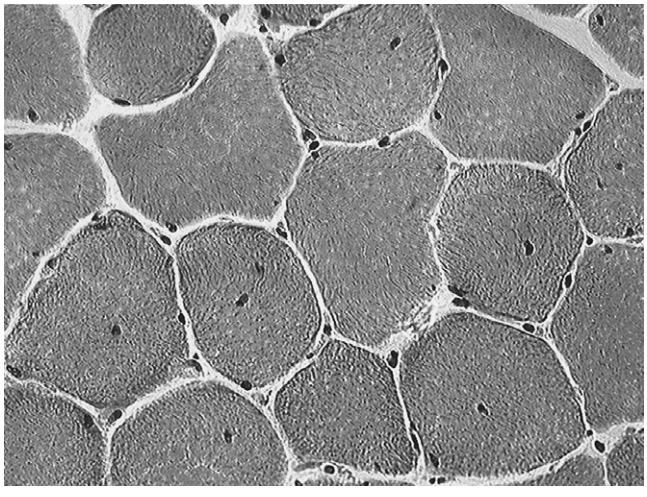

Fig. 84-6 Cryostat cut transverse sections of a biopsy of the semitendinosus muscle of a Thoroughbred with recurrent exertional rhabdomyolysis. Centrally located nuclei are present in mature muscle fibers, which is a common feature of biopsies of horses with recurrent exertional rhabdomyolysis. (Hematoxylin-eosin stain.)

Polysaccharide Storage Myopathy

A subset of horses with chronic ER have a glycogen storage disorder characterized by the accumulation of glycogen and an abnormal polysaccharide in skeletal muscle.[53] Abnormal polysaccharide accumulation occurs in Quarter Horses, American Paint horses, Appaloosas, Draft breeds, Draft crossbreeds, Warmbloods, and a small number of TB riding horses that have a history of muscle stiffness and increased serum CK activity after exercise.[42,62,74,75]

Pedigree analysis has been performed in affected Quarter Horses, Paint horses, and Appaloosas.[54] The sires and dams for almost all of these horses with polysaccharide storage myopathy (PSSM) traced back to one of two related sires within 7 to 9 generations in the pedigree. An inherited trait in Quarter Horse–related breeds is further supported by a small breeding trial where mares with PSSM, bred to a related stallion, produced PSSM-affected foals.[76]

Clinical Signs

Horses with PSSM often have a calm and sedate demeanor. Clinical signs of muscle stiffness, reluctance to exercise, exercise intolerance, or overt muscle contractures and reluctance to move usually are apparent at the commencement of training. Most horses have numerous episodes of ER or a consistent history of poor performance. However, some mildly affected horses have only one or two episodes of ER per year.[62] Serum CK activities are often elevated, even when horses are rested, and increase by 1000 U/L or more 4 hours after 15 minutes of exercise at a trot. Muscle atrophy, renal failure, and severe colic-like pain are less common complaints. More recently, PSSM has been identified in 4-month-old to weanling Quarter Horses and Paint horses with severe non-ER (see pages 732 and 733) and concurrent pneumonia.[77]

A variety of other clinical signs have been reported in Belgian and Percheron horses that have PSSM. These include a generalized decrease in muscle mass, overt muscle atrophy, weakness in the hindlimbs with difficulty rising, reluctance to back up, and gait abnormalities such as shivers[74,75,78] (see Chapter 49). Such horses often have only a mild elevation in serum CK and AST. Muscle biopsies from these Draft horses show, in addition to accumulation of abnormal polysaccharide, more extensive atrophy, centrally located nuclei, and basophilic sarcoplasmic masses, not seen in Quarter Horse breeds with PSSM. Whether Draft horses have a cause for PSSM identical to that described for Quarter Horses in the following discussion is unclear.

Diagnosis

A diagnosis of PSSM is based on histopathological examination of muscle biopsies (Fig. 84-7). The distinctive features of PSSM are subsarcolemmal vacuoles, dark periodic acid–Schiff (PAS) stains for glycogen in snap-frozen samples, and abnormal PAS-positive inclusions in fast twitch fibers.[53,62] Other features that may be present include muscle necrosis, macrophage infiltration of myofibers, regenerative fibers, rimmed vacuoles, and occasionally atrophied type II fibers. Pre-incubation of muscle sections with amylase should result in complete digestion of glycogen in normal horses. The PAS-positive inclusions in horses with PSSM are slow to digest, leaving distinct residues that indicate an abnormal polysaccharide is present. Analysis of the structure of polysaccharide in PSSM muscle by iodine spectra absorption indicates that the polysaccharide is less highly branched than normal muscle glycogen. A combination of β-glycogen particles and a filamentous form of glycogen also are found on electron microscopy of PSSM-affected muscle.

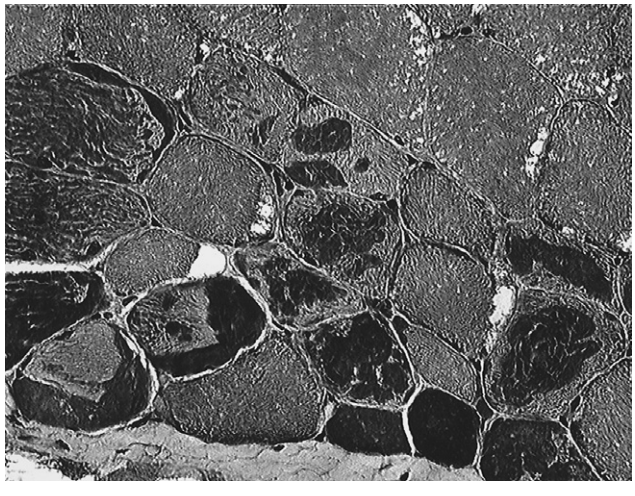

Fig. 84-7 Cryostat cut transverse sections of semitendinosus biopsy of a horse with polysaccharide storage myopathy. White subsarcolemmal vacuoles are present in some fibers, and the dark periodic acid–Schiff-positive granular inclusions represent abnormal polysaccharide in numerous other muscle fibers. (Periodic acid–Schiff stain; hematoxylin counterstain.)

Causes

PSSM appears to be an inherited abnormality associated with increased skeletal muscle uptake of glucose from the blood stream and increased synthesis of glycogen and abnormal polysaccharide.[79] Muscle glycogen concentrations in PSSM horses are 1.5 to 4 times normal, and glucose-6-phosphate concentrations are up to 10 times normal.[80] Glycogen accumulation in horses with PSSM does not appear to be caused by an inability to metabolize glycogen.[80,81] Rather, horses with PSSM appear to have a novel defect characterized by enhanced insulin sensitivity of skeletal muscle. After an intravenous or oral bolus of glucose, blood glucose clearance is 1.5 times faster in horses with PSSM than in normal horses, despite a lower increase in insulin.[76] Administration of insulin to horses with PSSM results in a much faster decline in blood glucose, which persists for 4 hours compared with 2 hours in healthy horses, even when fed grain. In addition, although glucose clearance is enhanced by exercise in healthy horses, it appears to be depressed by exercise in horses with PSSM.[82] The link between enhanced glycogen storage and rhabdomyolysis is not readily apparent. Potentially, altered intra-cellular glucose homeostasis may transiently affect hexokinase binding to mitochondria, leading to insufficient adenosine triphosphate production and rhabdomyolysis.

Management

Horses with acute rhabdomyolysis can be managed in a fashion similar to that described for sporadic rhabdomyolysis[83] (see page 729). Corticosteroids (1 mg/kg of prednisone or prednisolone orally per day) may be of additional benefit in temporarily decreasing insulin sensitivity in horses with acute signs. Muscle glycogen concentrations may be lowered by feeding a diet that is low in starch, supplemented with fat and high in fiber.[84] Such diets consist of a good-quality grass hay, no concentrate feed, and a fat supplement, such as 1 to 3 kg of rice bran (a by-product of rice processing) or 250 to 500 ml (1 to 2 cups) of vegetable oil.[62,85] Rice bran is 20% fat and when compared with isocaloric amounts of grain, no postprandial elevations in blood glucose or insulin occur. Daily exercise is essential to return horses with PSSM to athletic endeavors. As much daily turnout as possible, combined with a gradual training program, has a significant impact on decreasing serum CK activity within 30 days.[84] Box stall rest for more than 12 hours per day appears to increase the incidence of rhabdomyolysis in these horses.

NON-EXERTIONAL RHABDOMYOLYSIS

Although tying-up after exertion is the most common muscle disorder in horses, many horses can suffer severe rhabdomyolysis without any preceding exertion. Causes for non-ER include metabolic, immune-mediated, infectious, nutritional, and toxic factors.

Metabolic Myopathies

Polysaccharide Storage Myopathy

Clinical signs. The most common presentation for PSSM is the development of muscle necrosis, pain, and firm muscles in adult horses with the onset of training (see the previous discussion). A subset of horses with PSSM and a concurrent illness may develop rhabdomyolysis without any preceding exercise. Rhabomyolysis may be so severe that horses become recumbent and unable to rise. This form of PSSM has been described in weanling and yearling Quarter Horses with various concurrent bacterial pneumonias.[77] In addition to serum CK

concentration greater than 200,000 U/L, electrolyte abnormalities, such as hyponatremia, hypochloremia, hyocalcemia, hyperphosphatemia, and hyperkalemia, are common results of renal compromise and the loss of partitioning between extracellular and the large intra-muscular fluid compartments.[86]

Diagnosis A diagnosis of PSSM can be challenging in young horses. The standard diagnostic criteria of abnormal polysaccharide in PAS stains of muscle biopsies may be obscured by the extensive loss of membrane integrity, causing glycogen to leach from tissues. In addition, a diagnosis may be complicated because rhabdomyolysis in weanlings with PSSM may precede the later stage of accumulation of abnormal polysaccharide. Subclinical elevations in serum CK have been noted in foals at 1 month of age that, when serially followed, did not show abnormal polysaccharide accumulation until 18 months of age.[76] The early accumulation of abnormal polysaccharide in the young foals may indicate a particularly severe affliction with PSSM. The diagnosis of PSSM in a weanling may be supported by identifying PSSM in a muscle biopsy from the dam.

Many other differential diagnoses are possible for acute rhabdomyolysis in foals. Neonatal foals may have increased CK at birth with a history of placentitis or dystocia and elevated creatinine concentration.[87] Septicemia could potentially cause an inflammatory reaction in skeletal muscle of neonatal foals. Most commonly, myodegeneration is caused by vitamin E and selenium deficiency with subsequent peroxidation of cell membranes by oxygen free radicals[88] (see page 736). Weanling and older Quarter Horses have developed an immune-mediated myositis on exposure to *Streptococcus equi*.[89]

Treatment Treatment is similar to that for the adult form of PSSM (see page 732). However, the prognosis for weanlings with non-ER is guarded because of the high likelihood of recurrence of the disorder.

Glycogen Branching Enzyme Deficiency

Clinical signs A fatal glycogen storage disorder distinct from PSSM recently has been identified in Quarter Horse foals.[90] The disorder is caused by a deficiency in the glycogen branching enzyme (GBE) responsible for producing a normally configured glycogen molecule in numerous tissues. Clinical signs appear to be caused by a lack of intracellular glucose stores for normal tissue metabolism. Foals may be stillborn in the last third of gestation, weak after birth, or live to up to 7 weeks of age. Death may be sudden when exercised on pasture, associated with weak respiratory muscles, or the result of euthanasia because of persistent recumbency. Treatable flexural deformities of all limbs and recurrent hypoglycemia occur in some affected foals. Persistent leukopenia, intermittent hypoglycemia, and high serum CK, AST, and γ-glutamyltransferase activities are common laboratory findings.

Diagnosis Routine post-mortem examination usually reveals few abnormalities, apart from pulmonary edema in some foals, and basophilic inclusions in skeletal muscle and cardiac tissues in foals older than 1 month of age. PAS staining of muscle, heart, and sometimes liver shows notable lack of normal PAS staining for glycogen and a variable amount of abnormal PAS-positive globular or crystalline intracellular inclusions. Electron microscopy and iodine spectra absorption indicated that the polysaccharide is filamentous, with a minimally branched structure. Reduced GBE activity in the red blood cells of the dams of the affected foals and several siblings support an autosomal recessive mode of inheritance. Because the seven affected foals identified to date have more than 2000 half siblings, GBE deficiency may be a common cause of neonatal mortality in Quarter Horses. A diagnosis of GBE deficiency should be suspected in foals from Quarter Horse–related breeds that have weakness and contracture of all limbs at birth and have a combination of persistent hypoglycemia, leukopenia, and elevated CK (1000 to 15,000 U/L), AST, and γ-glutamyltransferase levels.

Inflammatory Myopathies

Immune-Mediated Myopathies

Severe, fatal rhabdomyolysis has been seen in horses with *S. equi* infections. The reason for the massive rhabdomyolysis is not completely clear, but a toxic shock-like syndrome may occur in some of these horses.

Vascular infarction Mild elevations in serum CK activity have been observed with purpura hemorrhagica in horses.[91] Rarely, some horses vaccinated for or exposed to *S. equi* within the last month develop high serum CK activity, acute colic, firm swellings within muscle and under the skin, and unilateral lameness, without the extensive edema associated with purpura.[89]

Infarction of skeletal muscle, subcutaneous tissue, focal areas of the gastrointestinal tract, and lungs resulting from a severe vasculopathy have been identified in these horses. Such horses often have leukocytosis, hyperfibrinogenemia, hypoproteinemia, and extremely elevated serum CK and AST. Treatment with intravenous penicillin and dexamethasone (0.12 to 0.2 mg/kg), followed by tapering doses of prednisone at an initial dose of 1 mg/kg have been successful in a few hoses. Without aggressive corticosteroid therapy, horses usually die of intestinal infarction.

Immune-mediated myositis Myocarditis in people with rheumatic fever is believed to result from antigenic similarities between the M protein of some streptococcal organisms and the contractile protein myosin in the heart. A form of immune-mediated myositis in Quarter Horses and related breeds also appears to be related to exposure to streptococcal organisms.[88,92] The primary clinical manifestation of this myopathy is rapid atrophy of lumbar and gluteal muscles. Horses often are exposed to a respiratory infection, especially *S. equi*. However, affected horses usually have few or no signs of respiratory disease. Malaise and a persistent elevation in serum CK and AST (1000 to 40,000 U/L) are common. Muscle mass in untreated horses may decrease by 50% within 5 days and the horses become weak.

The characteristic features of muscle biopsies taken during the first week of atrophy are a lymphocytic vasculitis, atrophy of type II fibers, intense lysosomal staining with an acid phosphatase stain, occasional lymphocytic myofiber infiltration, and waves of rhabdomyolysis and regeneration[93] (Fig. 84-8). Untreated horses may show substantial fibrosis around blood vessels. A diagnosis is made on the basis of a history of exposure to strangles, elevated serum CK activity, and muscle biopsy results.

Corticosteroid therapy, such as dexamethasone (0.05 mg/kg) for 3 days followed by prednisone (1 mg/kg for 7 to 10 days) tapered by 100 mg per week over 1 month, is usually successful in halting the atrophy and restoring appetite. Concurrent antibiotic therapy is recommended if leukocytosis, hyperfibrinogenemia, or lymphadenopathy is present. Muscle mass gradually returns over 2 to 3 months. Some horses may show signs of recrudescence of the syndrome on re-exposure to respiratory infections.

Virus-Associated Myopathy

Necrosis of skeletal and cardiac muscle may occur with viral diseases such as equine influenza and equine infectious anemia. In most situations, virus-induced muscle damage represents a component of systemic multiple organ system involvement. Equine influenza A2 has been found to cause severe rhabdomyolysis. Equine herpes virus has been reported to induce primary muscle stiffness and clinical signs resembling ER.[38,94]

Clostridial Myonecrosis

Various species of clostridial organisms cause acute myonecrosis in horses. Infections are characterized by a rapid clinical course,

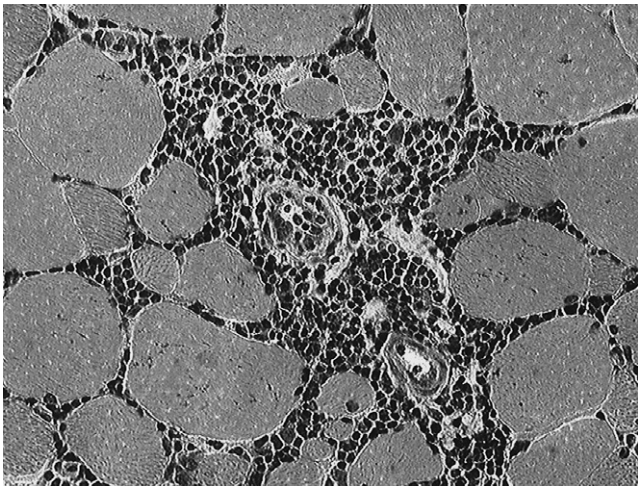

Fig. 84-8 Immune-mediated myositis: cryostat cut transverse sections of biopsy of the longissimus dorsi from horse with rapid muscle atrophy. Prominent cuffing of the blood vessels with mononuclear cell infiltrates, and the lymphocytes surrounding a number of muscle fibers, are characteristic of immune-mediated myopathy in Quarter Horses. (Hematoxylin-eosin stain.)

fever, systemic toxemia, and high mortality.[95,96] Specific bacteria associated with clostridial myonecrosis include *Clostridium septicum*, *Clostridium perfringens (welchii)*, *Clostridium chauvoei*, *Clostridium novyi* type B, and occasionally *Clostridium fallax*. Mixed infections involving several agents are common.

Clinical signs Horses often have a prior condition such as colic, exertional myopathy, or laminitis for which they have received intra-muscular injections in the preceding 48 hours.[97] Affected horses usually rapidly develop depression, swelling, and crepitus at the injection site, and a fever, toxemia, and tachypnea. Tremors, ataxia, dyspnea, recumbency, coma, and death may occur within the next 12 to 24 hours. Mortality may approach 100%. There is usually only one primary site of infection that is associated with an injection or deep wound.[96] Direct clostridial spore deposition into the tissue may occur with penetration, and if suitable necrotic conditions exist, the spores convert to the vegetative, toxin-producing form of the organism. Alternatively, clostridial spores may lie dormant in muscle tissues until necrosis ensues after infection. Powerful exotoxins responsible for the local necrotizing myositis and systemic toxemia are released by proliferating clostridia. Hematological and serum biochemical analyses usually reflect a generalized state of debilitation and toxemia (e.g., hemoconcentration and a stress/toxic leukogram may be present). Elevations in the activities of serum CK and serum AST usually occur; however, they often do not reflect the toxicity of clostridial myonecrosis.

Diagnosis Aspirates from the affected tissues can yield diagnostic information. Obtaining tissue specimens for direct smear examination and fluorescent antibody testing and for anaerobic bacterial culture from affected tissues is preferable. Frequently a diagnosis is made post mortem. Swelling and autolysis are rapid and blood-stained fluid often is observed discharging from body orifices. Extreme swelling and crepitus may be noted over the affected body area. Tissue cut from the affected area may reveal abundant malodorous, serosanguineous fluid. The carcass usually has a foul odor similar to that of rancid butter.

Treatment Although clostridial myonecrosis is often fatal, aggressive specific therapy combined with supportive care may be successful in individual horses.[96] Clostridial myonecrosis resulting from infections with C. *perfringens* seems to be most amenable to treatment and horses with this form have the best prognosis for survival, although extensive skin sloughing over the affected area is common. Antibiotic therapy, aggressive surgical debridement including fasciotomy, and supportive care are the hallmarks of successful treatment. Sufficient fenestrations should be made to establish drainage and aeration over the entire affected area. High doses of intravenous potassium penicillin every 2 to 4 hours are given until the animal is stable (1 to 5 days) and are followed by metronidazole given orally.

Supportive fluid therapy and anti-inflammatory agents for control of pain and swelling are recommended. Short-acting corticosteroids, such as prednisolone or hydrocortisone, may be used for initial therapy of systemic and toxic shock, but continued use is contraindicated in the face of overwhelming sepsis.

Post-Injection Muscle Soreness and Abscessation

Intramuscular injection of a variety of drugs and vaccines may be followed by severe localized muscle soreness. with or without swelling. Injections in the neck may result in neck stiffness and a bilaterally shortened forelimb stride. Injections in the gluteal muscle mass or thigh region can cause unilateral hindlimb stiffness and lameness. These reactions are usually transitory, but occasionally muscle abscessation is a sequel.

A muscle abscess results in localized swelling, heat, and pain. The extent of the abscess, its depth, and the thickness of the walls may be determined by ultrasonography. Surgical drainage is required.

Other Muscle Abscesses

Suppurative myositis may arise through penetrating injuries, hematogenous spread of infection, or local spread of infection. Initially an ill-defined cellulitis occurs, which may heal or progress to a well-defined abscess (Fig. 84-9). An abscess may heal, expand, or fistulate, usually to the skin surface. Once fistulated the abscess may collapse and heal or result in a chronic granuloma with intermittent discharge. *Staphylococcus aureus, S. equi*, and C*orynebacterium pseudotuberculosis* are common causes of skeletal muscle abscessation.

The effect of an abscess on the horse's gait depends on its location and varies from mild stiffness to severe lameness.

Diagnosis is confirmed by ultrasonography or by culture of aspirated fluid. Abscesses lying deep within muscles can be difficult to diagnose. Fibrinogen level and nucleated white blood cell count may be raised. The synergistic hemolysin inhibition test, detecting antibodies to C. *pseudotuberculosis*, can be helpful for detecting internal abscesses.[98]

Treatment consists of poulticing, lancing, flushing, and draining. Occasionally, surgical removal may be required for complete excision. The use of antimicrobial drugs is controversial but may be recommended for corynebacterial abscesses. Commonly recommended drugs include procaine penicillin (20,000 IU/kg IM bid) and crystalline penicillin (20,000 to 40,000 IU/kg IV qid) alone or in combination with rifampin (5 mg/kg PO bid). If antimicrobial therapy is used, it should be continued for several weeks.

Prognosis is usually good for horses with superficial abscesses. Deep abscesses are more difficult to manage successfully. Prolonged resolution or recrudescence often occurs with corynebacterial abscesses.

Sarcocytosis

Cysts of the sporozoan parasite *Sarcocystis* are seen commonly in routine histological sections of the heart, esophageal, and skeletal muscles.[99] More than 90% of horses older than 8 years of age have sarcocysts in the esophageal muscles. Cysts may pose no problem, but with heavy infestations multisystemic dysfunction occurs. Horses with heavy infestation show signs of fever, anorexia, stiffness, weight loss, muscle fasciculations, atrophy, and weakness.[100] Diagnosis of sarcocystosis requires history, clinical signs, laboratory evaluation, and the demon-

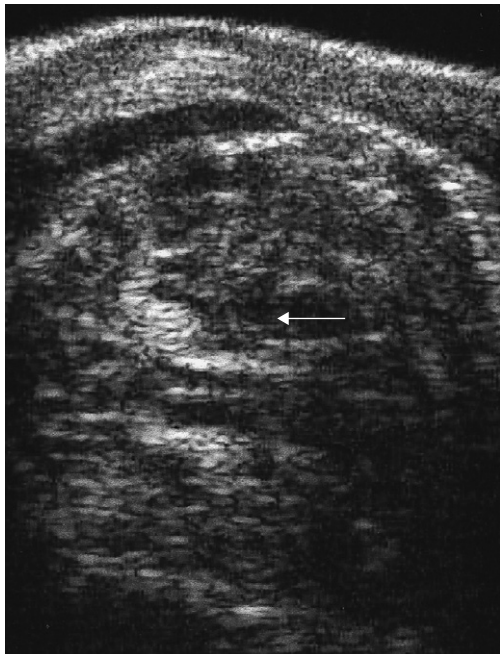

Fig. 84-9 Transverse ultrasonographic image of the lateral aspect of the antebrachium of a pony with cellulitis previously unresponsive to antimicrobial treatment. There was extensive soft tissue swelling throughout the antebrachium and carpal regions, with effusion in the carpal sheath and the tendon sheaths of extensor carpi radialis and the long and lateral digital extensor tendons. The pony was severely lame. There is a loculated, partly fluid-filled developing abscess *(arrow)*.

stration of an inflammatory reaction to immature cysts in muscle biopsies. Infection occurs from contamination of feed by infected canine feces. Successful treatment of one horse with sarcocystosis using phenylbutazone, trimethoprim sulfa, and pyrimethamine is reported.

Traumatic Myopathies

Post-Anesthetic Myopathy

Post-anesthetic myopathy occurs as a unilateral problem such as triceps myopathy, a bilateral problem such as hindlimb adductor myopathies, or as a generalized condition.[101] In horses anesthetized in lateral recumbency the dependent triceps muscle is most commonly affected, whereas the longissimus dorsi and gluteal muscles usually are affected in horses that have been in dorsal recumbency.

Hypoperfusion of muscle groups is the single most important causative factor, often resulting from a raised intracompartmental pressure. Positioning of the horse on the operating table is critical. Compressing muscles against a hard, unyielding surface, venous drainage obstruction, and hypotension may all be contributory factors. Generalized myopathies may occur independent of positioning and hypotension may play a greater role in these horses. The longer the duration of anesthesia, the higher the risk.

Clinical signs Clinical signs are usually evident as soon as the horse tries to stand, but they may be delayed for up to 2 hours. If clinical signs are severe, the horse is unable to stand. Triceps myopathy often is characterized by a dropped elbow stance typical of radial nerve paralysis. Involvement of the gluteal muscles may result in unwillingness to bear weight on the hindlimbs. Horses may appear distressed, with profuse sweating, tachycardia, and tachypnea. The degree of distress depends on the severity of the muscle damage. Affected muscles may feel hard, and localized swelling may occur.

Diagnosis Diagnosis is confirmed by measuring serum CK. The concentration often is increased after general anesthesia, but levels greater than 2000 U/L are significant. The CK concentration may be normal immediately after the horse stands, but as blood flow returns to the affected muscles, the concentration rises.

Treatment and prognosis Treatment aims to relieve distress and pain, to encourage perfusion of muscles, and to keep the horse standing if at all possible. Pain relief is provided by NSAIDs (phenylbutazone, 4.4 mg/kg; flunixin meglumine, 1 mg/kg), combined with opiate analgesics (e.g., butorphanol, 0.1 mg/kg) if necessary. Tranquilization with acepromazine (0.05 mg/kg) and sedation with α_2-agonists may be required. Fluid therapy is important to maintain renal perfusion and urine output and to ensure adequate muscle perfusion. A balanced polyionic electrolyte solution should be infused at up to 20 ml/kg per hour for the first several hours.

The prognosis for horses with unilateral myopathy is usually good, although with severe damage residual muscle fibrosis may develop, which may compromise function. With persistent clinical signs, ultrasonographic examination may be useful to determine the extent and severity of muscle damage.[102] The prognosis for horses with generalized myopathy is more guarded.

Prevention Prevention requires careful pre-operative planning to minimize the time under general anesthesia, careful positioning of the horse on the operating table, and maintenance of arterial blood pressure above 60 mm Hg using fluid therapy and inotropic agents such as dobutamine (1 to 5 μg/kg per minute). The position of the horse on the operating table is in part dictated by the surgical procedure. In lateral recumbency the dependent forelimb should be pulled forward and the upper limb should be supported at least parallel to the table. The hindlimbs should be supported parallel to, or above parallel, and adequately separated to permit venous drainage. In horses in dorsal recumbency, support of the forelimbs or hindlimbs in a semi-flexed position with the help of an overhead hoist can be helpful.

Fibrotic Myopathy

Fibrotic myopathy is discussed in Chapter 81.

Compartment-like Syndrome in the Antebrachium

Compartmental syndrome is a condition in which high pressure within a closed fascial space reduces capillary blood perfusion below a level necessary for tissue viability. The syndrome develops in skeletal muscle enclosed by relatively non-compliant osseofascial boundaries.[103] Elevated intracompartmental pressure may result from increased intracompartmental fluid or from decreased compartment size. Increased pressure because of fluid accumulation may result from muscle trauma and hemorrhage, or it may be a sequel to prolonged ischemia and subsequent reperfusion and edema. Prolonged raised pressure above 30 mm Hg resulted in myonecrosis in the dog.[104]

A compartment-like syndrome has been described in the horse involving the caudolateral muscle compartment of the antebrachium.[105] This encloses the lateral digital extensor, ulnaris lateralis, superficial and deep digital flexor and flexor carpi ulnaris muscles, and also the median artery, vein, and nerve.

Lameness is a sequel to trauma and is acute and severe in onset, with the horse reluctant to bear weight on the limb, associated with firm swelling on the caudolateral aspect of the antebrachium. Digital pulse amplitudes in the more distal part of the limb may be reduced if the limb is flexed or extended. With time the affected muscle mass may become cold.

Treatment is by fasciotomy. Incising the superficial fascia over ulnaris lateralis resulted in immediate separation of the fascia by 3 to 4 cm, and rapid relief of clinical signs.[105]

NUTRITIONAL MYODEGENERATION

• John Maas and Stephanie J. Valberg

Causes Nutritional myodegeneration (NMD) (white muscle disease, nutritional muscular dystrophy) is an acute degenerative disease of cardiac and skeletal muscle caused by a dietary deficiency of selenium or vitamin E.[88,106] Marginally to severely selenium-deficient areas occur in regions of numerous countries.[107,108] This syndrome occurs in young, rapidly growing foals born to dams that consumed selenium-deficient diets during gestation. The disease also has been implicated in masseter muscle myopathy and occasionally non-ER in adult horses. Selenium and vitamin E appear to be synergistic in preventing NMD. However, on the basis of prophylaxis and response to treatment, selenium deficiency appears to be the most important contributor.

Clinical signs Foals with primary necrosis of myocardium and respiratory muscles show dyspnea, a rapid irregular heartbeat, profound weakness, and recumbency.[86,88] Death often occurs in less than 24 hours despite medical therapy. If an animal responds to treatment, it often fails to thrive because of residual myocardial damage. Animals with predominantly cardiac signs also may manifest mild skeletal muscle problems associated with NMD.

The skeletal muscle form of NMD frequently has a slower onset, characterized by muscular weakness or stiffness. Animals may be recumbent and unable to stand. Animals that are able to rise without assistance, or with assistance, show muscle weakness, trembling of limb muscles, or stiffness. Stiffness is more pronounced as fibrosis occurs after extensive degeneration and calcification of muscle fibers. Most affected animals are able to stand for only short periods. Supporting muscle groups of the forelimbs and hindlimbs may appear swollen and may be hard and painful on palpation. Commonly affected muscle groups include the gastrocnemius, semitendinosus, semimembranosus, and biceps femoris, and muscles of the lumbar, gluteal, and neck regions. If the diaphragm and intercostal muscles are affected, the animal may show respiratory distress and evidence of increased abdominal effort when breathing. Dysphagia, because of necrosis in the tongue, may be the only sign in some affected foals and frequently is accompanied by aspiration pneumonia.

In the western United States we have seen some selenium-responsive NMD in adult horses that were extremely deficient in selenium in the winter time (snow on the ground), and the only clinical signs have been myoglobinuria (red snow) and mild stiffness in the morning. These mainly have been work horses and Quarter Horses. Some animals exhibit what appears to be abdominal pain, with violent thrashing. Myocardial damage and signs consistent with cardiac dysfunction may be present in horses with skeletal NMD. Animals with primary skeletal NMD often respond favorably to treatment and rest. Improvement is evident after a few days, and within 3 to 5 days animals can often stand and walk.

Clinical pathological findings Obvious elevation in CK, AST, and LDH activities occur during myodegeneration. CK activities often will be in the thousands to hundreds of thousands of units per liter. Progressively decreasing CK activity can be used as a prognostic indicator of cessation of myodegeneration. Electrolyte derangements are common in horses with severe rhabdomyolysis.[86] Hyperkalemia, hyperphosphatemia, hyponatremia, hypochloremia, and hypocalcemia can occur when the normal distinction between extracellular and intracellular compartments is destroyed by massive tissue necrosis. Myoglobinuria is common. Elevated serum protein concentrations and hemoconcentration commonly reflect dehydration in foals unable to nurse or drink water and reflect fluid shifts into damaged tissues. Neutrophilia is common because of the high incidence of aspiration pneumonia.

Diagnosis Whole blood selenium and plasma vitamin E samples provide satisfactory information for assessing the intermediate to long-term nutritional status. Whole blood selenium analysis is preferred over plasma and serum.[109] Whole blood selenium concentrations ranging from 0.07 to greater than 0.1 ppm are considered normal. Short-term oral or intra-muscular supplementation of selenium can confuse interpretation of circulating selenium concentration. Selenium-dependent glutathione peroxidase (GSH-Px), formed in the red blood cells during erythropoiesis, also provides an index of body selenium status. Adequate GSH-Px activities are greater than 20 to 50 units per milligram of hemoglobin per minute in horses. However, GSH-Px reference values are only specific to the laboratory where the analysis is performed and must be validated by comparison with blood selenium concentration. The activity of GSH-Px in red blood cells of domestic species remains constant for 4 to 6 days when maintained at 39° F (4° C); after this time significant decreases occur. The critical concentration of vitamin E (α-tocopherol) in plasma is 1.1 to 2 ppm. Vitamin E deteriorates rapidly in plasma samples. Therefore, plasma samples for α-tocopherol analysis need to be put on ice immediately, protected from the light by wrapping in tin foil, and stored frozen (–21° F, –70° C) if analysis is to be delayed.

Pathological findings Bilaterally symmetrical myodegeneration is a consistent finding in NMD. Skeletal muscle degeneration is characterized by pale discoloration and a dry appearance of affected muscle, white streaks in muscle bundles, calcification, and intramuscular edema. The white streaks in muscle bundles represent bands of coagulation necrosis or in horses with chronic disease where insults may have occurred weeks before may represent fibrosis and calcification. Affected muscle bundles are often adjacent to apparently normal or minimally affected muscle. Histologically, affected muscle fibers may be hypercontracted and fragmented, with some mineralization of muscle fibers and macrophage infiltration. Tissue biopsies and tissue specimens obtained at necropsy can be assayed for selenium content. Normal liver concentrations of selenium are 1.05 to 3.5 ppm dry matter.

Pathophysiological findings During normal cellular metabolism, highly reactive forms of oxygen (free radicals) are produced. These include hydrogen peroxide, hydroperoxides, lipoperoxides, superoxide, various hydroxy radicals, and singlet oxygen. Vitamin E is active within the cell membrane as a lipid-soluble antioxidant that scavenges free radicals that otherwise might react with unsaturated fatty acids to form lipid hydroperoxides. In contrast, GSH-Px destroys hydrogen peroxide and lipoperoxides that have already been formed and converts them to water or relatively harmless alcohols. Other enzymes, such as catalase and superoxide dismutase, also are involved in this protective process. It is believed that a deficiency of selenium results in rhabdomyolysis through oxidant damage to muscle cell membranes. The precise interrelationships between selenium, vitamin E, other metabolic factors and triggering mechanisms in NMD are not fully understood, because many animals deficient in selenium or vitamin E have no evidence of muscle disease. In certain situations deficiencies of selenium and vitamin E are necessary for disease to occur. In other animals NMD can occur when a deficiency of only one of the nutrients is present and the other is normal in blood and tissues.

Treatment and prognosis Myocardial damage is often extensive and incompatible with life with the cardiac form of NMD. Only rarely is treatment successful. In contrast, the skeletal muscle form of NMD is more generally amenable to treatment, although the prognosis for clinical recovery from the skeletal form of NMD is guarded and depends often on whether secondary complications, such as respiratory disease, develop. In all horses with NMD, therapy should involve specific supplementation with selenium and vitamin E and general supportive care.

Alleviation of selenium-responsive NMD requires use of injectable selenium products, available with selenium concentrations varying from 1 mg of selenium per milliliter to 5 mg/ml. All products contain 50 mg/ml (68 IU) of vitamin E as *dl*-α-tocopherol acetate. The label dose for selenium is 0.055 to 0.067 mg/kg (2.5 to 3 mg/45 kg) body mass given intramuscularly or subcutaneously. Dosage should not be increased greatly above the label dose to prevent an inadvertent selenium toxicosis. Absorption and distribution of injectable selenium occurs rapidly and may account for the rapid improvement in clinical signs seen in horses with reversible clinical signs.

The amount of vitamin E in vitamin E/selenium combinations is insufficient for vitamin E supplementation. Injectable vitamin E products are now available that contain 300 IU vitamin E per milliliter as *d*-α-tocopherol (Vital E; Schering-Plough Animal Health, Kenilworth, NJ). Administration increases the tissue and plasma level of vitamin E activity for about 3 weeks. Bioavailability of vitamin E from injectable products depends on the form of vitamin E (the alcohol form, *d*-α-tocopherol, is the most active) and amount and quality of the solution emulsifier used. Oral vitamin E supplementation is a good approach to supplement dietary levels. Daily recommended levels of supplementation for horses range from 600 to 1800 mg of *dl*-α-tocopherol acetate.[110] Oral α-tocopherol is now available for all species and contains 500 IU vitamin E per milliliter (Vita/E, Schering-Plough Animal Health). The recommended dosage of this product is 0.5 to 1.5 IU/kg body mass.

Supportive therapy may include administration of antibiotics to help combat secondary pneumonia and infected decubital lesions, which are common in recumbent patients. When dysphagia is present, feeding by nasogastric tube, provision of adequate energy intake, and attention to fluid and electrolyte balance are critical if recovery is to be successful. Hyperkalemia may be life threatening in affected foals. Mineralocorticoids, alkalinizing fluids, dextrose, and insulin may be used to reduce circulating potassium concentrations.[86]

Prevention and control The prevention and control of NMD is achieved through supplementation of selenium and vitamin E. Oral supplementation for horses at 1 mg of selenium per day increases blood selenium concentrations above levels known to be associated with NMD.[109] Supplementation of pregnant mares is advised in areas known to be selenium deficient. However, only limited selenium may cross the placenta.[106] Supplementation during lactation increases levels of selenium in milk and thus provides a potential means of selenium supplementation in foals. However, evidence in cattle indicates that this increased level of selenium in milk may not meet the foal's nutrient requirements.[111] Supplementation by injectable selenium products alone would require treatment every 30 to 45 days and would provide only partial amounts of the recommended level of selenium.[112]

Regardless of the supplementation method, periodic blood (or tissue) sampling of animals at risk is necessary to ensure maintenance of desired levels of selenium. In high-risk areas, samples should be taken every 60 to 90 days to determine selenium status in susceptible animals and every 6 to 12 months to monitor supplementation. Based on these assessments, adjustments to the rate or extent of selenium supplementation may be made. Feeding animals properly prepared and stored hay and grain or allowing them access to high-quality green forage should ensure adequate vitamin E intake.

TOXIC MYOPATHIES

• Stephanie J. Valberg and Sue J. Dyson

Ingestion of a number of toxic substances in feed or forage may cause of rhabdomyolysis in horses.

TOXIC SUBSTANCES

Ionophores

Ionophores are commonly added to ruminant feeds for growth promotion and coccidiostat properties. Horses, however, are 10 times more sensitive than cattle to the toxic effects of ionophores in feed. When equine feeds are inadvertently contaminated with ionophores or horses eat cattle feed, cardiomyopathy is the most common chronic sequela. However, some animals may die acutely with colic-like signs, myoglobinuria, hypokalemia, cardiac arrhythmia, and tachypnea.[113]

Pasture Myopathies

Trematones Horses ingesting 0.5% to 2% body weight of trematone-containing plants are likely to die from skeletal muscle and cardiac muscle necrosis. Horses show depression, weakness, low head posture, and increased cardiac and respiratory rates. Serum AST and CK often are elevated greatly, and serum electrolyte abnormalities such as hypocalcemia, hyponatremia, hypochloremia, hyperkalemia, and hyperphosphatemia may be present. Treatment is generally supportive as described in the section on acute ER. Trematone has been identified in white snakeroot (*Eupatorium rugosum*) and rayless goldenrod (*Haplopappus heterophyllus*). White snakeroot grows in shaded areas of the eastern and central United States.[114-116] Rayless goldenrod is common in the southwestern United States on open pastures. Trematone remains active in the hay and in the stalks of the dead plants on pasture, so the fresh and dried forms of the plants should be kept from horses.[115,116]

Cassia occidentalis Muscle necrosis also may occur in horses ingesting *Cassia occidentalis* seeds, prevalent in the southeastern United States.[117] Horses develop incoordination and recumbency and die. Gross skeletal muscle lesions are not present, but histopathological lesions include segmental myonecrosis.

Blister Beetles One of 70 horses poisoned with blister beetles developed muscle necrosis.[118]

Atypical Myoglobinuria Atypical myoglobinuria occurs sporadically in horses kept at pasture, usually with no supplemental feeding.[119] The condition has been recognized most commonly in the United Kingdom. The cause is unknown. Atypical myoglobinuria occurs most often in spring and autumn and often is associated with a sudden deterioration in weather conditions. The clinical signs are sudden in onset and rapidly progressive, frequently resulting in death. Several horses in a group may be affected, although some may remain without clinical signs. Affected horses are reluctant to move, have muscle weakness, and may become recumbent. Gut sounds may be reduced, with reduction in fecal production, although appetite may be unaffected. The horses do not show signs of pain, despite post-mortem evidence of widespread myopathy. Typically myoglobinuria and substantial increases in serum CK and AST occur.

Post-mortem examination reveals widespread myodegeneration in skeletal muscles and the myocardium. Supportive therapy has resulted in recovery of some horses although, being low value pleasure horses, it is difficult to assess what level of work they were subsequently able to cope with.

Disorders Associated with Muscle Fasciculations or Myotonia

A variety of muscle disorders exist in the horse that can cause muscle fasciculations, muscle cramping, and sometimes recumbency. These include metabolic alkalosis combined with hypocalcemia, hypomagnesemia, infestation with ear ticks, hyperkalemic periodic paralysis, myotonia congenita, and dystrophic myotonia. With the exception of ear ticks, these disorders are not associated with a significant elevation in serum CK activity.

Hypocalcemia in Horses

Hypocalcemia (lactation tetany, transport tetany, idiopathic hypocalcemia, and eclampsia) is a rare disorder in horses. Clinical signs of increased muscle tone may resemble tetanus. Horses may show a stiff, stilted gait; hindlimb ataxia; muscle fasciculations (especially temporal, masseter, and triceps muscles); trismus; dysphagia; salivation; anxiety; profuse sweating; tachycardia; elevated body temperature; cardiac dysrhythmias; synchronous diaphragmatic flutter; convulsions; coma; and death.[120-122] Clinical signs of excitability usually are seen when serum calcium values are below normal but above 8 mg/dl. Values of 5 to 8 mg/dl usually produce tetanic spasms and incoordination. Concentrations below 5 mg/dl usually result in recumbency and stupor. This disorder often progresses and may cause death within 48 hours, particularly in lactating mares. Metabolic alkalosis, hypomagnesemia/hypermagnesemia, and hyperphosphatemia/hypophosphatemia have all been found in association with hypocalcemia in horses.[121,122]

Treatment involves the intravenous administration of calcium solutions, such as 20% calcium borogluconate, or those recommended for the treatment of parturient paresis in cattle. Administration of these solutions at the rate of 250 to 500 ml/500 kg, diluted 1:4 with saline solution or dextrose, often results in full recovery, although in some horses recovery may take several days.[120] Relapses do occur. If no response to an initial infusion occurs, a second dose may be given 15 to 30 minutes later. Cardiac rate and rhythm should be monitored closely when calcium-containing solutions are infused intravenously.

Ear Tick–Associated Muscle Cramping

Intermittent painful muscle cramps, not associated with exercise, have been described in horses with severe *Otobius megnini* infestations.[123] These horses show intermittent signs of severe muscle cramping of pectoral, triceps, abdominal, or semitendinosus/semimembranosus muscles, lasting from minutes to a few hours, with severe pain that often resembles colic. Horses may fall over when stimulated. Between muscle cramps, horses appear to be normal. Percussion of triceps, pectoral, or semitendinosus muscles results in a typical myotonic cramp. Horses have serum CK activities ranging from 4000 to 170,000 U/L. Numerous ear ticks, *O. megnini*, can be identified in the external ear canal of affected horses. Without treatment for ear ticks, the spasms continue. However, local treatment of the ear ticks, using pyrethrins and piperonal butoxide, results in recovery within 12 to 36 hours. Acepromazine is helpful to relieve painful cramping.

Myotonia

Myotonic muscle disorders represent a heterogeneous group of clinically similar diseases that share the feature of delayed relaxation of muscle after mechanical stimulation or voluntary contraction. Skeletal muscle ion channel dysfunction, producing abnormal muscle membrane excitability, appears to be the shared abnormality among myotonias in many species.[124,125]

Foals with myotonia congenita usually have conspicuously well-developed musculature and mild hindlimb stiffness.[126,127] Gait abnormalities usually are most pronounced when exercise begins and frequently diminish as exercise continues. Bilateral bulging (dimpling) of the thigh and rump muscles is often obvious and exacerbated by stimulation of affected muscles by percussion. Affected muscles may remain contracted for up to a minute or more, with subsequent slow relaxation.

A diagnosis is best made by electromyography. High-frequency crescendo-decrescendo action potentials, with a classic dive-bomber pattern, are characteristic for myotonia. Muscle biopsies may reveal an increased proportion of type I fibers, fiber hypertrophy, fiber splitting, and centrally located nuclei.

Foals with myotonia congenita usually do not demonstrate progression of clinical signs beyond 6 to 12 months of age. A variety of breeds of horses have been described with this disorder, but an inherited basis for myotonia has not been established.[128,129] Phenytoin may diminish clinical signs, but no long-term treatment is available.[130,131]

A more severe, progressive form of myotonia that eventually results in debilitating muscle atrophy, fibrosis, and stiffness has been observed in Quarter Horse foals. At birth, foals appear well muscled and slight stiffness disappears with exercise. As the condition progresses, muscle hypertrophy is less obvious and exercise may produce debilitating muscle contractures. Foals may become so stiff that they are unable to stand. This condition resembles myotonia dystrophica in people, in that numerous organ systems may be involved.[131] Retinal dysplasia, lenticular opacities, and gonadal hypoplasia have been reported in one such Quarter Horse foal.[131,132] In people, abnormal sodium channel regulation has been identified in myotonic dystrophy, with reduced protein kinase activity.[125] A diagnosis is established by electromyography and muscle biopsy. Electromyography reveals increased numbers of high-frequency dive-bomber–like electrical discharges. Muscle biopsies show fiber-type grouping, increased numbers of cells with centrally located nuclei, sarcoplasmic bodies, ring fibers, and fibrosis. The prognosis is extremely poor and most foals are humanely destroyed by 1 year of age.

Stiff Horse Syndrome

A condition called *stiff horse syndrome* has been described in Belgium, characterized by stiffness and muscle spasms, associated with an abnormally straddled posture.[133] The muscle spasms typically were triggered by voluntary movements, such as going to eat from the manger, or being led from the stable. Electromyography showed persistent motor unit activity in the axial and gluteal muscles. The clinical signs were responsive to oral prednisolone therapy but recurred after treatment stopped. Several similar horses have been seen in the United Kingdom.[134,135] The cause of the condition is currently unknown. Similar conditions have been recognized in people, some of which are thought to be autoimmune.

HYPERKALEMIC PERIODIC PARALYSIS

• Sharon J. Spier

Hyperkalemic periodic paralysis (HyPP) is an autosomal dominant trait affecting Quarter Horses, American Paint horses, Appaloosas, and Quarter Horse crossbreed animals worldwide.[136-138] The genetic disease has been linked to a prolific Quarter Horse sire named Impressive. Current estimates indicate that 4% of the Quarter Horse breed may be affected.[139] Affected horses may have been selected preferentially as breeding stock because of their pronounced muscle development, and evidence exists of selection of HyPP-affected horses as superior halter horses by show judges.[140]

Clinical Signs

Clinical signs among horses carrying the same mutation range from asymptomatic to daily muscle fasciculations and weakness. In most horses intermittent clinical signs begin by 2 to 3 years of age, with no apparent abnormalities between episodes.[136,137] Ingestion of diets high in potassium (>1.1%)—such as those containing alfalfa hay, molasses, electrolyte supplements, and kelp-based supplements—or sudden dietary changes commonly trigger episodes.[141] Fasting, anesthesia or heavy sedation, trailer rides, and stress also may precipitate clinical signs. However, the onset of signs is often unpredictable, without a definable cause. Other possible precipitating factors that have been noted in people and horses are exposure to cold, fasting, pregnancy, concurrent disease, and rest after exercise. Exercise itself does not appear to stimulate clinical signs, and serum CK shows no change to modest increases during episodic fasciculations and weakness.

In most horses clinical episodes begin with a brief period of myotonia, with some horses showing prolapse of the third eyelid. Sweating and muscular fasciculations are observed commonly in the flanks, neck, and shoulders. The muscle fasciculations become more generalized as additional muscle groups are involved. Stimulation and attempts to move may exacerbate muscular fasciculations. Some horses may develop severe muscle cramping. Muscular weakness during episodes is a common characteristic of HyPP. Horses remain standing during mild attacks. In more severe attacks clinical signs may progress to apparent weakness, with swaying, staggering, sitting on the haunches, or recumbency within a few minutes. Heart and respiratory rates may be elevated and horses may show manifestations of stress, yet remain relatively bright and alert during episodes. Affected horses usually respond to noise and painful stimuli during clinical manifestations of the disorder. Episodes last for variable periods, usually from 15 to 60 minutes. Several horses have died during acute episodes.[136,137] Respiratory distress occurs in some animals as a result of paralysis of upper respiratory muscles, and a tracheostomy may be necessary. In addition, young horses that are homozygous for the HyPP trait have been observed to manifest a respiratory stridor and periodically may develop obstruction of the upper respiratory tract.[141,142] Horses homozygous for HyPP may show dysphagia or respiratory distress. Endoscopic findings include pharyngeal collapse and edema, laryngopalatal dislocation, and laryngeal paralysis. Once the episode subsides, horses show no apparent or minimal gait abnormalities. Although HyPP horses appear normal between attacks, electromyographic examination of affected horses reveals abnormal fibrillation potentials, complex repetitive discharges with occasional myotonic potentials, and trains of doublets between episodes.[137]

Cause

HyPP is caused by a point mutation that results in a phenylalanine/leucine substitution in a key part of the voltage-dependent skeletal muscle sodium channel alpha subunit.[138] In horses with HyPP, the resting membrane potential is closer to firing than normal horses. Sodium channels normally are activated briefly during the initial phase of the muscle action potential. The HyPP mutation results in a failure of a subpopulation of sodium channels to inactivate when serum potassium concentrations are increased. As a result, an excessive inward flux of sodium and outward flux of potassium ensues, resulting in persistent depolarization of muscle cells and temporary weakness.

Diagnosis

Descent from the stallion Impressive on the sire's or dam's side in a horse with episodic muscle tremors is strongly suggestive of HyPP. Quarter Horse foals born after 1998 that are offspring of an affected parent have a statement recommending DNA testing for HyPP on the Certificate of Registration. In most horses with hyperkalemia (6 to 9 mEq/L), hemoconcentration and hyponatremia occur during clinical manifestations of the disease, with normal acid-base balance.[136,137,142] Serum potassium concentration returns to normal after abatement of clinical signs. Some affected horses may have normal serum potassium concentrations during minor episodes of muscle fasciculations. Differential diagnoses for hyperkalemia include delay before serum centrifugation, hemolysis, chronic renal failure, and severe rhabdomyolysis.

Because clinicians may not be present during acute episodes, the definitive test for identifying HyPP is demonstration of the base-pair sequence substitution in the abnormal segment of the DNA encoding for the alpha subunit of the sodium channel.[140] Submission of mane or tail hair should be made to appropriate genetic laboratories.*

Treatment

Low-grade exercise can sometimes abort an episode of mild disease or if horses are just beginning to exhibit clinical signs. Feeding grain or corn syrup to stimulate insulin-mediated movement of potassium across cell membranes also may be helpful. Other treatment options that may abort an episode include intra-muscular administration of epinephrine (3 ml of 1:1000/500 kg) and administration of acetazolamide (3 mg/kg orally every 8 to 12 hours). Many horses experience spontaneous recovery from episodes of paralysis and appear normal by the time a veterinarian arrives.

With severe clinical signs, administration of calcium gluconate (0.2 to 0.4 ml/kg of a 23% solution diluted in 1 L of 5% dextrose) often provides immediate improvement. An increase in extracellular calcium concentration raises the muscle membrane threshold potential, which decreases membrane hyperexcitability. To reduce the serum potassium, intravenous dextrose (6 ml/kg of a 5% solution) alone, or combined with sodium bicarbonate (1 to 2 mEq/kg), can be used to enhance intracellular movement of potassium. With severe respiratory obstruction, a tracheostomy may be necessary.

Control

Decreasing dietary potassium and increasing renal losses of potassium are the primary steps taken to prevent HyPP episodes.[143,144] Feedstuffs to avoid include high-potassium feeds, such as alfalfa hay, brome hay, canola oil, soybean meal or oil, and sugar molasses and beet molasses. Optimally, later cuts of timothy or bermuda grass hay; grains such as oats, corn, wheat, and barley; and beet pulp should be fed in small meals several times a day. Regular exercise and frequent access to a large paddock or yard are also beneficial. Pasture works well for horses with HyPP, because the high water content of pasture grass makes it unlikely that horses will consume large amounts of potassium in a short period of time. Ideally, horses with recurrent episodes of HyPP should be fed a diet containing between 0.6% and 1.1% total potassium concentration. Because of the wide variation in potassium concentration of forages depending on maturity and soils, it is advisable to have feeds analyzed for potassium concentrations and other nutrient requirements.

For horses with recurrent episodes of muscle fasciculations despite dietary alterations, acetazolamide (2 to 4 mg/kg orally every 8 to 12 hours) or hydrochlorothiazide (0.5 to 1 mg/kg orally every 12 hours) may be helpful.[142-144] Effects of these agents are exerted through different mechanisms; however, both cause increased renal potassium adenosine triphosphatase activity. In addition, acetazolamide stabilizes blood glucose and potassium levels by stimulating insulin secretion. Breed registries and other associations have restrictions on the use of these drugs during competitions.

Prognosis

In most horses, HyPP is a manageable disorder, although recurrent bouts may occur and severe episodes may be fatal. Owners of affected horses should be strongly discouraged from breeding these animals for the long-term health of the Quarter Horse and other breeds. Breeding of an affected horse to a normal horse results in a 50% chance of producing a foal with HyPP. Owners of affected horses should advise veterinarians of HyPP status before anesthesia or procedures requiring heavy sedation.

SECTION • 1
Traditional Therapy

CHAPTER • 85

Principles and Practices of Joint Disease Treatment

John P. Caron and Ronald L. Genovese

Recent advances reveal that osteoarthritis is a dynamic process, unlike previous concepts of a passive wear-and-tear phenomenon. Although many questions remain unanswered, our understanding of the pathophysiology of osteoarthritis and biological effects of therapeutic agents has expanded. Technical improvements in imaging modalities and arthroscopic surgical techniques allow early diagnosis and have broadened our perspective, paving the way for future progress in managing equine osteoarthritis.

MEDICAL TREATMENT

Pain (lameness) is the main reason most horses are examined, and rapid resolution of signs is the principal concern of most owners and trainers. Ideally, medical management of osteoarthritis would serve to arrest or at least slow the progression of lesions, a treatment objective termed *chondroprotection* or *disease modification*. Several factors influence therapeutic decisions in the medical management of osteoarthritis in horses, including the following:

1. The specific joint involved
2. The stage of osteoarthritis
3. The current and intended use of the horse
4. The age of the horse
5. Regulations governing anti-inflammatory medication use in competition
6. Treatment cost
7. Response to therapy

Therapeutic decision making also is complicated by the inherent nature of osteoarthritis, a condition that progresses at a variable rate and with signs difficult to quantify. Also, important degenerative changes and structural damage of cartilage matrix may precede the development of clinical signs, and late diagnosis precludes the possibility for complete resolution. Variability in response of horses with similar lesions supports the contention that osteoarthritis is a spectrum of disease. Despite recent progress, established osteoarthritis is incurable and frequently limits the serviceability of affected horses.

Non-Steroidal Anti-Inflammatory Drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) are agents that inhibit one or more reactions involved in the production of prostaglandins and thromboxanes. Prostaglandins, particularly those of the E series, are associated with synovial inflammation and cartilage matrix depletion,[1,2] and although the specific effects of prostaglandins on joint metabolism are unclear, it is widely believed that prostaglandin E_2 plays a role in processes leading to joint degeneration. Prostaglandin E_2 has been demonstrated in the synovial fluid of horses with osteoarthritis,[3] and in vitro studies indicate that synoviocytes and chondrocytes synthesize prostaglandin E_2 after exposure to other inflammatory mediators.[4-6] Prostaglandin E_2 was implicated in the erosion of cartilage and adjacent bone,[7] and other studies suggest that prostaglandins may modulate latent metalloproteinase release and subsequent cartilage matrix degradation.[8,9] Paradoxically, reports suggest that matrix metalloproteinase expression in human synovial fibroblasts is inhibited by E-series prostaglandins.[10] These and other data suggest that prostaglandin E_2 may serve a regulatory function in inflamed joints and inhibition may not produce uniformly favorable results.[11] Thus recent evidence suggests that prostaglandin inhibition, although effective in providing symptomatic relief, may have deleterious effects on cartilage metabolism in the long term.[12] Establishing the specific biological effects of prostaglandin E_2 and the consequences of its inhibition in the equine joint is important, given the widespread use of NSAIDs in osteoarthritis treatment and the recognized toxic side effects that can result.

The principal action of most NSAIDs is the inhibition of cyclooxygenase (COX), the first in a series of enzymes responsible for converting arachidonic acid to prostaglandins (Fig. 85-1). Importantly, two forms of COX exist: the first produces physiological levels of prostaglandins in a constitutive manner (COX 1) and the second, an inducible form of the enzyme (COX 2), is responsible for the elevated levels of

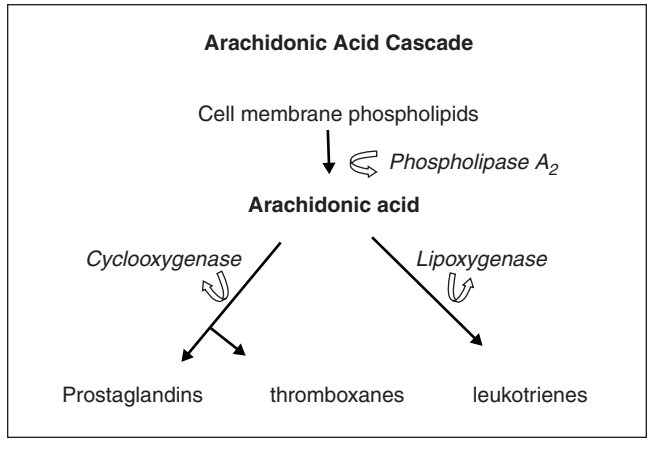

Fig. 85-1 Arachidonic acid cascade. Common therapeutic targets include phospholipase A_2 (corticosteroids) and cyclooxygenase (corticosteroids and non-steroidal anti-inflammatory drugs). Prostaglandins, particularly those of the E series, are associated with synovial inflammation and cartilage matrix depletion; however, accumulating evidence indicates that prostaglandin E_2 plays a role in regulating over-production of proteolytic enzymes by articular chondrocytes.

prostaglandins observed during inflammatory events.[13,14] The constitutive activity of COX 1 is responsible for many of the homeostatic properties ascribed to prostaglandins and toxicity is related to sustained COX 1 inhibition.[15,16] Most currently available NSAIDs inhibit the activities of both COX isoforms. However, the proportionate inhibition of COX 1 to COX 2 varies among compounds, and many aspects of the specific anti-inflammatory profiles of most NSAIDs used in horses remain to be explored in detail. A number of selective COX 2 inhibitors have been approved recently for use in people and to date have similar clinical efficacy to that of non-specific COX inhibitors, largely unaccompanied by typical NSAID side effects.[17-19] COX 2 inhibitors have been introduced to companion animal practice and likely will soon find use in horses, particularly when more affordable generic forms become available. This development may address existing problems with toxicity and potential unfavorable effects on cartilage metabolism of currently used NSAIDs.[20-22]

In addition to COX inhibition, NSAIDs have other anti-inflammatory effects. For example, carprofen reduces edema and effusion in experimental osteoarthritis in horses by a non–COX-mediated pathway.[23] Ketoprofen inhibits lipoxygenase and COX.[24] Moreover, at least some NSAIDs are capable of inhibiting elements of cellular inflammation.[25,26] Thus it is clear that at least some NSAIDs possess anti-inflammatory actions other than COX inhibition, although the biological significance of these effects is uncertain and may occur only at tissue concentrations achieved by exceeding normal dosages. These side actions may complicate the premise that selective COX 2 inhibitors are devoid of side effects, particularly when used at higher dosages where effects unrelated to COX inhibition are evident.

Pain relief from NSAIDs is mainly, but not exclusively, related to COX inhibition. Prostaglandins do not produce pain, except when present in large quantity.[27] Prostaglandin E_2 sensitizes peripheral nerve endings to mechanical stimuli and amplifies the chemical activation of pain receptors by other inflammatory mediators such as bradykinin and histamine, both of which act to lower the pain threshold.[28,29] Reducing prostaglandin levels also appears to modulate pain perception centrally, at the level of spinal receptors distant from sites of inflammation.[30] In addition to COX inhibition, certain NSAIDs possess other mechanisms of analgesia, because COX inhibitory activity of some compounds is not correlated closely with analgesic potency.[31] For example, the R-enantiomer of flurbiprofen is a weak COX inhibitor compared with its D-enantiomer, but it has comparable analgesic potency.[32] Among other ancillary mechanisms, NSAIDs may contribute to analgesia by inhibiting sensory neurotransmitter synthesis at a spinal level.[33]

At present, phenylbutazone is the least expensive and most popular agent used in horses, and its clinical efficacy appears to compare favorably with other NSAIDs.[34] (Table 85-1). Other choices include flunixin meglumine, meclofenamic acid, naproxen, ketoprofen, and carprofen, for which the basic pharmacology in horses was recently reviewed.[35,36] It should be noted that considerable variation exists in the pharmacokinetic profiles of NSAIDs among horses, and clearance is influenced by a variety of factors such as dose, the presence or absence local inflammatory conditions, and feeding schedule (for orally administered drugs).[37-40] The latter effect can be a consideration in estimating withdrawal times, given that the peak plasma concentration and apparent half-life can be substantially delayed when NSAIDs are given to horses with

Table • **85-1**

Non-Steroidal Anti-Inflammatory Drugs Used to Treat Musculoskeletal Pain

GENERIC NAME	TRADE NAME(S)	FORMULATION(S)	RECOMMENDED DOSE (mg/kg)	RELATIVE PRICE (per day)
Phenylbutazone*	Phenylbutazone injection Bizolin 200 Equipalazone Equiphen paste etc.	Tablets Paste Granules/powder Injectable (IV only)	4.4 bid 1, 2.2 bid (4 days), then 2.2 sid (IV, PO)	(Dose is 2.2. mg/kg bid) Tablets (1 g) = 1.0 Paste (12 g) = 2.8 Injectable = 6.9
Flunixin meglumine†	Banamine Citation Meflosyl, etc.	Granules Paste	1.1 daily for 5 days (IV, IM, PO)	(Dose is 1.1 mg/kg sid) Granules (500 mg envelope) = 5.0 Paste (1500 mg tube) = 12.4 Injectable (50 mg/ml) = 6.8
Meclofenamic acid†	Arquel	Granules	2.2 sid (5-7 days), then 2.2 sid or less (PO)	(Dose is 2.2 mg/kg sid) Granules = 1.6
Naproxen†	NM	Tablets	10 sid for up to 14 days (PO)	(Dose is 10 mg/kg sid) Tablets (500 mg) = 7.1
Ketoprofen†	Ketofen	Injectable	2.2 sid (IV)	(Dose is 2.2 mg/kg sid) Injectable (100 mg/ml) = 27.4
Carprofen†	Rimadyl‡	Injectable	0.7 sid (IV)	(Dose is 0.7 mg/kg sid) Tablets (100 mg) = 4.2

NM, Not currently marketed by veterinary distributors in the United States.
*Enolic acid.
†Carboxylic acid.

access to hay. Dose rates and schedules may have to be adjusted for individual horses to accommodate these effects.

The chondroprotective (and potential deleterious) effects of NSAIDs have been investigated in vitro, although the clinical relevance of the results is not clear. Certain NSAIDs are known to inhibit anabolic activities in chondrocytes, whereas others stimulate matrix synthesis.[41-44] Concern over the potential unfavorable side effects of these agents began with the observation that aspirin inhibited proteoglycan synthesis and could encourage cartilage destruction[45,46] and that ibuprofen was implicated in accelerated joint destruction in people with osteoarthritis.[47,48] Fears of enhanced rates of cartilage degradation with NSAID use were not borne out in a number of clinical and experimental studies.[49,50] In vitro data may not parallel ex vivo data in the same species. For example, indomethacin reduces proteoglycan synthesis in canine cartilage explants; however, cartilage obtained from indomethacin-treated and control dogs had similar synthetic rates.[44] Indeed, certain NSAIDs have shown to be chondroprotective in some osteoarthritis models.[51-53]

Similar to the effects on cartilage matrix synthesis, NSAIDs vary in the ability to inhibit both catabolic events in cartilage and the effects of degradative enzyme activity.[54] Although many studies have focused on direct inhibition of degradative enzymes, NSAIDs may be of benefit by suppressing other mediators.[55,56] For example, in one of the few equine studies, phenylbutazone limited proteoglycan depletion that accompanies in vitro culture of articular cartilage,[57] but the effect was not mediated by stromelysin inhibition.[58]

Corticosteroids

Corticosteroids are the most potent anti-inflammatory agents used to treat osteoarthritis. Normally injected directly into affected joints, corticosteroids depress numerous inflammatory processes, including capillary dilatation; margination, migration, and accumulation of inflammatory cells; and liberation of enzymes, cytokines, and other inflammatory mediators.[59,60] Notably corticosteroids also inhibit prostaglandin production by inhibiting phospholipase A_2 and COX 2 (but not COX 1).[61] The consequence of inhibiting arachidonic acid metabolism is a rapid and pronounced reduction in pain.

A long-standing controversy surrounds the use of corticosteroids in treating osteoarthritis because of the concern that overuse of a pain-free joint could result in accelerated degeneration.[62-64] This impression has been compounded by demonstrated negative effects of corticosteroids on chondrocyte metabolism. Particularly at high concentrations, corticosteroids inhibit proteoglycan synthesis and unfavorably influence the structural organization of cartilage collagens, even in normal cartilage.[65-70] Conversely, other studies have demonstrated that corticosteroids have certain chondroprotective properties. At low doses, they are capable of inhibiting the process of cartilage degradation by inhibitory effects on the synthesis of matrix metalloproteinases (MMPs) and cytokines[71-73] These in vitro data are supported by results in animal models demonstrating cartilage-sparing effects of low-dose corticosteroids, without significant effects on chondrocyte health.[74-76] It is well established that corticosteroids inhibit the gene expression of MMPs; however, this effect must be weighed against a similar effect on the expression of the natural inhibitory protein of these enzymes (tissue inhibitor of matrix metalloproteinase, or TIMP) and matrix collagen and proteoglycan synthesis.[77,78] The magnitude and relative contributions of these inhibitory effects need to be defined more fully, although it may be possible to determine a concentration of drug that produces chondroprotective effects while minimizing negative consequences on chondrocyte anabolic activity.

Although proteoglycan depletion with high doses of corticosteroids is an incontestable phenomenon, its importance as a clinical entity is contentious.[79-81] Noteworthy are recent studies using horses with iatrogenic osteochondral lesions of the carpus treated with betamethasone and triamcinolone acetonide. After treatment horses were exercised on a treadmill. Lesions of cartilage and bone in treated horses were comparable to those in controls.[82,83] To investigate the possibility that different corticosteroid preparations may exert varied effects on joint metabolism, a similar protocol was conducted by the same research group, using methylprednisolone acetate. In this study, morphological lesions were observed that the authors considered related to corticosteroids.[84] It should be noted that, as in other studies evincing unfavorable effects of methylprednisolone acetate, the dose used (100 mg the first and fourteenth days) would be considered generous by current standards. Additionally, the effects of methylprednisolone acetate on chondrocyte metabolism differ between normal and inflamed joints. In inflamed joints modest concentrations of methylprednisolone acetate may have less dramatic effects on matrix synthesis than in normal joints.[85] In summary, although intra-articular use of corticosteroids may potentially aggravate existing cartilaginous lesions, the potential deleterious effects are overemphasized.

The type, dose, and frequency of corticosteroid administration remain subjective. Common choices and dose ranges are given in Table 85-2. In general, pharmacokinetic data suggest that corticosteroid suspensions have short intra-articular half-lives.[86-88] Considerable variation in the clearance of corticosteroid suspensions exists. For example, the active moiety of methylprednisolone acetate can be liberated for up to 1 month.[89] The specific reasons for divergent pharmacokinetic profiles and the duration of anti-inflammatory effect far exceeding intra-articular half-life of corticosteroids are unclear.

Table • **85-2**

Corticosteroid Suspensions Used Intra-Articularly

CORTICOSTEROID	TRADE NAME	MANUFACTURER	CONCENTRATION (mg/ml)	DOSE (mg)*	POTENCY RELATIVE TO HYDROCORTISONE
Betamethasone sulfate	Celestone Soluspan	Schering-Plough	6†	3-18	30
Triamcinolone acetonide	Vetalog	Solvay	6	6-18	5
Flumethasone	Flucort	Syntex	0.5	1.25-2.5	120
Isoflupredone acetate	Predef 2X	Pharmacia and Upjohn	2	5-20	50
Methylprednisolone acetate	Depo Medrol	Pharmacia and Upjohn	40	40-120	5

*Dose ranges are somewhat arbitrary. Magnitude and duration of clinical effects vary widely.
†Each milliliter contains betamethasone acetate (3 mg) and betamethasone sodium phosphate (3 mg).

Most clinicians currently use lower doses of corticosteroids than their predecessors, because the dose-dependent deleterious effects are now recognized and most are now aware that favorable response is achieved using lower doses. For example, intra-articular injection of 120 to 200 mg of methylprednisolone acetate was commonplace years ago, but now it is performed using 10 to 40 mg, depending on the specific joint involved. Another popular and potentially beneficial practice is the co-administration of a low dose of a depo-corticosteroid and hyaluronan. Therapeutic synergy was reported for people with osteoarthritis, and a similar effect in horses is possible.[90] Many veterinarians (and trainers) find the idea of combination therapy appealing, because the corticosteroid dose can be reduced and it can be combined with the putative cartilage-sparing effect of hyaluronan. The minor risk of infectious arthritis exists with any intra-articular injection, and after intra-articular corticosteroids, signs of infection may be delayed from the potent anti-inflammatory effects of these preparations.[91]

Hyaluronan (Sodium Hyaluronate)

Hyaluronan is a glycosaminoglycan composed of the disaccharides D-glucuronic acid and *N*-acetyl-*D*-glucosamine. This glycosaminoglycan is an important component of articular cartilage, where it plays a major role in forming proteoglycan aggregates. The viscoelasticity of synovial fluid is due to its rich hyaluronan content and this molecule serves as the principal lubricant of synovial soft tissues. These physical properties, along with other incompletely characterized pharmacological effects, help maintain synovial homeostasis. The biological characteristics and therapeutic use of hyaluronan in equine osteoarthritis have been reviewed.[92] Characteristics of hyaluronan formulations are summarized in Table 85-3.

Despite not knowing the specific mode(s) of action, hyaluronan frequently is used to treat osteoarthritis in people and horses. Documented clinical benefits after intra-articular injection in people include reduced pain and improved joint mobility,[93,94] and effects compare favorably with NSAIDs and corticosteroids.[90,95] Most equine studies report beneficial effects, but most lack appropriate controls and outcome criteria and are subjective.[96-98]

Hyaluronan has modest analgesic effects,[99] but it has mostly anti-inflammatory effects that may be physical (steric hindrance) or pharmacological (inhibition of inflammatory cells and mediators).[100-104] Symptomatic improvement can be dramatic. In an ovine osteoarthritis model, cartilage lesions in hyaluronan-treated animals were attributed to excessive limb use.[105-107] Hyaluronan may improve range of motion by improving synovial fluid viscosity and soft tissue lubrication. In osteoarthritis, reduced joint excursion may be caused in part by the dilution and depolymerization of endogenous hyaluronan that accompanies synovitis.[108-110]

The specific effects of hyaluronan on articular metabolism remain unclear. Exogenous hyaluronan may stimulate synthesis of a highly polymerized endogenous form of hyaluronan by synoviocytes, but evidence was lacking in studies using cultured synovial fibroblasts derived from normal equine joints or those from joints with osteochondral fragments.[111] Hyaluronan stimulates proteoglycan synthesis by equine chondrocytes.[112] In vitro, hyaluronan is protective for cartilage matrix loss induced by interleukin-1.[113-115] Recent studies have revealed that hyaluronan regulates the production of prostaglandins by articular cells and can protect cartilage against the effects of oxygen-derived free radicals and degradative enzymes.[102,103,116-118] However, compelling evidence for the ability of hyaluronan to inhibit the activity of MMPs has not been reported to date.[111,119] Interestingly, a number of studies have demonstrated that several inflammatory mediators, including prostaglandins, interferon, and certain protein factors, can augment the production of hyaluronan by synovial fibroblasts in vitro.[120,121] Therefore elevated synthesis of hyaluronan in early osteoarthritis may constitute a protective response by the synovium to joint inflammation, providing a rationale for exogenous administration. Like corticosteroids, the protracted pharmacodynamic

Table • **85-3**

Common Hyaluronan Preparations Used in Horses

TRADE NAME	MANUFACTURER	CONCENTRATION	MOLECULAR WEIGHT (IN DALTONS, FROM MANUFACTURER)	HOW SUPPLIED	RECOMMENDED DOSE*
Hylartin V (Hylartil Vet)	Pharmacia and Upjohn	10 mg/ml	3.5×10^6	2-ml syringe	20 mg

*Intra-articular dosages are those recommended for small- to medium-size joints (e.g., metacarpophalangeal). Some manufacturers recommend twice the dose for larger joints (e.g., tibiotarsal).
†Marketed as an ophthalmic preparation but popular for intra-articular use at this dose.
‡Marketed as a topical preparation for wounds but used intra-articularly.
§Marketed for both intravenous and intra-articular use.

influences of exogenously administered hyaluronan are attributable to indirect effects on synovial and cartilage metabolism, because intra-articular half-life is only several hours in normal joints[122,123] and is further reduced in synovitis.[124] Favorable in vitro effects of hyaluronan are supported by observations of cartilage-sparing effects after intra-articular administration of hyaluronan in animal models of arthritis.[106,107,125-128]

Hyaluronan preparations of a molecular weight exceeding 1×10^6 d may provide superior clinical and chondroprotective effects, although this claim is controversial.[129] Certainly, many potentially beneficial effects observed in vitro depend on molecular weight,[99,103,108,118] but whether these effects occur in vivo is unclear. Cartilage-sparing properties of a high molecular weight hyaluronan were superior to those of a less polymerized preparation in rabbits in a limb immobilization model,[128] and better clinical results in horses were reported when using hyaluronan exceeding 1×10^6 d, rather than lower molecular weight formulations.[130,131] Conversely, others maintain clinical efficacy is related to the purity of the preparation, rather than molecular weight.[98,132]

Recently a form of hyaluronan intended for intravenous use has become available. The precise mechanisms of action are uncertain, but beneficial clinical and biochemical effects were observed in an equine lameness model,[133] suggesting that the product need not cross the blood-synovial barrier to exert its action(s). When used in horses with synovitis, intravenous hyaluronan appears to decrease lameness and synovial effusion. Recent studies have demonstrated that hyaluronan receptors exist on numerous extra-articular cell types, and if involved with joint inflammation, intravenous hyaluronan may exert a positive effect.[134,135]

In the horse, hyaluronan appears to be most effective in treating acute synovitis, and results when used in more advanced disease are frequently disappointing. The frequency of hyaluronan administration for the treatment of osteoarthritis in people (often weekly) is higher than that typically used in the horse. Optimal results in horses may require more frequent injections than routinely recommended, particularly in those with established joint lesions. Although often heralded as being virtually free from side effects, data from animal models suggest that despite its putative chondroprotective properties, continued joint deterioration in treated animals may occur when the primary cause of osteoarthritis remains uncorrected.[105-107]

Polysulfated Glycosaminoglycan

Polysulfated glycosaminoglycan (PSGAG) is a semi-synthetic preparation from bovine trachea, comprised principally of chondroitin sulfate, a glycosaminoglycan found in the aggregating proteoglycan of cartilage. The molecular weight of PSGAG varies between 2 and 16 kd; the mean molecular weight is 6 kd. PSGAG is purported to have chondroprotective and anti-inflammatory properties; however, the exact nature and mechanism(s) by which it exerts these effects are unknown. Thorough reviews of the biological properties and clinical use of PSGAG are available in the veterinary literature.[136,137]

PSGAG reduces the severity of clinical signs in people and horses with arthritis.[138-143] Clinical improvement is likely attributable to anti-inflammatory effects, including the inhibition of prostaglandin E_2 synthesis and inhibition of cytokine release.[117,144,145]

PSGAG is reported to have numerous favorable effects on joint metabolism, including stimulation of hyaluronan production by synoviocytes and synthesis of proteoglycans and collagen by chondrocytes.[146-149] The latter effects are thought to be more pronounced in arthritic cartilage.[149] Despite the existence of in vitro studies supporting anabolic properties of PSGAG, subsequent research has questioned modes of action, particularly PSGAG putative stimulation of cartilage proteoglycan synthesis. Dramatic stimulatory effects on chondrocyte biosynthesis were not clearly demonstrable in studies using equine cartilage explants, particularly those in which normal or mildly osteoarthritic cartilage was used.[150,151] An anabolic response may be more evident in chondrocytes from joints with significantly deranged cartilage metabolism,[149] but clinical benefit of such response is questionable. Moreover, PSGAG has limited effects on the early healing of cartilage lesions, and repair tissue formed in healing cartilage wounds under the influence of PSGAG may be inferior to that in untreated animals.[152,153]

Although the nature and magnitude of its anabolic effects are unclear, PSGAG is widely held to have anti-catabolic effects. PSGAG is capable of inhibiting the activity of a number of degradative enzymes known to be present in articular tissues, including elastase, some cathepsins, serine proteases, and neutral MMPs.[58,136,137,154-156] Mechanisms of enzymatic suppression are characterized incompletely, but they may include direct inhibition or abrogation of the synthesis or activity of other mediators that stimulate degradative enzyme release. For example, our recent data (J.P.C.) indicate that PSGAG inhibits inducible nitric oxide synthase expression and synthesis in cytokine-stimulated equine chondrocytes in culture. A variety of animal models of arthritis have provided support for a cartilage-sparing effect of PSGAG in vivo,[153,157-160] and in most cases beneficial effects were attributed mainly to the inhibition of degradative enzymes.[155,160]

PSGAGs can be administered intra-articularly or intramuscularly, but slight risk of infection (quantitatively exceeding that of corticosteroids) with intra-articular administration of PSGAGs has reduced enthusiasm for this route.[161] Most clinicians now combine an aminoglycoside (e.g., amikacin, 125 mg) with PSGAG as a preventative measure. Articular cartilage concentrations of PSGAG after intramuscular administration are capable of inhibiting some cartilage-degrading enzymes,[162] yet the duration of a persistent effective concentration is unclear. As for other anti-arthritis preparations, the frequency of administration of PSGAG usually is based on the therapeutic response and its duration. Typically, when a favorable therapeutic response occurs, it is rapid. For intramuscular use the manufacturer recommends that PSGAG be given at a dose of 500 mg every 4 days for 28 days. Clinical experience suggests that if improvement is not evident within 7 to 10 days using this schedule, a dramatic response from subsequent injections is unlikely.

Pentosan Polysulfate

Pentosan polysulfate is a compound prepared by sulfation of beechwood hemicellulose, consisting of xylopyranose chains, to which are attached methylated glucuronyl rings at regular intervals. Like PSGAG, pentosan polysulfate is a highly sulfated molecule, a property that likely contributes to its biological activity.

Pentosan polysulfate appears to have chondroprotective effects similar to PSGAG, including promotion of anabolic activity of chondrocytes and synoviocytes and inhibition of degradative enzymes.[163,164] Studies using animal models support these chondroprotective effects.[161,163,165,166] Pentosan polysulfate is not presently available in North America but is approved for use in Australia, and anecdotally, pentosan polysulfate is effective in reducing lameness in racehorses with chronic osteoarthritis.[163] Experienced clinicians report pentosan polysulfate provides symptomatic relief in some horses that have been unresponsive to PSGAG. The recommended dosage regimen is 2 to 3 mg/kg intramuscularly every 7 days for 28 days, and the series can be repeated every 3 months as required.[163] Further clinical experience with pentosan polysulfate is required to define specific indications.

Glucosamine and Chondroitin Sulfate

Glucosamine and chondroitin sulfate are compounds extracted from animal products that have been used to treat osteoarthritis in people in Europe for more than a decade. In North America an interest in using these products in people and animals has developed. These supplements reportedly possess anti-inflammatory and disease-modifying effects, and because of the relative safety, they could have great use in managing osteoarthritis even if they are only modestly effective. In vitro and appropriately designed and rigorous clinical trials are lacking, but available data suggest beneficial effects.

Glucosamine sulfate is a precursor of the disaccharide subunits of cartilage proteoglycans. Glucosamine salts appear to be well absorbed after oral administration.[167] In vitro studies indicate that glucosamine sulfate increases proteoglycan synthesis by chondrocytes and may have a number of anti-inflammatory activities.[168-171] Glucosamine was protective for proteoglycan loss and inhibited MMP synthesis and activity in equine cartilage explants.[172] Follow-up experiments using a variety of glucosamine derivatives and sulfated glucose controls demonstrated that cartilage-sparing properties of glucosamine are shared by the 3-sulfate and hydrochloride salts but that glucose-3-sulfate and *N*-acetylglucosamine are devoid of chondroprotective effects at equimolar doses.[173] Glucosamine also appears to reduce the suppressive effects of some cytokines on cartilage proteoglycan synthesis.[174] The hydrochloride salt of glucosamine is less expensive than the sulfated forms and constitutes the principal form of glucosamine marketed in North America.

Chondroitin sulfate consists of chains of sulfated galactosamine and glucuronic acid molecules and is the principal glycosaminoglycan of aggregating proteoglycan (aggrecan). Chondroitin sulfate is less sulfated but resembles PSGAG in structure and mechanisms of acton. Data from in vitro studies have demonstrated anti-inflammatory properties of the drug on leukocytes.[175] Experiments have provided evidence of chondroprotective effects of chondroitin sulfate, including stimulating the synthesis of proteoglycans and inhibiting the activity of certain matrix degrading enzymes, particularly when chondroitin sulfate is present in a polymerized or long-chain form.[176-178] Chondroitin sulfate also has protective effects for cartilage proteoglycan loss in animal models of joint inflammation.[179,180]

Controversy persists regarding the efficacy of enteral absorption of chondroitin sulfate in a biologically active (long-chain) form. In monogastric species, the oral bioavailability is less than 20%,[175] and although isotope recovery is possible in animals fed radiolabeled chondroitin sulfate,[181] absorbed radioactivity may reside in small-chain or monomeric forms of the sugar that lack the biological effects of polymers.[182] Gastrointestinal absorption of polymerized chondroitin sulfate in the horse is unknown.

Clinical trials with chondroitin sulfate and glucosamine, used alone or in combination in people, revealed symptomatic relief similar to that of ibuprofen.[183] Unfortunately, most studies lack appropriate controls and are complicated by the co-administration of other medications.[184,185] Recommendations from recent meta-analyses, a type of study using stringent criteria for inclusion and statistical analyses of other published studies, call for additional trials with larger cohorts of patients studied for longer periods of time.[186,187] Interestingly, in military personnel with spinal and knee osteoarthritis, symptomatic relief was reported using a variety of subjective measures, but running times were unaffected by treatment.[188]

To date, clinical research in horses is limited,[189] and reported results vary from beneficial effects to limited value. Which horses will respond to oral supplementation is not known. Formulation of glucosamine and chondroitin sulfate–containing supplements is not regulated by the Food and Drug Administration (United States), so purity and content are not always ensured. Products with certified content from reputable sources should be used.

Common Practices in Medical Management

There are two principal objectives of medical management of the equine athlete: symptomatic relief and arresting progression of joint degeneration. As for people with rheumatic disease, no equine compound exists for which incontrovertible in vivo evidence of disease modification exists. Efficacy of most drugs is based subjectively on clinical experience. To assess trends in current practices of medical management of osteoarthritis, we sent questionnaires to 20 members of the American Association of Equine Practitioners for whom the treatment of performance horse lameness was particularly common. The survey included questions regarding the use and perceived efficacy of NSAIDs, corticosteroids, hyaluronan, PSGAG, and nutriceuticals (glucosamine and chondroitin sulfate–containing products). Fourteen responses were returned, including from five veterinarians working exclusively with Thoroughbred racehorses, two exclusively with Standardbred racehorses, four with Western or show horses (hunting, jumping, dressage, other show) or both, and three who treated racing and show breeds. Collectively, respondents treated an estimated 17,000 horses with osteoarthritis annually and most estimated that osteoarthritis accounted for at least 60% of their lameness case load.

Non-Steroidal Anti-Inflammatory Drugs

All respondents used NSAIDs and phenylbutazone was the most frequently used. Cited advantages included cost, efficacy, and anti-inflammatory potency compared with other compounds; ability to administer the drug by a variety of routes; and relative lack and predictability of toxic effects. NSAIDs were considered adjunctive and were seldom used alone.

Corticosteroids

All respondents but one used intra-articular injections of corticosteroids regularly (29%) or frequently (71%). Common indications for corticosteroid use included recurrent osteoarthritis in horses that had previously responded well to intra-articular medication and subacute or chronic osteoarthritis that was unresponsive to other therapies. Acute signs of osteoarthritis were managed less commonly with intra-articularly administered corticosteroids. Some clinicians combined corticosteroids with local anesthetic solutions when performing diagnostic analgesia. Corticosteroids were seldom used alone and in 50% of horses were used with intra-articularly administered hyaluronan.

Among the available products, methylprednisolone acetate was the most popular; it was used (although not exclusively) by 12 respondents. Among these veterinarians, eight opined that methylprednisolone acetate was more effective or had a greater duration of activity than other corticosteroid preparations. The second most popular preparation was triamcinolone acetonide. Dose varied among veterinarians and was also dependent on the volume of the synovial cavity being treated. About 50% of clinicians used methylprednisolone acetate and triamcinolone acetonide at relatively low doses (e.g., 40 mg and 6 mg per articulation, respectively), and the rest used higher doses (e.g., 100 to 120 mg and 12 to 18 mg per articulation, respectively). Intra-articularly administered corticosteroids were more popular and tended to be used at higher doses by racetrack clinicians than by those treating other sport horses. Overall, intra-articularly administered corticosteroids were considered effective for managing horses with acute synovitis and somewhat less so in those with established osteoarthritis (Fig. 85-2, *A*). Notably, estimates of efficacy were similar, regardless of whether low or high doses were used.

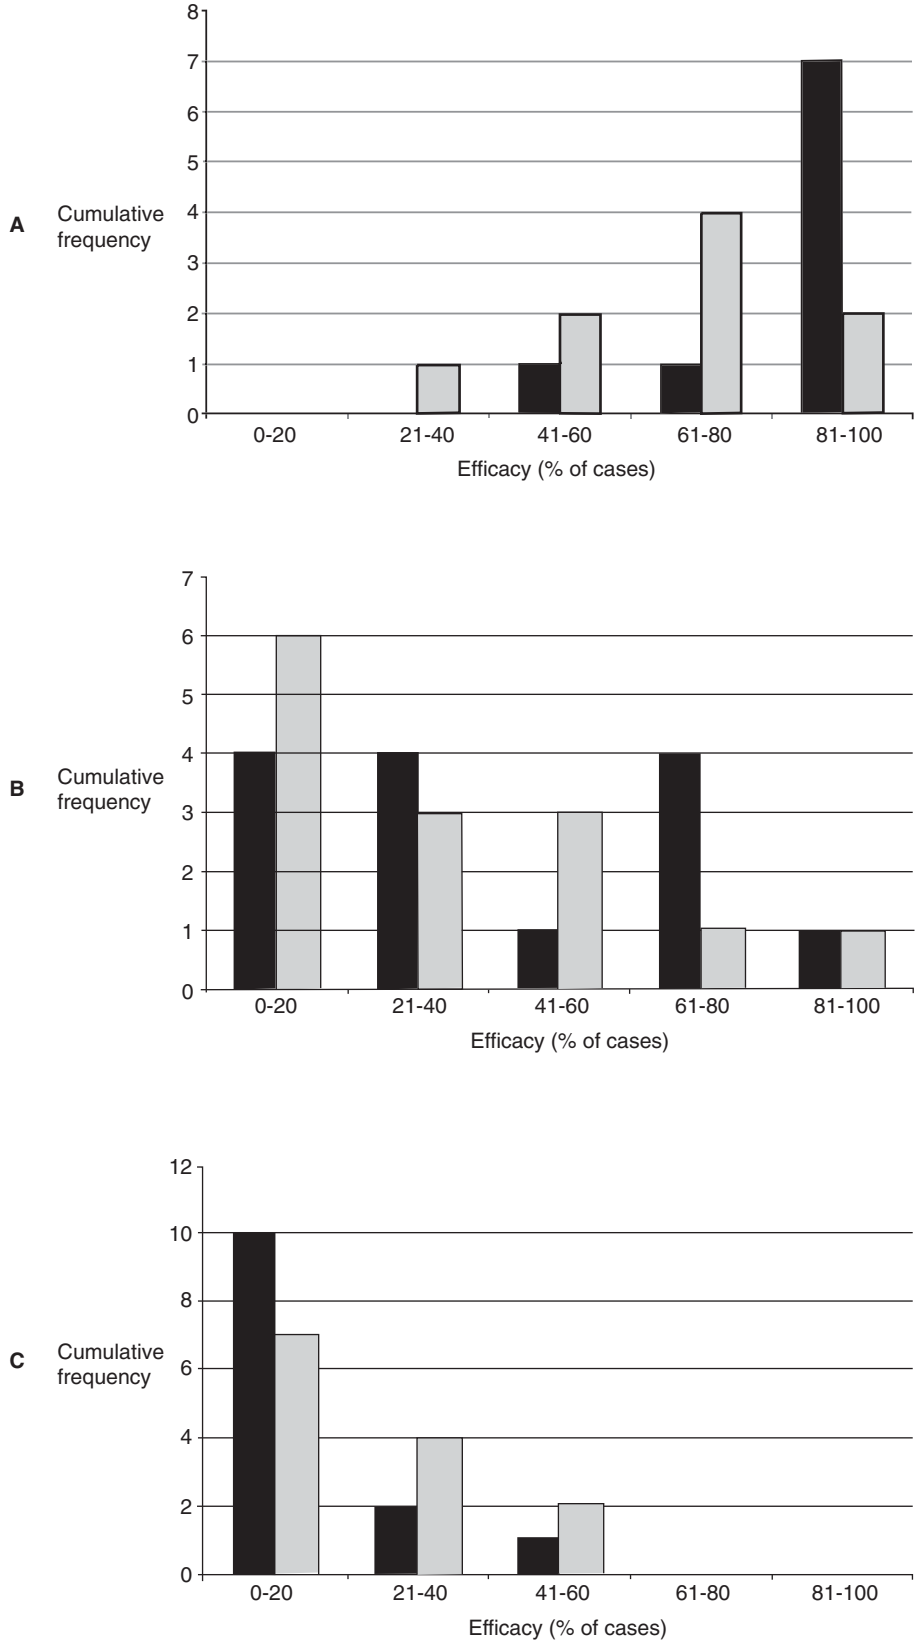

Fig. 85-2 Selected survey results to a joint disease medication survey of 14 members of the American Association of Equine Practitioners for whom the treatment of performance horse lameness was particularly common. The graphs represent the perceived efficacy of the symptomatic treatment of acute synovitis *(solid bars)* and established joint disease *(gray bars)* as follows: **A,** intra-articularly administered corticosteroids; **B,** intravenously administered hyaluronan; and **C,** orally administered glucosamine/chondroitin sulfate–containing nutriceutical products.

Hyaluronan

All respondents used intra-articularly administered hyaluronan, but for hyaluronan to be used initially or alone was uncommon, particularly in horses with established osteoarthritis. Twelve (86%) of 14 supplemented hyaluronan injections with other forms of treatment, most commonly concurrent administration of intra-articularly administered corticosteroids, particularly among those who treated Thoroughbred racehorses. Although combined use of corticosteroids and hyaluronan was also common among veterinarians treating show horses, two used hyaluronan alone 80% of the time.

Interestingly, seven clinicians chose to use hyaluronan preferentially in high-motion joints (e.g., middle carpal joint), whereas seven used the drug equally between high-motion and low-motion joints (e.g., centrodistal and tarsometatarsal joints). A variety of hyaluronan preparations were used and respondents were divided in their views on the relative efficacy of high and low molecular weight products. An unbiased evaluation of the therapeutic efficacy of intra-articularly administered hyaluronan was hampered by the co-administration of a corticosteroid preparation.

Most clinicians had experience treating horses with intravenous hyaluronan, but few, regardless of the type of horse treated, were impressed by its efficacy, particularly when used alone (Fig. 85-2, *B*). They opined that effects on osteoarthritis signs were not dramatic and duration was short.

Polysulfated Glycosaminoglycan

PSGAG use was common. Six of seven racehorse veterinarians used intra-articularly administered PSGAG at least occasionally, whereas a similar number of non-racehorse veterinarians avoided the practice. Intra-articularly administered PSGAG was used most commonly in horses with recurrent clinical signs or those with sub-acute or chronic conditions that were unresponsive to other therapy. Indications for intramuscular use varied widely. In addition to the indications listed for intra-articular administration, intramuscularly administered PSGAG was used to treat horses with acute or recurrent chronic osteoarthritis, or both types. PSGAG was also used as a preventative measure. PSGAGs were used with other treatments and estimates of efficacy were diverse, ranging from completely ineffective, to constituting a major element of therapy.

Glucosamine and Chondroitin Sulfate

Most respondents had experience with nutriceuticals, but unlike other compounds they were used most commonly as a preventative measure, often at the request of an owner or trainer. These products were considered substantially less effective than the other medications (Fig. 85-2, C). Most considered these products adjunctive at best, and no trend favored one product over another.

Overall, considerable variation existed regarding medical management of osteoarthritis, but certain themes emerged. Phenylbutazone remains the most popular NSAID, was effective, and often is used with intra-articular injections. Intra-articular injections of corticosteroid and hyaluronan, often in combination, are frequently used to manage acute and chronic osteoarthritis in all sport horses. Opinions were divided regarding the purported superiority of high molecular weight hyaluronan when injected intra-articularly, but the consensus was that intravenously administered hyaluronan was of limited value. PSGAG use remains popular, but considerable variation existed in the indications for use and perceived efficacy. Little support was given for the routine therapeutic use of nutriceuticals.

Intra-Articular Medications: Practical Considerations

Intra-articularly administered medications are important in managing osteoarthritis, yet no clear consensus is apparent regarding specific practices and precautions. Given the gravity of post-injection infection, in particular when resistant bacteria such as methicillin-resistant *Staphylococcus aureus* are involved, strict adherence to aseptic technique is mandatory. An appropriate standard includes thorough surgical preparation of the intended injection site and using sterile gloves and single-use syringes and needles. Multiple dose bottles or vials of any preparation intended for intra-articular use should be avoided. Although long accepted, the practice of clipping or shaving the injection site has been challenged recently by a study demonstrating that bacterial numbers were comparable between surgically prepared clipped and unclipped injection sites of the equine carpus and distal interphalangeal joints.[190]

No consensus exists on duration of rest after an intra-articular injection, largely from lack of objective information. Supported by various reports, recommendations vary from immediate resumption of exercise to 30 days of rest from training after any injection. Variation in recommendations is not unique to the equine practitioner. In a survey of the members of the American College of Rheumatology, recommendations for rest after intra-articular corticosteroid injections in people varied from 48 hours or less to 1 week or more.[191] Clearly the nature and severity of osteoarthritis should be considered. Because compelling evidence exists that corticosteroids have inhibitory effects on cartilage matrix metabolism, the dose of corticosteroid must be considered. Mechanical properties of cartilage in corticosteroid-treated joints are altered,[192] and although normal loading of cartilage has beneficial metabolic effects, heavy loading can compound the inhibitory effects of corticosteroid on matrix synthesis.[193] Unfortunately, most studies have used generous corticosteroid doses and normal cartilage that responds differently to osteoarthritic cartilage.[82-84,194] Nonetheless, the deleterious effects of exercise after intra-articular corticosteroid injections have been over-rated.[82,83] Moreover, industry pressures often militate against prolonged periods of rest after injections. After considering all factors, we recommend horses be given 2 to 3 days of box (stall) rest with hand walking, followed by a gradual return to light training, after intra-articular injections of corticosteroid. Similar recommendations are given for injections with hyaluronan and PSGAGs, even though issues such as inhibition of matrix synthesis are less important with these drugs.

Despite a near complete lack of knowledge of effects of mixing local anesthetic solutions with corticosteroids for intra-articular injections, rheumatologists commonly mix both in the same syringe to reduce pain, dilute corticosteroid suspensions, reduce post-injection flare, and help diagnose the source of pain.[191] Equine veterinarians often combine the two solutions to investigate and treat a source of pain simultaneously. Conversely, some clinicians avoid a second intra-articular injection if local anesthetic solution was injected recently. Local anesthetic agents cause a mild inflammatory response in joints,[195] but it is unclear whether inflammation or drug interactions influence the therapeutic response to concurrently or sequentially injected medications or substantially increase the risks of post-injection infection. We do not recommend routine use of combined injections.

Post-injection flare causes pronounced synovial effusion and often substantial lameness and usually occurs 4 to 24 hours after injection. Rapid response to lavage and anti-inflammatory therapy is usually seen. However, appropriate antimicrobial therapy should be instituted, and synovial fluid samples should be submitted for culture and susceptibility testing and cytological examination.

Medical Management: Conclusions

From objective and subjective information presented, clearly specific recommendations for all situations are difficult to make. Management choices are still made based on general principles, past experience, and economic considerations,

and the evolution of these regimens often is determined by therapeutic response. Given the complexity and variations of osteoarthritis and paucity of specific knowledge regarding the effects of available medications, veterinarians still must tailor treatments individually.

SURGICAL TREATMENT

Diagnostic and Surgical Arthroscopy

The application of arthroscopic techniques to the horse has revolutionized the treatment of traumatic joint injuries.[196,197] The advantages and disadvantages of arthroscopic surgery are discussed in Chapter 23, but importantly, arthroscopic surgery is the imaging modality of choice to evaluate articular cartilage (Fig. 85-3), although magnetic resonance imaging may supersede it in the future, particularly in joints with limited surgical access (see Chapter 21). Diagnostic arthroscopy is particularly useful in horses without radiographically visible lesions.[198]

Arthroscopic surgery is useful in surgical management of osteoarthritis. Since the advent of arthroscopic surgery, fractures of the proximal, dorsal aspect of the proximal phalanx are once again removed, with favorable results. The practice had previously been suspended when arthrotomy was performed, because low-grade lameness attributed to capsular fibrosis or calcification was often seen.[196,199] Intra-articular lavage is a benefit from arthroscopic surgery, because inflammatory debris and cartilage fragments are washed from the joint. Joint lavage is itself an important consideration in managing inflamed joints. In people with osteoarthritis, joint lavage alone is comparable to other forms of medical therapy. In Standardbreds in training, injection of small volumes of saline solution combined with 3 weeks' rest was more effective than rest alone in alleviating clinical signs of traumatic arthritis.[200-203]

Arthroscopic surgery is most useful in surgical management of osteoarthritis by eliminating the inciting cause and preventing the progression of osteoarthritis rather than treating established lesions. The most common indication for arthroscopic surgery is the removal of osteochondral fragments of traumatic or developmental origin. The ideal candidate is a horse that has not been injected previously with corticosteroids. Prognosis is favorable for horses after arthroscopic surgery to remove small osteochondral fragments, but before secondary changes of osteoarthritis have developed. However, osteochondral fragments often occur with, or result from, osteoarthritis (see Chapter 39) and this reduces the prognosis.[204,205] Presence of radiographic changes of osteoarthritis before surgery reduces prognosis in any horse with osteochondral fragments. In horses with advanced radiographic evidence of osteoarthritis, arthroscopic surgery may be useful to assess the magnitude of cartilage damage and to provide temporary symptomatic relief, but it is of dubious value in making a positive impact on long-term prognosis. In horses with established osteoarthritis, client education is important and horses may best be managed medically. Case selection is most important when considering arthroscopic surgery or arthrotomy for management of any articular problem (see Chapter 23).

Specific arthroscopic techniques are well established and detailed descriptions are available.[196] Controversy lingers regarding the vigor with which debridement of articular tissues should be performed. Currently, minimal effective debridement is advocated because articular cartilage has limited capacity for intrinsic repair.[197] Conversely, diseased bone should be completely removed.

Care after surgery involves the principles of providing an environment for resolution of inflammation, providing stability and restricting joint motion to facilitate optimal healing of articular tissues, and preventing post-operative contamination. Rest is important to reduce articular trauma and to minimize disruption of fragile repair tissues. NSAIDs are administered for 3 to 5 days to reduce inflammation from surgical trauma. Appropriate bandaging and rehabilitation are important (see Chapters 87 and 92). Although popular, the intra-articular use of hyaluronan and PSGAG after surgery had no beneficial effects on healing experimental cartilage defects.[206,207] Prognosis depends on several factors, but most importantly the magnitude and location of cartilage damage should be considered. For example, horses with carpal osteochondral fragments with 50% or more cartilage or subchondral bone loss have a significantly inferior prognosis than those with less severe lesions.[208]

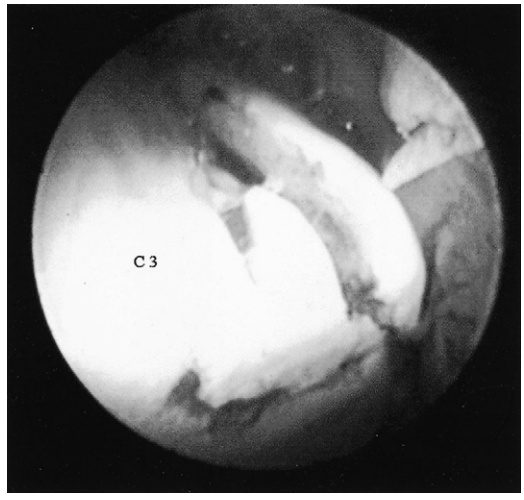

Fig. 85-3 Arthroscopic view (proximal is to the bottom) of the middle carpal joint in Standardbred racehorse with sizeable osteochondral fragments from the third carpal bone (C3). Beyond removal of osteochondral fractures, arthroscopic examination allowed determination of the magnitude of cartilage damage extending onto the weight-bearing surface of the third carpal bone and assessment of the degree of cartilage damage to the opposing surface of the radial carpal bone.

Internal Fixation of Intra-Articular Fractures

Common intra-articular fractures managed by lag screw techniques include third carpal bone slab fractures, lateral (and medial) third metacarpal/metatarsal bone condylar fractures, and sagittal fractures of the proximal phalanx. Internal fixation of displaced, intra-articular fractures involving sizable portions of the articular surfaces of these and other bones offers the greatest possibility for the horses to return to function. Repair of non-displaced fractures may improve healing time and substantially reduced risk of delayed displacement of fracture fragments. In addition, experimental evidence suggests that cartilage healing is superior with stable internal fixation of intra-articular fractures.[209]

Internal fixation can and should be combined with diagnostic arthroscopy. Arthroscopic surgery can be useful to assess cartilage damage, facilitate the identification and removal of small osteochondral fragments and debris in the fracture line, assess for comminution,[210] and evaluate reduction before implants are placed. The size and number of implants is dictated by fracture configuration and surgeon preference, and cortical bone screws are placed according to principles of the Association for the Study of Internal Fixation.[211,212] Appropriate positioning of implants to optimize reduction and congruity of articular components is facilitated by intra-operative radiography or fluoroscopy.

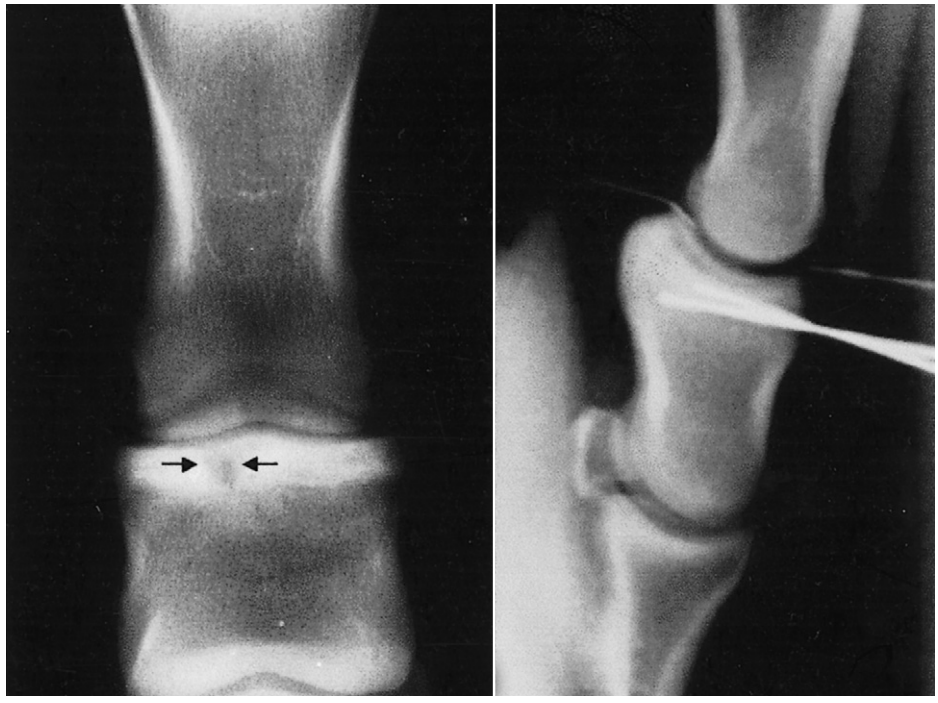

Fig. 85-4 **A,** Dorsopalmar and **B,** lateromedial radiographic views of the distal limb of a yearling with lameness referable to the proximal interphalangeal joint. **A,** There is an osseous cyst-like lesion (*arrows*) in the proximal aspect of the middle phalanx. **B,** The area was decompressed using transcortical drilling, and the procedure successfully abolished lameness.

Osseous Decompression

On occasion, joint pain may be referable to lesions of subchondral and epiphyseal bone that are not accessible arthroscopically. For example, subchondral cysts or osseous cyst-like lesions lacking a direct articular communication may occur under weight-bearing surfaces. Transcortical decompression has been successful in reducing lameness (Fig. 85-4). This empirical treatment is based on the principles of debridement of malacic bone and on the physiological premise that elevated metaphyseal pressures contribute to articular pain.

Synovectomy

Synovial resection, or synovectomy, involves removing inflamed, hypertrophic, or infected synovial membrane and can be accomplished surgically, with chemical agents, or using radioactive isotopes.[213] Synovial resection can be local (partial synovectomy) or generalized (subtotal or complete synovectomy).

In people with rheumatoid arthritis, early synovectomy provides temporary pain relief and reduces synovial inflammation. Symptomatic relief is typically more long-lasting for patients treated early in the course of the disease.[214,215] The rationale for the use of synovectomy in rheumatoid arthritis is intuitively clear, because the synovium has a well-established role in the disorder. In osteoarthritis the synovium plays a minor role in the disease process, and only mild response is observed in people with osteoarthritis treated by synovectomy.[216]

Specific indications and potential benefits of synovectomy in equine joint surgery have yet to be determined. Regeneration of the equine synovium after arthroscopically assisted synovectomy is slow compared with other species, but the procedure has negligible ill effects.[217-220] Arthroscopic synovectomy is considered beneficial in reducing bacterial load and attenuating profound synovitis in chronically infected equine joints.[221] Results of synovectomy in managing horses with chronic, unresponsive infectious arthritis of the tarsocrural joint are favorable (Fig. 85-5).

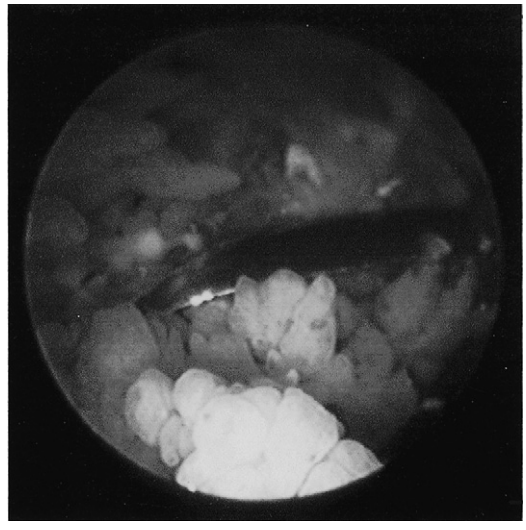

Fig. 85-5 Arthroscopic view of the tarsocrural joint of a racehorse with chronic active synovitis that was refractory to medical treatment. Greatly enlarged and club-like synovial fronds (under the stainless steel elevator) are evident. The gelding responded favorably to subtotal synovectomy.

To date, no compelling evidence supports the routine use of subtotal synovectomy in treating horses with osteoarthritis. Synovectomy was reported to be effective in reducing lameness from chronic proliferative synovitis of the fetlock and carpal joints of racehorses.[222]

Arthrodesis

In some horses, osteoarthritis is severe and cannot be managed medically or by conventional surgical techniques. Often concern

exists about laminitis of the contralateral limb and euthanasia may be considered if the horse has no residual value as a breeding prospect. In horses with chronic, severe, and refractory osteoarthritis of low-motion joints, such as the proximal interphalangeal and distal tarsal joints, arthrodesis can preserve athletic function.[223-227] Arthrodesis can be performed using internal fixation and external coaptation or by using chemical means.[228,229] Arthrodesis of high-motion joints, including the scapulohumeral, antebrachiocarpal or middle carpal, metacarpophalangeal, and distal interphalangeal joints, is performed as a salvage procedure.[230-233]

INVESTIGATIONAL TREATMENTS

Experimental treatments used in people may be applicable to horses. Active areas of research include cartilage resurfacing and limiting the effects of known biological mediators of osteoarthritis. Preliminary results using these approaches, alone or in combination, have been encouraging, though a number of biological and technical obstacles remain.

Joint Resurfacing

Cartilage loss is one hallmark of osteoarthritis. Cartilage has limited capacity for repair and considerable effort has been expended in attempts to augment intrinsic healing or to replace it. A number of approaches currently are being explored to provide a biochemically and biomechanically suitable repair tissue for equine osteochondral defects.

The healing of partial thickness cartilage defects is ineffectual, and the recruitment of a larger population of cells than that which exists in the adjacent matrix is required for optimal healing to occur. Attempts to improve the natural healing process typically involve debridement of the subchondral plate, or other methods to recruit pluripotent cells from the marrow cavity (stimulated endogenous repair), or the delivery of chondrogenic tissues, chondrocytes, or pluripotential cells to the defect (articular grafting). To date, the long-term efforts to modulate healing of cartilage defects have been disappointing, because formation of true hyaline cartilage has not occurred.[234-236] The biochemical composition of repair tissues frequently lacks appropriate macromolecules, specifically type II collagen, and a normal concentration of proteoglycans of suitable size and structure. Lacking the required composition, the biomechanical performance of the tissue is less than ideal and ultimately leads to its breakdown.

Stimulated Endogenous Repair

Stimulating endogenous repair in equine joints involves techniques to provide access of marrow elements to the cartilage defect (e.g., subchondral drilling), but results have not paralleled those in laboratory species. Problems of dedifferentiation of the repair tissue to a largely fibrous tissue composition have occurred. This fibrous tissue lacks the required functional characteristics.[237,238]

More recently, a technique involving the creation of microfractures in the subchondral plate to allow access of marrow pluripotential cells to the cartilage defect was developed. Known as *micropicking* or *breaching,* a stainless steel awl is used to create small crack-like defects in the articular end plate, usually under arthroscopic control.[239,240] Micropicking is a simple and atraumatic way to provide pluripotent cells, and proponents cite the lack of heat generated as one reason that results are superior to drilling techniques.[241] Another advantage of micropicking is that it preserves the subchondral plate. This is noteworthy because destruction of the subchondral plate typically compromises any resurfacing effort.[234] Experimental use of micropicking in normal horses resulted in more voluminous repair tissue than controls; however, little difference in repair tissue quality was apparent.[242] Although reports of using micropicking to treat traumatic injuries in human athletes are encouraging, the indications and long-term results of the procedure in the horse are unknown.

Articular Grafting

Initially, studies using onlay grafts of periosteum or perichondrium for resurfacing of cartilage defects in laboratory animals generated much excitement. Attempts to apply this approach in the horse were disappointing and research efforts have shifted focus to grafts of cultured chondrocytes or cartilage-progenitor cells contained in an appropriate substrate.[235,243,244] To date, uniformly successful results have not been achieved using these methods. The problems of graft incorporation, cell survival, and an inability to maintain a functional hyaline cartilage repair persist. Recent studies are beginning to shed more light on the specific idiosyncrasies of cell metabolism in cartilage defects, and soon improving repair tissue quality through more precise regulation of cell metabolism in the various strata of the healing wound may be possible.[245-247]

Biologically Based Therapies

Biological therapy is intended to modulate the extent of immunological or inflammatory events while maintaining appropriate tissue function and responses. The goal of this approach is to control the excessive activation of the various mediators leading to cartilage degradation. Inhibition can be accomplished directly or indirectly. Areas of active investigation include administering MMP blockers, drugs that directly inhibit inflammatory cytokines (e.g., interleukin-1), and providing natural inhibitors of proteinases or cytokines. For example, efforts at suppressing cartilage matrix degradation have been conducted using natural[248,249] or synthetic matrix MMP inhibitors.[248,250,251] Another strategy to prevent proteolytic cartilage degradation is to inhibit the synthesis or activity of mediators responsible for stimulating the synthesis enzymes. For example, matrix MMP release is stimulated by interleukin-1, a process that can be blocked by interleukin-1 receptor antagonist protein, a naturally occurring inhibitor of interleukin-1. Intra-articular administration of interleukin-1 receptor antagonist protein slows the progression of lesions in experimental osteoarthritis.[252,253] Similarly, antibodies and soluble receptors to tumor necrosis factor-α, another pro-inflammatory cytokine implicated in arthritis, reduced cartilage loss in collagen-induced arthritis in mice.[254,255] In addition to specific inhibitors, treatment with proteins that indirectly block the effects of inflammatory mediators may be of therapeutic value. An example includes administering interleukin-4, a blocking cytokine with metabolic effects opposite to those of recognized pro-inflammatory forms, such as interleukin-1 or tumor necrosis factor-α.[256] Another approach is to attempt to enhance matrix synthesis and repair. This method involves administering cytokines such as basic fibroblast growth factor or insulin-like growth factor, which have been shown to influence cartilage metabolism and healing favorably.[257,258]

Unfortunately, the actions of many of these therapeutic proteins are short-lived, which necessitates frequent administration. Gene therapy represents a potential means by which delivery of some of the mentioned therapeutic proteins may be possible.[259,260] Although technical aspects of the approach vary, the general principle involves introducing a gene that enables cells within the joint to synthesize one or more therapeutic product(s) (Fig. 85-6). Genes coding for anti-arthritic proteins are the most obvious choice, but bioactive ribonucleic acid (RNA) molecules or antisense RNA could also be valuable. The advantage of gene therapy is that, once the gene is present, theoretically the gene could be transcribed and translated many millions of times to produce a therapeutic level of its product. Candidate proteins for gene therapy include natural MMP inhibitors (e.g., tissue inhibitors of metalloproteinases), cytokines (e.g., insulin-like growth factor), and cytokine

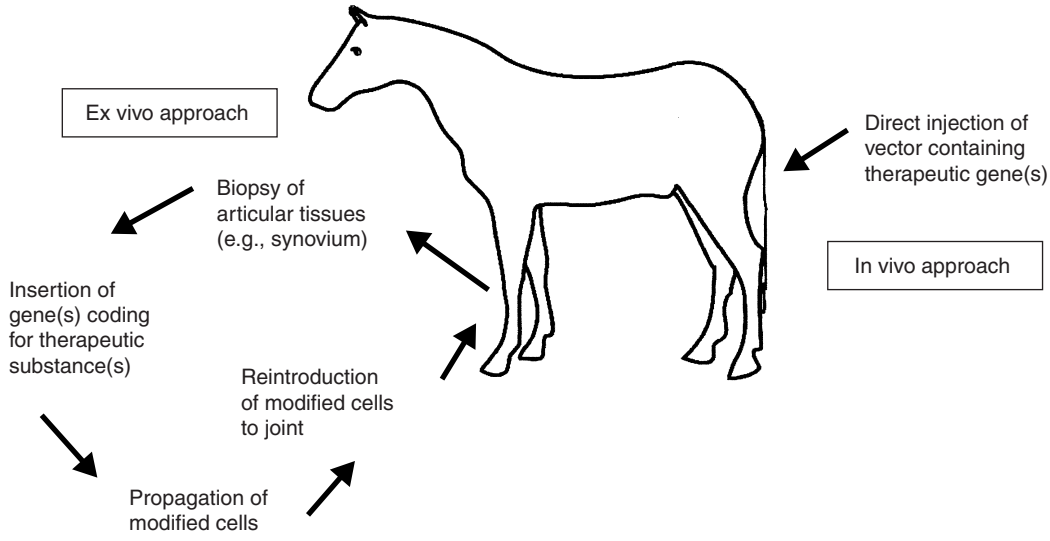

Fig. 85-6 General approaches for equine joint disease using local gene therapy. A vector containing one or more therapeutic genes can be injected directly into the affected joint (in vivo approach), or a biopsy containing patient cells may be transfected with a vector (frequently viral) containing the genes of interest, after which the cells are propagated in culture and re-introduced to the joint in large numbers (ex vivo approach).

inhibitors (e.g., interleukin-1 receptor antagonist protein). Inhibition of cartilage degradation has occupied much of the research efforts to date, many involving experiments designed to block the effects of interleukin-1 on cartilage degradation.[261,262] The interleukin-1 receptor antagonist gene was introduced successfully into normal equine joints, and preliminary results in an experimental joint disease model were favorable.[263,264] Promoting matrix synthesis is another potential application of gene therapy. For example, transfer of growth factor constructs (transforming growth factor-β1, insulin-like growth factor 1, and bone morphogenic protein 2) to chondrocytes was successful in increasing synthesis of collagen and proteoglycan.[265,266]

Durable resurfacing of cartilage defects ultimately may be accomplished with a combination of chondroprogenitor cell transplantation and gene therapy, with the introduction of genes coding for one or more selected growth factors. Theoretically, if the correct combination of proteins could be expressed in appropriate quantities, at the correct times during healing and incorporation of the transplanted cells, modulation of grafted or endogenous repair tissues to hyaline cartilage may well be possible.

CHAPTER • 86

Epidural Analgesia and Hindlimb Lameness

Rose M. McMurphy

The benefits of providing analgesia for acute and chronic pain have been well established in many species. Inadequate treatment of pain in animals can result in inappetence and weight loss, increases in serum cortisol and catecholamines, tachycardia, hypertension, and compromise of the immune system.[1] Increases in serum cortisol and catecholamines can cause derangements in serum glucose, protein metabolism, and immune function. In addition, horses with a painful limb may remain recumbent for prolonged periods of time, with resultant decubital ulcer formation and secondary infection.

Designing an appropriate plan for analgesia in horses, particularly for those with severe, chronic pain can be challenging. Parenterally administered opioids and α_2-adrenergic agonists may be associated with side effects such as ataxia and excitement, and adverse effects on the gastrointestinal and cardiovascular systems. Non-steroidal anti-inflammatory drugs (NSAIDs) can cause gastrointestinal ulceration or renal disease, and they may be inadequate for horses with acute, intense pain. Epidural administration of drugs provides a more localized analgesia and fewer systemic effects than parenteral administration.

Epidural drug administration places a drug in close proximity to its site of action within the spinal cord or spinal nerves as they exit the spinal cord. A greater analgesic effect may be achieved with a smaller total dose of a drug. The duration of analgesia is usually longer than with parenteral administration.

CHAPTER • 86

Epidural Analgesia and Hindlimb Lameness

Rose M. McMurphy

The benefits of providing analgesia for acute and chronic pain have been well established in many species. Inadequate treatment of pain in animals can result in inappetence and weight loss, increases in serum cortisol and catecholamines, tachycardia, hypertension, and compromise of the immune system.[1] Increases in serum cortisol and catecholamines can cause derangements in serum glucose, protein metabolism, and immune function. In addition, horses with a painful limb may remain recumbent for prolonged periods of time, with resultant decubital ulcer formation and secondary infection.

Designing an appropriate plan for analgesia in horses, particularly for those with severe, chronic pain can be challenging. Parenterally administered opioids and α_2-adrenergic agonists may be associated with side effects such as ataxia and excitement, and adverse effects on the gastrointestinal and cardiovascular systems. Non-steroidal anti-inflammatory drugs (NSAIDs) can cause gastrointestinal ulceration or renal disease, and they may be inadequate for horses with acute, intense pain. Epidural administration of drugs provides a more localized analgesia and fewer systemic effects than parenteral administration.

Epidural drug administration places a drug in close proximity to its site of action within the spinal cord or spinal nerves as they exit the spinal cord. A greater analgesic effect may be achieved with a smaller total dose of a drug. The duration of analgesia is usually longer than with parenteral administration.

Pain that is related to a disease process of the hindlimb is particularly amenable to treatment with epidural analgesia. The site of injection for epidural drug administration in horses is usually the first coccygeal (caudal) interspace. When deposited into the epidural space, the drug diffuses across the meninges, into the cerebrospinal fluid (CSF), and then into the spinal cord. The degree of cephalad diffusion of the drug within the CSF depends on several factors, including the volume of the drug injected, concentration of the drug, and lipid solubility.[2] Although studies in dogs and people have reported analgesic effects with epidural morphine or α_2-agonists that extend to the mid-thoracic area or farther cranially,[3,4] this generally does not occur in horses.[5-8] This limits the use of epidural analgesia for treatment of limb pain in horses to the hindlimb.

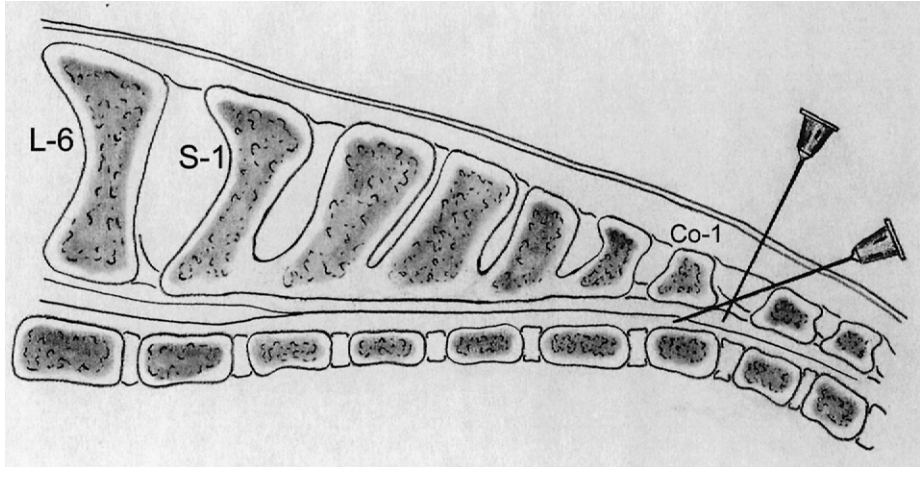
TECHNIQUE FOR EPIDURAL ADMINISTRATION

Caudal epidural drug administration can be done by single injection at the first coccygeal interspace or by placing an epidural catheter at this same site for repeated drug administration. The lumbosacral space is also a potential site of injection and may have a more rapid onset of hindlimb analgesia. However, positioning the tip of the needle within the epidural space rather than the subarachnoid space can be difficult. Subarachnoid administration of drugs in the horse is certainly acceptable, but the dose should be reduced by 40% to 50%.

The first coccygeal interspace (between the first and second coccygeal vertebrae) is identified while raising and lowering the tail and palpating for the articulation between these two vertebrae. This space is just caudal to the most angular portion of the bend of the tail, about 5 cm cranial to the first long tail hairs (Fig. 86-1). The site is prepared aseptically. Administration of 2 to 3 ml of 2% lidocaine subcutaneously using a 25-gauge needle helps decrease the response of the horse to placement of the needle for epidural injection. An 18- or 20-gauge, 6.35-cm spinal needle with stylet is recommended for epidural injection in horses, although many clinicians use a standard 18-gauge needle. The bevel of a spinal needle is not as sharp as a standard needle, and the bevel angle is less acute. This design difference makes it easier to identify penetration through the interarcuate ligament and the subsequent loss of resistance as the epidural space is entered. The needle is inserted at a 30° to 60° angle to horizontal, with the tip pointed cranioventrally, and is advanced until it contacts the floor of the vertebral canal (Fig. 86-2). The depth of insertion is 3 to 6 cm, depending on the size of

Fig. 86-1 The first coccygeal interspace between the first and second coccygeal vertebrae is identified while raising and lowering the tail and palpating for the articulation between these two vertebrae. This space is just caudal to the most angular portion of the bend of the tail.

A



B

Fig. 86-2 **A,** The needle is inserted at a 30° to 60° angle to horizontal and is advanced until it contacts the floor of the vertebral canal. **B,** Sagittal view of the sacral vertebrae and placement of the needle within the epidural space. *Co-1*, First coccygeal vertebra; *S-1*, first sacral vertebra; *L-6*, sixth lumbar vertebra.

the horse and the angle of the needle. The needle placement can be tested by attempting to inject 2 to 3 ml of air or solution in a 3-ml syringe. Resistance to injection should be little or absent. Appropriate epidural injection of local anesthetic solution and xylazine often is confirmed when anal tone decreases and the tail relaxes, but because the drugs most commonly used for epidural analgesia of the hindlimb (morphine, detomidine) have little or no effect on motor nerves, these responses will be absent.

EPIDURAL CATHETER PLACEMENT

The site for inserting an epidural catheter is the same as for a single epidural injection. Placement of the catheter requires the use of a needle with a curved point (Tuohy, Hulstead; Becton Dickinson, Franklin Lakes, NJ) that will direct the catheter cranially, along the floor of the vertebral canal (Fig. 86-3). The epidural catheter is made of polyamide (nylon) or teflon, with a closed or open end, and it can be purchased with a wire stylet if desired. I use an 18-gauge, 8.89-cm Tuohy needle and a 20-gauge, 100-cm radiopaque, polyamide catheter with a closed tip (bullet tip) without a stylet (Fig. 86-4). Epidural catheters have marks every centimeter and multiple marks at 10, 15, and 20 cm from the end. Before needle and catheter placement, slide the catheter inside the needle and note the distance from the tip of the needle to the hub on the catheter. The clinician then should determine which mark on the catheter will be at the hub of the needle once the catheter is advanced to the desired position.

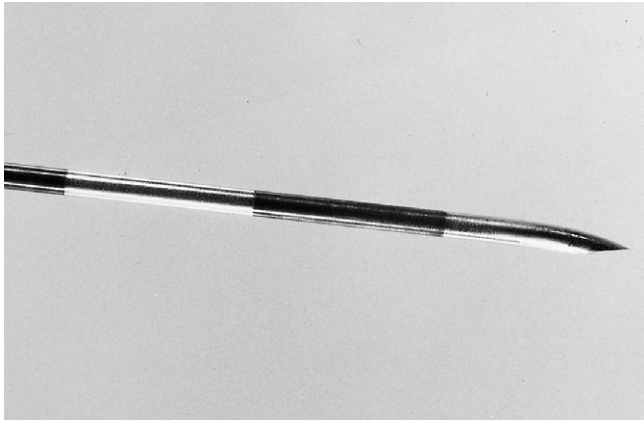


Fig. 86-3 Curved point of a Tuohy needle.

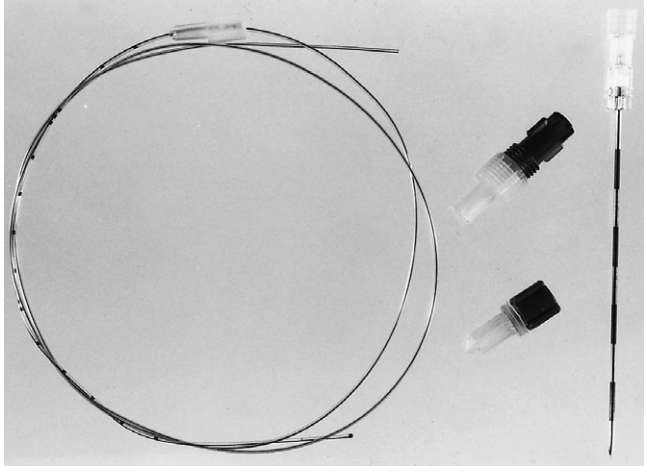

Fig. 86-4 Tuohy needle and epidural catheter.

As with the single epidural injections, strict attention should be paid to aseptic technique, and sterile gloves must be worn. Lidocaine is injected into the subcutaneous tissues at the desired site. A small incision is made through the skin with a No. 11 scalpel, because the Tuohy needle has a blunt tip. Once the needle is positioned, the bevel should be directed cranially (the notch on the hub of the needle should face cranially). The catheter is threaded through the needle and along the floor of the vertebral canal (Fig. 86-5). Provided the needle is positioned in the epidural space, the advancing catheter receives little resistance. Getting the catheter to advance initially into the canal can be difficult, however. If the tip of the needle is angled incorrectly, the catheter tends to bump up against the vertebrae and will not advance. If this occurs, the needle is withdrawn 1 to 2 mm and the catheter is rotated slightly as it

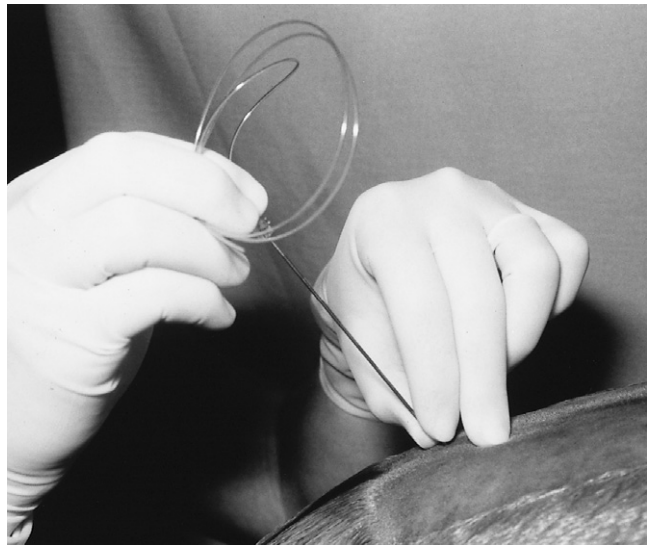

Fig. 86-5 The epidural catheter is threaded through the needle and along the floor of the vertebral canal. If the catheter will not advance, the needle is withdrawn 1 to 2 mm, and the tip of the needle is angled up slightly.

Fig. 86-6 Once the catheter is in place, the needle is carefully withdrawn over the catheter and removed.

is advanced. It is critical that once the catheter has advanced any distance outside of the needle that it is never withdrawn back into the needle. This may result in cutting or sheering off the catheter. The catheter is advanced 5 to 10 cm past the tip of the needle, and the tip is positioned in the mid-sacral region. Once the catheter is positioned, the needle is carefully withdrawn over the catheter and removed (Fig. 86-6). Most epidural catheters intended for human use are long to facilitate positioning of the injection port in a convenient place on the body. I usually cut the catheter with a scalpel (scissors tend to crush the catheter), leaving about 10 cm of the catheter to secure to the horse. The catheter/ syringe adapter is attached and an injection cap secured to the adapter. A portion of tape is secured to the catheter at the point of insertion and then sutured to the skin (Fig. 86-7). The syringe adapter also should be sutured to the skin, making sure tension will be minimal on the catheter during any movement of the horse. The catheter and injection cap then are covered with a sheer, adhesive dressing. Each injection into the catheter is made through the catheter cap after thoroughly cleaning it with alcohol and while wearing sterile gloves. It is critical that the catheter system remains sterile. The catheter site should be examined daily for signs of inflammation or infection, which would necessitate removing the catheter and submitting the tip for culture. With diligent aseptic technique and catheter care, we have kept catheters in place for 2 weeks in clinical patients, and some researchers have reported epidural catheters being maintained for 5 weeks in research horses.[9]

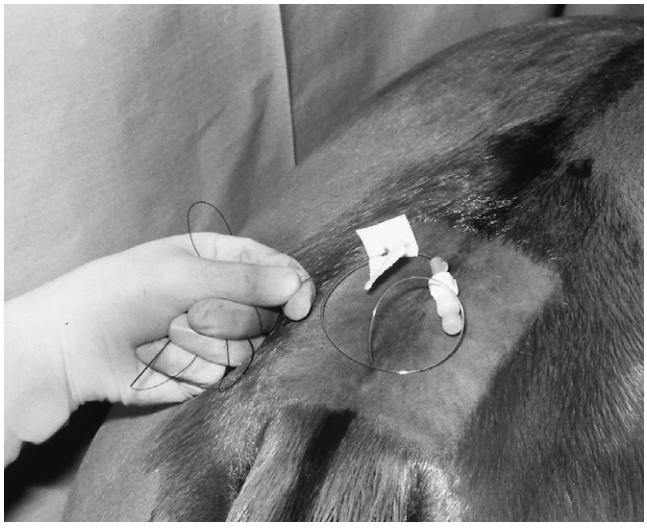

Fig. 86-7 The catheter/syringe adapter is attached and an injection cap is secured to the adapter. A portion of tape is secured to the catheter at the point of insertion and then sutured to the skin.

DRUG SELECTION

Epidural Opioids

The primary advantage of epidural administration of an opioid is the intense and prolonged segmental (localized) analgesia achieved without either sedation or possible excitement that may accompany the parenteral administration of an opioid. Unlike epidural local anesthetics or xylazine, epidural opioids do not affect neuromuscular function or the sympathetic nerves.

The analgesia obtained with epidural opioids is primarily from the effect of the opioid within the spinal cord rather than supraspinal. Opioids bind to presynaptic receptors of the afferent nerve terminals in the dorsal horn and inhibit the release of excitatory neurotransmitters, such as glutamate and substance P. Opioids also act postsynaptically to inhibit transmission of impulses in ascending tracts. Evidence also shows that opioids enhance the effects of descending inhibitory pathways on the processing of pain within the dorsal horn.[10]

The onset and duration of action of epidural opioids vary greatly between drugs. The time to onset of analgesia reflects the time required for a drug to diffuse from the epidural space, across the meninges, into the spinal fluid, and ultimately into the spinal cord. Physicochemical properties of the drug such as molecular weight, molecular shape, degree of ionization, and particularly lipid solubility influence the diffusion across the meninges.[3,11] The more lipid-soluble drugs, such as fentanyl and butorphanol, have a rapid onset but a shorter duration, whereas the more water-soluble drug, morphine, has a delayed onset and a long duration (Table 86-1).[3]

Table • **86-1**

Characteristics of the Analgesia and Side Effects after Epidural Administration of Various Drugs

DRUG	DOSE (mg/kg)	ANALGESIA		SEDATION	ATAXIA	COMMENTS
		ONSET (MIN)	DURATION			
Morphine	0.1*	150-180	12-18 hr	Minimal	No	Onset time for peak analgesia may be up to 6 hours.
Butorphanol	0.04	†	2.5-3 hr	No	No	Degree of analgesia may be inadequate.
Xylazine	—	—	—	—	Marked	Drug is not suitable for hindlimb analgesia.
Detomidine	0.05	10-25	2-3 hr	Moderate	Mild	Heart rate, blood pressure, and respiratory rate are decreased.
Ketamine	1-2	5-10	30-75 min	Mild	Mild	Ataxia occurs only at higher dose.
Detomidine and morphine	0.03 and 0.1-0.2	10-25	12-18 hr	Moderate	Mild	Heart rate, blood pressure, and respiratory rate are decreased.

*Although a dose of 0.2 mg/kg has been used and reported in horses, I no longer recommend this high dose.
†Onset time has not been documented.

The more water-soluble opioids also tend to have greater degree of craniad diffusion within the CSF.[2]

Morphine is the drug of choice (see Table 86-1).[5-7,12] Fentanyl has a faster onset of action but a considerably shorter duration of action (4 to 6 hours). Butorphanol provides inadequate analgesia. Oxymorphone is too expensive. I use preservative-free morphine (Abbot Laboratories, North Chicago, IL) that is intended for epidural use at a dose of 0.1 mg/kg. There are some parenteral preparations of morphine that have been used for epidural administration in horses in an attempt to lower the cost, but some of these may contain substances such as phenol or formaldehyde, which may be neurotoxic. The preparation of morphine (25 mg/ml) with sodium bisulfite as the preservative has been used in the horse epidurally, but the dose to be administered should be diluted in 20 ml of sterile saline solution. Epidural morphine has been used at a dose of up to 0.2 mg/kg combined with epidural detomidine.[13,14] The higher dose may potentially speed the onset of action and extend its duration, but it may increase the incident of side effects.

Potential side effects include respiratory depression, pruritus,[15] and urinary retention. These are rarely seen in horses and can be treated with naloxone (0.005 to 0.01 mg/kg). I have experience with a horse that developed substantial central nervous system effects after administration of morphine (0.2 mg/kg in 50 of ml saline solution), resulting in collapse, tachypnea, muscle rigidity, and hypoxemia. The horse was treated with naloxone (0.01 mg/kg), furosemide (2 mg/kg), diazepam (0.01 mg/kg), and a neuromuscular blocker to facilitate positive-pressure ventilation after intubation and anesthesia with isoflurane. The horse recovered.

Epidural α_2-Adrenergic Agonists

Epidural administration of an α_2-adrenergic agonist can induce profound analgesia mediated by α_2-adrenergic receptors in the spinal cord.[16] The exact mechanism for the analgesia is not known. However, the α_2-adrenergic agonists traditionally have been thought to induce analgesia by mimicking the action of norepinephrine released from descending noradrenergic inhibitory pathways.[17] Additional proposed mechanisms of action include modulation of pain via serotonergic and adenosinergic pathways, inhibition of the release of substance P, and effects on opiate receptors.[18,19]

Xylazine, an α_1- and α_2-receptor agonist, is commonly used to induce analgesia of the perineal area of horses.[20] However, xylazine is not suitable for severe hindlimb lameness because of its effects on somatic motor innervation.[8] Doses that exceed 0.25 mg/kg can cause substantial ataxia and have the potential to cause temporary hindlimb paralyis. Detomidine is a more selective α_2-adrenergic agonist, which primarily affects nerve fibers involved in pain transmission (C fibers and A delta fibers) and appears to have limited effect on somatic motor function at clinically used doses. Detomidine therefore is less likely to cause motor dysfunction and hindlimb paralyis, making it more appropriate for the treatment of horses with hindlimb pain. However, detomidine has a relatively short duration of action (see Table 86-1) and also has systemic effects, such as decreased blood pressure and heart and respiratory rates. Detomidine is best used with morphine and can provide additional analgesia. I use a combination of morphine (0.1 mg/kg) and detomidine (30 µg/kg).

CLINICAL APPLICATIONS

Epidural analgesia can make a profound difference in the comfort and convalescence of equine patients and is frequently used with other forms of analgesia such as NSAIDs. Epidural analgesia is often used during the first stages of recovery from various disease processes, when the pain may be more intense, or immediately before or after surgical treatment of pelvic limb injuries or disease. Procedures such as fracture repair and arthrodesis can be painful intra-operatively and post-operatively. Pre-operative administration of epidural opioids can decrease the concentration of inhalation anesthetic required, and some evidence shows that pre-operative administration of epidural opioids is effective pre-emptive analgesia. Evidence also shows that effective pre-emptive analgesia can make post-operative pain management more successful. Because the onset of action of epidural morphine is prolonged in horses, administration of the drug 1 to 3 hours before anesthesia and surgery may be necessary to achieve the greatest effect post-operatively. A clinical impression exists that horses treated with epidural morphine have longer recovery times. My impression is that recovery might be prolonged slightly, but not dangerously so, and that the horses are far more comfortable in the immediate post-operative period. Epidural administration of morphine provides far superior analgesia to that which we can achieve with NSAIDs and parenterally administered opioid agonist-antagonists, such as butorphanol, without substantial systemic effects.

Horses with trauma to the hindlimb that require long-term therapy may benefit from the placement of an epidural catheter. I have left catheters in place for 1 to 2 weeks in some of these patients and, as of yet, have seen no complications attributable to the catheter. In some horses, however, the analgesia seemed gradually to become less effective, despite increasing the dose and frequency of epidural morphine. The addition of 30 µg/kg of epidural detomidine every 6 to 8 hours was beneficial in these horses. Ultimately ketamine[9] or other α_2-agonists, such as medetomidine, may have a role in treating horses with pain that is refractory to epidural morphine.

CONTRAINDICATIONS AND COMPLICATIONS

Complications associated with epidural analgesia can be grouped according to those caused by the drugs administered, those caused by the actual insertion of the needle or the catheter, and those caused secondary to the maintenance of an epidural catheter. Complications reported with epidural morphine are rare in horses. Detomidine may cause cardiopulmonary depression, sedation, and ataxia. Careful assessment of the patient's cardiovascular status and appropriate dosing of the drug can minimize the risks associated with epidural detomidine.

Introduction of the needle or catheter into the epidural space potentially can cause trauma to the spinal nerves roots or the epidural venous sinus. Substantial bleeding in patients with normal clotting times and platelet numbers is unlikely. The possibility exists that if the tip of the needle is in the venous sinus, the drug administration will be intravenous as opposed to epidural and will not have the desired effect of prolonged, segmental analgesia. I have also, on one occasion, inadvertently catheterized the epidural venous sinus. If blood is obtained after aspiration of the catheter, the catheter (and needle if still in place) should be removed and a new catheter should be placed.

Potential complications secondary to the maintenance of an epidural catheter include localized soft tissue inflammation, and rarely, epidural abscess, vertebral osteomyelitis, and meningitis. The catheter site should be inspected daily for signs of infection or inflammation.

Possibly the most serious potential complication would be the inadvertent injection of an inappropriate substance or an overdose of the drug into the epidural catheter. The epidural catheter should be marked clearly as such, and all personnel working with that patient should be instructed in the care of the catheter and the amount and type of drugs that are administered through the catheter.

Bandaging, Splinting, and Casting

Alan J. Ruggles and Sue J. Dyson

Indications for bandaging and cast application include protection of limbs during transport and performance, reduction of soft tissue swelling, protection of surgical wounds, management of skin defects and granulation tissue, protection of surgical implants, management of fractures, and first aid before transport of injured horses. This chapter discusses methods of bandage, splint, and cast application and the acute management of a horse with a suspected fracture or soft tissue injury.

STABLE AND TRAVELING BANDAGES

Bandages used routinely as stable bandages or for transport consist of a padded, quilted, fleece or interwoven sheet cotton as a protective layer, held in place by a flannel wrap or commercially available bandage material. Horses that continually wear stable bandages tend to develop ridges in the hair coat, and this should be noted at a prepurchase examination. Proper bandaging prevents limbs from filling in a stabled horse and prevents injury during transport. The coronary band region is particularly vulnerable during transport, loading, or unloading, and the bandage ideally should extend to cover this area. Alternatively, overreach (bell) boots should be used. Improper bandage application or management can cause the development of white hairs, transient edema, structural damage to soft tissue structures and, under severe circumstances, pressure necrosis. An excessively tight bandage can result in severe tissue necrosis within 24 hours, resulting in full-thickness skin loss and damage to the underlying soft tissues. The mid-metacarpal region seems to be particularly vulnerable. Alternatively, commercially available boots can be used for transport, the best of which extend from proximal to the dorsal aspect of the carpus, or the plantar aspect of the tarsus, to cover the coronary band. The use of exercise bandages and boots for protection and support is discussed in Chapter 38.

CHAPTER • 87

Bandaging, Splinting, and Casting

Alan J. Ruggles and Sue J. Dyson

Indications for bandaging and cast application include protection of limbs during transport and performance, reduction of soft tissue swelling, protection of surgical wounds, management of skin defects and granulation tissue, protection of surgical implants, management of fractures, and first aid before transport of injured horses. This chapter discusses methods of bandage, splint, and cast application and the acute management of a horse with a suspected fracture or soft tissue injury.

STABLE AND TRAVELING BANDAGES

Bandages used routinely as stable bandages or for transport consist of a padded, quilted, fleece or interwoven sheet cotton as a protective layer, held in place by a flannel wrap or commercially available bandage material. Horses that continually wear stable bandages tend to develop ridges in the hair coat, and this should be noted at a prepurchase examination. Proper bandaging prevents limbs from filling in a stabled horse and prevents injury during transport. The coronary band region is particularly vulnerable during transport, loading, or unloading, and the bandage ideally should extend to cover this area. Alternatively, overreach (bell) boots should be used. Improper bandage application or management can cause the development of white hairs, transient edema, structural damage to soft tissue structures and, under severe circumstances, pressure necrosis. An excessively tight bandage can result in severe tissue necrosis within 24 hours, resulting in full-thickness skin loss and damage to the underlying soft tissues. The mid-metacarpal region seems to be particularly vulnerable. Alternatively, commercially available boots can be used for transport, the best of which extend from proximal to the dorsal aspect of the carpus, or the plantar aspect of the tarsus, to cover the coronary band. The use of exercise bandages and boots for protection and support is discussed in Chapter 38.

BANDAGING WOUNDS

The principles of bandages used to protect wounds are to absorb exudate, reduce soft tissue swelling, and provide an environment conducive to wound healing. Each wound has its own characteristics that make a specific type of bandage, or even the absence of a bandage, ideal. All bandages prevent or reduce edema by providing pressure. A bandage can immobilize a region to a certain extent; the degree of immobilization depends on the type of material used and the manner of its application.

Surgical wounds are generally created under ideal conditions and proper apposition of the skin edges occurs during suturing. Protection is provided by a non-adherent, porous dressing (Telfa, Kendall Co., Mansfield, MA) over the wound. The dressing is held in place with a sterile gauze roll (Conform, Kendall Co.) and then a cotton combine roll 45 cm wide (for the lower limb only), or alternatively a soft conforming bandage (Soffban, Smith & Nephew, Hull, North Humberside, UK). The gauze is held in place with an elastic conforming bandage (Vet-Wrap, 3M Animal Care Products, St. Paul, MN; Elastikon, Johnson and Johnson, Arlington, TX). These dressings are changed every 2 to 3 days, or earlier as needed, until suture removal. If a full-limb bandage is placed to extend above the carpus or tarsus, an additional bandage 40 cm wide is applied above the first bandage. For bandaging hocks, one author (A.J.R.) prefers to use a 45-cm wide combine roll on the distal limb and then 0.5-kg roll of cotton wool, which is divided lengthwise over the hock to provide greater compression. A layer of gauze (Ken Vet Co., Ashland, OH) is used over the combine and cotton, and an elastic conforming bandage (Elastikon) is then applied. Finally, additional elastic tape is used to secure the top of the bandage to the skin. These types of bandages are used post-operatively for most horses with orthopedic procedures, such as arthroscopy or splint removal, and for most horses with limb wounds, assuming the limb is stable.

In a forelimb the area of the bandage over the accessory carpal bone is incised with a scalpel blade to prevent rub sores from developing. In a hindlimb the point of the hock can be covered by the bandage if bandaging is anticipated for less than 1 week. If prolonged bandaging is required, the point of the hock should not be covered, to prevent rub sores and potential development of white hairs.

Roll cotton (cotton wool) rather than combine roll often is used for the proximal portion of carpal bandages, because it stays in position best. Roll cotton is particularly useful for reducing soft tissue swelling after desmotomy of the accessory ligament of the superficial digital flexor tendon. A non-adherent layer and conforming gauze is covered by elastic adhesive bandaging tape before applying a full-limb padded bandage. This provides protection of the wound from the environment and prevents hematoma and seroma formation. Care must be taken to avoid excessive tension being applied to the elastic adhesive tape to prevent pressure necrosis.

Pressage Bandages

Pressage bandages (Pressage bandage, S.C. Meades, Cardiff, Wales) are commercially produced elasticized bandages designed specifically for the carpus and hock and available in three sizes. They provide an excellent method of securing a light bandage in place and providing pressure, with a minimal risk of pressure sores, and are used routinely by one author (S.J.D.). Two turns of an elastic conforming bandage over the proximal extent of the Pressage bandage and application of a stable bandage in the more distal part of the limb help to keep the Pressage bandage from slipping.

Ether Bandage

Ether bandages are used to cover surgical incisions, but they do not provide any compression to the incision. For the ether bandage to stay, the area to which it is applied must be clipped, or preferably, shaved. Cleansing of the skin with surgical scrub, followed by alcohol rinsing, provides the best environment on which to apply this bandage. Strips of adhesive elastic tape about 15 cm in length are cut and ether is applied using a syringe to the adhesive side of the bandage tape. The ether soaked bandage is then applied over gauze sponges and held in placed while the ether evaporates and the adhesive dries to the skin and elastic tape. Three to four strips of elastic tape typically are used. Ether bandages are useful to protect surgical wounds made for stifle arthroscopy, bone grafts from the tuber coxae, and plate fixation of the olecranon. Because of the explosive nature of ether, proper precautions should be followed in its use and storage. Commercially available Primapore dressings (Smith & Nephew) provide a simpler alternative.

Stent Bandages

Stent bandages are towels or gauze rolls that are sutured over wounds to protect the wound from the environment or to relieve tension at the sutured site. A sterile hand towel or gauze sponges, rolled like a cigar to the proper width of the wound, are sutured over the wound with No. 2 or larger suture. A cruciate pattern is usually used. Stent bandages are used after shoulder arthrotomies, after olecranon or femur fracture repair, to cover wounds over the point of the hock, and for other incision sites unsuitable for bandaging. If the stent is to be changed routinely, then loop sutures are placed on either side of the incision, and umbilical tape can be used as suture to hold the bandage in place between changes.

Wet-to-Dry Bandages

Wet-to-dry bandages are used to absorb exudates and to provide an environment conducive to wound healing, particularly in the proliferative phase of wound healing. After cleansing of the wound, sterile sponges moistened with saline solution are applied to the wound and held in place with normal bandaging techniques. The bandaged is changed daily, or as needed, and the process can be repeated as often as necessary until the granulation bed has formed.

With any wound there is a combination of dressings, bandaging, immobilization, and systemic therapy that is appropriate. The management changes as the wound heals and sometimes alternative strategies need to be adapted. Careful attention to the progress of the wound and understanding of wound healing principles optimize outcome.

Foot Poultice

If a subsolar abscess is suspected, applying a poultice may be necessary, along with foot soaks, to soften the sole to permit drainage and to draw the abscess. A commercial poultice such as Animalintex (3M Animal Care Products; Robinson Animal Healthcare, Chesterfield, UK) is the simplest to use. A half piece is usually adequate. It should be thoroughly soaked in hot water and partially squeezed out before being applied to the sole of the foot. The poultice is covered by a thick layer of cotton wool and then conforming bandage is wrapped around the foot to hold the poultice in position. To keep the moisture in, the foot can be placed in a used fluids bag, which is then covered by duct tape to provide a durable bandage.

Robert Jones Bandage

A Robert Jones bandage is used when additional support or compression is required. The bandage is particularly useful for immobilizing the limb of a horse with a suspected fracture for transport or for recovery from general anesthesia after fracture or wound repair; for example, after lag screw repair of a simple proximal phalangeal fracture or a condylar frac-

Fig. 87-1 A forelimb full-limb Robert Jones bandage. Note the cylindrical shape and proximal extent of the bandage.

Fig. 87-2 A full-hindlimb Robert Jones bandage, before application of elasticized tape, extending to the proximal tibia.

ture of the third metacarpal bone. The Robert Jones bandage also can provide limb support if the suspensory apparatus is disrupted, can control severe post-traumatic limb edema, and can provide substantial pain relief to a horse with a severely injured superficial digital flexor tendon. This bandage has a multi-layered construction. Compared with a single-layered bandage, a Robert Jones bandage compresses air-filled cotton wool layers to increase rigidity and spread pressure evenly. A half-limb bandage requires 4 to 5 rolls of cotton wool, 8 to 10 conforming bandages, and 3 to 4 rolls of elastic adhesive tape. A full-limb bandage needs twice as much. For a half-limb bandage in a forelimb the cotton wool should be applied snuggly from the foot to the distal aspect of the carpus, incorporating the foot. The first layer using 1½ to 2 rolls of cotton wool should be 2 to 3 cm thick. This layer is then compressed using several conforming bandages at least 15 cm wide. Each bandage is applied using fairly firm, constant pressure to compress the cotton wool evenly. Filler layers of cotton wool usually are needed at the top and bottom of the bandage to create a uniform cylinder. A length of cotton wool is folded in half and placed around the top and bottom of the bandage as a filler layer. Another 2- to 3-cm layer of cotton wool is then applied and is compressed using a conforming bandage. At least 3 layers are constructed to create a thickness of 6 to 8 cm. The entire length of the bandage is now covered with elasticized tape, which should extend the entire length of the bandage and above and below it, to prevent dirt and bedding material from getting into the bandage. The end of one roll of elasticized bandage and the beginning of the next should overlap to prevent unraveling of the bandage. The end of the last roll is covered by zinc oxide tape. A full-limb bandage is applied similarly. In a forelimb the bandage should extend the entire length of the limb, incorporating the elbow (Fig. 87-1); in a hindlimb the bandage should extend to the proximal aspect of the tibia (Fig. 87-2).

SPLINTING

Splints should be used to support unstable fractures, when disruption of the suspensory apparatus is suspected, and when a full-limb Robert Jones bandage is used to provide additional support. Proper splinting helps protect bone from further trauma, prevents further soft tissue damage, and may also increase the horse's comfort. Wood (45 × 20 mm), or plastic guttering (diameter about 112 mm) cut in half to give a U shape, can be used. Polyvinyl chloride (PVC) piping is lightweight, inexpensive, and strong, but wood is generally more suitable for lateral splints. The length of the splint depends on the size of the horse and the position of the injury. It is critical that the splints are adequately padded, especially at the top and bottom, to avoid rub sores. A gutter splint can be padded throughout its entire length using cotton wool. Wooden splints should be padded at the top and bottom. The splint should be covered with elastic adhesive tape proximally and distally to prevent it from becoming damaged and developing rough, sharp edges. A splint generally is applied over the dorsum to immobilize the distal limb. If a transverse or oblique fracture is suspected, or support of the suspensory apparatus is lost, the limb should be splinted to align the dorsal cortices of the third metacarpal bone and phalanges to eliminate the bending forces of the metacarpophalangeal joint. An assistant is needed to hold the limb off the ground, supporting it under the antebrachium (Fig. 87-3). One layer of the Robert Jones bandage is applied and then the splint is strapped to the dorsum of the limb before applying the second layer of the Robert Jones bandage (Fig. 87-4). The splint should be well reinforced at the toe. If a sagittal plane fracture or subluxation or luxation of a joint is suspected, supporting the limb in its normal position is preferable. The splint then can be applied over the full thickness of the Robert Jones bandage. To immobilize the carpal region, or if a fracture in

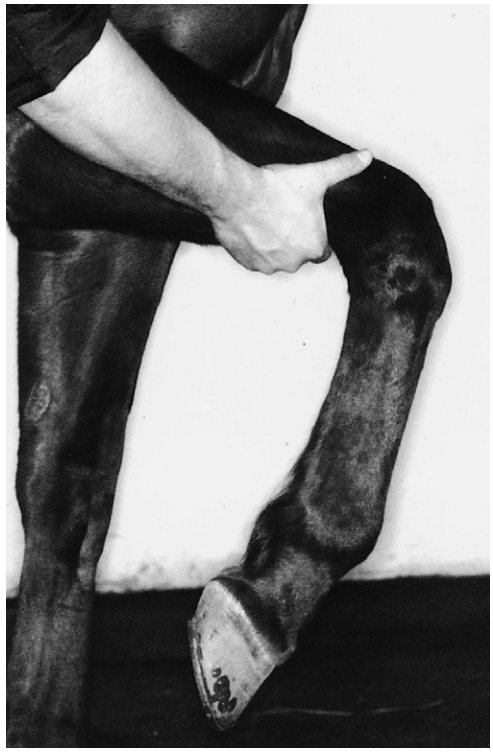

Fig. 87-3 An assistant holds a forelimb before application of a half-limb Robert Jones bandage, aligning the dorsal cortices of the distal limb bones.

Fig. 87-4 A half-forelimb Robert Jones bandage incorporating a dorsal splint. The horse is standing happily, bearing weight on the toe.

the mid-metacarpal region or distal radius is suspected, caudal and lateral splints are used, extending to the elbow. With a fracture of the mid- or proximal radius, abduction of the limb is prevented by placing a lateral splint extending from the ground to mid-scapula level. The top of the splint must be well padded to prevent rub sores. With a fracture of the ulna and loss of triceps function, it is best to fix the carpus in extension by using a caudal splint extending from the ground to the proximal olecranon. Similar principles apply in a hindlimb. Not all horses tolerate immobilization of the hindlimb and the clinician must be prepared for the horse to react adversely when it first moves. For horses with fractures of the distal metatarsal region and distally, the limb is held above the hock by an assistant while the Robert Jones bandage and dorsal splint are applied. With a suspected fracture of the mid-metatarsal and proximal metatarsal regions, the Robert Jones bandage should be applied with the limb bearing weight, and caudal and lateral splints are applied. The caudal splint should extend up to the calcaneus, to fix the tarsus to the distal limb fracture. Wood splints are stronger than gutter splints. Splinting of the hock and distal tibial regions aims to counteract the medial forces of the lateral musculature of the femur and the destabilizing effect of flexion of the stifle through the reciprocal apparatus. To immobilize the hock, a lateral splint is contoured to the angle of the hock by heating PVC gutter pipe over a flame, or by using a 12-mm steel rod that can be shaped by hand but is strong enough to provide support. The splint should extend to the proximal tibia. An additional contoured splint can also be placed distal to the stifle and proximal to the fetlock on the plantar (caudal) side.

Several commercial splints are available that are particularly useful in an emergency situation, being easy to apply and rapidly providing pain relief by immobilization of the limb. These include the Kimzey Leg Saver Splint (Kimzey, Woodland, CA), the Monkey Splint (Kruuse, North Yorks, UK), and the Australian Equine Salvage Splint (Ballarat Veterinary Practice, Ballarat, Victoria, Australia). They are all designed to align the dorsal cortices of the distal limb bones and are appropriate for fractures distal to the distal third of the metacarpal or metatarsal regions or suspensory apparatus breakdown. The Kimzey splint also has an extension that reaches to the proximal antebrachium and is suitable for use in horses with fractures up to the carpus. The Kimzey splint generally is well tolerated. The Monkey and Australian splints have an extra heel and some horses walk awkwardly.

TRANSPORT OF AN INJURED HORSE

With appropriate immobilization of a limb, a horse with a suspected fracture or major soft tissue injury can be safely transported long distances to a clinic with suitable diagnostic and surgical facilities and a skilled surgeon. Ideally the horse should be transported in a low-loading vehicle. Alternatively the horse should be loaded via a loading ramp, or with the ramp of the vehicle placed on a slope, so that the incline up the ramp into the vehicle is shallow. Ideally a horse with a forelimb injury should travel facing backward so that major load is placed on the hindlimbs when the vehicle decelerates. A horse with a hindlimb injury should travel facing forward. A clinic expecting to receive such horses also should have a loading ramp to minimize the incline down which the horse has to walk when unloaded.

CAST BANDAGE

Cast bandages are a combination of a standard bandage, casting tape, and splint material (typically PVC). After place-

ment of a standard bandage, two layers of cast material are placed over the bandage in the area to be splinted. The splint is then applied and held in place while at least two additional layers of casting tape are applied. In 2 to 3 days the cast material is split to create a bivalve to allow access to the surgical site. The cast can then be reapplied to provide immobilization. Clinical indications for this technique include management of wounds over the carpus, including transverse lacerations or hygroma resection.

Cast Application

Indications for cast application include after fracture repair or suturing of lacerated tendons or for wound management. Commonly used materials include plaster of Paris, resin-augmented plaster, and fiberglass. Fiberglass casting tape consists of knitted fiberglass fabric impregnated with polyurethane resin and is used most commonly because of its greater strength, lighter weight, and quicker setting times, despite increased cost. Full- (up to elbow or stifle) and half-limb (up to carpus or tarsus) casts can be applied. Full-limb casts are not well tolerated by all horses, and the horse's temperament should be assessed carefully, particularly before applying a full-hindlimb cast. Casts are changed as needed because of rub sores, suture removal, breaking or buckling of the cast, or usually within 4 weeks after placement. In some circumstances a cast can be left on up to 6 to 8 weeks; however, the risks of cast rubs increase the longer the cast is left on the horse.

Casts can be applied in a conscious, sedated horse but are commonly applied with the horse under general anesthesia, after internal fixation or wound repair. The limb should be clean and dry before cast application. Sterile dressings are applied over the surgical site, and non-binding materials such as cotton cast padding should be used to secure the wound dressings. A double layer of sterile stockinette is applied over the limb and extends above the proximal extent of the cast. Four to 5 cm of orthopedic felt is placed at the proximal extent of the cast. Wider felt is used in full-limb casts. Additionally, orthopedic felt with the centers cut out can be placed over bony prominences, such as the styloid processes or accessory carpal bone, to avoid cast rubs. The felt is secured with adhesive tape. Wire can be placed through holes placed in the hoof wall near the toe and secured to a twitch handle to provide a means for an assistant to hold the limb and maintain the proper angle of the digit. In general, the hoof is placed at or near a weight-bearing position. Alternatively, the hoof can be extended to a lesser extent, by manual pressure at the toe. Cast padding is applied and overlapped about 50%. The use of 3M Custom Support Foam (3M Healthcare, St. Paul, MN), which has a polyurethane resin–impregnated cast padding, is helpful in reducing cast rubs. It is important not to use too much foam, because the cast will compress it and the cast will become loose, predisposing the horse to rub sores. Casting tape (3M Scotchcast, 3M Healthcare; 10 to 12 cm wide) is applied, beginning on the orthopedic felt at the top of the cast. The material is spiraled down the limb, taking care not to apply it too tightly, while avoiding wrinkles. Because the limb is not a perfect cylinder, wrinkles tend to develop in areas where contouring is necessary. Tension across the width of the casting tape eliminates potential folds or wrinkles. The next roll of casting tape begins where the first leaves off. At least five rolls of casting tape are used on the limb and sometimes one or two more additional rolls. When finished, more casting tape should be at the fetlock and distally, because this is the most common site of breakage. If the distal limb is extended using wires through the hoof wall, the toe region is not cast until the rest of the limb is finished and the twitch handle is no longer necessary. The wire and twitch handle are removed and the foot is covered with one to two rolls of casting tape. If a heel wedge is required, folded casting tape or a wood block can be incorporated in the casting tape applied to the hoof. Polymethylmethacrylate (Technovit, Jorgenson Laboratories, Loveland, CO) is applied to the bottom of the cast, especially if the cast is to remain more than 2 weeks, to prevent wearing through of the casting tape.

For application of a cast in a standing horse the same protocol is followed, except a 2.5- to 5-cm block is placed under the horse's hoof, so that the heel is left hanging slightly over the edge of the block, and the cast is applied. After the limb is cast, the limb is lifted and casting tape and polymethylmethacrylate are applied to the hoof. When standing casts are applied for first aid treatment of unstable fractures, a dorsal splint can be incorporated to maintain the bony column in a straight line. Foot casts are sometimes useful in managing heel bulb lacerations.

Potential cast complications include rub sores and cast breakage. Rub sores can occur over any bony prominence or an area where the cast folds or fingerprints are present. Common sites for cast rubs include the proximal dorsal metacarpal and metatarsal regions, proximal sesamoid bones, and heel bulbs in half-limb casts and the elbow, distal radius, accessory carpal bone, stifle, and point of the hock in full-limb casts. Increased lameness, fever, drainage, heat, foul odor, and proximal swelling are signs of cast rubs. Rub sores are common complications of cast application and usually are managed easily by cast change or removal. Failure to recognize rub sores can lead to serious problems, such as large wound defects, infections of synovial structures, or laminitis in the supporting limb. Proper application and careful monitoring of cast is essential to prevent serious rub sores.

Transfixation Pin Casts

The use of transfixation pin casts is discussed in Chapter 88.

CHAPTER • 88

External Skeletal Fixation

David M. Nunamaker

HISTORY AND DEVELOPMENT

Using external skeletal fixation to treat fractures in the horse has, until recently, received little enthusiasm from equine surgeons. Although external skeletal fixation of fractures works well in small animals and has enjoyed periods of enthusiastic use, these same devices do not withstand the loads of weight bearing in the adult horse and therefore are not versatile enough to meet the needs of the equine surgeon. Using transfixation pins in plaster, or more recently transfixation pins in fiberglass casts, has allowed salvage of some horses with difficult fractures that could not have been saved using internal fixation.

The incorporation of a walking bar cast, with transfixation pins placed in the bone above the fracture, was described in 1999 to manage fractures in horses and ponies. An overall success rate of 57% was reported for a variety of fractures in 35 horses and 21 ponies. The authors suggested that using transfixation pins incorporated into the cast material may help prevent fracture through these pin sites. Major complications of the technique included infection in nine animals, fracture through the bone or pin sites in six animals, and loss of circulation to the distal phalanx in two animals. Complications in the remaining seven non-survivors were not reported.[1] Using in vitro tests, McClure et al.[2,3] suggested that the walking bar was not necessary when using fiberglass casts and that divergent transfixation pins may be helpful in preventing fracture through the pin tract sites.

Although transfixation pins have been used successfully in fiberglass casts, this technique represents a compromise compared with classical external skeletal fixation. In horses managed with transfixation pin casts, wounds, skin, and pin sites must be covered in the cast, and at the time of every cast change, fractures are remobilized, allowing fracture collapse or shortening of the limb segment. In addition, pin loosening and local infection at pin sites are common sequelae using this form of transfixation pinning, often necessitating pin replacement through new pinholes.

The development of an external skeletal fixation device has lagged behind other internal fixation devices for use in the horse because of perceived or real problems with device design, strength, and versatility. Our early experience with the AO Tubular System (Synthes, Paoli, PA) or Hoffmann Device (Howmedica, Inc., Rutherford, NJ) in the 1970s showed the inability of these human-oriented systems to withstand the rigors of full weight bearing in the horse. Design and development of an equine external skeletal fixation device was undertaken in 1981 in the Richard S. Reynolds, Jr. Comparative Orthopedic Research Laboratory at New Bolton Center, University of Pennsylvania. A grant from the Swiss AO/ASIF North American group was instrumental in early design and development. The original device incorporated three threaded transfixation pins in the intact bone above the fracture. The pins were connected to sidebars that extended distally to a footplate that allowed the animal to bear full weight on the limb but protected the immobilized fracture below the last transfixation pin. The hoof was attached to the footplate using conventional hoof nails, assuring immobility of the fracture with continued full weight-bearing function of the limb (Fig. 88-1). The results using the external skeletal fixation device in the initial 15 horses were reported in 1986.[4] Eight horses were admitted with open fractures that were not amenable to other acceptable forms of treatment. Primary fracture healing was achieved in seven horses and an additional three horses progressed to frame removal during the course of treatment. Only 4 of 15 horses survived long term. Fatal complications included unrelenting infection in four horses. Two horses fractured the third metacarpal bone (McIII) through the pin sites while wearing the device, and two horses fractured McIII through the pin holes during anesthetic recovery to remove the external skeletal fixation device. We changed the transfixation pin diameter and the ground contact area of the footplate to address these early bone failure problems. In addition, removal of the frame while the horse was standing prevented any further failures through the pin holes in the bone, associated with recovery from anesthesia. In 1991, we reported our continuing experiences with the external skeletal fixation device, which included using the device in another 20 clinical patients. The results of 11 horses with fractures of the proximal phalanx in which the external skeletal fixation device was used were reviewed.[5] Five (45.5%) of 11 horses survived. We felt overall that improvement in survival continued from our original reports, attributed in part to improvements in the design of the external skeletal fixation device. Overall, using the original and modified device in 26 horses, we found the survival rate for the first 13 horses was 15%, whereas the survival rate for the second 13 horses was 53% (overall survival rate 34%).

We continued our work to attempt to reduce fractures through the pin sites (approximately 15%), a complication that occurred with the earlier frame design. In 1994 we described a newly developed concept of loading the external skeletal fixation pin in shear, instead of bending[6] (Fig. 88-2). The concept involved using large-diameter sleeves over the transfixation pins, which were bi-axially loaded in tension and shear. The device used only two pins and incorporated the pins in a stronger, lighter frame (Fig. 88-3). Compared with the old configuration that allowed for pin bending, the loads to bone failure with the new design were nearly an order of magnitude higher. Because bone failure occurs at a finite strain level, it appeared that the larger loads to failure were indicative of lower strain levels in the bone at the working stress level required by the horse fully weight bearing in the frame. Although research and development of this device continues, the current external skeletal fixation device is available commercially (Ron Nash Engineering, Magnolia, AR).

Regardless of the type of external skeletal fixation used, concerns regarding the pin holes remain. Experimental studies in other species suggest that pin holes are remodeled and stress concentrations reduced in 8 to 12 weeks. The holes themselves may never fill in completely. Holes in the bone change sectional properties and bone strength may not equal

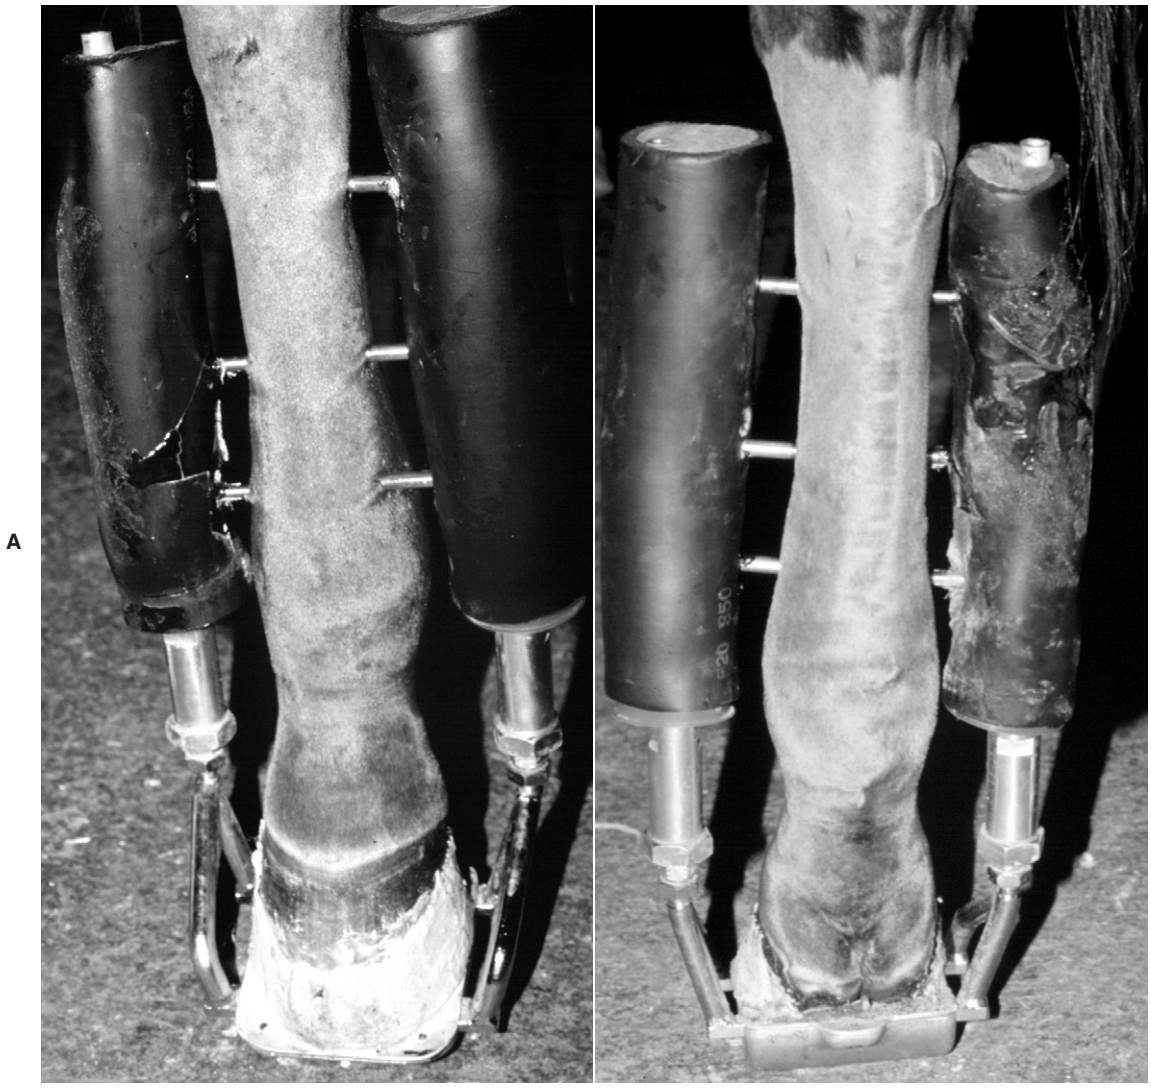

Fig. 88-1 **A,** A dorsal view of the three-pin external fixator shows the relationship of the pins traversing the intact third metacarpal bone and supporting the distal fracture of proximal phalanx. **B,** A plantar view shows the back of the limb with the same fixator in place. The base of the device is attached to the hoof using the glue-on system.

that of bone without holes. Treatment with large diameter external skeletal fixation pins should be reserved for horses that are not expected to return to athletic pursuits and where other methods of fixation are unlikely to preserve the horse's life. Most horses in which external skeletal fixation is contemplated presently have life-threatening injuries and are not likely to return to athletic competition. Treatment of these fractures aims to allow the patient to become pasture sound or to be used for breeding. It is noteworthy that several horses treated with the external skeletal fixation device have returned to light riding or carriage driving, even with fusion of the joint involved in the original fracture.

PRE-OPERATIVE PLANNING, INDICATIONS, TIPS, AND LIMITATIONS

The external skeletal fixation device was designed to treat horses with catastrophic injuries of the distal limb. Indications include comminuted fractures of the proximal phalanx when no strut (intact piece of bone from the proximal to the distal

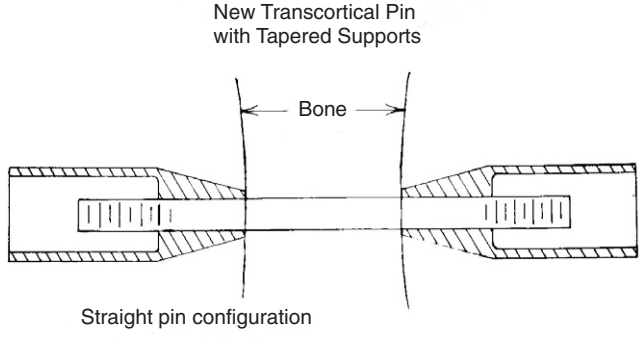

Fig. 88-2 This drawing shows the concept of sleeves that slide over the transfixation pins to give protection from bending in the external skeletal fixation device. The large diameter of the sleeves and the proximity to the bone eliminate bending as a loading mode and ensure a more uniform loading on the pin in shear. This protects the outer bone cortex from the loads of a bending pin and allows the device to be loaded to a greater extent before bone or pin failure.

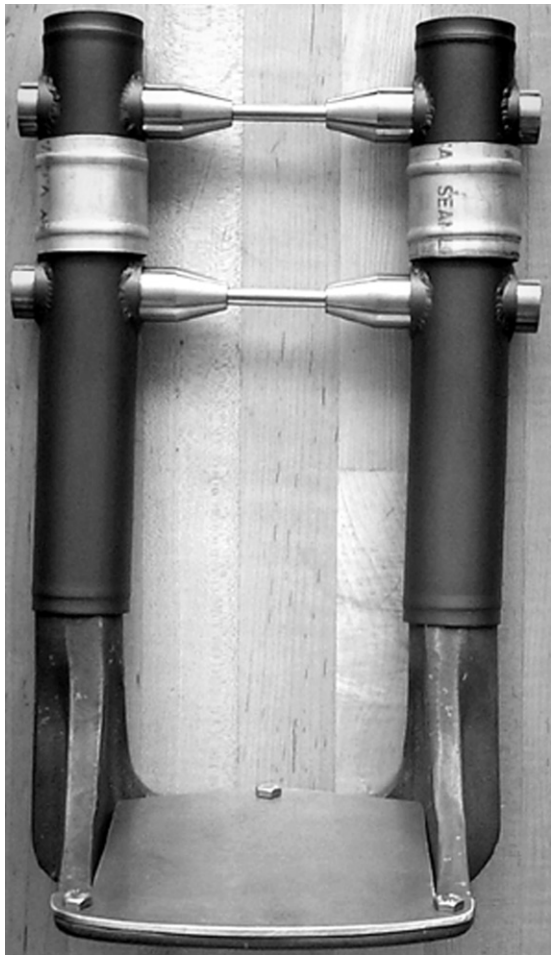

Fig. 88-3 The present external skeletal fixation device design is shown with two transfixation pins and tapered sleeves. The device is assembled easily over the tapered sleeves using the footplate attached to the base.

articular surface) is available for use with internal fixation (see Chapter 36), comminuted fractures of the middle phalanx, fracture dislocations, or traumatic disruptions of the suspensory apparatus with massive soft tissue injury (see Chapter 37). Expanded use of the external skeletal fixation device could be considered in horses with severe laminitis. In its present form the external skeletal fixation device is designed for use when McIII or the third metatarsal bone (MtIII) is intact. The only other requirement is that the blood supply to the distal limb must be intact. In addition to applying the external skeletal fixation device, it is sometimes helpful to insert bone screws, used in lag fashion through stab incisions, to hold large fragments together. This can be done under radiographic guidance and these fixations do not need to resist weight-bearing forces, because the external skeletal fixation device supports the entire weight of the animal. It is necessary that the hoof fits on the base plate of the device and, if large, the hoof needs to be trimmed. This must be accomplished to allow the aluminum base plate to attach to the magnesium-alloy base using the three cap screws. A compression bandage (elastic bandage) is wrapped around the fractured bone before and during surgery to bring the bone fragments closer together and reduce swelling, which helps with reduction of badly comminuted fractures.

Abbreviated instructions for application of the external skeletal fixation device are included to show the simplicity of the system. The procedure is completed with the horse under general anesthesia. The only surgical requirement for application of the external skeletal fixation device is to drill two holes in McIII, although additional internal fixation can be used when appropriate. The footplate is attached using nails or a glue-on system. The limb is prepared for aseptic surgery and, using the drill guide supplied, two 7.94-mm holes are drilled, one at the junction of the proximal and middle thirds and the other at the junction of the middle and distal thirds of McIII from the lateral aspect. Holes are placed in the center of the bone and marrow cavity and perpendicular to the long axis of the bone. This process is facilitated by using a dual drill guide. Next the 7.94-mm pins are inserted using the threaded cap to protect the threads. The sleeves over the pins are assembled on the medial and lateral sides and secured with nuts. The sleeve-skin junction is wrapped with a sterile bandage and the rest of the assembly is done using non-sterile technique. The side tubes are then assembled using ring connectors over the tapered sleeves on both sides of the limb. The base is slid into the distal ends of the tubes, and the base is fastened to the footplate using cap screws supplied. The reinforcing rods are then inserted into tubes on the medial and lateral sides and electrical tape is placed around all the tubular junctions to prevent leakage. The fracture is reduced and stabilized by placing traction on the limb in a position that allows the tubes to be filled. The polymer (Conathane UC41, Cytec Industries, Inc., Olean, NY) is then mixed (2:1 by volume) and poured into the sidebars. The tubing is cooled, using cold saline solution if necessary, to prevent heating of the pins. Last, the now wet sterile wrap around the tapered sleeves is removed, and the external skeletal fixation device is covered with a bandage. The horse is then recovered from general anesthesia.

POST-OPERATIVE CARE

After anesthetic recovery the horse is immediately fully weight bearing and comfortable on the limb. In fact, this is a major advantage of this type of fracture management. Skin care around the pin sites is important during the initial post-operative period and is done easily using antiseptic-soaked sponges. The external skeletal fixation device is checked for tightness using an appropriate deep socket wrench every few days. Pin loosening does not occur, because one has the ability to tighten the pins with the fastener nuts already in place, which is easily done and does not require sedation of the patient. Reducing pin loosening helps to diminish pin tract infections and allows the horse to remain fully weight bearing. Local antiseptic application at the pin sites may decrease severity of pin hole infections. Some patients may be discharged from the hospital with the external skeletal fixation device in place. If the owner or trainer can provide pin care, discharging the horse as soon as possible decreases the cost of hospitalization. The horse is returned to the hospital for removal of the external skeletal fixation device, which is usually after 8 to 10 weeks. Although the external skeletal fixation device can be left on longer, substantial osteoporosis of McIII or MtIII below the lower pin may be detrimental to the end result. Radiographically the fracture site may not appear healed (based on the observation of mature callus) at this time, because osteoid will have formed, but calcification of this soft callus will not have occurred without the stimulus of weight bearing. The external skeletal fixation device is removed in the standing, sedated horse, and a fiberglass cast is applied. Serial radiographic examinations are then performed until radiographic evidence of fracture healing is visible. Premature removal of the external skeletal fixation device may result in collapse of the fracture. Mild collapse of the fracture may occur if the external skeletal fixation device is left in place for only 6 to 8 weeks. However, by this time skin and soft tissues will allow for some fracture collapse without

penetration of bone fragments, and the horse can be managed in a fiberglass cast without complications. Spontaneous fusion of the proximal interphalangeal joint will occur in horses with comminuted proximal phalanx fractures. If fusion of the metacarpophalangeal or metatarsophalangeal joint is necessary, additional internal fixation is needed because spontaneous fusion does not usually occur.

REMOVING THE EXTERNAL SKELETAL FIXATION DEVICE

With the horse sedated, the external skeletal fixation device is removed by using the special pin removal device supplied with the instrumentation. If the footplate has been glued on using the Sigafoos glue on system (Sound Horse Technologies, Unionville, PA), the hoof and footplate are separated using a sharp knife to cut the hard glue. If the footplate was nailed on, the cap screws, bolt, and nut should be removed from the alloy base using a wrench. A hacksaw is then used to cut the lateral sidebar tube just below the lower tapered sleeve. The nuts are removed from the threaded pins on the tapered sleeves. The pin extractor is placed over the distal tapered sleeve and the pin is engaged and removed by turning the extractor with an end wrench. This can be repeated in the proximal tapered sleeve if necessary. Once the pins are removed, the frame can be lifted away and the base plate can be removed like a shoe, if the base plate was nailed in place.

A standing cast is recommended to preserve the structure and function of the extremity for additional time, until healing is sufficient for unrestricted weight bearing. Radiographic control is helpful in making those decisions.

In one horse managed using the original three-pin external skeletal fixation device for a severely comminuted, open proximal phalanx fracture, inadequate reduction of the metacarpophalangeal joint at the time of application of the fixator was noticed. However, rather simple fixation was used to fuse the metacarpophalangeal joint without major collapse of the proximal phalanx. This animal survived and was used successfully as a broodmare. The current external skeletal fixation device is shown in Fig. 88-4.

Using external skeletal fixation for treatment of horses with severe, comminuted fractures or other injuries in the distal extremity is a reasonable choice, but device design and development are still being refined. Transfixation-pin casts are a suitable alternative to rigid external skeletal fixation devices, but soft tissue and pin care cannot be performed.

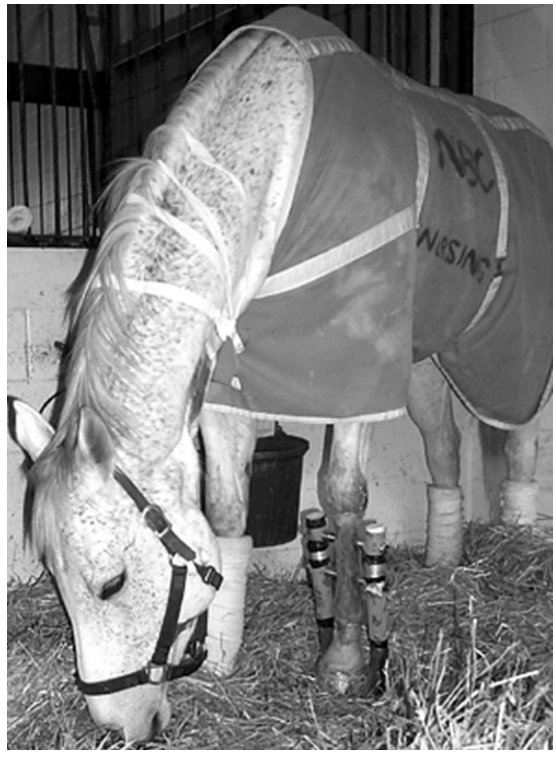

Fig. 88-4 An external skeletal fixation device has been used to manage a comminuted fracture of the middle phalanx.

CHAPTER • 89

Counterirritation

David Ellis and Stephen P. Dey III

BRIEF HISTORY AND OUTLINE OF TECHNIQUES

Counterirritation techniques have long been a part of veterinary therapy, particularly in horses. Major veterinary texts, such as those by Percivall[1], Wooldridge,[2] and even Stashak[3] as late as 1987, devoted considerable attention to indications and techniques. To some this now seems misguided and even cruel, but one only has to read a few of the older texts to admire the authors' inquiring minds and their thorough observations on matters medical and particularly orthopedic. They were not far from the truth, but they did not have the benefit of modern anesthetics or imaging equipment to learn and apply more direct and rational therapies. Techniques currently used include hot or cold firing and blisters, but use of those therapies is much reduced because of changes in the horse ownership and veterinary attitudes. This chapter considers both British (D.E.) and American (S.P.D.) perspectives.

BLISTERING

Limited availability of ingredients and ignorance of preparation and safe use has restricted blistering of horses in the United Kingdom. Although veterinary surgeons or equine wholesalers are the source, the horse owner is usually the user. More severe blisters, such as those containing cantharides or croton oil, are used less commonly than the working blisters that are iodine or mercuric iodide based and mainly used on splints, sore shins, or curbs. The technique involves rubbing or brushing the liquid preparation onto the clipped skin once daily until a scale forms. The animal is kept in light exercise, such as walking, trotting, or hack cantering, and this phase usually is undertaken after the initial rest and anti-inflammatory treatment has removed heat, swelling, and pain, 7 to 10 days after initial signs. When the heat and soreness from counterirritation has settled, which takes 2 to 3 weeks, the horse resumes work.

Irritation from working blisters is minimal, and protective measures such as anti-inflammatory treatment, keeping the horse cross-tied, or fitting a bib or cradle are not necessary.

Strong blister was made mostly from cantharides (Spanish fly) or croton oil, but nowadays these ingredients are difficult to obtain and, because they are not licensed drugs in the United Kingdom, are probably illegal for a veterinary surgeon to import without permit. As a consequence the strong blister that is used most commonly is made as a cream using red mercuric iodide. The skin is clipped and the blister rubbed into the area for 5 minutes. Excess is removed and petroleum jelly is applied to flexor surfaces distal to the blistered areas. The horse is kept shod for blistering, in case it paws the ground, and a neck cradle is applied until the initial inflammatory phase has subsided. It is essential that the horse continues walking exercise, usually 30 minutes twice daily. A substantial risk of laminitis or lymphangitis exists if blistered horses do not have this regular exercise. When blisters form and burst, they are left alone and sprayed with antibiotic powder. Rarely is the reaction severe enough to warrant anti-inflammatory treatment. After 10 days the blistered areas of the legs are smeared with petroleum jelly, which is left on overnight and then washed off with warm water and soft soap. This softens and lifts the scabs free, without causing bleeding or further irritation. Any blistered areas that are still moist are dressed with antibiotic wound powder and walking is continued. Scabs that persist after 7 to 10 days are removed by repeating this procedure. After 6 weeks the horse can be turned out to pasture or start light ridden exercise. The program for a return to training depends on the nature and progress of the original injury.

Areas treated most commonly with strong blister are the flexor tendon region of forelimbs and the fetlock joints. Indications are tendonitis, tenosynovitis, suspensory desmitis, and chronic effusion of fetlock joints.

In North America, curbs frequently are treated by blistering and both hindlimbs are usually treated. The area is clipped and rubbed aggressively for 3 minutes with medical-grade turpentine and then with kosher salt for 3 minutes, alternating for a total of 15 minutes. This is repeated once daily for 3 days. The horse is exercised immediately after each treatment for at least 20 minutes. The skin excoriates and remains thickened and inflamed for some time, but therapeutic effects are almost immediate.

Blistering also is used to manage suspensory desmitis, tendonitis, sesamoiditis, and other fetlock problems. The severity of the injury determines which blister is used and the degree of exercise modification. If suspensory desmitis or tendonitis is being treated, the metacarpal region usually is wrapped (bandaged) with a gauze layer, a leg quilt, and a bandage to control swelling. Moving areas such as the carpus or tarsus are not wrapped.

The blistering process is allowed to continue for 5 days and then a firing paint is applied to the area for another 7 days, with the bandages reset every day if the blistering process involves the distal area. After the firing paint application period ends, usually an iodine glycerine–based product is applied every day to soften the blister scabs and help lift the outer skin layers that have separated. Once a horse begins to be painted with the firing paint, it can be exercised on a walker or in a small paddock. This reduces inflammation and begins to re-establish normal venous and lymphatic flow.

Internal blisters have more widespread use in North America. A 2% iodine mixture, in almond oil or a lighter base, can be injected into tissues. One author (S.P.D.) treats muscle soreness by injection of 1 ml of internal blister per site using an 18-gauge needle of variable length, depending on the depth of the injection. The mechanism of action is unknown, but trainers usually report that the gait improves. Internal blisters also are used to treat horses with suspensory desmitis, curbs, and splints. Varied results may reflect the inconsistency of the available products.

ACTUAL CAUTERY OR FIRING

Cautery or firing is performed less frequently in the United Kingdom since the Royal College of Veterinary Surgeons deplored the practice in 1991. Cautery or firing is used on soft

and hard tissues, and some clinicians and clients are still enthusiastic about its value. Pin or needle firing is the most common technique.

Cold firing is used mainly for persistent sore shins or splints, and the thermal injury is made with liquid nitrogen (see Chapter 90). The procedure is done soon after the initial inflammatory phase has subsided and is preferred for horses with intractable injuries that have not responded to anti-inflammatory measures or blisters. The area is clipped and sedation and local anesthesia are administered. An ordinary firing iron can be cooled by leaving it in the liquid nitrogen, or a special "gun" point freezes a small area of skin. Spots of lubricant gel on the areas to be fired improve the contact. The pattern should not allow the frozen spots to be closer than 3 cm apart. No systemic or local treatment is needed and the horse is kept in walking exercise for 6 weeks. Ultimately the skin develops persistent white point scars. Results have been good enough to ensure its continuing use, but the rationale is difficult to ascertain. Cold firing probably causes local analgesia of some duration within periosteal nerves and may necrose small areas of the periosteum and underlying cortical bone.

Acid firing enjoyed a vogue 10 to 25 years ago but has deservedly fallen from use. Concentrated nitric acid was soaked into a small cork, which was then pressed onto the clipped and desensitized skin. The inflammatory reaction was substantial but, like line firing, appeared only to affect the skin and not the underlying tendon.

Line or bar firing was used for tendonitis or curbs. For the lines to be made evenly, the area was clipped the day before firing and covered with a mustard plaster overnight, which caused subcutaneous edema to smooth out the grooves between the structures before firing. Curved, blade-shaped irons were used, and management was the same as for pin firing. One author (S.P.D.) has minimal experience with this technique but agrees with Silver et al.[4] that it would not be "a useful therapeutic exercise."

Horses are still pin fired regularly in the United Kingdom. The procedure is used for superficial digital flexor tendonitis, suspensory desmitis, and sesamoiditis and has value for horses with persistently painful splints. Pin firing is no longer used for bone spavin or carpitis. The horse is fired after the initial inflammatory response has subsided and when the area is no longer warm or painful, 4 to 6 weeks after the injury. The area is clipped and anesthetized before being dressed with surgical spirit. Firing is started 10 to 15 minutes later and patterned no closer than 3 cm apart over the structure being treated. It is important to use a fine point so that minimal burning of the adjacent skin occurs. The point penetrates the underlying tendon or periosteum. An iodine-based ointment is then applied, and petroleum jelly is smeared distally, particularly in the flexural regions of joints. The horse is cross-tied, or fitted with a cradle, and walked in hand twice daily for 30 minutes. As mentioned before for blistered horses, walking is essential. It is wise to keep front shoes on and only rarely is analgesia indicated. The area is powdered with antibiotic daily and after 10 days is smeared with petroleum jelly, which is left on overnight and washed off the following morning, as previously described. Walking exercise continues for at least 6 weeks and then the horse can start to spend increasing periods of time turned out in a paddock. The horse should not return to training following a soft tissue injury for about 1 year after the injury. Those horses that have had bony tissue fired, such as with splints, can return gradually to training after the 6 weeks of walking.

In North America, pin firing is used mostly to treat splints; curbs; tendons and ligaments; and fetlocks and surrounding soft tissue injuries. A similar pattern is used for pin firing curbs and splints (S.P.D.). Marks are made down the center of the lesion, 1 cm apart. Alternating rows, medially and laterally, 0.5 cm between the original marks are then made. When firing tendons or ligaments, a similar pattern is used, but the point never goes through the deep layer of epidermis. However, areas of maximum damage are re-fired to ensure deeper penetration to focus the healing process. The horse may require sedation and analgesia for 24 hours after treatment to control pain. The area is painted with firing paint for 10 days, covering it with gauze, a quilt, and bandage. Another 30 days of rest are required before re-evaluating the horse. The total convalescent period depends on the initial injury. In sport horses, use of cryotherapy to treat splints and some soft tissue injuries is more common. Although cryotherapy is less invasive, the procedure is often less effective (see Chapter 90).

Current thoughts on thermal injury to tissues still emphasise the gulf between veterinary science and veterinary practice. Although much excellent science has illuminated the injury and healing of strained tendons, such injuries are still the most significant injuries a flat racehorse can sustain and are a long-term threat to the horse's continuing career. Horses that race over fences (steeplechasers) or hurdles seem to manage better than those that race at a faster pace on the flat. The expectation that counterirritation would produce a fiber pattern with crimp and better-quality collagen may have been ill-founded, but the results that veterinarians have experienced over the years need to be explained. Perhaps the mechanical side effect of pin fire scars, evening out the differing strength and elasticity along the length of the injured tendon and in the contralateral limb, has kept pin firing in equine orthopedics. Beyond enforced rest and low-grade exercise, seeing benefit accruing from blisters used in horses with tendon strain is difficult.

Aggressive anti-inflammatory treatment in the early post-injury phase is important, but one author (D.E.) is uncertain if subcutaneous corticosteroids are essential to a good long-term result.

New treatment regimens such as intralesional glycosaminoglycans or β-aminoproprionitrile fumarate have disappointed, and surgical splitting or proximal accessory desmotomy have not always justified the expense in the United Kingdom. Prolonged rest and controlled exercise regimens seem as successful as any treatments.

The choice of treatment still emerges from consensus between the experiences of the veterinary surgeon, the trainer, and the owner. All equine veterinary surgeons share the fervent hope that successful and rational therapy for strained flexor tendons will emerge soon.

Restrictions on using firing by the Royal College of Veterinary Surgeons were initiated by a question in the Houses of Parliament about the firing of horses. The Horserace Betting Levy Board then funded a research program by the Bristol group, led by Professor Ian Silver. This work was published in a supplement to the *Equine Veterinary Journal*.[4] Extensive discussion followed, but in 1991 the Royal College of Veterinary Surgeons tried to outlaw the technique of firing tendons, by declaring that they deplored it and would bring disciplinary action against any member performing it. This was not well received by a substantial number of respected equine veterinary surgeons and the policy was one that had been poorly thought through, did not recognize hard tissue firing, and proved to be unenforceable. A compromise was later reached, whereby veterinary surgeons had to show that other treatments had failed and to justify their choice of firing a particular horse. The technique continues to be used, but since the introduction of ultrasonography and the retirement of veterinarians who preferred it, firing has diminished considerably. One author (D.E.) believes that firing would have gradually disappeared without legislation.

Techniques currently used in equine orthopedics have become more conservative since the introduction of ultrasonography and the development of finer sensitivity among horse owners. The regular monitoring of these horses has

enabled more rational advice to be given as to healing of the lesions and programming of exercise. Thus the implementation of direct therapy has taken second place among certain groups of clinicians. They remain cynical about therapy while maintaining client confidence through regular observation of the patient. Splitting or needle decompression of a tendon core lesion soon after injury is a rational first step, followed by regular monitoring and controlled, graded exercise throughout a long convalescence. The old adage of the longer the rest, the better still seems valid.

CHAPTER • 90

Cryotherapy

Kjerstin M. Jacobs and Thomas P.S. Oliver

Cryotherapy has been used widely in veterinary medicine since the 1970s, primarily for tumor ablation. Percutaneous cryotherapy, called *freeze firing* or *freezing,* is a useful palliative technique for various musculoskeletal disorders in the horse, but little research has been published on specific techniques or results.[1-4] Most of the information in this chapter comes from our clinical experience using cryotherapy to manage selected lameness conditions. Cryotherapy generally is used for pain management and our recommendations are made assuming the horse will continue or resume athletic performance.

MECHANISMS OF CRYONECROSIS

Freezing mammalian tissue results in direct and indirect cell destruction. Direct cell injury occurs by formation of intracellular and extracellular ice crystals, which destroy cell walls and cause intracellular dehydration, respectively. Intracellular dehydration causes severe electrolyte concentration and pH shifts, which damage lipoprotein membranes and organelles. Loss of cellular homeostasis results in cell death. Indirect cell injury occurs by damage to the endothelium of arterioles and venules, causing increased vascular permeability, edema, and hemoconcentration. Local tissue damage occurs from thrombosis and infarction of small vessels. Two rapid-freeze, slow-thaw cycles are used. Rapid freezing maximizes intracellular crystal formation and crystal size. Slow thawing causes additional cell damage by a process of re-crystallization, during which time crystals increase in size before melting. Pre-cooled tissue freezes faster than normal tissue; therefore a second freeze-thaw cycle optimizes the processes of tissue destruction.

Because cryotherapy causes tissue destruction in situ, fibrous structures such as epineurium remain intact. This allows for regeneration of large myelinated nerves. Experimental percutaneous cryotherapy of equine palmar and plantar digital nerves resulted in neuropraxia (temporary ablation of nerve function, but the axons remaining intact) or axonotmesis (Wallerian degeneration of axonal tissue, with the fibrous supportive tissue remaining intact). All nerves regenerated.[5] The degree of nerve damage is temperature dependent, with lower temperatures resulting in longer duration of analgesia.[6]

Presumably, percutaneous cryotherapy causes destruction of local type C nerve fibers. Type C fibers are small, unmyelinated, nociceptive nerve fibers that contribute to chronic pain. The inflammatory response to cryotherapy appears to cause thickening and fibrosis of certain soft tissues, such as the suspensory ligament and subcutaneous tissues, and although this effect has not been studied, the clinical result is a stronger ligament and one less likely to be re-injured in the same location. Cryogens must be used judiciously on the distal limb to avoid cryonecrosis of tendon, ligament, joint tissues, or cortical bone.

BASIC TECHNIQUE

Cryotherapy instruments and cryogens are described elsewhere, and only basic principles are discussed here.[7-9] Instruments used to apply cryogens vary from simple cryoprobes to cryounits with continuous closed-system flow of cryogen liquid. We use liquid nitrogen that is stored in a commercial 10- to 20-L tank. For all techniques we use individual brass probes, 1.5 cm in diameter (Fig. 90-1), pre-cooled in liquid nitrogen and positioned on the lesions for a double freeze-thaw cycle consisting of freezing (60 seconds), thawing (60 seconds), and freezing (60 seconds). Local edema formation is minimal and has no effect on the second freezing cycle. Earlier work suggested that a thaw duration of 15 seconds was optimal, but our modified cycle appears effective.[4] We prefer to use solid metal probes, because consistent freezing to a specific depth is easy to control (Fig. 90-2). The cooling ability of solid metal probes has been questioned, but in one study solid metal probes were most effective in freezing to specific depths.[7]

Cryotherapy is well tolerated by most horses, but sedation and a twitch are used. Local analgesia (a ring block proximal to the freeze site) may be necessary for highly strung or fractious horses. The area over the lesion is clipped with a No. 40 blade and cleaned of gross contamination with iodophor or chlorhexidine solution. The limb is dried and a 0.5-cm thick

enabled more rational advice to be given as to healing of the lesions and programming of exercise. Thus the implementation of direct therapy has taken second place among certain groups of clinicians. They remain cynical about therapy while maintaining client confidence through regular observation of the patient. Splitting or needle decompression of a tendon core lesion soon after injury is a rational first step, followed by regular monitoring and controlled, graded exercise throughout a long convalescence. The old adage of the longer the rest, the better still seems valid.

Cryotherapy

Kjerstin M. Jacobs and Thomas P.S. Oliver

Cryotherapy has been used widely in veterinary medicine since the 1970s, primarily for tumor ablation. Percutaneous cryotherapy, called *freeze firing* or *freezing,* is a useful palliative technique for various musculoskeletal disorders in the horse, but little research has been published on specific techniques or results.[1-4] Most of the information in this chapter comes from our clinical experience using cryotherapy to manage selected lameness conditions. Cryotherapy generally is used for pain management and our recommendations are made assuming the horse will continue or resume athletic performance.

MECHANISMS OF CRYONECROSIS

Freezing mammalian tissue results in direct and indirect cell destruction. Direct cell injury occurs by formation of intracellular and extracellular ice crystals, which destroy cell walls and cause intracellular dehydration, respectively. Intracellular dehydration causes severe electrolyte concentration and pH shifts, which damage lipoprotein membranes and organelles. Loss of cellular homeostasis results in cell death. Indirect cell injury occurs by damage to the endothelium of arterioles and venules, causing increased vascular permeability, edema, and hemoconcentration. Local tissue damage occurs from thrombosis and infarction of small vessels. Two rapid-freeze, slow-thaw cycles are used. Rapid freezing maximizes intracellular crystal formation and crystal size. Slow thawing causes additional cell damage by a process of re-crystallization, during which time crystals increase in size before melting. Pre-cooled tissue freezes faster than normal tissue; therefore a second freeze-thaw cycle optimizes the processes of tissue destruction.

Because cryotherapy causes tissue destruction in situ, fibrous structures such as epineurium remain intact. This allows for regeneration of large myelinated nerves. Experimental percutaneous cryotherapy of equine palmar and plantar digital nerves resulted in neuropraxia (temporary ablation of nerve function, but the axons remaining intact) or axonotmesis (Wallerian degeneration of axonal tissue, with the fibrous supportive tissue remaining intact). All nerves regenerated.[5] The degree of nerve damage is temperature dependent, with lower temperatures resulting in longer duration of analgesia.[6]

Presumably, percutaneous cryotherapy causes destruction of local type C nerve fibers. Type C fibers are small, unmyelinated, nociceptive nerve fibers that contribute to chronic pain. The inflammatory response to cryotherapy appears to cause thickening and fibrosis of certain soft tissues, such as the suspensory ligament and subcutaneous tissues, and although this effect has not been studied, the clinical result is a stronger ligament and one less likely to be re-injured in the same location. Cryogens must be used judiciously on the distal limb to avoid cryonecrosis of tendon, ligament, joint tissues, or cortical bone.

BASIC TECHNIQUE

Cryotherapy instruments and cryogens are described elsewhere, and only basic principles are discussed here.[7-9] Instruments used to apply cryogens vary from simple cryoprobes to cryounits with continuous closed-system flow of cryogen liquid. We use liquid nitrogen that is stored in a commercial 10- to 20-L tank. For all techniques we use individual brass probes, 1.5 cm in diameter (Fig. 90-1), pre-cooled in liquid nitrogen and positioned on the lesions for a double freeze-thaw cycle consisting of freezing (60 seconds), thawing (60 seconds), and freezing (60 seconds). Local edema formation is minimal and has no effect on the second freezing cycle. Earlier work suggested that a thaw duration of 15 seconds was optimal, but our modified cycle appears effective.[4] We prefer to use solid metal probes, because consistent freezing to a specific depth is easy to control (Fig. 90-2). The cooling ability of solid metal probes has been questioned, but in one study solid metal probes were most effective in freezing to specific depths.[7]

Cryotherapy is well tolerated by most horses, but sedation and a twitch are used. Local analgesia (a ring block proximal to the freeze site) may be necessary for highly strung or fractious horses. The area over the lesion is clipped with a No. 40 blade and cleaned of gross contamination with iodophor or chlorhexidine solution. The limb is dried and a 0.5-cm thick

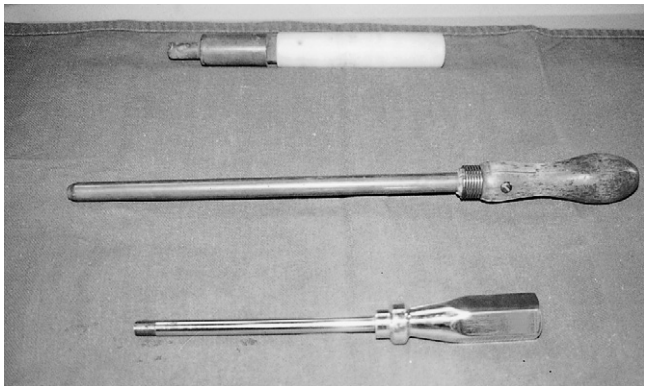

Fig. 90-1 Solid brass cryoprobes commonly used for cryotherapy in the horse.

Fig. 90-2 Cryotherapy is being used to manage pain associated with exostosis of the fourth metacarpal bone in a Standardbred racehorse. A double freeze-thaw cycle has been used in one site, and the probe is being applied at a distal site.

layer of water-soluble gel is applied generously over the site. This layer provides a template to ensure accurate positioning for the second freeze cycle.

The metal probe tip is applied to the skin for 60 seconds, then removed to allow thawing, and re-applied (see Fig. 90-2). No benefit accrues from a third freeze-thaw cycle, and in fact a third cycle may lead to underlying bone necrosis. Freeze sites should be located 1 cm apart in staggered, parallel rows that cover the lesion site and extend 1.5 cm beyond the margins of the lesion. If freezing sites are closer than 1 cm, the areas of skin necrosis will coalesce and later slough.

After completing the procedure, the leg is cleaned of lubricant and the sites are covered with an anti-bacterial spray. The leg should be left unbandaged, but it is kept dry, and antibacterial spray is applied daily until skin healing is complete. Local soft tissue swelling and edema develops and persists for 7 to 10 days and then gradually resolves. The administration of anti-inflammatory agents should be avoided, because this medication limits the intended effect of cryotherapy. Percutaneous cryotherapy destroys melanocytes in skin cells, so hair regrowth will be white. This negative cosmetic effect should be considered when discussing complications of cryotherapy.

TREATMENT OF SPECIFIC LESIONS

Diagnosis always should be confirmed using diagnostic analgesia, because results obviously are improved if the painful area is identified correctly. Most horses return to full function and race performance within several days to weeks, but some (e.g., those treated for severe suspensory desmitis) require up to 120 days of rest after treatment. When managing horses with suspensory desmitis, rest is paramount but is a source of frustration for trainers and owners, who often want to rush a horse back to the races.

Splint Exostoses (Splints)

Exostoses of the second, third, and fourth metacarpal and metatarsal bones should not be treated until acute inflammation has subsided, because cryotherapy may exacerbate periosteal reaction. Horses are given 2 weeks of rest during which a poultice is applied for 5 days, followed by the application of a cedar oil blister for 5 to 7 days. Scurf from the blister is removed by sweating before cryotherapy is performed. Horses with chronic splints can be managed with cryotherapy without this 2-week preparation period. After cryotherapy in any horse, stall rest is recommended for 3 to 5 days. The horse then may be jogged or galloped lightly and brought back into full training within 7 to 10 days after treatment. Prognosis is good for return to racing. The procedure may be repeated at the same site, or at additional sites, if pain recurs or new sites develop.

Second and Fourth Metacarpal or Metatarsal Fractures

Ostectomy of distal fragments of the second or fourth metacarpal or metatarsal bones is ideal, but in some horses surgery is not an option and cryotherapy can provide analgesia. Acute inflammation must be resolved before treatment. A single freeze site is placed directly over the fracture site, and four more sites are frozen in a circular pattern around the fracture site. Prognosis and rest depend mostly on extent of associated suspensory desmitis, if present, because horses with simple splint bone fractures can return to work immediately. Horses with mild suspensory desmitis have a good prognosis for return to racing and usually receive 60 days of rest after cryotherapy. Horses with severe suspensory desmitis require a minimum of 120 days of rest and have a guarded prognosis.

Periostitis of the Third Metacarpal Bone (Bucked Shins)

Cryotherapy can be used to manage pain associated with bucked shins once acute inflammation has subsided. A dorsal cortical fracture of the third metacarpal bone must be ruled out, because cryotherapy in horses with fracture is contraindicated. Once swelling and palpable pain resolve, cryotherapy is performed using three vertical rows of eight to nine freeze sites per row. After cryotherapy, 2 weeks of stall rest with hand walking followed by 4 weeks of turnout exercise is given. Prognosis is excellent and few horses require additional treatments.

Suspensory Desmitis

Ultrasonography must be performed first to determine the severity and extent of desmitis. Before cryotherapy, acute inflammation is managed using rest, anti-inflammatory medication, and local therapy, such as cold-water hosing and poultice application. Cryotherapy is then performed using a vertically

oriented row of freeze sites, beginning 3 cm proximal and extending 3 cm distal to the lesion. It is crucial that each freeze site is 1 cm apart and is located directly over the body of the suspensory ligament and not over the deep and superficial digital flexor tendons. Cryotherapy is performed over each affected branch. If suspensory body desmitis is present, the procedure is performed on the medial and lateral aspects. Horses are given a minimum of 2 weeks of stall rest with hand walking, followed by 2 weeks of turnout or swimming physiotherapy. The suspensory ligament and overlying tissue become fibrotic and rigid after treatment and, although tissue may appear strong to laypersons and the horse may be sound at the walk and trot, it is essential to recommend a conservative return to training and racing. Prognosis always is guarded, but most Standardbred racehorses return to racing. Suspensory desmitis is often a compensatory condition caused by contralateral limb lameness, or lameness in a diagonal or ipsilateral limb, and management of the primary problem is critical in decreasing recurrence. Cryotherapy is seldom effective for long-term management of suspensory desmitis if primary lameness continues. After developing suspensory desmitis, horses may drop in race class and value, but cryotherapy has been a useful adjunct in managing pain and allowing continued racing.

Distal Hock Joint Pain (Jack Spavin or Cunean Tendonitis)

Cryotherapy is useful in managing horses with distal hock joint pain. A double horizontal row of freeze sites over the proximal and distal borders of the cunean tendon is used. The horse is given stall rest with hand walking for 2 weeks. Prognosis is excellent for return to racing in the Standardbred racehorse.

Osteoarthritis of the Proximal Interphalangeal Joint

Chronic pain from osteoarthritis of the proximal interphalangeal joint may be alleviated partially using cryotherapy and is most useful in those horses in which palmar digital neurectomy fails to abolish all pain originating from the proximal interphalangeal joint, especially in those with severe bone lysis and proliferation and in which arthrodesis is not an option. Pain relief sometimes can be achieved by placing cryotherapy sites 1 cm apart, encircling the proximal interphalangeal joint proximal to the lesion, and directly over the sites of bony proliferation. It is important to avoid the superficial digital flexor and deep digital flexor tendons. After treatment, horses are given stall rest with hand walking for a minimum of 3 weeks. Prognosis is guarded.

Curb

Curb, a collection of injuries located along the distal, plantar aspect of the tarsus, can be managed successfully using cryotherapy (see Chapter 79). Acute inflammation must be resolved, a process that may take as long as 7 to 10 days. The number of cryotherapy sites depends on the size of the curb, but 8 to 12 sites are usually required. Horses are given stall rest with hand walking for 2 to 3 weeks, but further rest depends on the structure involved and severity of initial lameness. Prognosis is usually good, but some horses require additional treatment within 6 to 12 months.

Cryoneurectomy

Cryotherapy can be useful to provide analgesia to the palmar or plantar aspects of the digits, but the degree of cryoanalgesia depends on the technique used. Percutaneous cryoneurectomy has limited clinical use, because only temporary pain relief (3 to 4 weeks) is achieved.[5] Cryoneurectomy was more effective in producing neuroanalgesia than was simple transection, but the former procedure requires a surgical approach.[10] The nerves are exposed and transected, and the proximal ends are frozen.

A modified approach can be used.[5] The palmar or plantar digital nerves are exposed and a double freeze-thaw technique is used to freeze the nerve within the perineurium, but the nerve is not transected. Analgesia is longer than with percutaneous cryotherapy, but having to expose the nerves limits the practical application of this technique.

Tendonitis

We feel management of superficial digital flexor or deep digital flexor tendonitis with cryotherapy is contraindicated. After cryotherapy, fibrous tissue formation along the tendon fibers and possible scarring and adhesions of the tendon sheath can occur and limit prognosis. Although we are aware of horses that have raced after cryotherapy for tendonitis, we suggest that other management options be explored (see Chapters 70 and 71).

CHAPTER • 91

Radiation Therapy

Alain P. Théon

Radiation therapy is the use of ionizing radiation to treat patients with malignant tumors and, occasionally, selected benign diseases. The analgesic action of ionizing radiation for chronic orthopedic conditions has long been recognized and was first reported soon after the discovery of x-rays.[1] The effectiveness of radiotherapy has been demonstrated in people suffering from painful, degenerative joint diseases that were refractory to first-line conservative treatment; for example, non-steroidal anti-inflammatory drugs and physiotherapy.[2] In horses radiation therapy was found to be effective for painful degenerative and inflammatory musculoskeletal conditions early in the development of veterinary radiation therapy.[3] However, limited access to treatment facilities for horses, fear of the long-term hazards of ionizing radiation, and the availability of potent anti-inflammatory drugs have decreased the impact of radiation therapy in the overall management of equine lameness. Although most clinical studies on using radiation therapy for equine chronic orthopedic conditions were reported in the 1960s and the 1970s, current interest is renewed because of a better understanding of the mechanisms of action of radiation and identification of specific indications for treatment. Two studies are currently under way at the University of California, Davis, Veterinary Medical Teaching Hospital for treatment of chronic synovitis and prevention of excessive bone proliferation. In addition the emergence of the specialty of veterinary radiation oncology will provide the expertise and personnel for expanding the applications of radiation therapy for treatment of non-cancerous conditions at veterinary schools and private referral practices.

RADIOBIOLOGICAL ASPECTS

Radiotherapy of non-malignant conditions requires low doses of radiation, usually one fifth to one tenth the dose used in cancer treatment. The radiobiological mechanisms involved in the therapeutic effects of low-dose radiation used for benign conditions are different from those mediated by high radiation doses used to treat cancer. The therapeutic effects of radiotherapy for cancer result from cell death and inhibition of tumor cell proliferation. The therapeutic effects of low-dose irradiation in treating painful musculoskeletal disorders result from several distinct mechanisms.

Early data indicating an increase in dermal blood flow and cutaneous temperature after treatment[4] led to the misconception that radiation therapy produces a deep counterirritation that promotes increased blood flow and cell recruitment to the treated area to expedite healing.[5] This theory, however, is not supported by any current data. The previously observed effects merely reflect inaccurate dosimetry that resulted in high radiation doses to the skin. In addition, evidence shows that counterirritation during the chronic stage of inflammation prolongs healing time and results in further damage.[6]

Modern theories on mechanisms of low- to medium-dose radiation for treatment of non-cancerous conditions are based on new experimental data. The mechanisms are grouped into anti-inflammatory effects, analgesic effects, and anti-proliferative effects.

Anti-Inflammatory Effects

Whereas good evidence exists that high radiation doses induce strong inflammation in normal tissues, equally good evidence exists that low radiation doses have the opposite effect in inflamed tissues. Low-dose radiation therapy has a pronounced anti-inflammatory effect on acute and chronic inflammatory processes in joints and peri-articular tissues. In experimental animal models of osteoarthritis, low-dose irradiation reduced bone loss, synovial proliferation, cartilage degradation, joint swelling, and pain.[7]

The anti-inflammatory effects of irradiation are not caused by cytotoxic effects, because the low doses used are not lethal to cells, and activated inflammatory cells, including lymphocytes,[8] monocytes, and macrophages,[9] have lost the clonogenic potential and are therefore radioresistant.

Clinically observed anti-inflammatory effects of low-dose irradiation appear to result from functional alteration in cells involved in the inflammatory response. Adhesion of white blood cells to activated endothelial cells and induction of nitric oxide synthetase in activated macrophages are reduced. Radiation decreases leukocyte adhesion, thereby reducing recruitment of granulocytes to inflamed tissue, which results in decreased proteolytic enzyme release and reduced tissue necrosis. Radiation-induced inhibition of nitric oxide production results in reduced inflammatory reaction.[9,10] Good evidence also exists that radiation-induced reduction of monocyte and macrophage cytokines prevents excessive fibrosis.[11]This may explain subjective reduction in joint capsule fibrosis and the functional improvement after treatment of osteoarthritis.[12]

Analgesic Effects

The analgesic effects of ionizing radiation on degenerative and inflammatory disorders are manifested by early effects of short duration, followed by long-term, delayed effects. The delayed effects, characterized by long-lasting pain relief that develops several weeks after treatment, result from the anti-inflammatory effects of radiation. Early effects, characterized by fast pain mitigation, result from radiation-induced modulation of the afferent nociceptive pathways. Analgesia involves non–opioid- and opioid-mediated mechanisms. Although the opioid-mediated analgesia is poorly understood,[13] the non-opioid mechanisms (which include modification of pain transmission and perception) appear to be mediated in part by nitric oxide.[14-16] Radiation-induced decrease in local nitric oxide production results in desensitization of the nociceptors[17] and prevention of neuropathic pain development.[18]

Anti-Proliferative Effects

Ionizing radiation inhibits cell proliferation and temporarily reduces the production of new cells. This mechanism is assumed for prevention of new bone growth and treatment of chronic synovitis. Low-dose irradiation does not interfere with normal bone healing, because native osteoblasts are not

irreversibly inactivated by radiation. However, irradiation can inhibit excessive new bone formation from existing bone and within muscle after trauma or surgery. Radiation target cells are pluripotent mesenchymal stem cells that are stimulated to proliferate and differentiate into osteoblasts after trauma (e.g., injury or surgery) as a result of the healing process.[19]

Surgical trauma initiates a sequence of events during which cell proliferation takes place within a specific time. Radiation done during this period induces a delay in cell production that results in a full and permanent therapeutic effect. In people the ability of irradiation treatment to interfere with the formation of heterotopic bone is limited to 4 hours before surgery to 48 hours after surgery.[20] In horses the timing of radiotherapy to prevent new bone growth is also important and irradiation usually is done immediately after surgery. In ponies with experimental osteochondral defects in the antebrachiocarpal and middle carpal joints, radiation therapy was not effective in preventing periostitis and peri-articular osteophytes when given 6 weeks after surgical trauma.[21] For mature ossification, irradiation alone has no value beyond pain control.

In treating chronic synovitis the anti-proliferative effects of irradiation only delay progression of the disease process, because no critical period exists during which cell proliferation is required for the expression of damage. The goal of radiation-induced synovectomy is to ablate inflamed, proliferative synovium, with the expectation that after treatment the regenerated synovium will be free of disease.

Treatment Side Effects

Much of the concern surrounding using irradiation to manage benign conditions is the presumed risk of radiation-induced malignancy. The low doses used, however, are below the threshold associated with an identifiable risk of malignant transformation. In horses, development of in field sarcoma secondary to radiation therapy to manage benign conditions has not been reported. Reported skin and bone damage likely reflect inadequate treatment techniques according to modern standards.

Skin Damage

Skin damage including epilation, dry desquamation, and regrowth of depigmented hair was often seen when low-energy orthovoltage radiation or insufficiently filtered radioisotope sources were used. The use of modern irradiation techniques and high-energy megavoltage radiation has eliminated the risk of skin overdose and skin reactions are no longer observed.

Osteopenia

Similar to findings in people, experimental[21,22] and clinical (University of California, Davis, Veterinary Medical Teaching Hospital, unpublished data) studies in mature horses have shown that low doses of radiation (<10 Gy) do not affect bone density measured radiographically and do not increase risk of fracture. Although irradiation inhibits excessive bone remodeling and periosteal reactions after surgery, it does not appear to interfere with bone healing. In immature horses, the use of radiation therapy to treat periostitis and arthritis is discouraged because radiation interferes with bone growth.[23]

IRRADIATION TECHNIQUES

The administration of ionizing radiation is analogous to the prescription of medications based on pharmacological principles. Radiation doses are expressed in gray (Gy), the Système International unit, which has replaced the roentgen (R) and the rad (radiation absorbed dose; 1 Gy = 100 rad).

Before treatment, areas to be irradiated must be identified radiographically to ensure delivery of the radiation dose to the appropriate target volume. Radiotherapy techniques vary considerably based on tissue involved, location, and equipment available. Two methods of irradiation available for treatment of benign lesions in horses are teletherapy (external beam therapy) and brachytherapy.

External Beam Irradiation

Teletherapy involves the external administration of radiation therapy (at a distance of 50 to 100 cm from the area to be treated) by machines that emit x-rays or γ-rays, which can be collimated and directed precisely at the lesion. No difference exists in the mechanism of action between x-rays or γ-rays. In the past, treatments were done with low-energy orthovoltage x-ray units[24-26] producing low-energy x-rays (60 to 90 keV), and the radiation dose was given in a series of three to five exposures. Dosimetry was inaccurate because of the poor penetration of radiation and movement of the standing horse that was physically restrained during treatment. Currently, teletherapy is done exclusively with linear accelerators that produce high-energy x-rays or telecobalt units that produce high-energy γ-rays.[27] The advantages of high-energy (>1000 keV) radiation include skin sparing, deep penetration into tissue, and precise dosimetry. A distinct disadvantage of this technique is the need for general anesthesia to ensure accurate positioning and immobilization of the horse during treatment. Delivering a single radiation dose ranging from 8 to 12 Gy takes 6 to 8 minutes, so complete immobilization is crucial. Accurate radiographic definition of the area to be treated is essential for efficacy and sparing of the surrounding normal tissues.

This treatment method requires high investment in equipment and involves the registration of the radiation therapy unit with government agencies. As a result, such treatments for horses are usually provided at veterinary schools.

Brachytherapy

Brachytherapy is a treatment in which radioactive sources are applied directly to the area to be treated. The short distance between the radiation source and the lesion allows delivery of the radiation dose with minimal exposure to surrounding, uninvolved normal tissues. The disadvantage is radiation exposure to the radiotherapist during positioning and removal of the sources and to personnel responsible for the care of horses during treatment.

Treatment involves using sealed radioactive sources implanted directly into tissues (interstitial brachytherapy) or arranged into an applicator positioned on the skin above the area to be treated (surface brachytherapy). An alternative approach consists of injecting unsealed radioisotopes into a joint space (intracavitary brachytherapy) to deliver the radiation dose directly to the synovium.

This treatment method requires minimum facility and equipment investment, but obtaining a license for laboratory and industrial use of radioactive materials is necessary. This type of license is issued only to an individual that can document extensive training and experience in the safe use of radioisotopes for medical and veterinary purposes.

Interstitial Brachytherapy

Radon gas (^{222}Rn) in beads and radioactive gold (^{198}Au) pellets that emit γ-rays have been used for interstitial brachytherapy. Radioactive sources are inserted permanently and slowly deliver the radiation dose to the surrounding tissue, until complete decay occurs. To minimize personnel exposure, the implantation procedure is done in two steps: first, the insertion of unloaded needles in tissues according to specific radiation planning rules; and second, the loading of the needles with radioactive sources using a special implantation instrument. Achieving consistently satisfactory implants requires a good deal of practice. Treatment is expensive, because radioactive

sources can be used only once. This technique is now used rarely and is not allowed in most areas of the United States (the reader may inquire at the local department of social and health services for state regulations, or with the appropriate government agency in other countries). The major drawback is potential radiation hazard, because the implant is still radioactive when the horse is discharged from the hospital.

Surface Brachytherapy

Surface brachytherapy (plesiotherapy) involves using a surface applicator containing an array of linear radioactive sources. The most common brachytherapy technique involves inserting radioactive sources in the form of rigid needles applied on the skin overlying the lesion. Radioactive cobalt (^{60}Co) and cesium (^{137}Cs) emit a useful beam of γ-rays and are the most common radioisotopes used. Rigid (cast)[28] or flexible (pack)[29] applicators must be light, immobile, well fitted, and comfortable because they are left in position for an extended period to deliver the radiation dose. Dose distribution in tissues depends on arrangement and number of radioactive sources. Treatment doses range from 5 to 15 Gy, given at a low-dose rate over 48 to 72 hours (Table 91-1). Horses must be confined to an isolation facility during treatment to manage the radiation safety hazard posed by large ambient exposure rates around the applicator. Once the dose is delivered and the pack is removed and stored in a shielded container, a radiation hazard no longer exists. The horse then can be discharged safely from the hospital.

Table • 91-1

Radiation Therapy for Painful Degenerative and Inflammatory Musculoskeletal Conditions in Horses

CONDITION	TREATMENT TECHNIQUE	RADIATION DOSE	NO. OF CASES	RETURN TO RACING (%)	REFERENCES
Osteoarthritis					
Carpus	Plesiotherapy with γ-radiation (^{222}Rn, ^{60}Co)	5-10 Gy	39	80	12, 24, 36, 37

Villonodular synovitis	Post-operative teletherapy with orthovoltage x-rays	12 Gy in 4 dose fractions	14	90	33
Tendonitis/Desmitis					
Suspensory ligament	Plesiotherapy with γ-radiation (^{222}Rn)	4.5-7 Gy	4	50	36
Flexor tendon	Plesiotherapy with γ-radiation (^{222}Rn, ^{60}Co, ^{182}Ta)	7-15 Gy	4	25	28, 37
	Teletherapy with orthovoltage x-rays (HVL: 0.5-1.3 mm Cu)	4.5-15 Gy given in 3 to 7 dose fractions	5	80	24, 26
New Bone Growth					
Splints	Plesiotherapy with γ-radiation (^{222}Rn)	4.5-9 Gy	4	50	36
	Post-operative plesiotherapy with γ-radiation (^{60}Co)	5 Gy	5	100	12
McIII periostitis	Plesiotherapy with γ-radiation (^{222}Rn)	9 Gy	2	100	35
	Teletherapy with orthovoltage x-rays (HVL: 0.5 mm Cu)	4-10 given in 3 to 7 dose fractions	8	37	26

* *HVL,* Half-value layer; *PIP,* proximal interphalangeal; *MCP,* metacarpophalangeal; *McIII,* third metacarpal bone.

Surface application has a distinct disadvantage over a therapeutic x-ray machine, because movement of the pack above the skin affects the radiation dose distribution on the area to be irradiated. The potential for source damage, release of radioactive material, and contamination of the facility for several years are other disadvantages.

Intracavitary Brachytherapy

Intracavitary brachytherapy is a new approach developed to concentrate the radiation dose in the target tissue and is used primarily to treat synovitis. Radiation is delivered by intra-articular administration of unsealed β-emitting radioisotopes. The short emission range of the β particles (electrons) provides a high radiation dose to the synovium in contact with the radioisotope. Diseased synovium is ablated, but the effects on the peri-articular tissues and underlying cartilage are minimal.

Several formulations have been developed to prevent leakage of radioisotope from the site of injection. Radiocolloids labeled with radioactive gold (^{198}Au), yttrium (^{90}Y), phosphorus (^{32}P), and rhenium (^{186}Re) and particulate radiopharmaceuticals labeled with radioactive dysprosium (^{165}Dy), holmium (^{166}Ho), and samarium (^{153}Sm) have been used successfully in people. The radioisotope used is based on the expected thickness of the synovium.[30] Hydroxyapatite microspheres labeled with ^{153}Sm have been shown to be safe and effective for intra-articular administration in horses. The estimated treatment doses ranged from 7 Gy to 34 Gy.[31]

CLINICAL APPLICATIONS

Irradiation has been shown to be efficacious for clinical treatment of painful degenerative and inflammatory musculoskeletal conditions in horses. The treatment goal is long-term pain relief and return to racing or performance. Although modern standards of clinical research cannot be applied to these clinical studies, the general message is a remarkable consistency in the response pattern.

Although radiation therapy should not be used indiscriminately, it should not be viewed as a last resort. Radiation therapy is effective in managing refractory, chronic stages of various degenerative disorders and should be used for conditions that do not respond within a few months to conservative treatments, including administration of non-steroidal anti-inflammatory drugs, local injections (corticosteroids or other anti-inflammatory products), physical therapy, and physiotherapy. Strenuous exercise should be avoided, and the horse should be given state-of-the-art physiotherapy after radiation therapy is used. General recommendations include stall rest with hand walking for 30 to 90 days and a gradual return to regular training over 60 to 90 days.

A summary of clinical results of radiotherapy for painful refractory orthopedic conditions is found in Table 91-1. Overall success rate was 60% to 70%, although data are not contemporary and techniques are different from those practiced today. Onset and duration of analgesia were often difficult to measure. Low success rates were found in horses with chronic conditions or in those in which many unsuccessful treatments had previously been performed.

Chronic Synovitis

When synovitis plays a major role in the arthritic process, radiation therapy may be advantageous. Treatment is directed at reducing synovial inflammation and proliferation to prevent progressive joint deterioration and control of joint effusion, fibrosis, and pain. Inflamed synovium induces damage to the articular surfaces by causing effusion, up-regulation of endothelial adhesion molecules, liberation of inflammatory mediators and destructive enzymes, and alterations in the synovial fluid constituents.[32]

Chemical, surgical, or radiation-induced synovectomy can be performed. Similar to surgical synovectomy, radiation synovectomy destroys diseased synovium, and the intent is to allow regeneration of normal synovium and amelioration of clinical signs. In people the duration of response after radiation synovectomy is related inversely to the amount of cartilage and bone destruction. These findings emphasize the importance of screening horses for radiological evidence of cartilage and bone destruction before considering radiation synovectomy. It is imperative to discriminate pain arising from inflamed synovium from that originating from cartilage or bone damage, so that horses with pain from the latter, which is likely to be unaffected by radiation synovectomy, do not undergo unnecessary treatment.

Irradiation is recommended in horses with chronic osteoarthritis, after osteochondral fragment removal if synovium is proliferative, in horses with idiopathic synovitis, and potentially as an ancillary treatment for infectious arthritis. The role of radiation therapy in treating infectious arthritis is limited to preventing chronic synovitis and treating reactive arthritis. Radiation therapy should not be used until bacteria are eliminated, because the anti-inflammatory effects of radiation can exacerbate infection. In addition, radiation therapy should be limited strictly to adult horses, because the anti-proliferative effects of radiation damage growing bones and joints in young horses. External beam irradiation can be used as adjuvant to incomplete surgical synovectomy.[33,34] Radiation doses of 7 to 10 Gy do not cause delayed wound healing or wound complications when the incision is excluded from the field of radiation. Intra-articular administration of ^{153}Sm is used as a single modality when thickness of the inflamed synovium does not exceed 1 mm.[30] Treated horses may experience transient pain (lameness), pitting edema, and effusion. In people, concomitant intra-articular injection of triamcinolone acetonide has been shown to prevent transient local reaction and to reduce pain.

Degenerative Bone and Joint Disorders

Radiation therapy is used to treat various types of equine lameness caused by inflammatory and degenerative changes affecting bones, joints, and tendons. The most common indications for radiation therapy include chronic traumatic arthritis and osteoarthritis of the carpal and fetlock joints, sesamoiditis, active carpitis with swelling and mild mineralization, and chronic carpitis. Radiographic examination should be performed before radiation therapy is performed. This helps ensure that the cause of lameness is not an osteochondral fragment or another condition that is best handled surgically. The anti-inflammatory and analgesic effects of radiation may stabilize the injury process in subacute and chronic painful disorders, when peri-articular new bone proliferation is minimal and damage to cartilage is not obvious. Joints with end-stage osteoarthritis are unlikely to benefit from irradiation.[25] Because radiation has no inhibitory effect on the degenerative processes in osteoarthritis, the treatment goal is limited to pain relief.

Radiation therapy can be used for tendonitis, tenosynovitis, and desmitis. Long-term results in horses with acute and subacute conditions are better than those with chronic conditions. In horses with chronic osteoarthritis, in which substantial peri-articular radiographic changes have occurred, radiation therapy is used to control inflammation and pain, and to prevent excessive fibrosis and calcium deposition, which can result in dysfunction, reduced joint motion, and deformity. Horses with severe osteoarthritis, which show extensive new bone, large amounts of mineralization of soft tissues, and evidence of cartilage destruction, are not treated routinely because they rarely improve enough to perform satisfactorily.

Treatment results have not been uniform because of many variables, including severity and location of the lesion, degeneration of the articular cartilage and pre-existing arthritis,

radiation dose and technique used, and duration of rest after treatment. In addition, questionable causes and pathogenesis make degenerative disorders prone to polypragmasy. Finally, the effects of enforced rest periods in the overall management are not known, which makes definitive assessment of the value of radiation therapy impossible.

The efficacy of plesiotherapy using ^{137}Cs packs was evaluated in 147 horses (46% Thoroughbreds, 27% Quarter Horses, and 12% Standardbreds) treated at the University of California, Davis, Veterinary Medical Teaching Hospital. The treatment dose was 12 Gy given over 24 to 32 hours. Treatment responses were judged to be good, meaning that the horse returned to racing and was sound, or poor, meaning that the horse showed no response or the response was temporary. The most common use was to treat osteoarthritis (characterized by bone remodeling, with lysis or proliferation, and narrowed joint spaces) affecting the carpal, metacarpophalangeal, and proximal interphalangeal joints. Treatment was most effective for carpitis (84% good response, $n = 51$), osteoarthritis of the proximal interphalangeal joint (77% good response, $n = 22$), and sesamoiditis (80% good response, $n = 12$), and least effective for osteoarthritis of the metacarpophalangeal joint (60% good response, $n = 25$) and splints (55% good response, $n = 20$). Overall results were less favorable for treatment of desmitis and tendonitis (64% good response, $n = 17$); however, horses treated in this study had a long history of lameness. Prognosis for horses with mild lameness caused by curb appeared favorable, because five of seven horses had a good response. Compared with previous reports (see Table 91-1), the better responses observed in this study may reflect the use of a higher radiation dose. The results should be interpreted cautiously, because this was not a controlled study and objective criteria of response were not available.

Preventing New Bone Growth

Post-traumatic exostosis occurs after repair of bone fractures (third carpal bone and third metacarpal or metatarsal bone condylar fractures) and after certain surgical procedures, such as arthrodesis and distal splint bone removal. The incidence of radiographic findings is higher than that of clinical signs and functional impairment. Risk factors that predispose horses to develop exostoses are not known. A history of previous new bone growth after surgery is the most substantial predisposing condition. Although a report described regression of excessive callus on a splint bone,[35] horses with painful mature exostosis or peri-articular and soft tissue calcification usually do not benefit from radiotherapy except for pain relief. These patients require excision of calcified tissue followed by post-operative irradiation.

Radiation therapy is a powerful prophylactic treatment to prevent abnormal ossification in stress-related bone and periosteal injury in racehorses. Treatments should be done with high-energy radiation, such as that produced by linear accelerators, or telecobalt units. Doses of 8 to 10 Gy are given in a single treatment. The effective therapeutic window reaches from a still undefined pre-operative time to about 2 days after surgery or traumatic soft tissue injury. In an ongoing, prospective study conducted at the University of California, Davis, Veterinary Medical Teaching Hospital, prophylactic irradiation was given to horses at risk of developing abnormal mineralization after surgery or horses with a previous history of peri-articular calcification and exostosis. A single dose of 10 Gy (1000 rad) was given using a linear accelerator (Clinac 4, Varian, Lake Oswego, OR) immediately after surgical curettage of the excessive bony proliferation. While they were under general anesthesia, horses were moved from the operating room to the radiation therapy suite. Close proximity of the two rooms at the hospital minimizes the potential for surgical and anesthetic complications during transportation. Interim results in 15 Thoroughbreds with a minimum of 12 months follow-up after treatment indicate that irradiation is effective in long-term prevention of abnormal mineralization, even after unsuccessful previous treatments including surgery, medical treatment, laser therapy, acoustic shock wave therapy, and ultrasound hyperthermia. Horses entered in this study had exostosis after trauma or fracture of splint bones, osteoarthritis of the proximal interphalangeal joint, or osteophytes associated with mild osteoarthritis.

Rest and Rehabilitation

Barrie Grant

The number of publications about the effects of exercise on bone, cartilage, and tendons has increased substantially in the past decade. The results of these investigations have allowed not only the research community, but also practicing veterinarians, to gain more insight into the effects of mild, moderate, and strenuous exercise on the skeletal system, especially regarding the pathogenesis of fractures and osteoarthritis. Unfortunately, results of controlled studies of the effects of deconditioning on bone, cartilage, and tendons have not been disseminated widely. Presently each clinician recommends a rest and rehabilitation program based many times on intuition, anecdotal experience, and tradition. These recommendations have withstood the test of time, however, and can serve as a guide.

In the last decade the number of alternative therapies and therapists has also increased. Although some benefits to this approach are possible, many of the modalities have not been tested in a standard scientific method, and popularity often is based on the principle that alternative approaches are less expensive, with faster results.

PRINCIPLES OF REST AND REHABILITATION PROGRAMS

The following are some basic principles that should be considered when formulating a specific plan for a specific injury.

1. Is the diagnosis complete? An incomplete diagnosis and thus treatment lead to poor results. Arthroscopic removal of a carpal fracture in the apparently lame limb will have poor results if an osteochondral fracture is in the contralateral fetlock joint. Hindlimb suspensory desmitis is unlikely to resolve satisfactorily if mild ataxia is concurrent. An expedient, complete, and accurate diagnosis affords the best chance for long-term success.
2. Horses can tolerate extensive periods of stall confinement without becoming deranged psychopaths. They do need to be in clean airy stalls, so they can see other horses, and energy intake should be reduced. Clinicians should avoid walking horses every 4 or 5 days to see how they are doing, because horses tend to find any excuse suddenly to jump or rear and possibly cause re-injury.
3. The heart and muscle do not undergo any significant deconditioning for at least 4 weeks after a standard anaerobic training program. Therefore many horses with minor injuries, or even a suspicion of a minor ligament or tendon problem, possibly can heal with 4 weeks of rest, with little loss in performance. The cardiac parameters actually improve 5 days after the last extensive training effort. Little will be lost and much could be gained if experienced jumping and dressage horses with lameness problems could be walked under tack for a week before major events.
4. An earlier return to training, in the form of walking under saddle, swimming, or controlled exercise on a treadmill, can reduce the potential chance for further injury than if a previously stall-confined horse is turned out in a paddock and allowed to run, buck,

Rest and Rehabilitation

Barrie Grant

The number of publications about the effects of exercise on bone, cartilage, and tendons has increased substantially in the past decade. The results of these investigations have allowed not only the research community, but also practicing veterinarians, to gain more insight into the effects of mild, moderate, and strenuous exercise on the skeletal system, especially regarding the pathogenesis of fractures and osteoarthritis. Unfortunately, results of controlled studies of the effects of deconditioning on bone, cartilage, and tendons have not been disseminated widely. Presently each clinician recommends a rest and rehabilitation program based many times on intuition, anecdotal experience, and tradition. These recommendations have withstood the test of time, however, and can serve as a guide.

In the last decade the number of alternative therapies and therapists has also increased. Although some benefits to this approach are possible, many of the modalities have not been tested in a standard scientific method, and popularity often is based on the principle that alternative approaches are less expensive, with faster results.

PRINCIPLES OF REST AND REHABILITATION PROGRAMS

The following are some basic principles that should be considered when formulating a specific plan for a specific injury.

1. Is the diagnosis complete? An incomplete diagnosis and thus treatment lead to poor results. Arthroscopic removal of a carpal fracture in the apparently lame limb will have poor results if an osteochondral fracture is in the contralateral fetlock joint. Hindlimb suspensory desmitis is unlikely to resolve satisfactorily if mild ataxia is concurrent. An expedient, complete, and accurate diagnosis affords the best chance for long-term success.
2. Horses can tolerate extensive periods of stall confinement without becoming deranged psychopaths. They do need to be in clean airy stalls, so they can see other horses, and energy intake should be reduced. Clinicians should avoid walking horses every 4 or 5 days to see how they are doing, because horses tend to find any excuse suddenly to jump or rear and possibly cause re-injury.
3. The heart and muscle do not undergo any significant deconditioning for at least 4 weeks after a standard anaerobic training program. Therefore many horses with minor injuries, or even a suspicion of a minor ligament or tendon problem, possibly can heal with 4 weeks of rest, with little loss in performance. The cardiac parameters actually improve 5 days after the last extensive training effort. Little will be lost and much could be gained if experienced jumping and dressage horses with lameness problems could be walked under tack for a week before major events.
4. An earlier return to training, in the form of walking under saddle, swimming, or controlled exercise on a treadmill, can reduce the potential chance for further injury than if a previously stall-confined horse is turned out in a paddock and allowed to run, buck,

slide, and turn quickly. If paddock turnout is used, then administering sedation and gradually increasing the size of the paddock are recommended. Leaving a horse in a paddock continuously also is best once the horse has been introduced to the freedom. If a horse is stabled each evening, then it tends to buck and play again each morning when released.

REST

The basic principle of rest is to reduce the force and strain on injured tissue and allow the normal reparative processes to proceed without further insult. Muscle tissue can heal in a much shorter period than tendons or ligaments, but the repair of cartilage is accomplished by the metaplasia of replacement tissue, which takes 4 to 6 months. The quality and quantity of rest depends on the severity of the condition, the disposition of the horse, the owner, and the trainer, and their expectations.

Complete Immobilization

Although complete immobilization can be accomplished with internal fixation, external coaptation with using a cast also can reduce the motion of fracture fragments and excessive strain placed on damaged ligaments or tendons. The long-term use of cast immobilization can result in osteoarthrosis (fracture disease) and osteopenia. Normal joints can tolerate at least 4 weeks of cast immobilization without significant irreversible change to the articular cartilage.[1] Well-designed splints and braces offer an alternative for conditions that do not require complete rest or as intermediary support in the transition from a cast to no external support.

Stall Rest

Stall rest is the most common form of rest recommended and is highly effective as long as weekly episodes of outside activity do not interrupt it. The effects of controlled exercise on articular cartilage remain controversial. French et al.[2] concluded that early post-operative exercise is not detrimental to repair of experimentally created osteochondral defects of the carpus. Other investigators suggested deleterious effects of early exercise on the healing of carpal osteochondral defects.[3] However, exercise may be beneficial in maintaining normal concentrations of glycosaminoglycan in insulted articular cartilage.[4] The administration of polysulfated glycosaminoglycans may have a protective effect against the deleterious results of early post-operative exercise on experimentally induced osteochondral defects.[3] Only a cost-benefit investigation with a significant number of horses will show if the expense of the medication is justified, with an earlier return to competition compared with horses restricted to stall rest.

Owners are always concerned about the effect that enforced stall rest can have on the mental status of horses, but provided energy intake is restricted and horses have visual contact with other horses, most adapt satisfactorily. Many horses lose muscle mass and tone during inactivity, which are rapidly restored, and horses that become overweight are less likely to return to athletic competition than leaner cohorts. It is important to stress good husbandry practices, because soiled wet bedding or infrequent hoof care can lead to chronic hoof problems. I have seen many horses with joint disease develop subsolar hematomas on the opposite limb predisposing to or because of the joint disease. These hematomas can become subsolar abscesses if the husbandry is inadequate.

Experience has shown that 60 days is the minimum amount of time necessary for the repair of soft tissues following orthopedic surgery,[2] but convincing eager and aggressive owners and trainers that this time is a positive economic decision is often difficult.

Reduction of Excessive Movement

Recent improvement in slings has helped horses with severe orthopedic and neurological problems to reduce the risk of further injury from difficulties in lying down and getting up and the risk of contralateral laminitis. We prefer the Liftex sling (Liftex, Inc., Warminster, PA) to the more complicated Anderson sling (CDA Products, Potter Valley, CA) for everyday use, although we recognize that the Anderson sling has some features that are helpful in lifting severely injured or neurologically compromised patients. Not all horses accept a sling, especially those under a year of age, and further injury can possibly occur if a horse becomes violent. Giving the horse a small amount of acepromazine reduces anxiety before a sling is applied. Having a short introductory period for the first session and rewarding acceptable behavior with food is helpful. Slings are not meant to provide vertical stability to patients who cannot stand by themselves. They are best used to provide a method for injured horses to reduce weight bearing for short periods. Experienced horses take full weight off the legs and sit as a person might in a hammock for short periods, two to three times an hour.

Use of cross-ties or overhead chains can also prevent excessive movement and force on injured areas from horses lying down and struggling to rise. Young horses do not accept this form of restraint well, which may increase the chance of injury because they fight the system. It is important to allow horses three to four sessions a day with the head down to prevent aspiration pneumonia that can occur with improper drainage of pulmonary secretions.

Paddock Rest

After stall confinement, tradition has stressed a period of paddock rest before a horse is returned to active training. When and how much paddock rest is based on each individual horse. The type of injury, response to treatment, personality of the horse and owners, and the season of the year are major considerations. In my experience horses can over-exercise and re-injure healing tissue or incur new injuries when turned out. The use of small paddocks (6 × 6 m) to inhibit running is a suitable compromise.

The initial introduction of the horse to the paddock is the time when most mishaps can occur. Sedation, protective boots (tendons and bell or overreach boots), and avoiding muddy, snowy, frozen conditions and unfamiliar horses greatly reduce injuries. Ideally the horse should be allowed to remain in the paddock at all times, instead of being turned out each morning after a night of stall confinement. It is necessary to continue to monitor the general health care of the patient, including anthelmintic prophylaxis and immunization against respiratory pathogens that are spread easily with horses communicating over adjacent fences. Foot care is still a concern. Many horses may require shoeing to prevent abnormal hoof wear, which could result in an uneven gait when they return to active training.

Ridden Walking

After stall confinement and hand walking, I prefer to ride the horse at walk, beginning with 10 minutes a day and progressing to 30 minutes a day after 30 days, rather than use paddock exercise. This increase of activity is felt to stimulate the maturation of repair tissue in cartilage and tendons.

EXERCISE

Passive Exercise

Passive exercise can begin immediately after joint surgery to reduce the amount of post-operative immobility. Theoretically, passive exercise improves distribution of nutrients to chondrocytes and reduces the number of synovial adhesions to any osteochondral defects on the edge of the joint. The type of

reparative tissue that develops under synovial adhesions is fibrous and not the hyaline-like material that fills a full-thickness defect when no synovial tissue has adhered to the defect.[5] We routinely begin passive joint movement on the first post-operative day. The joint is flexed just to the position that produces discomfort 15 to 20 times twice a day, for 30 days. Passive exercise is not indicated in joints with any detectable instability or in which a problem with primary healing of the joint capsule exists.

Hand Walking

Hand walking is the mildest form of active exercise and often is recommended along with stall rest. Although recommending hand walking early in the post-operative period is easy to appease owners, trainers, and the caretakers, it is also essential to realize that early disruption of a primary clot in an osteochondral defect can result in poor healing of the defect.[5] The chances of excessive and unpredictable behavior that can result in removal of the clot are increased with removing active horses from their stalls for short periods. The benefits of complete stall rest for the first 30 days far outweigh any benefit that 5 to 10 minutes of hand walking may produce. Hand walking for 5 to 10 minutes a day beginning at day 30, and gradually increasing to 30 minutes at post-operative day 60, is common practice. Hand walking seems to be the most objectionable form of exercise to owners and caretakers, because horses act up or the potential for them to do so is anticipated and dreaded. The new form of caged horse walkers appear to be much safer and, although horses are constantly turning, this appears to be a suitable form of exercise to replace hand walking. Alternatively, ridden walking exercise can be used.

Aquatreds and Swimming

Using swimming pools and submerged treadmills (aquatreds) is still popular and at least in specific locations has withstood the test of time. Minimal controlled data are available to document the benefits of these modalities for treating athletic injuries. That the cardiopulmonary system responds significantly to swimming has been documented, but only anecdotal information exists for aquatreds. Both modalities assist in increasing joint mobility and producing some physical activity in a controlled environment. The force to the axial skeleton is reduced and this benefits horses with a non-displaced fracture or a joint with advanced osteoarthritis. However, the reduction of the weight-bearing force in rehabilitation may not be desirable, because osteoporosis develops when training is curtailed for more than 30 days.[6] Returning the skeletal system to its previous competitive state requires a longer period of time than for muscles and the cardiopulmonary system. Reconditioning the muscles by swimming or aquatreds, before reconditioning the skeletal system, increases the possibility of having horses that are too eager and able to produce more force than the bones, joints, tendons, and ligaments can tolerate. The recognition that stress fractures of the humerus are more common in horses returned to training after only 30 to 60 days of rest bears testimony to the inability of the skeletal system to adapt to the stress of training as quickly as the muscle does.[7]

High-Speed Treadmills

The increase in the number of privately owned treadmills could increase the quality of healing of athletic injury. High-speed treadmills have a number of benefits for reconditioning equine athletes. The speed, distance, slope, heart rate, and climatic conditions can be controlled, monitored, and indeed with some systems, even programmed. Work effort can be increased with a weighted saddle and raising the slope of the treadmill, without having to increase the speed. The force on the tendons can be increased slowly by increasing the slope of the treadmill slowly.

Using treadmills for exercising horses is now accepted widely because the injury rate has been low if good judgment is used, especially when introducing a new horse. It is important to realize that training on a treadmill is not the same as racing or training on a racing surface. Horses require twice as much work on the treadmill at maximum oxygen consumption (V_{O_2}) to produce the same muscle changes as galloping on a training track with a rider.[8] Horses also require speeds of at least 14 m/sec to produce the same changes on implanted strain gauges in the third metacarpal bones as breezing on a racetrack.[9] Some treadmills cannot achieve this speed and lay operators often are reluctant to exercise horses at 14 m/sec, because they feel the horses may become injured.

We have found little problem with long-term training on a treadmill. Horses usually trot 1000 m at 4 m/sec and then gallop for 2000 m at 10 m/sec. We have not recognized any foot problems that may result from excessive time on the treadmill,[10] although the training plates are hot to the touch after a training session. A constant fine mist applied to the treadmill belt is supposed to reduce the heat. Recently it has been shown that prolonged treadmill training can result in carpal articular cartilage changes.[11]

Active Training

The importance of periodic monitoring for any subtle clinical signs as a horse progresses through the final stages of training before competition cannot be overstressed. The trainers with the most success in returning horses with athletic injuries to a successful career are those who are patient and careful observers. Horses often show signs of increased inflammation and gait abnormalities as the training intensity increases from tack walking and jogging to galloping. Reducing the amount and quality of the exercise for 30 days may be all that is necessary to reduce the inflammation, without medication.

Hill Training

It is possible to produce the same training effect by exercising horses on moderate inclines (e.g., ½ mile at 13% incline) at a 50% reduction in the speed of horses trained on a racetrack.[12] Trotting downhill is not necessary for most conditioning programs other than endurance or cross country eventing. Trotting downhill may lead to an increase in the incidence of proximal suspensory problems and also increases the forces on the stifle joint. I used interval training in fifteen 2-year-old Thoroughbreds being trained for racing, using a program consisting of three intervals with the first at an extended trot, the second at a canter, and the third at a gallop, and found the horses had minimal unsoundness and were competitive. Walking the horses downhill allowed time to recover and kept the horses relaxed and manageable.

Acupuncture

EQUINE ACUPUNCTURE FOR LAMENESS DIAGNOSIS AND TREATMENT

• Allen M. Schoen

Recently interest in veterinary acupuncture for lameness diagnosis and treatment has increased greatly in the public and veterinary medical communities. With this increased awareness has been an increase in veterinary acupuncture research and thus a better understanding of the physiological basis of acupuncture and its clinical applications. Acupuncture may be used as an adjunct diagnostic and therapeutic tool to our traditional lameness examination and to the treatment of lameness, but it is not meant to be a substitute.

With the increased interest in equine acupuncture, there has also been additional controversy and use and misuse of this modality. It is important to understand the scientific basis, traditional Chinese medical theories, and clinical indications and limitations for acupuncture to become part of an integrated approach to equine lameness in a professional manner. Currently, equine acupuncture is practiced by veterinarians trained in the Western medical perspective of scientific acupuncture and the traditional Chinese and Japanese medical theories. The approach may vary slightly based on the practitioner's perspective.

The history of equine acupuncture dates back to 2000-3000 BCE during the Shang and Chow dynasties in China. Around 650 BCE Bai-le wrote, *Bai-le's Canon of Veterinary Medicine*, one of the first veterinary textbooks, which described acupuncture and moxibustion in equine medicine. The first atlas of equine acupuncture points and channels, *Ma Jing Kongxiue Tu*, was written during the Sui period, between 581-618 CE.[1] Equine back pain was first addressed in the ancient veterinary textbook *Yuan-Heng Liao Ma Ji* (*Yuan-Heng's Therapeutic Treatise of Horses*).[2] Periodically, anecdotal reports of using equine acupuncture would come to the Western world. The first substantial introduction occurred in the 1970s, when the International Veterinary Acupuncture Society was established and developed training programs in veterinary acupuncture in the United States. In 1996 the American Veterinary Medical Association stated, "Veterinary acupuncture and acutherapy are considered valid modalities, but the potential for abuse exists. These techniques should be regarded as surgical and/or medical procedures under state practice acts. It is recommended that extensive continuing education programs be undertaken before a veterinarian is considered competent to practice acupuncture."[3] Postgraduate education in veterinary acupuncture throughout the world—including Australia, Europe, Scandinavia, North and South America, and other areas—is offered by the International Veterinary Acupuncture Society, based in Fort Collins, Colorado.[4] The Chi Institute of Traditional Chinese Medicine in Reddick, Florida[5]; Colorado State University College of Veterinary Medicine continuing education program in Fort Collins, Colorado[6]; Tufts University School of Veterinary Medicine in North Grafton, Massachussetts[7]; and the Veterinary Institute for Therapeutic Alternatives in Sherman, Connecticut,[8] also offer postgraduate programs in the United States.

SCIENTIFIC BASIS

Acupuncture may be defined in a Western medical perspective as the stimulation of specific predetermined points on the body to achieve a therapeutic or homeostatic effect. Recent research has provided evidence for the anatomical classification of acupoints. Acupuncture points are areas on the skin of decreased electrical resistance or increased electrical conductivity. Acupuncture points correspond to four known neural structures. Type I acupoints, which make up 67% of all acupoints, are considered motor points. The motor point is the point in a muscle which, when electrical stimulation is applied, will produce a maximal contraction with minimal intensity of stimulation. Motor points are located near the point where the nerve enters the muscle. Type II acupoints are located on the superficial nerves in the sagittal plane on the midline dorsally and ventrally. Type III acupoints are located at high-density foci of superficial nerves and nerve plexi. For instance, acupoint GB-34 is located at the point where the common fibular (peroneal) nerve divides into the deep and superficial branches. Type IV acupoints are located at the muscle-tendon junctions, where the Golgi tendon organ is located.[9] Recently, histological studies have revealed that small microtubules, consisting of free nerve endings, arterioles, and venules, penetrate through the fascia at acupuncture points (Fig. 93-1).[10]

Acupuncture has many varied physiological effects on all systems throughout the body. No one mechanism can explain all the physiological effects observed. The traditional Chinese medical theories have explained these effects for four thousand years, based on empirical observations and descriptions of naturally occurring phenomena. The Western medical theories include the gate and multiple gate theories, autonomic theories, humeral mechanisms, and bioelectric theories.[10] Detailed discussions of the neurophysiological basis of acupuncture are reviewed in a number of texts.[9-12] Essentially, acupuncture stimulates various sensory receptors (pain, thermal, pressure, and touch), which stimulate sensory afferent nerves, which transmit the signal through the central nervous system to the hypothalamic-pituitary system (Fig. 93-2). The acupoints correlate with cutaneous areas containing higher concentrations of free sensory nerve endings, mast cells, lymphatics, capillaries, and venules. Various neurotransmitters and neurohormones are then released and have subsequent effects throughout the body. Recent research in rabbits using electroacupuncture-induced neural activation, detected by the use of manganese-enhanced functional magnetic resonance imaging, demonstrated a corresponding cerebral link between peripheral acupoints and central neural pathways. Research like this is aiding in further

understanding the effects of local peripheral stimulation on specific areas in the brain.[13] Electroacupuncture has also been found to stimulate endogenous opioids, vasoactive peptides, adrenocorticotrophic hormone, cortisol, and catecholamine in cerebrospinal fluid and peripheral plasma in ponies.[14] Bossut et al.[15] documented changes in plasma cortisol and β-endorphin in horses subjected to electroacupuncture for cutaneous analgesia. Changes in serum proteins and blood gases also have been demonstrated in donkeys following acupuncture.[16,17] Xie et al.[18] documented that electroacupuncture could relieve experimental pain in the horse via the release of β-endorphin. They found that acupuncture stimulation using local acupuncture points with high frequency (80 to 120 Hz) is more effective than using distal points with low frequency (20 Hz). They found that acupoints close to the painful areas require high-frequency electroacupuncture stimulation, whereas the acupoints far from the painful areas may be stimulated with low-frequency electroacupuncture. Electroacupuncture generally is considered to have stronger effects than other types of acupuncture methods.[18] The degree of stimulation appears to depend on the location of the specific acupoints.[19,20]

Through understanding the neurophysiology and neuroanatomy of acupuncture, one can appreciate that acupuncture may stimulate nerves, increase local microcirculation to joints and muscles, relieve muscle spasms, and cause a release of various neurotransmitters. Clinically, one may see the benefits of these effects in treating equine lameness caused by soft tissue injury, muscle spasms, nerve trauma, and other causes.

TRADITIONAL CHINESE MEDICAL THEORIES

Acupuncture has been used in China to treat equine lameness for a few thousand years. Chinese acupuncture was based on the empirical use of acupoints for certain conditions. Historically, acupuncture meridians were not acknowledged in animals. Specific empirical points based on experience were identified and named for location or function. Equine acupuncture meridians, or pathways, have been transposed onto horses from human acupuncture maps only in the past thirty years.

Traditional Chinese medicine acupuncture diagnosis and treatment are based on the pattern differentiations that are developed from two main theories of traditional Chinese medicine: the Five Element theory and the Eight Principles, which require a great deal of study.[21] The traditional Chinese medicine diagnosis is defined as a specific pattern based on imbalances in the five elements (also called five phases), imbalances and disorders in specific meridians or organs, or specific patterns of disharmony. The diagnosis is based on a physical examination of the horse, including evaluation of the tongue and pulse. Tongue inspection includes evaluation of the color of the tongue, the moisture, and the color and thickness of any tongue coating. Palpation of the jugular pulse would be described as weak, strong, wiry, and so on. Tongue and pulse examination and an overall examination would lead to a traditional Chinese medicine diagnosis and treatment of appropriate acupuncture points. Xie[22] describes a traditional Chinese medicine five-step method for diagnosis and treatment. This includes the following:

1. Collection of empirical data from the history, tongue, and pulse diagnosis
2. A Western medical diagnosis
3. A traditional Chinese medicine pattern differentiation
4. A treatment strategy based on traditional Chinese medicine
5. A selection of appropriate acupuncture points, Chinese herbs, or both

In contrast, the Japanese technique, frequently termed *meridian therapy,* is based more on palpation of the acupuncture points and the reaction. The anatomical location of equine acupoints is based on the traditional Chinese acupuncture atlases or a transpositional atlas based on transcribing human acupuncture points onto the equine anatomy. The location of the points is similar in each method, though anatomical variation exists, as discussed by Fleming[23] (Fig. 93-3).

TECHNIQUES AND INSTRUMENTATION

Numerous techniques exist to stimulate acupuncture points. The following modes of stimulation are commonly used in equine acupuncture: dry needle stimulation, electroacupuncture, aquapuncture, moxibustion, laser stimulation, gold

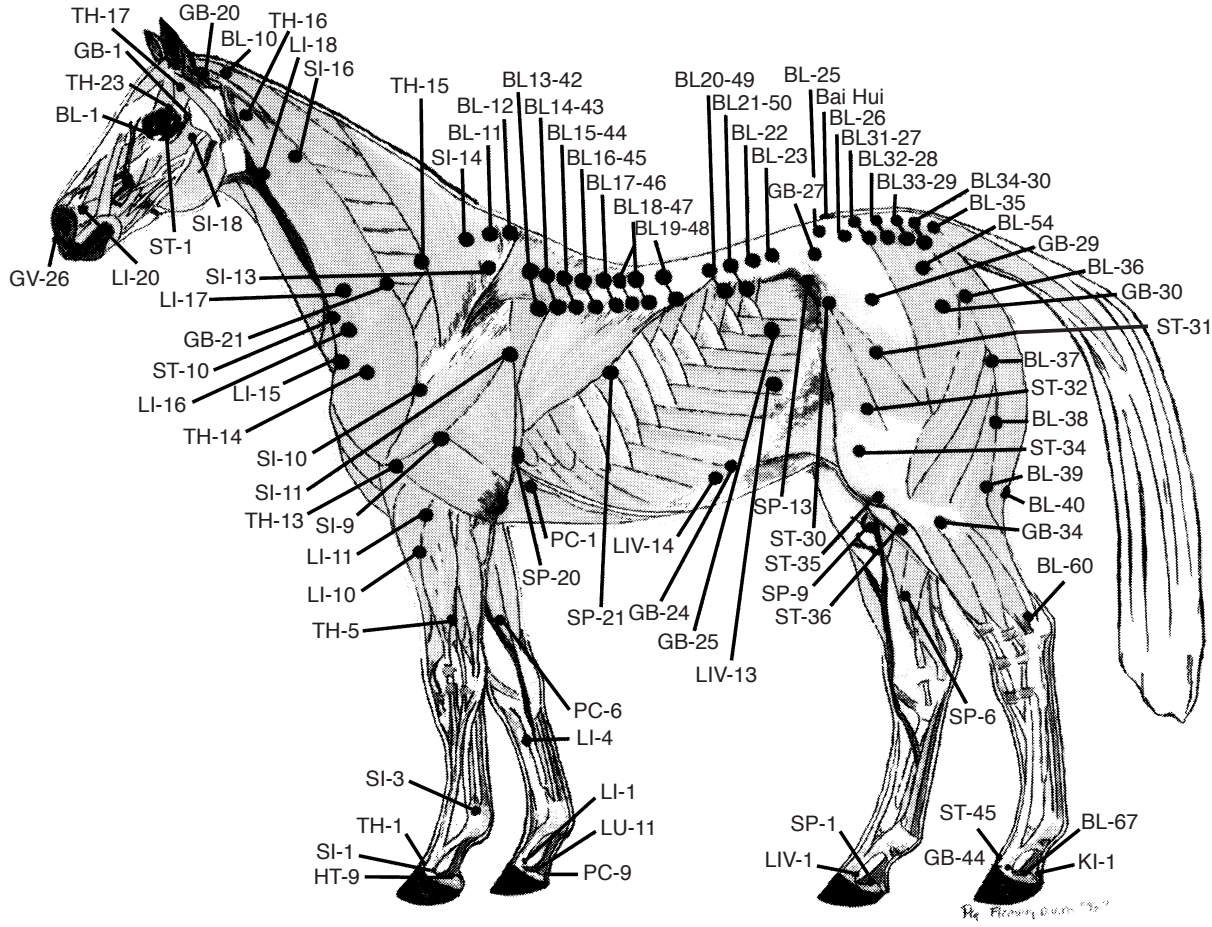

Fig. 93-3 Acupoints of the horse: lateral view in relation to muscles. (Courtesy Peg Fleming. From Schoen AM, editor: *Veterinary acupuncture: ancient art to modern medicine,* ed 2, St Louis, 2001, Mosby.)

implants, and acupressure. Each method has its indications and limitations. Dry needle and aquapuncture are used most routinely in the West.

Aquapuncture is the injection of various solutions into the acupuncture points. The hypodermic needle is stimulating the acupuncture point as a traditional acupuncture needle would. In addition, the solution is stimulating the pressure receptors for a period of time, and the solution is having its specific effect as well. Solutions injected include saline, vitamins such as B_{12}, non-steroidal analgesics, local anesthetics such as lidocaine, and occasionally homeopathic and herbal solutions, depending on the veterinarian's preference. Electroacupuncture, using a portable electroacupuncture unit, normally is used for nerve stimulation to treat severe chronic cervical, thoracolumbar, or lumbosacral problems or an affected joint, tendon, or ligament. These electroacupuncture units have electrodes attached to the acupuncture needles. Positive results with electroacupuncture have been documented for treatment of lameness in horses. Electroacupuncture decreased the lameness score in horses ($P < 0.001$).[24] Though poorly documented, electroacupuncture without needles is sometimes applied as well. Moxibustion is a form of thermostimulation using a Chinese herb, *Artemesia vulgaris.* Low-level or cold laser therapy is also used to stimulate acupuncture points. Gold implants have been used to treat navicular disease and chronic back problems and provide long-term stimulation of acupoints. This approach is an adaptation of the Chinese technique of sutures embedded into acupoints. Acupressure often is taught to the client to administer in between acupuncture treatments to potentiate the effect. Detailed descriptions of these techniques are described by Altman.[25]

From a Western medical perspective, acupuncture point selection is based on locating points on the body where stimulation produces a beneficial change in the central nervous system by modulating ongoing physiological activity, releasing local muscular spasms, and increasing local microcirculation. From a traditional Chinese medicine perspective, acupoints are selected based on a pattern differentiation developed from the Five Element theory or Eight Principles. The choice of acupoints based on the Eight Principles depends more on tongue and pulse diagnosis and a comprehensive history. The Japanese approach to point selection follows a diagnostic acupuncture point examination, palpating diagnostic acupoints, including association (*Shu*) points on the dorsal thoracolumbar region, alarm (*Mu*) points on the ventral abdomen, and other diagnostic points. Many clinicians choose their points based on a combination of Chinese, Japanese, and Western diagnostic techniques, including tongue and pulse diagnosis, diagnostic acupuncture point examination, sometimes including *Ting* points (points around the coronary band), and a comprehensive Western medical examination and history.[26,27] The number of acupuncture points treated may vary from one to more than 20, depending on the condition treated and the approach and experience of the practitioner. The depth of needle insertion varies from 1 mm to 12 cm, depending on the location of the point, such as the coronary band versus dorsal lumbar musculature. The number of treatments required depends on the condition treated and the chronicity of the problem, usually

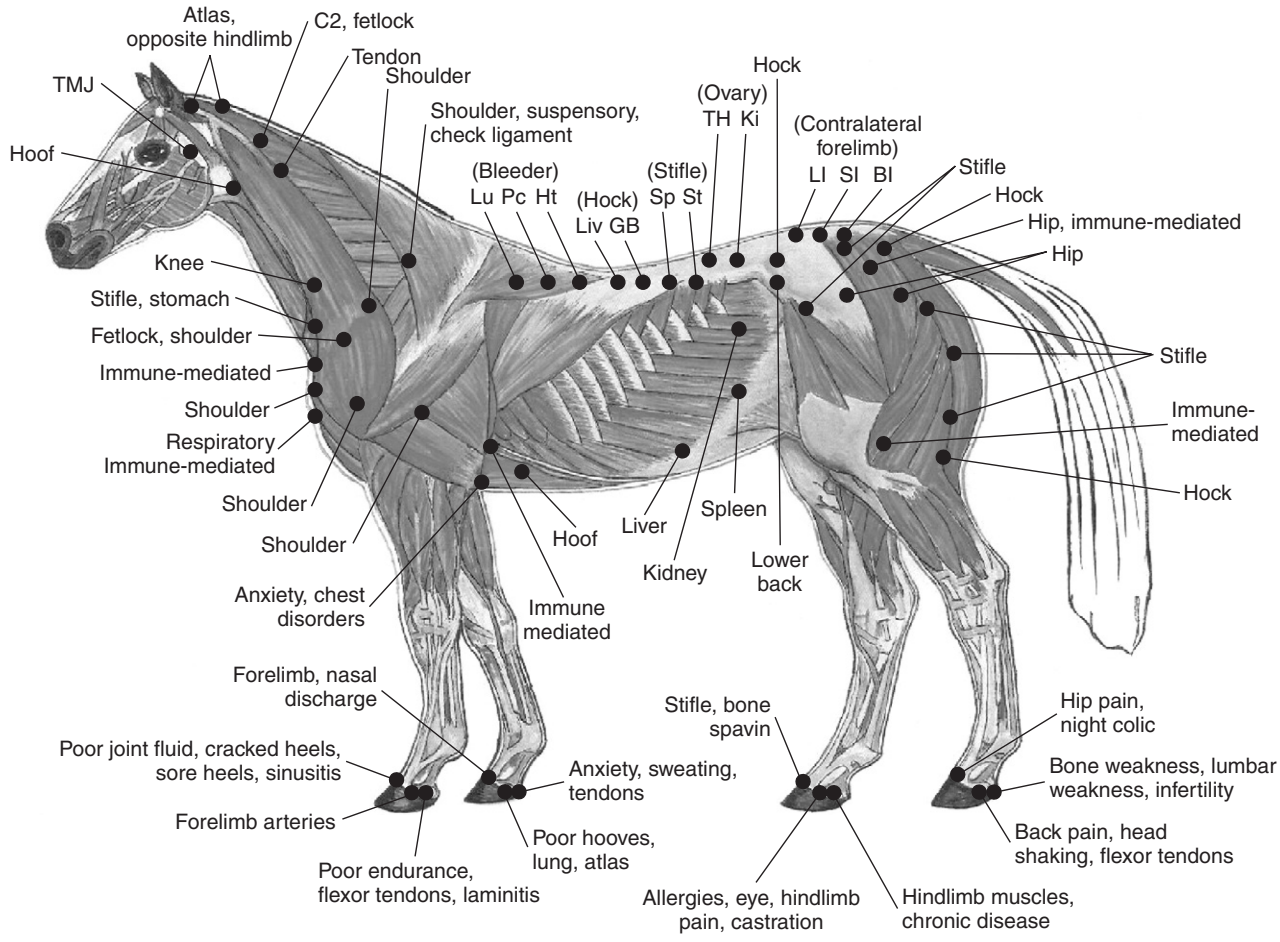

Fig. 93-4 Diagnostic acupuncture palpation points. (Courtesy Peg Fleming. From Schoen AM, editor: *Veterinary acupuncture: ancient art to modern medicine,* ed 2, St Louis, 2001, Mosby.)

ranging from one to eight treatments. The length of treatment varies from 5 to 30 minutes.

Manual therapies, such as chiropractic or osteopathy, are often applied along with acupuncture. They appear to work synergistically, acupuncture relieving muscle spasms and increasing circulation, chiropractic helping to correct skeletal fixations (see Chapter 94), and osteopathy affecting the fascia and skeletal structures (see Chapter 98). The combination of these therapies often leads to a more rapid response and greater efficacy, with fewer treatments required.

CLINICAL APPLICATIONS IN LAMENESS EXAMINATION AND TREATMENT

Acupuncture Diagnostic Examination

Acupuncture and manual therapies may be used diagnostically to aid in evaluating various lameness and performance problems. Acupuncture is an excellent diagnostic aid as an adjunct to our conventional lameness examination. Many of the diagnostic acupoints are located lateral to the dorsal midline, between the longissimus and iliocostalis muscles, along the acupuncture meridian known as the bladder meridian.[26] In addition, some diagnostic points are actually trigger points, knots or tight bands in a muscle. For instance, a triceps trigger point is often sensitive to palpation when a lower forelimb lameness is present and correlates with the acupoint Small Intestine 9. A triceps trigger point may not indicate exactly where the lameness is or what the cause is, but it does indicate that something is reactive in that region (Fig. 93-4).

Diagnostic acupoints also are located around the coronary band on the forelimb and hindlimb, known as *Ting* points (Fig. 93-5).[15] Each diagnostic acupuncture point may have four or five meanings, depending on which other points show up as reactive on the examination. For instance, one point, Large Intestine 16 (located in a depression on the cranial border of the scapula, at the intersection of the cranial margin of the scapular muscle and the caudal margin of the brachiocephalicus muscle, cranioventral to the first thoracic vertebrae) may be reactive in horses with forelimb lameness, cervical conditions, or a contralateral hindlimb lameness.[26] Sensitivity on acupoints along the bladder meridian, lateral to the dorsal midline, along the back may indicate that a hindlimb lameness is related to the stifle or hock, or that a primary back problem is related to the saddle fit, rider, or a conformational problem. Sensitivity at acupoints suggesting a problem in the hock region also may be reactive with nearby injuries, such as a proximal suspensory problem. In addition, reactivity may indicate internal organ problems via a somatovisceral reflex. The combination of reactive points often aids the clinician in localizing the cause of the problem and determining a diagnosis. Often a horse may have a localized lower limb lameness along with a back problem. Sometimes acupoint diagnosis assists the veterinarian in figuring out which may have come first, the lower limb lameness or the back problem, based on the degree of sensitivity of the various points. Acupuncture diagnosis can be an excellent adjunct to conventional lameness examination, flexion tests, diagnostic

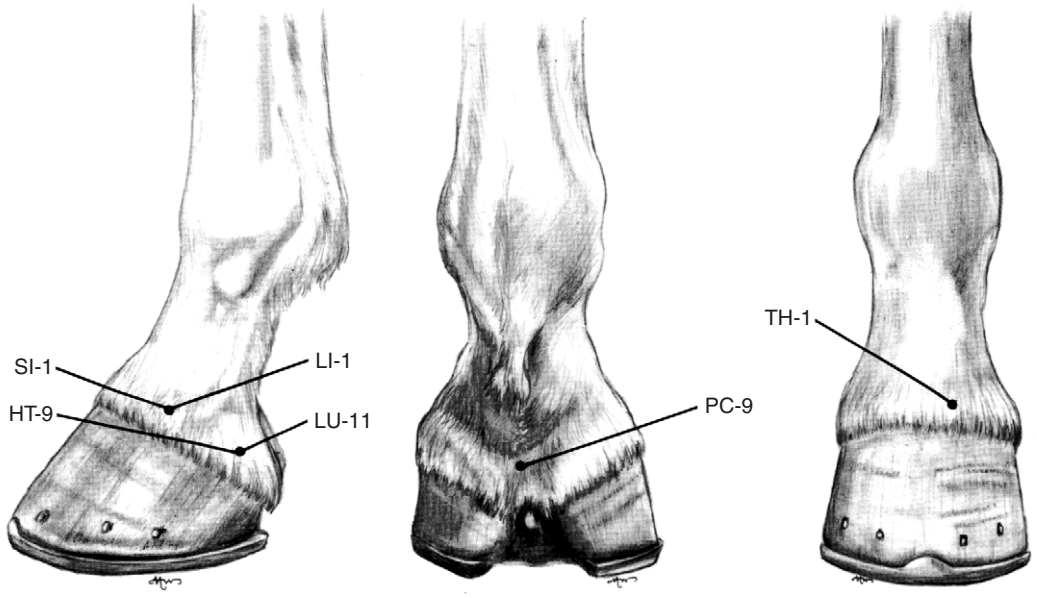

Fig. 93-5 *Ting* points of the equine front foot. In a lateral position the points are SI-1 and HT-9; in a medial position the points are LI-1 and LU-11. (From Schoen AM, editor: *Veterinary acupuncture: ancient art to modern medicine,* ed 2, St Louis, 2001, Mosby.)

analgesia, radiography, ultrasonography, and other diagnostic approaches. Not uncommonly we use all of our diagnostic capabilities, including nuclear scintigraphy and magnetic resonance imaging, and still do not arrive at a diagnosis. Acupuncture is often an excellent adjunct technique that may assist in elucidating the problem. In people, musculoskeletal pain often is accompanied by muscle shortening in peripheral and paraspinal muscles from spasms and contractures, and secondary trigger points and autonomic manifestations of neuropathies are also present in chronic musculoskeletal pain.[28] Patterns of trigger points distant to the primary problem, compensating for the primary musculoskeletal problem, also have been found.[29] These patterns are also evident in equine acupuncture lameness examinations. For instance, the horse may have a primary hock or stifle problem and then develops compensatory patterns of trigger points in the back and neck and contralateral forelimb. These patterns show up as standard patterns of trigger points that may assist the veterinarian in the primary diagnosis.

An integrative approach to diagnosis is incorporated along with the acupuncture diagnostic palpation examination and includes evaluation of conformation, saddle fit, shoeing, rider and training programs, and the conventional lameness examination. Chiropractic evaluation, including static and motion palpation, also are included, which allows for a more comprehensive evaluation of all potential causes of lameness.

Acupuncture Therapy for Lameness

Acupuncture has been reported to be effective for treating various musculosketetal pain-producing conditions and has been found to be beneficial in treating cervical, thoracolumbar and lumbosacral hyperpathia,[30,31] and chronic back pain, chronic lameness, osteoarthritis, and colic. Hyperpathia, increased pain sensation detected as muscles spasms and increased sensitivity of acupuncture points, is often secondary to numerous causes, including work-related muscle soreness and injuries, metabolic diseases, infectious diseases, and underlying soft tissue and orthopedic problems. Wherever possible, primary underlying causes of lameness should be explored with appropriate diagnostic procedures. Conventional and complementary therapies should be considered based on what is most appropriate for the particular condition.

Back Pain

Chronic back pain can be a major cause of poor performance and may be caused by soft tissue damage or lesions to the thoracolumbar vertebrae. Numerous studies have documented the benefits of acupuncture for equine back pain.[32-42]

Xie et al.[24] documented the success of electroacupuncture for treating chronic back pain in performance horses in a controlled clinical trial. They found that three electroacupuncture sessions were needed for clinical improvement. Conventional medical approaches, including the administration of muscle relaxants and analgesics, usually offer only temporary and minimal improvement, decreasing the clinical signs but not addressing the specific problems. Acupuncture is able to address specific muscle spasms and trigger points. Recent research suggests that electroacupuncture may be stronger and more effective than dry needle techniques or aquapuncture.[24] Clinically, aquapuncture and dry needle techniques appear to be effective.

Pain Associated with Lower Limb Lameness

Acupuncture has been reported to be beneficial in horses with various lower limb lameness[43-65] and has been beneficial in treating lameness related to the shoulder, elbow, carpus, tarsus, fetlock, stifle, hip, and numerous soft tissue injuries. In one experiment evaluating acupuncture in the treatment of lower limb lameness, Xie et al.[24] found that electroacupuncture can partially relieve pain caused by the mechanical pressure induced by tightening a screw against the sole. They found that electroacupuncture significantly reduced the degree of lameness ($P < 0.001$). Electroacupuncture simultaneously increased plasma β-endorphin concentration, which suggests that endorphin release may be one of the pathways in which acupuncture relieves experimental pain. Electroacupuncture did not alter adrenocorticotrophic hormone concentrations, which indicates that the hormone may not be involved in this type of analgesia. This indicates that the mechanism of acupuncture analgesia is not merely a nerve block, such as with local anesthetic solution, but also has central acting effects. This correlates well with other clinical studies demonstrating the benefits of acupuncture in relieving equine lameness caused by joint contusion, muscular atrophy, rheumatic pain, and laminitis. Using a similar experimental design in a controlled clinical trial,

Hackett et al.[65] found that acupuncture alleviated equine pain, based on heart rate measurements as an indicator of pain response. In this study acupuncture was found to be more beneficial than non-steroidal anti-inflammatory medications.

The experience of numerous clinicians suggests that acupuncture, combining local and distant points and using various techniques, can be beneficial as a primary or secondary modality. In clinical practice, acupuncture is beneficial in resolving chronic back pain. Establishing a primary cause of back pain is critical and includes evaluating the feet, saddle fit, rider, training, and conformation. If pain primarily is caused by conformation problems, long-term resolution may include periodic electroacupuncture, traditional acupuncture, or gold bead implantation.

Acupuncture and chiropractic are used successfully in treating various equine musculoskeletal conditions as primary treatments or as adjuncts to conventional veterinary therapeutic techniques. For instance, a horse may have primary distal hock joint pain and may be treated with an intra-articular injection. However, the injection may not completely resolve hock lameness. The horse may still "not be right" or "be off." Often secondary compensation and subsequent patterns of trigger points, muscular spasms in the longissimus, and vertebral fixations in the lumbar and cervical regions remain unresolved. Acupuncture and chiropractic therapy may then be used to treat the sequelae of the primary hock problem successfully. Hence the clinician then may resolve 100% of the lameness and increase client satisfaction.

Acupoint selection for lameness may include specific local points or *ah shi* (tender points) around a specific joint or region, points related to the secondary compensation for the primary lameness, and points based on traditional Chinese medicine or Japanese meridian therapy. Acupuncture may be used as primary therapy for lower limb lameness if conventional medical approaches have not demonstrated substantial improvement, or as an adjunct to conventional therapy. Horses with limb lameness that may benefit from acupuncture include those with laminitis; navicular disease; carpal, metacarpal, tarsal, fetlock, and pastern problems; soft tissue injuries; and some idiopathic problems. Horses with acute and chronic laminitis have responded favorably to acupuncture using dry needles, hemoacupuncture, or electroacupuncture. In the treatment of laminitis, local points around the coronary band are used along with distant points based on traditional Chinese medicine therapy.

SUMMARY

Acupuncture can be beneficial in diagnosing and treating various lameness conditions, including lower limb and back problems. A thorough conventional diagnostic examination should be conducted along with an acupuncture diagnostic examination. All therapeutic options appropriate for a specific lameness condition should be considered. The advantages and disadvantages of each therapy should be discussed. Acupuncture can be considered as a primary therapy, or as an adjunct treatment, depending on the condition. No one form of medicine has all the answers. Clinicians should consider the most appropriate conventional and complementary diagnostic and therapeutic modalities for the particular horse and its owner to develop a comprehensive, integrative approach to equine lameness. Acupuncture is one of these complementary approaches that may be beneficial for the patient.

UNDERSTANDING THE USE OF ACUPUNCTURE IN TREATING EQUINE LAMENESS AND MUSCULOSKELETAL PAIN

• William H. McCormick

Mastery of the Oriental examination is the key to treating equine musculoskeletal pain with acupuncture. The basis of the traditional Chinese medicine examination is pattern differentiation. This principle, as stated in Chinese, is "*bien jheng lun jhi*," or in translation, "treatment is based on the pattern."[1] The *si jhun*, or four examinations of looking, asking, palpating, and listening/smelling, outline the procedure for determining patterns. A patient's pattern is defined by the sum total of the signs, symptoms, tongue and pulse, as determined by the *si jhun*.[2]

How does the Oriental pattern-based therapy differ from the Western disease-based approach? The Western clinician arrives at a diagnosis by using the available technologies, such as diagnostic analgesia, radiography, and nuclear scintigraphy. The strict traditional Chinese medicine practitioner must rely on the traditional patterns demonstrated by the patient using the *si jhun*, without technical support. Hypothetically, a horse with navicular disease might exhibit the following patterns: *blood stasis* or fixed pain; *Qi stagnation* or moving, referred muscle pain; *liver depression*, or anger expressed in stereotypical behavior; and *heart Qi vacuity*, or anxiety. The total of the patterns describes the presentation of the disease in traditional Chinese medicine. Any disease may have a number of different patterns. Therapy is defined by the pattern, because each pattern must be addressed in the subsequent therapeutic principles used in treatment. For example, the pattern of *blood stasis* (fixed pain) requires a traditional Chinese medicine therapy that will *quicken the blood* and *resolve stasis*. The stated functions of each acupoint or herbal medicinal are used to determine which acupoints to select. The proper use of the descriptive methodology of traditional Chinese medicine forces a clinician to depict each horse in terms of patterns that then will be used to direct therapy.

One also must evaluate acupuncture by the resultant effect on the described pattern. Any other therapy, be it Western or Oriental, can also be evaluated in terms of its effect on the pattern. For example, consider a horse with navicular disease that is not yet lame, but the rider describes a change in performance caused by pain, including stiffness in the corners and a sore back. In such a horse the traditional Chinese medicine pattern may add significant information, whereas radiography, scintigraphy, and magnetic resonance imaging are technological overkill, expensive, and perhaps misleading. Treating the horse as presented with available modalities, such as shoeing, drugs, acupuncture, and herbs, and subsequently evaluating the change in pattern and performance may be more efficient. Because patterns change over time, frequent follow-up examinations and good record keeping are required. Sophisticated imaging techniques can and should be used to establish an anatomical diagnosis. The therapeutic advantage of the integrated Western and Oriental approach is most applicable to a horse with subclinical lameness as opposed to overt lameness.

Channel diagnosis can add information about any horse's response to musculoskeletal pathological conditions. This technique involves palpation of acupoints to determine the status of *Qi* flow. The information attained can be useful in a Western context. Acupoint examination should include the following grading system for severity of reaction and a recording of those reactions over time. Grade I is normal, supple and non-painful response to deep palpation. Grade II is a slight muscle twinge that is fatigable. Grade III is consistent pain or avoidance response to deep palpation. Palpation of an acupoint with grade IV sensitivity elicits a sharp avoidance response, accompanied by a kick or a bite (Figs. 93-6 to 93-8). Grade III and IV sensitivity are of sufficient severity to warrant therapy. Each of the following acupoints corresponds to a traditional Chinese

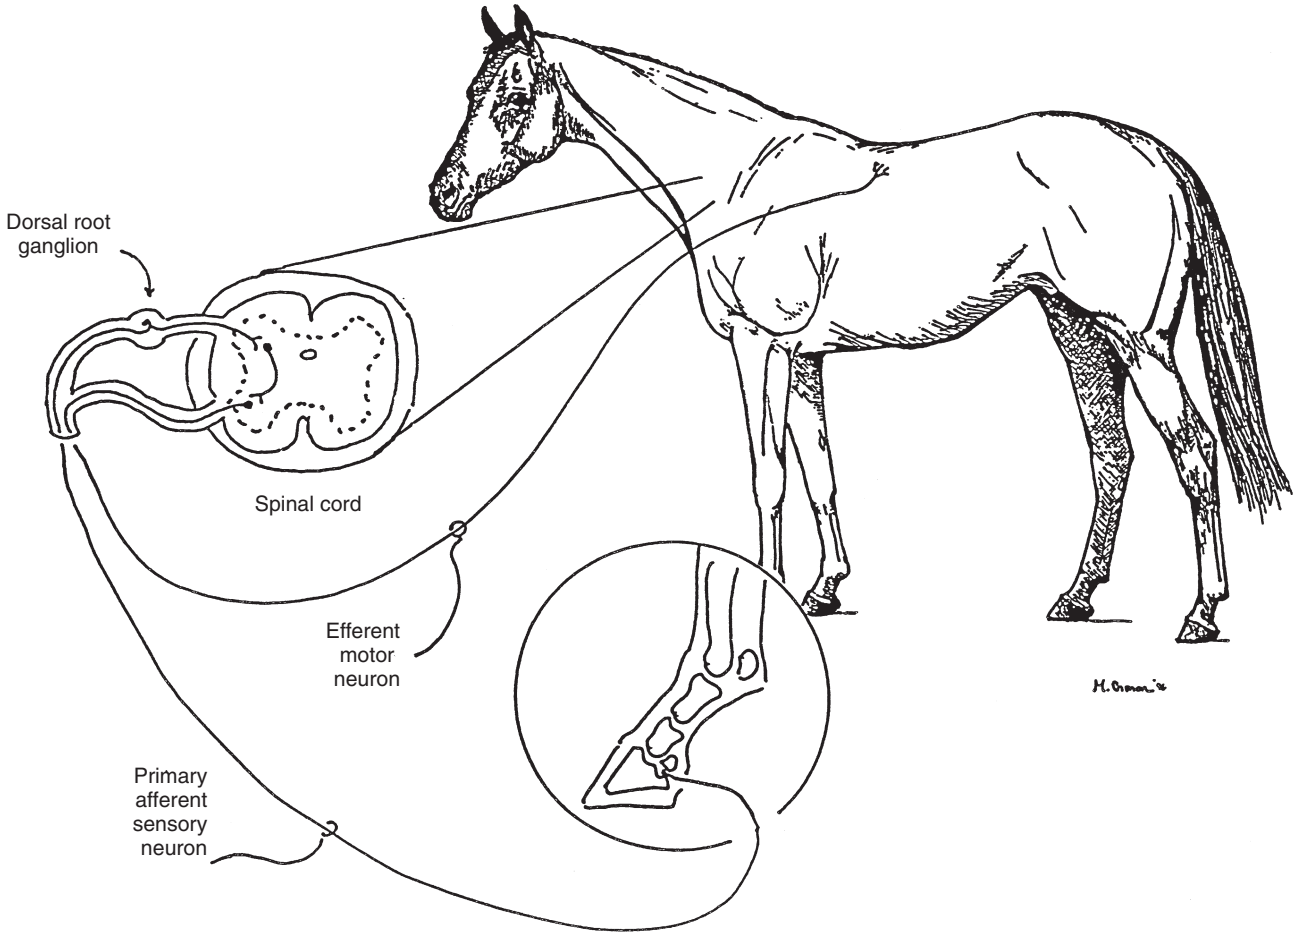

Fig. 93-6 The mediation of channel pain through the spinal reflex. (Courtesy William E. Jones.)

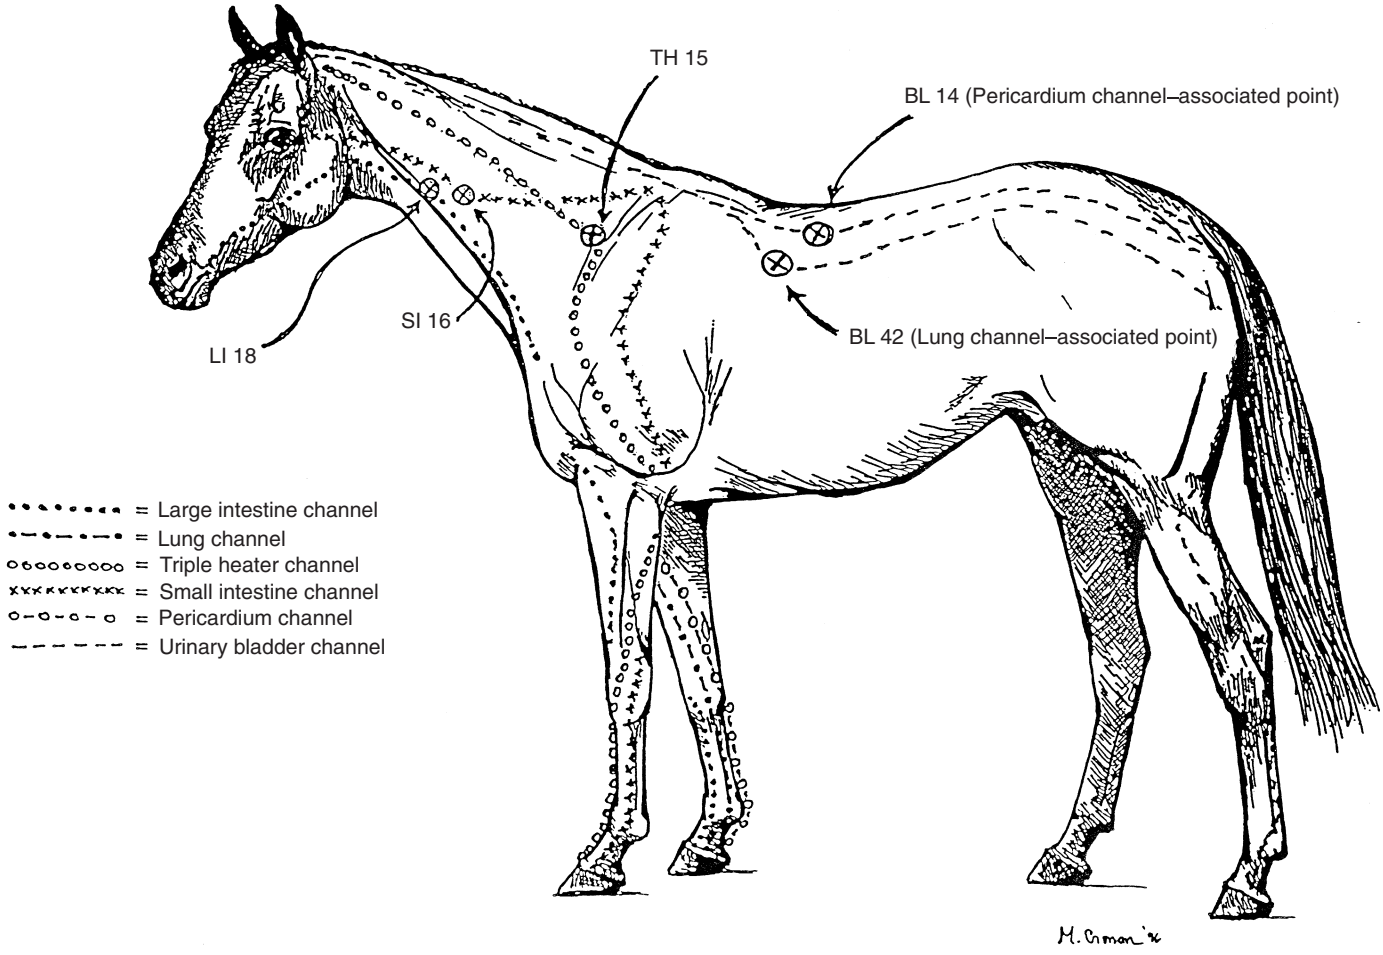

Fig. 93-7 The principal acupoints used in the diagnosis of channel pain referable to the equine limb. (Courtesy William E. Jones.)

medicine channel, which in turn is named after an internal organ. The 12 channels govern the flow of *Qi*, or life forces, for the whole body.

1. Large Intestine (LI) 18: An acupoint at the level of the caudal aspect of Viborg's triangle, on the ventral aspect of the sternocleidomastoideus muscle, at the junction of the third and the fourth cervical vertebrae. The distal course of this channel passes over the *dorsomedial aspect of the distal extremity of the forelimb.*[3,4]
2. Small Intestine (SI) 16: An acupoint located caudal to the angle of the mandible, in a depression on the dorsal border of the sternocleidomastoid muscle and dorsal to the transverse processes of the third and fourth cervical vertebrae, or 8 to 10 cm caudal to Large Intestine 18. *Distally the small intestine channel courses over the dorsolateral aspect of the forelimb.*[3,4]
3. Triple Heater (TH) 15: An acupoint located on the cranial border of the scapula, in a depression about one third of the distance from the cranial angle of the scapula to the shoulder joint. Triple Heater 15 is defined by the ventral borders of the cervical serratus and the cervical trapezius muscles. *The course of this channel crosses the dorsal midline of the distal extremity of the forelimb.*[3,5]
4. Urinary Bladder (UB) 42: An acupoint located in a depression over the seventh intercostal space, just caudal to the scapular cartilage, in a muscular groove between the longissimus thoracis and the iliocostalis thoracis muscles, about 20 cm from the dorsal midline. Urinary bladder 42 is the *shu* or associated point for the lung channel, which runs over the *medial aspect of the distal forelimb.*[3,5]
5. Urinary Bladder (UB) 14: An acupoint about 12 cm lateral to the midline and parallel to the caudal border of the dorsal spinous process of the ninth thoracic vertebra. In the ninth intercostal space, this acupoint is situated about 10 cm caudal and dorsal to Urinary Bladder 42. Urinary Bladder 14 is the *shu* point of the pericardium channel in the International Veterinary Acupuncture Society transpositional system. *The pericardium channel courses over the palmar midline of the distal digit.*[3,6]
6. Urinary Bladder (BL) 18, *Gan Shu*: An acupoint located about 12 cm lateral to the caudal border of the dorsal spinous processes of the thirteenth and fourteenth thoracic vertebrae, at the thirteenth and fourteenth intercostal spaces, in the muscular groove between the iliocostalis and the latissimus dorsi muscles. Urinary Bladder 18 is associated with the liver channel, the distal course of which passes over the *dorsomedial aspect of the distal hindlimb.*[3,7]
7. Urinary Bladder (BL) 19, *Dan Shu*: An acupoint located about 12 cm lateral to the caudal border of the dorsal spinous processes of the fifteenth and sixteenth thoracic vertebrae, at the fifteenth and sixteenth intercostal spaces, in the muscular groove

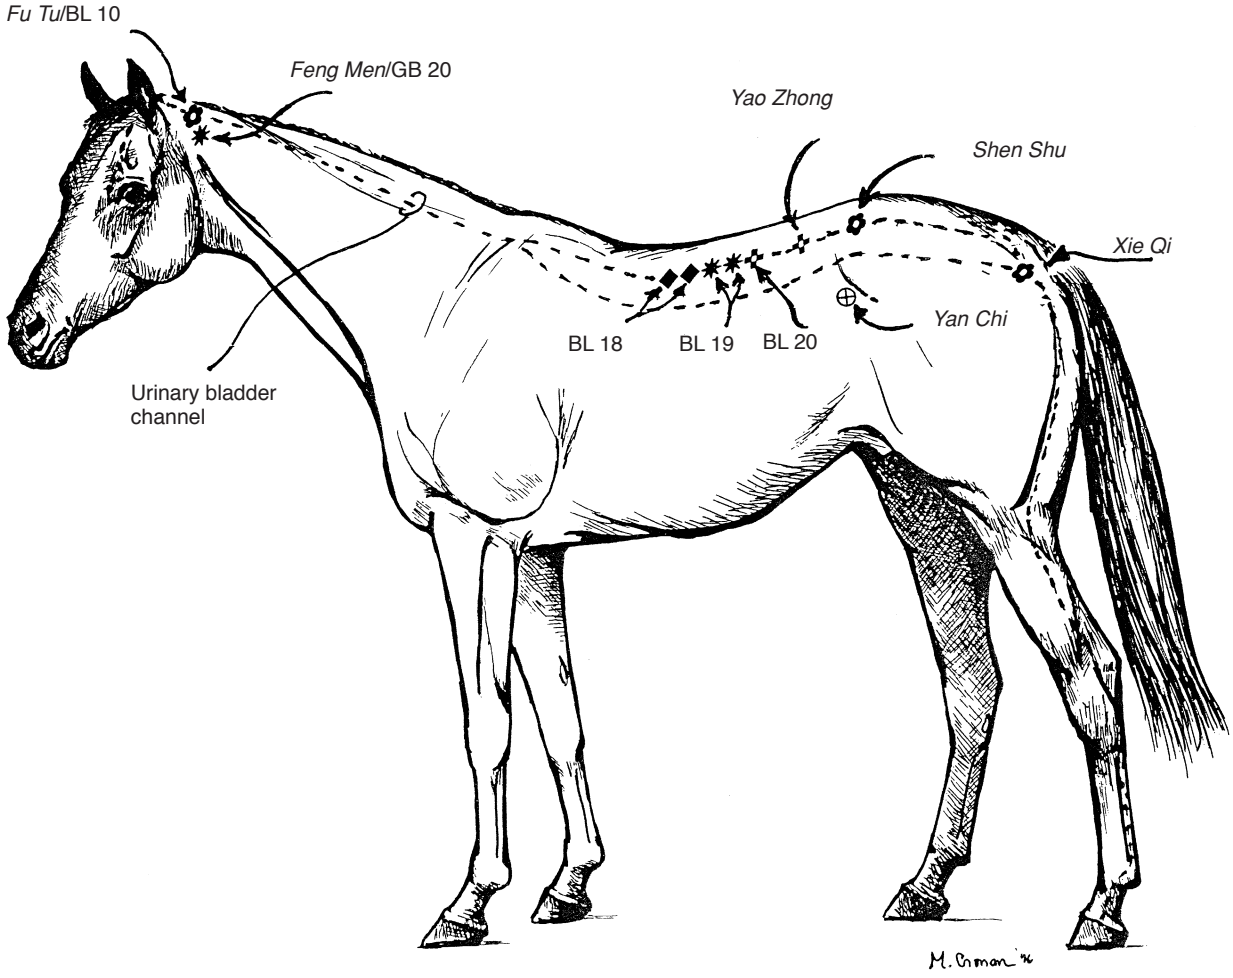

Fig. 93-8 The principal acupoints used in the diagnosis of channel pain referable to the equine hindlimb. (Courtesy William E. Jones.)

between the iliocostalis and latissimus dorsi muscles. Urinary Bladder 19 is associated with the gall bladder channel, which courses over the *dorsolateral aspect of the distal hindlimb.*[3,7]

8. Urinary Bladder (BL) 20, *Pi Shu*: An acupoint located about 12 cm lateral to the caudal border of the spinous process of the seventeenth thoracic vertebra, at the last intercostal space, in the muscular groove between the iliocostalis and latissimus dorsi muscles. Urinary Bladder 20 is associated with the spleen channel, which crosses the *medial aspect of the distal hindlimb.*[3,7]
9. *Yao Zhong*: An acupoint about 12 cm lateral to the dorsal midline, between the third and the fourth lumbar vertebrae, midway between the caudal border of the last rib and *Shen Shu*, a traditional veterinary acupoint. *Yao Zhong* is associated with the stomach channel, which courses over the *dorsal aspect of the distal hindlimb.*[5,8]
10. *Shen Shu*: An acupoint about 6 cm lateral to the lumbosacral space. *Shen Shu* is the traditional veterinary acupoint associated with the kidney channel, which courses over the *plantar medial aspect of the tarsus and the plantar midline of the distal hindlimb.*[5,8]
11. *Xie Qi*: An acupoint in the muscular groove between the biceps femoris and the semimembranosus muscles and at a level horizontal to the anus. *Xie Qi* is used as the associated point of the urinary bladder channel, which courses over the *plantarolateral aspect of the distal hindlimb.*[5,8]
12. *Feng Men* (GB 20): An acupoint in a depression cranial to the wing of the atlas, 6 cm ventral to the dorsal midline and 3 cm caudal to the ear base. *Feng Men* reflects the *dorsolateral aspect of the distal hindlimb.*[5,7]
13. *Fu-Tu* (BL 10): An acupoint in a depression cranial to the wing of the atlas, 6 cm caudal to the ear base and 4.5 cm ventral to the dorsal midline. *Fu-Tu* reflects the *plantarolateral aspect of the distal hindlimb.*[5,7]
14. *Yan Chi* (SP 14): An acupoint in a depression 4.5 cm ventral to the wing of the ilium. *Yan Chi* reflects the *medial aspect of the distal hindlimb.*[9,10]

The usefulness of recognizing reactive acupoints depends on the meaning attributed to those acupoints. I previously have published a series of articles on using reactive acupoints in pain referable to the shoulder joint,[11] metacarpophalangeal joint,[12] distal interphalangeal joint,[13] and the joints of the lower hindlimb.[14] These articles were based on 712 lame and sore horses. Over 14 years, which succeeded 13 years of strictly Western lameness practice, many thousands of examinations were conducted to establish a protocol and subsequently to confirm the following principles for evaluating reactive acupoints:

1. Palpable reactive acupoints in musculoskeletal disease depend on neural control through the spinal reflex (see Fig. 93-6).

2. Reactive acupoints that reflect the lower limb can be differentiated from somatovisceral pain, local muscular injury, and spinal pain by intra-articular medication. That is, if a pattern of reactive acupoints is present and intra-articular medication abolishes the pattern, then the treated joints alone are responsible for the changed reactive acupoints. Intra-articularly administered mepivacaine hydrochloride changes acupoint reactivity within 10 minutes. Intra-articularly administered triamcinolone acetonide, methylprednisolone acetate, or hyaluronan changes the acupoints within 24 hours.
3. In musculoskeletal extremity pain (*Bi* syndrome), acupuncture channel reactivity reflects only synovial inflammation in the distal interphalangeal, proximal interphalangeal, metacarophalangeal, and carpal joints and the distal interphalangeal, proximal interphalangeal, metatarsophalangeal, and distal tarsal joints and stifle in the hindlimb. Non-synovial pain, such as subchondral bone or extra-articular pain, are not reflected directly by reactive acupoints, except as a secondary event, such as metacarpophalangeal inflammation in tendon disease, or distal interphalangeal joint inflammation in laminitis.
4. Potentially any one joint can produce any pattern of reactive acupoints, but some joints have patterns that occur statistically more frequently than others, such as Urinary Bladder 14 in distal interphalangeal joint inflammation,[13] *Yao Jhong* in metacarpophalangeal joint inflammation,[12] or *Yan Chi* in stifle inflammation.[9,15]
5. Most complex diseases are represented by a number of different patterns occurring simultaneously. The projection of reactive acupoints by inflamed synovial structures is a clinical finding that can be confirmed easily by practical Western diagnostic tests. If a careful evaluation of the acupoints has been performed before joint injection, then the effect on the acupuncture pattern is evaluated easily.

In a sore horse that is not overtly lame and also has a multipattern presentation, intra-articular medication allows for the removal of patterns one at a time. A horse without overt lameness that has reactive acupoints reflecting forelimbs and hindlimbs could be treated only for distal tarsal inflammation. If the primary source of inflammation is the tarsus, then the whole acupuncture presentation will change. But if the metatarsophalangeal joint, stifle, or a forelimb joint is concomitantly involved, then only the pattern reflecting the distal tarsus will change. The other patterns will remain the same. Non-articular or non-traumatic pain, such as painful hind splints, suspensory ligament enthesopathy, or joint infection, do not directly cause a reactive acupoint pattern. Routinely re-examining horses that have received joint therapy or acupuncture the day after therapy and in 1 week is good practice to assess the rider's or trainer's evaluation and any change of pattern. If the pattern is balanced and the horse is doing well, then one's efforts should be directed toward maintaining the acupuncture balance. If a few remaining points show low reactivity, they usually can be treated with acupuncture. However, if lameness or sharply reactive acupoints remain, then the diagnosis must be re-evaluated. Other medications that effect, or are purported to effect, articular inflammation also can be assessed. Shoeing changes, track surfaces, and training or management regimens directly affect acupuncture balance.

No direct relationship exists between lameness and the severity and distribution of reactive acupoints. For example, a very sore racehorse can have severely unbalanced acupoints without appreciable lameness, whereas a horse with an acute radial fracture may have none. This is because acupoint reactivity in joint pain is a function of highly innervated, intra-articular synovial structures, which are activated by the mediators of traumatic inflammation.[16] The distribution, incidence, and severity of acupoint activity depend on the spatial distribution of nociceptor sites within a joint, and the quantity and characteristics of inflammatory mediators released within a joint. Lameness is a function of a much broader range of pain perception.

Joints that project reactive acupoints vary according to the occupation of the horse. Thoroughbred racehorses have a greater incidence of synovial inflammation in the metacarpophalangeal joint compared with the distal interphalangeal joint, whereas the converse is true for show hunters. Both occupations have a high incidence of distal tarsal inflammation. Steeplechase horses and show jumpers have a high incidence of metatarsophalangeal joint inflammation. Multiple joint involvement is not unusual. Determining multiple joint inflammation is difficult if lameness is not severe enough to warrant diagnostic analgesia, but careful observation of horses after joint therapy should reveal demonstrative changes in acupoint reactivity.

Two papers published in English define the limits of acupuncture. Martin and Klide's work on back pain showed the efficacy of modulation of muscle tension on the performance of equine athletes.[17] Steiss showed that acupuncture in foot lameness was no better than that expected in untreated controls.[18] Martin and Klide were treating the traditional Chinese medicine pattern of *Qi* stagnation, or abnormal muscle tension, as opposed to the Steiss' fixed-pain pattern of blood stasis. The strength of acupuncture is its ability to restore normal physiological activity in the face of functional abnormality. However, structural disease associated with foot pain cannot be reversed as easily as can abnormal muscle tension. Acupuncture can be used effectively as an adjunct therapy in structural disease, if muscle hyperactivity is part of the pattern. Careful examination of the channels should allow one to recognize patterns with a good therapeutic potential.

The basis of acupuncture diagnosis and therapy in musculoskeletal disease depends on pattern differentiation. The patterns most easily determined by the Western clinician involve the precise palpation of key acupoints in channel diagnosis. Acupoint reactivity of musculoskeletal dysfunction is a reflection of the body's response to intra-articular trauma. Because only highly innervated synovial structures of a small number of joints of the extremities are reflected by reactive acupoints, the primary disease may be reflected only indirectly or not at all. However, abnormal patterns are common and are worth investigating, regardless of the type of therapy contemplated. At the least, the abnormal pattern is a warning. The ease of elimination of a pattern gives an idea of the persistence and severity of the underlying traumatic pathological condition.

The pattern projected by synovial structures is a protective mechanism, the presence of which has the teleological function of limiting joint excursion. Therefore effective treatment must go beyond the elimination of acupoint imbalance and address all the underlying problems as well. Because disease in traditional Chinese medicine is described in terms of all of the patterns that are present, treatment requires evaluation and elimination of multipattern presentations. In my experience, the channel approach to sore but non-lame horses is effective and useful. With the exception of lameness caused by muscle tension, acupuncture is generally not sufficient by itself to manage frank lameness.

Chiropractic Evaluation and Management of Musculoskeletal Disorders

Kevin K. Haussler

MANUAL THERAPY AND CHIROPRACTIC

Manual therapy involves the application of the hands directly to the body, with the goal of treating soft tissue injuries or articular dysfunction. Chiropractic, osteopathy, massage therapy, therapeutic touch, and certain physical therapy techniques are considered forms of manual therapy. Chiropractic is a health profession concerned with the diagnosis, treatment, and prevention of disorders of the musculoskeletal system and the effects of these disorders on the nervous system and general health.[1] The word *chiropractic* is derived from the Greek words *cheir,* meaning "hand," and *praktike,* meaning "business" or "to practice." The goal of chiropractic is to optimize health through the inherent healing ability of the body (i.e., homeostasis) as affected by and integrated through the nervous system.[2] The practice of chiropractic focuses on the relationship between structure (primarily the spinal column) and function (as coordinated by the nervous system) and how that relationship affects the preservation and restoration of health. Chiropractic uses controlled forces (i.e., adjustments), which are applied to specific joints or anatomical regions, to induce therapeutic responses through induced changes in joint structures, muscle function, and neurological reflexes. Human research has demonstrated reductions in pain and muscle hypertonicity and increased joint range of motion after chiropractic treatment.[2,3]

Joint mobilization and manipulation are two types of induced articular movements used in musculoskeletal rehabilitation to restore joint function. Mobilization is characterized as repetitive joint movements induced within the normal physiological range of joint motion (Fig. 94-1). Joint manipulation (e.g., chiropractic adjustment) occurs within the paraphysiological zone, which lies outside of the active (i.e., patient induced) and passive ranges of joint motion. In people, joint mobilization and manipulation induce different physiological responses. Manipulation in people has been shown to relieve adjacent spontaneous myoelectrical activity immediately, whereas mobilization has not.[2]

PRACTITIONER QUALIFICATIONS

Equine practitioners have seen a recent proliferation in the use of chiropractic techniques on horses, in one form or another. Veterinarians currently do not receive any formal education in chiropractic principles or techniques; therefore many equine clinicians do not have a basic understanding of chiropractic principles or clinical applications. Conversely, chiropractors (doctors of chiropractic) do not have any formal training in comparative anatomy, physiology, pathology, or clinical equine experience. Veterinary medicine, for the most part, has been forced to acknowledge the use of chiropractic

MANUAL THERAPY AND CHIROPRACTIC

Manual therapy involves the application of the hands directly to the body, with the goal of treating soft tissue injuries or articular dysfunction. Chiropractic, osteopathy, massage therapy, therapeutic touch, and certain physical therapy techniques are considered forms of manual therapy. Chiropractic is a health profession concerned with the diagnosis, treatment, and prevention of disorders of the musculoskeletal system and the effects of these disorders on the nervous system and general health.[1] The word *chiropractic* is derived from the Greek words *cheir,* meaning "hand," and *praktike,* meaning "business" or "to practice." The goal of chiropractic is to optimize health through the inherent healing ability of the body (i.e., homeostasis) as affected by and integrated through the nervous system.[2] The practice of chiropractic focuses on the relationship between structure (primarily the spinal column) and function (as coordinated by the nervous system) and how that relationship affects the preservation and restoration of health. Chiropractic uses controlled forces (i.e., adjustments), which are applied to specific joints or anatomical regions, to induce therapeutic responses through induced changes in joint structures, muscle function, and neurological reflexes. Human research has demonstrated reductions in pain and muscle hypertonicity and increased joint range of motion after chiropractic treatment.[2,3]

Joint mobilization and manipulation are two types of induced articular movements used in musculoskeletal rehabilitation to restore joint function. Mobilization is characterized as repetitive joint movements induced within the normal physiological range of joint motion (Fig. 94-1). Joint manipulation (e.g., chiropractic adjustment) occurs within the paraphysiological zone, which lies outside of the active (i.e., patient induced) and passive ranges of joint motion. In people, joint mobilization and manipulation induce different physiological responses. Manipulation in people has been shown to relieve adjacent spontaneous myoelectrical activity immediately, whereas mobilization has not.[2]

PRACTITIONER QUALIFICATIONS

Equine practitioners have seen a recent proliferation in the use of chiropractic techniques on horses, in one form or another. Veterinarians currently do not receive any formal education in chiropractic principles or techniques; therefore many equine clinicians do not have a basic understanding of chiropractic principles or clinical applications. Conversely, chiropractors (doctors of chiropractic) do not have any formal training in comparative anatomy, physiology, pathology, or clinical equine experience. Veterinary medicine, for the most part, has been forced to acknowledge the use of chiropractic

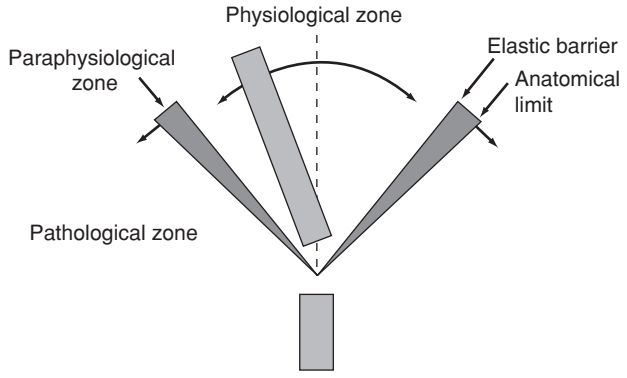

Fig. 94-1 Schematic representation of the three articular zones of joint motion: physiological, paraphysiological, and pathological. The elastic barrier and the anatomical limit mark the transitional boundaries between the three articular zones.

and other non-traditional modalities by horse owners that have sought practitioners who use these techniques and have experienced their perceived therapeutic effects.[4] However, limited research has been done to evaluate the clinical effectiveness of chiropractic techniques in horses. If veterinarians have not taken the time or effort to learn more about these non-traditional techniques, objectively evaluating the use of chiropractic, discussing the indications or contraindications for a specific treatment modality, or applying these techniques clinically is difficult. Therefore owners often seek advice about alternative therapies or treatment from someone who is not their regular veterinarian and often without his or her knowledge. To complicate matters, many laypersons claiming to be equine chiropractors are not professionally trained or licensed in chiropractic or veterinary medicine. These lay practitioners often have a limited knowledge of equine musculoskeletal anatomy, physiology, biomechanics, or pathology. Because of the potential misapplication, chiropractic evaluation and treatment should be provided only by licensed professionals (i.e., veterinarians or chiropractors working under the direct supervision of a veterinarian) who have pursued additional post-graduate training in animal chiropractic principles and techniques. The primary organization currently involved in training and certifying veterinarians and chiropractors in animal chiropractic is the American Veterinary Chiropractic Association. A similar post-graduate education program designed to qualify veterinarians and chiropractors as animal chiropractic practitioners exists at the RMIT University in Melbourne, Australia. Attendees can earn a master of chiropractic science (animal chiropractic) degree after successfully completing 3 years of part-time study. A recently offered veterinary manual therapy course at Colorado State University is available to veterinarians only and includes instruction in chiropractic, osteopathy, therapeutic massage, and other forms of manual therapy. Several other veterinary colleges are expected to develop post-graduate programs in the near future that include chiropractic and other forms of complementary medicine modalities.

Most state chiropractic and veterinary medical boards do not allow chiropractors to treat animals unless they are working under the direct supervision of a veterinarian. This requires that the veterinarian and chiropractor must work together in evaluating and treating the horse and provide appropriate follow-up care as indicated. It is strongly recommended that owners and referring veterinarians seek out licensed professionals (veterinarians or chiropractors) who have had specialized training and experience in chiropractic evaluation and treatment of horses. Veterinarians who have not pursued formal post-graduate training are not qualified to provide chiropractic care and risk producing more harm than potential benefit. It is a good idea to ask equine chiropractors about their professional and post-graduate training or certification, horse experience, and the types of techniques that they use (i.e., hands only versus more aggressive techniques or the use of additional instruments). Chiropractic requires a working knowledge and understanding of vertebral anatomy, physiology, biomechanics, pathology, and rehabilitation. Combining the knowledge and expertise of the veterinary and chiropractic professions provides practitioners with new insights and methods for diagnosing and managing horses with select vertebral or musculoskeletal disorders. A similar multidisciplinary approach has developed in human medicine to address chronic pain syndromes and vertebral column disorders in the last decade.

HISTORY OF EQUINE CHIROPRACTIC

Chiropractors often have been asked to treat the animals of clients who have experienced the benefits of chiropractic care for their own back or neck problems. Horse owners often want the opportunity to have the same type of care for their horses, without the potential adverse effects of medications or surgery. The recent increased awareness of the prevalence and management options to address back problems, with which traditional veterinary medicine has had difficulty in dealing, has also stimulated horse owners' interest in complementary forms of treatment.[5] Any vertebral column disorder can have serious effects on a horse's ability to perform. Back problems can be classified into three basic types of injuries involving the muscles, tendons and ligaments (soft tissue injuries), bones and joints (osseous injuries), or nervous system (neurological disorders). However, several concurrent injuries have been reported in 17% of horses with back pain.[6] Diagnosis of the underlying vertebral pathological conditions in horses with back pain is important for the appropriate treatment and management of these disorders (see Chapter 54).

Many horses in which chiropractic may be useful often have a history of a traumatic event or an injury related to overexertion.[7] Trauma may occur as a single event (i.e., macrotrauma), such as a trailer accident, flipping over backward, or substantial falls over jumps. Severe musculoskeletal injuries may improve gradually, but they never resolve totally or subsequently debilitating arthritis or soft tissue fibrosis may develop. Chronic, overuse injuries (i.e., microtrauma) usually are associated with poor saddle fit, improper riding techniques, inadequate shoeing, or faulty conformation. Long periods of confinement, inconsistent training programs, or cumulative stresses and strains related to prolonged, high-level athletic activities also may predispose horses to musculoskeletal injuries and reduced performance. Older horses, similar to elderly people, are susceptible to loss of vertebral column flexibility, joint degeneration, and loss of muscle strength. Aged horses also have increased healing times and increased chances of having chronic conditions or abnormal musculoskeletal compensations from prior injuries. Chiropractic techniques have helped identify and treat some of these previously undiagnosed or poorly managed problems in horses. Most veterinarians use chiropractic techniques to complement their conventional veterinary practice.

COMPLEMENTARY APPROACHES

Prevalence of back problems in horses varies greatly (from 0.9% to 94%), depending on the specialization or type of practice surveyed: general practice (0.9%); Thoroughbred

racehorse practice (2%); veterinary school referrals (5%); mixed equine practice including dressage, show jumpers, eventing (13%); spinal research clinic (47%); or equine chiropractic clinic (94%).[8] Clinicians often have difficulties when dealing with horses with no obvious localized pain or vague, unspecified lameness. Neck or back problems and limb injuries often are interrelated. Distal limb injuries can cause an alteration in carriage of the affected limb and altered gait, which subsequently can overwork or injure proximal limb musculature and the paraspinal musculature. Similarly, vertebral column injuries can produce gait abnormalities, increased concussive forces, and distal limb lameness. The diagnostic dilemma facing clinicians is to decide whether the limb or the vertebral column is the primary or initial cause of the horse's clinical problem. Unless the primary cause of the neck or back pain is identified and treated, most horses will have recurrent back pain when returned to work after a period of rest or trial of anti-inflammatory medications. Non-specific back pain most likely is related to a functional impairment and not a structural disorder. Therefore many back problems may be related to muscle or joint dysfunction, with secondary soft tissue irritation and pain generation.[9]

Chiropractic provides expertise in evaluating vertebral column disorders and can provide an additional means of diagnosis and early treatment options in certain types of gait abnormalities or performance problems. Prepurchase examinations using chiropractic examination techniques also can help identify horses that have chronic underlying neck or back problems.[7] Chiropractic addresses subclinical conditions or abnormal biomechanics, which may progress to future debilitating musculoskeletal injuries. Chiropractors also are trained in using physiotherapy modalities, strength training exercises, massage, stretching techniques, and other forms of musculoskeletal and nerve rehabilitation. Equine chiropractic is a complementary modality that can be used in veterinary medicine for the diagnosis, treatment, and potential prevention of select musculoskeletal disorders in horses. However, limited published information exists that investigates the effectiveness and safety of chiropractic procedures in veterinary medicine.

PATHOPHYSIOLOGY AND MECHANISMS OF ACTION

The vertebral motion segment is the functional unit of the vertebral column, which includes two adjacent vertebrae and the associated soft tissues that bind them together. The basic elements of joint dysfunction include altered articular neurophysiology, biochemical alterations, pathological conditions of the joint capsule, and articular degeneration.[2,3] Vertebral segment dysfunction (i.e., chiropractically defined subluxation) is a vertebral lesion characterized by the following:

1. Asymmetrical or loss of normal joint motion (Fig. 94-2)
2. Diminished pain thresholds to pressure in the adjacent paraspinal tissues or osseous structures
3. Abnormal paraspinal muscle tension
4. Visual or palpatory signs of active inflammation or chronic tissue texture abnormalities (i.e., edema, fibrosis, hyperemia, or altered temperature)[2]

Multiple theories have been proposed and tested over the years to explain the causes of vertebral segment dysfunction in people and its effects on the neuromusculoskeletal system.[2,3] The chiropractically defined vertebral subluxation complex is a theoretical model that incorporates the complex mechanical and biochemical interactions of injured nervous, muscular, articular, ligamentous, vascular, and connective tissues.[10] The theory of a "bone out of place" is outdated and not supported by current human spinal research.

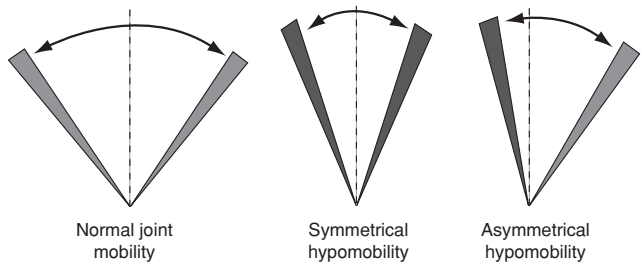

Fig. 94-2 Diagram of patterns of normal and altered joint range of motion. Symmetrical joint hypomobility is characterized by generalized stiffness. Asymmetrical joint hypomobility is characterized by reduced joint mobility in one or more directions (e.g., left lateral bending).

The goal of chiropractic treatment is to reduce pain and muscle hypertonicity, restore joint motion, and stimulate neurological reflexes. The exact mechanisms by which chiropractic techniques produce therapeutic effects are not certain. Chiropractic treatment may reduce musculoskeletal pain by stimulating nociceptive reflexes and release of neuropeptides (i.e., endorphins and enkephalins).[2,11,12] Concurrent muscle spasms restrict joint motion and may contribute to the further development of joint stiffness. In people, palpatory changes in osseous symmetry after manipulation often are associated with soft tissue alterations and not actual reduction of an articular misalignment.[9] Chiropractic care can improve restricted joint motion and may reduce the associated harmful effects of joint immobilization.[2,3] In response to chronic pain or stiffness, new movement patterns are learned by the nervous system and adopted in an attempt to reduce pain or discomfort. Long after the initial injury has healed, adaptive or secondary movement patterns may continue to persist that predispose additional joints or muscles to injury.[9] Chiropractic treatment is thought to affect mechanoreceptors (i.e., Golgi tendon organ and muscle spindles) to induce reflex inhibition of pain and reflex muscle relaxation and to correct abnormal movement patterns.[10,12] Additional modalities used to address altered movement patterns in people and horses include stretching or relaxing hypertonic muscles, strengthening weak muscles, and re-education of movement patterns.[9]

Successful chiropractic treatment requires specific techniques and psychomotor skills.[3] A thorough knowledge of vertebral anatomy and joint biomechanics is required for proper chiropractic evaluation and treatment. Joint manipulation often induces a palpable release or movement of the restricted articulations. An audible cracking or popping also may be heard during chiropractic treatment as the applied force overcomes the elastic barrier of joint resistance.[13,14] The rapid articular separation produces a cavitation of the synovial fluid.[15] Radiographic studies of synovial articulations after manipulation in people have shown a radiolucent cavity within the joint space (i.e., vacuum phenomenon) that contains 80% carbon dioxide and lasts for 15 to 20 minutes. A second attempt to recavitate the joint will be unsuccessful and potentially painful until the intra-articular gas has been reabsorbed (i.e., refractory period).

CLINICAL EVALUATION

Chiropractic, like any medical evaluation, begins with a thorough history, discussion of the chief complaint, and observation of the patient from a distance for conformation, posture, and signs of lameness. Chiropractic evaluation and treatment is not a substitute for a thorough lameness examination and diagnostic workup, because many horses have musculoskeletal

conditions that are identified readily and managed with traditional approaches. In veterinary medicine, many structural abnormalities of the vertebral column are becoming easier to diagnose with newer imaging modalities (e.g., computed tomography, scintigraphy, and ultrasonography). Currently most clinicians are not well educated or experienced in procedures required to perform a thorough functional evaluation of the equine vertebral column. Therefore horses with conditions not diagnosed readily using traditional modalities, or with suspected concurrent neck or back problems, may require referral for chiropractic evaluation.

Horses with conditions that may be responsive to chiropractic care have a variety of non-specific or vague problems (Box 94-1). The focus of the chiropractic examination is placed on evaluating static and dynamic characteristics of the musculoskeletal system. Initially the horse's general attitude and behavior are monitored for signs of pain or discomfort. Vertebral column conformation then is evaluated for proper alignment and symmetry, with special attention to the top line, shape and height of the withers, and osseous pelvic symmetry. A short-coupled horse is thought to have a higher incidence of osseous disorders, whereas a long-backed horses is more prone to soft tissue injuries.[16] Conformation is a structural relationship of body segments, whereas postural analysis deals more with functional relationships. The horse is made to stand on a hard, level surface and is evaluated for a preferred or shifting stance, head and neck carriage, vertebral curvatures, and muscular symmetry. Chiropractic gait analysis focuses on evaluating regional vertebral mobility and pelvic motion symmetry, in addition to the typical assessment of forelimb and hindlimb lameness. Gait analysis may help to rule out distal limb disorders and to rule in vertebral dysfunction, although limb lameness has been reported in about 85% of horses with back problems.[17] Motion asymmetries, restricted vertebral or pelvic mobility, not tracking straight, or lack of propulsion are a few characteristics that are evaluated. Tape on the tubera coxae or vertebral column midline may help to see subtle motion asymmetries. Normal vertebral column motion consists of small cumulative amounts of segmental motion, which produce an overall smooth curve or movement of the vertebral column (Fig. 94-3). Evaluation of the response to placing a saddle on the horse and being ridden is important for a complete assessment of horses with back problems. Inspection of the tack for proper use and fit are always suggested on initial examination. Saddles and restraint devices should be evaluated for proper fit, padding, and positioning on the horse.

A thorough physical examination is used to eliminate other more common causes of lameness or neurological disorders. Chiropractic evaluation focuses on evaluating and localizing segmental vertebral dysfunction, which is characterized by localized pain, muscle hypertonicity, and reduced joint motion.[10] Palpation is used to localize and identify soft tissue and osseous structures for changes in texture, tissue mobility, or resistance to pressure.[16,18] Soft tissue layers are evaluated from superficial to deep in two ways: by increasing digital pressure and by shifting attention with discrete palpatory movements. Shapes of structures, transitions between structures, and attachment sites also may be palpated.[9] Soft tissue texture and mobility can be compared between the skin, subcutaneous tissue, thoracolumbar fascia, and muscle. Patient response to palpation is important especially in evaluating tenderness or hypersensitivity. Osseous palpation involves evaluating osseous structures for pain, morphology, asymmetries, and alignment. Many horses with dental problems or malocclusion have localized pain during palpation of the temporomandibular joints and hypertonicity of the adjacent muscles of mastication. Osseous asymmetry of the space between the ramus of the mandible and the lateral wing of the atlas (first cervical vertebra) can be identified in horses with upper cervical congenital malformations, poll trauma caused by pulling back or falling over, or in some horses that head toss. The apices of the thoracic and lumbar spinous processes are readily palpable in most horses, unless they are grossly overweight. The dorsal apices of individual spinous processes are palpated with firm manual pressure, while monitoring for a localized pain response or muscle hypertonicity, indicative of local injury or impinged spinous processes. Palpable deviations of individual spinous processes are common, but usually

Box • 94-1

Potential Clinical Indications for Chiropractic Evaluation and Treatment of Horses

Poor performance
Back or neck pain
Reduced neck or back flexibility
Not able to raise or lower head and neck
Localized muscle tightness
Vague lameness
Uneven or asymmetrical gait
Recent change in spinal conformation
Difficult or improper saddle fit
Discomfort with saddle placement
Resentment of tightening of the cinch or girth
Stiff and slow to warm up
Bucking or pinning ears when ridden
Lame only when ridden
Constantly on one rein or line
Difficulty with a lead or gait transition
Refusing jumps
Resisting collection
Difficulty with turning in one direction
Consistent stumbling or toe dragging
Muscle mass asymmetry
Pelvic asymmetry
Not standing squarely on all limbs
Difficulty standing for the farrier
Holding tail to one side
Resentment of being groomed
Behavior or avoidance problem

Modified from Willoughby SL: *Equine chiropractic care,* Port Byron, Ill, 1991, Options for Animals Foundation.

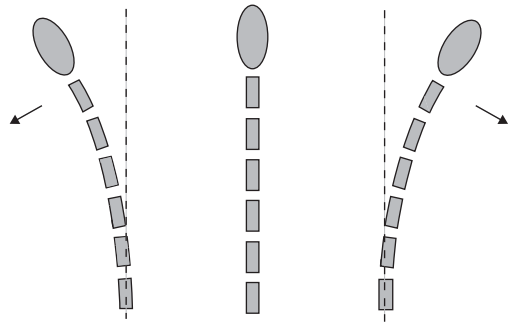

Fig. 94-3 Diagram of normal segmental vertebral contributions to overall vertebral column mobility during active left and right lateral bending. Note the smooth vertebral curve produced by cumulative segmental joint motion.

they are not associated with spinous process fracture or vertebral malposition (i.e., bone out of place), as is commonly thought. Overlapping or malaligned dorsal spinous processes are often caused by spinous process impingement, developmental asymmetries in the neural arch, or isolated dorsal spinous process deviation of unknown cause.[5,19] During induced kyphosis, the abaxial borders of each individual thoracolumbar spinous process and the overlying supraspinous ligament are palpated for pain, thickening, or deviation from midline. The tubera sacrale are palpated for height asymmetries and evaluated for a localized pain response to manual pressure applied dorsally or during abaxial compression. The apices of the sacral spinous processes (of the second to fifth sacral vertebrae) are palpated for pain or deviation from midline.

A complete musculoskeletal examination includes assessment of active and passive ranges of joint motion for all axial and appendicular articulations. Active joint range of motion is evaluated during induced vertebral movements (carrot stretches) and gait analysis. Assessment of passive range of motion requires muscular relaxation as the articulations are moved passively throughout the individual joint ranges of motion (Fig. 94-4). Abnormal segmental vertebral motion is detected when joint motion is asymmetrical or restricted bilaterally (see Fig. 94-2). Causes of segmental vertebral motion restrictions include capsular fibrosis, effusion, or inflammation. Regional causes of vertebral movement restrictions may include peri-articular soft tissue adhesions, musculotendonous contractures or, more commonly, protective muscle spasms. Combining the evaluation of joint range of motion and the presence or absence of pain at the extremes of joint motion, diagnostic interpretations can be implied.[20] Normal joint motion is painless, suggesting that articular structures are intact and functional. Normal joint mobility that has a painful end range of movement suggests that a minor sprain of the associated articular tissues is present. Painless joint hypomobility suggests that a contracture or adhesion is present. Painful hypomobility suggests an acute strain with secondary muscle guarding. Painless hypermobility of an articulation may indicate a complete rupture, whereas painful hypermobility suggests a partial tear of the evaluated structure.

Motion palpation is used to evaluate each vertebral segment for loss of normal joint motion and overall resistance to induced motion (Figs. 94-4 and 94-5). Vertebral segments with altered motion palpation findings can occur with or without localized muscle hypertonicity and pain. Using palpation to evaluate the musculoskeletal system requires an understanding of how joint motion is assessed.[9] Moving an articulation from a neutral position first involves evaluating joint motion that has minimal and uniform resistance. As the articulation is moved toward the end range of motion, a gradual increase in the resistance to movement occurs (i.e., elastic barrier) (see Fig. 94-1). End range of motion starts when any change in resistance to passive joint movement is palpable. The elastic barrier is evaluated by bringing the articulation to tension and applying gentle, rhythmic oscillations to qualify the resistance to movement. The normal joint end feel is initially soft and resilient and gradually becomes more restrictive as maximal joint range of motion is reached. This elastic barrier marks the end of physiological joint movement. A pathological or restrictive end range of motion is palpable earlier in passive joint movement and has an abrupt, restrictive end feel compared with normal joint end feel. The goal of palpating joint movement is to evaluate the initiation of motion resistance, the quality of joint motion and end feel, and the overall joint range of motion. Joint movement beyond its normal anatomical limits is characterized by ligamentous or articular capsule disruption and joint subluxation.

Individual vertebral segments are evaluated for altered motion palpation findings in flexion and extension (Figs. 94-6 and 94-7); right and left lateral flexion (see Figs. 94-4 and 94-5); and right and left rotation. In a relaxed horse the articulations of the individual second to sixth cervical vertebrae are assessed for the presence or loss of the normal elastic barrier during combined lateral flexion and rotation. The articulation between the fourth and fifth cervical vertebrae seems to be commonly affected in most performance horses, presumably because of locally altered biomechanical influences. The individual spinous processes of the third to twelfth thoracic vertebrae are deviated manually from midline, while monitoring for signs of reduced vertebral motion, localized pain, and induced muscle hypertonicity. Horses with poorly fitting saddles (i.e., tree too narrow) resent motion palpation of the affected vertebrae. The remaining thoracolumbar region is assessed in lateral bending and flexion and extension for similar signs of

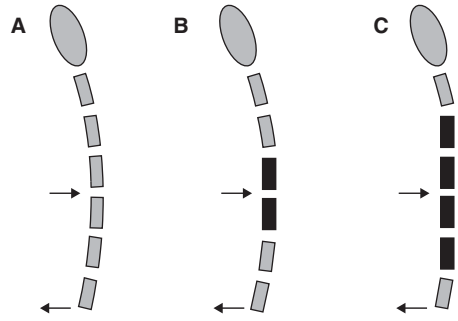

Fig. 94-4 Diagram of segmental vertebral motion during manually induced left lateral bending of the vertebral column. *Arrows* indicate direction of applied forces to vertebral column. **A,** Normal segmental motion of the vertebral column. **B,** Locally restricted vertebral motion involving two vertebrae. **C,** Regionally restricted vertebral motion involving several vertebrae.

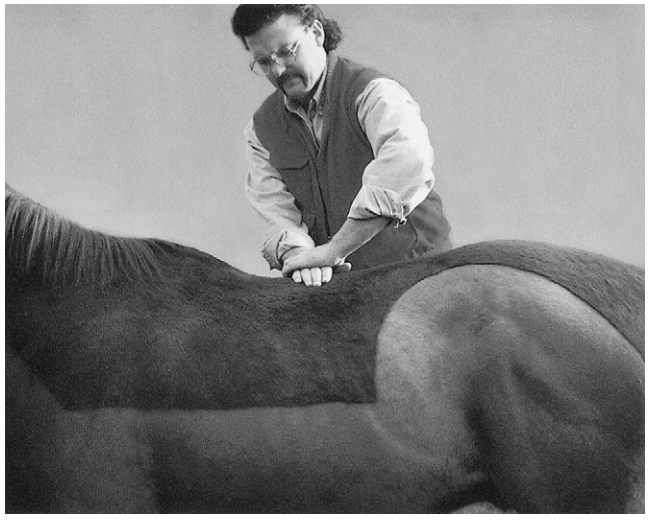

Fig. 94-7 Demonstration of motion palpation with induced extension of the thoracolumbar vertebral column.

joint dysfunction. While the clinician stands next to the horse, segmental vertebral motion in lateral bending is assessed with one hand lying over the intervertebral articulation to be evaluated. The other hand is placed at the tail head and is used to induce rhythmic oscillations to the caudal vertebral column. Normal lateral bending is maximal at the mid-thoracic vertebral region and gradually diminishes toward the lumbosacral junction. Conversely, flexion and extension are minimal in the thoracic region and gradually increase until the lumbosacral junction, the site of maximal flexion and extension. Segmental vertebral motion in flexion and extension requires the clinician to be on an elevated surface to induce ventrally directed rhythmic oscillations to the intervertebral articulations of the thirteenth to sixteenth thoracic vertebrae. The sacroiliac joints are evaluated for motion restriction or pain during induced joint motion, with an applied force directed ventrally over the tuber coxae, or during abaxial compression of the tubera sacrale (see Chapter 53). The caudal vertebrae are assessed by manipulation of individual vertebrae or by applying axial traction. The range of motion of the individual forelimb and hindlimb articulations also are evaluated in flexion and extension, internal and external rotation, abduction and adduction, and circumduction for signs of reduced joint motion, localized pain, and induced muscle hypertonicity. Palpation of the entire musculoskeletal system, including joint motion assessment of the axial and appendicular skeleton, can be accomplished within 15 to 20 minutes.

A neurological examination is indicated to evaluate horses with back problems to rule out traumatic, infectious, and toxic causes (see Chapter 11). Postural reactions also help to assess the proprioceptive status, which may be compromised in horses with certain vertebral column disorders. Rectal palpation is a commonly forgotten diagnostic test in horses with back problems. Osseous palpation rectally is useful for evaluating fractures, pelvic canal symmetry, and lumbosacral or sacroiliac joint degenerative joint disease. Externally induced pelvic motion during rectal palpation helps to assess lumbosacral joint motion internally. Palpation of the iliopsoas muscles for pain, swelling, or asymmetry is also important in evaluating horses with back pain. An orthopedic examination commonly is indicated to rule out or identify concurrent limb problems. Hematological evaluation, diagnostic analgesia, muscle biopsies, or cerebral spinal fluid analysis may be required in certain horses before chiropractic assessment and treatment. Imaging modalities that may contribute to a definitive diagnosis in horses with neck or back problems include radiography, myelography, ultrasonography, scintigraphy, computed tomography, and thermography. A thorough diagnostic workup and a definitive diagnosis, when available, are important for tailoring the appropriate chiropractic treatment and rehabilitation program. Horses with developmental osseous abnormalities, cervical vertebral fractures, thoracolumbar impinged dorsal spinous processes, equine protozoal myelitis, and sacroiliac joint luxation have been referred to me for chiropractic consultation. It was critical that these horses were properly diagnosed and that inappropriate chiropractic treatment was not applied, especially as the sole or primary therapeutic modality.

INDICATIONS FOR CHIROPRACTIC CARE

Chiropractic provides additional diagnostic and therapeutic approaches that are not currently available in veterinary medicine. The principal indications for equine chiropractic evaluation are acute or chronic neck or back pain, localized or regional joint stiffness, poor performance, and an altered gait that is not associated with overt lameness (see Box 94-1). Musculoskeletal conditions that are chronic or recurring, are not diagnosed readily, or do not respond to conventional veterinary care also may be indications for chiropractic consultation. A thorough diagnostic workup is required to identify soft tissue and osseous pathological conditions, neurological disorders, or other lameness conditions that may not be responsive to chiropractic care. Horses with a localized limb lameness or diagnosed neurological disease are better treated with conventional veterinary medicine. However, if a residual lameness continues or a secondary vertebral column disorder (e.g., stiffness or asymmetry) is identified, then concurrent chiropractic care is indicated. Horses that have concurrent hock pain (e.g., osteoarthritis) and a stiff, painful thoracolumbar or lumbosacral vertebral region are best managed by addressing all areas of musculoskeletal dysfunction. A multidisciplinary approach entails concurrent medical treatment of the hock osteoarthritis and chiropractic evaluation and treatment of the back problem. Most horses respond favorably to concurrent management, and owners appreciate a complete and thorough medical evaluation and treatment. Similarly, horses with chronic forelimb lameness often have compensatory pain and stiffness in the withers region that is readily addressed with chiropractic or physical therapy techniques.

The primary clinical signs that equine chiropractors assess are areas of localized musculoskeletal pain, muscle hypertonicity, and restricted joint motion. This triad of clinical signs can be found in a variety of distal limb disorders but it is most

evident in neck or back problems. In general, localized pain, reduced vertebral segment motion, and local muscle spasms in the vertebral column are indications of a primary spinal disorder. In contrast, regional or diffuse pain, generalized stiffness, and widespread muscle hypertonicity are indications of a chronic or secondary spinal disorder, and further diagnostics should be done to identify the primary cause of lameness or poor performance. Chiropractic care may provide symptomatic relief in horses with early vertebral osteoarthritis if related to joint hypomobility and subsequent immobilization degeneration. Research suggests that spinal manipulation also may affect certain visceral disorders (e.g., cardiovascular, respiratory, and gastrointestinal) through somatovisceral reflexes in animals and people.[2,3] However, consistent and predictable long-term changes in visceral disorders rarely occur with chiropractic treatment in people or horses.

Specially trained veterinarians or chiropractors, with advanced training and experience in animal chiropractic techniques, should be able to evaluate vertebral column disorders and determine if the condition will respond to chiropractic care, if further diagnostic evaluation is required, or if the patient would be better managed with traditional veterinary care. Unfortunately, equine chiropractors often are asked to treat animals as a last resort, when all else has failed, or the disease has progressed to an irreversible condition. Chiropractic care has helped some of these horses with chronic conditions when other types of conventional treatment have failed. However, chiropractic is usually much more effective in the early stages of clinical disease versus end-stage disease, where reparative processes have been exhausted. Chiropractic care and other holistic modalities often fail to produce their fully desired therapeutic effects when used as a last resort.

CONTRAINDICATIONS

Chiropractic is not a cure-all for all back problems and is not suggested for treatment of horses with fractures, infections, neoplasia, metabolic disorders, or non–mechanically related joint disorders. Serious diseases requiring immediate medical or surgical care need to be treated by conventional veterinary medicine before any chiropractic treatment is initiated. However, chiropractic care may contribute to the rehabilitation of most horses post-operatively, or those with medical conditions, by helping to restore normal musculoskeletal function. Chiropractic care usually is contraindicated in horses with acute stages of soft tissue injury. However, as the soft tissue injury heals, chiropractic has the potential to help restore normal joint motion, thus limiting the risk for future re-injury.[9] Acute episodes of osteoarthritis, impinged dorsal spinous processes, and severe articular changes, such as joint subluxation or luxation, are often contraindications for chiropractic. All horses with neurological diseases should be evaluated fully to assess the potential risks or benefits of chiropractic treatment. Cervical myelopathy occurs because of structural and functional disorders in the cervical vertebrae. Static compression caused by malformation and dynamic lesions caused by vertebral segment hypermobility are contraindications for cervical manipulation. However, adjacent hypomobile vertebrae may require chiropractic treatment to help restore joint motion and reduce biomechanical stresses in the affected vertebrae. Chiropractic care cannot reverse severe degenerative processes or overt pathological conditions.

CHIROPRACTIC TECHNIQUES

Chiropractic provides important therapeutic approaches that are not currently available in veterinary medicine. Most of the current knowledge about equine chiropractic has been borrowed from human chiropractic techniques, theories, and research and adapted to animals. Therapeutic trials of chiropractic manipulations often are used because knowledge is limited about the effects of chiropractic care on animals. Chiropractic addresses mechanically related disorders of the musculoskeletal and nervous systems and provides a conservative means of treatment and prevention for horses with back problems. Chiropractic treatment uses an applied, controlled force to a specific anatomical region or osseous structure to produce a desired therapeutic response. Chiropractic manipulations are applied to areas of vertebral segment dysfunction. The condition of the horse is monitored closely as the neuromusculoskeletal system responds to the applied treatment. The applied treatment influences joint, muscle, and nerve function via mechanical and biological mechanisms.[2] The therapeutic dosage of the applied chiropractic manipulation is modified by the number of vertebrae treated, the amount of force applied, and the frequency of treatment. The goal of chiropractic care is to restore normal joint motion, stimulate neurological reflexes, and reduce pain and muscle hypertonicity. Comparisons of sensitivity to palpation, muscle tone, and joint motion are made before and after treatment to evaluate the response to chiropractic treatment.

Clinicians and clients often ask how can a 500-kg horse be treated with chiropractic techniques? The answer is one vertebral segment at a time. Recent equine chiropractic research has demonstrated that forces applied to instrumented vertebral segments do induce substantial vertebral motion, usually beyond the normal range of segmental motion that occurs during locomotion.[21] Segmental vertebral motion characteristics induced during chiropractic treatment in horses are similar to those reported in people.[22] In a relaxed horse, the mass (i.e., vertebral segment) that is affected by the rapidly applied force is proportionately smaller than the mass of the clinician applying the treatment. However, if the horse does not relax the paraspinal musculature, then the mass that is affected increases dramatically from the mass of a few vertebral segments to the mass of the entire vertebral region, or potentially the entire horse. Effective joint mobilization or manipulation cannot be applied to a nervous, tense horse without risk of injury to the horse or the clinician. Chiropractic treatments in horses usually are done without any sedation or other medications, but they may occasionally be done with the horse under general anesthesia, or coupled with intra-articular injections, if indicated.[23] Typical indications for manipulation in people under anesthesia includes chronic myositis or fibrosis, or acute musculoskeletal pain, where reflex muscle spasms prevent a thorough assessment or impede manipulative treatment. Untrained professionals who do not have thorough understanding of joint physiology, vertebral anatomy, or chiropractic principles resort to overly aggressive and forceful means of applying an external force (e.g., mallets and 2 × 4s). Small, rapidly applied manual forces are easier to control and have a lower risk of soft tissue or bone injury than more often forceful types of manipulation. A good rule of thumb is that if the procedure does not look like something that the practitioner would be willing to have done to himself or herself, then maybe the procedure should not be done to a horse.

Horses are usually held by a trained handler on a loose lead during chiropractic treatment. The cervical vertebrae, sacrum, and extremities are evaluated and manipulated as needed from ground level. However, the thoracolumbar vertebrae and pelvis often require an elevated surface on which to stand for effective manipulation and proper positioning of the clinician (see Fig. 94-7). Equine chiropractic is physically demanding and requires significant mental concentration. The clinician and the horse must be relaxed and focused on each other. Environmental distractions are counterproductive to effective chiropractic care.

Muscle relaxation allows evaluation of the elastic barrier of the joint. Motion palpation is used to evaluate joint motion restrictions so that the manipulative thrust can be applied correctly. Stabilization of adjacent joints or vertebral segments is required for proper joint manipulation.

Typically, an immediate reduction in pain and an increase in segmental vertebral motion is noted. Most horses also have increased muscle relaxation, but other therapies (i.e., acupuncture or stretching) often are used with chiropractic treatment to completely resolve any remaining muscle hypertonicity. In general, conditions with an acute onset respond rapidly, whereas chronic conditions usually require longer treatment or rehabilitation. Horses with acute pain or vertebral column trauma may require initial anti-inflammatory medication, physiotherapy modalities (e.g., ice), or rest before chiropractic treatment. If stiffness, local muscle hypertonicity, or pain remains, then two or three chiropractic treatments may be indicated. Horses with chronic neck or back stiffness may require monthly evaluation and treatment for several months' duration. Owners often request chiropractic evaluation at the beginning of the performance season, a few days after athletic competition, or as a general assessment of the overall musculoskeletal system. Similarly, horses may benefit from chiropractic treatment several days before an event. Because of ethical considerations or possible masking of musculoskeletal dysfunction, it is not recommended that chiropractic treatment be performed immediately before or during any competition.

Post-treatment recommendations for actively training horses usually include stall rest or pasture turnout for one day, which provides an opportunity for the musculoskeletal system to respond to the applied treatment without immediate re-exposure to potential inciting factors of the vertebral segment dysfunction. The horse is asked to return to normal work the next day, unless other musculoskeletal injuries are present, for which appropriate supportive care is recommended. If stiffness or soreness is noted after chiropractic treatment, then an additional day of rest is suggested.

COMPLICATIONS OR ADVERSE EFFECTS

Potential adverse effects from properly applied chiropractic treatments include a transient stiffness or worsening of the condition after treatment (i.e., aggravated complaint, worsening of pre-existing state, regional soreness, or lameness).[3] Adverse reactions from properly applied vertebral manipulation are typically uncommon, but they may occur immediately after treatment or insidiously within 6 to 12 hours. The undesired effects usually last less than 1 to 2 days and resolve without concurrent medical intervention. If increased or acute musculoskeletal dysfunction or lameness is noted after chiropractic treatment, then a thorough re-examination and appropriate medical treatment or physiotherapy should be pursued. If the condition does not improve with conservative care, referral for more extensive diagnostic or therapeutic modalities is recommended. Potential harmful side effects from improperly applied manipulation from untrained individuals may include permanent articular damage or loss of function (i.e., torn ligaments, injured muscles, luxated joints, fractures, or possible paralysis if a severe underlying pathological condition is present).

ADJUNCT RECOMMENDATIONS AND PROGNOSIS

Chiropractic care often is supplemented with massage, physiotherapy modalities, and stretching or strengthening exercises to help soft tissue rehabilitation and to help restore normal vertebral joint motion (see Chapter 96). These concurrent therapies also help to encourage owner participation in the healing process and provide close monitoring of the patient's progress. Other recommendations may include changes in training schedules or activities, corrective shoeing, or tack changes. Horses with poorly fitting saddles often have localized pain and muscle hypertonicity in the caudal withers region. Saddle refitting, coupled with chiropractic treatment of the painful withers region, leads to rapid recovery and management of a common problem for many horse owners. A horse with a 6-month history of consistently resenting saddle placement and bucking the owner off was treated chiropractically and the next week won 11 ribbons at the local country fair. Many horses with repetitive-use disorders may benefit from cross-training activities. Clinicians also have reported synergistic therapeutic effects with the combined use of chiropractic, acupuncture, and other holistic modalities in equine patients. In general, horses with conditions with an acute onset respond rapidly and have a good prognosis for return to function. Horses with chronic injuries may gain only short-term improvement of restricted motion, pain, or muscle hypertonicity. This corresponds to current research on joint immobilization and spinal learning.[9] Horses with chronic conditions usually require a series of treatments to affect a more lasting improvement. Musculoskeletal health depends on movement and use. Scientific evidence suggests that long-term rest or inactivity is contraindicated for back problems in people.

SUMMARY

A thorough knowledge of equine vertebral anatomy, biomechanics, and pathology is required to understand the principles and theories behind chiropractic and to apply its techniques properly. Anecdotal evidence and clinical experience suggest that chiropractic is an effective adjunct modality for the diagnosis and conservative treatment of select musculoskeletal-related disorders in horses. Chiropractic provides additional diagnostic and therapeutic means that may help equine clinicians to identify and treat select musculoskeletal disorders. Chiropractic provides specialized evaluation and treatment of joint dysfunction and conservative treatment of neuromusculoskeletal disorders that currently lack treatments in traditional veterinary medicine. However, limited research is currently available on the efficacy of equine chiropractic. Direct measures of chiropractic techniques in horses demonstrate substantial induced vertebral motion, usually beyond the normal range of segmental motion that occurs during locomotion.[21] In 1996 the Committee on Alternative and Complementary Therapies of the American Veterinary Medical Association suggested that the research community should be encouraged to prioritize avenues of research and to allocate research funds to projects that will provide further scientific evaluation of these modalities.[24] Because of its potential misuse, animal chiropractic evaluation and treatment should be provided only by licensed and specially trained clinicians or chiropractors. Future studies should evaluate the use of chiropractic techniques in horses and evaluate the long-term functional effects.

Therapeutic Use of Ultrasound, Lasers, and Electromagnetics

Michael A. Ball

The use of therapeutic ultrasound, lasers, electromagnets, and magnets may be important for lameness treatment, but the body of equine-specific research about correct usage is small. These treatment modalities are widely promoted to horse owners without veterinary involvement. No statutory control is exercised over the manufacturing and sale of this equipment, which may not meet the minimum technical requirements to be useful. Certain types of equipment may cause harm if used incorrectly.

Evidence exists that therapeutic ultrasound, lasers, and magnets do have value to manage some equine injuries, and there are vague therapeutic protocols derived from limited objective research to allow for safe clinical experimentation.

THERAPEUTIC ULTRASOUND

Objective study of therapeutic ultrasound in people or horses is limited and conflicting. Comparison of studies is difficult because of the use of differing treatment protocols. A placebo effect does appear to occur in people. Nonetheless, I believe that therapeutic ultrasound can be beneficial, but more information is needed about appropriate machine settings, particularly because ultrasound does have the potential to damage tissues.

Equipment

Therapeutic ultrasound machines are available as portable units powered from wall outlets (110 V or 220 V) or cordless and battery operated. Transducer size varies from 5 to 10 cm in diameter surface, appropriate for treatment of distal extremities or large muscle masses, respectively. The sound waves emitted from regular transducers are relatively unfocused and have the potential to penetrate all tissue directly underneath, with the waves being most intense at the skin level and attenuating as they pass through soft tissue. Newer transducers allow for the focusing of ultrasound waves on the target tissue, thereby decreasing exposure to surrounding tissue. Time, frequency, power as watt per square centimeter (W/cm^2) or overall watts, or duty cycle can be controlled. *Duty cycle* refers to the ultrasound emissions being continuous

Therapeutic Use of Ultrasound, Lasers, and Electromagnetics

Michael A. Ball

The use of therapeutic ultrasound, lasers, electromagnets, and magnets may be important for lameness treatment, but the body of equine-specific research about correct usage is small. These treatment modalities are widely promoted to horse owners without veterinary involvement. No statutory control is exercised over the manufacturing and sale of this equipment, which may not meet the minimum technical requirements to be useful. Certain types of equipment may cause harm if used incorrectly.

Evidence exists that therapeutic ultrasound, lasers, and magnets do have value to manage some equine injuries, and there are vague therapeutic protocols derived from limited objective research to allow for safe clinical experimentation.

THERAPEUTIC ULTRASOUND

Objective study of therapeutic ultrasound in people or horses is limited and conflicting. Comparison of studies is difficult because of the use of differing treatment protocols. A placebo effect does appear to occur in people. Nonetheless, I believe that therapeutic ultrasound can be beneficial, but more information is needed about appropriate machine settings, particularly because ultrasound does have the potential to damage tissues.

Equipment

Therapeutic ultrasound machines are available as portable units powered from wall outlets (110 V or 220 V) or cordless and battery operated. Transducer size varies from 5 to 10 cm in diameter surface, appropriate for treatment of distal extremities or large muscle masses, respectively. The sound waves emitted from regular transducers are relatively unfocused and have the potential to penetrate all tissue directly underneath, with the waves being most intense at the skin level and attenuating as they pass through soft tissue. Newer transducers allow for the focusing of ultrasound waves on the target tissue, thereby decreasing exposure to surrounding tissue. Time, frequency, power as watt per square centimeter (W/cm^2) or overall watts, or duty cycle can be controlled. *Duty cycle* refers to the ultrasound emissions being continuous

or pulsed. To avoid potential equipment damage the clinician should never turn on ultrasound emission without the transducer being properly coated with contact jelly and in contact with the tissue being treated.

Mechanism of Action

The exact mechanisms by which sound waves are potentially beneficial to damaged tissue are unknown. The main effect is the production of heat, because sound energy is converted to thermal energy as it interacts with tissue. Mechanical effects are also caused by the high-frequency vibrational energy, such as cellular friction and cavitation, which are proposed to have a micromassage effect at the cellular level. Factors influencing the production of thermal energy within the tissues and the mechanical bioeffects include the output power and frequency, the profile of the ultrasound beam, and temporal aspects of the sound emission. Some evidence indicates that the biomechanical effects are responsible for some of the positive alterations in cellular physiology within damaged tissue, such as increases in cellular protein synthesis and effects on fibroblasts. Possibly, pulsed ultrasound emissions could decrease the overall heat production within the tissue, decreasing the potential for thermal injury at the cellular level, while maintaining the positive bioeffects of isonation (the exposure of tissue to ultrasound energy).

In vitro studies have demonstrated alterations in blood flow and angiogenesis and increases in collagen and protein synthesis and in osteogenesis. The effects depend on the power and frequency of the ultrasound applied.[1,2] In vivo studies have demonstrated improved healing of pressure sores and surgical wounds in people.[3,4] Clinical trials have shown conflicting results for therapeutic ultrasound in treating tendon injuries.[5-7] Therapeutic ultrasound had no effect on regeneration of experimentally injured muscle fibers[8] and failed to alleviate chronic heel pain in people.[9]

The effect of therapeutic ultrasound on surgically split superficial digital flexor tendon (SDFT) was assessed in horses with the contralateral limb acting as control. The treated limb received 1.5 W/cm^2 with continuous duty cycle for 10 minutes daily, 6 times weekly for 2 weeks. At 4 and 6 weeks the control tendons showed perivascular inflammatory reactions and degeneration of tendon tissue, and the treated limbs showed good healing characterized by vascularization and fibroblastic proliferation.[10]

More is not always better. Excessive exposure to ultrasound may cause thermal injury. Certain therapeutic benefits observed using one treatment dosage are not observed when a higher dosage is used in the same situation. The interval between injury and treatment is important: the clinician should avoid treatment during the acute phase of inflammation. Cold hydrotherapy and anti-inflammatory medications should be used for acute tendon and ligament injuries for 3 to 5 days before using therapeutic ultrasound.

Clinical Application

Clipping the hair over the treated area aids transmission of ultrasound waves. A liberal amount of contact gel should be applied to both the treated area and the head of the transducer to minimize the risk of thermal damage. The transducer should be in constant motion when emitting and in contact with the body. I usually move the transducer slowly up and down the leg when treating tendons or in a spiral circle pattern if treating muscles.

To treat tendons or ligaments, I use 3 MHz with 1.5 W/cm^2 power and a continuous duty cycle for 10 minutes of therapy once daily for 14 days.[10] The treatment is started 3 to 5 days after the initial injury, when the acute inflammatory phase is subsiding. For muscle tissue I use a lower frequency (1 MHz) to provide deeper penetration.

No good clinical trials are available that document the efficacy of therapeutic ultrasound, but subjectively I believe that some horses do benefit when this treatment is used with other standard therapies. More information is needed about the ideal time and duration of treatment and the power and frequency of the ultrasound for different injuries.

THERAPEUTIC LASER THERAPY

Laser Physics

The term *laser* stands for *l*ight *a*mplification by *s*timulated *e*mission of *r*adiation. A laser emits monochromatic, parallel, coherent light, creating a uniform, focused beam of photon energy. The physical characteristics of laser light are determined by the wavelength and power. Power is the energy contained in the photon beam in watts, which is equal to joules per second. The power output of lasers used in medical physical therapy is in the milliwatt range. The wavelength is the relationship of the frequency of the emitted laser light to the speed of light; the wavelength of laser light used in low-intensity laser medicine is between 300 and 10,600 nm. The intensity is the relationship of power to the surface area of the tissue irradiated and is indicated by watts per square centimeter. The dose summates the total of power, time, and area of tissue irradiated and is indicated by joules per square centimeter (J/cm^2).

Medical Laser Equipment

A variety of laser equipment is marketed for equine use, some of which comes with detailed treatment protocols, offering settings for a variety of musculoskeletal problems. However, these protocols are not likely supported by scientific study because of the dearth of literature related to laser use in the horse. It is essential that the power and wavelength output are adequate to penetrate the horse's skin. Many machines currently available are inadequate. Even deep therapeutic lasers with wavelengths of 632 to 950 nm penetrate only 0.5 mm beyond human skin.[11-14]

Mechanism of Action

The mechanisms behind the biostimulatory or biomodulatory effects of low-intensity laser irradiation are not understood fully, but they are thought to include alterations in mitochondrial enzymes, cytochromes within the electron transport chain, and cellular calcium channels.[15-17] The net effect of these cellular alterations includes the triggering of mitosis and cellular proliferation.[18] Laser light of the correct wavelength and intensity may have a variety of biomodulatory effects, including alterations of circulation, production of pharmacologically active compounds, and analgesia; excessively high doses inhibit cellular metabolism.[19,20] Any effect depends on power, wavelength, dosage, and intensity.

Clinical Application

Low-intensity laser irradiation may influence wound healing. Application of an 860-nm diode laser at a dose of 2 J/cm^2 increased cell proliferation and enzyme activity of human fibroblasts. Experimentally created teat wounds in cattle were treated with a 632-nm continuous wave helium-neon laser, with an output of 8.5 mW and a dosage of 3.64 J/cm^2. Healing was improved by minimizing inflammation and edema formation, improvement of skin regeneration, and enhancement of collagen synthesis.[21] To my knowledge, only one experimental study has evaluated the effect of laser therapy on wound healing in the horse, which showed no benefit in treatment with an 830-nm laser at a dose 2 J/cm^2.[22]

I have obtained beneficial results treating skin wounds and after excision of exuberant granulation tissue, using a 69-diode laser cluster probe containing 34,660-nm and 35,950-nm diodes, with a total power of 865 mW for an

approximate dosage of 25 J/cm^2 (continuous wave) daily for 7 to 10 days. The cluster probes are advantageous because they allow treatment of a larger unit of area per unit of time, thereby decreasing the overall treatment time.

Several uncontrolled clinical studies have evaluated laser treatment of superficial digital flexor tendonitis in the horse.[23,24] Whether current equipment has adequate penetration is debatable,[12,13] although using detection equipment, I estimated that a 200-mW diode laser at 810 nm penetrated up to 2 cm in equine neck muscle.

Low-level laser therapy may provide analgesia.[25-27] An 830-nm diode laser used at an intensity of 3 W/cm^2 and a dosage of 24 J/cm^2 reduced post-operative abdominal incisional pain in people.[25] A large meta-analysis assessed the efficacy of analgesia for patients with osteoarthritis or rheumatoid arthritis of the knee, hand, or fingers.[27] Patients were treated three times weekly for 3 to 6 weeks. An analgesic effect was achieved at 632 nm or 830 nm, although the lower wavelength appeared superior. Lower doses (≤3 J/cm^2) tended to be more effective than higher doses.

No studies have evaluated analgesia in the horse, except relating to acupuncture. I have used a 200-mW single-diode laser operating continuously at 810 nm at a dose of 3 J/cm^2 as an adjunct therapy for horses with centrodistal and tarsometatarsal osteoarthritis. The treatment targeted the joint spaces, moving circumferentially around the joints, especially treating the area of the cunean tendon. The treatment was performed three times weekly and was subjectively beneficial in some horses. Several horses with pronounced pain on palpation of the cunean tendon were treated only with laser therapy and had reduced pain and lameness after six treatments. Further controlled clinical trials are essential in the horse to determine whether beneficial therapeutic effects can be achieved and the optimum treatment protocols.

I believe that therapeutic laser can be a useful adjunct therapy but not a replacement for any traditional therapies for musculoskeletal lameness. I do feel that the benefits of therapeutic laser on wound healing are profound and recommend its use as part of primary wound care where applicable.

MAGNETIC AND ELECTROMAGNETIC THERAPY

Considerable controversy surrounds the use of magnetic and electromagnetic therapy, with conflicting published results. A large amount of anecdotal information exists, with a strong marketing push by equipment manufacturers to the lay horseman, with a general lack of technical information, understanding, and direction for use.

Basic Physics

An electromagnetic field is created by passing an electric current through a coil of insulated wire. The strength of the magnetic field measured in gauss is proportional to the magnitude of the current. The nature of the Gaussian field can be altered by pulsing the electric current and altering the waveform of the signal. With a single coil the magnetic field emanates perpendicular to the coil and then bends. Use of two coils is necessary for a magnetic field to pass through tissue staying perpendicular to a particular plane. To treat a horse's third metacarpal bone coils are placed lateral and medial to the bone. The distance between the coils cannot be greater than the diameter of the coils, otherwise the uniform nature of the magnetic field breaks down. If a single coil is used, the magnetic field only penetrates tissue to a depth of one half the diameter of the coil.

Magnetic Equipment

Magnetic/electromagnetic devices available range from small, solid magnetics (stationary magnets) imbedded in bell (overreach) boots and a variety of other boots and bandages, to full-size blankets containing large coils and transformers, allowing for adjustable field strength and characteristics or pulse therapy (electromagnet). The U.S. Food and Drug Administration regulates the use of electromagnetic therapy in people, but no quality control is exercised over the products available for use on the horse.

Mechanism of Action

Since the discovery of the piezoelectrical properties of bone, a large body of research has supported the effects of an electromagnetic field on bone healing.[28-31] Electroporation is a universal, non-thermal, bio-electrochemical phenomenon relating to the rate of two-way transmigration of chemical ions through cell membranes, defining the metabolic rate and ultimately the energy level of the cell. Pulsed electromagnetic field therapy may stimulate electroporation and provide pain relief.[32] Pulsed electromagnetic field therapy enhanced nerve regeneration in experimental rat models[33-36] and was beneficial in treating rotator cuff tendonitis, using a magnetic field generated by a single coil, peaking at about 27 G (specific waveform varied over 4.23 ms) pulsed at 73 Hz. The treatments were applied for 1 hour, 5 to 9 hours per day.[37]

Studies of electromagnetic therapy in the horse are limited. Some benefit in fracture healing was observed using two coils coupled to a signal generator creating a 50-ms, 2-G field pulsed at 2 Hz, applied for 2 hours per day.[38] Horses with bucked shins also improved. However, pulsed electromagnetic field therapy delayed repair tissue maturation and collagen-type transformation in experimentally created defects in the SDFT in horses.[39] In contrast, electromagnetic stimulation increased tissue maturation, tensile strength, and collagen content in experimentally damaged rabbit collateral ligaments[40] and increased breaking strength in experimentally damaged rat tendons.[41] Variations in temporal relationship of therapy to injury and overall dosage protocol may mean the difference between no effect, positive effect, and negative effect.

Despite the widespread use of electromagnetic treatment in the horse, I am skeptical that many commercially available magnetic products generate a magnetic field strong enough to have any bioeffects. The effects of magnetic treatment on bone healing are well documented, but for other conditions determining the degree of therapeutic benefit, if any, is difficult because many horses receive a combination of treatments. I do not use any form of magnetic therapy as a primary treatment for any musculoskeletal disorders. I believe more research is required to demonstrate efficacy. If I am approached by a client who is using magnetic therapy, I encourage him or her to allow me to make a diagnosis and perform more standard treatments. Many clients use magnetic body blankets as an adjunct treatment for back muscle soreness, but results are anecdotal.

CHAPTER • 96

Massage, Stretching, Homeopathy, and Herbs

Joyce C. Harman

The addition of massage, stretching, herbal treatment, and homeopathy to a conventional treatment protocol can help return horses with sports injuries to full performance more quickly. Performance problems may be alleviated despite the absence of obvious painful foci.

RECOGNIZING MUSCLE PAIN, TENSION, AND LOSS OF JOINT MOTION

The clinical examination should include assessment of muscle tension and joint mobility. Muscle pain can result in subtle or overt lameness and a variety of behavioral problems. A horse with a recent muscle injury often becomes sorer toward the end of a ride, whereas a horse with an old muscle injury starts out stiff and sore, takes a long time to warm up, and then improves. The clinician should observe the natural stance of the horse at rest, because many horses with pain develop a compensatory positioning of the limbs. Symmetry should be assessed from all angles, including from above, by standing on a stool behind the horse. Many horses with muscle pain move freely on the lunge, but they may become stiff or sore when ridden, resulting in stiffness or resistance when asked to perform certain movements, such as circling left or right, rather than overt lameness.

The clinician should gently palpate the muscles of the neck, back, and thorax, looking for tension, sensitivity, flinching, or discomfort. A healthy muscle feels soft and springy. Muscle under tension feels tight and hard and has little spring. Muscle spasms and fasciculation can be seen both locally and at a distance from the palpation site of tense muscle. Muscle in spasm is more prone to injury and takes longer to warm up because blood flow is restricted. A horse with muscle pain may splint its back or hold it rigidly in place to avoid movement. The clinician should then probe more deeply into the muscle. If the horse is accustomed to a light touch, any spasm, hardening, or flinching with deeper palpation confirms and defines sites of pain and hard knots in the muscle. If deep palpation is started too quickly, the horse may flinch from the touch rather than from pain.

The clinician should assess joint mobility by using the stretches described subsequently. Healthy joints move freely and have spring to them, whereas problem joints often feel stiff and have reduced motion.

MASSAGE

Massage techniques can be used to treat horses with specific muscle injuries, to prevent injuries, for pre-event preparation, and for post-event recovery.[1] Damaged, contracted muscle has less blood flow through the capillaries than healthy muscle. One of the primary benefits of massage is restoration of even blood flow to the muscle, a result that can be confirmed thermographically. Mechanical breaking of scar tissue is often reported, but evidence that physical change occurs in any tissue is lacking. Massage currently is used routinely on many human athletic teams to prevent and treat muscle injuries and might be useful if used more routinely in equine athletes.

Much subtle lameness can be attributed to muscle damage that responds well to massage.[2] Frequently injured muscles include the adductor, gracilis, psoas, semimembranosus, semitendinosus, gluteals, quadriceps, longissimus dorsi, rhomboideus, trapezius, and ventral strap muscles of the neck. With recent injury massage is used to enhance the clearing of lymphatic fluid and blood from the damaged area. Massage is used in horses with older, chronic injuries to restore circulation and flexibility.

Massage therapy consists of manipulation of the muscle using a variety of techniques. Massage can be specific to treat a small area, known as *trigger point therapy* (also known as *myotherapy* or *neuromuscular therapy*), where concentrated finger pressure is applied to trigger points (painful irritated areas in muscles) to break cycles of spasm and pain. Trigger points commonly occur in the gluteal muscles, the longissimus dorsi muscles over the last few ribs, and the lumbar muscles. However, trigger points can occur in any muscle. Swedish massage is a system of long strokes, kneading, and friction techniques on the more superficial layers of the muscles, combined with active and passive movements of the joints. Generally this form of massage feels good and relaxes the horse, but it is less effective for treating a problem. Several forms of deep tissue massage are also used and release the chronic patterns of tension in the deeper layers of muscle tissue, through slow strokes and deep finger pressure on the contracted areas, following or going across the grain of muscles, tendons, and fascia.

Myofascial release is a particularly useful form of massage for horses that releases tension in the fascial covering of the muscle. Long, stretching strokes are used to release muscular tension. In many horses the fascia feels tighter than the underlying muscle. *Shiatsu* and acupressure are Oriental-based systems of finger pressure that treat special points along acupuncture meridians (Chapter 93). Acupressure can be a useful form of massage, although its effects generally are longer lasting and require less repetition.

Massage usually is performed by laypersons, many of whom have little training other than a 1-week course. Currently the best way to find a qualified person is to locate someone who has completed a full 500-hour massage course for people and who has then taken one of the more extensive equine courses. Clinicians are advised to locate a few top-quality massage therapists for client referrals, so that effective therapy is performed and the clinician stays involved with the horse. Riders also should be advised of the benefits to muscle of slow warm-up before exercise and a cool-down period after exercise to facilitate clearance of lactic acid.

STRETCHING

Stretching is one of the simplest, most effective ways to enhance performance, aid in rehabilitation after an injury, maintain or restore full joint mobility, and assess flexibility.

Stretching can be performed by an owner regularly or by a clinician as part of an examination and treatment. In my experience, horses that are stretched regularly (daily or at least 2 to 4 times a week) are generally more flexible and stay sounder than horses that are not stretched.

Stretching must be done correctly and carefully, keeping the horse comfortable and relaxed, to avoid injury. The use of force can damage muscles and joints. Any joint can be stretched safely through its full range of motion if the handler holds the leg in position and waits for the horse to release and relax the muscles; then the stretch can be taken further. A horse is always stronger than its handler, and if the horse pulls back, it tightens the muscle the handler is trying to loosen. An analogy is persons bending down to touch their toes. Without some warming up and gentle stretching, many persons feel pain and tension at the back of the knees, but with time and progressive further stretching, reaching further without pain is possible.

Upper Body

Carrot stretches, where the horse is asked to reach to the tuber coxae and down between the forelimbs, are one of the most effective stretches to increase flexibility. A carrot or other treat is used to entice the horse to stretch. A horse with normal flexibility can reach each tuber coxae and come close to its stifle, as well as reach down well between its forelimbs. This stretch restores flexibility to the neck, withers, and thoracic area, with some muscle stretching even as far as the lumbar area. Many horses have restricted motion in the neck after trauma such as pulling back when tied and falling. Some horses may need chiropractic care to restore complete motion (see Chapter 94).

Motion through the thoracic vertebrae and ribs is critical to allow a horse to perform lateral movements demanded by many sports, including cutting, reining, barrel racing, dressage, and jumping. Subtle lameness and particularly stiffness in one direction often results from lack of motion through the rib cage. The stretch to diagnose and treat restricted motion through the thorax is the belly lift or sideways belly lift. Regular use of these stretches can improve performance substantially. To perform the belly lift, a handler places finger tips on the midline of the sternum behind the elbows and presses upward. The fingers can be moved along the midline to the center of the abdomen to raise different parts of the back. The handler starts with a light touch and increases pressure until the back rises. For some horses a blunt plastic tool such as a needle cap or plastic writing pen may be needed to raise the back. To perform the sideways belly lift, the handler stands on one side of the horse and reaches across the midline to the girth area behind the elbows on the opposite side and then pulls the rib cage diagonally upward toward the withers on the side on which the handler is standing (toward the handler's head).

When belly lifts are comfortable for the horse, the abdominal muscles should contract, the longissimus muscles should fill out and relax, the withers should rise, and the head and neck should stretch out and down. With sideways belly lifts the rib cage should move easily laterally, the same amount from both sides. The withers (trapezius and rhomboideus) on the side at which the handler is standing should fill with relaxed muscle, while the opposite side should form an even concave bend. The head and neck should stretch down and forward, curved slightly away from the handler.

When pain and tension exist, parts of the longissimus group of muscles contract, as can be seen by depressed areas in the muscle as the back is raised. The withers may or may not rise, depending on the location of the pain, and the head and neck usually rise up. Many horses are incapable of rising or moving the back laterally without significant pain, and they kick or bite; thus caution must be used. The pain preventing a comfortable belly lift may be from muscle tension in the psoas, lumbar area, intercostal muscles, pectorals, or withers. Pain also results from the loss of motion or arthritis that may be present throughout the thoracic vertebrae and may require chiropractic treatment (see Chapter 94).

The withers stretch can relieve tension and pain through the cranial thorax and partly under the shoulder blades. The handler places his or her hands over the withers and then leans back, gently pulling on the withers, starting at the cranial edge and moving toward the caudal part of the withers. When the stretch is ended, the handler should release the withers slowly. If little pain is observed, and the horse is enjoying the stretch, the horse will pull against the handler and relax into the stretch. If pain is substantial, muscle fasciculations and spasms may be felt under the handler's hands, and the horse does not pull into the stretch. This is especially useful with horses wearing tight blankets and those that appear to be lame while wearing blankets.

The tail stretch relieves tension in the tail and in the dorsal and ventral muscles surrounding the sacral area (sacrocaudalis dorsalis and ventralis). Many horses have substantial tension in the tail and sacral area, which can contribute to muscle tension in the hindlimbs, especially the hamstring area. The tail stretch is performed in several stages, with the handler first taking the tail and rotating it in circles, holding it at the base and the tip of the bone. After some relaxation is achieved, the tail may be brought gently up over the back, waiting for the muscles to relax as the stretch goes further. Then the tail can be pulled slowly caudally away from the body. When this part of the stretch is complete, the handler releases the tail slowly; otherwise, tension increases as the tail snaps back.

Lower Limbs

Stretches for the joints and muscles of the limbs include leg circles, psoas stretch, and hamstring stretch. These stretches are particularly for the large joints, hip and shoulder, and associated large muscle groups. Subtle lameness sometimes can be attributed to restriction of motion of the hips and shoulders and pain in the large muscle groups.

Leg circles are performed by holding the foot in the position for cleaning and then, as if a pencil were attached to the toe of the foot, a circle is drawn in the ground five or six times in clockwise and counterclockwise directions, with the entire leg moving. A horse with a full range of motion produces an even circle in all directions. A horse with restricted motion may give an uneven circle, square, or oblong pattern, with intermittent signs of discomfort. Using circles as a regular stretch improves range of motion, stride length, and ease of shoeing.

The psoas and hamstring stretches are perhaps the most important stretches for a performance horse. The psoas muscle is a large hip flexor muscle that inserts on the ventral side of the ribs and is often tight, causing many horses to have difficulty stretching the hindlimb caudally. The pull of a tight psoas muscle often restricts the flexibility of the rib cage in the belly lifts. These stretches are performed by holding a hindlimb cranial or caudal to the vertical, at the limit of the range of motion, and then waiting for the horse to release the leg a bit. As the muscles relax, the stretch can go further, until the leg reaches the back of the carpus (hamstring stretch) or can touch the ground behind the vertical. If force is used, the horse pulls back and tightens the muscle. If the horse is comfortable with the stretch, it releases the leg quickly, but if uncomfortable, the horse may only release small amounts at a time.

HOMEOPATHIC TREATMENT OF INJURIES

Homeopathy is a branch of complementary medicine that is perhaps least well understood, but it does have a place in

the management of lameness. Homeopathic remedies can be used with any conventional treatments, but faster results are achieved by using the remedies alone, together with supportive care such as cold hosing, bandages, or controlled exercise. The principles of homeopathy are discussed elsewhere.[3]

Homeopathic remedies usually are supplied in small tablets or sand-size granules listed with a potency of 30X, 30C, or 200C. The standard dose is six to eight tablets, or one-half teaspoon of granules for an adult horse and less for a pony or foal. The remedies can be given once or twice daily for the 200C formulation, or 2 to 3 times daily for the 30X or 30C potency, and can be fed with small quantities of food or placed directly in the mouth. Homeopathic remedies are prepared by diluting the original substance and therefore do not yield positive results in a drug test during competition in the strengths just described. Several remedies are particularly useful for treating lameness. I have used *Arnica montana* successfully to decrease the pain, swelling, stiffness, and healing time in many traumatic injuries. *Arnica* can be given 1 to 3 times daily, with the more frequent dosing used for more severe injuries. *Arnica* can be administered at any point in the healing process to improve healing, but it is most effective if used for horses with acute injuries.

Ruta graveolins is a remedy that has particular affinity for injuries to the periosteum, including splints, ringbone, strained joints, and blows to the bone. In my experience, the injuries listed previously heal more quickly and with less exostosis than would be expected with conventional treatments. For acute injuries, *Arnica* is used for the first few days or a week until the main swelling and pain is reduced, and then *R. graveolins* is used for 3 to 5 days. Horses with chronic ringbone respond well to *R. graveolins* administered once or twice a week as needed to keep the horse comfortable and in many horses, sound. *R. graveolins* also is used for horses with acute tendonitis or desmitis and is given 2 to 3 times a week for several weeks and then is followed by *Rhus toxicodendron*. *R. toxicodendron* is indicated when an injury to muscle, tendon, ligament, or joint has healed to the point where the horse is stiff when starting out but warms up and moves much better. In the later stages of a tendon injury, *Rhus toxicodendron* is given for 2 to 5 days in a row and then 1 to 3 times weekly for a few weeks. *R. toxicodendron* also is used commonly for arthritic conditions, administered once or twice weekly.

HERBAL THERAPY FOR LAMENESS

Herbs have been used for centuries to treat various injuries, and in China martial arts practitioners also used herbal preparations to strengthen tendons and ligaments. Herbs can be used internally (as powders or teas) and externally as ointments, liniments, or poultices.[4] Herbs contain active ingredients and some, such as yucca and white willow bark, yield test positive results in blood and urine testing for drugs, mainly when the herbs are ingested rather than topically applied.

A. montana can used as a poultice, ointment, body wash, or liniment as a topical treatment for bruising or muscle, tendon, and ligament injuries and overworked and tired muscles. *Arnica* should never be used on broken skin because it irritates the skin. *Arnica* has mild anti-inflammatory activity.

Comfrey has anti-inflammatory properties and is best used as an external poultice. The herb is easy to grow, and a poultice can be made simply by crushing the leaves slightly and bandaging them onto the injured area. Some horses have sensitive skin and should have the poultice applied for only part of the day.

Internally administered dried herbs or liquid extracts of devil's claw, meadowsweet, white willow bark, and yucca are known for anti-inflammatory action. In general, herbs such as these take several days of feeding or longer for the effects to be seen, so they are usually more effective when given to horses with chronic rather than acute problems. Products containing herbs with anti-inflammatory effects can be used in acute situations; however, homeopathic remedies may be more effective.

CHAPTER • 97

Physical Therapy and Rehabilitation

Michael A. Ball

Physical therapy and rehabilitation techniques have been well defined in human medicine for many decades and play an important role in recovery from a variety of injuries. Programs use trained therapists and an array of therapeutic equipment to help persons regain strength, stamina, balance, and coordination, and to assist healing of specific injuries while attempting to minimize the risk of re-injury. The field of physical therapy and rehabilitation focusing on horses has grown tremendously in the past 10 years, but it is still in the embryonic stages of development. Much is still to be learned about the best ways to rehabilitate various injuries in the horse and how to evaluate and treat the variety of compensatory problems that can develop. I believe this area will continue to evolve, with the growth of specialty centers providing physical therapy and rehabilitation services for horses, working with clinicians.

Equine physical therapy and rehabilitation techniques have been reviewed recently.[1] In Canada, the United Kingdom, and

the management of lameness. Homeopathic remedies can be used with any conventional treatments, but faster results are achieved by using the remedies alone, together with supportive care such as cold hosing, bandages, or controlled exercise. The principles of homeopathy are discussed elsewhere.[3]

CHAPTER • 97

Physical Therapy and Rehabilitation

Michael A. Ball

Physical therapy and rehabilitation techniques have been well defined in human medicine for many decades and play an important role in recovery from a variety of injuries. Programs use trained therapists and an array of therapeutic equipment to help persons regain strength, stamina, balance, and coordination, and to assist healing of specific injuries while attempting to minimize the risk of re-injury. The field of physical therapy and rehabilitation focusing on horses has grown tremendously in the past 10 years, but it is still in the embryonic stages of development. Much is still to be learned about the best ways to rehabilitate various injuries in the horse and how to evaluate and treat the variety of compensatory problems that can develop. I believe this area will continue to evolve, with the growth of specialty centers providing physical therapy and rehabilitation services for horses, working with clinicians.

Equine physical therapy and rehabilitation techniques have been reviewed recently.[1] In Canada, the United Kingdom, and

several other countries some physical therapists are certified, having completed an extensive training protocol, and work collaboratively with veterinarians. No training or certification process is available in the United States, and worldwide many completely unqualified persons practice under a number of titles. An accurate diagnosis of lameness is essential before any physical therapy begins, because inappropriate treatment could lead to serious complications.

MASSAGE

Massage may be beneficial in treating a variety of muscle problems to promote relaxation and improve venous return[1] (see Chapter 96). I have used massage for horses with focal muscle spasms or knots, particularly on the longissimus muscles of the back, where tightness and spasm is often secondary to poor saddle fit or padding. The primary problem also must be identified and treated. I have found light massage therapy to be helpful in horses in the later stages of convalescence from an episode of exertional rhabdomyolysis when the serum creatine kinase concentrations are nearly normal. In addition to hand massage a number of massage aids are available, such as handheld units with knob-like protrusions and electric vibrating devices.

MUSCLE STIMULATION

Selective muscle groups can be stimulated to work using an electric muscle stimulator or transcutaneous electrical nerve stimulation (TENS). A variety of devices are available that trigger the contraction of a muscle body through the application of an interrupted direct current across the skin, in the vicinity of a major motor nerve. Some units have handheld electrodes, whereas others have connectors for contacts on stick-on electrodes or attachment to acupuncture needles. Intensity and duration of the current can be controlled. The current is typically pulsed at a rate of 15 to 30 contractions per minute, allowing for complete relaxation and cycling of the muscle group before the next contraction. The current jumps into the nearby motor nerve, causing its depolarization and subsequent contraction of the muscle. I have found this modality to be particularly useful in horses recovering from neurogenic atrophy. TENS provides some analgesia, and care must be taken to avoid over-exercising an injury when pain has been masked.[1]

CONTROLLED EXERCISE

Advanced versions of the traditional hot walker enclose a horse in a system of moving partitions or gates, allowing for forced or controlled exercise. The horse's head is free, allowing for a natural gait. The speed can be controlled accurately from a walk to a fast trot (or faster). If weakness in a limb is apparent, the muscles of the affected limb can be loaded by adding extra weight (2 kg) to the limb by using a weighted boot or applying a heavier shoe.[1] By selectively loading muscle groups, an isolated increase in work can increase strength and power development relative to the non-loaded muscle groups. This technique also can be used with the horse exercising under saddle or in long lines, but care should be taken not to over-work the horse. The clinician should ensure that the injury is at the appropriate stage of healing for exercise to be beneficial and should enter this stage of rehabilitation gradually and with careful monitoring.

Treadmill exercise can be useful, but it does not induce a natural gait because of the effects of the moving traction belt under the horse's feet. The treadmill forces the hindlimbs into protraction farther behind the horse and the forelimbs into retraction farther underneath the horse, leading to an imbalance of working muscle groups. Treadmill exercise quickly builds loin muscle, but because of the protracting action of the forelimbs the horse tends to over-develop muscles over the shoulder. Many horses with chronic lameness develop an asymmetrical or unbalanced gait during compensation for the lameness and often retain some degree of abnormal gait (a memory effect) after the lameness has been resolved. The straight-moving traction belt of a treadmill makes maintaining an asymmetrical stride length difficult for a horse, thus forcing it back into balance. Forced exercise on a treadmill for about 5 minutes daily develops a normal pre-injury gait pattern after 5 days.[1]

SWIMMING

Swimming is anaerobic exercise and helps to retain cardiovascular fitness. Heart rate increases up to 200 beats/min in 30 seconds.[1] The horse is not a natural swimmer and often cannot breath efficiently when forced to swim. If an individual horse does not take readily to swimming and resists the process, the horse may do itself more harm than good. Some horses develop back soreness during swimming, so the exercise should be used with care.

A treadmill in water reduces load on the muscles because of buoyancy of the water and may decrease the gait alterations observed with a treadmill alone, allowing for a better balance of muscle group working while maintaining a forced symmetrical gait. Moving against water increases the work while reducing the excessive lordosis or kyphosis of swimming, which predisposes the horse to back pain, and increasing the cardiovascular benefits at low speeds.

CHAPTER • 98

Osteopathic Treatment of the Axial Skeleton of the Horse

Chris Colles and Anthony G. Pusey

Osteopathy originated in the United States with a Kansas physician, Andrew Taylor Still. He envisaged a system of healing that placed emphasis on the structural integrity of the body as being vital to the well-being of the organism. As knowledge of physiology and anatomy have advanced, a concept has evolved of the nervous system as an information network constantly changing and adapting in response to sensory information from the body and the environment. This knowledge allows a move away from the ideas of pathological dysfunction as the only cause of illness to a concept of physiological (or somatic) dysfunction.[1] To use a computer analogy, the body may suffer from software failures (physiological malfunction) and hardware failure (pathological malfunction). To extend the analogy, osteopathy may be thought of as a form of reprogramming.

Chiropractic treatment evolved from osteopathy and is similar, but subtly different. The differences are largely philosophical; both forms of treatment rely on manipulation. Chiropractors in animal practice tend to look primarily for positional changes associated with skeletal dysfunction. Treatment is directed principally at restoring joint mobility, with manipulation directed to the local site of dysfunction.

The osteopathic approach considers local tissue dysfunction as the direct result of trauma or the breakdown of compensatory mechanisms consequent to past trauma. The diagnostic approach is based on identifying patterns of dysfunction, with minimal reliance on appositional factors and emphasis on the interactions of the entire spine. Treatment is aimed not only at restoring local function, but also at identifying and removing factors that predispose to acute relapse. Treatment therefore frequently involves tissues distant to the perceived area of local dysfunction.

NEUROPHYSIOLOGICAL BASIS OF OSTEOPATHY

The concept of somatic dysfunction is fundamental to osteopathy. In other words, somewhere in the course of entering information from the environment and body, processing the information in the central nervous system, and then generating a motor response, something has gone wrong. Clinically this manifests as a horse with clinical signs such as stiffness, loss of performance, poor coordination, or gait abnormality, where no pathological process can be identified. Osteopathic treatment is directed at changing the signals to the neural network to modify the way sensory information is processed and thus to correct the motor response generated in the central nervous system.

In the normal animal the body constantly makes small adjustments to movement to interact with the environment. The basic motor pattern is one of mutual inhibition of flexor and extensor neurons,[2] providing a balance between agonist and antagonist muscles. To refine the movements, proprioceptive information is sent constantly from muscle spindles and Golgi tendon organs back to the spinal cord. As the nerves enter the spinal cord, they send off sprays of ascending and descending collateral fibers, which synapse on interneurons with connections within the spinal cord segment, with other spinal segments up and down the cord, and with tract cells up to the brainstem. The result is a network of neurons processing information from the body and environment that generate flexible patterns of motor activity (sometimes referred to as *central pattern generators*). Thus a pattern of nerve activity is generated where the primary function is to move a limb, but simultaneously vital secondary functions are engendered—for example, changing the tone in the central musculature to counteract the changing load on the axial skeleton. With this skeletal activity, autonomic changes such as alterations in blood flow are incorporated to provide the necessary humeral environment. The number and variety of interconnections, determined by cellular and synaptic connections of the neurons, together with the balance of excitation and inhibition from many different tissues, allow the central pattern generators to generate many different routine motor patterns. These patterns develop over time by a process of repetition and learning. Thus the inconsistent swing of the learner golfer is trained to become a confident, automatic swing after many hours of repetitive practice. This involves a process of chemical changes, new synaptic connections and fast tracking, resulting in a consistent and reproducible pattern of motor activity.

The ability to generate rapid, appropriate patterns of motor responses to environmental demands depends on sensory information. This information comes from an appreciation of the position of the body (proprioception) and conditions prevailing in the outside world (exteroception). Both inputs significantly modify the central pattern generators.

The greatest concentration of proprioceptors is found in the upper cervical spine,[3] a vulnerable area when a horse falls. Joint stiffness and muscle pain in this area after an injury alter proprioceptive feedback from this level. This affects the ability of motor pattern generators throughout the spinal cord to modify activity in response to alterations in body position and may produce changes ranging from subtle gait disorders to ataxia. Clinically this may not result in obvious clinical signs, but it does affect the horse's potential and leaves the horse more susceptible to acute injury.

Environmental information is provided by exteroceptors that continually sample external conditions by precise localizing receptors of the A-afferent system (e.g., touch receptors) or by the more primitive, poorly localized pain receptors (nociceptors) of the B-afferent system. In a clinical setting, the effects of the B-afferent system are commonly encountered. A painful stimulus is conveyed to the spinal cord and passes on to the brain to register pain and also stimulates motor neurons in the ventral horn, resulting in paravertebral and peripheral muscle spasm,[4] and stimulates sympathetic activity in the lateral horn causing reduced blood flow to the skin.[5] To avoid constant discomfort, a control mechanism exists at the level of the spinal cord that is mediated by the A-afferent input of

discriminatory touch and proprioception and by descending inhibitory activity (creating a gate for painful stimuli). This can be demonstrated by rubbing an injured area to ease pain. The balance between A-afferent stimulation and B-afferent input determines the activity of the interneurons and the sensory, motor, and autonomic responses.

This balance can be affected in a number of ways:

1. A-afferent activity from joint receptors is reduced if movement is restricted. Thus inhibitory effects on the interneurons are reduced, and B-afferent activity may even increase and register as pain, without direct stimulation of pain receptors. Physical treatments to increase mobility restore the A-afferent input and reinstate the gating effect.
2. B-afferent activity, if intense or prolonged, causes changes in the chemistry and structure of the interneurons,[6] which can be traced 3 to 7 days after only 45 minutes of moderate nociceptive stimulation.[7]

These changes reduce the threshold for interneuron firing in a process called *facilitation*. They become supersensitive to afferent input and to internal network activity within the spinal cord. This mechanism underlies hyperesthesia. Facilitation is interesting for two reasons. First, the peripheral endings of sensory nerves feeding into the sensitized interneuron pools produce pro-inflammatory neuropeptides,[8] which further stimulate the nerve endings. This increases central stimulation, thus creating a spinal cord response out of proportion to the peripheral stimulation. This may explain horses with recurrent joint and soft tissue swellings. They may respond to corticosteroid injections that reduce inflammation at the local site, but if sensitization of the central interneuron pool remains, the inflammation returns.

Second, even when afferent activity has been blocked by sectioning the dorsal (sensory) root, a sensation of pain and the autonomic and motor responses may still be present, driven by the output of the sensitized interneurons. This means that pain may persist long after the original injury has resolved. Even when pain is no longer felt, the neuronal pool remains sensitive, and nociceptive inputs produce a pain response inappropriate to the magnitude of the stimulus. The interneurons respond to inputs on a segmental level, but also to input from distant segments, given the span of nociceptive fibers over several segments.

These mechanisms may explain some of the non-specific lameness and back pain that tend to be recurrent. A diagnosis based on pathological condition of tissue (demonstrated by x-ray, scintigraphic examinations, or nerve blocking) is not possible, because the abnormality results from physiological changes in the motor patterns generated by the facilitated neuronal segment. Gait disturbance may be observed and muscle spasm, joint stiffness, and tissue texture changes may be appreciated by palpation and passive motion testing. One diagnostic tool that does reflect this concept of somatic dysfunction is thermography. In the normal horse a reproducible thermographic pattern is observed, reflecting cutaneous blood flow (see Chapter 25).[9] Where facilitated segments exist, sympathetic activity in the lateral horn reduces surface blood flow, giving distinctive segmental cooling. In addition to local segmental changes, the pattern may be disrupted throughout the length of the spine, giving a visual record of changes in autonomic nerve output.[10]

EFFECTS OF OSTEOPATHIC TREATMENT

Osteopathic treatment aims to reverse changes in the areas of somatic dysfunction. Most techniques are directed toward restoring movement to stiff joints to optimize maintenance of postural position. This causes relaxation of the local musculature and improved mobility, which is associated with a resultant increase of mechanoreceptor activity stimulating the A-afferent system, thereby inhibiting the interneuron pool and blocking the B-afferent (pain) signals. The treatment may take a number of forms, including soft tissue techniques, articulatory techniques, and mobilization and functional techniques.

Soft tissue and articulatory techniques stretch the skin, fascia, and muscles to improve pliability of and nutrition to the peri-articular tissues and also allow the joints to move in a full range. This increased movement increases A-afferent input from the muscles and joint structures, inhibiting (or gating) incoming pain signals. These techniques include massage and repetitive flexion and extension of restricted joints.

Mobilization techniques involve taking a joint with poor mobility to the point of maximum resistance (the restrictive barrier) and pushing through this barrier with a short-amplitude, high-velocity thrust. This causes relaxation of the muscles and improved mobility resulting from a sudden increase of mechanoreceptor activity stimulating the A-afferent system, thereby inhibiting the interneuron pool and blocking the B-afferent (pain) signals.

A useful approach in horses with long-standing, complex injuries is the use of functional techniques, using the concepts of ease and bind. A normal joint reaches a point (usually at the middle of its range of movement) where tension on the capsular ligaments and the overlying muscles is minimal. This is the point of ease, where a joint tends to rest naturally. Any movement away from the point increases tension or bind. This information is used by the central nervous system to monitor joint position and to generate an appropriate pattern of motor activity. Where the normal relationships between the joint structures have been disturbed, this point of ease is offset and afferent information from that joint is changed. New reference points become imposed on the established networks and the joint is less able to perform appropriately or to coordinate movement with other joints.

This new abnormal point may be detected clinically by testing each range of movement (flexion/extension, side bending, rotation, translocation, and traction/compression). With the joint held in the position of ease, tension is minimal and therefore afferent input into the spinal cord is minimal. This appears to reduce conflicting information entering the network and allows the old pattern to reassert itself. The old pattern is preferred by the system, because over time neuronal connections have been created that fire more readily to generate this original learned response. This form of treatment relies on the osteopath establishing and maintaining one or, more commonly, several joints at the point of ease, until the original central pattern generators can reassert influence over the newly acquired patterns. This is a learned skill on the part of the osteopath and requires considerable tactile sensitivity and skill to adjust the tissues as the neurological patterns are modified. Among injured horses is a clinically challenging subgroup of 4- to 6-year-old horses that develop clinical signs as work becomes more demanding, rather than as a response to direct trauma. In these horses, it is tempting to conjecture that some form of perinatal injury may have occurred, which has prevented the normal patterns from developing. These horses frequently undergo more treatment and require more careful rehabilitation than other horses.

Details of osteopathic treatment techniques are beyond the scope of this chapter, but several excellent textbooks[9] are available on the subject.

DIAGNOSIS OF SUITABLE CASES FOR OSTEOPATHIC TREATMENT

Diagnosis should involve positive selection of horses with a somatic dysfunction and exclusion of horses with a pathological condition. Initially a conventional veterinary lameness

examination should be performed. If the examination indicates a change in quality of movement rather than lameness, or that lameness is centered in the axial skeleton and no pathological process can be demonstrated readily (e.g., by x-ray or scintigraphic evaluation), then the likelihood of a somatic dysfunction as the cause of lameness should be considered. Somatic dysfunction alters the way a horse moves and so may contribute to pathological change (e.g., synovitis in an overloaded joint). Once a primary pathological condition has been excluded, the process of making an osteopathic diagnosis can proceed. This diagnosis is based on somatic dysfunction, that is, how the component parts of the horse work together as a whole and how different areas of dysfunction or stiffness may contribute toward the problem.

An accurate case history is essential and should include the type of work the horse is expected to do and the level it is expected to attain. The history also highlights past injuries and illnesses and may reveal idiosyncrasies in behavior or movement that, while noticed by the owner, have not interfered with performance sufficiently to be a cause for concern. When considering the history, these subtle disturbances in motor function may, in retrospect, have been early signs of the coming crisis.

Examination begins by assessing muscle development and distribution of weight through all limbs in the standing horse. The horse should stand naturally with all cannon bones vertical and not shift weight constantly between limbs. Muscle development should be symmetrical, and the areas of muscle should be consistently developed throughout the horse. Areas of poor development over the top of the back, neck, or quarters should be noted. Similarly, uneven development or hypertrophy may be substantial. In particular, hypertrophy of the pectoral muscles may indicate forward propulsion of the horse unduly depends on the forelimbs because of poor hindlimb function. Hypertrophy of the muscle over the atlas and axis frequently accompanies restricted joint movement at this level. Foot placement, shape, and shoe wear are also important for locating areas of dysfunction. When assessing feet, however, it is necessary to differentiate between change caused by altered limb movement and problems caused by poor farriery.

Movement at a walk is more revealing than at the trot, when the horse tends to fix the neck and back to guard against pain. Observation gives an impression of how the horse moves as a whole and indicates which areas are functioning poorly. Balance and fluidity of movement from head to tail are as important as stride length, foot placement, and frank lameness. How the horse copes with long and short turns indicates problems with lateral flexibility. In particular, when the horse is turned short, the head and neck should flex evenly in the direction of the turn and the hindlimbs should be crossed as the quarters move around. All limbs should be moved with easy flowing strides, showing consistent stride length and straight limb flight. The feet should be placed easily, and in particular the hind feet should not dig into the ground when placed. Limb movement that appears heavy, stiff, inconsistent, or mechanical should alert the observer to potential problems. Excessive head and neck movement in time with the limbs is also abnormal. Substantial lateral movement of the pelvis, often associated with patches of worn hair under the back of the saddle, indicates reduced movement in the lumbosacral spine. The pelvis and tail being carried to one side also indicates uneven tone in the spinal musculature. Uneven height between the two tubera coxae also should alert the clinician to potential problems.

The transition from walk to trot can be revealing, and any tendency to raise the head or skip in the transition indicates problems, probably in the region of the cervicothoracic junction. Assessing individual joint movements is useful, but it requires considerable skill and powers of observation. Running the hands down the paravertebral muscles from the occiput to the tail may reveal areas of muscle hypertrophy or spasm, and most importantly tissue texture can be felt. Moving the joints through the relevant ranges of motion identifies those that are stiff.

Diagnosis requires consideration of past injuries, the way the horse moves overall, and identification of dysfunction in specific areas. Initially, the clinician may only be able to form a working hypothesis, which will be refined once treatment is begun. Where problems have been present for some time, the horse will have developed altered patterns of posture and movement to work round poorly functioning areas. These alterations may occur at several levels because of the interconnections of the neural networks. Ascertaining what is the site of the primary injury and what are secondary changes may be difficult.

INFRARED THERMOGRAPHIC IMAGING

Thermographic examination in the horse has proved to be an invaluable tool to confirm somatic dysfunction.[11] It is important to realize that areas of cooling are more important in diagnosing sympathetic dystonia than are increased temperatures. Thermography is prone to artifactual results and interpretation can be reliable only if image acquisition is carried out in a temperature-controlled environment (between 18° and 22° C), using an absolutely consistent technique.

The horse must be clean and dry, because moisture absorbs infrared radiation and causes false readings. Hair length should be consistent, because hair has an insulating effect, and horses that have clipped coats or rubs from rugs present difficulties in interpretation. Different coat colors may be of different hair length or density, which causes artifacts. When moulting, areas of different colored hair may moult at different times, again giving rise to artifactual results. Before thermography, horses should be acclimatized to the room temperature for as long as it takes for the surface temperature to remain stable. The time required depends on the difference in ambient temperature of the environments inside and outside the thermography room. The room should be free of drafts and direct sunlight.

In a normal horse a reproducible thermographic pattern is observed, reflecting cutaneous blood flow.[10] Where facilitated segments exist, sympathetic activity in the lateral horn reduces surface blood flow, giving distinctive segmental cooling. In addition to local changes, the pattern may be disrupted throughout the length of the spine, giving a visual record of changes in autonomic nerve output. Certain specific injuries do give areas of increased blood flow and rise in surface temperature. These injuries are usually around the head, or in the lower limbs, where little or no overlying muscle is present.

In the normal horse the surface temperature should be within 1° C over the neck and body of the horse and in the limbs proximal to the carpus and tarsus. The head and lower limbs are generally cooler. A useful guide when setting the thermographic factors is to assume the eye will be the hottest normal area and to set up the camera with this as the maximum temperature. Changes of 5° to 6° C are severe, so a temperature range of about 6° C is ideal. If the horse has parts of the coat clipped, then changes in the level of the window may be required to accommodate the clipped areas of the body. Particularly important is the dorsal view of the back, where a relatively warm dorsal midline stripe is seen, with the muscle on either side symmetrical and between 0.5° to 1° C cooler. When interpreting thermographs of the neck and back, changes of less than 1° C from the normal may be discounted. Changes in excess of 1° C usually indicate sympathetic dystonia, the importance of which must be interpreted in the light of clinical information regarding clinical signs seen and the use to which the horse is put. It is likely that horses frequently suffer low-grade

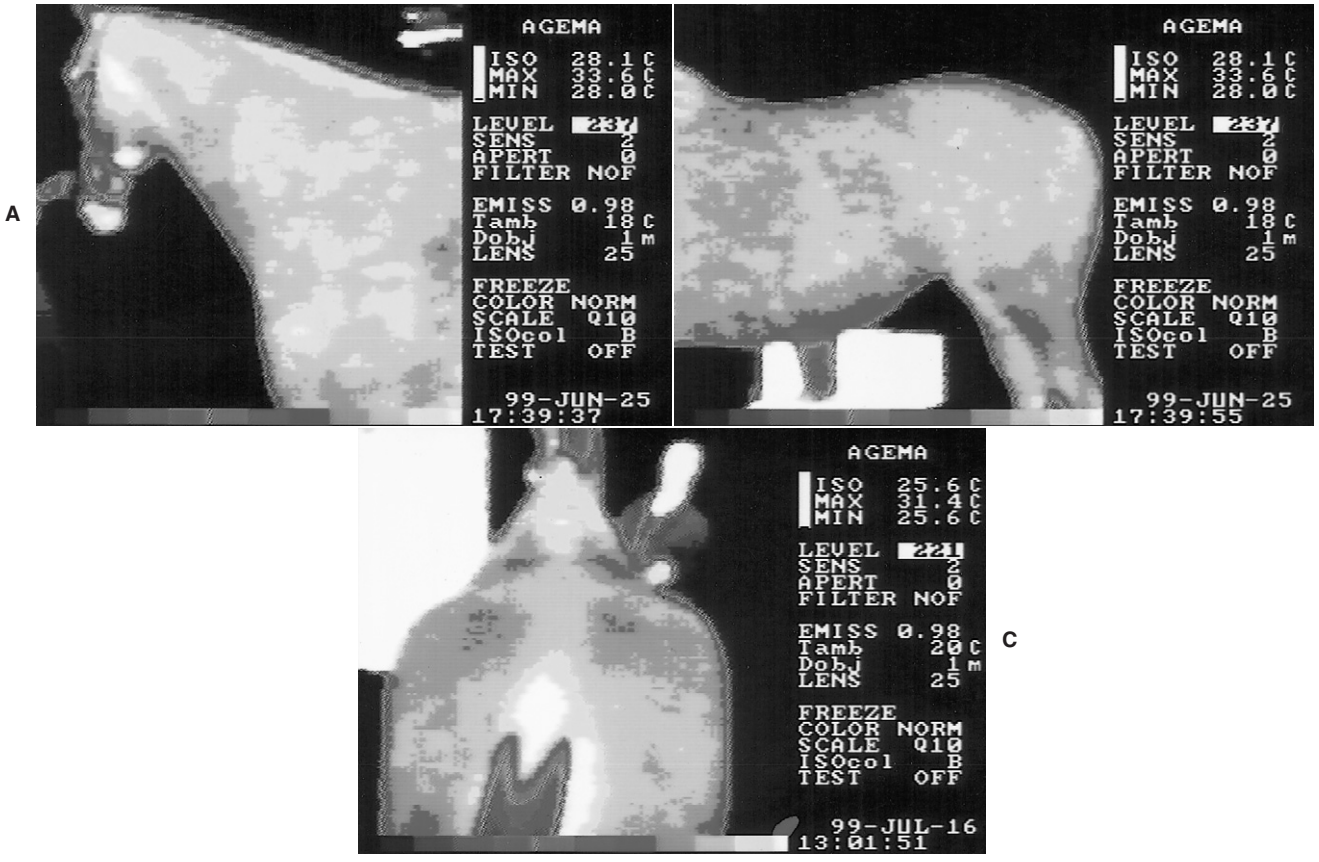

Fig. 98-1 Thermographs show the appearance of normal horses. The color scale represents 5.6° C, using 10 colors; that is, each color represents about a 0.5° C change in temperature. The color bar under the image shows the colors used; those to the right-hand side are the hottest and those to the left are the coldest. White is above the top of the scale and black below the scale. **A,** Lateral view of the head, neck, and shoulder. **B,** Lateral view of the thorax, abdomen, and hindquarters. **C,** Oblique dorsal view from behind the horse looking toward its head and neck. Temperature variation is 1° C over the neck, trunk, and hindquarters. A warm midline dorsal stripe along the back extends from the withers to the base of the tail, with symmetrical muscle temperature on either side.

back pain or stiffness, which may not be of particular significance if they live relatively sedentary or gymnastically undemanding existences (e.g., a racehorse or hunter performs satisfactorily with minor changes in the upper neck or thoracolumbar spine, which would cause unacceptable stiffness or gait modification in an event or dressage horse).

Fig. 98-1, *A* to C (Color Plate 5), show the thermographic appearance of a completely normal horse. One should bear in mind that few horses meet this degree of perfection, but they may still perform adequately at the required use. The most common area of the spine to show joint stiffness is the upper neck, with changes to the occipito-atlantal and atlanto-axial joints. This group of injuries results in a cold band running obliquely down the neck from about the level of the occiput (Fig. 98-2; Color Plate 6). This band becomes narrower with time, and although a substantial temperature change is visible in the acute stage, over an initial period (probably about 2 years) the temperature change becomes more noticeable. Stiffness or injury farther down the neck is accompanied by cooling of the surface temperature overlying the affected area (Fig. 98-3; Color Plate 7). Because the nerve supply to the muscles of the shoulder arises from the lower neck, injuries to the spine in between the shoulders are difficult to see thermographically, but a cold band running vertically down the back of the shoulder region (Fig. 98-4, *A*; Color Plate 8, *A*), usually accompanied by cooling of the entire thoracic area and hindquarters, is an indicator of injury to the cervico-thoracic area. Cooling of the hindquarters arising caudal to a diagonal band from the level of about the twelfth thoracic vertebra generally indicates injury at this level of the thoracic spine (Fig. 98-4, *B*; Color Plate 8, *B*). Two other changes are of particular clinical significance. Any break in the normal dorsal stripe running down the midline of the back, or significant cooling on either side of this stripe, indicates a change in sympathetic activity in that region (Fig. 98-5; Color Plate 9). Second, cooling of the distal limb may be substantial. If the ambient temperature drops below about 15° C, normal physiological changes reduce blood flow in the distal limb to conserve body temperature. This causes cooling of the distal limb (distal to the carpus or tarsus, unilaterally or bilaterally), but such limbs should still show a surface temperature 5° to 6° C cooler than the trunk temperature. If severe injury has occurred at the base of the neck, or in the lumbar region, then the temperature of the distal limb may drop to equal the ambient temperature. More detailed analysis of the thermographic changes seen is beyond the scope of this chapter.

TREATMENT

Because of the vast number of interneural connections and the ramification of effects on the spinal cord, the entire spine must be considered as one interrelated structure, and treatment may have to be provided at several levels. Sedating the

Fig. 98-2 Lateral view of the neck of horse with reduced mobility in the occipito-atlantal and atlanto-axial joints. A cool line runs obliquely from the region of the atlanto-axial joint caudally to the base of the neck and is 1.5° C cooler than the surrounding muscle, indicating an area of sympathetic dystonia.

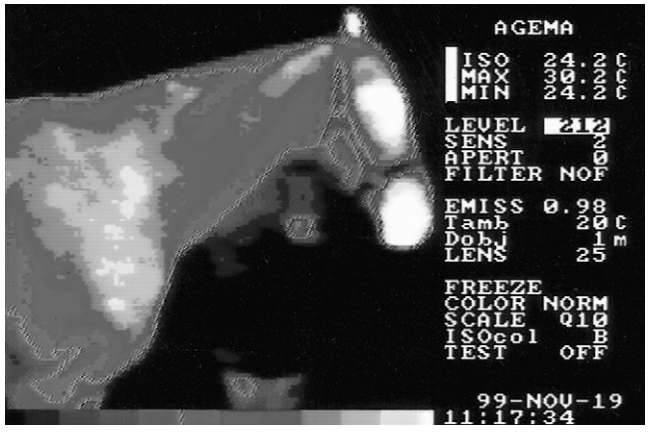

Fig. 98-3 Lateral view of the neck of horse with reduced mobility in the neck. Note the significant cooling from the occiput back to the level of the sixth and seventh cervical vertebrae, indicating a problem involving all joints in the neck.

horse is useful, because treatment requires identification of specific areas of stiffness or reduced movement. If the horse is sedated adequately, then the absence of conscious movement allows the osteopath to feel underlying deficiencies more easily. Sedation is particularly helpful when using functional techniques, which monitor subtle changes in joint position. Osteopaths in the United Kingdom undergo a 4-year university course, which includes considerable theory and practical training. The techniques used require considerable practical experience to be successful, so this chapter can only begin to explain the outlines of treatment.

After the osteopath performs the static and moving examinations described earlier, he or she starts a physical examination, feeling the tone and physical character of the muscles and the extent of movement of the joints, usually starting at the head and working back down the neck and to the tail. It is necessary to try to determine which joints show restricted movement and to decide which areas show abnormalities caused by primary injury and which changes are secondary to the principal affected areas. Experience allows the osteopath to determine which area must be treated first. The areas showing somatic dysfunction tend to be interrelated and must be treated in a specific order if treatment is to be successful. Starting treatment on an area showing restricted movement secondary to another abnormal area is doomed to failure.

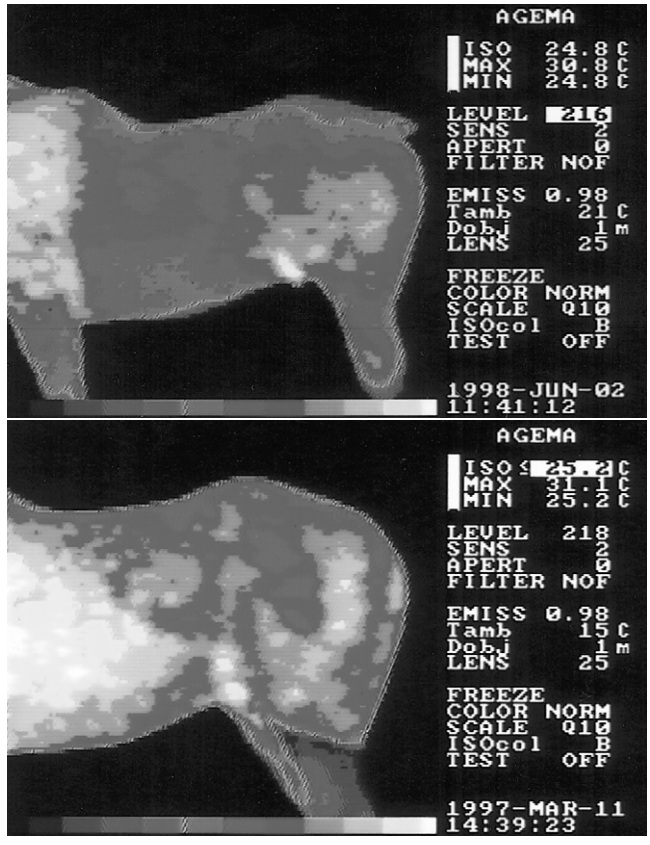

Fig. 98-4 Lateral views of the thoracolumbar area of two horses, both showing significant cooling in the musculature of the dorsal spine from the saddle region caudally. **A,** The vertical cranial boundary to the zone of cooling indicates that the injured area is in the region of the cervicothoracic junction, but the shoulder muscles overlying this area receive innervation from the lower neck, partly masking the muscles supplied by the upper thoracic area. **B,** The typical appearance of cooling in the muscle resulting from an injury to the region of the twelfth thoracic vertebra, with the cranial border of the region running obliquely down and back. This horse has been clipped, but long hair left on the hind limb shows as an area 5° C cooler than the surface temperature of the thorax of the horse.

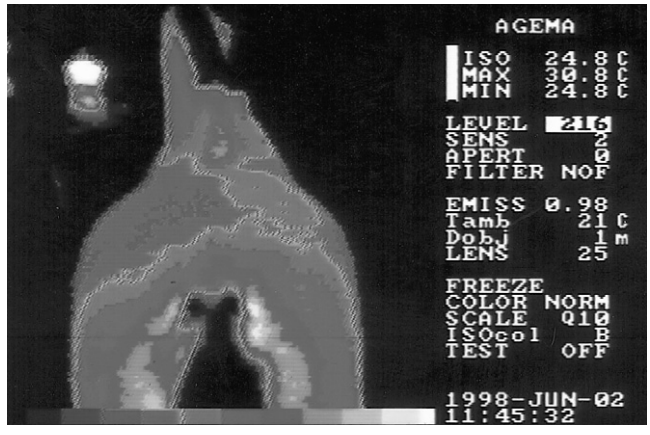

Fig. 98-5 Dorsal view of horse showing abnormal heat patterns of the thoracolumbar spine. Note the complete loss of the normal central stripe, with significant cooling indicating the presence of reduced mobility of the entire thoracolumbar spine and pelvis. The asymmetrical nature of the heat pattern indicates the horse is likely to move with an asymmetrical gait, resulting from increased muscle tone on the left-hand side of the body.

Treatment of a key area, however, often results in dramatic relaxation throughout the spine. The basic techniques of treatment have already been outlined and rely on stimulating the activity of the A-afferent system, thereby inhibiting the interneuron pool and blocking the B-afferent (pain) signals. The results are effective in most horses, and once the neural activity has been returned to normal, the horse tends to maintain this state.

In a small number of horses the problem may be so ingrained and widespread that general anesthesia may be needed to facilitate assessment and treatment. The plane of anesthesia is light, the horses are in good health, and so the risks of the procedure are minimal. Assessment of individual joint complexes can be made throughout the spine with the horse under general anesthesia. It is remarkable how often gross dysfunction of these complexes can be detected with the horse under general anesthesia, when they previously had been concealed effectively by the capacity of the body for setting up compensatory mechanisms. Treatment is still based on the principles outlined so far, but the horse is positioned on its back, allowing movements such as rotation of the thoracolumbar spine, which cannot be achieved in a standing horse. Using all limbs simultaneously is also possible, allowing functional techniques (outlined previously) to produce a massive A-afferent input to the interneuron pool. This is done by moving each limb to its position of ease, and then holding the position until relaxation is felt. By moving the limbs to maintain the positions of ease, the sympathetic dystonia can be unwound gradually. This technique, used with the horse under general anesthesia, allows a potent but gentle treatment to be carried out. In a standing, conscious horse techniques are necessarily limited and are most effective with relatively short-term injuries.

RESULTS OF TREATMENT

Pusey et al.[12] reported on a trial carried out over four years, treating horses with chronic dysfunction using osteopathic techniques. Eighty percent of treated horses returned to the previous use, performing at the same or a better level than before treatment, at least 12 months after the last treatment. As might be expected, the authors concluded that results were substantially better among the later horses because of increasing experience of treatment techniques.

Another study was made of horses that had been treated under general anesthesia, having failed to respond satisfactorily to treatment under sedation. Follow-up information was obtained at least 1 year after the treatment was finished. Thirty-five horses were treated. Twenty-four (71%) of these had maintained improvement and returned to the previous level of work, 11 at the previous level and 13 at a higher level than previously. Eight (24%) horses did not respond to treatment, and two horses deteriorated. One horse was lost to follow-up. The authors concluded that given that these horses had long-term intractable problems, this was a justifiable and useful treatment technique.

We hope this brief overview shows the potential for osteopathy in a complementary role, alongside veterinary science, in treating neuromusculoskeletal problems in the horse.

CHAPTER • 99

Extracorporeal Shock Wave Therapy

Darryl Bonder and Joseph K. Boening

Extracorporeal shock wave treatment developed from lithotripsy, a technique in which shock waves are used to treat renal and ureteral stones. Extracorporeal shock wave treatment has been used to manage selected orthopedic conditions in people for some years and more recently has been used in horses. Extracorporeal shock waves are acoustic waves generated outside the body, characterized by transient high peak pressures, followed by negative pressure and then return to zero pressure. Peak pressures achieved by currently available equipment range from 10 to 100 MPa, with a rapid rise time (30 to 120 ns) and short pulse duration (5 µs).[1,2] Other variables include energy level, defined as energy flow density (mJ/mm^2) or as kilovoltage, pulse frequency, and depth of penetration.

Shock waves can be defined as focused or radial. Focused shock waves can be generated electrohydraulically, piezoelectrically, or electromagnetically. Radial shock waves are generated pneumatically. Each mechanism creates a characteristic waveform and energy density. Focused shock waves converge on a small target point and do not expose surrounding tissues to the same peak pressures, and the target point is guided by ultrasonography or radiography. Radial shock waves have lower peak pressures and reduced depth of penetration and expose all tissues to similar pressures.

When a shock wave meets an interface of different impedance, compression and shear loads develop.[1] Cavitation occurs, with development of gas bubbles, resulting from the rapid interaction between compression and shear. The collapse of the gas bubbles leads to development of fast flows, or jet streams, that are postulated to have an effect on bone. However, the exact mechanisms of action of shock waves on bone or soft tissues are not known and the effects are influenced by the pressure, energy flow, and pulse frequency. The optimal combinations of energy level, pulse frequency, and number of pulses, and the number of treatments and interval between treatments to exert therapeutic effects are currently unknown. Work in laboratory animals has demonstrated dose-dependent effects, including microfracture of cortical bone, medullary hemorrhage, subperiosteal hemorrhage, and stimulation of osteogenesis.[3-6] Relatively low energy levels may have no osteogenic effect. Dose-dependent effects also have been demonstrated in tendons, with high pressures (>0.28 mJ/mm^2) having the potential to cause hematoma formation and tendon cell damage.[7] Shock wave treatment may increase regional blood flow, have direct cellular effects, and activate osteogenic factors.[4] That shock waves can provide analgesia is well recognized, but the duration of this effect and the mechanism of action currently are defined poorly. Analgesic properties are of concern to racing officials, because horses with fractures or other injuries might suffer severe injury if treated before racing.

Extracorporeal shock wave treatment is used in people to treat plantar fasciitis or calcaneal spurs (heel spurs), epicondylopathic humeri radialis (tennis elbow), tendonitis calcarea of the shoulder, and selected non-union fractures.[8,9] Clinical trials using focused and radial shock wave treatment for tennis elbow and heel spur have shown similar results, with improvement in clinical signs in approximately 80% of patients.

Limited experimental work has been done in the horse and much of the currently available information concerning efficacy of extracorporeal shock wave treatment is anecdotal. In an experimental study, subperiosteal (cortical) and endosteal hemorrhage was induced in third metacarpal and metatarsal bones treated using 1000 pulses from an electrohydraulic generator at an energy level of 0.89 to 1.80 mJ/mm^2.[10] No observable lesions occurred in the overlying soft tissues and no evidence of bone microfracture was found. Comparing the results of currently published clinical trials using extracorporeal shock wave treatment is difficult, because diagnostic criteria, duration, severity of injury, and degree of lameness vary. Treatment protocols are not identical, with variable peak pressures, energy levels, pulse frequency, depth of penetration, and number of treatments. Some trials have used focused shock waves, whereas others have used radial. Focused shock wave machines are considerably more expensive than radial shock wave machines, but the latter are more mobile. Greater depth of penetration, variable energy levels, and the ability to treat the desired tissue specifically are potential advantages of the focused machines.

Numerous conditions have been treated in the horse, including the bucked-shin complex, tibial stress fractures, proximal sesamoid bone fractures, incomplete proximal phalangeal fractures, subchondral bone pain, insertional desmopathies (notably proximal suspensory desmitis, suspensory branch insertions, and avulsion fractures at the proximal attachment of the suspensory ligament), impinging dorsal spinous processes, osteoarthritis of the distal hock joints, navicular disease, and superficial digital flexor tendonitis.

The treatment itself is painful and requires sedation of the horse or, for some procedures, perineural analgesia or general anesthesia.[11] Detomidine or a combination of detomidine and butorphanol is usually effective. The area to be treated is finely clipped and thoroughly cleaned, and coupling gel is applied to ensure good transmission of the energy waves. Usually up to 2000 impulses are delivered to the target area at a frequency of about 10 per second. Energy levels may be increased during treatment. During treatment a local analgesic effect may be induced. Horses usually tolerate the procedure well. One to three treatments are administered at 1- to 2-week intervals. Horses are restricted to box rest and controlled exercise between treatments. Precise exercise levels and posttreatment convalescent time is guided by the nature of the original injury and serial clinical and radiographic or ultrasonographic re-examinations.

Generally no adverse effects from treatment occur. Small areas of hair loss may develop at the treatment site. Because of the analgesic effect, the potential exists for premature resumption of work, so control of the exercise regimen is important. Rough guidelines for return to work after treatment of a bone injury (D.B.) include 1 to 2 weeks of walking under tack for 20 minutes daily; 1 to 2 weeks of walking under

tack for 10 minutes, jogging for 10 minutes (1 mile), and walking for 10 minutes; 1 to 2 weeks of jogging under tack for 15 minutes (1.5 miles) plus walking; and gradual resumption of full work. A typical program following proximal suspensory desmitis (PSD) includes 6 weeks of hand walking for 20 minutes; 6 weeks of walking under tack for 20 minutes; 2 weeks of walking under tack for 15 minutes and 5 minutes of trotting; and 2 weeks with increased walking and trotting.

The most widespread use of extracorporeal shock wave treatment has been for PSD. Data from clinical trials in Germany using radial and focused shock wave treatments showed similar results.[12,13] Using a focused machine with energy flow density of 0.07 to 0.17 mJ/mm^2 and 2000 impulses, 83% of horses with forelimb or hindlimb PSD were improved 6 months after treatment. Radial shock wave treatment with maximum energy flow density of 0.16 mJ/mm^2 resulted in 71% of treated horses in full work 6 months after treatment, compared with only 50% of untreated control horses.[13] In a similar study in the United States, 71% of horses with chronic PSD were treated successfully.[14]

Further clinical trials with large numbers of horses with accurate diagnoses, well-documented lesions, and accurate follow-up data are required to validate the success of these methods of treatment for different clinical conditions, to compare success rates with other treatment modalities, and to determine optimum treatment parameters and exercise programs during convalescence. Further information is required about the usefulness of focused or radial shock wave treatment for specific conditions. Extracorporeal shock wave treatment seems to have a role in chronic pain management and may speed recovery in some injuries, permitting a more rapid return to full athletic function, and may stimulate repair in some chronic injuries that are refractory to conventional management.

SECTION • 1
Poor Performance

CHAPTER • 100

Poor Performance and Lameness

Sue J. Dyson

Horses may be presented to a veterinarian because of a change in performance, or behavior or failure to live up to the expected level of performance, rather than because the rider or trainer has recognized overt lameness. Many of these horses do have musculoskeletal problems. The type of complaint often reflects the discipline in which the horse is used. For example, an event horse may be assessed because it has started stopping at drop fences, whereas a dressage horse may be evaluated because it takes uneven steps behind in passage or piaffe.

CHALLENGE OF ASSESSMENT

This type of horse presents the veterinarian with a diagnostic challenge, which may involve assessment not only of the horse, but also of the horse and rider together and the rider's ability. Such an assessment requires knowledge of the sport in question and an ability to recognize when the problem is a lack of athletic ability or a mental problem, rather than a pain-related musculoskeletal disorder, or some other pathological condition, such as an upper airway disorder. The assessment also requires good knowledge and appreciation of how horses normally move, the variation between different breeds and types, and an ability to recognize subtle changes in gait, such as slightly reduced lift to the stride or stiffness in movement of the back. The assessment requires basic knowledge of equine locomotion and how gait may be modified by pain and also requires the ability to recognize when a rider may actually be creating the problem. Training methods and style of riding may contribute to the development of lameness.

This section sets out to discuss some of the different problems that may be encountered and the types of conditions that may be the cause of poor performance and to suggest some methods of approach to diagnosis. These may vary to some extent depending on whether the clinician is dealing with a competent professional rider or trainer, or an inexperienced or even experienced amateur, who lacks ability.

HISTORY

It is essential to obtain a comprehensive history to determine whether the horse has genuinely performed better previously at this level of competition, or moved better, and precisely what changes have been observed. It is important to listen carefully to the owner to understand properly the perceived problem, however small it might be. This is particularly important if the clinician does not have prior knowledge of the horse.

Determine the answer to the following questions:

1. What is the age and training history of the horse?
2. Does the horse have the musculoskeletal coordination and strength to do what is being asked?
3. Has the horse recently moved up a level of competition: Does the horse have the confidence or athletic ability to cope?
4. What is the current work program? How does this vary from day to day? Is the horse allowed turnout?
5. Has a recent change in the work pattern or intensity or some other change in management occurred?
6. Has the bit been changed?
7. Did the horse sustain a fall or any other trauma before the onset of the problem?
8. Has a recent change in the rider or trainer occurred?
9. Has an alternative rider been tried?
10. Has the horse ever suffered exertional rhabdomyolysis?
11. Under what circumstances is the problem apparent?

Viewing videos of the horse when it was performing normally sometimes can be helpful to compare with the findings of your own clinical evaluation. If the horse has recently changed ownership, comparing video recordings of the horse ridden by the previous rider and by the current rider can be useful to determine whether a change in riding style or training techniques may be responsible for making a previously subclinical problem become symptomatic, or to determine if the problem could be related directly to the manner in which the horse is being worked.

The types of clinical problems that may be encountered include the following:

- Not jumping as well: knocking down rails. This may be pain related or caused by the rider presenting the horse poorly to the fence.
- Not jumping as well: stopping. This may be a horse or rider confidence problem or pain related.
- Not making distances in combination fences. This may be because the horse is landing too steeply, saving one or both front feet and therefore having too much ground to make up, or through lack of push from behind, reflecting a hindlimb lameness. Alternatively, if the horse is presented poorly to the first element of the fence, the subsequent elements become increasingly difficult.
- Reluctance to land leading on a specific leg. This can reflect a forelimb or less commonly a hindlimb lameness. Peak ground reaction forces at landing are significantly greater in the trailing forelimb than the leading forelimb[1]; therefore a tendency to land with the right forelimb leading is most likely to reflect pain in the right forelimb.
- Napping (resistance) on the approach to a fence off a turn. Nappiness may be pain related or behavioral.
- Not jumping straight (e.g., jumping to the right), with a tendency for the hindlimbs to drift toward the direction in which the horse is jumping (to the right). This usually reflects pain or weakness in the ipsilateral hindlimb of the side to which the horse is jumping. Less commonly the problem may be caused by reluctance to land on the contralateral forelimb (e.g., the left).

- Loss of hindlimb power. This may be caused by back pain or hindlimb lameness.
- Change in the shape the horse makes over a fence; for example, loss of bascule (jumping with a rounded arc over a fence). This may reflect back pain or forelimb or hindlimb lameness. It may also reflect the way in which the horse is presented to the fence.
- Rushing fences. This can be the way an excitable horse always jumps, but if the horse used to jump normally, rushing the fence usually reflects a painful problem. However, if the horse has been stopping for whatever reason and has been chased to the fences, it will inevitably rush.
- Loss of action. This can reflect the way in which the horse has been ridden and trained. Some loose, free-moving young dressage horses become much more restricted in their stride when ridden exercise is commenced. An apprehensive rider may restrict a potentially exuberant horse. A bored horse, particularly with a Warmblood mentality, may just switch off and refuse to go forward freely and loosely. Loss of action also may reflect forelimb or hindlimb lameness or back pain.
- Stiffness. Stiffness should be evaluated carefully to differentiate between loss of action and back stiffness, or restriction of gait caused by a bilateral forelimb or hindlimb lameness.
- Inability to perform medium or extended trot. Unless a horse is properly balanced with adequate hindlimb impulsion, it cannot perform medium or extended trot. Horses vary considerably in the ability to collect and extend. In general the Thoroughbred breed has much less natural ability than many of the Warmblood breeds. Some horses have to learn how to perform a medium and an extended trot and must first develop sufficient muscular coordination and power before they are able to do so. However, if a horse was previously able to work in medium and extended paces and now cannot do so, or the rhythm becomes irregular, this can reflect forelimb or hindlimb lameness or back pain.
- Inadequate hindlimb impulsion in trot, with a tendency to break to canter if asked to work harder. This usually reflects hindlimb lameness.
- Difficulty in performing specific dressage movements; for example, right half pass.
- Tendency to become disunited behind in canter. This usually reflects hindlimb lameness. However, it is important to recognize that young horses can find maintaining true canter difficult, sometimes just in one direction, or sometimes in both directions. This often can be overcome by training and development of muscular strength and coordination. Some trained horses that canter true when ridden may become disunited when cantering on the lunge. Hindlimb lameness may predispose to a horse becoming disunited. If the problem occurs to a similar extent on both reins, it often reflects a bilateral problem, but if it occurs on only one rein, the problem is more likely to be unilateral.

  Although the canter stride is initiated by the trailing hindlimb, which bears weight alone, the stance time, peak vertical ground reaction forces, and range of motion of the proximal limb joints are higher in the leading hindlimb.[2,3] Therefore if the horse consistently becomes disunited on the left rein, this is likely to reflect discomfort in the leading left hindlimb.
- Late flying changes, or difficulty in changing from right to left, or from left to right. This usually results from hindlimb lameness.
- Unlevelness in certain movements. Mild irregularities in rhythm may be detectable only in certain movements; for example, left half pass and right shoulder in. Such irregularities can reflect forelimb or hindlimb lameness or may be induced by the rider overrestricting with the hand and not creating sufficient hindlimb impulsion. Dressage riders often refer to bridle lameness, implying that lameness is not true because it cannot be detected when the horse is trotted in hand or lunged. This usually is a misnomer, because most bridle- or rein-lame horses have a genuine lameness, which may be apparent only when the horse is ridden.
- Crookedness, or reluctance to take the bit evenly on the rider's left and right hands. This can result from a training problem or be caused by lameness or unwillingness to accept the bit because of oral pain.
- Taking unequal length strides behind in walk, despite appearing sound in all other gaits. This can be seen in some otherwise normal horses that show no response to analgesics. Alternatively, irregular strides may reflect hindlimb lameness.
- Lameness apparent only when the horse is working to a contact, on the bit, and not when worked on a long rein. Problems in these horses can be difficult to solve. Some reflect a forelimb lameness, upper forelimb muscular pain, or caudal cervical pain.
- Inability to engage the hindlimbs; on the forehand. This usually reflects hindlimb lameness or back pain.
- Hanging, or on one line. This often reflects hindlimb lameness or forelimb lameness in a Standardbred.
- Loss of power cross country. This may be caused by subclinical exertional rhabdomyolysis, discomfort associated with superficial digital flexor tendonitis, or other causes of lameness. Alternatively, the horse may have acute onset back muscle pain.
- Reluctance to jump drop fences. This can be a rider or horse confidence problem, but it also may be caused by forelimb lameness or back pain.
- Cold-backed behavior when tacked up or first mounted. This is manifest by the horse tensing, roaching the back, sometimes freezing and refusing to walk forward, and then sometimes exploding into a series of violent bucks. Often this abnormal behavior stops within a few minutes, and the horse then works completely normally.

  Cold-backed behavior can be unrelated to pain and may be a problem initiated by pain, which then becomes a behavioral response. Such behavior may reflect fear, especially if a rider has fallen off several times, and less commonly is associated with chronic pain because of a rib fracture, fractured sternum, or nerve-related pain.

  The behavior may be precipitated by rapidly tightening the girth, especially if the girth has an elastic inset.

  Cold-backed behavior is generally manageable by an experienced rider, but such behavior is potentially dangerous to a nervous or inexperienced rider. Affected horses should be tacked up slowly and the girth tightened progressively, walking the horse forward each time. The horse should be lunged and made to go forward at the trot and the canter, before being mounted. The rider should be legged up onto the horse and should not attempt to mount from the ground.

  Horses with cold-backed behavior may improve with careful management but should never be trusted completely.
- Bucking. Bucking behavior can be similar to cold-backed behavior, or it may occur only after the horse has been ridden for a period. Although the horse may appear to buck with a flexible back, primary back pain is sometimes the underlying cause. Back pain secondary to hindlimb lameness may also result in bucking. Bucking can be a behavioral problem unrelated to pain.

- Rearing. Rearing is often part of nappy or resistant behavior: the horse tests the rider. Relatively rarely is rearing associated with a pain-related problem.
- Tendency for the saddle to slip to one side. This may be because of the rider's inability to sit straight, a poorly fitting saddle, or unilateral hindlimb lameness.
- Reluctance to work on the bit. Difficulties in working on the bit may be one of the first signs noted by a rider when the horse develops a minor musculoskeletal problem involving the back or limbs, or a mouth problem.
- Unwillingness to work. This may be behavioral or pain related. Warmblood breeds in particular are strong-willed horses, which easily recognize when their rider is not competent enough, and rapidly a vicious circle can ensue. However, reluctance to work equally may reflect lameness or back pain.
- Nappy (resistant) or evasive behavior. This may reflect pain or the dominance of the horse over the rider. Although some horses have a compliant temperament and never take advantage of an incompetent handler or rider, other horses rapidly recognize lack of ability, or apprehension of the rider, and develop resistant or awkward behavior.
- Progressive agitation with work, with or without loss of action. This may reflect the horse's temperament or pain caused by exertional rhabdomyolysis, for example.
- Episodic complete loss of rhythm and lack of synchronization of movement of all limbs. This may reflect a multilimb lameness, but it may also be an evasion or reflect tension. If the horse puts its head up and hollows its back, maintaining a regular rhythm is difficult. Working the horse in draw reins, a change in work environment, and the use of sedatives or analgesic drugs can help to differentiate a pain-related problem from an evasion.

Investigation of this type of horse is time consuming and usually requires repeated clinical examinations, together with ancillary diagnostic techniques. Ideally the horse should be in full work at the time of the investigation. The horse must be assessed in its entirety, including full visual appraisal and palpation at rest, and evaluation of the horse moving in hand and on the lunge on soft and hard surfaces, and the response to flexion tests.

CLINICAL ASSESSMENT

It is generally essential to see the horse ridden by the regular rider, performing the movements that are causing difficulty. If the veterinarian does not feel competent to judge the rider and the influence the rider may be having on the problem, the assistance of a professional rider or trainer may be necessary. However, it is important to recognize that not all so-called experts are truly experts, and the advice of a misguided professional may only serve to muddy the waters.

It is important to appreciate the profound influence that back pain arising from the thoracolumbar or sacroiliac regions can have over the horse's entire manner of moving. Back pain may not only induce back stiffness, but also may result in the horse holding itself tensely and not accepting the bit properly, with a restriction in stride length and reduced lift to the stride in all limbs.

Clinical assessment of back pain is not easy. A normal horse should be able to flex and extend the thoracolumbar spine repeatedly in the sagittal plane and flex from side to side with ease, without inducing tension in the epaxial muscles. Holding the back stiffly, sinking on the hindquarters to avoid extension, and evidence of muscle fasciculation or spasm may indicate pain. Alteration of facial expression and a tendency to bite or kick out may also reflect pain. However, some nervous, thin-skinned horses guard the back and do not flex normally unless they are relaxed completely. Some stoical cob-type horses show little response at all. Some horses respond to digital palpation, whereas in others firmer pressure must be applied using, for example, the closed tips of a pair of artery forceps to induce flexion and extension of the back.

In a normal horse at the trot and canter appreciable up-and-down movement of the back occurs, along with swing from side to side, with an easy swinging movement of the tail. The degree of movement is to some extent determined by the horse's natural athleticism. The degree of movement often is reduced with back pain. The degree of restriction of movement reflects the temperament of the horse and hence its reaction to pain and the severity of the pain. Clinical signs of back pain may be subtle unless the horse is assessed while it is ridden. Restricted back mobility may be more obvious when the rider sits continuously in the saddle, in sitting trot and canter, compared with when the rider sits light, or rises up and down in the trot. Movement of the tail may be restricted. The restricted movement of the back may be much more obvious to a rider than to an observer and may induce back pain in the rider. Further investigation of thoracolumbar and sacroiliac pain is discussed elsewhere (see Chapters 52 through 54).

It is important to recognize that many horses with hindlimb lameness show signs only when the horse is ridden. The modification of stride variables because of hindlimb lameness is much less than for forelimb lameness. The diagonal on which the rider sits in rising trot often substantially influences the lameness. Lameness is usually most obvious when the rider sits on the diagonal of the lame limb and may be unapparent on the other diagonal. The horse may deliberately try to make the rider sit on the non-lame diagonal. Low-grade irregularities in gait may be most apparent when the horse changes direction when performing small figures of eight or when decelerating from canter to trot or from trot to walk. Subtle delayed release of the patella may be apparent only as a horse decelerates.

Recurrent low-grade equine rhabdomyolysis may occur almost every time an affected horse is ridden, without any of the classical clinical signs of tying up. Measurement of serum concentrations of creatine kinase and aspartate aminotransferase reveal elevation of both. Some of these horses have increased uptake of radiopharmaceutical in the affected muscles in bone-phase images if examined using nuclear scintigraphy.

It is often necessary to compare the horse's performance when ridden by a different rider, bearing in mind that riders with varying abilities can make horses appear different, and riders of differing weights and ability to follow the rhythm can make a great difference in the horse's gait. A good rider can make a slightly nappy horse go forward freely, with a totally rhythmical stride, whereas a less competent rider may be unable to ride the horse through, and the horse may take uneven steps behind because it is not going forward enough. A heavy rider or a rider who is unable to ride properly in balance may induce hindlimb lameness. The same horse ridden by a lighter rider may be completely sound. A horse that evades the bit and runs along with its head in the air may take irregular steps in front and behind and appear stiff in the back, especially if a rider attempts to make the horse work on the bit. The same horse, when encouraged to submit and work on the bit when ridden by an expert with draw reins, may appear completely different, relaxing the back, stepping under more from behind and becoming much more rhythmical. It is often necessary diplomatically to separate the owner from the horse to assess how the horse responds to a skilled rider over several days.

It is also important to recognize that inappropriate work patterns on the flat or over fences actually can induce muscu-

loskeletal pain, which may progress to chronic lameness. For example, repeatedly placing the horse too close to a jump (putting the horse in deep), which also alters the bascule over the fence and the way in which the horse lands, may predispose the horse to patellar ligament soreness. This may alter the horse's way of moving and predispose to the development of pain elsewhere. In the early stages the problems potentially may be managed with a change in work program and methods of training the horse. However, long-term problems may be more difficult to resolve satisfactorily.

Paradoxically, it may be helpful to see a usually well-ridden horse with a subtle performance problem ridden by a less clever rider. The professional rider may be making subtle adjustments to the gait inadvertently and thereby masking gait irregularities reflecting low-grade lameness.

The fit of the tack and its suitability must be evaluated. The veterinarian should not assume that because the saddle has been fitted by a professional saddle fitter that it necessarily does fit. The position of the bit in the mouth, the size of the bit relative to the size and shape of the mouth, the suitability and the severity of the bit should all be assessed. The mouth should be inspected carefully to ensure that no lacerations of the tongue, gums, or corners of the horse's mouth have occurred and that the teeth have no sharp points or hooks.

In some instances the horse may appear to be clinically normal, and it is necessary to try to establish whether the complaint is indeed pain related. In my experience, phenylbutazone is the most effective analgesic drug for trying to determine whether a problem is pain related. The drug must be given at a high enough dose (minimum 4.4 mg/kg twice daily) for long enough (at least 7 days if the horse does not respond within 2 to 3 days). A comparison with records of the horse's attitude, behavior, and action before, during, and after treatment should be assessed as objectively as possible. A positive response confirms the presence of a pain-related problem, whereas a negative response does not definitively exclude a pain-induced problem. The potential exists to create a placebo effect for the rider, and in selected horses, "blinding" the rider to the treatment may be worthwhile.

If the problem seems to induce considerable anxiety and tension when the horse is worked, mild tranquilization with acepromazine or sedation with detomidine can be helpful to determine if the problem is pain induced or reflects tension. The tension actually may be induced by the rider or the environment in which the horse is worked. Working the horse in a different situation with another skilled rider can be helpful.

If the horse is fresh and exuberant, minor gait abnormalities can be difficult to assess, especially in a big moving dressage horse. In these circumstances mild sedation can be useful.

It is important to try to determine if a problem reflects pain or weakness caused by a neurological problem. Low-grade hindlimb toe drag may reflect a mild proprioceptive deficit rather than lameness. When in doubt, a comprehensive neurological examination should be performed (see Chapter 11). This is particularly important in areas (North and South America) where equine protozoal myelitis occurs. In other countries it is important to establish whether the horse has ever been to America.

It is also important to recognize that some horses that are mild wobblers, with mild hindlimb gait abnormalities seen when moving loose or in hand, may actually move loosely and freely when ridden, with apparent good coordination, and perform rather well in dressage despite a problem.

Diagnostic Analgesia

In some horses taking an educated guess about a potential source of pain and medicating the suspect joints with, for example, triamcinolone and assessing the response to medication (so-called diagnostic medication) may be necessary. For example, in a dressage horse taking uneven height steps behind in piaffe, or failing to maintain a regular two-time rhythm in piaffe, medicating the distal hock joints may be worthwhile. However, it is necessary to recognize that a negative response does not exclude definitively distal hock joint pain as the primary problem. Paradoxically, in some horses the response to intra-articular analgesia may be better than the response to intra-articular medication, whereas in others the response to medication is better than that after analgesia, even in the absence of radiological abnormalities.

Frequently through careful clinical evaluation of the horse, a low-grade, bilateral, symmetrical lameness can be identified that can be investigated further through local analgesic techniques and then appropriate imaging modalities. With low-grade bilateral forelimb lameness, blocking both front feet simultaneously, for example, may be more useful than blocking one at a time and then assessing the change in the horse's overall way of moving. With poor hindlimb propulsion, blocking the region of the origin of both hindlimb suspensory ligaments may be more useful than blocking one at a time. In some horses concurrent forelimb and hindlimb lameness may be detected. Alternatively, back stiffness may be identified, requiring further investigation by nuclear scintigraphy, radiography, and ultrasonography.

Diagnostic Imaging

Thermographic evaluation, particularly of the neck and back, is thought by some to be helpful in diagnosing low-grade performance abnormalities (see Chapters 25 and 98). However, others have found thermography much less rewarding. It is vital to recognize the normal thermographic patterns, the responses to exercise, and the many other external factors that may influence the results.

In horses in which no obvious gait abnormalities can be identified or in which subtle changes are noted that cannot be investigated further by local analgesic techniques, performing a comprehensive nuclear scintigraphic examination of the horse may be helpful (see Chapter 19). However, interpretation of the results can be notoriously difficult, because areas of increased radiopharmaceutical uptake (hot spots) are not necessarily synonymous with pain, and not all musculoskeletal problems are associated with hot spots. For example, bilateral proximal suspensory desmitis may result in a slightly restricted and stiff hindlimb gait, but nuclear scintigraphic examination may be normal. Great care must be taken not to overinterpret the results of scintigraphic examination. Results must be correlated carefully with the clinical signs, the responses where possible to local analgesic techniques, and the response to diagnostic medication.

Evaluation of gait and other aspects of performance on a high-speed treadmill are discussed in Chapter 101.

COMMON PERFORMANCE PROBLEMS

The most common causes of poor performance not related to readily recognizable overt lameness are these:

Possible clinical problems
- Bilateral foot pain
- Bilateral fetlock pain
- Bilateral proximal suspensory desmitis, forelimb or hindlimb
- Bilateral carpal pain
- Thoracolumbar or sacroiliac pain
- Intermittent upward fixation of the patella or delayed release of the patella
- Bilateral distal hock joint pain
- Tying up

Rider-induced problems
- Hand brake on (i.e., too much restriction by the rider's hands) and no legs
- Overweight; inability to follow the rhythm
- Lack of confidence
- Over horsed rider being too restrictive
- Misunderstanding of how to achieve "on the bit"
- Poor eye for a stride; therefore repeatedly placing the horse in less than ideal positions for take off for a fence, making the jump more awkward, or requiring more effort
- Sitting crookedly
- Lack of rapport with the horse

Trainer-induced problem
- Monotonous training program with no variation

Horse problems
- Lack of ability
- Unsuitable temperament
- Loss of confidence
- Lack of rapport with the rider
- Staleness
- Lack of focus in a dual-purpose breeding stallion and competition horse
- Inconsistency of a mare

These horses are time consuming to investigate, often requiring a multifaceted approach to diagnosis. Although it is often essential to see the regular rider riding the horse, separating the horse from the rider for several days can be helpful, particularly with horses ridden by amateurs or semi-professionals. It is essential to have access to adequate facilities to see the horse ridden (or driven) properly on a daily basis and to be able to perform local analgesic techniques and then re-evaluate the horse ridden or driven under the same circumstances.

CHAPTER • 101

Experiences Using a High-Speed Treadmill to Evaluate Lameness

Benson B. Martin, Sue J. Dyson, and Mike W. Ross

The advent of the high-speed treadmill has led to many advances in evaluating equine poor performance in exercise physiology, gait analysis, cardiac disease, and lameness diagnosis.[1-5] This chapter describes our experience using a high-speed treadmill for lameness evaluation in the performance horse.

Lameness has been implicated as a cause of poor performance in several studies involving a complete physical examination, lameness examination, and where possible a high-speed treadmill examination.[1-3] In one study, 74% of horses were found to have lameness as a component of poor performance.[1] In another study, in which horses were examined for poor performance with no apparent history of lameness, significant lameness in 23.9% of horses precluded a high-speed treadmill investigation.[2] In a third study, 4.3% of horses sound enough to undergo a high-speed treadmill examination for poor performance were significantly lame after high-speed treadmill exercise.[3]

In our experience, convincing trainers and owners that lameness is a cause for poor performance can be difficult. Several studies using a shoe model to induce lameness to assess the metabolic cost of pain related to lameness suggested a trend that pain related to lameness may not increase the metabolic cost of exercise, but it does increase the heart rate in response to pain.[6-8] However, another study suggested that a metabolic cost of pain and exercise does occur.[9] Pain may alter a horse's ability or willingness to perform up to expectations or previous performance levels.[10]

CRITERIA FOR CASE SELECTION

The most common criterion for a treadmill lameness examination is lameness that occurs at only high speeds or after an extended period of exercise. The treadmill examination is used most commonly in Standardbred (STB) racehorses or endurance horses. However, a treadmill lameness examination can be used in any breed or discipline, although a horse in which lameness is only apparent when the horse is ridden may be unsuitable.

Horses in which a complete lameness investigation, including diagnostic analgesia and appropriate imaging technologies, fails to reveal a diagnosis are potential candidates for treadmill lameness examination. Additional candidates include horses that require considerable work at low, medium, or higher speeds before the lameness becomes apparent, such as endurance horses or STB racehorses. A treadmill lameness examination also may be useful in horses that are fractious or otherwise pay little attention when jogged in hand or ridden. Horses must pay close attention when trotting on a treadmill and therefore have a more even, rhythmical, relaxed gait that is easier to evaluate.

Rider-induced problems
- Hand brake on (i.e., too much restriction by the rider's hands) and no legs
- Overweight; inability to follow the rhythm
- Lack of confidence
- Over horsed rider being too restrictive
- Misunderstanding of how to achieve "on the bit"
- Poor eye for a stride; therefore repeatedly placing the horse in less than ideal positions for take off for a fence, making the jump more awkward, or requiring more effort
- Sitting crookedly
- Lack of rapport with the horse

Trainer-induced problem
- Monotonous training program with no variation

Horse problems
- Lack of ability
- Unsuitable temperament
- Loss of confidence
- Lack of rapport with the rider
- Staleness
- Lack of focus in a dual-purpose breeding stallion and competition horse
- Inconsistency of a mare

These horses are time consuming to investigate, often requiring a multifaceted approach to diagnosis. Although it is often essential to see the regular rider riding the horse, separating the horse from the rider for several days can be helpful, particularly with horses ridden by amateurs or semi-professionals. It is essential to have access to adequate facilities to see the horse ridden (or driven) properly on a daily basis and to be able to perform local analgesic techniques and then re-evaluate the horse ridden or driven under the same circumstances.

CHAPTER • 101

Experiences Using a High-Speed Treadmill to Evaluate Lameness

Benson B. Martin, Sue J. Dyson, and Mike W. Ross

The advent of the high-speed treadmill has led to many advances in evaluating equine poor performance in exercise physiology, gait analysis, cardiac disease, and lameness diagnosis.[1-5] This chapter describes our experience using a high-speed treadmill for lameness evaluation in the performance horse.

Lameness has been implicated as a cause of poor performance in several studies involving a complete physical examination, lameness examination, and where possible a high-speed treadmill examination.[1-3] In one study, 74% of horses were found to have lameness as a component of poor performance.[1] In another study, in which horses were examined for poor performance with no apparent history of lameness, significant lameness in 23.9% of horses precluded a high-speed treadmill investigation.[2] In a third study, 4.3% of horses sound enough to undergo a high-speed treadmill examination for poor performance were significantly lame after high-speed treadmill exercise.[3]

In our experience, convincing trainers and owners that lameness is a cause for poor performance can be difficult. Several studies using a shoe model to induce lameness to assess the metabolic cost of pain related to lameness suggested a trend that pain related to lameness may not increase the metabolic cost of exercise, but it does increase the heart rate in response to pain.[6-8] However, another study suggested that a metabolic cost of pain and exercise does occur.[9] Pain may alter a horse's ability or willingness to perform up to expectations or previous performance levels.[10]

CRITERIA FOR CASE SELECTION

The most common criterion for a treadmill lameness examination is lameness that occurs at only high speeds or after an extended period of exercise. The treadmill examination is used most commonly in Standardbred (STB) racehorses or endurance horses. However, a treadmill lameness examination can be used in any breed or discipline, although a horse in which lameness is only apparent when the horse is ridden may be unsuitable.

Horses in which a complete lameness investigation, including diagnostic analgesia and appropriate imaging technologies, fails to reveal a diagnosis are potential candidates for treadmill lameness examination. Additional candidates include horses that require considerable work at low, medium, or higher speeds before the lameness becomes apparent, such as endurance horses or STB racehorses. A treadmill lameness examination also may be useful in horses that are fractious or otherwise pay little attention when jogged in hand or ridden. Horses must pay close attention when trotting on a treadmill and therefore have a more even, rhythmical, relaxed gait that is easier to evaluate.

HISTORY

Important historical facts need to be ascertained. Some questions are general and some are use related. Some may need to be repeated in a different order to elicit an accurate answer and may include the following.

General Questions

How long has the horse been lame?
When do you notice the lameness?
Does the lameness improve with exercise?
Does the lameness become worse during or after exercise?
Does the horse ever appear to become anxious or frantic?
Does the horse sweat?
Has the horse's performance level changed?
Has the horse changed how well it performs?
Has the horse changed the style of performance?
Has the horse had any behavioral changes?
Has the horse been treated for lameness?
Has the horse been "tapped"?
Has the horse ever had any joints treated?
Has the horse received any intramuscular treatments?
Has the horse received any other therapy or medication?
How much and for how long?
What has been the response?
Does the horse receive any special supplements (e.g., sodium bicarbonate)?
What type of shoes does the horse wear and why?
Does the horse have any special shoeing or trimming and why?

Use-Specific Questions

Standardbred Racehorses

At what speed is the horse the worst?
At which gait (trot or pace) is the lameness most easily seen?
Is the horse worse on the straight or on turns?
Is the horse worse when turned the correct direction of the track?
Is the horse worse when jogging?
What is the horse's normal gait?
Has any change in the horse's gait occurred, and what is the change?
Is the horse on a line?
Is the horse on a shaft?
Does the horse get into his knees?
Is the horse worse when jogging free legged or in full harness?
Is the horse worse when checked-up?
Does the horse use any special gaiting equipment?
Does the horse wear any head poles?
Does the horse wear any other special equipment and why?

Thoroughbred Racehorses

Does the horse bear in or out?
Does the horse break out of the starting gate as well as before?
Does the horse require any special bit or tack and why?
At what speed is the lameness best seen or felt?
Is lameness worse with or without a rider?

Endurance Horses

How far does the horse have to go before the lameness appears (time or distance)?
What does the lameness feel like or look like?
Does the horse have any bruising of the feet?
Does the horse feel or look like it is tying up?
Does the horse sweat normally?

Dressage and Show Horses

Is the horse worse when ridden?
Is the horse worse on a large turn or small turn?
Is the horse worse going up or down a hill?
Is the horse worse when collected or on a free rein?

EQUIPMENT

The treadmill must have a speed of at least 7 to 10 m/sec. Most horses will not canter until the speed exceeds 7 m/sec. Lameness is usually evident at lower speeds, but occasionally it is necessary to see a horse trot at up to 7 m/sec for lameness to become manifest. In addition, for further poor performance evaluation the treadmill needs a speed of at least 14 to 15 m/sec and the capability of being elevated to at least a 6° slope. Ideally the treadmill should be mounted in the ground, which is safer. In our experience clients and horses easily adapt to an in the ground treadmill. It is easier to use video equipment with a treadmill in the ground, rather than above the ground.

At least 4 to 5 m of space in front of, behind, and on either side of the treadmill is needed to allow for equipment, cameras, and personnel and to allow room for the horse to move off the front, rear, or side. The moving treadmill surface is relatively forgiving. In one study in which a horse had a strain gauge placed on the left third metacarpal bone, bone strain was measured as the horse galloped on a dirt track, wood chip track, and on a treadmill. Compared with the direct track bone strain was 75% less when the horses galloped on the wood chip track and an additional 75% less when galloped on the treadmill.[11]

Kinematic analyses include high-speed cinematography, videography, electrogoniometry, or accelerometry to quantify the movements of the limbs and torso during exercise. Kinetic analyses use instrumented shoes, force plates, and pressure-sensitive mats to measure forces that affect, arrest, or modify motion. The reader is referred to Chapter 22 and other references. Many of these systems are expensive, time consuming, cumbersome, and require considerable expertise to use. The ideal gait analysis system provides considerable data, which are obtained easily, visually and statistically analyzed, and not too expensive. The system must be fast enough to assess correctly diagnostic nerve blocks in a timely fashion and simple enough to not alter the gait of the horse.[12,13]

Simple systems can be assembled with a digital video camera, a tripod, and a computer, using simple video editing software to review and edit the images. If a computer is not available, video editing tape decks can be used. The camera or cameras are placed perpendicular to the side and front or rear of the treadmill. Caution must be used with the rear camera. Enough light must be available for adequate video viewing (at least two 1000-W lights or equivalent).[12,13]

The video camera can be a Hi-8 or digital camera, with a video stabilization system and should have a shutter speed of at least 1/2000 (digital) or 1/4000 (analog).[14] Most consumer-grade cameras film at 30 frames per second (fps). Therefore some video loss is apparent compared with more sophisticated (200 fps) and expensive systems. Digital and Hi-8 video create less video noise and provide a superior viewing experience. For rapid viewing the recorded tape can be placed into a Hi-8 or digital videocassette recorder that has a jog-shuttle device for stop frame viewing or frame grabbing. Alternatively, video editing tape decks, which are more expensive than traditional videocassette recorders can be used. Digital images also can be reviewed on a computer and thus more accurately analyzed and edited. Turnkey systems including hardware and software using universal serial bus or IEEE 1394 rapid transfer technology are available.

Using video technology allows the clinician to critically examine the baseline lameness and lameness after diagnostic analgesia, record them in real time, analyze the differences in real time slow motion, maintain a permanent record for follow-up examinations, and demonstrate to the owner or trainer the difference in gait before and after a successful block. Video analysis also can be useful in demonstrating initial footfall, footfall after trimming or shoeing, and the

effects of different types and weights of shoes. The technology gives one a new appreciation for lameness, motion, conformation, and gait at a walk, trot, or higher speed. The camera is much more sensitive than the human eye and can answer many questions and create new ones.[12]

PREPARATION OF THE HORSE AND SAFETY CONSIDERATIONS

It is important that a horse is reasonably fit to perform an accurate treadmill lameness examination. STBs should be trained down to at least a 2-minute mile. Endurance horses, in which lameness may not occur for several miles, need to be at least fit enough to accomplish this task easily. For other horses, they should be in regular work. To do otherwise places the horse and examination at risk. Unfit horses run the risk of exertional myopathy, thus obfuscating the results of any lameness examination.

We prefer horses to wear shoes when being examined for lameness. Tremendous friction and therefore heat are generated by the contact of the horse's foot and the treadmill belt. Whenever a foot contacts the belt, the foot slips and therefore causes friction. Many research horses that exercise daily on a high-speed treadmill have chronic foot problems secondary to the heat generated. This heat can be enough to melt the glue of glue-on shoes at higher speeds. If the horse is not shod, the toes of the hind feet can break off and bleed, leading to substantial lameness for several weeks. We do not place any type of tape on the horses' shoes. We recommend using flat shoes, with no toe grabs, stickers, borium, or turndowns. This minimizes wear to the treadmill belt, which lasts 9 to 12 months before replacement is required when used daily. We recommend that shoeing changes be made 3 to 5 days before a treadmill examination, in case foot problems related to shoeing are found that may mask the horse's actual primary lameness.

Examination for lameness on a treadmill requires at least three people. One person controls the treadmill and the horse's head; one person stands behind the horse to keep it moving forward if necessary, and one person is the clinician. The clinician is responsible for operating the video equipment and observing the horse at a walk, trot, and any other desired gait. Occasionally, two people are required at the head in fractious horses.

Schooling of the average animal usually takes about 30 minutes to one hour before the horse is ready to be examined for lameness. Most (>99%) horses can be schooled and examined for lameness or poor performance in the same day. This period includes acclimating the horse to the treadmill and the fan noise, to standing on the treadmill with the machine off, and to moving with the treadmill at the walk, the trot, or pace at medium speed, a canter at low speed (7 m/sec) for non-STBs, and then at rest. STBs then are harnessed and moved up to a speed of about 7 m/sec for 200 to 300 m. Most horses adapt easily using this method of schooling, which is safe and successful in 99% of horses examined for lameness or poor performance. Occasionally, horses are recalcitrant or scared and need to be reschooled a day later and usually adapt well. Some horses (<1%) cannot be examined because the examination would not be safe for the horses or personnel.[15]

Safety of horses and personnel is paramount. Personnel must be cautioned to be alert at all times and not to stand behind the horse when the treadmill is moving. Shoes and horses can come off the treadmill without warning. Substantial injuries (e.g., tendononitis) occur in less than 1.5% of horses. Lacerations, broken up hind feet, and myositis occur in less than 5% of horses.[15] All horses wear protective boots on all limbs. All STBs are schooled first without equipment, but with protective boots, and then they wear the normal equipment plus protective boots if they move at speeds greater than 7 m/sec.

To minimize the risk of injury to personnel and horses, it is important to have a trained team to examine each horse. Personnel should block any windows through which the horse can see out, eliminate as many noise distractions as possible, and ensure that no doors can be opened in front of the horse during schooling or exercise. This allows the horse to concentrate on staying up with the treadmill and minimizes frightening or distracting the horse during the examination.

LAMENESS DIAGNOSIS

Most lameness is seen best in all breeds with a minimum of equipment in place. STBs, which usually race checked up, are examined first with a minimum of equipment (i.e., no hobbles) and not checked up. Many lameness conditions in STBs can be obfuscated, changed, or eliminated when a horse wears its equipment and in particular, when checked up. Other horses are examined wearing just a halter unless some equipment change exacerbates the lameness (rare). A riding horse may need to wear side reins. Occasionally, STBs with carpal or stifle lameness are worse when wearing hobbles.

Horses are first examined at the walk and then at the trot and are recorded on video. Recording from the side is useful to evaluate stride length and frequency. Examination from the rear is helpful in evaluating the swing of the forelimbs and hindlimbs and the footfall.

Observation of lameness using a treadmill is different from the standard lameness examination because the horse is stationary relative to the observer, allowing viewing and video recording of the horse's gait from the side, front, and rear. The most useful gaits for observing lameness are the trot and pace. These are symmetrical gaits and allow for easier evaluation of lameness and gait rhythm.[13]

The horse should become comfortable at the trot, so that the lameness or gait abnormality can be established. An audible rhythmic pattern to the gait also becomes apparent. The horse is in rhythm (normal) or out of rhythm (lame). In addition to video recording for later viewing, it is important to evaluate the lameness concurrently to establish a baseline. If lameness is not readily apparent, reviewing the video immediately before performing diagnostic analgesia may be advantageous. Although detecting a difference in footfall is a standard part of any lameness examination, in our experience footfall may be exacerbated on a treadmill. Sound horses that trot have a symmetrical, diagonal, two-beat gait, and pacers have a symmetrical, lateral two-beat gait. The horse should be observed carefully for a change in how the horse swings its forelimb or hindlimb. In STB pacers, any change in how the horse moves from side to side at the poll or hips, when viewed from the rear after diagnostic analgesia, is important. These horses, whether pacing free legged (no harness) or when in harness or checked up, have a tendency to swing from side to side and land more heavily or with greater excursion on the sound side. An in-depth description of these gaits is available.[13]

In addition to eliminating lameness, a change in stride characteristics may occur, including stride frequency, length, and swing plane. Some horses not accustomed to the treadmill, or not comfortable on the treadmill, may have an increased stride frequency and shortened stride length, which also may be seen in lame horses.[13] Once accustomed to the treadmill, many sound horses exercised at medium to higher speeds on a treadmill have a longer stride and thus a lower stride frequency.[16] However, lame horses may have an increased stride frequency and shortened stride length.[17] This can best be demonstrated and seen using video.

Other more subtle changes include improvement in gait fluidity, improvement in use of the head and neck and shoulder, and change of an anxious eye expression, flexion of major joints, foot flight, width and rhythm of gait, and footfall.

Occasionally, horses may become stiff or anxious and lame or lamer behind during or after exercise. Exercise should be discontinued. Exertional myopathy (see Chapter 84) or aorto-iliac thrombosis (see Chapter 52) should be considered likely causes.[18]

ADDITIONAL TESTS

It is useful to measure creatine kinase and aspartate aminotransferase concentrations before and after exercise to monitor horses for subclinical myopathy, overt myopathy, or previous undiagnosed myopathy.[19] If aorto-iliac thrombosis is suspected, a rectal examination and an ultrasonographic examination per rectum should be performed. Horses with aorto-iliac thrombosis commonly become lame behind during or shortly after commencement of exercise.[18] They have an anxious look and can sweat more profusely than their level of exercise would dictate.

The treadmill provides a smooth, even surface at a constant, controllable speed and a horse that is stationary relative to the observer. Some horses are lame in hand, but not on treadmill, and some are lame on treadmill, but not in hand. Horses that are only lame on turns are difficult to evaluate on a treadmill, which only operates in a straight line. Some patients will not tolerate working on a treadmill.[20-22]

The Racehorse

CHAPTER • 102

The Sales Yearling

PURCHASE EXAMINATION OF A THOROUGHBRED SALES YEARLING IN NORTH AMERICA

• Benson B. Martin, John C. Kimmel, and Mark W. Cheney

Veterinary inspection of a Thoroughbred (TB) yearling at public auction requires expertise and experience.[1-13] Previously, yearlings commonly were examined after purchase and if a problem was discovered subsequently, a lengthy, expensive, and frequently unsatisfactory arbitration for buyer and seller alike was implemented. Recently a shift has occurred toward a comprehensive examination of yearlings before purchase.

It is important that the veterinarian's role be defined in advance with all the necessary parties, such as the potential trainer, owner, and syndicate manager. Clinicians should determine whether they are prepared to offer advice concerning the pedigree or whether their advice will be strictly veterinary. It should be made clear that no guarantees of future performance can be given. Any potential conflicts of interest must be declared, including whether the veterinarian is involved as an agent, breeder, purchaser, or consignor.

Veterinarians should establish precisely for whom they are working and to whom information can be divulged. They should not give privileged, confidential information to anyone else. Provide a representative estimate of the fee for the examination. Sometimes a buyer may wish to gain access to information obtained by another. This is acceptable provided that the original client gives permission. In this way the fee may be split between two or more prospective purchasers. If clinicians work regularly with purchasers, they may be able to contribute to their buying policy, which may include consideration of pedigree information, budget, conformation type, sex, and potential resale breeding value. Excellent communication with trainers is important, because they ultimately have most control of the horse when it enters training.

It is also important to establish a good relationship with the consignor or agent. Veterinarians should be courteous and respectful and should arrange a mutually suitable time to examine the yearling and should request permission before carrying out endoscopic or radiographic examinations.

Experience is essential to make accurate interpretations of conformational or gait abnormalities, radiographic or endoscopic findings, and the results of examination of the eyes and heart. Knowledge of pedigrees also can be helpful.

Conditions of Sale

It is important to be aware of the conditions of sale for each sales company. These conditions usually differ with the age of the horse, use of the horse, and sales company. Sales are weighted in favor of the consignors and conducted with an attitude of caveat emptor. The warranty is limited, with no implied warranty for use or soundness other than those conditions published in the sales catalog. The repository is an area at the sales set up for viewing radiographs, and videotapes of the upper airway at rest, in selected horses. If veterinarians determine this information is not adequate or satisfactory, it is their responsibility to obtain the desired information. They should examine all available information carefully. If any problem is discovered after the sale that was evident in the repository information, the consignor is not liable. The sales company makes no warranty about the accuracy or completeness of repository information and makes no interpretation of it. Repository information is for the convenience of potential buyers and as a courtesy of the consignors and also decreases the exposure of yearlings to repetitive and stressful examinations. Other information, such as previous surgery, medical problems, eye problems, current medication, vaccination, Coggins and equine viral arteritis status, and presence of radiographs, may be available from the consignor, if the veterinarian asks.

Presale or Postsale Examination

Currently many persons prefer presale inspection. This eliminates the process of arbitration and places the onus of disclosure on the consignor and makes the buyer responsible for obtaining all available information before sale. If the buyer does not obtain such information (such as identification of a chip fracture), the buyer has no recourse. With examination after sale the only problems for which a horse may be returned are listed in the catalog as conditions of sale. The veterinarian is responsible for knowing these conditions and the terms under which arbitration can occur. Arbitration usually must be implemented within 24 hours after the sale of the yearling, and the yearling must still be on the sales grounds. Failure to comply with this negates any chance of arbitration.[14] Arbitration usually involves a veterinarian representing the sales company, the consignor, and the buyer.

Clinical Examination

A yearling TB is immature and its physical appearance may change considerably. Developing the skills to predict how each horse may develop by learning from experienced persons is worthwhile. Assess the general attitude of the horse, its eye, and presence. Be aware that many yearlings are tranquilized for ease of inspection, so one may not get a true picture of the animal's attitude, which can be important in training and racing. Evaluate the horse's conformation. Look at the horse's feet, because the old adage "no foot, no horse" is true. Assess the horse's shoulder, hip, top line, length of back, and then the lower limbs. A good shoulder and hip can accommodate many conformational defects lower in the limb. In our opinion the following conformational abnormalities may predispose to lameness and should be avoided: back at the knee, tied in behind the knee, offset knees, and exceptionally straight hindlimbs. Carefully evaluate the shoeing and trimming of the

feet, because a good farrier can make a horse that toes in or out appear to be almost normal, and they are most adept at repairing an abnormal hoof appearance. After examining the horse walking in hand, perform a more detailed examination in the stall, out of sight of the general public, as a courtesy to the consignor. Assess carefully any swellings and palpate the joints, tendons, and ligaments. Examine the eyes and auscultate the heart. Look for evidence of previous periosteal stripping or other surgery, evident as dermal thickening or white hair in areas where surgery is commonly performed.

Endoscopy and Echocardiography

The veterinarian should ask the consignor or his manager for his assistance and permission to perform an endoscopic, radiographic, and echocardiographic examination of the animal and should arrange a time to do so. A resting endoscopic examination of the horse's upper airway should include stimulating the horse to swallow and holding off the horse's airway. This allows more complete evaluation of the horse's upper airway function at rest. Echocardiographic examination is not performed routinely but can be used to assess heart size and left ventricular free-wall contractility or to detect abnormalities.[15]

Radiography

For many yearlings radiographs are obtained up to 30 days before the sales and are stored in the repository at the sale. Most states allow only veterinarians licensed in the state to examine these radiographs. The examining veterinarian is responsible for ensuring that all the desired views are present, that the radiographs are properly identified, and that they are of suitable quality. The radiographs should be interpreted carefully. If the radiographs are incomplete, of poor quality, or absent completely, the veterinarian should should arrange to have his or her own complete set of radiographs obtained. In our opinion a comprehensive examination consists of 46 views, plus any additional views needed on the basis of clinical examination. These views include the following:

- Front feet: lateromedial (LM) and dorsopalmar (DPa)
- Front fetlocks: DPa, LM, flexed LM, dorsolateral-palmaromedial oblique (DL-PaMO), and dorsomedial-palmarolateral oblique (DM-PaLO)
- Carpi: DPa, LM, flexed LM, DL-PaMO and DM-PaLO
- Hind fetlocks: dorsoplantar (DPl), LM, dorsolateral-plantaromedial oblique (DL-PlMO), and dorsomedial-plantarolateral oblique (DM-PlLO)
- Tarsi: DPl, LM, DL-PlMO, DM-PlLO
- Stifles: caudocranial, LM, and caudolateral-craniomedial oblique (CdL-CrMO)

However, the following 36 views are those required by the Keeneland sales repository in 2001:

- Front fetlocks: dorsal 15° proximal-palmarodistal oblique, LM, flexed LM, DL-PaMO, and DM-PaLO.
- Hind fetlocks: dorsal 15° proximal-plantarodistal oblique, LM, flexed LM, DL-PlMO, and DM-PlLO
- Carpi: flexed LM, DL-PaMO, and DM-Pa LO
- Tarsi: D10°L-PlMO, LM, and DM-PlLO
- Stifles: LM and CdL-CrMO

This provides a comprehensive, but not all-inclusive, picture of the horse's musculoskeletal system. Other sales companies may have different requirements. The veterinarian is responsible for ascertaining the requirements.

A number of common radiographic findings may eliminate a horse from further consideration.[16] Fractures of the carpus, distal phalanx, tarsus, proximal sesamoid bones, and the second or fourth metacarpal (metatarsal) bones generally are considered unacceptable, whereas small osteochondral fragments on the dorsal aspect of a fetlock joint may be acceptable. Osteoarthritis of the carpus, fetlock, or proximal interphalangeal joint is not acceptable. However, small osteophytes on the dorsoproximal aspect of the third metatarsal bone do not preclude necessarily a successful athletic career.

The relevance of osteochondrosis depends on the location of the lesion, its size and severity, the presence or absence of osteoarthritis, and the prognosis for racing after surgical treatment. A small fragment may be amenable to surgical treatment and should be discussed with the buyer. If a fragment has been removed previously and no evidence of osteoarthritis exists, the horse may be a reasonable risk for purchase. Horses with osteochondral fragmentation of the distal intermediate ridge of the tibia or small lesions of the lateral trochlear ridge of the femur usually are treated successfully by surgical removal. Horses with osteochondral fragments on the proximoplantar aspect of the proximal phalanx in the hindlimbs (which may actually be traumatic in origin) represent a reasonable risk.

If an osseous cyst-like lesion is identified, especially one involving the stifle or fetlock, the horse generally should be considered at high risk for developing lameness. Other radiographic abnormalities that may preclude purchase include sesamoiditis, laminitis, or active splints.

PURCHASE EXAMINATION OF A THOROUGHBRED SALES YEARLING IN EUROPE

• David R. Ellis

Yearling sales occur in Europe later in the year than in the United States. The earliest, at Deauville in Normandy, is in early August, but in England and Ireland the main sales are conducted between the end of September and early December.

Monitoring and Sale Selection

Most higher-class farms that offer yearlings regularly monitor the growth rates, weights, and conformation of the young stock. Such monitoring often is done with veterinary help and is conducted in close cooperation with the farrier. This should ensure that any corrective farriery is undertaken as early as possible, thus gaining maximum benefit and not leaving correction to too late in the growth of the animal. The second growth spurt, between 9 and 12 months of age, is an important window of opportunity in which to make substantial changes through corrective techniques. Regular veterinary inspections also help to detect disease, such as acquired deformities or developmental orthopedic disease, early enough to allow successful remedial measures to be undertaken. As in the United States, selection of the sale at which the yearling is to be offered is made in the spring, usually April. A few consignors conduct radiographic surveys at this time to help this selection and to deal with potential problems such as bone chips and osteochondrosis.

Preparation

Yearlings are brought in from pasture 6 to 8 weeks before sale for increasingly intensive preparation. This involves walking exercise with the horse led by hand, sometimes using uphill work, or using a walker. Treadmills used to be used, but they have fallen from favor because they tend to give the animal a goose-stepping type of action. Lunging is introduced later in preparation, particularly for the heavier or fatter animals, and this will be short and at a sharp trot and canter, on both reins and often twice daily. Lunging is more important to sale preparation in Europe because most yearlings, particularly the more expensive, will undergo respiratory examination at the canter by the purchaser's veterinary surgeon immediately after sale. Education and fitness are important if this postsale test is to be conducted safely and satisfactorily. A substantial risk of injury exists during lunging if the exercise is not conducted carefully and on a suitable surface. Interference injuries, such as brushing or overreach wounds. can be prevented by using protective boots, farriery, and careful buildup of speed and fitness and particularly by using a sympathetic surface. Surfaces such as deep sand or dry wood chip may become too deep or slide away under the horse. Paddock turf can be too firm and slippery to be safe. Modern surfaces, such as Fibresand (Fibresand UK Ltd., Mansfield Sand Co., Nottinghamshire, UK), or Polytrack (Martin Collins Enterprises, Hungerford, UK) on a slight camber are safer. Some of the more successful vendors place more emphasis on lunging to achieve fitness and muscle condition than on walking. Excessive walking usually makes the person leading the yearling fitter and leaves the yearling bored and slovenly.

Yearlings usually come up from summer grazing in good, perhaps heavy, body condition. Converting the fat yearling into a well-muscled potential athlete by judicious feeding and exercise is an art. Overfeeding the leaner animal may lead to physitis (see Chapter 59). As the weather starts to cool, most yearlings will be rugged (blanket applied) in the stable to ensure that they do not start changing to a winter coat. This change in management means that less energy is required in the diet.

Using medication to promote growth or body condition is much less common nowadays, partly because certain vendors became renowned for these practices and suffered in the long term. Anabolic steroids are not licensed for use in the horse, now deemed in mainland Europe to be a food animal. Several years ago Tattersalls, the important Bloodstock Auctioneers, conducted a pilot program of drug testing yearlings for steroids at their premier sale to assess steroid use. Although the results were never published, the effect of this exercise was salutary.

During the preparation period, front shoes will be fitted, and some changes can be made to hoof trimming and balance to conceal slighter conformation faults, fill horn defects, and ensure that hoof wear during exercise is not excessive. Few yearlings will be fitted with hind shoes. It is important that the final shoeing is not too close to the sale date, so that tight nails or other shoeing problems do not cause lameness.

Orthopedic problems encountered in the yearling year can include physitis—mainly at the distal radial growth plate, but occasionally also the distal tibia—splints, sesamoiditis and strain of suspensory ligament branches, osteochondrosis, or bone cysts. Horses with bone cysts often have clinical lameness when forced exercise commences, as in sale preparation, or breaking in immediately after sale. Managing orthopedic problems in the months before the sale not only requires the ideal veterinary measures according to the disease, but also requires giving consideration to the importance that potential purchasers place on the problem (little perhaps in animals with small settled splints) and to alternative strategy if the chosen sale has to be missed. If, for example, a yearling develops a bog spavin that requires surgical removal of osteochondral fragments 3 months before sale, having the joint back to normal, the clipped hair regrown, and the yearling adequately fit to offer for auction would be a close race to run. The ethics of offering such an animal also have to be considered.

Conditions of Sale

Conditions of sale for yearlings at the main European auction houses do not include orthopedic conditions or surgery, with the exception of denerving at Doncaster (United Kingdom) and Goffs (Ireland). The latter auction house also deems wobblers to be returnable. Purchaser power and the example from the United States have introduced more pre-sale radiographic examinations at premier sales. These now mostly are conducted by the vendor, and films of standard views of the carpi, hocks, all fetlocks, and stifle joints are available for examination by purchasers' veterinary surgeons. No official repository exists, but viewing facilities are available at the sale paddocks.

Radiographs are not essential to a profitable sale, because some of the most successful vendors at Tattersalls have not allowed pre-sale radiography or endoscopy. They stand by their yearling on orthopedic matters and rely on the auctioneer's condition of sale regarding wind conditions. The latter is more stringent than in the United States regarding laryngeal hemiplegia but does not include other upper respiratory disorders, which are considered intermittent, treatable, or so rare (for example, rostral displacement of the palatine arch has been detected three times in 17 years) as to be dealt with on a single-case basis. Conditions of sale for English and Irish yearling sales state that a horse is returnable if it is found to make a characteristic abnormal inspiratory sound when actively exercised (a roar or whistle at the canter) and have endoscopic evidence of laryngeal hemiplegia that was not declared before sale. Horses are lunged for this examination soon after sale and before they leave the sale paddocks.

Orthopedic Conditions

The most commonly found orthopedic condition to cause significant difficulty after sale is the subchondral bone cyst in the medial condyle of the distal femur (see Chapter 47). Characteristically, lameness occurs soon after the horse starts

lunging exercise for breaking in. Clinicians experienced with yearlings always radiograph a yearling's stifles if lameness develops in a hindlimb under these circumstances, with no obvious clinical sign of origin of pain. Vendors usually are approached with a view to taking the animal back, particularly if the money has not changed hands, but not all will do so. No case has yet come to court, and it must be admitted that after conservative or surgical treatment, some such horses have gone on to race satisfactorily, but not as 2-year-olds.

Conditions commonly found during prepurchase veterinary examination include the following:

- Enlargement of the proximal sesamoid bones can be the most important condition, because enlargement may result from fractures sustained as a young foal that have healed by fibrous union (see Chapter 37). Enlargement is often multiple and can involve the apex or the base of the bone. Sesamoiditis, with or without suspensory branch desmitis, also is seen in yearlings (Fig. 102-1).
- Any effusion of a joint must be viewed with suspicion, particularly if forced flexion is painful. Purchase cannot be recommended, and even if good quality radiographs reveal no abnormality, a guarded opinion is given.
- Asymmetry of front feet is common, and a slightly narrow hoof need not detract, providing the hoof is not twisted or shear heeled. Feet are sometimes overcorrected, which leaves them unlevel when viewed from the front standing on a hard, level surface or when the foot is held up and the solar surface is inspected. These conditions can cause orthopedic problems in training, and only mild imbalances are acceptable. The narrow, boxy foot is probably a lesser evil than the broad, flat foot with collapsed heels.
- Lameness rarely is seen at sale examinations, but it can be difficult to spot because routine examination only involves inspection at the walk. Trotting can confirm or deny lameness. Ataxia can be difficult to discern because the frequently inspected yearling tires during the day and can appear weak. Also, some yearlings are given mild sedatives to control behavior, which may give a similar effect.
- Presale injuries are common. Yearlings travel by road or ferry, and knocks and abrasions often cause more distress to the vendor than the animal. Capped hocks are particularly common but rarely important.

Fig. 102-1 Dorsolateral-palmaromedial oblique radiographic view of a metacarpophalangeal joint. Irregularity and enthesophyte formation on the abaxial margin of the lateral proximal sesamoid bone reflect sesamoidits. (Courtesy I.M. Wright, Newmarket, England.)

Ultrasonographic Examinations

Ultrasonographic examinations have been introduced by some purchasers. Ultrasonography has been used mainly to measure dimensions of the cardiac chambers, but some horses that have had injuries or other soft tissue anomalies may be offered with ultrasonographic images provided by the vendor or, with the vendor's permission, may be examined by ultrasonography by a purchaser's veterinarian. Conditions that may warrant such an examination to give purchasers confidence include thickening of suspensory ligament branches or fleshy superficial digital flexor tendons (SDFTs). The former is seen distally where the suspensory ligament branch attaches to the proximal sesamoid bone and usually results from a mild strain. Whatever the fiber pattern appearance in these horses, they often need considerable patience in training as 2-year-olds but ultimately can stand racing. Fleshy tendons are a thickening or bowing of the SDFT in the forelimbs that is seen in yearlings or 2-year-olds in training. They show minimal or no soreness on digital pressure and on ultrasonographic examination have an increased cross-sectional area of the middle third of the tendon and a coarseness of fiber pattern, but no core lesion or accumulation of fluid (Fig. 102-2). These horses do well if they are shown patience in training (horses with mild lesions are capable of light cantering exercise, but not galloping) and are not given aggressive veterinary treatment. With regular monitoring the tendon(s) usually thins and straightens to normal during the summer months, and many horses can be raced as 2-year-olds. This condition is probably an adaptive mild inflammation, because it occurs in yearlings that have had no managed exercise and in 2-year-olds in early training. Fleshy tendons should not be considered in the same serious manner that a strain or core lesion would demand in an older horse and pose only a slightly greater risk of tendonitis later in the racing career. Local anti-inflammatory or counterirritations are sometimes applied, but the efficacy is dubious.

NORTH AMERICAN STANDARDBRED SALES YEARLING

• Mike W. Ross

Veterinary inspection of the Standardbred (STB) sales yearling at the major sales is limited compared with that of the North American TB yearling. At most sales the number of veterinarians inspecting horses for their own potential purchases is similar to the number of those hired by owners and trainers to provide opinions.

Location and Time of Major Sales

The major sales take place in the fall in Kentucky and Pennsylvania, with smaller sales elsewhere. Small consignors may sell directly through the sales company, but large breeding farms or well-known agents sell most STB sales yearlings. Separate dispersal sales of broodmares, sucklings, and weanlings occur with the yearling sales or at a later date. Horses of racing age sell at various sales across North America, but no specific sales occur for 2-year-old horses in training.

Conditions of Sale

All STB sales yearlings sell as is, meaning when the hammer falls, the buyer owns the yearling in the condition in which it was sold and must pay according to the conditions of sale. The sales companies are not responsible for determining the suitability of the horse for racing or for unsoundness discovered after the sale. The sales company announces the yearling's sex and reproductive changes (gelding, spayed, ridgeling, cryptorchid), if the yearling was conceived by embryo transfer, and if the horse has been "nerved." Consignors sign a contract with

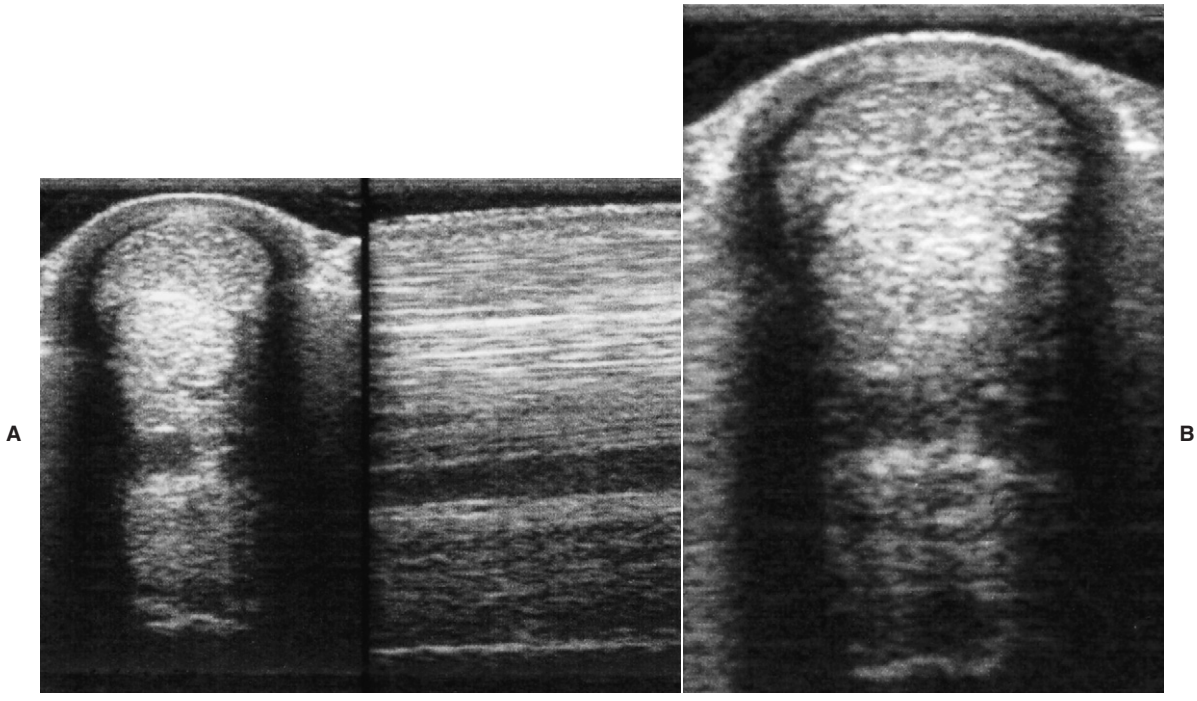

Fig. 102-2 **A,** Transverse (on the left) and longitudinal ultrasonographic images of the mid-metacarpal region of a 2-year-old Thoroughbred with fleshy tendons. There is subcutaneous edema and enlargement of the superficial flexor tendon. **B,** Enlarged transverse image seen in **A.** The entire cross-sectional area of the tendon has a diffuse reduction in echogenicity.

the sales company that includes details about remediation if a dispute regarding soundness occurs, but the legal responsibility is with the consigner, not the sales company. Arbitration, according to the laws of the state in which the yearling was sold, is used if a suitable arrangement cannot be made.

Consignors, usually large farms acting as agents or independent sales agents, have a separate contract with individual owners to represent them at a sale. Owners are required to give information about neurological status, cribbing, fractures, neurectomy, or unsoundness of sight or wind at least 30 days before sale. The consignor determines if information regarding these conditions is announced at the sale, but no contract stipulates that known conditions, such as lameness or previous surgery, be announced at the sale. To prevent disputes and to preserve their integrity, consignors may request that surgical procedures, such as arthroscopy to remove osteochondritis dissecans fragments, or other pertinent information are announced. Verbal announcements and the availability of presale radiographs and surgical reports may be detrimental to the sales price, despite resolution of the condition, although removal of tarsocrural osteochondritis dissecans fragments is usually acceptable. Philosophical differences exist between consignors and only some provide presale information. Thus little incentive exists to disclose information or to investigate problems before sale. Many owners prefer that problems are not investigated so that the yearling may be consigned without disclosure.

Resolution of Disputes

The consignor is primarily responsible for adjudicating conflicts about STB sales yearlings. Because sales companies stipulate yearlings are sold as is and arbitration is the final remedy for disputes, consignors often are forced to provide flexible remediation when disputes arise. If consignors are owners, they deal with problems directly with buyers. If consignors are agents for owners, they become the intermediary. In most instances consignor and buyer attempt to avoid arbitration. Problems arise when a condition is found after the sale, usually on postsale radiographs, that is judged to be detrimental to the yearling's future potential as a racehorse. The buyer refuses to pay and contacts the consignor. Influential large buyers can often stand their ground, and the consignors may refund money, give credit to the buyer for the future purchase of a yearling, pay for surgery if necessary, or lower the sales price. If agreement cannot be reached, arbitration ensues. The high prevalence of osteochondritis dissecans fragments means that most disputes concerning these are judged in favor of the consignor. Disputes regarding carpal chip or other fractures, osseous cyst-like lesions, extensive radiolucency of the proximal sesamoid bones, or unusual osteochondritis dissecans or traumatic conditions often are resolved in favor of the buyer. Fractures are considered important, and the term should be avoided if a condition is known by most to be a manifestation of osteochondritis dissecans. Failure to disclose a condition is most difficult to prove but often is suspected by disgruntled owners.

Role of the Veterinarian

Because repository radiographs are not available, the veterinary presence at major sales is minimal. Veterinarians are sometimes asked to accompany buyers to farms before sale, or to the sale itself, but are handicapped by not having the ability to review radiographs. Influential buyers may be able to convince consignors to allow radiographic and endoscopic examinations and may otherwise threaten not to bid on horses. Veterinarians often are asked to judge conformation and interpret what effect abnormalities may have on future race performance. They may be asked to review pedigrees, but in general, trainers and owners are extremely knowledgeable. Veterinarians are usually prohibited from performing radiographic and endoscopic examinations at a sale or, if they are allowed to do so, must perform the examinations after normal

sales hours. However, these examinations usually are allowed for horses of racing age.

Conformation

A definite relationship between conformation and the development of certain lameness conditions exits in the STB sales yearling (see Chapter 109). A difference in the relevance of abnormal conformation exists between a trotter and pacer. Sickle-hocked conformation is acceptable in a pacer, unless severe, but in a trotter this conformation leads to lameness. A sickle-hocked trotter is usually fast but lame. Mild sickle-hocked conformation is considered by some to be desirable in a pacer, but in horses of either gait, this abnormality predisposes to curb, osteoarthritis, and fracture of the distal hock joints (see Chapter 79). In-at-the-hock conformation is undesirable in the trotter and pacer. Calf-knee or back-at-the-knee conformation is prevalent in STB yearlings, and if mild and in a pacer the conformation is acceptable, but in a trotter this abnormality should be avoided. Any conformational abnormality of the carpus in a trotter should be considered carefully. Bench-knee or offset-knee conformation is undesirable in a trotter or pacer. Tied-in below the knee leads to superficial digital flexor tendonitis, especially in a pacer. I believe TB racehorses can tolerate clubfoot conformation better than STBs, and this abnormality should be avoided. Metacarpal and metatarsal exostoses are common, but usually of little concern, unless large or proximally located near the carpus and tarsus, respectively.

Videotapes of yearlings in action (loose exercise in paddocks or jogging on the track) are usually available and are thought to be much more informative in trotters than in pacers. Desirable characteristics of trotters include a wide gait behind and a narrow gait in front. An acceptable trotter can be base narrow and toed out in front, because hindlimbs often land lateral to the forelimbs (called *passing gaited*), and interference injury is minimal. Base-narrow, toed-out conformation predisposes a pacer to considerable interference injury. In pacers, base-wide forelimb conformation is acceptable, whereas in a trotter this predisposes to interference. Toed-in conformation, if mild, is acceptable in a pacer but not in a trotter, because interference injury and lateral branch suspensory desmitis are problems.

Radiographic Examination

Because no repository for radiographs is provided and many consignors actively discourage presale radiography, radiographs are usually unavailable. However, some farms examine all Standardbred sales yearlings radiographically before the sale, remove osteochondritis dissecans fragments, and have radiographs available on request. Because osteochondritis dissecans fragments of the tarsocrural joint generally cause effusion in late weanlings and early yearlings, these often are removed surgically before sale, but this may not be announced. Radiographs may be available for other types of injuries, such as lumps or bumps in the metacarpal or metatarsal region or elsewhere, to demonstrate that the injury is unlikely to affect future race performance.

Radiographs commonly are obtained after sale and may lead to questions about future soundness and, in some horses, arbitration. In general, radiographic changes that affect racing performance are radiolucent defects of the proximal sesamoid bones (sesamoiditis and osseous cyst-like lesions), large conglomerate osteochondritis dissecans fragments involving the plantar processes of the proximal phalanges (intra-articular and extra-articular fragments) in trotters, osseous cyst-like lesions of the distal aspect of the proximal phalanx and middle and distal phalanges, large osteochondritis dissecans lesions of the lateral trochlear ridge of the femur and subchondral bone cysts in the medial femoral condyle, single or multiple fragments located in the distal sesamoidean ligaments (rare form of fragmentation seen in the forelimb, thought to be a manifestation of osteochondritis dissecans), carpal chip fracture, and various forms of osteoarthritis. The mere presence of osteochondritis dissecans fragments does not necessarily affect sales price if the condition is known before the sale, and certainly in most yearlings, does not preclude future soundness and successful racing. The most common sites of osteochondritis dissecans involve the tarsocrural joint and the metatarsophalangeal and metacarpophalangeal joints. Once discovered, these fragments are often removed prophylactically before training begins. Management of fragments in the metatarsophalangeal joint is discussed elsewhere (see Chapter 43).

Future Direction

Many disputes occur between buyers and consignors concerning abnormalities in postsales radiographs, lameness, or neurological disease. Determination of when a lesion developed, if a true fracture exists, real or perceived effects on prognosis, and chain of custody (in whose care the yearling was when the problem was noticed) complicate final payment. These issues generally are resolved between the consignor and buyer (see the previous discussion), but occasionally arbitration is necessary and usually favors the consignor. Availability of presale radiographs in a repository would be preferable and a strong forward step for the STB industry, and although this change is not yet well accepted, mandatory radiographic examination is gaining support from some of the most influential owners and agents.

CHAPTER • 103

Biochemical Markers of Bone Cell Activity

Joanna Price

Bone is a complex tissue that undergoes change throughout life by the processes of bone formation by osteoblasts and bone resorption by osteoclasts. Bone remodeling is necessary for bone health and allows the skeleton to respond rapidly to changes in its internal and external environment.[1] Bone formation and resorption are coupled; the cycle begins with the recruitment of osteoclast precursors, which attach to the bone surface and resorb the subjacent matrix. Osteoblasts then differentiate from mesenchymal precursors and fill in the resorption pit with new bone. In the healthy adult, skeleton formation and resorption are balanced. However, changes in this balance occur during growth in response to increased or decreased exercise, as a consequence of hormonal changes, during aging, after therapeutic intervention, in metabolic bone disease, or in response to damage. One of the challenges facing researchers in equine orthopedics is development of sensitive and specific non-invasive methods to evaluate these changes in bone turnover in vivo.

Long-term changes in bone mass and structure can be assessed using techniques such as quantitative ultrasound, dual-energy x-ray absorptiometry, or quantitative computed tomography.[2-4] However, for changes in bone mass and architecture to be of a sufficient magnitude that they can be detected using these methods may take several months. Furthermore, quantitative computed tomography and dual-energy x-ray absorptiometry cannot be used in the conscious horse, and use currently is restricted to ex vivo or research studies. In contrast, biochemical markers measure dynamic changes in bone cell activity and can be measured in body fluids using straightforward methods, which are inexpensive.[5] Bone marker measurements can be repeated at frequent intervals and so are convenient to use in the field. Presently, biochemical markers of bone cell activity remain research tools, and most published studies reviewed in this chapter relate to fundamental aspects of bone marker research (such as assay validation and sources of variability). However, an increasing amount of work is being undertaken by several groups on the potential clinical applications of bone markers in horses. Progress in equine bone marker research has been facilitated greatly by the increased use of bone turnover markers in human clinical research relating to metabolic bone disease, particularly osteoporosis.[6,7] In fact, most equine studies have used markers originally developed for people, and many have involved successful collaborations between veterinary and medical research laboratories.

Biochemical markers of bone cell activity are classified as markers of bone formation or of bone resorption, although some reflect changes in both processes. In general the markers are enzymes expressed by osteoblasts, osteoclasts, or organic components released during the synthesis and resorption of bone.[8] Because each marker may reflect a different physiological process in bone, assaying for a combination of markers is preferable, because this provides more information on bone (re)modeling rates. Furthermore, studies in people have shown that in certain diseases individual markers yield more useful information than others.[9]

Box • 103-1

Abbreviations Used in Discussion of Bone Cell Activity

ALP	Alkaline phosphatase
BAP	Bone-specific alkaline phosphatase
BMC	Bone mineral content
CTX	Type I collagen C-terminal telopeptide
DEXA	Dual-energy x-ray absorptiometry
DYR	Deoxypyridinoline
GGHyl	Glucosylgalactosylhydroxylysine
Ghyl	Galactosylhydroxylysine
HPLC	High-performance liquid chromatography
Hyp	Hydroxyproline
ICTP/CTX-MMP	Carboxyterminal cross-linked telopeptide of type I collagen
OC	Osteocalcin
PICP	Type I collagen carboxyterminal propetide
PYR	Pyridinoline
QUS	Quantitative ultrasound
QCT	Quantitative computerized tomography
RIA	Radioimmunoassay

An ideal biochemical marker should be measurable in body fluids (urine, serum, or plasma) by a sensitive and specific technique and should be specific to its tissue of origin. Other criteria that determine the value of a biochemical marker are whether the factors that control its synthesis and metabolic pathway are understood and the factors that influence its biological variability. To date, little is known about factors that regulate the synthesis and metabolism of bone markers in horses.

Some common abbreviations used in discussion of bone cell activity are found in Box 103-1.

BIOCHEMICAL MARKERS OF BONE FORMATION

Bone formation markers are synthesized by osteoblasts and are all measured in serum or plasma (Table 103-1).

Alkaline Phosphatase

The enzyme alkaline phosphatase is associated with the osteoblast plasma membrane and is required for osteoid formation and matrix mineralization. Total serum alkaline phosphatase is derived from multiple sources and thus is not a specific marker

Table • **103-1**

Markers of Bone Formation

MARKER	METHODS USED	BODY FLUID	SOURCE	COMMENTS
Total alkaline phosphatase	Colorimetric	Serum	Bone, liver, kidney, placenta	Not bone specific
Bone-specific alkaline phosphatase	Elecrophoresis Precipitation ELISA	Serum	Bone	Some cross-reactivity with liver alkaline phosphatase
Osteocalcin	RIA ELISA	Serum	Bone	Specific osteoblast product
Type I collagen propeptide	RIA	Serum	Type I collagen in bone, skin, tendon, and other soft tissues	May be contribution from tissues other than bone

ELISA, Enzyme-linked immunosorbent assay; *RIA,* radioimmunoassay.

of bone formation. However, tissue-specific alkaline phosphatase is posttranslationally modified, and this provides the basis for a number of methods that have been used to separate and quantify different equine alkaline phosphatase isoenzymes. Bone alkaline phosphatase predominates in serum during growth, although the proportion of the bone isoform decreases in adults.[10,11] No studies have yet described changes in circulating bone alkaline phosphatase associated with equine musculoskeletal disease. However, alkaline phosphatase activity increases in subchondral bone in osteochondrosis,[12] which indicates that bone-specific alkaline phosphatase potentially may be a useful marker of this condition, and this requires further investigation.

Osteocalcin

Osteocalcin, otherwise known as bone Gla protein, is the most abundant noncollagenous protein in bone, and a small fraction of the protein is released into the circulation following synthesis by osteoblasts. Osteocalcin fulfils one of the main criteria for a bone marker: it has tissue specificity. Several studies have described the measurement of osteocalcin in horses, and the work of Olivier Lepage has made a substantial contribution.[13-16] Osteocalcin is the most labile of the bone markers, thus samples should be processed rapidly, and longer-term storage should be below –25° C.[17] Osteocalcin levels are affected by anesthesia; therefore sampling during surgery should be avoided.[18]

Carboxyterminal Propeptide of Type I Collagen

Type I collagen is the most abundant collagen in bone, and the procollagen molecule contains a carboxyterminal extension domain that is split off before fibril formation and released into the circulation. The carboxyterminal propetide of type I collagen provides a measure of newly synthesized type I collagen and is normally measured by radioimmunoassay (RIA).[19] However, type I collagen is not bone specific and synthesis in other soft tissues may contribute to carboxyterminal propetide concentrations. For example, increased levels have been observed following tendon injury,[20] and a peak occurs in carboxyterminal propetide levels during rapid weight gain in growing Thoroughbreds.[21]

BIOCHEMICAL MARKERS OF BONE RESORPTION

Most bone markers that reflect resorption of bone matrix are degradation products of type I collagen[22] (Table 103-2). Until recently these markers generally were measured in urine, but this clearly presents practical difficulties in the horse. Fortunately, several of the newer markers developed for people can be measured in serum, and this may increase the repertoire of resorption markers available for use in horses.

Hydroxyproline

Hydroxyproline is formed from the posttranslational hydroxylation of proline. However, hydroxyproline now is used rarely as a resorption marker because of poor specificity. Concentrations reflect collagen turnover in bone, cartilage, skin, and other soft tissues. Hydroxyproline was first measured in horses more than 25 years ago.[23]

Hydroxylysine Glycosides

Hydroxylysine glycosides occur in two forms, glucosylgalactosylhydroxylysine and galactosylhydroxylysine, which are released during collagen degradation. Bone contains mostly galactosylhydroxylysine and this has been used as a measure of bone resorption in people.[24] We have adapted a human high-performance liquid chromatography assay for measuring galactosylhydroxylysine in horse serum, and levels are correlated significantly with concentrations of another bone resorption marker, the carboxyterminal telopeptide of type I collagen.[25,26]

Pyridinium Cross-Links of Collagen

Cross-links of fibrillar collagen are formed extracellularly in the telopeptide domains and stabilize collagen molecules.[27] If the telopeptide interacts with a hydroxylysine residue in the triple helix, the mature cross-link is pyridinoline found in cartilage, bone, ligaments, and vessels. If the residue is lysine, the cross-link is deoxypyridinoline, which is found almost exclusively in bone. Pyridinium cross-links in body fluids mainly are derived from bone and for many years deoxypyridinoline, measured by high-performance liquid chromatography, has been considered the gold standard of resorption markers. Recently a more convenient enzyme-linked immunosorbent assay has been used to measure the free fraction of urinary deoxypyridinoline in horses and the assay also can be adapted for measuring serum deoxypyridinoline.[28,29]

Cross-Linked Collagen Telopeptides

Cross-links are located at both termini in the type I collagen molecule. A number of peptide assays measure telopeptides generated during resorption. The first of these assays to be developed measured the carboxyterminal telopeptide of type I collagen (ICTP or CTX-MMP), which has been studied extensively in horses, mainly because for several years it was

Table • **103-2**

Markers of Bone Resorption

MARKER	METHODS USED	BODY FLUID	SOURCE	COMMENTS
Hydroxyproline	Colorimetric HPLC*	Urine	All recently formed and mature fibrillar collagens	Not bone specific
Deoxypyridinoline	HPLC ELISA	Urine Serum	Mature collagen in bone and dentine	Good specificity "Gold standard"
Pyridinoline	HPLC ELISA	Urine Serum	Mature collagen in bone and cartilage	Some contribution from cartilage
Carboxyterminal cross-linked telopetide of type I collagen	RIA	Serum	Type I collagen in bone and skin	May be contribution from tissues other than bone
Carboxyterminal cross-linking telopeptide of type I collagen	ELISA ECLA	Urine Serum	Type I collagen	Good specificity Preliminary results suggest equine cross-reactivity
Hydroxylysine glycosides	HPLC	Urine, serum	Bone and soft tissue collagen but enriched in skeletal tissues	High proportion in bone

* *HPLC,* High-performance liquid chromatography; *ELISA,* enzyme-linked immunosorbent assay; *RIA,* radioimmunoassay; *ECLA,* enhanced chemiluminescence assay.

the only marker of resorption that could be measured in serum.[16,19] Recently an immunoassay has been developed that recognizes the C-terminal telopeptide of type I collagen containing an isoaspartyl peptide bond[30] (CTX, Grosslaps Osteometer, BioTech, ALS), and a preliminary report describes its measurement in horse serum.[29]

FACTORS THAT INFLUENCE BIOCHEMICAL MARKERS OF BONE CELL ACTIVITY

Because bone markers reflect instantaneous changes in bone cell activity, a large number of factors can be a source of preanalytical variability. These factors recently have been classified as controllable (e.g., food intake, circadian changes, or exercise) or uncontrollable (e.g., gender, age, or intercurrent disease).[31] A failure to define and appropriately manipulate controllable sources of variability and to account for uncontrollable variability limits interpretation of the results of bone marker measurements in clinical studies.

Circadian Variability

Circadian variability may have a significant effect on markers of bone turnover, particularly urinary markers of bone resorption.[31] Black et al.[32] described circadian rhythms in urinary pyridinoline and deoxypyridinoline excretion in adult geldings, with peak levels between 2 and 8 AM. Circadian rhythmicity in osteocalcin concentrations also has been described, although this remains somewhat controversial.[14,32] Until further data on the circadian changes in other bone markers is available, the safest approach is to assume that this is potentially an important source of variability, and in any study samples should be collected at the same time of day.

Diet

Little is known about the influence of diet on bone turnover markers in horses. Lepage et al.[14] did not observe a short-term effect of feeding on osteocalcin concentrations,[14] and a more recent study found no effect of dietary calcium on plasma hydroxyproline or osteocalcin.[33] However, food intake can influence bone marker concentrations significantly in people and may exacerbate biological variability. For example, fasting reduces the circadian variation in serum levels of C-terminal telopeptide of type I collagen[34] and, although this marker can predict osteoporotic fracture if samples are collected during a fast, the marker has no predictive value in samples collected under uncontrolled conditions.[35] Another potential influence on bone turnover is dietary mineral supplements, which are widely used in horses. For example, higher hydroxyproline levels were reported in ponies fed increased levels of aluminum, which may reflect altered bone turnover.[36]

Seasonal Changes

Some evidence shows that time of year may influence bone turnover, and this may be particularly important during growth. Maenpaa et al.[37] observed some monthly variability in alkaline phosphatase and osteocalcin concentrations in Finnhorse foals, and we have seen an increase in bone turnover markers in Thoroughbred yearlings between midwinter and early summer.[21]

Age

In horses, as in people, biochemical markers of bone turnover are higher during skeletal growth than in adults. Age-related decreases in several bone markers have been described, including osteocalcin,[13,38] bone-specific alkaline phosphatase,[10,11,21] carboxyterminal propetide of type I collagen, carboxyterminal telopeptide of type I collagen,[19] pyridinoline, and deoxypyridinoline.[38] The decrease is most significant during the first year of life and levels do not tend to plateau until animals reach 3 to 4 years of age. Markers of bone formation and bone resorption show a similar pattern of change, because bone modeling involves resorption of bone at some sites (e.g., the endosteum) and formation at others (e.g., periosteal surfaces and the metaphysis). Clearly any study of bone markers must control for the effects of age, and this is particularly important in the young horse, when serial measurements (i.e., use of the horse as its own control) are likely to be most informative. A number of developmental orthopedic diseases occur during growth, and finding a biochemical

marker that could be used to identify animals that have or are at risk of abnormal skeletal development would be of great value. Already some evidence shows that bone turnover markers may be altered in developmental orthopedic disease. Osteocalcin concentrations were lower in a foal with generalized dyschondroplasia and vertebral epiphysiolysis,[39] and in a small cross-sectional study of horses with osteochondritis dissecans, we found that carboxyterminal telopeptide of type I collagen concentrations were elevated, indicating increased bone resorption.[21]

Gender and Breed

Chiappe et al.[38] described higher osteocalcin levels in Thoroughbred fillies between 24 and 36 months of age, whereas no gender difference was observed in younger horses. However, Lepage et al.[13,16] found no influence of sex on osteocalcin concentration in Standardbreds, or on osteocalcin, or carboxyterminal telopeptide of type I collagen concentrations in Warmblood or Draft horses more than 4 years old.

Ethnic differences in bone turnover have been described in people,[31] and horse type also must be considered as a potential effect on bone markers. Lepage et al.[16] showed that concentrations of osteocalcin were lower and carboxyterminal telopeptide of type I collagen levels higher in Draft horses compared with Warmbloods and suggested that this may relate to different rates of bone remodeling in the two breeds.

Disease

At this stage little is known about the effect of different diseases on markers of bone turnover in the horse. Clearly any medical condition that affects bone metabolism influences marker concentrations (e.g., nutritional hyperparathyroidism), as does any disease that changes marker clearance (e.g., liver or kidney disease). In equine athletes, undiagnosed musculoskeletal conditions unrelated to the problem under investigation could lead to misinterpretation of results.

POTENTIAL CLINICAL APPLICATIONS OF BONE MARKERS

The studies reviewed in the previous section have shown that bone markers provide a sensitive, straightforward method for monitoring bone cell activity in horses in vivo and have made a substantial contribution to our understanding of cellular processes in equine skeletal tissues. Although the value of bone markers as clinical tools has yet to be established, a significant amount of research is being undertaken in this area. It is important that the studies designed to test the clinical validity of bone and cartilage markers address specific hypotheses, use carefully selected populations of animals, and standardize outcome measures. Furthermore the clinical validity of markers can be established only if their inherent biological variability is controlled. More work also is required to improve knowledge of the factors that influence the metabolism and clearance of biochemical markers in horses. Continued collaboration between basic scientists and clinicians is important if progress is to be made, and collaboration between different laboratories will ensure the standardization of assays and that protocols are established for sample collection and storage.

Because bone markers reflect turnover in the *whole* skeleton and are affected by numerous variables, in my opinion it is unlikely that any single bone marker measured on one occasion will be able to function as a diagnostic test with a high level of discriminatory power. However, in horses as in people, the most useful applications of bone markers, if measured serially in the same horse, are likely to be as methods for identifying horses at risk of injury and as objective measures for monitoring treatment.[40-42] A further research application for the markers is as a method for monitoring the effects of exercise on bone cell activity.

Injuries to the skeleton are a major cause of morbidity and mortality in the equine athlete, and any method that could help identify animals at risk of injury before clinical signs develop would have significant benefit from welfare and economic perspectives. One study has shown that bone markers can be used to predict osteoporotic fracture in women, although this issue remains controversial.[40] A pilot study that we have undertaken recently showed that a single bone marker measurement taken at the start of the training season did not predict fracture risk in 2-year-old Thoroughbreds.[43] However, the study included fewer than 200 horses and a variety of fracture types. Larger numbers of horses would need to be studied over a long follow-up period to address the question of whether bone markers can predict fracture. It is also likely that using bone markers with another non-invasive measure of bone structure (e.g., quantitative ultrasound) will improve prediction of fracture risk.

USE OF BONE MARKERS TO STUDY THE EFFECTS OF EXERCISE

The extreme responsiveness of the bone to changes in its mechanical environment ensures that the skeletal mass and architecture are appropriate to prevent injury.[44] Evidence that biochemical markers provide a potentially valuable tool for studying the effect of exercise on short-term changes in bone cell activity is accumulating. Lepage et al.[16] suggested that a higher ratio of osteocalcin to carboxyterminal telopeptide of type I collagen in Warmblood compared with Draft horses may reflect a positive remodeling response in horses having regular daily work. We observed increased carboxyterminal propetide of type I collagen, carboxyterminal telopeptide of type I collagen, and bone-specific alkaline phosphatase concentrations in 2-year-olds exercised on a treadmill for 18 months. These results may reflect increased remodeling, caused by accumulated fatigue damage, associated with a long period of training on a hard surface.[45] In contrast a shorter period of treadmill training was associated with decreased carboxyterminal telopeptide and osteocalcin concentrations.[46] A decrease in osteocalcin also was observed when Quarter Horses commenced race training.[47] Of particular interest is a recent observation that marker levels change as the intensity of work increases during race training.[43] However, if a training regimen is not sufficiently osteogenic, changes in bone turnover may not be revealed using bone markers. For example, lunging yearling Quarter Horses had no effect on osteocalcin levels,[48] and no change on deoxypyridinoline or osteocalcin concentrations was observed when previously stabled Arabian horses returned to training.[38]

Although increased loading has anabolic effects on bone, disuse leads to increased resorption, and this can occur when a horse is transferred from pasture to a stable or result from a clinical condition that leads to restricted exercise. Bone markers have shown that immobility can lead to altered bone cell activity, which may predispose horses to injury. For example, when Arabian yearlings were confined to a stable, concentrations of the resorption marker deoxypyridinoline increased, whereas levels of the formation marker osteocalcin decreased. These changes were associated with a decrease in bone mineral content.[28] A decrease in osteocalcin levels after transfer of foals from pasture to winter stabling also has been described.[37] In a study of horses with acute tendon injury we observed that urine pyridinoline and deoxypyridinoline concentrations were increased. This probably reflected increased bone resorption associated with disuse of the affected limb.[49]

MONITORING RESPONSES TO THERAPY

To date, monitoring responses to therapy has proved to be one of the most valuable applications of bone markers in human medicine. The newer bone resorption markers in particular provide a sensitive measure of the effects of antiresorptive agents on bone turnover in human metabolic bone disease.[42] In my opinion, using biochemical markers to monitor the effects of treatment may prove to be one of the most important applications for the bone and cartilage markers in equine orthopedics. In the twenty-first century the veterinary profession must embrace evidence-based medicine, and this will require using objective measures, which should include biochemical markers, to monitor the effects of different therapeutic regimens on skeletal tissues in prospective clinical trials.

Some evidence already shows that bone markers in horses may be useful for monitoring responses to therapy and also for assessing the potentially harmful effects of drugs on the equine skeleton. For example, bone markers have shown that corticosteroids have a negative effect on osteoblast activity, and in the long term this could lead to osteoporotic changes in bone. Osteocalcin levels were found to be decreased significantly after intravenous, intramuscular, and oral administration of dexamethasone and triamcinolone acetonide.[50,51] Levels did not decrease after intra-articular injection of methylprednisolone acetate, which suggests that this route of steroid administration may not have long-term adverse effects on bone.[51] A recent study showed that serum bone-specific alkaline phosphatase did not reflect decreased mineral apposition rate associated with phenylbutazone administration.[52] However, the study was short term, and studies in people have shown that changes in bone formation markers may not occur for several months after treatment. We recently showed that bone marker levels were increased after administration of growth hormone in horses and thus could be useful as indirect measures for detecting its abuse in racehorses.[53]

In conclusion, biochemical markers of bone turnover provide a simple, inexpensive, non-invasive method for studying changes in the activity of groups of cells forming and resorbing bone. To the basic scientist, biochemical markers can contribute significantly to an understanding of the cellular mechanisms that underlie normal bone development and remodeling. To the clinical scientist, bone markers offer an opportunity to study the pathogenesis of disease and improve strategies for reducing the morbidity and mortality associated with a variety of orthopedic conditions in horses.

The Bucked Shin Complex

ETIOLOGY, PATHOGENESIS, AND CONSERVATIVE MANAGEMENT

• David M. Nunamaker

Conditions of fatigue failure of bone and inadequacy of bone remodeling of the third metacarpal bone (McIII) in the racehorse are part of a condition known as *bucked shins* or *dorsal metacarpal disease.*[1,2] Bucked shins start in young healthy racehorses, usually Thoroughbreds (TBs) and Quarter Horses, but occasionally Standardbred (STBs), that undergo intense training for racing, usually as 2-year-olds, while the skeleton is still immature and in the growth phase (Fig. 104-1, *A*). The true incidence of bucked shins is unknown and may vary geographically, but reports range from 30% to 90%. A North American questionnaire cited an incidence of 70%.[1] Stress fractures (dorsal cortical or saucer fractures) usually occur some months after initial signs of bucked shins and may be a potential life-threatening injury if a horse is raced or exercised at speed (Fig. 104-1, *B*). The diagnosis of bucked shins is easy and often made by the trainer or owner. The history of sudden tenderness or soreness of the left (in North America) or both

CHAPTER • 104

The Bucked Shin Complex

ETIOLOGY, PATHOGENESIS, AND CONSERVATIVE MANAGEMENT

• David M. Nunamaker

Conditions of fatigue failure of bone and inadequacy of bone remodeling of the third metacarpal bone (McIII) in the racehorse are part of a condition known as *bucked shins* or *dorsal metacarpal disease.*[1,2] Bucked shins start in young healthy racehorses, usually Thoroughbreds (TBs) and Quarter Horses, but occasionally Standardbred (STBs), that undergo intense training for racing, usually as 2-year-olds, while the skeleton is still immature and in the growth phase (Fig. 104-1, *A*). The true incidence of bucked shins is unknown and may vary geographically, but reports range from 30% to 90%. A North American questionnaire cited an incidence of 70%.[1] Stress fractures (dorsal cortical or saucer fractures) usually occur some months after initial signs of bucked shins and may be a potential life-threatening injury if a horse is raced or exercised at speed (Fig. 104-1, *B*). The diagnosis of bucked shins is easy and often made by the trainer or owner. The history of sudden tenderness or soreness of the left (in North America) or both

Fig. 104-1 **A,** Dorsolateral-palmaromedial oblique radiographic view of a third metacarpal bone. Periosteal new bone formation *(arrows)* over the dorsomedial aspect of the third metacarpal bone is evidence of bucked shins. **B,** Lateromedial radiographic view of the metacarpal region. This dorsal cortical fracture of the dorsolateral third metacarpal bone represents a common type of fatigue fracture *(arrows)* that usually occurs months after an episode of bucked shins.

McIIIs after high speed work or the first race, or soreness developing the day after, are cardinal signs of early bucked shins. Horses with severe disease manifest acute lameness and extreme sensitivity to palpation of the dorsal cortex of McIII and are unwilling to train or race. All gradations of pain or disability may be seen. Swelling and tenderness may suggest new bone proliferation in this area. Radiography is helpful to determine the amount of periosteal new bone formation, which determines prognosis. Large accumulations of periosteal new bone on the dorsal or dorsomedial surface of McIII suggest a serious imbalance between exercise and bone fatigue and may portend the actual stress fractures seen on the dorsolateral aspect of McIII some months hence.

RESEARCH FINDINGS

An understanding of the cause, pathomechanics, and pathogenesis of bone fatigue failure in the TB is helpful in determining prevention or treatment modalities and training regimens. It was formerly suggested that bucked shins resulted from microfractures on the dorsal aspect of McIII, caused by high-speed exercise. However, microfractures should heal without periosteal callus, which does not fit with the clinical observation of extensive periosteal new bone on the dorsomedial aspect of McIII. Work in our laboratory over the past 19 years has led us to propose a different cause of bucked shins[3] and an exercise program that may prevent bucked shins and stress fractures. The following summarizes our investigations.

Geometric Properties of the Third Metacarpal Bone: Comparison of Thoroughbreds and Standardbreds

The McIIIs of STBs and TBs of known age were examined, and comparisons were made between breeds of a particular age group and between the age groups of a particular breed. The second moments of area relate to bending stiffness in dorsopalmar and mediolateral directions and were used to determine the minimum and maximum principal moments of inertia (I_{min} and I_{max}). The most significant changes in the bone occurred at the midsections between the ages of 1 and 2, but

continued change occurred until age 3 or 4. I_{min} was smaller in the yearling TBs but larger in the adult TBs compared with STBs. During the first 2 to 4 years of life, I_{min} changed to a greater extent in TBs.[4]

In Vitro Comparison of Local Fatigue Failure of the Third Metacarpal Bone

Dumbbell-shaped specimens machined from adult McIII from TBs and STBs were tested in fully reversed cyclic bending experiments using a constant strain rotating cantilever model that measured load decrement. All tests were performed at 40 Hz and continued until the specimen broke or had a 30% loss of stiffness. Three different offsets were used to establish nominal strains of 7500, 6000, or 4500 microstrain in the specimens.

Data were analyzed using a power regression model for each horse and for each breed. Statistical differences were not found among the curves for individual horses of the same breed or for the curves between breeds. Pooled data then were used to describe fatigue characteristics of cortical specimens of McIIIs from TBs and STBs of various ages, subjected fully to reversed cyclic loading (Fig. 104-2).[5] The bone from young horses was much more susceptible to fatigue failure.

Because the in vitro fatigue was similar in TBs and STBs, other factors appeared to be important in the pathogenesis of fatigue failure of bone in the TB. This, together with the different inertial properties noted in STBs and TBs, led to the hypothesis that differences in training regimens or racing speeds between breeds might influence the incidence of disease.

Third Metacarpal Bone Stiffness Measurements

Whole bone stiffness measurements were made from horses of 2 months to 28 years of age using an Instron testing machine (Instron, Canton, MA) and a non-destructive three-point dorsopalmar bending test. The bones showed general increases in stiffness until they reached a plateau at about 6 years of age.

The material included McIIIs from twelve 2-year-old TBs, three of which had bucked shins. These three horses had differences in stiffness between the left and right McIIIs of 16% to 27%, respectively, whereas other trained or control 2-year-olds had considerably smaller left-right differences.[6]

In Vivo Strain Measurements: Relationship to Exercise

Bone strain in McIII was measured in horses of varying age, training at or near racing speed, by placing a rosette strain gauge on the dorsolateral aspect of McIII and recording using telemetry.[7] The mean peak compressive strain in four horses 2 years of age was –4841 ± 572 microstrain, compared with –3317 in a horse 12 years of age. One 2-year-old developed bucked shins, and its strain measurements were about 6 standard deviations greater than the other three.

After acquiring in vivo strain data, we correlated this data with in vitro fatigue data previously generated by determining the average number of cycles that a young TB would gallop in training before onset of bucked shins. The training records of six 2-year-old TBs that developed bucked shins were analyzed to determine the total distance worked before the onset of bucked shins. Stride length at canter, gallop, and racing speed was measured in a group of TBs to determine the number of strides (cycles) per mile. The total number of gait cycles was estimated based on the distances covered in a canter, gallop, and at work. The six horses were trained in these gaits between 10,000 and 12,000 cycles per month and developed bucked shins between 35,284 and 53,299 training cycles. This data was compared with the in vitro data described previously and showed good correlation (see Fig. 104-2).

Changing from the trot to the gallop changed the principal strain direction by more than 40° on the dorsolateral surface of McIII. Although trotting horses showed tensile strains in the long axis of the bone on the dorsal/dorsolateral surface, at racing speeds this same surface of the bone showed compressive strains.[8]

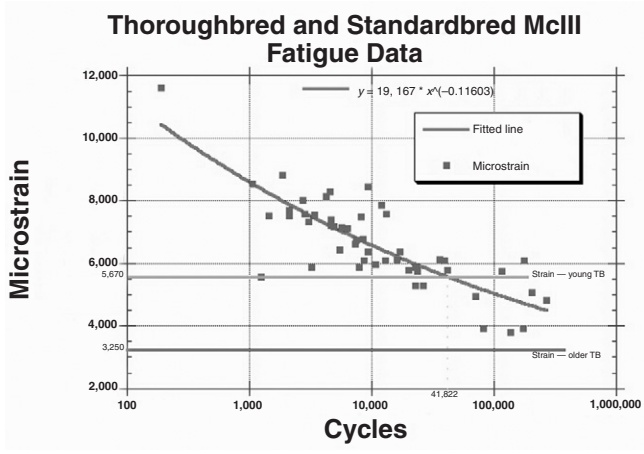

Fig. 104-2 In vitro fatigue data are plotted for the adult Thoroughbred and Standardbred. The regression line shows where the third metacarpal bone *(McIII)* will fail from repeated cycles. Superimposition of the strain levels of young Thoroughbreds shows that 41,822 cycles would result in fatigue failure. The superimposition of an older Thoroughbred shows more than a million cycles would be needed before bone failure.

Relationship of Exercise to Bone Fatigue

With the understanding that slow-speed gaits produce tensile strains on the dorsal surface of McIII, although high-speed exercise induces compressive strains in this same region, a study was undertaken to determine the effects of different training regimens and track surfaces on the modeling and remodeling of McIII in TBs.

Eight untrained 2-year-old TBs were divided into four groups of two horses each. Classical training methods were used for the horses in groups I and II. Group I horses trained on a dirt track. Group II horses trained on a wood chip track. Group III horses (control group) were not trained, but they were allowed free exercise in a large pasture. Group IV horses were trained using a modified classical training program on a dirt track.

The classical training program comprised daily gallops (~18-second furlongs, ~11.2 m/sec) of 1 to 2 miles per day (1.6 to 3.2 km), followed by shorter workouts or breezes at racing speed (~14-second furlongs, ~14.4 m/sec) once every 7 to 10 days that increased in distance from 2 to 6 furlongs (0.4 to 1.2 km) progressively over the course of the study. The modified classical training method used similar daily gallops, but the frequency of the high-speed workouts increased to three per week, while distances increased progressively from 1 to 4 furlongs (0.2 to 0.8 km). After 5 months the McIII was harvested in all horses. Microradiographs of bone sections were made to determine the extent of the remodeling activity (Fig. 104-3). Bone modeling on the periosteal and endosteal surfaces of McIII changed the cross-sectional geometry differently between the experimental groups. Classically trained horses (groups I and II) responded by appositional new bone formation on the dorsomedial periosteal surface, giving the impression that the medullary cavity, although reduced in diameter, was displaced laterally. Horses in the modified training group (group IV) had bone deposition dorsally and a slightly larger medullary cavity that was not displaced laterally. Control horses (group III) had new bone

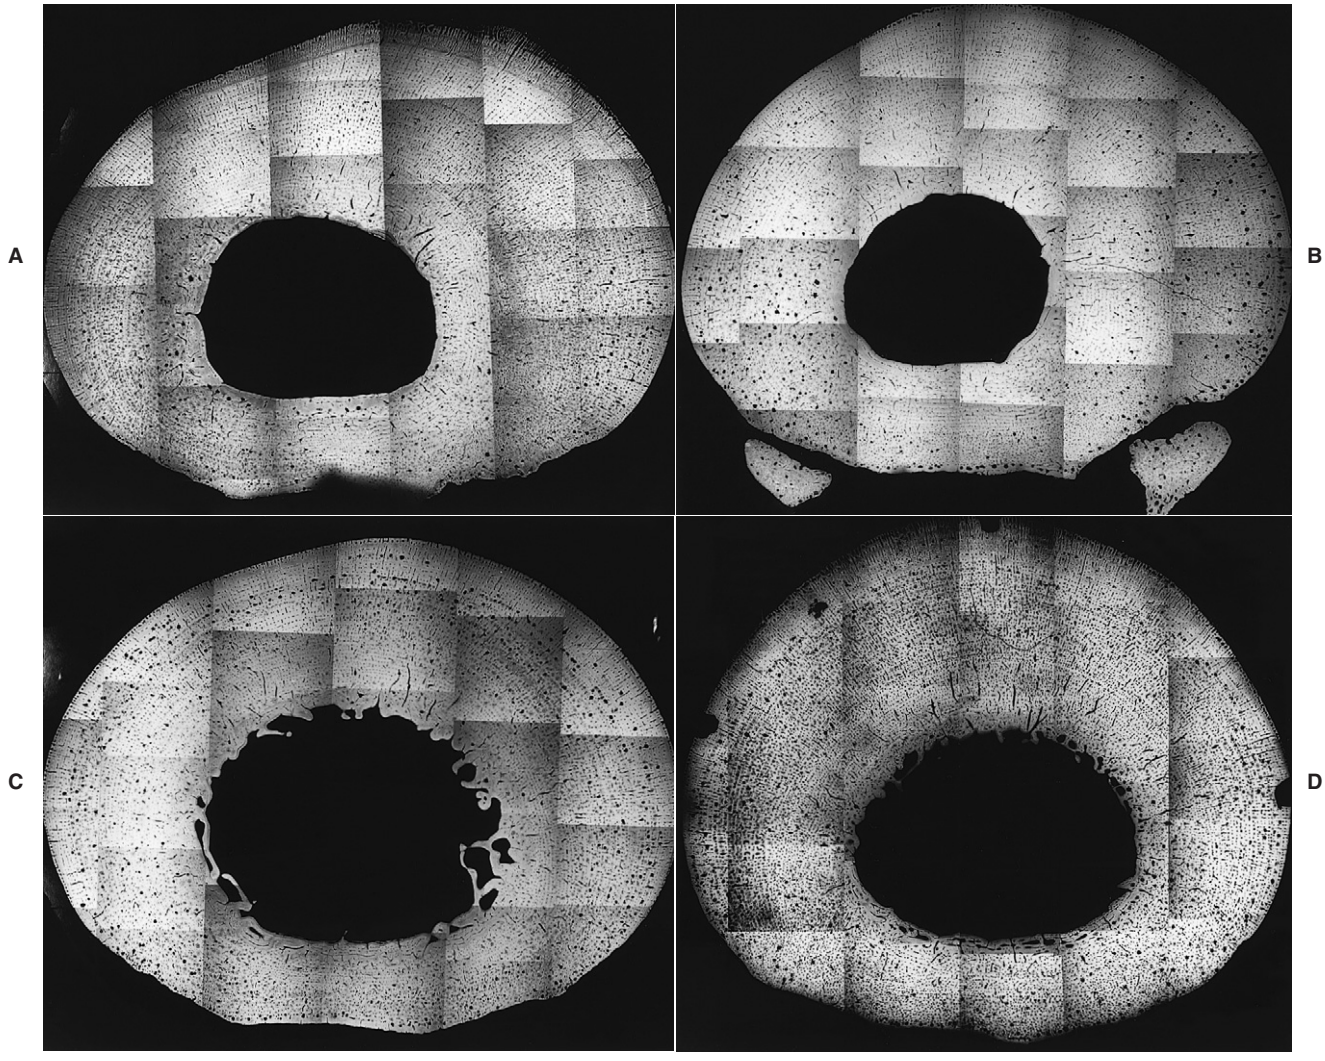

Fig. 104-3 Fifty percent length cross-sections of the third metacarpal bone were used to make these microradiographs. Individual photographs were taken with cross-sections magnified four times, and giant montages (~50 × 70 cm) were constructed to be able to evaluate individual haversian systems of each individual bone of each animal. Lateral is to the left. **A,** Group I horses: classically trained on a dirt track. **B,** Group II horses: classically trained on a wood chip track. **C,** Group III horses: controls. **D,** Group IV horses: modified training on a dirt track. Changes in modeling, remodeling, and shape can be seen easily by comparing different groups. Group II horses appear to be earlier in the remodeling cycle than do group I horses that already have remodeled in the medial and lateral cortices. All specimens are from the left forelimb, and increased new bone formation is seen on the medial surface of the classically trained horses (groups I and II). Modified training (group IV) and the control horses (group III) do not show this change. The lack of haversian remodeling in the dorsal-dorsolateral cortex of the classically trained horses in groups I and II is notable. In this area catastrophic stress fractures occur in racing animals.

formation on the medial, lateral, and dorsal surfaces. The medullary cavity remained large and centrally placed. Examination of McIII inertial properties showed that the I_{min} of groups I, II, and III were similar, but I_{min} of group IV horses was greater and was similar to the I_{min} previously reported for mature racehorses.

Microradiographic sections from the mid-diaphysis of McIII showed that bone remodeling occurred only medially and laterally in groups I and II. Filling of secondary haversian systems with new bone was most complete in group I specimens, indicating that the remodeling process was advanced further in horses exercised on a harder surface. A distinct lack of remodeling activity was apparent in the dorsal and dorsolateral regions in groups I and II. Horses in groups III and IV showed extensive remodeling throughout the cortex, including remodeling in the dorsal and dorsolateral aspects.

These data suggested that in horses training on a hard surface, bone remodeling occurred at a faster rate than in horses training on a compliant (wood chip) surface. Previous studies showed that classically trained horses on a hard surface have a higher incidence of bucked shins than do horses trained on a more compliant surface. One horse in group I developed bucked shins during the training period. Inertial properties (I_{min}) of McIII in the dorsopalmar direction were no different in horses trained on a hard or soft track. Horses in group IV had a significant change in I_{min} of the dorsal cortex of McIII,

similar to that seen in adult racehorses evaluated previously that were no longer at risk of developing bucked shins.[3] This supported the concept that exercise could be designed to optimize the shape and modeling/remodeling status of McIII and thus reduce the incidence of bucked shins.[9]

Exercise Programs Designed to Decrease the Incidence of Fatigue Failure

To determine the efficacy of an adapted training program to decrease the incidence of bucked shins, a prospective and retrospective study was performed using work training data from five commercial training stables. Two of the stables (2 and 5) were already using our modified classical training program, and the others (1, 3, and 4) were training in a classical manner. Horses in stables 1, 2, and 4 were trained on a commercial racetrack, whereas those in stables 3 and 5 were trained on private farm training tracks. All horses in the study were TBs, 2 years of age, and starting training for the first time and were followed for 1 year. Data collection stopped if horses developed bucked shins, were sold, or stopped training because of another event not related to bucked shins. The study included 11 years of training data from 226 2-year-olds. Fifty-six of the 226 horses developed bucked shins, and 170 horses completed the observation period or were sold.

Regression analysis and survival analysis techniques were used to explore the data. Horses in stable 2 had the best survival, and those in stables 1 and 4 the worst, and evaluation of data suggested that relationships between galloping and breezing were important. Horses in stable 2 had the highest breezing rate and the lowest incidence of bucked shins, whereas those in stables 1 and 4 had the highest galloping rates and the highest incidence of bucked shins.

Galloping increased the likelihood of bucked shins by 36.4%, whereas breezing short distances was protective, reducing the likelihood of bucked shins by 98.6%.[10] One should note that long-distance breeze rates are detrimental.[11] The winter of 1994 brought severe ice storms to the northeast. Horses in stable 2 could not be trained using the modified program and instead were trained using the standard classical program. An unintentional crossover design was created, and 62% of the horses trained that year developed bucked shins. Without using 1994 data only 9.3% of horses developed bucked shins.

DISCUSSION

Nineteen years of evolutionary experiments, based on an initial observation of a significant difference in the incidence of fatigue fractures between two breeds of racehorses, have led to a natural model for fatigue failure of bone. We can now compare in vitro and in vivo fatigue behavior and observe bone adaptation with different exercise regimens. Adaptive exercise has been shown to change the geometric properties of McIII, to influence bone modeling and remodeling, and to reduce the incidence of fatigue failure of McIII in the TB.

Comparisons of TBs and STBs show major changes in inertial properties of McIII resulting from growth and superimposed training. Comparisons of young TBs that are susceptible to fatigue failure, with older, resistant animals suggest that changes in bone inertial properties are an important factor affecting the incidence of bucked shins. Large McIII I_{min} values reflect probable increases in McIII stiffness in the dorsopalmar direction and thus reduced peak strain during high-speed exercise. The inertial properties of the proximal tibia have been shown to predict development of fatigue fractures in military recruits,[12,13] just as the inertial property measurement of McIII of 5-year-old TBs shows that these horses are no longer at risk for bucked shins.[4]

In vivo strain measurements of McIII demonstrated higher peak strains under physiological loading than ever had been reported previously in any species. Although in vitro test conditions differed from the in vivo loading, both involved significant bending components that can be expected to produce accumulated fatigue failure in bone. Superimposition of the in vivo strains reported for the young and older horses at racing speed produced a striking predictive relationship for risk of developing bucked shins (see Fig. 104-2).

Large surface strains, measured in vivo at high speeds on the dorsolateral aspect of McIII in young TBs in training, contrast dramatically with the smaller strains measured in adults that have raced successfully. Strains, under a given load regimen, measured on the surface of bone relate to the modulus and inertial properties (section modulus) of the bone. Because inertial properties have been shown to increase with age, and bone strains during high-speed exercise have been shown to decrease in older horses, the hypothesis was that changes in bone inertial properties and modulus serve to lower the peak bone strains as the young racehorse matures. However, training regimens possibly can outpace adaptive response. In fact, we observed that a certain percentage of young animals actually increased McIII surface strains after several months of training. Whole bone stiffness measurements showed right to left differences of up to 27% in horses in training, whereas no right to left difference was found in the non-trained control animals. Because bucked shins occur bilaterally but sequentially in TBs, usually on the left side before the right, the developmental stiffness changes in limbs possibly are not synchronized but may respond to the predominance of the left lead used by the horse in its racing gait as the horse works in a counterclockwise direction. Maximal strains at exercise and bone stiffness parameters probably change with time and may be declining on one side, while increasing on the other. Increasing bone strain measured at high speed during training, as seen in four of seven TBs, suggested rapid bone stiffness changes in vivo from exercise. Two possibly related explanations exist for this observation:

1. Bone stiffness decreases in vivo, much as it does in vitro, when the bone undergoes cyclic fatigue.
2. Bone stiffness increases from inertial property changes in McIII, but it may be overwhelmed by decreasing intrinsic material stiffness.

If Wolff's law is applied strictly, it follows that a bone that adapts to a particular peak tensile strain may not be prepared adequately to resist far larger peak compressive strains in the same location.

A recent in vitro fatigue study of equine McIIIs showed a difference in fatigue resistance to bending loads in different anatomical quadrants. Bone that was loaded in bending around the physiological bending axis had greater fatigue resistance than bone bent at 90° to this axis.[14]

We hypothesized that to adapt adequately for racing, McIII should be exposed during training to strains of the actual magnitude and direction experienced during racing. Furthermore, the high incidence of bucked shins in TBs suggested that loading to produce such peak strains and concomitant adaptive remodeling did not occur in a large number of TBs in classical training programs before racing.

Previous in vivo studies, using a functionally isolated rooster ulna, have shown that low numbers of loading cycles (four per day) were adequate to maintain bone mass. Thirty-six cycles were enough to stimulate bone formation.[15] The resulting periosteal new bone formation is the same type of bone reaction observed in TB McIII with fatigue injury.

Taking these observations into account, an exercise (training) regimen was developed that modestly increased the small numbers of high-load cycles using peak load magnitudes and directions that are seen during racing. Increasing the number

of short-distance workouts (breezes) from once every 7 to 10 days, as occurs with classical training programs, to three per week produced large changes in modeling, remodeling, and inertial property measurements of McIII. Classical training produced little progressive change in the inertial properties of McIII, seemingly no better than no training at all, whereas the new modified training program showed inertial property development that equaled or surpassed that observed in established older TBs, those horses apparently no longer susceptible to bucked shins.[3]

The idea of using exercise to produce adaptive bony remodeling is not new. Woo et al.[16] showed that 12 months of exercise in young pigs produced dramatic changes in the femur, increasing cross-sectional area by 23% and inertial properties (I_{min}) by 27%, without intrinsic bone property changes.[16] Most recently, Milgrom et al.[17] looked for exercise that can adapt bone and showed that playing basketball for 2 years or more was protective in reducing the incidence of bone fatigue failure in military recruits.

In the 11-year longitudinal study, we proved that adaptive exercise could be used to reduce the incidence of bucked shins. The relative incidence of bucked shins in classically trained TBs is probably higher than we found. The mean time taken for horses to develop bucked shins was about 25 days shorter than the mean time to loss for other reasons. Removing those stables where loss occurred before onset of bucked shins would have strengthened the data, but efficacy was shown including all the data. We would not expect horses in the modified training program to experience additional fatigue fractures after the observation period, because McIII should resemble more closely that of adult, non-susceptible racehorses.

Adaptive exercise has been shown to change the geometric parameters of a specific bone in a way that would be expected to reduce fatigue damage while, at the same time, significantly reducing the incidence of bucked shins. This correlation, although not explicit proof of the interrelationship between the factors measured, is convincing.

TRAINING TO PREVENT BUCKED SHINS

A training program has been developed to limit the incidence of bucked shins and can be modified by trainers to suit their situation.[18]

The principles of this training program are the following:

1. Bone changes its shape and structure based on its use (Wolff's law). It therefore follows that training adapts bone to training, racing adapts bone to racing, and training that mimics racing adapts bone to racing.
2. Short, high-speed workouts are introduced into the training program early and often (two per week) to introduce bone to the forces it will experience during racing.
3. Galloping is done in moderation (1 mile/day, 6 days/week). Long gallops result in high mileage that may induce high strain cyclic fatigue of bone.
4. Jogging is used for warm-up only and is not used to increase a horse's level of fitness, because jogging induces tension on the dorsal surface of McIII. (This principle is not supported by the survival analysis studies, but it did seem to be relevant when comparing 1994 data within stables 1 and 2.)
5. Once bone adapts to racing (6 to 8 months), this training program is no longer needed, because bone will not regress into its previous shape and architecture. Any successful program can then be instituted.

These principles were developed based on experimental studies that showed that at slow gaits the dorsal surface of McIII is under tension and at high speed is bending to produce compression. Structurally, materials are designed differently to support tension or compression. Think how strong a rope is in tension and how useless it is in supporting loads in compression. Short, high-speed exercise exposes the bone to compression on its dorsal surface and introduces the bone to the loads expected during a race. Experimental studies showed that this sort of training regimen changed the cross-section of McIII to the adult racing shape within 6 months.

Long, low-speed jogging only adapts the bone to jogging, creating tension on the dorsal surface of McIII. In stable 2 in the icy winter of 1994 the horses were jogged for 30 days, without any high-speed exercise, and then resumed the exercise program. The incidence of bucked shins increased fivefold compared with previous years and returned to normal the following year.

Because training is not always a cookbook recipe for success, the fundamentals of the program are described without an actual schedule. The horse should start galloping in December of its yearling year and be able to gallop a mile easily in 18-second furlongs. As training progresses, short, higher-speed events are included two times a week at the end of the gallops. Initially, horses are urged on to a faster speed for ½ or 1 furlong (15-second furlong). This higher-speed event is increased in length, and then speed is increased again. Two weeks elapse between speed or distance changes. The animals continue training and are breezing 12- to 13-second furlongs before the first race (usually by mid-June).

Horses with bucked shins can be trained using this program, provided that the horse is sound and periosteal new bone formation is not substantial. The secret is to decrease the horse's galloping distance (cut it in half) and add short workouts. For example, if a horse usually gallops 1½ miles/day, reduce the distance to ¾ mile/day and introduce short workouts twice weekly. We usually back the horse up about 1 month in its exercise program and get the high-speed workouts started over short distances. If horses are sore or lame, training is stopped and cold therapy and administration of non-steroidal anti-inflammatory drugs (NSAIDs) are begun. Once sound, horses are returned to training. In some horses NSAIDs may need to be administered for chronic soreness, but horses with frank lameness should be allowed to rest until sound.

If a horse's training schedule is interrupted by an unrelated lameness or upper respiratory tract disease, remodeling that starts with a resorption is sudden. When the primary problem resolves, if horses are returned to training at a level similar to that before rest but McIII porosity is increased, the horse is at risk of bucked shins. Therefore if a horse is out of the exercise program for 10 days or more, the horse should be backed up in its training schedule to minimize the risk of bucked shins.

Horses with bucked shins are at increased risk to develop dorsal cortical fractures or may have catastrophic failure of McIII. Horses without bucked shins are at low risk to develop fracture.

STRESS FRACTURES OF THE THIRD METACARPAL BONE: SURGICAL MANAGEMENT

• Alan J. Ruggles

Most stress fractures of the third metacarpal bone (McIII) occur on the dorsolateral aspect of the left forelimb but may be bilateral (Fig 104-4). Treatment options include controlled exercise (see page 852), screw placement in the dorsal cortex, and cortical drilling around the fracture line. Recently extracorporeal shock wave therapy has been used with apparent early success (Editors). The placement of a screw does not result in interfragmentary compression, but it may have a local effect on bone modeling and remodeling. Cortical drilling is thought to improve vascularization and new bone formation at the fracture line.[1] Advantages of cortical drilling alone are that a second surgery is not necessary to remove the screw, and in some horses this procedure can be performed standing. However, drill breakage in a standing horse is a risk and, if the bit piece is not retrieved, may lead to chronic lameness. Clinical reports indicate that the use of cortical drilling and screw placement has a lower rate of fracture recurrence than cortical drilling alone. Success rates were 97% and 85%, respectively.[2,3] I use the combination technique.

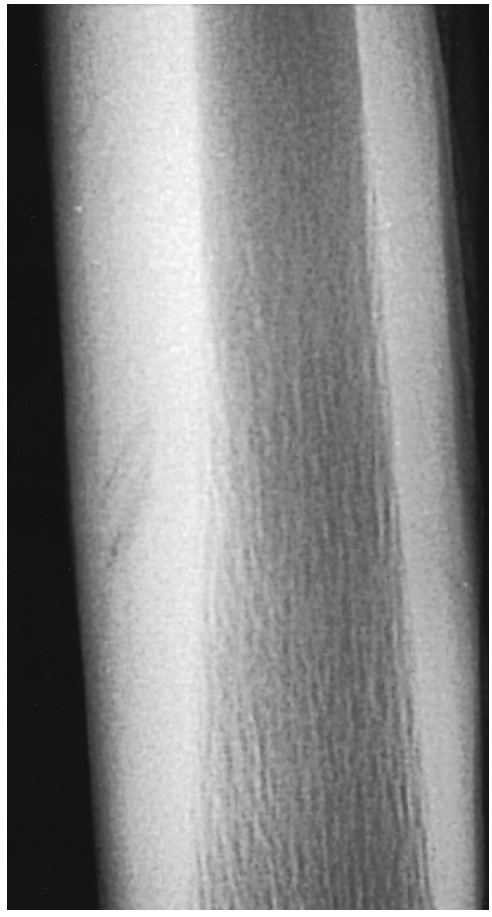

Fig. 104-4 Lateromedial radiographic view of a third metacarpal bone of a 4-year-old Thoroughbred. Dorsal is to the left. There is a typical dorsal cortical fracture of the third metacarpal bone, cortical thickening of the third metacarpal bone, and numerous oblique fracture lines. This horse is a candidate for drilling or screw placement.

Horses with radiographic evidence of substantial endosteal or perisoteal healing often heal satisfactorily without surgical intervention. Horses with severe fractures that are in multiple locations, or spiral around the bone, have a risk of catastrophic failure on recovery from general anesthesia and usually are treated conservatively (Fig. 104-5). To my knowledge no objective reports of conservative management of dorsal cortical stress fractures exist. In my experience conservative management is less reliable than surgical treatment, and does not result in a reduction in training days missed. In addition I have experienced a higher rate of recurrent fracture, or failure of fracture to heal, with conservative compared with surgical management.

Surgical Procedure

The horse is positioned in lateral recumbency with the affected limb uppermost. Both limbs can be operated on from this position. The periosteal new bone usually can be felt

Fig. 104-5 Lateromedial radiographic projection of the third metacarpal bone of a 2-year-old Thoroughbred. Dorsal is to the left. There is a severe, dorsal cortical fracture of the third metacarpal bone. Conservative management in horses with severe fractures is recommended. This fracture is saucer-shaped in appearance and could propagate during recovery from general anesthesia.

through the skin, and a 6- to 8-cm vertical incision is made over the fracture, usually between the common and lateral digital extensor tendons. Radiographic control is used if necessary. The periosteum should not be elevated. A sharp 2.5-mm drill is used to drill a thread hole for a 3.5-mm screw perpendicular to the fracture line. Only the dorsal cortex is drilled. Overdrilling may result in impact on the palmar cortex and instrument breakage. During or after screw placement, radiographic control is necessary to determine proper screw placement. The screw is placed after countersinking, tapping, and measuring to determine appropriate screw length. Usually a single screw is used, but occasionally several screws are used for a long fracture. Five to 6 unicortical drill holes approximately 1 cm apart are made using a 2.5-mm drill bit in the region of the fracture, before routine closure and bandaging the limb.

If dorsal cortical drilling alone is performed standing, under sedation and perineural analgesia, a 3.2-mm drill bit is used to decrease the risk of drill breakage if the horse moves during the procedure.

Postoperative Treatment

Four weeks of stall rest with hand walking followed by 4 weeks of small paddock turnout, continued hand walking, or swimming are recommended. Screw removal is performed with the horse standing at 8 weeks, based on fracture healing. Return to light jogging can occur 2 weeks after screw removal, but more intense training should not start until at least 16 weeks after surgery and should be based on lack of clinical signs of lameness and radiographic signs of healing.

Prognosis

Prognosis is considered good, with 85% to 97% of horses returning to racing.[2,3] Recurrence of fracture occurs more commonly after cortical drilling alone, compared with cortical drilling and screw placement combination. Catastrophic failure has occurred after cortical drilling alone but not with the combined technique.

CHAPTER • 105

On-Track Catastrophe in the Thoroughbred Racehorse

Ted Hill

Horses in racing and high-intensity training are subject to a variety of musculoskeletal injuries. For North American racing the overall incidence of musculoskeletal injuries ranges from 3.3 to 7.3 per 1000 starts, depending on variables such as reporting criteria and degree of follow-up. A much closer range of 1.1 to 1.8 injuries per 1000 starts is reported for catastrophic injuries resulting in euthanasia.[1] Catastrophic or fatal injuries are documented more reliably and are considerably less subject to bias or misinterpretation by the reporter. The rates for training injuries may be somewhat higher, although accurate acquisition and evaluation of these data is more difficult. To date, limited information is available for training injuries.[1,2] Several factors cannot be controlled during training, making information obtained inaccurate and incomplete. The absence of a veterinary observer during most training sessions allows many lameness incidents to go unreported. Often only injuries requiring an ambulance come to the attention of the track veterinarian. During training, no

There is a severe, dorsal cortical fracture of the third metacarpal bone. Conservative management in horses with severe fractures is recommended. This fracture is saucer-shaped in appearance and could propagate during recovery from general anesthesia.

through the skin, and a 6- to 8-cm vertical incision is made over the fracture, usually between the common and lateral digital extensor tendons. Radiographic control is used if necessary. The periosteum should not be elevated. A sharp 2.5-mm drill is used to drill a thread hole for a 3.5-mm screw perpendicular to the fracture line. Only the dorsal cortex is drilled. Overdrilling may result in impact on the palmar cortex and instrument breakage. During or after screw placement, radiographic control is necessary to determine proper screw placement. The screw is placed after countersinking, tapping, and measuring to determine appropriate screw length. Usually a single screw is used, but occasionally several screws are used for a long fracture. Five to 6 unicortical drill holes approximately 1 cm apart are made using a 2.5-mm drill bit in the region of the fracture, before routine closure and bandaging the limb.

If dorsal cortical drilling alone is performed standing, under sedation and perineural analgesia, a 3.2-mm drill bit is used to decrease the risk of drill breakage if the horse moves during the procedure.

Postoperative Treatment

Four weeks of stall rest with hand walking followed by 4 weeks of small paddock turnout, continued hand walking, or swimming are recommended. Screw removal is performed with the horse standing at 8 weeks, based on fracture healing. Return to light jogging can occur 2 weeks after screw removal, but more intense training should not start until at least 16 weeks after surgery and should be based on lack of clinical signs of lameness and radiographic signs of healing.

Prognosis

Prognosis is considered good, with 85% to 97% of horses returning to racing.[2,3] Recurrence of fracture occurs more commonly after cortical drilling alone, compared with cortical drilling and screw placement combination. Catastrophic failure has occurred after cortical drilling alone but not with the combined technique.

CHAPTER • 105

On-Track Catastrophe in the Thoroughbred Racehorse

Ted Hill

Horses in racing and high-intensity training are subject to a variety of musculoskeletal injuries. For North American racing the overall incidence of musculoskeletal injuries ranges from 3.3 to 7.3 per 1000 starts, depending on variables such as reporting criteria and degree of follow-up. A much closer range of 1.1 to 1.8 injuries per 1000 starts is reported for catastrophic injuries resulting in euthanasia.[1] Catastrophic or fatal injuries are documented more reliably and are considerably less subject to bias or misinterpretation by the reporter. The rates for training injuries may be somewhat higher, although accurate acquisition and evaluation of these data is more difficult. To date, limited information is available for training injuries.[1,2] Several factors cannot be controlled during training, making information obtained inaccurate and incomplete. The absence of a veterinary observer during most training sessions allows many lameness incidents to go unreported. Often only injuries requiring an ambulance come to the attention of the track veterinarian. During training, no

standard exists for soundness, medication use, and exercise rider skill. Differences between training injuries and racing injuries are documented when they exist.

Information about racing injuries presented in this chapter applies to racing worldwide. However, discussions of the regulatory veterinarian primarily refer to racing in America.

REGULATORY VETERINARIAN

The official veterinarian and staff members at an American Thoroughbred racetrack have many duties. The primary responsibility is monitoring the soundness of horses during racing and, to some degree, training. This task is accomplished by an efficient prerace inspection and observation of all horses before, during, and after a race. After the horse is identified, a visual assessment is made of the overall condition and attitude, and vital parameters are assessed. Ideally the temperature, pulse, and respiratory rate are recorded, and the eyes and mouth are examined closely. The mouth should be free of any inflammation or lacerations, which the bit would aggravate, possibly causing control difficulties for the rider. The forelimbs and hindlimbs are palpated, and attention is paid to the type of shoes worn and the condition of the feet. When bar shoes, aluminum pads, or quarter crack patches are noted, closer inspection of the foot is indicated. A palmar digital neurectomy is permitted in most jurisdictions. The clinician must always check for a neurectomy to ensure compliance with the rules. Usually a horse that has undergone neurectomy must be reported to the track veterinarian and its name conspicuously displayed for claiming races.

Any horse determined to be sick or unsound for racing is reported to the track stewards and withdrawn from the day's racing card. Only the stewards have the authority to officially scratch a horse, although in practice a track official rarely questions the veterinarian's recommendation. The veterinary department must function as an independent authority and neither management nor anyone connected to a horse should interfere with the veterinarian's decisions.

Once withdrawn for a veterinary reason, a horse is usually placed on an ineligible list and requires further evaluation before being permitted to race again. Depending on the nature of the illness or lameness, the evaluation may involve only a quick check, or if more serious, a monitored workout and thorough examination. The importance of the prerace inspection and follow-up examinations of identified horses cannot be overstated. Evidence exists that horses with prior pathological conditions are at increased risk of recurrent or more severe injury, possibly career ending or catastrophic.[3,4]

A veterinarian is present in the paddock, where horses are saddled, and at the starting gate. An injury or lameness requires prompt evaluation and contact with the stewards for a late withdrawal. The track veterinarian is the ultimate authority over all horses in the paddock and on the racetrack during racing and training.

Racing officials rely on the veterinarian for information and guidance. Objective data on injuries may assist the track superintendent to address concerns about the track surface and dispel rumor and exaggeration among horsemen. The stewards and judges need the veterinarian's input regarding the use, safety, and validity of new equipment such as shoes, bandages, protective eye covering, bridles, and therapy modalities. The official veterinarian also can be an invaluable source of information on medication for private practitioners, horsemen, and racing officials.

A brief comment on managing spills is appropriate. A *spill* is defined as a sudden fall of horse and rider that usually causes other horses and riders to fall. Ideally, one may call for immediate assistance from other veterinarians and experienced track personnel to assess and attend promptly to more than one horse injured in the incident. Horses may rise after a spill, although seriously injured, and move to other areas on the racetrack, thus further complicating the situation. A prompt overall assessment of the number of horses involved, the location on the track, and the major injuries are essential to prevent misallocation of resources. Triage and communication, with preferably one experienced veterinarian coordinating the activities, are key to an efficient professional outcome.

MANAGEMENT CONSIDERATIONS

Efficient management of the on-track catastrophe, while maintaining the horse's best interests, is the primary objective. The key elements required include trained personnel, equipment, and communication.

Communication is critical to make the best use of available resources. The track veterinarian must be prepared to respond to the injured horse and direct support personnel and equipment at the scene. The injured horse is under the care and direction of the track veterinarians until it is moved to a clinic or stable to be attended by the veterinarian employed by the owner or trainer. The stable veterinarian may be called to the scene for severe injuries and if time permits. The track veterinarian acts promptly to attend the injured horse on the track, thus facilitating an efficient transfer for further evaluation and treatment. Efficiency is important for the care for the injured horse and to allow the official veterinarian to be in position for subsequent races without undue delay. Ideally a communication network of two-way radios and mobile telephones works well to keep an orderly process in motion. Radio communication with track departments such as security serves to relay information as required.

The operator of the horse ambulance should have sufficient training to understand fully the ambulance features and how to use them. Knowing how to back up and position the loading doors properly is essential. Failure to accomplish these basic skills could cause further injury or delay proper treatment.

In most situations, track personnel are the first on the scene of the injured horse, but in other countries, such as the United Kingdom, a veterinarian follows the race and would be on the scene immediately. Track personnel routinely are equipped with radios and are crucial for initiating communication with veterinarians and providing the immediate care. Knowing who and how to call for assistance can save valuable time and distress for all involved.

Those individuals should be instructed in the basics of emergency care. The track veterinary department should provide such instruction to ensure a defined, reliable standard, without confusion and delay. Topics such as restraint, controlling hemorrhage, support of an injured leg, and when to apply a splint are well worth the time. Most if not all persons are willing to do whatever may be required to assist an injured horse, but they are often reluctant for fear of making a mistake. These first-line members of emergency care should be encouraged and recognized for their valuable assistance. Splint selection and application should be kept as simple as possible to avoid potential legal complications, which fortunately are uncommon. An overzealous and poorly trained person may assume too much responsibility, however, placing the horse at risk of further injury and subjecting track management to extensive liability. Outriders, who monitor training in the mornings, may be instructed in using a commercially available support, such as a Kimzey splint (Kimzey, Inc., Woodland, CA). The splint may be applied safely whenever loss of support in the fetlock joint is obvious, because the splint is simple, quick to apply, and generally well tolerated. Restraint is

often a critical issue for horse and handlers' safety. Usually keeping the horse quiet and still while supporting a distal limb injury is adequate until a veterinarian arrives to provide professional care. However, in some situations the horse is best kept recumbent (e.g., a horse with such a severe injury that it is unable to remain standing, even with assistance). Such horses may lunge repeatedly and fall, risking further injury to themselves and endangering all present. A fallen rider near the horse may be incapable of movement for several minutes while being attended, making control and restraint of the horse all the more imperative.

EQUIPMENT

Substantial improvements in the equine ambulance over the past decade have contributed to saving horses that otherwise would have been euthanized within minutes of injury.

The ambulance should be partitioned, well ventilated, allow ample daylight, and be equipped with interior lights. Sturdy, rubber floor matting and padded sidewalls, all easily washed, are required. A partition separating the horse holding area and a forward compartment provide a storage area and some protection for handlers. Ideally the ambulance trailer can be lowered hydraulically to facilitate loading of a severely injured horse and eliminating the need for a rear ramp. Side access doors with ramps provide convenient and safe off-loading, without having to back or turn the horse around. An extremely valuable feature is a movable middle partition, which serves as a squeeze chute to help support the horse during transport. A seriously injured horse will make excellent use of this feature, by leaning on it or the wall when turning, thus drastically reducing lateral movement and unnecessary weight bearing. The Kimzey Equine Ambulance is an excellent example of such a fully equipped vehicle.

The ambulance should be well equipped with splints and bandaging materials. Splints to support the metacarpophalangeal (fetlock) joint are essential, as are compression boots in two or three sizes. Bandage material should include sterile pads, gauze and cotton bandages, and elastic and adhesive wraps. Sufficient material to make a modified Robert Jones bandage always should be available. Duct tape is an excellent means to secure a heavy support bandage or splint, preventing shifting and providing axial stability. Inflatable compression splints are sometimes helpful to stabilize carpal fractures, but application of a cotton and elastic bandage is often faster and more effective.

Some of this material can be kept on the equine ambulance, but space and security considerations require that most of the splints and medications are kept in a track vehicle that transports the veterinarians. Emergency supply bags can be equipped and organized to facilitate quick access at the scene of the injured horse.

Containers of ice should be kept on board the ambulance during racing for prompt application to acute injuries. Rubbing alcohol is also useful for cooling horses in warm climates.

Although it is not frequently required, a portable oxygen supply with a simple flow delivery system and two endotracheal tubes should be readily available. A sling of suitable design to support a horse for extended periods is recommended (Liftex Inc., Warminster, PA).

MEDICATION

Security concerns may preclude keeping medications in the ambulance in some jurisdictions. An emergency bag with select drugs is an efficient means to attend the injured horse on the track and in the ambulance. A suggested inventory includes butorphanol, xylazine, flunixin meglumine, ketamine hydrochloride, detomidine, hydrocortisone sodium succinate, epinephrine, phenylbutazone, and euthanasia products, such as pentobarbital and succinylcholine. Although it is not an approved drug for humane euthanasia alone, succinylcholine can be a valuable adjunct with other drugs to control an extremely difficult horse. A dose of 5 ml (100 mg), given with an initial dose of pentobarbital acts, safely to drop an uncontrollable horse with a catastrophic injury, thus permitting administration of the required full dose. An assortment of syringes, needles, tourniquet, scalpels, scissors, hemostats, and blood collection tubes complete the emergency kit.

TRAINING INJURIES

Humeral Fractures

During morning workouts and gallops, horses are subject to the same injuries as those that occur in racing. A few injuries, such as humeral fractures, are not encountered commonly in racing, but they are often seen while the horse is only galloping. For the reporting period 1993-2000, 12 of the 15 humeral fractures occurred during morning training.[5] Horses with spiral humeral fractures, with or without displacement, almost always are considered candidates for immediate euthanasia. The injuries usually involve the horse falling suddenly and remaining down, although some do rise. The rider may have no warning before the fall, but some horses may change leads and bobble or shorten the stride.

The diagnosis is straightforward if the horse is standing. The horse bears little or no weight and the limb is in a hanging position, with the horse unable to advance the leg if encouraged to move. There may be obvious swelling of the area, and palpation or manipulation with auscultation often reveals crepitus. Horses that are down on the track when the veterinarian arrives present a diagnostic challenge. They may make some attempt to rise, particularly with encouragement, but with the fractured humerus on the down side they are rarely successful. Rolling the horse over can be accomplished with at least two people and the use of shanks or similar equipment to avoid being kicked in the process. Once the horse is turned over, the fracture is often apparent and the horse may rise with the good foreleg down. These horses often fall dramatically when the fracture occurs and may be slow to recover because of the shock of both the fall and the fracture.

Although some injured horses may be loaded and transported to the stable, no treatment is recommended other than analgesia and physical support. These horses are extremely difficult to load without the assistance of capable and readily available personnel. Loading becomes substantially more difficult with time, and the increased swelling and pain make the horse reluctant to move at all after several minutes. A horse is best left supported on the equine ambulance until the stable veterinarian arrives to confirm the diagnosis before euthanasia. At the request of an owner, or to satisfy insurance requirements, radiographing the limb may be attempted to document the diagnosis, particularly for horses with minimally displaced fractures. For most horses with this severe injury, radiographs are obtained more humanely post mortem. Humeral and scapular fractures do occasionally occur during racing and horses should be managed in the same manner.

Collision Injuries

Collision injuries usually are associated with training, because many horses are often on the track, exercising at various speeds, distances, and directions. Maintenance equipment and personnel moving on and near the training surface open gaps permitting access to the track, and insufficient outriders to monitor and control the congestion all predispose to collision

injuries with other horses and inanimate objects. Injuries may be of any type, but include trauma to the head, axial skeleton, shoulder, and pelvis. Bruising and lacerations from impact are not uncommon. The severity can range from minor abrasions and contusion to severe, life-threatening fracture and hemorrhage.

Location of Injuries on the Racetrack

Considerable anecdotal and published information exists regarding the location of injury occurrences on the track surface.[5,6] Any injury type can be encountered at any point in a race, and trained personnel should be prepared to respond to any location. From experience, it is safe to conclude that most catastrophic injuries occur in turns and in the stretch run to the finish. Most racing operations position the equine ambulance in the area of the ½- to the ¼-mile pole to be available for a prompt response. Many injuries are evident immediately after a race and when horses are pulling up and begin galloping back to be unsaddled. Horses with carpal chip or proximal sesamoid bone fractures and new or recurrent tendonitis or suspensory desmitis usually show lameness after they are pulled up. The jockeys should alert an outrider for assistance. Some riders may be hesitant to pull up and dismount because of inexperience and uncertainty, but the track veterinarian should make this policy clear to the jockeys and encourage conservative, prudent decisions. Any horse suspected of being lame, by a jockey or outrider, should be held at that location until evaluated by an official veterinarian.

Horsemen, riders, and officials often express concern about unsafe track conditions. Extreme conditions, such as freezing, washouts, and gross discrepancies in uniformity, may be potentially hazardous. However, muddy or sloppy conditions are not a significant risk factor for serious injury, but they may contribute to rundown injuries, the bruising and abrading of soft tissue at the palmar/plantar aspect of the fetlock from contact with the track surface. Random injuries can cause poor performance. Most catastrophic injuries occur on a fast racetrack.[3,5-7] Muddy and sloppy tracks usually produce numerous late withdrawals and smaller fields, especially if a race was originally scheduled for the turf. Thus some degree of selection of horses occurs in these races. In addition, horses that are not in contention and showing response entering the stretch on a poor track usually are not encouraged persistently by the riders. They are allowed to ease themselves, a situation that may not occur on a fast track with the rider more optimistic of a good finish.

PUBLIC RELATIONS AND MEDIA ISSUES

The track veterinarian must be keenly aware of humane considerations and prepared to respond to questions from the media, patrons, horsemen, and track personnel.

In situations that expose the public to catastrophic injuries in the racehorse, the track veterinarian also must be cognizant of aesthetic considerations, such as using screens and covers to eliminate unnecessary viewing of horses and the process of euthanasia. During racing, time constraints may become critical to management. Most seriously injured horses can be supported, loaded, and transported for further evaluation off the track. On-track euthanasia should be reserved for those few horses for which no other alternatives exist.

During the 1990 Breeders Cup at Belmont Park, catastrophic injuries resulted in the euthanasia of three horses and considerable media attention. The need for more efficient liaison with the media was demonstrated clearly. In response, the American Association of Equine Practitioners initiated the "On Call" program at the 1991 Kentucky Derby and has continued this program to date. The program consists of veterinarians with media training who donate their time to respond to questions from the media regarding equine health care concerns. The "On Call" veterinarian is available to provide accurate and expert commentary, answering vital questions during a busy event, thus releasing the event veterinarians to attend the injured horse. "On Call" covers more than 60 equestrian events each year.

RACING INJURIES

Fractures of the Forelimb

Fractures range in severity from relatively minor chip and non-displaced incomplete fractures to open, comminuted fractures of long bones, which are considered the most severe on the track catastrophes. Fortunately the latter are rare. Available data support the clinical findings that most fatal fractures involve the forelimb and that most of these fractures are of the carpus or more distal part of the limb.[1] This section provides an overview of the most common types of fractures that are encountered on the racetrack, beginning with the foot and working proximally in the forelimb and hindlimb.

Foot and Pastern

Fractures of the distal phalanx are often articular, but they may be non-articular and involve only the wing. An affected horse usually completes the race or begins easing in the later stages, rather than pulling up abruptly. Distal phalanx fractures commonly are diagnosed after the race while the horse is on the track or is cooling out. Lameness may vary in intensity, but it usually increases to non–weight-bearing status within 30 to 60 minutes. Moderate to severe lameness is present, without palpable swelling. Non-displaced metacarpal or proximal phalanx fractures should be considered as a differential diagnosis. If the lameness is apparent at a walk, a compression boot to stabilize the limb distal to the carpus may be useful until other fractures are ruled out. Distal phalanx fractures are not as commonly diagnosed on the track as those of the proximal phalanx, and some may be missed initially, only to be diagnosed later and go unreported.

Middle phalanx fractures are rare as a primary injury and usually are seen as part of a multiple injury breakdown of the fetlock and pastern.

Fractures of the proximal phalanx usually occur suddenly during a race or while the horse is pulling up. Such fractures range from an incomplete fracture to varying degrees of fragmentation and severe comminution. Most horses with these fractures are lame and require prompt analgesia and application of a supportive splint or bandage. These horses do not tolerate a heavy compression boot well. Displaced fractures are diagnosed readily on the track. These require considerable attention to provide adequate support for transport to prevent further bone and soft tissue damage, thus optimizing the chances of repair and recovery. Proximal phalanx fractures are the most commonly diagnosed injury of the pastern and occur equally in the left and right forelimbs.

Metacarpophalangeal Joint

The metacarpophalangeal joint is involved in most catastrophic injuries. Horses with simple, non-displaced third metacarpal bone (McIII) condylar fractures usually develop acute lameness at the end of a race or after the race. Lameness is noticeable at a walk by the time the horse is loaded. With minimal swelling, diagnosis is presumptive initially, and appropriate supportive measures are required. Although the lameness may be substantial, localizing the injury is often difficult when displacement and swelling are minimal. However, some condylar fractures are diagnosed after the horse has returned to the stable to cool out, without the assistance of an ambulance. An open, comminuted McIII condylar fracture causes severe lameness. The horse is pulled up during a race or immediately

after the race. The proximal aspect of the displaced fragment penetrates the skin with some mild hemorrhage, making the diagnosis readily apparent.

Because the potential for further displacement and contamination is great, considerable care must be exercised to support the fracture site. Preferably a sterile bandage should be applied to the area and then the leg supported with a heavy bandage or compression boot. Excessive movement of the horse should be avoided while the horse is loaded and transported on the ambulance. Newer ambulances are equipped with a sliding partition to support the horse firmly. The prognosis is guarded because of the compound nature of this injury, and extreme care in managing these horses on the track is essential to a successful outcome.

Proximal sesamoid bones The proximal sesamoid bones (PSBs), especially of the forelimbs, are a frequent site of racing and training injury. The PSBs of the forelimbs are primarily involved. Classically, a simple fracture of the PSB results in a progressive lameness while the horse is cooling out after successfully completing a race or workout. The official veterinarian may not see many of these horses and only learns of their injuries after receiving information from the test barn personnel, trainers, or attending veterinarians.

A more severe sagittal or mid-body fracture of one or both of the PSBs causes severe, acute lameness during a race or immediately after a race. If only one PSB is involved, the loss of support of the metacarpophalangeal joint is minimal. The limb should be held by the first attendant on the scene, to prevent weight bearing and further movement, before application of the Kimzey splint. Once supported, these horses are relatively cooperative and confident to move for loading and transport.

In horses with biaxial PSB fractures, loss of metacarpophalangeal joint support is immediate. A dramatic drop of the metacarpophalangeal joint occurs whenever the horse attempts to bear weight. The limb must be supported immediately and the horse controlled to allow prompt application of a splint. These horses may attempt to move on the injured limb and, if they are not restrained, may cause substantial secondary damage to the soft tissues of the fetlock joint (see Chapter 37).

Fractures involving the metacarpophalangeal joint frequently are complex and involve some combination of McIII condylar and PSB fractures, thus compromising the suspensory apparatus. Horses running at race speeds that sustain an McIII condylar or PSB fracture continue to gallop several strides on the injured limb before pulling up. Often they may unseat the rider and gallop considerable distances before being stopped. Additional fractures and disruption of the suspensory ligament (SL) and distal sesamoidean ligament may result, and the injury may become open, with subluxation and disarticulation of the metacarpophalangeal joint. Depending on the severity of the injury, some of these horses may be manageable for ambulance transport. However, many require immediate euthanasia because of the extensive damage. The metacarpophalangeal joint is involved in two thirds of all catastrophic racing injuries at the New York Racing Association tracks.[5]

Third metacarpal bone The McIII condylar fracture has been discussed previously. Horses with minimal displacement have a good prognosis for return to racing after surgery. Those with substantial displacement or skin penetration have a less favorable prognosis, but with proper on the track management, many can have a reasonable outcome in an alternative career.

The McIII diaphysis is the site of a common racing and training injury referred to as *bucked shins* (see Chapter 104). If not properly managed, horses with bucked shins may not stride out well, move with a choppy action, and trail the field during a race. These horses may be pulled up by the jockey, but they require little on-track care.

Dorsal cortical fracture of McIII may result from the bucked shin complex, an injury that is seen most frequently in late 2-year-olds or in 3-year-olds. Lameness may be intermittent and palpation of the affected area often provides inconsistent findings. Dorsal cortical fracture of McIII poses a serious risk to horse and rider if not detected and properly treated. If a horse with a fracture is returned to training and racing prematurely or the fracture is undiagnosed, a complete diaphyseal fracture may develop. This catastrophic injury causes a horse to fall without warning during morning workouts or a race, risking serious injury to the rider and others in close proximity. The track veterinarian is faced with an essentially unmanageable horse. The fracture usually is comminuted and open. The limb distal to the fracture site is often attached by only tendons and remaining skin. The horse may attempt to rise or manage to rise, but it is extremely unstable and usually falls again. For the safety of all assisting at the scene and for the riders who may still be down on the track, the horse should physically be kept down by capable track personnel. Immediate euthanasia is indicated. If the trainer or owner is present and requests another opinion, the attending veterinarian can sedate or anesthetize the horse long enough for another veterinarian to be summoned. Attempts to develop an anesthetic protocol to facilitate transport of these horses for potential surgical intervention have been unsuccessful. Historically, this catastrophic injury has been the cause of spectacular horse spills in racing, causing considerable loss to the horse industry, serious jockey injury, and negative media attention. Because essentially no treatment alternatives are available, all effort must be directed toward prevention. Accurate diagnosis and the removal of horses from high-intensity training and racing are essential.

Carpus

Although the carpus is a frequent site for lameness, it is seldom an area associated with catastrophic injury (see Chapter 39). Carpal chip and slab fractures cause a range of clinical signs. Small chip fractures may be difficult to detect and, without obvious effusion or pain on palpation, are difficult to differentiate from McIII condylar fractures. A horse with a carpal slab fracture, especially if displaced, is usually severely lame. If a slab fracture is suspected, the carpus should be supported with a cotton wrap and elastic bandage or an inflatable compression splint. Comminuted carpal fractures occur and cause collapse of the proximal and distal rows of carpal bones and obvious instability. Although a horse with multiple carpal fractures may fall, most horses pull up abruptly, stopping in just a few strides. The horse is in acute distress and non–weight bearing and usually difficult to load and transport. If possible, a horse with a comminuted carpal fracture should be examined by consulting veterinarians, because euthanasia may be highly likely. Such examination avoids unnecessary movement and distress for the horse. Some horses may be salvaged for breeding purposes with surgery and extensive nursing care.

Radius

Radial fractures are rare. For an 8-year period, four horses were destroyed because of comminuted radial fractures. Interestingly, all four horses suffered a fracture of the left radius.[5]

Shoulder

Fractures of the shoulder, though rare, are always catastrophic. Those of the humerus most often occur during training and have been discussed previously (see page 856). The scapula may fracture during a race, and in my experience the injury always involves the joint. The horse may fall suddenly, but some horses manage to pull up in the race without going down. Horses are severely lame, have rapid, severe swelling from hemorrhage, great difficulty in advancing the limb, and a

dropped shoulder appearance. This is an excellent example of the benefit of viewing the entire horse from a short distance before commencing a close-up examination.

Inexperience with this injury often leads the clinician to an early misdiagnosis of a lower limb problem, only to be frustrated and embarrassed when enlightened by lay assistants. Swelling over the area may become extensive in a few moments but be overlooked if one remains focused on assessing the distal limb. On numerous occasions, support splints have been applied to the limb distal to the carpus, with the shoulder recognized as the primary injury only when attempting to load the horse onto the ambulance.

Nevertheless, once the diagnosis is made, the horse may be difficult to load, even with abundant help. As a rule, horses are more willing to attempt to move shortly after the injury occurs. Once loaded, the use of a movable partition for support is a tremendous aid. Euthanasia is best performed while the horse is still in the ambulance.

Fractures of the Hindlimb

Pastern

Fractures of the hind phalanges occur considerably less frequently than in the forelimb. Similar injuries occur, but fractures of the proximal phalanx predominate. Only 10 proximal phalangeal fractures of the hindlimb were diagnosed for the period 1993-2000 at the New York Racing Association tracks, compared with 28 for the forelimbs.[5] Horses appear considerably more able to support on only one hindlimb, and protect the injured site from further weight bearing, than to support on only one forelimb. Open fractures are much less common and the prognosis is improved. A lightweight splint and bulky bandage are recommended, because horses do not tolerate a heavy splint or boot well. Complex fractures involving the proximal and middle phalanges and the third metatarsal bone may be seen, although these are rare.

Third Metatarsal Bone

Third metatarsal bone condylar fractures occur less commonly than those seen in McIII. Horses do not tolerate the weight of a compression boot on a hindlimb and often do better with a thick support bandage. It is important to obtain good-quality radiographs, because many of these fractures are located medially and have a tendency to spiral, making surgical repair a challenge.

Tarsus and Tibia

Fractures of the tarsus are an uncommon cause of acute training and racing injuries. Osteoarthritis of the distal tarsal joints commonly results in reluctance to break from the gate and overall poor performance, but it rarely causes an acute on-track incident.

Catastrophic tibial fractures are rare and generally result from pre-existing stress fractures (see Chapter 46). Complete fracture may occur hours after a race or training, when the horse is moving about and resting in the stall. In horses with obscure hindlimb lameness, scintigraphic examination is a valuable diagnostic aid for preventing catastrophic injury.

Stifle and Femur

Femoral fractures are rare in the racing Thoroughbred. Osteochondritic lesions of the distal femur are not uncommon and cause subtle hindlimb lameness that is often difficult to diagnose (see Chapter 47). Stifle lameness, including that caused by osteochondritic lesions, often leads to compensatory lameness conditions. Tarsal or stifle problems may not cause catastrophic injury primarily but rather lead to a compensatory forelimb lameness and secondary breakdown, often involving the PSBs and metacarpophalangeal joint. Accurate diagnosis and treatment of many mild to moderate lameness conditions often helps prevent more serious injury.

Acute hindlimb lameness, other than that caused by complete tibial or femoral fracture, is generally difficult to assess on the track. The horse may pull up abruptly or be lame at the completion of a race and often is reluctant to bear weight. Unlike those with forelimb lameness, horses with acute severe hindlimb lameness are often relatively easy to load into the ambulance and transport with minimal effort. The clinician must keep in mind that a horse may have an incomplete fracture, such as of the third metatarsal bone. Thus maximizing support while the horse is on the ambulance and walking the horse minimally should be standard care for these horses.

Pelvis

Pelvic fractures can cause acute hindlimb lameness and occur predominantly in fillies while racing or training (see Chapter 51). Between the years 1993 and 2000 at the three New York Racing Association tracks, a diagnosis of pelvic fracture was made in 20 horses, 17 of which were fillies.[5] A horse with a pelvic fracture is in obvious distress and reluctant to move, but with proper analgesia and physical assistance, most horses can be loaded and relocated carefully to a stall. Extreme care must be taken, because displacement of the fracture is a potential risk, specifically in those with ilial body fractures. Severe hemorrhage and death can occur even when a horse is in the ambulance or stall. This potential for fracture displacement and hemorrhagic shock keeps survival numbers discouragingly low. Of the 20 horses with pelvic fractures, 6 horses died within 1 hour, and 11 were euthanized at the scene or less than 1 week after injury.[5] With increased use of scintigraphy and early diagnosis of stress-related bone injury, the hope is that catastrophic injuries such as displaced pelvic fractures can be avoided.

Head and Axial Skeleton

Horses involved in collisions or spills may suffer any number of head or spinal injuries. Loose horses attempting to jump railings and run through gaps frequently fall, but they seldom sustain serious injury. Young horses not uncommonly become fractious while being saddled, rearing, lunging, and occasionally falling. Horses with obvious injury, regardless of the severity, should be withdrawn from the race immediately. The track veterinarian must take responsibility for withdrawing a horse after a fall, often consulting with the trainer or owner. The most serious head injuries usually result from flipping in the saddling paddock and striking the hard ground or a wall partition. Sinus hemorrhage, although dramatic and at times copious, is generally not a serious concern. Horses that sustain a hard blow to the head may become disoriented and show ataxia initially. Prompt treatment with corticosteroids and dimethylsulfoxide may be indicated while the horse is kept quiet in a reasonably safe area. Horses should be led to and held in a grass paddock away from trees and fences. If ataxia subsides, the horse may be moved to a stall by ambulance or by walking with attendants.

I find it interesting that some horses may appear normal immediately after a hard fall and head trauma, only to become dull and ataxic or reluctant to move after a short time. Managing all of these horses as if they had potential injury to the central nervous system trauma injuries is advisable. The horse should be monitored closely while moving to the stable, and track personnel should communicate their concerns personally to the attending veterinarian whenever possible. A horse that sustains a serious fall resulting in fractures at the base of the skull is often recumbent, has aural hemorrhage and unfortunately, dies quickly. Fractures or other injuries of the axial skeleton may occasionally result from falling, but a definitive diagnosis may be difficult to make. A horse may be stunned or winded and remain recumbent after falling and make no attempt to rise. Vital signs are usually normal. After ensuring the airway is unobstructed and the saddle removed, the horse is given time to rise. Oxygen from a continuous-flow mask and an

intravenous corticosteroid (hydrocortisone sodium succinate, 100 to 500 mg) are recommended. It may be half an hour before a winded horse is ready to get up. When ready, and with a mild prompt of a slap on the neck or rump, many horses then stand unassisted. Some may be slower and assume a sternal position briefly before rising. Those that are unstable and appear weak behind will need assistance, by helping lift on the tail.

If a horse attempts to rise unsuccessfully several times even with assistance, rolling it on its other side may be best. Injury to the down leg may have occurred. A horse with fractures of the cervical or thoracic vertebrae makes little or no attempt to move, depending on the level of injury.

Horses down on the track with normal vital signs and no apparent limb injury must be presumed to have injury of the axial skeleton. The horse can be positioned on a mat while still recumbent and carefully pulled onto the ambulance for transport to the stable or emergency clinic. An anatomical diagnosis may be established, but the prognosis is extremely poor for horses that have not stood within 12 to 24 hours.

Soft Tissue Injuries

Injuries sustained at the speeds of racing and training workouts are often complex, with soft tissue and bone injury. Fracture of a PSB or McIII causes abrupt loss of action and compensation by the horse and concomitant reaction by the rider. Several strides may follow with some weight bearing on the affected limb. What began as a simple fracture may progress to a catastrophic, life-threatening injury in only seconds because of progressive soft tissue and bony disruption.

The soft tissues supporting the metacarpophalangeal joint are particularly prone to injury. Disruption of the digital flexor tendons or SL can cause gross hyperextension of the metacarpophalangeal joint and potential damage to the digital vessels and nerves. Inadequate perfusion of the injury site may limit or prevent a successful surgical repair or other attempts at recovery.

The metacarpophalangeal joint may subluxate with a primary soft tissue injury. This usually results from a traumatic disruption of the suspensory apparatus, although complete disruption of the digital flexor tendons also may be involved secondarily. If luxation is closed, the joint may become locked in hyperextension, requiring manual reduction before a splint can be applied. If open luxation occurs, the distal aspect of McIII can be seen. Complete luxation usually results from a complete disruption of the SL or the distal sesamoidean ligaments. Immediate support of the limb and splint application is essential for the closed injury. The horse with an exposed, open fetlock injury must be euthanized on the track.

Digital Flexor Tendon Injuries

Digital flexor tendon injury (tendonitis) primarily involving the superficial digital flexor tendon (SDFT) is a substantial cause of economic loss in the Thoroughbred industry. Tendonitis varies in severity, but horses with even the most minor tear require time to recover and return to training. Racing data from the three New York Racing Association tracks supports a recurrence rate approaching 25% for horses with tendonitis.[3] The overall rate is clearly higher when one considers horses lost to follow-up or re-injured before reaching racing fitness.

Acute tendonitis is usually not apparent on the racetrack and usually is diagnosed by the attending veterinarian several hours later. Severe or total disruption of the SDFT causes obvious lameness at the completion of training or a race. Lameness usually increases rapidly and hyperextension (dropping) of the metacarpophalangeal joint is apparent.

Recurrent tendonitis is usually more severe than the initial injury. A horse may pull up before completing training or a race. Swelling is often substantial, the mid-metacarpal region lacks definition, and the metacarpophalangeal joint drops moderately. The degree of swelling may preclude accurate diagnosis of what soft tissue structure is involved. The prerace inspection is particularly important in horses with a history of tendonitis, because this may be the determining factor in preventing re-injury. Careful palpation for sensitivity and swelling can reveal subtle changes that may have gone undetected by the trainer and exercise rider, because these horses usually continue to train without obvious lameness. The track veterinarian may require an ultrasonographic evaluation before permitting the horse to race. Comparison with previous examinations may demonstrate a substantial lesion, although the horse is sound at the trot and gallop. Despite all efforts, tendon re-injury occurs to some horses during racing or in workouts. When re-injury does occur, the application of a compression boot or splint is required. Horses with severe tendonitis, even with loss of metacarpophalangeal joint support, can heal with time to become pasture sound.

Digital flexor tendonitis in the hindlimb is unusual, but tendons are vulnerable to severe laceration and blunt trauma by being cut down during a race. Injury may occur when the foot of a following horse strikes the tendons of the hindlimb. The shoe, particularly one with a toe grab, may lacerate and completely sever the SDFT and less commonly the deep digital flexor tendon. Wounds often are badly contaminated and prognosis is guarded because of complications from infection. A clean support bandage is applied initially, and light sedation and analgesia are given. Further splinting is usually unnecessary and is not well tolerated. Immediate transport to an emergency hospital is best.

Suspensory Ligament Injuries

Injuries of the SL and digital flexor tendons have many similarities, are relatively common, vary considerably in severity, and predominantly involve the forelimb. Branch or body desmitis often is detected after the morning exercise when the horse is cooling out. Moderate or severe desmitis causes acute lameness, possibly with some degree of metacarpophalangeal joint drop, but swelling may initially be minimal. A presumptive diagnosis is made while the horse is still on the track, but differentiating between the SL and digital flexor tendon injury may be difficult. An important principle in emergency management is providing immediate support. A splint that supports the metacarpophalangeal joint is always indicated whenever suspensory disruption is suspected. Obvious dropping of the metacarpophalangeal joint during weight bearing reinforces the decision to use the standard Kimzey splint. PSB fractures often may occur concomitantly, but they may not always be readily apparent. Progressive loss of metacarpophalangeal joint support occurs as the severity of suspensory tearing increases. If the injury is closed, the on-track management remains the same. Complete SL disruption and disarticulation of the metacarpophalangeal joint was discussed previously (see page 858).

The distal sesamoidean ligaments are a vital component of the suspensory apparatus and even mild desmitis should be considered a serious injury in the Thoroughbred. Horses with mild desmitis look similar to those with digital flexor tendon or SL injuries. These injuries may appear to heal, but recurrence is common and problematic. My strong clinical impression is that horses with previous distal sesamoidean desmitis are at risk to develop catastrophic injury, and close monitoring of the status of these injuries is imperative when horses return to training. Any indication of recurrence of desmitis is sufficient cause for retirement or at least additional time off for re-evaluation. Re-injury is often catastrophic, with complete rupture of the ligaments, proximal displacement of the PSBs, and disarticulation of the metacarpophalangeal joint with multiple secondary injuries. Euthanasia usually is required for these horses.

REGULATORY CONSIDERATIONS

Attending veterinarians must be aware of their responsibility to the regulatory body, that is, the state racing commission or its equivalent. Some jurisdictions require a written report to be filed for any horse euthanized on official racetrack grounds. In lieu of a formal report, a good policy is to contact the track stewards and state or association veterinarian to inform them of catastrophic injuries that occur during training or racing. A necropsy and samples for pathological examination may be commission requirements and are vital for statistical evaluation of injuries at the racetrack. Important information can be obtained relative to the nature of the injury, track condition, age and sex of the horse, and other possible risk factors. The official track veterinarian, whether state or association, is fully knowledgeable of commission requirements and appropriate procedures and so is a valuable source of information for the veterinary practitioner on the backstretch. Free exchange between professionals is mutually beneficial. The official veterinarian frequently requires the prompt assistance of the stable veterinarian to continue the management and treatment of a seriously injured horse.

EUTHANASIA AND INSURANCE

When attending a horse with a catastrophic injury, the veterinarian should instruct the owner to notify the insurance carrier, if applicable, as soon as possible. In the event that euthanasia is not immediately essential but is later considered, most insurance companies require a second opinion. Horses with catastrophic injuries may require immediate euthanasia at the scene on the racetrack when supporting and loading the horse onto the ambulance is not possible. Regardless of the circumstances, thorough documentation with photographs of the injury and specifics of the incident should be maintained. If possible, radiographs should be obtained to document the nature of the injury. It is always advisable to have a representative of the stable present to provide consent for euthanasia, but this is rarely the owner. When consent cannot be obtained, the veterinarian on the scene must do whatever is indicated to alleviate distress and protect the horse from further injury until a consulting veterinarian arrives.

On rare occasions the veterinarian may be confronted with an uncontrollable horse or a situation in which euthanasia is the only course of action remaining, consent and consulting opinion being unavailable. After exhausting reasonable attempts to stabilize the horse and obtain assistance, the professional decision for euthanasia can be exercised without excessive concern. Documentation in these horses should include necropsy examination. Although extremely unlikely to result in a legal challenge, thorough communication and documentation is always advisable. Euthanasia is the final option available to the clinician and is justified to prevent further pain and distress. Although the technical aspects of the procedure are simple, resulting in a fast and humane death for the horse, veterinarians must exercise discretion and sensitivity. As disturbing as the situation may be for the attending veterinarian, there is no way to gauge the emotional and aesthetic impact to others who might be present. Persons with direct connections to the injured horse, track workers, media representatives, and patrons may all be within viewing range. An effort to screen the horse from onlookers during euthanasia and while removing the body is recommended. Those immediately connected with the horse should be afforded the opportunity to leave, although some will wish to remain. Finally, the veterinarian must remain in control of the scene, being cognizant of not only the needs of the horse, but also the concerns and safety of all others present.

CHAPTER • 106

Epidemiology of Racehorse Injuries

Calvin N. Kobluk

Veterinarians and trainers have long recognized that racing injuries can be caused by racetrack design and track surfaces, but little scientific data relate musculoskeletal injury to these factors or document the economic impact on the racehorse industry.

Early studies in the United Kingdom demonstrated that lameness was the most common reason that horses in training failed to race.[1,2] Premature retirement, reduced performance, and injury result in economic losses to racehorse owners. In North America, most emphasis has been placed on catastrophic breakdown injuries because of the dramatic nature of these injuries, controversy in the media, and public awareness.[3-6] Attempts have been made to define factors involved in the incidence of these injuries.[7-12] A limited number of studies

correlate day-to-day injury with racetrack surface characteristics[13-15] and other risk factors associated with Thoroughbred racing.[16-20]

EFFECT OF RACETRACK SURFACE

Components and Geometric Design of a Racetrack

Thoroughbred (TB) and Quarter Horse (QH) racetracks are similar in design worldwide, except where horses race on turf (see Chapter 108). The dirt track comprises a roadbed, covered with crushed stone and sand, with an overlying cushion of fine sand and organic material (Fig. 106-1). Standardbred (STB) tracks are harder to accommodate the sulky and different nature of the trot and pace gaits compared with the gallop. Turf tracks in North America consist of grass grown on a sandy soil base covering a crushed stone layer and the roadbed. Some turf tracks in Europe are natural surfaces, sown with special grass mixes.

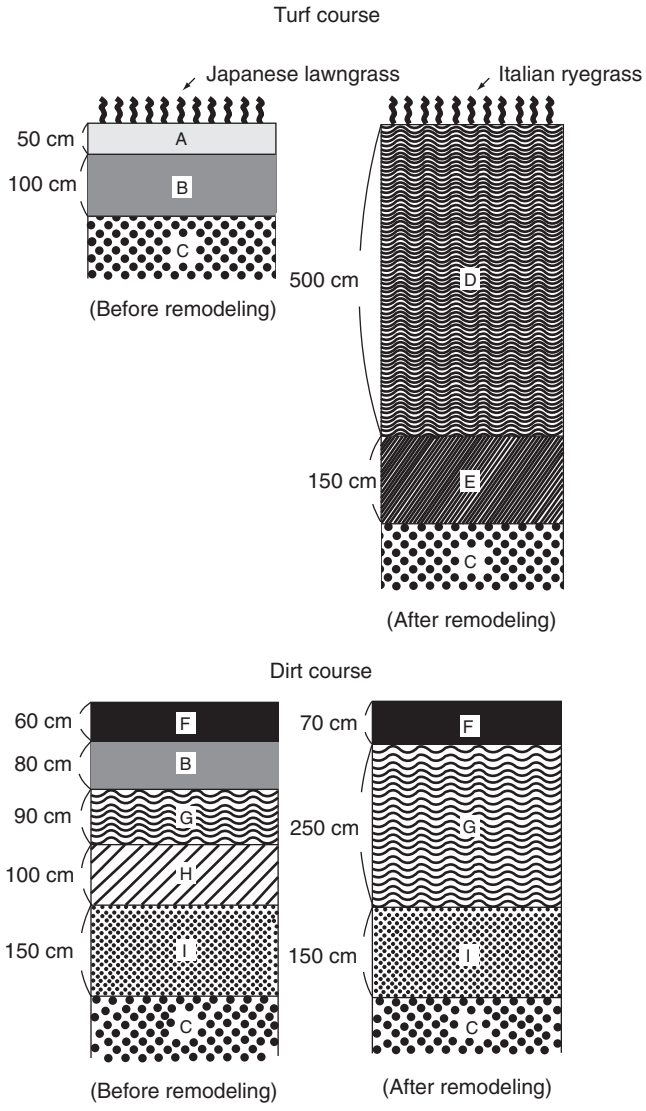

Fig. 106-1 Cross-sectional diagram showing the components of a section of the turf and dirt tracks before and after remodeling of the surface. Incidence of several racing injuries was significantly less after surface remodeling.[22] *A*, sandy clay; *B*, screened hill sand; *C*, road bed; *D*, sandy soil; *E*, single-sized aggregates of crushed stone; *F*, river sand; *G*, hill sand; *H*, volcanic gravel; *I*, crushed stone. (From Oikawa M, Veda Y, Inada S, et al: Effect of restructuring of a racetrack on the occurrence of racing injuries in thoroughbred horses, *J Equine Vet Sci* 14:262, 1994.)

Although racetracks in North America and many other countries are oval shaped and similar in size, with horses consistently racing in the same direction, in Europe each turf track is different, and horses race both left- and right-handed. However, the all-weather tracks in Europe are more consistent in design.

The discussion in this section on banking focuses on the purpose-built oval tracks. Banking in the turns is generally inadequate. A 6% grade is recommended for TB dirt racetracks, but this creates difficulties in track maintenance. The track surface material shifts along the rail, making maintaining a uniform depth of cushion difficult. An 8% grade is recommended for turf tracks. Anecdotal evidence and some research indicate that properly banked turns are extremely important in preventing breakdowns, and this is especially true at the end of the race when horses are fatigued. The banking of racetracks in Japan varies from 1.7% to 3% on dirt and 1.6% to 4.5% on turf, both far less than ideal.[21,22] A technique called *spiraling* also may improve track safety. The spiral curves improve the geometry of the racetrack, because no longer does the curve start at a single point, and a horse enters and leaves a turn in a more gradual manner.

Effect of the Physical Properties of the Racetrack and the Weather

A limited number of studies have attempted to document physical characteristics of the racetrack. The University of Minnesota American Association of Equine Practitioners Breakdown Study, hereafter referred to as the Minnesota study, conducted the first series of larger studies attempting to characterize racetrack conditions.[15,16] Weather conditions, the physical properties of the soil, including moisture content, composition, strength, cone penetrometer, and coefficient of friction between the surface and the hoof were documented at three successive racing meets at Canterbury Downs, Shakopee, Minnesota. The moisture content of the track was significantly different at various locations around the track and on different days. Rainfall contributed heavily to the moisture content of the track surface.

Track management can compensate for excessive dryness by adjusting the water management program. Racetracks located in the southwestern United States are far less affected by rainfall, and thus track management and moisture content become important management tools. Racetracks in California absorb about 136,500 L (30,000 gal) of water daily.[13] Excessive water in a track cushion eliminates air pockets between the soil materials and affects the load-bearing capacity of the track. Conversely, too little moisture prevents the soil materials from holding together. Studies at Washington State University suggest that high moisture content was the least efficient and indicate that intermediate moisture content is optimal (9% to 11%).

Organic matter content of the track is important because it enhances the moisture retention, decreases dusty conditions, decreases the ability of the soil to compact, and helps create a spongy surface. Excessive organic material results in increased drying time and stickiness of the track material. The Minnesota study monitored soil particle distribution, but no logical pattern was observed.[15,16] Diameter of the soil material is thought to be important. Too much soil matter of one diameter will pack, resulting in a firm track surface. Material of uneven diameters breaks up, causing traction problems for the horses. Further studies are necessary to determine the effect of soil particle distribution on track surface characteristics.

Shearing strength was measured using a hitch dynamometer. Some areas of the track were compacted, such as at points of high traffic from horse movement, starting chutes, maintenance equipment, water trucks, and general access to the track. These compacted areas in the Minnesota study were correlated with areas that had a high incidence of breakdown injuries. Changing the entry point for maintenance equipment and water trucks to a different area in the track with less racing traffic could have a positive effect on this compacted area. Shearing strength of the soil was determined by a cone penetrometer. The penetration force next to the rail was reduced, indicating that resistance in the soil was lower. The cone penetrometer also revealed differences in track surface between racing seasons. This may be attributable to increases in moisture content or organic matter in the track surface. Anecdotal evidence suggested that the jockeys learned that the soil next to the rail was looser and thus was not an ideal location for racing. By moving slightly farther away from the rail, where the cone penetrometer showed more resistance, the jockeys had a perception that the track was faster.

Anecdotal evidence suggests that harder tracks are faster tracks. The thought is also that harder tracks result in more mild to moderate injuries. Track surface studies at the University of Minnesota suggested the hitch dynamometer was useful in identifying compacted areas of the track where a cluster of injuries had occurred. Further research is necessary to determine whether the hitch dynamometer or the cone penetrometer is a better method of monitoring track surface hardness.

The Minnesota study indicated that the primary factor affecting the track surface is moisture content and the second most important factor is the organic material. Soil particle distribution should be evaluated to monitor the change in track composition, and cushion depth should be determined to ensure that areas of accumulation, especially near the rail, do not occur. Conversely, thinning of the cushion near the crown of the track could represent a significant increase in compaction and thus become a risk factor. Areas of high traffic access to the track need to be located where racing is minimal and not toward areas where racing traffic is high, at turns, or where fatigue becomes a major factor for the racetrack, such as the final turn.

The Japanese Racing Association demonstrated a seasonal effect, suggesting that cool weather has a strong influence on early morning training and potential for accidents. Whether cool weather influence is a track-related or a horse-related factor is unknown. The Japanese Racing Association conducted another study using horses with shoes that were fitted with accelerometers.[21] The higher the acceleration recorded by the accelerometer, the greater the force of impact to the limb. Thus any risk factors that can reduce acceleration of the limb reduce the forces exerted on the limb. Acceleration declined dramatically as the water content rose in turf courses. Lower acceleration was related to an increased depth of cushioning sand on dirt courses. Harrowing the racetrack reduced the acceleration rates by 38% compared with a track that had not been worked.[21,22] The shock wave patterns measured by the accelerometers were found to be a dangerous type when the track bed was exposed and the cushion was thin. Harrowing resulted in more uniform leg motion, and 94% of the shock wave patterns were of the safe type, indicating a stable running surface.

As a result the Japanese Racing Association developed new racetrack maintenance equipment, including a turf perforator to prevent hardness, a level harrow to even out the cushioning sand, a track hardness measuring van using a penetrometer, a dirt cleaner to remove pebbles from the cushioning sand, a water absorption roller to improve turf courses, an automatic water sprinkler system to ensure evenness in the water content of the track, a sand thickness gauge to ensure evenness of the cushion, and a side raker to ensure the cushion does not accumulate under the rail.

Synthetic Surfaces

Tracks composed of a large proportion of organic particles, such as wood fibers, wood chips, or sawdust, have the greatest dampening ability. Synthetic track surfaces were used on two major racetracks in the United States with a relatively low injury rate, but both have been removed and replaced with a conventional surface. Synthetic surfaces are still used in various training centers with success and at some all-weather racetracks in the United Kingdom. The synthetic tracks appear to be safe, with injury rates reported well below the industry standard, and also require less water and remain fast, even in adverse weather conditions. Unfortunately, synthetic tracks exhibit variability in the surface during hot, dry spells. Some portions were excellent, whereas other sections were uneven and fluffy. This lack of consistency resulted in the decision to remove the synthetic surfaces in the United States and replace them with conventional surfaces. The basic approach with a synthetic material is to add particles with the polymer coating and use this material for the track and the cushion. Synthetic materials also play a role in turf courses where they are used to anchor the roots of the grass, thus resulting in fewer divots and greater integrity to the turf course.

EPIDEMIOLOGICAL STUDIES OF RACETRACKS

A case-control study performed in New York identified one racetrack with a lower incidence of injuries.[20] The Equine Racing Injury Reporting System identified great variation in injury rates among participating racetracks, suggesting race surface is an important factor in the development of musculoskeletal injuries in North America. The reporting system information in 1992 showed the fatal injury rates for dirt starts on various tracks ranged widely, with a twofold difference between the lowest and the highest.[7] Great variability in track fatality rates also has been demonstrated in the United Kingdom.[23] Fatal injury rate at a given track varies from year to year. At some tracks racing injuries occur more frequently on certain days of the week and during specific race numbers. Racing on dirt surfaces represents 90% of all TB races in North America, and a higher fatal injury rate was observed on dirt versus turf. The Equine Racing Injury Reporting System study provided the first nationally based number for fatal racing injuries in TBs (1 death per 629.6 starts). The study also documented a range of fatal injuries between racetracks. The difference between dirt and turf racing has been demonstrated (1 death per 619.5 dirt starts and 1 death per 759.4 turf starts). More compelling evidence implicating the racing surface exists in the Japanese Racing Association study, which identified one particular racetrack with an increased incidence of injuries compared with the other tracks.[21,22] Changes in racetrack surface management were implemented and the injury rate was lowered. A strong perception exists in the racing industry that turf courses are safer than dirt courses. Analysis of this issue is clouded to some degree in North America because horses that race on turf still spend most of training time on dirt surfaces. The incidence of catastrophic breakdown injuries is much less in the United Kingdom, where many horses train and race on turf, but training and racing also take place on more varied terrain, including hills, and involve considerably fewer turns. The New York case-control study indicated a decreased risk of injury associated with racing on turf courses. An Australian study reported low catastrophic injury rates associated with turf racing.[24] The turf as a surface may be more forgiving for TB racing, but one of

the difficulties in the analysis is that most of the horses racing on turf are of higher quality, and thus factoring the comparison of turf racing versus dirt racing, without taking into account the quality of the horses, may yield invalid conclusions. A study comparing similar-quality horses racing on turf versus dirt is necessary. In addition, monitoring groups of horses that trained and raced on dirt versus horses that trained on dirt and raced on turf versus horses that trained and raced on turf would be interesting.

Many of the case-control and descriptive studies have included track condition and type as part of the study,[7-15,20] which is due to the reporting of track condition and type as assessed by the racetrack and commercially available on databases. In the New York study, horses that raced on firm turf had significantly lower risk of severe injury compared with those that raced on normal dirt.[14] Fast, sloppy tracks resulted in a higher risk of injury. Slower, muddy tracks resulted in a lower risk of catastrophic injury. The Minnesota study showed no apparent relationship between breakdown occurrence and the length of the race, and whether the race was on dirt or turf. Fifty-four percent of the major injuries occurred in the final turn (Fig. 106-2). This clustering of injuries was at an area where all the mechanized equipment was brought on to the track, was a transition point from a turn into a straightaway, and at a stage in the race when the horse is experiencing major fatigue.

The risk of catastrophic injury is not necessarily the same as the risk of other musculoskeletal injuries. Using other data collected from New York racetracks, the prevalence of fractures and soft tissue injuries could not be correlated to track conditions, environmental conditions, length of races, track location where the fractures occurred, or age of the horses. However, pooling of the data from four New York tracks showed that injuries increased from 2.12 injuries per 1000 starts on a fast track to 3.26 per 1000 starts on a muddy track and 2.76 injuries per 1000 starts on a sloppy track. Pooling also indicated that one track had twice as many fractures as another track in the study, strongly supporting the physical condition of the racetrack as a major risk factor in TB racing.

A Japanese Racing Association study indicated that the rate of accidents on turf courses was 1.58% compared with 1.65% on dirt courses.[21,22] Accident rates on turf courses were highest when the tracks were in fast condition, and the firmness of the track was thought to be a major factor. Dirt tracks had highest accident rates when the tracks were heavy, with high water content, possibly as a result of loss of the shock-absorbing effect of the cushion. The Japanese study also indicated that racetracks with higher injury rates had tighter turns and tended to be flatter courses.

A descriptive study involving 1100 racing injuries from 33 racetracks revealed that most musculoskeletal injuries occurred while horses are racing on dirt (948). Fatal injuries had slightly higher prevalence (27%) on dirt tracks compared with turf tracks (23%). Forelimbs accounted for most of the injuries. Stallions were overrepresented in the fatal proximal sesamoid bone fracture group. A prospective study of fractures in TB racehorses in England revealed an annual incidence of 9%, with 206 occurring during training compared with 21 during racing.[25] A seasonal distribution was identified and coincided when fast work was commenced. A German study showed that training failure was from lameness 57% of the time and again intensified with the onset of speed work.[26] An Australian case-control study found that horses running in stakes races were 2.3 times more likely to suffer a musculoskeletal breakdown than horses in a non-stakes race.[27] This is a substantially different finding from North American studies.

A recent Australian study demonstrated that fatalities are less common on Australian racetracks than those in the United Kingdom or in the United States.[27] The study demonstrated that the most significant factors associated with serious injury included track condition and location of the track. Horses racing on a fast, good track were twice as likely to suffer a serious limb injury as those running on a slow or heavy track. In addition the type of race had a large affect on the risk of injury, with horses in the hurdle races being 4 times more likely to suffer a serious injury and those competing in steeplechase races 7.5 times more likely to sustain a serious injury compared with racing on the flat.

The racing industry is keenly aware of the effect of the racetrack surface conditions and design contributing to musculoskeletal injuries at all levels. Information is limited, however, on how to correlate these data with the physical condition of the horse. Measurements of forces between the hoof and the ground indicate that peak vertical forces are 175% of body weight for the gallop, with forces 10% to 15% less on the hindlimb than the forelimb. Early studies used the drop-hammer technique to test the ability of the track surface to absorb kinetic energy from the hoof, as a model of the physical characteristics of the cushion.

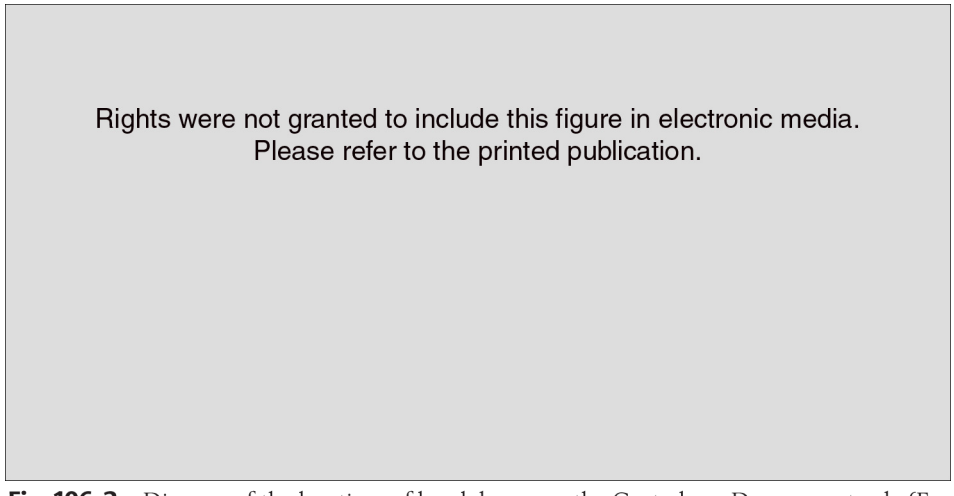

Fig. 106-2 Diagram of the locations of breakdowns on the Canterbury Downs racetrack. (From Clanton C, Kobluk CN, Robinson RA, et al: Monitoring surface conditions of a thoroughbred racetrack, *J Am Vet Med Assoc* 198:613, 1991.)

TRAINER-RELATED FACTORS AND EFFECTS

Information is limited about the effects of training programs on the prevalence of musculoskeletal injury. The Minnesota cohort study demonstrated large variations in training programs of the 11 participating trainers.[18] An arbitrary exercise score, problem score, and success score was assigned to each horse participating in the study. Only 17 of 95 horses did not develop any type of injury. Fifty-seven percent of the study horses were removed from training before conclusion of the study, 33% because of musculoskeletal injury. The relationship between the exercise and the problem score was linear. As the problem score increased, the exercise score decreased. As the exercise score decreased, the success score decreased. The trainer that had the highest average success score also had the highest exercise score and the lowest average problem score. As expected, the most successful training programs had a relatively low injury rate that allowed horses to be worked on a more regular basis and to compete more successfully. This trainer also routinely used ice whirlpool baths far more often than any other trainer in the study. A Kentucky study showed that injured horses had significantly less cumulative high-speed exercise than did control horses.[28] In my opinion, further cohort studies emphasizing the trainer as a risk factor are required to reduce the incidence of musculoskeletal disease in racehorses.

HORSE-RELATED FACTORS AND EFFECTS

Breed

The incidence of catastrophic injury in TB racehorses is much higher than in QHs and STBs, possibly from differences in training practices in QHs and the less stressful racing gait and slower speeds of STBs. The fatal injury rate in TBs was equal during training sessions and racing. QHs had much fewer training injuries. The Equine Racing Injury Reporting System survey had a low number of reports on QHs, but the injuries were more severe. Sixty percent of QHs died or were euthanized compared with 22% of TBs. No studies document the incidence of mild to moderate injuries in the three breeds.

Conformation and Quality

Preliminary conformation evaluations were carried out during the Minnesota study.[17] This suggested that horses with certain forelimb and hindlimb ratios were less likely to experience musculoskeletal injury. A subsequent study at Colorado State University on the conformation in racing QHs revealed an association between conformation and the odds of sustaining various racing injuries.[29] The study used 160 2-year-olds in race training and compared measurements taken from photographs with the prevalence of musculoskeletal injuries. This is discussed further in Chapter 4.

Pre-Existing Pathological Conditions

A study performed using data collected from New York racetracks was the first indication that pre-existing pathological conditions may be important in the development of catastrophic musculoskeletal injuries.[30] This study suggested that pre-existing pathological conditions and not racetrack conditions were the primary causes of catastrophic injuries. The authors proposed that pre-existing osteochondrosis, chondro-osteonecrosis, and tendon and ligament injuries predisposed to injury. The controversial conclusions also incriminated the overuse of corticosteroids.

The Minnesota study attempted to address the issue of pre-existing pathological conditions by a clinical, radiological, and ultrasonographic evaluation of the 97 horses in the cohort study. Prestudy and poststudy radiographic examinations revealed detectable lesions in the carpus in 72%, in the metacarpal region in 42%, and in the fetlock in 82% of horses. The incidence of definitive pathological lesions using pre-ultrasonographic and post-ultrasonographic examination was low. Post-mortem studies have shown a predisposition to complete humeral fractures often caused by pre-existing stress fractures of the humerus.[31] Seventy-seven percent of horses with complete fractures of the humerus had evidence of pre-existing stress fractures. Pre-existing stress related bone change was found in horses with pelvic fractures, scapular fractures, tibial fractures, and metacarpal fractures.[32,33] A descriptive study from Kentucky identified that a significantly greater number of horses with racing injuries and catastrophic injuries were in the last half of the racing group at the quarter pole, possibly indicating that pre-existing pathological conditions impaired racing ability.[8,10] Most studies strongly support a higher catastrophic injury rate in claiming horse compared with stakes and allowance horses. Many claiming horses were previously higher-quality horses, but because of musculoskeletal injury they dropped to a lower racing class. Anecdotal evidence suggests a much higher incidence of pre-existing musculoskeletal injuries in lower-quality horses, because many of these horses were previously racing in a higher class but were lowered because of injury.

Age

Racing in all breeds clearly is dominated by younger horses, with most of the purse directed toward horses in the 2- to 4-year-old range. The issue of racing younger horses, especially 2-year-olds, has long remained a controversial one. In some cases, scientific data supports the discontinuation of 2-year-old racing, but in other cases it does not. Further research is necessary to define whether 2-year-old racing is appropriate or at least how such racing is best accomplished to reduce the incidence of musculoskeletal problems. California studies showed that fatal injuries occurred most commonly in the 2-, 3-, and 4-year-old horses; but this reflects the largest group of horses in racing or training. More 2-year-olds were injured during training than during racing, possibly reflecting the stress of the change in environment when they arrive at the track. An investigation of 1100 reports of racing injuries (Equine Racing Injury Reporting System) indicated that racing injuries in 2-year-olds had a lower rate, 3.21 per 1000 starts, and that the fatal injury rate was lower than the other age groups, 1.43 per 1000 starts. In addition, more injuries occurred in the latter half of the year, suggesting more starts later in the year for the 2-year-old population or possibly an effect of fatigue and injury later in the racing year of these 2-year-olds. An Australian study showed that horses in the 4 to 5 years of age range were about 1.5 times more likely to suffer a serious catastrophic injury compared with those aged 2 and 3 years. In contrast a New York study identified a negative association between the risk of severe injury and the age of the horse.

Shoeing

The Minnesota study was the first study to investigate the possible effect of shoeing practices on TB racehorses.[17] In the cohort study of 97 horses, those shod at a higher angle were less likely to experience injury, earned significantly more money, and were more successful. A case-control study published from the California post-mortem program reported an association between toe-grabs and the increased risk of catastrophic musculoskeletal injuries, suspensory apparatus failure, and condylar fractures, demonstrating an association between the height of toe grabs and a twofold to sevenfold increased risk for these injuries.[19] Rim shoes were found to be associated with a decreased risk of catastrophic injury, lowering the odds of injury 2 to 3 times. This study has led to the intervention of racing regulatory officials in mandating certain types of shoeing for racehorses.

Post-Mortem Evaluations of Catastrophic Injuries

The New York study, suggesting that pre-existing pathological conditions were a primary cause for catastrophic accidents, was the first major post-mortem investigation of racing injuries.[30] The Minnesota study also attempted a post-mortem evaluation of horses with catastrophic racetrack injuries. Left forelimb injury predominated. The design of the case-control study used two randomly selected control horses from the same race in which the breakdown occurred. Lifetime earnings were significantly less for injured horses than control horses. Horses with bone injures were 7 times more likely than the control horses to have made less than 40% of race starts at Canterbury Downs and were 7 times more likely to have raced within the previous 12 days. Horses with soft tissue injuries were 2.5 times more likely to have been scratched by the track veterinarian. Fifty-four percent of the major injuries occurred during the final turn in this study. Fractures below the carpal joint accounted for 75% of all the injuries, with 60% of the horses having some post-mortem evidence of a previous injury, and 72% of the injuries involved the lead leg.

In Japan the Japanese Racing Association administers all racing and is able to document racing and training injuries. From 1985 to 1994 a greater number of fractures occurred during training than during racing each year, suggesting that training injuries are at least as significant as racing injuries in TB racehorses.[21] Fractures tended to be more severe during racing than during training.

The case-control study of racetrack breakdowns in New York associated a higher risk with years racing, racing in a later race, number of starts per year, and the total number of starts and age of the horse. Risk of injury was greater in the summer than in the winter or spring.[20] California studies showed the most common catastrophic musculoskeletal injury occurred in the proximal sesamoid bone and the suspensory apparatus. In a case-control study of racing-related risk factors, severe injuries in TB racehorses in California showed that stress-related injuries accounted for 83% of the deaths.[34] Complete fracture of the long bones accounted for 32% of the deaths. Seventy-seven percent of the complete fracture of the humerus had pre-existing stress fractures.

In a study from Kentucky the forelimb below the carpus was the most commonly injured area. The forelimb accounted for 90.2% of the racing injuries, with the suspensory apparatus the most frequently involved (44.7%). The right forelimb was injured more commonly after the wire, whereas the left forelimb was injured more commonly in the stretch turn. Many risk factors were assessed, including weight carried during the race, weight carried during the previous race, number of competitors in the race, duration of the race, changes in distance between the race in which the injury occurred and the previous race, number of career starts, interval between races, number of career wins, the amount of career earnings, sex, racing surface, race speed, track identity, status of jockey, and racing class or changes in racing class. None appeared to affect incidence of injury.

RACING ACCIDENTS

A descriptive study from the Japanese Racing Association, using video recordings of races, found that accidents from physical interactions or stumbling were predisposed by changing of the line of racing, oblique movements, or some action that upset the center of gravity of the jockey or horse.[35] The Kentucky case-control study demonstrated by video that horses had a 2.5 times greater chance of injury if a physical interaction occurred during the race.[8,10] The horses were at a 4.2 times greater odds of injury if they stumbled during the race, and a 7.7 times greater odds of catastrophic breakdown if stumbling occurred. An Australian study at two racetracks over a 10-year period found that horses with outside positions were twice as likely to suffer an injury versus those starting close to the rail. The Japanese Racing Association found that accidents during racing were common in the early spring, whereas training accidents were more frequent during the winter months.

FUTURE INITIATIVES IN THE STUDIES OF MUSCULOSKELETAL INJURY

In a report by the Equine Racing Injury Reporting System to the American Association of Equine Practitioners the value of accurate records documenting racing injuries has led to an injury monitoring system. Standardization of the reporting practices will facilitate comparison of databases from different racing jurisdictions. A national monitoring system implemented in 1992 provides a common format for regulatory veterinarians to record injury information and accumulate comparable data on a large scale. Routine racing and surface monitoring is being used at some level worldwide, and further techniques currently are being investigated. Some of the techniques are relatively easy to perform, such as monitoring cushion depth, moisture, and soil particle distribution. The development and use of modern technology allows the recording and maintenance of track parameters within desired guidelines and eventually will allow the correlation of surface condition parameters to the occurrence of musculoskeletal injury. Monitoring the following environmental conditions, including weather reports, track superintendent's logs, moisture content, cushion depth, bulk density, organic matter, shearing strength, and conditions at specific injury sites, will document the physical parameters of the racetrack. In addition, significant work on racetrack dimensions such as track slopes and configurations should be determined to facilitate comparison of injury rates with other tracks. Case-control studies will continue to allow the evaluation of these major racing injuries and hopefully will identify risk factors associated with them. In my opinion, cohort studies that follow a large number of racehorses on a day-to-day basis will be far more valuable in determining the risk factors on musculoskeletal injury. Such studies will identify better not only the risk factors associated with the catastrophic injuries, but also the mild to moderate injuries that have such a major economic effect on the racing industry. Many of the studies suggest catastrophic injuries tend to be random events, but certain risk factors clearly are associated with occurrence. The evidence for pre-existing musculoskeletal injury subsequently leading to catastrophic breakdown is compelling, and thus studies that identify these pre-existing injuries and correlate them to risk factors would be especially important in subsequently reducing catastrophic breakdown.

The Japanese Racing Association clearly has demonstrated that identifying the prevalence of racing injury rates, analyzing associated risk factors, and subsequently making management changes result in a reduction in injuries. Some of the risk factors are relatively easy to identify and make appropriate management changes; for example, toe grabs used on racing plates. Other risk factors, such as the effect of the trainer and the training program, are far more complex and will require large-scale cohort studies to demonstrate clear and useful conclusions. In my opinion the use of these types of studies, involving a number of trainers in a number of environments, will clearly define optimal training programs and methodologies that will significantly reduce mild to moderate injuries and subsequent catastrophic injuries.

CHAPTER • 107

North American Thoroughbred

Rick M. Arthur, Mike W. Ross, Patrick J. Moloney, and Mark W. Cheney

DESCRIPTION OF THE SPORT

King James I of England established horse racing as the Sport of Kings in the early seventeenth century and the earliest English immigrants brought the sport to the American colonies. Colonials imported fine-blooded horses and staged informal race meets almost as soon as they hit land. Richard Nicolls took command of New Amsterdam, renamed New York, became the first governor of the colony in 1664, and established a racecourse.

Many of the founding fathers of the new country, including George Washington and Thomas Jefferson, raced horses. John Wickham, Aaron Burr's attorney at his treason trial, lost one of the top American stallions of the emerging Thoroughbred (TB) breed, named Boston, in a card game in 1835. Nathaniel Rives won the difficult 2-year-old colt and ignored advice to geld him. Boston not only won 40 of 45 starts, but he also sired Lexington. A foal of 1850, Lexington became the top racehorse in the country by winning from New York to New Orleans.

Lexington was named for the Kentucky town that became the center of TB breeding. Horsemen quickly realized that healthy horses could be raised on the limestone base of Central Kentucky, and the horse, Lexington, helped establish the area by becoming the top sire in the United States for 16 years.

Racetracks sprung up in many cities, and although the industry suffered during the Civil War, Saratoga was the exception. The New York social elite took in the waters at the Spa to escape the heat and humidity of the city, attended the races during the day, and partied through the summer evenings in spite of the war. A few years after the conflict, Col. M. Lewis Clark founded the Louisville Jockey Club to conduct race meets in Kentucky. In 1875 the Louisville Jockey Club opened a new racetrack, later called Churchill Downs, and that year Aristides won the first edition of the Kentucky Derby (the Derby).

The Derby did not begin as America's most famous race. Col. Matt Winn's genius at marketing in the early twentieth century was required to create the legend the Derby has become. When the filly Regret won the race in 1915, the Kentucky Derby rose to prominence quickly as a premier American sporting event and a major stop for 3-year-old TBs.

Fans were disappointed when owner Sam Riddle and trainer Louis Feustel deemed the Derby too early in the year for their strapping colt, Man o' War, the horse that had broken many records the previous year, winning 9 of 10 races. However, Man o' War added to his reputation without the Derby, going through a perfect season of 11 wins in as many races. To many he remains the finest TB racehorse the United States has ever produced.

A new moral climate was sweeping the nation after the turn of the century. Gambling, including on horse racing, was banned in many states as a precursor to Prohibition that began in 1919. Kentucky was the exception and horsemen and racing fans found many ingenious ways to skirt the law. The need for more state revenue from the depression in the 1930s prompted the ban on racehorse wagering to be lifted in many states. Until the 1970s horse racing was often the only legalized form of gambling in most states. From the 1930s to the 1960s horse racing, boxing, and baseball were the most popular sports in the United States.

War Admiral, sired by Man o' War, gained such a following in the 1930s that the whole country listened to the Seabiscuit–War Admiral match race. Because the older Seabiscuit had lost his first 17 races as a 2-year-old, everyone expected War Admiral to win. Yet Seabiscuit, "the people's horse," beat War Admiral that day, and in 1938 Seabiscuit was said to have had more newspaper space than Hitler.

As a 3-year-old, War Admiral won the Derby, the Preakness, and the Belmont Stakes, races that became known as the Triple Crown. Only 11 horses have ever won all three races. In 1948 Citation so impressively captured the series that some thought the horse replaced Man o' War as the greatest racehorse. That argument ensued for the next 25 years, despite names like Native Dancer, Swaps, Kelso, and Dr. Fager, none of which won the Triple Crown. However, in 1973 a bright chestnut colt, Secretariat, so captured the public imagination when he won the Triple Crown that *Time*, *Newsweek*, and *Sports Illustrated* all put him on the cover. He won the 1½-mile Belmont stakes by a spectacular 31 lengths.

Although the Triple Crown increased in stature, California developed a strong racing circuit. Santa Anita, east of Los Angeles, opened in 1934 and gained immediate attention by offering the then unheard of sum of $100,000 (U.S.) for the inaugural Santa Anita Handicap. Across town, Hollywood Park began attracting movie stars and established its own fixture, the Hollywood Gold Cup. Bing Crosby and friends built Del Mar about 100 miles south.

As transportation by air became more popular in the last half of the 20th century, horses from the East and West began meeting regularly. In fact, Affirmed, the latest horse to win the Triple Crown, in 1978, prepared for racing at Santa Anita and Hollywood Park.

Regional rivalries became popular, which added to the success of the Breeders' Cup series, inaugurated at Hollywood Park in 1984. Unlike the Triple Crown, which is solely for 3-year-olds, Breeders' Cup Day offers races for various divisions. Two-year-olds show what might emerge at the next year's Kentucky Derby. European horses often invade for the grass events. The Breeders' Cup Classic attracts elite runners on the dirt from coast to coast and from abroad.

The Breeders' Cup epitomizes the tenacity of the racing TB. Spectacular victories—including the triumph of Sunday Silence over archrival Easy Goer in the 1989 Classic, the victory of Personal Ensign over the Kentucky Derby–winning filly Winning Colors in the 1988 Distaff, and the devastating move Arazi made to capture the 1991 Juvenile after shipping to the United States from France—are legendary. American TBs regularly compete in Europe, Japan, Australia, and Dubai. Not even King James I could have envisioned the Sport of Kings developing into the international phenomenon it is today.

TB racing always has been an expensive sport. Since the introduction of parimutuel gambling, financial support and revenue has been derived from two groups, racehorse owners and the gambling public. The third leg of the horse racing industry is the racetrack operator. Racetracks are generally for-profit corporations, with the exception of Del Mar, Keeneland, and a few others. Racehorse ownership was once the domain of the wealthy, but now opportunities and partnership options are available for many. In the past, most owners maintained breeding operations to supply horses for their personal racing stables; commercial breeders were few. The focus of breeding was for successful racehorses and rigorous selection for soundness was as important as racing ability. Commercial breeders have now become a major source of racehorses and have a different goal. They produce horses to satisfy the commercial market, an entirely different objective, often unrelated to producing a racehorse.

Commercial breeders offer horses at public auction, primarily as yearlings but also as weanlings and 2-year-olds in training. The auction market is fashionable and in many ways fickle and trendy. Buyers favor precocious yearlings, relatively more mature than others. Sprinting bloodlines and well-muscled yearlings sell better than classic distance pedigree and conformation for all but the most expensive horses. Little is known of soundness of the sire and dam. Although these trends are worrisome, one positive consequence has been the ever improving quality of horse offered at public auctions. Now some of the best pedigreed horses in the world are sold at public auction, a fact not true 20 years ago, and even traditional owners and breeders have entered the lucrative commercial market.

The commercial market is a straightforward avenue for owners to buy a quality racehorse without maintaining broodmares. The September Keeneland yearling sale offers nearly 5,000 yearlings over a 10-day period. Numerous other sales are conducted throughout the year. Presale examination is an important part of veterinary practice at racetracks (see Chapter 102). The auction environment can be extremely high pressure for the veterinarian because the knock-down price may reach millions of dollars.

Owners can also buy horses in claiming races. In claiming races the prospective owner buys the horse for a predetermined price *before* the race, and the horses is considered sold once the starting gate opens, regardless of whether the horse wins or ever finishes the race. Purses and monies from purchase (claim) go to the previous owner. Potential buyers of claiming horses cannot examine the horse, but they can watch it walk into the saddling paddock. Buying a horse by claiming gives an owner a ready-made racehorse, while owners and breeders have to wait at least 3 years before racing a homebred horse, and yearling buyers have to wait at least a year. Unfortunately, the risks in claiming are considerable, because the claiming game has no honor and the new horse may already be at the end of its career.

Racetrack operators have changed to meet demands of the racing fans. The state, racetrack operator, and horsemen, through purse distributions, obtain income from a percentage of the moneys wagered, called handle. Revenue from simulcasting races across the United States and internationally is now an important source of handle, and Internet and at-home wagering are already realities. On the track attendance has dwindled and contributes only a fraction of what it did 20 years ago, when a fan had to come to the track to place a wager. The importance of simulcasting to the future of horse racing has led to consolidation of racetrack ownership.

Because track operators emphasize handle, races are run in a manner to encourage betting. Races must be competitive and the more horses the better. An anathema to the non-gambling race fan and many horsemen is that gamblers bet more money on a large field of poor-quality horses than on a small field of high-quality horses. In the United States, field size rarely exceeds 12 horses, because dirt racetracks are relatively narrow and have tight turns, and turf courses, usually inside of the main dirt track, are even narrower with tighter turns.

Races are made to be competitive by restricting which horses are eligible to run in a particular race. Most important are age, sex, distance, and surface (turf or dirt). Sex and age restrictions limit which horses are allowed to compete in a race. Age is a major factor, and 2-year-olds are never raced against older horses, because they would not be competitive. Distaff races are those restricted to fillies and mares, and although the distaff side is not excluded from open races, such races are seldom competitive, except early in the 2-year-old year.

Distance and surface are conditions selected to suit the horse. Another set of conditions, handicaps and allowances, can be confusing but work well. Handicap and allowance races are set up to even the race by varying the weight carried by the horse. Weight variation is a subjective value, determined by racing officials for handicap races. In allowance races, weight variation is determined by a set of published criteria. For example, 3-year-olds carry less weight than older horses, fillies less than colts, and non-winners may get additional weight off.

Most races in the United States are claiming races. In claiming races, horses of similar ability are pitted together. Because of the risk of loosing a horse by claim, owners and trainers are discouraged from running more valuable horses to steal a purse. The claiming aspect of American racing is popular, but it has several negative effects on racing.

Stakes races are for the best horses. Stakes races require an entry fee and some require an additional starting fee. Stakes races are raced according to sex, age, distance, and surface. Stakes races are graded, listed or restricted. Restricted stakes races, popular in recent years, restrict eligibility to the state of foaling or to conditions similar to allowance races. Stakes races are run even if only one horse is entered, but this is rare and is called a walkover. Stakes can be handicaps, allowances, or weight for age races. In weight for age races all horses carry the same weight, except for the well-established allowances for age and sex. The Kentucky Derby is a weight for age race for 3-year-olds. All horses are assigned the same weight (126 lb), but a filly receives a weight allowance and carries 123 lb. The best stake races are graded by a national committee and classified as Grade 1, Grade 2, and Grade 3; Grade 1 races are the top races. Graded stakes races are similar to the group or pattern race classification in Europe. The Kentucky Derby and Breeder's Cup Classic are examples of Grade 1 races.

Non-stakes races fall into several categories. Maiden races are for horses that have never won a race and can be allowance or claiming races. Races can be restricted to horses that have not won a certain number of lifetime starts. Other specific conditions for races can include eligibility for horses that have not won a race in a certain time period or over a certain distance. Claiming races also are restricted by age, sex, distance, and surface. Although races are devised to maximize competitiveness, the uncertain offering of races for non-stake horses greatly complicates training and veterinary care, because timing for future races can be difficult to judge.

Stakes races are predominantly for horses 2 and 3 years of age, whereas horses may continue to race in claiming races up to 10 to 12 years of age. Claiming horses may drop progressively in class and value, and the lowest level of TB racing in the United States is considerably below that of the United Kingdom. Much of the following discussion reflects our dealings with high-quality, younger horses. These situations are easier for the veterinarian to be in control and to dictate the diagnostic approach and therapeutic plan, working with the

trainer. With low-value claiming horses the trainer is more likely to dictate what is treated and with what. Frequently joints are treated with corticosteroids alone, rather than in combination with hyaluronan.

CONFORMATION

Many mild conformational defects appear to be well-tolerated by TB racehorses (M.W.C., P.J.M.). Mild toe-out and toe-in conformation causes few problems, but horses with moderate or severe toe-out conformation develop interference injuries. Toe-out conformation may predispose the horse to sub-solar bruising of the medial heel. The most severe conformational defect is calf-knee or back-at-the-knee conformation. This defect leads directly to carpal lameness. Short, straight pasterns increase concussion and long, sloping pasterns are undesirable because they may lead to soft tissue injuries or fractures of the proximal sesamoid bones (PSBs). Offset (bench) knee conformation leads to splint disease and injury of the antebrachiocarpal joint. Horses that are tied in behind the knee develop tendonitis. Sickle-hocked conformation leads directly to lameness of the distal tarsal region. Horses with straight hindlimbs develop lameness of the stifle region and are prone to upward fixation of the patella.

TRACK SURFACE AND LAMENESS

Track surface is a significant factor in the development of lameness and frequently is overlooked or neglected in lameness discussions (P.J.M., M.W.C.). Track surface dictates frequency and type of lameness. Surfaces that favor speed also predispose horses to catastrophic breakdowns. Quality of racing surface is much more important than whether the surface is dirt or turf. Hard racetracks with little cushion are the worst surfaces. One of us (M.W.C.) observed 38 horses with bone injury in a 4-week period when horses were training and racing on a hard racetrack. When sand was added to the track and the cushion increased from 6 to 11 cm, over the ensuing 4-week period only four horses developed bone injury. However, race times increased substantially. Horses need not train on hard surfaces to be able to race on them. Training on a forgiving surface and racing on a fast surface is safer than the opposite approach or working on a hard surface constantly. Uneven surfaces may predispose horses to injury.

Banking around turns can influence how horses negotiate turns and lameness distribution and expression. The hindlimbs of horses negotiating flat turns appear to slip out from under them and, in some instance, horses nearly go down.

Track surface can make a difference on how horses with injuries are managed or rehabilitated. Horses rehabilitating after fractures or other bone injuries should not train on hard tracks. Likewise, horses coming back after soft tissue injuries or racing with minor infirmities should not be trained on deep or muddy tracks.

More information is needed about how surfaces should be managed. For example, how should the track be harrowed and how frequently? What is the ideal moisture content of the cushion?

Many European horses that previously trained on grass now race in North America. Most race and continue to train on grass, but some make the switch to training and racing on dirt successfully (see Chapter 108). Our impression is that European horses appear to have fewer forelimb and more hindlimb lameness problems than North American TBs. European horses often train on long straightaways and this, combined with a forgiving surface (grass), is a situation different from training on dirt in North America. Horses bred to race on the turf appear to have an inherent conformational difference that allows superior performance on grass.

TEN MOST COMMON LAMENESS CONDITIONS

1. Lameness of the foot
2. Lameness of the metacarpophalangeal/metatarsophalangeal (fetlock) joints
3. Lameness of the carpus
4. Suspensory desmitis
5. Dorsal third metacarpal bone disease
6. Superficial digital flexor tendonitis
7. Tibial stress fractures
8. Distal hock joint pain
9. Myositis
10. Other stress fractures

LAMENESS EXAMINATION

A racetrack clinician has distinct advantages over other practitioners. A racetrack veterinarian is involved intimately in the day-to-day operation of a racing stable and becomes familiar with the normal gait, disposition, and general health care factors of each horse, such as appetite, coat condition, weight, training and racing status, and performance. Numerous examinations can be performed easily if needed. Horses can be examined before and after training to see if lameness worsens or improves.

History

The most important piece of information is the training history. What did the horse do today, yesterday, and the day before? How far is the horse from racing? When was the last work or race? Did any problems occur? Did the horse want to train? Did the horse lug in or out? Did the horse cool out normally? When did the trainer or exercise rider notice a problem? When was the last time the horse was shod?

Most fractures occur in horses with a history of a recent hard workout or race. Sometimes lameness may not become apparent until the horse returns to the track several days later, but the injury occurred in the previous workout or race. Humeral stress fractures are the exception, because they usually occur in horses returning to work after not working for 45 to 90 days. Horses that lug in (drift toward the inside rail) or lug out (drift toward the outside rail) usually are moving away from the source of pain. Many lameness conditions are insidious in onset. Subtle signs, such as a horse that is unusually nervous and prefers to break into the gallop instead of jogging, are easy to overlook. Lameness the day after a shoeing change may implicate a close nail or a drastic change in hoof angle.

The age of the horse is important. Dorsal third metacarpal bone disease and other stress-related bone injuries are unusual in older horses if they do not have problems at 2 or 3 years of age. Older claiming horses are much more likely to have chronic osteoarthritis, osteochondral fragmentation, or tendon injuries.

Palpation

The physical examination should be routine and complete. Horses are first examined in the stall, where they are comfortable and are more willing to tolerate manipulation. One of us (P.J.M.) feels strongly enough about thorough examination that if trainers want to start with a visual examination while horses are tacked up and proceed directly to injection, they should find another veterinarian. Many lameness conditions are acute and signs of inflammation are clearly useful. Horses

with chronic lameness can be challenging, but long-term association with a horse is of great benefit. Regardless, the examination is the same. With the horse standing squarely, all limbs are palpated for heat, pain, and swelling. During individual flexion of the front fetlock joints and carpi, pain response is important. Pain during carpal flexion almost always indicates a problem in that region. The clinician should remember that during lower limb flexion tests, joints other than the fetlock are being stressed. If concerned, we flex joints independently if possible. All aspects of the PSBs should be examined with the limb in flexion. Suspensory ligament (SL) branches, body, and origin and flexor tendons are carefully palpated along the entire length. The dorsal aspect of the third metacarpal bone (McIII) is palpated by placing the palm of the hand around the tendons and applying firm finger pressure. The forelimb is then brought forward while elevated and the dorsal cortex of McIII is palpated with firm thumb pressure. Careful palpation of the dorsal and palmar aspects of McIII is important in detecting fracture of this bone (M.W.C.).With the palm of the hand on the dorsal aspect of McIII the fingers can be used to palpate the proximal SL and each splint bone. Care must be taken when examining the dorsal and palmar metacarpal regions, because the clinician may inadvertently cause pain on the dorsal cortex by examining the palmar aspect of the metacarpal region and vice versa (P.J.M.). Proximal palmar metacarpal pain is important to detect, but false positives can occur (M.W.C.). Any suspicious response should be evaluated further with ultrasonography (P.J.M.). The carpus is flexed and the dorsal surfaces of the antebrachiocarpal and middle carpal joints are palpated with thumb pressure. An effort should be made to stretch the joint capsule around the borders of each carpal bone, because stretching often elicits pain if a lesion present. To evaluate the elbow and shoulder regions, the limb is pulled backward and forward. With the limb extended, a jerking, upward motion sometimes causes pain in horses with humeral stress fractures. The shoulder joint and intertubercular (bicipital) bursa should be palpated with firm digital pressure.

The hands should be run lightly over the back to assess for sore or tense muscles. The lumbar and sacroiliac regions, gluteal muscles, and greater trochanter of the femur should be palpated from each side. Although appearing hazardous, the gluteal muscles and greater trochanter also should be palpated from behind. If necessary a forelimb can be elevated. Firm pressure should be used to detect gluteal myositis or trochanteric bursitis. Standing behind the horse is the best way to compare effusion of the femoropatellar joints. Each hindlimb should be examined in the standing and flexed positions. The Churchill test should be performed bilaterally (see Chapter 6). A positive response suggests distal hock joint pain. Negative findings on palpation and manipulation do not eliminate a joint from consideration, but positive findings often point to the source of lameness.

Movement

It is mandatory to observe the horse during the first few steps out of the stall. Then the horse is usually walked down the shed row and back. Occasionally the horse is trotted immediately. It is important to trot the horse at a comfortable speed for the *horse,* not the handler, and the horse must be trotted far enough to reach an even speed. The head must be free, without allowing the horse to throw the head. Surface is important and the harder, the better; soft surfaces may hide lameness. The horse is trotted in a straight line and while circling. Trotting the horse in a circle is the best way to differentiate diagonal or ipsilateral lameness (i.e., left forelimb from right or left hindlimb) and exacerbates many lameness conditions. Horses with tibial stress fractures are much worse while circling. Horses with third carpal bone pain and medial foot lameness are worse with the affected limb on the outside. Horses with lameness of the fetlock joint are usually worse with the affected limb innermost. Although characteristics of lameness while trotting are important, they are subjective.

At times, observing a horse under tack is useful. Often, horses with hindlimb lameness are best examined on the racetrack, because many horses do not use themselves behind. Only when horses are absolutely sound in hand is examination at speed warranted, and even then, with the exception of understanding the complaint of the rider, obtaining useful diagnostic information is rare. However, one of us (P.J.M.) likes to examine horses with obscure lameness on the track, under tack at the trot.

The usefulness of flexion or other manipulative tests is debatable. Lameness may be exacerbated, but disagreement exists over what a positive response means. For instance, when performing a fetlock flexion, a positive response is common even in horses with lameness unrelated to the fetlock joint (R.M.A.). One of us (P.J.M.) finds fetlock and lower limb flexion tests worthwhile, but not carpal flexion, and finds hindlimb flexion tests non-specific. One of us (M.W.C.) finds forelimb flexion tests useful but finds all but the lower limb flexion test in the hindlimbs questionable. Each clinician needs to develop a protocol and be consistent.

Diagnostic Analgesia

Diagnostic analgesia is important to localize sources of pain and sequential, distal to proximal, intra-articular, and perineural blocks should be performed. One of us (P.J.M.) feels strongly that shortcuts, such as skipping immediately to a low palmar/plantar block rather than performing a palmar/plantar digital block first, lead only to misdiagnoses. Another (M.W.C.) feels confident in clinical examination and blocks only when unsure of his diagnosis but admits that when a trainer or owner wants a definitive answer, this approach is unacceptable. However, to diagnose proximal plantar metatarsal pain definitively, a block must be performed. Blocking horses with long winter coats can be difficult. For distal third metacarpal or metatarsal (MtIII) bone disease one of us (M.W.C.) uses specific palmar/plantar metacarpal/metatarsal analgesia. A novel approach is taken to desensitize the distal 50% to 75% of McIII. Five milliliters of local anesthetic solution is injected into the nutrient foramen. This block is not specific for bony disease, because the nearby accessory ligament of the deep digital flexor tendon can be affected; however, injury of this ligament is rare.

Whether to clip for intra-articular injections or analgesia is personal preference, but two of us do not clip (M.W.C. and P.J.M.). Although medicating and performing intra-articular analgesia simultaneously is acceptable, one of us (M.W.C.) prefers to wait at least 1 day after blocking to medicate.

Horses may be difficult to handle during analgesic procedures or during intra-articular injections, but usually a lip chain or twitch provides adequate restraint. Gentle, confident, sure hands with painless technique are best (P.J.M.). If sedation is necessary, a combination of 5 mg butorphanol and 200 mg xylazine or 0.15 mg (0.125 ml) detomidine is useful (M.W.C.).

IMAGING CONSIDERATIONS

Routine radiographic views often are supplemented with views looking specifically at problem areas of the TB racehorse. For instance, for the metacarpophalangeal and metatarsophalangeal joints, flexed dorsopalmar or dorsoplantar (DPa, DPl), the dorsal 35° distal-palmaro(plantaro)proximal oblique, a standard horizontal DPa or DPl, lateromedial (LM), flexed LM, and the dorsolateral-palmaro(plantaro)medial oblique and dorsomedial-palmaro(plantaro)lateral oblique views should be considered

routine. For the carpus the four standard views and a skyline each of the proximal and distal rows of carpal bones are routine.

Scintigraphic examination is important, because TB racehorses frequently develop cortical and subchondral stress-related bone injuries. Horses with obscure or undiagnosed lameness and those suspected of having stress-related bone injuries are candidates for scintigraphic examination. Because complete fracture often results from pre-existing stress-related bone injuries in cortical and cancellous bone, horses with signs consistent with pelvic, tibial, humeral, and McIII or MtIII stress fractures should undergo scintigraphic examination before continuing in work. However, interpretation is not always straightforward. False-negative results have been found in horses with pre-existing tibial stress fractures (P.J.M.) and false-positive results in those with modeling reflecting changes in work intensity. Therefore experienced interpretation is essential, and follow-up examinations are required if findings do not concur with clinical observations.

For ultrasonographic examination horses are routinely clipped. Ultrasonographic examination is valuable in diagnosing and staging tendonitis, suspensory desmitis, carpal tenosynovitis, lateral branch superficial digital flexor tendonitis, and other swellings of the pastern, swellings of the medial stifle region, and distal sesamoidean desmitis.

SHOEING

Trimming and shoeing of the TB racehorse are extremely important. In many practices, veterinarians are not involved in trimming and shoeing, and decisions often are made exclusively by trainers and farriers. Because recent evidence has linked catastrophic injury to toe grabs on shoes, now a general trend is to see horses shod with low grabs, or none at all. Toe grabs are thought by many to cause forelimb lameness. The rationale for using grabs is questionable, because the forelimbs are propelled by the hindlimbs and traction on the front feet makes little sense. Toes grabs may shorten the cranial phase of the stride, prevent forward sliding of the forelimbs, and cause lameness. One of us (M.W.C.) has observed many horses that are stiff and short up front, and by simply removing the grabs and applying Queens plates (aluminum shoes with a low toe grab; Victory Racing Plate Company, Baltimore, MD), lameness abates in 2 to 3 days. Lameness associated with toe grabs appears most common on dirt tracks with hard bases and cushions of less than 7.5 cm. For racing on dirt the Queens plates or variations are popular, and for turf the Queens plates and Queens XT shoes are required. Turndown shoes have received negative press, but they may be advantageous in horses with low heels. Slight turndowns without toe grabs on hind feet may actually benefit horses with hock and stifle pain. Many lameness problems may be created or exacerbated by poor shoeing, including proximal suspensory desmitis (PSD), tendonitis, and fractures of the PSBs. One of the major problems is shoeing horses with small shoes. Overzealous use of acrylic can cause severe foot lameness. Horses with thin walls are predisposed to nail bind and those with sheared heels suffer repeated heel bruising.

INABILITY TO MAKE A DIAGNOSIS

In many horses, despite taking a methodical and time-consuming approach to diagnostic analgesia, the source of pain cannot be identified (M.W.C.). These horses are referred for additional clinical and scintigraphic examinations (M.W.C. and P.J.M.). Horses with stress-related bone injuries may show few clinical signs, and scintigraphy is the imaging modality of choice. Lameness in young horses in training may be more difficult to diagnose than that in horses that are racing (M.W.C.). Many horses with undiagnosed lameness are confined to at least 6 weeks of walking.

SPECIFIC LAMENESS CONDITIONS

Lameness of the Foot

The most common cause of lameness in the TB racehorse is foot pain. Horses may be observed in the stall to pile bedding under the feet, presumably to cushion the feet or to change angles. Lameness is often worse with the affected limb on the inside of a circle. Heat at the coronary band and increase in digital pulse are frequent signs. TB racehorses have little hoof. Many are shod at least monthly, but most are shod more frequently, with thin, lightweight shoes. When shoes are changed frequently, little natural hoof is available with which to work if adjustments are necessary. The tendency is for the farriers to remove too much foot, particularly toward the heel, resulting in low heels. Thin feet have prompted the use of acrylics to augment the hoof wall, but overzealous use may also result in foot soreness itself (M.W.C.). Soreness and bruising are common, particularly on the medial quarter, just forward or at the bar. The center of load distribution for a TB racehorse is medial and palmar to the anatomic center of the foot, close to the medial bar.

Most racehorses react positively to the application of hoof testers because only a thin covering of horn protects the sensitive structures of the foot. Degree of sensitivity to hoof testers is important and is learned through experience. Hoof tester examination is best done when an assistant holds the foot (R.M.A.). Hoof testers can be placed carefully on front and hind feet, and slight differences in positioning make a significant difference. Left and right feet should be compared at least twice before reaching conclusions. The diagnosis of palmar heel pain can be confirmed readily by selective medial or lateral palmar digital analgesia. Horses with a naturally wide gait, or with carpal pain, bruise the medial quarters and can have concomitant foot pain. Acquired bruises of this nature are difficult to treat in horses with wide gaits without lameness and without managing primary lameness in those with carpal pain. In most horses with foot lameness, diagnosis is made with clinical findings and diagnostic analgesia. If abnormalities of the sole or hoof wall cannot be found, radiographs are occasionally necessary (P.J.M.). In most horses without fracture, lameness resolves in 2 to 3 weeks with specific therapy and the administration of non-steroidal anti-inflammatory drugs (NSAIDs).

Bruised Heels and Quarters

Lameness caused by bruised heels or quarters is often mild, and horses usually are kept in training. More often than not, little heat is associated with a bruised quarter. Mild dilation of one or both digital arteries and hoof tester sensitivity are the most common signs. The best treatment is rest, however. The foot should be examined for any conformational or shoeing faults; sheared heels or unbalanced feet are common causes of bruised quarters. Horses with toed-out conformation often bruise the medial heel (M.W.C.). Corrective shoeing is really the only treatment option. Steel shoes distribute force along the hoof wall evenly and can be applied to horses in training but not racing. Bonded shoes can be applied to horses that are racing. If the foot is warm, the horse should stand in iced water, but if the foot is normal temperature, the horse should stand in foot tub of hot water with Epsom salts. A poultice of warm, cooked flax seed or commercially available products such as Animalintex (3M Animal Care Products, St. Paul, MN) should be applied. A common practice of applying hoof-hardening agents such as iodine and turpentine should be avoided, because hard hooves bruise easily.

Abscesses

Foot abscesses are a common problem, particularly during the wet seasons. A foot abscess is the most common eventual diagnosis when a horse is found three-legged in the stall in the morning without a recent history of hard work or racing. TBs are prone to foot abscesses because of the manner and frequency of shoeing. Foot abscesses occur most commonly in the medial quarter, where bruising is also most common. Sole abscesses not involving the quarter are uncommon, take more time to resolve, and cause different clinical signs than do abscessed quarters. Although abscesses in the heel or quarter usually are located easily and precisely with hoof testers, a sole abscess can produce a large area of soreness. Identifying the specific area of pain is difficult.

Horses with foot abscesses are best managed with hot water baths with Epsom salts and poulticing. The longer the horse stands in hot water with Epsom salts, the better. Ideally, the shoe should be removed, and the abscess should be allowed to open naturally. Usually more damage is done to the hoof wall by attempting to open the abscess manually than by allowing it to open naturally. Probing the white line to identify an abscessed area can be worthwhile. Sole abscesses are more likely to require manual opening and debridement than are abscessed quarters. The integrity of the hoof wall needs to be evaluated and preserved, if possible, but wet, infected areas need to be exposed, opened, and dried. Foot abscesses or infections also can originate from grabbed quarters, which occur frequently in horses that stumble out of the starting gate. When grabbed, the hoof wall of the quarter may separate at the heel bulb or quarter, well down the foot. The opened area becomes contaminated with track dirt, and infection can occur several days to weeks after the original injury. Fortunately a pathway for drainage is already present.

Quarter Cracks

Quarter cracks are common for the same reasons as bruising and abscessation. The quarters and heels take continual pounding, particularly in a TB racehorse with poor hoof wall support. Quarter cracks may be caused by poor hoof balance but most commonly result from innate hoof weakness. Farrier-incurred hoof imbalance can contribute to the development of quarter cracks, but most commonly a single horse in a stable has numerous cracks. Horses with an initial crack are prone to develop subsequent cracks in the same hoof or other hooves. A horse ran successfully with seven quarter crack patches at one time (R.M.A.). If identified early, quarter cracks can be patched readily with acrylic or epoxy. The goal is to stabilize the hoof wall and eliminate uneven movement. Mild cracks should be patched if any movement occurs at all. As little patching material as possible should be used to stabilize the hoof wall. If a quarter crack is infected, a drainage path needs to be established. Some epoxies are much harder than the natural hoof wall and trapped infection eventually drains through natural tissues rather than the patch.

Osteoarthritis of the Distal Interphalangeal Joint

Most lameness conditions of the foot seen in other sport horses also occur in racing TBs. Considerable controversy exists over the frequency of osteoarthritis of the distal interphalangeal joint. Some veterinarians diagnose the problem regularly, whereas others never recognize it. In our experience, osteoarthritis of the distal interphalangeal joint is uncommon. Effusion is the most common clinical sign. Osteophytes may be seen on the extensor process of the distal phalanx. Frequently, horses with bilateral osteoarthritis of the distal interphalangeal joint have poor performance rather than overt lameness, and lameness is worse at the end of a race (M.W.C.).

Navicular Syndrome

Navicular disease and navicular bursitis are unusual to rare conditions in the TB racehorse (P.J.M.). Lameness can be localized using palmar digital analgesia, but most often horses have bruises, cracks, and abscesses, and those with navicular syndrome are unusual. One of us (M.W.C.) diagnoses navicular bursitis commonly. Successful management of this type of palmar heel pain has been achieved by injecting the digital cushion with orgotein (Palosein) and Sarapin and methylprednisolone acetate, applying a bar shoe, increasing heel angle, and giving NSAIDs. Intra-articular injection of the distal interphalangeal joint with hyaluronan and corticosteroids affects numerous structures in the foot and improves horses with navicular syndrome or osteoarthritis of the distal interphalangeal joint.

Distal Phalanx Fractures

Fractures of the distal phalanx occur occasionally. Most fractures are non-articular palmar process (wing) fracture, and horses do well with the application of a bar shoe. Articular wing fractures are more serious. Extensor process fragments are rare and can be removed arthroscopically.

Palmar digital neurectomy is permitted in most racing jurisdictions, but it must be reported to the race office. Indications for neurectomy are few, but occasionally a horse with a distal phalanx fracture and chronic pain is a candidate. Occasionally, palmar digital neurectomy is performed in horses with recurrent quarter cracks to eliminate pain, but the procedure does nothing to solve the original problem. Surgical neurectomy should be performed because percutaneous techniques are often ineffective.

Lameness of the Fetlock Joint

The metacarpophalangeal (fetlock) joint, carpus, and tarsus are the most important joints associated with lameness in racing TBs, especially the metacarpophalangeal joint. Clinical findings of fetlock joint lameness usually include effusion, heat, a positive response to flexion, and elimination of lameness using intra-articular analgesia. However, in some horses with subchondral bone pain, perineural blocks are most effective. Horses also can have substantial lameness associated with the fetlock joint without localizing signs. The most common lameness conditions of the fetlock can be divided into four categories: synovitis, distal palmar McIII or MtIII disease, fractures, and osteoarthritis.

Synovitis

Fetlock joint pain associated with effusion, pain on joint manipulation, a positive response to a distal limb flexion test, and moderate lameness is common, but horses generally respond well to intra-articular treatment with hyaluronan and corticosteroids, combined with systemic treatment with polysulfated glycosaminoglycans (PSGAGs). Intravenous hyaluronan may be useful in these horses. However, recurrence of clinical signs indicates that the horse should be removed from training, because continued training may result in chronic problems (M.W.C.). Firing and blistering may be useful.

Distal Third Metacarpal/Metatarsal Bone Disease

Stress and non-adaptive remodeling, a form of stress-related bone injury, of the distal aspects of McIII and MtIII is a common cause of lameness. During training and racing, these areas undergoe considerable modeling and remodeling, change shape, and are at risk to develop fracture and cartilage damage. Scintigraphic examination reveals focal areas of increased radiopharmaceutical uptake (IRU) and is the imaging modality of choice for diagnosis, because radiographs are often negative. Ultimately, damage to the distal McIII and MtIII leads to osteoarthritis and fracture. Early in the course of the disease pain originates from subchondral bone, without effusion or heat. However, intra-articular analgesia is usually effective in eliminating pain. In some horses all fetlock joints are affected simultaneously, and the horse appears sore all over. Once pain is abolished in one limb, lameness appears in the contralateral limb. Distal McIII/MtIII disease is so prevalent that some veterinarians first perform intra-articular analgesia of the fetlock

joint rather than beginning with palmar/plantar digital analgesia. As the disease progresses, radiographic changes can include flattening of distal McIII/MtIII, sclerosis and radiolucency, and when severe, pitting of McIII/MtIII. A form of severe flattening of the distal McIII has been recognized that may result in severe osteoarthritis by the end of the 3-year-old year (M.W.C.). Negative radiographic findings do not eliminate this disease as a source of pain, and scintigraphy is more sensitive for its detection. Areas of IRU can represent subchondral bone damage from non-adaptive remodeling or fracture, and a combination of imaging modalities is necessary to differentiate these conditions.

Osteochondral Fragmentation

Osteochondral fragments (chip fractures) of the proximal, dorsal aspect of the proximal phalanx are common in TB racehorses. Fragments are more often medial than lateral, but they can occur biaxially and bilaterally. Often disease of the fetlock joint occurs before fragments are recognized. Subtle radiographic changes in the silhouette of the dorsal rim of the proximal phalanx are important and indicate this area is experiencing stress. The distal dorsal aspect of McIII at the joint capsule attachment can be injured at the same time that chip fractures are seen.

Once fractures are recognized, arthroscopic surgery should be performed. After surgery the horse can be back in training as soon as 6 weeks if cartilage damage is minimal. Horses with small fragments can be managed conservatively using local ice therapy, NSAIDs, and a reduction in exercise intensity. Inflammation (effusion) subsides within 7 to 10 days and training resumes. Small osteochondral fragments appear to demineralize and no longer irritate the joint. If inflammation and lameness recur, the horse should be taken out of training, and surgery is recommended. Intra-articular injection of corticosteroids and hyaluronan is one option and is effective at reducing inflammation, but if training and racing continue, deep scoring of the articular cartilage of distal McIII occurs and leads to osteoarthritis. If the goal is long-term racing, surgery should always be recommended.

Osteoarthritis

Osteoarthritis is a common problem and usually is associated with fractures of the proximal phalanx or palmar/plantar McIII/MtIII disease, but it can develop as a primary condition. Arthroscopic examination often reveals considerable articular cartilage scoring and thinning, or complete erosions through the articular cartilage, without any evidence of an associated fracture. Because osteoarthritis is chronic and cartilage cannot regenerate, the disease must be identified early so preventative measures can be taken. Judicious use of NSAIDs and intramuscular PSGAGs is the best long-term treatment for osteoarthritis of the fetlock joint. If present, fractures need to be repaired or fragments removed. Young horses should be taken out of training and allowed to mature. Immature horses are particularly prone to overextension injury of the fetlock joint. Some horses may require PSGAGs throughout the racing career. Oral supplements may be beneficial, but intramuscular administration is best. Repeated use of intra-articular corticosteroids exacerbates chronic osteoarthritis, but whether this is a direct result of the medication or simply allows a horse to continue in training and racing is unknown. Unfortunately, heat, effusion, positive response to flexion, and lameness resulting from osteoarthritis need to be treated, because horses are expected to perform. Intra-articular injections are unavoidable, and a combination of hyaluronan and corticosteroids is preferred (R.M.A.). Horses with recurrent synovitis may need additional injections in combination with 2 to 3 weeks of rest (M.W.C.). In spite of information to the contrary, methylprednisolone acetate is the drug of choice, because if used prudently at well spaced intervals, the drug is preferable to repeated injections of shorter-acting corticosteroids (R.M.A.). Intra-articular injections of PSGAGs every 2 weeks are beneficial in horses with chronic osteoarthritis (P.J.M.).

Other Conditions

Distal McIII/MtIII condylar fractures, PSB fractures, sesamoiditis, and proximal phalanx fractures are discussed in Chapters 37 and 47. Distal McIII/MtIII condylar fractures often result from non-adaptive remodeling and may be more common in certain racetrack practices than others. One of us (P.J.M.) includes these fractures as a top 10 lameness condition. Prognosis is much better in horses with incomplete fractures, with or without surgery. One author (P.J.M.) recommends surgery in horses with fractures longer than 4 to 5 cm above the joint surface.

Lameness of the Carpus

The carpus is similar to the fetlock joint in several ways. The third carpal bone undergoes considerable modeling and remodeling with associated subchondral bone pain similar to distal palmar/plantar McIII/MtIII. Fractures and osteoarthritis are often the end-stage result of this process of stress-related bone injury. The response of the third carpal bone to stress-related bone injury is similar to that of cortical bone.

Non-Adaptive Remodeling of the Third Carpal and Radial Carpal Bones

The third carpal bone and other carpal bones such as the radial carpal bone become sclerotic (model) to withstand the stress of training and racing. The change in the third carpal bone is seen on the skyline radiograph as sclerosis of the radial facet. Sclerotic bone becomes painful if the condition of stress remodeling becomes pathological, called *non-adaptive remodeling.* If training and racing continue, bone loss or lysis, or fracture occur. Third carpal bone subchondral bone pain is common, particularly in young horses, but because pain involves bone, no treatment other than reducing training and racing intensity is available.

Diagnosis of third carpal bone subchondral bone pain can be challenging, because many young horses do not develop effusion. Heat may occur over the dorsal aspect of the carpus, and horses move wide and tend to abduct the limb during advancement (M.W.C.). Response to flexion varies, but in horses with subchondral bone pain, response is often negative. Diagnostic analgesia is essential for diagnosis. Careful interpretation of results of diagnostic analgesia is necessary because inadvertently blocking the proximal palmar metacarpal region with middle carpal joint analgesia and vice versa is easy (M.W.C.). The middle carpal and antebrachiocarpal joints always should be blocked separately. Radiographic changes of sclerosis and later radiolucency can be seen with good-quality skyline views, but they are missed easily with poorly positioned and exposed views. To assess radiographic exposure, the veterinarian should evaluate the second and fourth carpal bones. These bones rarely have alterations in trabecular pattern, and both bones should be clearly visible on the skyline view. Scintigraphy is an excellent tool with which to diagnose stress-related bone injuries of the third carpal bone and other bones, and although not needed in many horses, scintigraphy assists in early diagnosis and helps convince skeptical trainers and owners. Sclerosis of the third carpal bone changes the mechanical properties of bone, and sclerotic bone is brittle and at risk of fracturing. Few osteochondral fragments, small (chip fractures) or large (slab fractures), of the third carpal bone occur in normal bone. At the time of arthroscopic surgery to repair a third carpal bone frontal slab fracture, a wedge-shaped piece of sclerotic and often necrotic bone often can be found between the fracture fragment and parent third carpal bone.

Once sclerosis of the third carpal bone develops, treatment is difficult. Rest may not help remodel dense bone, so prevention is important. The training programs of young TBs with

evidence of third carpal bone sclerosis should be modified, but trainers are often unwilling. Although little evidence supports using isoxsuprine or aspirin to improve blood flow, some veterinarians prescribe these medications.

Carpal Fractures

Osteochondral fragmentation of the carpus is a common problem. Clinical signs are unique for each fracture type, and radiographic examination is most important. Horses with distal radial carpal bone fractures exhibit pain on direct palpation of the fracture site and often have effusion of the middle carpal joint. Horses with third carpal bone pain and fractures are unwilling to rock on the limb, evaluated by picking up the contralateral limb, and forcing the horse to rock on the affected limb by putting side-to-side pressure against the horse's body. Horses with distal, lateral radius fractures generally have pain on direct palpation. Horses with proximal intermediate carpal and radial carpal bone fractures may be surprisingly lame, without obvious palpable abnormalities.

A rare fracture, but one to keep in mind, is a sagittal fracture of the proximal aspect of the intermediate carpal bone (M.W.C.). Horses train and race but come back to the barn obviously lame (grade 3 of 5). When walking and jogging, they exhibit a stiff-legged gait and significant abduction during advancement. Horses respond positively to carpal flexion, and lameness is abolished using antebrachiocarpal analgesia. Intra-articular treatment does not improve lameness. The skyline view of the proximal row of carpal bones is mandatory for diagnosis, because fractures will be missed on other views. Early arthroscopic surgery is recommended, because osteoarthritis can develop if horses are continued in work with a fracture.

Arthroscopic surgery has improved the management of carpal joint lameness greatly. Removal of small osteochondral fragments and repair of large fragments substantially reduces the severity of osteoarthritis. PSGAGs can be useful in limiting the development of osteoarthritis, particularly if pain is originating from the third carpal bone. After surgery in horses with carpal osteochondral fragmentation, one of us (M.W.C.) recommends hyaluronan injection 2 to 3 weeks later. Horses with fractures of the middle carpal joint need additional rest compared with horses with antebrachiocarpal joint fractures (M.W.C.). One of us (P.J.M.) prefers to manage horses with incomplete or non-displaced third carpal bone slab fractures conservatively by giving 60 days of rest and re-evaluating the horse. The prognosis for TB racehorses with displaced third carpal bone slab fractures even with surgery is guarded to poor. Horses with fractures extending into the weight-bearing surface of carpal bones more than 0.5 cm have a poor prognosis. Horses with recurrent and chronic osteoarthritis appear to benefit from topical blisters and 3 or more months of rest.

Osteoarthritis

In young horses with early signs of osteoarthritis, rest is recommended. In horses with chronic osteoarthritis but that are able to race, intra-articular injection of a combination of hyaluronan and PSGAG produces better results than does injection of either product alone (M.W.C.). In horses with mild or moderate lameness, intra-articular injection of hyaluronan and triamcinolone acetonide 5 to 7 days before racing decreases clinical signs for 6 to 8 weeks. Most horses exhibiting carpal lameness appear to benefit from the intramuscular administration of PSGAG once every 4 days for seven to eight treatments, and intravenous injection of hyaluronan appears beneficial before racing.

Rest should be recommended for young horses with early osteoarthritis even though recurrence of signs is common. NSAIDs are useful in managing pain in horses with osteoarthritis of the carpus.

Intercarpal Ligament Damage

Because the complex carpal joint is highly dynamic and moveable, fractures and soft tissue damage can lead to osteoarthritis. Although fractures are more common, recently injury of the medial palmar intercarpal ligament has been recognized (see Chapter 39).

Suspensory Desmitis

Proximal Suspensory Desmitis

Suspensory desmitis is a most important cause of lameness in the TB racehorse and previously has been underestimated. Suspensory desmitis is much more common in the forelimb than in the hindlimb (P.J.M.). Hindlimb proximal suspensory desmitis (PSD) is difficult to diagnose because horses have a stiff, hopping-type gait similar to that in horses with tibial stress fractures, and heat and swelling are unusual (M.W.C.). Lameness in horses with forelimb PSD is similar to that in horses with carpal disease. Horses travel wide, with a shortened cranial phase of the stride, and are worse with the limb on the outside of a circle. Ultrasonographic examination has improved our understanding of many soft tissue injuries, but compared with superficial digital flexor tendonitis, which always has been well recognized, PSD is recently recognized. Conformational faults such as offset knees and upright pasterns and fetlock joints predispose horses to PSD. PSD is most commonly a 2-year-old lameness condition, perhaps caused by immaturity, and can be diagnosed by manual palpation in some horses, but that is the exception rather than the rule (M.W.C.). More often, horses with PSD require diagnostic analgesia, and one author (R.M.A.) uses the lateral palmar block, the site for which is just below the accessory carpal bone. Using the lateral palmar block it is unlikely to inadvertently cause analgesia of the carpometacarpal and middle carpal joints. In many horses lameness thought to originate from PSD after a positive response to high palmar analgesia, was later found to originate from the carpus (M.W.C.).

Considerable variation occurs in the ultrasonographic appearance of the normal and diseased proximal SL. Overt tears are easy to diagnose. However, hypoechoic areas can be identified in sound horses. Furthermore, bony pathological conditions of the proximal, palmar aspect of McIII can be seen in horses without obvious tearing of the SL. Avulsion fractures of McIII are diagnosed in horses that develop acute, severe lameness abolished by lateral palmar analgesia. Scintigraphy is the best way to diagnose bony injury of proximal McIII in horses without ultrasonographic evidence of PSD and negative radiographic findings. With avulsion fracture comes focal, intense IRU, but many horses have diffuse IRU of the proximal aspect of McIII. Whether these horses have chronic avulsion injury or whether this represents stress reaction or other injury of proximal McIII is unknown. Regardless, horses with bony injury of proximal, palmar McIII have a good prognosis if given a minimum of 120 days of rest. Horses with PSD often can be managed and allowed to continue racing. Local infiltration with corticosteroids or other products is of questionable benefit, and systemic therapy is more effective and rewarding (R.M.A.). Others disagree and recommend local injection with triamcinolone acetonide in horses with mild PSD (P.J.M.). The combination of Sarapin, methylprednisolone acetate, and in some horses Palosein has been successful, and 2-year-old horses may never take another lame step (M.W.C.). Systemic corticosteroids and NSAIDs reduce inflammation enough to relieve the lameness. Where regulations permit, phenylbutazone and triamcinolone acetonide (12 to 18 mg intramuscularly) can be administered 3 to 5 days before racing. A good alternative is two boluses of Naquasone (a combination of the diuretic trichlormethiazide [200 mg] and dexamethasone [5 mg]) 48 hours before racing, if permitted by the rules of racing. Triamcinolone lasts longer, but Naquasone contains a diuretic that is also useful for reducing swelling. An ice boot or an ice tub is beneficial.

Horses in which lameness is mild when trotted in hand or even under tack but refuse to give a full effort toward the end of a race should be given rest.

Corrective shoeing can make a difference in horses with PSD. In fact, PSD may be secondary to lameness of the foot (M.W.C.). The toe should be shortened, and the shoe should have only minimal toe grabs. Horses with PSD do not develop catastrophic disruption of the suspensory apparatus but return from the race sore.

Suspensory Branch Desmitis

Suspensory branch desmitis is a different situation and can easily lead to catastrophic breakdown if horses are managed improperly. Management of suspensory branch desmitis with infiltration of corticosteroids in a TB racehorse is a high-risk treatment, with no therapeutic benefit to the patient. Systemic anti-inflammatory therapy similar to the approach described for PSD is useful for horses with suspensory branch desmitis, but the horse should not be raced if the SL remains hot and painful. Suspensory branch desmitis is a dangerous injury, and current research is investigating the correlation between suspensory desmitis and condylar fractures in horses with catastrophic breakdown.

In horses with suspensory branch desmitis the splint bones should be evaluated carefully. Radiographs to check for fracture, flaring, or thickening of the second and fourth metacarpal bones should be obtained. A clear relationship exists between suspensory branch desmitis and pathological conditions of the splint bone. Splint ostectomy is recommended in horses with fractured, flared, or thickened splint bones, not just in those with fracture.

Mid-Body Desmitis

Horses with mid-body desmitis can be managed similarly to those with PSD, but if desmitis extends distally into the branches, the risk of catastrophic breakdown exists. Horses with suspensory desmitis may benefit from rest (45 to 120 days) and blistering (P.J.M.).

Bucked Shins: Dorsal Metacarpal Disease

Bucked shins or dorsal metacarpal disease (periostitis) is common but readily manageable. This condition is simply the mismatching of exercise with modeling and remodeling of McIII necessary for the bone to withstand the rigors of training and racing. Bucked shins are most commonly seen in young horses early in training. The simplest and best treatment is to modify the training program to match the horse. With bucked shins, horses are usually only mildly lame after exercise, unilaterally or bilaterally (P.J.M.). Bucked shins are common in young horses with other primary lameness conditions, particularly of the hindlimbs (M.W.C.). Heat and pain over the dorsal cortex are commonly found, but care must be taken not to place pressure on the palmar metacarpal structures while palpating the dorsal cortex of McIII (P.J.M.). One of us (M.W.C.) feels that careful palpation of the palmar cortex is useful in identifying McIII disease. Clinical signs are usually sufficient for diagnosis, but low or high palmar nerve blocks, infiltration of the nutrient foramen of McIII, or local infiltration of local anesthetic solution occasionally is required (M.W.C.). Radiographs reveal a typical modeling response, but in some horses with fracture xeroradiographs or computed radiographs should be obtained, because fractures may be missed on plain films (P.J.M.). Scintigraphic examination can be useful, mostly in horses with dorsal cortical fracture (M.W.C.).

Great strides have been made in changing training techniques to manage TB racehorses with bucked shins. This requires close monitoring of the dorsal cortex of McIII. Overall, the incidence of authentic dorsal cortical fractures has decreased greatly. Although all trainers have horses with bucked shins, those that still have major problems train in the old-fashioned style.

Once inflammation is noticed, ice, NSAIDs, and topical cooling muds, such as Uptite poultice (Uptite Co., Lawrence, MA), are often all that is necessary if training intensity is reduced and modified. Once periosteum becomes hot, thickened, and sore over a large portion of the dorsal cortex of McIII, modifying training is usually too late. Training should be stopped, and when necessary thermocautery may still be the best treatment, once inflammation has subsided (R.M.A., P.J.M., and M.W.C.). When done properly thermocautery is humane and effective. An old-time racetrack practitioner was asked a few years ago if he still fires horses and if so why? His response was simple: "I can tell you in two words: It works." The real problem with thermocautery is perception. Most persons who adamantly are opposed to thermocautery generally have no experience with the procedure. Regardless, alternative treatments are available, but none in one author's opinion work as well as thermocautery (R.M.A.). All treatments require extended periods of rest or light training. Others prefer a relatively recent technique called periosteal scratching. A 16-gauge needle is used to create linear incisions of the periosteum using aseptic technique. This procedure, as with thermocautery, is combined with rest and is done after the inflammation has subsided (P.J.M.). Prognosis after periosteal scratching is estimated at 70% (M.W.C.).

Bucked shins can progress to dorsal cortical (stress) fracture if horses with periostitis are forced to continue training. Stress fractures occur most commonly on the dorsolateral aspect of McIII, but those located in the distal third to distal fourth of McIII are most problematic. Fractures in this location under the extensor tendons can be difficult to palpate, but they may be extensive.

Horses with bucked shins should not be lame at the jog 1 to 2 days after the last workout, but if lameness persists, a dorsal cortical fracture should be suspected. Radiographs should be obtained. Success in treating horses with dorsal cortical fracture relates directly to the duration of fracture. Horses with acute fractures are treated more easily than those with chronic fractures. In horses with acute fractures, rest, with or without thermocautery, is successful. Chronic dorsal cortical fractures are essentially non-unions and heal slowly or not at all and require surgery. Cortical drilling (forage, osteostixis) using numerous small-diameter holes drilled across the fracture line is effective and is one author's treatment of choice (R.M.A.). Rarely a cortical bone screw placed in lag fashion or as a positional screw is needed. Whether compression is needed remains unanswered. Implants must be removed before training begins. Extracorporeal shock wave therapy appears promising for the management of dorsal cortical fractures of McIII (M.W.R.).

Superficial Digital Flexor Tendonitis

Superficial digital flexor tendonitis usually is advanced before lameness is observed and diagnosis is made. Lameness is one of the last clinical signs observed. Superficial digital flexor tendonitis is usually a career-threatening or career-ending injury, and estimates indicate that superficial digital flexor tendonitis is the single most common injury ending a TB racehorse's career. However, many horses with superficial digital flexor tendonitis return to racing or, on occasion, race through the injury. One author (R.M.A.) feels strongly that local infiltration of corticosteroids and continued racing are contraindicated. Intralesional injection of corticosteroids can cause tendon necrosis and result in complete rupture of the superficial digital flexor tendon (SDFT). Some horses may be able to race after treatment with systemic corticosteroids, NSAIDs, and ice therapy. The SDFT will set up on occasion, but that is certainly an exception, and horses fall in value.

Recognizing superficial digital flexor tendonitis before overt fiber tearing occurs has distinct advantages. To recognize tendonitis early, horses must be monitored closely, and ultra-

sonographic examination must be performed at the earliest indication of inflammation. Heat and swelling are early clinical signs but may not indicate necessarily the tendon is involved, because peritendonous injury can cause similar signs. *The key is pain on palpation of the suspect tendon*. Pain, even without obvious heat or swelling, is an important clinical finding. Ultrasonographic examination must include cross-sectional area measurements, because subtle enlargement of the SDFT precedes fiber tearing. Once recognized, horses with early superficial digital flexor tendonitis should be given rest, or at least the training intensity should be reduced.

One author (R.M.A.) prefers to manage horses with core lesions of the SDFT with tendon splitting. The surgery can be done with the horse standing and is inexpensive, and aftercare is minimal. To perform tendon splitting, a core lesion must be present, and the earlier the procedure is done, the better. A double-edged tenotome is used. The tendon fibers are split longitudinally with five rows of about 15 percutaneous stab incisions each. After surgery horses are surprisingly sound. β-Aminoproprionitrile fumarate also has been used successfully but requires a complex injection and exercise regimen, making the entire treatment expensive and impractical. Horses with superficial tearing along the edge of the SDFT have a poor prognosis with any treatment and may be the only candidates for peritendonous injection of corticosteroids, provided the horse is removed from training and rested.

Horses with superficial digital flexor tendonitis should have as much time off as possible. However, if owners and trainers are unwilling to give 6 to 8 months of rest before the horse returns to training, any treatment is a waste of time. One of us (P.J.M.) has stopped recommending any form of surgery or injections and simply recommends walking rest for 4 to 16 weeks. A blister is applied at least twice, and tendon healing is monitored with ultrasonography. Even with this approach, recurrence rate is 60% to 80%. The trainer plays a major role in rehabilitating horses with superficial digital flexor tendonitis. Those that are successful give the horse the most time off and are patient getting the horse fit, before starting hard work.

Tibial Stress Fractures

Tibial stress fractures are the most common cause of acute, unilateral hindlimb lameness in the TB racehorse. Lameness from tibial stress fractures usually is recognized after a hard workout or after breaking from the gate. Lameness can be severe, and the horse may not bear weight on the limb. Tibial stress fractures are usually unilateral, but bilateral fractures can cause unusual hindlimb lameness (P.J.M.). Similar to humeral stress fractures, tibial stress fractures often occur after a horse has had 60 to 90 days of training, often after a period of rest for an unrelated cause. Two of us (R.M.A. and P.J.M.) do not find manual palpation of the tibia useful diagnostically, but one of us (M.W.C.) finds deep palpation and tibial percussion helpful. Scintigraphy is the diagnostic modality of choice. Less than 50% of horses diagnosed with tibial stress fractures using scintigraphy have radiographically apparent fractures, even if follow-up examination is performed after 2 weeks. If scintigraphy is unavailable, even small areas of periosteal, endosteal, or cortical change should be considered important, if clinical signs suggest tibial stress fracture. Tibial stress fractures are located most commonly on the caudolateral cortex, proximally or mid-shaft, but can occur caudolaterally and caudomedially distally. Bilateral tibial stress fractures are occasionally seen, even in horses with unilateral hindlimb lameness. One of us (P.J.M.) has examined a number of horses with clinical signs consistent with tibial stress fracture but in which scintigraphic examination was negative. Horses returned to the track and developed complete tibial fractures. Now this author (P.J.M.) recommends re-examination in 3 weeks. False-negative results are unusual in horses with stress-related bone injuries unless fractures are located medially and only lateral scintigraphic views are obtained (M.W.R.).

Horses with tibial stress fractures are given 90 to 120 days of rest. The prognosis is excellent. The tibia is well-muscled and has a good blood supply and callus formation does not interfere with nearby structures. Complications develop when horses have spiral fractures and severe lameness or when horses with unrecognized tibial stress fractures are trained or raced. Catastrophic failure can result. Tibial stress fractures can recur if horses are given inadequate time for healing, but this is otherwise unusual.

Some horses with only mild lameness at the time of initial diagnosis and in which lameness rapidly resolved can be kept in light work. In these horses scintigraphic examination reveals mild IRU and radiographs are negative. Horses are given a minimum of 60 days without hard work, but if lameness recurs, 90 to 120 days of additional rest is recommended.

Tibial stress fractures were misdiagnosed as stifle lameness for years at some racetracks and the same error is still made today. Tibial stress fracture is a relatively recent diagnosis, but even with the introduction of high-quality non-portable radiography equipment at referral centers, the diagnosis was difficult to make because radiographs are often negative and clinicians have to isolate pain, a difficult task in many TB racehorses. Scintigraphy has taught us that tibial stress fracture is an important and frequent cause of hindlimb lameness in TB racehorses.

Distal Hock Joint Pain

Distal hock joint pain, or distal tarsitis, is a common cause of hindlimb lameness. One of us (M.W.C.) feels strongly that the hock joint is the most important articular structure in equine locomotion. Compensatory lameness caused by primary distal hock joint pain is important. The skeleton of the TB foundation sire Eclipse at the Racing Museum in Newmarket and the skeleton from an extinct breed from the La Brea Tar Pits in Southern California reveal extensive osteoarthritic changes. Radiographic changes in the tarsometatarsal joint of young horses are common and can be found in yearlings before training begins. The importance of osteophyte formation involving the dorsal proximal aspect of MtIII, often called juvenile spavin, is difficult to evaluate without signs of lameness.

Horses with distal hock joint pain have a typical gait. The hindlimbs travel close together and may even cross midline. Horses with bilateral lameness may not show overt lameness, but they are observed to be not right behind (P.J.M.). Some horses may break from the gait slowly, may not switch leads properly behind, or cross fire and develop abrasions on the medial aspect of the tarsus (M.W.C.). Horses often wear the outside aspect of the toe of the shoe. Horses that are positive to the Churchill test likely have distal hock joint pain involving the tarsometatarsal joint (R.M.A.). Some clinicians place emphasis on upper limb flexion, and certainly the response rate is high, but this test lacks specificity. Diagnostic analgesia should be performed to localize lameness to the distal hock joints. Distal hock joint pain can cause lameness without radiographic changes, particularly in young horses, but radiographic changes can be present in horses with pain originating elsewhere. Involvement of the centrodistal (distal intertarsal) joint is difficult to assess without radiographic and scintigraphic examinations. Nuclear scintigraphy is useful to identify slab fractures of the third and central tarsal bones. Oddly, horses with radiographically evident osteophyte formation may show little IRU.

The simplest and best treatment is intra-articular injection of methylprednisolone acetate (100 mg) into each affected joint. The centrodistal and tarsometatarsal joints are small, and injecting more than 3 ml of medication without encountering resistance is often difficult. Using hyaluronan gives little

advantage, because the joints are low-motion joints (R.M.A.). However, two of us (P.J.M. and M.W.C.) use hyaluronan (20 mg) and methylprednisolone acetate (40 mg), and one of us (M.W.C.) feels strongly that the combination of hyaluronan and corticosteroids prolongs the racing careers of affected horses by delaying progression of osteoarthritis. Rarely the cunean bursa is injected. There appear to be few complications following repeated injections of corticosteroids into low motion joints, such as the centrodistal and tarsometatarsal joints. If the diagnosis is correct, the response to therapy is rewarding. However, lameness recurring rapidly after one or two injections may indicate that the primary source of pain is elsewhere or that subchondral pain is a substantial component of lameness. Corrective shoeing may help horses with distal hock joint pain. A high hoof angle (≥54°) and the application of slight turndown shoes may help horses push off and prevent sliding. In horses with primary, chronic distal hock joint pain turnout or complete rest actually may worsen lameness, and better results are achieved in these horses by maintaining a low level of training (M.W.C.).

The tarsocrural joint usually is not involved, but if effusion exists, one author (R.M.A.) injects the joint with hyaluronan and corticosteroids, because the joint is a high-motion joint. If dark synovial fluid is obtained during arthrocentesis of the tarsocrural joint, cartilage damage should be suspected (M.W.C.). Repeated injections of corticosteroids into the tarsocrural joint should be avoided.

Myositis

Exertional rhabdomyolysis (ER) and non-specific localized myositis frequently are overlooked sources of lameness in TB racehorses. ER is a common problem, especially in young horses, and primarily is seen in fillies. Male horses can be affected, but much less frequently. Diagnosis usually is not a challenge if a veterinarian observes a hot, sweaty horse with obvious muscle cramps. Lameness is mostly bilateral, transient after exercise, and resolves within a few hours. Some horses have unilateral lameness. Colts often develop unilateral forelimb ER, resembling other causes of upper limb pain. Horses may have generalized whole body stiffness if ER is unrecognized and untreated. Serum levels of creatine kinase and aspartate aminotransferase are necessary to diagnose ER definitively. Horses at risk are given acetylpromazine (5 to 15 mg, intravenously) before exercise to prevent ER. Dantrolene (500 mg, PO) given 4 hours before exercise is used in horses that have had serious episodes of ER and have missed training.

Interestingly, some horses are found to have IRU during bone (delayed) phase scintigraphic imaging, and serum muscle enzyme levels may be normal or only mildly elevated. In some horses a history of previous ER is known, but others have no known history of ER. Large muscles or individual muscle bellies within muscles can be affected. Lameness associated with IRU of skeletal muscles may or may not be seen and depends on the muscles involved. Muscles of the hindlimb most commonly are affected, such as the gluteal, biceps femoris, and semitendinosus muscles, but forelimb or trunk muscles can be involved. Serum muscle enzyme levels are usually within the normal range.

Gluteal myositis occurs in TB racehorses. Lameness is characterized by a reluctance to reach forward during the cranial phase of the stride and to push off to extend the hindlimbs at the end of the stride. Lameness may result from a loose, cuppy racetrack that breaks away from the horse. Whether the trochanteric bursa is involved is unclear. Pain is best identified by using direct digital pressure over the greater trochanter of the femur. Local pain is eliminated with injection of corticosteroids (methylprednisolone acetate, 100 mg/site) with an 8-cm, 18-gauge spinal needle into the middle gluteal muscle. The needle is directed horizontally at a 45° angle to the sagittal plane toward the opposite tuber coxae. One author (R.M.A.) does not make any effort to inject the trochanteric bursa.

The lumbar region is prone to myositis. Diagnosis is made by palpation of pain and recognition of hindlimb stiffness. An effective treatment is methocarbamol (10 gm, PO, tid). This high dose is effective with no substantial side effects. The withdrawal time for methocarbamol can be long in some racing jurisdictions. Alternatively the affected muscles can be injected with corticosteroids diluted with Sarapin (2.5 ml/site of a mixture of 50 ml Sarapin and 200 mg methylprednisolone acetate).

Other Stress Fractures

TB racehorses are prone to stress-related bone injuries of several sites other than the tibia, including the humerus, pelvis, and scapula. Humeral stress fractures account for an estimated 5% of the fatal musculoskeletal injuries in California. Horses typically develop lameness between 45 and 90 days after returning to training, following rest for an unrelated cause. Acute lameness quickly abates within 1 to 2 days, typical of many horses with stress fractures. The cranial phase of the stride is shortened, and the horse may drag the forelimb. This fracture is dangerous. When humeral stress fractures displace, they spiral and invariably cause the destruction of the horse on humane grounds. However, when identified before displacement, fractures heal well without complications. Fractures are non-articular and rarely recur. Horses are given 90 to 120 days of rest. Scintigraphic examination is the best method to diagnose humeral stress fractures, because location precludes adequate radiographic examination in many horses. Humeral stress fractures occur medially and involve the proximal, caudal cortex immediately below the humeral head; the caudal, distal cortex; and the cranial, distal cortex. Radiographs may show proliferative changes and fracture lines in horses with distal, craniomedial fractures, but in other sites neither the fracture line nor proliferative changes often can be seen. Proximally, any loss of distinction in the proximal, caudal humerus should be considered diagnostic for a humeral stress fracture until proved otherwise.

Stress fractures of the scapula are unusual, but clinical signs are similar to those caused by humeral stress fractures. Nuclear scintigraphy is the only way to diagnose this fracture. Most scapular fractures occur where the spine of the scapula meets the neck, in the same location as scapular fractures that necessitate destruction on humane grounds.

Pelvic stress fractures are underestimated grossly, overlooked, and misdiagnosed as a source of lameness in racehorses. Pelvic stress fractures most commonly involve the ilium, anywhere from the tuber sacrale to the tuber coxae. Stress fractures at the base of the tuber sacrale frequently are misdiagnosed as strains of the sacroiliac ligament. Fractures involving the base of the tuber coxae can be incomplete or complete (knocked-down hip).

Pelvic stress fractures can be catastrophic injuries, if a fracture becomes complete and displaced and results in laceration of the iliac artery. All horses with stress fractures usually have a history of transient recent lameness. Considerable evidence indicates that catastrophic pelvic fractures develop from preexisting stress-related bone injuries in horses that were continued in training. We find it interesting that the incidence is higher in fillies. Nuclear scintigraphy is useful for identifying pelvic stress fractures, but several factors decrease sensitivity, including the overlying muscle mass. Even a minor area of IRU should be considered important. Motion-correction software recently has been introduced and improves accuracy and image quality. Ultrasonographic examination can be used to identify fracture if displacement exists but is less sensitive than scintigraphy. Ultrasonography is most useful in horses that cannot be moved. Pelvic stress fractures should be included in the differential diagnosis of any TB with hindlimb lameness. Horses returning from training with a severe, undiagnosed hindlimb lameness should be tied and not allowed to become recumbent until a pelvic fracture can be eliminated.

Horses with a pelvic stress fracture may not exhibit severe lameness and may be confused with those suspected of having sacroiliac pain or pelvic muscle pain.

Sacroiliac strain is diagnosed in horses when lameness results from slipping while the horse is coming out of the starting gate (M.W.C.). Horses with sacroiliac pain resent pressure applied between the tubera sacrale. Certainly, sacroiliac strain needs to be differentiated from pelvic fracture, because management may include local, deep injections of corticosteroids and Sarapin. Injecting the back or hip muscles in a horse with a pelvic fracture gives no benefit and incurs considerable risk.

The prognosis for horses with pelvic stress fractures is good, unless displacement exists. Even horses with complete, displaced fractures of the tuber coxae can return to racing if the displacement is not severe.

Other Lameness Conditions

Stifle

Stifle lameness causes unilateral and occasionally bilateral lameness in TB racehorses (M.W.C. and P.J.M.). Horses have mild or moderate lameness and appear to swing the limb. Other characteristics include a stiff hindlimb gait, not using the hindlimbs or weak behind, getting out in the straightaway, slipping behind, and locking up behind. The most common clinical finding is effusion of the medial femorotibial joint. Lameness is exacerbated by upper limb flexion. Pain on palpation of the medial collateral ligament is found occasionally.

Diagnostic analgesia is important, but eliminating the lameness totally in most horses is difficult. Radiographic findings are generally negative, unless osteochondritis dissecans or subchondral bone cysts are present. Horses with osteochondrosis usually are treated surgically before arriving at the racetrack. Ultrasonographic examination is useful in identifying soft tissue lesions such as collateral desmitis, and when identified, affected horses are given 7 to 10 days or more of hand walking.

Most horses with stifle lameness appear to have synovitis or early osteoarthritis. Differences of opinions exist regarding the type of intra-articular injections to use in the stifle. One of us (M.W.C.) uses hyaluronan and betamethasone, but avoids using methylprednisolone acetate, because synovitis may worsen. On the other hand, one of us (P.J.M.) uses hyaluronan (50 to 200 mg) and methylprednisolone acetate (160 to 200 mg) in the medial and lateral femorotibial joints.

Secondary Shoulder Region Pain

Horses with forelimb lameness characterized by a shortened cranial phase of the stride may have some degree of secondary muscle soreness in the shoulder region or mild intertubercular (bicipital) bursitis (M.W.C.). Horses often have primary lameness in the foot or fetlock joint, but management of the primary lameness conditions does not alleviate all clinical signs. Injection of a combination of methylprednisolone acetate, isoflupredone acetate, and hyaluronan into the bicipital bursa and 2 days of hand walking resolves remaining clinical signs in some horses.

CHAPTER • 108

The European Thoroughbred

Robert C. Pilsworth

HISTORY OF HORSE RACING IN THE UNITED KINGDOM

As long as man has ridden the horse, matches of speed probably have been held informally between proud owner-riders. Racing horses under saddle became established in England during the Roman occupation. The glorious Knavesmire racecourse at York has witnessed racing almost continually since then. Since the time of James I (1603-1625), a link has existed between royalty and the town of Newmarket in Suffolk, leading to its reputation as the headquarters of racing in the United Kingdom. Charles I, the successor of James I, established regular spring and autumn race meetings in Newmarket and built a palace and stables that have survived. Racing at that time consisted of matches between pairs of horses, over long distances by modern standards. Distances as long as 4 miles were not unusual. Over the succeeding two centuries the race distances declined, as did the age at which horses were allowed to race. Initially horses had to be older than 5 years of age, but this was reduced gradually until in 1859 even yearlings were allowed to race. This practice soon ceased, but 2-year-old racing had become established and became, unfortunately in the opinions of many, part of the Thoroughbred (TB) spectrum. During this time the breed itself changed considerably.

Throughout the seventeenth and eighteenth centuries, sea transport became reliable enough to contemplate moving a living horse from the Orient to the United Kingdom. This introduced the Arabian horse to our bloodlines and established the modern TB breed, producing profound changes in size and conformation from the native stock. Eight percent of the TB racehorses alive today are descended from just one of these stallions, the Darley Arabian, through his great, great grandson Eclipse.

As the distance of races declined, speed became an increasing factor and the fields of competitors increased in size. Eventually the handicap system was introduced in an attempt to avoid the dominance of the sport by a few exceptionally gifted individuals. All of this led to an increase in interest in racing as a spectator sport and a vehicle for gambling. From the nineteenth century onward, racing was more or less recognizable as the sport we enjoy today.

PATTERN OF RACING

The most prestigious races in Europe belong to a worldwide system of accreditation, which groups together races of similar standing. The best horses competing at top level meet each other in a group of internationally acknowledged races known

Horses with a pelvic stress fracture may not exhibit severe lameness and may be confused with those suspected of having sacroiliac pain or pelvic muscle pain.

Sacroiliac strain is diagnosed in horses when lameness results from slipping while the horse is coming out of the starting gate (M.W.C.). Horses with sacroiliac pain resent pressure applied between the tubera sacrale. Certainly, sacroiliac strain needs to be differentiated from pelvic fracture, because management may include local, deep injections of corticosteroids and Sarapin. Injecting the back or hip muscles in a horse with a pelvic fracture gives no benefit and incurs considerable risk.

The prognosis for horses with pelvic stress fractures is good, unless displacement exists. Even horses with complete, displaced fractures of the tuber coxae can return to racing if the displacement is not severe.

Other Lameness Conditions

Stifle

Stifle lameness causes unilateral and occasionally bilateral lameness in TB racehorses (M.W.C. and P.J.M.). Horses have mild or moderate lameness and appear to swing the limb. Other characteristics include a stiff hindlimb gait, not using the hindlimbs or weak behind, getting out in the straightaway, slipping behind, and locking up behind. The most common clinical finding is effusion of the medial femorotibial joint. Lameness is exacerbated by upper limb flexion. Pain on palpation of the medial collateral ligament is found occasionally.

Diagnostic analgesia is important, but eliminating the lameness totally in most horses is difficult. Radiographic findings are generally negative, unless osteochondritis dissecans or subchondral bone cysts are present. Horses with osteochondrosis usually are treated surgically before arriving at the racetrack. Ultrasonographic examination is useful in identifying soft tissue lesions such as collateral desmitis, and when identified, affected horses are given 7 to 10 days or more of hand walking.

Most horses with stifle lameness appear to have synovitis or early osteoarthritis. Differences of opinions exist regarding the type of intra-articular injections to use in the stifle. One of us (M.W.C.) uses hyaluronan and betamethasone, but avoids using methylprednisolone acetate, because synovitis may worsen. On the other hand, one of us (P.J.M.) uses hyaluronan (50 to 200 mg) and methylprednisolone acetate (160 to 200 mg) in the medial and lateral femorotibial joints.

Secondary Shoulder Region Pain

Horses with forelimb lameness characterized by a shortened cranial phase of the stride may have some degree of secondary muscle soreness in the shoulder region or mild intertubercular (bicipital) bursitis (M.W.C.). Horses often have primary lameness in the foot or fetlock joint, but management of the primary lameness conditions does not alleviate all clinical signs. Injection of a combination of methylprednisolone acetate, isoflupredone acetate, and hyaluronan into the bicipital bursa and 2 days of hand walking resolves remaining clinical signs in some horses.

The European Thoroughbred

Robert C. Pilsworth

HISTORY OF HORSE RACING IN THE UNITED KINGDOM

As long as man has ridden the horse, matches of speed probably have been held informally between proud owner-riders. Racing horses under saddle became established in England during the Roman occupation. The glorious Knavesmire racecourse at York has witnessed racing almost continually since then. Since the time of James I (1603-1625), a link has existed between royalty and the town of Newmarket in Suffolk, leading to its reputation as the headquarters of racing in the United Kingdom. Charles I, the successor of James I, established regular spring and autumn race meetings in Newmarket and built a palace and stables that have survived. Racing at that time consisted of matches between pairs of horses, over long distances by modern standards. Distances as long as 4 miles were not unusual. Over the succeeding two centuries the race distances declined, as did the age at which horses were allowed to race. Initially horses had to be older than 5 years of age, but this was reduced gradually until in 1859 even yearlings were allowed to race. This practice soon ceased, but 2-year-old racing had become established and became, unfortunately in the opinions of many, part of the Thoroughbred (TB) spectrum. During this time the breed itself changed considerably.

Throughout the seventeenth and eighteenth centuries, sea transport became reliable enough to contemplate moving a living horse from the Orient to the United Kingdom. This introduced the Arabian horse to our bloodlines and established the modern TB breed, producing profound changes in size and conformation from the native stock. Eight percent of the TB racehorses alive today are descended from just one of these stallions, the Darley Arabian, through his great, great grandson Eclipse.

As the distance of races declined, speed became an increasing factor and the fields of competitors increased in size. Eventually the handicap system was introduced in an attempt to avoid the dominance of the sport by a few exceptionally gifted individuals. All of this led to an increase in interest in racing as a spectator sport and a vehicle for gambling. From the nineteenth century onward, racing was more or less recognizable as the sport we enjoy today.

PATTERN OF RACING

The most prestigious races in Europe belong to a worldwide system of accreditation, which groups together races of similar standing. The best horses competing at top level meet each other in a group of internationally acknowledged races known

as Group 1. This group includes all of the classics in the United Kingdom and the most prestigious races throughout Europe and North America. These races are open to all horses, but they have expensive entry fees and often have to be entered well ahead of time. This self-regulation prevents people from putting horses of limited ability into these races. Beneath Group 1 are two other groupings (Group 2 and Group 3) for horses that have excellent ability but are not up to the extreme rigors of Group 1 racing. Competitors in these races face a weight for performance penalty system. For instance, a Group 1 winner running in a Group 2 race carries a weight penalty in an attempt to equalize the competition.

The next tier down from Group races are the Listed races. Again the International Pattern Committee decides which races are of sufficient stature to belong to this list. Usually horses enter a Listed race when they have already won a maiden and possibly another race with specific conditions. Such horses have few other realistic options, because after two wins a horse carries a lot of weight in an open handicap. Often success in a Listed race increases potential breeding value far more than winning such a handicap. These limited opportunities are often the reason why horses that are good, but not quite good enough to be top class, are sold out of Europe to continue racing in North America, where races are more suitable. Horses are also often able to recoup in prize money the owner's investment, a situation that is often impossible racing in Europe, with its relatively lower prize money.

Beneath the upper echelon of horses racing in Listed and Group company is an open handicap system in which horses are allocated weight according to speed rating. These speed ratings are assessed by professional handicappers, who monitor the performance of the horses when they run in the first three maiden races. The horse's rating rises and falls during its racing career, depending on its most recent form. Although this system is obviously open to abuse by trainers running horses at inappropriate distances for the horse's ability, the system does allow horses of moderate or differing ability to compete against one another on more equal footing and produce an exciting finish.

Until recently all flat racing in the United Kingdom took place on turf. This led to a certain divergence in bloodlines and ability patterns of racehorses in North America and Europe. About 15 years ago all-weather racing was developed at two tracks, Lingfield and Southwell. Although initially introduced for hurdle racing as a way of keeping the betting public satisfied when the National Hunt cards had to be abandoned through bad weather, both tracks rapidly discontinued hurdle racing on all-weather surfaces because of the high injury rate. This left the way open for flat racing on the all-weather tracks to become established. Since that time another all-weather course at Wolverhampton has been established.

The all-weather track surface is not the same as the dirt commonly used in North America. The depth of the cushion is greater, and the material is a composite of oil, plastics, and sand. Few races with significant prize money are run on the all-weather surfaces, and the racing tends to be of a humble grade. However, the track does give horses of limited ability somewhere to race and also allows trainers with small stables to compete with each other in the absence of top-level horses and trainers with many horses. Several successful all-weather horses have made a transition to racing in North America to end up running in Group races on dirt, and the all-weather surface can act as a screening academy to pick out horses that seem particularly adept at performing on these artificial surfaces.

In the rest of Europe, racing takes place on American-style dirt in Norway and Sweden, and flat-racing artificial surface tracks are found in Germany and Belgium. Many other countries have all-weather tracks but for harness racing only.

Flat racing is popular in the United Kingdom, Ireland, and France but less so in the rest of Europe. Although training centers exist in Germany along with a significant number of high-grade races, flat racing has not really caught the imagination of the public in the same way as in Britain and Ireland and receives little media attention. Ireland always has had a strong tradition of horsemanship and racing, centered around the Curragh, is buoyant and popular. Standardbred racing is popular in France, Germany, and Scandinavia, where flat racing opportunities are limited. Many European countries enjoy racing in the absence of a substantial breeding industry, and this creates a market for the surplus racehorses produced and raced in the United Kingdom, Ireland, and France. Horses in the United Kingdom, Ireland, and France are raced at 2 and, ability permitting, 3 years of age, and at the end of the 3-year-old career many are submitted for sale if they have not shown sufficient ability to be retained for racing as older horses. This makes room in the yards for the incoming yearlings. These large dispersal sales at the end of the 3-year-old career supply the horses for National Hunt racing in the United Kingdom and for flat racing areas of the world lacking breeding programs. The need for yards to clear out the less gifted 3-year-olds to make room for the influx of yearlings also produces enormous pressure on trainers and consequently their veterinary surgeons to have a racehorse fit and able to race at 2 and 3 years of age, often without consideration for the long-term consequences of any treatments.

The small window of opportunity available to these horses impinges directly on many of the surgical and medical management decisions that need to be made when problems arise. The economics and practicality of any advice given has to be considered from the owner's viewpoint and the welfare of the horse.

COMPARISONS WITH RACING IN NORTH AMERICA

One of the major differences between training and racing in North America and Europe is in the geographical location and logistics of stabling and training of the horses. In the United States almost all horses train at the racetrack and are stabled there continuously. In Europe the horses live and train in yards often well away from the racetrack. These yards tend to be clustered around a training area, with gallops and conditioning canters available for use by local trainers. The horses travel on a daily basis to race at race courses that may be up to 200 miles away.

In the United States the horses, trainers, jockeys, and veterinary surgeons tend to move from one race course to another, but they stay at each track for long periods. Racing at each location takes place for many days or even weeks before horses and trainers move on to another track. Although some horses stay behind at one track, racing does not occur at that track when the primary focus is elsewhere.

In Europe racing seldom occurs at any one racecourse for more than 3 consecutive days. Horses are trained in traditional stables, some of which date back many centuries. Horses travel to race courses the day before racing, if the journey is particularly long, or even on the day of the race. Some horses make extremely long round trips. For instance, it is not usual for a trainer in Arundel on the south coast to send horses as far north as Ayr in Scotland, a round trip of 936 miles. Obviously the cost of transport has to be weighed against the potential gains, but the traditional system of training and traveling to the races in the United Kingdom seems to be holding up for now.

In 2000, two of the all-weather racetracks opened training barns adjacent to the track with a view to introducing

American-style training, track side. How popular and successful this system is going to be and whether it will spread to other racecourses remains to be seen.

In North America almost all training and racing takes place on a left circle, and this might be expected to have influences on the incidence rates of injury to the left and right limbs for many lesions, such as proximal sesamoid bone (PSB) fractures, third metacarpal/metatarsal bone condylar fractures, and tendonitis (see Chapter 107). In the United Kingdom much conditioning work and even race speed training takes place in straight lines (Fig. 108-1). Racing itself can be on straight tracks (e.g., 1000 and 2000 Guineas at Newmarket), predominantly to the left (Epsom Derby), or to the right (Doncaster St. Ledger). The tracks themselves divide into about one third right-handed and two thirds left-handed throughout the country. This has an important impact on the lack of specific incidence of injury to the left or right limbs. One large fracture survey in Newmarket showed few instances of left or right dominance for any injury.[1]

Making categorical comments about the impact the new all-weather tracks have made on specific lameness and injury in the United Kingdom is difficult for several reasons:

1. Although the racing is on a specific surface, because of the way British horses travel long distances to race, the horses in any race have trained on a variety of surfaces at home. Because it is believed that the accumulation of the daily work sets up stress-related injuries, the actual failure that may take place in a race often can have little to do with the track surface the horses are racing on that day.
2. Tendonitis is relatively rare in the populations of 2- and 3-year-olds in a large flat training yard, and I might expect to see one bowed tendon in a yard of 100 horses in any one season. Horses that race on all-weather tracks have a far higher incidence, but they often include many older horses (3 to 9 years of age) and a higher incidence of horses with chronic, low-grade gait abnormalities, both of which could help to raise the incidence of tendon injuries.
3. The incidence of fractures in horses racing on all-weather surfaces seems to be higher than on good grass, but turf described as firm or hard is just as testing. Generalizations about turf versus artificial surfaces in terms of impact on injury have to be more specific, because turf can vary from bottomless mud to baked clay in mid-summer. The older population of horses that race on the all-weather tracks, many of which carry a legacy of subchondral bone change from the previous training at 2 and 3 years of age for turf racing, could influence the higher incidence of fractures.

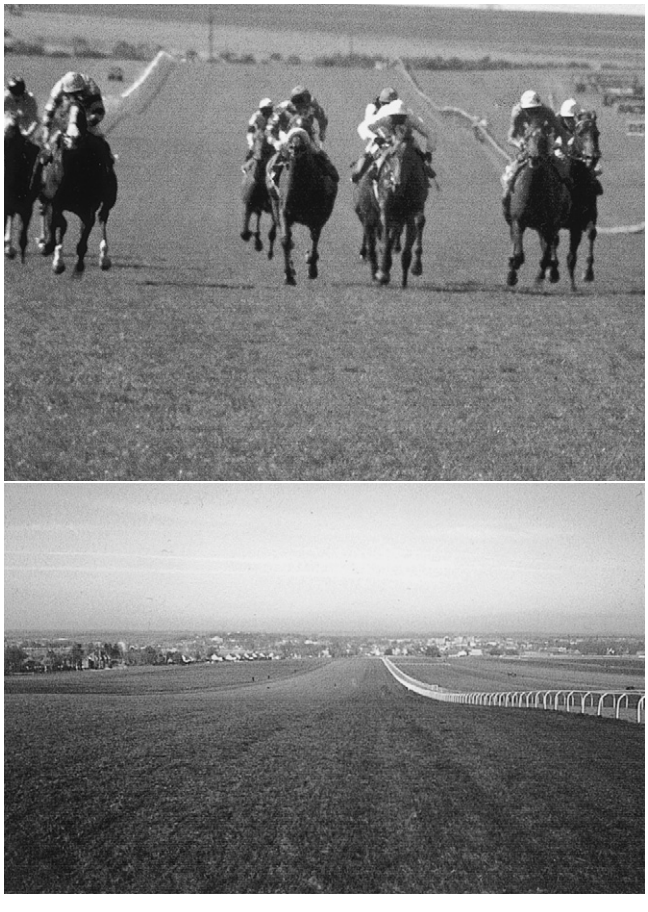

Fig. 108-1 **A,** Horses approach the finish of the long and lonely Rowley mile racetrack at Newmarket. This photograph illustrates the undulating nature of the straight 1-mile track over which both 3-year-old Group 1 classics are run. **B,** The long straight of the training track gallops up Warren Hill just outside Newmarket. An all-weather surface is between the white railings. The rest of the heath is used in strips, which are changed on a daily basis. Each strip of grass is used only once every 3 years.

TRAINING REGIMENS IN EUROPE

Yearlings arrive in the yards for breaking from the sales in September and October and, unlike the situation in North America, often go straight to the trainer for breaking rather than to a specialist pre-training center.

After breaking, the yearlings usually start steady cantering exercise until Christmas. As the racing season approaches, horses showing precocity and ability to withstand faster exercise step up in pace throughout February and March. The first 2-year-old races occur in April, encouraging hard training of skeletally immature horses. However, until the racing calendar changes and while these races are open and available, trainers will train horses for them.

All-weather racing has altered the seasonal impact of flat racing in the United Kingdom forever, and some flat race horses are now in training throughout the year. However, most of the high-quality flat race horses do not compete on the all-weather circuit and are put into a slow-speed maintenance program from November until January, involving light cantering and trotting. Fillies may be turned out for a period.

All of this is substantially different from the position in North America, where the horses often do not arrive at the racetrack until they are fully broken, in cantering exercise, and ready to do fast work. The breaking and pre-training often takes place in specialized pre-training centers, away from the city center tracks. This has important affects on the perception of racetrack veterinarians in North America concerning the incidence of developmental orthopedic disease linked to lameness. In North America developmental orthopedic disease often causes lameness leading to diagnosis and removal from training before a horse reaches the racetrack, and horses therefore are not commonly seen by track veterinarians. An example is a subchondral bone cyst in the medial femoral condyle. Subchondral bone cysts are a regular occurrence in the annual intake of yearlings in the United Kingdom, diagnosed by the trainers' veterinarians. Discussion with colleagues working at Californian racetracks reveals that they rarely see horses with subchondral bone cysts, presumably because of the effect of the earlier screening at the pre-training centers.

Once on the track in North America the racing is often less seasonal and less age specific, removing a lot of the pressure for success at 2 or 3 years of age within a short season. Whether a horse races on turf or dirt does not matter: all training takes place on dirt, and this should be borne in mind by veterinarians assessing horses for potential purchase to move from Europe to America. Asking potential purchasers whether the horse is intended for turf or dirt racing is largely irrelevant, because the daily training almost certainly will be on dirt. The dirt surface is more testing in many ways than anything these horses have seen before, and horses able to train and perform well on grass sometimes fail to make the transition to dirt.

CLINICAL HISTORY

Taking a detailed history is a prerequisite for a medical examination in any species. In racehorse practice one often is seeing a succession of lame horses during any morning in several different yards, and the detailed information may be limited. The trainer may not be present to supply it. However, I always try to ascertain the following information before examining a TB racehorse for lameness:

1. How old is the horse? This is probably the single biggest determinant for different types of lameness. The chronological age is important, but far more important is the skeletal naivete of the horse. An unbroken horse of 3 or 4 years of age behaves in essentially the same way as an unbroken yearling, irrespective of the difference in age, and may suffer similar problems when confronted with an inappropriate training program.
2. What stage of training has the horse reached? Has a yearling reached race-speed exercise yet, is it simply trotting, or has it entered normal conditioning cantering exercise? For a yearling that is lame while being broken or in early cantering exercise, one has to consider subchondral bone cysts and other osseous cyst-like lesions, osteochondritis dissecans, and associated osteoarthritis. Problems may be bilateral, resulting in a peculiar gait. Bilateral sacroiliac joint pain considerably affects the freedom of movement of the hindlimbs and may mimic the clinical signs of exertional rhabdomyolysis, but plasma creatinine kinase (CK) levels often will be normal or only slightly raised (500 to 1500 IU/L).

   Stress-induced bone injuries are more likely to become apparent as work intensity increases. Stress-induced bone injuries include all the long bone stress fractures of the humerus, tibia, third metacarpal (McIII) and third metatarsal (MtIII) bones, and the ilial wing of the pelvis. Similarly, in a 2-year-old that has reached advanced training speed, the carpus and metacarpophalangeal joint are common sources of forelimb lameness, and lateral condylar stress injuries of MtIII are common causes of hindlimb lameness. At 2 years of age the horse is less likely to have lameness associated with a subchondral bone cyst, osseous cyst-like lesion, or osteochondritis dissecans, because these lesions usually cause lameness when the horse is young and begins conditioning exercise. However, occasionally subchondral bone cysts and osseous cyst-like lesions may arise or show clinical signs for the first time at 3 years of age.
3. Has the horse raced yet? If a horse has raced successfully at 2 years of age, the horse is unlikely to have hidden osseous cyst-like lesions or osteochondritis dissecans. Also, the skeleton has probably been conditioned adequately, and the incidence of stress fractures can be expected to be lower. However, in countries where racing is seasonal, 3-year-olds can detrain through the closed season if they are not maintained in cantering exercise. Stress fractures then may occur in the following season if speed training starts too quickly. A Californian study showed an associative link between the occurrence of stress fracture of the humerus and previous long-term removal from training.[2]

   If a horse did not race at 2 years of age, then all of the differential diagnostic criteria used in the recently broken 2-year-old should be applied to the 3-year-old.
4. Has the horse had any previous orthopedic problems? Often in practice I know each horse personally and am able to recall the problems that affected the horse in its early years. The history of a horse with previous problems may guide the use of diagnostic analgesia in an unorthodox, but timesaving manner, to establish whether the current lameness is a recurrence of a previous problem.
5. What is the pattern of the lameness? One should ascertain whether the lameness is constant from day to day and for how many days the horse has shown a gait abnormality. The veterinarian should ask if the lameness gets better or worse within an exercise period. In some conditions, such as proximal suspensory desmitis (PSD), the lameness tends to get worse as the horse exercises, only to resolve with 24 to 48 hours of rest. Horses with lameness from other causes, such as osteoarthritis, often warm out of clinical signs considerably from the start of exercise.

   In horses with acute-onset, severe lameness, questions of clinical history become less important because the horse is often not bearing weight, and a suspicion of skeletal failure is raised. Knowing if this horse has been a good mover before onset of severe lameness is often helpful, because some injuries (third metacarpal/metatarsal bone condylar fractures, PSB fractures) often are associated with poor gait before the actual fracture takes place. The same is true of slab fractures of the third carpal bone, which often are preceded by a long period of subchondral bone sclerosis associated with bilateral third carpal bone pain (Fig. 108-2). One of the most useful questions to ask about a horse with severe lameness is what stage of training the horse has reached, because only advanced training to fast canter or gallop speeds usually results in bone failure. However, bacterial infection subcutaneously or within the hoof also can produce severe lameness.
6. Has the horse had a prolonged layoff for any reason? Horses brought back from a long period of box rest after illness or injury, without adequate prior bone conditioning, can get bizarre injuries from unusually low-speed exercise. These include complete, displaced scapular and humeral fractures, bilateral fractures of the PSBs and tibias, or displaced fractures of the proximal phalanx or condyles of McIII. This is a reminder of the vital need for time to allow adequate skeletal conditioning necessary to avoid injury.

Clinical Examination

The veterinarian always should get the horse out and see it walk and trot to determine which limb is lame. Riders are notoriously unreliable at detecting the correct lame limb. The veterinarian should determine whether the lameness is unilateral or bilateral by the way the horse moves. Many racehorses are slightly lame in all limbs and have a typical crouching,

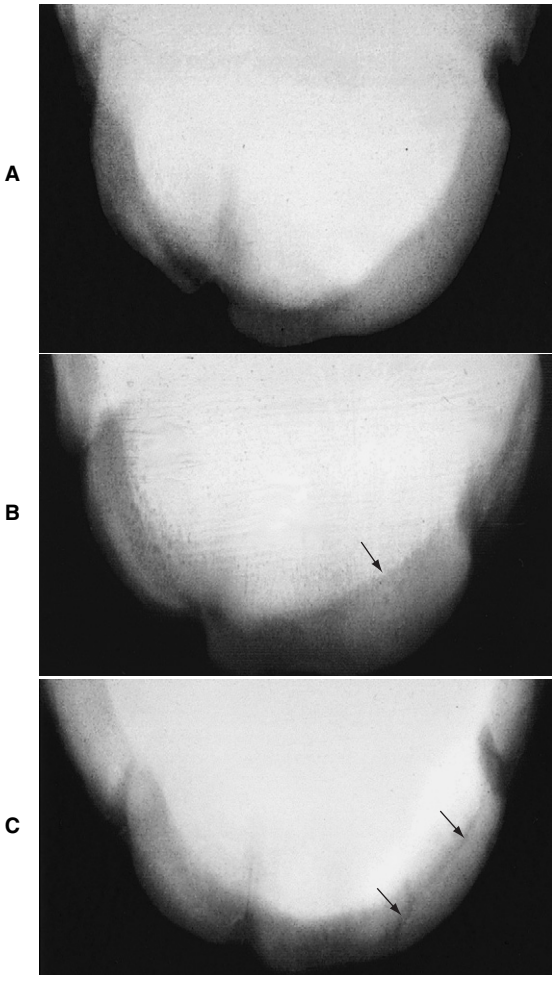

Fig. 108-2 Flexed dorsal 60° proximal–dorsodistal oblique projections of the third carpal bone of three Thoroughbreds. Lateral is to the left. **A,** Mild to moderate sclerosis of the radial facet of the third carpal bone. **B,** A short fissure fracture *(arrow)* can be seen propagating from the dorsal margin of the sclerotic radial facet of the third carpal bone. **C,** A non-displaced fracture is in the center of an area of intense sclerosis in the third carpal bone *(arrows)*.

shuffling trot or may try repeatedly to break into a canter because trotting is so uncomfortable. New lameness may be superimposed on a chronic level of unsoundness.

Increasing experience usually leads one away from the belief that any one injury is linked to a particular gait. Lameness typical of a shoulder or typical of a stifle tends to become a more remote belief, because so-called typical lamenesses so often are linked eventually to the most unexpected site. However, a few types of lameness do remain that seem to be linked to one particular pathological syndrome. Young TBs often show bilateral forelimb lameness related to carpal pain. These horses often trot with the limbs abducted from the midline and not fully flexed during forward motion. This gives a rolling, stiff-legged forelimb gait. The horse's attempt to get the contralateral limb down quickly to get off the sore limb as soon as possible shortens the forward phase of the stride, leading to a choppy, stilted action.

Pain associated with the metatarsophalangeal joint is often bilateral and leads to a fairly characteristic gait typified by low limb flight, often with dragging of the toe during protraction, and an exaggerated pelvic excursion dorsoventrally on both sides (in this clinic termed the *Marilyn Monroe trot*), because the horse dips off each painful limb. Horses with a humeral stress fracture often abduct the limb, with shortened cranial protraction at the walk.

Having ascertained which limb is the lamest, the limb should be examined in detail, using basic examination protocols (see Chapters 4 through 8 and 10). The following specific points apply to the TB racehorse.

1. Many racehorses show a pain response to squeezing of the foot with hoof testers, which is not related to a current lameness. The TB has a thin-soled foot, which often is shod incorrectly, allowing palmar third soft tissue bruising to occur. If the horse responds to hoof testers in the lame limb, I normally test the contralateral foot to see if the response is different. If the response to hoof testers is the same in both limbs, I would assume that the foot may not be the primary source of lameness.
2. Suspensory branches are best appraised by centering each branch between opposing thumbs and following the branch from the most proximal portion which is palpable down to the PSB. Subtle thickening in the suspensory branch may be detected as the thumbs separate running toward the PSB.
3. The metacarpophalangeal joint should be checked for distention of the palmar pouch of the joint capsule. Thumb pressure is applied to the dorsoproximal aspect of the proximal phalanx and the dorsodistal aspect of McIII, common sites for fragmentation and impingement lesions producing soreness. The limb then should be flexed partially and the response to flexion of the metacarpophalangeal joint monitored. Many young horses show a mild pain response to flexion, and the contralateral limb should be compared to gauge whether a difference exists. However, in a 2-year-old a bilateral pain response may reflect true problems in both limbs. A normal metacarpophalangeal joint should not be painful to flex.
4. The proximal suspensory ligament (SL) should be examined with the limb raised by squeezing the ligament between the thumb or fingertips and the palmar surface of McIII, first medially then laterally. Normal untrained horses show no pain response. However, many young racehorses show a variable degree of discomfort on SL palpation. Differentiating pathological and normal response to palpation associated with increased training can be difficult.
5. The dorsal surface of McIII should be squeezed with the finger tips with the limb raised and the pain response noted as an indication of sore shins. The surface of the shin should be palpated for periosteal thickening or even focal callus formation associated with a stress fracture.

   Running a finger down the shin with the horse bearing weight often causes a horse to buckle the limb for months or even years after shin soreness has subsided and is not a reliable diagnostic test.
6. To detect distention of the antebrachiocarpal or middle carpal joint capsules, pushing on the dorsal surface of the joint with the finger and thumb of one hand while observing the palmar pouches of the joints is useful. Mild effusion then may be detected.
7. Many young racehorses resent extension of the shoulder joint in the absence of a lesion.
8. Many racehorses mildly object to forced tarsal flexion equally in both hindlimbs unrelated to a lesion. A profound response to flexion of the tarsus of the lame limb, which is not matched in the contralateral limb, usually signifies a tarsal bone fracture or a distal tibial stress fracture. If pain is noted on flexion, thumb

Fig. 108-3 Application of torsion to the tibia. The metatarsophalangeal joint is rotated medially, the os calcis laterally, and firm shoulder pressure maintained with the stifle. Horses with incomplete linear fracture of the tibia often show a sharp pain response to this test.

pressure should be applied to the proximodorsal aspect of MtIII and the dorsolateral surface of the tarsal bones to determine a pain response. Pain response is often marked if there is a slab fracture of the third tarsal bone.

9. The tibia is a common site for stress fractures and is examined by curling the fingers around the caudal surface of the tibia from the medial aspect and squeezing on a common predilection site for stress fracture, the caudal surface of the distal third of the tibia. Torsion of the tibia also is attempted by flexing the limb, applying lateral traction to the os calcis with one hand while maintaining firm contact on the stifle with one's shoulder, and medially twisting the distal MtIII with the other hand (Fig. 108-3).
10. The pelvis is another frequent site of stress fractures and is examined by monitoring the position of the bony landmarks—the tubera sacrale, tubera coxae, third trochanter of the femurs, and tubera ischia—looking for displacement (see Chapter 51). Response to deep palpation of the muscles that lie between these sites is also noted. The most common clinical sign in horses with a non-displaced pelvic fracture is guarding of the musculature as a response to deep palpation. Guarding gives a hard, board-like texture to the muscle and often is accompanied by fasciculation of the gluteal mass. Similar clinical signs can be seen in horses suffering from exertional rhabdomyolysis, and this may be a difficult differential diagnosis to establish. Muscle enzyme concentrations may be elevated (creatine kinase 500 to 1500 IU/L) in horses with a pelvic fracture. The tail should be raised and lowered and tail tone monitored. A flaccid tail often indicates a sacral or coccygeal fracture.

Imaging Considerations

Radiography

Many lesions in the TB racehorse are associated with subtle changes in bone density and structure rather than overt fragmentation of bone. These variations result in subtle changes in radiopacity (increased radiolucency and or sclerosis), which often are seen best on high-quality radiographs using single-screen film and excellent radiographic technique or by using digital radiography.

These standards usually are not achievable in the field, and for this reason we encourage all trainers to bring horses to the clinic for radiography. Radiography is notoriously unreliable in detecting early fracture lines and subchondral bone collapse. For this reason, if lameness is linked to a particular site by diagnostic analgesia and nothing is visible radiographically, repeating the radiography 2 weeks later is often advisable. Any horse with subtle changes in bone density can be given time to develop to the point where additional damage can be seen. During investigation of individual joints, special projections are often most useful (Fig. 108-4). Radiographic examination of the metacarpophalangeal joints always should include the flexed 125° dorsopalmar projection, which is extremely useful for evaluating the palmar and plantar surface of the condyles.[3,4] In a hindlimb this view often is achieved best as a plantarodorsal projection. The limb is cupped loosely by a hand underneath the tarsus and allowed to hang in a semi-flexed position. The cassette is placed in a cassette holder and positioned dorsal to the metatarsophalangeal joint, and the x-ray machine is positioned above and behind to achieve the orthodox 125° projection (see Fig. 108-4).

Radiographic examination of the carpus always should include a flexed proximal 55° distal skyline view of the third carpal bone, which is sometimes the only projection in which lesions in this bone can be seen clearly. The projection is easy to do well but is still often done poorly. Small changes in the angle of projection make a significant difference to the amount of the third carpal bone visible in this projection.[5] One should not be satisfied unless the whole of the radial facet is seen clearly (see Fig. 108-2).

The relevance of changes in bone density should not be underestimated. Many stress fractures of the long bones are seen only by the occurrence of endosteal or periosteal callus. Periosteal callus may only be visible with the aid of a bright light. Fracture lines are relatively rare. Despite the difficulty in imaging incomplete fracture lines, some horses may develop complete, displaced fractures during periods of box rest.

Scintigraphy

Scintigraphy has allowed enormous advances to be made in the detection and understanding of stress fractures in the racehorse.[6,7] Scintigraphy should not be used as a first line of investigation in an obvious single-limb lameness, unless a strong suspicion exists that the pelvis or tibia is involved and radiography has been unrewarding. Examination of a whole TB racehorse that cannot trot and has a multilimb lameness is often useful. These horses are difficult to assess using diagnostic analgesia, because one is often racing against time, moving from one limb to another with the predominant lameness constantly changing. Scintigraphy in these horses often results in a list of lesions that can be investigated radiographically and by judicious use of diagnostic analgesia. The other roles of scintigraphy include examining a site identified by diagnostic analgesia but in which no abnormality can be found on radiography and safety screening of an initially severely lame horse that has become sound before a diagnosis has been reached. Making a diagnosis in these horses at post-mortem is thus avoided.

Ultrasonography

Ultrasonography is the imaging modality of choice for investigating soft tissue injuries in the metacarpal and metatarsal

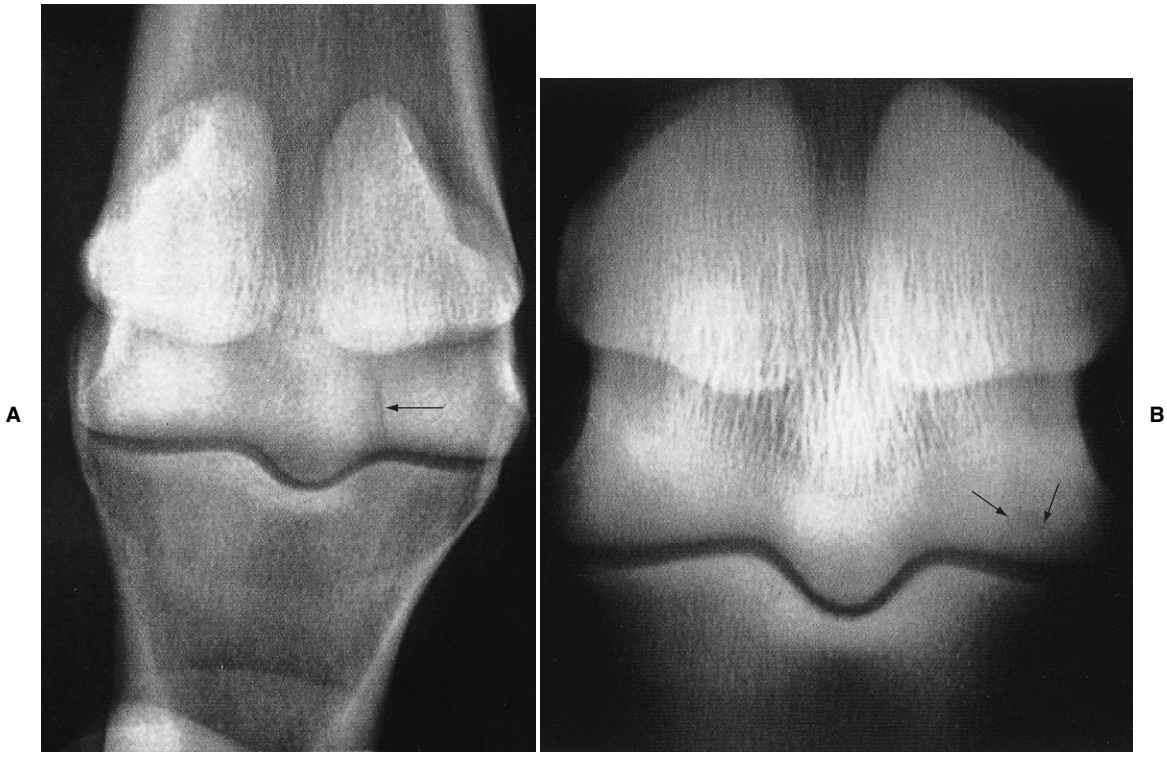

Fig. 108-4 Flexed dorsopalmar radiographic view of a metacarpophalangeal joint. Lateral is to the right. **A,** There is an incomplete linear fracture *(arrow)* in the lateral condyle that was not visible on any other projection. **B,** Flexed dorsal distal 125°–palmar proximal oblique radiographic view of a metacarpophalangeal joint. Lateral is to the right. There is a semi-lunar radiolucency *(arrows)* in the lateral condyle at the site of a chronic stress injury.

regions (see Chapter 16). The only observation pertinent to the young TB alone relates to PSD in horses of 2 years of age. Lesions are often subtle, with enlargement and loss of the neat rectangular shape of the normal SL.

The clinical relevance of bilateral enlargement of the superficial digital flexor tendons along with intratendonous edema in a 2-year-old may be difficult to interpret, because normal tendons increase in size in response to training[8] (see Fig. 102-2). If obvious distortion of the contour of the tendons exists, I advise that the horse not gallop or race at 2 years of age. The horse is maintained in alternate day trotting and cantering for 3 months. This treatment has not led to true tendonitis at 3 years of age in any horse. I refer to these horses as having juvenile tendonitis but have never been comfortable that this degree of caution is mandatory. Perhaps these horses could do more work without further injury.

Ultrasonography is also useful for detecting and monitoring some fractures of the ilial wing and shaft of the pelvis (see Chapter 51).

Diagnostic Analgesia

Having carried out the clinical examination described, one structure causing lameness may be obvious. For instance, the horse may show a sharp pain response on palpation of the SL or distention of the middle carpal joint capsules with pain on flexion. Diagnostic analgesia may not be necessary in these horses and diagnostic imaging of the site may be the next step. Many horses have a list of diagnostic possibilities: the horse may have shown a pain response to hoof testers and some tenderness to palpation of the SL and have some distention of the middle carpal joint capsule. To tease apart these findings, diagnostic analgesia is mandatory. Diagnostic analgesia is done most efficiently at the clinic rather than the training yard, because the procedure is time consuming. If a horse is fresh when admitted for diagnostic analgesia, the increase in muscle tone and general excitement can obscure a mild lameness, and acetylpromazine (2 to 5 mg per horse intravenously) can help settle the horse, without affecting its ability to trot.

If the horse is admitted to the clinic for a day, a positive block can be allowed to wear off, so that more localized blocks can be carried out. For this reason, my own first block is usually an abaxial sesamoid block so that the foot can be eliminated or investigated in greater detail later. Many horses with mild lameness exhibit a detectable deterioration in the degree of lameness if the foot is desensitized and is not the source of pain.

If this block renders the horse sound, the block is allowed to wear off and more detailed diagnostic analgesia is performed. A palmar digital block is carried out, one nerve (either medial or lateral) at a time, the lameness being re-evaluated after each branch is blocked. If effusion of the distal interphalangeal joint is present, an intra-articular block is performed.

If the abaxial sesamoid block is negative, a low palmar (four-point) block is used. This may alleviate lameness; not improve lameness, indicating the problem is much higher; or give a 30% to 50% improvement in lameness. Such results are observed commonly in horses with PSD.

The next logical step is the subcarpal block, which I perform using 1.6-cm needles and 2.5 ml of mepivacaine in the recess immediately palmar to the top of the small metacarpal bones. Short needles and small volumes of local anesthetic solution are used in an attempt to reduce the frequency of false-positive analgesia of the middle carpal joint. False positives can occur by inadvertent direct penetration of the distopalmar outpouchings of the carpometacarpal joint[9,10] or by diffusion of local anesthetic solution up the facial planes to a site proximal to the middle carpal joint.

A positive subcarpal block always is allowed to wear off, and the middle carpal joint subsequently is blocked to ascertain which site is responsible for the lameness. Unfortunately in some horses complete soundness follows both the middle carpal joint and subcarpal blocks. When this occurs, ultrasonographic examination of the proximal SL and a radiographic examination of the carpus are performed before an informed guess is made about the most likely source of lameness. If no lesions are found after imaging both sites, defining the source of pain categorically may not be possible, and the horse is a candidate for nuclear scintigraphy.

Negative subcarpal and middle carpal analgesia are followed by median and ulnar nerve blocks. Although these blocks leap-frog the antebrachiocarpal joint, median and ulnar nerve blocks usually abolish lameness associated with lesions of this joint. Intra-articular analgesia of the antebrachiocarpal joint may fail to abolish lameness originating from distal radial chip fractures in some horses.[11] The jump directly to median and ulnar blocks avoids the possibility of false negatives misleading the lameness diagnosis.

Negative median and ulnar blocks usually are followed by advice to carry out scintigraphy because scapulohumeral joint lameness is relatively rare and intra-articular analgesia does not alleviate lameness associated with humeral stress fractures, which are common. Although osteochondritis dissecans and osseous cyst-like lesions of the scapulohumeral joint are found in late yearlings and early 2-year-olds, these often show scintigraphically and can be confirmed later by radiography and diagnostic analgesia if necessary. Intra-articular analgesia of the elbow and scapulohumeral joints is performed if the median and ulnar blocks and scintigraphy fail to establish the seat of lameness.

Hindlimb investigation follows a slightly less rigorous approach for three reasons:

1. Some young TBs become difficult with repeated needle entry of the hindlimbs, resulting in a serious risk to the veterinary surgeon, the member of staff holding the horse, and the horse itself.
2. The common occurrence of stress fractures in the more proximal sites in the hindlimb, particularly in the tibia and the pelvis, means that many horses potentially would be blocked in detail from toe to stifle, without producing any improvement in lameness. For this reason in a hindlimb an abaxial sesamoid block is performed first, followed by a six-point (low plantar) block above the metatarsophalangeal joint. A positive response to a six-point block is allowed to wear off, and the response to intra-articular analgesia of the joint is assessed. If these blocks produce negative results, a subtarsal block is performed and then followed by a tarsometatarsal joint block. If the horse behaves satisfactorily, tibial and fibular (peroneal) nerve blocks are performed. If lameness is still present, the horse may be allowed to rest undiagnosed or the stifle is examined radiographically, or scintigraphy is performed, depending on the wishes of the trainer and owner. Only if lameness recurs after a period of rest and the absence of a scintigraphic diagnosis are the stifle joints blocked.
3. Bilateral lameness associated with subchondral injury to the lateral condyle of MtIII is common in TBs and often can be abolished by blocking the lateral plantar metatarsal nerve only, just dorsal to the button of the splint, using 2 ml of local anesthetic solution.[12] This often produces an overt lameness in the contralateral limb. This block is easy to perform and the problem is common, so it is tempting to use this block first in horses showing the typical bilateral gait abnormality often seen in this condition.

Shoeing Considerations

TB racehorses have notoriously bad horn quality and hoof conformation. They appear to have uniformly thin soles and a tendency to develop long toes and low heels. Medial to lateral hoof balance is vital to the TB racehorse remaining sound, but it is sometimes not pursued adequately. All horses should be shod wide at the heels to allow full weight bearing by the horn structures. However, in racehorses this tends to produce an abundance of pulled shoes by the trapping of the metal of one shoe underneath the other foot in the stable, particularly on rubber floors, which do not allow the trapped shoe to slip out. This encourages farriers to tuck the shoes out of reach under the foot, which leads to progressive collapse of the heels and long-toe, low-heel conformation. Farriers have to be reassured that they will not be held responsible for pulled shoes within the stable and that the health of the horse's foot is more important than the management problems sometimes associated with correct shoeing.

Interference injuries are not as common in the TB as in Standardbreds and are more common when the horses are on a reduced exercise plane or in 2-year-olds in early training. Interference injuries seem to become less common as the horse strengthens and becomes more fit. In every horse such injuries should be approached as a joint exercise, with the full involvement of the farrier. The following approaches are helpful.

Brushing Injuries of the Hindlimbs

Hindlimb brushing injuries are caused by the contralateral foot in flight and produce cuts on the medial aspect of the fetlock. Most of these horses toe out and are base narrow, and some swing the foot inward during protraction at walk and trot. Traditionally three-quarter round shoes have been used, with the medial branch missing. Over time, however, this shoeing results in progressive collapse of the medial hoof wall, pushing the limb even further out of line, and brushing may actually increase. An alternative is to use light steel or alloy plates behind. This lowers the weight of the foot and often stops the problem. If this fails, we use a 2-cm lateral trailer on the shoe. Half-round shoes are always a help, because they remove the cutting edge if interference does take place.

Brushing Interference in the Forelimbs

Brushing in forelimbs is difficult to treat. Affected horses usually toe out significantly from distal to the metacarpophalangeal joint and are base narrow. Horses often first show interference when galloping at speed and injury causes significant hemorrhage and swelling over the medial PSB. This swelling then makes future interference even more likely, and a downward spiral begins. The steps I usually take involve careful medial to lateral correction by the farrier, rest and anti-inflammatory treatment to reduce swelling, and application of closely fitted half-round section shoes. Topical application of dimethylsulfoxide containing flumethasone is indicated unless there is an open wound. If a full-thickness skin wound is present, topical antisepsis and systemic antibiotic treatment may be indicated to prevent undue swelling at the site.

Protection of the site of injury on return to training with a thin layer of cohesive exercise bandage can help, but great care should be taken in applying this type of bandage because the lack of padding can all too easily produce a bandage bow (bind). Even with all these measures, for affected horses to suffer repeated intermittent problems throughout their careers is not uncommon.

Scalping, Forging, and Over-Reaching

Scalping, forging, and over-reaching are produced by the hind foot arriving in the site occupied by the front foot too soon in the gait cycle.

Scalping produces cuts on the dorsal aspect of a hindlimb pastern, too dorsal to have been caused by the contralateral limb. Scalping is caused by the tip of the front shoe striking

the front of the advancing hind pastern, as the horse just misses forging. Such injuries often are avoided by a four-point trim or shortening the toe and using a rolled-toe shoe in front to speed breakover fractionally, thus getting the front foot out of the way by the time the hind foot arrives. If this alone fails, then using a light steel or alloy plate with a square toe in front and heavy steel shoes behind often eliminates the problem. The same measures are used to reduce true forging, when the hind shoe strikes the tip of the front shoe, producing the characteristic steel on steel noise from which the name is derived. Over-reaching, when the hind toe strikes the bulb of the front heel, can be approached in the same way. Over-reach boots can help but can only be used in slow work. Over-reaching is most common when the horse is fresh and being restrained hard in its exercise or is being exercised in deep sand, preventing easy limb clearance. For this reason these horses can be helped by judicious use of mild sedation before exercise (10 to 25 mg of acetylpromazine PO, 30 minutes before exercise) and by exercising on a non-impeding surface. In many horses all of these measures can cease as the horses become fully fit.

TEN MOST COMMON LAMENESS CONDITIONS

The following are the 10 most common lameness conditions; these are discussed in detail in this section.

1. Foot-related lameness
2. Suspensory desmitis
3. Lameness associated with the middle carpal joint
4. Subchondral bone injuries to the distal third metacarpal/metatarsal bone
5. Lameness subsequent to bacterial infection
6. Stress fractures of the long bones (third metacarpal bone, tibia, and humerus) and pelvis
7. Exostoses of the second and fourth metacarpal/metatarsal bones (splints)
8. Undiagnosed hindlimb lameness
9. Fractures of the proximal phalanx and condyles of the distal third metacarpal/metatarsal bone
10. Lameness associated with the tarsometatarsal joint

Foot-Related Lameness

TB feet are usually thin soled, and most racing TBs have a pain response to hoof testers, even in the absence of genuine lameness. To minimize laminar bruising, good shoeing technique is essential and horses should not be exercised on a surface that is too firm. Medial to lateral foot balance is also vital but often neglected. Farriers often are expected to shoe in the dark of the early morning, with the horse loose in the stable on deep bedding. This often leads to poor visual assessment of foot-pastern axis and balance. Clinicians should all help farriers to change this attitude in favor of a system that allows these skilled professionals to achieve their potential. Such a change involves providing staff members to lead out and hold the horses for the farrier to inspect.

Bruising usually is diagnosed when the horse shows an exquisite pain response to hoof testers in a fairly localized area, but no obvious tract leading to the deeper structures. Careful paring with a hoof knife often reveals pink discoloration in the horn layers immediately above the area of the bruise. Removing the shoe and applying a poultice to the foot for a day is usually successful in managing this condition. If the horse is close to a race and time is of the essence, the foot is iced morning and night in an attempt to decrease the pain associated with the bruise. Once the pain is clearly only from the bruising and no pus pocket has formed under the sole, poulticing is stopped to dry up the sole again before shoeing. If foot lameness is associated with infection, then draining the subsolar abscess is mandatory. Although traditional textbooks talk about radical curettage and establishing sufficient drainage, in the racing TB removal of too much horn is associated with an extended period of lameness because of laminar damage and pain from exposed soft horn. Initially the hole to the pus pocket should be as small as possible. Once drainage has been established, hoof testers can be used to expel pus and to pull in soaking agents or hydrogen peroxide. The hole often can be enlarged by a bent 16-gauge needle. The foot usually is soaked then in warm salt water for 10 minutes morning and night and in between is wrapped in saline-soaked cotton wool dressing contained within polyethylene. Walking these horses twice a day if the degree of lameness permits is a good idea to encourage extrusion of the pus, which leads to a quicker return to full work and decreases the risk of rhabdomyolysis on return to training. Some horses with infection within the foot are infuriating, because although an exquisite pain response occurs and a clear tract leads into the foot, blood in the sensitive laminae is reached before the infected focus is found. The horse then usually resents further digging in the sensitive laminae. Radiographic examination is justified in these horses to rule out infectious osteitis of the distal phalanx, usually evident as a radiolucent area. The condition is treated by radical curettage after sedation, local nerve blocks, and application of a tourniquet. A treatment (hospital) plate is then applied.

Traumatic corns can be one of the most frustrating conditions with which to deal. Affected horses usually have a long-toe, low-heel conformation and inwardly collapsing heels. Intense pain occurs when hoof testers are applied across the seat of corn and yet exploration simply reveals subsolar blood pockets or bleeding tissue. When these are exposed, localized prolapse of the sole may occur at the seat of corn. These horses take a long time to regain soundness and normally are shod with a bar shoe to bridge the weight bearing from the non-affected heel to the wall of the other quarter. The horse should be kept in walking exercise only for at least 2 weeks to allow some horn growth before an attempt at retraining. Training and racing on hard surfaces is contraindicated, which can be realistic advice in the United Kingdom. These horses may be more difficult to manage if sold to train on the tracks in North America. The farrier should be involved in attempting to bring up the heel angle in these flat-footed horses, and the four-point trim is often helpful in achieving this quickly. Medial to lateral balance should be checked, because traumatic corns often occur on the lower heel of a horse that has been allowed to become unbalanced. This seems to occur because of second contact concussion as the foot strikes the ground in a biphasic manner, which is corrected by lowering the longer of the two heels to make sure that the foot strikes the ground evenly.

Sometimes a breach in the horn at the seat of corn allows infection to enter, producing an infected corn. The condition often is linked to swelling and pain on palpation of the bulb of the heel above the corn. Drainage, poulticing, and remedial shoeing are the standard treatments.

In lameness associated with the horse being pricked by the farrier, with or without development of infection, using a glue-on shoe when reshoeing after the problem has been resolved is sometimes a good idea. Most farriers shoeing racehorses are extremely skilled, and if they have managed to puncture the sensitive laminae during a routine shoeing, the cause is usually because the horse has extremely little wall outside the white line. The direct glue-on technique, using a normal alloy racing plate stuck directly to the sole without nails, allows the horse 3 to 4 weeks of extra horn growth before further nailing is done. The more traditional tab-glue shoes are less satisfactory, because the shoes tend to become loose and the horse's foot shape may change. This is not the

case with direct glue-on shoes. Horses that repeatedly lose shoes and have increasing wall avulsion and damage are treated best using direct glue-on shoes to allow time for wall recovery.

Suspensory Desmitis

The SL can be injured at any location, but PSD is most common in a young racehorse. PSD is often bilateral, although the lameness observed is almost always unilateral. PSD is characterized by weight-bearing lameness of grade of 1 to 3 of 5, which seems to disappear rapidly after periods of rest. Even 24 hours of box rest often renders these horses sound. However, within an exercise period, the lameness is typified by becoming worse the more the horse does (warms into the lameness). Horses with PSD often show significant pain when the SL is squeezed between the thumb and the back of McIII with the limb flexed. The veterinarian should start at the apex of the PSB and work along the SL, squeezing it against the bony structures of the limb. The response should be compared with the contralateral limb. Most normal young TBs show some degree of tenderness to palpation of the SL, although unbroken and untrained horses of the same age usually do not. This may indicate that many racehorses suffer a degree of PSD during early training in the absence of observable clinical signs.

Local analgesia is discussed on page 885. When performing subcarpal analgesia, the needles should be applied to the syringe before injection to prevent the introduction of air into the fascial planes, which can preclude later ultrasonographic examination. This air appears as a hyperechoic band between the SL and the accessory ligament of the deep digital flexor tendon, obscuring evaluation of the SL.

The other common predilection site for injury of the SL is the interface of a distal branch and the ipsilateral PSB. These lesions usually occur when the horse starts faster exercise. In horses with conformational defects the same site can be affected in both forelimbs. For example, in a horse with offset carpi and toe-in conformation, the lateral branch of the SL and the lateral PSB are affected. Typical radiographic changes of sesamoiditis are seen with clear disruption of the SL/PSB interface. Central hypoechoic lesions are identified by use of ultrasonography. The SL branches often are enlarged palpably, but ultrasonographic imaging reveals this to be a zone of periligamentous fibrosis, rather than true swelling of the branch itself.

Horses with PSD are confined to box rest for 2 to 4 weeks until clinically sound and then walk on a horse walker for 4 to 6 weeks, followed by a month of walking and trotting exercise. Then ultrasonographic re-assessment is recommended to determine whether the horse should start alternate day cantering exercise or continue trotting for another month. Horses with distal branch lesions may have a guarded prognosis if substantial sesamoiditis exists. Most of these horses are taken out of training altogether as 2-year-olds and given the same rest program as horses with PSD. At the end of the period of controlled exercise, the horse usually is turned out and brought back in at the end of the year for further education, before resuming training as a 3-year-old.

Most young racehorses with PSD have an increase in size of the proximal SL and irregularity of contour, with bulging of the normally flat palmar border, detectable by ultrasonography. The fiber pattern may be heterogeneous. Ultrasonographic monitoring of these lesions may reveal a decrease in size of the SL, with more linear borders. However, in many horses the SL never returns to normal. Exercise level is increased when the ligament shows good echogenicity, although it still may be enlarged. Some horses seem to have long-term hypoechoic lesions within the SL that do not change with further rest.

Less commonly, a unilateral, acute, focal core lesion occurs in the SL after a race or gallop associated with significant lameness, swelling in the subcarpal region and an exquisite pain response to palpation.

The prognosis for horses with mild to moderate PSD in 2-year-old TBs is good, but in horses with acute core injuries the prognosis is more guarded. Some of these horses take 4 to 5 months before they are able to withstand training and have a risk of re-injury. The prognosis in older horses is also less good.

In a 3-year-old horse that had PSD at 2 years of age, mild lameness may recur as training speed increases, in the absence of any real changes that can be identified using ultrasonography, radiography, or scintigraphy. This lameness always can be abolished by subcarpal analgesia. These horses with subcarpal ache often can be managed by administration of 5 to 10 mg of triamcinolone acetonide in 3 ml of local anesthetic solution, injected in the same site as a subcarpal block. Lameness often is abolished for long periods after this treatment, without apparent degeneration of the SL, even with continued training. It is vital to complete a full diagnostic evaluation before treatment in these horses to eliminate the possibility of training horses tolerating incipient catastrophic lesions under the influence of corticosteroids.

Lameness Associated with the Middle Carpal Joint

Several distinct syndromes appear to be associated with the middle carpal joint. One of the most common syndromes is exemplified by a 2-year-old in early training that develops an increasingly short, choppy gait at the trot. The limbs are held abducted during the protraction phase, and the carpi are barely flexed. This gives a stiff, rolling action. Often the horse has bilateral middle carpal joint effusion and pain on carpal flexion. Injection of local anesthetic solution into one middle carpal joint produces lameness (grade 1 to 2 of 5) in the contralateral limb. The gait changes so that the desensitized limb often is brought back toward the midline. Some of these horses have mild sclerosis of the third carpal bone, seen on a skyline projection, but others have no detectable radiographic abnormality. These horses probably are suffering from pain produced by concussion of immature cartilage and excessive torsion on untrained ligaments within the carpus, and should be given rest. If excessive effusion occurs, the joint may be drained and medicated with triamcinolone acetonide (5 mg) and hyaluronan, but only if rest is to follow. Non-steroidal anti-inflammatory drugs (NSAIDs) may be administered for the first 4 or 5 days of rest. Most horses are restricted to box rest for 1 month, followed by walking exercise for 2 weeks, followed by a month of trotting, before resuming full training. Many horses never show lameness again during the second introduction to exercise loading.

The second syndrome, which may include some horses in the first category if training has continued, involves development of more severe sclerosis in the third carpal bone. Focal overloading of the third carpal bone results from a conformational defect (offset carpi with toe in is the worst) or from a mismatch between loading of the limb and time allowed for adaptation. These horses are usually bilaterally lame; often one lame limb dominates, and contralateral limb lameness is only recognized when the lamest limb is blocked. Radiographic signs include sclerosis in the radial facet of the third carpal bone seen on the 55° flexed skyline projection, associated with local areas of rarefaction around the nutrient foramina or with small comma-shaped fissure fractures extending from the dorsal cortex. Further training of these horses risks development of a full sagittal fracture (see Fig. 108-2).

Despite statements to the contrary in the literature, we believe that the early sclerotic changes in the third carpal bone are reversible after a period of box rest. However, there seems to be a certain degree of pathological damage from which there is no return. Once the radial facet becomes completely devoid of trabecular detail and has a ground glass

appearance on radiographs, the changes are often permanent. These lesions often are associated with recurrent lameness each time the horse reaches racing speed. Identifying sclerosis of the third carpal bone at an early stage is therefore vital. Screening radiographic examinations of the third carpal bone in a 2-year-old may be useful before starting full race speed galloping. Without radiographic information, lameness may be the first indicator of sclerosis, which may already be advanced.

Lame horses with third carpal bone sclerosis are confined to box rest for 2 months followed by a month of walking exercise. Radiographic examination is then repeated. We advise that these horses are not trained with a view to racing at 2 years of age, although they may re-enter the training environment so that they acclimatize to respiratory disease and other management problems that might influence the 3-year-old career.

Problems related to the distal radial carpal bone are also common, associated with lameness and distention of the middle carpal joint capsule. Radiographic abnormalities include spur formation on the distal aspect of the radial carpal bone and radiolucent changes in the same site leading to modeling of the dorsal margin. This usually leads to secondary sclerosis of the opposing third carpal bone, because the load becomes borne by the medullary bone, instead of the weight-bearing pillar of the dorsal cortex. These radiographic abnormalities result from overloading the carpus, leading to bone stiffening, cartilage damage, and secondary osteoarthritis. Debate exists over whether spurs should be removed surgically. Osteoarthritis of the middle carpal joint is already established. Although removing the spur is logical, it is not curative, and the joint still will require treatment the following season. With cheap horses and in yards where money is tight, many horses with mild carpal osteoarthritis can be treated once by intra-articular medication with hyaluronan and triamcinolone acetonide, followed by 4 to 6 weeks of rest and a graded return to exercise.

If a chip fracture occurs, then removal of the fragments is probably still mandatory. One should explain to the owner and trainer, however, that the horse has pre-existing osteoarthritis that will persist after surgery and that further problems should be anticipated the following season.

The antebrachiocarpal joint is more forgiving than the middle carpal joint in the amount of pathological change that can be seen radiographically in the absence of clinical signs. Large fragments can be removed surgically with a favorable prognosis for the following season.

A small group of horses with middle carpal joint pain remains in which lameness recurs after periods of rest, despite absence of radiological changes. These horses often have unilateral lameness associated with middle carpal joint effusion. Some of these horses have tears of the palmar intercarpal ligaments. Response to conservative treatment often is disappointing and, even after prolonged periods of rest, lameness recurs as soon as work intensity increases. I normally medicate these carpi with hyaluronan and corticosteroids, but in the absence of a firm diagnosis, this empirical treatment is illogical and usually unrewarding. Diagnostic arthroscopy probably is always indicated in these horses but is also often unhelpful in producing a permanent cure.

Subchondral Bone Injuries to the Distal Third Metacarpal/Metatarsal Bone

Subchondral bone injury is an extremely common cause of lameness in young TBs and is vastly underacknowledged. Subchondral bone pain seems to be increasingly implicated in much joint-related lameness in other classes of horses (e.g., navicular syndrome, tarsal pain, and third carpal bone pain). In the young TB subchondral bone injuries in the distal MtIII and McIII often are linked to bilateral or quadrilateral lameness, which limits performance. Horses with bilateral subchondral bone injuries of the distal aspect of MtIII fail to push from behind at exercise. Often these horses appear to bunny hop for the first section of canter. The rider reports that the horse feels wrong behind and does not perform as well as it previously did. With American-bred horses equine protozoal myelitis (EPM) is an important differential diagnosis, because the clinical appearance can be similar. Onset of clinical signs can be delayed, so that a yearling bred in America and sold in Europe could have EPM. The clinical history (see page 882) and response to diagnostic analgesia (see page 885) have been described.

Subchondral bone injuries are extremely difficult or impossible to identify radiographically. If radiographic lesions are visible, these are usually end-stage and warrant a guarded prognosis (Fig. 108-5). These lesions usually represent necrosis and collapse of subchondral bone and are visible as a crescent-shaped lucency in the middle of the lateral condyle, seen on the flexed plantarodorsal oblique or flexed dorsal distal 125°–palmar proximal oblique projections (see Fig. 108-4, *B*). Sclerosis of the lateral condyle also occurs and is most visible on the lateromedial view. Deliberate over-exposure may be necessary to demonstrate a triangular sclerotic region just palmar to the mid-point of the articular surface (Fig. 108-6). All racing TBs seem to develop some degree of sclerosis in this site as a normal physiological response to loading from the PSB as the limb assumes full extension.

On scintigraphic examination these stress injuries are remarkable because increased radiopharmaceutical uptake (IRU) is focal in nature and markedly increased. On a plantar view, IRU in MtIII is mistaken easily for IRU in a PSB, because the shape of the lesion is similar to that bone. However, on a lateromedial view, the PSBs can be seen clearly plantar to the region of the IRU, localized within the condyle itself (Fig. 108-7). In the forelimb, subchondral bone injuries in the metacarpophalangeal joint seem to occur in the medial or lateral condyle or both. Horses usually have bilateral lameness and trot with the head held low with a short, stumbling gait as they try to get off each weight-bearing limb as fast as possible. If all fetlock joints are injured, a horse may refuse to trot and attempts to break into a slow, rolling canter as speed

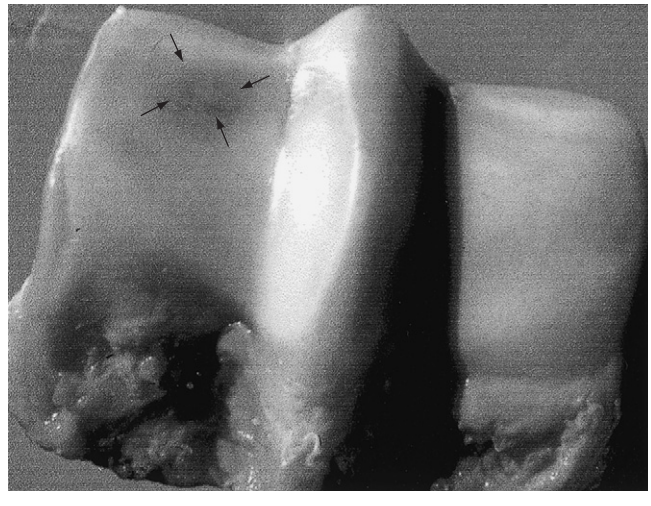

Fig. 108-5 Post-mortem specimen of the distal aspect of a third metatarsal bone from a horse with plantarolateral focal increased radiopharmaceutical uptake seen on a bone scan. Lateral is to the left. The specimen was collected when the horse was euthanized for unrelated reasons. The area in the center of the plantarolateral aspect of the condyle is dark colored, and the cartilage surface is irregular *(arrows)*. Histopathological sections cut through the site revealed abnormal irregular subchondral bone.

increases. Lameness often becomes apparent in the contralateral limb after local analgesia of one metacarpophalangeal joint. Radiographic examination is often unremarkable, but scintigraphy confirms significant focal bone activity.

Treatment is difficult, and we have no protocol that results in uniform resolution of lameness. Many different treatment regimens have been used, including intra-articular injection with hyaluronan or corticosteroids, systemic medication with isoxsuprine and aspirin and with polysulfated glycosaminoglycans, and rest alone. Often the lameness disappears rapidly after the instigation of rest but returns when the horse resumes fast galloping speed. Although some horses have been able to perform without further problems, predicting which horses may respond favorably is not possible, although those with subchondral lucency and sclerosis rarely remain sound. This does not mean that these horses cannot perform, and many racehorses seem to withstand training despite lameness. However, this may be a performance-limiting problem that directly interferes with racing ability and determines the level at which the horse can compete.

Fig. 108-6 Post-mortem lateromedial radiographic view of a thin bone section of the third metatarsal bone cut through the area shown in Fig. 108-5. There is intense sclerosis of the bone *(arrows)* adjacent to the site of the injury in the condyle. This change sometimes can be seen in radiographs of horses affected with condylar stress injuries.

Because horses with advanced lesions rarely return to sustained soundness, it is advisable to stop hard training as soon as the condition is noted in a 2-year-old and allow 3 months of rest. This is not a guarantee that the problem will not recur at 3 years of age, but going on with training these young horses in the face of this lameness seems illogical. Many horses can be trained at 3 years of age without problems. When the clinical syndrome appears in a horse of 3 or 4 years of age for the first time, the prognosis is much worse than when subchondral bone lesions occur in a 2-year-old and the horse is allowed to rest. In an older horse end-stage pathological damage in the affected condyle is more common. These horses may well have been trained through the problem at 2 years of age, with a low-grade bilateral lameness that was not recognized.

Some horses first show hindlimb lameness associated with the lesions in the lateral condyles of the MtIII after a race on unsuitably firm ground. They are described as jarred up. Although clinical appearance of a jarred-up horse has long

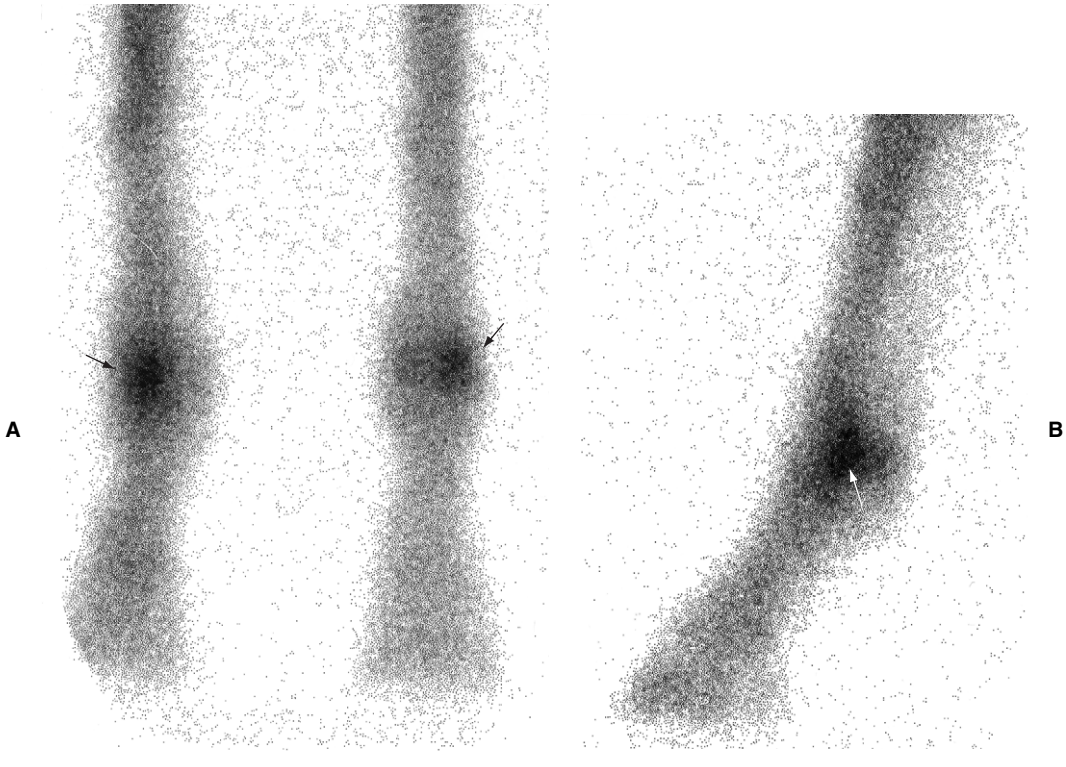

Fig. 108-7 **A,** Plantar delayed (bone) phase scintigraphic image of horse with bilateral stress injuries to the lateral condyle of the third metatarsal bone. The shape and distribution of the increased radiopharmaceutical uptake *(arrows)* easily can be mistaken for the proximal sesamoid bone. **B,** Lateral delayed (bone) phase scintigraphic image of the same horse clearly shows the increased radiopharmaceutical uptake to be situated in the plantar aspect of the condyle *(arrow)* rather than the proximal sesamoid bones, which are in a more plantar position.

been recognized, no precise definition of the syndrome has ever been made. The syndrome may well represent multifocal subchondral bone pain. Affected horses may never regain normal action. The reasons why some horses become progressively more lame while others can race with success and maintain a steady-state lameness are not understood.

A few horses with subchondral bone injury have been examined at postmortem (see Figs. 108-5 and 108-6). The degree of damage to the subchondral bone at the injury site easily explains why some horses are untrainable. We need to understand why some horses develop these lesions while others do not, whether the type of training surface may be a predisposing factor, what pathological mechanisms are involved, and why these lesions produce pain.

Lameness Subsequent to Bacterial Infection

Bacterial infection in a limb of a horse can cause a degree of pain greater than almost any other injury, including a displaced fracture. Although wounds in any part of a limb can become infected, leading to an obvious swelling and lymphangitis, some discrete syndromes in the racehorse deserve mention.

Staphylococcal Abscesses on the Palmar Aspect of the Metacarpophalangeal Joint

Horses exercising on sand or wood chip surfaces seem to be prone to bacterial infections around the ergot that produce small, focal abscesses, which can be difficult to find if the horse has a winter coat. The horse often initially points the limb, is severely lame (grade 4 of 5), with swelling on the palmar aspect of the metacarpophalangeal joint. Manipulation of the joint is resented. The abscess can mimic the appearance of an infected joint and must be differentiated, because synoviocentesis inadvertently may introduce infection into the joint. Careful evaluation shows that the metacarpophalangeal joint capsule is not distended. By working through the hair coat with the fingernails, localizing the point of a small abscess is often possible. The horse shows a severe pain response, and a pink pore-like hole may be observed discharging serosanguineous pus. Bacteriological culture almost invariably results in the growth of a hemolytic *Staphylococcus aureus*.

Treatment is by external application of kaolin paste or a similar open poultice, combined with systemic antibiotic therapy along with NSAIDs and forced walking exercise. Horses are normally sound after 12 to 24 hours, and if this is not the case, then the diagnosis should be re-established. Bandaging should be avoided because the limb often continues to swell and the bandage may become constricting, which can lead to ischemic necrosis and sloughing of the skin.

Focal Peritarsal Cellulitis

Focal peritarsal cellulitis is a syndrome in the hindlimb that appears to be related to the architecture of lymphatic drainage and is characterized by acute-onset severe lameness (grade 4 or 5 of 5), often with a shock-like state, hyperventilation, and sweating. Rectal temperature is elevated (39° to 40° C). Clinical examination of the limb reveals an exquisitely painful area on the medial aspect of the hock, with focal swelling (Fig. 108-8). Brushing this area lightly with the fingertips usually causes the horse to stagger sideways and abduct the limb sharply to get away from the pain. Almost always a small skin lesion of some sort is evident in the distal part of the limb, through which the initial infection may have entered.

Although the horse is severely lame in the stable, if forced to walk, the lameness usually improves after a few steps and the horse bears weight reasonably well. The focal swelling on the medial aspect of the tarsus appears to be linked to a nidus of lymphatic drainage because the swelling is so consistently positioned. The pain is so great because of involvement of the retinacular ligaments immediately beneath the site, causing a compartment-like syndrome. Some clinicians from North America describe emergency surgical drainage of these abscesses. However, conservative treatment using antibiotics (oxytetracyclines), along with NSAIDs administered morning and night, and forced exercise several times daily is usually adequate.

Often within 24 hours the swelling changes from a small egg-sized swelling on the medial aspect of the hock to involve the entire distal part of the limb. Swelling gradually resolves with exercise over the next month.

A great risk of laminitis in the contralateral limb exists in the early stages, because of the combination of severe lameness in the affected limb and toxin production from the abscess. It is therefore vital that the horse is bedded on deep bedding during its initial treatment and that regular exercise is encouraged in spite of obvious lameness in the affected limb.

Axillary and Scrotal Intertrigone Infections

Horses are affected by skinfold infections, particularly in the axilla and groin. The infection begins in the fold of skin and causes an exudative, purulent dermatitis. The swelling of the affected region results in more occlusion and development of anaerobic infections deep in the skin folds. Affected horses often stand with the limb abducted and appear as if they have a proximal long bone fracture. Because the swollen skin folds close themselves off, these lesions can be missed unless the limb is pulled away from the body to expose the raw pink exudative dermatitis. Treatment is by systemic administration of antibiotics and analgesics and topical cleansing of the affected area with a debriding agent, followed by application of an antibiotic ointment. Fusidic acid creams are often effective because most of these infections involve staphylococci. Topical treatment often requires profound sedation of the horse so as to be carried out safely, because of the pain involved. Exercise should be limited to a short period of hand

Fig. 108-8 A horse with focal peritarsal cellulitis. There is tight focal distention caused by swelling beneath the skin, retained at either extremity of the tarsus by the retinacular ligaments.

walking, until the edema of the skin folds of the axilla subsides, because walking produces friction that makes the condition worse. Less commonly the area between the scrotum and the medial aspect of the thigh can be involved, especially in horses exercising on dirt or sand. Affected horses walk in a crouching gait, with abduction of each hindlimb during protraction.

Stress Fractures of the Long Bones and Pelvis

Post-mortem studies carried out on racehorse fatalities in California have revealed that horses have evidence of previously undetected stress fractures of the long bones. We have been aware clinically of these fractures for some time, particularly when they became complete and displaced in horses in training. With the advent of scintigraphy, the early diagnosis of these stress fractures has been increased.

Certain rules apply to all stress fractures in the TB. Fractures usually occur after repeated cyclical loading of bone over time rather than as an acute incident. Lameness itself may be acute in onset, as the bone reaches the stage where it can no longer bear weight and the cortex begins to collapse. However, because the lesions are chronic, periosteal new bone formation, irregular ill-defined lucencies in the cortex, and occasionally cortical displacement may be detectable radiographically. Because stress fractures result from repeated focal over-loading, they tend to occur in predilection sites in the bone, reflecting the architecture of that bone and the manner in which weight is borne during locomotion. The repeatability of these sites makes looking for these injures on radiographs straightforward.

Skeletal bone seems to detrain almost as effectively as it can be trained. For this reason any horse that has been removed from training for longer than 3 weeks should be given sufficient time to allow reconditioning of the skeleton on return to training. Stress fractures may occur in horses of any age if they have been removed from training for a period of more than a month and have been returned to cantering exercise too rapidly.

Periostitis of the Dorsal Cortex of the Third Metacarpal Bone (Sore or Bucked Shins)

Sore shins are a common problem in 2-year-old racehorses or in older horses that have not reached race speed previously or have had a long layoff. Most of these horses are not shown to the veterinary surgeon. The stable staff and trainers know how to recognize sore shins and treat them in a variety of traditional methods. It is advisable to restrict the horse to trotting until the area is no longer painful to light fingertip pressure with the limb flexed. The horse is then re-introduced to the exercise level one step beneath the level that produced the soreness. This speed is maintained for 1 month before increasing. If the shin soreness returns as speed increases, the cycle is repeated.

Rarely, more invasive therapy is required for horses that have three serial episodes and for which normal management strategies have failed. The shin is pin fired under local analgesia, and the horse is walked for 2 weeks and then trotted for 2 weeks, before gradually increasing speed work. Freeze-firing is a local temporary neurectomy only and confers no long-term benefit. The shin is a barometer of what is going on in the rest of the skeleton, and when sore the shin indicates that the skeleton needs more time to adapt. Freeze-firing simply lets us ignore this and allows the horse to develop real damage elsewhere. This subject is controversial, and the views expressed here are not shared by all veterinarians.

Dorsal Aspect of the Third Metacarpal Bone

Fracture of the dorsal aspect of the third metacarpal bone presents as an extension of the sore shin complex. When a true stress fracture (dorsal cortical fracture) is present, the pain to palpation usually is localized to one area rather than being distributed across the entire surface of the shin. Normally a periosteal callus is present at the site of the fracture, causing a bump on the surface of McIII. Radiographic examination should include unorthodox lesion-oriented oblique projections because the fracture lines are often extremely difficult to see, particularly in the acute phase of the injury. Horses are usually slightly lame, but continued training results in a significant increase in lameness after each exercise period, which reduces rapidly. A lame horse with focal periostitis that is painful to palpation should be considered to have a stress fracture in that site, even if the fracture is not visible radiographically. Treatment is by rest, which can include walking exercise. These injuries normally take about a month to heal, after which light training may begin, but 3 months should elapse before full training speeds are achieved. If the injury has progressed to a clear tangential fracture line in the cortex, some veterinarians recommend surgical drilling (osteostixis), or even screw insertion across the fracture line, to encourage healing. This has never been necessary in my experience. Extracorporeal shock wave therapy also is being used to treat this type of fracture, but its clinical efficacy remains to be proved. Normally early diagnosis allows full healing with conservative treatment alone.

Tibia

Stress fractures of the tibia are one of the most common causes of hindlimb lameness in 2-year-old racehorses in race training. In the seasonal racing calendar, when yearlings enter training in October or November, peak incidence of tibial stress fractures is in April or May as speed work increases. The tibia has three main predilection sites. The most common, in naive horses entering training for the first time, is the proximolateral cortex, 7 to 8 cm distal to the proximal articular surface of the tibia. Stress fractures in this site are visible on radiographs as poorly defined callus, often associated with an oblique fracture line in the cortex itself. The second common predilection site, often seen in a 3-year-old or in a 2-year-old in more advanced training, is in the caudal distal cortex, 10 cm proximal to the tarsocrural joint. On radiographic examination endosteal callus can be seen as a subtle sunburst of increased radiopacity extending forward from the caudal cortex on a lateromedial projection. On a caudocranial projection a lucent line is usually visible, surrounded by an area of sclerosis in the middle of the distal tibia. The third common site is the middle of the medial cortex. In this site the injuries usually are seen as periosteal and endosteal new bone formation only, and rarely are fracture lines visible.

Occasionally a complete, comminuted displaced fracture of the tibia can occur during racing or training. The prognosis in these horses usually is regarded as hopeless. In this practice complete tibial fractures occurring at exercise have almost disappeared because of the advent of scintigraphy, suggesting that in the past some complete fractures were the end stage of chronic stress fractures, which are now being detected early.

Diagnosis of tibial stress fracture is difficult because these injuries are not affected by diagnostic analgesia. The typical history is of a 2-year-old being brought into faster speed exercise or of a 3-year-old that did not race at 2 years of age being prepared in the same way. The lameness is usually acute in onset and can be severe (grade 3 or 4 of 5) but usually diminishes rapidly with rest. Forced flexion of the hock and torsion of the tibia produces pain in horses with severe lameness (see Fig. 108-3). Scintigraphy is ideal to confirm these lesions, but the degree of IRU seen in the mid-shaft and distal shaft sites is often low.

Treatment is by rest and a gradual return to training. The horse is restricted to box rest initially for 2 to 6 weeks depending on the severity of the radiographic signs. Occasionally, stress fractures of the tibia do become complete and displaced during periods of convalescence after normal recumbency. The horse should be tied up by the head for the first 3 to 4 weeks if the weight bearing ability of the tibia is severely

compromised (for precautions, see Chapter 51). Less severely affected horses are exercised as soon as it is practical. If a treadmill or horse walker is available, horses can be walked as soon as clinically sound, allowing a total healing period of between 2 and 3 months. Trotting exercise can be included in the second and third months.

Humerus

A horse with a humeral stress fracture has an acute-onset forelimb lameness with features of proximal forelimb pain. The horse walks with a short cranial phase to the stride and circumducts the limb in protraction. Substantial weight-bearing lameness is evident at the trot. Horses often drag the toe of the affected limb in the bedding during protraction in the stable. The lameness rapidly diminishes, and in 2 days horses may be sound, only to go severely lame again after return to exercise.

Two main predilection sites exist for humeral stress fractures. One site is on the caudal cortex just distal to the humeral head, about 5 cm distal to the weight-bearing surface. Loose periosteal callus usually is visible, with sclerosis of adjacent bone and occasionally incomplete tangential fracture lines. The other site is the cranial cortex of the distal humerus about 5 cm proximal to the elbow joint surface. A focal sunburst of callus usually is visible on a mediolateral radiographic view, and a linear fracture line is sometimes seen. Treatment is as described for tibial stress fractures. Complete, displaced humeral fractures can occur in exercise and horses have a hopeless prognosis.

Pelvis and Axial Skeleton

Fractures of the sacral wing of the ilium are often stress fractures and are described in detail elsewhere (see Chapter 51). Recently laminar stress fractures of the vertebrae immediately adjacent to the pelvis have been described.[13] There is usually a unilateral lameness for which no other reason can be ascribed after routine diagnostic analgesia and survey radiography. Scintigraphic examination of these horses reveals focal IRU associated with the lumbar vertebrae on the same side as the lameness. Some horses simply show bilateral poor hindlimb propulsion, short stepping at the walk, and a hunched-up lumbar spine, coupled with poor performance without an obvious lameness. Being certain that the laminar stress fracture is the cause of the reduced performance is difficult. However, if scintigraphy reveals an active bone injury in the spine, continuing full training cannot make sense, and these horses subsequently are allowed to rest. Although this lesion is described as widespread in the Californian pathological survey, the clinical presentation is uncommon. I have examined the lateral lumbar spine routinely in all bone scans over the past 2 years and have not encountered the lesion as a common incidental finding.

Exostosis of the Second and Fourth Metacarpal/Metatarsal Bones (Splints)

Splints are more of a nuisance in a racehorse than a major problem. They are clinically obvious and a sharp pain response can be elicited by squeezing the area. Splints normally are associated with lameness in the initial stages, although this can subside rapidly. Splint lameness is one of the few conditions with which lameness is often more obvious with the affected limb on the outside of a circle. Splints are common in horses of 2 years of age, but can occur in horses of any age, particularly if they experience a change in loading because of a different type of training surface or a different angle of camber. In many horses a fracture line is not detectable radiographically, but most horses with obvious exostosis formation associated with lameness probably do have fractures within the body of the bone, which often can be identified scintigraphically. For this reason a period of stable rest is probably indicated until the horse is clinically sound. The horse then can recommence trotting for 2 to 4 weeks to allow the injury to heal fully. If pain on palpation and lameness immediately recur when the horse returns to exercise, then pin-firing may be considered to encourage more aggressive callus formation. This is one of the few orthopedic indications in which firing achieves a good clinical result in most horses. Horses with displaced fractures of the distal aspect of the second and fourth metacarpal/metatarsal bones are treated by surgical removal of the distal portion of the bone.

Multiple comminuted fractures of the second and fourth metacarpal/metatarsal bones sometimes result from external trauma and heal surprisingly well. Many fragments may be identified by digital palpation with a gloved finger through an open wound and confirmed radiographically. Most horses with fractures heal satisfactorily with antibiotic treatment, bandaging of the wound, and stable rest. If infectious osteitis does occur with sequestrum formation and recurrent fistulation, then affected bone should be removed surgically.

Undiagnosed Hindlimb Lameness

Despite all our modern diagnostic aids, the cause of hindlimb lameness in a significant number of horses remains elusive. Given the huge muscle mass involved in the quarters of the horse, some horses must have muscular origin and insertion pathological conditions. In human athletes lameness is commonly linked to strains, tears, and cramps in the semimembranosus and semitendonosus muscle groups and in the adductor and gluteal muscles. Horses are presumably no different. As yet, no definitive test appears to be available to confirm genuine muscle injury. Thermography is helpful in some horses but is disappointing in others. Increases in CK and aspartate aminotransferase levels, although pathognomonic for exertional rhabdomyolysis, do not seem to occur following genuine tears of muscle tissue. Presumably these tears result in little cellular disruption, the damage being more in the fascial planes and connective tissue.

If a horse remains undiagnosed after all available diagnostic analgesia and imaging modalities have been used, then the horse is confined to box rest for 1 month. Most horses become sound in this period. The horse walks for another month and then returns to walking and trotting exercise, before resuming a normal ascending exercise program. Although admitting defeat and being unable to give a definitive diagnosis is frustrating, we should try to avoid attributing a definite cause for the lameness if we have no evidence to support it. We have to educate our trainers and clients to accept the fact that ascribing lameness to injury of a specific structure in every horse is not possible.

Fractures of the Proximal Phalanx and Condyles of the Distal Third Metacarpal/Metatarsal Bone

The most dramatic example of a proximal phalanx fracture is a split pastern that is a frequent injury, particularly in a 2-year-old racehorse as it enters fast work. The length and configuration of these fractures include complete sagittal fractures involving both articular surfaces, multiple comminuted displaced fractures, and incomplete fractures extending short distances from the proximal articular surface. Diagnosis is usually straightforward with a complete fracture or an extensive incomplete fracture. With extreme injury a horse pulls up severely lame during or at the end of exercise. With less severe injuries, horses may finish exercise apparently sound but become increasingly lame on return to the stable. The horse is usually not bearing weight by the time of examination. Pain always occurs on flexion of the metacarpophalangeal or metatarsophalangeal joint and on pressure applied with the fingertips to the proximal phalanx along its sagittal dorsal midline. Radiographic examination is usually confirmatory.

Short incomplete sagittal fractures of the proximal phalanx can be notoriously difficult to see radiographically, when the fracture line only extends 1 or 2 cm into the bone. Clinical signs are of a severe lameness (grade 3 of 5) that rapidly improves so that the horse may be sound within 2 days.

Flexion of the fetlock joint is usually not painful. Firm squeezing of the proximal dorsal surface of the proximal phalanx usually is resented, particularly approaching the proximal articular surface, and this is a reliable clinical sign. A horse with this type of fracture should be given box rest for at least 2 weeks before further radiography. Short, incomplete fractures easily become complete comminuted fractures if a horse is exercised after 2 weeks of rest, because the fracture weakens by normal osteoclastic activity. Therefore although the horse may be sound, a premature return to work may result in a catastrophic fracture.

Fractures of the condyles of McIII/MtIII are a frequent injury, but they occur more often in 3- and 4-year-olds than in 2-year-olds. The lateral or medial condyle can be affected, and medial MtIII fractures often spiral proximally. The whole fracture may not be seen on one radiographic view, and several oblique views should be obtained to determine the extent of the fracture before contemplating general anesthesia for surgical fixation. Spiral fractures present a risk during anesthetic recovery.

A complete, displaced condylar fracture presents little diagnostic challenge. The horse is extremely lame and resents palpation of the lateral or medial condyle. Flexion of the metacarpophalangeal/metatarsophalangeal joint invariably is associated with sharp pain, and joint capsule distention and effusion usually occurs because of hemorrhage. Short, incomplete condylar fractures are more difficult to diagnose. Lameness is usually severe (grade 2 or 3 of 5) and diminishes rapidly. Horses often become lame again as soon as they are returned to cantering exercise. Diagnostic analgesia localizes lameness to the metacarpophalangeal/metatarsophalangeal joint, but nothing may be seen radiographically. A flexed 125° dorsopalmar view is vital if these lesions are to be seen adequately.[3] If radiography is performed in the field, using portable equipment, then an upright flexed view that moves the PSBs proximally is useful to identify the fracture[4] (see Fig. 108-4, *A*).

If a condylar fissure is suspected, the horse should be restricted to walking and trotting exercise for 2 weeks before follow-up radiography is performed. Many horses that eventually develop full, displaced condylar fractures are described as having been bad movers before injury, and almost certainly significant prodromal pathological damage contributes to the cause of these fractures.

Pain Associated with the Tarsometatarsal Joint

Sore hocks are probably much more common in the United States than they are in the United Kingdom. Tarsometatarsal joint lameness can be bilateral or unilateral and often does not resolve with rest, and the response to intra-articular administration of corticosteroids varies extremely. I treat horses with triamcinolone acetonide (10 mg) at the time of intra-articular analgesia to avoid having to re-enter the joint. After this therapy, many horses are sound, and lameness never returns. However, other horses require intermittent repeated medication, and others will not respond at all.

Horses with bilateral lameness are more difficult to diagnose. Bilateral plantar stress injuries in the distal aspect of MtIII should be eliminated first by diagnostic analgesia. If diagnostic analgesia is negative, local analgesia of one tarsometatarsal joint should be performed in the hope that an obvious lameness will become visible in the contralateral limb. Care should be taken if medicating both tarsometatarsal joints to avoid a laminitis-inducing dose of corticosteroid (e.g., no more than 20 mg of triamcinolone acetonide per horse).

CHAPTER • 109

The North American Standardbred

James B. Mitchell, John S. Mitchell, Paul M. Nolan, and Mike W. Ross

DESCRIPTION OF THE SPORT

The Standardbred (STB) was developed as a racing breed by registering any horse that could trot or pace a mile in a set time, called the standard. An early standard was 2:30 (2 minutes, 30 seconds, 0 fifths). Early STBs were diverse because they were different types with a large genetic pool. Crossing many types resulted in a strong, rugged breed that lacked refinement of the head, ears, and bone structure. Trotters were large and coarse, whereas pacers were smaller and more refined. The breed has progressed rapidly by selective breeding in the last 3 decades. Although trotters and pacers now are bred separately, the physical appearance has become more alike, and both lines have a racy appearance similar to Thoroughbreds (TBs). Early trotters were farm or buggy horses, selected for good disposition and durability, traits that are still characteristic. Early STBs were raced several 1-mile races in the same day, called heats, a part of the sport demanding stamina and gameness.

A TB stallion, Messenger, imported from England in 1788, was prominent in the formative period of the STB. Many of his offspring had a natural inclination to trot. In 1849 a descendent of Messenger sired Hambletonian 10, the foundation sire of the STB breed. The breed developed in the northeastern United States, where it was influenced by the Hackney and Morgan breeds and local mixed-breed horses.

The STB races at two different gaits, the trot, a diagonal two-beat gait in which the left forelimb (LF) and right hindlimb (RH) move together, and the pace, a lateral two-beat gait in which the LF and LH move together. High knee action and a lateral (left to right) nodding of the head are typical of a trotter (Fig. 109-1, *A*). A trotter travels straight ahead (Figs. 109-1, *A*; 109-2, *A*; and 109-3), but a pacer sways from side to side while moving forward (see Fig. 109-1, *B*).

Thirty years ago trainers had to spend several months determining at which gait a STB was more talented; some could not handle speed at either gait. As late as the 1970s and 1980s, for a horse to race one season at one gait and the next season at the other was not unusual. A few horses raced at different gaits weekly, but today most STBs race at only one gait. Many foals pace or trot naturally. Although while racing, trotters trot, when they are lame, they occasionally break into a pace. Pacers often jog, the term used for trotters and pacers when trotting the slow or wrong way (clockwise) of the track at the trot, but train and race at the pace. The pace is faster than the trot. The world record for the pace during a parimutuel race is 1:47.2 and that for the trot is 1:50.4. Many pacers race near record time, but trotters do not. Trotters and pacers do not race against each other in parimutuel races. A STB racehorse must qualify for racing, meaning the horse must better or match a minimal speed before being entered into a parimutuel race. Another form of speed test is called a time trial. At certain 1-mile long racetracks, horses compete against a prompter, usually a TB in harness, and go as fast as possible, but the prompter cannot pass the STB. The world record for the time trial is 1:46 set by a pacer. Mean race times of STBs are decreasing constantly (the horses are becoming faster) because of selective breeding, changes in track surfaces and banking, popularity of 1-mile racetracks (racing is faster because horses only negotiate two turns), refinement in race bikes (sulky), and advances in veterinary care.

Early trotters were raced under saddle and then with carts and wagons, with a time under 3 minutes being noteworthy. Sulkies appeared regularly in races in the 1840s, and the 2:30 barrier fell in 1845, becoming a time standard for the era. Race times fell steadily, and in 1897 a stallion named Star Pointer paced a mile in under 2 minutes. The first horse to trot the 2-minute mile was Lou Dillon in 1903.

North American STBs start a race behind a moveable starting gate, a vehicle carrying a barrier to keep the horses in line until the gate pulls away, at which time the horses accelerate to start the race evenly. In some countries horses start from standing, a staggered standing start, or a moving start without a gait. In Europe, races are only for trotters, and top 3-year-old and older North American trotters often are sold to European buyers.

STBs in North America are divided into four classes. The first is the International trotter that races in the top competitions in North America and Europe. The second is the Grand Circuit or stakes horse that travels from track to track, racing against the top 2- and 3-year-old horses. These horses may earn more than a million dollars a year. The third class includes the greatest number of horses stabled at or near a parimutuel track. These horses race repeatedly at one or two different tracks and are referred to as overnight horses. Overnight horses are raced in condition races, grouping similar quality horses by earnings, age, or sex, or in claiming races, where horses are grouped by price. The fourth class, county fair racehorses, popular mostly in the northeast and midwest United States, race for small purses at county fairgrounds, often under adverse track conditions, but they provide thrills for fans and owners beyond those of races with richer purses.

Amateur STB driving and racing under saddle are hobby type of events that are increasing in popularity. STBs compete at horse shows in the Roadster, hitched to a bike or wagon, and also as road horses under saddle. Former STB racehorses are not only popular in the Amish community, but they also can be found performing diverse sporting activities such as low-level dressage and jumping.

TRAINING

A classically trained STB has about 9 months of schooling and training before its first race. Most horses start training in the fall at 1½ years of age and begin racing the next summer. Many states have racing programs for 2-, 3-, and 4-year-old horses and require a horse to be nominated early in life. Eligibility then is maintained by periodic payments, called stake payments, creating a large pool of money divided among the winners of elimination and final events. Although some stake races receive track or corporate purse assistance, owners who put up their own money support most races. Stake races

are limited by age and sex. For example, 2-year-old trotting fillies race together. Stake payments must be made early in the spring, before talent and speed of individual horses can be confirmed, and owners, trainers, and veterinarians must decide which horses to stake. Emphasis on racing young STBs and the money necessary to maintain stakes eligibility place extreme pressure on trainers to race horses at 2 and 3 years of age. Horses often are pushed farther and faster than is reasonable, placing them at risk of stress-related bone injury, usually of subchondral bone. Many owners do not realize the difficulty of having a horse compete based on a calendar of scheduled events, expecting the horse to peak for the biggest purses, rather than on the horse's training and fitness level. The process of nominating and planning for stakes races is an art and science, and often a staking service is hired to organize periodic stake payments. Stake payments are a considerable expense and some owners spend several hundred thousand dollars a year. Horses not nominated, those dropped from stakes programs because of injury or lack of talent, or those in which payments were missed are still eligible for overnight racing. More and more late closer and entry-only stakes are becoming available for non-staked horses.

An STB is trained in a jog cart that is stronger, longer, and about three times as heavy as the 14-kg sulky or race bike (Fig. 109-1, *A*). A young pacer is soon equipped with hobbles, leather or plastic straps encircling the ipsilateral forelimbs and hindlimbs, to keep legs moving in unison (see Fig. 109-1, *B*). A horse capable of sustaining a pace without hobbles is called a free-legged pacer, but few race without hobbles. Hobbles can cause areas of hair loss on the cranial forearm and caudal crus called hobble burns, which are typical marks of a pacer.

Equipment is important in understanding gait and lameness. Head poles, boots, brace bandages, gaiting straps, and gaiting poles are used to improve gait and performance. A head pole keeps the horse from turning the head and neck to the opposite side. A horse with right forelimb lameness usually bears left, called bearing in or on the right line, because the driver pulls on the right line, causing the horse to turn the head to the right. This horse would wear a left head pole. Gaiting straps and poles run alongside the horse and attach to the cart beside the driver's seat and are used to keep the horse straight. Horses with unilateral hindlimb lameness often carry the hindquarters near the contralateral shaft, called being on the shaft. A horse with right hindlimb lameness goes on the left shaft and requires a left gaiting pole or strap. Boots are applied to minimize interference injury. Some horses chronically interfere, whereas interference in others is accidental. Soft brace bandages are used for protection and to widen the hindlimb gait.

Training the Young Standardbred

STBs are usually exercised 6 days a week at slow speed, jogging. Yearling STBs are introduced to the harness and bridle in the stall and then are line driven at a walk for several days before being hitched and jogged on the track. Once the horses can go to the track with a single driver, trainer, or groom, they are jogged 1 to 2 miles each morning, usually in a clockwise direction (wrong way) first. Young STBs are encouraged to jog at the intended gait as soon as possible. This is usually natural for trotters, but many pacers need hobbles or special shoeing. Weight usually is added to hind shoes of pacers, especially to the outside web, while the front feet may be left unshod. In trotters, weight is added to the front shoes. Shoeing and equipment changes begin early to produce the best gait possible.

Jogging is increased a mile every few weeks, up to 4 to 5 miles daily. Horses are taught to jog both ways on the track. Most young horses are jogged in groups, so horses overcome fear of traveling in close proximity. In large stables horses are trained in sets of three to five, to teach passing and racing in tight quarters, and to simulate racing. In addition to jogging, horses are trained fast every 3 to 4 days initially, but later twice weekly, going counterclockwise, the race or right way on the track. Horses are trained 2 and sometimes 3 fast miles on training days, but usually go back to the barn for a breather (to blow out) between fast miles (trips). STBs develop tremendous stamina compared with TBs, but fatigue and strain cycles predispose them to stress-related injury of the subchondral bone, not commonly of long bones as in TBs. When the fastest miles approach racing speed, young horses are ready for baby or schooling races to learn how to leave the starting gait. It is interesting that most STBs are trained, schooled, and qualified in the morning daylight and then make the first parimutuel start at night under the lights.

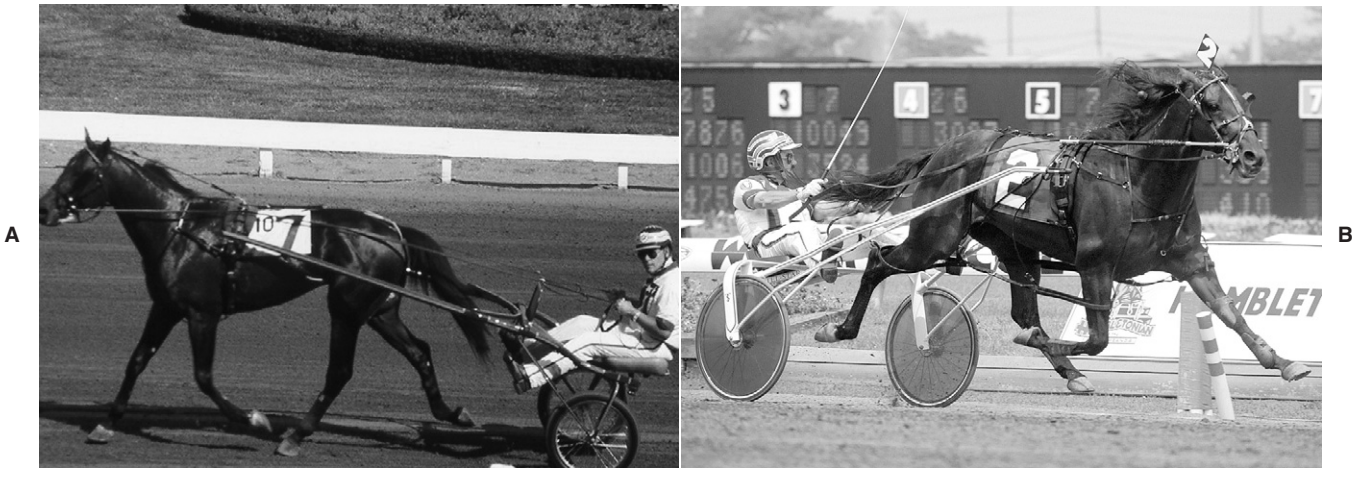

Fig. 109-1 The jog cart (**A**) is longer, stronger, and heavier than the race bike (**B**) and is used for training and jogging. **A,** Victory Dream is being warmed up by trainer Ron Gurfein in a jog cart. **B,** John Campbell and Real Desire on Hambletonian Day at the Meadlowlands (2002). The race bike is shorter and lighter weight than the cart. Note this pacer is in suspension, when all four limbs are off the ground. (Courtesy United States Trotting Association, Columbus, Ohio.)

Retraining a Racehorse

The classic retraining approach involves jogging 2 to 5 miles a day and additional training 1 to 2 times a week. A fast workout usually consists of two to three fast trips, which are simulated race miles taken at increasing speed. Horses usually are allowed to blow out between trips. Some are given double headers, two 1-mile workouts without returning to the barn, but they walk or jog slowly between trips. A break is when a horse leaves the expected gait and breaks into a gallop. Many training miles are given to obtain maximum physical fitness and to condition the horse to travel at speed without breaking. Many training miles are considered necessary to evaluate and adjust equipment and shoeing. Diagnostic analgesia can be performed between trips.

Alternative training methods produce good results and are customized to the disposition and physical condition of the horse. Trainers now use interval training, straight tracks, inclines and hills, swimming, towing behind a vehicle, and mechanical walker or joggers. With relocation of European trainers to North America, more alternative techniques have been introduced, including riding trotters between races.

Once racing, work is customized to each horse's needs. Hard training using the classic training method consists of one race and two training trips a week, but in this system horses are under considerable stress. Now that the breed is refined and heat races are fewer, racing horses are given much less training between races, and fast work may not be given at all. Reducing exercise intensity between races is important in managing STBs with chronic lameness.

LAMENESS AND POOR RACING PERFORMANCE

Lameness is the leading cause of poor performance and a major cause of STBs making breaks. Some overnight and some stakes horses are chronically lame but race weekly, although lame horses race slower, and as lameness progresses, horses drop in class. The major effect of lameness is seen during the last quarter of the race, called the last quarter time. Lower-class horses usually have a fast opening quarter, but slow last quarter time, whereas open and stakes horses have fast quarter times anytime during the race. Evaluation of last quarter time is useful to determine cause and severity of poor race performance. Lameness often costs a horse 1 to 2 seconds in last quarter race time, equating to 5 to 10 horse lengths. For example, a horse that normally paces the last quarter in 27.1, but for the last few starts has been coming home in 28.4 to 29.2 is probably lame, but concomitant respiratory and metabolic problems cannot be overlooked.

TRACK SURFACE AND LAMENESS

STBs usually race around an oval track, ½ to 1 mile in circumference; a 1-mile track is most common. Races are usually 1 mile in length, but a few are ⅝-mile sprints to 2-mile races. The track surface is a crushed rock base, covered with a packed, sandy soil and a thin sand or stone dust surface. STB racing requires a much firmer track surface than galloping horses. Sulky tires are more efficient if rolling over a firm smooth surface, and the STB gaits require a firmer and smoother surface than does the gallop. Track surfaces have become firmer, because year-round racing requires a surface suitable for racing in rain and sub-freezing temperatures. Hard tracks with loose surfaces require horses to wear shoes with added grabs and welded on spots of borium to avoid slipping. Excessive slipping or overzealous use of shoes with additives predisposes horses to lameness. A soft or deep surface can predispose horses to tendonitis and suspensory desmitis. Hard tracks with a covering of loose stone dust are slippery and may predispose horses to carpal synovitis, bruised soles, and muscle soreness. Racetracks get soft and sticky with small amounts of rain, and hard and unyielding with heavy rainfall that may wash the top surface into the infield.

TRACK SIZE AND LAMENESS

Track size has substantial implications in the development and expression of lameness. Tracks are 1 mile, ⅞ mile, ⅝ mile, and ½ mile, and in general, race times are lower (faster) on large tracks. Because most STB races are 1 mile, track size determines the number of turns during the race. During a race on a ½-mile track, an STB must negotiate four turns. Turns on shorter racetracks are much tighter than those on larger tracks (Fig. 109-2). Horses racing with mild chronic lameness are less

Fig. 109-2 **A,** A young trotter is on the left shaft coming out of a turn on a small farm track. On this track a horse has to negotiate four turns to train a mile. **B,** Horses approach the start of a race at the Red Mile, Lexington, Kentucky, a track that is 1 mile long. Compared with the turn in **A,** the turn on this track is substantially larger, and horses must negotiate only two turns for a mile race.

likely to sustain speeds necessary to be competitive on large tracks, so they may race on smaller tracks, but if lameness is worse in the turns, the horse may be less competitive on small tracks and better suited for a 1-mile track. If lameness is worse in the straightaway, the horse may be best suited for a small track. This is particularly important when lameness worsens as the race goes on, because large tracks have a long straightaway at the end.

During counterclockwise racing, right-sided lameness conditions exert more influence, even though the LF and LH are on the inside. Horses with left-sided lameness can race successfully on small tracks and apparently negotiate turns well. However, those with right-sided lameness cannot trot or pace the turns well, most likely from the effect of centripetal and compressive forces. Ideally, all racehorses should be sound, but many horses can race successfully with mild infirmity. Horses with substantial lameness should be treated or rested until the condition improves.

CONFORMATION

Forelimb and hindlimb faults lead to lameness and interference. Severity often depends on gait. A trotter should be as long from front to back as it is tall. Trotters are passing gaited if hind feet land outside the front feet, and in-line gaited if hind feet land in plane with the front feet. Wide hindlimb gait is advantageous because it allows a passing gait. Trotters can be mildly to moderately toed out in front without substantial interference problems, but they should not be toed in, because winging out leads to interference and lateral suspensory branch desmitis. Pacers can be wide and mildly toed in, but not toed out, because this fault predisposes the horse to hitting the knees. A club foot is less well tolerated by a STB than a TB and usually results in foot lameness. Low, underslung heels and long toes are acquired by attempts to increase stride length or to decrease interference. Back at the knee is undesirable and leads directly to carpal lameness in a trotter, but it is better tolerated by a pacer. Offset (bench) knee is a major fault and, although horses may race successfully, lameness of the carpus and metacarpal region often develops. Mild carpus valgus is tolerated by pacers but can lead to lameness of the carpus and metacarpal region. Pacers that are tied in behind the knee are at risk of superficial digital flexor tendonitis, but trotters are not. Short, straight pasterns and short backs are undesirable.

A serious hindlimb fault leading directly to moderate to severe lameness is sickle-hocked conformation (see Chapter 79). Mild sickle-hocked conformation typified many early pacers and is desired by some trainers. Sickle-hocked trotters are fast but develop curb and osteoarthritis of the distal hock joints, particularly severe in the dorsal aspect, and are chronically unsound. Straight hindlimb conformation is unusual but is a severe fault, leading to metatarsophalangeal and stifle joint lameness and suspensory desmitis. In horses with straight hindlimb conformation excessive extension of the metatarsophalangeal joint occurs. Long, sloping pasterns also predispose horses to fetlock hyperextension, but a primary metatarsophalangeal joint weakness is seen in some trotters with normal pastern lengths, in which the base of the proximal sesamoid bones (PSBs) is level with the mid-proximal phalanx. Abnormal elasticity or loss of support from the suspensory apparatus predisposes horses to run-down injury and suspensory desmitis. Cow-hocked conformation is prevalent in trotters but is not problematic unless severe. In-at-the-hock conformation predisposes horses to osteoarthritis of the distal hock joints, curb, and medial splint bone disease. Base-wide and base-narrow conformational faults, if severe, can lead directly to interference and lameness.

DISTRIBUTION OF LAMENESS

STB racehorses have a higher percentage of hindlimb lameness than TBs. The STB trains and races using a two-beat gait: two limbs bear weight simultaneously. Load is shared almost equally between forelimbs and hindlimbs. The caudal location of the cart and driver (load) and the addition of the overcheck apparatus shift the center of balance caudally, increasing hindlimb lameness (see Figs. 2-2 and 2-3). The distribution of forelimb to hindlimb lameness is approximately 55% to 45%.

TEN MOST COMMON LAMENESS CONDITIONS

The following are the top 10 lameness conditions in the STB racehorse:

1. Front foot lameness
2. Carpal lameness
3. Metatarsophalangeal joint lameness
4. Distal hock joint pain and other tarsal lameness
5. Suspensory desmitis: forelimb and hindlimb
6. Metacarpophalangeal joint lameness
7. Splint bone disease
8. Stifle joint lameness
9. Rhabdomyolysis and muscle soreness
10. Other soft tissue lameness: curb and superficial digital flexor tendonitis

LAMENESS IN THE YOUNG STANDARDBRED

The top 10 list contains those conditions seen in STB racehorses of all ages when grouped together, but unraced 2- and early 3-year-olds develop a subset of lameness conditions. Osteochondrosis (see Chapter 58), splint exostoses (splints), and curbs are common. Forelimb splints are usually medial but can occur laterally. Hindlimb splints are almost always medial and are more common in trotters. Splints can cause primary lameness or be secondary to carpal lameness, especially if exostosis is proximal. Forelimb splints develop when the limb is carried or lands abnormally. Young horses develop splints from difficulty learning the racing gait and by making breaks. While breaking, pacers often hit themselves, because galloping in hobbles is difficult. Curb is common in young pacers and may be recognized while horses are jogging, before training begins (see Chapter 79).

Carpal lameness is common in young horses. The middle carpal joint is the most common site, but synovitis can occur in the antebrachiocarpal joint. Carpal lameness is caused by early subchondral stress-related bone injury of the third carpal bone and is particularly common in trotters. Paddock turn out for 30 days is recommended. Middle carpal joint lameness must be differentiated from proximal suspensory desmitis (PSD). The thought once was that the distal radial physis was a source of occult carpal region lameness, but diagnosis was never confirmed. Physeal pain is a rare diagnosis today, but some veterinarians feel such pain is a possible source of colt soreness.

Bucked shins are rare but do occur in 2-year-old pacers in July and August. Most bucked shins occur in the forelimbs. Genuine bucked shins rarely occur in trotters, but interference trauma of the dorsal cortex of the third metatarsal bone (MtIII) is common.

Distal hock joint pain is a common cause of acute unilateral lameness, but if pain is bilateral, overt lameness may not be present. Horses appear stiff and sore when starting out and warm out of lameness. Gait abnormalities and repeated breaking may cause distal hock joint pain. Lameness may be difficult to abolish completely with intra-articular analgesia, because

pain is multifactorial, arising from peri-articular soft tissues and secondary gluteal myositis and trochanteric bursitis. Horses should be rested for 1 week and given non-steroidal anti-inflammatory drugs (NSAIDs) such as phenylbutazone (2.2 to 4.4 mg/kg PO bid). Intra-articular injections are avoided if possible, but treatment of the tarsometatarsal joint with hyaluronan alone, or in combination with corticosteroids, often resolves residual lameness. Using a less aggressive training schedule for 20 to 30 days is recommended. Shoeing should be evaluated and grabs and calks should be removed or minimized.

Interference injuries are common and plague many STBs throughout the racing career. Trotters interfere primarily by striking the toe of the ipsilateral front foot to the shin, pastern, or coronary band regions of the hindlimb (see Chapter 7). Interference from a front foot striking the medial aspect of the contralateral forelimb (cross firing) occurs occasionally in trotters but is a major form of interference injury in pacers. Injury to second (McII) and third metacarpal (McIII) bones, PSBs, carpus, heel, and hoof wall causes bruising and hematoma formation. Contusions can lead to soreness or frank lameness and can cause an altered gait. A trotter attempting to avoid striking the LH shin shortens the cranial phase of the stride, causing what appears to be a pelvic hike, mimicking LH lameness. Deliberate hiking can alter load distribution, causing compensatory lameness in the RH and RF. Local trauma is treated, and changes in equipment and shoeing such as applying brace bandages and boots are performed. A brief (5 to 7 days) reduction in exercise intensity is useful to allow a young horse to gain confidence in the corrected gait.

Young horses with poor gait should be examined carefully for neurological disease. Equine protozoal myelitis (EPM) is endemic in STBs and can be a real cause of gait deficits, or a catchall diagnosis (see Chapter 11).

CLINICAL HISTORY

Clinical history is critical for lameness diagnosis and to put lameness into context with other causes of poor racing performance. The attending veterinarian with an established relationship with the horse may know the horse's history. A trainer often refers to mild lameness by saying, "The horse is just sore, Doc" or, "The horse is off when jogging, but throws it away when going the right way." STBs have unusual resiliency and race rather well with chronic lameness, but lameness does not resolve with speed. Owners do not understand this concept. Signs of lameness become less visually apparent when horses go fast. Because STBs often race with numerous compensatory lameness problems, one must be open to the possibility that current lameness is not worsening of an existing problem but is an entirely new one.

A good starting place is to determine the chief complaint from the person(s) closest to the horse, usually the groom and trainer. What differs now from the horse's normal activity, gait, or performance? Has a change in training or racing schedule occurred? Any change in track surface? A horse noticed to be stiff and sore up front when walking to the track may be foot sore the day after the horse raced on a hard track. Have any equipment or shoeing changes been made? Additions of head poles, gaiting straps, and boots point to high-speed lameness and gait abnormalities. Shoeing changes, such as adding or removing bar shoes, are important because horses used to wearing bar shoes may have sore feet if bars are removed. Metacarpophalangeal joint lameness may be worse if bars are added. Stress-related bone injury of the metatarsophalangeal joint is seen soon after aluminum shoes with toe grabs are applied. Is the horse receiving any current medication and when was the horse last examined? What treatments, if any, were given? Although an acute injury or worsening of chronic osteoarthritis can cause acute synovitis, inflammatory and infectious arthritis can develop days to weeks after intra-articular injections, particularly if corticosteroids were used, because these drugs can suppress signs of inflammation and infection for weeks. Infectious arthritis is common 14 to 21 days after intra-articular injection, but often owners and trainers are incredulous because recent injections were not performed. What has the trainer and groom done recently to solve or treat the problem? Topical therapy may reduce or worsen inflammation and mask or augment clinical signs. Skin soreness after application of paints and blisters can cause a false-positive response to deep palpation.

Is the horse a trotter or a pacer? This information is critical. The usual distribution of pacers to trotters is about 3:1. Interference problems are different between gaits. Trotters develop contralateral or diagonal compensatory lameness, whereas pacers develop contralateral or ipsilateral compensatory lameness. A pacer with a left carpal lameness often develops LH compensatory lameness, but a trotter is more likely to develop compensatory lameness in the RH. The distribution of lameness differs between gaits. Fractures of the proximal phalanx and McIII/MtIII and superficial digital flexor tendonitis are less common in trotters. Trotters with stifle lameness, specifically osteoarthritis of the medial femorotibial joint, can cope better than pacers. Race times are different. Prognosis for certain problems such as osteochondral fragments of third carpal and radial carpal (RC) bones is worse in trotters. Pacers are more likely than trotters to start a race and to have five starts before and after surgical removal of osteochondral fragments of the carpus.[1] Osteochondrosis is common in certain bloodlines of trotter and pacers.

Is the condition worse at the trot or pace? Trotters and many pacers trot while jogging the wrong way, but assume the intended gait when turned the right way. Most forelimb lameness conditions are less obvious at the pace, but hindlimb lameness differs. In general, STBs with stifle lameness are worse at the pace than the trot. If trainers comment that the horse is worse on the pace than on the trot, the veterinarian should suspect stifle lameness until proved otherwise. Pacers wear hobbles, but trotting hobbles, those that encircle only the forelimbs and attach to a pulley caudally, are used if trotters are making breaks.

Is lameness different depending on what direction the horse moves? Problems on the right side are worse going the right way. Horses with medial foot and carpal lameness may show signs in the turns, especially entering the turning radius going the right way, but not when jogging.

What is the horse's last quarter time? Although high-speed lameness can cause a 1- to 2-second decrease in last quarter time, horses with mechanical upper airway disease and rhabdomyolysis have a 2- to 4-second reduction, and those with severe lameness or atrial fibrillation have a 5- to 10-second reduction in last quarter time.

Is the horse on a line? This is one of the most important pieces of information to obtain. Trainers sometimes dismiss young horses being mildly on the line, because nervous and inexperienced horses may change directions suddenly, but in reality most of these abnormal movements are caused by lameness. During counterclockwise racing of a horse on the right line, the driver has to increase the tension (pull harder) on the right rein to keep the horse straight and prevent it from bearing toward the infield. Just the opposite occurs when horses are on the left line (Fig. 109-3). Because of bit pressure, when a horse is on the left line, it turns or cocks the head to the left, toward the inside rail, and vice versa. If history is unclear, the veterinarian should watch the horse on the track and observe head position. Because most horses bear away from pain, a horse on the right line is most often lame on the right side, but exceptions occur. A common finding is metacarpophalangeal effusion

Fig. 109-3 This trotter is on the left line and the right shaft in the straightaway. The horse's head is turned to the left because the driver (Rich Ringler) has to pull harder on the left rein to keep the horse going straight. The horse's hindquarters are closer to the right shaft. This combination of left line and right shaft would be consistent with left hindlimb lameness.

and a positive response to lower limb flexion. The trainer states, "The horse was on the left line when finishing the mile, but is usually on the right line especially in the turns." Primary lameness may be in the right carpus, but chronic RF lameness has caused compensatory overloading and lameness of the left metacarpophalangeal joint, and both areas should be treated. Most horses on a line from forelimb lameness have foot or carpal lameness. However, problems located medially, such as medial sole bruising, quarter cracks, or carpal lameness paradoxically can cause a horse to be on the contralateral line. Therefore a horse with a medial LF quarter crack could be on the right line, whereas those with a right carpal lameness could be on the left line. All limbs should be examined, because not all horses read the book. "If a horse is on the left line, think right hind," one old saying goes, and rarely a horse with RH bruised or cracked heels will be on the left line.[2]

Horses on a line without overt signs of lameness are among the most difficult lameness mysteries to solve. Because compensatory lameness problems may be numerous in a horse in which primary lameness cannot be ascribed, deciding on which limb to begin diagnostic analgesia is a dilemma. Most horses need to be examined at speed after blocking, a time-consuming and frustrating process. In many horses on a line, obscure sources of pain such as subchondral bone can be difficult to identify, and horses often are referred for scintigraphic examination. Most horses chronically on a line have had many intra-articular or other injections, and trainers will state, "We've done his knees, hocks, stifles, and feet and nothing helped." Often forgotten are the metatarsophalangeal joints. In many horses numerous sites of pain must be managed simultaneously rather than sequentially. Recommending numerous intra-articular and regional injections, a shoeing change, and a change in exercise intensity in a horse that is on a line is not unusual.

Is the horse on a shaft? A horse with RH lameness drifts to the left (see Fig. 109-2) and positions the hindquarters closer to the left shaft of the sulky and is thus on the left shaft; the reverse is true with LH lameness (Fig. 109-3). Not all hindlimb lameness problems cause horses to be on a shaft. Horses with osteoarthritis of the medial femorotibial joint may not be on a shaft, but those with distal hock joint pain will be. A horse may be falsely on a shaft if it is hard on a line and the driver pulls hard to keep the horse straight, compelling the horse to twist its entire body, positioning the hindquarters close to one shaft to maintain balance.

Is the horse worse in the turns or on the straightaway? Although nothing is pathognomonic, a few findings are consistent. Horses with front foot lameness, splints, and curbs get worse as the mile progresses and so appear worse on the final straightaway. Horses with distal hock joint pain appear to be worse when going into or coming out of a turn but usually can pace and trot the turns successfully. Horses with carpal, metatarsophalangeal, and stifle joint lameness are worse in the turns. If a horse gets rough in the first turn just after leaving the gate, a medial RF problem such as a splint or carpal lameness should be suspected.

On what size track does the horse race? The relationship of track size to expression of lameness and the differences between left- and right-sided lameness problems were discussed (see page 897).

Is the horse making breaks? Unsound trotters often break stride and gallop but occasionally break into a pace. Lame trotters may pace when trotted in hand. Interference injury causes breaks and current shoeing or recent changes should be evaluated. A different way to hang up a horse, meaning how to shoe and equip it, may be all that is needed.

The veterinarian must be current on all medication rules in the racing jurisdiction.

LAMENESS EXAMINATION

The lameness examination can be divided into three stages: palpation, observation while moving on a lead shank, and observation under harness. The veterinarian should avoid narrowing the examination to the area suspected by the groom and trainer but should first stand back and observe the horse and watch the horse moving around and coming out of the stall. Subtle neurological signs may be apparent. Asymmetry, such as muscle atrophy, may point toward chronic lameness or neurological disease.

Palpation

Careful palpation is the art of diagnosis in the racehorse but often is sacrificed because palpation is time consuming. Palpation is critical in STBs because of numerous compensatory lameness problems. The veterinarian needs to be able to read the horse to make a diagnosis. A successful lameness detective respects what the horse is trying to say. The veterinarian should move over the entire horse with a light touch to see if a withdrawal response is elicited. A light touch along the neck and gluteal regions may elicit pain from secondary muscle soreness or painful previous intramuscular injection sites. Horses often exhibit a withdrawal response when a limb is first picked up, indicating a problem even before the specific region is manipulated. Horses may exhibit false-positive responses in areas that have been painted recently, blistered, or freeze fired. Once horses have been freeze fired for splints and curbs, many trainers assume the problem has been solved and are incredulous if the veterinarian suggests the area is still the source of pain. Cryotherapy is not a panacea and may have to be repeated, or another form of management may be needed (see Chapters 79 and 90).

Palpation should be done in a quiet place, before the horse is trotted in hand, so that all potential lameness problems are detected. Careful and detailed examination of the front feet should be performed. Hoof tester examination is critical, but

most horses show a painful response for 1 to 2 days after racing, particularly if the track was hard. Effusion of the distal interphalangeal joint capsule often accompanies early osteoarthritis and sore feet. Shoes on the front and back feet should be evaluated critically for wear, type, weight, and the presence of additives. The proximal, dorsal aspect of the proximal phalanx should be palpated for pain associated with mid-sagittal fractures of the proximal phalanx. Palpation findings in the metacarpophalangeal and metatarsophalangeal joints often do not correlate well with degree of lameness, response to diagnostic analgesia, and results of scintigraphic examination. Pain on palpation of the PSBs may indicate sesamoiditis. Normally the horse responds little to compression of the suspensory ligament (SL), deep digital flexor tendon (DDFT), and superficial digital flexor tendon (SDFT). Pain is often the first sign of desmitis or tendonitis. Chronic enlargement of the SL and SDFT are common in lower-class horses, and although the horse may not react to palpation, it may have associated high-speed lameness. Splint exostoses are most painful after training or racing but may be non-painful several days later. Standing and flexed subcarpal palpation may reveal pain from PSD, longitudinal and avulsion fractures of McIII, proximal superficial digital flexor tendonitis, and a dorsal medial articular fracture of McIII.

No palpable abnormalities may be associated with carpal lameness. The veterinarian should carefully assess for warmth and compare the limb with the contralateral limb. Effusion occurs in 2-year-old horses early in training, but it often is minimal in horses with subchondral bone pain. The antebrachiocarpal joint is rarely a site of carpal lameness in older racehorses, but in young horses, especially trotters, effusion may occur. The medial carpus and distal antebrachium are common sites for interference injury. Carpal tenosynovitis is unusual to rare, but occasionally hyperextension injury and hemorrhage or, rarely desmitis of the accessory ligament of the SDFT, occur. Pacers develop hobble burns and cellulitis in the proximal antebrachium. Elbow and shoulder joint lameness is rare, but horses may exhibit pain when the biceps brachii, intertubercular bursa, and other muscles are palpated or the shoulder joint is flexed, from muscle soreness secondary to primary carpal lameness. The neck, back, and rump regions should be palpated for symmetry and muscle soreness. Young horses will occasionally manifest sore withers from an improperly fitted harness. Because intramuscular injections of counterirritant and anti-inflammatory solutions are common in STBs, careful palpation is necessary to discover deep abscesses causing pain, lameness, and fever. Disease of the thoracic dorsal spinous processes is rare. In an 8-year period, none of 1020 STBs undergoing scintigraphic examination had increased radiopharmaceutical uptake in the dorsal spinous processes.[3]

Secondary muscle soreness of the gluteal region is a common problem, and the diagnosis of trochanteric bursitis often is made based on a painful response to compression. Trochanteric bursitis (whorl bone disease) may be overdiagnosed and difficult to authenticate, but injections often improve hindlimb gait and performance (see Chapter 48). Rhabdomyolysis also can cause pain on palpation of the rump region. Young horses with loose stifles often knuckle behind, but palpation is often negative. Pain associated with the medial aspect of the stifle may be present, but abnormalities when manipulating the patella are absent. Femoropatellar effusion in young horses can signal osteochondrosis. The medial femorotibial joint capsule should be palpated, because osteoarthritis is the most important lameness of the stifle. The crus is a rare site of pain. Hobble burns on the caudal aspect can cause soreness in young pacers.

The tarsocrural joint is the most common site for osteochondrosis and effusion in young horses should prompt radiographic examination. Peri-articular pain in the distal tarsus and proximal metatarsal region often accompanies distal hock joint pain. The Churchill test is done routinely, but in addition to those with distal hock joint pain, STBs often respond positively with other common distal limb lameness. Bony enlargement (bone spavin) is rare. Plantar soft tissue swelling and pain associated with curb is a common cause of lameness (see Chapter 79). The plantar metatarsal region commonly is overlooked, but it should be palpated carefully for the presence of suspensory desmitis. Signs of inflammation may be difficult to detect, because the SL is enclosed within the bony confines of the metatarsal bones. The first evidence of suspensory desmitis is mild enlargement and pain of the suspensory body in the mid-metatarsal region. Compression of the splint bones puts indirect pressure on the SL and explains why the Churchill test is non-specific. The dorsal aspect of MtIII is a common site for interference injury in trotters. Palpation of the fetlock region is critical, because the region is an important source of lameness, but often no localizing clinical signs are apparent. Pain from interference injury should be differentiated from that associated with mid-sagittal and dorsal frontal fracture of the proximal phalanx. The hind foot is an unusual source of lameness, but fractures of the distal phalanx, bruising, navicular disease, and osteoarthritis of the distal interphalangeal joint are diagnosed occasionally. STBs normally respond positively to hoof testers placed across the heels.

Movement

The horse should be examined at a walk and trot in hand. The pace is a forgiving gait, and head and neck nod and pelvic hike can be difficult to see. Evaluating lameness in pacers is easier while they are trotting, but correlation between lameness seen in hand and during pacing at high-speed is questionable. Forelimb lameness is less obvious at the pace. Degree of pelvic hike is comparable at the pace and trot. Baseline lameness should be determined before the harness is applied, because horses that are fracture lame should not be taken to the track, and in horses with obvious lameness, a good correlation exists between lameness seen in hand and in harness. The ability to trot horses in hand at the racetrack may be limited because of too much activity, lack of room, and often poor or slippery surfaces. Flexion tests are performed but lack specificity. The carpal flexion test is the most reliable and specific of all flexion tests. Direct compression of a painful splint, proximal SL, and curb followed by trotting is useful. Subtle hindlimb lameness is best evaluated in harness, because little correlation may exist with lameness seen in hand. Pulling a cart and different surface likely explain this observation. Subtle (less than grade 1 of 5) hindlimb lameness at the trot in hand should be taken with a grain of salt. Observation on the track puts lameness into perspective and allows evaluation of compensatory lameness. Lameness is most pronounced when horses are jogged slowly and is much less obvious with speed. High-speed lameness is evaluated by communication with the trainer and by resolving signs such as being on a line.

DIAGNOSTIC ANALGESIA

Diagnostic analgesia is essential to pinpoint lameness, but trainers and owners often prefer treatment of a suspected area rather than lengthy investigation. With weekly racing no time may be available for blocking, because levels of local anesthetic solution will be detectable. Diagnosis often is made based on response to treatment. Many common lameness conditions involve subchondral stress-related bone injury, and often horses can be blocked sound but do not improve with intra-articular treatment. Perineural analgesia is more effective than intra-articular analgesia for diagnosing subchondral bone pain.

Controlling as many variables as possible is important when observing STBs in harness. The same gait, equipment,

driver, approximate speed, and track direction should be used. Sometimes horses exhibit lameness when driven by the groom but not the trainer, because trainers expect a higher level of performance and often carry a whip. A false positive occurs when a horse exhibits lameness at the pace but after diagnostic analgesia returns to the track without hobbles equipment and trots soundly. The diagnostic analgesia procedure should be the only variable. STBs often warm out of lameness and should be evaluated immediately when starting out after each block. Over zealous use of a twitch and rough handling may compromise evaluation, and administration of drugs can add another variable. If horses are observed in harness after diagnostic analgesia, the person driving the horse should be instructed to return the horse to the stable as soon as improvement is recognized, because training a horse after blocking risks further injury.

Complete description of blocking techniques is found in Chapter 10. A few points about diagnostic analgesia in the STB must be kept in mind. Palmar or plantar digital analgesia desensitizes most of the foot. Horses with metacarpophalangeal or metatarsophalangeal joint lameness can be sound after palmar or plantar digital analgesia, particularly those with mid-sagittal fracture of the proximal phlanx.[4] The abaxial sesamoidean block is avoided, because inadvertent analgesia of fetlock pain can be misinterpreted as lameness of the foot or pastern. Individual carpal joints should be blocked separately, and differentiation between carpal and proximal metacarpal region lameness is necessary. The median and ulnar nerve block is underused.

A low plantar block must be done routinely, or many lameness conditions will be diagnosed erroneously as high up. The fetlock region is a major source of hindlimb lameness. The high plantar block is often overlooked, but PSD cannot be substantiated without it. The centrodistal joint is difficult to enter but should be blocked separately from the tarsometatarsal joint, because communication occurs in only 8% to 39% of horses. The medial femorotibial joint should be blocked separately from the femoropatellar joint, even though they communicate in a high percentage of horses.

IMAGING CONSIDERATIONS

Radiography

Routine radiographic examination of STBs does not differ from that of other sport horses. However, a few specific views should be kept in mind. Down-angled oblique (dorsolateral 45° proximal-palmaromedial distal oblique and dorsomedial 45° proximal-palmarolateral distal oblique) and horizontal oblique (dorsolateral-palmaromedial oblique [DL-PaMO] and dorsomedial-palmarolateral oblique) views should be obtained to evaluate the distal interphalangeal joint. The tangential (palmaroproximal-palmarodistal oblique) view of the navicular bone is less valuable in the STB than in other older sport horses. To evaluate the distal aspect of McIII/MtIII for subchondral stress-related bone injury and the space between the proximal plantar aspect of the proximal phalanx and the base of the PSBs for the presence of fragments, down-angled oblique (dorsolateral 15° proximal-palmaromedial distal oblique and dorsomedial 15° proximal-palmarolateral distal oblique) views should be obtained (see Chapter 43). The most important views of the carpus are the DL-PaMO view and the tangential (skyline) view of the distal row of carpal bones. In STBs it is essential to have a well-exposed and well-positioned skyline view to evaluate the third carpal bone for sclerosis, radiolucency, and osteochondral fragments (see Chapter 39). Radiographic changes of osteoarthritis of the centrodistal and tarsometatarsal joints are seen best on the lateromedial and dorsomedial-plantarolateral oblique (DM-PlLO) views. A common misconception is that changes associated with bone spavin occur medially, but not in young STBs. The DM-PlLO view is essential in evaluating the tarsocrural joint for osteochondritis fragments, because the two most common locations, the cranial intermediate ridge of the distal tibia and the lateral trochlear ridge of the talus, are evaluated best using this view. The caudocranial view is essential when evaluating the medial femorotibial joint for narrowing, osteophytes, and subchondral bone cysts. Inadequate exposure and positioning often result in views that cannot be interpreted.

Computed radiography and xeroradiography are useful in evaluating stress-related bone injury of subchondral bone and incomplete fractures. Computed tomography and magnetic resonance imaging have limited availability.

Ultrasonographic Examination

Suspensory desmitis, superficial digital flexor tendonitis, curb, and desmitis of the distal sesamoidean ligaments are common in the STB, and ultrasonographic examination is essential for diagnosis and assessing prognosis (see Chapter 16).

Scintigraphic Examination

Referral for scintigraphic examination is common, and horses with poor performance often have numerous areas of increased radiopharmaceutical uptake (IRU), indicating high-speed lameness is a part of the problem. Common areas of IRU include the distal phalanx, metacarpophalangeal joint (medial condyle of McIII and PSBs), proximal aspect of McIII, carpus, especially the third and radial carpal bones, metatarsophalangeal joint (proximal aspect of the proximal phalanx and distal plantarolateral aspect of MtIII and PSBs), the proximal plantar aspect of MtIII, tarsometatarsal and centrodistal joints, and medial femorotibial joint (see Chapter 19).

PROCEEDING WITHOUT A DIAGNOSIS

Proper identification of lameness as the cause of poor performance and localizing the site(s) of pain can be challenging and relies heavily on experience. It is particularly important to differentiate lameness from interference, because interference can cause signs that mimic lameness, lameness can result from interference, or lameness can cause interference. Horses on a line without obvious lameness and a negative response to diagnostic analgesia can be frustrating. Horses can become stubborn and react to equipment and twist and bend the head and neck, causing signs similar to being on a line. Occasionally, horses with tooth-related pain get on a line. An ocular problem is a rare cause of a horse being on a line. Trainers may use bridles with partial blinds or vision-restricting cups to control a horse on a line.

Simultaneous RF and RH or LF and LH lameness, or even primary hindlimb lameness, can be difficult, because hindlimb lameness can cause a head nod mimicking ipsilateral forelimb lameness. Diagnostic analgesia should start in the hindlimb. In trotters with foot and carpal lameness the caudal phase of the lame forelimb is longer, and to avoid interference, the cranial phase of the ipsilateral hindlimb is shortened (hiking), mimicking hindlimb lameness. Pelvic hike abates when the source of forelimb lameness is localized. The clinician should obtain a fresh perspective and ask a fellow veterinarian or refer the horse for advanced imaging.

To differentiate lameness from interference gait abnormalities, phenylbutazone (4.4 mg/kg bid for 5 to 10 days) is administered (the bute test). Horses with pain should improve, whereas those with pure interference gait abnormalities should not. However, not all horses with musculoskeletal pain respond to NSAIDs, particularly those with chronic lameness or numerous compensatory problems. Alternatively, the veterinarian

should medicate the suspected area and see if performance improves, because mimicking the maximal exertion of racing is difficult. A trotter on a line only going into the first turn may be helped by injection of corticosteroids around a mildly painful medial splint or into the middle carpal joint. Sometimes treating a different area between several races may allow a fortuitous discovery, but this requires good record keeping, and it may be expensive. Occasionally, horses with subtle or nondescript lameness or a rough gait are managed using a shotgun approach, and numerous intra-articular treatments are given simultaneously. This approach should be reserved for horses in which normal management procedures have failed and an important race is rapidly approaching. Sometimes a positive response to intra-articular corticosteroid injections results from systemic absorption and effect on a distant, rather than the intended, site.

A brief turnout period of 7 to 10 days is sometimes useful. In 2-year-olds a decision often is made to stop training and give 3 to 4 months of turnout rather than risk compensatory lameness or fracture. The decision to stop training a horse should not be taken lightly. Getting an older horse back to the same level of racing is often difficult, even with a planned turnout period, and jogging the horse 3 to 4 times a week to maintain condition and range of joint motion may be best. The older the horse is, the more difficult returning the horse to racing is. Older horses with chronic lameness do not thrive with rigorous training and often come out of a solo training mile lamer than after schooling or qualifying races. Older horses often are raced into fitness, rather than trained rigorously. A common mistake is to train or race these horses too often.

A complete neurological examination should be performed in any horse with gait deficits and even some with overt lameness, if neurological signs are noticed concomitantly. EPM is frequently diagnosed, but positive identification of the source of neurological signs is difficult to make, because serum and cerebrospinal fluid analyses are not accurate (see Chapter 11). A common method to manage horses when all else fails is to treat for EPM and observe the results. Some horses improve despite having no overt neurological signs.

SHOEING AND LAMENESS

Shoeing to obtain ideal high-speed gait is an art, especially in trotters that are difficult to balance. The farrier must be a part of the lameness team. Veterinarians have to take a back seat to the trainer and farrier and cannot be overtly critical of the shoeing approach. Sore front feet are common and many approaches are used. Sometimes a simple shoeing change redistributes load away from a sore area, and a common approach in trotters is a switch from a half-round to a flip-flop shoe (see Fig. 110-11). Classically, trotters are shod with more weight up front, whereas pacers are shod with more weight behind. Recently the tendency has been to lighten shoe weight in trotters and pacers in front and behind. The typical hind shoe of a pacer (a half-round, half-swedge) has been replaced by aluminum shoes with a low toe grab. Aluminum shoes are used commonly in front in pacers. In trotters, heavy front shoes may predispose to interference injury and carpal lameness, and now aluminum shoes often are used behind, allowing a lighter shoe to be used in front. Light aluminum shoes with grabs allow maximal track purchase and increase speed, but they may worsen existing osteoarthritis of many distal joints behind and in front. A STB can jog and train abnormally with a sprung shoe or a broken bar shoe. Special attention should be given to the medial half of the front feet because interference bruising is substantial.

A low-heel, underslung foot is not common in modern day STBs, although low-heel, long-toe conformation was previously favored in the erroneous assumption that it would increase stride length. When combined with heavy shoes, long toes prolong breakover, increase stress on the dorsal aspect of the forelimb, and predispose the horse to lameness. Using a shorter toe and more upright front foot is a major improvement in trimming trotters.

Quarter cracks and other hoof wall defects are common. Acrylic and composite repair of hoof defects have aided many sore-footed STBs. Acrylic often is applied to augment the hoof wall. In horses with thin walls, shoes are difficult to maintain, especially when shoes may be changed every 2 to 3 weeks. Overzealous application of acrylic can weaken a normal hoof wall.

SPECIFIC LAMENESS CONDITIONS OF THE STANDARDBRED RACEHORSE

Front Foot Lameness

Front foot lameness is the most common lameness condition. Palmar heel pain abolished using palmar digital analgesia is a common finding, but the veterinarian should keep in mind that palmar digital analgesia also abolishes most of the pain associated with the distal interphalangeal joint and toe and lower pastern regions. Palmar heel pain can be caused by bruised heels, corns, sheared heels, hoof cracks, contracted heels, wall separations and gravel, stress remodeling and stress fractures, traumatic fractures, osteoarthritis, or various combinations of these conditions.

Bruises, Corns, and Abscesses

Bruised feet can be caused by faulty conformation such as that seen in a large, flat-footed horse that develops bruised heels and bars. Small, narrow-footed horses are prone to quarter and heel cracks and sore heels. Young STB feet are trimmed and pared and subjected to daily concussion on a firm and unforgiving surface. Aggressive paring can predispose to palmar sole bruising. Overt lameness may not be seen. Horses are often sore when starting from the barn and warm out of lameness after jogging a short distance. Because early carpal lameness can produce similar signs, careful hoof tester examination is necessary and often reveals profound sensitivity across the heels.

Base-wide, toed-out conformation causes overload of the medial heel and quarter, and long, sloping pasterns cause overload of the palmar aspect of the foot. Shoes that are too narrow or those with short branches can cause sole bruising and corns. Horses that interfere (cross firing or forging) are often shod with the inside branch of the shoe turned in to prevent grabbing and pulling of the shoe, and this can cause corns. Shoeing to correct interference is important but so is management of lameness that may lead to interference. Tubbing and soaking may compound the problem, creating a softer, more easily bruised sole. Poulticing may reduce inflammation initially, but continuous poulticing has the same undesirable result. The sole should be hardened with daily applications of an iodine-based paint, such as Rites paint, an iodine-ether preparation. Attention should be given to the stall bedding, since overly dry stall may lead to dry, cracking hoof walls. Digging out the bruise prolongs lameness and predisposes the hoof to abscessation. A wide web, concave inner surface steel bar shoe is applied if the horse can tolerate this much weight. A trainer may prefer a lighter aluminum bar or egg bar shoe. Full pads may afford protection for an upcoming race, but bruises cannot be re-assessed, and sole paint cannot be applied. In trotters the flip-flop shoe is advantageous, because the pad can be lifted and the sole painted, and without shoe branches the heels can spread. Deep-seated bruises can become corns, corns can fissure and crack, and bacterial invasion can cause infection. With abscessation, judicious paring to establish drainage is necessary, but the more

sole that is removed, the longer it takes to heal. Soaking in warm water with Epsom salts (magnesium sulfate) and then wrapping with ichthammol (an iodine-based drawing salve) promote drainage.

Sheared Heels

Quarter and heel cracks, wall separations, and contracted heels can result from sheared heels. Improper and asymmetrical rasping over time results initially in lowering of one heel and later to vertical heel walls, contracted heels, and flaring of the wall on the side of the lower heel. With mediolateral hoof imbalance, the vertical heel strikes the ground first, and uneven impact causes structural breakdown between the bulbs of the heel. The bulbs are painful and little resistance is offered to digital displacement of the bulbs in opposite directions. Corrective shoeing involves shoeing the steep side full and floating the quarter. The flared wall is shod tight and rasped off over several trimmings. For a horse with a long-toe and underrun heel predisposed to sheared heels, the toe should be shortened and the heel maintained. Recurrent quarter and heel cracks are common sequelae.

Hoof Cracks

Hoof cracks, depending on location, are known as heel or quarter cracks. Cracks may begin at the coronary band or at the bearing edge of the hoof wall. If the quarter crack extends to the sensitive laminae, local tenderness and variable lameness result. Horses with dry, shelly feet or vertical walls are predisposed to quarter cracks. Untreated chronic inflammation, inappropriate rasping of the periople and application of excessive acrylic predispose horses to dry feet, because exposure of horn tubules results in loss of moisture. Indiscriminate cutting of bars predisposes horses to contracted heels and results in vertical walls. A vertical wall is more likely to crack than a normal one. Quarter cracks can develop if horses are shod with the web of the shoe set in. To manage quarter cracks, weight bearing is prevented by floating, and artificial support to the weakened and cracked wall is applied, using a full or egg bar shoe. Extensive, deep, or painful cracks are repaired and stabilized. Acrylic patches are now preferred, but the crack must be prepared by paring and drying with iodine paint or gentian violet, or infection may develop.

Contracted Heels

Contracted heels can result from palmar heel pain rather than cause it. Dry, brittle feet cannot expand normally and may contract, as does a foot that has a long toe and low heel. When faced with a choice, farriers too often pick a shoe that fits tight (narrow), rather than full (wide), when the horse really needs a size in between. The wall inevitably grows to the small shoe and contracts. The indiscriminate use of acrylic results in heel contraction, because the material restricts expansion. Acrylic should be placed on the weight bearing wall surface only to repair broken or brittle walls for nail placement or for rebuilding low heels. The last shoe nail should be placed at the bend in the foot quarter, rather than in a more palmar location, to prevent restriction of heel movement. Other causes of palmar heel pain reduce weight bearing at the heels, leading to contraction. To manage contracted heels, the quarter is softened, the toe is shortened, and an extended bar shoe that fits full (wide) is applied. Lowering the heel to achieve frog pressure is contraindicated.

Wall Separation and Gravel

Gravel is caused by separation of the white line at the quarter and heel and bacterial invasion. Lameness, insidious at first, progresses to nearly non–weight bearing. Digital pulse amplitude is increased, and the horse responds intensely to hoof tester examination over the affected area. The coronary band or heel bulb become sensitive just before infection breaks out. Local therapy such as soaking and poulticing may hasten coalescence and proximal migration of exudates. If pastern cellulitis occurs, broad-spectrum antimicrobial agents should be given. The horse is generally sound within 24 hours after drainage, but a full pad may be necessary to avoid repeat infection during wall healing. Wall separations and gravel are common complications to sheared heels and dry, brittle feet. Seedy toe is an infected wall separation at the toe.

Fig. 109-4 Dorsomedial proximal-palmarolateral distal oblique xeroradiographic view of right front foot of a Standardbred racehorse. There is a typical articular fracture of the medial palmar process *(arrows)*. The horse is shod with a bar shoe with clips.

Sidebone

Ossification of the cartilages of the foot (sidebone) is a rare cause of lameness. Ossification may be hastened in horses with poor hoof conformation or in those in which interference injury occurs. Sidebone is found more often radiographically in aged horses with large, round, flat feet, but it may be seen incidentally in yearlings. If sidebone is painful to digital palpation, a bar shoe with heel clips and local subcutaneous injection of corticosteroids and Sarapin may provide temporary relief. Interference injury may cause fracture and infection of a cartilage of the foot.

Fractures of the Distal Phalanx

Fractures of the distal phalanx occur most commonly in the LF lateral and RF medial palmar processes and are usually articular (Fig. 109-4). Clockwise training and racing may account for asymmetrical location of fractures. Non-articular palmar process and mid-sagittal fractures are rare. Predisposing factors include hard racing surfaces (most fractures occur during a race, more often in winter months), foot imbalance, impact on an uneven surface, and overloading. Fractures of the distal phalanx may be the end result of stress-related bone injury of the distal phalanx, because IRU often is seen in the lateral aspect of the LF and medial aspect of the RF distal phalanx in horses with lameness abolished by palmar digital analgesia but in which radiographs are negative (Fig. 109-5).[5] Most fractures of the distal phalanx occur in aged horses. Treatment includes application of a wide web, concave inner surface steel straight or egg bar shoe with two side clips on each side. Horses are given 3 months of stall rest and then 3 months of turnout in a small paddock. Most fractures are complete, but non-displaced; mild displacement results in a step in the articular surface. Fractures take months to heal, and some appear to develop chronic nonunions, but many horses return to racing soundness even with a radiographically apparent non-union. Osteoarthritis of the distal interphalangeal joint often occurs, particularly in horses with displacement or non-union, but unless severe, prognosis

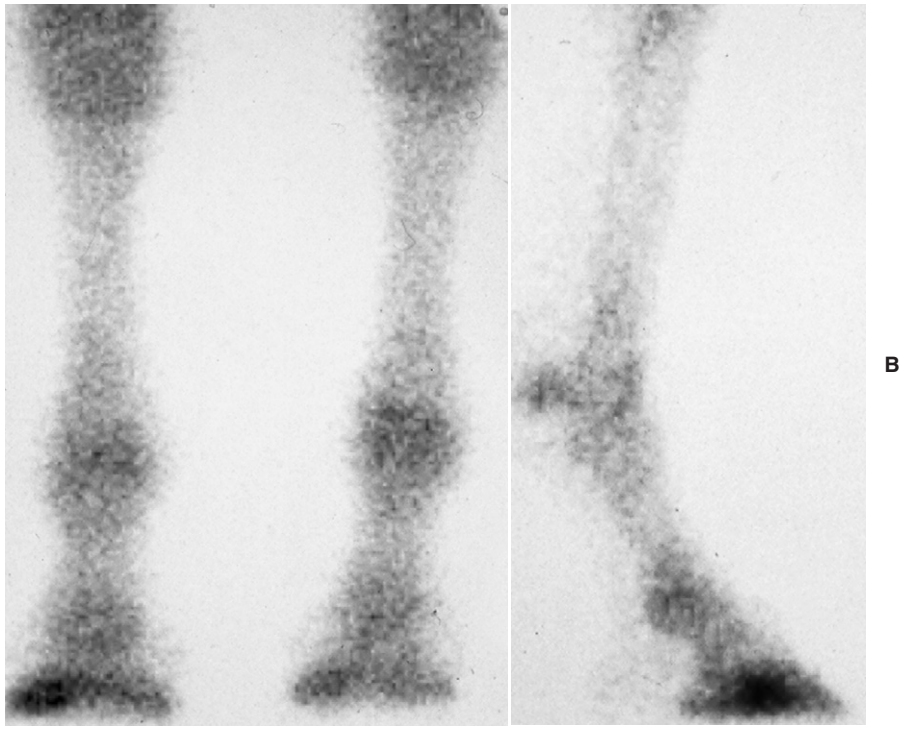

Fig. 109-5 **A,** Dorsal delayed (bone) phase scintigraphic image showing a typical distribution of increased radiopharmaceutical uptake of the Standardbred front feet. The left forelimb is on the left. (**B**) Lateral delayed (bone phase) scintigraphic image of the left forelimb. This Standardbred was lame in the left forelimb, and lameness was localized to the lateral aspect of the distal phalanx. In the left forelimb, stress remodeling of subchondral bone of the distal phalanx was diagnosed. Increased radiopharmaceutical uptake involving the lateral aspect of the left forelimb and medial aspect of the right forelimb distal phalanx is thought to be caused by counterclockwise training and racing, and stress-related bone injury can lead to fracture in these locations.

for racing is good. Osteochondral fragments of the extensor process are unusual, but arthroscopic removal of small fragments and repair of large ones are indicated. Prognosis is fair, but osteoarthritis of the distal interphalangeal joint can affect prognosis negatively.

Osteoarthritis of the Distal Interphalangeal Joint

The earliest sign of primary osteoarthritis of the distal interphalangeal joint is effusion. Effusion is also common in horses with nondescript foot soreness. Intra-articular distal interphalangeal injections of hyaluronan and corticosteroids are often performed. Progressive osteoarthritis can cause severe lameness, chronic fibrosis and thickening of the distal interphalangeal joint capsule, radiographic evidence of proliferative changes on the dorsal aspect of the middle phalanx and extensor process of the distal phalanx, and narrowing of the distal interphalangeal joint space.

Other Foot Lameness

Navicular disease is a rare cause of palmar heel pain. In 2-year-olds and early 3-year-olds IRU in the navicular bone is seen in delayed (bone) phase scintigraphic images, indicating abnormal bone modeling, but rarely do radiographs show substantial changes, except for mild medullary sclerosis. Navicular bone fracture, cysts, or acute separation of bipartite navicular bone are diagnosed rarely in forelimbs and hindlimbs. Horses with bipartite bones or fractures have a poor prognosis and palmar digital neurectomy is recommended.

Undiagnosed foot lameness, sore feet, is common. Horses have sensitivity to hoof testers and likely have soft tissue trauma, but a definitive diagnosis cannot be made. Treatment of the distal interphalangeal joint with corticosteroids and hyaluronan, perineural injection of anti-inflammatory agents, and shoeing changes are recommended.

Carpal Lameness

The carpus is the most common articular location for lameness and conformational faults. In 2-year-olds, carpal synovitis is common. High prevalence of carpal lameness is caused in part by racing young, immature STBs around tight turns on firm surfaces. The medial aspect of the middle carpal joint and the right carpus are predisposed to injury. Lateral injury of the carpus is unusual. Heat, effusion, and pain on careful palpation of the dorsal surfaces are common. Lameness varies with severity of injury, and horses carry the limb in an abducted position during advancement (see Chapter 39). Response to flexion varies, and diagnosis should be confirmed using intra-articular or median and ulnar analgesia. Secondary shoulder muscle soreness often develops. Horses warm out of lameness and weeks to months may pass before consistent lameness is seen. Radiographs are usually negative or equivocal initially, but sclerosis of the third carpal bone and mild marginal osteophyte production can predispose the horse to small osteochondral fragments or slab fractures of the third carpal bone. Scintigraphic examination often reveals focal areas of IRU, usually involving the third carpal bone or the medial aspect of the middle carpal joint collectively; bilateral lesions are common. Stress-related bone injury results in a continuum of subchondral and overlying cartilage damage, eventually leading to osteoarthritis or osteochondral fragments. Rest is the best form of management but is unacceptable to trainers and owners. Topical counterirritation with iodine paints is still

popular and is used with apparent success, because blistering usually is accompanied by a reduction in exercise intensity. The administration of NSAIDs for 3 to 5 days and a brief period of reduced exercise (2 weeks) may be an acceptable compromise between the veterinarian and the trainer. Intra-articular injections of hyaluronan or polysulfated glycosaminoglycans (PSGAGs) may reduce inflammation and theoretically may be useful in cartilage healing, but these often are used in a palliative rather than therapeutic manner. Injections may be of little benefit when pain originates from subchondral bone. Ten 2-year-old STBs with mild carpitis were treated with 3 to 5 weekly intra-articular injections with PSGAGs (Adequan) and were compared with a control group receiving NSAIDs and topical counterirritation.[6] The treated group had substantially less carpal lameness during the ensuing racing season. All horses raced, but horses in the control group required intra-articular injections to maintain soundness. Early aggressive intra-articular therapy may forestall development of progressive osteoarthritis in young STBs.

Palmar heel pain may play a role in the development of carpal lameness in young STBs. Early carpal lameness is easier to treat if palmar heel pain is recognized early and managed aggressively. In horses with bruised bars and poor mediolateral hoof balance the application of wide web bar shoes reduces inflammation and signs of carpal lameness. In all ages of trotters, the flip-flop shoe appears to be effective in reducing clinical signs of carpal lameness. Small osteochondral fragments of the carpus are the most common fractures and involve the third and radial carpal bones and rarely other bones in the middle carpal and antebrachiocarpal joints. Arthroscopic surgical removal and PSGAG therapy after surgery are recommended. Frontal and sagittal slab fractures occur commonly, and repair using 3.5-mm screws placed in lag fashion is recommended. Small, frontal slab fracture fragments can be removed. Although rest is an option in horses with non-displaced fractures, internal fixation may shorten recovery period and reduce risk of recurrence (see Chapter 39).

Metatarsophalangeal Joint Lameness

The metatarsophalangeal joint is a common source of pain causing lameness in STBs, and diagnostic analgesia is usually essential for diagnosis.

Stress and Non-Adaptive Remodeling

Stress or non-adaptive (maladaptive) remodeling of the metatarsophalangeal joint most often involves the distal, plantarolateral aspect of MtIII, PSBs, and the proximal aspect of the proximal phalanx (see Chapters 19 and 43).[7] Initially the horse has a variable, subtle, high-speed lameness, most commonly manifested around turns or by horses making breaks. Later, grade 1 to 2 of 5 hindlimb lameness is seen at the trot in hand. Lameness can be localized to the metatarsophalangeal joint, but it does not respond to intra-articular treatment. Palpation findings are negative or equivocal. Horses show variable responses to flexion and have negative radiographic findings but positive responses to diagnostic analgesia. The low plantar block is most effective, but horses may respond partially to intra-articular analgesia (and may require 12 ml). Later, sclerotic and radiolucent changes of plantarolateral MtIII are seen on down-angled radiographic views. Ultrasonographic evaluation may reveal a defect in articular cartilage late in the disease process. Scintigraphic examination is the best way to establish diagnosis and shows focal IRU involving the distal MtIII (see Fig. 43-2). The disease can affect both hindlimbs. The distal aspect of MtIII appears at risk to develop stress-related bone injury before other sites in the metatarsophalangeal joint, possibly from anatomical variations or uneven loading during the full extension and landing phases of the stride. Shoe additives such as calks or grabs may play a mechanical role. The metatarsophalangeal joint is a high-motion joint and subject to high-strain cyclic fatigue (repetitive loading) that is encountered during intense exercise around turns and on hard surfaces. This continuum of stress-related bone injury can lead to osteoarthritis and fracture (see Fig. 43-7 and accompanying text).

Exercise intensity is reduced for 1 to 3 weeks. If lameness is prominent, a 3- to 4-month rest period is necessary. Exercise reduction allows the modeling and remodeling processes to equilibrate and microdamage to heal. A flat shoe is applied. Cold water therapy and the administration of NSAIDs (phenylbutazone or acetylsalicylic acid) appear helpful initially. Intra-articular injections of hyaluronan and PSGAGs may help, but early in disease, overlying cartilage damage and synovitis are not prominent, and response to intra-articular injections is minimal. When radiolucent changes and synovitis develop, response to intra-articular injections is better, but prognosis is worsened.

Fractures

Acute, severe lameness is seen most commonly in STBs with fractures of the metatarsophalangeal joint, but some horses can race with incomplete fractures. Horses shorten the cranial phase of the stride, land on the toe, and rapidly compensate with other limbs. Often no effusion or pain on flexion is apparent unless a fracture is displaced. Diagnostic analgesia and examination in harness are avoided if fracture is suspected, because comminution or displacement can occur. Radiographs, including a flexed dorsoplantar or 125° dorsoplantar and flexed lateromedial views, should be obtained.

Mid-sagittal fractures of the proximal phalanx are most common, causing severe intermittent or severe unrelenting lameness, depending on fracture length and configuration. Fractures can be short, incomplete with mild periosteal proliferation on the dorsal aspect of the proximal phalanx (Fig. 109-6) or long, incomplete or complete mid-sagittal fractures, fractures that break out of the lateral cortex, and comminuted fractures (see Fig. 36-1). Horses with short, mid-sagittal fractures often race or train, because lameness is intermittent and often abates after several days. Clinical signs precede radiographic evidence of fracture for 7 to 21 days and scintigraphic examination reveals focal IRU of the proximal aspect of the proximal phalanx (see Fig. 43-4). Horses with short, mid-sagittal fractures can be rested or have internal fixation and have a good prognosis with either treatment.[8] Long incomplete, complete, displaced, or comminuted fractures should be repaired. Prognosis depends on degree of comminution and displacement and whether a strut of bone is intact to which to attach fragments. Horses with comminuted fractures rarely race again and are at risk of infection, fracture displacement, and osteoarthritis of the metatarsophalangeal and proximal interphalangeal joints and contralateral laminitis (see Chapter 36).

Dorsal frontal fractures of the proximal phalanx can be unilateral or bilateral, are most common in the RH, and occur in trotters and pacers (see Figs. 43-12 and 43-13 and accompanying text). Fractures of the PSBs are common and most often involve the lateral PSB. Small medial abaxial fragments can be difficult to identify. Apical PSB fractures are most common, but abaxial, mid-body, and rarely basilar fractures occur, and the combination of suspensory desmitis, splint bone, and PSB fractures is not uncommon. Horses show acute lameness after training or racing, with grade 3 to 4 of 5 lameness, and prefer to bear weight only on the toe. Effusion and a positive response to flexion are usually present, and the diagnosis is confirmed radiographically. Ultrasonographic examination of the SL should be performed to establish baseline information and assess prognosis. Surgical removal of apical, abaxial, and basilar fragments and surgical repair of displaced mid-body fractures using bone screws or wiring techniques are recommended. Prognosis is guarded in trotters and fair in pacers that have raced before fracture. Horses in which fractures occur early in training have a poor prognosis.

Fig. 109-6 **A,** Dorsoplantar and **B,** flexed lateromedial xeroradiographic images showing a short, incomplete, mid-sagittal fracture of the proximal phalanx *(arrow)*. There is slight periosteal new bone on the proximodorsal aspect of the proximal phalanx seen in the flexed lateromedial view. Radiographic changes often lag behind clinical signs and follow-up radiographic and scintigraphic examinations often are needed to establish a diagnosis.

Condylar fractures of MtIII occur, with similar distribution of short medial and lateral fractures. Clinical signs are similar to those caused by mid-sagittal fracture of the proximal phalanx, but diagnosis can be difficult unless good-quality radiographs and proper views are taken. A flexed dorsoplantar or 125° dorsoplantar view should be obtained. Medial condylar fractures often spiral proximally and should be repaired.

Osteochondrosis

The metatarsophalangeal joint is a major site for osteochondrosis, and the most common manifestation is plantar fragmentation. A complete discussion of axial, articular fragments and abaxial, non-articular fragments and other forms of osteochondrosis can be found in Chapter 43. Some debate exists over the management of STBs with axial, articular fragments and abaxial, non-articular fragments and other fragments. Horses with axial, articular fragments and dorsal fragments respond well to arthroscopic removal and post-operative intra-articular injections of PSGAGs or hyaluronan. We believe that surgical removal prolongs racing careers and decreases metatarsophalangeal joint lameness. Some horses, particularly pacers, race successfully without surgery.

Proliferative synovitis, radiolucent defects of the PSBs, traumatic small osteochondral fragments of the proximal phalanx, and osteoarthritis are discussed in Chapter 43.

Distal Hock Joint Pain and Other Tarsal Lameness

The hock joint is under considerable stress and strain, especially going into turns and with quick acceleration. Distal tarsitis, progressive osteoarthritis of the tarsometatarsal and centrodistal joints, is common. Horses warm out of lameness, often dramatically, because they may come out of the barn or paddock on the toe and eventually be able to train or race successfully. Horses show a mildly shortened cranial phase of the stride and a stabbing type of gait, with medial deviation of the limb during protraction and landing first on the outside toe (stabbing laterally), but this gait is not pathognomonic for distal tarsitis. Palpation in a flexed position often reveals pain of peri-articular soft tissue structures, and the Churchill test is often positive. Upper limb flexion is positive, but diagnostic analgesia is essential for diagnosis. Radiographs may show evidence of osteoarthritis in older horses, but in most 2- and 3-year-olds radiographs are negative or equivocal. Changes are seen most often in the DM-PlLO view, but dorsoplantar, lateromedial, and slightly off dorsoplantar views can be helpful. Scintigraphic examination confirms that osteoarthritis of the tarsometatarsal joint is most common, and changes are lateral and dorsolateral (Fig. 109-7). Focal IRU is sometimes seen involving only the centrodistal joint in horses that failed to respond to intra-articular analgesia of the tarsometatarsal joint, emphasizing the need to block and treat each joint separately.

Treatment comprises intra-articular injections, NSAIDs, shoeing changes, and rest. Intra-articular hyaluronan is useful to decrease inflammation, and concomitant use of NSAIDs such as phenylbutazone (4.4 mg/kg PO sid for 5 days and 2.2 mg/kg PO sid for 5 days) is recommended initially. As osteoarthritis progresses, methylprednisolone acetate (80 mg per joint every 6 to 8 weeks) is necessary to manage inflammation. A series of intra-articular and intramuscular injections of PSGAGs also can be given. In horses with severe osteoarthritis a period of 4 to 6 months of rest is successful, but recurrent lameness often mandates a limited racing schedule (10 to 15 starts). The toe is shortened, and a flat aluminum or steel squared-toe shoe is applied to allow easy breakover. All shoe additives are removed to decrease shear stress.[8]

Slab fractures of the third tarsal bone and proximal aspect of MtIII result from stress-related bone injury or from pathological fractures in horses with osteoarthritis. Third tarsal bone fractures are the most common and are best seen on a DM-PlLO view. Fractures of the central tarsal bone are usually

Fig. 109-7 **A,** Plantar delayed (bone) phase scintigraphic image of the hocks. There is focal, intense increased radiopharmaceutical uptake in the dorsolateral aspect of both tarsometatarsal joints (left hindlimb is on the right) in this 2-year-old Standardbred filly. **B,** Dorsomedial-plantarolateral oblique xeroradiographic projection of the left hindlimb showing minimal changes. Lameness and scintigraphic evidence of distal tarsitis precede radiographic changes by many months.

oblique, involve the dorsal aspect of the bone, occur without concomitant osteoarthritis, and are best seen in lateromedial views. Conservative management is recommended in horses with non-displaced fractures, but displaced fractures should be repaired. Ninety-two percent of horses with slab fractures of the third tarsal bone and 88% with slab fractures of the central tarsal bone raced after conservative management.[9]

The tarsocrural joint is often injected, but tarsocrural joint lameness is uncommon, except in young horses with osteochondrosis. Trainers often request injection of the upper and lower hock joints (tarsocrural and tarsometatarsal joints), but lameness most likely is caused by distal tarsitis. Bog spavin occurs most commonly in weanlings and yearlings, and radiographic identification of osteochondritis dissecans fragments prompts surgical removal. Most yearlings begin training without fragments. Although debate exists about the significance of tarsocrural osteochondrosis and lameness, we recommend surgical removal to resolve current inflammation, if present, and to prevent future lameness. However, osteochondrosis fragments are seen in some older racehorses in which neither lameness nor effusion are present. Tarsocrural lameness may occur without effusion and diagnostic analgesia is necessary to differentiate the site of hock pain. Good-quality radiographs are essential to discover occult osteochondritis dissecans fragments and fractures. The DM-PlLO view is best for evaluating the cranial intermediate ridge of the distal tibia and an off dorsoplantar view (dorsal 5° to 7° lateral-plantaromedial oblique) is best to evaluate for medial malleolar fragments. The most common sites for osteochondrosis are the distal intermediate ridge of the tibia, lateral trochlear ridge of the talus, medial malleolus of the tibia, medial trochlear ridge, and lateral malleolus. Osteochondrosis fragments can be large, numerous, loose, and free floating, and cartilage damage can be prominent even in yearlings, but with removal prognosis is good. If distention of the tarsocrural joint is unexplained, osteochondrosis of the medial malleolus of the tibia should be suspected, and diagnostic arthroscopy is recommended. Small osteochondrosis fragments (dewdrop lesions) of the distal medial trochlear ridge may be incidental, but can cause lameness if displaced, or if impinging on the central tarsal bone. Surgical removal is recommended.

Tarsocrural osteoarthritis occurs in older horses (usually >5 years) and may be associated with osteochondrosis, because fragments often are seen concomitantly. Osteoarthritis causes progressive lameness and effusion, but intra-articular analgesia should be performed to validate the source of pain. Large volumes of local anesthetic solution (30 to 50 ml) are necessary, because pain is severe; false negatives occur if 10 to 15 ml is used. Radiographs may reveal sclerosis and narrowing of the tarsocrural joint space, but end-stage osteoarthritis can be present with only subtle radiographic findings. Scintigraphic evaluation reveals diffuse IRU on both sides of the tarsocrural joint and is useful to differentiate osteoarthritis from sagittal fracture of the talus or subchondral injury of the distal tibia. Prognosis is grave.

Sagittal fracture of the talus is unusual. Acute, grade 3 to 4 of 5 lameness is localized to the tarsocrural joint by diagnostic analgesia, but often subtle tarsal lameness precedes fracture. Focal IRU is seen involving the talus, and off dorsoplantar views reveal subchondral lucency or fracture (Fig. 109-8). Of eight horses managed conservatively, seven raced and one was sound in training.[10]

Enthesitis of the long, lateral collateral ligament of the tarsocrural joint, on the lateral aspect of the calcaneus, results in mild to moderate lameness and mild tarsocrural effusion (Fig. 109-9). Soft tissue swelling is easy to miss initially, and radiographic changes lag behind clinical signs for at least 14 to 21 days, but lameness abates with intra-articular analgesia.

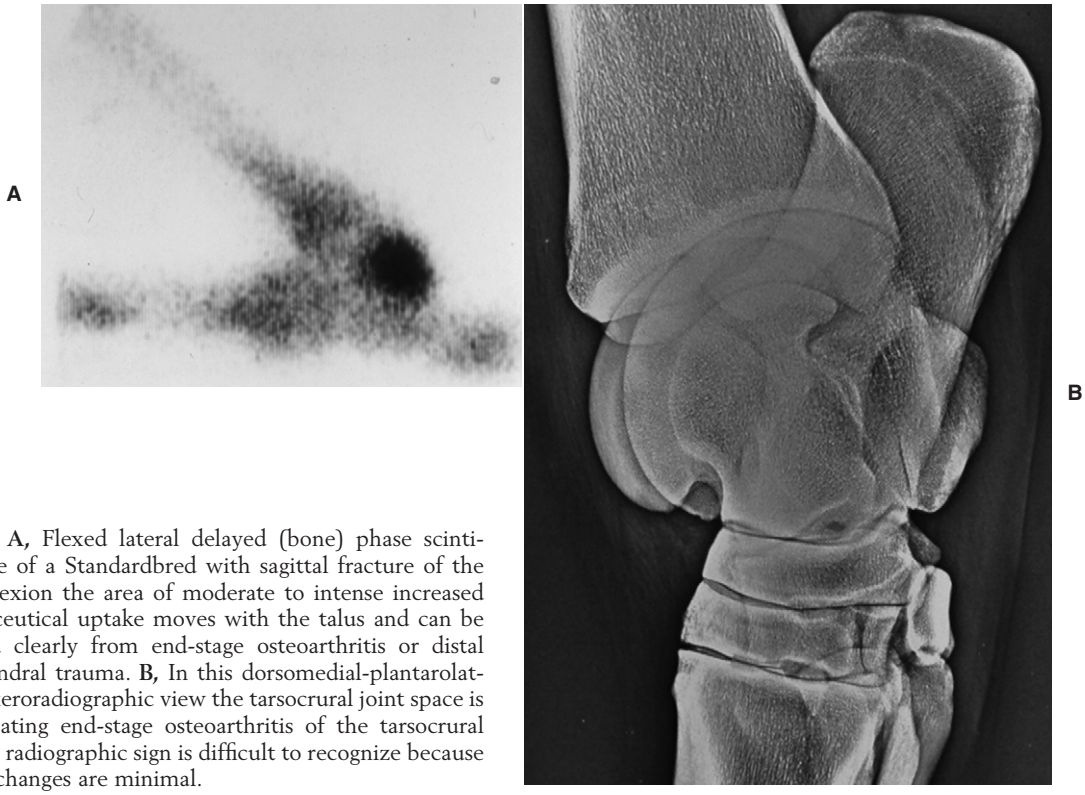

Fig. 109-8 **A,** Flexed lateral delayed (bone) phase scintigraphic image of a Standardbred with sagittal fracture of the talus. With flexion the area of moderate to intense increased radiopharmaceutical uptake moves with the talus and can be differentiated clearly from end-stage osteoarthritis or distal tibial subchondral trauma. **B,** In this dorsomedial-plantarolateral oblique xeroradiographic view the tarsocrural joint space is narrow, indicating end-stage osteoarthritis of the tarsocrural joint, but this radiographic sign is difficult to recognize because proliferative changes are minimal.

Fig. 109-9 **A,** Lateral delayed (bone) phase scintigraphic image of a hock showing focal, moderate to intense increased radiopharmaceutical uptake of the calcaneus. **B,** Dorsoplantar xeroradiographic view showing proliferative changes associated with the collateral ligament attachment on the lateral aspect of the calcaneus *(arrows)*.

Scintigraphic examination reveals focal IRU in the lateral calcaneus. Local injections and radiation therapy may allow continued racing, but rest to allow enthesitis to subside is often necessary.

Injury of the fibularis tertius tendon anywhere from the mid-crus to the distal tarsus can occur, but it is most common at the insertion on MtIII and the third tarsal bone. Soft tissue swelling is present, and the hock can be pushed forward without concomitant extension of the stifle with the limb in standing position. Horses require 4 to 6 months of rest.

Inflammatory synovitis or infection of the tarsocrural joint is not uncommon. Prognosis depends on the extent of existing cartilage damage and the financial ability to manage infection aggressively (see Chapter 66).

Suspensory Desmitis

Suspensory desmitis is the most common soft tissue injury and can be classified as unilateral branch desmitis, bilateral branch desmitis, body desmitis, and PSD. Suspensory desmitis is often an overload compensatory lameness condition, because fatigue and improper landing occur in lame horses. Suspensory desmitis is seldom a single-event injury but is caused by accumulated damage over weeks to months (see Chapter 73). Diagnosis is made by careful palpation from the origin to the insertion of the SL with the limb in standing and flexed positions. The splint bones and PSBs are examined for associated injuries. One of us (J.B.M.) has found that horses with core lesions are lamer, but exhibit fewer outward signs of inflammation, than those with peripheral lesions. Horses with suspensory branch desmitis are common and heal quicker (6 to 8 weeks) with lower recurrence than do those with body desmitis and PSD (4 to 6 months). Core lesions recur frequently. Because suspensory desmitis is often a compensatory injury, the primary lameness needs to be resolved. For example, osteoarthritis and osteochondral fragments of the left carpus frequently cause suspensory desmitis of the RF in horses of both gaits, RH suspensory desmitis in trotters, and LH suspensory desmitis in pacers.

Ultrasonographic examination is critical in assessing the SL and its entire length should be examined systematically. In hindlimbs, enlargement of the origin and body is more common than core lesions, and cross-sectional area measurements of the affected and contralateral limb are mandatory. Branches are evaluated for change in shape, loss of margin definition, central or marginal hypoechoic lesions, subcutaneous hemorrhage and edema, fibrosis and calcification, irregular contour (step line defects), and avulsion fragments of the PSBs. The intersesamoidean ligament rarely is involved.

Forelimb unilateral branch desmitis results from toed-in or toed-out conformation, hoof imbalance, and uneven landing. To correct interference injury with knee knocking resulting from toed-out conformation, the hoof is commonly lowered on the inside, causing uneven loading and medial unilateral branch desmitis, whereas in horses with toed-in conformation, lateral unilateral branch desmitis occurs. Improper impact can occur from fatigue or if a horse is stopped suddenly. Lameness varies with severity of injury and presence of associated splint and PSB disorders.

Forelimb bilateral branch desmitis is caused by acute or chronic hyperextension of the metacarpophalangeal joint. Prognosis depends on the degree of fetlock drop seen when the contralateral limb is held in flexion. Concomitant PSB fractures can occur. Dorsal subluxation (flexion) of the proximal interphalangeal joint is seen in horses with bilateral branch desmitis and body desmitis, whereas palmar subluxation (extension) is seen in horses with distal sesamoidean desmitis and loss of palmar support. If the axis of the proximal interphalangeal joint is altered, the prognosis for racing is poor.

Forelimb body desmitis often begins just proximal to the bifurcation of the SL, and careful palpation reveals pain and mild enlargement. The first sign may be mild swelling, without lameness, and training and racing are often continued, leading to further suspensory desmitis. Horses often race successfully with chronic suspensory branch desmitis, but if desmitis progresses into the body, lameness becomes pronounced. Chronic enlargement and thickening of the SL often causes bowing of the splint bones, and concussion leads to fracture. Horses with recalcitrant swelling of the SL should be examined with ultrasonography, because exuberant exostosis from fractures may encroach on the SL and cause swelling and pain.

Proximal palmar metacarpal pain is common and often called a check ligament problem, although genuine desmitis of the accessory ligament of the DDFT is rare. Palmar metacarpal pain can be caused by avulsion or longitudinal fracture of McIII and stress reaction/stress fracture of McIII, but PSD is most common. STBs are often painful to palpation of the proximal palmar metacarpal region and may have compensatory PSD, with primary lameness elsewhere. Lameness is noticed in the first half of the support phase of stride. An exaggerated head nod is often noted (J.S.M.). A carpal type of gait may be seen. Lameness is most prominent when the affected limb is on the outside of a circle. Local analgesia and ultrasonographic examination should be performed. Radiographs are necessary to identify bone injury. Scintigraphic examination is useful to differentiate proximal metacarpal from carpal injury.

In hindlimbs unilateral branch desmitis, bilateral branch desmitis, body desmitis, and PSD occur but less frequently than in forelimbs. Degree of lameness varies and similar concerns exist about MtIII, splint bone, and PSB involvement. Horses often land on the toe and are reluctant to put the heel down, especially if a concurrent pathological condition of the PSB exists. Suspensory branch desmitis often occurs first and can be managed successfully with continued work in some horses, but proximal progression toward the bifurcation and body causes substantial increase in lameness and may involve the splint bones, and often horses lose support of the metatarsophalangeal joint. Racing can no longer continue. Hindlimb suspensory desmitis is particularly important in young trotters. Many top 2- and 3-year-old trotters have been retired because of hindlimb suspensory desmitis. Second to carpal lameness, hindlimb suspensory desmitis is the most dangerous, career-limiting cause of lameness in trotters.

Early PSD can go unrecognized because of lack of obvious swelling. Local analgesia is critical for diagnosis. Once desmitis involves the body, swelling may be recognized, but damage is now extensive.

Inflammation can be suppressed, but rest is essential for healing. Rest is not well received by owners and trainers, who often exert pressure to keep a horse in work. Cryotherapy is used to manage horses with suspensory branch desmitis and distal body desmitis. Horses with marginal lesions respond well, but not those with core lesions. Cryotherapy decreases pain and seems to promote more or better-organized scar tissue. Periligamentous injections of sclerosing agents such as sodium oleate promote fibrosis and can be used to cause a swollen SL to set up. Periligamentous injections of corticosteroid mixtures reduce inflammation and lameness, but if training and racing continue, further damage occurs. Many naive owners lack understanding that the latest popular injection does not promote healing but simply masks inflammatory signs. Although horses may continue to race a few more starts, further damage inevitably occurs. Horses with PSD often can be managed using injections of corticosteroids, internal blisters and, if available, radiation therapy and, if lameness is mild and support is not lost, racing may continue. Shock wave therapy has gained prominence and shows promise.

Rest is the best approach, and between 3 to 6 months of rest may be necessary to allow healing. A combination of stall rest, hand walking and walking in the jog cart, and swimming is recommended. We do not recommend turnout, but many horses are blistered and turned out, although this has been shown to be detrimental to healing. Healing progress is assessed by ultrasonography. Surgical management using a modified Asheim approach and ostectomy of fractured splint bones and PSB fragments are recommended. One of us (M.W.R.) has performed bone marrow injection and fasciotomy on a limited number of top trotters with hindlimb PSD and body desmitis with modest success.

Prognosis depends on level of injury, gait (trotters worse than pacers), severity of injury (poor prognosis with fetlock

drop), and associated bony pathological conditions. Unless the SL is totally disrupted, prognosis for racing is good, but racing class is an important consideration, because few STBs return to the same or improved race class after sustaining suspensory desmitis.

Metacarpophalangeal Joint Lameness

Fatigue from underconditioning and other factors causing overload may lead to hyperextension of the metacarpophalangeal joint. Hyperextension leads to dorsal injury, such as small osteochondral fragments of the proximal phalanx and proliferative synovitis and to palmar injury, such as fractures of the PSB and suspensory branch insertional injury. Traumatic disruption of the suspensory apparatus is rare but usually involves rupture of the SL. Stress-related bone injury of subchondral bone leading to osteoarthritis and fracture occurs in the metacarpophalangeal joint, as described for the metatarsophalangeal joint. In a STB with normal conformation, metacarpophalangeal effusion should be a red flag (a barometer), often a sign of compensatory lameness. Young horses often have bilateral metacarpophalangeal synovitis secondary to palmar heel pain, because toe-first landing overloads the joint. Corrective trimming and shoeing often helps. In older horses unilateral carpal lameness often causes contralateral metacarpophalangeal synovitis. Primary lameness of the metacarpophalangeal can begin when horses break stride, stumble, or stop quickly.

Osteoarthritis and stress-related bone injury are the most common problems of the metacarpophalangeal joint. Early radiographs are usually negative, but radiolucency and sclerosis of distal medial McIII develop later. Scintigraphic evidence of IRU is more prominent medially, unlike in the metatarsophalangeal joint in which IRU is more common laterally. In older horses (about 4 years of age) with progressive severe osteoarthritis, narrowing of the medial joint space indicates severe cartilage damage. Owners are incredulous that the horse has end-stage osteoarthritis, because lameness can be acute and severe, and fracture often is suspected.

Early osteoarthritis is treated using intra-articular injection of hyaluronan alone or a combination of hyaluronan and PSGAGs. The latter is preferred and 3 to 4 weekly injections are combined with a reduction in exercise. Horses that do not respond may have proliferative synovitis, usually seen in older horses with chronic osteoarthritis. Injecting the joint in the dorsal pouch may be difficult and little synovial fluid may be present. Surgical resection of synovial pads and post-operative intra-articular injections of PSGAGs are recommended.

Fractures and osteochondritis dissecans occur, but palmar fragments are rare (see Chapter 37).

Splint Bone Disease

Exostoses and Fractures of the Second and Fourth Metacarpal Bones (Splints)

Splints are a common problem in 2- and 3-year-olds (see page 898). Poor conformation and hard track surfaces predispose horses to splints. Whether tearing of the interosseous ligaments occurs is unknown. Medial splints are most common. Yearlings can begin training with dormant, so-called field splints that become active as training advances. Splints rarely cause severe head nodding lameness, but put a horse on a line and signs become worse as work progresses. Splints on the abaxial surfaces of the McII and McIV are visible and can be palpated readily, but those on the axial surfaces require the limb to be lifted to relax the SL. Axial splints cause more obvious lameness than do abaxial splints.

Management includes reducing inflammation and limiting callus. Cold-water therapy and poultice should be applied, and horses are given NSAIDs. Blistering and external heat therapy may be contraindicated if reduction in the size of the callus is desirable. Ionophoresis with corticosteroids is successful. Peri-lesional injection of corticosteroids and cryotherapy are used successfully. If signs fail to abate, a fracture may be present. Improper toe-heel impact and mediolateral hoof imbalance predispose horses to splints. Chronic splint disease in older horses is almost always related to palmar heel pain. Aggressive therapy for palmar heel pain and restoring normal hoof strike is critical. Direct trauma from interference and breaking must be prevented.

Fractures of McII and McIV can be caused by direct trauma. Interference injury can cause fracture of McII, and accidents involving carts and other equipment predispose horses to fractures of McIV. If fractures are located proximally and displacement exists, surgical fixation using small plates and screws is best. McIV fractures can heal functionally without fixation. Most distal splint bone fractures are secondary to suspensory desmitis. Exuberant callus can impinge on the SL. Fracture callus and fragments should be removed.

Exostoses and Fractures of the Second and Fourth Metatarsal Bones

Exostoses most commonly involve MtII, but chronic painful splint exostoses are not as common as in the forelimb. Perilesional corticosteroid therapy is recommended (80 mg methylprednisolone and 8 ml of Sarapin). Fractures of MtII and MtIV occur occasionally and usually result from direct trauma, but distal splint fractures can be secondary to suspensory branch desmitis. Fracture fragments should be removed.

Stifle Joint Lameness

The stifle joint often is incriminated as a source of pain, but diagnostic analgesia identifies a problem in the more distal part of the limb. Osteoarthritis of the medial femorotibial joint is the most important stifle lameness, but in young horses osteochondrosis should be considered. Osteoarthritis is a progressive disease beginning in late 2-year-olds, and degree of lameness varies from grade 1 to 4 of 5. Distention of the medial femorotibial joint capsule is an important finding. The limb may be carried forward slightly lateral or outward during the cranial phase of the stride. The cranial phase is shortened and lameness is worse in the turns. Radiographs are usually negative or equivocal in 2-year-olds, and arthroscopic evaluation reveals generalized cartilage thinning and fissure formation. Later, in caudocranial radiographic views, narrowing of the medial femorotibial joint space and mild osteophyte formation on the proximal medial tibia and distal medial femur are visible (Fig. 109-10). Scintigraphic examination can confirm extensive osteoarthritis. Diffuse IRU involves both sides of the medial femorotibial joint. Arthroscopic evaluation at this time reveals exposed subchondral bone and severe synovitis, but therapeutic value of arthroscopy is negligible. If the diagnosis of osteoarthritis is made in a 2-year-old, a period of 3 to 4 months of rest is recommended. The stifle joint often is injected in horses without stifle lameness and few untoward effects are seen. Treatment of osteoarthritis with methylprednisolone acetate is contraindicated early in the course of the disease. Although the drug is effective and allows continued racing, osteoarthritis can progress rapidly, resulting in severe lameness. Hyaluronan (40 mg) and isoflupredone acetate (4 to 6 mg), or PSGAGs (750 to 1000 mg), are preferred, and although they are less effective than methylprednisolone acetate, they decrease inflammation and prolong the racing career. Systemic administration of PSGAGs or hyaluronan is helpful. Methylprednisolone acetate is necessary for older horses with advanced osteoarthritis, but if no improvement is seen, the racing career is usually over. Once severe lameness occurs, rest may improve comfort slightly, but horses will not tolerate training again. Trotters can tolerate racing with more advanced osteoarthritis than can pacers.

In young horses osteochondrosis can cause lameness and effusion in early training, prompting radiographic examination, but signs of osteochondrosis often are seen in weanlings and yearlings, and surgery is performed before training begins. Osteochondritis dissecans of the lateral trochlear ridge of the femur is most common, causes considerable effusion of the femoropatellar joint, and if bilateral may cause a bunny-hopping gait. Surgical treatment, 4 to 6 months of rest, and intra-articular therapy are recommended. Prognosis for racing is good, unless lesions are severe or cartilage damage of the patella is advanced. Subchondral bone cysts most commonly involve the medial femoral condyle but can occur in the proximal tibia. Lameness is often progressive, with horses first being on a line. Surgical debridement of the cyst is recommended. Horses need a minimum of 6 to 8 months of rest to allow healing and for lameness to abate. Prognosis is only fair (50% to 70%) for successful racing.

Rhabdomyolysis and Muscle Soreness

We divide muscle lameness into metabolic disease (recurrent exertional rhabdomyolysis, RER) and non-metabolic disease (muscle soreness). Signs vary, but horses appear stiff and hindlimbs are not fully engaged in the stride unilaterally or bilaterally. Palpation often reveals muscle pain but must be done carefully, because aggressive, sudden, and deep palpation elicits false-positive responses.

RER occurs more commonly in females and can cause swollen muscles. Overt clinical signs of tying up after racing and training can be seen, but subclinical RER can be a cause of poor performance. Myoglobinuria and elevation of serum creatine kinase (CK) and aspartate aminotransferase (AST) levels are diagnostic. Horses are managed initially with intravenous fluids, NSAIDs, tranquilization, and methocarbamol (22 mg/kg IV or 33mg/kg PO bid). Care must be taken when using acetylpromazine and methocarbamol simultaneously, because effects may be additive and horses may act severely tranquilized (J.S.M.). Walking is recommended in horses with mild RER but is contraindicated in those with severe RER. In horse with severe RER dantrolene sodium (2 mg/kg IV or via nasogastric tube) and intravenous dimethylsulfoxide solution are recommended. Large quantities of intravenous or oral fluids should be administered. After an acute episode, signs may recur or subclinical myositis may persist, reflected by elevations in CK and AST concentrations. Enzyme levels should return to baseline before intense training or racing resumes.

In horses with subclinical RER or those with recurrent acute episodes, we recommend a management protocol that includes a reduction in carbohydrate intake, especially before exercise, a high-fat diet, vitamin E and selenium supplementation, supplementation with oral potassium, and a regular 7-day exercise program combining jogging, brief periods of intensive training, and paddock exercise, if feasible. Chronic administration of dantrolene sodium (2 mg/kg) or phenytoin (8 to 10 mg/kg PO bid) is recommended, but racing jurisdiction rules must be followed.

Non-metabolic myositis is common, and gait is similar to that described for stifle lameness. Signs are similar to RER, but serum CK and AST levels are usually within or just above normal limits. The middle gluteal muscle and associated tendons commonly are affected unilaterally or bilaterally. Myositis may be a secondary problem or a primary source of pain after traumatic injuries such as accidents during transport, paddock injuries, slipping while racing on muddy or other undesirable surfaces, or by making a break. Horses are managed initially with muscle relaxants, NSAIDs, and rest (5 to 7 days). Horses with chronic soreness are treated with an internal counterirritant or corticosteroids injected strategically in the sore areas (see Chapter 89).

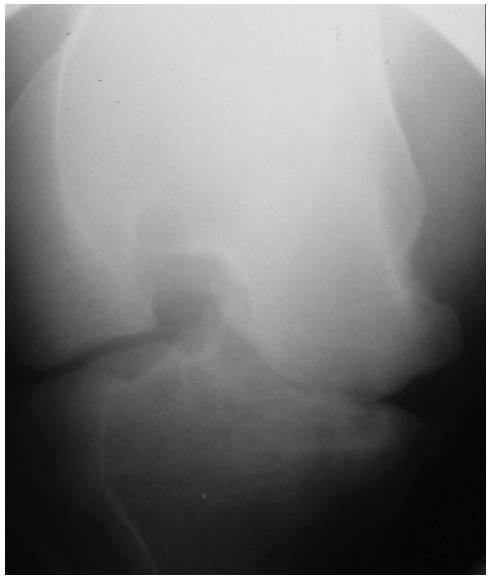

Fig. 109-10 Caudocranial radiographic view of a stifle showing advanced narrowing of the medial femorotibial joint space in a pacer with advanced osteoarthritis. Medial is to the right. Narrowing of medial femorotibial joint is often the only radiographic sign of advanced osteoarthritis of this joint. Subchondral lucency of the medial femoral and tibial condyles and osteophyte formation also are seen in this pacer, and unfortunately this horse will not race again.

Curb and Superficial Digital Flexor Tendonitis

Other soft tissue injuries such as curb and superficial digital flexor tendonitis occur commonly. Curb in the STB is discussed in detail in Chapter 79. Superficial digital flexor tendonitis is discussed in detail in Chapter 70.

CHAPTER • 110

The European and Australasian Standardbreds

THE EUROPEAN STANDARDBRED

• Fabio Torre

DIMENSIONS AND CHARACTERISTICS

The European Standardbred (STB) is historically the result of different crosses between the classic American bloodlines and European families. The French STB is known for its stamina and aptitude for long distances. The American-derived families, however, have been selected for speed and racing at a fixed distance of 1 mile and are represented more widely in Italy and Sweden. Several countries (especially France, Italy, Germany, and Scandinavian countries) have developed individual bloodlines and today are able to produce good-quality STB trotters. In Europe no races are available for pacers. In Table 110-1 the STB population and racing activity of different European countries are listed.

Europe has a large number of racetracks for STBs, and they are characterized by different circuit lengths, surfaces, and designs. Half-mile tracks have been replaced progressively by 1-km (⅝-mile) tracks, and no 1-mile racetracks (with the exception of training centers) are present in Europe. The most characteristic and popular racetrack is the Plateau de Gravelle in Vincennes, Paris, where the Prix d'Amerique is held. The track surface is made in pressed charcoal powder, slopes and descents are present, and the circuit is egg-shaped, which is unique in Europe where other racetracks have a regular design. Another famous French racetrack, Cagnes-sur-Mer in Nice, is well known for being 1200 m in length and for hosting the Criterium de Vitesse, one of the main European free-for-all races. In Sweden, Solvalla racetrack in Stockholm represents the heart of the Swedish STB racing, and in late May the multiple-heat race Elitlopp is held. In Norway, next to well-developed STB racing (the main racetrack being Bjerke near Oslo), races for Warmblood horses (a breed historically devoted to hard work but now genetically selected for speed) are still popular and meet the special interest of the local public.

A variety of track designs and purposes are present in Europe. For example, a large number of small country tracks are found in France and local races are organized in a fair-like fashion, whereas the main racing activity is concentrated in Paris. In Italy, however, important races have a more even distribution among racetracks, Milan and Rome being the main places. In Table 110-2 the distribution of racing tracks in the main European countries is summarized.

Differences exist in availability of prize money among different countries, and this makes France and Italy the most attractive countries for trainers and owners. A number of well-known trainers started to move in the early 1980s toward France and Italy, especially from Northern Europe, and this has enhanced the exchange of experiences between trainers and veterinarians.

Prize money distribution among horses of different ages has strongly influenced racing, especially in Italy, where 2- and 3-year-olds have the richest races. Higher purses for younger horses have also affected breeding programs and have stimulated an interest in many of the orthopedic problems affecting young horses, especially osteochondrosis, which has been studied widely in Northern Europe.

Table • **110-2**

Racetrack Distribution in Different European Countries

COUNTRY	RACETRACKS (NO.)*	HALF-MILE RACETRACKS (NO.)	1-KM RACETRACKS (NO.)	>1-KM RACETRACKS (NO.)
Denmark	9	1	7	1
Finland	43	0	43	0
France	240	0	0	4
Germany	16	3	3	5
Holland	7	1	3	1
Italy	25	11	13	0
Norway	9	1	7	0
Sweden	26	1	25	0

Data from UET (European Trotting Union), update December 2000.
*The total number includes all racetracks in which at least 1 day of racing is held, but less important, occasional, and fair-like tracks (which are especially popular in France) are not considered in the subsequent columns.

APPROACHING LAMENESS PROBLEMS

Only STB trotters are allowed to race in Europe, and this makes the trainer's work more challenging. Any possibility to switch gaits or to move an unnaturally fast gaited trotter to a potentially good pacer is precluded. When the fast gait is compromised by biomechanical problems and significant interference between limbs (unlike in the pacer), corrections aimed at avoiding interference are attempted. Finding a solution for mechanical problems is not always possible, and corrective shoeing that alters the natural gait may cause compensatory lameness in different locations.

A series of mechanical limitations may be present at the beginning of training, and relatively soon they are followed by pain-related problems, usually affecting joints and less frequently digital flexor tendons and the suspensory ligament. A less than 100% natural trotting athlete is more likely than a natural trotter to have its gait totally compromised, even by a mild subclinical lameness problem, and consequently gait limitations increase. However, anything that is attempted by the trainer to improve gait (corrective shoeing, special equipment that prevents turning the head and neck toward one side, or shifting the hindlimbs toward one shaft) forces the horse to a non-natural fast gait and often results in lameness. In fact, when a non-natural gait is forced, the end result is usually that a single limb (or a biped) is overloaded, and the uneven loading is exacerbated by the progression of training.

When young horses start training, they frequently have been subjected to basic lameness and radiographic evaluations. This allows trainers the opportunity to treat conditions such as osteochondrosis or to be aware of other abnormalities. Prepurchase radiographic examinations and, when needed, preventative arthroscopic surgery (mostly for osteochondrosis of the tarsocrural joint and osteochondral fragments in the fetlock joints) are now practices that have received general acceptance. The reason to operate early is to have the horse rested before any training program is started. In yearlings eligible for autumn sales, it is important to perform surgery early to have presale radiographs without osteochondral fragments and to decrease effusion before the sale.

When moderate gait anomalies are present, experienced trainers usually give the horse time and keep going with a light exercise program instead of making radical changes. This allows, in many horses, a complete maturation of the equine athlete and, when the growth is complete and the muscular function well conditioned, the gait in many horses automatically improves without injuring the immature skeleton. Shoeing is also central in early training. Light plastic shoes are ideal to allow foot growth and expansion and to minimize trauma in the early phases of fast training.

TEN MOST COMMON LAMENESS CONDITIONS

The following are the 10 most common lameness conditions:

1. Hoof or foot pain
2. Osteoarthritis of the distal interphalangeal joint
3. Osteoarthritis of the metacarpophalangeal joint
4. Lameness of the middle carpal joint
5. Proximal palmar metacarpal pain including proximal suspensory desmitis (PSD)
6. Sesamoiditis
7. Suspensory branch desmitis
8. Lameness of the metatarsophalangeal joint
9. Superficial digital flexor tendonitis
10. Osteochondrosis of the tarsocrural joint

LAMENESS EXAMINATION

Horses with acute, severe lameness should be allowed to rest. Radiographs are frequently diagnostic, revealing the most common severe musculoskeletal injuries affecting trained STBs, such as incomplete sagittal fractures of the proximal phalanx, fractures of the proximal sesamoid bones, splint bone fractures, fractures of the third or radial carpal bones, fractures of a palmar process of the distal phalanx, fractures of the lateral condyle of the third metacarpal bone (McIII), slab fractures of the third tarsal bone, and stress fractures of the palmar aspect of McIII or the plantar aspect of the third metatarsal bone (MtIII). Apical fractures of the proximal sesamoid bones (PSBs) are a common injury in young STBs, and the lateral sesamoid in the hindlimbs is the most common location.[1]

The conditions mentioned previously represent injuries of the racing STB requiring rest or surgical repair. More commonly the veterinarian is consulted for mild or obscure lameness, gait disturbances, or poor performance. In any case a thorough history is mandatory before the lameness examination is initiated.

A basic lameness history must include the following:

- What is the trainer's complaint?
- What is the horse's gait (naturally born versus artificial trotter)?

- Describe shoeing management: recent changes, difficulties in combining appropriate shoeing and fast gait, ideal shoeing for the horse, and attempts at correcting the problem
- What is the horse's recent performance?
- When was the onset of the problem and correlation with previous lameness, if any?
- When does the problem arise during the race? Does the horse worsen in the turns or on the straight? Is the horse better at the beginning of the race and does it worsen at the end?
- Is the horse lame after the race?
- What about the day after the race?
- How is the horse during daily jogging, a question best addressed to the groom or assistant trainer?
- How does the horse behave when trained clockwise (though races are counterclockwise)?
- Is the horse better when trained on a straight track, when available?
- Does the problem worsen on a particular racetrack and specifically on hard tracks?
- Is the horse on a line?
- Is the horse on a shaft?
- Does the horse break stride? If so, when? At the start, approaching turns, in turns, coming out of turns, or in the straightaway?
- Does the horse deviate left in the turns and right on the straight lines? Does the tendency worsen at the end of the race?
- Has the horse been submitted to any previous lameness examination?
- Was the horse subjected to any previous treatment with paints, ointments, or local injections?
- Did previous therapy lead to any improvement?
- Was any other problem diagnosed or suspected (exercise-induced pulmonary hemorrhage, rhabdomyolysis)?

Concerning conformation, the clinician should check the following:

- Foot conformation (club foot or low heels, toed in, toed out, hoof wall angle, correction of the lateral-to-medial balance, quality of the horn, characteristics of the sole and quarters, type of shoeing). Club feet may indicate osteoarthritis of the distal interphalangeal joint. Toed-out horses have the most frequent gait disturbances because they tend to hit the contralateral carpus or the ipsilateral metatarsal region. Toed-in horses have less significant gait problems, but the uneven distribution of the weight is likely to produce lameness of the middle carpal joint or suspensory desmitis.
- Torsional defects proximal to the hoof (fetlock and carpus and, more rarely, the tarsus), uncorrected angular limb deformities, offset (bench) knees, tied in behind the knees, straight conformation of the hindlimbs. Any of these abnormalities invariably produce secondary injuries such as suspensory desmitis, superficial digital flexor tendonitis, and middle carpal joint lameness.
- Conformation of the foot is important. Asymmetrical foot size is often a consequence of reduced weight bearing and lameness on one side and the smallest foot is generally on the lame side.

Palpation

Many clinicians spend little time palpating a lame horse, a practice that I feel is a mistake. Areas of warmth (heat), especially in the hoof wall, must be detected, and regions of special interest include the fetlock joints, the metacarpal and metatarsal regions, carpus, hock, stifle, and back.

In the forelimb the distal interphalangeal joint capsule just above the coronary band is palpated to detect effusion. The digital arteries are located abaxially at the base of the PSBs, and the character of the pulse is evaluated and compared between limbs.

Hoof tester examination can be considered part of palpation. When possible, feet are first tested without removing the shoes, and ideally the horse should be kept shod until any examination in movement is completed. When diagnostic analgesia is needed, hoof testing must precede palmar digital analgesia, and shoes may be removed temporarily if bar shoes or pads prevent accurate testing. These six points are tested in each horse: lateral and medial quarters, lateral and medial middle sole, and lateral and medial toe. Testing the frog rarely produces useful information, and squeezing the quarters from lateral to medial with hoof testers may cause pain unrelated to the primary lameness.[2] Pain arising from quarters, especially mild pain medially, should not be overevaluated because this region is frequently sensitive to hoof testers in normal horses. The contralateral foot may serve as a reference. In my experience the right medial quarter is the most common area where clinically important pain is elicited by hoof tester examination in STBs, and this is probably secondary to the counterclockwise direction of racing. Generally speaking, a painful response is considered more important when it arises from the toe or from the lateral side of the sole. When shoes are removed, a further evaluation of the lateral-to-medial balance is performed. The sole itself is observed, and when it appears flat and painful, this may correlate with type of shoes and padding that are used. Overzealous padding may add to, rather than relieve, pressure on the sole. A leather or rubber layer may allow sand to pack quickly under the pad and create pressure and secondary bruises. These horses are better managed with shoes in which the contact is limited to hoof wall and no contact is made with the sole.

In the forelimb the fetlock joint is examined for effusion, alteration of the dorsal outline, and enlargement of the suspensory branches. The latter are palpated carefully with the joint flexed. Each branch is pressed gently axially, and alterations in consistency and pain response are noted. Range of motion of the fetlock joint is assessed. In a normal STB the fetlock joint can be flexed up to 90° (angle between the metacarpophalangeal region and the proximal phalanx) without eliciting a painful response. With one hand holding the dorsal pastern region, the dorsal aspect of the fetlock joint can be palpated further by using the other hand to compress the dorsal joint capsule against the bony prominences of the sagittal ridge and condyles of McIII. Horses with osteochondritis dissecans or a hypertrophic synovial pad exhibit a response. The bony profile of McIII must be followed with fingers to detect painful areas in the dorsal, lateral, and medial aspects. Palmar soft tissues are evaluated with the limb in a weight-bearing position and while being held off the ground. Each structure is palpated accurately to detect heat, pain, and edema in horses with acute lesions or fibrotic consistency and adhesions in those with chronic conditions. Fingers must be pressed firmly, deep in the proximal palmar metacarpal region, where pain originating from the proximal suspensory ligament (SL) is hard to detect. The carpus is better evaluated by holding the leg in a moderate degree of flexion. Careful digital palpation along the dorsal aspect should be performed. Of particular importance is the dorsomedial aspect where a thickened joint capsule and painful response corresponds to the common finding of osteoarthritis of the middle carpal joint. Palpation of the forelimb proximal to the carpus is rarely helpful. Elbow and shoulder lameness are rare, and bicipital bursitis has seldom been reported.

In the distal hindlimb, palpation is similar to that described for the forelimb with the exception that foot lameness is less

important. The metatarsophalangeal joint region is best evaluated while holding the limb in a semi-flexed position. When the regions of proximal metatarsal region and distal tarsus are palpated, some painful reactions frequently are elicited, especially on the medial aspect. This pain frequently is overemphasized in horses with back pain, especially when the trainer thinks the horse has primary lameness in the tarsus. Effusion of the tarsocrural joint often indicates osteochondrosis. The stifle must be palpated deeply and carefully, because the joint is complex and palpation is limited. The femorotibial joints seldom appear distended, but increased pressure in the medial femorotibial joint is an important sign. More frequently, joint effusion is limited to the femoropatellar joint. Distention of the latter must lead to specific examination of both femorotibial joints, because inflammatory processes involving the femorotibial joints may cause distention of the femoropatellar joint. With the exception of acute trauma, painful responses to palpation are rare in this area, even from the patellar ligaments that are identified easily. On the medial side, scar tissue and irregularities or enlargement of the medial patellar ligament may suggest previous desmotomy. When associated with femoropatellar effusion, the latter sign may suggest apical patellar fragmentation, and radiographic examination is indicated. The stifle can be flexed only in unison with most other hindlimb joints, so a painful response is not specific. With moderate flexion the medial collateral ligament can be stressed by the veterinarian pulling the tibia in a lateral direction with both hands and pressing the shoulder against the femur.

Palpation of the back is aimed at evaluating pain arising from joints (intervertebral, lumbosacral, sacroiliac, and sacrococcygeal), nerve roots, and muscles. The latter are the most likely origin of pain elicited by palpation, but other problems must be ruled out if associated clinical signs (atrophy, asymmetry) are present. Pain in the gluteal area may be secondary to many problems, including straight hindlimb conformation, hock or stifle pain, sore feet, gait imbalance, and stiff corrective harness equipment. So pain in this area should not be treated as a primary problem unless a thorough clinical examination has ruled out other sources of pain.

Movement

After palpation, the horse is examined during movement. I commonly tranquilize each horse I examine for lameness. Tranquilization (10 mg acetylpromazine maleate intravenously) improves the possibilities of handling the horse and lowers the risk of injuries to the veterinarian. Furthermore, the horse appears less stiff, mild lameness becomes somewhat more obvious, and the horse stands better for radiographic or ultrasonographic examination. The trainer must be consulted before injecting a tranquilizer, because this practice may preclude racing because of doping (the term used in Europe for a positive blood or urine drug test of a prohibited substance). Lameness is rarely detectable at the walk, but it is important to observe the way the horse lands with each foot to identify lateral-to-medial hoof imbalance. The horse is then trotted in a straight line on a firm surface, and the character of movements is observed. Abduction or circumduction of forelimbs is considered characteristic of carpal lameness, because the horse appears to attempt to avoid flexion. In the hindlimb, stiffness has been related anecdotally to distal tarsitis but in fact is not a specific sign. In horses with pain arising from the distal part of a hindlimb (frequently the metatarsophalangeal joint) the horse tends to moderately overflex the hock and stifle to shorten the weight-bearing phase of the stride.[3] In horses with more severe lameness, drifting forward of the sound limb is observed and a drop of the fetlock joint is easily seen. Abduction of the hindlimb is thought to be related to stifle lameness.

Flexion tests are used to supplement findings during movement and are similar to those used in other sport horses. Flexion of the carpus is accomplished by pulling the metacarpal region laterally, and the clinician's elbow may act as a lever against the horse's radius to stress the medial aspect. In young horses affected by carpitis, this maneuver frequently elicits pain.

DIAGNOSTIC ANALGESIA

Diagnostic analgesia can be performed in sequence from distal to proximal, or to save time, selective analgesic techniques can be used. For example, European trotters with a positive response to forelimb lower limb flexion inconsistently respond to palmar digital analgesia, so analgesia of the metacarpophalangeal or distal interphalangeal joints may be the first option. Perineural analgesia is preferred, however, to avoid minor risks of joint infections or to save the opportunity to provide intra-articular therapy immediately (when working in stables, trainers frequently are interested more in treatment than in diagnosis). I frequently start with low plantar analgesia in the hindlimbs, because lameness of the digit is rare. In young STBs with forelimb lameness and a positive response to carpal flexion, I block the middle carpal joint first.

In horses with obscure lameness or when lameness is only apparent during fast exercise, examining the horse on the track may be useful. The horse is rigged in full harness and first examined trotting in a clockwise direction. Speed then is increased, and the horse is turned to train in a counterclockwise direction, the same as racing. Clinicians can drive the horse themselves, sit in a two-seat wagon, or observe the horse from a car or from a distance. In my opinion, watching the horse during exercise is important, especially when routine training and racing can be simulated, and I prefer the horse to be driven by its usual trainer. Having the horse fully equipped, mimicking the stress of racing, and observing the horse in turns are important advantages to this form of lameness examination.

Diagnostic analgesia is useful, but the clinician must be aware of related risks and make the trainer and owner aware as well. Diagnostic blocks should be avoided in horses suspected of having incomplete fractures. Radiographic examination should precede diagnostic analgesia in these horses. When examining a horse on the track after local analgesia, the trainer should be told to limit the speed as much as possible, avoiding any sudden stop or sharp turn. An experienced trainer normally is able to appreciate the benefits of a block quickly and without stressing the horse. Examination at speed is needed to make a diagnosis in horses with plantar process osteochondrosis fragmentation of the proximal phalanx and fragmentation of the distal border of the distal phalanx.

DIAGNOSTIC IMAGING

Sophisticated equipment for diagnostic imaging is now available in most European equine clinics. Scintigraphy is available in Europe but is limited to large referral hospitals. Radiography remains the mainstay of equine diagnostic imaging, and the availability of excellent portable units has improved the radiographic examination under field conditions. Ultrasonographic examination commonly is performed.

Common pathological findings in the distal limb of European trotters include osteophyte formation on the distal aspect of the middle phalanx, sometimes associated with remodeling of the extensor process of the distal phalanx, as seen on a lateromedial view of the foot (Fig. 110-1). This radiographic pattern often is associated with heel growth proceeding faster than toe growth (club foot). When associated

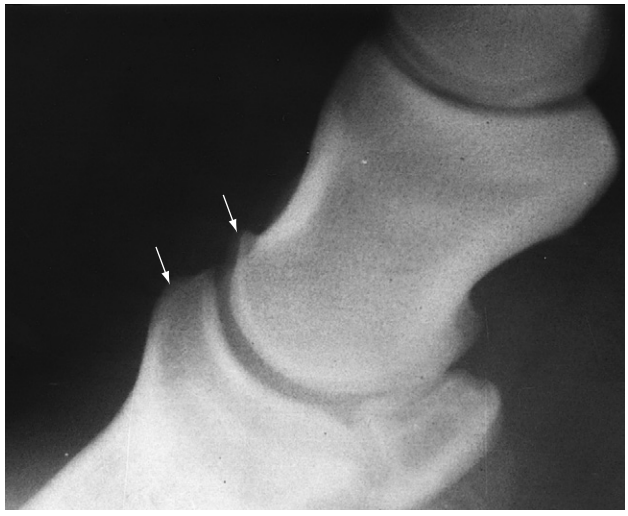

Fig. 110-1 Lateromedial radiographic view of the distal interphalangeal joint of a Standardbred trotter. Osteophyte formation on the distal border of the middle phalanx associated with moderate remodeling of the extensor process of the distal phalanx *(arrows)* is a common finding in European trotters.

with a positive lower limb flexion test and lameness abolished using analgesia of the distal interphalangeal joint, this radiographic finding is important and indicates osteoarthritis. Fragmentation of the extensor process of the distal phalanx has controversial clinical significance, but in my experience these fragments cause synovitis of the distal interphalangeal joint and are removed best by arthroscopy.

The solar radiographic view of the foot, unlike scintigraphy, rarely helps in diagnosing pain arising from stress remodeling of the distal phalanx, so the diagnosis of pedal osteitis is limited to horses with chronic lameness characterized by substantial radiolucency.[4] Fragmentation of the lateral and medial palmar processes of the distal phalanx, although controversial as a cause of acute lameness, may be an important source of pain best managed by shoeing.

The flexed lateromedial view of the metacarpophalangeal or metatarsophalangeal joints is useful in evaluating lesions of the distal aspect of McIII or MtIII. In the hindlimb the oblique views must be taken in a proximal to distal direction (downangled) to see better the area between the proximal phalanx and the base of the PSBs. Fragmentation of the proximal plantar aspect of the proximal phalanx represents a major cause of subtle hindlimb lameness (Fig. 110-2).

A dorsopalmar view of the carpus helps to evaluate the proximal suspensory attachment, and focal or diffuse palmar cortical sclerosis may be found (Fig. 110-3). In yearlings and young horses, this view allows examination of the distal radius, and pathological modifications of the growth plate on the medial side (physitis) are a frequent cause of early lameness. The most common lesions of the carpus are seen with the dorsolateral-palmaromedial oblique view and the dorsal 33° proximal-dorsal distal oblique (skyline) view of the flexed carpus to highlight the distal row of carpal bones. The latter must be of excellent quality, and the appropriate projection must be performed, because false-negative radiographs are frequent. Abnormal findings include areas of radiolucency in the dorsoproximal articular border of the radial fossa of the third carpal bone, radiolucent lines suggestive of fractures, and sclerosis of the third carpal bone.[5] A moderate degree of sclerosis in the radial fossa of the third carpal bone is considered normal in racing horses, but more severe sclerosis associated with radiolucent areas represents a pathological finding.[6,7]

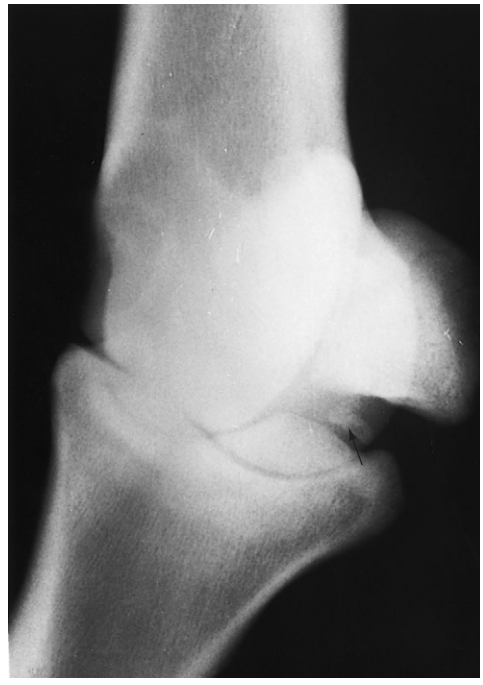

Fig. 110-2 Dorsoproximal 45° medial-plantarodistolateral oblique radiographic view of a hind fetlock of a 2-year-old Standardbred. There is plantar fragmentation *(arrow)* of the proximal medial aspect of the proximal phalanx.

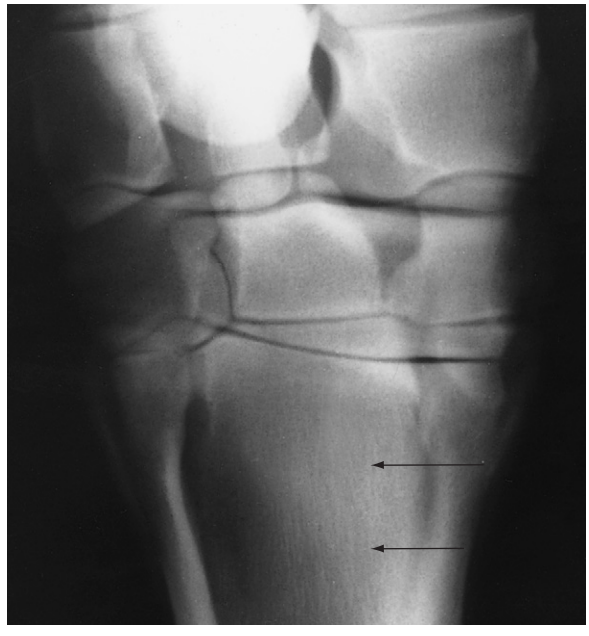

Fig. 110-3 Dorsopalmar radiographic view of the proximal metacarpal region of a Standardbred trotter. Sclerosis of the palmar cortex of the proximal aspect of the third metacarpal bone *(arrows)* is a common finding in trotters with chronic proximal suspensory desmitis.

In the hindlimb the centrodistal and tarsometatarsal joints frequently appear normal radiographically even when distal tarsitis is diagnosed clinically as the source of pain. Scintigraphy is an excellent tool for diagnosing osteoarthritis of these joints.[8]

The tarsocrural joint is a predilection site for osteochondosis in STBs, and fragments associated with effusion may represent an indication for arthroscopic surgery. Lesions affecting the lateral trochlear ridge of the talus and medial malleolus of the distal tibia more frequently cause lameness and effusion than do those of the cranial intermediate ridge of the distal tibia. In horses with effusion but without obvious fragmentation a specific dorsal 20° lateral-plantaromedial oblique projection is indicated to evaluate the axial aspect of the medial malleolus. Subtle osteochondral fragmentation or radiolucency easily can be overlooked (Fig. 110-4).

Curb is not seen frequently but can develop in the early stages of training in young horses. Curbs represent thickening of the plantar aspect of the hock and must be differentiated from the soft swelling caused by distention of a tarsal sheath. Abnormal stress to the plantar soft tissue structures can be predisposed by sickle-hocked or cow-hocked conformation. Accurate palpation differentiates curb from tarsal tenosynovitis. Ultrasonographic evaluation helps characterize the soft tissue structures involved in curb and assess severity (see Chapter 79). In the European STB, curb nearly invariably represents inflammation and thickening of the plantar ligament, but ultrasonographic evaluation is necessary to differentiate plantar desmitis from other soft tissue injury.

Trainers frequently ask for radiography or ultrasonography of the stifle because they seem to incriminate this joint as the source of pain in horses with obscure hindlimb lameness. Radiography of the stifle is important in foals and yearlings when femoropatellar effusion is present. Lateromedial and caudocranial views must be obtained. Osteochondritis dissecans of the lateral trochlear ridge and, less frequently, subchondral bone cysts of the medial femoral condyle can cause effusion and lameness in young STBs. Ultrasonographic evaluation of the stifle is useful in detecting soft tissue injuries, but these lesions are rare in STBs. Mild dimples or cartilaginous defects on the articular surface of the medial femoral condyle can be detected using ultrasonographic examination by holding the stifle in a semiflexed (90°) position.

Fig. 110-4 Dorsal 20° lateral-plantaromedial oblique radiographic view of the hock of a 2-year-old Standard bred colt. There is axial fragmentation of the medial malleolus *(arrows)*, which is difficult to detect unless oblique views are obtained. The condition can cause effusion of the tarsocrural joint and lameness.

FINAL DIAGNOSIS, PROGNOSIS, AND TREATMENT OPTIONS

A final diagnosis is made easily when the horse has obvious severe lameness, as is the case in horses with the more common fractures and tendon or ligament injuries (incomplete sagittal fracture of the proximal phalanx, proximal sesamoid bone fracture, carpal chip or slab fractures, superficial digital flexor tendonitis, and acute suspensory desmitis). Surgery or rest most often is recommended for these horses. In some horses, rest is the best option, and accurate monitoring of the healing process must follow (fracture of the distal phalanx, stress fractures of the proximal aspect of the third metacarpal bone, and proximal suspensory desmitis).

Osteoarthritis of the distal interphalangeal, metacarpophalangeal/metatarsophalangeal, and middle carpal joints (particularly in young horses) can cause chronic lameness. Racetrack clinicians frequently inject the tarsometatarsal, centrodistal, and tarsocrural joints, but the true incidence of problems arising from these joints has not been substantiated using diagnostic analgesia. Problems affecting the proximal hindlimb, in the absence of visible lameness, frequently are diagnosed, but definitive diagnosis is difficult to substantiate.

Intra-articular therapy includes steroids or non-steroidal anti-inflammatory drugs (NSAIDs). A series of four intra-articular injections of polysulfated glycosaminoglycans (PSGAGs), 250 mg every fourth day and then at weekly intervals, is helpful in treating STBs with juvenile osteoarthritis, especially in the carpus. PSGAGs also have been useful parenterally (500 mg every 4 days for seven treatments).[9] High molecular weight hyaluronan (20 to 40 mg) may be used alone or with corticosteroids. Hyaluronan (20 to 40 mg) may be used intravenously.[10] The most popular corticosteroids for intra-articular therapy in horses include methylprednisolone acetate (40 to 60 mg), betamethasone disodium phosphate or betamethasone acetate (3 to 9 mg), and triamcinolone acetonide (6 mg). A basic treatment includes three intra-articular injections, using 60 mg methylprednisolone acetate for the first injection, followed by two injections of 40 mg at 2-week intervals. A similar protocol may be applied to betamethasone disodium phosphate and betamethasone acetate (6 to 9 mg the first time followed by two injections of 6 mg each). This treatment is usually helpful in horses with chronic osteoarthritis of the distal interphalangeal, metacarpophalangeal/metatarsophalangeal, and distal tarsal joints and sometimes resolves acute synovitis in young horses. When using triamcinolone acetonide (6 mg), clinicians must be aware of systemic effects and problems (laminitis and rhabdomyolysis) if several joints are injected at the same time. Although the cause is unsubstantiated, these complications may develop because of iatrogenic hyperadrenocorticism.

Liniments, paints, and blisters are still popular, and despite lack of scientific support, they appear strongly tested by time. Iodide-based light paints diluted in dimethylsulfoxide may be helpful in improving circulation to the distal limbs and help to remove edema. Stronger blisters (with iodide mercury, cantharids, cedar oil, or turpentine) may play a role in improving circulation in some areas, but trainers must be made aware of possible secondary effects of the chemical induced inflammation (scars, adhesions, cellulitis, and excessive joint inflammation) and that using most irritant blisters is not justified anymore. Thermocautery (pin firing) is now less popular in Europe but is still used to treat STBS with curbs and proximal splint exostoses. Paints and blisters are used more frequently in France and Italy than in northern Europe.

CORRECTIVE SHOEING

Corrective shoeing is important for many forelimb lameness conditions. Generally speaking, a good lateral to medial

balance and an ideal dorsal hoof wall angle must be provided before any shoe is applied. Then a large-based (wide web) shoe is ideal but not always possible because of gait characteristics. Many trainers prefer thinner and lighter shoes, because they are associated with increased speed. In horses with a flat sole the shoe must be in contact only with the wall border, and any rubber, leather, or silicon pad must be avoided. In these horses a rigid (aluminum) sole may prove helpful, but frequent cleaning is required to avoid sand accumulation under the sole. In horses with osteoarthritis of the metacarpophalangeal or metatarsophalangeal joints, bar shoes must be avoided because the bar prevents the natural slipping of the foot when landing and increases stress on these joints. A bar shoe may prove helpful in horses with superficial digital flexor tendonitis, but I prefer to leave this shoe on only during the recovery phase and during light training, whereas an open shoe is preferred for fast training and racing.

TRAINING PROGRAMS

Alternative training programs can be a valuable adjunct therapy, especially when dealing with unnatural fast gaited trotters. Clockwise jogging and training, training on straight tracks (using interval training schedules), and swimming are preferred. Training programs aimed at reducing speed and stress on the large upper limb muscles, such as fast trotting in a circle in deep sand, use of heavy wagons or wagons with preselected brake sets (power carts) have been used, but scientific studies and objective data to support use of these alternatives are lacking.

PROCEEDING WITHOUT A DIAGNOSIS

Progress in diagnostic imaging has made the situation rare in which an clinician cannot determine a diagnosis. When available, whole body scintigraphic examination in horses with occult lameness is useful. Results of scintigraphy must not be overinterpreted, and clinicians must be aware that conditions may be subtle or difficult to detect. Bone remodeling around osteochondritis dissecans or osseous cyst-like lesions may be subtle. When detailed clinical examination has failed to reveal a diagnosis, I suggest the following options:

1. The horse should be re-assessed 10 to 15 days later. This may help in horses with acute lesions without initial radiographic signs and when scintigraphy is not available.
2. A second opinion can be considered, especially if the horse can be referred to a center that is equipped with advanced imaging equipment.
3. The horse should be treated with NSAIDs (phenylbutazone, 2.2 mg/kg a day orally for 5 days and then every second day for 10 days) and then re-evaluated.
4. The clinician should treat the most likely site or sites of pain with short-acting corticosteroids. Some trainers prefer this approach because they feel the horse does not lose time and often feel something has been done. In some horses, experienced horsemen may help the clinician effectively by asking for a specific therapy that may help the situation.
5. The clinician should give the horse a period of controlled exercise or rest. This decision is particularly helpful when dealing with young horses, in which early training may have promoted bone and soft tissue adaptation and remodeling that requires time to heal. Before resting the horse, a complete radiographic examination is a good idea because horses with advanced disease may have a poor prognosis or may require additional rest.

LAMENESS IN THE EUROPEAN TROTTER

Hoof Pain

This non-specific definition refers to a number of conditions, including what most clinicians and trainers call foot pain. Lameness varies and the response to flexion may be equivocal. Negative flexion tests in a lame horse may suggest nonarticular hoof pain, and the same applies to horses in which the trainer's complaint is pain (with compromised gait) at the end of the race. Horses may break stride on the last turn or may get on a line in the straightaway.

Physical examination includes visual inspection of the feet (club foot, lateral-to-medial hoof imbalance, or toed-in or toed-out conformation), accurate palpation of the coronary band, appreciation of alterations in the digital pulse, and hoof temperature. A complete hoof tester examination is essential. A series of selective diagnostic analgesic procedures follows. Palmar digital analgesia commonly improves lameness by 75% to 90%. If a less than 50% response is obtained, an abaxial sesamoid block is performed. I avoid analgesia of the distal interphalangeal joint, because I may choose to medicate the joint. Recent evidence suggests analgesia of the distal interphalangeal joint is not specific, and pain originating from the sole may be abolished.[11]

Diagnostic imaging includes radiography and scintigraphy. Stress remodeling of the distal phalanx is a common finding in trained STBs. Radiographs are usually negative, although occasionally marginal changes of the distal phalanx suggestive of pedal osteitis are present.

Management includes corrective shoeing, controlled exercise, distal interphalangeal joint injections, and local application of iodide ointments or blisters. Temporary pain relief has been reported anecdotally after perineural injection of cobratoxin, alcohol, or other preparations and after percutaneous cryotherapy. Horses with mild lameness respond to corrective shoeing: rubber or leather soles may be added to wide web shoes, or different types of rubber flaps may be used temporarily. Light training for 2 to 3 weeks is suggested, and the horse is best trained on a soft track or on a straight track if available. Swimming is a good alternative method of training.

Osteoarthritis of the Distal Interphalangeal Joint

History, character of the lameness, response to flexion tests, and shape of the hoof are points to consider when osteoarthritis of the distal interphalangeal joint is suspected. Horses can be lame or reported to be intermittently lame. The tendency is for horses to develop osteoarthritis of the distal interphalangeal joint and club foot because the hoof growth in the heel region is faster than in the toe region. Evaluation and trimming of the hoof wall to lower the dorsal angle may help prevent this conformational change. Palpation of the area over the coronary band may elicit pain, especially medially where the condition must be distinguished from chronic, distal interphalangeal collateral ligament strain. Mild pain also may be detected by palpation of the proximal SL in the forelimb and muscles of the back, two common compensatory lameness conditions. Diagnosis can be frustrating because horses are not always improved with distal interphalangeal analgesia (this may suggest pain originating in the subchondral bone), and the gait may be abnormal because of other problems frequently secondary to pain originating from the distal interphalangeal joint. An 80% to 90% positive response to the perineural analgesia must be considered clinically relevant.

Lateromedial radiographs of the distal limb frequently show a prominent osteophyte on the distal aspect of the middle phalanx, sometimes associated with secondary remodeling of the proximal aspect of the distal phalanx (see Fig. 110-1). Fragmentation of the extensor process of the distal phalanx may also be observed, in which case the hoof wall frequently has a grossly triangular shape. Osteoarthritis of the

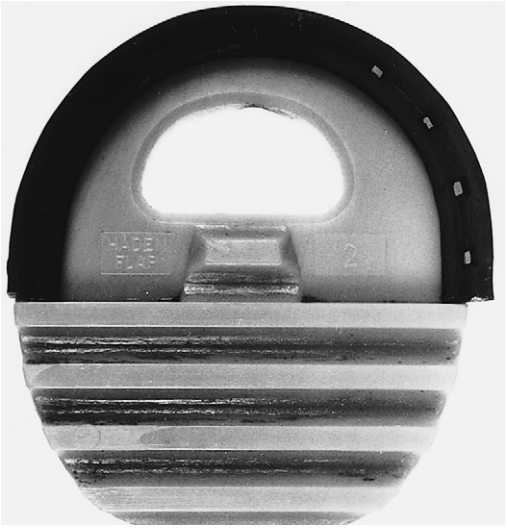

Fig. 110-5 A flap or flip-flop shoe can be useful in trotters with foot pain.

distal interphalangeal joint may be bilateral but is most commonly unilateral.

Suggested therapy includes intra-articular therapy with corticosteroids, PSGAGs, high molecular weight hyaluronan, or a combination of these drugs 3 times, at 7-day intervals (14 days when using corticosteroids). Corrective trimming to decrease excessive heel growth and maintaining the hoof angle at about 50° appear important. Wide-web shoes distribute load on a large surface area, and when possible, a rubber or leather pad is needed. The shoe should have a rolled toe to ease breakover. A thick rubber pad (flap or flip-flop) is used sometimes to replace the classic shoe (Fig. 110-5).

Osteoarthritis of the Metacarpophalangeal Joint

Osteoarthritis of the metacarpophalangeal joint may be acute or chronic. Acute synovitis is seen in young horses when training is intensified or when the track surface changes. Clinical signs include mild to moderate lameness, pain on palpation, and lameness after flexion. Radiographs are usually negative in young horses, but flattening or more severe changes of the sagittal ridge of McIII in older horses with chronic osteoarthritis often are seen. Contrast radiography reveals a filling defect corresponding to the hypertrophic synovial pad in the dorsal aspect of the distal, dorsal aspect of McIII. Ultrasonographic examination reveals various degrees of dorsal joint capsule thickening and increase in echogenicity of the synovial pad. Intra-articular analgesia abolishes the lameness in most horses.

In horses with acute synovitis, training program modulation (2 to 3 weeks of light jogging), corrective shoeing (wide-based shoes and pads), and intra-articular corticosteroids (a series of three injections at 2-week intervals) may resolve the problem. In these horses, concurrent pathological conditions of the articular cartilage, subchondral bone, and the synovial pad usually are lacking or mild. Horses with hypertrophic synovial pads benefit from arthroscopic surgery to remove the thickened tissues, because response to medical management is poor. This is frequently the case in older horses, in which advanced osteoarthritis is often present. Prognosis after surgery is only fair to guarded, however.

Middle Carpal Joint

The middle carpal joint is the most common site of lameness in young STBs. Typically, affected horses tend to trot with a wide gait, abducting the affected limb or limbs in an attempt to minimize carpal flexion.[12] Visual inspection from a dorsolateral perspective reveals abnormal contour of the dorsomedial aspect of the carpus. Palpation often elicits a painful response over the dorsal aspect of the radial and third carpal bones. Usually the response to carpal flexion is positive, and intra-articular analgesia abolishes lameness in most horses. A negative result from intra-articular analgesia does not rule out the middle carpal joint as the source of lameness, because subchondral bone damage under a relatively normal cartilage layer may cause pain that may not be desensitized completely. Radiographs are usually diagnostic, especially the skyline view of the distal row of carpal bones. Radiographic findings range from complete slab fracture of the third carpal bone to more subtle signs of radiolucency of the radial fossa of the third carpal bone. Scintigraphy is a sensitive and excellent tool in the early diagnosis of middle carpal joint lameness.[8]

Training program modulation and intra-articular injections of PSGAGs, hyaluronan, or small amounts of corticosteroids are the first steps in the treatment program. Arthroscopy is suggested when evidence of more severe bone damage exists. Chip fractures in STBs most frequently involve the third and radial carpal bones. Counterclockwise racing, especially in the turns, concentrates forces along the medial aspect of the right forelimb, and this makes the right middle carpal joint more predisposed to injuries.[13-15] The proximal border of the third carpal bone is involved more frequently than the distal border of the radial carpal bone in the STB, unlike in the Thoroughbred (TB) and in the pacer.[13,15,16] Arthroscopic surgery and rest generally yield a fair to good prognosis.[15] Incomplete slab fractures of the third carpal bone may heal with rest, possibly preceded by diagnostic arthroscopy and curettage of the lesion. Horses with complete slab fractures are best treated by internal fixation. Thin fragments are removed. When arthroscopy shows substantial loss of articular cartilage, the micropick technique may augment the possibilities of cartilage repair.[17] Arthroscopic findings in young STBs have been shown to correlate poorly with radiographic findings, and lesions appear frequently more severe than expected.[16] In horses without radiographic changes, I frequently find depressions and discoloration of articular cartilage (especially in the radial fossa of the third carpal bone), loss of articular cartilage in focal areas of the third and radial carpal bones, and partial or complete tearing of the medial palmar intercarpal ligament. Ligament injuries, especially affecting the medial palmar intercarpal ligament must be suspected in the absence of radiographic findings.[18] However, medial palmar intercarpal ligament injuries are rare. These horses are treated using arthroscopic trimming and are given 4 to 6 weeks of stall rest followed by 4 weeks of stall rest with hand walking exercise, and joints are injected with short-acting corticosteroids.

Proximal Palmar Metacarpal Pain Including Proximal Suspensory Desmitis

Proximal palmar metacarpal pain affects many more horses than we once thought. Mild pain in the proximal palmar aspect of the metacarpal region may be secondary to other gait disturbances and may reflect attempts to maintain balance when trotting fast. In this case the lesion rarely is substantiated by ultrasonography, but pain may be detected with accurate palpation (racetrack clinicians used to diagnose and treat blind splints in this area).

PSD is usually acute in onset, and direct palpation of the SL elicits pain. A carpal flexion test is often positive. Intra-articular analgesia of the middle carpal joint produces a variable amount of improvement, but some degree of lameness still is elicited by flexion. Subcarpal analgesia (4 mg of local anesthetic solution placed axial to each of the second and fourth metacarpal bones or direct infiltration of 2% mepivacaine over the proximal suspensory ligament) usually abolishes lameness.

Diagnostic imaging includes radiography, scintigraphy, and ultrasonography. Scintigraphy is useful in identifying horses with bony injury, including horses with an avulsion fracture at the attachment on McIII or those with a longitudinal fracture of McIII, or with enthesopathy. Horses with PSD without bony involvement may have positive pool-phase images, but delayed images are usually negative. Radiography (dorsopalmar and flexed lateromedial views) may reveal associated longitudinal or avulsion fractures of the palmar aspect of McIII or, in horses with chronic lameness, sclerosis of McIII at the SL origin (Fig. 110-3). Ultrasonography is useful in identifying patterns of ligamentous injury, palmar cortical bone damage, and monitoring the healing process.

The prognosis is fair to good, provided the affected horse is subjected to walking exercise and controlled training with concurrent monitoring of the healing process. STBs may tolerate an acceptable level of training with chronic injuries of the SL compared with TBs, possibly because of the increased percentage of muscle fibers present in the SL.[19] The prognosis in horses with PSD is better than those affected with lesions in the body of the ligament.

Therapy includes 6 to 8 weeks of rest followed by 4 to 6 weeks of 20 to 60 minutes of walking exercise or swimming. Local application of blisters and injections of corticosteroids or PSGAGs have been suggested, but they rarely are able to shorten the healing period. Cryotherapy has gained some popularity in treating STBs with PSD in racetrack practice, but its usefulness has not been substantiated scientifically. Intralesional injection of liquid bone marrow is a new, promising therapy that can be combined with fasciotomy.[20] More recently, shock wave therapy has been used to treat horses with PSD (see Chapter 99).

Sesamoiditis

Sesamoiditis may be defined as enthesopathy at the attachment of the branches of the SL to the abaxial surface of the PSBs. The condition also may affect the base of PSBs, but this form is rare and is best defined as distal sesamoidean desmitis. Two types of sesamoiditis are recognized. Type 1, or juvenile sesamoiditis, is characterized by radiolucent lines (vascular channels) in the proximal third of the PSB, radially oriented as seen in lateromedial or oblique radiographic views, and is a frequent feature in young (2- and 3-year-old) STBs (Fig. 110-6). This radiographic pattern is not associated constantly with lameness, and no link has been observed between the presence of these lines and PSB fractures.[21] Affected horses tend to be lame after training, but pain subsides with rest. Intra-articular analgesia does not abolish lameness. Lameness disappears after perineural analgesia of the medial and lateral plantar (palmar) nerves. The condition usually involves one or both hindlimbs, and the lateral PSB is affected more frequently. Scintigraphic findings indicate increased bone metabolism, but radiographic changes are seen in only 50% of STBs showing increased radioisotope uptake.[8] The lateral PSB represents one of the most frequent locations for abnormal scintigraphic findings in racing STBs.[8,22]

Type 2 sesamoiditis is chronic, frequently affects a single PSB, and is found more commonly in the forelimbs of older horses. Radiographic signs of type 2 sesamoiditis (evidence of radiolucent lines in the proximal half of the bone, irregular palmar/plantar and abaxial outline of the bone, enthesophytes, and mineralization of the adjacent intersesamoidean ligament) are associated with ultrasonographic evidence of suspensory insertion desmitis. One or both suspensory branches often are involved. Focal loss of echogenicity in horses with acute disease and increased echogenicity in horses with chronic lameness are common ultrasonographic findings. The insertion on the PSB (enthesis) becomes grossly irregular.

Fig. 110-6 Dorsolateral-plantaromedial oblique radiographic view of a metatarsophalangeal joint of a lame 2-year-old Standardbred colt with juvenile sesamoiditis. Note the radiolucent lines on the abaxial aspect of the lateral proximal sesamoid bone.

In horses with type 1 sesamoiditis, treatment involves rest, slow training, or turnout for 30 to 90 days, depending on the degree of lameness present. Radiographic monitoring of the lesion is probably not helpful, because lameness may improve substantially despite the persistence of radiolucent lines. More information is provided by scintigraphy initially and during follow-up examination. Medical treatment includes local application of paints or mild blisters, corrective shoeing (bars must be avoided, the quarters must be lowered moderately, and shoes must provide a wide base in the hindlimbs). Medical treatment is aimed at improving local blood flow, and isoxsuprine hydrochloride (0.6 to 1.2 mg/kg per os bid) and sodium acetylsalicylate (10 mg/kg PO bid) are recommended for 45 to 60 days. The efficacy of this therapy, however, is questionable. The prognosis is fair if lameness is not severe and if the horse tends to warm out of lameness. If severe lameness is observed and associated radiographic changes are pronounced, the prognosis is guarded. These horses are best given long periods of rest and paddock turnout (6 to 8 months). Treatment of horses with type 2 sesamoiditis includes rest, corrective shoeing (wide web aluminum shoes, leather pad, with particular attention to lateral-to-medial hoof balance), local application of dimethylsulfoxide, and paints and blisters. Pin firing is no longer justified. Cryotherapy has become popular in recent years, but in my opinion its clinical efficacy is poor. The prognosis is fair, but hoof balance must be monitored to prevent recurrence. Low-level or alternative (swimming) training is indicated.

Suspensory Branch Desmitis

Suspensory branch desmitis can be acute or chronic and is caused by lateral-to-medial hoof imbalance, exercise over uneven track surfaces, strains, and chronic fractures of the second and fourth metacarpal/metatarsal (splint) bones. Acute desmitis can be associated with metacarpophalangeal/metatarsophalangeal joint effusion. Shoeing changes, particularly when the hoof angle is modified (usually increased), frequently precede the condition, and when treating the condition, hoof

imbalances must be identified and corrected. Ideally the dorsal hoof angle in the forelimb should be kept between 48° and 52°, with a shoe providing good support to the heels. The routine training regimen, track conditions, and the counterclockwise direction of racing may affect the distribution of suspensory branch desmitis. In my experience the right forelimb and right hindlimb are most commonly affected, and lesions of the medial branch are twice as common as those of the lateral branch. Radiography and ultrasonography are performed to assess ligament damage and bone involvement. Enlargement and loss of definition of the margins of the branch, focal hypoechoic areas, or diffuse loss of echogenicity and hyperechoic foci in horses with chronic desmitis are the most frequent ultrasonographic findings.[23] Radiographically the ipsilateral splint bone may appear deviated abaxially, and in horses with chronic lameness, adhesions may develop between the splint bone and suspensory branch, causing fracture during fast exercise. For the latter reason, radiographic monitoring of the splint bones is suggested in horses with chronic desmitis. The insertion of the branch on the PSB must be assessed by ultrasonography for lesions affecting the branch insertion on the bone.

The treatment in horses with acute desmitis includes rest, anti-inflammatory drugs (phenylbutazone 2.2 mg/kg), or local application of dimethylsulfoxide and poultices. Intra-articular injection of corticosteroids may be beneficial when the condition is associated with metacarpophalangeal/metatarsophalangeal joint effusion. In horses with chronic or severe desmitis, rest and local application of mild blisters may help. Fast training must be avoided when possible, and corrective shoeing must be provided. Alternative training programs, especially swimming physiotherapy, are indicated and can allow an acceptable level of exercise without worsening the lesion.

Metatarsophalangeal Joint

The metatarsophalangeal joint represents a major source of hindlimb lameness in STBs.[24] Lameness of the metatarsophalangeal joint and specifically the plantar aspect is frequently subtle, and diagnosis can be challenging. Stress or non-adaptive remodeling of the plantar aspect of the metatarsophalangeal joint, proximal plantar fragmentation of the proximal phalanx, and non-union of the lateral eminence of the proximal phalanx represent the most common conditions. Traumatic osteochondrosis of the distal plantar metatarsal condyles and mineralization of the distal sesamoidean ligaments are observed rarely.

Subchondral stress remodeling of MtIII has been described recently and represents a scintigraphic finding, with a corresponding radiographic pattern not easily identifiable (Fig. 109-7).[22] Proximal plantar fragmentation of the proximal phalanx has been reported by several authors in radiographic surveys of young STBs and is commonly seen (see Fig. 110-2).[25,26] Plantar fragments from the proximal phalanx rarely are associated with lameness at a trot in hand. Trainers' complaints include gait disturbances during fast exercise, especially in turns, and the tendency for the horse to be on one shaft. Intra-articular analgesia of the metatarsophalangeal joint can alleviate lameness, but a fast exercise test is required and owners must be aware of the potential consequences of this procedure. For this reason, when the clinical pattern indicates pain arising from the metatarsophalangeal joint, a radiographic examination including the oblique projections (dorsoproximolateral-plantarodistomedial oblique and dorsoproximomedial-plantarodistolateral oblique) is required. In horses with plantar process osteochondritis dissecans fragments, arthroscopic surgical removal of fragments is indicated. The prognosis after surgical treatment is good. In horses with stress remodeling of the distal MtIII, rest or reduced training, intra-articular injections of PSGAGs, or low doses of corticosteroids and hyaluronan, are recommended.

Fig. 110-7 Radiolucent defect in the distal, plantarolateral aspect of the third metatarsal bone is visible on the dorsal 45° lateral 45° proximal-palmarodistal oblique radiographic view, the result of stress or non-adaptive remodeling.

Superficial Digital Flexor Tendonitis

The incidence and morbidity of tendonitis in STBs is lower compared with TBs, but tendonitis of the superficial digital flexor tendon (SDFT) represents the main indication for ultrasonographic examination of the distal limbs in STB racehorses in Europe.

In my experience, most of the lesions are located in the middle and distal thirds of the tendon. A core lesion located in the palmarolateral border of the tendon during ultrasonography characterizes more than 30% of the lesions. More rarely central core lesions are seen. Horses with chronic lesions have the typical pattern of diffuse tendonitis. Therapy includes rest, corrective shoeing, local application of anti-inflammatory ointments, poultices, dimethylsulfoxide, paints, or blisters, tendon splitting, desmotomy of the accessory ligament of the SDFT, and desmotomy of the palmar annular ligament. Intralesional injections of hyaluronan or PSGAGs have been reported. My treatment of choice in horses with acute lameness includes corrective shoeing (moderate lowering of the heels, correcting lateral-to-medial balance, and using wide-based shoes without pads, especially rubber pads), local application of dimethylsulfoxide, cold water therapy twice a day, poultice application, and walking exercise for 2 to 4 weeks. The initial treatment is followed by the local application of an iodide blister, and the horse is given an additional 4 to 8 weeks of walking exercise. The horse usually is able then to resume jogging unless lameness is present. Ultrasonographic examination is performed 12 weeks later.

In horses with recurrent tendonitis, our treatment of choice includes desmotomy of the accessory ligament of the SDFT (superior check desmotomy). Desmotomy of the palmar annular ligament also is performed when substantial tendonitis involving the distal aspect of the tendon or digital flexor tendon sheath effusion is present. After surgery, horses are given 2 weeks of box stall rest, followed by 8 weeks of walking exercise.

Tendonitis of the SDFT within the pastern region is less common but more difficult to manage than tendonitis in the metacarpal region. Lameness is more pronounced, and recurrence of clinical signs is common. With ultrasonography lesions can be detected at the tendon insertion over the lateral or medial aspect of the middle phalanx. Treatment includes

rest, local and systemic anti-inflammatory drugs, blisters, corrective shoeing, and alternative training, particularly swimming. Monitoring of the healing process is important to prevent recurrence.

Osteochondrosis of the Tarsocrural Joint

Joint effusion represents the most common feature of tarsocrural osteochondrosis, a condition that has been reported with a prevalence ranging between 4% and 20% in several surveys.[25-33] Tarsocrural osteochondrosis frequently is diagnosed in yearlings, and breeders are particularly concerned because the condition may lower the yearling's price at the autumn sales. For this reason, tarsocrural effusion in yearlings now represents a frequent indication for radiographic examination and preventative arthroscopy.

Lameness associated with osteochondrosis is rare, but selected lesions may cause gait disturbances. In horses with effusion and osteochondral fragmentation, it is important to rule out other causes of lameness. Lesions affecting the lateral trochlear ridge of the talus and medial malleolus of the tibia are more likely to cause lameness and synovial effusion than are lesions of the cranial aspect of the distal intermediate ridge of the tibia. Focal areas of radiolucency or loss of radiopacity on the medial malleolus may be associated with osteochondral fragmentation and may represent an indication for diagnostic arthroscopy.[34] In young horses with effusion, arthroscopic removal of fragment(s) represents the best option. Prognosis after arthroscopic treatment of tarsocrural osteochondrosis is good, but synovial effusion may persist especially when osteochondrosis involves the lateral trochlear ridge of the talus and the medial malleolus.[35,36] Recent studies performed in Europe found no significant differences in the racing performance and longevity of STB trotters with or without tarsocrural osteochondrosis dissecans.[1,32,37]

THE AUSTRALASIAN STANDARDBRED

• Chris Whitton

DESCRIPTION OF THE SPORT

STB horses have been racing in Australia and New Zealand for more than 130 years. In both countries the sport does not enjoy the same high profile as TB racing, and prize money is generally lower, which attracts fewer professional trainers than TB racing. Owner/trainers are common, with most stables having fewer than 10 horses. Horses can begin racing at 2 years of age and generally race until 8 or 9 years of age.

Most races are for pacers, with trotting races being much less common. In Australia races range in distance from 1600 to 2400 m, and most pacing races are from a mobile start, with an occasional standing start. All trotting races are from a standing start. In New Zealand, races tend to be longer, up to 3200 m, and standing starts are more common.

Regional meetings carry prize money of $A2000 (Australian dollars) to $A4000 per race, whereas metropolitan meetings offer $A15,000 per race. The 15 most valuable pacing races in Australia and New Zealand make up what is called the Grand Circuit. Prize money for Grand Circuit races ranges from $A100,000 to $A500,000 for the Interdominion Pacing Championship Final. Prize money for trotting races is substantially less than that for pacers. The Interdominion trotter's Championship Final carries a $A200,000 prize.

An increased number of stakes programs for young horses have become available in recent years. The Australasian Breeders Crown is held over all states of Australia and both islands of New Zealand for 2-, 3-, and 4-year-old pacers and trotters. Australian Pacing Gold is a program for yearlings sold at the sales of the same name and also has feature races for 2-, 3-, and 4-year-olds. The value of these programs puts great pressure on trainers and clinicians to persist with young horses that may benefit from rest.

Race speeds generally are expressed as mile rates, which is the time taken to travel 1 mile averaged over the whole race. Tight tracks result in slightly slower rates than large tracks. Typical mile rates for pacers in 1600-m races are 1:56 to 1:58. For 2400-m races mile rates of 2 minutes are typical.

TRACK SURFACE OR TRAINING SURFACE AND LAMENESS

Most of the racetracks are 700 to 1000 m in circumference, and races are run in a counterclockwise direction, except for the north island of New Zealand where races are run clockwise. Track surfaces vary but usually consist of sand or fine gravel. Banking of turns tends to be modest, although a trend to greater degrees of banking and reduced injury rates has been demonstrated. Many trainers have their own homemade training track that is often just graded dirt or sand and not always well maintained, and recurrent foot bruising can be a major problem. Banking on these tracks tends to be minimal. In coastal areas, training on the beach is popular and considered beneficial for horses with injuries.

TRAINING METHODS

A typical training program involves a period of jogging exercise, generally of about 6 weeks, and these sessions generally last 35 to 40 minutes. Higher-speed work in hobbles (pace work) is introduced 2 to 3 times a week. A typical workout is two intervals of half to three-quarter pace over 1½ miles. The speed of these workouts is steadily increased over 4 to 6 weeks until speeds approaching those of race speed are achieved. A horse that is racing generally is hobbled twice a week and jogged on the other days. Training in New Zealand is similar, with the major difference being the tendency to house horses in paddocks rather than in stables.

THE TEN MOST COMMON LAMENESS CONDITIONS

The following are the 10 most common lameness conditions:

1. Subsolar bruising
2. Foot abscess
3. Osteoarthritis of the metacarpophalangeal or metatarsophalangeal joint
4. Suspensory desmitis
5. Osteoarthritis of the distal tarsal joints
6. Superficial digital flexor tendonitis
7. Fracture of the distal phalanx
8. Sagittal fracture of the proximal phalanx
9. Carpal joint disease
10. Osteochondrosis of the tarsocrural joint

LAMENESS EXAMINATION

Experience in examining STBs for lameness is essential because of their awkward gait, even when trotting. An extremely high incidence of lameness occurs in horses in full work, and often several limbs are affected.

Examination at Rest (Preferably in a Stable)

The clinician should observe the horse standing for any obvious swelling, abnormal weight bearing, and areas of hair loss on the proximal limbs associated with the position of the hobbles. The clinician should palpate the neck and back to detect any areas of pain; palpate the supraspinous ligament,

dorsal spinous processes, and dorsal sacroiliac ligament, along with the longissimus dorsi muscles; and then examine each limb in turn. Palpation is performed with the limb bearing weight and not bearing weight. The veterinarian should palpate the digital pulses on the distal pastern or over the abaxial surface of the proximal sesamoid bones; observe each joint and palpate for swelling or effusion. Palpate the tendons and ligaments for heat, pain, and swelling. Particular attention should be paid to all levels of the SLs of the forelimbs and hindlimbs. The clinician should take time to examine the hind fetlock joints for effusion; flex the joints firmly to detect pain and apply hoof testers to each foot.

Trotting in a Straight Line

The horse should be trotted on a firm flat surface. Many horses pace initially, which makes the diagnosis of subtle lameness difficult. Persistence is important, because most horses will trot after 2 or 3 runs up and down. The horse should be observed trotting away from and toward the observer and should be observed from the side.

Flexion Tests

Flexion tests have limitations but are a useful addition to the lameness examination. It is important to perform hindlimb fetlock flexion tests separately from proximal limb flexion tests because hindlimb fetlock problems are common.

DIAGNOSTIC ANALGESIA

Nerve blocks generally are required where no cause of lameness is obvious or the significance of a clinical finding is not clear. Where no localizing clinical signs are apparent, the clinician uses a standard approach: in the forelimb a pastern ring block is performed. The veterinarian should avoid nerve blocks at the level of the PSBs, because distinguishing between PSB pain and foot pain is difficult. This is followed by a low four-point block and then a subcarpal block and intra-articular blocks of the middle carpal and then the antebrachiocarpal joints. Should the horse fail to respond to these blocks, median and ulnar nerve blocks are performed to rule out the lower limb as a source of pain. Rarely are blocks of the elbow joint, intertubercular (bicipital) bursa, or shoulder joint required.

A similar sequence of blocks is used in the hindlimb. A single lateral plantar metatarsal nerve block may be performed if plantar condylar subchondral bone pain is suspected. A subtarsal block is followed by an intra-articular block of the tarsometatarsal joint and then the centrodistal joint. The tarsocrural joint is seldom blocked because swelling generally is associated with intra-articular pathological conditions. Tibial and fibular blocks are performed to rule out the lower limb as the source of pain. Occasionally an intra-articular stifle block is required, in which case all compartments should be blocked at one time.

IMAGING CONSIDERATIONS

Radiography remains an important imaging technique. Oblique views of the distal phalanx are important when a fracture is suspected, because some may be missed on dorsopalmar views. A flexed lateromedial view of the metacarpophalangeal joint should be obtained to highlight the sagittal ridge of the distal aspect of McIII and the dorsal surfaces of the PSBs. Proximodistal oblique views of the hind fetlocks are obtained to demonstrate proximal plantar fragments of the proximal phalanx and the lateral condyle of MtIII. Carpal views should always include a skyline of the third carpal bone.

Ultrasonographic examination of the flexor tendons and SLs commonly is required. SDFT lesions are often peripheral rather than core lesions. Lesions also may involve the distal third of the metacarpal region or the proximal metatarsal region, areas that are examined less commonly by ultrasonography and may be more difficult to assess. Cross-sectional area measurements comparing affected and non-affected limbs are essential when assessing subtle lesions. When examining the SLs, it is important to assess the full length, because lesions can affect the origin, body, and branches.

PROCEEDING WITHOUT A DIAGNOSIS

Intra-articular corticosteroids often are used to assist in diagnosing subtle hindlimb lameness. Bilateral intra-articular injection of the tarsometatarsal and centrodistal joints may be used in horses in which hindlimb lameness is too subtle for accurate assessment by nerve blocks. Triamcinolone acetonide is the most commonly used intra-articular corticosteroid because of its relatively short and predictable detection time, combined with a long duration of action. Treatment of metatarsophalangeal joints also is often performed, because lameness can be subtle. The clinical relevance of plantar proximal fragments of the proximal phalanx is often questionable, and intra-articular therapy may be the only method of confirming that metatarsophalangeal joint pain exists.

SHOEING CONSIDERATIONS

Most horses are shod and trimmed by the trainer or owner. The quality therefore varies extremely. Steel rim shoes generally are used, with trailers on the hind feet being universal. These shoes are thin and provide little protection for the sole. An occasional horse is trained and raced barefoot. Wider web aluminum shoes, similar to those used on TB racehorses, are available, but the use of these shoes is less common. These shoes generally have steel inserts to improve grip. Glue-on shoes rarely are used. In an attempt to promote increased length of stride, toes are often left overlong. The combination of overlong toes and the lack of sole protection predisposes horses to subsolar bruising.

DIAGNOSIS AND MANAGEMENT OF LAMENESS

Subsolar Bruising

The diagnosis of subsolar bruising is based on pain with the application of hoof testers over the sole, either localized or generalized, and increased lameness after concussion of the foot. Lameness is localized to the foot with a pastern ring block, and radiography is performed to rule out a fracture of the distal phalanx. Chronic bruising may result in lysis and modeling of the margins of the distal phalanx, but these changes do not necessarily mean that the bruising is active. Hemorrhage within the horn of the sole may or may not be evident. Horses with acute lameness are treated with rest and NSAIDs. Careful attention should be paid to foot balance and wide web aluminum shoes should be fitted.

Fracture of the Distal Phalanx

STBs with a sudden onset of forelimb lameness after racing or fast work but with no localizing signs should be suspected of having a fracture of the distal phalanx. Application of hoof testers usually elicits pain, but this is not always consistent. Oblique radiographic views of the foot often are required to assess the fracture properly. It is important to determine whether the fracture enters the distal interphalangeal joint.

Most fractures are intra-articular. In horses that race counterclockwise, left forelimb fractures are generally of the lateral palmar process and right forelimb fractures are generally of the medial palmar process. Horses with non-articular fractures are treated with a bar shoe with quarter clips or a rim shoe and 12 months of rest. Horses with articular fractures may be treated in the same manner or by internal fixation with a single 4.5-mm lag screw along with a bar shoe with quarter clips. Evidence on the success of these treatments is limited, with the choice depending on individual preference.

Sagittal Fracture of the Proximal Phalanx

The clinical presentation of horses with sagittal fractures of the proximal phalanx depends on fracture configuration. Short, incomplete fractures may be associated with chronic lameness that is localized to the fetlock joint with nerve blocks. Longer fractures often cause acute onset of lameness. Swelling may be present, and the horse often has pain on palpation of the dorsal aspect of the proximal phalanx. Nerve blocks are contraindicated because of the risk of progression of the fracture. Radiography confirms the diagnosis. Horses with non-displaced fractures may be treated with external coaptation. Internal fixation with lag screws is recommended for horses with complete and displaced fractures. Horses with short, incomplete fractures may heal with rest. Lag screw fixation has been recommended for fractures that fail to heal.

Osteoarthritis of the Fetlock Joint

Osteoarthritis of the metacarpophalangeal or metatarsophalangeal (fetlock) joint may or may not be associated with joint effusion and swelling. Usually the horse shows pain on passive flexion and a positive response to a fetlock flexion test. Lameness should be improved with a low four-point block or intra-articular analgesia. If lameness is recent, no radiographic abnormalities will be apparent, but more chronic lameness is associated with modeling changes on the dorsal aspects of the proximal phalanx and McIII/MtIII. Modeling also may be observed on the articular margins of the PSBs and the palmar/plantar aspect of the proximal phalanx. In advanced osteoarthritis, subchondral lysis or cystic lesions may be observed in the palmar/plantar aspect of the condyle of McIII/MtIII. This is most common in the lateral condyle of MtIII and is best observed on a proximodistal oblique view. Scintigraphy may be required for horses with few radiographic changes and demonstrates increased radiopharmaceutical uptake in the subchondral bone.

Proliferative Synovitis

Proliferative synovitis occasionally causes lameness in STBs. Lameness generally is localized to the metacarpophalangeal joint by either perineural or intra-articular analgesia. Abnormal concavity proximal to the sagittal ridge of McIII is observed on the dorsal and occasionally the palmar aspects on lateromedial radiographs. Ultrasonography demonstrates enlargement of the synovial pad medial or lateral to the sagittal ridge on the dorsal aspect, which must be differentiated from the joint capsule. Intra-articular corticosteroids may be used, but the results often are disappointing. Surgical excision of the synovial pad via arthroscopy is usually effective in resolving the lameness. The prognosis is poorer in horses with modeling of the palmar aspect of McIII, because this usually reflects a more advanced, chronic condition.

Axial, Articular (Type 1) Osteochondral Fragments of the Proximal Plantar Aspect of the Proximal Phalanx

Proximal plantar fragments of the proximal phalanx are best observed on proximodistal oblique radiographs of the metatarsophalangeal joints. These views should be included in the workup of horses with low-grade hindlimb lameness or a history of not running straight. Lameness is generally mild or not present at low speeds. Osteochondral fragments of the proximal plantar aspect of the proximal phalanx are most common on the medial aspect but can occur laterally or biaxially. These fragments are present by 1 year of age and are thought by some to be traumatic in origin. Treatment involves arthroscopic removal, and treated horses can be returned to training within 6 weeks. Intra-articularly administered corticosteroids are sometimes used to determine the significance of these lesions, because not all are associated with poor performance.

Superficial Digital Flexor Tendonitis

Tendon injuries are easy to diagnose when the mid-metacarpal or mid-metatarsal area is involved. Swelling and pain on palpation are indications for ultrasonographic examination to confirm the diagnosis and differentiate from peritendonous inflammation. Horses with moderate to severe injuries are treated with rest and anti-inflammatory therapy until the swelling is reduced, followed by a controlled exercise program. Full work should not be re-introduced until 12 months after injury. Less severely injured horses may be kept in work, provided the exercise level is reduced and the tendon is monitored by ultrasonography. Such management is more successful with hindlimb injuries. Tendon injuries at the level of the digital flexor tendon sheath may result in secondary palmar annular ligament (PAL) constriction and tenosynovitis. Lameness and tendon sheath effusion are observed when the horse is returned to training. Provided healing of the tendon injury is adequate, the PAL can be sectioned and the horse rapidly returned to training to prevent the formation of adhesions.

Suspensory Desmitis

In most horses with suspensory desmitis, swelling and pain on palpation of the affected area of the SL is obvious, but lesions confined to the origin may be more difficult to diagnose, and subcarpal/subtarsal nerve blocks are required for diagnosis. Ultrasonographic examination confirms desmitis based on increased cross-sectional area and areas of decreased echogenicity. Radiography is used to assess the palmar/plantar aspect of McIII/MtIII and the PSBs at the proximal and distal attachments of the SL. The ideal treatment involves an initial period of rest and anti-inflammatory treatment to allow the inflammation to resolve, followed by a period of controlled exercise. Horses should not return to full work for 12 months. In practice this is not always possible, and many horses can be managed by reducing the work load for shorter periods, treating with anti-inflammatory drugs, and monitoring the response with ultrasonography.

Carpal Joint Disease

Intra-articular fractures of the carpal bones generally involve the middle carpal joint. Fractures involving the antebrachiocarpal joint are less common. The horse may be performing poorly or have mild lameness. More severe lameness is associated with slab fractures or severe joint injury. Joint swelling and pain on flexion are common. Radiographs should always include a skyline view of the third carpal bone. Often lameness may be localized to the middle carpal joint with intra-articular analgesia, and only sclerosis with or without focal lytic areas of the third carpal bone are observed. Treatment options include arthroscopic surgery to remove diseased bone and cartilage, intra-articularly administered corticosteroids, and rest.

Osteoarthritis of the Distal Tarsal Joints

Confirmation of the distal tarsal joints as the source of lameness involves using intra-articular analgesia or intra-articular medication in horses with more subtle lameness. Although

radiographs are useful for determining the extent of bony changes, they are not always diagnostic. Treatment involves intra-articular injection of long-acting corticosteroids. Triamcinolone acetonide is the most commonly used because of its reliable excretion times and relatively long duration of action.

Tarsocrural Osteochondrosis

The most common osteochondrosis lesion affecting the tarsocrural joint of STB horses involves the distal intermediate ridge of the tibia. Most horses have effusion of the tarsocrural joint, and lameness is absent or subtle. Radiographs demonstrate fragmentation of the intermediate ridge. The fragments are removed arthroscopically.

Stifle Disease

Lameness localized to the stifle is rare in the STB racehorse. These horses appear to be able to race successfully with radiographic evidence of osteoarthritis of the femorotibial joints. Direct trauma to the stifle may result in soft tissue and bony injuries as in other types of horses. Trainers often are concerned that a horse may be locking its stifles, but this generally resolves with increased fitness, and sectioning of the medial patellar ligament is rarely necessary.

CHAPTER • 111

The Racing Quarter Horse

Robert D. Lewis

HISTORY AND DESCRIPTION OF THE SPORT

In the early 1600s, horses imported to Virginia from England were crossed with local horses of Spanish ancestry to produce a compact and heavily muscled horse that could run short distances at incredible speeds. Colonists referred to these horses as Quarter Pathers, and they were the forerunner of what are now known as American Quarter Horses. Early races were generally match races between two horses running no more than a quarter of a mile. These sprint races were the earliest known examples of Quarter Horse (QH) racing in the United States. The first QH races were recorded in Enrico County, Virginia, in 1674.

Racing popularity grew as the breed grew, and racing spread west as pioneers and early settlers moved in that direction. Organized QH racing started in Tucson, Arizona, with the first track devoted to QH racing being Rillito Park, built in Tucson in 1943. Today QH racing is conducted at more than 100 racetracks throughout North America, with total purses reaching $53 million. The goal of many in this industry is to own, saddle, or ride the winner of the $2 million All American Futurity, run each year on Labor Day at Ruidoso Downs in New Mexico. The racing QH today is faster than ever, some having been clocked at speeds exceeding 50 mph, earning them the title America's Fastest Athlete.

Racing QHs traditionally are broken to ride as yearlings in the fall, and breaking commonly is not delayed beyond the year end, with the exception of delays from previous injury or illness. Training a racing QH is quicker than training a Thoroughbred (TB), and most race as early as 2-year- olds, and although some jurisdictions prohibit racing of 2-year-olds before a certain date (e.g., March 1 or actual second birthday of the horse), many regions commence racing early in the year. In general, QHs are raced younger than TBs.

Futurities are races for 2-year-olds for which a horse must be nominated, with regular payments. Scheduling of these races largely dictates the planning of races for 2-year-old QHs. Derbies are managed similarly for 3-year-old horses. Similar races also exist for older horses. Preliminary trial races usually are held to determine qualifiers for the final race, which is run about 2 weeks later.

Purses for futurities and derbies vary, but they are usually attractive and drive the racing QH industry. Owners strive to acquire horses that are talented enough to be competitive in these races.

TRAINING THE RACING QUARTER HORSE

Actual training methods vary widely, but the number of gallops and amount of work performed before the first race and subsequently between races is substantially less than for TBs. Many older racing QHs exercise daily on a mechanical walker and may have one or two easy gallops per week between races.

LAMENESS RELATED TO TRACK SURFACE

QHs race at many racetracks throughout the United States, with some racing conducted on track surfaces devoted primarily to QHs and other racing being conducted on track surfaces also used for TB racing. Some tracks conduct separate racing meets for TBs and QHs, whereas others conduct mixed race meets. Characteristics of track surfaces vary. In my experience, QH trainers prefer a firmer, faster surface than do TB trainers. Racetrack management often requests that maintenance crews produce a firm surface during QH race meets. Uniformity across the entire width of the racing surface is paramount.

Most racing QH trainers agree that deeper, more yielding surfaces result in more soft tissue injuries, such as suspensory desmitis and flexor tendonitis, and a higher incidence of hindlimb lameness and what is typically described as muscle soreness in the hindquarters and loin muscles. Harder surfaces are considered to produce more lameness attributed to bones and joints of the forelimb, and these reflect most of the lamenesses diagnosed in racing QHs.

radiographs are useful for determining the extent of bony changes, they are not always diagnostic. Treatment involves intra-articular injection of long-acting corticosteroids. Triamcinolone acetonide is the most commonly used because of its reliable excretion times and relatively long duration of action.

Tarsocrural Osteochondrosis

The most common osteochondrosis lesion affecting the tarsocrural joint of STB horses involves the distal intermediate ridge of the tibia. Most horses have effusion of the tarsocrural joint, and lameness is absent or subtle. Radiographs demonstrate fragmentation of the intermediate ridge. The fragments are removed arthroscopically.

Stifle Disease

Lameness localized to the stifle is rare in the STB racehorse. These horses appear to be able to race successfully with radiographic evidence of osteoarthritis of the femorotibial joints. Direct trauma to the stifle may result in soft tissue and bony injuries as in other types of horses. Trainers often are concerned that a horse may be locking its stifles, but this generally resolves with increased fitness, and sectioning of the medial patellar ligament is rarely necessary.

The Racing Quarter Horse

Robert D. Lewis

HISTORY AND DESCRIPTION OF THE SPORT

In the early 1600s, horses imported to Virginia from England were crossed with local horses of Spanish ancestry to produce a compact and heavily muscled horse that could run short distances at incredible speeds. Colonists referred to these horses as Quarter Pathers, and they were the forerunner of what are now known as American Quarter Horses. Early races were generally match races between two horses running no more than a quarter of a mile. These sprint races were the earliest known examples of Quarter Horse (QH) racing in the United States. The first QH races were recorded in Enrico County, Virginia, in 1674.

Racing popularity grew as the breed grew, and racing spread west as pioneers and early settlers moved in that direction. Organized QH racing started in Tucson, Arizona, with the first track devoted to QH racing being Rillito Park, built in Tucson in 1943. Today QH racing is conducted at more than 100 racetracks throughout North America, with total purses reaching $53 million. The goal of many in this industry is to own, saddle, or ride the winner of the $2 million All American Futurity, run each year on Labor Day at Ruidoso Downs in New Mexico. The racing QH today is faster than ever, some having been clocked at speeds exceeding 50 mph, earning them the title America's Fastest Athlete.

Racing QHs traditionally are broken to ride as yearlings in the fall, and breaking commonly is not delayed beyond the year end, with the exception of delays from previous injury or illness. Training a racing QH is quicker than training a Thoroughbred (TB), and most race as early as 2-year- olds, and although some jurisdictions prohibit racing of 2-year-olds before a certain date (e.g., March 1 or actual second birthday of the horse), many regions commence racing early in the year. In general, QHs are raced younger than TBs.

Futurities are races for 2-year-olds for which a horse must be nominated, with regular payments. Scheduling of these races largely dictates the planning of races for 2-year-old QHs. Derbies are managed similarly for 3-year-old horses. Similar races also exist for older horses. Preliminary trial races usually are held to determine qualifiers for the final race, which is run about 2 weeks later.

Purses for futurities and derbies vary, but they are usually attractive and drive the racing QH industry. Owners strive to acquire horses that are talented enough to be competitive in these races.

TRAINING THE RACING QUARTER HORSE

Actual training methods vary widely, but the number of gallops and amount of work performed before the first race and subsequently between races is substantially less than for TBs. Many older racing QHs exercise daily on a mechanical walker and may have one or two easy gallops per week between races.

LAMENESS RELATED TO TRACK SURFACE

QHs race at many racetracks throughout the United States, with some racing conducted on track surfaces devoted primarily to QHs and other racing being conducted on track surfaces also used for TB racing. Some tracks conduct separate racing meets for TBs and QHs, whereas others conduct mixed race meets. Characteristics of track surfaces vary. In my experience, QH trainers prefer a firmer, faster surface than do TB trainers. Racetrack management often requests that maintenance crews produce a firm surface during QH race meets. Uniformity across the entire width of the racing surface is paramount.

Most racing QH trainers agree that deeper, more yielding surfaces result in more soft tissue injuries, such as suspensory desmitis and flexor tendonitis, and a higher incidence of hindlimb lameness and what is typically described as muscle soreness in the hindquarters and loin muscles. Harder surfaces are considered to produce more lameness attributed to bones and joints of the forelimb, and these reflect most of the lamenesses diagnosed in racing QHs.

CONFORMATION RELATING TO LAMENESS

Many successful racing QHs have obvious flaws in conformation, but good conformation is at least as important, if not more so, than in other breeds of racehorses. Racing QHs do not have the option of being shipped to Europe to race on grass courses, which is a common practice with TBs with less than desirable conformation.

Undesirable conformation flaws in forelimbs include calf knees, upright pasterns, and unusually small front feet, especially because of the hard racing surfaces. Excessively straight stifles and sickle-hocked or excessively cow-hocked conformations should be avoided. It is critical that horses break sharply from the starting gate, and horses with hindlimb pain for any reason are likely to fail to break competitively.

LAMENESS EXAMINATION

Examination of racing QHs is done largely in the same fashion as for other breeds of racehorses. Although not always entirely achievable at many racetracks, observing the horse at a trot on a hard surface is the most productive means of detecting lameness. Jogging the horse in a circle, in both directions, is useful for evaluating hindlimb pain.

Variations do exist in interpreting results of an examination. Normal TB racehorses often show some pain on fetlock flexion (lower limb flexion), but pain on fetlock flexion in a QH is of greater clinical significance. Many TBs exhibit positive responses to the Churchill test and to flexion of the hocks for 90 to 120 seconds. This may be viewed as normal, but in a racing QH this response is important.

If obvious lameness is noted at a trot in hand, the affected limb is evaluated for heat or swelling, and the character and intensity of digital pulses are assessed.

In a forelimb the fetlock and the carpus are flexed separately to detect pain, and comparison is made with the contralateral limb. Firm digital palpation of the lower limb is performed to detect pain, including deep palpation of the fetlock, suspensory ligaments (SLs), flexor tendons, and both carpal joints. Palpation of the dorsum of the third metacarpal bone (McIII) is routine, especially in 2-year-olds, to detect pain. With the forelimb pulled craniad, resting on the clinician's thigh, deep digital pressure is applied just proximal to the dorsal aspect of the coronary band, to detect pain caused by synovitis of the distal interphalangeal joint. Hoof tester examination is performed routinely on any horse observed to be lame, but results must be assessed with care, because many horses respond to pressure with hoof testers, especially those training and racing on firm surfaces. Horses with significant hoof pain usually have a prominent increase in the digital pulse amplitude. I look elsewhere if the digital pulse amplitude is not increased after exercise.

If no abnormalities are detected from the carpus down, the elbow is assessed by maximal forced flexion. This quick test yields a positive response in some but not all horses with elbow pain. I detect pain in the shoulder joint by picking up the lower limb and allowing the horse to relax with the carpus partially flexed, applying deep digital pressure in the depression between the cranial and caudal eminences of the greater tubercle of the humerus, and then comparing the response in the contralateral limb. Horses with pain in the shoulder joint often try to withdraw from this pressure.

For hindlimb lameness, palpation for heat and character of the digital pulse is done as for the forelimb. Fetlock flexion, hoof tester examination, and the Churchill test for pain in the distal joints of the tarsus are performed routinely. If pain in the tarsus is suspected, flexion of the limb for 90 to 120 seconds, followed by observing the horse at a trot often yields valuable information. I assess the stifle joint by holding the hindlimb partially flexed with one hand, and exerting deep pressure over the medial femorotibial joint with the thumb, followed by similar pressure over the lateral femorotibial and femoropatellar joints. In my experience, effusion usually is associated with femoropatellar joint pain, but that is not necessarily the case with femorotibial joint pain. The medial femorotibial joint most often is affected in the racing QH. Soreness in the loin and gluteal muscles occurs as in other racehorses, and palpation of these muscle groups is routine.

At times it is necessary to use perineural and or intra-articular analgesia to localize the source of pain causing lameness. Assessing the horse jogging under tack with a rider up can be helpful. Extended examinations at the racetrack are the exception rather than the rule, and horses with more difficult lameness are referred for further investigation.

THE TEN MOST COMMON LAMENESS CONDITIONS

The following are the 10 most commonly diagnosed lamenesses:

1. Bucked shins
2. Desmitis of the interosseous ligaments (splints)
3. Synovitis of the metacarpophalangeal and distal interphalangeal joints
4. Carpal synovitis
5. Distal hock joint pain
6. Stifle pain
7. Foot soreness
8. Osteochondral fractures of the carpus
9. Osteochondral fractures of the metacarpophalangeal joint
10. Osteochondrosis

IMAGING CONSIDERATIONS

Radiography is the most common imaging modality and is particularly invaluable for assessing carpal and fetlock lameness. The incidence of flexor tendonitis and suspensory desmitis is low, but diagnostic ultrasonography is useful in selected horses. I identify pain in the proximal SL in young horses in training that have just begun speed work. In most horses structural abnormalities cannot be detected with ultrasonography, and the problem resolves with 30 days of rest and slow resumption of training. Nuclear scintigraphy is used less than in TB racehorses because the incidence of stress fractures is considerably less.

SHOEING

The two most commonly observed errors in shoeing are the long toe, low, underrun heel configuration, and improper medial to lateral hoof balance. QHs do not race on turf. Many trainers break horses with flat plates, and later horses train in a level grip type of shoe, but by the time they begin racing, nearly all horses have toe grabs. Aluminum shoes are the norm. Full pads and rim pads are used commonly to try to avoid foot soreness.

In my opinion, training or racing a QH with chronic soreness anywhere in the limb inherently results in increased trauma to the carpus. Although many of the orthopedic conditions that create soreness (such as bucked shins and metacarpophalangeal or distal interphalangeal joint synovitis) cannot be avoided totally, many conditions of the foot can be avoided with careful attention to good shoeing.

DIAGNOSIS AND MANAGEMENT OF SPECIFIC LAMENESS

Although nothing is unique about the methodology in treating lameness in the racing QH, close attention must be paid to minor sources of pain. For horses to perform competitively, they need to be sound. QHs race at tremendous speeds for short distances and must break sharply and competitively to race successfully. One of the earliest indications of developing lameness is refusing to break from the starting gates properly.

Rules of racing in most jurisdictions make no distinction between breeds relative to permitted therapeutic medications, doses, and times of administration. The use of intra-articular medication is more prevalent in the day-to-day management of the racing QH than in other racehorses. The incidence of synovitis is high, and several joints often are treated simultaneously.

In my experience, lameness and soreness in the forelimbs are identified easily, but detecting subtle lameness in the hindlimb often is more challenging. Yet given the nature of the way these horses race and the tremendous speed required at the start of a race, hindlimb pain can be an insidious cause of poor performance.

Bucked Shins

Bucked shins are common, and they usually occur in 2-year-olds. In some horses clinical signs develop as speed work begins, before the first official race, but more often signs appear after racing, usually by the third official race. Occasionally, bucked shins occur later in a horse's racing career. Lameness varies in degree, and if severe, radiographic examination of McIII is recommended. Focal or widespread loss of bone opacity in the outer 50% of the dorsal cortex of McIII may occur with multiple parallel cortical stress fractures in more lame horses. Vertical fractures also occur; these appear as a vertical shear line between original cortical bone and newly developed bone. Stress fractures are common and are best managed if detected early.

Treatment of QHs with bucked shins varies. Managing horses with early bucked shins with continued but reduced training regimens has gained acceptance. With more severe signs, using counterirritants and mild blistering agents is popular. Other treatments include injections of corticosteroids (often diluted in saline or a local anesthetic solution), flooding the subcutaneous tissues over the dorsal aspect of McIII, thermocautery, and a percutaneous technique that produces vertical transection of the periosteum over the dorsal aspect of McIII using a 14-gauge needle (periosteal scratching). Periosteal scratching is used in horses with no radiographically apparent abnormalities that have experienced recurrent lameness, despite rest and a period of reduced training. The technique is performed in a standing horse, using appropriate sedation and local analgesia, flooding the dorsal metacarpal region with local anesthetic solution and 2 mg of dexamethasone. Lacerations in the periosteum from proximal McIII to the origin of the metacarpophalangeal joint capsule are created in three locations, dorsomedially, dorsally, and lateral to the common digital extensor tendon. This provides rapid relief from periosteal pain and in my experience allows a more rapid return to reduced training. The short-term relief of pain likely can be attributed to the corticosteroid used, but similar short-acting corticosteroids used in the past by simple subcutaneous injection did not give extended relief.

Full-thickness dorsal cortical stress fractures usually are detected after a race. Two-year-olds with acute injuries heal without surgical intervention if given immediate, sufficient rest for 90 to 120 days, followed by extended and slow return to full training. Follow-up radiographic examination is important, and if evidence of healing does not occur within 60 days, then surgical cortical fenestration with lag screw compression is recommended. If the fracture is unusually large or shows evidence of an exit line dorsally, surgery usually is recommended initially. Surgery also is recommended for horses with acute fractures if they are older than 2 years of age.

Exostoses of the Second and Fourth Metacarpal Bones

Exostoses of the second (McII) and fourth (McIV) metacarpal bones (splints) are common, and although they rarely produce profound lameness, they do cause acute discomfort. Exostoses usually involve the proximal 50% of McII. A firm bony swelling develops rapidly, with heat and pain on palpation. Swelling usually persists, although once the acute soreness dissipates, performance is unaffected. Distally located splints or those involving McIV are more troublesome. Radiography should be performed to eliminate the presence of a fracture.

Most horses respond to rest for 3 to 4 weeks. Treatment with counterirritant paints and mild blisters and therapeutic thermocautery is popular. If McII or McIV is fractured, surgical removal of the distal portion of the bone is necessary, and post-operative prognosis is excellent.

Acute Synovitis of the Metacarpophalangeal Joint

Acute synovitis of the metacarpophalangeal joint, characterized by heat, effusion, and pain on flexion, is fairly common in young QHs. Acute synovitis is distinguished from chronic fetlock disease (osteoarthritis) by the ability to reduce swelling in the joint to a clinically normal appearance by cessation of work, ice or cold therapy, non-steroidal anti-inflammatory drugs (NSAIDs), poultices, or a combination of these treatments. Usually no detectable radiographic abnormalities are apparent. The condition is usually bilateral and often is referred to as green osselets.

Although rest is desirable, racing schedules often create pressure on the trainer and veterinarian to manage these horses medically while the horse continues to train. Intra-articular therapy with hyaluronan, with or without corticosteroids, is common. The use of intravenously administered hyaluronan or intramuscularly administered polysulfated glycosaminoglycans (PSGAGs) is widespread.

Acute Synovitis of the Distal Interphalangeal Joint in the Forelimb

Acute synovitis of the distal interphalangeal joint in a forelimb is common, particularly when horses are training or racing on firm surfaces. The condition is usually bilateral, and affected horses move like horses with sore feet. Increased amplitude of digital pulses in both forelimbs often is detected, so a diagnosis of bruised soles often is made initially. Fetlock flexion often produces pain, but careful examination reveals that this pain is not originating in the metacarpophalangeal joint. Digital pressure just proximal to the dorsal aspect of the coronary band often elicits a painful response, and effusion may be detected by soft swelling in this area.

Radiographic examination usually reveals no abnormality, although enthesophyte formation on the extensor process of the distal phalanx often is seen in horses that have been racing with recurrent synovitis.

Treatment of this condition varies, with systemic NSAIDs; intra-articularly administered hyaluronan, with or without corticosteroids; intravenously administered hyaluronan; and intramuscularly administered PSGAGs all being used widely. Ice or cold therapy is routine, and most trainers tend to treat horses like those with bruised soles, using foot soaks and packing the bottom of the foot with various poultices or other medicaments. Prognosis is favorable.

Synovitis of the Carpus

Acute synovitis of the carpus is seen commonly and is often unilateral. Clinical signs may develop during training but more often develop after a horse commences racing. If the condition persists despite medical management, it often becomes bilateral.

The horse tends to travel wide with the forelimbs slightly abducted and somewhat stiff legged at the trot, especially on a hard surface. Localized heat and effusion are often present in both the antebrachiocarpal and middle carpal joints. Maximal flexion of the carpus sometimes elicits a painful response, but I rely more heavily on pain elicited by deep digital palpation with the joints flexed.

Medical therapy as described for synovitis of the metacarpophalangeal and distal interphalangeal joints is usually successful. In my experience, horses that are refractory to treatment or have recurrent clinical signs often develop osteoarthritis, and bone failure may result in osteochondral fragmentation (see later discussion). Extended rest always should be considered as a management option in horses with acute synovitis of the carpus.

Distal Hock Joint Pain

Pain in the centrodistal and tarsometatarsal joints is common and can have a profound effect on performance, resulting in failure to break sharply from the starting gates. The Churchill test and hock flexion test are useful diagnostic aids.

The condition is often bilateral, and affected horses often travel narrow behind, with the limbs adducted slightly. Many horses with painful hocks begin to interfere, striking the opposite limb from the pastern up to the tarsus. The condition may develop at any point during a horse's career and, if chronic, radiographic evidence of osteoarthritis is often apparent.

Treatment comprises intra-articularly administered hyaluronan or corticosteroids, with or without NSAIDs, intravenously administered hyaluronan, or intramuscularly administered PSGAG. In the absence of obvious radiographic evidence of osteoarthritis, most horses can be managed successfully, although repeated treatment often is required.

Stifle Pain

Lameness originating in the stifle is not uncommon and may cause signs similar to distal hock joint pain. In some horses performance is reduced without overt lameness. I find deep digital palpation of a partially flexed joint useful for identifying pain, but intra-articular analgesia is often required to confirm the source. The medial femorotibial joint is affected most often. In a young horse radiographic examination should be performed to rule out osteochondrosis; in older horses radiographic examination is useful to identify evidence of previous injury.

I prefer intra-articular treatment with hyaluronan and methylprednisolone acetate and consider that any horse showing pain on deep palpation should be treated. If lameness is more severe or a horse fails to respond to treatment, arthroscopic evaluation of the joint is indicated.

Foot Soreness

The incidence of sore feet varies from track to track, depending on the track surface, and is usually from bruising. Most trainers pack the soles with products such as ichthammol under a foot bandage and walk the horse for several days. If lameness persists, radiographic examination is warranted to determine the presence of pre-existing disease or a fracture of the distal phalanx. Solar margin fractures sometimes occur. A fracture of a palmar process of the distal phalanx usually causes a more severe, acute lameness. Subsolar abscesses are common, and routine extensive hydrotherapy resulting in soft soles may be a predisposing factor. Navicular disease occurs uncommonly.

Osteochondral Fractures of the Carpus

Chip fractures are common especially in the faster horses, particularly in 2-year-old horses that compete in futurities. Extent of injuries varies widely from microfractures of the subchondral bone to failure of bone integrity resulting in fragmentation. Major fractures, particularly of the third carpal bone, occur more commonly than in TB racehorses. Osteochondral fragmentation is usually bilateral and often involves the antebrachiocarpal and middle carpal joints.

The horse usually has a history of previous carpal pain, and the radiographic changes suggest accumulated trauma over time resulting in bone failure, emphasizing the need for careful management of acute carpal synovitis.

Arthroscopic surgery for removal of osteochondral fragments is common, particularly for more successful racehorses. Some good horses undergo arthroscopic surgery several times during a career. Lesser horses often are managed conservatively, with extensive intra-articular medication.

Osteochondral Fractures of the Metacarpophalangeal Joint

Fracture of the dorsomedial aspect of the proximal phalanx occurs most commonly; fracture of the dorsolateral aspect is less common. Fractures of the proximal sesamoid bones most commonly affect the medial sesamoid bone, but the incidence is less than in TBs. In my experience, condylar fractures of McIII do not occur. Subchondral bone trauma in the palmarodistal aspect of McIII is seen in older horses that have raced extensively.

Osteochondrosis

Osteochondrosis occurs in many joints in QHs and is usually clinically evident before a horse starts training. Osteochondrosis can be career limiting, but some horses are treated surgically and are suitable for racing. Mild lesions may not cause obvious lameness until a horse is racing, and some affected horses race successfully without apparent clinical problems.

Osteochondrosis of the stifle and hock usually is diagnosed before training begins. In my practice, osteochondrosis of the fetlock is the most common form in racing QHs. Osteochondral fragmentation involving the sagittal ridge of McIII or the third metatarsal bone is most common. Fragmentation of the proximopalmar (plantar) aspect of the proximal phalanx also occurs, especially in hindlimbs. Osseous cyst-like lesions occur occasionally in the distal aspect of McIII.

CHAPTER • 112

Lameness of the Arabian Racehorse

Mark C. Rick

HISTORY OF RACING

The Arabian racehorse originates directly from the Thoroughbred (TB) foundation sires of all light- or hot-blooded horses. In the seventeenth century, these TB sires—the Darley Arabian, Godolphin Barb, and Byerly Turk—were imported to England and bred to the Queen's mares. The Arabian was used originally as a war horse, and although the true beginnings of the Arabian horse are under a shroud of mystery and legend, the consensus is that the Middle Eastern desert Bedouin tribes played a large role in the breeding and early development of the breed.

Arabian racing in North America and around the globe is less popular, and the number of races is fewer and the amount of prize money is less compared with TB, Standardbred, and Quarter Horse racing. Throughout the Middle East and Europe, Arabian racing and performance are more deeply rooted than in North America. The popularity of Arabian racing has grown enormously in the United Kingdom in the last 15 to 20 years, with a growing number of professional trainers and jockeys and a progressive increase in prize money, in part because of the high Middle Eastern sponsorship.

The Arabian Horse Registry of America, founded in 1908, includes many types and uses. Known for stamina, speed, and elegance, Arabian horses often were bred and raised for showing in halter and performance classes. In the latter part of the twentieth century Arabian horse popularity and breeding selection shifted to criteria based more on aesthetics than athleticism.

The Arabian racehorse lineage reflects more athleticism than is found in Arabian show horses. Consistent winners often are more heavily muscled and have stronger hindquarters with a more sloping croup and a lower head and neck carriage than a typical Arabian show horse. Recent influx of new breeding lines has given rise to concern and controversy over the purity of the lineage and the possible infusion of impure Arabian blood. Certain new stallions appear to be much taller and longer, with a body type similar to the modern day TB racehorse. Constant vigilance and careful documentation of lineage is required to preserve the pure Arabian racehorse breed.

Arabian racehorses race on the same surfaces, dirt and turf, as TB racehorses. In North America selected meets are held from California to Delaware, Florida to Michigan, Colorado, Texas, and Washington and a few other tracks. Arabian racehorses perform in fair meets, allowance races, claiming races, and futurity nominated stakes races. Racing Arabian horses also compete in the United Kingdom, Poland, France, Russia, and South America and in many Middle Eastern countries. In North America, racing begins on March 1 of the 3-year-old year. Race distances are similar to those for TB races, but the length and configuration of the racecourses vary. Shorter sprint distances, 4½ to 6 furlongs, often are run on the small tracks, whereas the longest race (2 miles) is usually run on a large track. Typically, races are 4½ furlongs to 1¾ miles. A sound racehorse may compete as often as every 7 to 10 days, but most are given 2 weeks between races. Because relatively few Arabian racehorses are raced, lack of entries may mandate racing whenever enough horses are entered to meet race conditions rather than when trainers and owners prefer. Racing in the United Kingdom starts in late April. Until 2001, horses did not race until 4 years of age, but in 2001 a restricted number of races for horses 3 years of age were introduced. These are high-value races and also attract horses trained in France and other European countries. Races range from 5 furlongs to 3 miles.

TEN MOST COMMON RACING-RELATED LAMENESS CONDITIONS

The following are the 10 most common racing-related lameness conditions in the Arabian racehorse:

1. Dorsal third metacarpal bone (McIII) disease
2. Superficial digital flexor tendonitis
3. Suspensory desmitis
4. Stifle lameness
5. Tarsocrural osteochondrosis and distal hock joint pain
6. Back pain
7. Proximal sesamoid bone (PSB) fractures
8. Metacarpophalangeal joint lameness
9. Carpal osteochondral fragmentation
10. Lameness of the foot

Dorsal Third Metacarpal Bone Disease

Many racehorses trained intensely at speed at a young age experience the sore-shin or bucked-shin complex. Although intense training may not begin until the 3-year-old year and the Arabian racehorse is smaller in stature and weight than its TB counterpart, bucked shins remain a major cause of lameness requiring reduction in training intensity. Trainers are well aware of this problem and often can diagnose it accurately based on clinical findings and the observation of a sore horse, traveling short. A veterinarian usually confirms the diagnosis clinically, but in some horses radiography and occasionally scintigraphy are necessary. With advanced dorsal cortical pain. typical dorsal cortical periostitis or a dorsal cortical fracture is seen radiographically (see Chapter 104). With periostitis comes intense, diffuse increased radiopharmaceutical uptake (IRU), whereas focal IRU is seen in horses with a dorsal cortical fracture (see Chapter 19). However, scintigraphy is used more commonly to diagnose stress-related bone injury and stress fracture of other long bones in Arabian racehorses. Conservative management is preferred with rest, reduction in strenuous training, or return to the layup farm. Pin firing and blistering are not used routinely. Dorsal cortical fractures are rare, but if present, I prefer surgical management using osteostixis (dorsal cortical drilling) or insertion of a bone screw placed in lag fashion in the dorsal cortex. The prognosis is good.

Superficial Digital Flexor Tendonitis

Superficial digital flexor tendonitis (bowed tendon) is common and occurs from a combination of training overload and fatigue. Occasionally, horses run uphill at the end of a

race, and superficial digital flexor tendonitis occurs commonly under this condition. Sudden changes in track surfaces or training conditions are associated with an increased incidence of tendonitis. Severe tendonitis usually is recognized by the trainer, because swelling and pain are present during palpation. More subtle swelling and pain are detected during careful palpation by a veterinarian. Thorough ultrasonographic examination is imperative to confirm the diagnosis. Careful assessment requires proper patient preparation, sedation, clipping and cleaning the leg, and use of a high-quality ultrasound machine and a 7.5 (or greater) MHz linear transducer. Cross-sectional area (CSA) of the tendon and lesion, fiber alignment, and echogenicity of the lesion are evaluated, and any associated pathological conditions such as palmar annular ligament constriction, carpal tenosynovitis, or other soft tissue damage are assessed. Swelling is often mild if horses have been given local and systemic anti-inflammatory therapy and rest. A slight increase in CSA measurement may be the only indication of superficial digital flexor tendonitis, and comparison with the contralateral superficial digital flexor tendon (SDFT) is mandatory. Initial management includes rest, local ice and bandage application, and administration of systemic non-steroidal anti-inflammatory drugs (NSAIDs). Horses with mild or moderate superficial digital flexor tendonitis often are sent to a layup or rehabilitation farm for 3 to 6 months. Follow-up examinations are performed at 2-month intervals to determine quality of the healing and the appropriate time to return the horse to race training. A slow return to training includes progressive walking, jogging, cantering, speed work (breeze), and then racing. Time span and progression depend on maintaining an acceptable ultrasonographic appearance during each incremental increase in stress or exercise level. Tendon splitting and desmotomy of the accessory ligament of the SDFT used separately or concomitantly are successful in horses with with moderate or severe tendonitis. Intra-lesional injections of β-aminoproprionitrile fumarate (Bapten; no longer commercially available) have been used successfully. Prognosis varies with the severity of the injury and the stage of racing when the injury occurred. Because many Arabian horses race as older horses, even stallions and mares, providing up to a year or more of rest is not uncommon, assuming the lesion heals, before returning the horse to race training.

Suspensory Desmitis

Forelimb suspensory desmitis is an intermittent problem of many Arabian racehorses early in training. Suspensory desmitis is not considered to be as debilitating or career limiting as it is for TB racehorses. A trainer often complains that the horse is sore, but overt lameness is not present. The differential diagnosis includes bucked shins, superficial digital flexor tendonitis, and metacarpophalangeal joint and carpal lameness. Careful palpation reveals pain and enlargement of the suspensory ligament. Although ultrasonographic examination should be performed to confirm and grade desmitis, this pattern of subtle inflammation and soreness often precedes lesions detectable by ultrasonography. Scintigraphy may be useful but is seldom recommended. Suspensory desmitis is not severe, and most often the finding of body soreness in response to increased training intensity is the only apparent clinical sign. Traumatic disruption of the suspensory apparatus is rare. Horses with suspensory desmitis usually are kept at the track because they do not require or benefit from extensive time off. I recommend 1 to 2 weeks of rest or simply a decrease in training intensity to allow for tissue adaptation. The prognosis for horses with early suspensory desmitis is good if the condition is recognized early and horses are given a period of much reduced work intensity and slow rehabilitation.

Stifle Lameness

The most common source of hindlimb soreness is the stifle region. Early in training a horse may become sore and stiff, usually bilaterally. Intermittent upward fixation of the patella is common as in other young sport horses. Stifle soreness is common in young horses shod with flat shoes and training on a soft track. Soft tissues around the stifle become inflamed. Clinical signs include a shortened stride and an unwillingness to extend the stride behind, or actual upward fixation of the patella, with characteristic stifle and hock extension and toe drag. With early detection, horses with stifle region lameness are assumed to have a soft tissue problem and are treated with decreased training and NSAIDs. Occasionally, an internal blister is injected around the patellar ligaments, especially if evidence of upward fixation of the patella exists. If effusion of the femoropatellar joint accompanies the upward fixation of the patella, radiographs should be obtained. Results are usually negative, but some horses have underlying osteochondritis dissecans of the lateral trochlear ridge of the femur. Surgical debridement is recommended, especially if a flap-like lesion exists. Osteochondritic lesions usually are detected early in race training if they are clinically important. Rarely, subchondral bone cysts of the medial femoral condyle are seen. Horses with subchondral bone cysts are treated by rest, injection with corticosteroids, or surgery. If radiographs reveal evidence of osteoarthritis, such as enlargement of the medial tibial plateau, or if ultrasonographic examination reveals flattening, wrinkling, or other change of the medial meniscus, then the prognosis for racing is diminished. If discovered early in training, horses with osteochondrosis and subchondral bone cysts are best managed with arthroscopic surgery. The prognosis for a horse with a sore stifle, ligament laxity, and intermittent upward fixation of the patella is good, assuming a favorable response to alterations in training regimen. Lameness in Arabian racehorses with sore stifles appears similar to that seen in young TBs with tibial stress fractures, but the origin of pain is different. The prognosis for horses with osteochondrosis varies but is poorer if evidence of osteoarthritis exists.

Tarsocrural Osteochondrosis and Distal Hock Joint Pain

Tarsocrural osteochondrosis is an occasional cause of hindlimb lameness. If bog spavin is recognized when the horse is a weanling or yearling, arthroscopic surgical removal of osteochondritic fragments usually is performed then. However, horses may arrive at the racetrack or training stable with mild tarsocrural effusion. If lameness is observed, if a horse has a positive response to upper limb flexion, or if moderate effusion is persistent, then radiographs should be obtained. If osteochondritic fragments are found, I recommend arthroscopic surgery and a short (2- to 3-month) period of rest before training resumes.

Distal hock joint pain occurs in the Arabian racehorse and is seen most commonly after changes in track surfaces. These horses often do not push off or propel themselves well behind, may refuse to grab the bit or bow the neck, and use the front end to pull ahead, a gait that may lead to secondary forelimb lameness. Clinical signs often are lacking, and an upper limb flexion test may be only mildly positive. Radiographs are often negative, but scintigraphic examination reveals IRU in the distal hock bones.

Back Pain

Primary hindlimb lameness causes secondary back pain in most Arabian horses, particularly those with primary lameness of the stifle and hock joints. Often back pain resolves after management of the primary hindlimb lameness. However, treatment of back pain concomitantly allows earlier resolution of both problems. Exercise riders or jockeys may suspect back pain and

often report a sensitivity or soreness over the top line. Horses usually show pain on palpation or when pressure is applied along the back. The back is palpated carefully, and pressure should be applied uniformly and gently. Thermography has been of some value in horses with back pain resulting from a poorly fitting saddle. The saddle can be evaluated thermographically and compared with any warm spots on the horse's back. Nuclear scintigraphy may reveal IRU in the summits of the dorsal spinous processes. Radiographic examination may confirm overriding of the dorsal spinous processes. However, radiography and scintigraphy are often negative, and back pain is assumed to originate from soft tissues. Nonetheless, if back pain is severe, I suspect a bony source of pain. The back can be evaluated by ultrasonography, dorsally or rectally, for myositis, nerve root impingement or enlargement, and osteophytes associated with the vertebral articulations.

Proximal Sesamoid Bone Fractures

PSB fractures do occur in Arabian racehorses but are less common than in TBs. Clinical signs, management, and prognosis are similar to the TB racehorse (see Chapter 37). Other fractures, such as mid-sagittal fractures of the proximal phalanx and condylar fractures of the distal aspect of McIII, are rare in North America. However, in the Middle East both medial and lateral condylar fractures of McIII occur.

Metacarpophalangeal Joint Lameness and Carpal Osteochondral Fragmentation

Osteochondral fragmentation or chip fractures of the carpal and metacarpophalangeal joints occur in Arabian racehorses but less frequently than in TBs and Quarter Horses. Smaller body size, a more gradual training regimen, and racing older horses likely account for the difference in incidence. Early signs of arthrosis without chip fracture resolve quickly, with minor interruption in race training. The diagnosis of fetlock or carpal osteochondral fragments is straightforward. Arthroscopic surgery to remove osteochondral fragments is well accepted and successful. The prognosis depends on location, size, duration, previous treatment, and amount of associated cartilage damage. Horses with acute osteochondral fragments with only mild cartilage damage have a good prognosis. The decision for surgery often is based on economic factors.

Proliferative synovitis (villonodular synovitis) and associated fragmentation of the dorsal, proximal aspect of the proximal phalanx occurs in the young Arabian racehorse. Horses have characteristic signs of effusion and a noticeable dorsal swelling. Dorsal swelling can be insidious and go unrecognized early in the disease process. Plain radiographs often reveal soft tissue swelling on the dorsal, distal aspect of McIII and osteochondral fragments of the proximal phalanx. Radiolucent changes of McIII are seen in horses with severe proliferation. Ultrasonographic examination usually reveals enlargement of the dorsal synovial pad. I recommend arthroscopic evaluation, removal of osteochondral fragments, and debridement of the synovial pad with a 5.2- or 3.4-mm suction punch (Dyonics; Andover, MA).

In older Arabian racehorses, chronic osteoarthritis of the metacarpophalangeal joint is recognized. The trainer complains of poor performance or racing below previous levels. The metacarpophalangeal joint is enlarged from effusion or fibrosis and is warm. Horses usually respond positively to lower limb or fetlock flexion tests. Comprehensive radiographic examination should be performed. Radiographic evidence of osteoarthritis, such as marginal osteophytes of the PSBs and joint space narrowing, enthesophytes at capsular attachments, and soft tissue thickening often are seen. Osteoarthritis of the metacarpophalangeal joint is seen frequently without osteochondral fragments and appears to be related to chronic wear and tear. In some horses osteoarthritis can be managed by judicious use of intra-articular medication, but the prognosis for return to previous performance levels is guarded.

Lameness of the Foot

Although Arabian horses are alleged to have solid foot structure, they do get sore feet. Long-toe, low-heel conformation is not common. Arabian horses are protected from some of the lameness conditions of the feet simply because of small body size and weight. Sore feet develop after a fast workout or race on a hard, packed racetrack. Trainers often recognize signs, and the condition is managed using ice baths, NSAIDs, and 3 to 4 days of rest.

PROCEEDING WITHOUT A DIAGNOSIS

Occasionally, lameness is suspected but cannot be pinpointed. Horses with such lameness are characterized by a drop in performance, increase in race times, a subtle gait change, refusing to switch leads, a drop in class, or acting sore, but no clinical signs are observable. In this situation, I usually recommend a whole body scintigraphic examination, but correlating findings with clinical signs is often difficult. Comprehensive evaluation for poor performance considers not only a musculoskeletal problem but also cardiovascular and muscle abnormalities. Arabian horses may be more fragile and highly strung than other racehorses, and some trainers attribute poor performance to this portion of the horse's personality. Under certain circumstances the Arabian racehorse may not endure hard training or racing.

CHAPTER • 113

National Hunt Racehorse, Point to Point Horse, and Timber Racing Horse

Sue J. Dyson, Rob van Pelt, Kevin Keane, Alastair Nelson, James Wood, and Anthony Stirk

DESCRIPTION OF THE SPORT

For as long as horses have been domesticated and ridden, they have been raced. The oldest record of racing in Britain shows that the Romans used to race their horses in Chester. Subsequently, little is known about any organized horse racing during the Middle Ages, but by about 1150 racing had become established at Smithfield, a horse market, where horses were tried and sometimes raced before sale. By the early part of the sixteenth century, racing had returned to Chester, where the prize for the winner in 1511 was a silver bell.

All of these races were on turf with no obstacles to negotiate. At about the same time that horses were competing for the Chester bell, fox hunting (rather than hunting deer or wild boar) started to become established and rapidly increased in popularity. One reason for this may have been the changing agricultural landscape as more and more land was enclosed, providing natural obstacles for those following the hunt to jump. Inevitably, rivalry developed between those who regularly followed fox hunts across country as to who had the fastest horse, and a new sport was born, known as steeplechasing. The origin of the name is simple. Because no courses were defined over which the races could take place, the participants had to race from one church to another, using the high church steeple toward which they were heading as a landmark. The riders could choose their own route and had to jump a variety of fences such as hedges, banks, walls, timber fences, and brooks during the course of the race. The first steeplechase of this type was held in Buttevant in Ireland in 1752, when two neighbors raced between Buttevant church and the St. Leger church, a distance of 4½ miles (7.2 km).

After a time this new sport was formalized, with specially constructed courses, which allowed more participants to take part and more spectators to watch. The first such organized race meeting in Britain was held at St. Albans in 1830. The Grand National was first staged in 1839, the National Hunt Steeplechase followed at Market Harborough in 1859, and the first meeting at Cheltenham (Prestbury Park), arguably the best known modern jump racing venue, was in 1898.

As the sport developed, regulating it became important, but the Jockey Club, which had been regulating flat racing since the mid-eighteenth century, regarded the new sport with suspicion. Accordingly, a separate National Hunt Committee was established in 1866 and continued to run jump racing until 1969, when it and the Jockey Club merged to bring all racing, on the flat and over jumps, in Britain under one governing body. The National Steeplechase Association oversees racing over fences in the United States.

Modern National Hunt racing now consists of several categories, all run on turf on clockwise and counterclockwise courses. Horses run under similar rules in the United Kingdom, Ireland, and France. Elsewhere in Europe, racing over fences takes place but on a much lower scale. Most races are hurdle races or steeplechases, but some races run over more natural obstacles remain, some over exclusively timber fences and some, called National Hunt flat races, that are run without obstacles.

Apart from the fences, three major differences exist between National Hunt and flat racing, which are important in the epidemiology of the injuries that may occur in the different sports. These differences are the race distance, the age of the horses, and the weights of the riders. All National Hunt races are more than a minimum of 2 miles (3.2 km) compared with the minimum distance of 5 furlongs (1 km) on the flat, and the horses are at least 3 years old. Forty percent of National Hunt Flat races involve horses of 4 years of age, a slightly higher percentage are 5 years of age, and less than 20% are 6 years of age or older. Most horses competing in flat races are 2 or 3 years old, although for horses over the age of 10 to race in National Hunt races is not unusual, especially in steeplechases. Finally, National Hunt horses carry between 133 and 175 lb (60 to 79 kg), considerably more weight than flat horses.

Hurdle races are held over fences smaller than those encountered in steeplechasing. In Britain, most hurdles are based on the simple portable fences used to create temporary pens for sheep. They are usually 72 inches (1.83 m) wide and must be not less than 42 inches (107 cm) from top to bottom bar and constructed of ash or occasionally oak. Several hurdle sections are placed end to end to produce an obstacle that must be at least 30 feet (9 m) wide. Each hurdle section consists of two uprights with pointed legs that are driven into the ground and five horizontal rails, between which is interwoven birch or another suitable material. Gorse, which is durable but has sharp thorns, is not permitted. The hurdles must be driven into the ground at an angle of 62° so that the top bar is set back 20 inches (51 cm) from the vertical, and the effective height of the hurdle is 37 inches (94 cm). All of the exposed timber parts must be padded with a minimum of ½ inch (1.3 cm) of high-density polyethylene or closed cell foam rubber (Fig. 113-1).

Timber hurdles have the advantage that if a horse misjudges the fence and does not jump it cleanly, the hurdle gives way on impact. Old style hurdles were not padded as well as the modern versions and occasionally led to lacerations on the dorsal aspects of the hindlimbs, which could be extensive with degloving injuries of much of the metatarsal region. These injuries have been virtually abolished by the new padding.

In countries other than Britain and Ireland, timber hurdles are replaced by fences that look like small versions of steeplechase fences. Such fences also are seen on a small number of racecourses in Britain, and proponents of these types of fences argue that they provide a better introduction to racing over obstacles for horses that ultimately are intended to be steeplechasers. This may be true, but only 35% of horses that run over hurdles convert to steeplechasing, indicating that hurdle

Fig. 113-1 A hurdle race. The jump of the leading horse, which has almost run through the hurdle, is awkward, the hindlimbs are positioned asymmetrically, and the horse's back is hollow.

racing has become a specialty sport that draws many of its participants from horses that have raced previously on the flat.

Steeplechases are run from 2 to 4½ miles (3 to 7 km) over fences which, with the exception of those at Aintree over which the Grand National is held, have a standard construction. The course must have at least six fences per mile, one of which must be an open ditch, with the other plain fences. The plain fences must be a minimum of 54 inches high (1.37 m) and constructed of birch, or birch and spruce, in a frame. The use of gorse is not permitted. The base of the fence must be 72 inches (1.83 m) from front to back, with the thickness of the fence at its top not less than 18 inches (46 cm) (Fig. 113-2, *A*). Plain fences usually have a guard rail on the face of the fence that usually is padded with the same material as the hurdles. An open ditch has similar overall dimensions, but the ditch in front of the fence, which may or may not be dug out, must be at least 72 inches (183 cm) from front to back and be delineated by a takeoff board that is up to 24 inches high (146 cm). Designers of racecourses also, if they wish, may include a water jump in steeplechases. These consist of a smaller fence, up to 36 inches (91 cm) high with a 108-inch (2.74-m) wide water ditch, that must be 3 inches (7.6 cm) deep, on the landing side of the fence.

Point to point races (Fig. 113-2, *B*), named because originally they were run from one point to another, represent the amateur branch of steeplechasing and are restricted to horses that have qualified to race by hunting with a registered pack of hounds. Races for such horses also take place on licensed racecourses and are known as Hunters' Steeplechases.

Some races, notably in France, at Punchestown in Ireland, and at Cheltenham in Britain, are run over more natural obstacles, including banks and growing hedges. Timber races are held over upright (United States) or sloping (Britain) post and rail fences (Fig. 113-3). To make the obstacles less dangerous, the top rails may be sawn through so that they will knock down if they are hit hard.

Finally, National Hunt flat races are staged for horses that have not run previously on the flat and are at least 4 years old. The races are intended to teach horses to acclimatize to the environment of a racecourse and the rigors of a race, without the additional hazard of obstacles. They also provide a way of demonstrating a horse's ability, so that it can be sold. Colloquially, National Hunt flat races are known as bumpers, because originally they were restricted to amateur riders, and the combination of inexperienced riders and horses led to their pejorative nickname.

NATIONAL HUNT HORSES

British and Irish National Hunt horses may be Thoroughbreds, which are registered in the General Stud Book, or non-Thoroughbreds that are in the Non-Thoroughbred register. Many top-quality French jumping horses are of the Selle Français breed. Horses are started in jump racing by one of two routes. They are raced on the flat at 2 or 3 years of age before moving on to hurdling and possibly to steeplechasing, or they are bred specifically for National Hunt racing. Red Rum, who won the Grand National on three occasions, is an example of a horse that started racing in flat races as a 2-year-old. In general, however, horses that graduate from the flat tend to be restricted to hurdle races, and this is why only 35% of horses that race over hurdles go on to race in steeplechases.

Steeplechasers, however, tend to be bred for that particular type of racing and are usually bigger framed Thoroughbreds compared with flat racehorses. Breeding steeplechasers is less straightforward than breeding for flat races, because most steeplechasers are geldings, meaning that it is unlikely that males can be chosen based on racecourse performance. Finding performance-tested mares also is difficult, because the average age of steeplechasers is the oldest of all racing categories, and by the time a mare has proved her ability, she may be past her breeding prime. Therefore most stallions that are popular as sires of steeplechasers are horses that have shown stamina on the flat and then prove to sire successful progeny. Many mares

Fig. 113-2 **A,** A steeplechase race in France. **B,** A Point to Point race. The fences are smaller than in steeplechase races, and the amateur jockeys tend to be less well positioned.

that are used to breed steeplechasers are chosen because of pedigree rather than performance.

Once foaled, many horses destined for steeplechasing are left unbroken until 3 or 4 years of age, when they are often sold as National Hunt stores intended to start a racing career at 4 or 5 years of age. This traditional system has been used for many years and could be said to have stood the test of time. However, recent preliminary research suggests that horses benefit from an early introduction to regular exercise and from early racecourse experience, and this may reduce the risks of injury.

TRAINING NATIONAL HUNT HORSES

At its simplest, training involves conditioning the cardiovascular, respiratory, and musculoskeletal systems of horses to tolerate maximal exercise. The skill of the trainer is to exert the horse sufficiently to achieve this while avoiding physical injury and without inducing an aversion to hard work. Human athletes, being motivated to succeed, tolerate extreme discomfort during training to achieve their goals. Horses have to be encouraged to exercise and never to anticipate that the result of exercise will be discomfort or pain.

Horses that move to National Hunt racing from flat racing receive the basic conditioning as yearlings and young 2-year-olds. Store horses (horses bred specifically for National Hunt racing), however, may do little regular exercise until they are virtually skeletally mature at 4 years. Because they are older, thinking that they require less time to adapt to exercise is tempting, whereas the reverse may be true. It is therefore essential that early preparation is graduated gently and that early signs of failure to adapt, such as sore shins or joint effu-

Fig. 113-3 A timber race. The horse is jumping well, and the rider is in good balance.

sions, are noted and training intensity adjusted. If clinical signs go unrecognized or ignored, more serious skeletal defects may develop, such as stress fractures of the tibia, humerus, or pelvis, which may precede catastrophic fractures on the gallops or racecourse. Traditionally, store horses spent at least 6 weeks walking and trotting on quiet roads and tracks before they commenced any faster work. This initial slow preparation has now been abandoned by many trainers, partly because of the difficulty of finding a suitable safe, quiet environment and partly because of the economic pressure to see the horse on the racecourse.

Most trainers of National Hunt horses now use a simple adaptation of interval training over distances of about 1000 m, almost invariably up an incline that may be steep. An average morning workout would be an initial slow warm-up, followed by two brisk canters up the incline on an easy morning, alternating with three faster ascents on a work morning.

One of the most important aspects of training National Hunt horses is teaching them to jump appropriately. Hurdle races are conducted at a fast pace, and some trainers believe that horses that jump the obstacles without touching them and with the same action as a show jumper, use energy unnecessarily and concede ground to rivals who jump low and flat. This is possible because the timber hurdles give way if the horse hits them, although the ease with which they do this depends on the ground into which the legs of the hurdles are driven. Once horses have acquired this style of jumping, some trainers argue that the horse finds it difficult to jump the larger, more solid, steeplechase fences. This accounts for the relatively low number of horses that make the transition from hurdling to steeplechasing and the demand in Britain by some trainers for a brush hurdle that, although relatively small, has to be jumped with care. Specialist steeplechasers are encouraged to jump much as horses intended for other disciplines that involve jumping, and they jump low poles and logs, with and without a rider, before progressing to larger obstacles. However, the amount of training carried out over fences by steeplechasers is proportionately much less in the United Kingdom and Ireland than for event horses or show jumpers.

RACING NATIONAL HUNT HORSES

Jump racing developed as a winter sport, probably originally because of the connection with fox hunting, which also is conducted during the winter months. However, jump racing is now held in Britain throughout the year, although those courses that hold summer jump meetings are required to ensure by artificial irrigation that the ground conditions are kept no worse than good to firm. This is because epidemiological studies have shown that firm ground conditions are more likely to be associated with serious injuries. The reason for such a relationship is complex. It is probably related to the speed at which the horses travel, but other complex factors influence the interaction of the horse's foot with the ground under various conditions, some of which are related to ground hardness, and these require further research and elucidation. Jump racing remains seasonal, however, because the major races take place between November and March, and many horses spend a few weeks turned out during the summer. Seasonal racing influences injury management, because if a horse sustains a significant injury in, for example, late February, the owner or trainer applies pressure for the horse to be ready for the next season, that is, to resume training by October of the same year.

Horses are trained by individual trainers spread throughout the United Kingdom, Ireland, and France who may travel long distances to compete. Therefore any single veterinary surgeon usually does not deal with more than 4 or 5 trainers and their horses. At race meetings the horses are subjected to pre-race veterinary inspections, and each race is monitored carefully by veterinary surgeons driving on the outside of the track alongside the race and a veterinarian observing the entire race from an appropriate vantage point.

Point to point races are held between January and June. Point to point racing is an amateur sport, raced over obstacles that are smaller and softer versions of the steeplechase fences on licensed racecourses. Some horses that perform well in Point to Points successfully graduate to steeplechasing, and this route to steeplechasing is chosen by some owners in preference to hurdle racing, possibly after one or more National

Fig. 113-4 A faller at a Point to Point race. Note the extreme position of the hindlimbs.

Hunt flat races. While National Hunt horses run on average between four and five times per year, Point to Point horses may run more frequently during the season, because the race meetings are usually held at weekends. However, the average number of starts per Point to Point horse in 2000 was only three.

Because of the two distinct sources of horses that enter National Hunt racing, a wide variety of injuries are seen, ranging from injuries related to beginning training to degenerative injuries associated with overuse. In addition to the injuries sustained while the horse is in training, a National Hunt horse is more prone to injury after a fall than is a flat racehorse (Fig. 113-4). It is also important to be aware that horses that are skeletally mature when they begin training (4- to 5-year-old store horses) still suffer from the same pathophysiological processes that lead to stress fractures, albeit in different sites from the 2- or 3-year-old Thoroughbred. Because National Hunt racing continues throughout the year, the going under foot (footing) can vary and both extremes of soft and firm going place the National Hunt horse under extra stress from injury.

A substantially higher death rate occurs in National Hunt racing compared with flat racing. In a retrospective analysis of data from all starts between January 1990 and December 1999, 2015 deaths were recorded on racecourses from 719,099 starts.[1] The death rate per 1000 starts was substantially higher in steeplechasers (6.7; 34.5% of the total) and hurdlers (4.0; 43.4% of the total) compared with flat racehorses (0.9; 18.8% of the total). Spinal injuries occur much more frequently in hurdlers (19% of all hurdle deaths) and steeplechasers (23% of steeplechase deaths) compared with flat racehorses (1% of flat racehorse deaths). Tendon breakdown injuries resulting in humane destruction at the racecourse were also substantially higher in hurdlers (20% of hurdler deaths) and steeplechasers (14% of all steeplechase deaths) compared with flat racehorses (8% of flat racehorse deaths). Risk of mortality was associated with a number of variables. With steeplechase horses a higher risk occurred in horses that started steeplechase racing at 8 years of age or older. The weight carried was also influential, with horses carrying more than 70 kg minimum weight being more at risk. Races longer than 4 miles had a higher risk than shorter races. Heavy going, resulting generally in slower speeds, reduced the risk. Good to firm or hard going increased the risk of mortality in hurdlers and steeplechasers.

TIMBER RACING

Timber racing is considerably more popular in the United States than in the United Kingdom and is more structured. Novice or stakes horses compete only against each other, with greater prize money for stakes races, the most valuable being the Maryland Hunt Cup. The most prestigious race in United Kingdom is the Marlborough Hunt Cup. Both of these races are open only to amateur jockeys. Timber racing horses often have raced previously on the flat or over hurdles, are usually 6 to 12 years of age, and may have injuries from earlier racing.

TRACK SURFACE OR TRAINING SURFACE AND LAMENESS

The surfaces and terrain over which horses train vary extremely because the trainers are dispersed widely geographically. Much of the work is done on grass, but fast work often is done on all-weather purpose built gallops. Many horses hack up to a mile to and from the gallops, ensuring good warm-up and warm-down. However, the standard of maintenance of the gallops varies. Poor gallops with an inconsistent surface varying from soft to deep may increase the risk of tendon injuries or predispose horses to stumbling and accidents such as third carpal bone fractures. Many trainers are based in areas of chalk downland (natural rolling hills with a chalk subsoil), which drains well, but the large number of flints (sharp stones) in the soil may result in a high incidence of bruised soles or sole punctures unless the horses have well-conformed feet. The steepness of the terrain over which the horses do fast work may influence injury. An increased number of pelvic fractures was noted after a new gallop was laid, the last section of which was up a steep incline (R.v.P.).

Fig. 113-5 Horse No. 12 is about to be brought down by a fallen horse and jockey.

The influence of falls on the nature of injuries is substantial. Most falls occur on landing over a fence. Falls may result from the horse or jockey making a jumping error, from interference by another horse still in the race, or from a loose horse that had previously unseated its rider. The fall of one horse may result in the fall of one or more other horses (Fig. 113-5). Thus injuries may result from the fall and impact with other horses. Falls may result in fatal fractures of the cervical or thoracolumbar vertebrae. Rib fractures usually result from a fall and may cause severe lameness and or respiratory signs. Other fractures seen commonly, usually resulting from a fall, include scapular, radial, and humeral fractures; fractures of the accessory carpal bone; and fractures of the lateral malleolus of the tibia. Major muscle ruptures, especially in the hindlimbs (e.g., semimembranosus, quadriceps, or adductor) also usually result from a fall. Rupture of fibularis tertius may occur if the horse falls with forced hyperextension of the hock.

A significant statistical correlation exists between certain factors and the incidence of injury on racetracks:

- Increased firmness of the going results in an increased injury rate in all forms of National Hunt racing.
- Increased incidence of injury on firm ground is further increased by increasing the length of the race.
- In hurdle races run over more than 2½ miles with only a few obstacles (6 to 8), the casualty rate increases compared with the same distance with nine or more fences.
- Races ridden by amateur riders carry a higher risk of serious injuries.

Flexor tendon lacerations frequently are sustained as horses race over fences and generally occur on the palmar aspect of the metacarpal region, proximal to the proximal sesamoid bones (PSBs). It is important to recognize that the site of a skin laceration may not coincide with the site of a tendon laceration.

Some important injuries occur more commonly during racing than training. Luxation of the superficial digital flexor tendon (SDFT) from the tuber calcanei sometimes occurs. Rupture of the musculotendonous junction of the superficial digital flexor muscle is an unusual injury, but is an important injury in steeplechasers. Superficial digital flexor tendonitis is common in National Hunt horses, and recurrent injuries may result in complete rupture of the tendon.

CONFORMATION AND LAMENESS

With an increasing proportion of National Hunt horses starting training earlier, and running first on the flat at 3 years of age and then over hurdles at 4 years of age, the trend has been toward using smaller, lighter-framed horses. Although such horses are not necessarily more prone to injury, they seem less able to cope with deep, holding going often encountered in the winter months compared with the more traditionally bred rangy National Hunt store horses, which are often rather late maturing.

For a National Hunt steeplechaser or hurdler to race until 10 years of age is not uncommon, so the racing career is considerably longer than for a European flat racehorse. Horses should be well balanced and proportioned, with good feet and adequate bone for body size and weight. Horses with back-at-the-knee conformation, carpus valgus, offset knees, or substantial toed-in or toed-out conformation particularly maybe predisposed to forelimb problems. A long back may be associated with an increased risk of back problems. A horse with straight hocks or long, sloping hind pasterns may have an increased risk of hindlimb lameness.

THE TEN MOST COMMON CAUSES OF LAMENESS

The following are the 10 most common lameness conditions of hurdlers, steeplechasers, and Point to Point horses:

1. SDFT injuries
2. Suspensory ligament (SL) injuries
3. Lameness associated with the carpus
4. Lameness localized to the hocks
5. Lameness associated with the pelvis

6. Lameness localized to the feet
7. Fractures of the third metacarpal (McIII) and third metatarsal (MtIII) bones
8. Lameness localized to the metacarpophalangeal joints
9. Traumatic injuries, particularly of the back and neck, after falls
10. Back problems

The following are the 10 most common lameness conditions of timber racing horses:

1. Superficial digital flexor tendonitis
2. SL desmitis
3. Osteoarthritis of the distal hock joints
4. Distal sesamoidean desmitis
5. Osteoarthritis of the metacarpophalangeal joint
6. Soft tissue trauma of the stifle
7. Interference injuries during racing
8. Timber shins
9. Fracture of the patella
10. Fracture of the accessory carpal bone

LAMENESS EXAMINATION

Diagnosis of lameness starts with a full history, which should include stage of training, because, for example, a 6-year-old store horse starting training is as susceptible to stress fractures as an immature athlete. The clinician should establish whether the horse has run recently. Is the lameness of recent onset, or is it a chronic problem that has been getting progressively worse? Some trainers request advice as soon as lameness is recognized, whereas others may restrict the horse to light work and seek veterinary advice only if lameness persists. Some trainers treat a lame horse with phenylbutazone. Many trainers are happy for horses to come out rather short, shuffly, and stiff and warm up to move more freely; however, inevitably more overt lameness usually supervenes or a back problem develops secondarily.

It is important to determine if the horse has had any time off recently with the present trainer or a previous trainer that may suggest a previous injury. There may be a history of warmth associated with the palmar metacarpal region which, if the horse has been subsequently rested, may not be obvious on clinical examination. Does the horse have any history of trauma? Jumping history is also important: did the injury occur while the horse was schooling over fences or in a race? Did the horse fall or collide with another horse (Fig. 113-6)? Does the lameness improve with rest or with work?

If the horse had a history of a fall, it is important to establish how the horse fell. Did the horse turn a full somersault and land on its pelvis and develop lameness thereafter? A pelvic injury should be suspected. Did the horse fall at the end of a 3-mile race on heavy going and lay winded? Information from the racecourse veterinarian may be particularly useful.

If a horse has a history of poor jumping performance, trying to establish if the horse has ever been a good jumper over hurdles or fences is worthwhile. Many of these horses are lame. The veterinarian needs to find out how the horse is jumping. Does the horse stand off the fences or jump flat? If a horse does not want to take off, it may have a hindlimb problem. If the horse jumps flat, it may have a back problem. If the horse is reluctant to land, it may have a forelimb problem.

If a horse is presented for evaluation for poor performance, it is important to try to assess the orthopedic component. About 50% of horses with a complaint of poor performance are lame. When did the horse last race and over what ground conditions? Did the jockey make any comments when he dismounted? Has the horse coughed? Is rectal temperature routinely monitored? Routine hematological examination and measurement of fibrinogen, comparing results with a baseline for that horse, are useful for detecting systemic abnormalities. Endoscopic examination of the upper airways and trachea, combined with a tracheal wash, are useful screening tools to eliminate a respiratory component to the problem.

Fig. 113-6 A fall at The Chair at the Grand National. The horse pitches steeply and lands on its neck.

The clinical examination does not differ from a routine lameness evaluation of any other type of horse, but because many horses have chronic problems with which they have been living until more obvious lameness supervened, the entire horse should be assessed, not just the postulated lame limb. In view of the high incidence of superficial digital flexor tendonitis and suspensory desmitis, particular attention should be paid to the palmar metacarpal soft tissues. If the horse has a history of a fall while jumping, particular attention should be paid to the neck, back, and pelvic regions.

A thorough clinical examination may reveal palpable abnormalities in the palmar metacarpal region, evidence of effusion, or pain on flexion of a particular joint. Skeletal pelvic asymmetry or muscle wastage over the quarters also may be evident. Back and pelvic reflexes and the tone of the back and pelvic muscles should be assessed. Is any evidence of guarding apparent? Abnormal shoe wear may give clues about which limb or limbs are lame, which is otherwise not always easy to determine in a horse moving short because of pain in several limbs.

Dynamic examination at the walk and trot in a straight line, followed by flexion tests, should be followed by examination on firm and soft going on the lunge at the trot and canter. The horse should be turned tightly to the left and to the right. If a history of a fall exists, a complete neurological examination should be performed.

If a horse is lame after a recent fall, the investigative approach depends on the degree of lameness and the rate of improvement. A horse with a pelvic injury is usually very lame initially, although lameness associated with an ilial wing fracture usually improves substantially within 24 hours. Lameness associated with an ilial shaft fracture is usually persistent, and the horse remains extremely lame. These horses should be cross-tied, assuming the horse's temperament is suitable. Some ilial wing fractures can be detected with ultrasonography, but the diagnosis of others requires nuclear scintigraphy. Nuclear scintigraphy may give false-negative results if done before 5 to 7 days after injury. If a horse shows only mild to moderate lameness after a recent fall, the horse generally is allowed rest for 7 to 10 days and is then re-assessed, and only if lameness persists is further investigation carried out.

DIAGNOSTIC ANALGESIA

If no obvious cause of lameness is apparent, then diagnostic analgesia is performed, but no particular differences in approach exist for this type of horse. However, if clinical signs suggest an intra-articular problem, such as synovial effusion and pain on passive manipulation of a joint, then intra-articular analgesia of the suspect joint may be performed first. If intra-articular analgesia is carried out, clipping a small area is preferred, but some trainers are reluctant to allow this, and provided that the hair coat is not excessively long, a timed 5-minute surgical scrub is performed before injection.

If a fracture is suspected based on the history or clinical signs, nerve blocks are not performed. A horse that pulled up lame on the gallops or finished work and then became severely lame while walking home may have a stress fracture. Stress fractures of McIII and MtIII and the tibia are common. If a stress fracture is suspected, the horse is examined radiographically or scintigraphically.

If soft tissue swelling is identified clinically, then ultrasonography is performed routinely as the next diagnostic step.

IMAGING CONSIDERATIONS

Radiography is performed routinely using standard radiographic projections. Special views at different angles may be required for demonstrating specific lesions, based on the preliminary examination. Some stress fractures are difficult to identify radiographically, and if a fracture is suspected on clinical grounds, radiographic examination is repeated 10 to 14 days later.

If the clinician suspects an abnormality of the palmar metacarpal soft tissues, an ultrasonographic examination should be performed. In view of the high incidence of bilateral lesions, both limbs should be examined routinely. A systematic approach is essential, focusing on the SDFT, deep digital flexor tendon, and SL in turn. It is almost invariably necessary to clip the metacarpal and metatarsal regions to achieve satisfactory image quality, because most National Hunt horses have thick guard hairs. However, satisfactory images of the pelvis usually can be obtained after washing with chlorhexidine for about 10 minutes, soaking with alcohol, washing off (to avoid alcohol-induced damage to the transducer), and liberal application of coupling gel.

Transverse and longitudinal images of the metacarpal and metatarsal regions are required to gain a full appreciation of the severity of injury. An injury index giving a quantitative assessment of damage can help in communication with trainers and may help to convince them of the significance of an injury associated with only mild clinical signs. Each structure should be evaluated sequentially from proximally to distally at predetermined measured intervals (4 or 5 cm) distal to the accessory carpal bone or examining each zone (see Chapter 17). Cross-sectional area (CSA) or circumferential measurements are made at comparable sites in each limb. Measurement of the size of damaged fibers is also useful. One author (R.v.P.) describes the severity of a core lesion by multiplying the percentage of CSA of the tendon damaged by the length of the lesion and by the percentage of the fibers damaged within the injury (assessed visually). For example, a core lesion that occupies 10% of the CSA of the tendon and extends 10 cm proximodistally and is assessed visually as having 75% of the fibers within the core lesion damaged has an index of $10 \times 10 \times 0.75 = 75$. A similar lesion occupying 30% of the CSA has an injury index of $30 \times 10 \times 0.75 = 225$. All images should be recorded routinely for future comparisons.

Nuclear scintigraphy is indicated as a screening tool when a lame horse is presented after a bad fall, particularly when a moderate to severe lameness has persisted for more than 3 or 4 days. Scintigraphy also may be indicated if severe, sudden-onset lameness occurs with no localizing clinical signs to rule out fracture before a dynamic workup is contemplated. Scintigraphy often is more rewarding in horses with acute injuries than those with chronic lameness. Scintigraphy usually can be targeted to specific areas such as the pelvis or both hindlimbs unless the horse has lameness involving several limbs. During evaluation of the pelvis, radioactive urine in the bladder can confound interpretation. The use of furosemide may help, but this drug may make the horse fidgety, and catheterization of the bladder, followed by flushing with warm water, may be preferable.

PROCEEDING WITHOUT A DIAGNOSIS

National Hunt horses have a longer career than flat racehorses, and less prize money is available to be won. Therefore the pressure to get a horse sound quickly often is less, and many trainers accept resting the horse if a diagnosis cannot be achieved by the techniques described previously. However, an attempt to reach a diagnosis always should be made.

SHOEING CONSIDERATIONS AND LAMENESS

Most National Hunt horses train and run in light steel shoes with one toe clip in front and two side clips on hind shoes. Some trainers change to a hind shoe with a single toe clip for

racing. Good shoeing is essential. Given the high incidence of foot problems causing lameness, a good relationship with a skilled farrier is invaluable. Poor foot conformation, especially low collapsed heels, may predispose the horse to superficial digital flexor tendonitis. Bar shoes combined with a rolled toe often are used for horses with collapsed heels. If a foot is conformed poorly, the risk exists of shoes being pulled off repeatedly in training, particularly if the branches of the shoe are set too far medially or laterally.

DIAGNOSIS AND MANAGEMENT OF LAMENESS IN STEEPLECHASERS, HURDLERS, AND POINT TO POINT HORSES

Superficial Digital Flexor Tendonitis

An epidemiological study demonstrated an 86 % incidence of SDFT injuries in National Hunt horses.[2] Although most of the injuries occur in the forelimbs, hindlimb injuries also occur. Many trainers routinely assess forelimb SDFTs daily, and some are adept at detecting relatively subtle lesions. Veterinary involvement may enhance these skills. Many, but not all, trainers are keen to have ultrasonographic assessment of suspected tendon injuries. Some trainers tend to ignore suspicious injuries at the end of a season, contrary to veterinary advice. This may be one reason why a peak incidence of tendon injury tends to occur at the beginning of the season when horses start galloping after a short summer break. Other horses may have been kept in training late in the season to get an extra race and may have suffered injury, which may or may not have been manifest clinically. A second peak incidence of injuries tends to occur at the end of the season, perhaps related to races run on faster going. Superficial digital flexor tendonitis is more common in steeplechasers than in hurdlers, but this may reflect the older population of the horses rather than the type of racing itself. The degree of lameness at the time of acute injury may reflect the severity of tendon damage.

Horses with acute lesions are managed with aggressive anti-inflammatory treatment for 5 days, including systemic non-steroidal anti-inflammatory drugs (e.g., phenylbutazone and eltenac), with or without a single dose of corticosteroids (e.g., dexamethasone), and cold hosing several times daily. Cold water bandages or cold kaolin is applied to the limbs. Some thin-skinned horses are prone to blistering, so any bandaging must be done with care. Other popular proprietary poultices, such as Animalintex (Robinson Animal Health Care, Chesterfield, UK) and a variety of clay-based preparations, may irritate small unnoticed wounds and are therefore avoided.

A first ultrasonographic examination is performed about 7 days after the injury is first recognized. Horses with central core lesions may be treated by decompression, using needle fenestration or a fixed blade. This is performed with the horse sedated and using regional analgesia. Follow-up ultrasonographic examinations frequently are performed 3 to 4 weeks after injury, because the preliminary examination may underestimate the degree of damage because of ongoing enzymatic degradation. This gives a baseline scan for the injury.

Many differing views are given on the best management of superficial digital flexor tendonitis in National Hunt horses. Adequately rehabilitating a tendon that was injured late in a season so that the horse can race the following season, without a disproportionately high risk of re-injury, is difficult. Firing remains a popular treatment, and because many owners and trainers are prepared to rest a horse for 12 months after firing, when they would not give such a long convalescent period if rest alone was recommended, this treatment still is carried out widely. Nonetheless, the re-injury rate remains high, so many alternatives have been tried with various success. These alternatives range from at least 9 months of field rest, intralesional injection of hyaluronan, polysulfated glycosaminoglycan, a phenol derivative, β-aminoproprionitrile fumarate or growth factors, combined with a variety of exercise regimens. Intralesional β-aminoproprionitrile fumarate combined with a strictly controlled exercise program has produced good results in selected horses (R.v.P. and S.J.D.); however, the time for return to racing often is prolonged, in part dictated by the time of injury and the seasonal nature of racing. The average time to return to racing was 17 months. The owner or trainer must be committed to at least 3 to 4 months of walking exercise after treatment, and some horses are unsuited to this temperamentally, unless a horse walker is available. Regardless of the methods of management, a slow, gradual rehabilitation before resuming ridden work seems beneficial. Ideally the horse should be walking on a horse walker daily for 3 months before resuming ridden exercise. The horse can be turned out during this 3 month period. A cage horse walker in which the horse is free and in which the speed can be set manually to encourage the horse to walk briskly is best.

Serial ultrasonographic examinations are particularly useful as exercise is resumed, about 1 month after resuming walking, then again before cantering commences, and a third time before fast work commences. Commonly as work intensity increases, small hypoechoic areas develop, especially in areas in which the fiber pattern is not parallel. In some horses these lesions disappear, provided the horse is maintained at the same exercise level, whereas in others a core lesion redevelops, and the trainer should be warned accordingly.

The prognosis is related partly to the severity of injury.[3] In a follow-up study of 73 National Hunt and Point to Point racehorses, lesions were graded by ultrasonography as mild (<50% CSA or <100 mm in length), moderate (50% to 75% CSA or 110 to 160 mm in length), or severe (>75% CSA or >160 mm in length). All mildly affected horses returned to training and 63% raced. Fifty percent of horses with a moderate lesion resumed training and 23% raced, but only 30% of horses with severe lesions resumed training, despite up to 6 months longer convalescence, and 23% raced. The mean re-injury rate of those resuming work was 40% in the period of follow-up (9 to 30 months).

The type of racing in which the horse is involved may influence the prognosis for return to racing after superficial digital flexor tendonitis. Fifty-one (73%) of 70 hurdlers raced five or more times after desmotomy of the accessory ligament of the SDFT for treatment of tendonitis compared with 39 (58%) of 67 of steeplechasers.[4]

Cellulitis, skin necrosis, and necrosis of the underlying SDFT are poorly understood conditions that have been recognized in National Hunt horses (S.J.D.) and flat race horses that have run over long distances (>1½ miles) (R.v.P.). Many horses run in boots or exercise bandages, which are removed after racing. Whether exercise bandages would be on long enough to cause pressure necrosis is debatable. The typical history is that a proprietary clay-like substance (Kaolin, Ice-Tite) or commercial poultice (e.g,. Animalintex) is applied to the metacarpal regions after racing, with or without overlying bandages. The applied substance is removed the following day. Clinical signs may be apparent within 24 to 72 hours, with the development of peritendonous edema and serum ooze, progressing to skin slough and slough of deeper tissues, which may take several weeks. The degree of damage varies between horses, and one or both limbs may be affected. One author (S.J.D.) has seen this unassociated with superficial digital flexor tendonitis, whereas another (R.v.P.) often has seen concurrent superficial digital flexor tendonitis. The prognosis depends on the depth of the lesions. One author (R.v.P.) recommends that horses should be thoroughly cooled after

racing before anything is applied topically to the limbs to minimize the risks of these complications. If a SDFT injury is suspected, then the advice of the course veterinarian should be sought.

Suspensory Desmitis

Suspensory desmitis is a major problem in National Hunt horses, especially steeplechasers and Point to Point racehorses. Injuries of the body or branches occur in forelimbs and hindlimbs, sometimes with a fracture of the distal third of the second (McII/MtII) or fourth (McIV/MtIV) metacarpal or metatarsal bones, apical or abaxial sesamoid fractures, or sesamoiditis. Proximal suspensory desmitis does occur in forelimbs and hindlimbs and is recognized more commonly in hindlimbs, but the true incidence may be underestimated.

Body and branch injuries of the SL often go unrecognized until the ligament is grossly enlarged; possibly some of these are cumulative injuries rather than single-event injuries. More careful monitoring of the SLs by regular palpation with the limb not bearing weight may lead to earlier detection of important lesions. The degree of swelling sometimes makes it difficult to palpate accurately the distal end of McII and McIV.

Assessment of structural damage is done by ultrasonography in a way similar to that described for SDFT lesions. Lesions are assessed acutely (up to 7 days after injury and 4 to 6 weeks later) to determine the baseline degree of injury. Some of the swelling contributing to the apparent swelling of a SL branch is often a periligamentous reaction. Radiographic examination is necessary to evaluate McII/MtII or McIV/MtIV and the PSBs.

Body and branch injuries are associated with a prolonged convalescence irrespective of the way in which they are managed, and returning to racing often takes longer than for a horse with superficial digital flexor tendonitis. The rate of recurrent injury is high. Surgical removal of fractures of McII or McIV (MtII or MtIV) has little bearing on the horse's final outcome.

Conservative management of rest alone, splitting the SL, intralesional injections of β-aminoproprionitrile fumarate, and pin firing have been used with no significant differences in outcome.

Fractures of the Third Metacarpal and Metatarsal Bones

The most common long bone fractures in National Hunt horses are condylar fractures of the McIII or MtIII bones. Such fractures often are recognized in hindlimbs and frequently involve the medial condyle and may spiral proximally. Full evaluation of the fracture may require multiple oblique radiographic views of MtIII. Such fractures are more common in hurdlers than in steeplechasers. With prompt surgical treatment by internal fixation the prognosis is good. Compound, comminuted fractures of the distal aspect of McIII and MtIII may occur during racing and may be associated with luxation of the fetlock. These horses have a guarded prognosis for return to racing.

Incomplete palmar cortical fatigue fractures of McIII occur commonly, especially in horses older than 4 years of age entering National Hunt or Point to Point training for the first time. Pre-existing sclerosis in the proximomedial aspect of McIII detected when lameness is first recognized in some horses suggests that abnormal bone modeling has existed for some time, subclinically or without clinical signs being recognized. Lesions are often bilateral. Lameness is characterized by the horse becoming lamer the further it trots and then improving if walked a few steps. Usually no localizing clinical signs are apparent, and diagnosis depends on localizing pain to the proximal palmar metacarpal region, and identifying radiographic lesions or scintigraphic evidence of increased bone turnover, in the absence of ultrasonographic abnormalities of the proximal aspect of the SL. Treatment of 3 months of rest with a graduated return to work is usually successful, and recurrent injury is unusual.

Less commonly transverse stress fractures of the distal metaphyseal region of McIII cause acute-onset lameness. No localizing signs may be apparent, but lameness is alleviated by a four-point nerve block of the palmar and palmar metacarpal nerves. Usually pre-existing callus formation is evident on the distal metaphyseal region of McIII on the dorsal or palmar aspects.

Lameness Associated with the Hock

The degree of lameness caused by hock pain varies, and lameness is more commonly unilateral, unlike bilateral lameness usually seen in the flat racehorse. The most common cause is osteoarthritis of the distal hock joints, although traumatic injuries also occur. The horse may adduct the lower limb as the leg is brought forward at the walk and trot. The lameness often worsens after flexion and when the lame limb is on the inside on the lunge. More subtle signs of poor jumping or back pain may herald a problem originating in the hocks.

Lameness most often is alleviated by intra-articular analgesia of the tarsometatarsal joint. It is rare to have to inject the centrodistal joint as well, despite the variable communication between the joints and the fact that osteoarthritic changes seen radiographically often affect both joints. Radiography of the hocks should include four standard views, because radiographic changes may be visible only on one projection. Abnormalities range from mild peri-articular osteophyte formation to osteolysis, with narrowing of the joint spaces, with or without peri-articular new bone. Occasionally, young horses in the first year in training have significant radiographic changes in one limb. The damage was probably present before onset of training and may be associated with collapse of the distal tarsal bones or a traumatic incident earlier in the horse's life.

Care should be taken when interpreting scintigraphic images of the hocks in National Hunt horses. Often areas of increased radiopharmaceutical uptake (IRU) are seen but do not appear to correlate with clinical signs of lameness (A.N.).

Treatment of horses with osteoarthritis of the distal tarsal joints usually consists of intra-articular medication of the tarsometatarsal joint with combinations of hyaluronan and corticosteroids. Consideration should be given to chemical fusion of painful distal hock joints in young National Hunt horses.

Traumatic injuries involving the hock are common. Injuries frequently sustained after a fall include fracture of the lateral malleolus of the tibia and tearing of the attachments of the collateral ligaments. The lameness associated with lateral malleolar fractures can be mild, and lesions may be missed if radiography is not carried out. Ultrasonography may be more useful than radiography for the early diagnosis of collateral ligament injury. Follow-up radiography some weeks later may reveal some entheseous new bone formation. Horses with these injuries have a good prognosis for a return to racing, although improvement in lameness may be slow. Some debate exists about the optimal management of horses with lateral malleolar fractures: conservative or surgical. Both treatments carry favorable prognoses. Surgical removal is usually easiest by making an incision directly over the fracture fragment(s) rather than by attempting arthroscopic removal.

Lameness Associated with the Pelvis

Lameness associated with the pelvis in the National Hunt horse is more likely to result from a traumatic incident than a stress fracture. Falls or poor landings while jumping (see Fig. 113-4) may lead to subluxation of the sacroiliac joint or pelvic fractures. However, ilial stress fractures also occur, especially

in horses entering training at 5 years of age or older. A strong correlation between pelvic lameness and working horses on loose all-weather surfaces, especially an unmanaged wood chip surfaces and particularly uphill, has been noted (A.S. and R.v.P.).

Clinical signs can vary from severe lameness with obvious crepitus to mild stiffness. It is important to examine the pelvis per rectum when pelvic damage is suspected. A horse with an ilial fracture sustained during a fall may be lame initially and improve rapidly within 48 hours. If an ilial wing fracture is non-displaced, the horse could return to cantering exercise before lameness recurs. Muscle spasm may result in significant asymmetry of the tubera coxae in the acute stage, but this usually also resolves within 24 hours. Severe lameness associated with an ilial shaft or acetabular fracture is invariably persistent. Ilial stress fractures may cause only mild clinical signs, and sometimes the most important abnormality is shortening of the contralateral forelimb stride as the horse moves off from standing still. This gait abnormality rapidly resolves.

Fractures of the ilial wing involving the dorsal surface often can be diagnosed by ultrasonography, but incomplete stress fractures involving the ventral aspect cannot be seen.

Nuclear scintigraphy is invaluable for assessing pelvic pain. With sacroiliac disease IRU in the sacroiliac joint contralateral to the lame limb occurs, in one contributor's (A.N.) experience. Assessment of pelvic fractures should be delayed for at least 5 to 7 days after injury to avoid false-negative results. If scintigraphy indicates IRU in the region of the coxofemoral joint, obtaining multiple oblique scintigraphic views is worthwhile to try to assess whether the fracture involves the joint. Other scintigraphic changes seen include IRU at the greater and third trochanters of the femur associated with damage to the insertions of the deep and middle gluteal tendons and the superficial gluteal insertion, respectively.

Horses with non-displaced ilial wing fractures have a good prognosis, whereas the prognosis for those with fractures of the ilial shaft or ilial fractures involving the acetabulum is poor.

Back Pain

Back pain in the National Hunt horse may be primary or may develop secondary to chronic lameness in one or more limbs and is being recognized with increasing frequency. Nuisance problems include the development of seromas underneath the saddle, which are probably attributable to an ill-fitting saddle and poor riding. Most trainers regularly use a physiotherapist, who may be the first person asked to look at a horse that is not right. Only if the horse fails to respond to one or two treatments, or if the physiotherapist recognizes obvious lameness, is veterinary advice sought. A good working relationship with the physiotherapist is valuable, because without a doubt the rehabilitation and long-term management of horses with chronic back pain can be helped by regular physiotherapy treatment. However, the veterinarian should have responsibility for both the diagnosis and the development of the treatment program.

Knowledge of back problems in National Hunt horses has increased greatly with more routine use of nuclear scintigraphy. Thorough investigation of the back is warranted in horses with chronic back pain, a history of jumping awkwardly (see Fig. 113-1), or after bad falls. Physical examination of the back often can be unrewarding concerning specific diagnosis, because the examination may only reveal stiffness and pain on palpation. Underlying problems such as active kissing spines or osteoarthritis of the dorsal articular facets of the vertebrae are common in the National Hunt horse and can be ruled in or out using scintigraphy and radiography. In a horse with an acutely sore back after a fall, scintigraphy can be used to determine if any bony damage occurred. The clinician should bear in mind that falls may involve more than one horse, and a fallen horse may get shunted (pushed) by one behind. Serious vertebral fractures can produce nothing more than severe stiffness and guarding in some horses after a fall, if the spinal cord itself is not compromised. For example, scintigraphy may reveal intense focal IRU suggesting a fracture in the region of the second or third lumbar vertebra. Radiography may demonstrate an obvious change in orientation of the spinous processes at this level, without being able to demonstrate a fracture. Lateral and dorsal scintigraphic images are useful to identify fractures of the transverse processes of the lumbar vertebrae.

Ultrasonographic examination is also useful for identifying some soft tissue injuries such as desmitis of the supraspinous or dorsal sacroiliac ligaments.

Horses with traumatic injuries often respond well to prolonged rest combined with physiotherapy. Horses with kissing spines often improve after local infiltration with corticosteroids.

Successful management of chronic back pain needs a broader approach. Many National Hunt horses have an inadequate jumping education and poor technique (see Fig. 113-1). Traditionally in the United Kingdom and Ireland, horses learn to jump by loose schooling over small fences; horses are schooled ridden over two or three small fences, once or twice when they are fresh. In France horses often are trained to jump out of deep going, when they are tired, providing a better grounding for racing conditions. The standard of riding of the work riders is often only moderate, and employing some staff with a background of working with event horses or show jumpers may be beneficial. Time should be spent teaching the horse to jump properly. Often more time is available in the summer break period to devote to such problems.

Additional work from the field, or keeping the horse in work, or bringing the horse in early should be advised. The horse should be encouraged to work in a round outline by exercising in draw reins to improve the development of the epaxial muscles. The horse can be given a warm-up period on a horse walker before being ridden. Use of a well-fitting hunting saddle rather than a racing saddle should be encouraged. After exercise the horse may benefit from being led home from the gallops rather than ridden.

Neck Lesions

Neck trauma usually results from a fall (see Fig. 113-6) and is more common in steeplechasers and Point to Point racehorses than in hurdlers. Neck trauma may result in ataxia or a stiff neck, with or without forelimb lameness, and can cause death. Ataxia may be transient or persistent. Radiographic examination should be performed if ataxia or neck pain and stiffness persist for more than a few days. Fractures in the cranial or mid-neck regions are most common, but occasionally fractures occur caudally, which may be difficult to assess without a fixed, high-output x-ray machine. Nuclear scintigraphy can be helpful in localizing such fractures, but false-negative results in the caudal cervical spine are possible. Horses with persistent ataxia have a guarded prognosis. Most horses with a fracture unassociated with ataxia can return to racing despite residual neck stiffness.

Lameness Associated with the Front Feet

Lameness associated with the front feet may vary from a shortened gait to an obvious lameness. The most common causes of foot lameness include solar bruising, corns, and subsolar abscesses. Other commonly recognized causes of foot lameness in the National Hunt horse include pedal osteitis, palmar heel pain, and fractures of the distal phalanx. Palmar heel pain may be caused by bruising of the heel bulbs or may be caused by deeper pain associated with the deep digital flexor tendon or navicular bone, with a much poorer progno-

sis. Horses that train on downland are particularly at risk to bruising the feet or penetrating injuries of the sole caused by flints. The latter may result in infectious osteitis of the distal phalanx. Protective aluminium pads may prevent solar penetrations but do not prevent bruising, because the pad is distorted and puts pressure on the sole if a horse stands on a flint.

In horses with chronic lameness associated with foot pain, local analgesia, radiography, and ultrasonography sometimes can be unrewarding or give equivocal results. Nuclear scintigraphy using soft tissue and bone-phase images is sometimes helpful.

Lameness Associated with the Carpus

Synovitis and osteoarthritis of the middle carpal joint are common and are treated by intra-articular injection with hyaluronan, with or without triamcinolone. A horse with synovitis may be treated more conservatively than a flat racehorse when the pressure is great to maintain the horse in training if at all possible. With a young National Hunt horse with a career of several years ahead, restricting the horse to walking exercise until clinical signs have resolved fully often is more prudent.

Chip fractures of the dorsal border of any of the carpal bones are common and often are associated with pre-existing osteoarthritis. Treatment is by surgical removal of the fragment(s), and prognosis depends on the degree of osteoarthritis; most horses are able to return successfully to racing. Slab fractures of the third carpal bone are also common but are not always associated with obvious clinical signs. Lameness is often mild and associated with only slight effusion of the middle carpal joint.

Accessory carpal bone fractures usually result from a fall and are common in National Hunt horses. Most fractures are longitudinal and occur midway between the dorsal and palmar borders of the bone, but less commonly articular chip fractures occur on the proximal or distal dorsal articular margin. The latter must be removed surgically or otherwise severe osteoarthritis ensues. Horses with the more common longitudinal fractures do not require treatment other than prolonged rest. Some fractures heal only by fibrous union, but the prognosis for return to racing is good. Some horses have effusion in the carpal sheath when work is resumed, which responds well to the intrathecal administration of triamcinolone and for which retinacular release is seldom necessary.

Lameness Associated with the Metacarpophalangeal Joint

Most lameness associated with the metacarpophalangeal (fetlock) joint is degenerative. Fetlock lameness is often present bilaterally with a shortened forelimb gait, warmth around the joint, and reduction of range of motion. Flexion often exacerbates lameness. Lameness often is improved by intra-articular analgesia of the metacarpophalangeal joint. Radiography may reveal peri-articular osteophytes or a small fragment on the dorsoproximal border of the proximal phalanx. If the proximal sesamoid bones and SL attachments are involved in sesamoiditis, a low palmar or four-point nerve block is required to alleviate lameness. New bone formation and osteolysis may occur on the abaxial surface of the PSBs at the attachments of the SL. This form of sesamoiditis more commonly is associated with damage to the attachments of the SL onto the PSB rather than a primary sesamoid bone disease and is seen much more frequently in National Hunt horses than other types of horses. The condition is related to the stress to which the palmar metacarpal soft tissues are subjected during jumping and galloping.

Treatment options include the following:

1. Injection of the fetlock joint with hyaluronan, with or without corticosteroids
2. Arthroscopy and removal of any free fragments
3. Blistering the palmar aspect of the fetlock to treat sesamoiditis

The prognosis for lameness affecting the fetlock is more guarded in the National Hunt horse than in the flat racing horse but occurs much less frequently.

Other Injuries

National Hunt horses seem particularly to lacerations involving the distal palmar (plantar) aspect of the metacarpal (metatarsal) region, which may involve the SDFT or the digital flexor tendon sheath (DFTS), usually resulting from the horse being struck or from penetration by a sharp stone. Such injuries should be treated early and aggressively, especially if the DFTS is involved. With early lavage of the DFTS using an arthroscope, combined with intravenous broad-spectrum antimicrobial treatment for 5 to 7 days, the prognosis is usually excellent unless significant damage of the SDFT has occurred.

A high number of complex injuries to the palmar (plantar) soft tissues of the pastern have been seen in National Hunt horses as sequels to previous superficial digital flexor tendonitis in the metacarpal region or as primary injuries. Although injury to one or both branches of the SDFT may occur alone, simultaneous injuries of the oblique and straight sesamoidean ligaments are not uncommon. The prognosis for such injuries generally is guarded.

DIAGNOSIS AND MANAGEMENT OF LAMENESS IN TIMBER RACING HORSES

Lameness falls into three groups: acute injury or breakdown after racing, chronic wear injury caused by the horse's age and length of competitive career, and traumatic injuries caused by interference from another horse or hitting a fence.

Eighty-five percent of acute injuries after racing are caused by superficial digital flexor tendonitis and SL desmitis. Many timber horses have had previous SDFT injuries from earlier flat racing. The long courses (up to 4 miles), variable turf quality and terrain, fatigue, and weather conditions predispose horses to injury. Injuries range from small tears to catastrophic breakdowns that may necessitate humane destruction. Regular clinical and ultrasonographic monitoring is useful for detecting subtle changes and for making recommendations about running on specific footing (ground) conditions (K.K.).

Once recognized, osteoarthritis of the metacarpophalangeal and the distal hock joints requires management, because increased lameness may be induced by the increased work leading up to a race. Keeping horses as comfortable as possible throughout training is preferable, which may necessitate intra-articular medication 2 to 3 times during a season, using hyaluronan for the metacarpophalangeal joints and hyaluronan and corticosteroids for the distal hock joints (K.K.). Orally administered glucosamine and chondroitin sulfate are used commonly. It is important to keep the horse well shod and to use cold hydrotherapy after strenuous exercise.

Traumatic injuries sustained during racing are common, with the hindlimbs particularly vulnerable because of the horse hitting fences at speed. Damage to the quadriceps muscles, peri-articular soft tissues of the stifle, and stifle joint are common, although determination of the severity of injury is usually easiest several hours after a race rather than immediately. Radiographic examination is indicated to rule out a patellar fracture, which requires surgical management. Bruising of the patellar ligaments is common, with or without effusion of the femoropatellar joint, and is treated by drainage of excess synovial fluid and injection of hyaluronan (4 to 6 ml) combined with controlled exercise and non-steroidal anti-inflammatory drugs.

Timber shin describes firm enlargement of the dorsal aspect of the metatarsal region because of chronic bruising of the long digital extensor tendon, with fibrosis of the tendon and peritendonous soft tissues. Timber shin is unsightly and is not associated with long-term lameness, but recent trauma results in lameness from severe swelling of the leg, with pain on protraction.

Injuries sustained by interference from another horse, for example, traumatic heel bulb laceration or strike injuries on the palmar or plantar aspect of the fetlock, are common (see page 939). Injuries also can result from falls, for example, fracture of the accessory carpal bone, or from a galloping horse treading on a faller.

The Finnish Horse and Other Scandinavian Cold-Blooded Trotters

Kristiina Ertola and Jukka Houttu

HISTORY OF THE BREEDS

The Finnhorse is the only original horse breed in Finland. Sweden and Norway also have similar cold-blooded breeds. The Finnhorse has been known for about 1000 years and originally was used for farm and forest work and in the army. The Stud Book of the Finnhorse was founded in 1907 for Draft and carriage horses but is now divided into four parts for racing trotters, riding horses, draft horses, and small pony-type horses. Seventy-five percent of the registered Finnhorses are trotters. The Finnhorse is heavy and well muscled, with a short neck and usually a heavy head. The average height is 155 to 160 cm, but pony-sized Finnhorses exist. Swedish and Norwegian cold-blooded horses are slightly lighter and smaller than Finnhorses, with an average height of 150 to 160 cm.

Trotting competitions are the main use of Finnhorses. In Scandinavia all harness races are for trotters; there are no pacing races. The first records of trotting races are from 1817, when races were arranged on the ice of the river Aura in Turku. The first races with official timing took place 1862 in Viipuri. In the early years the trotting races were arranged by the state to support and develop horse breeding in Finland. In the first races the distance was 2138 m, and they were on a straight track. The horses raced individually, and prizes were given according to the times. The first official Finnish record was from 1865 by the mare Brita. The average time for 1000 m and was 1.51.3 (1 minute 51.3 seconds, equivalent to a mile in 2 minutes 59 seconds). Today the record is held by Viesker and is 1.19.9 (2:08.5). Betting was first introduced 1928 but developed slowly until the 1960s, after which rapid growth has followed.

In Sweden, racing also was started in the early nineteenth century on roads and icetracks. The first permanent tracks were built in the early twentieth century. The first official record in Sweden was in 1829, 1.37.6 (2:37), held by a Norwegian horse, Sleipner Varg. Today the record is 18.6 (2:07) by a Norwegian stallion, Spikeld. When racing became more popular, Swedish and Norwegian horsemen started trading horses across the border, and the Swedish and Norwegian breeds began to merge together. Today the breeds are genetically alike, and they now are considered to be the same breed. Sweden and Norway have a close collaboration in breeding and racing, and their horses race in the same races.

Today the races are held at modern dirt tracks, and in the same events there are separate races for Finnhorses and Standardbreds (STBs). The Finnhorses are allowed to race first at the age of 3 years, but not uncommonly they start racing as late as 5 or 6 years old. They are allowed to race until 16 years of age, and a Finnhorse usually is considered to be best between 7 and 10 years of age. Some stakes races are held for 4- and 5-year-olds, but the main events are for older horses. The biggest event for Finnhorses is the Kuninkuusravit, The Royal Trot, which is held annually in July and August at a different track in Finland each year. The race is one of the major sporting events in Finland, attracting about 50,000 people. Separate races are held for mares and stallions; geldings are excluded. To be allowed to race in the Kuninkuusravit, the horse has to be approved for public breeding and has to be entered in the Stud Book, which requires inspection and approval by a special board. The horses race 3 times in 2 days over distances of 1609 m, 2100 m, and 3100 m, and the final result is based on the total time for all three races. To win the royal title is the biggest honor a Finnhorse can ever get, and the best stallions have won the title 5 times (Vieteri, Vekseli, and Viesker), and the best mares, 4 times (Suhina and Valomerkki). This is a good proof of stamina and endurance, which are typical for the Finnhorse at its best.

In Sweden and Norway horses usually start racing at 3 years of age and are allowed to race until the age of 16. Stakes

Timber shin describes firm enlargement of the dorsal aspect of the metatarsal region because of chronic bruising of the long digital extensor tendon, with fibrosis of the tendon and peritendonous soft tissues. Timber shin is unsightly and is not associated with long-term lameness, but recent trauma results in lameness from severe swelling of the leg, with pain on protraction.

Injuries sustained by interference from another horse, for example, traumatic heel bulb laceration or strike injuries on the palmar or plantar aspect of the fetlock, are common (see page 939). Injuries also can result from falls, for example, fracture of the accessory carpal bone, or from a galloping horse treading on a faller.

To be allowed to race in the Kuninkuusravit, the horse has to be approved for public breeding and has to be entered in the Stud Book, which requires inspection and approval by a special board. The horses race 3 times in 2 days over distances of 1609 m, 2100 m, and 3100 m, and the final result is based on the total time for all three races. To win the royal title is the biggest honor a Finnhorse can ever get, and the best stallions have won the title 5 times (Vieteri, Vekseli, and Viesker), and the best mares, 4 times (Suhina and Valomerkki). This is a good proof of stamina and endurance, which are typical for the Finnhorse at its best.

In Sweden and Norway horses usually start racing at 3 years of age and are allowed to race until the age of 16. Stakes

races are open to Swedish and Norwegian horses, and big races are held for 3- and 4-year-olds and for older horses. Finnish horses are not allowed in these races, and only a few races are held in which all Scandinavian horses race together.

TRAINING A COLD-BLOODED TROTTER

Traditionally the horses have been bred and trained by farmers, and many remain home bred and trained. There are no sales for Finnhorses, Swedish, or Norwegian trotters. Most horses are broken at 2 years of age, spend the next summer at pasture, and then start more serious training in the winter at 3 years of age, often with a summer break. Farm and forest work has been part of the training to build up strength. Speed work is not done at all at this stage, and traditionally some trainers have never used speed work. Horses started racing at 5 to 6 years of age and raced themselves to condition. However, many professional trainers now train cold-blooded horses, and the horses are better prepared for the races and start racing younger. The race times for the beginners are faster, which has caused problems for many old-school trainers. Many Finnhorses are not natural trotters, and building them up to speed takes time and training. If fast speeds are demanded too early, gait abnormalities develop at higher speeds, and horses lose complete control of the trotting action while appearing sound at a slower trot.

Training cold-blooded trotters takes much more time than for STBs, making training more expensive and leading to problems in getting new owners and trainers. In all Scandinavian countries, fewer cold-blood races are held than STB races, and they are concentrated in the north. Nonetheless, cold-blood racing is supported by the central racing organizations of each country and continues to thrive.

RACETRACKS AND WEATHER CONDITIONS

The racetracks in Scandinavia are 1000-m oval dirt tracks, and the horses race counterclockwise. The climate is cold in the winter, and the tracks freeze and get covered by snow (Fig. 114-1). In winter temporary tracks also are made on ice for smaller races with no betting. The variable climate causes track problems. In late autumn when the track is frozen but not yet covered by snow, the surface can be treacherous. Snowfall makes the tracks smooth but not hard, and provided the horse is shod properly, the track is not slippery. In the springtime, when the snow begins to melt, the track conditions vary throughout the day, being hard in the morning after a night frost, becoming good for a few hours when the frost melts, and then becoming wet and soft the rest of the day. Keeping the track in good condition requires much skill.

Because of the long winter, much of the training has to be done on snowy or icy surfaces. Snow is a good surface on which to train a horse, but special shoeing with studs is essential so that the horses do not slip. In the winter many trainers do much of the speed work in snow, which can be deep. The training speeds can be lower because of the resistance, but the training effect is equal or even better than when the training is done on the track. Snow provides a soft and smooth surface, acting as a shock absorber. Many horses with lameness problems race better in winter because of the training in snow. Horses also are trained on the ice of lakes, which is also a good surface. The surface of the ice gives slightly, and shoes with studs can get a good grip. The worst training surface is ground frozen hard like asphalt, creating many lameness problems.

SHOEING CONSIDERATIONS

In the winter (November to April) special requirements for shoeing are needed to prevent the horses from slipping on ice. Studs, 5- to 15-mm in length with sharp tips that offer a good grip of the ice or snow, are screwed into the shoes. Four to 15 studs are used per shoe; more studs usually are used in the hind shoes. It is important to have enough studs to avoid slipping slightly at every step, causing joint and muscle soreness. A risk of interference injuries exists, and some horses with poor action cannot race in the winter. Forelimb heel

Fig. 114-1 Winter racing. (Courtesy Olavi Ilmonen, Lahti, Finland.)

injuries are common if a horse breaks stride. Elbow boots may be necessary to protect the elbows from stud-induced trauma. Some lameness problems get worse during the winter, because traction by the studs stops the feet abruptly. Hock-related lameness is often worse during the winter, and tendon and suspensory ligament (SL) problems increase.

The shoeing of racing Finnhorses is otherwise much like that in STBs, but many Finnhorses are not natural trotters and tend to gallop or pace, so many trainers use special shoeing to help the horse to balance. Young horses often need heavy front shoes with toe weights and bell (overreach) boots when they are learning to trot. The total weight per foot can be up to 500 to 800 g, and this predisposes the horses to lameness, particularly tendon and SL injuries. On the hind feet Finnhorses usually wear normal STB shoes. The lateral branch of the shoe is often longer and bent slightly outward to make the hind action wider and therefore avoid interference between the forelimbs and hindlimbs. Although many STBs race unshod, this is rare in Finnhorses.

CONFORMATION AND LAMENESS

The Finnhorse is a heavy, draft-type horse compared with other racehorses. The forehand is heavier than the rear of the horse and is combined with a heavy head and a thick and short neck, causing much stress to the forelimbs. Finnhorses often stand back at the knee, and this sometimes is combined with lateral deviation of the carpus (offset knees). Forelimb tendon, SL, and carpal injuries are not uncommon. The rear end usually is conformed better in Finnhorses than the front end. The most common faults are sickle hocks and cow hocks, which can cause curbs or other lameness problems in the tarsal area. Fetlock conformation is often good, and most Finnhorses have big hooves with good-quality horn.

LAMENESS EXAMINATION

Many Finnhorses complete a racing career without serious lameness problems and require substantially less veterinary treatment than STBs, perhaps because of slower racing speeds. The lameness examination for a Finnish horse is similar to that for a STB racehorse, and similar problems occur. Clinical history is particularly important, and the following questions should be asked:

1. How long has the horse been in training, and how has it been trained? What is the duration of lameness, and has the horse ever trotted sound at high speed? A Finnhorse often develops slowly and has to be taught to trot. Therefore many action problems in young horses are not caused by lameness but by lack of coordination. Lack of strength or condition may predispose horses to lameness.
2. Does the horse trot straight? Is the horse hanging on a line? Is the horse hanging on a shaft? Does the horse need sidepoles or headpoles? A great many lameness problems only show at higher speeds, especially in the early stages of the problem. This is particularly true with hindlimb lameness. Usually in right hindlimb lameness the horse's rear end turns to the left shaft, and the horse hangs on the right line. Correspondingly problems in the left hindlimb cause hanging on the left line and turning the rear end to the right shaft. In forelimb lameness this is less obvious. A horse with bilateral lameness may move straight.
3. Does the horse trot better in turns or straightaways? In which direction are the turns better? In a counterclockwise direction horses with right hindlimb lameness are usually worse in the turns. Horses with left hindlimb lameness are worse in the straightaways and usually are worst in the turns in a clockwise direction.
4. Is the horse better on soft or hard surfaces? Sidebones often cause lameness on hard surfaces, as do many other foot problems.
5. Is the horse worst when it starts to trot? Does the horse warm into or out of the lameness problem? In young horses (4- to 5-year-olds) bilateral hind fetlock pain is a common cause of lameness, resulting in a short hindlimb stride when first trotting. The lameness usually improves if the horse is jogged for about 1000 to 3000 m.
6. Do the studs in the shoes affect the lameness in the winter? Many horses with carpal or tarsal lameness are worse with studs.

The veterinarian should assess the type and use of the horse, its conformation, muscular development, and general condition and should systematically palpate all the limbs, because concurrent lameness in several limbs often occurs.

Many horses are trained with sleighs in the winter and are harnessed with collars. If the collar is not fitted properly, it can cause shoulder musculature soreness. Soreness of the shoulder or scapular musculature also can point to other problems in the forelimbs, especially when the lameness is bilateral. Inflammation of the carpal sheath is common because of the heavy front of Finnhorses and the conformation of the carpi and invariably is associated with palpable distention. Proximal suspensory desmitis (PSD) sometimes occurs, and pain may be induced by palpation of the proximal metacarpal region.

The second (McII) and fourth (McIV) metacarpal bones in Finnhorses are sometimes thick and prominent, but this is not usually significant (Fig. 114-2), although thick metacarpal bones are sometimes seen in horses with PSD or tenosynovitis of the carpal sheath. Ossification of the cartilages of the foot

Fig. 114-2 Dorsomedial-plantarolateral oblique radiographic view of the metacarpal region. The splint bone is enlarged, which usually has no clinical significance.

usually can be felt by thickening and loss of elasticity in the region of the coronet, but pain is seldom evident in palpation.

In the hindlimbs special emphasis needs to be given to palpation of the tarsus. Tarsal pain is common in Finnhorses with poor conformation. Curbs are common in younger horses (3 to 6 years of age), and distal hock joint pain is common in older horses. The Churchill test works well in Finnhorses. Stifle lameness is not common in Finnhorses, and upward fixation of the patella is rare. Osteochondrosis of the lateral trochlear ridge of the femur occurs occasionally in foals and young horses, sometimes with large defects that respond poorly to arthroscopic debridement.

The gait and response to flexion tests can be evaluated properly only when the horse is calm and well controlled by the handler. It is essential that the horse trots straight and not too fast. Most horses are too eager and excited and need to be sedated or tranquilized mildly for flexion tests. Acepromazine (0.01 to 0.025 mg/kg) or romifidine (0.01 to 0.03 mg/kg) are suitable. Sedation is especially important for Finnhorse stallions, which are often difficult to handle, and sometimes two leaders are necessary to control the horse and keep it trotting straight. Horses used for riding can be examined in a circle on the lunge, but trotters are seldom taught to lunge.

When doing flexion tests, it is essential for the veterinarian always to examine all limbs and not only those that are suspected to be lame. The tests always should be done in a similar manner and order. When doing flexion tests, the clinician should note all reactions. We do not think false-positive reactions exist, only reactions of different grades. The clinician needs to collect all the information and decide which reactions are significant. Proximal and distal limb flexion tests are done separately in the forelimbs and hindlimbs, using a force of approximately 40 kPa for 60 seconds.

In general, all the trotting Finnhorses also are examined at the track at high speeds. Many action problems, especially in the young horses, show only at high speeds. The horse is harnessed in a higher sulky than normal, so the driver of the vehicle does not obscure the horse. The veterinarian drives a car behind or beside the horse at the racetrack. Examining the horse from the car is more helpful than driving the horse, because the clinician can be some distance away from the horse to see the action more clearly, and abnormalities can be assessed more easily.

Diagnostic analgesia is used as in STBs. The clinician must keep in mind that high-speed lameness seldom can be resolved totally by analgesic techniques. Every block changes the horse's action, and when the veterinarian does several blocks on the same horse, assessing the meaning of each block is difficult. When examining a horse with high-speed lameness, the clinician must believe what vision, touch, and experience indicate.

IMAGING CONSIDERATIONS

In Finnhorse trotters, radiographic changes are found much less commonly than in STBs. Carpal chip fractures are rare in Finnhorses, and sclerosis of the third carpal bone is unusual. Osteochondrosis is also rare in the Finnhorse, though the prevalence has been increasing slightly in the past decade. Because osteochondrosis is unusual, young Finnhorses are not radiographed routinely if clinical signs are absent. Controlling osteochondrosis in Finnhorses is attempted by radiographing all stallions that are proposed for public breeding. Stallions with osteochondrosis generally are not accepted. Ossification of the cartilages of the foot is a common radiographic finding in Finnhorses. Navicular disease is a rare diagnosis. Enlargement of McII and McIV is common and often does not cause clinical signs. Flake-like fragments adjacent to McII usually result from interference.

Ultrasonography is invaluable for assessing soft tissue injuries and may be more useful than radiography in examining the splint bones, because splint-bone problems often are associated with carpal canal syndrome or PSD.

UNDIAGNOSED LAMENESS

Some young trotting Finnhorses trot soundly at slow speeds and show no signs of lameness during a lameness examination, but when asked for speed, the horses lose the action completely. Loss of rhythm causes this; the horse simply cannot trot at higher speeds. This often happens to talented horses that have early speed with little training but do not have the strength to maintain it. The training regimen must be aimed at building strength, especially in the hindlimbs. Horses are trotted in 1- to 3-minute intervals with resistance with a special resistance cart, in deep snow, or uphill. Training takes a long time, sometimes up to a year, until these horses learn to trot again, and some horses never recover. Because the main racing events are for aged horses, time is not as big a factor for Finnhorses as for STBs. It is quite possible for a horse to recover completely and become a top-class racehorse at an older age.

THE TEN MOST COMMON CAUSES OF LAMENESS

The following are the 10 most common causes of lameness:

1. Carpal lameness
2. Tarsal lameness
3. Superficial digital flexor tendonitis
4. Suspensory desmitis
5. Curb
6. Ossification of the cartilages of the foot
7. Splints
8. Metatarsophalangeal joint pain
9. Tenosynovitis of the digital flexor tendon sheath
10. Loss of rhythm

LAMENESS CONDITIONS TYPICAL OF FINNHORSES

Carpal synovitis is common in Finnhorses, and signs are similar to those seen in STBs. In the early stages a horse warms out of lameness quickly. Often horses with carpal problems begin to roll over and may try to pace or gallop instead of trotting. The horse may trot if the shoes are weighted more, but this may accentuate the primary problem. Without treatment the lameness deteriorates, and the horse begins to hang on a line and gradually becomes overtly lame. Radiographic changes rarely are seen, probably because of the slower racing speeds compared with those of Thoroughbreds and STBs. Treatment consists of intra-articular medication with hyaluronan, polysulfated glycosaminoglycans or corticosteroids, alone or in combination, together with rest for several weeks.

Carpal canal syndrome is also common in Finnhorses, sometimes simultaneously with carpitis, sometimes on its own. Ultrasonography is useful for confirming the diagnosis. The treatment is usually rest, combined with intrathecal administration of hyaluronan or corticosteroids. Some horses do not respond to conservative therapy, and surgical treatment using tenoscopy may be necessary.

Tarsal lameness is common in Finnhorses and is the most frequent cause of hindlimb lameness, usually because of distal hock joint pain. Mild lameness in horses is not noticed easily at slow speeds, but with increasing speed the horse begins to

drag the affected limb, and the rear end moves to the opposite shaft. The horse usually hangs on the line on the side of the affected limb. Radiographic evidence of osteoarthritis may or may not be apparent. Intra-articular treatments with corticosteroids, hyaluronan, or polysulfated glycosaminoglycans are used widely. In some horses cunean tenectomy can be useful.

Superficial digital flexor tendonitis and suspensory desmitis are common. Superficial digital flexor tendonitis usually occurs in forelimbs, and poor conformation or overweighting the shoes may be predisposing factors. In the hindlimb, tendon injuries are usually traumatic. Suspensory desmitis occurs more frequently in forelimbs than hindlimbs, probably because of the heavy front conformation. Suspensory branch injuries are most common.

Finnhorses cope better with chronic suspensory desmitis than do STBs because of the lower racing speeds, longer rest periods, the horses being able to race at an older age, and thus better opportunities to heal. Suspensory desmitis is sometimes associated with splint bone fractures or exostoses.

Treatment of Finnhorses with superficial digital flexor tendonitis and suspensory desmitis is most often conservative, with long rest periods. Tendon splitting or desmotomy of the accessory ligament of the superficial digital flexor tendon sometimes is used for tendonitis. Hot firing has been a traditional treatment for tendonitis and desmitis for many decades, and some veterinarians still use it in some horses, though with mixed success.

Curbs (soft tissue enlargement in the proximal plantar metatarsal region) often are seen in young horses (3 to 5 years old) in early training, especially those with sickle hocks (see Chapter 79). Curbs seldom cause spontaneous lameness. Usually the signs show first at higher speeds, when the cranial phase of the stride in the affected limb is shortened, and the horse begins to drag the limb. Most veterinarians treat curbs symptomatically, without ultrasonographic examination to determine the structure involved. Treatments include rest, corticosteroid or dimethylsulfoxide injections, or pin firing. Cryotherapy is not used as widely as pin firing. The prognosis with all treatments is very good.

Ossification of the cartilages of the foot (sidebones) is a common finding in the front feet of heavy horses, occurring in 80% of Finnhorses. The condition is more common in females than in males and positively correlates with the size of the horse. The grade of the ossification is usually mild, but extensive ossification sometimes occurs. The cause is unclear, but a heritable component exists. The cartilages start ossifying at an early age, unassociated with training of the horse. Other contributory factors may include hoof conformation, shoeing, and concussion.

The clinical significance of sidebones is questionable. Most horses with mild or moderate ossification show no clinical signs. Ossification is detected only by radiography. With extensive ossification the cartilages are palpable proximal to the coronary band. Palpation does not induce pain. In general, horses with large sidebones show some clinical signs, especially on hard ground. Lameness at slow speeds is rare, but at high speeds with increased concussion the forelimb stride is shortened and the horse breaks to pace or gallop.

The diagnosis is confirmed radiographically, using dorsopalmar views. Osteoarthritis of the distal interphalangeal joint and navicular disease may cause similar clinical signs and may be present concurrently with sidebones.

The treatment options are limited, because the condition persists. Shoeing with egg bar shoes, often combined with thick pads, is helpful in some horses. Most horses with sidebones can race with moderate to good success when shod properly and raced only on good surfaces. Because of the hereditary background all Finnhorse stallions that are used for public breeding have to be radiographed for sidebones before being accepted.

Splints are fairly common in the forelimbs of young, growing horses and horses are usually treated conservatively with rest. Most splints resolve spontaneously, but local corticosteroid injections or cryotherapy sometimes is used. Interference injury may result in a flake of bone detached from McII. These fragments do not heal with rest and respond poorly to corticosteroid injections or cryotherapy. Surgical removal is usually necessary.

Chronic tenosynovitis of the digital flexor tendon sheath is a common cause of lameness in aged cold-blooded trotters and usually develops gradually, with mild or moderate swelling and no lameness for long periods. In time the sheath becomes fibrotic, and masses and adhesions develop. At this stage constriction by the palmar annular ligament may occur. Many horses can perform well despite chronic tenosynovitis, especially in hindlimbs. Intrathecal administration of hyaluronan, with or without corticosteroids, is used for horses with acute tenosynovitis. Frequent corticosteroid injections often seem to increase tenosynovial masses. Tenoscopy and transection of the palmar annular ligament is used if the condition is advanced. Cold-blooded horses with chronic tenosynovitis seem to respond poorer to treatment than do STBs with similar lesions. This may be because Finnhorses are often older and of greater weight.

In young Finnhorses, bilateral hindlimb fetlock pain is fairly common and causes a short and stiff hindlimb stride when they start to trot, which improves with exercise early in the condition. When both hind fetlocks are blocked simultaneously, the action changes completely. Pain is considered to be associated with subchondral bone remodeling of the distal aspect of the third metatarsal bone.

A variety of treatments have been used, including joint lavage and intra-articular treatment with hyaluronan or corticosteroids, often combined with NSAIDs. If lameness is severe, surgical drilling of the subchondral bone is performed. Horses remain lame for several months, but the long-term prognosis is reasonable.

Osteochondrosis is rare in Finnhorses, but when it does occur, osteochondrosis most often is seen in the distal intermediate ridge of the tibia and causes effusion of the tarsocrural joint. Treatment is removal of the fragment(s) by arthroscopy.

Prepurchase Examination of the Performance Horse

Richard D. Mitchell and Sue J. Dyson

The purchase or prepurchase examination is a much discussed and sometimes feared subject for equine practitioners. Careless conduct and poor documentation can leave veterinarians wishing they had not agreed to perform the examination, whereas forethought and good planning can lead to a rewarding experience for the practitioner and the client. In the United States the examination is referred to as the *purchase examination*, because in many cases the deal already has been completed, whereas in Europe the examination usually is referred to as *the prepurchase examination*, because generally the purchaser has agreed to buy the horse subject to a satisfactory veterinary examination. However, in some countries (e.g., Holland), where many horses are sold through professional dealers, a horse may be purchased by the dealer and then examined by a veterinarian on behalf of the dealer before resale within a few days.

GOALS OF THE EXAMINATION

When requested to evaluate a horse for purchase, the veterinarian should keep several goals in mind. First, the examination should be an objective assessment of the horse's physical condition. Second, the examination should be a fact-finding mission to aid the purchaser in his or her decision to make a purchase. This may involve the veterinarian in making some predictions based on experience and probability, but care must be taken to be factual and objective. Last, the prepurchase examination can serve as a formal introduction to a horse for which the practitioner may provide long-term care. Such relationships may affect the veterinarian's decision-making process relative to a client's needs.

It is helpful to have knowledge of the disciplines in which the horse has been and will be involved. Various equine sports place differing demands on the horse, and the clinician should be aware of sometimes subtle, yet important, differences. Some physical characteristics or conditions may be acceptable for certain levels of performance but not acceptable for others. For example, a previous strain of a superficial digital flexor tendon (SDFT) may be an acceptable risk for a show hunter but may carry a high risk for a racehorse. Veterinarians should avoid performing prepurchase examinations on horses that will be involved in disciplines with which they are not familiar.

The veterinarian needs to discuss the goals of the examination and horse ownership with the prospective purchaser. Understanding the client, the trainer, and what is expected of the horse will help the veterinarian in assessing the horse's potential suitability. Passing or failing the horse is not the veterinarian's job, but it is his or her role to advise on how existing conditions may affect the future use of the horse. It is therefore self-evident that prepurchase examinations should not be performed by recent graduates, who may be fully competent in performing clinical examinations, but generally do not have the experience of how to interpret the findings of the examinations and are not in a position to evaluate risk. The prospective purchaser requires advice about the risks of proceeding with the purchase. Prior knowledge of clients, their expectations of the horse, and their attitude toward risk make offering such advice easier, compared with clients about whom clinicians know little.

A veterinarian must be open-minded and should consider themselves as a facilitator for the sales contract: the vendor wishes to sell the horse, the purchaser may have searched for a long time to find a suitable horse, and the veterinarian's role is to enable the transaction to take place if such is reasonable. Nonetheless, the veterinarian must be streetwise and recognize that a minority of unscrupulous vendors may try to misrepresent a horse. Caveat emptor. Veterinarians also should be aware that prospective purchasers often are keen to buy horses and in their enthusiasm may wish to overlook any problems that are identified during the prepurchase examination. A veterinarian who believes that the risks of buying a horse are too high is responsible for trying to dissuade the purchaser from proceeding further. If the purchaser ignores the advice, it is essential that the veterinarian has documented adequately his or her observations and advice. Purchasers can have remarkably selective memories when things start to go wrong.

The scope of the examination can range from a comprehensive clinical examination of the horse, using basic powers of observation, to a complex investigation using advanced techniques such as radiography, ultrasonography, endoscopy, thermography, and scintigraphy. The wishes of the buyer are important in determining the extent and depth of the examination, which also must be dictated to some extent by the value of the horse and its future athletic expectations. Some consideration to cost should be given, however, but not at the cost of the quality of the examination. The veterinarian should allow some latitude for deciding what is needed to answer questions posed by the clinical examination.

CONTRACT

A veterinarian enters a business arrangement with a purchaser when he or she agrees to perform a prepurchase examination. It is imperative for the veterinarian to understand the buyer's intentions for the horse and the expectations of the proposed examination. The terms, details, and costs of the examination should be discussed at the time of the initial request. The extent and depth of the examination and its limitations should be emphasized. This is straightforward when the veterinarian is dealing directly with the purchaser, assuming that the purchaser has knowledge of horses. The terms of

agreement become more difficult when a veterinarian is speaking to an agent for the owner or to the prospective rider of the horse, when the actual purchaser has no knowledge of horses. Such persons may have expectations of the horse as if it was a mechanical object like a car.

Purchaser's Reservations

The veterinarian is responsible for the following:

1. Establishing if the purchaser has any reservations about the horse
2. Determining whether the horse has been in regular work up until the examination
3. Warning the client of the hazards of performing an examination on a horse that has not been in regular work; previous lameness or back problems may be inapparent until the horse is in regular work. It may be helpful to suggest that the purchaser check the horse's official competition record to determine whether any unexpected breaks from competition have occurred.

Purchase for Resale

If the horse is to be purchased for resale, this should be noted. The purchaser should be warned that the clinician's interpretation of the findings may not be identical to that of another veterinary surgeon. The examining veterinarian may regard the horse as a reasonable risk for purchase, but this is not a guarantee that others have the same opinion. All observations should be well documented so that comparisons can be made should questions arise at a subsequent resale examination. Such notes may well help save a sale in the future and save face for the initial veterinarian.

Insuring the Horse

It is important to establish if the horse will be insured for loss of use for a specific athletic activity or for veterinary fees. The purchaser should be advised that the examining veterinarian may consider the horse a reasonable risk for purchase but that does not necessarily equate with the horse being a normal insurance risk. The veterinarian may consider that a small, well-rounded osseous opacity on the dorsal aspect of the distal interphalangeal joint is unlikely to be of clinical significance, but for an insurance company to place an exclusion on problems related to the joint would not be unreasonable. The veterinarian should advise the purchaser that if such problems arise, the purchaser should communicate with the insurance company before completing the purchase transaction.

Blood Tests and Limitations

The client should be informed clearly that the results presented are good for the day of examination, but predictions about future soundness and suitability are impossible. The limitations of analysis of blood for drugs must be detailed, bearing in mind the difficulties of detection of many drugs administered by the intra-articular route. The client should be warned that several days may elapse before the results of blood tests are known and that the purchase transaction should not be completed until the results are known. The veterinarian should discuss with the client how the findings will be transmitted and what kind of report will be issued.

Conflicts of Interest

Any potential conflicts of interest for the veterinarian must be disclosed to the buyer. Previous dealings with the vendor, although the vendor may not be a current client, could be perceived as a conflict of interest. In the horse world today, not to have such conflicts arise is difficult, but such conflicts should be acknowledged, and the buyer should be given the option of having someone else perform the examination.

COMMUNICATION WITH THE VENDOR

The vendor must understand clearly what facilities are required for the examination and should be advised that the horse should be stabled before the examination and not worked earlier in the day. If the vendor is unable to be present at the examination, the veterinarian should establish the answers to a number of important questions in advance:

1. How long has the horse been in the owner's possession?
2. Is the horse in regular work?
3. Has the horse had any previous lameness?
4. Has the horse had any previous medical problem?
5. Is the horse receiving any medication, or has it done so in the last 8 weeks?
6. Does the horse have any vices (crib-biting, wind sucking, box walking), or does it bite or kick?
7. Has the horse been seen to shake its head?
8. Has the horse had previous surgery?
9. Does the horse normally live in or out?
10. Does the horse have dry or soaked hay or a haylage preparation?
11. When was the horse last trimmed or shod?

Ideally vendors should sign a copy of their responses to these questions (Fig. 115-1).

When the examination actually is performed, ideally all involved parties or their agents should be present. This provides an environment in which the veterinarian can ask pertinent questions of the buyer and seller regarding the horse's history and future use and can assure the buyer a complete examination was performed. Problems that arise during the examination can be discussed with the purchaser.

The veterinarian should not compromise the standard of the examination because of physical conditions. If modifying the procedure of the usual examination technique is necessary, such should be noted in the subsequent report, and the purchaser should be advised accordingly. The limitations of the conclusions drawn from the examination should be documented. If an uncooperative vendor or agent makes conducting the usual examination difficult, the veterinarian may choose not to continue the examination to protect the interests of the buyer and personal interests.

EXAMINATION AT A DISTANCE

A client may request the veterinarian to examine a valuable competition horse that is a long distance away or possibly in a foreign country. A number of alternative strategies can be applied. It may be prudent to first have the horse undergo radiographic examination and proceed with visiting the horse only if these radiographs are considered acceptable. The veterinarian is of course relying on the honesty of everyone concerned that the radiographs provided are current images of the horse in question. It is critical that the veterinarian provide clear guidelines of the views required and be prepared not to compromise on quality. Alternatively, the veterinarian can travel and examine the horse and be present for the radiographic assessment. However, this may mean that the clinical examination is compromised by inadequate riding facilities at a veterinary clinic or that substantial time is spent traveling between the site where the horse is examined and the veterinary clinic where ancillary tests are performed. However, clinic facilities may be required anyway for ultrasonography or endoscopy.

A client may inform the veterinarian of an intended purchase of a horse from a foreign country and that he or she has been recommended to employ a specific clinician from that country to carry out the prepurchase examination. The client

should be warned that the method of carrying out and reporting the examination may differ from what he or she is used to seeing and may have limitations of which he or she is unaware. For example, in some countries in Europe the examination is much more limited and does not encompass assessment of conformation. It is not usual practice to examine the horse being ridden. It is worthwhile developing a group of professional colleagues whose clinical expertise and trustworthiness the veterinarian respects, one of whom can be recommended to the purchaser. The veterinary surgeon performing the examination should be requested to communicate with the client's own veterinarian and to send radiographs for assessment. Discussion between two colleagues, one of whom has examined the horse and the other who knows the client, can result in a highly satisfactory outcome.

CLINICAL EXAMINATION AT REST

Various national bodies have established guidelines for the way in which a prepurchase examination should be carried out and reported, to which the veterinarian obviously should adhere. The legal responsibilities for the veterinary surgeon and the vendor may vary in different countries. For example, in Holland the expectations of the veterinary examination performed on behalf of an amateur purchaser are higher than that for a professional purchaser. In Denmark, if clinically significant radiological abnormalities are discovered soon after purchase, which obviously predate the purchase, the vendor is liable.

The clinical examination should evaluate all organ systems as comprehensively as possible. The examination should be methodical and repeatable. Using a checklist may help. The principle aims of this chapter are to focus on the examination of the musculoskeletal and neurological systems[1,2] and to discuss the interpretation of abnormal findings.

The veterinarian should identify the horse, including name, breed, sex, age, markings, tattoos, freeze marks, brands, and height. In Europe a freeze brand L signifies that the horse has previously been a loss of use insurance case. The horse's identity should be compared with its passport or vaccination certificate.

The horse first should be examined in the stable, with assessment of demeanor, attitude, stance, conformation, and thorough observation and palpation of the head, neck, back, and limbs as described in Chapters 4 to 6. Collection of blood samples may be performed at this stage or when the examination is completed and the veterinarian deems that purchase will probably be recommended. More comprehensive evaluation of the feet, overall conformation, and evaluation of muscle symmetry is best performed outside, where the horse can be viewed better from all angles.

If the horse will be used for show purposes, when the cosmetic appearance of the horse is important, the veterinarian should draw the purchaser's attention to all possible abnormalities, such as a prominent head to the fourth metatarsal bone, that a lay judge may misconstrue as a curb. If the purchaser has expressed reservations about a swelling such as a splint, the veterinarian should be sure to document its size and possible significance. If the purchaser is concerned about the horse's hock conformation, recommending radiographic examination of the hocks is worthwhile, even if the veterinarian considers the conformation to be acceptable and the horse appears sound.

Conformation

Although assessment of conformation as far as it may influence future lameness is considered an important part of the examination in the United States and Great Britain, this is not usual practice, and in Holland, for example, is not included. It is important to recognize that breed differences in conformation exist and that what might be acceptable in one breed does not necessarily apply to others. The significance of conformational abnormalities in part is dictated by the discipline in which the horse is involved.[1]

Most Arabian horses have a short-coupled and slightly lordotic back; thus they are likely to have some degree of impingement of dorsal spinous processes. However, this is unlikely to compromise the horse's show performance. However, a dressage horse with a short back may well develop a clinical problem associated with impinging dorsal spinous processes when working at an advanced level. In such a horse the flexibility of the back at rest and when the horse is moving in hand and ridden must be assessed with great care, paying great attention to the freedom and elasticity of the gaits. Even if the horse is symptom free currently, the purchaser should be advised that problems may occur in the future.

Young Warmblood breeds have a relatively high propensity for intermittent upward fixation or delayed release of the patella, especially those with a straight hindlimb conformation. Although the condition may be manageable in some, in others it can become a chronic problem, albeit a subtle one, resulting in low-grade discomfort and unwillingness to work. The veterinarian should observe the horse carefully as it moves over in the stable, to assess smooth or jerky movement of the patella on the left and right sides, and should check carefully for a surgical scar and the size of the medial patellar ligament, which if enlarged is likely to reflect a previous desmotomy.

Very straight conformation of the hocks or abnormal extension of the hind fetlock joints are predisposing factors for proximal suspensory desmitis and suspensory branch injury. A purchaser should be advised not to proceed with purchase for any form of athletic activity except light pleasure riding. The examination should be terminated at this stage rather than the veterinarian running up a large bill and antagonizing the vendor by wasting more time.

The clinician should pay particular attention to the conformation of the feet and relate this to the type of ground surface on which the horse will have to work. A horse with flat feet and thin soles is not a good candidate for endurance riding. A horse with crumbly hoof walls is predisposed to losing shoes, and this can be disastrous for three-day event horses. Although changing the horse's nutrition and foot management may result in some improvement, accurate prediction of the degree of improvement that may be achieved is difficult. Sheared heels and underrun heels in the forelimbs or hindlimbs may be primary problems or predispose horses to altered ways of moving, causing soreness in the more proximal parts of the limbs. These findings are particularly important in jumping and dressage horses and those used for cutting and reining.

The veterinarian should assess the forelimb conformation carefully from the front and ensure that the foot is positioned symmetrically under the central limb axis of the more proximal parts of the limb. A disproportionately high incidence of distal limb joint problems occurs in horses in which the pastern and foot are set more to the outside, with a tendency for the medial wall to become more upright and the lateral wall flared (Fig. 115-2).

Many Warmblood breeds naturally have much narrower and upright foot conformation than other breeds. This predisposes the horses to develop thrush, and careful stable hygiene and foot cleanliness are necessary to control this problem. Asymmetry of front foot shape and size always should be documented and may reflect previous lameness in the limb with the more contracted foot but also may reflect development of a mild flexural deformity of the distal interphalangeal joint when the horse was a foal, which may be of no long-term significance. The veterinarian should beware if the feet are long and misshapen; this finding may mask underlying conformational problems or asymmetry in foot shape and size. Postponing further assessment of the horse until the feet have been trimmed and shod properly is preferable.

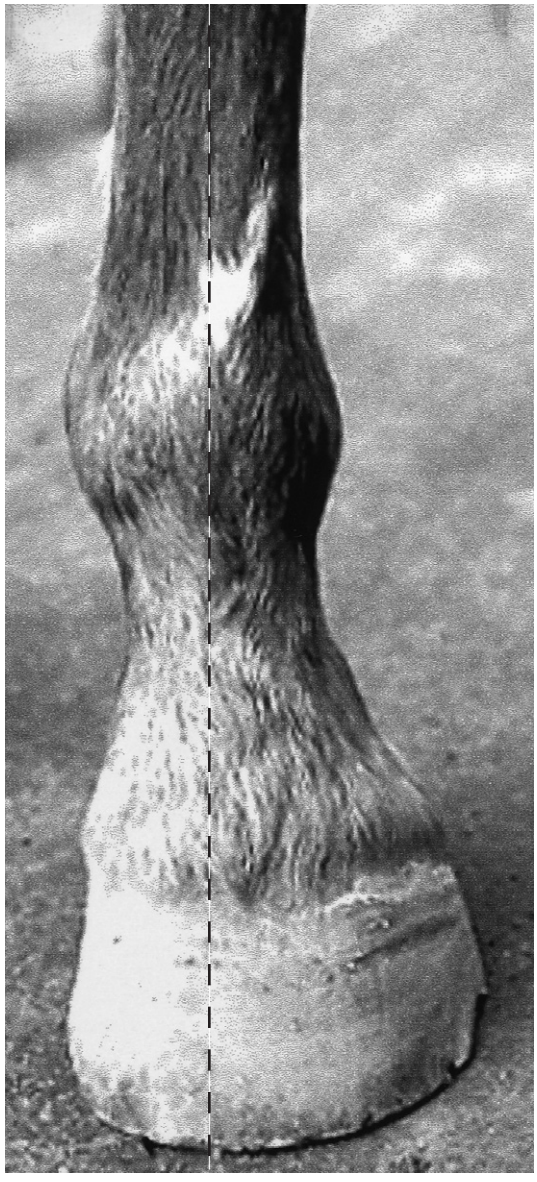

Fig. 115-2 Dorsal view of a forelimb with significant conformational abnormalities. Note the position of the foot and pastern relative to the central axis of the metacarpal region *(dotted line)*. The hoof capsule is distorted, and the foot shape is asymmetrical.

Some conformational abnormalities, such as over at the knee, do not appear to influence a horse's future soundness greatly but must be described. Failure to document observations leaves the veterinarian open to litigation if future problems arise.

Muscle Symmetry

Muscle asymmetry of the hindquarters may reflect previous or current hindlimb lameness, although it is not necessarily associated with future chronic lameness. Muscle asymmetry should alert the veterinarian to pay particular attention to the hindlimb gait in hand, on the lunge, and ridden and to the response to flexion tests. Asymmetry is an indication for flexion tests before and after ridden exercise. The potential significance of muscle asymmetry must be discussed with the purchaser. Slight asymmetry of the tubera sacrale is a common finding and frequently is not of clinical significance. Nonetheless, the purchaser should be informed.

Tendons and Ligaments

Particular attention should be paid to the size, shape, and stiffness of the tendonous and ligamentous structures of the metacarpal and pastern regions, bearing in mind that if the horse has sustained a bilateral tendon injury, both tendons may be enlarged slightly, and the clue to previous damage may be rounding of the margins of the tendons or abnormal stiffness. The significance of a previous injury to the SDFT or suspensory ligament must be assessed in the light of the horse's previous and future career. These injuries carry a high risk of recurrence in racehorses, event horses, high-level show jumpers, and endurance horses. However, the horse may perform satisfactorily as a hunter, a dressage horse, or a pleasure horse or at a low level in more demanding sports. The purchaser should be advised that further information about the repair of the injury may be obtained by ultrasonographic examination. Further information about when the injury was sustained and what the horse has done since then may be helpful. Decision making must be based on the athletic expectations of the horse, all other aspects of the horse's suitability, and whether the horse is being bought for resale. If the horse is a perfect schoolmaster for a junior rider and the price is reasonable, the risk/benefit ratio may be acceptable.

Assessment of Joints

Many horses have mild fetlock joint capsule distention or thickening. The significance of distention must be assessed based on the environmental temperature: if it is cold joint capsules are more likely to be tight than if it is warm. Asymmetry between left and right is of greater significance than bilateral symmetry. The joints should be assessed carefully for any evidence of restricted range of motion or pain on manipulation. The range of motion varies between horses and is in part a reflection of age and work history, but asymmetry between left and right should be viewed with caution. The response to distal limb flexion and the horse's action on the lunge on a hard surface must be assessed carefully. Distention of the antebrachiocarpal or middle carpal joint capsules is rarely an insignificant finding and even if unassociated with detectable lameness should prompt radiographic examination.

During hindlimb assessment, care should be taken to differentiate between pain on flexion of the proximal limb joints and reluctance to stand on the contralateral hindlimb, perhaps associated with sacroiliac pain. Abnormal limb flexion may be present if the horse is a shiverer. A high incidence of this condition occurs among high-performance Warmblood breeds and does not appear to compromise performance. However, an intending purchaser must be warned that the condition may be progressive and may make the horse difficult to trim and shoe.

Flexibility of the neck and back should be assessed, and the presence of any abnormal muscle tension or abnormal reaction to palpation of acupuncture trigger points should be noted. The veterinarian also should pay attention to the presence of sarcoids in a position where they may be abraded by tack. If a sarcoid is identified, the client always must be warned that such lesions may increase in number, but assuming that the client is aware of the risks, a small number of lesions at sites removed from the tack should not mitigate against purchase. The mouth should be examined carefully. Large hooks on the rostral aspect of the first upper cheek teeth are usually an indicator that large hooks also may be present on the caudal aspect of the lower caudal cheek teeth, which may be difficult to manage.

Sensation in the heel region of the forelimbs and the reaction to vigorous application of hoof testers should be assessed carefully to determine if a previous neurectomy may have been performed. The absence of a visible or palpable scar does not preclude previous surgery.

ASSESSMENT OF GAIT

The horse should be examined moving freely at a walk and trot on a firm surface, with particular attention directed to the stride length and lift to the stride relative to the horse's type. The veterinarian should bear in mind that a horse with a bilateral forelimb or hindlimb lameness may not appear overtly lame but merely may have a slightly restricted gait. The veterinarian should beware of the situation encountered particularly in a professional's yard when the horse is encouraged by an assistant to trot excessively quickly, is unduly restrained, or is excessively fresh and trots crookedly. The horse must trot in a regular, relaxed rhythm with freedom of the head and neck; otherwise, lameness may be missed. The veterinarian should pay particular attention to how easily the horse turns when changing direction and the flexibility of the neck and back. If the horse trots in a particularly loose and extravagant way, the veterinarian should bear in mind that the horse may be mildly ataxic. Ataxia may not jeopardize a dressage horse when competing at lower levels, but when finer degrees of muscular strength and coordination are required in advanced dressage, performance may be compromised. The safety of a mildly ataxic horse jumping must be questioned. The veterinarian should watch the horse carefully as it decelerates, when signs of mild ataxia or jerky movement of the patella associated with its delayed release may be apparent. Watch the horse turning in small circles and moving backward, assessing flexibility of the neck and back, limb coordination and placement, and any quivering movement of the tail suggestive of shivering.

Flexion Tests

The interpretation of flexion and extension tests is controversial.[3,4] The force applied, the duration of flexion, the way in which the joints are flexed, and the work history of the horse may all influence the response. Positive results of flexion tests in a horse that does not demonstrate lameness before flexion may not be a cause for termination of the examination, unless other suspicious clinical signs have been identified already. The horse should be evaluated on the lunge and ridden for evidence of lameness. Many positive results on flexion tests are found to change during the course of the exercise examination (perhaps as the horse warms up or loosens up), and these may not have clinical significance. A difference in response between distal limb flexion of the left and right forelimbs may be more important than a symmetrical response. A positive response to carpal flexion or to proximal limb flexion of a hindlimb must be viewed with caution. A veterinarian should aim to perform flexion tests as consistently as possible so that they know the ranges of response anticipated in clinically normal horses.

Lunging and Ridden Exercise

The requirements for lunging and ridden or driven exercise vary between the guidelines for prepurchase examinations in different countries and also are dictated by the type of horse under examination. The methods used for a 3-year-old Thoroughbred racehorse differ from those for a 6-year-old destined for horse trials. Seeing the horse lunged on soft and hard surfaces and ridden is helpful to gain maximum information about any potential lameness problems. The vendor should be encouraged to use any protective boots or bandages that might be used normally. Subtle lameness or restriction in gait because of thoracolumbar or sacroiliac discomfort may not be evident until the horse performs specific movements when it is ridden.[5,6] Small figures of eight may be particularly revealing. Watching the horse do what it specifically is intended to do is good practice. The veterinarian should watch the horse being tacked up and mounted to learn about any cold back behavior or evidence of back pain or other behavioral abnormalities. The horse should be worked reasonably hard relative to its fitness. In many European countries, evaluating a ridden horse is not standard practice, and if an examination is being performed on behalf of the client by a foreign veterinarian, the client should be advised accordingly.

Clinicians who have the prerequisite skill and experience may wish to evaluate horses further by riding or driving them themselves. Feeling the horse in this fashion may answer questions regarding a peculiar gait or way of going and may aid the evaluation of subtle lameness or respiratory noises. Such practice should be done with caution, because legal problems could arise from an unfortunate accident. A signed disclaimer may be helpful in this situation.

After strenuous exercise the horse should be allowed to stand for 15 to 20 minutes before being re-evaluated in hand at the walk and the trot. This is a mandatory part of the examination in Great Britain but is not practiced widely in the rest of Europe. Previously inapparent lameness now may become evident. Any previously questionable response to flexion tests may be re-assessed.

EVALUATION OF IDENTIFIED PROBLEMS

The veterinarian should now have gained enough information either to discontinue the examination after consultation with the purchaser or to make recommendations for further special examinations. If the horse is lame and a potential cause that may resolve is obvious (e.g., nail bind), re-evaluating the horse on a subsequent occasion may be worthwhile, but the veterinarian should try to ensure that the horse has been worked properly for several days before the re-examination.

The veterinarian should always bear in mind that in a mature competition horse, it is relatively unusual not to identify some problems. Taking no risks and advising against purchasing the horse is easy, but that actually may be doing the purchaser, the vendor, and the veterinary profession a disservice. It is important to weigh the risks and describe them to the purchaser as objectively as possible, based on previous experience. At this point having in-depth knowledge of the purchaser, his or her aspirations for the horse, and the attitude to risk and financial ability to take the consequences of risk is most valuable. Further information obtained from radiographic and ultrasonographic examinations may help provide further objective information on which decisions can be based. Decisions also must be related to the horse's recent competition record, its age, and the future expectations for athletic performance. Low-grade hindlimb lameness associated with mild radiographic changes of the distal hock joints might be an acceptable risk for a horse as a schoolmaster for a young rider, but similar abnormalities identified in a 6-year-old about to step up a level in competition must be regarded as potentially more serious. A veterinarian always must bear in mind that minor problems may become major problems with a change of rider, work pattern, and environment.

RECTAL EXAMINATION

Rectal examination is not a routine part of a prepurchase examination and should be performed only with the vendor's consent if indicated clinically or if a mare is to be used later for breeding.

RADIOGRAPHIC EXAMINATION

Radiographic examination is not a standard part of a prepurchase examination. The extent of routine radiographic examination in the United States and some European countries is probably higher than elsewhere. In Holland a strict grading system for evaluation of radiographs is used. The purchaser

must be made aware that the presence of some radiological abnormalities is not necessarily synonymous with future lameness and the absence of radiographic changes does not preclude future lameness.[7] If radiographs are to be obtained for a specific area, then a comprehensive set of radiographs should be ordered to avoid missing lesions apparent on only one view. In many European countries, obtaining only three views in evaluation of the hocks and omitting a dorsomedial-plantarolateral oblique view is common. This action may risk the veterinarian missing lesions such as peri-articular osteophytes, which are present only on the dorsolateral aspect of the joints (Fig. 115-3).

The regions to be examined and the interpretation of findings are dictated by the previous and intended career of the horse and the results of the clinical examination. Examination of the front feet, fetlock, and hock joints is considered routine in many countries. Evaluation of the carpi, hind fetlock and pastern joints, stifles, and dorsal spinous processes of the thoracic region may be considered. It is, however, important not to overinterpret the significance of some radiographic abnormalities, bearing in mind the variability between breeds and the knowledge that even some obvious changes may be clinically insignificant. For example, Warmblood breeds have a tendency to have a greater number of lucent zones along the distal border of the navicular bone than do Thoroughbreds (Fig. 115-4). A relatively high incidence of spur formation on the dorsoproximal aspect of the middle phalanx occurs in Warmbloods (Fig. 115-5), but this rarely is associated with lameness. However, one of the authors (R.D.M.) recognizes a higher incidence of clinically significant osteoarthritis of the proximal interphalangeal joint in Warmblood horses compared with other breeds.

Evidence of abnormal lucent zones in the proximal sesamoid bones (sesamoiditis) (Fig. 115-6) should alert the veterinarian to re-evaluate the branches of the suspensory ligament. An ex-racehorse may have periosteal new bone on the dorsal aspect of one or more carpal bones, but this is unlikely to influence the horse's career as an event horse. A small osteochondral fragment on the dorsal aspect of the distal interphalangeal or metacarpophalangeal joint is often asymptomatic.

A small spur on the dorsoproximal aspect of the third metatarsal bone (MtIII) is a frequent incidental finding. However, such findings also must be described to the purchaser, and the potential future significance must be discussed. Small spurs on the dorsoproximal aspect of MtIII do not necessarily reflect osteoarthritis but may reflect entheseous new bone at the attachment of the fibularis tertius or cranialis tibialis. Despite the fact that these spurs are a common finding, accurately predicting the future behavior is impossible. Some spurs may reflect osteoarthritis and may be progressive (see Fig. 115-3). Small osteochondral fragments at the distal intermediate ridge of the tibia in a 3-year-old that has done little work may be asymptomatic, but if they became unstable with increased work, it might result in distention of the tarsocrural joint capsule, and surgical removal may be indicated. Such a finding in a mature competition horse is usually of no consequence. Complete fusion of the centrodistal joint may be identified

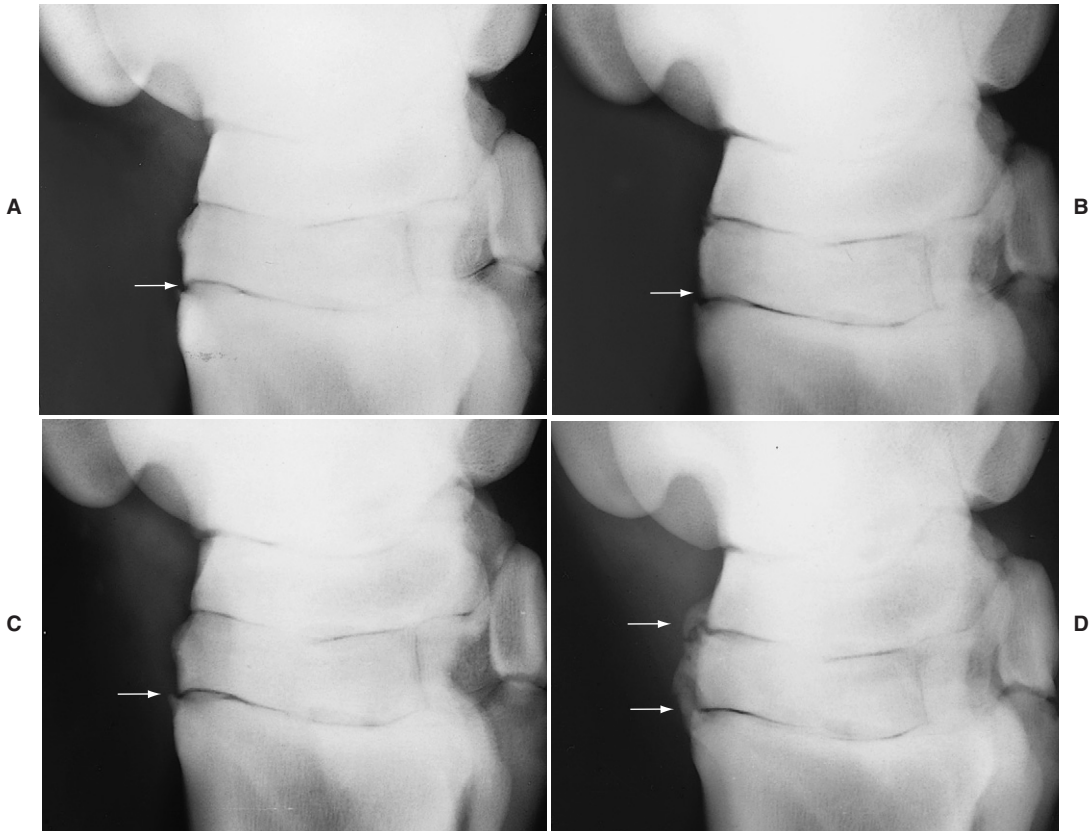

Fig. 115-3 Plantarolateral-dorsomedial oblique radiographic views of the left (**A**) and right (**B**) hocks of 9-a year-old Grand Prix show jumper. There is a small osteophyte on the proximal aspect of the third metatarsal bone *(arrow)*, and subtle modeling of the articular margins of the centrodistal joint in each hock. The horse was clinically sound. **C** and **D,** The same horse 24 months later. At this stage the horse showed right hindlimb lameness that was alleviated by intra-articular analgesia of the tarsometatarsal joint. Considerable peri-articular osteophyte formation *(arrows in **D**)* involves the centrodistal and tarsometatarsal joints of the right hock (**D**). The spur on the dorsoproximal aspect of the left third metatarsal bone was changed little *(arrow)*.

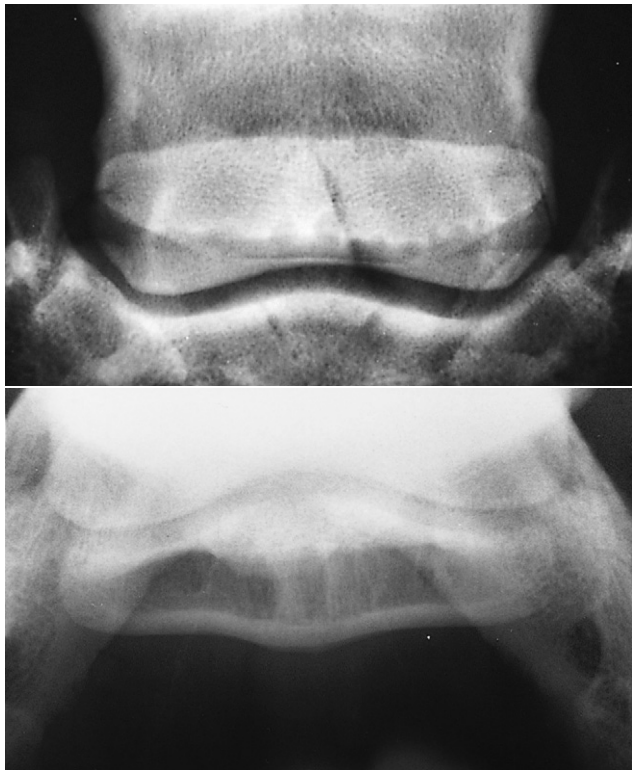

Fig. 115-4 **A,** Dorsoproximal-palmarodistal oblique view of the right front foot of a clinically normal 6-year-old Dutch Warmblood horse with good foot conformation. Note the large size and number of the radiolucent zones along the distal border of the navicular bone. The horse competed successfully for many years with no evidence of foot pain. **B,** Palmaroproximal-palmarodistal oblique view of the same foot. Note the large, oval-shaped lucent zones in the medulla of the navicular bone.

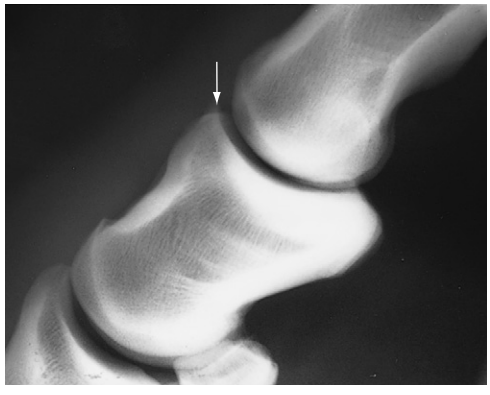

Fig. 115-5 Lateromedial radiographic view of the left front pastern of a clinically normal 7-year-old Belgian Warmblood show jumper. Note the modeling of the dorsoproximal aspect of the middle phalanx *(arrow)*. Such spurs are a common finding in Warmblood breeds and usually are not associated with lameness.

unassociated with any other radiological change of the hock (Fig. 115-7). Some horses may compete successfully with such changes for many years, but occasionally lameness subsequently develops because of pain associated with the talocalcaneal-centroquatral (proximal intertarsal) or tarsometatarsal joints. Well-rounded osseous opacities frequently are identified distal to a proximal sesamoid bone (Fig. 115-8). These are often innocuous, but ultrasonographic evaluation of the distal sesamoidean

Fig. 115-6 Dorsolateral-palmaromedial oblique view of a 6-year-old Thoroughbred that had raced previously on the flat and was used now for eventing. Note the large lucent zones in the lateral proximal sesamoid bone. The horse had no history of lameness.

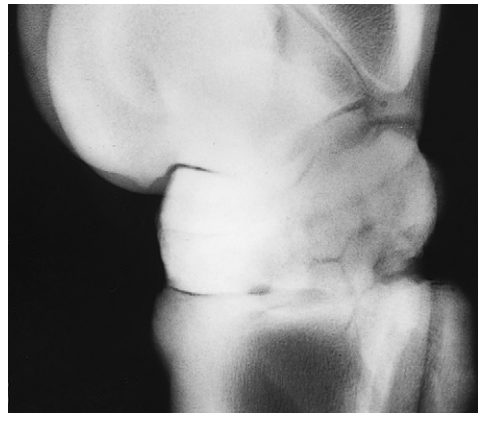

Fig. 115-7 Lateromedial radiographic view of the left hock of a 9-year-old clinically normal Thoroughbred advanced event horse. The centrodistal joint is fused completely. The horse competed successfully for another 8 years before being retired because of a tendon injury.

ligaments may be indicated. Evidence of osteochondrosis of the trochleas of the femur is of concern in a 3-year-old, even if the condition is asymptomatic, whereas mild flattening of the lateral trochlear ridge of the femur in a 10-year-old jumper free from lameness would be of no concern.

NUCLEAR SCINTIGRAPHIC EXAMINATION

Nuclear scintigraphic examination is not a routine part of a prepurchase examination. If the horse is clinically normal, the interpretation of results of whole body screening is difficult. This practice should be discouraged. In selected horses when interpretation of the significance of specific radiological abnormalities may be in dispute, focused nuclear scintigraphic examination may be helpful.

ULTRASONOGRAPHIC EXAMINATION

Ultrasonographic examination of the limbs requires three important pre-requisites: high-class image quality, experience of

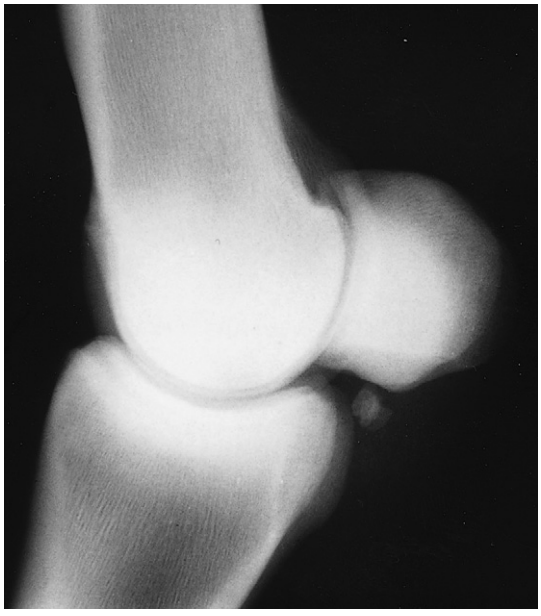

Fig. 115-8 Lateromedial radiographic view of the left forelimb of a clinically normal 7-year-old Thoroughbred. There are two well-rounded osseous opacities distal to the proximal sesamoid bones. Such opacities are usually clinically innocuous.

interpretation (knowledge of normal anatomy and its variations and the ability to detect abnormality and to interpret its potential significance) and client compliance. A number of clinical situations occur in a prepurchase examination when ultrasonographic examination provides invaluable clinical information not otherwise available. These situations include the following:

- An event horse that has competed in a three-day event within the last 6 months but has not competed since or a racehorse that has run recently but has not done fast work since. Strain of the SDFT, unilaterally or bilaterally, is a common injury in event horses and racehorses. Clinical signs of localized heat and swelling may resolve quickly or even pass unnoticed by the vendor (see Chapter 70). Clinical signs of tendonitis may be inapparent at the prepurchase examination but may become evident when fast work is resumed. If the left and right SDFTs are slightly enlarged with rounded margins but are symmetrical, this may pass unnoticed during the clinical evaluation.
- An event or racehorse that has not competed or raced in the last several months during the season. The purchaser may have given a plausible explanation for this, but the clinician should be suspicious that the absence from competition may reflect injury.
- Known previous tendon or ligament injury. Ultrasonographic examination gives more objective information than can be obtained from palpation alone but does not give information about strength of the structure.
- Suspected enlargement of one or more tendonous or ligamentous structures, detection of localized heat, or pain on palpation.
- Moderate enlargement of a digital flexor tendon sheath, especially if unilateral, particularly in a forelimb.
- Enlargement on the palmar (plantar) aspect of the pastern. It can be difficult to determine by palpation alone if thickening reflects localized fibrosis or swelling of a tendon or ligament.

Interpretation of findings in a horse with no identifiable clinical abnormality may not be straightforward, but enlargement of a tendon or ligament usually does reflect previous injury, the future significance of which depends on the intended use of the horse, chronicity of the lesion, severity of the lesion, and degree of healing.

If ultrasonographic examination is recommended but is refused by the vendor or the purchaser, this should be noted on the prepurchase examination certificate.

THERMOGRAPHIC EXAMINATION

Thermography also may provide a useful indicator of low-grade inflammation and help to identify signs of early tendonitis, suspensory desmitis, and splint development. However, a normal thermographic appearance does not preclude the presence of a subclinical tendon lesion.

BLOOD TESTS

The use of blood tests is controversial, and limitations should be discussed with the prospective purchaser. Screening for non-steroidal anti-inflammatory drugs, mood-altering drugs, sedatives, and possibly also corticosteroids is advisable, but the purchaser must be aware that blood tests are less sensitive for these drugs and metabolites than is urine analysis. If the vendor knows in advance that the horse will be tested, this knowledge may provide a deterrent to the unscrupulous. Alternatively, blood may be collected and stored suitably and be analyzed only if a problem arises within the first few weeks of purchase. In Great Britain the Veterinary Defence Society and the Horse Race Forensic Laboratory run a scheme jointly. The vendor signs a form to permit collection of the sample in a specialized container provided by the Horse Race Forensic Laboratory, to which is applied a bar-coded label. The purchaser can elect to have the sample analyzed immediately for a fee or it can be stored at the Horse Race Forensic Laboratory at no charge with the potential for analysis at a later date. This system has proved to be legally robust.

The purchaser must be aware that drugs administered intra-articularly may not be detectable, depending on the nature of the drug and the time of administration relative to the time of examination. In professional dealers' yards in Europe, a high incidence of joint medication to mask lameness occurs.

If the horse is being purchased in one country for export to another, testing for evidence of specific diseases may be necessary. For example, horses entering the United States should be tested for equine infectious anemia, dourine, glanders, and piroplasmosis. A horse from an area where African horse sickness has occurred should be tested. Screening for contagious equine metritis may be indicated. Use of hematological and serum biochemical screening and other assays, such as measurement of cortisol and insulin, as an aid to detect equine Cushing's syndrome in older horses is controversial. Serum testing for equine protozoal myelitis potentially is misleading and should be actively discouraged.

NERVE BLOCKS

In some circumstances, nerve blocks may aid interpretation of clinical findings. A horse may appear completely sound under all circumstances but have an unusually short forelimb stride. Does this reflect bilateral foot pain, or is this gait completely normal and natural for this horse? With the vendor's permission this question could be answered by bilateral perineural analgesia of the palmar nerves at the level of the proximal sesamoid bones.

If a horse is lame, but the vendor claims that the horse has never been lame previously, the situation should be discussed with the purchaser. Re-examining the horse on a subsequent occasion may be best, but the vendor should be advised that

after resolution of the lameness the horse must be worked for at least a week before re-assessment. The veterinarian should ask the vendor to sign a form declaring that the horse has been worked properly and has not received medication, and the veterinarian should collect blood for medication testing when the horse is re-examined.

The examining veterinarian's role is not to perform a lameness investigation; this would be unethical. A lameness investigation is a job for the vendor's own veterinarian.

SUMMARY OF OBSERVATIONS

The veterinarian should summarize the basic assessment of the horse's physical condition for the buyer. Abnormalities of conformation, insignificant swellings, and any clinical abnormality should be discussed and documented. The initial report should be made verbally to the client or the client's agent. When dealing with an agent, informing the agent that the client also will be receiving a complete written report is wise. Comments should be as factual as possible, with minimal personal bias, but findings must be interpreted and the risk assessed and documented.

Although the veterinarian is working for the buyer, the veterinarian does have an obligation to the seller. The findings should not be discussed with anyone other than those involved in the sale. With permission of the buyer, the veterinarian can divulge any and all information to the seller.

A written report reviewing the findings of the examination should be provided to the buyer. The American Association of Equine Practitioners has an excellent set of guidelines for reporting the prepurchase examination. This report can serve as documentation of significant findings for future reference.

The veterinarian should advise the buyer about the risks of purchase, without making the decision for the buyer. The veterinarian is not responsible for assessment of the suitability of the horse for a rider or for determining an appropriate value for the horse. However, if the horse is clearly likely to be unsuitable for the purchaser because of temperament or ease of management or riding, the purchaser should be advised accordingly.

GUIDELINES FOR REPORTING PREPURCHASE EXAMINATIONS

The American Association of Equine Practitioners has approved the following guidelines for reporting equine prepurchase examinations. The spirit of these guidelines is to provide a framework that aids the veterinarian in reporting a purchase examination and to define that the buyer is responsible to determine if the horse is suitable. These guidelines are neither designed for nor intended to cover any examinations other than prepurchase examinations (e.g., limited examinations at auction sales and other special purpose examinations such as lameness, endoscopic, ophthalmic, radiographic, and reproductive examinations). Although compliance with all of the following guidelines helps to ensure a properly reported prepurchase examination, the veterinarian has the sole responsibility to determine the extent and depth of each examination. The American Association of Equine Practitioners recognizes that for practical reasons not all examinations permit or require veterinarians to adhere to each of the following guidelines.

1. All reports should be included in the medical record.
2. The report should contain the following:
   a. A description of the horse with sufficient specificity to identify it fully.
   b. The time, date, and place of the examination.
3. The veterinarian should list abnormal or undesirable findings discovered during the examination and give his or her qualified opinions as to the functional effect of these findings.
4. The veterinarian should make no determination and express no opinion as to the suitability of the animal for the purpose intended. This issue is a business judgment that is solely the responsibility of the buyer that he or she should make on the basis of a variety of factors, only one of which is the report provided by the veterinarian.
5. The veterinarian should record and retain in the medical record a description of all the procedures performed in connection with the prepurchase examination, but the examination procedures need not be listed in detail in the report.
6. The veterinarian should qualify any finding and opinions expressed to the buyer with specific references to tests that were recommended but not performed on the horse (x-rays, endoscopy, blood and drug tests, EKG, rectal examination, nerve blocks, laboratory studies, and so on) at the request of the person for whom the examination was performed.
7. The veterinarian should record and retain the name and address of parties involved with the examination (buyer, seller, agent, witness, and so on).
8. A copy of the report and copies of all documents relevant to the examination should be retained by the veterinarian for a period of years not less than the statute of limitations applicable for the state in which the service was rendered. Local legal counsel can provide advice as to the appropriate period of retention.

CHAPTER • 116

Lameness in the Show Hunter and Show Jumper

Robert P. Boswell. Richard D. Mitchell, and Sue J. Dyson

HISTORICAL PERSPECTIVE

Show jumping and related competitions have origins in hunting sport and military tradition. The show hunter, most popular in North America, has evolved from the traditions of fox and stag hunting. These horses were expected to provide fast, safe, and athletic passage for the rider, and considerable pride was taken in being well mounted and having the horse admired. Today in the showring these horses are judged for beauty, athletic ability, manners, and way of going. Jumping style is important and must be coupled with consistent performance.

Some competitions encourage the development of a young horse to a higher level of training, others award a mature horse for outstanding performance, and others separate amateur and professional riders. Horses often are selected based on suitability for a particular division of competition.

The modern show jumper has many of its origins with military traditions. Many cavalry officers were by necessity highly skilled and accomplished horsemen. Thus when the era of the modern Olympics began, the equestrian competitors were military men. With the mechanization of the military and the replacement of the cavalry with motorized transport, the private sector became more involved in Olympic show jumping. Many of the early civilian competitors were retired military men. Show jumping has become increasingly more popular, and many talented riders have emerged on the national and international scenes. Since the 1960s many women have entered the sport once dominated by men.

STRUCTURE OF THE SPORT

Show jumping combines athletic effort of the horse and rider. The scoring process is objective, with the winner jumping the course with the fewest rails knocked down and, in the jump off, in the fastest time. Heights of fences range from 1 m at novice level to 1.7 m for advanced competitions. As the jumps get bigger, the potential for injury increases, and many conditions develop from repetitive strain. Many of the fences are set at distances to each other so that the horse must adjust stride length to fit in the appropriate number of strides. A good horse must have explosive power and great athleticism, combined with carefulness—a desire not to hit fences. Contrary to many equine sports, similar numbers of mares and geldings or stallions compete.

Some older horses compete at levels of competition lower than they have reached to be schoolmasters for less experienced riders. These older horses may experience unique problems related to age and use. Today show jumping is a highly diverse and competitive sport enjoyed all over the world from beginners to the level of the Olympic Games. At the top level the sport is entirely professional, with horses changing hands for huge prices and with large amounts of prize money available, putting pressure on the veterinarian to keep horses sound. Competition continues throughout the year with outdoor shows during the summer months and indoor shows during the winter, so horses potentially get little break.

CHARACTERISTICS OF THE JUMPING SPORT HORSE

Many breeds are capable of show jumping and related activities and include Thoroughbred, European Warmbloods, Thoroughbred/Warmblood crosses, and American Quarter Horses and related crosses. The European Warmbloods most often are represented by the Hanoverian, Holsteiner, Trakhener, Dutch Warmblood, Selle Français, Swedish Warmblood, and Irish crossbred breeds. Breeding in continental Europe has become highly specialized and has developed in part through financial support from state governments. Most modern day top-level show jumpers are naturally well-balanced, good-moving athletes. Various pony breeds, such as the Welsh crosses, are used for children (see Chapter 127).

Current preferences are for lighter and taller horses than previously, with moderate muscling. This body type is associated with greater speed and agility, which are assets to a modern show jumper. This body type also benefits hunters because they have graceful movement, with good extension and natural balance. Larger horses, if not excessively heavy, are at an advantage for show jumping because of greater stride length and overall strength and explosive power. The Thoroughbred long has been preferred by American trainers for the hunter ring; however, in recent years Warmblood breeds and American Quarter Horses have gained favor because of a calmer nature and better manners.

Horses often start competing at 4 years of age, reach peak ability at 9 to 12 years of age, and may continue to compete until 18 to 20 years of age, therefore the competition career is exceptionally long.

TRAINING

Training of the hunter/jumper emphasizes using the hindquarters for engagement and collection, which places more weight and stress on the hindlimbs as they are brought forward and under the rider during locomotion. Such a posture is somewhat unnatural for the horse, whose normal inclination is to distribute weight over the forehand. These stresses may contribute to or accelerate the development of problems of the thoracolumbar and pelvic regions and joints of the hindlimbs. Early in the training of a young horse, lameness often reflects musculotendonous problems and relates to lack of accommodation to work.

When training over fences begins, new loads on the hindlimbs occur that place more stress on soft tissues and joints. Stresses on the forelimbs also are increased because they are involved in takeoff and landing. The forelimbs are involved in setting up the jump and aiding in the directional change from horizontal to vertical. On landing the forelimbs

receive considerable impact loads and absorb the entire weight of the horse. Increased load places stress on the foot, joints, and the soft tissues.

Horses must learn to adjust stride length by shortening or lengthening the stride, to jump from a line perpendicular to a fence or at an angle, to turn quickly, to change leading legs in canter, and to jump from variable speeds of approach. Unwillingness to change leads or always favoring one lead when landing after a fence may indicate a problem (see Chapter 100). Much of the basic flat work training is similar to dressage.

Many lameness conditions encountered early in a horse's training begin as subtle performance-limiting problems, progress relatively slowly, and may disappear with further conditioning. However, excessive training leads to the development of important problems such as chronic muscle soreness, fatigue, and behavioral changes. Slow, steady work with a gradual buildup in exercise intensity and duration results in fewer joint and soft tissue problems later.

TRAINING AND COMPETITION SURFACES

Training, warm-up, and competition surfaces may play a substantial role in the development of lameness in a jumper. Soft, deep footing requires much more effort by the horse and is responsible for early fatigue of muscles, tendons, and ligaments. Injuries include gluteal muscle strain and spasm, suspensory desmitis, desmitis of the accessory ligament of the deep digital flexor tendon (ALDDFT), and superficial digital flexor tendonitis. Sandy soils contribute to the development of hoof wall problems. Hard surfaces may result in bone- and joint-related injuries, including foot problems such as subsolar bruising, distal interphalangeal joint synovitis, and osteoarthritis of the proximal interphalangeal and distal interphalangeal joints.

Most outdoor competitions in Europe take place on grass, with a few of the higher-level competitions taking place on all-weather surfaces. The nature of the footing depends highly on the weather and can vary extremely. To enhance traction, screw-in studs often are used in the front and hind shoes. Studs may be used in the medial and lateral branches of the shoe or just the lateral branch to reduce risk of interference injuries. If studs are used in only one branch of the shoe, this immediately creates mediolateral imbalance and the potential for abnormal torque. Studs also alter the dorsopalmar balance, especially if the ground is firm. Horses that flex the carpi excessively during jumping may have to wear a girth guard to protect the sternal region from self-inflicted injuries. If a horse is jumping on firm going, studs concentrate the forces of impact and can predispose the horse to deep-seated bruising of the foot. There is a tendency in horses with poor quality horn for the hoof wall to break in the region where studs are placed.

Excessive work, such as long period of lunging a hunter to calm it down, prolonged competitive efforts, and long show schedules of repeated competitions play a role in the development of many injuries in hunters and jumpers.

Conformation and Lameness

Conformational abnormalities of the foot predispose horses to lameness. Underrun heels, long toe, and a broken hoof-pastern axis frequently contribute to palmar heel pain and distal interphalangeal joint synovitis. Horses with improper medial-to-lateral hoof balance may develop sheared heels, crushed bars, and chronic foot pain. Base-wide or base-narrow forelimb conformation may contribute to injuries to the suspensory ligament (SL), its branches, and the distal sesamoidean ligaments.

Toe-in or toe-out forelimb conformation may predispose horses to proximal interphalangeal and metacarpophalangeal joint problems. Short, more upright pasterns predispose horses to navicular disease and distal interphalangeal joint and proximal interphalangeal joint synovitis or osteoarthritis. These horses are often straight through the shoulder as well and lack the stride and extension necessary for jumping. Long, more sloping pasterns sometimes are associated with sesamoiditis and soft tissue injuries to the distal limb.

Over-at-the-knee conformation may predispose horses to SL strain and should be avoided in selecting a jumper. Offset-knee conformation predisposes a jumper to medial splint problems. However, attention always should be paid to subclinical contralateral hindlimb lameness in a mature horse that develops an acutely painful medial splint bone. Subtle angular limb deformities are rarely a problem, provided proper attention is paid to shoeing and hoof balance.

Extremely sickle-hocked conformation is associated with weak hindlimbs and places more stress on the plantar ligaments and the centrodistal and tarsometatarsal joints. A straighter hock is actually more desirable, but an overly straight hock may predispose to SL strain and distal hock joint pain.

Horses that are extremely straight through the stifle are poor jumping prospects and have a high incidence of instability and upward fixation of the patella. A more angular stifle gives the horse a longer, more powerful stride and is thought to provide more strength for jumping.

A long, sloping hip and croup are desirable characteristics in a jumping horse, providing strength and power. Horses with a flat croup often suffer from thoracolumbar and sacroiliac pain. Asymmetry of the tubera sacrale and tubera coxae can be seen in the absence of lameness and may reflect previous trauma. An experienced rider usually can manage these horses.

Horses with excessively base-wide or base-narrow hindlimb conformation place abnormal stress on the feet and joints. Base-wide horses may have an increased incidence of hock problems, whereas base-narrow animals may suffer more from stifle problems.

SHOEING CONSIDERATIONS

Many lameness problems are a direct result of trimming and shoeing. Neglected feet are frequently a source of lameness, and a poorly shod foot also may contribute to lameness by forcing the horse to transfer abnormal and excessive stresses to other parts of the limb or to other limbs. Many of the Warmblood breeds have relatively tall, narrow upright feet, which are predisposed to the development of thrush and sheared heels. Studs in the shoes may create foot imbalance and may increase the severity of interference injuries. A good cooperative relationship with an experienced farrier is an essential element in lameness prevention and management. This can be a problem for top-level competition horses that are constantly moving from show to show and are being trimmed and re-shod by different people with varying talent.

TEN MOST COMMON LAMENESS PROBLEMS

The following are the 10 most common lameness problems of show hunters and show jumpers:

1. Palmar foot pain
2. Distal hock joint pain
3. Osteoarthritis of the distal interphalangeal joint
4. Proximal suspensory desmitis
5. Thoracolumbar and sacroiliac pain
6. Osteoarthritis or trauma of the metacarpophalangeal joint

7. Stifle pain
8. Osteoarthritis or trauma of the proximal interphalangeal joint
9. Gluteal myositis
10. Superficial digital flexor tendonitis and desmitis of the ALDDFT

Many of these problems are interrelated, and more than one problem may occur simultaneously. We have attempted to list these in relative order of frequency; however, this is not intended to imply that one is more serious than another.

LAMENESS EXAMINATION

Before examining a horse for a suspected lameness problem, several factors should be considered. If the horse is currently competing, will any diagnostic tests or treatment have an effect on the horse's ability to continue competition? Knowledge of the competition rules and drug use guidelines are essential. Has the horse recently competed? Has a change in exercise intensity or duration been made? Does the horse have a new trainer? When was the horse last shod? If the horse has been competing away from home, it is important to determine if another veterinary surgeon already has examined and treated the horse, and if so with what.

The lameness examination should begin as the horse is walked from the stall or paddock, because movements such as a small circle to reverse its direction may offer clues as to which limb or limbs may be affected. The horse should be examined at the trot in hand on a firm, level surface; lunging in small circles in both directions on firm footing may exacerbate subtle lameness. It is sometimes necessary to see the horse ridden to determine which limb is lame.

Proximal and distal limb flexion tests are performed on all limbs. The method and duration of flexion is a personal preference but should be consistent and interpreted with care, bearing in mind that joints and soft tissue structures may be stressed simultaneously. It has become common practice for top-level competition horses to be examined periodically throughout the year to try to detect early warning signs of impending problems. A positive response to flexion is often followed by treating the stressed joint(s). The true value of this practice is difficult to determine objectively.

The response to hoof testers is assessed, and each limb is palpated systematically. An obvious source of pain may be identified, but perineural or intra-articular analgesia often is required to determine the sources of pain. Results are sometimes confusing and always should be related to the clinical examination.

Aseptic preparation is essential for intrasynovial injections to minimize the risk of infection. One author (R.P.B.) also administers gentamicin intravenously before entering any synovial space. The conditions of the work area and the temperament of the horse being examined influence which local analgesic technique to use. Intrasynovial analgesia may be delayed or not performed if no clean, dry place is available for safe injection. Although intra-articular analgesia is considered to be more specific than perineural analgesia, it may influence peri-articular pain. In some instances the response to medication may be helpful in localizing pain to a joint. In situations where subtle lameness makes interpretation of nerve blocks difficult, in horses with multiple-limb lameness, for animals that are difficult or dangerous, or when comprehensive blocking fails to localize the lameness, other techniques such as nuclear scintigraphy should be considered.

When horses are competing regularly, especially away from home, owners, riders, trainers, and peers often put pressure on the veterinarian to treat the horse based on an index of clinical suspicion, rather than a complete lameness evaluation, including local analgesia. Although this can be successful and a positive response to treatment clearly indicates a correct diagnosis, one must bear in mind that some injuries do require rest for the best long-term outcome. A transient response only to treatment or lack of response warrants further investigation of the lameness, and this routinely should include local analgesic techniques.

IMAGING CONSIDERATIONS

Only after successfully localizing the source of pain causing lameness or after an extensive physical examination has provided the veterinarian with a reasonable indication of the problem should the examination progress to diagnostic imaging, including radiography, ultrasonography, and if indicated, nuclear scintigraphy, computed tomography, or magnetic resonance imaging. Routine techniques are used, with no special views. High-quality diagnostic imaging is related directly to the veterinarian's success as a diagnostician.

FAILURE TO MAKE A DIAGNOSIS

Every veterinarian, no matter how astute as a lameness diagnostician, eventually will be confused, unsure, or simply have no idea as to why a horse is lame, and consultation with associates or referral to other experts should be considered. Just as a good relationship with a farrier is paramount to the successful management of many foot-related problems, good relationships with other veterinarians are necessary. The veterinarian must be honest and open about the horse with the owners and trainers. Re-examination at a later date also may be beneficial. Some bone lesions may take a few weeks to become visible on plain radiographs, so the veterinarian should consider re-imaging if the lameness has been localized.

TREATMENT

In recent years the trend has been toward much more aggressive treatment, with many different treatment modalities often being combined to manage a single condition. Although in some circumstances this can be justified, it does mean that the veterinarian is often not sure which treatment really is effective. More targeted treatment actually may be equally effective.

DIAGNOSIS AND MANAGEMENT OF COMMON CAUSES OF LAMENESS

Palmar Foot Pain

Foot Soreness

The most common site of forelimb lameness in a hunter/jumper is the foot. The horse naturally supports 60% to 65% of its body weight over the forelimbs, and impact forces when jumping dramatically increase load and structural stresses in tissues within the hoof capsule. The manner in which a horse is shod has a tremendous significance in the development of hoof- and foot-related problems. Long toe and underrun heels are common hoof conformational defects and frequently contribute to heel pain because of hoof wall separation or bruising in the heel, quarter, and bar areas. The heels themselves may be excessively long and collapsed inward, and the horse actually may be bearing weight on the outer wall. This often results in sensitivity to hoof tester pressure applied to each heel and when the heels are squeezed together. Lameness is often improved by analgesia of the palmar digital nerves.

Lateromedial radiographic views of the foot may reveal that the distal phalanx is abnormally oriented, so that the palmar most aspect of the bone is lower (more distal) than the toe. A flattened and chronically bruised heel and bar area (corns) may be seen after removal of the shoe. In horses with chronic lameness deep digital flexor tendonitis and distal sesamoidean impar desmitis may contribute to pain associated with underrun heels. Clinically relevant lesions recently have been documented using magnetic resonance imaging in show jumpers with poor and good foot conformation (S.J.D.).

Some horses with underrun heels do not respond well to shoeing. Removing the shoes, trimming back the abnormal heel wall, and placing the foot in a support bandage is recommended. One author's (R.P.B.) preference is to fashion a cushion support for the palmar hoof using a two-part putty elastomer material (EDSS, Equine Distal Support System, Inc., Penrose, CO). Using the sulci of the frog for support is believed to suspend the heels and promote the new growth to be more vertical in its orientation. This process, however, requires a long-term commitment by the owner and trainer, because new heel growth may take up to 6 months to be sufficient for the reapplication of shoes.

Subsolar Bruising

Horses with subsolar bruising often respond well initially to Epsom salt poultices and non-steroidal anti-inflammatory drugs (NSAIDs), for example, phenylbutazone, followed by corrective shoeing. Rasping excessive toe from the solar surface proximally up the dorsal wall to create a 45° angle with the ground surface and application of a shoe fitted full in the heels may be of benefit by removing resistance to breakover. Ideal breakover is located between two points; the first is located by extending a line distally along the dorsal surface of the distal phalanx to the bearing surface, and the other by drawing a perpendicular line from the toe of the distal phalanx to the bearing surface. Egg bar shoes may be required to gain adequate heel support. Shoes such as the EDSS natural balance shoe (Equine Digital Support System, Inc.), with the web behind and squared off at the toe, also improve breakover and reduce stress in the palmar portion of the foot. We do not recommend the application of plastic wedge pads because they actually may contribute to further crushing of the heel and promote the heel bulbs to slide forward and grow horizontally. Leather pads may be helpful in some horses if sole pain is present and sole protection is desired. In horses with a chronic problem, long-term use of aspirin (60 g every other day) may be helpful. Hoof growth supplements containing biotin and methionine also may be of benefit, and we recommend feeding of biotin (100 mg daily) to promote hoof wall growth. Careful attention should be paid to the condition of the gastric mucosa with long-term NSAID use in show horses, because gastric ulceration may occur. Concurrent administration of acid pump inhibitors such as omeprazole should be considered.

Extreme sensitivity to hoof testers may be evident along the periphery of the sole at the level of the distal phalanx. Such pain may be associated with bruising, solar margin fractures or inflammation of the distal phalanx caused by chronic concussion from hard ground, or excessive sole pressure from the shoe. These conditions may be more common in North America than in Europe. Radiography is necessary for diagnosis of solar margin fractures of the distal phalanx. Shoeing should be directed at reducing local pressure on the affected areas and improving the overall hoof balance. Egg bar shoes and rim pads are often effective, but soft sole pours that provide extra cushion and shock absorption also help. Two-part putty elastomer is thought to benefit by providing support and lift from the sulci of the frog. Care should be taken with a pour or putty elastomer to avoid overfilling, causing excessive sole pressure.

Subsolar Abscess

Subsolar abscesses occur commonly and result from shoe nails improperly applied, poor environmental conditions, a shoe moving slightly, and poor hoof structure. Onset of clinical signs may be rapid, such as immediately following an event, or within the first several days following shoeing. The additional trauma of jumping exacerbates the condition, leading the rider or trainer to suspect trauma or serious injury. Warmth in the hoof wall, increased digital pulse amplitudes, and focal, extreme sensitivity to hoof testers are usually diagnostic, provided that the hoof horn is not excessively hard. Perineural analgesia is rarely necessary to confirm the suspected diagnosis and also may be confusing, because not all horses respond positively. After blocking and trotting the horse to reassess lameness, re-examination of the solar surface of the foot may reveal purulent drainage from the area of suspicion. Treatment is directed toward liberal opening of the solar surface of the foot at the point of maximum sensitivity to establish adequate drainage. If drainage is not established, bandaging the foot with hyperosmotic agents such as products containing magnesium sulfate (Epsom salts) is recommended. Twice daily soaking of the foot with a hot, supersaturated solution of Epsom salts with the bandage left on is also recommended for 3 to 5 days. Once drainage has been established, the foot is bandaged in a similar fashion, and NSAIDs also may be administered to reduce the inflammation. Antibiotics rarely are indicated but are sometimes used if soft tissue swelling occurs above the coronary band.

Navicular Disease

Initially to think that a horse is suffering from inflammation of the distal interphalangeal joint when the problem is navicular disease is not uncommon, but navicular disease is also overdiagnosed as a cause of heel pain. The diagnosis of navicular disease carries the stigma of a permanent and disabling lameness and is upsetting to the horse owner and trainer. Therefore the veterinarian should make an exhaustive effort to rule out all other possible sources for the pain causing lameness before making the diagnosis.

Navicular disease lameness usually is characterized by a slow, insidious onset. Early signs include shortening of the stride length, tripping, toe stabbing, and an intermittent unilateral lameness, although the lameness is almost always bilateral. Show horses are often more lame the day after a competition. Some horses with no previous lameness history become suddenly lame and are often refractory to standard therapies. Recent experience using magnetic resonance imaging suggests that a proportion of horses that were previously thought to have navicular disease have primary lesions of the deep digital flexor tendon within the hoof capsule (S.J.D.). The response to hoof testers varies, and often the horse shows only resentment when the heels are squeezed together. The wedge test may accentuate lameness. Lameness may be increased after distal limb flexion, but the response is non-specific. Lameness usually is eliminated by palmar digital nerve blocks, and a previously undetected lameness often appears in the contralateral limb. Analgesia of the distal interphalangeal joint or the navicular bursa often improves lameness.

Interpretation of the radiographic appearance of the navicular bone is not easy; many horses with navicular bone pain have no detectable radiological abnormality. We consider that radiolucent cyst-like lesions in the body of the bone, large lollypop-shaped radiolucent areas on the distal border of the bone, and enthesophyte formation on the proximal and distal borders of the bone should be considered significant.

Nuclear scintigraphy is useful in those horses that appear normal radiographically. The solar view is most useful and may reveal increased radiopharmaceutical uptake in the

navicular bone, reflecting abnormal bone metabolism. Lateral pool-phase images are also useful for highlighting horses that may have deep digital flexor tendonitis within the hoof capsule or navicular bursitis. Ultrasonographic examination of the navicular bone via the frog may demonstrate roughening of the flexor surface, but subtle changes easily are missed, and only a limited portion of the flexor surface can be examined.

Therapy for navicular disease includes pain management and corrective shoeing. Clients should be advised that this disease rarely is cured and requires a long-term commitment to its management. Horses with chronic, refractory lameness may require neurectomy.

Trimming and shoeing should be directed toward facilitating breakover, providing support to the palmar aspect of the foot, and in some horses elevating the heels to reduce tension in the deep digital flexor tendon (DDFT). A swelled heel egg bar shoe or the EDSS natural balance shoe is useful. The forward edge of the shoe should be set back from the toe and the branches fitted full at the heel. Leather wedge pads have been used to elevate the heels; however, the foot should be monitored closely to prevent crushed heels. A commercially available aluminum wedge-shaped shoe also may be used to provide heel elevation.

Medical management includes the use of NSAIDs, isoxsuprine, pentoxifylline, and aspirin; intra-articular injection of the distal interphalangeal joint and intrathecal injection of the navicular bursa with corticosteroids and hyaluronan; and rest. Many of these therapies, usually in combination, have proved successful in managing this condition, and we generally would recommend the least invasive therapies first. The degenerative nature of this disease, however, ultimately may result in the failure of any treatment, and palmar digital neurectomy may be considered. Surgical case selection is important, and consideration should be given to the overall condition of the horse and its level of performance. Horses with evidence of deep digital flexor tendonitis and proximal or distal distal interphalangeal osteoarthritis are not considered good candidates because of the possibility of tendon rupture or exacerbation of osteoarthritis. Some horses may experience temporary pain relief from the application of a chemical nerve block using a mixture of corticosteroids, ammonium sulfate, and Sarapin locally injected at the level of the palmar digital nerves. This procedure may work well initially only gradually to lose its effectiveness.

Shock wave therapy recently has been introduced as a non-invasive therapeutic option for pain management in navicular disease. Several investigators have reported good results, but differences in equipment and protocols require further investigation.

Sheared Heels

Sheared heels are a serious problem in hunters/jumpers. Lameness is often insidious in onset, or a critical point of instability may be reached, producing a more acute lameness. Subtle conformational abnormalities and poor hoof balance likely contribute to this condition. The medial heel often is displaced proximally, with the remainder of the foot splayed laterally. When viewed from the solar surface of the foot, the lateral half of the foot is larger and flared compared with the medial half. The medial heel may be painful to hoof testers, and the heel bulbs may be manipulated independently. Analgesia of the medial palmar digital nerve frequently improves lameness, but usually it is necessary to desensitize both heel bulbs before the horse appears sound. Many horses have radiographic lesions of the medial palmar process of the distal phalanx, such as roughening or demineralization of the margin of the bone, presumably because of chronic trauma and inflammation. The therapeutic goal is to stabilize the heel bulbs and reduce pressure on the driven up or proximally displaced bulb. Stabilization most often is accomplished best by improving balance and breakover so that the foot lands flatly and relieving the affected heel from excessive loading during weight bearing. In a jumper, an egg bar shoe is usually satisfactory. Horses with more severely affected feet may benefit from a heart bar, diagonal bar or G-bar shoe. A rim pad with the portion to lie beneath the affected heel cut away may float the heel enough to allow that side to descend into a more normal position. Six to 9 months of persistent treatment are required before a more stable heel structure is established.

Distal Hock Joint Pain

Distal hock joint pain is the second most common reason for lameness in a hunter/jumper and is the most common hindlimb lameness. Conformational defects, developmental abnormalities, and the incredible torsional stresses placed on the distal hock joints during jumping are thought to contribute to lameness. A variety of subtle signs becomes manifest before the onset of clinical lameness. Often the trainer or rider complains of a loss in the horse's stride length, poor impulsion, and a change in the horse's jumping style. Many horses may develop a tendency to switch leads in front of a jump or may have difficulty jumping from a particular lead. The horse consistently may develop the tendency to jump to one corner of the obstacle, and wider jumps appear to require more effort than usual or even necessary. Clinical examination reveals sensitivity to palpation of the muscles of the lumbar area and shortened cranial phase of the stride. The upper limb flexion test may or may not be positive, and some horses are reluctant to move forward immediately into a trot after flexion and may canter away from the veterinarian. The Churchill test is often positive in horses with tarsometatarsal joint pain but may be negative with centrodistal joint pain. Some horses with proximal suspensory desmitis also respond positively to the Churchill test (R.D.M.). Tarsocrural effusion may or may not be present. We (R.P.B. and R.D.M.) rarely perform regional analgesia of the fibular and tibial nerves, because we consider the procedure difficult to interpret and somewhat dangerous to perform. Intra-articular analgesia of the centrodistal and the tarsometatarsal joints is preferred. However, a negative response to intra-articular analgesia does not preclude centrodistal and tarsometatarsal joint pain, and using fibular and tibial nerve blocks to identify some horses with distal hock joint pain may be essential. With practice this is a highly reliable and safe technique (S.J.D.). With subtle hindlimb lameness or complaint of poor performance and no apparent lameness, it may be necessary for the horse to be ridden and for the rider to interpret the results of the block. The veterinarian should allow this with only the most experienced and talented riders.

Radiographic changes vary from none to severe, with what may appear as total radiographic evidence of fusion. Radiographic changes do not necessarily correlate to the degree of lameness. Osteochondral fragments on the distal intermediate ridge of the tibia, or at the distal aspect of the medial trochlea of the talus in a mature athlete in the absence of lameness, are an incidental finding of little if any clinical significance. The severity of the degenerative changes may be similar in the centrodistal and the tarsometatarsal joints; however, the tarsometatarsal joint often has less severe abnormalities. The reason for this is unclear.

Nuclear scintigraphy can be helpful and reveals increased radiopharmaceutical uptake (IRU) in the distal aspect of the tarsus. Occasionally, small, focal, moderate to intense areas of IRU may reflect focal areas of loss of joint space, bone trauma, or tearing of ligamentous attachments.

It has been generally accepted that radiographic evidence of distal joint(s) fusion is desirable, because the suggestion is that once joint fusion has occurred, the inflammation and therefore the pain should disappear. This is an unfortunate myth. Surgical arthrodesis is a currently accepted treatment for horses with osteoarthritis of the centrodistal or tarsometatarsal joints that have become refractory to routine therapies. We challenge this belief and have observed evidence to the contrary. Once arthrodesis has occurred, the normal function of the joint is lost. The distal joints are responsible for the dissipation of the twisting or torsional forces in that area. With this capability gone, these forces are concentrated, and stress fracture of the central or the third tarsal bones may occur or osteoarthritis of the talocalcaneal-centroquatral (proximal intertarsal) joint may develop.

Treatment of horses with distal hock joint pain varies. Intra-articular injections of corticosteroids (20 to 40 mg methylprednisolone acetate or 5 to 7.5 mg betamethasone in each joint) and hyaluronan (2 ml per joint) is usually the first treatment, combined with NSAIDs, and is usually the best and most expeditious means of treatment. With radiographic evidence of severe osteoarthritis we use a long-acting corticosteroids alone. Treating horses with more mildly affected joints with a low corticosteroid dose in combination with hyaluronan may be chondroprotective and extend the useful life span of the joint. Combined therapies have grown popular because of the perception that they work better and the effects last longer. Most horses respond favorably, and the riders comment on how much better the horse performs. Many horses, especially those with demanding show schedules, have the hocks (and perhaps other joints also) routinely injected at intervals predetermined by the history of when the horse has previously become unsound following previous injections. Maintenance treatment is performed about 1 month earlier. This reduces the risks of loss of performance, recurrent lameness, or development of a secondary problem.

Many horses also are treated with the oral nutraceuticals, parenterally administered polysulfated glycosaminoglycans (PSGAGs), and intravenously administered hyaluronan. These products are incorporated into a maintenance program designed to keep the horse comfortable and prolong the interval between intra-articular joint injections. Frequently the large size of these horses means that they are treated with twice the normal dose of PSGAGs. Horses often are treated with intramuscularly administered PSGAGs and intravenously administered hyaluronan the evening before competition. This is thought to enhance the horse's ability by making the joints more comfortable. Occasionally, horses with joints unresponsive to corticosteroids and hyaluronan do respond to intra-articularly administered PSGAGs, with or without corticosteroids. Once the horse is made more comfortable, an exercise program consistent in intensity and duration, emphasizing strengthening the hindquarters and abdominal muscles, improves performance. Recent reports describe shock wave therapy being used to control pain. Shoeing is aimed at encouraging breakover in the center of the hoof by squaring the toe. Some veterinarians prescribe a lateral trailer in an effort to decrease the twisting motion of the limb. Alternative therapies such as muscle massage and acupuncture are used commonly with traditional therapies.

Distal Interphalangeal Joint Synovitis and Early Osteoarthritis

Inflammation of the distal interphalangeal joint is common in jumping horses and usually results in subtle lameness that is frequently bilateral. Palpable joint effusion may or may not be present. Many horses, but not all, respond positively to the distal limb flexion test. Forelimbs are most commonly affected, but the hindlimbs also may be involved. The horse may have a reduction in stride length, and lameness is most obvious when the horse circles on firm footing. The rider or trainer may complain of a reduction in jumping performance, such as a reluctance to leave the ground and landing in a heap. Very hard surfaces for training or competition and surfaces that are too soft, irregular, and unstable may be predisposing factors. Soft footing, although not seemingly likely to contribute to excessive concussion, produces torsion forces on the distal interphalangeal joint that strain the peri-articular soft tissues. An underrun heel, long-toe conformation is probably the single most important contributing factor. The horse often shows a painful response to hoof testers with pressure applied from either heel to the opposite frog and from the center of the frog to the dorsal hoof wall. Lameness usually is improved with analgesia of the palmar digital nerves and eliminated with palmar (abaxial sesamoid) nerve blocks or intra-articular analgesia of the distal interphalangeal joint. Lameness in the contralateral limb may become apparent.

Radiographic changes may be absent or subtle; however, in horses with more chronic or severe disease, reactive periosteal bone may be present on the dorsal aspect of the middle phalanx, and remodeling of the extensor process of the distal phalanx may occur. With chronic, severe osteoarthritis of the distal interphalangeal joint there may be subchondral radiolucent areas in the distal phalanx consistent with collapse of the joint. Prominent radiolucent areas representing synovial invaginations may be present on the distal border of the navicular bone.

Nuclear scintigraphy is useful to rule out bone involvement. An area of IRU in the synovial structures of the joint may be visible in pool-phase studies. Differentiating the palmar pouch of the distal interphalangeal joint from the navicular bursa is difficult, and both structures may be involved in horses with severe lameness.

Therapy for distal interphalangeal joint synovitis depends on the severity of the lameness and the horse's competition schedule. Proper trimming and shoeing as for palmar heel pain is essential. The use of NSAIDs is common. Peripheral vasodilating agents such as isoxsuprine are of questionable value, although higher than standard doses are sometimes effective.

Intra-articular injection of high molecular weight hyaluronan and corticosteroids (triamcinolone or betamethasone) with proper shoeing and an appropriate amount of rest usually yields the best results. Occasionally, repeated injections are necessary after 4 to 6 weeks; however, injections repeated more frequently than once every 3 months should be avoided. Nutraceuticals and parenterally administered chondroprotective agents (PSGAGs) may be beneficial.

Collateral Ligament Injury of the Distal Interphalangeal Joint

Some horses with synovitis of the distal interphalangeal joint that are unresponsive to therapy should be evaluated for possible collateral ligament injury of the distal interphalangeal joint. In a few horses, we (R.D.M. and S.J.D.) have identified thickening and tearing of the collateral ligament ultrasonographically, and unusually, focal increased radiopharmaceutical uptake of the palmar aspect of the distal phalanx, scintigraphically. Differentiating this injury from other more common conditions of the distal phalanx may be difficult. Horses with this injury should be managed with corrective shoeing and rest. Work level is reduced substantially. Extracorporeal shock wave or therapeutic ultrasound therapy combined with a 2- to 3-month period of rest appears to be effective.

Suspensory Desmitis

Injury to the SL is the most common soft tissue injury and certainly one of the most serious injuries of the jumping horse. Early lesions may go unnoticed by even the most skilled horseman, because the rider or trainer is aware of only a vague

problem, from which the horse warms out of fairly quickly. Exercise continues and the injury eventually worsens to the point of causing enough damage to produce an obvious lameness. The lameness usually is more pronounced when the horse is trotted in a circle with the affected limb on the outside and also may be exacerbated in soft footing. Mid-body and branch lesions are diagnosed easily by palpation; however, diagnosis of injury to the proximal aspect of the SL is more challenging. The distal limb flexion test may increase the lameness with mid-body and branch lesions, whereas carpal flexion and upper hindlimb flexion frequently accentuate lameness associated with proximal suspensory desmitis, which can cause confusion with hock pain. A high palmar metacarpal nerve block, direct infiltration of the SL origin, or analgesia of the lateral palmar nerve eliminates lameness in the forelimb. Analgesia of the proximal aspect of the hindlimb SL requires caution, because injury to the veterinarian and patient can occur. Analgesia is best performed with the horse restrained with a twitch and the leg positioned in the veterinarian's lap as if the horse's foot were being examined. Displacing the flexor tendons medially and isolating the SL for injection is thus easier. The SL is infiltrated with local anesthetic solution from the axial aspect of the lateral splint bone, fanning across the SL from lateral to medial. During injection, the local anesthetic solution should go in with considerable resistance if it is being deposited within the SL itself. Alternatively, perineural analgesia of the deep branch of the lateral plantar nerve can easily and safely be performed with the limb bearing weight (S.J.D.). With direct infiltration of the ligament, soundness should be almost immediate. Some risk exists of entering the palmar outpouching of the carpometacarpal joint capsule using direct infiltration in the forelimb, causing potential diagnostic confusion; however, infiltration in the hindlimb inadvertently entering the tarsometatarsal joint is less likely.

Ultrasonographic examination of the SL may reveal obvious lesions; however, finding minimal evidence of damage in horses with acute injuries is not uncommon. Recent nerve blocks may confuse interpretation, so ultrasonographic examination is best delayed for 1 to 2 days. Alternatively, ultrasonographic examination may precede nerve blocks. In our opinion, ultrasonographic imaging of the proximal SL in the hindlimb is difficult. The transducer should be placed on the plantaromedial aspect of the limb to get the best-quality images. A cross-sectional area of greater than 1.5 cm^2 suggests proximal suspensory desmitis, even in the absence of a focal or diffuse loss of echogenicity.

Radiographic examination of the proximal aspect of the third metacarpal or metatarsal bone may demonstrate sclerosis with or without lysis in a dorsopalmar (dorsoplantar) view or subcortical sclerosis in lateromedial views. Incidental radiographic changes can be seen in hindlimbs.

Nuclear scintigraphy has proved useful in characterization and prognosis of horses with proximal suspensory desmitis. The pool phase may reveal increased radiopharmaceutical uptake in the ligament. A unique pattern of uptake is present in the forelimbs and hindlimbs in the bone phase. The lateral view is most important in the forelimb because focal IRU is present on the proximopalmar aspect of the third metacarpal bone (McIII) if bone injury accompanies proximal suspensory desmitis. Proximal suspensory desmitis occurs often without chronic changes in the palmar/plantar cortex of the third metacarpal or metatarsal bone. Dorsal views of the forelimb are less sensitive than lateral views. In the hindlimb the lateral view is equally important. The veterinarian should not confuse as a lesion IRU in the proximolateral aspect of the metatarsal region in plantar views, which is a normal finding. Ultrasonographic abnormalities of the SL and abnormal scintigraphic images confirm injury to the bone at the origin of the SL, indicating a complex injury involving two tissue types and adversely affecting the prognosis.

Therapy for horses with proximal suspensory desmitis varies. NSAIDs, combined with rest and physical therapy, are the most popular and yield the most consistent results. Clients should be advised that treatment may take 6 to 12 months. We recommend stall rest for 10 to 14 days after the injury, with twice daily hand walks. Phenylbutazone is administered (2 g BID for 4 days and then 1 g BID for 10 days). Walking under saddle then is commenced for 20 to 30 minutes once or twice daily for the next 30 days. Follow-up ultrasonographic examinations are performed after 44 days and every 30 to 60 days thereafter. The duration and intensity of exercise gradually are increased based on the ultrasonographic appearance of the SL and the clinical appearance of the horse. Trotting begins once the horse is sound. Many veterinarians in North America recommend an internal blister, using 2% iodine in almond oil infiltrated into the SL. Light exercise is continued immediately following this therapy, with a gradual return to full work. Shoeing should be improved if necessary. In horses with acute proximal suspensory desmitis with no significant ultrasonographic changes, local injection of corticosteroids may decrease inflammation and eliminate pain. We use triamcinolone (12 to 18 mg), betamethasone (30 mg), or isoflupredone acetate. Sarapin (4 ml) also may be added.

Recently a surgical procedure has been reported in which the tight fascia overlying the proximal SL is transected or released so as to reduce any increased pressures or compression created by this apparent compartmental syndrome. Bone marrow aspirate taken from the sternum then is injected in the area of the injury in an effort to stimulate healing. Early results from this technique appear promising; however, further investigation and long-term follow-ups are needed. Neurectomy of the deep branch of the lateral plantar nerve has been used successfully for management of hindlimb PSD (S.J.D.).

Shock wave therapy has been reported to aid healing of proximal suspensory desmitis, especially in horses with bone involvement. This technique provides profound analgesia and therefore a decrease or elimination of lameness. Further investigation is warranted.

Horses with larger lesions within the body of the SL or its branches may benefit from splitting. This appears to allow a more complete healing of core lesions, which otherwise may be slow to resolve. Following surgery, therapeutic ultrasound or infrared laser therapy may aid and reportedly speed healing, although evidence is mainly anecdotal.

Back Pain

Back pain is common in jumpers, and although signs are recognized easily, the etiological diagnosis may be elusive and complex. The trainer or owner may perceive that a horse has back pain from many clinical signs including sensitivity to grooming and saddling, resistance to rider weight, overall body stiffness, poor performance, and pain on palpation of the muscles over the back. Many of these signs are also common to other diseases or injuries and may be secondary to clinical or subclinical hindlimb lameness resulting in an altered gait. Primary back pain may be caused by severe muscle strain, impingement or overriding of the spinous processes, diskospondylosis, sacroiliac desmitis, supraspinous desmitis, osteoarthritis of the facet joints, and sacroiliac joint pain.

The veterinarian should first attempt to rule out any lameness. Horses with distal hock joint or stifle pain may swing the hindlimb outward away from the body or inward toward the midline in an attempt to reduce the degree of joint flexion required to advance the limb. Hindlimb lameness should be suspected in horses with simultaneous gluteal and back pain. Chronic forelimb soreness, particularly involving the foot, also may contribute to back pain because of an inverted way of jumping that somewhat protects the foot on landing. Teeth problems or neck pain also should be considered.

Severe back pain suggests a primary back problem. The horse may move with a shortened, stiff gait and appear to be flat or hollowed out in the back when ridden but appear much more comfortable when moving free in a paddock. Injection of local anesthetic solution into the painful areas of the back frequently changes the horse's movement.

Impinging Spinous Processes

Radiography of the thoracolumbar spinous processes may reveal impingement with sclerosis and bone proliferation and bone lysis. Nuclear scintigraphy can be used to diagnose and support the diagnosis of spinous process impingement and osteitis, although false-negative results are sometimes obtained. Occasionally, areas of IRU are visible in the spinous processes without any radiographic changes, and supraspinous ligament desmitis should be considered.

The treatment for impingement of the spinous processes or supraspinous desmitis is similar. NSAIDs and methocarbamol are prescribed routinely for a prolonged period. Sarapin and corticosteroids frequently are injected between and around the impinging spinous processes. The locations for injection are determined best by placing a radiodense marker on the top of the back during radiography and then identifying the affected vertebrae by clipping the hair.

Muscle Injury

Acute muscle strain may be accompanied by spasm, which is evident as a firm, painful swelling. Immediate application of ice and administration of NSAIDs such as phenylbutazone or naproxen are beneficial One author (R.P.B.) also administers between 20 and 40 mg of dexamethasone once daily for 2 days in horses with acute pain. Later, moist heat and therapeutic ultrasound reduce pain and inflammation. Acupuncture has proved useful in managing back pain no matter what the cause. Chiropractic manipulation may be of some benefit in relieving pain and muscle spasm in an injured back. Pulsating magnetic field therapy is used routinely in show jumpers for the long-term management of back pain. We believe that many owners feel pressure to do everything possible for their horses, and because of anecdotal reports of benefit in people, certainly no harm will come from using such therapy. Saddle fit always should be evaluated critically in a horse with chronic or recurrent back pain, and thermography may be helpful, together with advice available through most good saddle manufacturers.

Fracture of the Withers

Fracture of the withers is not uncommon if a horse flips over backward. The withers area may appear flat and is extremely painful to palpation. The horse plaits in front and holds the neck stiffly. Radiographs are diagnostic. Treatment is directed toward reducing pain and inflammation by applying ice and administering NSAIDs immediately following the injury. Bone sequestrae occasionally develop, and purulent drainage may appear weeks after the injury. However, most fractures are uncomplicated and horses usually may be able to return to work after 6 to 12 months of rest.

Sacroiliac Joint Pain

Sacroiliac strain is common in show jumpers. Many horses suffer from chronic low-grade pain that never seems adversely to affect the ability to perform. With severe pain a horse may stand parked out (the hindlimbs are extended unusually) and rest one hindlimb. Unilateral lameness may develop, and the horse's performance then is affected severely. The horse may experience pain on palpation around the lumbosacral region and directly over the tubera sacrale, but this is not specific. Exerting pressure on one of the tubera sacrale may reveal slight motion and even may be resented by the horse. The horse may offer considerable resistance when one of the hind feet is picked up and the limb is flexed high. Rocking the pelvis may cause the horse to grunt. A hunter's bump is not associated necessarily with this condition, although it may be. Injection of local anesthetic solution deep into the muscles directed toward the sacroiliac articulations should be performed with caution because the horse may lose its ability to stand, which causes severe distress. Nuclear scintigraphy may reveal little if any IRU in this region and is therefore unreliable, but with modern motion-correction software program and improved image quality, useful information is acquired in some horses (S.J.D.).

Rest and time are the most important factors influencing the outcome. These horses require at least 6 months to heal. Severely affected horses should be given stall rest for 30 days, followed by 2 to 3 months of controlled paddock rest. Light exercise then may begin, gradually increasing the intensity and duration of the work. In our experience, acupuncture has been extremely useful for pain management and the treatment of muscle spasm.

Horses with less severe injuries may be managed successfully by local injections of corticosteroids and Sarapin deep into the painful areas. These horses are able to continue to exercise and compete successfully. The procedure involves directing a 9-cm needle from a point just medial to one of the tubera sacrale along the inner surface of the ilium deep toward the sacroiliac articulation. Injection of the acupuncture points on either side of or parallel to the sacrum with the same solution also may be performed.

Chiropractic manipulation often is attempted in horses with sacroiliac injury. Although chiropractic has proved useful as a diagnostic tool and may be of benefit with mild sacroiliac strain, manipulation of the sacrum in more severe injuries never replaces the need for prolonged rest. Pulsating magnetic field therapy, cold laser, and therapeutic ultrasound may be used for the long-term management of chronic sacroiliac problems.

Fetlock Joint

Synovitis and Osteoarthritis

Metacarpophalangeal joint synovitis and osteoarthritis are common in older horses with lengthy careers. Chronic capsulitis results in a thickened, prominent joint capsule with a dramatic decrease in the flexibility of the joint. At least a moderate amount of joint effusion occurs, but many sound horses may have chronic effusion, thickening of the joint capsule, and reduced range of motion. The source of pain is confirmed by a low four-point palmar/plantar nerve block or intra-articular analgesia.

Radiographic examination may reveal osteophyte formation on the proximal aspects of the proximal phalanx and the proximal sesamoid bones, and flattening of the sagittal ridge of McIII. McIII may have a scalloped appearance on the dorsal or palmar aspect in horses with advanced disease. Subchondral lucent areas may develop in McIII or the proximal phalanx and result from severe, focal trauma or end-stage osteoarthritis. The prognosis for horses to return to athletic competition following the development of these lesions is considered poor. Acute fractures and small chips are uncommon in the hunter/jumper. Small, round, smooth fragments on the proximodorsal aspect of the proximal phalanx are seen in forelimbs and hindlimbs and likely are related to osteochondrosis. These fragments rarely are associated with lameness but occasionally may become unstable and require removal.

Nuclear scintigraphy may reveal mild to moderate IRU in the distal aspect of McIII, the proximodorsal aspect of the proximal phalanx, or both. In some horses flexed lateral views are required to separate the bones, especially if radiopharmaceutical uptake in one area is so intense that identifying the adjacent structures is impossible.

In the absence of substantial radiographic abnormalities medical therapy should include NSAIDs, intra-articularly administered corticosteroids and hyaluronan, and orally and parenterally administered PSGAGs. Physical therapies such as

icing, cool water therapy, poultices, sweats, cold laser, therapeutic ultrasound, support wraps, and rest are also beneficial. Arthroscopic exploration of the metacarpophalangeal joint is indicated if the response to medical treatment is transient or poor. Clients should be advised that although the causal problem may be revealed, treatment may not be possible. Debridement of damaged cartilage and subsequent replacement with fibrocartilage may be curative; however, excessive erosion of the articular cartilage warrants a poor prognosis for continued jumping.

Therapeutic shoeing targeted at providing support to the palmar aspect of the foot, such as a wide-web egg bar shoe, may be of benefit (R.D.M. and R.P.B.). Proper medial to lateral hoof balance is also important in reducing torque on the metacarpophalangeal joint.

Sesamoiditis

Sesamoiditis frequently is associated with chronic suspensory branch desmitis. Horses are variably lame and may warm out of the lameness. Distal limb flexion test usually is resented and results in increased lameness. The suspensory branches may be palpably thickened and painful. Intra-articular analgesia of the metacarpophalangeal joint may improve lameness but does not alleviate it. Lameness is abolished by a low four-point palmar nerve block.

Radiographic findings include linear lucent zones or lytic areas within the body of the proximal sesamoid bone (PSB). A generalized loss of bone opacity or proliferative, reactive bone also may be present on the abaxial margins in association with suspensory branch desmitis and insertional lesions of the SL and palmar annular ligament. We find proximodistal oblique views of the PSBs useful.

Nuclear scintigraphy is sensitive to inflammation in the PSBs, and IRU in the PSBs often is intense. A flexed lateral view helps to separate the PSBs from McIII. Dorsal or plantar views are required to distinguish between the medial and lateral PSBs.

Treatment for horses with sesamoiditis includes rest, NSAIDs, and supportive shoeing similar to that prescribed for fetlock joint problems. Shock wave therapy may be helpful.

Stifle Joint Pain

Problems involving the stifle joint are common in show jumpers and frequently accompany problems in the tarsus. Femoropatellar effusion is present variably. Stifle pain may be primary and related to trauma, mechanical problems, developmental diseases, and osteoarthritis, or it may be secondary to other lameness. Primary problems include osteoarthritis, osteochondrosis, meniscal and cruciate ligament trauma, upward fixation or delayed release of the patella, and patellar desmitis. Signs may be subtle at first, with mild shortening of the stride or switching leads at the canter or gallop. Caudal back pain also may be present. The proximal limb flexion test may or may not be positive, and the veterinarian should look closely for subtle gait changes such as a shortening of the cranial phase of the stride. Separation of stifle and tarsal pain may be accomplished by flexing the stifle with the hock slightly extended so that the metatarsal region is held behind the tail and perpendicular to the ground, with the tibia held parallel to the ground. The Churchill test also may help to separate hock from stifle pain. Cranial to caudal motion of the tibia relative to the femur during weight bearing (cruciate test) may produce a change in stride (R.D.M.). However, intra-articular analgesia always is required to confirm the source of pain. Horses with straight stifle conformation are predisposed to upward fixation and instability of the patella. Pain results from subsequent patellar ligament strain and synovitis. Although the limb may be observed to lock in extension, more frequently a slight hesitation in the advancement of the limb is noted. Femoropatellar effusion may be present. Ultrasonographic examination of the patellar ligaments may reveal desmitis characterized by thickening and a focal or diffuse hypoechoic region. Horses with transient upward fixation of the patella benefit from NSAIDs and an increased exercise program designed to increase muscle tone in the quadriceps group, which stabilizes the patella. Failure to respond to these measures may justify a more aggressive procedure, such as local injection of 2% iodine in almond oil at the proximal aspect, middle portion, and insertions of all three patellar ligaments and into the muscle just proximal to the stifle. This procedure has proved effective in treating transient upward fixation of the patella and subtle soreness in the adjacent muscles. Anecdotal reports describe benefit from estrone sulfate, estradiol, and calcium channel blockers.

Cranial Cruciate Ligament and Meniscal Injury

Trauma to the cranial cruciate ligament produces profound lameness. Intra-articular analgesia of the femorotibial joints may or may not abolish the lameness, and radiographs of the stifle may be normal in horses with an acute injury. With chronic injury new bone may be seen cranial to the intercondylar eminences, most obvious in a flexed lateromedial view. Injury to the medial meniscus is most common. Intra-articular analgesia of the femorotibial joint on the affected side usually produces improvement in the lameness. Radiographs may reveal osteophyte formation on the proximomedial aspect of the tibial plateau indicative of osteoarthritis and a subjective decrease in the joint space width on the affected side.

Osteochondrosis and Subchondral Bone Cysts

Osteochondrosis and subchondral bone cysts should be considered in a young Warmblood that has recently started training or increased its training intensity and has developed lameness localized to the stifle. Intra-articular analgesia usually at least partially eliminates the lameness. We recommend blocking all three joint spaces.

Radiographs are usually diagnostic. Arthroscopy may be indicated. Horses with subchondral bone cysts and other lesions on the medial femoral condyle usually have a poorer prognosis than those with osteochondritic lesions of the lateral trochlear ridge of the femur. We recommend radiography of the stifles as part of the routine radiographic study when examining a young Warmblood for purchase.

Nuclear scintigraphy of the stifle with osteochondrosis may reveal little if any IRU. The caudal view is important and should always accompany the lateral views. Visible uptake (to any degree) in the distal medial femoral condyle in the caudal view almost always is associated with a pathological condition (R.P.B.).

Synovitis and Osteoarthritis

Mature horses may develop synovitis and osteoarthritis of any one or a combination of the stifle joints. Often the femoropatellar and medial femorotibial joints are involved; however, lateral femorotibial osteoarthritis may occur alone. Intra-articular analgesia of all three joints should be performed.

The diagnosis may or may not be confirmed radiographically. Osteophyte formation on the proximal medial aspect of the tibia is not uncommon. Nuclear scintigraphy may reveal mild to moderate IRU in the femoral condyle and the opposing surface of the tibia on the affected side in a caudal view.

Intra-articular injection of corticosteroids and hyaluronan usually has favorable results. Each joint should be injected separately with double doses of a high molecular weight hyaluronan combined with methylprednisolone acetate (40 to 80 mg) or betamethasone (5 to 10 mg). NSAIDs, parenterally administered PSGAGs, and intravenously administered hyaluronan are also beneficial and may be used routinely with nutraceuticals as part of a maintenance program. Adequate rest also should be prescribed; however, strict stall confinement is not necessary.

Walking these horses under saddle for 30 minutes once or twice daily is preferred. Alternative therapies such as those described for distal tarsitis are also beneficial. Acupuncture commonly is used for managing horses with stifle pain.

Pastern

The pastern region is subject to considerable stress in the jumping horse. Osteoarthritis of the proximal interphalangeal joint is not uncommon and often is associated with distal interphalangeal osteoarthritis. Horses with base-narrow or toe-in conformational defects are affected most frequently. Distal sesamoidean desmitis is also a common problem. Trainers complain that many horses with osteoarthritis of the proximal interphalangeal joint start out stiff when training and feel much better after warming up, but eventually the lameness becomes persistent. With chronic injury comes obvious thickening in the distal aspect of the pastern. Palmar (abaxial sesamoid) nerve blocks normally eliminate the lameness, although a low palmar (four-point) block sometimes is required. Intra-articular analgesia of the proximal interphalangeal joint also usually produces soundness. The veterinarian must beware that a palmar digital nerve block may alleviate lameness associated with osteoarthritis of the proximal interphalangeal joint because of proximal diffusion of the local anesthetic solution.

Osteoarthritis

IRU usually occurs in the proximal interphalangeal joints of sound jumping horses relative to other joints. With osteoarthritis the intensity of the IRU usually increases. We (R.P.B. and R.D.M.) therefore believe that subclinical osteoarthritis of the proximal interphalangeal joint is common. Radiographic changes of osteoarthritis of the proximal interphalangeal joint include osteophyte formation on the proximodorsal aspect of the middle phalanx. Subchondral osseous cyst-like lesions in the proximal aspect of the middle phalanx may be associated with severe trauma or end-stage osteoarthritis. Acquired osseous cyst-like lesions usually are associated with focal, intense IRU.

Management of osteoarthritis of the proximal interphalangeal joint includes using NSAIDs, intra-articularly administered corticosteroids and hyaluronan, and orally and parenterally administered PSGAGs. The horse should be trimmed and shod to reduce resistance to breakover at the toe and to balance the foot to land as flat as possible. Occasionally, wedge pads provide comfort by opening up the dorsal aspect of the joint space. Recently, shock wave therapy has been suggested to be of benefit to horses with advanced ringbone, but this requires validation. Horses with severe osteoarthritis of the proximal interphalangeal joint may respond poorly to medical management, and arthrodesis may be required. Arthrodesis is often successful in the hindlimbs of jumping horses, but results are often unsatisfactory in forelimbs. Tibial neurectomy also has been used successfully.

Soft Tissue Injury

Injury to the distal sesamoidean ligaments may or may not be accompanied by obvious swelling or pain on palpation. Analgesia of the palmar (abaxial sesamoid) nerves usually eliminates the lameness. Ultrasonographic examination reveals focal or diffuse hypoechoic regions in the affected ligament. Palmar or plantar displacement of the DDFT medially or laterally may be secondary to distal sesamoidean ligament injury. The veterinarian should image all structures carefully in the pastern, because several structures may be injured simultaneously. DDFT injuries are more common in the pastern than in the metacarpal region. Chronic strain at the insertion of the middle distal sesamoidean ligaments may be evident radiographically as enthesophyte formation on the palmar or plantar lateral and medial borders of the proximal phalanx.

Horses with strains and tears of the distal sesamoidean ligaments usually respond to supportive shoeing, NSAIDs, and rest. Horses with acutely torn ligaments may benefit from cast or splint application for about 1 month. Physical therapy such as therapeutic ultrasound may speed recovery. Injury to these ligaments usually requires from 6 to 12 months for convalescence. Returning the horse to work too soon results in thickening and fibrosis of the pastern and prolonged lameness.

Gluteal Myositis

Strain and inflammation of the gluteal muscles is common in jumping horses and usually results from an altered gait secondary to lameness elsewhere in the ipsilateral or contralateral hindlimb. Primary strain may occur in a horse during jumping, when a horse refuses a jump, or after a fall. Palpation of the gluteal muscles at the insertion on the greater trochanter of the femur and over the middle gluteal region reveals milder reactivity in horses with secondary strains and a much more severe response or resentment after a primary muscle injury. Upper limb flexion tests may be positive, especially if the gluteal soreness is secondary to lameness involving the hock or stifle.

Treatment depends on the severity of the muscle injury or inflammation. Identification and appropriate treatment of the primary lower limb lameness, if present, may do much to reduce mild soreness in just a few days. Most horses with mild injury also respond well to NSAIDs, local application of moist heat, dimethylsulfoxide, and therapeutic ultrasound. Methocarbamol (20 mg/kg PO BID) may be of benefit. Acupuncture treatments, and in horses with severe injuries local injection of corticosteroids mixed with Sarapin (mix Sarapin, prednisolone, and betamethasone in equal parts in a 12-ml syringe and inject 3 ml per site), provide pain relief. Injections are performed on either side of the spine into the sorest portions of the muscle at 5- to 8-cm intervals or at specific acupuncture sites. Rest and a reduction in the intensity and duration of exercise also may help. Some horses may require total rest with exercise limited to hand walking for several weeks.

Superficial Digital Flexor Tendonitis, Tenosynovitis of the Digital Flexor Tendon Sheath, and Desmitis of the Accessory Ligament of the Deep Digital Flexor Tendon

Superficial Digital Flexor Tendonitis

Injury to the superficial digital flexor tendon (SDFT) in a hunter/jumper is far less common and severe than in a racehorse, probably because the horse is not trained at high speeds. Injuries are more likely to result from a misstep in deep footing rather than from muscle or tendon fatigue proceeding to failure, but low-grade injuries occur frequently in top-level horses from about 10 years of age. Spontaneous rupture of the SDFT also is seen in old (mid-teens) jumpers. Often no indication of any tendonitis is apparent before rupture. We also have seen several aged horses no longer in competition with spontaneous SDFT rupture. Geldings are overrepresented and there may be an association between this severe trauma and hormonal imbalance.

The diagnosis of superficial digital flexor tendonitis is not difficult, and unlike injury to the DDFT usually is not accompanied by substantial lameness, unless an acute injury occurs in the proximal metacarpal region. Ultrasonographic evaluation is recommended to assess the severity, location, and extent of the injury. Several re-examinations are important to determine the rate of healing and predict the time to return the horse safely to competition.

The therapeutic goals for management of a hunter/jumper with an acutely injured tendon are rapid reduction of the inflammatory response and elimination of edema. This is achieved with the administration of NSAIDs, low doses of corticosteroids, and diuretics. Ice, hydrotherapy, and support bandages also are used and applied as soon as possible, and in

many horses the trainer does these before the veterinary examination. For horses with strains or injury without actual fiber tearing (type 1 to 2 lesions), peritendonous injection of corticosteroids or intralesional injection of hyaluronan may dramatically decrease the size of the tendon and produce favorable cosmetic results. The trainer must be advised not to exercise the horse and that total healing actually may be delayed slightly. Following the injection, the limb should be supported with a firm, modified Robert Jones bandage to prevent the return of any swelling. Tendon splitting is indicated in horses with substantial core lesions (type 3 or 4 with a diameter greater than 0.5 cm). In horses with smaller lesions, injection of hyaluronan intralesionally may reduce inflammation. Therapeutic ultrasound after the initial phase of healing (3 to 4 weeks after injury) encourages resolution of inflammation and promotes healing.

Overall, the time required for tendons to heal sufficiently so the horse may return to jumping depends on the severity of the injury and to some degree the location of the injury. Routine superficial digital flexor tendonitis takes less time to heal than an injury to the SL at the same location. A mild injury takes 3 to 4 months and a severe injury takes about 12 months to heal. Monthly ultrasonographic examinations are used to determine the physical therapy schedule and the optimum time for the horse to return to jumping. Horses often can continue to compete despite active SDFT injuries, although the lesions may progress slowly.

Tenosynovitis of the Digital Flexor Tendon Sheath

SDFT injury within the DFTS frequently is seen in jumpers at any age or level of competition. Tenosynovitis also occurs without tendon injury. Superficial digital flexor tendonitis may result in a chronic tenosynovitis and often plagues older horses. Tenosynovitis is slightly more prevalent in the hindlimb, presumably because of the strain caused by the push off in jumping. The DFTS may be warm and swollen. Digital pressure at the proximal and distal aspects of the DFTS usually is resented. Pressure applied directly over the palmar/plantar aspect of the fetlock also may cause pain. The distal limb flexion test is usually positive. Moderate effusion is usually present in horses with an acute injury, but those with chronic injuries may have a thickened, fibrotic DFTS and much less fluid. The proximal aspect of the sheath may show effusion, yet none may occur distally in the pastern. Lack of effusion likely results from a compartment syndrome with thickening of the DFTS synovium, the SDFT, and possibly the palmar annular ligament, thus preventing the flow of fluid distally past the PSBs. Lameness may vary and may only be evident following flexion of the distal limb. Intrathecal analgesia of the DFTS usually improves lameness. Ultrasonographic examination should include the fetlock and pastern regions and reveals increased fluid, allowing the tendons and a thickened synovium to be evaluated easily. The flexor tendons may appear to be normal.

Therapy for horses with tenosynovitis of the DFTS varies depending on the severity of the problem and the structures involved. Anti-inflammatory therapy consisting of ice, cool water therapy, poultices, NSAIDs, and corticosteroids is effective in the mild injuries. In horses with more severe injuries, intrathecal injection of corticosteroids and hyaluronan is beneficial. Rest is essential. Horses with mild injuries may return to work in 1 to 2 weeks, but those with more severe injuries require more time. Good trimming and shoeing are beneficial. Horses with chronic, unresponsive tenosynovitis may require endoscopic examination or desmotomy of the palmar annular ligament.

Desmitis of the Accessory Ligament of the Deep Digital Flexor Tendons

Desmitis of the ALDDFT is a common problem, especially in older show jumpers, and often results in sudden onset of lameness after landing over a fence, with rapid development of localized swelling. These clinical signs are typical, but ultrasonography is required to determine the location, severity, and extent of the injury and subsequently to monitor healing. Treatment is similar to that for superficial digital flexor tendonitis. A premature return to work may result in recurrent injury and ultimately adhesion formation between the ALDDFT and the SDFT.

CHAPTER • 117

Lameness in the Dressage Horse

Svend E. Kold and Sue J. Dyson

THE SPORT

Dressage is the ultimate athletic challenge in equestrian sports because it combines balance, suppleness, and power in a unique gravity-defying manner. A good horse gives the impression of athletic elegance and expressive animation. The gaits are described using terms such as *balance, suppleness,* and *hindlimb activity.* The first demand is that the horse is completely obedient and has to go wherever the rider wants and carry out movements at his or her request. In doing so the horse has to rely on its rider, to trust and to accept the rider as its superior. The key to the training and development of a dressage horse from the lowest levels to International Grand Prix is gymnastic exercises, with the aim of strengthening the muscles and thereby avoiding injury to joints and tendons associated with an increased workload.

The Federation Equestre Internationale dressage rules state that the object of dressage is the "harmonious development of the physique and ability of the horse." Through the levels of dressage training, the center of gravity of the horse and rider is placed further caudally, obtained by increasing the degree of flexion and loading of the hindlimbs, while at the same time freeing the front end of the horse to create a more airborne, uphill set of movements. This can be obtained only by increasing the power of the hindlimbs, by synchrony in movement between the forelimbs and the hindlimbs, and through the freedom of movement of the back.

many horses the trainer does these before the veterinary examination. For horses with strains or injury without actual fiber tearing (type 1 to 2 lesions), peritendonous injection of corticosteroids or intralesional injection of hyaluronan may dramatically decrease the size of the tendon and produce favorable cosmetic results. CHAPTER • 117

Lameness in the Dressage Horse

Svend E. Kold and Sue J. Dyson

THE SPORT

Dressage is the ultimate athletic challenge in equestrian sports because it combines balance, suppleness, and power in a unique gravity-defying manner. A good horse gives the impression of athletic elegance and expressive animation. The gaits are described using terms such as *balance, suppleness,* and *hindlimb activity.* The first demand is that the horse is completely obedient and has to go wherever the rider wants and carry out movements at his or her request. In doing so the horse has to rely on its rider, to trust and to accept the rider as its superior. The key to the training and development of a dressage horse from the lowest levels to International Grand Prix is gymnastic exercises, with the aim of strengthening the muscles and thereby avoiding injury to joints and tendons associated with an increased workload.

The Federation Equestre Internationale dressage rules state that the object of dressage is the "harmonious development of the physique and ability of the horse." Through the levels of dressage training, the center of gravity of the horse and rider is placed further caudally, obtained by increasing the degree of flexion and loading of the hindlimbs, while at the same time freeing the front end of the horse to create a more airborne, uphill set of movements. This can be obtained only by increasing the power of the hindlimbs, by synchrony in movement between the forelimbs and the hindlimbs, and through the freedom of movement of the back.

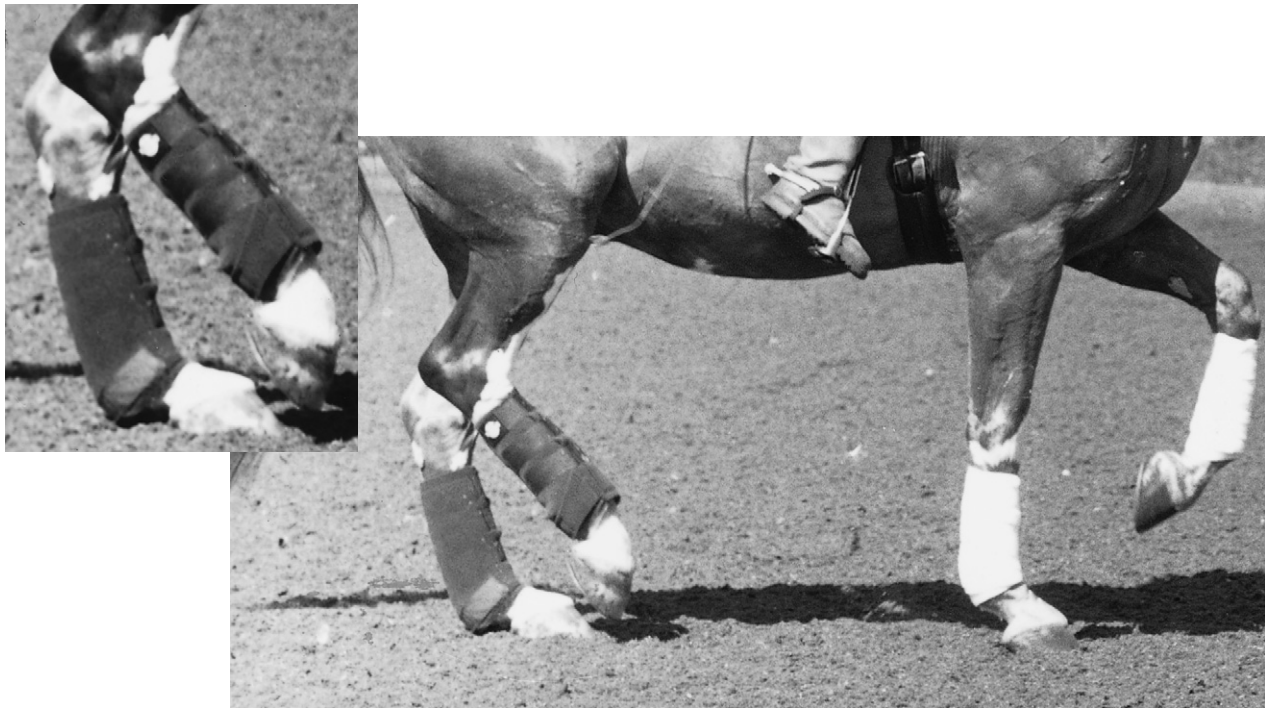

Fig. 117-1 Passage. Note the severe extension of the left metatarsophalangeal joint *(inset)*.

In the German equestrian literature the following terms describe the aims of the correctly trained dressage horse:

- *Takt* (i.e., rhythm)
- *Lossgelassenheit* (looseness and suppleness)
- *Anlehnung* (contact with the bit)
- *Schwung* (energy and swing)
- *Geraderichten* (straightness)
- *Versammlung* (collection)

Dressage is an international sport, although it always has had its main center of excellence in Northern Europe, most particularly Germany, but in later years also in Holland, Denmark, and Sweden. Dressage developed from the military institutes and only in the twentieth century became a truly civilian sport. Even up to the time of the Second World War military officers participated at all the major dressage games.

In Europe the competitive sport has been divided into three levels: L, M, and S. L covers novice level (novice and elementary); M covers medium and advanced medium; and S covers Prix St. Georges, Intermediare I and II, Grand Prix, and Grand Prix Special. The movements required at each of these levels reflects the horse's degree of collection, with the L classes expressing balance and freedom of movement, M classes requiring more collection and lateral movements, and S classes demanding ultimate collection to enable movements of maximum collection and suspension, such as piaffe, passage (Fig. 117-1), and canter pirouettes (Fig. 117-2). However, even the most skilled rider or trainer has difficulty selecting the right horses, because many promising young horses with excellent gaits fail to learn passage and piaffe, probably because of our insufficient knowledge of the biokinematics of collection.[1]

Lateral movements apply specific, unique strains to different structures within the skeleton. In shoulder-in, half pass, renvers, and travers the horse is bent evenly in its neck and body but moves on more than two tracks. In shoulder-in, the horse moves on three tracks (1, outside hindleg; 2, inside hindleg and outside foreleg; and 3, inside foreleg) with the body at an ideal angle of 30° to the direction of movement. In travers (quarters in) and renvers (head to the wall) the horse moves on four tracks. These movements create an unusual strain on the horse's back and an additional twisting movement on the appendicular joints.

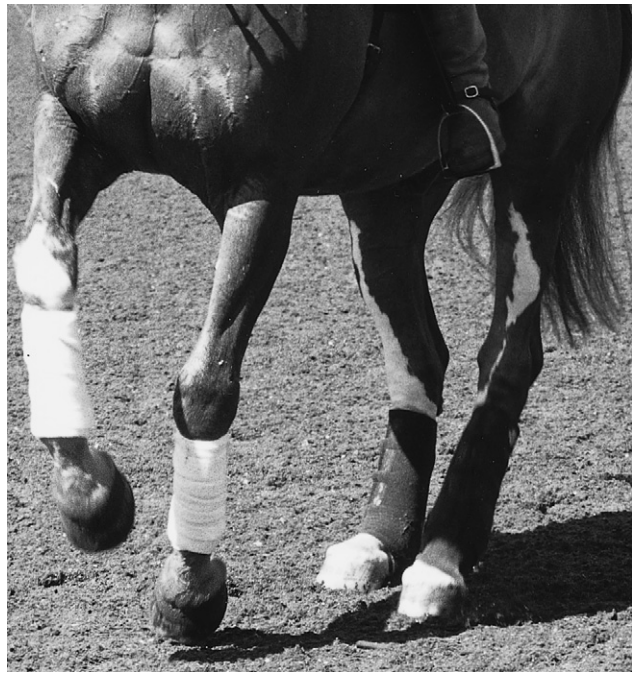

Fig. 117-2 Canter pirouette to the left. The horse intermittently takes all weight on the hindlimbs, resulting in extension of the metatarsophalangeal joints and great strain on the suspensory apparatus.

The increased engagement of the hindlimbs developed through collected work allows for greater storage of elastic

strain energy in the hock joints and pelvis which, via the increased lifting of the forehand, allows for high-energy movements such as medium and extended trot. The term *cadence* is associated closely with working through the back and self-carriage. Self-carriage reflects a level of training in which the horse has learned to balance itself and its rider and additionally has developed its musculature to allow movement with greater range of freedom.

Anlehnung (contact with the bit) is an important concept to understand, requiring the horse to move freely forward with impulsion, to take the bit, and to accept it and react to it without resistance. The Federation Equestre Internationale rules require the horse to work on the bit, that is, with the front of the head positioned in the vertical plane. In recent years the tendency has been toward training dressage horses in an over-bent fashion, with the horse's forehead behind the vertical plane. This is said to be a requirement for developing the trapezius, rhomboidius, and other muscles of the shoulder/withers region and thus enabling a greater lift of the forehand via the shoulder girdle. Although this method of training contradicts the Federation Equestre Internationale requirement for the horse's forehead to be in a vertical plane, top riders are able to place the horse's head in virtually any position according to what is required.

Contact with the bit and *on the bit* frequently are misunderstood terms. The horse must move with energy and impulsion, working through the back for correct contact with the bit. Misinterpretation leads to restriction of the horse by the hands, sometimes resulting in loss of action and gait irregularities.

THE DRESSAGE HORSE

Most dressage horses competing internationally are Warmbloods (WBLs) with a high proportion of Thoroughbred (TB) breeding. Dressage horses today combine the elegance and athleticism of the TBs with the power and trainable mind of the WBLs, which have been selected for many generations for these traits. Few pure TBs reach international standard. The TB has been bred to run fast or show courage jumping obstacles cross-country, which are not of great value when the rider requires complete obedience to perform movements that go as much upward and sideways as forward. Most TBs also lack the strength in all three paces compared with the WBLs, in particular the walk and the trot. Most TBs do not show the same degree of natural engagement of the hindlimbs typical of many WBLs. Many of the greatest TB sires in post-war European dressage breeding (Der Löwe, Velten, and Pik As) have been neither particularly physically impressive nor equipped with more than an average trot. Theoretically, TB stallions in WBL breeding have required a minimum general handicap to ensure that they had been physically and mentally strong enough to stand up to training and race reasonably successfully.

The dressage horse must be naturally well balanced. The head and neck must be set sufficiently high to facilitate working up hill and making easy contact with the bit. The shape of the withers region is important, so that the saddle sits easily in the correct position. The dressage rider spends a lot of time sitting in the saddle in sitting trot; therefore correct weight distribution is critical.

Most dressage horses are broken at 3 or 4 years of age and begin competing in young horse classes at 5 years of age. Medium classes are reached by the age of 7 and many future Grand Prix dressage horses do a small tour at the age of 8 and 9. Once a dressage horse has reached Grand Prix level, the training predominantly involves repetition of movements, maintaining suppleness, and increasing physical power. Thus dressage horses obviously rarely succumb to acute stress-induced traumatic injuries but more likely succumb to repetitive, accumulative subclinical injuries that may surface at irregular intervals. This means that, with the correct training and management, dressage horses can continue to compete at the highest level at an advanced age, often as old as 15 to 20 years. Many of the Lipizzaner stallions at the Spanish Riding School in Vienna are touring and performing adequately well after 20 years of age.

A true link between conformation and soundness is difficult to establish, because what creates an outstanding dressage horse in terms of conformation does not necessarily create a particularly sound dressage horse, and vice versa. However, in a study of 4-year-old Swedish WBL horses, highly significant correlations were found between conformation and movement and between conformation and orthopedic health, whereas no correlation was found between the overall conformation score and competition performance.[2] A series of elite dressage horses had larger hock joint angles and more sloping shoulders than more average horses, whereas good forelimb movements were characterized by a large range of flexion of the elbow and carpal joints during the second half of the swing phase. This is what previously has been referred to incorrectly as shoulder freedom. It is important that a young horse naturally places the hindlimbs well underneath itself, because the approach angle does not seem to be influenced by training.[1]

Wear and tear lesions frequently occur because of a less than ideal joint and limb angulation, but many other factors influence the durability of the horse, including genetic predisposition and less than ideal management conditions before skeletal maturity. The main requirement must be the ability of the horse to balance itself at all paces, because imbalance and asynchrony in movement apply unusual strains on many structures. Holmström[1] found that a large positive diagonal advanced placement (the spatial difference between the contralateral forelimb and hindlimb contacting the ground) correlates with high trot scores and suggests this as an important indicator of the horse's natural balance. The positive diagonal advanced placement does not change with more collection and therefore may become a useful selection criterion. Holmström also found that a group of selected elite horses with high gait scores had significantly larger stride duration, increased hind stance phase duration, and greater diagonal advanced placement than a group of horses with low gait scores.

TRAINING SURFACES

Dressage horses are trained predominantly on artificial surfaces with a high degree of cushion, providing a consistency in the training surface not paralleled in other equestrian sports. All dressage competitions in mainland Europe take place on artificial surfaces, and only in England does dressage at the lower levels (L) still take place on grass. A multitude of artificial surfaces have been developed over the last 20 years. Most are based on silica sand mixed with a variety of rubber and polyvinyl chloride material, together with a binding and dust-limiting agent such as vaseline, which ensures that such surfaces remain frost-free down to –10° C. This standardization of working and competition surfaces unquestionably plays a huge role in the low occurrence of many acute orthopedic problems in the dressage horse. Some trainers, however, consider constant working on ideal surfaces likely to soften the limb structures and recommend that the horses occasionally are jumped or hacked on less ideal surfaces to provide a stimulus for joint, tendon, and ligament adaptation.

Arena maintenance is paramount; drainage is an essential key to a good surface. An adequate drainage system through central and perimeter drains is absolutely essential to maintain

a good arena. Dead corners of deep sand predispose horses to momentary loss of balance and may predispose to the development of lameness. Any sudden change of surface integrity predisposes horses to lameness. Young horses in particular work more easily and confidentially on firmer artificial surfaces, where they can obtain a more confident grip and are less likely to fatigue.

TACK

The horse must be comfortable in its tack if it is going to work optimally. Dressage saddles are designed to position the rider with a deeper seat and with an extended leg position. The surface area over which the weight is distributed must be as large as possible, to avoid focal pressure points. The use of gel pads and layers of numnahs (saddle pads) is not a substitute for good saddle fit. The saddle must fit the horse and the rider and must position the rider appropriately in balance. The fit must be assessed with and without a rider. The shape of the horse's back musculature may change as the horse develops muscular strength and power; therefore a previously well-fitting saddle may become constricting.

Acceptance of the bit is crucial in the dressage horse. Horses vary considerably in the shape of the mouth and the sensitivity of the corners of the lips, bars, and tongue. Great variation also exists in the thickness of the tongue between horses. A slight crack in the corner of the mouth, caused by an inappropriate bit, can cause major problems with proper acceptance of the bit and the horse's willingness to work straight. At S level, horses have to compete wearing a double bridle, that is, the mouth has to accommodate both bradoon (snaffle) and curb bits. These vary greatly in shape and design, and selection of the most appropriate can be critical.

LAMENESS EXAMINATION

Examining the lame dressage horse does not differ in any great detail from examining any other equine athlete. However, examination frequently requires more time being spent observing the horse ridden, because many dressage horses only reproduce the perceived problem, often no more than a resistance, when ridden through certain movements. This, however, does not mean that the horse should not be examined in hand, including walking and trotting on a straight line and lunging on hard, non-slip surfaces (such as gravel) and on softer artificial surfaces. Not only does lunging on tarmac or concrete carry the risk of the horse slipping, with potentially disastrous consequences, but also in most horses such lunging alters the gait so much that it has little value in a lameness examination of an extravagant moving dressage horse. Leading the horse on a circle at a trot also tends to alter the horse's stride. The horse does not have the freedom to move its neck and instead will set its head on the leader's hand.

In many horses the usual rider has to be available to reproduce the described problem, if lameness is not overt. However, one should remember that just as bad riders create lameness, so good riders may hide lameness. The latter may take place completely unintentionally and may involve no more than a corrective change of point of balance of the rider through a corner, but enough that for a long time the problem may not be observable from the ground. Most veterinarians who are not competent riders are not experienced fully to appreciate the subtle differences in high-quality dressage horses and by attempting to ride the horse to better appreciate the problem may create an embarrassing situation. They are better advised to spend more time observing the horse from the ground.

The veterinarian should not just focus on the limbs when watching the horse ridden. It is important to observe changes such as an increased lathering of the mouth, audible change in the rhythm of the stride, or even absence of teeth grinding or grunting after a particular diagnostic test.

For many horses the veterinarian relies heavily on the conceived observations of the rider during the lameness examination; this may involve the appreciation of subtle change of gait, or even just an impression of a stronger rhythm or less heavy contact on the bit after a peripheral nerve block. Many riders feel through their own body that the horse is working crookedly, that is, not straight and is not in complete balance, and will be able to tell the clinician if this feeling has been altered by any of the diagnostic tests.

In many horses, alternating between lunging and ridden work is useful, often going back to lunging with full tack after the horse has been ridden to see a possible difference in the gait from being ridden.

A useful test is to ask the rider to ride deliberately on the wrong diagonal, that is, to sit to the trot in the saddle when the inside forelimb is bearing weight. Horses with forelimb or hindlimb lamenesses and horses suffering from back pain may alter the gait when the weight-bearing diagonal (of the horse) is changed. The difference between the horse's outline and attitude when changing between sitting and rising trot also may add valuable information.

In some horses lameness is *created* by the rider. This most commonly occurs with amateur riders who misunderstand the principles of creating an outline and working the horse forward to the bit. Over-restriction by the hands, with inadequate impulsion, can create gait irregularities. Lower-level trainers are sometimes unable to appreciate these problems and may themselves be unable to work the horse better. Using a good professional rider who is not the trainer to work the horse is therefore preferable. Determining definitively whether the problem is one of riding or of training or a reflection of a genuine lameness may require several days. A rider who sits consistently crookedly can create back pain and loss of hindlimb rhythm and symmetry. Some dressage horses are exuberant and expressive movers and also strong-willed characters that may refuse to go forward properly if ridden by an enthusiastic but less competent amateur rider, especially if the rider is somewhat apprehensive and inclined to be overrestrictive. Nappy (resistant) behavior and unwillingness to work may reflect a pain-related problem, but not necessarily so.

One should remember that not all horses are athletes. Many owners tend to think that all horses can learn to do dressage. Veterinarians must in certain situations be prepared to offer the opinion that the particular horse has too many shortcomings physically or psychologically to be able to perform advanced dressage. A veterinarian may be able to help a horse overcome a specific problem but cannot provide missing athleticism.

The veterinarian should not forget to check the obvious. Dressage horses physically alter during a training lesson. As the muscles over the withers and shoulders expand, a particular saddle that may appear to fit correctly before working the horse may be restricting an hour later, when the horse begins piaffe and passage movements. It is also important to check that the bit is the correct size and is placed correctly in the horse's mouth. Horses' tongues vary greatly in size and when using two bits some adjustments may be required. The corners of the mouth are easily cracked and can become sore. The horse may be apprehensive about taking the bit, may take irregular steps, or may be reluctant to bend properly. Wolf teeth frequently are blamed for reluctance to accept the bit properly and for irregularities in gait. Provided that a wolf tooth is immediately in front of the first upper cheek tooth and is not mobile, the tooth rarely is associated with pain.

Horses with a short poll and a relatively large mandible have difficulty in acquiring the correct degree of neck flexion. In these horses it is also important to check that air flow is not impaired. Restricted airflow is not necessarily accompanied by an audibly abnormal inspiratory and/or expiratory noise.

If a diagnosis cannot be made because clinical signs are too subtle, or if it is difficult to determine whether the presenting clinical problem is pain related, working the horse while treating it with anti-inflammatory medication (2 to 4 g phenylbutazone/day PO) for 2 to 3 weeks may be useful. If lameness returns once the medication is withdrawn, the performance problem can be attributed to pain. The lameness also may be worse, making further investigation easier. If the horse appears to have a low-grade bilateral problem, starting by blocking one limb (front or hind) to see if a contralateral limb lameness subsequently becomes obvious can be useful. This is sometimes misleading, however, and blocking both limbs simultaneously and then re-assessing the overall freedom of movement and balance may be more valuable.

DIAGNOSTIC ANALGESIA

Technically no differences exist between dressage horses and other equine athletes concerning diagnostic analgesia. However, the horse's response should be assessed when ridden and when trotted in hand. Because only minor irregularities in gait are often the point of investigation in lame dressage horses, it is particularly important that the conditions, including the surface, remain consistent throughout the lameness investigation. Starting the investigation on one surface only to find that halfway through the nerve blocks the horse has to be assessed on a different surface is not possible. Indoor arenas obviously are of great assistance in severe winter conditions.

Although the sequence of the nerve blocks in theory should be the same in all equine athletes, known common lameness sites in dressage horses often make focusing on these areas possible to save time and to avoid an unnecessary number of injection sites and undesirable number of clipped sites. If clipping is essential, many riders prefer the entire limb (and contralateral limb) clipped symmetrically rather than many small clipped sites in one limb.

IMAGING CONSIDERATIONS

Imaging of the lame dressage horse is no different from imaging any other equine athlete. However, the frequent lack of overt lameness in a sub-maximally performing dressage horse often makes including every possible diagnostic modality necessary. This is particularly true for evaluation of the neck and the back, both of which are important structures for balance and coordination. These are areas where diagnostic analgesia is less applicable than in the limbs.

Radiographic evaluation of the thoracolumbar region requires fixed or semi-mobile radiographic equipment. Use of a Dodger-T aluminum wedge filter to attenuate the primary x-ray beam facilitates acquisition of high-quality images of the dorsal spinous processes.[3]

Diagnostic ultrasonography of the thoracolumbar and pelvic regions is also useful, used transcutaneously or per rectum to image the supraspinous ligament and epaxial musculature, the synovial articulations (facet joints), and the ventral aspect of the lumbosacral junction.[4]

Nuclear scintigraphic evaluation can be particularly helpful in evaluating the thoracolumbar and pelvic regions. However, no studies have been done on the variation in radiopharmaceutical uptake in a population of normal dressage horses. Such a study may throw light on subclinical orthopedic problems in dressage horses. However, as with all imaging techniques great scientific integrity is demanded to distinguish between normal variations and pathological lesions, and results must be correlated carefully with clinical observations and with other imaging modalities.

Computerized thermographic image analysis may be helpful. Thermography is a non-invasive physiological imaging technique that may detect pathological changes before structural changes are apparent. Thermography is also capable of identifying more than one area of altered tissue metabolism, which may reflect a secondary area of pain. Thermographic data does not lie, but interpretation of data is challenging.

TEN MOST COMMON LAMENESS CONDITIONS

The 10 most common lameness conditions in dressage horses are listed not necessarily in strictly decreasing order of importance or frequency, but they represent a selection of the most commonly encountered lameness problems.

1. Proximal suspensory desmitis (PSD)
   a. Hindlimbs
   b. Forelimbs
2. Suspensory branch lesions
3. Synovitis or osteoarthritis of the forelimb distal interphalangeal joints
4. Desmitis of the forelimb accessory ligament of the deep digital flexor tendon (ALDDFT)
5. Osteoarthritis of the centrodistal or tarsometatarsal joints
6. Synovitis of the middle carpal joint (possibly with palmar intercarpal desmitis)
7. Synovitis or osteoarthritis of the metacarpophalangeal and metatarsophalangeal joints
8. a. Palmar/plantar annular desmitis
   b. Tenosynovitis of the digital flexor tendon sheath: forelimbs and hindlimbs
9. Palmar cortical stress fracture of the third metacarpal bone
10. Thoracolumbar and sacroiliac pain

Proximal Suspensory Desmitis: Hindlimbs

Probably the most important cause of lameness in dressage horses working at medium and advanced levels is PSD. The carrying capacity of the hindlimbs is increased with increased collection required for more advanced work, and movements such as piaffe, passage, and canter pirouettes (see Fig. 117-2) place great strain on the hindlimb suspensory apparatus. Suspensory desmitis is believed to be caused by an accumulation of repetitive strains within the suspensory ligament (SL) and its proximal origin. Detection of PSD is often delayed because of its bilateral nature, which often means that overt hindlimb lameness is not present or noticed by the rider. Accurate diagnostic nerve blocks therefore are required to reveal lameness. When no obvious lameness is present, lameness often is created subsequently in the contralateral hindlimb by diagnostic analgesia of either of the (non-lame) hindlimbs. A negative response can be misleading, and it is sometimes necessary to block both hindlimbs simultaneously, after which there may be a substantial improvement in gait. Direct palpation of the region often fails to indicate a problem because of the deep location of the proximal SL. The clinical diagnosis is confirmed by positive subtarsal analgesia, together with negative intra-articular analgesia of the tarsometatarsal joint.

Extensive ultrasonographic and radiographic changes often reflect a chronic and long-standing problem. Ultrasonographic images reveal enlargement of the proximal SL in the lateromedial and dorsoplantar planes, with areas of reduced echogenicity, often involving one or both of the dorsal quadrants of the

ligament. Radiographic diagnosis requires high-quality radiographs of the proximal metatarsal region; dorsoplantar and lateromedial views are the most useful. Irregularity of the proximal plantar cortex may occur in the region of insertion of the SL origin, with a varying degree of endosteal new bone resulting in trabecular sclerosis over a distance of up to 5 cm. On dorsoplantar radiographs this may be seen as a centrally positioned, triangular-shaped area of sclerosis within the trabecular metaphysis of the third metatarsal bone (MtIII). One should remember, however, that such radiographic changes may be present in an asymptomatic horse because of previous problems, leading to the risk of a false-positive diagnosis. Diagnosis should never be based only on radiographic examination.

Occasionally, nuclear scintigraphy can be useful in horses with early desmitis where no radiographic changes are present and subtle, equivocal abnormalities are detected with ultrasonography. Increased radiopharmaceutical uptake may occur in the proximoplantar aspect of MtIII in bone-phase (delayed) images. Pool-phase (soft tissue) images are rather insensitive, and not all horses have associated increased radiopharmaceutical uptake in MtIII. Thus a negative bone scan does not preclude PSD.

Treatment of this condition often is frustrating because of the chronic nature of the problem at the time of detection. Corrective shoeing using egg bar shoes provides some support in horses with severe hyperextension of the fetlock joint. Prolonged rest (3 to 6 months) often provides a disappointing response, and a controlled exercise program may be more successful. Periligamentous injection of 2 ml of hyaluronan (Hyonate, Bayer AG, Leverkusen, WG) plus a corticosteroid (e.g., 10 to 20 mg of methylprednisolone [Depo-Medron, Upjohn, Crawley, UK] or 10 mg of triamcinolone acetonide [Adcortyl, Squibb & Son, Hounslow, UK]) are now used frequently and are believed to provide an initial reduction in inflammation to enable a reasonably pain-free walking program to be initiated. This frequently is continued for as long as 12 weeks before slow, balanced trotting on a good surface is initiated.

The ultrasonographic appearance of the SL often changes little, even in horses that are returned successfully to full training. Egg bar shoes often are removed when normal training is initiated, because many riders believe that they provide too much breaking action on ground impact of the hindlimbs. The likelihood of recurrence of PSD is high, and special care should be taken not to over-work the horse on deep or holding surfaces. Modification of the training program often is required, particularly in terms of avoiding fatiguing training session in deep or loose surfaces.

Some horses have chronic lameness that fails to respond to therapy. Recently some encouraging results have been achieved by treatment of horses with acute and chronic desmitis with shock wave therapy, using three treatments at 2-week intervals, with substantial improvement in lameness and ultrasonographic appearance of the ligament. Neurectomy has a role in horses that fail to respond to medical management.

Proximal Suspensory Desmitis: Forelimbs

Forelimb PSD is seen more often than hindlimb PSD in younger horses and may result from hyperextension of the carpus in extravagantly moving horses, in particular horses volunteering extended trot. PSD often results from the horse working on less than ideal surfaces. Lameness is often unilateral and acute in onset but is sometimes bilateral. Most sound horses resent firm manual squeezing of the body of the SL, and the proximal region of the SL is difficult to access by palpation; therefore local analgesic techniques are required to verify the source of pain.

In horses with peracute PSD, slight filling in the proximal metacarpal region may occur, but this often resolves within 24 hours. Lameness may be transient unless the horse is worked again. In these horses, the veterinarian relies on a history of acute-onset lameness that is worse with the affected limb on the outside of a circle for diagnosis. Lameness is often easier to feel (by a rider) than to see.

Some improvement is often seen after perineural analgesia of the palmar and palmar metacarpal nerves at mid-cannon level. Lameness is substantially improved or resolved by blocking the lateral palmar nerve or the palmar metacarpal nerves at the subcarpal level. Because of the close proximity of the middle carpal joint capsule, positive subcarpal analgesia should be followed by intra-articular analgesia of the middle carpal joint to exclude articular pain.

Radiography is frequently of little or no value in dressage horses with forelimb PSD. Ultrasonography is required to confirm the diagnosis. Because subtle lesions may be present and may be a reflection of a previous pathological condition (possibly subclinical), high-quality ultrasonographic images of both limbs are required for comparison, together with knowledge of normal variations. Lesions vary from subtle enlargement of the proximal aspect of the SL with normal echogenicity to large areas of reduced echogenicity.

Rest, often for 12 to 16 weeks, together with a controlled, ascending walking program, in hand using a horse walker or ridden, is the treatment of choice. Intralesional injection using 2 ml of a polysulfated glycosaminoglycan (PSGAG [Adequan, Janssen Pharmaceutical, High Wycombe, UK]) may be tried.

The prognosis is good in horses with early PSD, provided that the horse is managed carefully subsequently, avoiding the medium or extended trot in training. In horses with chronic PSD the risk of recurrence is moderately high. Shock wave therapy has been useful in treating some of these horses. In some horses, ultrasonographic appearance may not change substantially, despite a favorable clinical response to treatment, leading to a risk later of false-positive diagnosis in an asymptomatic horse.

Desmitis of the Suspensory Ligament Branches: Forelimbs and Hindlimbs

Desmitis of a branch of the SL is often acute in onset and results in palpable enlargement of the suspensory branch and often moderate lameness. Occasionally, both medial and lateral branches are involved in a hindlimb. The branch is painful to palpation. Diagnosis is confirmed by ultrasonography. Enlargement of the branch is often accompanied by some subcutaneous echogenic material, often with a central (sometimes eccentric) hypoechogenic or anechogenic core lesion. The interface between the ligament branch and the proximal sesamoid bone may be disrupted. This is best seen on longitudinal images and merits a more guarded prognosis. If both branches in a hindlimb are involved, echogenic material may be visible between the branches. The PSBs may or may not show radiographic evidence of enthesopathy, with linear opacities extending from the palmar/abaxial margin. Ectopic mineralization within the SL branch is occasionally seen with ultrasonography and radiography.

Treatment is prolonged rest (4 to 6 months) with a slow return to exercise. Intralesional injections using 1 ml of a PSGAG may be tried but generally have met with disappointing results. Counterirritation (pin firing) has been tried on old, indurated lesions and chronic lameness, but again with disappointing results. Some horses have responded to intralesional treatment with β-aminoproprionitrile fumarate. Encouraging results also have been obtained recently with shock wave therapy (three treatments at 2-week intervals), combined with a controlled walking exercise program for 3 to 4 months.

The risk of recurrence is high. Any predisposing causes such as limb deviations or lateromedial imbalance of the feet should be corrected or at least adjusted.

Synovitis or Osteoarthritis of the Distal Interphalangeal Joint

Pain arising from the distal interphalangeal joint is a frequent diagnosis in all equine sports. The unique anatomical position of the distal interphalangeal joint, with the forces distributed on it through the rigidity of the hoof capsule and the forward thrust of the deep digital flexor tendon and the navicular bone during weight bearing and limb protraction, are likely to be contributory factors. Lateromedial imbalance of the foot contributes to the joint trauma in many horses.

The diagnosis is made from comparing the response to intra-articular analgesia with perineural analgesia of the palmar digital and palmar (abaxial sesamoid) nerves and occasionally intrasynovial analgesia of the navicular bursa. The interpretation of the response to intra-articular analgesia is not black or white. Recent studies have confirmed that intra-articular analgesia of the distal interphalangeal joint is not specific and can influence pain associated with the navicular bone, distal phalanx, and subsolar tissues. A rapid (within 5 minutes), positive response to a small volume (maximum of 6 ml) of local anesthetic solution may be a good indicator of the possible response to subsequent intra-articular medication. A good response to subsequent treatment requires at least 75% clinical improvement after intra-articular analgesia, together with absence of significant radiographic changes involving the distal interphalangeal joint or the navicular bone.

Radiographic changes usually involve the extensor process of the distal phalanx and the dorsoproximal margin of the navicular bone. One should remember that a considerable shape variation exists in the extensor process within sound horses. Minor modeling changes may not be of clinical significance. Small, mineralized fragments proximal to the extensor process may be seen incidentally. Large fragments may require surgical removal to prevent secondary osteoarthritis.

Intra-articular medication using a number of individual drugs or combination of drugs has given encouraging results, although results vary between clinicians and populations of horses. Horses with recent onset of lameness with palpable distention of the distal interphalangeal joint capsule may respond favorably to 10 mg of triamcinolone acetonide or 10 to 20 mg of methylprednisolone acetate, combined with a short period of controlled walking exercise (e.g., 2 weeks of ridden walk or on a horse walker). Injection with hyaluronan probably will provide a similar response in such horses. The most successful long-term results have been seen after a triple series of intra-articular injections of a PSGAG. PSGAGs received some negative press after a research study in North America in 1989 that suggested that PSGAGs have a potentiating effect on a subinfectious dose of *Staphylococcus aureus* in a joint. Subsequently, this preparation has been used sparingly intra-articularly and in many horses only in combination with intra-articular amikacin. We have not seen any negative reaction (inflammatory or infectious) to multiple intra-articular joint injections of PSGAGs and do not use systemic or intra-articular antibiotics. Strict asepsis and a skillful technique are essential. Because of its distal location in the limb, distal interphalangeal joint should always be bandaged for at least 24 hours after injection. Eighty-two percent of dressage horses returned to soundness after PSGAG medication of the distal interphalangeal joint, whereas only 65% of a similar size group of horses competing in cross-country jumping returned to soundness.[5] In most horses the initial triple injection proved adequate, and re-medicating the joint in successfully treated horses was rare. Corrective shoeing by improving the foot-pastern axis and re-establishment of correct hoof balance should be performed with intra-articular medication. Egg bar shoes often are used for an initial 3- to 6-month period.

Desmitis of the Accessory Ligament of the Deep Digital Flexor Tendon: Forelimbs

Desmitis of the ALDDFT frequently occurs as an acute injury associated with sudden onset of lameness and palpable inflammation (heat and swelling) in the proximal metacarpal region. Over-extension of the carpus, because of imbalance in young horses or resulting from imperfect working surfaces, often is believed to be a contributory cause.

The diagnosis is confirmed by ultrasonography in both transverse and longitudinal planes. There is enlargement of the ALDDFT, together with loss of definition of the margins and areas of reduced echogenicity. A definite, hypoechoic core lesion is recognized infrequently.

Horses with desmitis of the ALDDFT respond better to a controlled walking exercise program than to complete box rest. Three to 6 months of controlled walking often is required in horses with severe desmitis. The risk of recurrence is moderately high. Local invasive treatment of desmitis of the ALDDFT seldom has been rewarding, although some horses have responded favorably to treatment with β-aminoproprionitrile fumarate.

Osteoarthritis of the Centrodistal and Tarsometatarsal Joints

Lameness or poor performance (e.g., inability to perform piaffe or passage) associated with pain arising from the centrodistal or tarsometatarsal joints occurs frequently in dressage horses. Likewise, a horse with an outstanding freedom of movement in the trot may have an unexplainably poor canter associated with distal distal joint pain. A poor correlation exists between the clinical signs, including response to intra-articular analgesia of the tarsometatarsal and centrodistal joints, and the radiographic appearance of these joints. Many dressage horses have confirmed pain from the joints but have fairly equivocal radiographic changes. One should remember that the degree of joint collapse and osseous ankylosis always is underestimated from conventional radiographs because of the curvilinear nature of the joints and the low radiodensity of immature bone bridging the joint centrally. Nuclear scintigraphy may be a sensitive indicator of increased bone modeling in the absence of radiological abnormalities or in horses with equivocal changes and also can be helpful in horses with subtle lameness, when the response to local analgesic techniques is difficult to interpret. Alternatively, diagnostic medication with intra-articular corticosteroids may be helpful.

Pain is often bilateral, and often the presenting problem is shortening of the hindlimb stride and an inability to collect. Clinical signs mimicking back pain, rather than overt lameness, may be present.

Most horses respond to intra-articular analgesia of the tarsometatarsal and centrodistal joints, although occasionally a better response is seen after fibular or tibial nerve blocks or after treatment of the joints. Intra-articular analgesia of the tarsometatarsal joint and the response to subtarsal analgesia should be compared. In horses with advanced radiological changes, false-negative responses to intra-articular analgesia may occur.

Horses with few or no radiographic changes may respond satisfactorily to intra-articular medication with a corticosteroid (e.g., 10 to 20 mg of methylprednisolone acetate or 10 mg of triamcinolone acetonide), and/or 1 ml of a PSGAG if lameness is of longer duration. Medical treatment often is combined with a program of controlled walking exercise for 4 to 6 weeks (pending response to treatment), together with alterations of the shoeing. Horses that tend to plait or swing the affected limb axially during protraction may benefit from a lateral extension shoe, which may help to normalize posture and hindlimb gait pattern with an additional effect on secondary back pain.

Repeated medication of the joint(s) may be required at monthly or quarterly intervals. A longer response may be achieved by combined use of corticosteroids and hyaluronan.

Additional PSGAG medication given intramuscularly on a weekly basis (500 mg/ml, 7 × 5 ml) may be beneficial. Glucosamines and chondroitin sulfate given orally on a daily basis often are administered, but clinical efficacy is unproven.

If substantial radiographic changes are present and the joint is changed irreversibly and the horse fails to respond to repeated intra-articular medication, fusion of the joints by surgery or by intra-articular injection of sodium monoiodoacetate can be considered, but the prognosis for high-level dressage is guarded.

Synovitis of the Middle Carpal Joint

Lameness associated with pain in the middle carpal joint has been seen in many dressage horses, in particular young horses that still may be struggling to establish balance and synchronicity in all paces with the additional weight of the rider. Lameness is often mild and most frequently unilateral, being most noticeable when the limb is on the outside of a 10-m diameter circle. Momentary hyperextension of the carpus, often on a tight circle, is believed to be involved.

If the response to analgesia of the middle carpal joint is positive, the proximal SL should be examined by ultrasonography to preclude injury.

Usually no radiographic or ultrasonographic changes involve the middle carpal joint. Arthroscopy of the middle carpal joint sometimes reveals damage to one or both (most frequently the medial) of the palmar intercarpal ligaments, which show edema, petechial hemorrhage, and fraying of superficial fibers.

Most horses respond well to intra-articular medication using a triple series of 1 to 2 ml of a PSGAG given 8 days apart, or treatment with short-acting corticosteroids combined with hyaluronan. Six to 8 weeks of ridden walk or on a horse walker should be followed by a modified training program for at least another 3 months.

Synovitis or Osteoarthritis of the Metatarsophalangeal and Metacarpophalangeal (Fetlock) Joints

Fetlock joint disease is not a common problem in dressage horses and certainly does not seem to be as common in this type of equestrian sport as in others. The absence of galloping across often firm and irregular surfaces associated with cross-country jumping is a likely explanation.

The diagnosis is confirmed by palpation and intra-articular analgesia. In the absence of radiographic changes, intra-articular medication using a corticosteroid (e.g., 10 mg of triamcinolone acetonide), together with 2 ml hyaluronan in horses with synovitis, or 1 ml of PSGAG in horses with more long-standing osteoarthritis, frequently has proved successful. Generally the response to medication is good and the likelihood of recurrence is low in the forelimbs. The response is poorer in hindlimbs. Horses with radiographic abnormalities consistent with osteoarthritis warrant a more guarded prognosis.

Palmar/Plantar Annular Desmitis

Desmitis of the palmar (plantar) annular ligament (PAL) occurs more commonly in forelimbs than in hindlimbs and usually results in acute-onset lameness. The PAL has localized heat and is palpably enlarged, with pain elicited by firm pressure. Mild distention of the digital flexor tendon sheath (DFTS) may occur. Diagnosis is confirmed by ultrasonography. The PAL is thickened, with a diffuse reduction in echogenicity or focal hypoechoic areas. Horses with acute desmitis usually respond well to box rest and controlled walking exercise for 3 months. In the acute phase, non-steroidal anti-inflammatory drugs (e.g., phenylbutazone 2 g bid PO for 5 days) are beneficial.

Tenosynovitis of the Digital Flexor Tendon Sheath

Tenosynovitis of the DFTS often results in sudden-onset lameness associated with distention. Some horses have long-standing distention of the DFTS without lameness (windgalls), especially in the hindlimbs, but subsequently develop clinically important tenosynovitis. Constriction of the DFTS by the PAL may be apparent. Lameness may vary from mild to severe and usually is accentuated by distal limb flexion. If distention of the DFTS is acute in onset, then local analgesia is usually unnecessary. However, if distention of the DFTS has been present for some time, then the source of pain should be confirmed by local analgesia. Intrathecal analgesia of the DFTS usually results in substantial improvement in lameness but often does not alleviate it fully. Perineural analgesia of the palmar (plantar) (mid-cannon) and palmar metacarpal (metatarsal) nerves usually eliminates lameness. Improvement sometimes is seen after perineural analgesia of the palmar nerves at the level of the PSBs. Excluding the metacarpophalangeal joint as a potential source of pain by intra-articular analgesia may be necessary.

Ultrasonographic examination should be performed in the metacarpal and pastern regions. Usually an abnormal amount of fluid within the DFTS allows better visibility of synovial plicae extending from the medial and lateral margins of the deep digital flexor tendon (DDFT) in the distal metacarpal region and the synovial fold on the palmar aspect of the DDFT in the pastern region. These should not be confused as adhesions or tears of the DDFT. In horses with chronic tenosynovitis, the DFTS wall may be thickened, with echogenic bands within the DFTS representing adhesions. Ultrasonography frequently underestimates adhesion formation. The SDFT and DDFT should be inspected carefully, because tenosynovitis may be secondary to a primary pathological tendon condition. Lesions of the DDFT occur more commonly, either as core lesions or marginal tears. The latter can be difficult to detect by ultrasonography. Enlargement of the cross-sectional area of the tendon compared with the contralateral limb suggests a lesion, which may be confirmed only by tensocopic evaluation of the sheath contents. Mineralization within the DDFT warrants a guarded prognosis.

Horses with early tenosynovitis without adhesions respond well to intrasynovial administration of a corticosteroid (e.g., 10 mg of triamcinolone acetonide) or 2 ml of hyaluronan, together with a pressure bandage and box rest with hand walking for 4 to 6 weeks.

If the horse fails to respond adequately to medical therapy, then surgical exploration is warranted. Tenoscopic evaluation should be performed to evaluate the extent of adhesion formation and to detect longitudinal tears in the medial or lateral margins of the DDFT, which may extend proximally under the manica flexoria. Resection of intrasynovial adhesions and lavage, with or without resection of the palmar/plantar annular ligament, may resolve the problem. Horses with lesions of the DDFT that may be debrided and possibly sutured warrant a more guarded prognosis. Surgery is frequently followed by intrasynovial injection of 2 ml of hyaluronan, repeated 4 to 6 weeks later to reduce inflammation and to try to prevent adhesions reforming.

The response to surgery depends on the chronicity of the problem, the number of intrasynovial adhesions, and the presence of lesions of the DDFT. Horses with lesions involving the forelimbs appear to have a better prognosis than those involving the hindlimbs. Surgery is accompanied by 8 to 12 weeks of absence from training, although controlled walking in hand or on a horse walker is essential to try to stretch any adhesions that reform.

Proximal Palmar Cortical Stress Fracture of the Third Metacarpal Bone

Proximal palmar cortical stress fracture of the third metacarpal bone occasionally is seen in dressage horses with an acute onset of moderate to severe lameness. Hyperextension of the carpus and imbalance of limb synchrony in immature horses are believed to be contributing factors.

The diagnosis sometimes can be suspected by inducing pain by digital pressure on the palmaroproximal aspect of the third metacarpal bone. When the horse trots on a firm surface, the lameness tends to increase the farther the horse trots. If the horse turns and then trots again, lameness appears to be improved and then increases again. Lameness usually is improved substantially by perineural analgesia of the palmar metacarpal nerves. If the fracture extends into the carpometacarpal joint, improvement also may be seen after intra-articular analgesia of the middle carpal joint.

On radiographs a fracture may be recognized on a dorsopalmar projection as a linear radiolucent line, usually in the medial aspect of the third metacarpal bone and extending up to 8 cm, possibly with surrounding sclerosis. In some horses a fracture line cannot be seen, although sclerosis is present. In some horses no radiographic abnormality is identified. In these horses diagnosis is confirmed by nuclear scintigraphy.

Treatment is complete box rest for 6 weeks, followed by 6 weeks of controlled walking exercise. The prognosis is good, and the likelihood of recurrence low.

Thoracolumbar and Sacroiliac Pain

Thoracolumbar and sacroiliac region pain are frequent causes of reduced performance in the dressage horse. Although caudal thoracic back muscle soreness may be secondary to primary hindlimb lameness, primary back pain does occur and usually is not associated with overt lameness. The horse may have a history of unwillingness to perform certain movements, stiffness, loss of impulsion and cadence, loss of action or being less easy to work in a correct outline, and sometimes bucking or other nappy (resistant) behavior. The horse usually moves better on the lunge than when being ridden. The most common causes of back pain include the following:

1. An ill-fitting saddle
2. The rider sitting crookedly
3. Primary muscle spasm
4. Impingement of dorsal spinous processes in the mid-thoracic to cranial lumbar regions
5. Osteoarthritic changes involving the synovial articulations (facet joints) in the region of the thoracolumbar junction
6. Sacroiliac disease
7. A combination of lesions in the thoracolumbar and sacroiliac regions

Definitive diagnosis of the cause of back pain can be a diagnostic challenge. Obvious causes such as ill-fitting saddle or the position of the rider should be eliminated first before proceeding with more sophisticated diagnostic tests such as nuclear scintigraphy, radiography, thermography, and ultrasonography. If back muscle tension or spasm is obvious, assessing the response to treatment using physiotherapy (e.g., manipulation and therapeutic ultrasound) or anti-inflammatory medication may be worthwhile before further investigation.

Thermography provides pictorial images of the surface temperature of the body, which gives a physiological identification of changes in tissue perfusion or sympathetic neuromuscular dysfunction. Thermography is a useful tool to demonstrate to an owner the effect of a poorly fitting saddle or the rider sitting crookedly and also may be useful in identifying acute superficial ligamentous or muscle injuries.

Nuclear scintigraphy is much more sensitive than radiography for detecting lesions in the thoracolumbar or sacroiliac regions, but radiography potentially gives more structural information, such as the proximity of the dorsal spinous processes. It is important to verify the clinical significance of any lesions identified by infiltration of local anesthetic solution whenever possible. If dorsal spinous processes are extremely crowded, injecting between them may not be possible, but injecting around them (20 to 50 ml of mepivacaine) usually results in substantial improvement within 15 minutes of injection. Ultrasound guidance is necessary for infiltration around synovial articulations.

Treatment is aimed at removing any predisposing factor and control of pain. Local infiltration with corticosteroids (e.g., methylprednisolone acetate combined with mepivacaine) or Sarapin is successful in some horses. If pain associated with impinging dorsal spinous processes fails to be controlled by medical management, then surgical treatment should be considered. Infiltration of a sclerosing agent, P2G (Martindale Pharmaceuticals, Ramford, Exxes, UK), around the sacroiliac joints produces clinical improvement in some horses with pain associated with these joints.

CHAPTER • 118

Lameness in the Three Day Event Horse

Andrew P. Bathe

SPORT OF EVENTING

The sport of eventing generally is considered the most all-round test of a horse's athletic ability, and as such the horses tend to be jacks of all trades rather than excelling in any one particular area. The competition consists of three disciplines, namely dressage, show jumping, and cross-country, with the latter being the most influential phase. The Three Day Event or Concours Complet is the pinnacle of the sport (Fig. 118-1) and is run over 4 days: 2 days of dressage, followed by a day for the speed and endurance phases and a day of show jumping. The speed and endurance test consists of roads and tracks at trotting speed, a steeplechase, and the actual cross-country phase over fixed obstacles. This is a severe athletic test, and horses normally only compete in two or maximally three such competitions in a year.

Fig. 118-1 Example of a cross-country fence at CCI**** level. (Courtesy Kit Houghton Photography, Bridgewater, Somerset, UK.)

One Day Events, or Horse Trials, compress the same disciplines into a shorter time frame, but without the roads and tracks and steeplechase phases. The distance and thus time for the cross-country are also much shorter, so that many such competitions may be completed in a season. For most advanced horses One Day Events are used as training for the Three Day Events, although a large number of recreational competitors only aspire to compete in One Day Events. The emphasis of this chapter is the Three Day Event horse, because the extreme demands placed on this horse give characteristic patterns of lameness; whereas the novice One Day Event horse can be considered a standard riding club or recreational horse from a veterinary point of view.

Eventing is an established Olympic sport and a substantial equine industry. The highest grade of competition is the four-star event (CCI****). Traditionally these have been the English events of Badminton and Burghley, although events of this level now have been established in Lexington, Kentucky, in the United States and in Adelaide, Australia. The sport has a high-risk element for rider and horse and a noticeable recent trend has been to try to make courses safer.

The sport includes substantial veterinary involvement. During a Three Day Event, the horse is examined by the official veterinarians on arrival, the day before commencing the dressage, before and after the cross country, and in the morning before show jumping. The horse must be deemed fit to compete—that is, the horse must be sound—throughout the competition, and thus any orthopedic disorders are of great significance. A mild degree of hindlimb gait asymmetry may be acceptable to the Inspection Panel, but any noticeable forelimb lameness normally is not permitted.

HORSE TYPES

Because the Three Day Event places great emphasis on the horse's speed and stamina, there is a preference toward the Thoroughbred (TB) or predominantly TB-cross breeds. A substantial proportion of horses are of uncertain or unknown breeding. Exceptions have been notable, but Warmbloods and classic Irish hunter types normally do not have the endurance required at the top level. Such horses often may do extremely well at the lower levels, however, because they move and jump better than the pure TB. Figure 118-2 demonstrates what could be considered the ideal modern eventing stamp, a highly successful New Zealand TB. A horse's ability and mental aptitude are the most important determinants, and other body types are successful (Fig, 118-3). An average ideal size would be 16.2 hands, but the rules are not hard and fast.

The financial value of event horses is considerably lower than that for racehorses, show jumpers, or dressage horses, so any horse with outstanding ability in one of these phases is likely to be used in that sport first. If the horses do not succeed, then they may be tried as potential event horses. These horses bring with them any injuries they may have accumulated, but because of the different stresses imposed

during eventing, this may not be a problem. For example, event horses tolerate low-grade carpal pathological conditions from previous race training. A small number of horses are bred specifically for eventing. Stallions generally are considered to lack the courage required to compete at the top level, and because the horse takes a number of years to reach its peak, choosing proven sires is a problem. The predominantly TB Irish sport horse and the relatively larger-boned New Zealand and Australian TBs are sought after.

Event horses normally commence dressage and show jumping training at 4 years of age and start competing in prenovice and novice One-Day Events from the age of 5. Depending on the horse's ability and rider's skill and patience, a horse usually competes in its first (graded as a CCI* or CCI**) Three Day Event at 6 to 7 years of age. A significant proportion of horses do not have the ability, courage, or physical durability to proceed beyond the CCI** or CCI*** level to the top grade of CCI****.

INFLUENCE OF THE SPORT ON LAMENESS

Event horses are generally skeletally mature when they commence training and are not trained at the same speed or intensity as racehorses. They therefore have different patterns of injury, although most of the problems are still related to training. Primary long bone pathological conditions are rare. Soft tissue injuries such as tendonitis are common and often career limiting. The amount of endurance training necessary produces repeated cyclic loading, and problems such as osteoarthritis are common. The other subset of event horse injuries is acute traumatic injuries sustained during competition. Because the horses are jumping large fixed obstacles at speed, they are prone to falls and to direct traumatic fractures.

Fence design has changed in recent years. Square-shaped fences are avoided and rounded top contours are now more common. These fences give horses more leeway to correct mistakes and cause less severe direct impact trauma. The fences may be 1.2 to 1.4 m high, with a 2-m spread and a 2-m drop, so substantial strain can be placed on the supporting structures of the limbs on landing. The quality of the terrain also appears to have an important impact on the incidence of lameness problems. The competitions are run predominantly on turf, the nature of which depends on the soil type, local weather, and management factors. At the lower level, financial constraints generally preclude much improvement on the quality of the ground, but some of the top events try to maintain a permanent track that is tended carefully.

The prolonged period and intensity of training required for horses to reach an elite level means that those horses not metabolically or physically suited to the sport are selected out. For instance, few elite horses have recurrent exertional rhabdomyolysis or navicular syndrome. Three Day Events are regulated by the Federation Equestre Internationale. A strict medication control program is enforced, which permits only emergency medication at the competition after official veterinary approval or the use of a small number of permitted forms of medication, including antibiotics, rehydration fluids, and preparations for treating gastric ulcers.

TRAINING METHODS

Event horses train in all three disciplines, with the actual methods varying greatly between riders. A complete description of training methods is available elsewhere.[1] Most competing horses have natural cross country ability, so little time generally is spent on training for this, because the progression of competitions provides sufficient experience. Event horses normally are selected for natural jumping action, but jumping technique during the cross country phase is different than that needed for show jumping. Therefore event horses may not be as careful when show jumping and can have a tendency to touch poles. Most event horses are show jumped regularly, especially during the off season. The event horse's weakest link is usually the dressage phase. The movements required are no more than a medium level of pure dressage, but the different breeding and level of fitness of these horses means that the major challenge can be to control the horse's temperament. Most of the skills training revolves around this discipline, and a high standard now is required to be competitive at the top level.

Fitness training is a major component of the preparation for a Three Day Event and is where most orthopedic damage is incurred. The horse is likely to undergo a 3- to 4-month training period for the target Three Day Event. Training methods vary greatly between riders and often depend on local factors such as the availability of hills for trotting or all-weather gallops. Restricting the horse to training solely on an artificial surface is not advisable, because this seems to predispose the horse to injury when the horse actually competes on a natural surface.

Event horses normally receive a 6-week initial period of walking and trotting on the roads, and then commence cantering exercise. Different riders vary in their use of conventional or interval training, but usually peak the quantity of work at around three canters of 8 minutes, or shorter if a hill is available. The quality of the work usually is increased closer to the Three Day Event to include faster work. One Day Events are used to monitor the horse's fitness and as additional training. The dressage and jumping training also substantially contributes to the fitness regimen.

CONFORMATION AND LAMENESS

Although the horse's stamp may vary, as discussed previously, the basic conformation must be correct. Eventing is unforgiving to conformational defects compared with show jumping and dressage. The general principles are the same as for any equine athlete. Serious conformational defects include being back at the knee, having upright pasterns and hocks, and a moderate or severe toed-out conformation. Of slightly lesser significance are a long or short back, being over at the knee, or having long, sloping pasterns. Defects such as offset knees and a slight to moderate toed-in conformation seem to be less important. A good foot conformation is always desirable, but many event horses have the TB trait of weak feet with collapsed heels.

The prepurchase examination for a young event prospect, with hopes of a Three Day Eventing career, is likely to be strict. The conformation should be assessed critically at this stage. Although the horse may have sufficient talent, defects in conformation may not allow it to stand up to the 5 or so years of training necessary to reach the top level of the sport. Conversely, it is possible to be more lenient in the interpretation of subtle problems when performing a prepurchase examination on an older, experienced horse. The horse's competitive record should be assessed carefully, because advanced horses are likely to have accumulated wear and tear changes during an extended career. Any conformational or subtle soundness queries can be addressed in the light of the horse's proven ability to perform its task.

TEN MOST COMMON LAMENESS CONDITIONS

Some conditions are more common during training and others are more common at competitions. The overall prevalence is as follows:

1. Thoracolumbar and cervical soreness and restriction
2. Foot soreness (bruising, imbalance, and nail bind)
3. Traumatic osteoarthritis
   a. Distal interphalangeal joint
   b. Metacarpophalangeal and metatarsophalangeal joints
   c. Tarsometatarsal and centrodistal joints
   d. Proximal interphalangeal joint
4. Superficial digital flexor tendonitis
5. Suspensory desmitis
   a. Branch desmitis
   b. Proximal suspensory desmitis
6. External trauma
   a. Lacerations including overreaching injury
   b. Penetrations
   c. Stifle bruising
7. Pain in the sacroiliac region
8. Fractures of the stifle region
9. Other fractures
10. Rhabdomyolysis

CLINICAL HISTORY

A routine lameness history should be obtained, emphasizing and obtaining the following information:

- Horse's competitive level
- Competition targets and timing, ahead or behind in its fitness schedule
- Previous problems
- Recent competitive/training program
- Current medications
- Prodromal signs
- Onset acute or insidious
- Exact nature of problem (limb swelling, lameness, or poor performance)
- Progression of problem
- Response to treatment

LAMENESS EXAMINATION

My standard approach to the lameness examination is found in the following discussion. The regions requiring particular attention and the most rewarding procedures are outlined for horses with subacute or chronic lameness problems. Care should be taken to palpate all limbs and the back thoroughly, because many concurrent or compensatory injuries can be found that way. Because many problems are subtle, the horse should be examined on a variety of surfaces and at different gaits.

Particular attention should be paid to the feet. The size, shape, and conformation should be assessed in relation to the size and breed of horse. The suitability of the shoe type for that horse should be determined, because farrier preference may have been influenced by fashion. The fit of the shoe should be correlated with stage in the shoeing cycle. Fortunately, the trend is to move away from the traditional problem of shoeing the horse short and tight at the heels. The hoof should be palpated for heat and any cracks or defects. The sole should be pared and hoof testers carefully applied over the entire solar surface, assessing the solar compliance and any painful response. Horses with recurrent bruising associated with soft soles may not have demonstrable pain at examination, but the lack of solar rigidity is clearly evident. Percussion may be helpful in a small proportion of horses. An increased digital pulse amplitude can be helpful in determining any inflammation in the foot and is especially important if the amplitude is asymmetrical in the limb or between feet. A subtle increase in digital pulse amplitude is best evaluated after trotting the horse in hand on a hard surface.

The horse should be palpated carefully for distention of the distal interphalangeal and metacarpophalangeal/metatarsophalangeal (fetlock) joint capsules. The range of joint flexion and any resentment to flexion should be assessed carefully. Particular attention should be given to the palmar metacarpal structures for presence of subtle, diffuse filling and any discrete swelling, heat, or pain in the tendonous or ligamentous structures. Owners and riders of event horses tend to be thorough in their own palpation of this region and often know the normal contours of their horse well. However, they

often are misled by distention of the medial palmar vein or diffuse swelling from a more distal inflammatory lesion.

In the hindlimbs, pain on palpation over the cunean bursa and in response to the Churchill test should be determined. The medial femorotibial and femoropatellar joint capsules should be palpated to detect distention. The muscle tension in the back and hindquarters should be assessed carefully. Trigger points and painful foci should be determined, and the range of spinal flexibility in response to running a blunt object along the back should be assessed.

During the static examination the horse should be assessed for symmetry. The horse's condition and degree of muscling should be assessed in relation to its level of fitness. The freeness of stride, dynamic foot placement, and foot flight arcs should be assessed at the walk. At the trot any head nod and the range of gluteal excursion should be assessed to determine any lameness. Lunging in a circle on a hard surface frequently is used to exacerbate subtle lameness. However, it is also critical to see the horse lunged on a soft surface, a portion of the lameness examination that often is omitted. Different lameness conditions may be evident on different surfaces, and this comparison is valuable. For instance, a horse may have a low-grade concussive distal limb lameness evident when lunged on the hard surface. However, the primary problem may be proximal suspensory desmitis, pain from which is evident only when the horse is lunged on a soft surface. Although not decrying the value of evaluating all the lameness problems present, many of these horses have multiple, low-grade sites of pathological conditions to which they have adapted. Evaluating these can be a frustrating business, and it is important to determine the current problem noticed by a knowledgeable owner or rider. Evaluation of the horse while the horse is being ridden can be more difficult, but this form of movement can exacerbate low-grade lameness. Riding may be the only way of observing problems evident during certain movements, such as lack of hindlimb impulsion during a change of gait or when jumping. Seeing the horse ridden by a different, preferably more experienced rider can be helpful in some horses suspected of having back pain or when schooling or behavioral problems are present.

Determining the normal range of soundness is a difficult and contentious issue. Because of age and level of work, most top-level event horses have some degree of orthopedic pathological condition. I prefer to score lameness on a scale of 0 to 10, with 0 being sound and 10 being non-weight bearing. An advanced horse should be sound in the forelimbs when trotted in a straight line, but a large proportion demonstrate a 1 of 10 bilateral forelimb lameness when trotted in a circle on a hard surface. Some horses that are competing satisfactorily may show a greater degree of symmetrical lameness, but asymmetry in lameness may indicate that an important problem exists. Advanced horses can demonstrate up to a 2 of 10 hindlimb lameness when trotted in a straight line, without being penalized for this in a trot-up at a Three Day Event. Many have a 2 to 3 of 10 bilateral hindlimb lameness while circling on a hard surface. Hindlimb lameness evident on soft surfaces is likely to produce lower dressage scores, because the horse will exhibit poor and asymmetrical action.

Flexion tests are useful to exacerbate any subtle lameness problems, but these tests are not specific. Flexion tests can be particularly helpful in evaluating horses with lameness evident only immediately after they have completed an event. These horses can be frustrating, because they are often clinically sound when evaluated subsequently. A persistent positive response to flexion that can be alleviated by diagnostic analgesic techniques is important. Limb protraction, retraction, adduction, and abduction can be helpful in exacerbating upper-limb pain. Turning the horse in a tight circle can be used to assess coordination and flexibility. The range of cervical movement is assessed by observing the horse reach for food (voluntary movement) and by manual manipulation (forced movement). Many horses can cheat and reach the flank by rotation of the upper cervical region, rather than by full lateral flexion of the entire neck.

Different considerations apply when examining the horse with a history of an acute, severe lameness, usually after the cross country phase of a competition. A comprehensive approach of evaluating the acutely lame horse must be performed (see Chapter 13).[2] Unfortunately, localizing signs may be minimal, the horse may be in cardiovascular shock, and initial efforts must be directed at providing support to the horse and the suspected region of injury. Fractures are caused most commonly by external trauma. Particular attention should be paid to the shoulder region for signs of fracture of the supraglenoid tubercle of the scapula and to the stifle for effusion or peri-articular swelling associated with patellar or other fractures. Soft tissue injuries such as severe suspensory desmitis or superficial digital flexor tendonitis may cause acute, severe lameness.

DIAGNOSTIC ANALGESIA

Diagnostic analgesia is an important tool in lameness diagnosis in event horses. Because the horse may have many palpable abnormalities, differential diagnosis is important. However, no localizing clinical signs may be apparent, and diagnostic analgesia is critical to identifying the painful region. Specific treatment can be given if a problem is identified accurately. A positive response to intra-articular analgesia usually means a horse is likely to respond to intra-articular medication, leading to a quicker return to work. In horses with lameness problems too subtle for accurate interpretation of diagnostic blocks, intra-articular administration of corticosteroids may be useful to assess the long-term response to treatment. Even with experienced riders this method of management can have a placebo effect, because the rider may desire for the problem to be veterinary rather than from schooling.

Perineural and intrasynovial analgesic techniques are used commonly. Intra-articular analgesia is particularly helpful because many problems are joint-related, and a quick and definitive diagnosis can be achieved. Owners greatly resist clipping of the hair during the competition season, and clipping is not necessary in fine-coated animals if a thorough scrub is performed. The preferred techniques for the most commonly performed blocks are described subsequently.

The palmar digital nerve block should be performed as far distal as possible, angling the needle axially and distally to the cartilages of the foot. Separate medial and lateral blocks may be helpful to localize the pain to a specific heel. Blocking the palmar nerves at the level of the fetlock is less likely to desensitize the fetlock joint with a block performed just below the base of the proximal sesamoid bones, rather than at the abaxial sesamoid level. The palmar portion of the low four-point block should be performed just proximal to the digital sheath to decrease the risk of proximal migration of local anesthetic solution, taking care to go above or below the communicating branch of the palmar nerves. The lateral palmar nerve block is a satisfactory method of achieving proximal palmar metacarpal analgesia. Because the middle carpal joint is not a likely source of pain in event horses, the risk of confusing pain from this site with that from the origin of the proximal suspensory ligament is minimal.

The distal interphalangeal joint is injected most easily at a site on the dorsal midline, using a vertically directed needle. Six milliliters or less of local anesthetic solution should be used to decrease the risk of diffusion from the joint. For the

fetlock joints I prefer the lateral sesamoidean ligament approach because most horses do not have gross joint distention and the fixed anatomy of this approach is reliable.

In the hindlimbs the distal interphalangeal, proximal interphalangeal, and metatarsophalangeal joints often are overlooked sources of pain. Perineural analgesia normally starts with a basisesamoid block, followed by a low six-point block if necessary. Analgesia of the proximal plantar metatarsal region can be performed most easily by blocking the lateral plantar nerve 1 cm distal to the tarsometatarsal joint. This blocks the nerve before it branches into the plantar metatarsal nerves and carries a minimal risk of inadvertent penetration of the distoplantar outpouchings of the tarsometatarsal joint capsule.

IMAGING CONSIDERATIONS

Radiography

Radiography is the mainstay of imaging, but a few special considerations are necessary in event horses. Lateromedial and dorsopalmar radiographs of the distal extremity can be helpful in assessing foot balance. The palmaroproximal-palmarodistal oblique projection often is under-used in assessing subtle pathological conditions of the navicular bone and the palmar processes of the distal phalanx. The flexed cranioproximal-craniodistal projection of the stifle is especially valuable for assessing the medial aspect of the patella for fractures. It is important to angle the x-ray beam so that the trochlear ridges are not superimposed over the patella, because some fractures or evidence of comminution may otherwise be obscured. A relatively underexposed and undercollimated lateromedial projection is also beneficial to detect small, displaced fragments, which otherwise may be missed.

Ultrasonography

Ultrasonographic evaluation of the palmar metacarpal structures is a vital part of the lameness evaluation of an event horse. Superficial digital flexor tendonitis is a common and career-threatening injury, and if the veterinarian has any doubt about even a subtle problem, an ultrasonographic examination should be performed. Even when primary forelimb lameness is located at a distal site, the most important lesion may be a compensatory tendonitis in the contralateral limb.

It is usually not necessary to clip the coat, particularly if the hair is fine, and diagnostic images can be obtained after thorough scrubbing and the liberal application of alcohol and gel. The coat may be clipped to obtain maximal detail if subtle tendonitis needs to be investigated. Clients are often reluctant to have the coat clipped for a precautionary scan during the competitive season, because they perceive that the horse will be flagged as having a problem when it next competes. In my experience, sufficient detail is visible in fine-coated horses without clipping, although the clients are warned that greater image quality can be obtained with clipping, and if the image quality is non-diagnostic, the coat needs to be clipped. Often the difficulty is not in identifying abnormalities within the tendon but in determining the significance of any changes that are present. Many advanced horses have changes in fiber pattern of the superficial digital flexor tendon. Transverse and longitudinal views should be obtained in a systematic fashion. Different focus, gain, and frequency settings optimize evaluation of different structures. The cross-sectional area of the superficial digital flexor tendon should be obtained routinely, because sequential monitoring of this may allow the early detection of tendonitis. Determining the cross-sectional area also assists in assessing the current significance of chronic lesions, which is an important and helpful part of the ultrasonographic examination and should not be omitted.

Ultrasonography also can be helpful in assessing articular and peri-articular pathological conditions in structures such as the patellar ligaments. Examination of the ventral sacroiliac ligaments per rectum also can be valuable when pain in this region is suspected.

Scintigraphy

Nuclear scintigraphy is a useful technique for evaluating some lame event horses. Scintigraphy commonly is used in horses with hindlimb lameness, back problems, multiple limb lameness, and forelimb lameness with an equivocal or negative response to diagnostic analgesia. Image quality can be a concern, because event horses are skeletally mature and the degree of pathological bone conditions is low. Normal bone uptake can be limited, except in horses with acute trauma. Good technique is therefore essential to obtain diagnostic images, and postprocessing techniques, such as using motion-correction software can be helpful. Case selection is also important, because the more chronic and low-grade the problem, the lower the likelihood of finding an obvious focal region of increased radiopharmaceutical uptake (IRU). Examples of conditions for which scintigraphy can be rewarding include non-localized foot pain (pedal osteitis and insertion injury of the deep digital flexor tendon attachment), stress fractures (although these are rare overall), and osteoarthritis of the thoracolumbar facet joints.

Normal scintigraphic patterns are described poorly in the literature, especially for non-racehorses. Regions that commonly have IRU in event horses, but without associated pathological conditions, include the distal phalanx, the proximal interphalangeal, fifth and sixth cervical and sixth and seventh cervical articulations, and the distal tarsal bones. The distal tarsus appears to have active bone remodeling when evaluated scintigraphically, but many event horses do not show lameness or a positive response to either flexion tests or local analgesia. In a study evaluating the accuracy of scintigraphy in horses with confirmed distal hock joint pain, we found a positive predictive value of 0.70 and a negative predictive value of 0.91 for focal IRU.[3] Because of this high false-positive rate, scintigraphy should be used with thorough clinical examination. Although relying on scintigraphy in fractious horses may be tempting, authenticating the diagnosis using diagnostic analgesia is important.

Thermography

Thermography has been used for more than 25 years but is still a developing diagnostic modality. The technology has improved recently, and thermography units are now affordable. The handheld infrared imaging cameras are particularly attractive. Thermographic imaging provides a sensitive representation of skin surface temperature, but many confounding variables make interpretation of these images difficult. To develop expertise involves a steep learning curve, and a considerable amount of time and experience are necessary to make consistently useful interpretations. Major advantages include that the technique is non-invasive and is quick to perform. Thermography is similar to scintigraphy because it is a physiological rather than an anatomical imaging technique. Given the high prevalence and importance of soft tissue injuries in event horses, thermography has applications in detection and in monitoring response to therapy. Because of low specificity, however, thermography should be used with other imaging techniques.

Thermographic imaging is useful in evaluating foot balance and in differentiating various types of inflammation of the foot (Fig. 118-4; Color Plate 10). Examinations before and after exercise are particularly useful for this purpose. Similarly, pre-exercise and post-exercise thermograms are helpful in identifying specific muscle injuries. Accurate

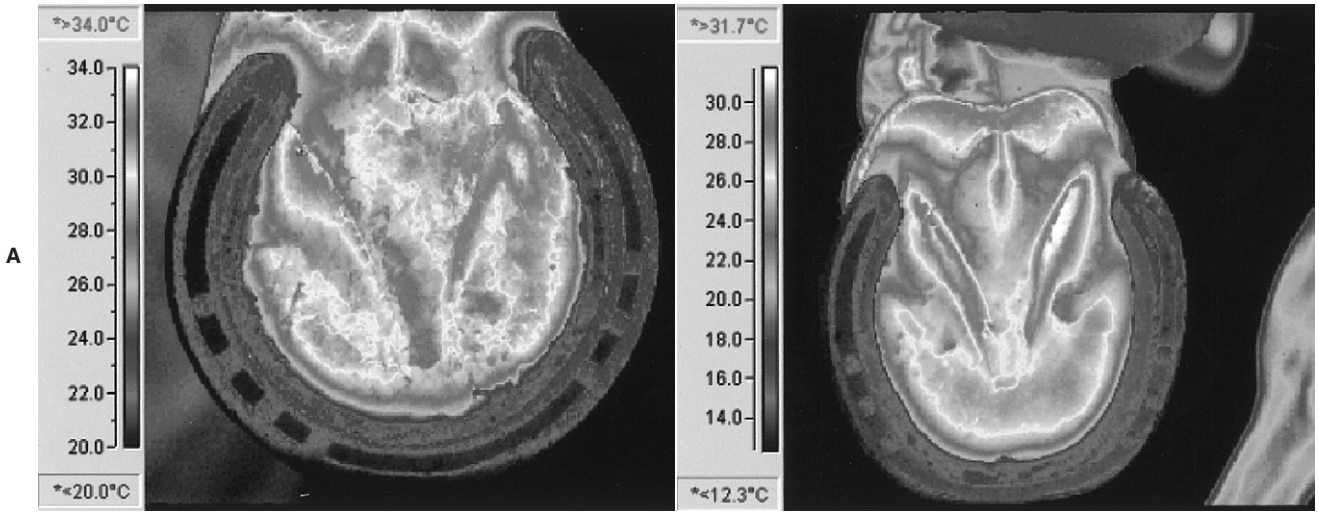

Fig. 118-4 Examples of different thermographic foot patterns (solar views). **A,** This hoof has a medial corn, manifested as a focal hot spot (*white*) within an area of increased temperature. **B,** This hoof has subacute laminitis, with a pattern of increased heat in the region of the tip of the distal phalanx.

identification of local muscle strain permits treatment to be focused on the affected area, with a consequently shortened convalescent period. Thermography is also a useful tool in evaluating neck and back problems, although interpretation is more complex in these regions.

Thermography can be particularly useful in monitoring superficial digital flexor tendonitis and can be used as part of a routine screening procedure, with regular examinations in the run up to a Three Day Event. Thermography can detect small lesions before clinical signs are evident, or it can be helpful in determining if a chronic lesion is active (Fig. 118-5; Color Plate 11). If thermography suggests a lesion is present, then ultrasonographic examination is indicated. During the convalescent phase after injury, regular thermographic screening allows detection of any signs of inflammation in the affected region, as the plane of exercise is increased. Care must be taken to avoid artifacts from bandaging, previous clipping, and topical medication.

SADDLE PRESSURE ANALYSIS

Computerized saddle pressure analysis using a force-sensing array system allows an objective assessment of pressure distribution beneath the saddle (Fig. 118-6; Color Plate 12). Poor saddle fit is an important problem in event horses and is discussed in greater detail (see pages 991 and 992). Computerized saddle pressure analysis is straightforward to perform and is complementary to conventional saddle fitting. By allowing an objective assessment, computerized saddle pressure analysis can be useful to confirm a problem to a rider, owner, or saddler. The better systems allow dynamic assessment of saddle fit at exercise, which is not otherwise possible.

PROCEEDING WITHOUT A DIAGNOSIS

Although in general a diagnosis can be made in most lame event horses, factors such as the experience level of the veterinarian, the thoroughness of the lameness workup, the number of imaging modalities available, and the nature, severity, and stage of the disease process affect diagnostic ability. If a horse is seen repeatedly on a first-opinion basis, stepping back and re-assessing the horse as if from the start is sometimes necessary. It may be necessary to refer the horse for a second opinion or for advanced imaging techniques, such as scintigraphy, if these have not been performed. In some horses the precise diagnosis continues to remain elusive. In horses with obscure forelimb lameness, I routinely perform an ultrasonographic examination of the palmar metacarpal soft tissue structures, because tendonitis and desmitis are important and highly prevalent. Serial cross-sectional area measurements of the superficial digital flexor tendons should be obtained, because the most significant problem with an undiagnosed low-grade lameness may be a compensatory tendonitis in another limb. Any evidence of tendonitis indicates that exercise level should be decreased. Similarly, any persistent clinical signs of swelling in the palmar metacarpal structures should prompt a cautious approach. Even in the absence of ultrasonographic changes, mild swelling should alert the veterinarian to the possibility of a subclinical problem with tendonitis or desmitis. It is important not to rely too much on ultrasonography for diagnosis of soft tissue injuries, because early lesions may not be apparent.

Generally in horses with low-grade, undiagnosed lameness the response to a period (few days to weeks) of rest should be assessed. If the response is poor, then most horses with an undiagnosed, low-grade hindlimb lameness can be continued in work, with or without the use of a systemic non-steroidal anti-inflammatory drug (NSAID) such as phenylbutazone. Greater caution normally is advised in horses with undiagnosed forelimb lameness, because the risk of developing a career-limiting injury with continued exercise is greater compared with similar injuries in the hindlimbs. If a subtle problem persists, then it may be necessary to increase exercise intensity to exacerbate the problem to a point where diagnostic local analgesia can be performed. If a competition is imminent, the owner or rider may apply considerable pressure to treat the most likely problem in the hope of rendering the horse sufficiently sound to compete.

If lameness is severe without initial diagnosis, then the horse should be given box rest, and the workup should be repeated until a diagnosis is achieved. If an upper limb soft tissue problem or a back problem is suspected, then a physiotherapeutic or chiropractic/osteopathic opinion can be helpful. Although veterinary opinion is divided on the validity and value of these techniques, an owner frustrated by the lack of a veterinary diagnosis is likely to turn to these. Horses with

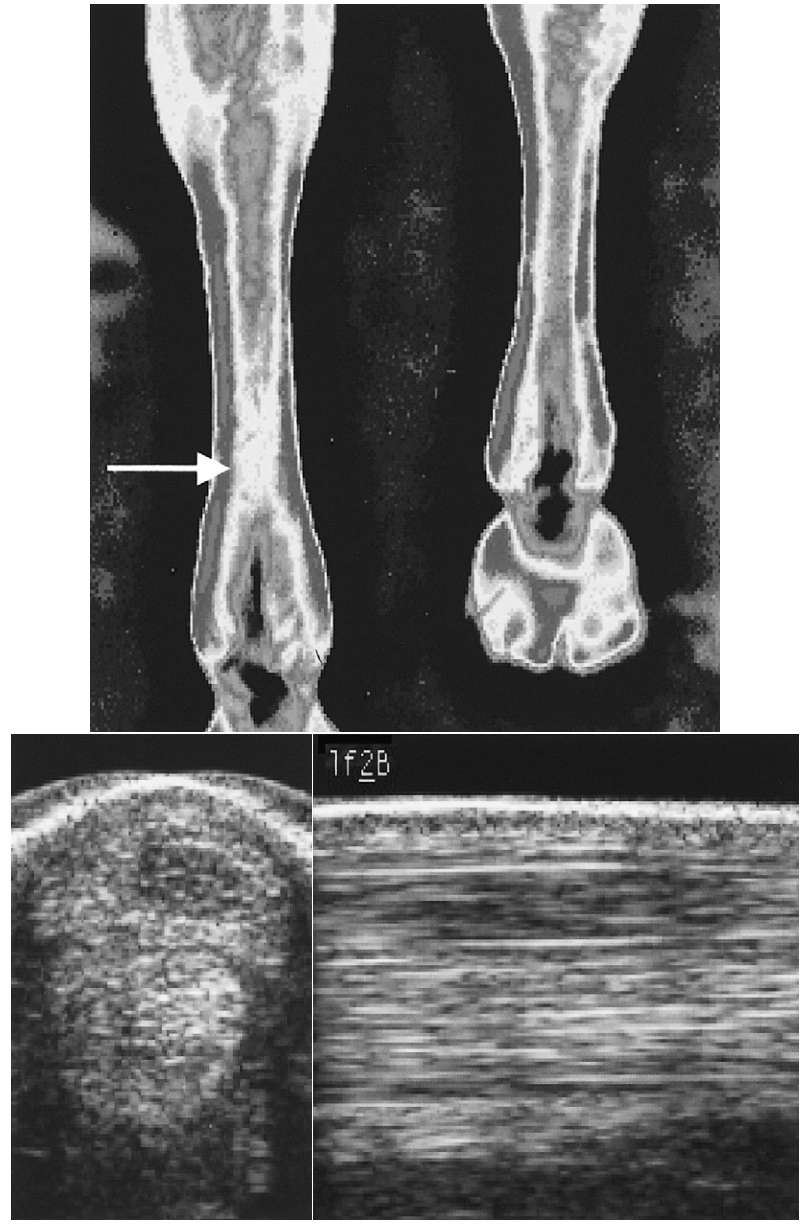

Fig. 118-5 Palmar thermographic image and subsequent transverse (on the left) and longitudinal ultrasonographic images of an advanced event horse 10 days after successfully completing a Three Day Event. The horse was having a routine examination, and no clinical localizing signs were evident in the tendon. The thermogram *(top)* demonstrates a focal hot spot over the left distal superficial digital flexor tendon (*arrow*), and the ultrasonographic images reveal a hypoechoic core lesion in the same region.

poor performance may have schooling or behavioral problems. Assessment by an experienced and different rider can be helpful.

SHOEING CONSIDERATIONS

Foot problems are vitally significant in event horses, and the importance of high-quality farriery in minimizing the incidence of lameness cannot be over-emphasized. Regular and good farriery is important in maintaining good medial to lateral and dorsal to palmar (plantar) hoof balance. Types of shoes vary between the traditional fullered hunter-type shoes, continental flat shoes, four-point style shoes, and various types of bar shoes. For routine shoeing the conventional fullered shoe offers the advantage of superior grip. Many farriers prefer the extra width of the flat section shoe, because this shoe is easier to fit, has sufficient width at the heels, and gives extra sole cover. If not applied correctly, flat-section shoes may cause excessive sole pressure in horses with flat feet. Traction devices are necessary if flat section shoes are put on horses working on tarmac. Natural balance shoeing has become popular recently in event horses, but although the technique suits some horses, others may actually develop lameness because of improper shoeing technique. However, the natural balance concept of a more palmar location for the breakover point has been well accepted. Seeing horses shod with the shoe set well back is now common, and quarter clips rather

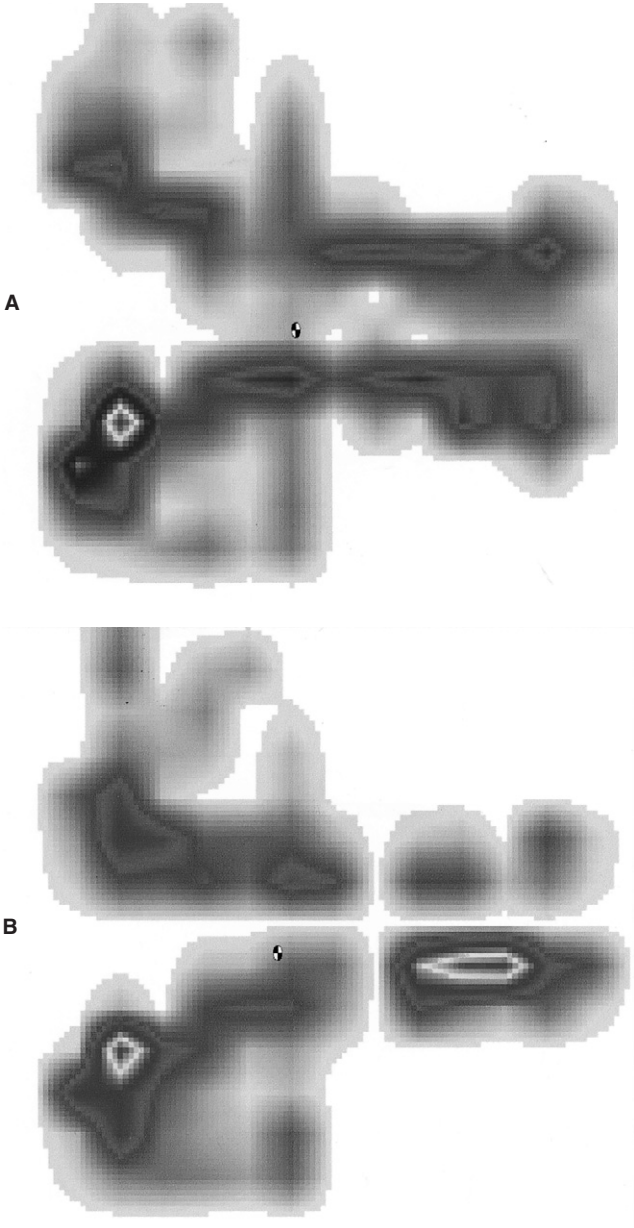

Fig. 118-6 Computerized saddle pressure analysis images. Cranial is to the left, and left is to the bottom. **A,** This image shows a poorly fitting saddle, with a focal pressure point in the left wither region. **B,** This image demonstrates failure of a gel pad to alleviate the pressure point and the development of an additional pressure point caudally.

than toe clips are most common. This is helpful in horses with long-toe conformation, osteoarthritis of the distal interphalangeal joint, or navicular syndrome. A rolled-toe shoe may give a similar effect, although bringing the breakover point back to the same degree is difficult, and care must be taken to set the shoe back sufficiently.

The most common therapeutic shoe used in event horses is the bar shoe. The egg bar shoe is used commonly to manage horses with navicular syndrome and other causes of palmar heel pain and to provide support in horses with collapsed heels. Egg bar shoes are heavy if they protrude beyond the heel bulbs and may be pulled off. Shoe loss is an important issue in event horses, more so than in other sport horses. As a compromise the straight bar shoe may provide additional foot stability while reducing the risk of shoe loss. In those horses requiring egg bar shoes, overreach boots can be used to reduce the risk of shoe loss, and by using a more palmar point of breakover, the front feet may leave the ground more quickly compared with horses with conventional shoes. In horses with weak heels or quarters, laminar separation, or focal osteitis of the distal phalanx, an egg bar shoe may provide inadequate support and a heart bar shoe can be beneficial. This shoe is heavy, does not project as far beyond the heels as does the egg bar shoe, and transfers some portion of weight-bearing load to the frog. In horses with pain localized to one heel or quarter, a half bar shoe can provide sufficient support and is lighter than a full heart bar shoe.

Pads and cushions are used infrequently in event horses. Although pads may provide short-term benefit in horses with solar pain, they promote excess movement of the clenches and premature shoe loosening. Full pads cause a poor solar microenvironment. Modern synthetic hoof repair materials can be beneficial in horses that have lost portions of the hoof wall, because the defect can be filled and shoe nails can be placed subsequently. However, routine use of hoof repair materials to augment hoof wall in horses with poor-quality, cracking, and flaking feet should be discouraged and may even cause the problem to persist. If used, repair material should be removed at the end of the season, and the horse should be turned out without shoes. The foot may break up initially but will grow back stronger without the repair materials.

Steel shoes are used routinely, but some riders switch to aluminium shoes at a Three Day Event. The foot must be of sufficient quality to cope with the lower degree of support offered by the more flexible aluminium shoe, and switching is not recommended if the horse has any history of foot-related lameness. Any speed and recovery benefits of the lighter shoes do not appear to be obvious in event horses. Synthetic shoes rarely are used.

Road nails or studs often are used, especially in broad section shoes, to decrease the risk of slipping on the roads during walking and trotting exercise. Improper use of road nails or studs may cause hoof imbalance. If the grip point is positioned near the middle of the foot (rather than near the heel), the foot may rock over this point during weight bearing. Event horses commonly wear studs for competition. Some advocate that a single stud be worn simply on the basis that if the stud is on the outside, the risk of the horse treading on itself is less. With a single stud, the foot can still twist, causing less jarring to the limb overall. Conversely, a single stud severely imbalances the foot, and because the roads and tracks phase of a Three Day Event often includes sections of metaled road or tracks, this could induce excessive strain on the joints (Fig. 118-7). Studs should be avoided for the roads and tracks phase if logistically possible. However, some horses will only jump with confidence if two or more studs per foot are applied. The studs always should be chosen based on ground conditions, and a blunt inside stud decreases problems from tread injury. Care should be taken to avoid positioning a stud hole over an area of defective hoof wall. Horses are normally re-shod one week before a Three Day Event, because if a horse is pricked or any foot soreness occurs after shoeing, the horse has time for recovery.

TACK CONSIDERATIONS

Saddle fit is of great importance in event horses. Injuries to the withers and back may manifest as poor performance in the dressage or show jumping phases of competition. Different saddles are required for the different disciplines of eventing, predisposing the horse to fitting problems. The fit of the saddle to the horse is sometimes a secondary consideration

Fig. 118-7 Palmar view of horse with single studs, showing the degree of mediolateral imbalance induced when the horse is on a hard surface.

to riders who may have a particular saddle in which they feel secure. Event horses often have high withers and fitting a saddle is often difficult. Saddle fit can be affected adversely by the tendency of event horses to lose weight dramatically in the run up to a Three Day Event. Therefore a saddle that is fitted 2 weeks before an event can sit too low by competition time. Unfortunately, the use of pads and numnahs to correct poor saddle fit is not effective. Computerized saddle pressure analysis has shown that even gel pads are ineffective in alleviating focal pressure points, and that numnahs and pads placed beneath well-fitting saddles can be detrimental (see Fig. 118-4).[4] Thick or multiple pads elevate the saddle and put pressure on the midline and over the dorsal spinous processes, a situation that impedes spinal flexibility.

Opinions vary on the benefits of protective leg wear. Tendon boots are used almost universally for the cross country phase, because the risk of direct traumatic injury to the distal limb is high. However, the additional insulation increases the temperature of the distal limb. There are theoretical concerns that elevation in temperature could damage tenocytes and predispose the horse to tendonitis, although no clinical evidence indicates that this occurs. Some boots have reinforced sections to give additional protection against speedy cut injuries to the palmar aspect of the tendons, but the large rigid section may rub against the tendons at exercise and cause abrasions. Conversely some of the flimsy boots do not give sufficient protection against this kind of laceration. Bandages give a greater degree of conformity, but they are more difficult to apply correctly and require inclusion of a reinforcing layer if they are to provide substantial protection. Neither bandages nor boots reduce risk of tendon strain but simply protect against direct trauma.

DIAGNOSIS AND MANAGEMENT OF LAMENESS

Thoracolumbar and Cervical Soreness and Restriction

Neck and back soreness are common clinical findings in event horses, although they do not always limit performance. Soreness may be secondary to lameness as occurs, for example, when pain on palpation of the brachiocephalicus muscle is found in horses with distally located forelimb lameness. Primary problems may be subtle, and determining the importance of clinical findings can be difficult. To know an individual horse's normal degree of sensitivity and flexibility can be extremely helpful, because any changes can be correlated with the onset of a performance problem. Questioning a knowledgeable owner, groom, or physiotherapist can be helpful. Sometimes the significance of any soreness can be assessed only by the horse's response to treatment.

Event horses are particularly prone to muscle soreness when exercise intensity is varied or increased. Intense dressage training initially causes a transient period of lumbar muscle soreness, especially during the sitting trot. Areas of focal pain and muscle spasm may be easily palpable, but assessing flexibility and range of movement is also important. Radiographs are not helpful in diagnosing the significance of dorsal spinous process impingement, and clinical signs, scintigraphic examination, and positive response to local analgesia are necessary to confirm if a lesion is active. Ultrasonographic examination can be helpful in diagnosing supraspinous ligament injury. Thermography is helpful in detecting acute soft tissue injuries in the thoracolumbar region (see Chapter 25).

Many horses with neck and back pain respond well to physiotherapy. If range of movement is decreased, then mobilization of the affected region is beneficial (see Chapters 94, 96, and 98), which then can be followed by continued stretching exercises, performed by the owner or rider. Massage is beneficial but yields only temporary improvement. Various modalities such as laser, therapeutic ultrasound, and neuromuscular stimulation can be helpful. Initial results with extracorporeal shockwave therapy have been encouraging. In some horses, chiropractic manipulation is beneficial. Acupuncture also can be effective in the right hands. Given the range of physiotherapeutic treatment options available, the degree of experience necessary for optimal treatment results, and the nature of these therapeutic modalities, I suggest that veterinarians should work with an experienced and qualified therapist. It behooves the veterinarian to be familiar with these techniques, because case selection and palpation skills can improve.

Horses with lower cervical restriction caused by osteoarthritis of the dorsal cervical articular facets may show a positive response to intra-articular or peri-articular medication with methylprednisolone acetate (80 mg) injected under ultrasonographic guidance. Each affected facet joint is injected, and the horse is rested for 2 weeks, after which time improvement is normally dramatic. Horses with mild to moderate impingement of the thoracic dorsal spinous processes

can be treated successfully using local injection of methylprednisolone acetate (80 mg) and Sarapin (4 ml). The horse is lunged or long reined for 2 weeks and then returned to exercise. The duration of effect can be as short as 6 weeks, but in a large proportion of horses, the problem resolves without repeat medication. Marks provides a review of the various veterinary options in treating back pain.[5] The importance of management and riding factors in treating these conditions cannot be overemphasized. Rehabilitation and reschooling of horses with moderate to severe pain are necessary to build up the local musculature and to develop flexibility.

Foot Soreness (Bruising, Imbalance, and Nail Bind)

Foot soreness is a common clinical problem in event horses. Temporary solar bruising is frequent, especially in flat- and thin-soled horses. Foot imbalances predispose horses to soreness, and medial to lateral hoof imbalance is commonly present. In horses with collapsed heels, pain to hoof testers and corns are commonly found. Horses with persistent foot lameness may have laminar separation or focal osteitis of the distal phalanx, and scintigraphy is helpful in differential diagnosis. Poor foot conformation in many horses can predispose them to nail bind or pricking when shod. Shoes often are pulled off, which can lead to breakup of the wall and further problems with shoe security. Regular, high-quality farriery is more import in maintaining good hoof quality than is the feeding of supplements or applying topical applications. Good stable hygiene is also important. Shoeing aspects have been discussed (see page 990).

Osteoarthritis

Distal limb joints are especially prone to traumatic joint disease, especially in the forelimb. Osteoarthritis of the distal interphalangeal joint is most common, followed by that of the metacarpophalangeal joint. Osteoarthritis of the proximal interphalangeal joint is rare. Diagnosis is confirmed by observing a positive response to intra-articular analgesia, effusion or fibrosis, a positive response to flexion, and low-viscosity synovial fluid. Radiographs are often unremarkable in horses with early or low-grade osteoarthritis. Response to intra-articular medication is normally excellent. Combining hyaluronan with a low dose of corticosteroid, such as triamcinolone acetonide (5 mg) produces the greatest therapeutic effect. Hyaluronan alone produces an inconsistent response, and low doses of triamcinolone have been shown to be chondroprotective. Medium viscosity hyaluronan usually is used initially based on economic factors, but high molecular weight products may give a greater effect in some horses. Systemic administration of hyaluronan (intravenously) or polysulfated glycosaminoglycan (intramuscularly) is not nearly as effective as is specific intra-articular medication. Systemic medication does not carry the same risk of iatrogenic infection and is easier to administer and so is used frequently as an adjunct therapy. Prophylactic use of systemic therapy frequently is used in horses in the run up to a Three Day Event or to manage those with pathological conditions of multiple joints or generalized stiffness. Feeding of nutraceuticals such as chondroitin sulfate and glucosamine is also common practice. Although in vitro evidence of efficacy is substantial, no convincing clinical studies demonstrate efficacy in vivo. In fact, studies have demonstrated a lack of oral absorption of chondroitin sulfate in horses.[6,7]

In horses with osteoarthritis of the distal interphalangeal and metacarpophalangeal joints that has been non-responsive to medication, and especially with radiographic evidence of osteochondral fragmentation, arthroscopic evaluation can be beneficial. Focal areas of pathological conditions of cartilage and subchondral bone may be identified, and the horse often responds positively to debridement. Access is limited in the distal interphalangeal joint, but lesions often are found on the extensor process.

Osteoarthritis of the tarsometatarsal and centrodistal joints is not infrequent, but the distal tarsal joints show scintigraphic evidence of remodeling even in normal event horses. Horses with authentic osteoarthritis of these joints usually respond well to medication with low doses of long-acting corticosteroids (40 mg of methylprednisolone acetate). The condition rarely seems to progress sufficiently to necessitate chemical or surgical arthrodesis.

Superficial Digital Flexor Tendonitis

Although not the commonest lameness problem in event horses, tendonitis is the most substantial cause of wastage because of prolonged convalescence and high recurrence rates. Although tendonitis can occur as a single-event injury, especially if the horse falls, stumbles, or trips badly, the condition most commonly results from repetitive cyclic loading. Unlike the suspensory ligament, tendons in adult horses do not strengthen in response to exercise and therefore are prone to develop accumulated microdamage during intense training. This damage can give the prodromal signs of slight filling or heat in the palmar metacarpal structures. The clinical signs of a tendon strain then may develop acutely after a training canter or competition. For horses to develop subclinical tendonitis after a Three Day Event is not uncommon. The condition may not be apparent during the rest period after the competition but develops into clinical tendonitis when the horse resumes training or competitive work, even after 3 to 6 months. Close monitoring is thus essential, and I recommend routine ultrasonography after each Three Day Event. Ultrasonographic evaluation is important to assess the severity of injury and to determine a prognosis and an appropriate treatment plan. Lesion length and percentage of cross-sectional area involvement should be determined. Tendons may increase in cross-sectional area up to 10% normally with intense training, but this tends to return to baseline at the end of the season. If ultrasonographic examination is performed soon after injury, the extent of the lesion may not be apparent and severity may be underestimated. Severity of tendon damage is assessed most accurately between 1 and 4 weeks after injury.

Initial treatment of event horses with tendonitis is aimed at limiting inflammation and preventing any further tendon damage. The horse should be given box rest for 2 to 4 weeks, and anti-inflammatory therapy should be commenced. Systemic NSAIDs appear to decrease swelling and pain, and no evidence indicates that they impede healing. Conversely, prolonged corticosteroid administration may interfere with fibroplasia, although a single systemic dose helps decrease inflammation without any apparent detrimental effects.

Support bandages or firm stable bandages should be applied for the first few weeks to reduce swelling. Topical dimethylsulfoxide can be useful to decrease inflammation early after injury but should not be used for more than 5 days, because it can weaken collagen fibers and blister the skin. Local treatment with cold water hosing and ice application is beneficial while the signs of acute inflammation persist. For horses with mild to moderate injuries, the benefits of being able to perform local therapy seem to outweigh the greater external support that can be provided by application of a Robert Jones bandage.

In horses with severe tendonitis in which loss of support (sinking) of the metacarpophalangeal joint has occurred, external support using a Robert Jones bandage is recommended. A heel wedge should be applied if the animal is severely lame. Heel elevation theoretically does not decrease load on the superficial digital flexor tendon but appears to provide analgesia to horses that stand with the heel off the ground. In horses with severe breakdown injury, support with a proprietary splint, such as a Kimzey LegSaver, (Kimzey, Woodland, CA) is recommended.

Controlled exercise, to encourage development of a longitudinal fiber pattern but without placing excessive load on the tendon to damage the healing fibers, is the mainstay of recuperation. Serial ultrasonographic examinations are helpful to determine the appropriate rate of progress and the response to increasing exercise. After the period of box rest, walking in hand normally is commenced. Mechanical horse walkers appear detrimental in the early stages of healing, because constant turning places excessive load on the weak tendon. However, such walkers are extremely helpful after the initial 4 to 6 weeks of walking in hand, when duration of walking is increased. A major problem during this stage is degree of tolerance shown by the horse to this restricted level of exercise. Many horses are too excitable to be walked safely in hand, but they behave appropriately on a horse walker or if ridden under saddle. Exercise programs must be tailored to account for rider competence and the horse's behavior. Once trotting has been commenced, the horse normally settles down into the exercise regimen.

A large number of treatment options exist for managing event horses with tendonitis. Tendon splitting, usually performed percutaneously in the standing horse, appears beneficial in horses with acute core lesions. Tendon splitting may decompress the core lesion and allow neovascularization but is most effective when performed in the first 10 days after injury. Intralesional injection of hyaluronan or a polysulfated glycosaminoglycan has not proved beneficial. Initial clinical studies investigating intralesionally administered β-aminoproprionitrile fumarate unfortunately lacked representative control groups. The drug has received a mixed reception since becoming licensed and is not the panacea that some initially promoted it to be. The drug has been used in a limited number of event horses that returned to compete at the top level.

Use of intralesional growth factors is an area of current research interest. Insulin-like growth factor 1 and equine growth hormone, which induces the production of insulin-like growth factor 1, have been studied. I have had success in a small number of horses using transforming growth factor β (TGF-β) in horses with tendonitis. The drug appears to promote fibroplasia. Although this gives a quicker healing rate and horses have returned to work successfully, whether the expected increase in strength and decrease in elasticity are desirable is theoretically debatable. I have had rewarding results using TGF-β in horses with chronic tendonitis. When ultrasonographic evidence of poor infilling exists, intralesional injection of TGF-β improves fiber pattern, and horses are able to withstand increased exercise intensity. After treatment, some horses have returned to CCI**** level and have completed successfully in up to three events.

Desmotomy of the accessory ligament of the superficial digital flexor tendon (superior check desmotomy) also can be beneficial in selected horses. Because of the risk of general anesthesia, I reserve its use for horses with recurrent tendonitis or those in which the ultrasonographic appearance of the tendon deteriorates inappropriately during the controlled exercise regimen. In a small number of horses in trotting exercise after tendonitis, increased cross-sectional area and decreased echogenicity are observed. Even after the plane of exercise is reduced to walking for another 6 to 8 weeks or even longer, the ultrasonographic appearance of the tendon does not change. After desmotomy, however, these horses tolerate an increased plane of exercise without ultrasonographic deterioration or subsequent recurrence of tendonitis. Because the procedure may increase the risk of suspensory desmitis after surgery, desmotomy should not be used in horses with a concurrent pathological condition of the suspensory apparatus.

Systemic medication with a polysulfated glycosaminoglycan is used as an adjunct treatment in horses with tendonitis. Ease of administration and lack of potential complications make such treatment popular, but no evidence indicates that any systemic medication, or feed supplements for that matter, has beneficial effects in tendon healing.

The total convalescent period depends on severity of initial injury, how well the injury appears to heal as viewed by ultrasonography, and the degree of compliance with the controlled exercise regimen. In horses with mild tendonitis (subtle loss of fiber pattern and ≤10% increase in cross-sectional area) as few as 6 weeks of walking exercise is sufficient. Horses with loss of fibers and frank tendonitis require a convalescent period of 9 to 15 months. Recurrence rate is less in horses that are given at least a year to recuperate before commencing full work. After tendonitis, many horses can be managed successfully to complete one Three Day Event, but sustaining the horse through a number of Three Day Events without recurrence is more difficult. A small number of horses seem to suffer recurrent clinical signs regardless of management protocol and these are best restricted to One Day Events in which they will often then compete successfully for many years.

Suspensory Desmitis

The two main levels of suspensory injury in Three Day Event horse are branch desmitis and proximal suspensory desmitis. Mid-body desmitis is rare. Suspensory branch desmitis can be considered an occupational disease of event horses. Advanced horses commonly develop inflammation and enlargement of the branches after a Three Day Event, and the condition is often transient with no associated lameness. Viewed by ultrasonography, the branches have periligamentous fibrosis with no areas of obvious hypoechogenicity, although some loss of longitudinal fiber pattern may occur. In many horses this pathological condition is missed or ignored, and the horse is just turned out. Even a short period of controlled exercise often decreases the risk of recurrence, however. Some degree of synovitis of the metacarpophalangeal joint commonly occurs and usually responds favorably to intra-articular medication.

Proximal suspensory desmitis is a common cause of forelimb lameness. Lameness may be acute in onset and inflammation obvious after exercise, or the disease can be insidious without any localizing signs. Diagnostic analgesia is mandatory, and ultrasonographic examination is valuable. Radiographic and scintigraphic examinations are useful adjunct tools. Most horses have true desmitis, although a small number have enthesopathy and associated bone remodeling, with significant IRU and minimal ultrasonographic abnormalities. Most horses respond well to 4 to 9 months of controlled exercise, and no convincing evidence exists that any intralesional medications are beneficial. Extracorporeal shock wave therapy has been used to treat horses with suspensory desmitis and may provide quick analgesic effect. However, this may encourage a premature return to full exercise, thus increasing the risk of recurrence. Shock wave therapy may well have a role in horses with chronic, active desmitis, especially those with bone involvement that does not respond appropriately to controlled exercise.

I feel that proximal suspensory desmitis in the hindlimb is a most important but underdiagnosed condition. Similar to that seen in the forelimb, hindlimb proximal suspensory desmitis may cause acute or chronic lameness. The prognosis is generally much poorer in the hindlimb, however, because of the development of a local compartment syndrome and associated pressure on the plantar metatarsal nerves. Thus most horses remain chronically lame, even after the ligament appears healed on ultrasonographs. I have had success in treating chronic lameness resulting from hindlimb proximal suspensory desmitis using local infiltration of triamcinolone (10 mg) in horses with static or healed ligaments but with persistent lameness. Although lameness abates, treatment needs to be repeated at 6-month intervals and may be detrimental to the ligament in the long term. Thus a surgical technique has been developed for use in

horses with chronic desmitis that has yielded extremely good results.[8] The surgical technique involves the resection of a 3-cm segment of the common branch of the plantar metatarsal nerve, distal to its origin from the lateral plantar nerve. This is combined with incision of the fascia (fasciotomy) overlying the origin of the suspensory ligament. This technique combines decompression with analgesia, and has allowed horses to return to a normal level of work within 3 months. The horses are restricted to walking only for the first month, after which time turnout and ascending exercise are permitted. I have long-term follow-up data on 20 horses, and all returned to the previous level of work (including CCI****). Recurrence of proximal suspensory desmitis was seen in only two horses.

External Trauma

Event horses are prone to traumatic lacerations during competition, the most common being overreach injuries to the heel bulbs. Standard principles of treatment apply, although owners often apply pressure to minimize healing time during the competition season. Aggressive early treatment is advised, and horses with deep foot or pastern wounds should be managed with a fiberglass cast for 10 to 14 days, a treatment that may shorten the convalescent period. Wounds should be assessed carefully for synovial penetrations. Thorn penetrations from brush or hedge fences can lead to infectious arthritis of the carpal or stifle joints, with only minimal clinical signs evident initially.

Direct trauma from jumping solid fences is common. Trauma directly over bone can lead to a severe, transient lameness. Acute lameness from this type of bone bruising can be difficult to differentiate from a fracture on an initial clinical examination. Trauma over the soft tissues may lead to the development of a considerable hematoma or edema, so local cold and pressure are indicated in the early stages.

Pain in the Sacroiliac Region

A low-grade form of sacroiliac disease is common in event horses and is manifest as a loss of impulsion and scope when jumping, with a reduced hindfoot flight arc. Most advanced event horses have bony pelvic asymmetry when critically assessed. Clinical signs include pain on palpation around the tubera sacrale and resentment of gentle lateral rocking action when the horse is in a weight-bearing position, with the opposite hindlimb held up. Often associated muscle soreness and spasm are present in the surrounding musculature, notably the middle gluteal muscle. Most of these horses appear to have sacroiliac joint instability, but minimal evidence of IRU is seen on scintigraphic examination. Clinical signs can be localized by assessing the response to infiltration of local anesthetic solution around the dorsal aspect of the sacroiliac joint, using a spinal needle angled ventrocraniolaterad from just caudal to the opposite tuber sacrale. Ultrasonographic evaluation of the ventral sacroiliac ligaments per rectum also can be helpful to localize any pathological condition. The condition usually occurs when the horse is unfit and being brought into work or when the plane of exercise is increased. Sacroiliac pain often is self-limiting because the musculature increases as the plane of exercise increases and stabilizes the sacroiliac joint. Administering a systemic NSAID such as phenylbutazone helps the horse work through the period of lameness. Physiotherapy can assist in treating the local muscle spasm, and some horses improve with chiropractic or osteopathic manipulation. Horses with refractory pain sometimes improve after the local infiltration of methylprednisolone (120 mg) or a sclerosing agent (50 ml; e.g., P2G Solution, Martindale Pharmaceuticals, Romford, UK) using the same approach as for local analgesia. Horses are continued in the same plane of work, and improvement normally is reported within a week. The duration of response varies, and some horses do not require repeat treatments.

Stifle Fracture

Fractures of the patella are common in event horses,[9] and the imaging aspects have already been discussed. For medial fractures, surgical removal offers the best prognosis. The original surgical description is for an incision 15 to 25 cm in length, but I prefer to use arthroscopic guidance, enabling me to create a minimal surgical incision (5 to 7 cm) centered directly over the fragment. This is satisfactory for small fragments and also allows for thorough evaluation of the femoropatellar joint and easy removal of any loose fragments.

Other Fractures

Fractures caused by direct trauma of the distal phalanx and second and fourth metacarpal bones are not uncommon. Occasionally, condylar fractures of the third metacarpal or metatarsal bones or sagittal fractures of the proximal phalanx occur during training or competition, although they are rare. The standard considerations apply for evaluation and treatment. Vertebral or upper limb fractures can occur after a fall, and the initial evaluation can be complicated by adrenaline dominance.

Rhabdomyolysis

Recurrent rhabdomyolysis is rare in advanced-level horses, because horses prone to this disease are selected out at the lower levels. Sporadic episodes are common at Three Day Events, however. Many potential trigger factors exists, including the stress of travel, stabling away from home, the competition itself, dehydration, climate changes, electrolyte imbalance, and dietary changes. I have noted a particularly high incidence in horses that were switched to haylage products immediately before a competition. This practice is done frequently because of the greater convenience of the small, packaged bales. A period of at least 4 to 6 weeks is recommended to allow adaptation to the new diet. The clinical manifestations at a Three Day Event can vary between collapse and recumbency on the roads and tracks phase to slight stiffness developing many hours after the completion of the cross-country phase.

To reduce the risk of rhabdomyolysis, attention should be paid to avoiding the trigger factors. Vitamin E levels are frequently low in event horse diets. Many commercial electrolytes do not contain sufficient quantities of salt, and horses may be at risk if owners follow manufacturers' recommendations. Routine blood sampling to monitor the muscle-derived enzymes aspartate aminotransferase and creatine kinase is performed frequently, but considerable fluctuation in asymptomatic event horses can occur,[10] making interpretation difficult. This variation tends to decrease as horses become fitter, as the muscle cells appear less leaky. With the recognition of polysaccharide storage myopathy as a cause of rhabdomyolysis, some event horses have been successfully managed on a diet high in fat and low in soluble carbohydrates, although actual diagnosis is difficult to confirm.

PREVENTION OF LAMENESS

When considering the time involved to train a horse to the top level and the potential for a long athletic career, preventing lameness is especially desirable in event horses. However, many important factors are beyond the veterinarian's influence. The number and frequency of competitions, having the opportunity to choose events with good going and an appropriate riding surface, and a high standard of riding ability are factors difficult to control. The veterinarian may be able to assist with other factors such as a high standard of farriery and optimizing training programs. Regular veterinary monitoring can be valuable by allowing the early detection and treatment of any

lameness problems. Monitoring for incipient tendonitis can be useful by performing periodic clinical examinations, using thermographic and ultrasonographic examinations, and by monitoring serum markers of tendonitis. Serial determination of markers such as cartilage oligomeric matrix protein holds promise. Initial studies have shown that cartilage oligomeric matrix protein increases as training intensity increases, and higher cartilage oligomeric matrix protein levels are found in horses that subsequently developed tendonitis.[11] The concurrent use of all of these maximizes the veterinarian's ability to detect subclinical tendonitis.

Many medications and supplements are sold with the aim of decreasing the risk of orthopedic disease. In racehorses, intramuscularly administered polysulfated glycosaminoglycan and intravenously administered hyaluronan have been shown to decrease the number of races missed, although the incidence of injuries was not decreased. Thus these drugs seem to be acting as anti-inflammatory rather than as disease-modifying agents. Glucosamine has disease-modifying properties in vitro, has been shown to be efficacious in human studies, and is a sufficiently small molecule that absorption would be expected. A role for oral glucosamine supplementation in horses may be found, but further studies are required. Many commercial products are available with unproven efficacy and variable and uncertain composition.

The future of lameness prevention may be the modulation of skeletal development by early training. Waiting until the horse is skeletally mature before breaking it in means that the different loads of carrying a rider and performing athletic exercises are imposed on a skeleton with little adaptive capacity. Conversely, overworking an immature skeleton can lead to a high incidence of orthopedic injury, such as is seen in young racehorses. A compromise position may be found that theoretically could lead to the early development of a skeleton adapted for the loads that will be placed on it and with the development of a higher-quality extracellular matrix that will better withstand the work that it has to perform.

Lameness in Endurance Horses

Martha M. Misheff

DESCRIPTION OF THE SPORT

The ancient Bedouin raced their horses long distances across the desert, British and American cavalry units used endurance tests as part of their military training, and nineteenth-century Austrians had a Vienna to Budapest ride, but organized endurance riding is a young sport. The first modern endurance ride, the 100-mile (160-km) Tevis Cup from Nevada to California has been run every year since 1955. The Tom Quilty Gold Cup, a prestigious 160-km endurance race named for its founder, was established in 1966 and is held every year in a different part of Australia. The oldest endurance organization, the American Endurance Ride Conference, has been in existence only since 1972. The American Endurance Ride Conference International was established in 1991.

The first Federation Equestre Internationale (FEI) European Championship was held in Florac, France, in 1984, and the first Endurance World Championship in Rome, Italy, in 1986. Since then many recognized international competitions have been held under the auspices of the FEI, including the Endurance World Championship, held every 2 years in a different country. Many countries have endurance or long-

lameness problems. Monitoring for incipient tendonitis can be useful by performing periodic clinical examinations, using thermographic and ultrasonographic examinations, and by monitoring serum markers of tendonitis. Serial determination of markers such as cartilage oligomeric matrix protein holds promise. Initial studies have shown that cartilage oligomeric matrix protein increases as training intensity increases, and higher cartilage oligomeric matrix protein levels are found in horses that subsequently developed tendonitis.[11] The concurrent use of all of these maximizes the veterinarian's ability to detect subclinical tendonitis.

Many medications and supplements are sold with the aim of decreasing the risk of orthopedic disease. In racehorses, intramuscularly administered polysulfated glycosaminoglycan and intravenously administered hyaluronan have been shown to decrease the number of races missed, although the incidence of injuries was not decreased. The first modern endurance ride, the 100-mile (160-km) Tevis Cup from Nevada to California has been run every year since 1955. The Tom Quilty Gold Cup, a prestigious 160-km endurance race named for its founder, was established in 1966 and is held every year in a different part of Australia. The oldest endurance organization, the American Endurance Ride Conference, has been in existence only since 1972. The American Endurance Ride Conference International was established in 1991.

The first Federation Equestre Internationale (FEI) European Championship was held in Florac, France, in 1984, and the first Endurance World Championship in Rome, Italy, in 1986. Since then many recognized international competitions have been held under the auspices of the FEI, including the Endurance World Championship, held every 2 years in a different country. Many countries have endurance or long-

distance riding associations, all of which have been established only in the last 30 years.[1] All of the organizations require that horses be at least 5 years of age to compete at distances of 80 km (50 miles) or more, and all of the organizations have stringent veterinary controls.

Competitors undergo an initial veterinary inspection. The total distance of the ride is divided into segments. After riding each section the competitor must pass a vet gate or veterinary checkpoint where a panel of veterinarians evaluates the horse for lameness and metabolic criteria. The heart rate must be at or under a maximum criterion (usually 64 beats per minute) set before the ride by the veterinary commission. A cardiac recovery index often is used, in which a second heart rate is measured 1 minute after the commencement of an approximate 80-m trot, during which time the horse is evaluated for lameness. Although not a criterion for elimination in and of itself, a positive cardiac recovery index, in which the second heart rate is elevated more than a few beats above the first one, is an indication that the horse merits further evaluation. Other metabolic parameters, such as mucous membrane color, capillary refill time, skin turgor, and auscultable intestinal motility are checked and recorded. Any saddle sores, girth rubs, or bit-related lesions also are noted. A heart rate above the maximum allowed, lameness, injury, and synchronous diaphragmatic flutter are grounds for elimination. Endurance horses are not permitted to compete on medication, and regulatory bodies conduct random testing for those substances that are not permitted. Some jurisdictions routinely test the first several finishers. Although smaller competitions often use the same veterinarians for control and treatment, many of the larger competitions now have separate veterinarians dedicated to treatment. Typically a horse that is eliminated by a control veterinarian for a lameness or metabolic problem is referred to the treatment veterinarian for further evaluation. If the treatment veterinarian deems that treatment is prudent, treatment may be provided at a field clinic at the ride site, or the horse may be transported to a local veterinary clinic with which prior arrangements have been made. Ride site treatment clinics at the larger venues are able to offer relatively sophisticated care, and only those horses that require continued care or further investigation are referred.

TYPE OF HORSE

Most endurance rides are open to horses of any breed, but horses of Arabian extraction are most popular for endurance riding because of their light build and stamina over long distances. Larger, heavier framed horses are less able to sustain the speed required over the distances traveled. A few Middle Eastern endurance rides are restricted to purebred Arabians or Arabian crossbreeds.

TRAINING METHODS

Methods differ considerably among trainers, but most would agree that horses take 2 to 3 years of training to make good endurance racers. Training distance and frequency depend largely on individual circumstances (terrain, weather, and availability of pasture or turnout paddocks), but in general endurance horses are ridden at least several times a week. A typical program might include rides of 10 to 20 km with 40- to 50-km rides at weekly or 10-day intervals. Horses are ridden at a walk, trot, and canter with the proportion of the time spent at each gait varying considerably among trainers. Horses aiming for a 100- to 160-km ride usually complete 60 km or more in a training ride on at least two occasions before the competition. Some endurance organizations require a horse to complete a qualifying ride at a lesser distance before being permitted to compete at the next distance level. Overtraining of endurance horses tends to be more of a problem than under-training, particularly by novice trainers. In some countries endurance competition is rapidly evolving from an amateur sport in which the same person owns, trains, and rides the same horse for many years, competing for pleasure with little financial reward, to large multiple-horse stables run by professional trainers with riders that may never have ridden their horses before, competing for high-value prizes. Even if the prize money is a paltry sum, compared with other sports, the value of a horse winning or running successfully in a prestigious international competition may increase exponentially. This amateur to professional shift has meant that the speed required to win international competitions over flat terrain has increased dramatically. Speeds at high profile rides over mountainous terrain have not changed substantially. Essentially the sport has changed at some venues from endurance riding to endurance racing. The winner of the 1998 World Championship in the United Arab Emirates averaged 17.77 km/hr for 160 km. The winner of the 2000 World Championship in France averaged 16.96 km/hr over 161.7 km, and at some competitions the winning speed has increased to greater than 25 km/hr. This is the equivalent of a continuous fast canter or gallop. Years ago this would have been unheard of, and opinions differ as to whether this is desirable progress. From a veterinary standpoint, at rides where speeds are increasing we are beginning to see injuries more like those seen in flat racing horses, as well as serious metabolic abnormalities, because horses tend to be pushed harder when high prize money is at stake.

COURSE TERRAIN

Endurance horses compete and train over some of the most highly variable terrain of any sport horses. They go up rocky mountains, through creeks, across sandy deserts, along tarmac and gravel or dirt roads, across grassy fields, and on other surfaces depending on where the ride is held. Course terrain has a bearing on the types of injury in a predictable way. On rocky ground more horses have stone bruises and painful joint injuries, whereas on soft or sandy ground more horses have ligament and tendon injuries.

CONFORMATION AND LAMENESS

Lameness in endurance horses essentially can be divided into ligament and tendon injuries, muscle problems, injuries to joints and feet, and miscellaneous less common causes. Lameness also can be separated into two categories: first, transient problems that may be cause for elimination on the day of competition but then resolve, and second, more persistent problems that are likely to be recurrent. Endurance horses, compared with other athletic horses, tend to be scrawny, scraggy-looking beasts. Like human marathon runners, the good ones are ectomorphs. Because endurance horses often compete over an 8- to 10-year period, most horses with glaring conformation defects tend to weed themselves out by attrition. Plenty of moderately toed-in, toed-out, sickle-hocked, post-legged (straight-legged), calf-kneed, bench-kneed, or club footed endurance horses are used. Provided the conformational abnormality is not extreme, the overall function of the horse may not be compromised. A toed-in horse may develop splint exostoses that impinge on the suspensory ligament (SL), causing desmitis that may be recurrent; such horses ultimately may be unsuitable for endurance use.

LAMENESS EXAMINATION AND PROCEEDING WITHOUT A DIAGNOSIS

A lameness examination in any horse is performed most easily and efficiently when the lameness is visible, and the endurance horse is no exception. Making a specific diagnosis concerning the cause of a horse's lameness is not possible if the horse is not lame at the time of examination. Watching the horse trot while lame, applying hoof testers, and noting any palpable abnormalities and response to flexion or other manipulative tests usually help to narrow the possible causes. Adhering to the principle of starting at the bottom and working upward during diagnostic analgesia is a particularly useful means of localizing the source of pain.

Sometimes, despite a careful and complete lameness examination, diagnostic analgesia, and ancillary diagnostic aids such as radiography, ultrasonography, and scintigraphy, a specific diagnosis cannot be reached. In some horses lameness can never be eliminated by local analgesia. In others pain can be localized to a specific region, but no lesion can be found. A horse with lameness localized to a specific region by local analgesia—with no identifiable radiographic, scintigraphic, or ultrasonographic abnormalities—should be re-examined by the most appropriate imaging modality after 2 to 4 weeks. Stress fractures are particularly notorious for not being visible on the first examination and being readily visible later. If the lameness has resolved and no abnormality is identified when the horse is re-examined, returning the horse to light training is reasonable. If lameness recurs, the lameness examination should be repeated.

Horses with a lameness that cannot be localized to a specific area should be evaluated for neurological disease, because this can be a cause of or mimic lameness. Generally, horses that have a lameness that cannot be localized are subjected to full body scintigraphy. If lameness resolves, scintigraphy can be repeated before training is resumed. This is probably less important in endurance horses than in Thoroughbreds, because of less risk of stress fractures turning into catastrophic fractures. Not all owners want to pursue a diagnosis to this degree, and sometimes despite every attempt at imaging and re-imaging the veterinarian is still left with a lame horse and no diagnosis. When this point is reached, benign neglect and a prolonged rest period (8 to 12 months) sometimes work miracles.

TEN MOST COMMON CAUSES OF LAMENESS

The following sections deal with the 10 most common causes of lameness in endurance horses (Box 119-1).

Suspensory Desmitis

The leading cause of chronic or recurrent lameness in endurance horses, regardless of terrain, is suspensory desmitis, most commonly proximal suspensory desmitis.[1-3] Suspensory desmitis may occur in a forelimb or hindlimb but is more common in front. Lameness typically develops in the later stages of a race, when the horse becomes fatigued, but is more likely to occur in the earlier stages in an unfit horse. Lameness from proximal suspensory desmitis may be sudden in onset and severe or more insidious. Often little swelling occurs, but careful palpation may elicit pain. Lameness associated with forelimb proximal suspensory desmitis often is accentuated by distal limb flexion. The diagnosis is confirmed by local analgesia. The origin of the SL may be blocked by the following methods:

1. Blocking the deep branch of the lateral palmar nerve at the level of the accessory carpal bone (proximal to its bifurcation into the medial and lateral palmar metacarpal nerves) and the lateral palmar nerve

Box • 119-1

Ten Most Common Causes of Lameness in Endurance Horses

Lameness	*Comments*
1. Suspensory desmitis	Suspensory desmitis is a common cause of chronic or recurrent lameness. More frequently localized to the origin than to the body or branches.
2. Foot problems	Bruising of the foot is a common cause of elimination during competitions. Laminitis is seen with increasing frequency as a sequela to serious metabolic abnormalities. Navicular problems are uncommon.
3. Myositis	Myositis may be a nuisance disease causing generalized shortening of the stride, bilateral forelimb or hindlimb lameness, and elimination from competition. In its more serious forms, coupled with metabolic abnormalities, myositis may be life-threatening.
4. Superficial digital flexor tendonitis	Tendonitis may be acute or chronic, low grade or severe. In general, endurance horses have a better prognosis for return to competition than do Thoroughbreds or horses that race faster over shorter distances.
5. Osteoarthritis of the fetlocks	Osteoarthritis can be present without causing lameness. Diagnostic analgesia helps in determining whether treatment is necessary.
6. Distal hock joint pain	Radiographic changes do not always correlate with clinical signs. Pain often is treated empirically and frequently occurs with sore feet and sore back (the terrible triad).
7. Paravertebral myalgia	Paravertebral myalgia is related to rider fatigue, occurring as the horse experiences muscle fatigue, and also is caused by sore feet and hocks causing gait alteration.
8. Splints	Splints are a common, often nuisance problem necessitating a short break from training.
9. Gluteal myalgia	Gluteal myalgia is related to strenuous work over long distances and may occur with primary forelimb lameness. Severe inflammation may occur with rhabdomyolysis.
10. Lumbosacral or sacroiliac pain	Pain also is related to rider fatigue and repetitive stress over long distances.

2. Direct infiltration
3. A high palmar and palmar metacarpal nerve block (high four-point)

Inadvertent desensitization of the carpometacarpal and middle carpal joints is rarely a problem with the latter blocks, because lameness in endurance horses seldom is localized to the carpus. If a high index of suspicion of proximal suspensory desmitis exists, but a horse does not improve with one of the three blocks, the block should be repeated or one of the other two should be tried, because some variability in response occurs. Ultrasonography is used to confirm diagnosis of proximal suspensory desmitis. Abnormalities include loss of echogenicity of the most dorsal fibers close to the third metacarpal bone immediately distal to the carpometacarpal joint, seen best in longitudinal images (Fig. 119-1). The farther distally the fiber loss extends (from zone 1 into zone 2), the worse the injury. The key to determining whether acute injury has occurred is symmetry. Both suspensory origins should be compared. Bilateral change often is present, but the clinically affected side appears less echogenic. If the SL appears normal with ultrasonography, inflammation of the ligament may exist but without accompanying detectable structural change. Horses in such condition have a better prognosis than those in which lesions are identified by ultrasonography. It is important to recognize that a horse that has undergone any strenuous work may have some degree of structural change in the proximal SL,[4] such as reduced echogenicity or fiber malalignment. Therefore diagnosis of proximal suspensory desmitis depends on response to local analgesia and comparison of the ultrasonographic appearance of the SL in each forelimb. Proximal suspensory desmitis is particularly treacherous to a horse's career because the initial lameness often responds to a short period of rest. The horse's caretakers are lulled into a false sense of security, and the horse is returned to work. Most of the time lameness recurs, which is why ultrasonographic evaluation is critical to management success. If substantial structural change is present, strenuous work should be avoided for at least 8 months. Radiography and scintigraphy are useful ancillary diagnostic aids, particularly in horses with avulsion of the origin of the SL (Fig. 119-2).

Initial management of horses with proximal suspensory desmitis should be aimed at reducing inflammation. Systemic corticosteroids (a single injection of triamcinolone acetonide, 0.03 mg/kg) along with 2 to 3 weeks of non-steroidal anti-inflammatory drugs (NSAIDs) and local therapy (ice, poulticing, and bandaging) are beneficial. The horse should be restricted to hand walking until no lameness is apparent trotting in hand on a hard surface without the influence of NSAIDs. If no structural change has been identified, the horse may walk under tack for an additional 2 weeks. The horse should be re-examined ultrasonographically to confirm that no substantial structural change is present, because lesions visible by ultrasonography can lag behind clinical signs. Assuming the ligament is structurally normal, training then may progress to gradually increasing periods of trotting for 1 month, and then normal training may be resumed. A horse with structural abnormalities of the SL should have the same initial local and anti-inflammatory therapy and 6 weeks of hand walking and then be re-evaluated with ultrasonography. If healing is satisfactory and the horse is quiet, turnout into a small paddock is recommended. Ultrasonographic examinations are repeated at 6-week intervals until 30 weeks, at which time trotting may be resumed if healing is satisfactory. Time for rehabilitation depends on the horse's temperament, the amount of help available, and the facilities available, but the best success is achieved with a controlled and gradual increase in exercise over 8 to 12 months. The bottom line has never changed: horses that sustain substantial damage to the SL or superficial digital flexor tendon (SDFT) need a long time off (8 months to 1 year) and will always be at higher risk of re-injury. The reason that conventional wisdom becomes conventional is that it has withstood the test of time.

Foot Problems

Problems with the feet are a common cause of elimination from endurance competition and are a common cause of chronic or recurrent pain. Foot problems may occur in the forelimb or hindlimb but are more common in front. Many

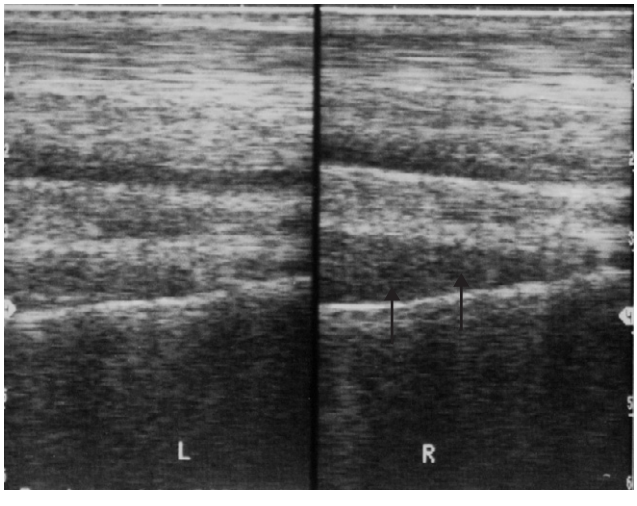

Fig. 119-1 Longitudinal ultrasonographic images of the palmar metacarpal soft tissues. The left forelimb is on the left. Proximal is to the right. There is marked loss of echogenicity and fiber pattern in the proximal aspect of the right forelimb suspensory ligament *(arrows)*. Some loss of echogenicity is also seen in the proximal aspect of the suspensory ligament of the non-lame left forelimb.

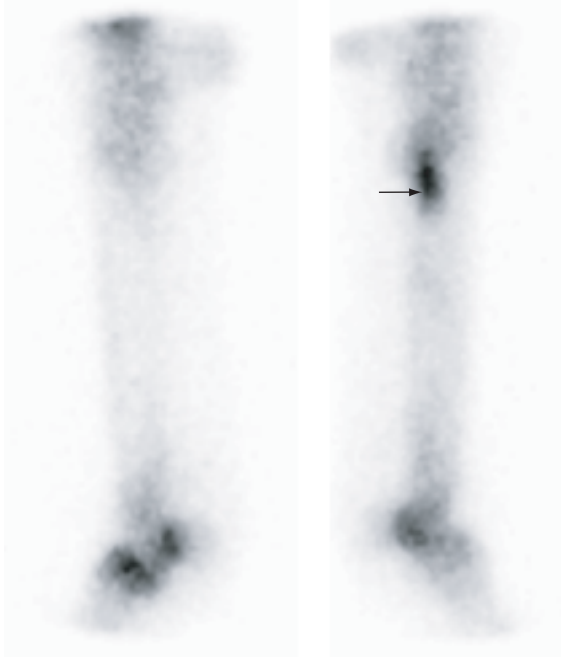

Fig. 119-2 Lateral bone-phase scintigraphic images of the left and right forelimbs. There is intense focal increased radiopharmaceutical uptake in the proximopalmar aspect of the right third metacarpal bone *(arrow)* at the site of attachment of the suspensory ligament.

problems are transient in nature, from bruising or a dislodged shoe. The importance of a properly trimmed, well-balanced, well-shod foot cannot be overemphasized. Because endurance horses go farther in a 24-hour period than any other horses, all of these things have a great impact, particularly on the support structures of the limb. Incredibly, the long-toe, low-heel syndrome still exists, even in endurance horses. This type of trimming and shoeing can lead to direct heel trauma and can increased strain on the SL and flexor tendons. Farriers who are accustomed to working with horses that wear keg shoes may be impatient with the requirements of endurance horses, which can sometimes require a more innovative approach aimed at providing the foot with increased protection and support. Inflammation of the solar structures occurs frequently in horses moving on hard ground. Lameness is manifest as a shortened, choppy gait, and hoof tester examination reveals a painful response around the solar margins. Lameness often is more pronounced in one foot. Diagnostic analgesia (abaxial sesamoid block) in the limb in which the lameness is most noticeable may result in a switch in lameness to the other side. Inflammation of the solar structures may or may not be accompanied by remodeling of the distal phalanx (pedal osteitis). Radiographic changes associated with remodeling of the distal phalanx include decreased radiopacity at the solar margin and increased size and number of vascular channels, resulting in a ragged appearance. Management is aimed at protecting the solar margins and reducing concussion. Wide webbed shoes, orthotic shoes, full pads, or rim pads can be used to accomplish these goals. Inflammation of the distal interphalangeal joints also may occur and can be treated with intra-articular medication. Sore feet often occur in horses with hock and back pain (the terrible triad), and each area must be addressed separately, but the horse must be considered as a whole. Navicular syndrome is uncommon in Arabian and Arabian crossbreeds but should be ruled out using diagnostic analgesia and imaging.

Endurance horses are subject to traumatic laminitis, which often becomes apparent in the first 24 to 72 hours after a competition, and may range from mild but frightening to disastrous. Separation of the hoof wall from the coronary band may occur, serum often oozes from the coronary band, and a bounding digital pulse is present. These clinical signs are alarming but do not always correlate with the final outcome. In some horses the outer layer of hoof wall peels away from the coronary band, but the horse is not lame and no rotation or sinking of the distal phalanx occurs. The episode is marked by a distinct defect in the hoof wall that must grow out. Horses without rotation or sinking usually are able to return to endurance competition. Sometimes horses with the worst outcome (death) do not show much in the way of early warning signs. Any horse that begins to shift its weight or act uncomfortably after competition should be scrutinized carefully. Predicting which horses will have a satisfactory outcome and those which will not is not possible, therefore aggressive treatment aimed at halting the progression of laminitis should always be instituted (flunixin meglumine [0.25 mg/kg intravenously tid], acepromazine [0.025 mg/kg intramuscularly qid], pentoxyfylline [8.5 mg/kg PO tid], and dimethylsulfoxide [1 g/kg intravenously diluted to 10% to 20% solution sid to bid]). However, the horse should receive fluid therapy before administration of NSAIDs or acepromazine.

Exertional Myopathy

Exertional myopathy, rhabdomyolysis, or myositis in endurance horses is not so much a lameness problem per se as a part of a larger picture of fatigue and metabolic abnormalities. Exertional myopathy is manifest as stiffening and shortening of the stride in all limbs and may be accompanied by trembling and profuse sweating. The condition usually occurs in the earliest or latest stages of a competitive ride. Horses with severe exertional myopathy often have pronounced swelling and hardening of the gluteal muscles. Asymmetry of the gluteal muscles may be present. Fluid therapy (0.9% sodium chloride) is the mainstay of treatment. Horses with severe exertional myopathy require large volumes (50 to 80 L) of fluids. Horses with myoglobinuria should urinate normal colored urine before flunixin meglumine (0.55 to 1.1 mg/kg or 250 to 500 mg/450 kg) is administered. When in doubt as to the status of renal function, it is better to give a lower dose and repeat as necessary. Blood urea nitrogen and creatinine should be monitored if possible. Highly portable, relatively inexpensive, user-friendly blood analyzers now make it possible to monitor kidney and muscle enzymes, and electrolytes and packed cell volume conveniently in the field. Dimethylsulfoxide (l g/kg intravenously in a 10% to 20% solution) also may be beneficial. Dantrolene may be useful but is not available in an intravenous form and is expensive to use orally at recommended dosages (15 to 25 mg/kg). Horses that have suffered an episode of exertional myopathy or myositis should not be returned to training until muscle enzymes return to normal.

Superficial Digital Flexor Tendonitis

Tendonitis of the SDFT may be acute or chronic, low-grade or severe. Acute ruptures or partial ruptures do occur occasionally during competition. Initial management is directed at trying to reduce swelling and inflammation and to relieve pain. Ice, bandaging, and NSAIDs are used. Dehydrated horses should not be treated with NSAIDs until they are rehydrated. A horse that sustains a rupture or partial rupture of the SDFT has a poor prognosis for return to endurance competition. Horses with less severe damage of the SDFT can be more challenging to diagnose and treat. Training injuries occur frequently. The SDFT may be warm and tender on palpation, but lameness is usually not apparent. Ultrasonography should be performed to determine if fiber damage exists. The ultrasonographic appearance does not change initial management, but it determines whether the horse may continue training after a short rest period or whether a more prolonged rest period is required. Those horses with transient heat and tenderness, but no swelling or fiber damage, usually can be safely returned to training within 2 to 4 weeks after the resolution of clinical signs. If the tendon is enlarged or if fiber separation has occurred, a substantially longer absence from training and competition is required. Horses that sustain tendon fiber injuries in training or competition are managed similarly to flat racing horses. Management with one injection of triamcinolone acetonide (0.03 mg/kg), local application of ice for the first few days, bandaging, poulticing, and NSAIDs for 2 to 3 weeks is beneficial in reducing inflammation. Surgical splitting of those tendons with central core lesions, autogenous bone marrow grafting of split SDFT[5] and desmotomy of the accessory ligament of the SDFT may be beneficial, but whether these therapies are more beneficial than rest alone is unproven. Because the career of endurance horses tends to span many years, time is on the veterinarian's side, and the tendency is to treat endurance horses with superficial digital flexor tendonitis conservatively rather than surgically. Endurance horses with tendonitis of the SDFT have a better prognosis for return to competition than horses that race over short distances at higher speeds.

Osteoarthritis of the Metacarpophalangeal Joint

Osteoarthritis of the metacarpophalangeal joints and the distal joints of the hock occurs with similar frequency. This is hardly surprising, given the ongoing nature of the degenerative process and the fact that endurance horses may compete until they are 18 to 20 years old. Osteoarthritis of

the metacarpophalangeal or metatarsophalangeal joints may occur with or without joint effusion and may be unilateral or bilateral. Osteoarthritis is far more common in the forelimbs but also occurs in the hindlimbs. Flexion of the joint produces pain, and the joint often has a decreased range of motion and thickening of the joint capsule. Radiographic changes may be subtle, such as narrowing of the joint space, or may consist of more severe peri-articular osteophyte or enthesophyte formation and joint remodeling. Radiographic changes do not always correlate with clinical significance, so diagnostic intra-articular or perineural (low palmar and palmar metacarpal blocks) analgesia is used to confirm the site of pain. Acute, traumatic synovitis or capsulitis of the metacarpophalangeal joint may occur occasionally, but in general, long-term management of chronic osteoarthritis is the more common scenario, and management is no different from that in any other athletic horse. Local therapy (ice, poultice, and sweats), intramuscularly administered glycosaminoglycans, intravenously administered hyaluronan, and judicious use of an intra-articularly administered hyaluronan and corticosteroid combinations are beneficial. Intra-articular corticosteroid injections should be low dose (20 to 40 mg methylprednisolone acetate with 20 mg sodium hyaluronan per joint), used with a rest period of 3 to 10 days, and should be spaced as far apart as possible, no more than 2 to 3 times a year, because the idea is to prolong the horse's career. Competitions should be selected carefully and spaced appropriately.

Distal Hock Joint Pain

Distal hock joint pain is common in the endurance horse. Osteoarthritis of the tarsus usually affects the tarsometatarsal and centrodistal joints and is often bilateral, with one limb being more affected than the other. Joint effusion is not palpable, but occasionally during intra-articular injection of the tarsometatarsal joint one gets the impression that the pressure and volume of synovial fluid is increased. Affected horses respond positively to hindlimb flexion and are sensitive to the Churchill test (see page 56). Radiographic abnormalities include joint space narrowing and peri-articular osteophyte formation. Radiographic changes do not always correlate with clinical signs, but intra-articular analgesia is used less frequently in the hindlimb compared with the forelimb. If the clinical picture suggests distal hock joint pain, intra-articular medication is administered. A positive response is empirical evidence of a correct diagnosis. Distal hock joint pain frequently occurs concurrently with paravertebral muscle pain and sore front feet, the terrible triad mentioned previously. This probably results from a horse with sore front feet altering its gait in such a way as to cause strain in the paravertebral muscles and hocks. The best results are obtained when all three problems are treated simultaneously; otherwise, the pain in one area and gait alteration and soreness in another become a never-ending cycle.

Paravertebral Myalgia

Paravertebral myalgia is caused by a fatigued, unbalanced rider. Unfortunately, diminished rider capability usually is occurring at the same time that the horse is experiencing its own muscle fatigue. Horses ridden by fit, experienced riders are less subject to battering of the paravertebral muscles than those ridden by novices. Similarly, those horses carrying live weight are less likely to be battered by flopping lead pads than those carrying dead weight, because a fit, competent rider is able to adjust his or her weight distribution to help a tiring horse. Horses competing in FEI rides often have to carry a minimum weight of 70 to 75 kg.

A horse that has strained or injured the paravertebral muscles appears stiff or rigid, and instead of flexing and extending the spine normally when palpated, tends to squat or crouch. Paravertebral myalgia also occurs in horses that alter the gait from sore feet or sore hocks. Treatment consists of removing the inciting cause and reducing inflammation. Most horses respond to a 2-week rest period with NSAIDs and injection of the paravertebral muscles with an anti-inflammatory agent. The longissimus dorsi muscles are injected bilaterally about 3 cm lateral to the spine at 5 or 6 sites about 5 cm apart, from the mid-thoracic area moving caudally, with methylprednisolone acetate (200 mg) or estrone sulfate (50 mg), mixed with an aqueous solution of soluble salts of the volatile bases from Sarraceniaceae (Sarapin, 10 ml). Complementary therapies (acupuncture, chiropractic manipulation, and physical therapy) may be beneficial in certain horses but require well-trained and experienced therapists under veterinary referral.

Splints

Periosteitis and exostosis of the second and fourth metacarpal and metatarsal bones (splints) are usually nuisance problems that may necessitate a 4- to 6-week break from training. Radiographs of horses with splint enlargements should be obtained to rule out fractures. Ice, NSAIDs, and bandaging can be used to reduce inflammation. Cryotherapy also can be used to reduce inflammation and sometimes enables horses to train after several days. Most splints resolve with time and treatment, although a non-painful enlargement remains. If the exostosis continues to enlarge, training should be discontinued to avoid impingement on and damage to the SL. Sometimes suspensory involvement occurs before the problem is recognized. These horses require a longer rest period. Exostoses that enlarge to the point that they impinge on the SL and are far enough distal to allow removal should be removed surgically before the rest period.

Gluteal Myalgia

Inflammation of the gluteal muscles occurs with relative frequency in horses subjected to strenuous work over long distances. The superficial and middle gluteal muscles are painful on palpation and the horse may crouch down or move away during palpation. Swelling or asymmetry may be apparent in the acute stages, with elevation of serum muscle enzyme concentrations. Severe inflammation of the gluteal muscles and accompanying rhabdomyolysis is a serious problem that is discussed with metabolic abnormalities (see page 1002). NSAIDs must never be administered in the acute stages of gluteal muscle inflammation unless it can be ascertained that hydration and renal function are not compromised. Horses with less severe gluteal muscle inflammation usually respond to NSAID therapy and a short (2- to 3-week) rest period. Soreness in the gluteal muscles often occurs with forelimb lameness, because horses alter hindlimb gait to protect themselves. It is important to identify and treat the primary source of pain. Once that is accomplished, the gluteal muscle inflammation will resolve.

Lumbosacral and Sacroiliac Pain

Lumbosacral and sacroiliac pain occur in endurance horses from repetitive stress over long distances. Rider fatigue and diminished rider capability are again likely to be important components in the development of pain in the surrounding musculature. Muscle spasm is likely to exacerbate any existing instability in the sacroiliac region. Horses exhibit stiffening and shortening of stride, and pressure over the tubera sacrale produces a painful response. Scintigraphic examination shows increased radiopharmaceutical uptake. Manipulation and deep muscle massage to alleviate muscle spasm, performed soon after injury, may be helpful. NSAIDs in conjunction with rest help resolve inflammation.

METABOLIC PROBLEMS

Avoidance, diagnosis, and management of metabolic problems are the most controversial topics currently facing the sport of endurance. The pressures alluded to earlier are manifest in an increasing number of horses that require treatment for metabolic abnormalities. On one hand, veterinarians are becoming more adept at recognizing subtle signs of exhaustion and are becoming more willing to treat horses aggressively before they get into serious trouble. On the other hand, more horses are getting into serious trouble. The exhausted horse syndrome was described many years ago[6] and unfortunately is still evident today. Exhausted horses undergo massive but poorly understood fluid and electrolyte shifts that lead to multiple organ system compromise. Most commonly the first signs are a persistently elevated heart rate and a profound ileus that do not respond to fluid therapy, electrolyte supplementation, or analgesics. Synchronous diaphragmatic flutter may be present. Horses with ileus should be checked for the presence of gastric reflux. It cannot be stressed enough or overemphasized that exhausted horses, or those with severe myositis, must not be treated with NSAIDs until they are adequately rehydrated. To do so risks renal failure, and these horses are already in a high-risk category. If lameness or myositis is present, the temptation always is to treat the horse immediately with phenylbutazone or flunixin meglumine. *This temptation must be resisted*. Lame horses, even those without evidence of metabolic compromise, should be rehydrated before administration of NSAIDs. Horses with acute tendon or ligament injuries should have the affected limb placed in ice while they are undergoing rehydration before NSAID administration.

Exhausted horses or those with severe myositis should receive at least 10 L, and preferably 15 to 20 L of intravenous 0.9% sodium chloride (or other available isotonic fluid), before NSAID administration. Collapsed horses or those on the verge of collapse may be given prednisolone sodium succinate (0.22 to 1.1 mg/kg or 100 to 500 mg/450 kg). Two intravenous catheters, one of which is 10 or 12 gauge, should be placed. Catheters should be 140 mm (5.5 inches) long and should be sutured in place to prevent dislodgment and extravasation of fluid. Time is always available to do a sterile skin preparation before catheter placement; most of these horses recover, but infectious phlebitis is an unwelcome complication. Sterile skin preparation materials should be handy in a catheter kit. Exhausted, dehydrated horses are also at risk of pleuropneumonia and laminitis. Some horses already have been stressed before competition by being shipped long distances. Profound leukopenia may precede the onset of pleuropneumonia. Laminitis may strike several days after the initial episode of post-race exhaustion. Treatment for laminitis, discussed elsewhere (see page 1000), should be instituted in horses that are depressed, inappetant, leukopenic, or febrile.

Prevention of Metabolic Problems

Most metabolic problems could be avoided by common sense, but in the heat of competition, common sense is often lost. Both horse and rider inevitably get tired, but a shrewd rider who knows his horse should know when the horse has had enough. If a horse is not eating and drinking at rest stops or is reluctant to move forward, the horse should be stopped. Horses must be allowed to drink at rest stops. Hay fed to a well-hydrated horse acts like a sponge or water reservoir in the large intestine. Endurance horses should be encouraged to eat hay and should have free access to water before competition so that they will have a fluid reserve available for absorption from the large intestine. Providing oral electrolyte replacement is helpful if the horse is drinking, and using electrolyte preparations may encourage a horse to drink. Concentrated electrolyte preparations that are force-fed, however, may actually be detrimental if the horse does not drink, because by raising the tonicity of the gastrointestinal lumen, more fluid is drawn into the lumen from the circulation, contributing to dehydration.

Synchronous diaphragmatic flutter, or thumps, a condition in which the phrenic nerve is stimulated by atrial depolarization, causing contraction of the diaphragm and consequent thumping of the flank in time with the heartbeat, is a sign of serious electrolyte imbalance, most commonly hypochloremic metabolic alkalosis. Sometimes, a low total or ionized calcium level can be demonstrated. Rest, food, and water may be all that is required for the condition to resolve. If treatment is required, however, horses with synchronous diaphragmatic flutter invariably respond to intravenous calcium supplementation (100 to 300 ml 20% to 23% calcium borogluconate diluted in 2 to 3 L of saline solution or 5% dextrose solution given over 15 to 20 minutes to effect). It has been proposed that horses subject to synchronous diaphragmatic flutter be fed a diet that is low in calcium before competition, which may enable more efficient mobilization of calcium from bone reserves during periods of stress.[7]

Recently an additional examination has been added at selected veterinary checkpoints on some rides. The purpose of the additional examination is to try to identify those horses that, because of aggressive cooling and perhaps high circulating catecholamines, pass the initial veterinary examination but then deteriorate during the mandatory hold period. Without this second look these deteriorating horses return to the trail and may deteriorate further until treatment is required. Although identifying all those horses that are going to have metabolic problems is probably not possible, an additional examination appears promising in at least identifying some of them. Therefore implementing the second look should be supported and encouraged by riders, trainers, ride organizers, and veterinarians.

CHAPTER • 120

Lameness in the Polo Pony

Paul Wollenman, P.J. McMahon, Simon Knapp, and Mike W. Ross

HISTORY OF THE SPORT

Polo was the first equestrian sport in recorded history. With strong ties to military traditions, the game originated in China in AD 272 and was often substituted for war games in preparation for military battle. Polo evolved into an organized sport and spread into Greece, India, and China, where the British colonies adopted the game. During the nineteenth century, the game became more refined in Great Britain and eventually found its way into the northeastern United States in 1876. Today polo continues to be one of the fastest and most dangerous equine sports in the world. Polo is no longer a sport for only the wealthy, but an increasing number of small clubs start up each year that attract people of moderate incomes to take lessons, buy horses, and begin to play. The sport has become more complex, with international professional players competing year-round on different teams around the globe. Professional polo coaches, umpires, trainers, and breeders have thus emerged, solidifying polo as a genuine equine sport industry. Playing seasons in the northern and southern hemispheres are followed by nomadic players, grooms, horses, and spectators. During the winter months in the United States, thousands of horses enter Florida and California, where the tropical climate is inducive to world-class polo tournaments. During the spring, summer, and fall seasons these horses travel across the Midwest, up the northeast coast and into Canada. The high-goal season begins in the summer in England and Spain, but the season in Argentina commences in the fall.

POLO AS AN INDUSTRY

Today three types of polo are played: outdoor, indoor (arena), and snow polo. Outdoor polo is by far the most popular and is played on a large, finely manicured grass field measuring 274 m (300 yards) by 137 m (150 yards) (Fig. 120-1). Injuries are related to fatigue (because of the distances covered), stopping, turning, and speed. Arena polo is played in much smaller arenas and is more common in collegiate settings. Injuries tend to be less frequent and are usually impact related. Snow polo is regarded as a novel exhibition sport played on the surface of a frozen lake and produces surprisingly few injuries. Obviously, footing and surface conditions often can be responsible for the type of lameness seen. Heavy, soft, grass polo fields and deep, sandy, uneven exercise tracks are frequently responsible for proximal suspensory desmitis, suspensory branch desmitis, and metacarpophalangeal joint sprains. Hard fields, exercise tracks, and polo field sideboards may cause hoof and pastern region injuries and hard, fast ground predisposes horses to superficial digital flexor tendonitis.

In outdoor polo each team is composed of four players, and each member brings an average of seven to eight horses to the field. A game normally runs for six chukkers (a chukker is 7 minutes), and a different horse is used for each chukker. Therefore a single match may have 50 to 55 horses playing over 1½ hours. The number of horses that are required to mount a polo team make each owner's total investment much larger than that for other equine disciplines.

Polo requires the speed and stamina of a Thoroughbred or a Thoroughbred-cross horse, the ability to stop and turn quickly, and the boldness to meet and collide with other horses at high speed. Although called ponies, polo horses stand 15 to 16 hands tall, and mares are preferred to geldings at a ratio of 10:1. Most trainers look for a fine neck and throatlatch, a good strong shoulder, powerful hip, quiet disposition, and a responsive, light mouth. Many horses have not raced, so few racetrack-related injuries are found in polo ponies. Argentina, New Zealand, and Australia are the only countries that specifically breed large numbers of horses for polo competition. Horses indigenous to these countries tend to have more bone than those in the United States and Europe, rendering them slightly more durable. Argentina has historically produced the most horses used solely for polo. Since 1970

Fig. 120-1 Outdoor polo is the most popular format for the game today. Close proximity of horses and riders explains why polo ponies often develop injuries related to direct trauma. Polo is only played right-handed.

thousands of Argentine horses have been imported into the United States and Europe, primarily because such a large selection was available at low cost. During the 1970s, inexpensive American ex-racehorses were sold as polo prospects, but many had numerous orthopedic problems. Today the price of high-goal Argentinian polo ponies continues to rise, and as the cost of importing horses into the United States increases, economic demands necessitate a greater influx of American Thoroughbreds into polo.

Most horses are 3 to 4 years old when introduced to the game, and 2 years of training and playing generally are required before a pony becomes seasoned. Exceptionally talented horses are playing high-goal polo at 6 years of age. By the age of 12 to 14 years, speed usually has begun to diminish, and horses are sold to less demanding players. By the age of 15 to 16 years, depending on temperament, polo ponies may be sold to beginners before being retired.

Neck reining is paramount in training a polo prospect, because the rider uses only one hand for control. Wide range of movement, the ability to stop and turn quickly, and the ability to exhibit rapid bursts of speed are required. How well and smoothly the horse performs these maneuvers often determines the number of years the horse stays sound and competes successfully. In addition to schooling, fitness training consists of daily galloping (legging up). Ponies often are tied together in sets of four to five. This time-saving practice teaches the horses to travel more calmly together in close contact but can result in traumatic injuries to the lower limbs (Fig. 120-2).

Polo ponies are shod with special rim shoes in front that allow for traction and pivoting without applying excessive torque to the lower limb. Medial and lateral heel calks on the hind shoes are helpful for stopping abruptly but often result in coronary band and pastern region lacerations to other horses during competition. For safety reasons, the Great Britain Polo Association only permits a lateral calk on each hind shoe, whereas the United States Polo Association allows medial and lateral heel calks. The size limit for calks is regulated but seldom enforced. Therapeutic corrective shoeing is problematic in playing horses (those being used in polo competition), because they may lose traction and maneuverability. Some common shoeing modifications include squared, rolled, and rocker toes; elevated and full-shod heels; and padded soles. The standard support and protection afforded the horse during exercise are leg wraps and coronet boots. All legs are wrapped with double-layer rolled cotton bandages. Impact-resistant European racing boots may be added to cover the metacarpal regions to protect against mallet and hoof trauma. More recently, especially on previously injured limbs, cotton leg bandages have been replaced with neoprene fabric wraps that extend below the fetlock joint and provide additional support. Despite these additional protective barriers, horses may still injure tendons and receive skin laceration during a game or practice.

Drug testing of polo ponies is not yet compulsory in the United States, and no mention of prohibitive medication is addressed in the United States Polo Association rulebook; however, limited testing is done in Great Britain and France. Attending veterinarians often work for many competing teams within the same tournament and prompt assessment of injuries is important. Low doses of non-steroidal anti-inflammatory drugs (NSAIDs) commonly are used, especially in horses with wounds and solar bruising. The general aim is to have as many sound horses as possible sharing the workload during a match to avoid the practice of double-chukkering (same horse used for two chukkers).

Minor conformation abnormalities in polo ponies often can be overlooked, but some faults predispose ponies to specific injuries. Long toes and underrun heels may result in tendonitis of the deep digital flexor tendon (DDFT) and palmar heel pain. Toed-in horses are prone to develop lateral suspensory branch desmitis, whereas toed-out horses are more likely to injure the medial branch. Horses with long pasterns and long third metacarpal bones (McIII) are at increased risk of tendonitis of the superficial digital flexor tendon (SDFT).

The most common sources of lameness in polo ponies are similar to those seen in most other equine sports. Polo ponies are at higher risk for traumatic injury because of the high-impact play and the practice of tethering of horses in close proximity to other horses during shipping, exercise, and polo tournaments. Causes of lameness often seen concurrently include palmar heel pain and proximal suspensory desmitis

Fig. 120-2 Daily legging up is an important part of training polo ponies. Ponies often are tied together in sets of four to five, and although this practice saves time, horses in close contact are at risk of traumatic injury.

and osteoarthritis of the fetlock joint with chronic suspensory branch desmitis.

TEN MOST COMMON LAMENESS PROBLEMS

The following are the 10 most common lameness problems in polo ponies:

1. Tendonitis of the superficial digital flexor tendon
2. Osteoarthritis of the metacarpophalangeal joint
3. Proximal palmar metacarpal pain and suspensory desmitis
   a. Proximal suspensory desmitis and third metacarpal bone disease
   b. Body suspensory desmitis and splint bone disease
   c. Suspensory branch desmitis and sesamoiditis
4. Injury to the hoof and distal phalanx
5. Palmar heel pain including navicular disease
6. Osteoarthritis of the distal interphalangeal joint
7. Desmitis of the accessory ligament of the deep digital flexor tendon
8. Splint bone disease
9. Distal hock joint pain
10. Gluteal myositis and back pain

LAMENESS EXAMINATION

Horses should be stabled overnight so that they cannot warm out of subtle lameness. The horse is first examined in the stall and then as it walks from the stall. The horse is observed at a trot in a straight line on a hard surface and is circled in both directions. Most polo ponies are reluctant to lunge. If necessary, the horse may be observed under saddle, but Argentine ponies generally resist trotting when ridden.

A systematic examination at rest is begun with the hoof and hoof tester evaluation and then continued proximally in the limb, noting evidence of pain, swelling, or obvious injury. Findings always should be compared with the contralateral limb, especially when palpating the body of the suspensory ligament (SL). Joints are assessed for range of motion and a painful response to flexion. Lower limb flexion is followed by carpal or tarsal flexion. Walking the horse briefly between flexion tests to allow an aggravated response to wear off is wise.

One of us (P.J.M.) attends to many older polo ponies that have effusion of the metacarpophalangeal joints, manifest a positive response to flexion, and even may have visible and radiographic evidence of osteoarthritis, but lameness often is abolished using low palmar digital analgesia. Palpation may reveal one or more fractured splint bones with callus, but the rest of the limb should be examined, because the cause of lameness may be elsewhere.

If a definitive diagnosis cannot be made, diagnostic analgesia is performed. Because drug tests are not performed, local anesthetic solutions can be used for diagnostic purposes in actively competing horses. When performing a nerve block, it is important to remember that the block may affect a larger area than intended, primarily related to diffusion of local anesthetic solution to surrounding tissue. High palmar analgesia can mask middle carpal joint pain, and an abaxial sesamoid nerve block can eliminate pain associated with the fetlock joint. For this reason the horse should be observed at the trot shortly after injection of local anesthetic solution and then again after an appropriate wait.

To reduce time and money spent on lameness diagnosis one author (P.W.) prefers to block large areas during the initial examination. Specific blocks then are performed, if necessary, the following day. For example, a horse that shows neither sensitivity to hoof tester examination nor an increased digital pulse may go sound after an abaxial sesamoid nerve block. The following day the same horse may show slight improvement after palmar digital analgesia and a 100% improvement with intra-articular analgesia of the distal interphalangeal joint. However, two authors (P.J.M. and M.W.R.) prefer to start distally and work proximally in systematic fashion.

Intra-articular analgesia is used extensively in polo ponies because it is more specific than perineural analgesia. Although intra-articular analgesia requires aseptic preparation and carries a small risk of infection, clients are generally receptive. If lameness is localized to a specific joint on clinical examination, therapeutic agents such as corticosteroids and hyaluronan can be added to local anesthetic solution to confirm diagnosis and initiate treatment simultaneously. One author (P.W.) uses combination diagnostic and therapeutic arthrocentesis typically in the distal interphalangeal and proximal interphalangeal joints. The horse's immediate response to local analgesia is noted, and response to therapy is usually evident 2 to 3 days later. Another author (P.J.M.) frequently uses combination diagnostic and therapeutic injections in the distal interphalangeal and distal hock joints. If treatment is not combined with intra-articular analgesia, injection of the joint with therapeutic medication should be delayed for 2 to 3 days. Combination injections can also be used simultaneously to diagnose and treat back pain. The dorsal aspect of the dorsal spinous process and the interspinous space can be infiltrated with a combination of local anesthetic solution, Sarapin, and a corticosteroid. Response to infiltration is evaluated immediately by riding the horse after injection, and response to medication is evaluated over the next several days.

Because metacarpophalangeal joint disease and splint bone injury are common sources of pain in the polo pony, one author (P.J.M.) prefers specifically to differentiate these sources of pain by first performing intra-articular analgesia of the metacarpophalangeal joint and then later performing a low palmar block. If low palmar analgesia is performed first, both potential sources of pain are eliminated. If pain is detected on palpation of bony exostoses of the splint bones, these areas can be blocked first, before a systematic blocking strategy is followed. One author (P.J.M.) refers to this as the splint block. This block is performed by first blocking the palmar metacarpal nerve distal to the exostoses. If improvement is not seen, the palmar metacarpal nerve just proximal to the exostoses is then blocked (2 ml of local anesthetic solution). A biaxial splint block can be performed if exostoses are found medially and laterally. This block should be done well below the origin of the SL to clearly differentiate proximal suspensory desmitis from splint bone disease. Splint disease, mainly from direct trauma from mallets and calk trauma, is common in the hindlimb. Diagnostic analgesia is performed as described in the forelimb.

Hindlimb proximal suspensory desmitis has become a common diagnosis because we are now more aware of it. In the United Kingdom a variation of the high plantar nerve block is commonly used to diagnose proximal suspensory desmitis. Three ml of local anesthetic solution is injected deep to the proximal aspect of the lateral splint bone and 2 ml each is placed over the medial and lateral plantar nerves. If this block is unsuccessful in abolishing pain, each hock joint compartment is blocked subsequently. This procedure then is followed by fibular and tibial nerve blocks. In Argentina chemical neurolysis (long-term nerve block) of the fibular and tibial nerves frequently is performed for horses with distal hock joint pain or proximal suspensory desmitis (P.J.M.).

UNDIAGNOSED LAMENESS

In some horses the lameness is inconsistent and/or subtle, and diagnostic analgesia cannot be performed. Nerve trauma on

the medial aspect of a proximal sesamoid bone (PSB) may cause episodic, transient severe lameness. An option in a horse with mild inconsistent lameness is to treat with phenylbutazone (2 g PO bid) for 5 days and then reassess the horse. If lameness resolves and does not return after treatment is discontinued, the horse gradually is put back into work. In horses with inconsistent lameness that fail to respond to rest or therapy, we recommend nuclear scintigraphic examination. Exercise intensity can be increased in horses with subtle lameness but is done so with caution. Lameness may become more apparent to the point which diagnostic analgesia can then be performed. In a horse with recurrent episodes of hindlimb lameness, the veterinarian should be aware of the possibility of an ilial stress fracture (S.K.).

Occasionally a polo pony becomes acutely non-weight bearing, with lameness lasting only a few minutes and resolving before examination is possible. If this sort of episode becomes recurrent in the same limb and physical examination reveals no significant findings, we refer the pony for nuclear scintigraphic examination.

Consultation with colleagues and seconds opinion are always options. It is also important to consider the option of extended turnout. Because the career of a polo pony can last 12 to 15 years, owners are often willing to give the horse 6 to 12 months of turnout to avoid any further injury. If subtle lameness resolves with phenylbutazone therapy, the polo pony can compete because there is no drug testing in polo competition. This option must be elected with caution, however.

Several lameness problems may exist simultaneously in a polo pony, a fact that makes observing the primary or baseline lameness difficult. Subtle signs such as the failure of a horse to stop appropriately, a horse that jumps on after stopping, or a horse that turns one way or the other when stopping (which is probably from outside hindlimb pain; horses turn away from lameness) may reflect low-grade lameness. If these observations have been made, having the horse ridden to witness the problems firsthand is useful. In one author's experience (P.J.M.) the most common source of pain in this type of situation is from the distal hock joints.

IMAGING CONSIDERATIONS

Conventional and computed radiography are the mainstays of imaging, with the front feet and front fetlock joints and hock joints being examined most frequently. The introduction of computed radiography has provided great advantages, because with the exception of faulty positioning, obtaining non-diagnostic radiographs is almost impossible. Exposure can be adjusted at the time of processing, and subtle details that would be difficult to see on conventional radiographs can be detected and scrutinized easily with computed radiography. Images can be enlarged, and the contrast and brightness can be improved, which are important factors in the diagnosis of incomplete fractures.

Scintigraphic examination is particularly useful in polo ponies with undiagnosed lameness and in those with palmar heel pain, but it is not always helpful in horses with chronic lameness (S.K.). Motion-correction software has been an important innovation.

Ultrasonography is extremely important in evaluating the damage and healing processes in tendons and the SL in the forelimb and hindlimb. Transverse views are used more frequently in identifying lesions, whereas longitudinal images aid in assessing healing. Ultrasonographic evaluation of the supraspinous ligament is often useful in horses with obscure hindlimb lameness. We have not found thermography particularly useful in our practices.

Diagnostic arthroscopy in horses with osteoarthritis of the metacarpophalangeal or carpal joints can be valuable in evaluating the condition of joint surfaces. Palmar intercarpal ligament injury has been diagnosed in ponies with lameness localized to the middle carpal joint but lacking radiographic and scintigraphic signs. Tenoscopy and bursoscopy also can be useful diagnostically and therapeutically.

SUPERFICIAL DIGITAL FLEXOR TENDONITIS

Tendonitis of the SDFT is the most common soft tissue injury seen in polo ponies and is by far the most common reason for early retirement. Tendonitis can be divided into three categories by location on the limb—high (proximal), mid-metacarpal, and low (distal)—or by cause: trauma, speed, and fatigue.

We believe that most peripheral injuries of the SDFT result from tendon trauma while the limb is bearing weight. However, peripheral injuries commonly are seen in other sport horses, such as Standardbred racehorses, in which direct trauma is usually not a factor (M.W.R.). These injuries occur much more frequently at the mid-metacarpal region on the lateral aspect and to a lesser extent on the palmar surface of the tendon (Fig. 120-3). Proximal tendonitis also can be caused by trauma (P.J.M.). These areas have a high degree of exposure to swinging mallets and flying hooves. Despite new protective boots the SDFT is still traumatized with surprising frequency. Traumatic tendon injuries are generally noticed 1 to 2 days after the incident and are characterized by a slight widening of the tendon (not a banana-shaped profile). Lameness is usually not present, but the area is warm and tender to palpation. Some horses have recurrent heat and swelling that resolves quickly with topical and systemic anti-inflammatory therapy. Peripheral lesions may involve 20% or less of the cross-sectional area (CSA) of the tendon. However, careful ultrasonographic examination of the medial and lateral borders of the SDFT and critical evaluation of longitudinal images are necessary. Recurrent tendonitis leads to typical

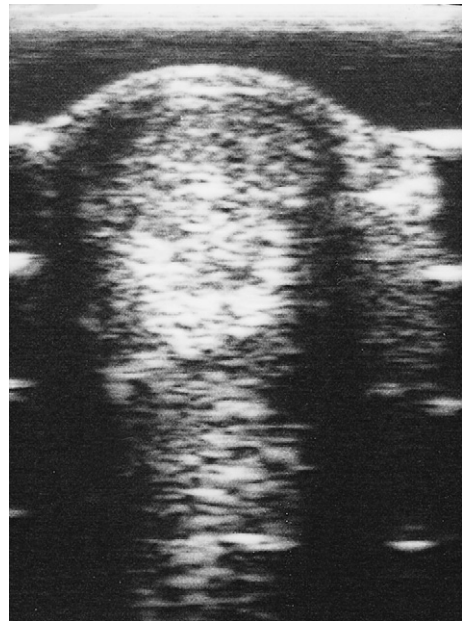

Fig. 120-3 Transverse ultrasonographic image of the palmar metacarpal region of a polo pony with traumatic tendonitis of the lateral aspect of the superficial digital flexor tendon. Lateral is to the left. After initial diagnosis the horse continued to play, and the lesion progressed.

swelling and later lameness commonly found with moderate or severe tendonitis of the SDFT.

Core lesions and lesions of the SDFT adjacent to the DDFT are thought to be injuries related to speed and fatigue. Hard, fast ground may a predisposing factor. Tendonitis of the SDFT may result in a banana-shaped profile of the metacarpal region (Fig. 120-4). Core lesions compromising between 20% and 25% of the CSA of the SDFT are serious, and the risk of recurrence is high. Horses with small CSA tears that extend more than 2.5 cm in length, or those with distally located tendonitis involving SDFT impingement by the palmar annular ligament, are at high risk of recurrence. Despite appropriate therapy these horses often have chronic and recurrent lameness, and ultrasonographic evaluation reveals a lesion that often fails to heal.

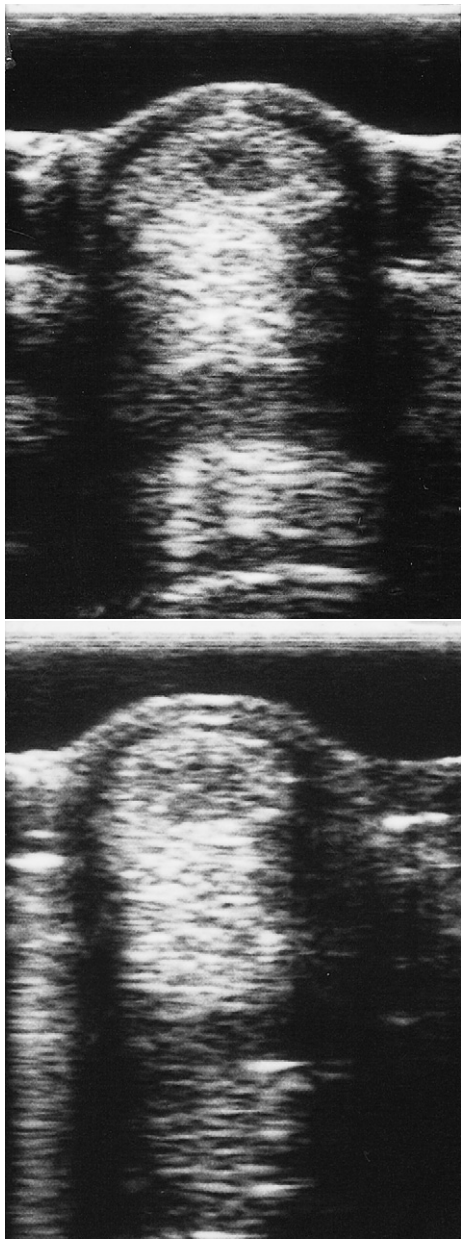

Fig. 120-4 **A,** Initial and **B,** 40-day follow-up transverse ultrasonographic images of the palmar metacarpal region of a polo pony with a typical core lesion of the superficial digital flexor tendon. Tendon splitting was done immediately after the initial image was obtained. The core lesion is more echogenic in the follow-up image but can still be seen.

Initial treatment for any polo pony with tendonitis regardless of location or cause includes cold therapy (ice boots and cold-water hosing), application of sweats and compression wraps, and administration of NSAIDs. Peritendonous injections of corticosteroids and hyaluronan may help to reduce inflammation, but it is important that corticosteroids are not injected directly into a tendon. Peritendonous corticosteroid injection is frowned on in the United Kingdom (P.J.M.). A combination of injection and rest or surgical management has been successful (M.W.R.). Tendon splitting within a week after injury appears to be beneficial in decompressing the lesion. Tendon splitting must be done early, because granulation tissue forms quickly and cannot be decompressed. After appropriate sedation, perineural analgesia, and aseptic preparation, 30 to 40 incisions with a No. 11 scalpel blade in a stabbing manner (a fan-shaped pattern is avoided) are used to decompress only the affected tendon segment. One author prefers using a double-edged tenotomy in a fan-shaped pattern (M.W.R.). The procedure can be performed with the limb in a weight-bearing or flexed position, but a weight-bearing position is preferred. With experience the texture of diseased tendon can be differentiated from surrounding normal tendon structure. Bandages are applied, and horses are confined to a box stall and given controlled, increasing hand walking over the next 8 to 10 weeks. Application of a cast to support the fetlock and to provide pressure is preferred by one author (S.K.) to tendon splitting. Topical blisters may be beneficial in increasing local circulation or inducing fibrosis and may eventually improve cosmesis and can be used alone or with tendon splitting (P.W. and P.J.M.). Some veterinarians favor bar firing or an internal blister using ethanolamine (S.K.). Controlled exercise is recommended for a minimum of 4 to 6 months before any form of turnout exercise is given, but client compliance with this timetable is poor unless a horse walker is available. Unfortunately, most horses are turned out to pasture after blistering within 1 month of injury, a conventional practice we feel is harmful to tendon healing. Total time of turnout exercise (after controlled exercise) is 8 to 12 months. Follow-up ultrasonographic evaluation is important to monitor healing and to determine when exercise level can be stepped up.

Other forms of therapy can be considered. Intra-lesional β-aminoproprionitrile fumarate injections have not been used extensively in polo ponies, because of the difficulty in garnering owner compliance with the required extensive rehabilitation program. Intra-muscular administration of polysulfated glycosaminoglycans (PSGAGs) may be beneficial (S.K.). Desmotomy of the accessory ligament of the SDFT (superior check desmotomy) has been useful in horses with large CSA core lesions (≥25%) and those with small CSA tears that are >2.5 cm in length. Combining the surgical procedures of desmotomy and tendon splitting early after injury has been successful in returning horses with tendonitis of the SDFT to polo. After surgery, horses are given stall rest and hand walking for 4 to 6 weeks, with a total of 4 to 6 months of controlled exercise, before being turned out or conditioned for polo. Desmotomy of the palmar annular ligament occasionally is performed when the SDFT is injured and enlarged just above the ligament. This surgery interrupts a self-perpetuating cycle of injury that develops between the enlarged tendon and the thickened palmar annular ligament. One author (P.W.) believes that horses with distal tendonitis of the SDFT involving the palmar annular ligament should initially be treated with peritendonous injection of short-acting corticosteroids followed by compression wraps, not only to reduce the size and cosmetic appearance of the SDFT but also to prevent the need for desmotomy of the palmar annular ligament.

The most common reasons for therapeutic failure in horses with tendonitis of the SDFT are lack of ultrasonographic follow-up after tendon splitting to determine if additional

therapy is needed, poor owner compliance concerning walking the horse and stretching the injured tendon in the early stages of healing, not allowing for adequate rest before the horse is returned to work, and failure to perform ultrasonographic examination at the time of initial injury, resulting in an inability to evaluate maximal medical improvement before returning the horse to unsupervised work.

OSTEOARTHRITIS OF THE METACARPOPHALANGEAL (FETLOCK) JOINT

Osteoarthritis of the fetlock joint is the most common articular problem in polo ponies and the most common articular problem necessitating early retirement. Ex-racehorses with mild osteoarthritis, osteochondrosis, or chip fractures may be sold for use as polo ponies and have a high risk of developing lameness. The fetlock region of any polo pony with forelimb lameness should be examined carefully. Lameness apparently originating from the fetlock joint based on the clinical observations of pain on palpation and a positive response to distal limb flexion must be differentiated from suspensory branch desmitis and splint bone disease. Intra-articular analgesia is important for differentiation. A full set of radiographs should be obtained. One author (P.J.M.) recommends using large cassettes to assess the fetlock joint and distal aspect of the splint bones. Common radiographic findings include fragmentation of the dorsoproximal aspect of the proximal phalanx, radiolucent areas in the distal aspect of McIII (Fig. 120-5), proliferative new bone formation on the palmar aspect of the PSBs, and mineralization of the proximal and distal fetlock joint capsule attachments (Fig. 120-6).

Intra-articular injections are the mainstay of treatment. One author (P.W.) injects both long- and short-acting corticosteroids and hyaluronan. Another author (P.J.M.) prefers PSGAG (Adequan) therapy or short-acting corticosteroids and hyaluronan or a combination of atropine, short-acting corticosteroid, and hyaluronan. Intra-muscular injections of PSGAGs at weekly intervals for 1 month, or possibly the entire season, are recommended. Horses that do not respond well to intra-articular injections are candidates for arthroscopic evaluation, because many of these horses have considerable cartilage damage. Daily icing, poulticing, and NSAID administration can help reduce inflammation in horses with chronic osteoarthritis. In horses with chronic osteoarthritis, radiographic changes may be extensive, but many horses are serviceably sound (Fig. 120-7).

Chronic proliferative synovitis (villonodular synovitis) is common in polo ponies with chronic osteoarthritis of the fetlock joint and may be associated with capsular tearing (S.K.). The dorsal aspect of the fetlock joint develops an apple-shaped appearance, with only mild or moderate effusion. Chronic proliferative synovitis is most common in horses previously used as racehorses and becomes evident after several years of polo. Plain

Fig. 120-5 Dorsolateral-palmaromedial oblique radiographic view of a metacarpophalangeal joint of a polo pony with osteoarthritis. Soft tissue swelling is apparent, a rounded osteochondral fragment is on the proximal dorsomedial aspect of the proximal phalanx, and proliferative changes involve the proximal aspect of the proximal phalanx and proximal sesamoid bones.

Fig. 120-6 Lateromedial radiographic view. Mineralization at the insertion of the common digital extensor tendon and metacarpophalangeal joint capsule on the proximal aspect of the proximal phalanx is a common radiographic finding in polo ponies with osteoarthritis of the fetlock joint. Although the finding is important, it does not preclude successful playing.

radiographs may reveal an abnormal contour of the distal dorsal aspect of McIII, and positive contrast radiographs may be diagnostic. We prefer ultrasonographic examination, because ultrasonography helps differentiate between horses that are surgical and non-surgical candidates. Chronic proliferative synovitis masses of 1 cm or larger should be removed arthroscopically to maximize long-term prognosis, whereas horses with smaller masses respond well to rest and intra-articular corticosteroid injections. Intra-articular atropine sulfate also has been used successfully (S.K.) to reduce effusion.

SUSPENSORY LIGAMENT

Suspensory desmitis is seen at three levels: proximal suspensory desmitis, suspensory body desmitis, and suspensory branch desmitis.

Proximal Suspensory Desmitis

Proximal suspensory desmitis occurs frequently and diagnosis is confirmed using high palmar or lateral palmar analgesia. Proximal suspensory desmitis results from polo ponies exercising on soft, uneven footing and is not related directly to playing polo. Lameness is usually only visible at a trot and varies in degree. The cranial phase of the stride is shortened, and lameness is usually most prominent with the affected limb on the outside of a circle. Palpation of the proximal palmar metacarpal region often reveals neither pain nor clinically appreciable enlargement of the SL. Polo ponies with proximal suspensory desmitis often fail to improve with rest and NSAID administration. Longitudinal ultrasonographic views are most useful in diagnosis of proximal suspensory desmitis. CSA measurements on transverse views are occasionally helpful if the same area is measured in the affected and contralateral limbs. One author (P.W.) has found that variation in CSA measurements leads to misdiagnosis, because even in normal polo ponies obtaining reliable repeat measurements is difficult. Hypoechogenic muscle tissue should not be confused as a lesion (S.K.).

Fig. 120-7 Lateromedial radiographic view of the distal forelimb of a serviceably sound polo pony. There is modeling of the proximal sesamoid bone and the dorsoproximal aspect of the proximal phalanx, and osteoarthritis and osteochondral fragmentation of the proximal and distal interphalangeal joints.

Proximal suspensory desmitis causes more subtle lameness and clinical signs in polo ponies than in other sport horses. Subtle injury and enlargement may cause the ligament to be pinched or compressed by overlying dense fascia, especially in hindlimbs. Horses with long-standing proximal suspensory desmitis often have sclerosis of McIII visible in lateromedial or dorsopalmar views. Absence of sclerosis does not rule out proximal suspensory desmitis, because horses with soft tissue injuries often lack bony involvement. Avulsion fractures of McIII associated at the origin of the SL, incomplete longitudinal fractures of McIII, and stress reaction can occur independently or concomitantly to proximal suspensory desmitis. Radiographic and ultrasonographic examination may reveal small or large fragments, or proliferative changes and radiolucency, associated with the palmar cortex of McIII. Computed radiography, xeroradiography, and nuclear scintigraphy are beneficial in diagnosing bony injury and differentiating it from proximal suspensory desmitis. Follow-up radiographs may be necessary, because avulsion or longitudinal fractures may not show up on initial radiographs.

Even without treatment, almost all horses with proximal suspensory desmitis and bony causes of proximal palmar metacarpal pain recover within a 3-month rest period. In polo ponies with proximal suspensory desmitis in which a quick return to work is mandated, local injection into and around the origin of the SL of a combination of short-acting corticosteroids and PSGAGs hastens resolution of clinical signs. Ponies are walked for 1 week and then put in light work the second week. By the third week they may be galloped and are able to play shortly thereafter. Owners tend to keep polo ponies with proximal suspensory desmitis in work if the end of the season is near, because ponies are turned out routinely for 3 to 6 months after the season. Owners may gamble successfully by continuing to play the horse through the end of the season without permanently damaging the ligament. Proximal suspensory desmitis in a hindlimb, although rare, has a much more guarded prognosis, and one author elects neurectomy (S.K.).

In the United Kingdom and Europe, injection of corticosteroids into the proximal SL is frowned on because this medication may slow healing and may mask the presence of fractures (S.K. and P.J.M.). This is especially true in horses with acute injuries. Shock wave therapy is popular and may prove beneficial once additional clinical studies are available. In horses with chronic proximal suspensory desmitis, once bony involvement has been ruled out, local injections of corticosteroid and Sarapin or internal blister may be warranted. Horses with known bony injury should be given rest. Recently fasciotomy and bone marrow injection has shown promise in polo ponies with chronic, recurrent desmitis.

Body Suspensory Desmitis

Body suspensory desmitis is a serious and often career-ending injury. Diagnosis is straight forward if the SL is thickened and painful. Ultrasonographic examination is crucial in assessing SL damage, but radiography is important to evaluate the medial and lateral splint bones, because splint bone disease often is associated with suspensory desmitis in the polo pony. Radiographs should be obtained even if obvious areas of pain or bony and soft tissue swelling associated with the splint bones are absent. Treatment of polo ponies with acute desmitis

includes immediate application of cold or ice therapy, alternating with topical sweats, and administration of NSAIDs. Periligamentous infiltration of short-acting corticosteroids early after injury improves cosmetic appearance and may minimize adhesion formation between the SL and splint bones. Injections are performed in polo ponies only if the owner agrees the horse is in need of long-term rest. The horse gradually is returned to hand walking in 5 to 7 days and can be turned out after 3 weeks. Sclerosing agents (e.g., ethanolamine) injected into the SL may be helpful (S.K.). Two authors (P.W. and P.J.M.) feel that long-term box stall rest may increase the chance of adhesion formation. One author (M.W.R.) prefers controlled exercise rather than turnout exercise. Ultrasonographic evaluation of ligament healing is important. One author (P.J.M.) has observed many polo ponies with distal body suspensory desmitis that involves the bifurcation and invariably at least one branch. If desmitis at the suspensory bifurcation is severe, the polo pony many never fully recover. The best results are seen with a combination of periligamentous injections of dimethylsulfoxide (DMSO) and corticosteroids and long-term rest. Performance level may need to be dropped to junior polo, and even at this level lameness may be persistent or recurrent.

Suspensory Branch Desmitis

Suspensory branch desmitis is common in polo ponies. The lateral branch is injured more frequently than the medial branch, and occasionally both branches are injured simultaneously. Pivoting of the distal limb at high speeds is likely the cause of suspensory branch desmitis. Faulty conformation is another important predisposing factor. Horses that are toed in tend to develop lateral suspensory branch desmitis, whereas those that are toed out tend to develop medial suspensory branch desmitis. Palpation of the branches while the fetlock joint is in partial flexion is a preferred technique of one author (P.W.). Firm palpation and lower limb flexion followed by trotting exacerbates the degree of lameness. Ultrasonographic examination of the branches is accomplished easily and allows assessment of the degree of suspensory branch desmitis. Radiography should be performed to evaluate the distal aspects of the splint bones, because fracture and fracture displacement are common in ponies with suspensory branch desmitis. Mineralization in a branch close to attachment on a PSB may occur in horses with chronic injury (Fig. 120-8). Horses with acute injuries are treated identically to those with suspensory body desmitis. The appearance of the branch can be restored cosmetically to near normal over time with periligamentous injection of short-acting corticosteroids. The branch can be split 2 to 3 weeks after injury, although results in the United Kingdom have been disappointing (S.K.). Horses with suspensory branch desmitis need about 6 months of layup time before returning to polo training. One author (P.J.M.) feels that adhesions between the inflamed branch and surrounding tissue or the ipsilateral splint bone negatively influence prognosis, and corticosteroid injections may limit adhesion formation. Surgical adhesiolysis and distal ostectomy of the fractured splint bone may be useful in horses with chronic suspensory branch desmitis and splint bone fracture, but the cosmetic appearance is usually less than desirable. Counterirritants still are used in Europe with variable results. We feel that pin firing (hot firing) is not successful for horses with suspensory body desmitis, but it can be useful for horses with suspensory branch desmitis as a last resort. Shock wave therapy may be useful, but clinical studies are currently lacking.

INJURY TO THE HOOF AND DISTAL PHALANX

Polo more than other types of equine sporting activity predisposes horses to direct hoof trauma. Direct trauma results from swinging mallets; horses stepping directly on the hard polo balls used during playing; interference or direct impact from hooves of nearby horses; and from horses stepping on wooden sideboards at great speed. Calk or stud injuries to the hoof wall and pastern region are most common. Careful evaluation of wounds for involvement of deeper structures such as the proximal interphalangeal and distal interphalangeal joints is necessary. A common lameness that occurs during polo competition is called *getting stung*, referring to a sudden crippling lameness, lasting only a few minutes, generally resulting from a blow to the hoof or pastern by a mallet or hoof of another horse. The horse is usually sound within minutes of the incident with no clinical evidence of injury. Occasionally a fracture occurs that may not be evident radiographically for up to 14 days.

Fig. 120-8 Dorsolateral-palmaromedial oblique radiographic view of metacarpophalangeal joint, with mineralization in the lateral branch of the suspensory ligament at the attachment to the proximal sesamoid bone. Note also the soft tissue swelling.

Fractures of the Distal Phalanx

Acute fractures of the palmar processes of the distal phalanx often occur from mallet blows, and because polo is played right-handed, fractures usually are seen in the medial aspect of the left forelimb and lateral aspect of the right forelimb. Oblique fractures are sometimes difficult to see in conventional radiographic views and several proximodistal oblique views may be necessary. Rarely, fractures of the margin or of the extensor process of the distal phalanx are seen. Management of polo ponies with distal phalanx fractures is similar to that in other sport horses.

PALMAR HEEL PAIN INCLUDING NAVICULAR DISEASE

Palmar heel pain in polo ponies with Thoroughbred and Thoroughbred-cross ancestry appears to be decreasing, primarily because of the successful efforts of farriers and owners. The problem may be worse in American Thoroughbreds than in Thoroughbreds originating from the United Kingdom,

Australia, and New Zealand (P.J.M.). The long-toe and underrun heel complex and the tendency to shoe front feet with shoes with short branches that sit tight at the heel (to prevent front plates from being pulled off by hind feet) gradually have been corrected. Squared or rolled toe shoes, with or without elevated heels (world plates and natural balance plates), have reduced the number of polo ponies with broken pastern foot axes and have reduced DDFT tension due to prolonged breakover. Owners have allowed blacksmiths to reset polo plates more frequently during the playing season and to perform more frequent four-point trims during the off season than in previous years. Palmar heel pain is often difficult to differentiate from navicular disease. In both conditions the horse may show a painful response to hoof testers and lameness is abolished using palmar digital analgesia. Differentiation may be possible using distal interphalangeal analgesia, radiography, and scintigraphy. Many polo ponies with palmar heel pain have secondary pain at the origin of the SL, which is thought to be caused by alteration of gait.

A common source of palmar heel pain is laminar tearing at the heels. Sudden stops force the horse to use the heels of the front feet as brakes. Corns or heel bruising can cause poor performance and lameness. Corns are diagnosed easily using hoof tests and by carefully inspecting the seat of the corn for hemorrhage or discoloration. One author (P.J.M.) has seen many polo ponies toward the end of the polo season with bilateral, biaxial horn staining resembling chronic corns that apparently did not result in overt lameness. Management of polo ponies with palmar heel pain resulting from corns is similar to that used for undiagnosed palmar heel pain, including the application of wedge pads to relieve heel pain for a few games, or by using the four-point trimming method with natural balance or straight bar shoes and acrylic rubber frog and heel support. One author (S.K.) has found that four-point shoeing provides poor grip and traction and considers it unsuitable for polo ponies. These shoeing techniques appear to decrease stress on the heels and the DDFT and navicular region. Hoof growth stimulants and NSAID administration may help horses with palmar heel pain.

Osteitis of the Distal Phalanx (Pedal Osteitis)

Although definition and accurate diagnosis of osteitis of the distal phalanx remain obscure, many polo ponies with palmar heel pain have scintigraphic and radiographic evidence of disease in the margins of the distal phalanx. A lateromedial radiograph may show new bone projecting distally from the palmar aspect of the distal phalanx. This finding should be interpreted carefully on radiographs taken during purchase examinations.

Navicular Disease

Navicular disease in a polo pony is characterized by chronic forelimb lameness, which is abolished using palmar digital analgesia, intra-articular analgesia of the distal interphalangeal joint, or analgesia of the navicular bursa, often with little radiographic abnormality. Nuclear scintigraphy may be helpful to differentiate navicular disease from other causes of palmar heel pain. Most horses with early navicular disease respond positively to intra-articular administration of hyaluronan and corticosteroids in the distal interphalangeal joint. Horses with advanced navicular disease or those unresponsive to therapy may be dropped from medium- or high-goal polo. The administration of NSAIDs and isoxsuprine and the application of corrective shoeing techniques (see "Palmar Heel Pain") are valuable. Those ponies unresponsive to distal interphalangeal intra-articular injections may improve after injection of the navicular bursa, best performed under radiographic guidance. Palmar digital neurectomy is considered undesirable and rarely is performed today. Chemical neurolysis (long-term foot block) is of limited value. Cryoneurectomy can give limited relief but the palmar digital nerves regrow and lameness recurs. Concomitant or solitary injury of the DDFT does not appear to be as common in polo ponies as in other sport horses (P.J.M.). Shock wave therapy may offer a viable solution for these horses.

OSTEOARTHRITIS OF THE DISTAL INTERPHALANGEAL JOINT

Early (synovitis) and chronic osteoarthritis of the distal interphalangeal joint can cause lameness in the polo pony, but diagnosis can be challenging due to the lack of specificity of analgesic techniques in the foot. For example if more than 6 ml of local anesthetic solution is injected into the distal interphalangeal joint, and lameness is evaluated after 3 to 5 minutes (S.K.) or 10 minutes (P.W.), pain from other areas of the foot including the sole can be blocked inadvertently. This effect can be avoided by using smaller amounts of local anesthetic solution. Horses with synovitis have distal interphalangeal effusion and manifest a painful response to lower limb flexion. However, this test may be positive in horses with many sources of pain, including either the navicular bone or the fetlock joint. Management of horses with osteoarthritis of the distal interphalangeal joint usually includes intra-articular medication. Short- or long-acting corticosteroids are preferred to injection with hyaluronan. One author (P.J.M.) combines corticosteroids and DMSO, because DMSO may improve distribution of corticosteroids to all parts of the joint and the navicular bursa. The distal interphalangeal joint is the only joint in which one author (P.W.) uses PSGAGs, combined with a single intravenous dose of gentamicin sulfate (6.6 mg/kg). Another author (P.J.M.) favors using PSGAGs in horses unresponsive to injections with corticosteroids. Most of these horses have clinical and radiographic evidence of advanced osteoarthritis. In some polo ponies lameness does not improve directly after intra-articular analgesia but inexplicably resolves 24 to 36 hours later, when presumably the effects of the corticosteroid begin. After intra-articular injection, horses are given 3 weeks of limited exercise and a tapered dose of NSAIDs. Weekly intramuscular administration of PSGAG for a minimum of 30 days and the application of corrective shoes to ease breakover are recommended.

DESMITIS OF THE ACCESSORY LIGAMENT OF THE DEEP DIGITAL FLEXOR TENDON

Trainers and owners commonly confuse chronic desmitis or acute tears of the accessory ligament of the deep digital flexor tendon (ALDDFT) with bowed tendons. Desmitis of the ALDDFT occurs in polo ponies, especially older ponies (S.K.), but is less frequent than tendonitis of the SDFT. Mild desmitis is characterized by a meaty, non-tender swelling of the proximal palmar metacarpal region between the SL and DDFT. Horses with severe or complete tears can have prominent swelling at or near the junction of the ALDDFT with the DDFT, but neither lameness nor the response to palpation is commensurate with the degree of damage. Diagnosis must be confirmed and healing monitored using ultrasonographic examination. Initially, horses are managed with rest, cold therapy including ice, application of sweats, and administration of NSAIDs. Local infiltration of short-acting corticosteroids around (but not in) the ALDDFT can help cosmetic appearance. Stall rest for 2 weeks is recommended, and thereafter horses can be turned out for 3 to 4 months. Follow-up ultrasonographic examination reveals an enlarged, hyperechoic ALDDFT. Prognosis for future soundness and return to polo is usually excellent but swelling persists. Chance of recurrence is slim.

SPLINT BONE DISEASE

Traumatic exostoses (Fig. 120-9) caused by swinging mallets and fractures of the splint bones are common in polo ponies and are sometimes referred to as *bamboo fever.* Although trauma is usually the inciting cause of exostoses, injury of the SL may play a role (P.J.M.). Horses with splint exostoses resent direct palpation, but many do not manifest overt signs of lameness. If lameness is present but the exostosis is only mildly painful, a splint block (see page 1005) should be performed to confirm the diagnosis. Splint disease can make a veterinarian look foolish, because an acute injury may be confused with proximal suspensory desmitis, but subsequent development of a large golf ball-size swelling reveals the true diagnosis. Oblique radiographic views are most helpful for evaluating the splint bones.

Local infiltration of corticosteroids and Sarapin is used to treat polo ponies with acute splint exostoses. Other injections include a combination of corticosteroids, Sarapin, calcitonin, and medroxyprogesterone acetate. Calcitonin (400 IU) and medroxyprogesterone acetate (200 mg) are used commonly in Europe (P.J.M.). Rest, compression wraps or sweats, and the administration of NSAIDs are useful. Polo ponies with chronic exostoses seem to benefit from pin freezing (cryotherapy), and this is the treatment of choice, with a quick return to work in 7 days. Cryotherapy appears to stimulate remodeling of chronic proliferative splint exostoses, and often a cosmetically acceptable limb profile is seen within 6 months. Despite the resulting white spots, clients seem to accept this form of therapy because of a high success rate. Thermocautery (hot firing) has merit, and early results of shock wave therapy appear promising (P.J.M.).

Proximal splint bone fractures may require surgical fixation, and certainly horses need prolonged stall rest and a slow return to work. If fractures are non-articular and fragments are not displaced or are displaced minimally, prognosis is favorable.

Polo ponies with non-displaced diaphyseal splint bone fractures respond well to cryotherapy. Cryotherapy not only produces local analgesia, but also induces deep fibrous tissue formation that stabilizes fracture fragments. Probes are applied in firm contact with the skin covering the abnormal splint for 1 minute at each site at sites 1.5 cm apart. Ponies with non-displaced splint bone fractures are given rest for 4 to 6 weeks. Distal splint bone fractures can be diagnosed easily using longitudinal ultrasonographic evaluation or radiography. These fractures usually are associated with chronic suspensory branch desmitis, which is thought to cause bowing of the distal splint bone and subsequent displacement and proliferative changes (Fig. 120-10). Distal fracture fragments generally are removed surgically in the standing position, and concomitant splitting of the involved SL branch(s) often is performed, although results in United Kingdom have been disappointing (S.K.).

Fig. 120-9 Dorsolateral-plantaromedial oblique radiographic view of the metatarsal region. There is a comminuted fracture of the proximal aspect of the fourth metatarsal bone caused by mallet injury. This fracture usually does not require internal fixation, and prognosis for future soundness is good.

Fig. 120-10 Dorsolateral-palmaromedial oblique radiographic view of the metacarpal region. A chronic displaced fracture of the fourth metacarpal bone is associated with suspensory branch desmitis. The second metacarpal bone is bowed away from third metacarpal bone; chronic proliferation has resulted from instability; sesamoiditis is apparent, and the suspensory branch shows mineralization.

DISTAL HOCK JOINT PAIN

Polo ponies can play successfully with moderate to severe radiographic changes in the distal hock joints (Fig. 120-11). Most of the distal hock joint pain appears to be subclinical, meaning lameness is not the most noticeable clinical sign. Most polo ponies with distal hock joint pain are noticed by owners or riders to lack quick jump-out speed and the ability to stop abruptly and are noticed to be running through the bridle. These ponies generally improve if they are given ample warm-up time before playing. Distal hock joint pain appears to be one source of lameness with which a polo pony can live, but such pain is a major cause of poor performance and may induce compensatory lameness such as proximal suspensory desmitis in the forelimbs. Proximal limb flexion tests may elicit little response, and detecting pain or effusion using careful palpation is difficult in some horses. Because lameness is not necessarily proportional to radiographic changes, scintigraphic examination is helpful, especially in polo ponies with subtle hindlimb lameness. Diagnostic analgesia is an important tool if lameness is perceptible, and in horses with bilaterally symmetrical lameness, analgesia of one side may induce obvious contralateral lameness. Combining diagnostic and therapeutic injections is commonplace, because the practice saves time and money. The tarsometatarsal and centrodistal (distal intertarsal) joints are injected most commonly with methylprednisolone acetate, but in some ponies the tarsocrural joint also is injected. Intramuscular administration of PSGAGs and intravenous injection of hyaluronan throughout the playing season appear to be helpful in allowing horses to play up to potential. Horses are kept in work and placed on low doses of NSAIDs throughout the season, and training is limited.

Fig. 120-11 Dorsomedial-plantarolateral radiographic view of a left hock with radiographic evidence of advanced osteoarthritis. This polo pony was not lame.

Although rare, avulsion injury and dislocation of the SDFT from the tuber calcanei is seen nearly once each year in a busy polo pony practice, resulting in extreme panic by the pony, necessitating sedation. The SDFT usually dislocates laterally, but diagnosis may be difficult before swelling develops. In our experience, surgical techniques including primary repair, mesh augmentation, and laterally located screws combined with full-limb cast application are neither successful nor necessary. Most horses respond well to confinement in a small pen and subsequent turnout for 6 to 12 months. Turnout exercise is recommended as soon as possible, and manually forcing the SDFT completely laterally is helpful if luxation is incomplete (P.J.M. and S.K.). Despite the fact that the SDFT remains displaced, causing a slight mechanical lameness, horses tend to perform well at the canter and gallop, with a fair to good prognosis for medium- and low-goal polo. Some polo ponies with lateral dislocation of the SDFT in one limb develop the same condition in the opposite limb 1 or 2 years later (P.J.M.).

GLUTEAL MYOSITIS AND BACK PAIN

Gluteal myositis often accompanies subclinical low hindlimb lameness and is often a compensatory problem. One or both hindlimbs shows a shortened cranial phase of the stride. Deep palpation of the gluteal muscles elicits pain, although the muscles never feel as hard as they do in ponies with rhabdomyolysis. If possible, it is important to determine if gluteal myositis is a primary or secondary problem. Guteal myositis can be differentiated easily from rhabdomyolysis, because serum creatine kinase and aspartate aminotransferase levels are invariably normal. Polo ponies with gluteal myositis can be treated with local injections directly into the gluteal muscles and between the biceps femoris and semitendinosus muscles. The horse is allowed light work and is placed on NSAIDs. One author (P.W.) has had modest success using a 5-day series of rubeola virus immunomodulator. If gluteal myositis is secondary, the primary source of pain must be identified and managed successfully.

Back pain in polo ponies is often secondary to lameness or results from mismanagement, including use of ill-fitting saddles, overweight amateur riders, and mouth problems. Poor dentition from lack of, or inappropriate, tooth floating procedures causes sharp molars to come in contact with gag bits. Horses carry the head and neck high to avoid pain and tend to hollow the back. Back pain can become a permanent or chronic problem if horses are mismanaged continually. Back pain generally is characterized by a painful response to palpation along the lateral edges of the longissimus dorsi muscles. The horse exhibits a crouching gait when mounted and during initial walking under saddle.

Intramuscular injections of corticosteroids combined with Sarapin (2:1 ratio) are performed along the length of the longissimus dorsi muscle, from the caudal border of the trapezius muscle to the level of the tuber coxae, 15 cm lateral to the dorsal midline. Injection sites are placed every 15 cm, and 5 ml of the mixture is administered at each site. Because back pain may be compensatory to primary distal hock joint pain or other lameness, it is important to evaluate the hindlimb and pelvis carefully. Primary management of the distal hock joint pain in horses with lameness in this region and local treatment of acupuncture points in the back is commonplace.

Dorsal spinous process (dorsal spinous process) impingement can be a source of back pain, and one author (P.J.M.) feels this is a major cause of back pain in the polo pony.

Diagnosis should be confirmed by assessing the effect of local analgesia and/or performing scintigraphy (S.K.). Treatment involves injection of the spaces between the dorsal spinous processes with corticosteroids and Sarapin. Shock wave therapy may be beneficial (P.J.M. and P.W.). Horses with back pain are given NSAIDs and are kept fit during a 4- to 6-week period using ponying (being led from another horse) exercise. In Europe a common management regimen includes paddock exercise as much as possible, lunging exercise with the horse's head down and little warm-up before polo games. Internal blisters have been used with some success, but care must be taken when injecting these compounds, because deep muscle abscesses can develop. Faradism is useful for longissimus dorsi and gluteal muscle strain (S.K.).

OTHER CONDITIONS

Fractures of the Cranial Thoracic Dorsal Spinous Processes (Fracture of the Withers)

Fracture of the withers is fairly common. Polo ponies are often tied next to each other for long periods, and a frightened horse occasionally rears up and flips over (Fig. 120-12), resulting in fractures of the longest dorsal spinous processes at the withers. Often up to four dorsal spinous processes are fractured, with ventral displacement of the fragments resulting in a flattened appearance of the withers. Ponies are usually only mildly painful to palpation but are generally reluctant to lower the head when grazing. The affected horse may travel with a painful, stiff, extended head and neck carriage, and some horses grunt with every stride. The prognosis for return to polo is excellent after rest for 4 to 6 months, as long as secondary infection does not develop. Special consideration should be given to saddle fit; a croup strap may be necessary to keep the saddle from sliding forward.

Osteoarthritis of the Proximal Interphalangeal Joint and Other Pastern Region Injuries

Osteoarthritis of the proximal interphalangeal joint (high ringbone) occurs occasionally in polo ponies and is seen most frequently in green horses playing on rough terrain in the western United States and generally results from irregular footing. Pain originating from the proximal interphalangeal joint is difficult to diagnose in horses with acute disease without radiographic changes, but it can be identified scintigraphically. Osteoarthritis of the proximal interphalangeal joint is often difficult to manage, and although motion of this joint is limited, lameness can be inappropriately severe. Rest (60 to 90 days), NSAID therapy, and intra-articular long-acting corticosteroid therapy are recommended.

A common finding in oblique radiographic views of the pastern region is periosteal reaction on the medial aspect of left forelimb and the lateral aspect of the right forelimb proximal phalanges (Fig. 120-13). Because polo always is played right-handed, powerful neck shots always hit the right side of each forelimb. Lameness is usually insignificant and short-lived. These radiographic changes should not be confused with those resulting from enthesitis at the attachment sites of the distal sesamoidian ligaments. To differentiate osteoarthritis of the proximal interphalangeal joint from these proliferative changes, intra-articular analgesia or pinpoint perineural or local analgesic techniques should be performed.

Sesamoiditis

Inflammation (sesamoiditis) of the PSBs can be caused by direct mallet or hoof trauma and by stress-related injury at the

Fig. 120-12 Polo ponies commonly are tied to rigid bars and in close proximity to each other. Occasionally a polo pony flips over and fractures the thoracic dorsal spinous processes at the withers.

suspensory branch insertions. Traumatic sesamoiditis occurs in the medial PSB in the forelimbs from interference injury and in the lateral PSB in the forelimb and hindlimb from mallet trauma. Diagnosis of sesamoiditis is straightforward using radiography and scintigraphy, but ultrasonographic evaluation provides information about the suspensory attachment as well. One author (P.J.M.) feels that shock wave therapy is a promising treatment modality for sesamoiditis.

Fractures of the PSBs are rare, and response to surgery is similar to that of other sport horses. Ponies with fractures of the base of the PSBs rarely return to athletic soundness with or without surgery. Polo ponies with basilar fractures and desmitis of the oblique distal sesamoidean ligament often can be helped by using shock wave therapy (P.J.M.). An apical fracture of the PSB may be mistaken for mineralization of the suspensory branch. Polo ponies with apical fractures of the PSBs have a good prognosis, provided that SL injury is not concurrent. Horses with apical fractures associated with sesamoiditis and insertional suspensory branch desmitis often have recurrent lameness. It is important to differentiate true fractures from sesamoiditis or a commonly seen radiographic abnormality in older polo ponies, one to three stress lines in the PSBs, which most often are considered incidental changes.

Fig. 120-13 Dorsomedial palmarolateral oblique radiographic view. Proliferative changes (*arrows*) along the medial aspect of the left forelimb proximal phalanx are typical of those seen from mallet injuries. Polo is played right-handed, and trauma usually involves the medial aspect of left forelimb and lateral aspect of right forelimb proximal phalanges.

Digital Flexor Tenosynovitis and Desmitis of the Palmar Annular Ligament

Tenosynovitis of the digital flexor tendon sheath (DFTS) is common in polo ponies. Debate exists as to whether this syndrome is caused by desmitis of the palmar annular ligament or whether the palmar annular ligament is a passive structure causing only constriction of the inflamed tendon sheath. The terms *tenosynovitis* and *desmitis of the palmar annular ligament* are sometimes used synonymously, but tenosynovitis with mild thickening of the palmar annular ligament is more common than primary desmitis. A normal or slightly thickened palmar annular ligament can restrict SDFT movement in horses with tendonitis, but this is a separate entity (see page 1006). In polo ponies desmitis of the palmar annular ligament can be solitary, diagnosed in horses with healthy flexor tendons. It can lead to tenosynovitis or can accompany tenosynovitis. Primary desmitis of the palmar annular ligament occurs most frequently from interference injury, when the hind feet strike the forelimb palmar annular ligament, or from direct mallet trauma. Initial trauma may be minor, but continued trauma can lead to substantial injury (Fig. 120-14). Whether primary or secondary, tenosynovitis with thickening and compartmentalization of the DFTS can occur proximal and distal to the palmar annular ligament. Diagnosis can be made by combining the results of clinical examination and intrathecal analgesia. Ultrasonographic evaluation is crucial and should include dynamic studies in which the flexor tendons and DFTS are evaluated for possible adhesions between tendons, DFTS, and the palmar annular ligament. Concomitant conditions such as osteoarthritis of the fetlock joint, sesamoiditis, and demineralization of the PSBs at the medial and lateral attachments of the palmar annular ligament should be assessed radiographically. Initial management is to apply cold therapy and sweats and to

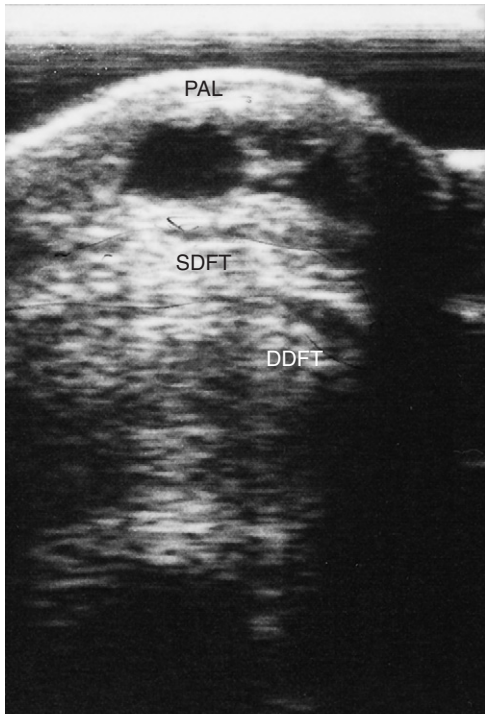

Fig. 120-14 Transverse ultrasonographic view of the distal palmar metacarpal region. An acute injury caused by direct trauma resulted in a chronically thickened palmar annular ligament. *PAL*, Palmar annular ligament; *SDFT*, superficial digital flexor tendon; *DDFT*, deep digital flexor tendon.

administer NSAIDs. Decompression of the DFTS and injection of hyaluronan and corticosteriods then is followed by 3 weeks of stall rest. Tenoscopy is valuable in identifying horses with tendon tears and to perform adhesiolysis. Desmotomy of the palmar annular ligament in horses with chronic desmitis or in those with chronic tenosynovitis may be helpful. Definitive therapy should be instituted early and aggressively to minimize adhesion formation.

Desmitis of the Distal Sesamoidean Ligaments

Desmitis of the distal sesamoidean ligaments (bowed pastern) is seen occasionally in polo ponies and usually involves the straight distal sesamoidean ligament. Diagnosis is made by detecting pain and swelling, by performing perineural analgesia (abaxial sesamoid block), and by using ultrasonographic examination.

Polo ponies with recurrent injury may not resent palpation, and ultrasonographic examination is necessary to differentiate this from other injuries. Proliferative changes along the base of the PSBs and abaxial surface of the proximal phalanx are often seen. These injuries may be career ending and at best are performance limiting. Long-term rest is necessary. Some owners request pinfiring.

Carpal Region Lameness

The carpus is an uncommon source of lameness in the polo pony. Pre-existing chronic radiographic changes are often incidental findings, even in horses with reduced range of carpal flexion and mild effusion. Carpal chip fractures can occur, but they are unusual. Tearing of the medial palmar intercarpal ligaments can cause lameness. Transient traumatic carpitis occasionally is seen after direct trauma from a mallet or ball. Rupture of the carpal sheath is a rare cause of lameness in the polo pony.

One author (P.J.M.) has seen two horses with massive swelling in the distal antebrachium, and ultrasonographic evaluation revealed rupture of the carpal sheath. Prognosis is not known. Fractures of the proximal aspect of the splint bones can lead to osteoarthritis of the carpometacarpal joint. Fracture of the medial splint bone is most serious, but polo ponies usually respond well to conservative management. Horizontal fracture of the accessory carpal bone may occur after collapse or a fall. Ponies are occasionally hit on the forehead by a hard struck polo ball, rendering them unconscious and causing the hind hoof to hit the back of the carpal region. Fracture can also occur if a horse trips inadvertently on a loose polo wrap. Prognosis appears to be indirectly proportional to fracture displacement.

Vertical (longitudinal) fracture of the accessory carpal bone occurs rarely in polo ponies that fall onto a flexed distal limb. Treatment is conservative. Physiotherapy, forcing full carpal flexion, is helpful to restore normal mobility (S.K.). Tenosynovitis of the carpal sheath can occur primarily or after fracture of the accessory carpal bone and in ponies with tendonitis of the SDFT and DDFT, and in horses with desmitis of the accessory ligament of the SDFT (ALSDFT), but this condition is rare.

Desmitis of the Accessory Ligament of the Superficial Digital Flexor Tendon

In the United Kingdom, between 10 and 15 polo ponies each year are diagnosed with desmitis of the accessory ligament of the SDFT, which may occur because of the fast and aggressive play of modern polo (P.J.M.). Awareness of the condition and use of ultrasonography may have resulted in increased recognition.

One high-goal player had five horses with this problem in a single year. Diagnosis is made by eliminating the distal limb and by palpating pain and swelling in the distal antebrachium and in the carpal sheath. Conservative management is usually successful, including the periligamentous injection of hyaluronan and corticosteroids. Surgical resection of the accessory ligament of the SDFT may be indicated, particularly in polo ponies with considerable fibrosis and bony proliferation on the caudal distal radius, or those that stand over at the knee.

Upper Forelimb Lameness

Lameness associated with the antebrachium, elbow, and shoulder regions is uncommon in polo ponies. Occasionally, fractures of the radius or olecranon and wounds with bony sequestration occur from kick trauma. Repair of fractures of the olecranon has been successful. Shoulder region soft tissue trauma, fracture of the supraglenoid tubercle of the scapula, or suprascapular nerve injury occurs occasionally from falls, dangerous play, or wrecks.

Other Hindlimb Lameness

The distal hindlimb is subject to the same type of bony injuries as seen in the forelimb, with the exception of navicular disease. Fractures of the distal and proximal phalanges and PSBs occur with the same frequency as in the forelimb, but prognosis is better in the hindlimb. In the hindlimb, osteoarthritis of the fetlock joint, flexor tendonitis, suspensory desmitis, and desmitis of the ALDDFT are not nearly as common as in the forelimb.

Two soft tissue problems occur specifically in the hindlimbs. A form of severe suspensory desmitis occurs in older polo ponies with exceedingly straight hock conformation. The hind fetlock joint drops and the pastern region is parallel to the ground. Lameness, however, is often minimal, and despite the abnormal angle of the fetlock joint these horses can continue to play for years with the help of support wraps. The second specific soft tissue injury of the hindlimb is spontaneous rupture of the common digital extensor tendon above the fetlock joint. This injury results in lameness and hyperflexion of the fetlock joint at the trot. These horses respond well to conservative management, with support wraps and rest, and prognosis is excellent.

Lameness from stifle injuries is uncommon. Osteochondrosis occasionally causes effusion and lameness or poor performance if present bilaterally. Collateral ligament injury may occur from severe bumps. Kick wounds to the tibial crest can cause pronounced lameness and may result in a fracture. Polo ponies with a history of poor stopping or turning ability respond favorably to injection of counterirritants (blisters) around the patellar ligaments and the insertion of the vastus lateralis and rectus femoris muscles. Horses are kept in a working schedule following these injections and typically may be played successfully several days later.

Pelvic injury in polo ponies is infrequent but may result from dangerous play, such as a high-angle ride off behind the saddle (S.K.), and is best diagnosed using scintigraphy. Stress fractures of the ilium and traumatic fracture of the acetabulum occur but are rare. Disparity in height of the tubera sacrale often is seen, but with no effect on performance.

Rhabdomyolysis

Rhabdomyolysis, or tying up, is fairly common, especially in mares. Two types of horses are predisposed to this syndrome. Unfit horses placed into work too rapidly often develop a stiff gait at the trot and tenderness to palpation over the dorsal musculature. Muscle enzyme levels are only moderately elevated and horses respond well to rest and NSAIDs. The most common form of rhabdomyolysis is seen in fit polo mares after an extended layup period for illness, unrelated lameness, or foul weather that prevents horses from being played regularly. Rhabdomyolysis can also occur on cold, clear mornings

or blustery days during which a drop in barometric pressure occurs. Horses generally become affected after exercise, when they return to the barn or trailer; are reluctant to move; and have firm, tight gluteal regions. Epaxial muscles rarely are involved. Clinical signs may be confused with colic because horses with rhabdomyolysis often paw, stretch out, and sweat profusely. Muscle enzyme levels are elevated greatly. Management is similar to that described for other sport horses (see Chapter 84). Nutritional management appears to be important in Europe where bran, which is high in phosphorus (reduces calcium), is fed to reduce recurrence.

Gracilis Muscle Tear

Gracilis muscle tears are seen in several polo ponies each year and are characterized by lameness at the trot and dramatic swelling in the medial thigh region. Abduction of the flexed hindlimb elicits a painful response and a large hematoma generally develops soon after the injury. The administration of NSAIDs, administration of DMSO intravenously, and the topical application of cold water are beneficial. If necessary seroma fluid can be drained surgically 5 to 7 days after injury, and exercise is limited for a minimum of 2 weeks.

Equine Protozoal Myelitis

Mild neurological signs typical of equine protozoal myelitis or lameness associated with the disease can be confused with other causes of musculoskeletal pain, in particular hindlimb lameness. Equine protozoal myelitis is prevalent in the United States but is rare in England (P.J.M.). Occasionally a polo pony in the United Kingdom that was imported from the United States develops clinical signs consistent with equine protozoal myelitis under the stress of the latter half of the season.

The Western Performance Horse

THE CUTTING HORSE

• Jerry B. Black

DESCRIPTION AND HISTORY OF THE SPORT

The cutting horse was born of necessity long ago on the open grass plains of West Texas. This was the era of Western history that included big cattle drives from the open ranges of ranches such as Burnett and the 6666 Ranch, Waggoner Ranch, the Pitchfork Ranch, and the Matador Ranch to Dodge City, Kansas. Cutting horses enabled big country ranches, where no barbed wire fences existed, the only means of working vast herds of cattle. In those days the task of the horse was simple, at least by definition. Guided by the rider, the cutting horse entered a herd of cattle quietly and deliberately. A single cow was cut, or separated, from the herd. The natural instinct of the cow is to return to the safety of the rest of the herd. The cutting horse, through breeding and training, controlled the calf with a series of moves and countermoves. The speed, agility, balance, and quickness of the cutting horse kept the cow from the herd, where other cowboys would hold the cut. The horse and rider would re-enter the herd again and again, cutting cattle out until the work was done. Only the top hands earned the right to ride the best horses of the remuda, the cutting horses.

The unique skills of the cutting horse were a great source of pride to the frontier cowboy. This often led to impromptu or jackpot cuttings on the open range or, from about 1900, in outdoor pens of the large ranches. From this love of the cutting horse and the subsequent competition to determine who had the best horse came the roots of cutting as we know it today. The first cutting horse contest for money was held at the 1898 Cowboy Reunion in Haskell, Texas. Twelve cutting horses competed for a purse of $150. From this start, regular events occurred on ranches of the Southwest and at the Fort Worth Stockyards. Rules and prizes varied greatly, but the ability of the cutting horse to separate a single calf from the herd always was and continues to be the goal of the competition. From these roots the National Cutting Horse Association was formed in 1946 during the Fort Worth Exposition and Fat Stock Show. The stated purpose of the organization was to standardize the rules and judging of competition and to preserve the tradition and history of the cutting horse with the ranching and livestock industry.

Today, competitions approved by the National Cutting Horse Association occur throughout the United States and Canada. In addition, many association members from other countries such as Australia are conducting competitions outside North America. The format of these competitions and other Western performance horse disciplines, such as reining, present a unique challenge to the equine veterinarian.

TRAINING

Training of the cutting horse begins at 2 years of age. Usually 60 to 90 days are spent in basic training before the horse is introduced to cattle. This generally is accomplished by turning one cow into a round pen that is 38 to 54 m in diameter. The horse is taught to mirror the movements of the cow as the cow moves around the perimeter of the arena. This process of training a cutting horse is repetitive and is done several days a week for months. The object of training is for the horse to develop an ability to perform identical movements with the cow. Simply put, when the cow stops or stops and turns, the horse does the same maneuver. This type of training is accomplished by asking the horse to stop with the aid of the bridle and turning the horse to move with the cow. The key to training is a complete and balanced stop. With time, the stop ultimately is followed by the instinctive ability of the horse to read the movement of the cow and to turn in the direction the cow is going. Because this ability to watch the cow and respond to its movement is instinctive to the working stock horse, breeding is of the utmost importance. Without this

or blustery days during which a drop in barometric pressure occurs. Horses generally become affected after exercise, when they return to the barn or trailer; are reluctant to move; and have firm, tight gluteal regions. Epaxial muscles rarely are involved. Clinical signs may be confused with colic because horses with rhabdomyolysis often paw, stretch out, and sweat profusely. Muscle enzyme levels are elevated greatly. Management is similar to that described for other sport horses (see Chapter 84). Nutritional management appears to be important in Europe where bran, which is high in phosphorus (reduces calcium), is fed to reduce recurrence.

THE CUTTING HORSE

• Jerry B. Black

DESCRIPTION AND HISTORY OF THE SPORT

The cutting horse was born of necessity long ago on the open grass plains of West Texas. This was the era of Western history that included big cattle drives from the open ranges of ranches such as Burnett and the 6666 Ranch, Waggoner Ranch, the Pitchfork Ranch, and the Matador Ranch to Dodge City, Kansas. Cutting horses enabled big country ranches, where no barbed wire fences existed, the only means of working vast herds of cattle. In those days the task of the horse was simple, at least by definition. Guided by the rider, the cutting horse entered a herd of cattle quietly and deliberately. A single cow was cut, or separated, from the herd. The natural instinct of the cow is to return to the safety of the rest of the herd. The cutting horse, through breeding and training, controlled the calf with a series of moves and countermoves. The speed, agility, balance, and quickness of the cutting horse kept the cow from the herd, where other cowboys would hold the cut. The horse and rider would re-enter the herd again and again, cutting cattle out until the work was done. Only the top hands earned the right to ride the best horses of the remuda, the cutting horses.

The unique skills of the cutting horse were a great source of pride to the frontier cowboy. This often led to impromptu or jackpot cuttings on the open range or, from about 1900, in outdoor pens of the large ranches. From this love of the cutting horse and the subsequent competition to determine who had the best horse came the roots of cutting as we know it today. The first cutting horse contest for money was held at the 1898 Cowboy Reunion in Haskell, Texas. Twelve cutting horses competed for a purse of $150. From this start, regular events occurred on ranches of the Southwest and at the Fort Worth Stockyards. Rules and prizes varied greatly, but the ability of the cutting horse to separate a single calf from the herd always was and continues to be the goal of the competition. From these roots the National Cutting Horse Association was formed in 1946 during the Fort Worth Exposition and Fat Stock Show. The stated purpose of the organization was to standardize the rules and judging of competition and to preserve the tradition and history of the cutting horse with the ranching and livestock industry.

Today, competitions approved by the National Cutting Horse Association occur throughout the United States and Canada. In addition, many association members from other countries such as Australia are conducting competitions outside North America. The format of these competitions and other Western performance horse disciplines, such as reining, present a unique challenge to the equine veterinarian.

TRAINING

Training of the cutting horse begins at 2 years of age. Usually 60 to 90 days are spent in basic training before the horse is introduced to cattle. This generally is accomplished by turning one cow into a round pen that is 38 to 54 m in diameter. The horse is taught to mirror the movements of the cow as the cow moves around the perimeter of the arena. This process of training a cutting horse is repetitive and is done several days a week for months. The object of training is for the horse to develop an ability to perform identical movements with the cow. Simply put, when the cow stops or stops and turns, the horse does the same maneuver. This type of training is accomplished by asking the horse to stop with the aid of the bridle and turning the horse to move with the cow. The key to training is a complete and balanced stop. With time, the stop ultimately is followed by the instinctive ability of the horse to read the movement of the cow and to turn in the direction the cow is going. Because this ability to watch the cow and respond to its movement is instinctive to the working stock horse, breeding is of the utmost importance. Without this

genetic instinct the horse simply does not respond to the movement of the cow and does not initiate the stop or turn necessary to continue to track the animal. A good cutting horse trainer knows in a relatively short period if a young horse has the instinct and athletic ability to be a successful cutting horse. The finished cutting horse must perform the necessary moves to keep the cow in proper position away from the herd, without any hand cues from the rider, relying on instinct to read the movement of the cow alone. Reining the horse is permitted only to make the cut of a single cow out of the herd. After the cut is successfully made, the reins are placed in a relaxed position on the horse's neck, and only leg cues are permitted from the rider during the actual working time. The ability of the working cow horses to contain the individual cow provides the excitement of competition in cutting.

Training of a cutting horse prospect that has shown good potential continues when it is a 3-year-old, preparing it for the first major competitions, the futurities. The futurity is the first of the horse's aged event competitions that continue for 4 years. No horse can compete in aged events beyond 6 years of age. Aged events consist of two elimination go-rounds, followed by semi-finals and the final competition. Substantial musculoskeletal stress is placed on these athletic performance horses, with multi-day competitions over a short period. In addition, the horses usually are practiced on cattle daily, including the day of competition, to sharpen performance skills. Competition in these aged events is heavy, with the major shows having more than 500 entries in a single age division. Purses in this type of event can exceed a total of $1 million. The nature of this aged event competition, with large purses in numerous events over a 4-year period, has caused the cutting horse economy to grow rapidly over the last several years. Select yearling and training sales are conducted annually that are beginning to parallel the racing industry in financial return on sales. This has contributed to the current popularity and resurgence of breeding of the cutting and Western stock horse, which in turn will ensure the preservation of the tradition and heritage that this horse played in the history of the great Old West.

LAMENESS EXAMINATION

The increasing popularity of the cutting and reining horse for show and performance is occurring nationally and internationally. Sales of this type of horse have increased to Europe, South America, and other countries. In North America the revival of interest stems primarily from excellent programs instituted by associations such as the National Cutting Horse Association and the National Reining Horse Association. These associations encourage owner participation at the amateur level in cutting and reining events. This type of performance horse creates a new diagnostic and treatment challenge for attending veterinarians, partially because of the rigid training schedules necessary for the 3- to 6-year-old horse to compete in futurities and aged events.

Hindlimb lameness presents one of the more interesting diagnostic challenges to the equine clinician. The lameness is often difficult to diagnose and even more difficult to manage. A systematic approach must be developed to achieve an accurate diagnosis consistently. The veterinarian must use a routine that is repeated with each horse and must allow sufficient time to complete a thorough examination. Western stock horses may be difficult to evaluate while being led. These horses usually are not taught to lunge and are often difficult to trot in hand. A 10- to 15-m round pen with firm footing has proved to be beneficial for evaluating lameness of this and other types of horses.

DIAGNOSIS AND MANAGEMENT OF SPECIFIC LAMENESS

Hindlimb lameness is more common than forelimb lameness in cutting horses. Mixed lameness with swinging and supporting components is common in the hindlimb, especially in upper limb lamenesses such as those involving the hock, stifle, and hip or sacroiliac region. Hindlimb lameness may be associated with two sources of pain; for example, chronic hock lameness and secondary lumbar and gluteal myositis. This section focuses on selected hindlimb lamenesses of the hock, stifle, and thoracolumbar regions.

Selected Lameness of the Tarsus

Osteoarthritis of the Distal Tarsus (Distal Hock Joint Pain)

Osteoarthritis of the distal tarsal joints is seen most commonly in horses that have repeated, excessive compression and rotation of the hocks at high speed, and a high incidence occurs in the young working cow horse, and in cutting and reining futurity prospects, reflecting the demanding training schedules of 5 to 6 days a week at 2 and 3 years of age. Sickle hocks, cow hocks, and narrow hocks also may predispose horses to lameness. Osteoarthritis also may develop secondary to partial collapse of the central and third tarsal bones, and affected horses often develop lameness within the first year after birth. In our practice, routine survey radiography of the tarsus in 20, 2-year-old cutting horse prospects before training began revealed evidence of osteoarthritis in 11 (55%).

Clinical signs include reduced height of the foot flight arc, resulting in abnormal toe wear, and a shortened cranial phase of stride. Hard work increases the degree of lameness, although most horses are lame and stiff when first taken out of the box stall and improve to some degree during the initial warm-up. Trotting in a circle increases the degree of lameness. Gait alteration or lameness may be observed with the affected limb on the inside or outside of the circle. Cutting, reining, and stock horses are reluctant to stop properly. Flexion of the hock often increases the degree of lameness. Palpation of the distal medial aspect of the hock may reveal exostosis and soft tissue thickening. Deep palpation of the area can cause a painful withdrawal response. Thoracolumbar pain is present in about 50% of horses.

Diagnosis is based on a positive response to intra-articular analgesia and radiography. Radiographic abnormalities are often only seen in a dorsolateral-plantaromedial view in 2- to 4-year-old cutting horses, findings that differ from those seen in other young sport horses.

Therapy varies depending on the degree of lameness. Rest is generally not helpful in horses with advanced osteoarthritis, and obtaining trainer compliance if the lameness is subtle is difficult. Training usually is continued with the help of non-steroidal anti-inflammatory drugs (NSAIDs), such as phenylbutazone (2 g sid or 1.5 g bid) and intra-articularly administered anti-inflammatory drugs. Shoeing changes include removing excessive toe, squaring the toe of the shoe and extending both branches of the shoe for more heel support. Half-round shoes help aid breakover in some horses with cow-hocked or sickle-hocked conformation. Changes in training schedules include more paddock or free-choice exercise and longer warm-up periods before training. Training in deep surfaces, overtraining, or conditioning in circles should be avoided. Varying the gait frequently during training and conditioning helps the horse to stay more comfortable.

Intra-articular medication is used to keep chronically lame horses in competition. A combination of methylprednisolone acetate (Depo-Medrol; 50 mg) and hyaluronan (10 to 20 mg) is injected separately into the centrodistal (distal intertarsal) and tarsometatarsal joints in horses with advanced osteoarthritis.

The veterinarian should not rely on communication between the two joints. If good results are achieved, these injections are repeated as necessary every 8 to 12 weeks. Horses with early osteoarthritis respond favorably to intra-articular treatment with hyaluronan (Hylartin-V; 20 mg) and triamcinolone (Vetalog; 3 to 6 mg). Intravenous injections of hyaluronan (Legend; 40 mg in 7-day intervals, series of three) or intramuscular injections of polysulfated glycosaminoglycan (Adequan IM; 500 mg in 5-day intervals, series of four to eight) are used frequently as concurrent therapy. Combinations of intermediate-acting corticosteroids and hyaluronan administered intra-articularly have been used in horses that are lame immediately before leaving for circuit shows or important multi-day competitions such as cutting horse, snaffle bit, and reining horse futurities.

Therapeutic levels of NSAIDs may be necessary during competition if allowed by the breed, performance, or state drug regulations governing the event. Phenylbutazone (2 g sid or 1.5 g bid) is usually effective. However, many stock horse trainers feel that this drug tends to dull the mouth and sides of the horse, thus limiting bit and spur response. Other NSAIDs that are effective include flunixin meglumine (Banamine; 1 mg/kg sid) or ketoprofen (Ketofen; 2 mg/kg sid). Horses vary in response to the therapeutic effects of each NSAID. If one drug is not effective, a different one should be assessed.

Surgery has been an important adjunct to osteoarthritis therapy in horses requiring repeated intra-articular injections or continual therapy with NSAIDs. Horses with mild to moderate radiographic changes but normal joint spaces respond favorably to cunean tenectomy. Horses with substantial intra-articular changes and joint space collapse are treated best surgically with a combination of cunean tenectomy and fenestration of the affected joint or joints using a 3.2-mm drill bit and creating three to four tracts. The horse is returned to work as soon as possible after surgery to encourage ankylosis. Hand walking is begun the day after surgery, and light riding at a walk may begin 2 to 3 weeks later. Light riding exercise continues for another 3 weeks, and full training begins 45 to 60 days post-operatively if the horse is reasonably comfortable. Phenylbutazone, 2 g once daily as needed, is used initially if obvious lameness persists. Most horses show almost immediate improvement after surgery. This improvement may be caused partially by the release of intraosseous pressure after the fenestration procedure, plus cessation of the rotational effect of the cunean tendon on the distal tarsus. Radiographic evidence of ankylosis occurs over a prolonged period. Soundness does not seem to be related to radiographic evidence of ankylosis.

Prognosis varies depending on the degree of osteoarthritis, the number of joints involved, and the type of competition in which the horse is engaged. Surgery offers the best prognosis for horses with chronic lameness.

Arthrosis of the Tarsocrural Joint

Distention of the tarsocrural joint capsule is usually from osteochondrosis or trauma. Osteochondrosis lesions occur on the intermediate ridge of the distal tibia, the trochlear ridges of the talus, and the lateral or medial malleolus of the distal tibia. Trauma is related to quick turns, hard stops, loss of balance, and poor footing. Faulty conformation, such as overly straight angulation of hock and stifle joints, may be a predisposing factor.

Distention of the tarsocrural joint capsule is observed most easily on the dorsomedial aspect of the hock, but swelling also occurs in the plantar pouches, laterally or medially. The horse may have pain on palpation, and lameness may follow trauma. The hock flexion test may or may not be positive, depending on the degree of joint capsule distention and synovitis. Radiographic examination is essential to determine the cause and should be repeated in 10 to 14 days if initial radiographs are normal.

Osteochondrosis is treated surgically. Traumatic distention of the tarsocrural joint is treated by intra-articular injection of intermediate-acting corticosteroids and hyaluronan, 2 or 3 times, 14 to 21 days apart. Intra-articular injections often are followed by hyaluronan (40 mg) administered intravenously weekly for 3 weeks. All injected hocks are bandaged concurrently to help reduce joint effusion. Pressage elastic contour bandages (Jupiter Veterinary Products, Harrisburg, PA) provide adequate pressure and are easy to maintain. The horse is given rest for 3 to 6 weeks.

Exploratory or diagnostic arthroscopy is justified in any horse that does not respond to conservative therapy, permitting identification of subtle osteochondrosis lesions not detectable radiographically and soft tissue injuries, and providing joint lavage.

The prognosis is good if treatment is initiated early, and in horses with osteochondrosis lesions or severe trauma, all fragments and debris are removed soon after the synovitis is recognized. If conformation is the predisposing cause, the prognosis is poor.

Selected Lameness of the Stifle

The stifle is a large, complex joint composed of two articulations: the femorotibial and femoropatellar joints. My experience has been that during arthroscopy of the femorotibial joint, despite high intra-articular fluid pressure, obvious distention of the femoropatellar joint capsule does not occur. Thus little or no distention of the femoropatellar joint capsule occurs in association with disease of the femorotibial joint. When performing intra-articular analgesia of the stifle, all three compartments should be injected separately.

Osteochondrosis

Osteochondrosis of the trochlear ridges of the femur is seen commonly in young horses. Clinical signs include distention of the femoropatellar joint capsule and varying degrees of lameness, depending on the amount of joint surface involved. Diagnosis is confirmed radiographically. Arthroscopic surgery is the treatment of choice to debride all diseased cartilage and bone and to remove all free-floating bone and cartilage. Aftercare consists of 45 to 60 days of stall rest, followed by an equal amount of stall and paddock confinement. Training generally resumes 3 to 6 months post-operatively. Intra-articularly administered hyaluronan (20 mg) followed by intramuscularly administered polysulfated glycosaminoglycans (PSGAGs; 500 mg in 5-day intervals, series of four to eight) 2 to 3 weeks after surgery has helped to reduce post-operative synovitis.

Subchondral Bone Cysts

Subchondral bone cysts of the medial condyle of the femur are the most frequently recognized bony lesions of the stifle in my practice. All horses with clinically relevant signs are lame at the walk or trot in one or both limbs. The degree of lameness varies greatly among horses. Some horses are subtly lame, requiring riding or repeated flexion to produce a recognizable lameness. Others have acute, severe lameness and are unwilling to trot. Moderately lame horses tend to swing the toe medially during protraction. This phenomenon is unlike the horse that carries the stifle out or abducts the limb with femoropatellar joint or patellar ligament lamenesses. Lameness may be more obvious with the affected leg on the inside of a circle.

Subtle distention of the femorotibial joint capsule may be palpated between the medial patellar and medial collateral ligaments. Some horses resent deep digital pressure over the medial femoral condylar region.

Diagnosis of subchondral bone cysts is based on clinical signs, response to intra-articular analgesia using 30 ml of mepivacaine and radiography. Conservative treatment for the most part yields only temporary improvement in the lameness and is used in our practice only when a performance horse needs to compete for the remainder of the season or when

finances prohibit surgical intervention. Conservative treatment consists of intra-articular injections of hyaluronan, with or without corticosteroids such as betamethasone or triamcinolone. An intramuscularly administered PSGAG given in a series of four to eight injections at 5-day intervals also is used. Many trainers report a pronounced effect about 24 hours after administration of PSGAGs. Therapeutic levels of systemic NSAIDs may be also necessary during multi-day competitions. Owners should be informed that continued training and competition over an extended period might lead to secondary osteoarthritis.

The treatment of choice in my experience is curettage and fenestration of the subchondral bone cyst. Before 1988, this procedure was done through an arthrotomy incision. Although the surgery was successful in most horses, wound dehiscence and prolonged hospitalization were of great concern. Currently the surgery is performed by arthroscopy, with the horse placed in dorsal recumbency and the limb in flexion. This position provides adequate visibility and good access to the cystic lesion via the instrument portal. Postoperative hospitalization is minimal, and to date no post-operative complications have been seen. The patient is confined for 60 days after surgery. Hand walking for 10 minutes daily is allowed during confinement. Free-choice exercise for an additional 2 to 4 months is allowed. Training usually resumes 6 months post-operatively or earlier, if the horse is sound.

The prognosis for horses with surgically debrided subchondral bone cysts has been good (60% to 70%) in my practice. Most of these horses return to a competitive level of performance, if given adequate rest.

Upward Fixation of the Patella

Partial or complete upward fixation of the patella is a common cause of stifle pain, which can eventually produce articular changes of the patella. In my experience this condition can occur in any type of body conformation and hindlimb angulation and may be related to the anatomical formation and depth of the notch on the proximal medial trochlear ridge. Lack of condition and loss of condition are contributory factors. Poor coordination between extensor and flexor groups of the stifle and lack of quadriceps development may explain why upward fixation is seen in young animals at the beginning of training. I have examined two horses in which upward fixation of the patella was secondary to a subchondral bone cyst in the medial femoral condyle. Upward fixation may have been caused by alteration of gait and foot placement because of pain in the medial femorotibial joint. Upward fixation resolved after arthroscopic treatment of the subchondral bone cyst. The duration of locking varies from an almost instantaneous release, with only slight backward jerk evident, to a complete locking that can last for hours and may require surgical release.

Diagnosis is based on clinical signs. Often, although no obvious upward fixation occurs in extension, the leg snaps with an audible click while in an extended position. Occasionally, pushing the patella over the top of the trochlear ridge when the leg is in extension can produce the locking. Clinical signs often are exacerbated if the horse can be walked down a steep slope. The diagnosis is sometimes based almost entirely on the owner's or trainer's description of the condition.

Treatment should remain conservative when at all possible. If complete upward fixation has occurred for any period, the femoropatellar joint usually shows effusion. Treatment should be aimed initially toward reducing inflammation and resting the tissues involved. Systemic corticosteroids (20 mg dexamethasone [Azium] IM sid) for 1 to 3 days, followed by 3 to 5 days of NSAIDs (2 g phenylbutazone bid) is a usual treatment schedule. Hand walking for 5 to 10 minutes is allowed if no further upward fixation occurs, but no free-choice exercise is allowed. Excessive toe is removed, and wedged shoes or wedge pad and flat shoes are used if the heel is low. Half-round shoes allow the horse to break over in its most comfortable and natural position.

Once the initial inflammation has subsided, a conditioning program is started. Long warm-up periods are essential. Thirty minutes of walking and trotting, followed by an increasing amount of extended trotting on the straightaway is recommended. Once the horse is becoming conditioned, trotting in the hills is prescribed, where possible. The concept of conditioning is to improve quadriceps development and tone and to improve overall coordination. Horses that are underweight should be fed to gain weight and to improve the overall body condition and the condition of the muscles involved in movement of the stifle.

Horses that do not respond to conservative treatment may require an internal blister or medial patellar desmotomy. Internal blister is accomplished by local infiltration of 2% iodine in peanut or almond oil injected directly into the body of the medial patellar ligament. Care must be taken to avoid the accidental penetration and injection of the femoropatellar joint with the counterirritant solution. Desmotomy should be reserved as a last form of therapy because the postoperative complications include fragmentation of the apex of the patella, soft tissue fibrosis, and mechanical alteration of gait.

Femorotibial Pain

Subtle soft tissue injuries may occur in the femorotibial joint, resulting in low-grade lameness that is most evident when the horse trots in circles. Such injuries often occur as training is increased. A typical example is a young cutting horse that is being worked hard on cattle before a futurity. The horse has a shortened cranial phase of stride and lowered foot flight, causing toe drag. Results of hindlimb flexion tests are generally negative. Mild distention of the medial femorotibial joint capsule may be palpable. Diagnosis is based on clinical signs, response to intra-articular analgesia of the femorotibial joint, and the absence of radiographic abnormalities.

Treatment comprises intra-articular medication with hyaluronan and corticosteroids such as triamcinolone (6 mg), plus intramuscularly administered PSGAGs. Systemic NSAIDs are given in decreasing doses over 10 to 14 days. All trailers and calks are removed from shoes. A wedge pad may be added with an egg bar shoe or extended branch shoe, depending on the amount of heel support needed.

Training is resumed after 14 to 21 days of rest. Long warm-up periods and extended straightaway trotting is recommended to condition the muscles of the upper hindlimb.

Prognosis is good if a consistent training schedule is maintained. Horses with irregular training schedules and frequent periods of several days off between exercise sessions tend to have recurrent problems.

Thoracolumbar Injuries

Thoracolumbar Myositis

Soft tissue injuries of the thoracolumbar region produce back soreness and are the most common injuries in a working stock horse. Thoracolumbar myositis may coexist with hindlimb lameness, such as distal hock osteoarthritis, or may be a primary traumatic lesion, frequently caused by the extraordinary forces of rotation and propulsion placed on the hindlimbs. Other factors include rigid training and competition schedules such as the fall futurities for 3-year-olds that result in an overworked young horse.

Local myositis involving the muscles of the thoracolumbar and pelvic region can have a profound effect on the performance of a stock horse. A cutting horse has three basic components to work: the stop, turn, and ability to track the cow in mirror image across the arena at high speed. Localized back pain results in decreased performance in all of these,

without obvious lameness. The trainer perceives the horse as simply not trying. Consequently the horse with back pain is forced to try even harder and soon falls into the overworked category.

Clinical signs of thoracolumbar myositis include pain to palpation of the affected muscle groups and associated spinous processes, obvious discomfort during saddling or mounting, subtle bilateral or unilateral hindlimb lameness, unwillingness to stop in form, and overall lack of performance. Flexion tests are seldom positive, unless the back problem coexists with distal tarsal disease. One may reasonably believe that arthrosis of vertebral articulations in the lumbar and lumbosacral region exists in some of horses. However, because of the depth and mass of the muscles involved, distinguishing the exact pathological condition or even the exact site of the injury is impossible.

Therapy is aimed at reducing inflammation and controlling the associated muscle pain and spasms. Prolonged rest periods from training always are indicated but in reality are difficult to achieve because of the rigid schedule of preparation for competition. For example, an average futurity horse being prepared for the National Cutting Horse Association futurity in December of its 3-year-old year accumulates a $20,000 to $24,000 debt in training and entry fees alone before competition. Convincing an owner and trainer that the horse should be allowed to rest immediately before the futurity is difficult, if appropriate therapy has even a remote chance of being effective.

The systemic use of skeletal muscle relaxants such as methocarbamol (Robaxin; 10 mg/kg PO bid for 5 to 10 days) has been effective in treating generalized back pain. Dexamethasone (10 mg PO bid for 3 to 4 days) is indicated in horses with acute pain. Chronic back pain may be treated successfully during competition with a single dose of triamcinolone acetonide (12 to 16 mg IM), while concurrently administering methocarbamol orally. NSAIDs generally have not been effective, unless the back pain is secondary or coexists with distal tarsal osteoarthritis. Care must be taken to comply with any medication rules.

Specific localized pain may be treated successfully by local injection of methylprednisolone acetate (200 to 400 mg) and Sarapin (50 ml). Treatment is repeated every 10 to 14 days until pain subsides.

Other management considerations are important for recovery. Horses with low, underslung heels of the hind feet should be shod using raised heels. Evaluation of the fit of the saddle, type of pad and specific pressure points when ridden should be considered. Other modalities of therapy, such as pulsed electromagnetic field and ultrasound, have been useful in keeping a horse in competition. Long warm-up periods without the rider for 30 to 45 minutes by ponying (leading from another horse) at a walk and trot always are indicated. The trainer must be cautioned that overwork and severe fatigue must be avoided at all times.

Sacroiliac Desmitis

Strain and subluxation of the sacroiliac joint are not uncommon in the working stock horse because of twisting and rotation of the back and pelvis during work. This rotation is complicated by the weight of tack and rider, who is attempting to maintain balance and remain stationary on top of the horse during sudden hard stops, turns, and bursts of speed.

Many of the clinical signs observed in horses with thoracolumbar myositis are also common in those with sacroiliac desmitis, because the epaxial muscles go into spasm to provide stability to the traumatized sacroiliac joint. However, bilateral or unilateral lameness with stiffness and alteration of gait usually is associated with sacroiliac desmitis. Protrusion of the tubera sacrale may be evident when the horse is walking away from the observer. Flexion of the contralateral limb for 2 minutes may result in elevation of the tuber sacrale, hip hike, and stiffness of the affected limb. Digital palpation adjacent to the tuber sacrale and over the gluteal regions usually elicits pain. Local infiltration of local anesthetic solution may result in improvement, but rarely are clinical signs fully alleviated.

Deep intramuscular injections of methylprednisolone (400 mg) and Sarapin (50 ml) into the region of the sacroiliac joint have been effective in treatment. Disposable needles at least 10 cm long are necessary to reach the affected area. Strict aseptic technique must be followed. Injections usually are repeated after 2 to 3 weeks. Concurrent systemic therapy with NSAIDs is beneficial. Horses must have rest, and 2 to 6 months out of training is often necessary, with strict stall confinement for the first 30 to 45 days.

Proper therapy and management of injuries to the thoracolumbar and sacroiliac regions generally are rewarding if initiated early in the course of the disease. Horses with chronic recurrent problems usually can be managed to allow some level of competition.

THE ROPING HORSE

• Robin M. Dabareiner, G. Kent Carter, and Richard Galley

TEAM ROPING HORSE

Description of the Sport

A unique handicapping system implemented in the early 1990s has contributed to team roping becoming a rapidly growing equestrian sport. Team roping began as a rodeo event many years ago, evolving from the everyday work of cowboys on ranches. If a cow needed to be treated on the open range, the only method of restraint was to secure the head and heel of the animal, or to team rope it. The cowboys soon began wagering among themselves to see which team of a header and heeler could accomplish this feat in the shortest time. Currently nearly 1 million people compete in team roping competitions in North America.

Because of the large number of participants, team roping has become of great economic importance. Many team roping organizations exist nationally, but the most prestigious is the United States Team Roping Championships. The numbering or handicapping system of the team ropers was begun by the United States Team Roping Championships and has become standard. A number, from 1 to 9, with 9 being the highest level of ability, is assigned to each of the team ropers. This number is based on various factors, including ability, previous prize earnings, experience, age, and physical handicaps.

The roping categories also are assigned a numerical value that cannot be exceeded by the total handicap numbers of the two participating ropers. The highest level of roping (11) is the open roping, which allows the world champions to compete together, and the lowest beginner level is 4. This method allows the lower-level ropers to compete as a team with the world champions and to level the playing field of competition at all levels. The entry fees of the participants usually generate the purse money in a jackpot fashion. A portion of the entry fee is held out by the producer of the roping to pay for the arena, the cattle, and advertising, and the rest of the fee is placed in the purse money to be divided among the winners.

Dally team roping is a timed event involving five basic elements: the header, the heading horse, the heeler, the heeling horse, and the steer. The steers that are used for the team roping event are usually horned cattle called Corriente cattle,

often from Mexico. Other types of cattle used are longhorns or other native homed breeds ranging in weight from 170 to 320 kg.

A typical run in dally team roping begins with a steer contained in a chute at the end of an arena. The heading box is to the left of the chute and the heeling box to the right of the chute. When the header calls for the steer, or asks that the steer be released from the chute, the chute gate is opened and the steer is allowed a head start called the score. If the header leaves the heading box before the steer crosses the score line, or reaches the predetermined head start, then the team is issued a penalty of 10 seconds. The timing of the run is begun when the steer crosses the score line.

When cued by the riders, the horses leave the roping box much as a racehorse leaves the starting gate to attain maximum speed as quickly as possible. As the header approaches the steer, now with the heading horse running at full speed, the horse is trained to rate off, or to slow up slightly, once the horse reaches the hip of the steer to position the steer properly so that the header may rope the steer. Team roping has three legal head catches: both horns (a clean horn catch), a half head (1 horn and the nose of the steer), or a neck. All other catches are considered illegal, and the team is given a no time.

After the header successfully catches the head of the steer and dallies (wraps in a full circle) the rope around the saddle horn, the heading horse drops its hindquarters and slows somewhat as it sets the steer and brings the steer's head around to the left. As the steer's body progresses to the left, the heading horse also is turned to the left and is moved out in front of the steer to allow the header to pull it across the arena at about a 90º angle to the original direction of travel, maintaining a constant slower speed, thus allowing the heeler to get into position to rope the hindlegs of the steer.

As the header sets and turns the steer, the heeler turns left following the steer and positions just behind and slightly to the left of the steer as it is taken across the arena. As the heeling horse follows the steer in this position, maintaining a constant speed equal to that of the header and steer, the heeler properly times his swing and then releases the heel rope, placing the loop under the steer and ropes the hindlegs of the steer. If only one hindleg is caught, then the team is issued a 5-second penalty. As the slack is taken out of the heel loop and as the dally is made on the saddle horn, the heeling horse is signaled to drop its hindquarters and come to an abrupt stop.

As the heading horse progresses away from the heeler with the steer still in tow, the ropes come tight, and when tight, the heading horse is cued to spin around to the right while maintaining a tight rope to face the steer. When the facing is complete, the rope is tight and in a straight line from the saddle horn of the header to the head of the steer and is tight from the hindfeet of the steer to the saddle horn of the heeler, and then the flagman signals the end of the run and the time is taken.

The roping can be accomplished by experts in 6 to 7 seconds but requires thousands of hours of practice to achieve this and to minimize the danger to all of the participants. Runs recorded in the range of 3.6 to 3.8 seconds have been made by the World Champion caliber team ropers.

Conformation

The horses, predominately geldings, used in team roping are usually American Quarter Horses (QHs), preferred because of exceptional athletic ability, quick acceleration over short distances, and a good mind. Other breeds are rarely used. The head horse must be larger and faster than the heel horse. Head horses typically weigh 545 to 590 kg and are heavily muscled to tow the steer across the arena. The heel horse is smaller and quicker with more cow sense than the head horse. Horses that are trained for cutting but no longer are competing often make good heel horses because of size and cow sense.

Team ropers prefer a mature, experienced horse, and so horses are usually over the age of 10 years, and many top ropers have horses in the mid to late teens. Repetitive injuries are therefore common, but because horses often have had several owners, a complete medical history is rarely available.

Training

The training of heading and heeling horses involves thousands of team roping runs and many thousands of miles of hauling. The horse must anticipate every variable of a team roping run, so that rider intervention is unnecessary. This allows the roper to focus on nothing but the speed of the run, which is an important factor contributing to injury. The current high demand for a finished team roping horse has greatly increased the value of these horses, and because replacement is difficult, veterinary advice is now sought more often.

Lameness Examination

Team roping horses experience many of the same problems as any of the Western performance horses. The hocks and the right front suspensory ligament (SL) are placed under tremendous pressure as the heading horse sets the steer. The right front is placed cranially and laterally to decelerate and brace against its forward motion and the weight of the steer, thus placing tremendous strain on this limb (Fig. 121-1). The distal tarsal joints are loaded with the rider's weight, the horse's weight, the deceleration of the full-speed forward motion, and the weight of the steer as primarily rotational forces. This occurs as the horse is asked to set and get under the steer and pull the steer's weight forward across the arena. After a successful catch by the heeler, the heading horse must face or spin around to the right while the hocks and distal hindlimbs are loaded as described, and do so with the addition of a backward motion to maintain tightness of the rope. When attempting to diagnose lameness, it is extremely important to remember that often in the early stages little or no lameness may be present. The complaint from the owner or trainer is often that the horse is coming untrained or is exhibiting increasing behavioral problems. It is imperative that the veterinarian is familiar with how the team roping horse works to arrive at a diagnosis. The history of a heading horse may include a reluctance to go willingly into the heading box, or reluctance to turn and face the front of the heading box and stand relaxed as the roper prepares to ask that the steer be released. As the problem worsens, many horses may rear up and spin around in the heading box, or lunge out of the box and refuse to re-enter. The horse may overrun the steer or even run past the steer, rather than rating off as it is supposed to do. The horse may duck or drop the left shoulder excessively as the header attempts to dally the rope and as they set the steer. The way the horse handles the steer may change, and the horse may tend to lunge across the arena with the steer in tow rather than taking the steer at an even, controlled gait. The horse may be reluctant to face at the end of a run. As the steer is followed to the end of the arena after the run, the horse may prance and jump around, rather than loping in a relaxed fashion as it follows the steer. These problems usually reflect pain, especially of the distal tarsal joints, but horses are seldom clinically lame at this stage.

The heeling horse often has a similar history, with problems in the heeling box, not making the corner properly as the steer is set and turned, or of nickering and bouncing out of the stop at the completion of the run while maximal tension is on the ropes. A common complaint by the rider is that the horse is not stopping anymore after the heeler's rope is thrown (Fig. 121-2). Horses are often unwilling to drop the head and relax after a run and tend to prance out of the arena.

Fig. 121-1 A header roping the steer and making a 90° turn to set the steer for the heeler. The weight of horse and rider result in excessive loading of the right forelimb of the head horse (grey horse).

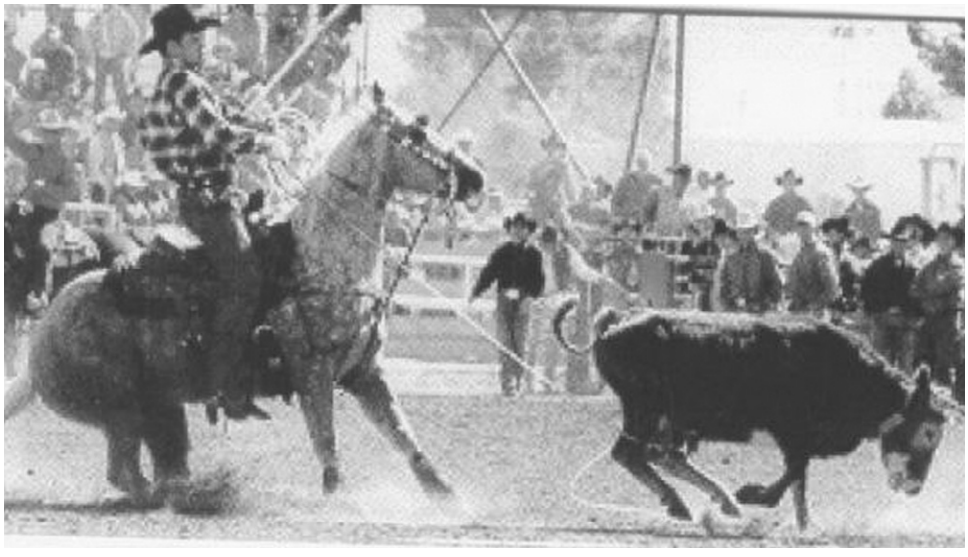

Fig. 121-2 A heel horse stopping after the heeler throws his rope. Note the flexion of the hock joints during the stop and the extreme forward placement of both hindlimbs.

Clinical examination often reveals pain on palpation of the caudal lumbar area, the gluteal muscles, and over the point of both hips. This pain often is accompanied by the complaint that the horse is sore in the kidneys. If only the distal tarsal joints are involved, effusion usually is not detectable, but the horse may be reluctant to allow palpation of the medial aspect of the tarsus, as if anticipating pain. The craniomedial aspect of the distal tarsus may be enlarged. High-quality radiographic examination of the hocks is essential; lesions may be missed unless the radiographs are examined under magnification.

Intra-articular analgesia is often ineffective because the horse has developed performance problems in response to the pain experienced during every run, and the pain is anticipated, even though the area has been blocked. Thus horses become intractable in the roping box because they dread the pain that they will experience during the run. However, horses often respond well to intra-articular therapy when they realize, after several runs, that the pain has been lessened or stopped.

Diagnosis and Management of Specific Lameness

Suspensory apparatus injury in the right forelimb is common, especially in a heading horse, and involves the SL, the accessory ligament of the deep digital flexor tendon, the distal

sesamoidean ligaments, or a combination of these. These injuries usually cause lameness of varying degrees, and diagnosis by clinical examination is straightforward. Ultrasonography should be used to confirm the diagnosis. Distal sesamoidean ligament injury may be more difficult to diagnose but often results in acute, moderate to severe lameness (grade 2 to 3 of 5) after a run, associated with pain on palpation of the palmar aspect of the pastern. Perineural analgesia of the palmar digital nerves may improve the lameness, but analgesia of the palmar (abaxial sesamoid) nerves is needed for complete soundness. Fractures of the middle phalanx are also common, so the horse should be examined by radiography and ultrasonography. Ultrasonographic evidence of enlargement or reduction in echogenicity in the straight or oblique distal sesamoidean ligaments is diagnostic (Fig. 121-3). Radiography is usually negative if lameness is acute; however, chronic injury is often associated with periosteal proliferation on the palmar aspect of the proximal phalanx associated with oblique distal sesamoidean ligament injury or entheseous new bone on the proximopalmar aspect of the middle phalanx associated with straight sesamoidean ligament injury. In hindlimbs deep digital flexor tendonitis, tenosynovitis of the digital flexor tendon sheath, and proximal suspensory desmitis are common, especially in the left hindlimb of head horses.

When turning to face the steer, the head horse turns 180° at fast speeds, putting a rotational torque on the distal aspect of the left hindlimb (Fig. 121-4).

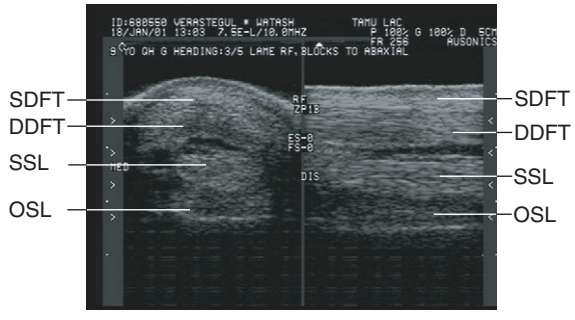

Fig. 121-3 Transverse *(left)* and longitudinal *(right)* ultrasonographic images of the mid-pastern region of the right forelimb of a head horse. There is a hypoechoic lesion in the straight sesamoidean ligament (SSL). *SDFT,* Superficial digital flexor tendon; *DDFT,* deep digital flexor tendon; *SDSL*, straight distal sesamoidean ligament; *OSL*, oblique sesamoidean ligament.

Management of these soft tissue injuries includes rest consisting of confinement and controlled exercise (Box 121-1), ranging from 4 to 6 months for horses with desmitis of either forelimb SL or the accessory ligament of the deep digital flexor tendon, to 8 to 12 months for horses with distal sesamoidean ligament injuries, deep digital flexor tendonitis, and hindlimb injuries (Box 121-2).

Given the usual QH conformation of large body size and small feet or short, upright pastern conformation, navicular disease and injuries to structures within the palmar aspect of the foot (navicular syndrome) are common. Diagnosis is based on the response to perineural and intra-articular analgesia and high-quality radiographs. Navicular bone pain results in a slowly progressive lameness, often bilateral, that responds to intra-articular medication of the distal interphalangeal joint, NSAIDs, and corrective shoeing. Soft tissue injuries of the palmar aspect of the foot (e.g., impar or collateral ligament desmitis and injury to the deep digital flexor tendon in the region opposing the flexor surface of the navicular bone) are also common in head horses and usually are acute, occurring

Exercise Regimen after Mild Injuries to Forelimb Suspensory Ligament or Accessory Ligament of the Deep Digital Flexor Tendon

Weeks 1-4	The horse is given stall rest or a small run (6 × 10 m) with support bandage on limb.
Weeks 5-8	Confinement is continued with 15 minutes of hand walking twice daily.
Weeks 9-12	Confinement is continued with 30 minutes of hand walking daily.
Weeks 13-16	If horse is sound at the trot, then confinement is continued, but the horse is walked under saddle or is ponied 15 minutes a day plus 5 minutes of trotting. Five minutes of walking and trotting are added every third day. The horse is re-examined by ultrasonography before returning to roping activity.

Fig. 121-4 A head horse (on the right) turns to face the heeler at the end of the run. Note the strain placed on the left hindlimb.

during a roping event. Lameness is improved by perineural analgesia of the palmar digital nerves or intra-articular analgesia of the distal interphalangeal joint. Often no radiographic abnormality is apparent. Extended rest is required for full recovery.

Osteoarthritis of the distal hock joints is common, and head horses seem especially at risk. Most respond well to intra-articular medication of the centrodistal and tarsometatarsal joints.

Injury to the back and pelvic area is seen, especially in the heading horse. Strain or tearing of the sacroiliac ligaments can occur. Diagnosis can be augmented by the availability of a level surface near a level reference point. When examining a horse with only the horizon or surroundings as reference, noticing a subtle change in one side of the pelvic area may be difficult. A level surface near a door, especially one with horizontal lines or ridges, offers a grid effect that makes asymmetry more apparent if the horse faces the door and is viewed from behind. Radiographic evaluation is difficult and often unrewarding, but ultrasonographic examination may reveal longissimus lumborum and gluteal muscle tearing and can be used to evaluate the sacroiliac area. Lameness predisposing to back pain must be eliminated. Rest combined with topical heat (hot towels) and dimethylsulfoxide helps many horses, but often months of rest are needed before the pain is eliminated. Treating the painful areas with local injections hastens the recovery time. We prefer a combination of 5 ml methylprednisolone acetate, 5 ml Sarapin, and 5 ml prednisolone diluted with 30 ml mepivacaine and depositing 3 to 5 ml in several sites around the painful muscle or ligament. The horse is given 2 to 3 weeks of light riding, with no roping activity, and then is re-evaluated by ultrasonography. Most horses return to roping activity within 4 weeks from the time of injury.

Obviously all team roping horses are also susceptible to any of the same injury problems that other equine athletes experience. Most of these injuries produce overt lameness, and diagnosis is usually straightforward.

Box • 121-2

Eight- to 12-Month Tendon Rehabilitation Program

Weeks 1-12	The horse is given stall rest or is confined to a small run (6 × 10 m) with 15 minutes of daily hand walking. Support bandages are used for first 30 days.
Weeks 13-16	The horse is re-examined by ultrasonography. If the lesion is healing, confinement continues, but hand walking is increased to 15 minutes twice daily.
Weeks 17-24	Confinement is continued. The horse is hand walked 30 minutes a day or walked under saddle for 20 to 30 minutes a day.
Weeks 25-32	If the horse is sound at the trot and greater than 70% healing has taken place as visible by ultrasonography, the horse is walked under saddle or ponied for 20 minutes and trotted for 5 minutes. Walking and trotting are increased by 5 minutes every third ride until the horse is walking 45 minutes and trotting 30 minutes. If the horse remains sound, treatment proceeds to next level. If lameness develops, treatment reverts back 30 days in the schedule and the horse is re-examined by ultrasonography.
Weeks 32-36	Riding is increased to include loping for 30 days. If horse remains sound, the horse can return to roping activity. The horse can be turned out into a larger pasture.

Shoeing Considerations

Because rope horses are often middle-aged, are used frequently, and commonly have navicular problems, maintenance of proper hoof balance is critical in keeping these horses sound. Long toes and collapsed heels are common. From a solar view the heels grow too far forward and are left unsupported and thus are at risk of abnormal concussion. We recommend trimming the heels back to the widest part of the frog and setting the shoe further back on the foot, so the heels of the shoe end at the widest aspect of the frog. Care must be taken to fit the front shoes properly so that little of the medial side of the shoe is exposed, because head horses have a tendency to grab this portion of the shoe and pull a shoe off, especially the left front shoe. Easing the breakover of the limb can be accomplished by rockering the shoe. A rim shoe or steel natural balance shoe provides good traction and allows an easier breakover by the rounded and rockered toe region of the shoe construction. The natural balance shoe has a wider web than a normal shoe and is beneficial for horses with sore feet acquired from performing on harder ground. If trimming alone cannot establish a correct hoof-pastern angle, a 1° to 2° wedge pad is recommended. We prefer a cutout pad to a full pad that often traps moisture and can lead to thrush problems. Care must be taken to avoid pad pressure over the central region of the frog in horses with navicular pain.

In horses with deep digital flexor tendonitis, we recommend applying a 2° to 3° wedge pad for the initial 4 to 5 months of rest to decrease tension on the tendon. The wedge is reduced gradually over three shoe resets, once the horse is sound. In horses with distal hock join pain, we try to ease breakover of the hindfeet by squaring the toes or by setting the shoe back under the toe 0.3 cm. Avoiding any type of trailer or extension on the rear shoes is also preferable, especially on the heading horse, because this can aggravate pain associated with distal hock osteoarthritis.

CALF ROPING HORSES

Description of the Sport

Calf roping originated on ranches of the Old West when sick calves were roped and tied down for medical treatment. Success in calf roping depends on the teamwork between a cowboy and horse. After the calf is given a head start (like a scoreline in team roping), horse and rider chase the calf, and as the rider ropes the calf, the rider dismounts and runs to the calf. As the rider dismounts, the horse must sit back on its hind end and come to a sudden stop, which takes the slack out of the rope and stops the running calf. This allows the cowboy to catch the calf and throw the calf to the ground, termed *flanking the calf.* Once on the ground the contestant ties three of the calf's legs together with a pigging string. The horse is trained to work the rope as the cowboy ties the calf, meaning to back up if needed to keep the rope tight, thus keeping the calf still for the rider to tie. When the cowboy completes his tie, he throws his hands up in the air as a signal to the judge

that his run is complete. The calf must stay tied for 6 seconds. A 10-second penalty is added if the calf roper breaks the barrier at the beginning of the run. An 8- to 9-second run is considered good, and Jeff Chapman of Athens, Texas, set the arena record in 1997 when he roped and tied a calf in 6.8 seconds.

Conformation

American QHs are used for calf roping and must be athletic and well trained. Because the rider must dismount during the event, calf horses are usually not tall, often being 14.2 or 14.3 hands high. Calf horses also have wide-base and muscular frontquarters and hindquarters. Many ropers believe that the performance demands on a calf horse are greater than that of a team roping horse.

Diagnosis and Management of Specific Lameness

Calf horses have lameness similar to that of team roping horses with a few exceptions. Hindlimb lameness is more common in horses used for calf roping. Osteoarthritis of the distal hock joints is the most common problem, but stifle lameness also occurs frequently. Collateral ligament damage or meniscus tearing occurs, but diagnosis is usually not apparent until after bony changes are seen radiographically, months after the initial injury. Bony reaction at the proximal medial aspect of the tibia is diagnostic. With rest, NSAIDs, and intra-articular medications, these horses often can return to roping, but at a lower level, perhaps as a calf roping horse for a child or beginner. Hindlimb proximal suspensory desmitis, traumatic fetlock osteoarthritis, and fractures of the proximal sesamoid bones and middle phalanx are common. The most common forelimb lameness is palmar heel pain, often resulting from improper shoeing.

Shoeing Considerations

The same shoeing considerations are used for balance and protection of the navicular region in the forelimbs as described for team roping horses. In the hindlimbs if the toes of the feet are too short, so that the horse has a broken forward hoof-pastern axis, then the hind toe digs deep into the ground and the limb stops abruptly, causing sudden torque on the distal limb. Having more toe length and a shoe that fits full with the heel branches of the shoe extending to the heel bulbs is preferable, so that the horse slides as it stops. This not only protects the heel bulbs from the ground surface, but it also puts less strain on the distal limb. Horses used for calf roping often wear skid boots, protective leg gear aimed at minimizing friction between the ground surface and the plantar aspect of the hindlimb fetlock joints, because the horse skids to a stop.

THE REINED COW HORSE

• Van E. Snow

The National Reined Cow Horse Association was initiated in 1949 as the California Reined Cow Horse Association and changed its name in 1970. The purpose of the association is to preserve the training traditions of the vaqueros, the horsemen of early California, who trained their horses for ranch work. As a result of selective breeding and refined training techniques, reined cow horses today are able to achieve more with livestock than was ever thought possible.

The National Reined Cow Horse Association held its first Snaffle Bit Futurity in 1970 in Sacramento, California. Bobby Ingersoll, a renowned cow horse trainer, had the idea to showcase the best all-around cow horses in the world. The competition involves showing the horse in three different disciplines: herd work (cutting), rein work, and cow work (working a cow down a fence). In the Snaffle Bit Futurity the top 20 horses from the first round of competition come back and do another round over 2 days, starting again with even scores. The sport of reined cow horse has evolved from 1970, when 27 horses competed for $3900, to 1999, when hundreds of horses competed at their annual futurity for nearly $1 million.

The professionals compete on multiple horses in four divisions: snaffle bit, hackamore, two rein, and bridle. Competition consists of multiple levels, including professional, non-professional, amateur, and limited open. An auction is held each year at the reined cow horse futurity at which horses that range from 1 to 12 years of age and breeding stock horses are available for sale.

Affiliate groups of the National Reined Cow Horse Association are organized in Canada, Germany, Belgium, and Australia, and a strong interest in the group exists in most of Europe and in South and Central America. No restrictions exist as to the breeds allowed to compete in the futurities. Numerically the American QH dominates, but Paint horses often compete successfully, and an Appaloosa has won.

The competition requires that the horse be accomplished in its ability to run, stop, turn, and read and control a cow. These horses also must have a high level of endurance. These qualifications do not necessarily dictate a particular body type, but the reined cow horse tends to be a taller, leaner horse than the cutting horse. Stallions, mares, and geldings compete equally, as do all genders and age groups of riders.

Reined cow horses are typically begun in training when they are less than 2 years old and start to compete at 3 years of age. They have about 20 months to learn all of the events and to become well enough conditioned to withstand the rigors of competition. This requires that the training surface, shoeing, and judgment of the trainer be optimal throughout the 20-month period.

Most trainers have become knowledgeable in the prevention and the early detection of lameness. Musculoskeletal evaluations are done quarterly on the futurity prospects, beginning in the fall of the 2-year-old year. These evaluations include a complete lameness evaluation, including flexion tests. At this time good baseline information on each horse is established, and future insidious problems can be detected before they become unmanageable. In the past, it was commonplace for a trainer to blame himself or herself or the horse's attitude for not being able to accomplish a certain task, when in fact low-grade lameness was developing. The trainer would continue to train the horse, and often a serious lameness would develop. For the trainer to suspect a subtle lameness and to have the horse evaluated is much more common now. Lameness detected at this point is usually manageable.

The reined cow horse continues to compete beyond 3 years of age. As 4-year-olds they can continue in the snaffle bit or begin in the hackamore or bridle class. The 5-year-olds are shown in the hackamore or bridle class, and the 6-year-old in the bridle class. Hackamore and bridle horses compete in the reining and cow work divisions, but they do not do herd work. The intention is to finish the horse's education by the time the horse is 6 years old.

TRAINING SURFACES

The training surface has a strong influence on lameness in terms of incidence, degree of severity, and type of injury. In general the arena or round pen is best constructed as follows: The original ground is graded to a 1.5% grade from one corner to the other and is compacted to 95%. A 15-cm thickness of base material such as limestone rock dust is then added, watered, and compacted to 95%. The type of base used is dictated by what is available in the area, but it should be smaller-

sized particles (not small rocks), which have interlocking edges. A 1.5% grade should be maintained. Sand is then added to the top of the base to a thickness of at least 5 cm and not more than 12 cm in the arena, and from 10 to 15 cm in a round pen. Adding the sand at the minimum levels first and adding more later if necessary is recommended. In general, less injury occurs with thinner layers of sand, but performance may be enhanced with thicker layers of sand. Fine beach sand is the best, because it has low abrasive characteristics and is light. These qualities are important because the sand gets between the skin and protective boots and also comes in direct contact with the back of the pasterns and fetlocks. If the sand is coarse and abrasive, it damages the skin and causes lameness. The density of the sand is important because the horse has to push the sand during sliding stops, and if the sand is too heavy, it causes injury and destroys the horse's confidence.

Water content of the training surface is also an important consideration. In general, applying the water a few hours before use is a good idea, so that the water is distributed evenly. If the training surface is too deep with sand or if the base is not consistent, I see more soft tissue injuries such as tendonitis, suspensory injuries, curbs, and sprained backs. If the training surface is too hard, I tend to see bone injuries such as osteitis of the distal phalanx, navicular syndrome, sesamoiditis, or fractured proximal sesamoid bones.

TRAINING AND ITS RELATIONSHIP TO LAMENESS

The types of injuries commonly seen tend to vary as the training progresses. The young 2-year-olds have hoof and sole problems during the initial breaking process, before they are shod, associated with an increased digital pulse and sensitivity to hoof testers. Subchondral bone cysts in the medial femoral condyle and osteochondrosis of the fetlock may manifest at this time. Chip fractures, present but unnoticed when the horse was a foal or yearling, may become clinically apparent when ridden work starts.

The work during the latter half of training for a 2-year-old involves more speed and collection, and low-grade lamenesses may develop that later become persistent problems. These lamenesses include suspensory desmitis, navicular syndrome, and hock and stifle pain. The 3-year-old year involves even more collection, cow work at speed, and harder stops. We generally see a continuation of the 2-year-old problems, if they are not managed well, and also more acute injuries to soft tissue and chip fractures of the fetlock and carpus.

CONFORMATION AND LAMENESS

Conformation does have an effect on the development of lameness, but I feel that conformation often is overemphasized. The component of conformation that has the biggest effect on soundness is body conformation and the degree of balance in motion. I have seen many horses whose conformation was not impressive when viewed at a standstill but were impressive when evaluated in motion. Balance in motion is that somewhat immeasurable quality that gives one the impression that the horse could jump, stop, turn, or do almost anything on any given stride without effort. In my experience, these horses remain sound while performing to an exceptional level, whereas horses that have less balance suffer more frequent injury. Although static conformation related to lameness is important and should be evaluated, in my opinion, conformation in motion is equally important.

The most common conformation problems that I see are toed in and toed out. These problems predispose the horse to lameness but are present to some degree in nearly all horses. Most often these conformational abnormalities are associated with injury to the SL and also can be associated with injury to the collateral ligaments of the digit. I try to manage these conformation faults before they cause injury to the horse by trimming and shoeing. A horse that toes out initially contacts the ground with the outside toe quarter with improper trimming. The hoof then slides along the ground and begins to rotate the toe out. The inside heel then makes contact with the ground, and the hoof rotation stops. However, this rotational force continues up the limb and places unnatural strain on the soft tissues below the carpus and eventually causes damage. I recommend removing more wall from the hoof at the point of contact and beveling the toe so that breakover is accomplished easily over a wide area. My goal is to get the entire hoof to contact the ground evenly and eliminate the rotational force. Horses that toe in generally contact the ground at the inside toe quarter. Horses with this problem need more hoof removed from the inside toe, the goal being to cause the foot to land flat.

TEN MOST COMMON LAMENESS CONDITONS

The following are the 10 most common lameness conditions in the reined cow horse:

1. Suspensory desmitis
2. Osteoarthritis of the centrodistal and tarsometatarsal joints
3. Navicular syndrome
4. Hoof-related problems such as bruises, abscesses, and cracks
5. Superficial digital flexor tendonitis
6. Subchondral bone cysts, osteochondrosis, and traumatic injuries of the stifle
7. Fetlock arthrosis
8. Sesamoiditis
9. Distal interphalangeal joint synovitis or osteoarthritis
10. Osteitis of the distal phalanx

LAMENESS EVALUATION

I begin the lameness examination by obtaining as complete a history as possible. I establish the duration of lameness; any change in lameness, if the horse has been rested or kept in work; any response to treatment; alteration in lameness with work; when the horse was last trimmed and shod; any changes in footing, type of work or shoeing; if lameness was associated with turnout or work; if the horse has received any intramuscular injections; if the horse kicks the paddock or stall; if the horse is turned out with others; if the horse stumbles; any known trauma; whether the lameness occurred insidiously or suddenly; and if the horse stands normally. Generally, the best history is obtained from the grooms and trainer, although some owners can provide information.

I watch the horse at the walk, trot, and canter, loose in a 9-m round pen, and on firm footing on a 2% slope. The degree of lameness often is amplified when the horse is loose, on hard ground, and allowed to work on a slight slope. Some lameness characteristics are best seen at a slow trot and some at an extended trot. The round pen enables one to evaluate the horse's ability to hold leads. Detecting low-grade ataxia is also easier when the horse works free, especially during downward transitions.

Lameness may be manifest in how a horse does a sliding stop; lameness may be accentuated after several sliding stops from a canter. A horse may slide stronger on one hindlimb

than the other. The complaint is often made that the horse is not stopping as well as previously, although lameness is not noticed. A horse may begin a sliding stop normally but then pick up the painful limb halfway through the stop and replace it. The stop is not held evenly. The stop becomes normal if pain is removed by local analgesia.

Another common situation occurs when the horse is cutting a cow, the horse runs off at one end or does not come back with the cow as strongly at one end. The hindlimb farthest from the cow before the weak turn is generally the lame limb. If this horse is asked to do rollbacks in a round pen, the horse is much weaker when it reverses direction one way. Generally the hindlimb on the outside of the circle after the weak rollback is the lame limb.

Competition is now so great that the difference between winning and losing is sometimes a matter of which horse feels the best. Performance diminishes before outright lameness is noted. Hindlimb lameness is particularly common in reined cow horses because of hock or stifle pain or proximal suspensory desmitis.

Flexion tests include flexion of the digit in all limbs and carpal, hock, and stifle flexions. Notes are made on the results and whether the horse resented flexion. The digit is flexed in an oblique plane (applying medial and lateral torque), and any resentment or diminished elasticity is noted.

All of the soft tissue structures are palpated, and any enlargements and sensitivity are noted. The hoof testers always are applied to the front feet, and to the hind feet of horses with hindlimb lameness. Any lameness or weakness is classified in degrees (grade 1 to 5); by the limb involved; by weight bearing or non-weight bearing or mixed status; by the effect of walking in a circle or on a straight line, on an incline or decline; by flexion tests; and by the effects of prolonged digital pressure over sensitive areas.

If lameness is serious enough possibly to be caused by fracture, radiography is performed first; otherwise, diagnostic analgesia is used to establish the source of pain. Intra-articular analgesia is more specific than regional analgesia, which can be done at a later time if necessary, so I often start with intra-articular blocks, especially in forelimbs. I rely on the flexion tests to direct the start point. If flexion of the distal limb is normal but carpal flexion is positive, I usually use perineural analgesia of the proximal palmar metacarpal and palmar nerves (high four-point). If lameness persists, I perform intra-articular analgesia of the carpus. If flexion of the distal limb is positive, I perform intra-articular analgesia of the distal interphalangeal joint first and then proceed to the pastern and fetlock joints if necessary to eliminate the lameness. If intra-articular analgesia is not helpful and the flexion test is still positive, I perform perineural analgesia of the palmar digital nerves, followed by the digital nerves (abaxial sesamoid) and later a low four-point block. Knowing whether the problem is articular is useful, because horses with articular problems are often more amenable to treatment.

For intra-articular analgesia I do a three-step povidone-iodine (Betadine) and alcohol skin preparation and use sterile gloves. I place a subcutaneous bleb of local anesthetic solution before injection and combine local anesthetic solution with gentamicin sulfate (40 mg).

In a hindlimb I usually use perineural analgesia proximal to the fetlock, local infiltration around the region of the SL, intra-articular analgesia of the centrodistal and tarsometatarsal joints separately, and intra-articular analgesia of the femoropatellar and medial femorotibial joints. The lateral femorotibial compartment rarely is involved. If the response to a low four-point block is positive but the response to plantar (abaxial sesamoid) nerve blocks is negative, intra-articular analgesia of the metatarsophalangeal joint is performed the following day.

IMAGING CONSIDERATIONS

Once the region of pain is localized, the area is examined using radiography and ultrasonography to identify the exact structure that has been damaged and to assess the degree of damage. The more specific I can be at this point, the more reliable the prognosis and treatment are. If the diagnosis is not specific, scintigraphy often is used. Generally a differential diagnostic list is generated based on the physical examination. Developing a therapeutic plan based on a tentative or vague diagnosis is a mistake. Nearly all diagnoses are tentative until the pain has been localized as specifically as possible through the use of diagnostic analgesia and appropriate imaging.

PROCEEDING WITHOUT A DIAGNOSIS

Sometimes the cause of lameness cannot be discovered, even after all of the joints and nerves have been blocked and a complete scintigraphic examination has been performed. I then treat the horse for myofascial pain with drugs or chiropractic therapy. If the horse responds to these therapies, then this is indirect evidence of the cause. Another possible cause is equine protozoal myelitis. Horses with equine protozoal myelitis may show chronic lameness without other neurological signs.

LAMENESS AND SHOEING CONSIDERATIONS

Proper foot balance is critical to resolving all lameness problems successfully. The foot should be trimmed to land evenly. Any medial-to-lateral imbalance should be removed by trimming. If the point of contact is the lateral toe quarter, then enough of the lateral wall should be removed so the foot lands flat. The foot should be trimmed or a wedge used to achieve a hoof angle that is the same as the pastern angle (about 55° in forelimbs and 57° in hindlimbs). A square-toed shoe that has a wide bevel, which extends from the medial to lateral toe nail holes, commonly is recommended and is useful. The shoe should be set back so the dorsopalmar axis is shortened. The heels are trimmed so the shoe comes in contact with the wall at the widest section of the frog. These specifications are designed to remove rotational forces up the limb that occur in horses with medial to lateral imbalances, to provide mechanical advantage to the palmar/plantar aspect of the limb that occurs in horses with with a long toe and low heels, and to reduce concussion to the digit that occurs in horses with the two-phase foot impact associated with foot imbalance.

An egg bar shoe is used for horses with moderate to severe tendonitis, suspensory desmitis, or an apical sesamoid fracture. A reverse shoe is used sometimes for horses with navicular syndrome, ringbone, sesamoiditis, suspensory desmitis, tendonitis, constricted palmar/plantar annular ligament, carpitis, and tarsitis. Horses with bruising in the sole are shod with soft dental acrylic pads. Horses with heel and quarter cracks are managed with egg bar shoes.

TREATMENT OF LAMENESS

Suspensory Desmitis

For horses with suspensory desmitis, it is important to optimize foot balance as previously described. Corrective shoeing is designed to minimize any further physical damage and therefore prevent further pain and inflammation. Other treatments provide short-term results and are aimed at reducing the existing inflammation.

Horses with minor to moderate fiber disruption are treated with perilesional injections of Sarapin and corticosteroids. If

the lesion is proximal, a sterile skin preparation is recommended, with the addition of gentamicin sulfate (40 mg) in case the carpometacarpal joint is entered inadvertently. The drugs are injected under the loose tissue between the SL and the accessory ligament of the deep digital flexor tendon. Middle carpal joint pain may occur concurrently and is treated using intra-articularly administered corticosteroids, provided that no radiographic abnormalities are apparent. Physical therapy in the form of electrical stimulus modalities or low-level light laser therapy is started 3 days after injection and continued as needed through the intended competition. Magnets of 600 to 1200 G strength placed over the site have been used successfully and are kept in place for 60 days and then as needed for soundness.

The lesion is monitored monthly using ultrasonography. If conservative treatment fails, extracorporeal shock wave treatment is used and administered with the horse under general anesthesia. Up to four treatments have been used, combined with rest for 60 to 90 days.

Centrodistal and Tarsometatarsal Joint Pain

Intra-articular injection of corticosteroids is effective at relieving pain and inflammation in the centrodistal and tarsometatarsal joints. Horses are allowed to rest for at least 10 days after injection and then work gradually is increased as soundness dictates. The systemic use of hyaluronan and acetylglucosamine is helpful for maintenance. Orally administered chondroitin sulfate and glucosamine products also have been useful. If medication is ineffective, joint drilling or forage to induce joint ankylosis, or peri-articular extracorporeal shock wave treatment can be used effectively.

Navicular Syndrome

Navicular syndrome is diagnosed based on a positive response to palmar digital analgesia and analgesia of the distal interphalangeal joint, radiography, and scintigraphy. Radiography can be misleading, and in my opinion scintigraphy is the most reliable method of diagnosis. Corrective shoeing is essential. Isoxsuprine hydrochloride (600 mg) is given orally once daily for 60 days. Aspirin (15 g) also is given orally once daily for 60 days. If this combination provides relief, it is continued for another 60 days or until the horse finishes the futurity season. Injection of the distal interphalangeal joint with corticosteroids, or a combination of corticosteroid and hyaluronan, often provides temporary relief (about 30 days).

If the horse fails to respond to the corrective shoeing and medications, shock wave treatment is indicated and has been effective, except in horses with entheseous new bone at the attachment of the collateral ligaments of the navicular bone. Palmar digital neurectomy is used as a last resort.

Traumatic Hoof Injuries

Horses with bruises and cracks in the hooves respond well to egg bar shoes with soft dental acrylic pads or metal pads. A horse with a quarter crack is treated by trimming the wall palmar/plantar to the defect, so that no contact is made with the shoe, that is, floating the heel. The air gap is up to 6 mm deep and is reopened daily using a hacksaw blade to relieve pressure between the hoof wall and the shoe, until the defect has grown out. If the crack is moving and bleeding, a copper patch is attached to the wall with screws to span the defect and therefore stabilize it.

Superficial Digital Flexor Tendonitis

Ultrasonography is used to characterize size and position of the lesion in horses with superficial digital flexor tendonitis. If a lesion is small, the owner or trainer usually decides to continue preparing for the futurity. It is important to try to determine the circumstances that caused the lesion to develop to eliminate further damage. Possible causes for tendonitis include poor hoof balance, deep footing, fatigue, speed, overexertion from working a difficult cow, uncontrolled exercise (turnout), interference from hindlimbs, tight bandages, poorly fitting support boots, and hanging a leg on a hot walker, tie rope, or fence.

Therapy for tendonitis involves depositing corticosteroids in the loose subcutaneous tissue in the proximity of the lesion. The leg is wrapped in a gelocast for 3 days and then is treated with ice and laser or electrical stimulus therapy. The horse is walked in hand or under saddle for 15 minutes twice daily for 7 days. Training then is resumed. The leg is maintained in a support wrap continuously. Shoeing, good footing, and conservative training are critical to the healing process.

Stifle Pain

If no abnormalities are detected in the stifle radiographically, the affected joints are treated with intra-articularly administered corticosteroids and hyaluronan. The horse is prescribed weekly injections of systemic acetylglucosamine, which continue through the futurity. Subsequent intra-articular injections are not performed sooner than 6 months and preferably not at all.

If radiographic evidence of osteochondrosis of the trochlear ridges of the femur exists, the same therapy is effective. The prognosis for horses with subchondral bone cysts of the medial femoral condyle is dismal, and I do not recommend that these horses continue training to be futurity horses.

Metatarsophalangeal Joint Pain

Metatarsophalangeal joint pain may be caused by traumatic arthritis, fracture of a proximal sesamoid bone, sesamoiditis, fragments detached from the proximoplantar aspect of the proximal phalanx, or peri-articular soft tissue injury. If no radiographic lesions are present, the horse is treated with intra-articularly administered betamethasone and hyaluronan, followed by 10 days of rest. Systemic glucosamine is given every 2 weeks as maintenance therapy. Orally administered glucosamine and chondroitin sulfate also seem to be useful in managing metatarsophalangeal joint pain. Shoeing imbalances must be corrected concurrently.

Sesamoiditis

The foot must be properly balanced to treat sesamoiditis. Egg bar shoes with a square toe and a wide roll or bevel are used. The shoe is set back to minimize the leverage on the palmar/plantar aspects of the fetlock. The hoof angle is optimal when it matches the pastern angle. Isoxsuprine hydrochloride (600 mg) and aspirin (15 g) are given orally once daily for 60 to 90 days. Electromagnetic energy is applied to the affected region every other day for 3 months and thereafter as needed for soundness. The amount of training is dictated by the degree of soundness.

Distal Interphalangeal Joint Pain

The foot must be properly balanced to treat distal interphalangeal joint pain. Soft dental acrylic pour-in type pads and shock-absorbing rim pads can be helpful. Intra-articular injection of a corticosteroid and hyaluronan is followed by the systemic use of acetylglucosamine and hyaluronan. It is imperative that training is continued on a soft surface.

Osteitis of the Distal Phalanx

Soft dental acrylic pour-in type pads and shock-absorbing rim pads are used to treat horses with osteitis of the distal phalanx. The horse is treated with isoxsuprine hydrochloride (600 mg), aspirin (15 g), and phenylbutazone (2 g) given orally once daily for 60 days and then as needed for soundness. Training must be done in soft footing to reduce concussion to the foot. Extracorporeal shock wave therapy has recently been introduced to manage horses with osteitis of the distal phalanx.

BARREL-RACING HORSES

• Robin M. Dabareiner and G. Kent Carter

Barrel racing began in 1948 when a group of Texas ranch women started riding horses around a cloverleaf pattern of barrels and the fastest horse around the course was the winner. Barrel racing has evolved into a multimillion-dollar industry called the Women's Professional Rodeo Association. From this original organization many other barrel racing associations, which host numerous futurities for horses 4 or 5 years of age or younger and derbies for older horses, have arisen. In 2000, five futurity events were held nationwide, with each futurity paying out more than $800,000 in prize money from which the winner is guaranteed more than $100,000. The major competitions are divided into rodeo, futurities, derbies, open jackpots, and professional levels. Futurities and derbies are classified by age of the horse. Open competitions are open to any horse or rider and are highly competitive. Within the open jackpots, a new classification of barrel racing has developed, termed a *3D* or *4D competition*, which includes a handicapping system that allows less experienced horses or riders to compete with seasoned horses and riders.

Barrel racing is a timed event with the clock beginning when a predetermined line is crossed. Three barrels (55-gallon steel drums) are positioned in a triangle or cloverleaf (Fig. 121-5). The contestant must turn the left or right barrel first (most choose to turn the right-hand barrel first) in a manner that the path always crosses. The distance covered for the pattern varies with the size of the arena, but generally the distance from the starting line to the first barrel is 14 to 18 m. The distance between the first and second barrel is 21 to 27 m and between the second and third barrel is 27 to 32 m. The horses must start at the alleyway or entrance to the arena, run at full speed to the first barrel, slow down and complete a 360° turn around the barrel, speed up and run to the second barrel, turn 360°, head to the third barrel, turn 360°, and then sprint to the finish line. The fastest time to complete the pattern varies with distance of the pattern and arena size, but a good run for a large arena pattern is 15 to 16 seconds. An electric eye timing system usually is used, and times are recorded in hundredths of a second. If a rider hits a barrel and tips it over, a 5-second penalty is imposed. If the horse and rider fail to negotiate the pattern correctly, they are disqualified. The arena is often leveled after each horse.

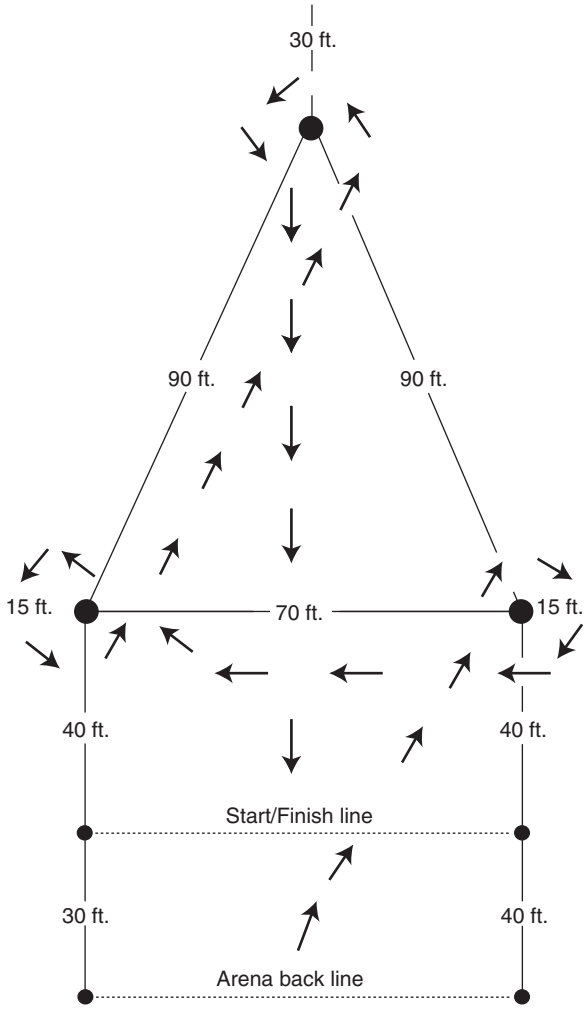

Fig. 121-5 Diagram of barrel racing cloverleaf.

CONFORMATION

Horses are predominately American QHs and Appendix horses (QH and Thoroughbred crosses), but occasionally Thoroughbred, Paint, or Arabian horses are seen. Speed, quick acceleration, and agility to slow down quickly to turn the barrel are essential. Many barrel horses have QH racehorse pedigrees. Some prefer stockbred horses, which usually have a calmer personality. Geldings are preferred. Horses usually range from 14.3 to 15.1 hands. Barrel horses are not usually as muscular and wide based as calf roping horses. They usually have long, leaner muscle mass that provides the speed and flexibility needed to perform the 360° turns.[4]

TRAINING

Futurity competitions are popular because of the amount of prize money, and training usually starts at 2 years of age. Futurity horses often have short careers because of the pressure to perform at a high level of competition at only 4 to 5 years of age, resulting in advanced osteoarthritis, often in the distal tarsal joints. Successful futurity horses seldom have long-term careers because of behavioral problems or performance-limiting injuries.[1]

Horses that are 5 years of age or older, started slowly, and are allowed to mature before performing in serious competition may compete professionally for 5 years.[2] The average age of a professional barrel horse is 10 to 15 years. Horses may compete in 50 to 100 rodeos per year and spend much time traveling. An experienced barrel horse is trained by practicing turns but rarely uses the barrels because the horse learns to anticipate the pattern and tires of it. Many professional horses are ponied (led from another horse), or are ridden just enough to keep them fit for competition, but they are never really worked unless competing.[4,6]

Older, semi-retired horses that are well trained to the barrel pattern, but not fast enough for upper-level competition, may be used for a child or beginner. These horses do make repetitive barrel pattern runs in a practice pen for the rider to learn and often have use-related injuries, requiring much maintenance to withstand the number of practice runs needed to teach a beginner.

LAMENESS EXAMINATION

A barrel horse does not run at top speed over long distances like flat racehorses; therefore fatigue-type injuries like

superficial digital flexor tendonitis or fetlock and carpal chip fractures are seen rarely.

Some of the common injuries seen in barrel horses are attributed to the twisting and turning motion of the horse at high speeds (Fig. 121-6). Other musculoskeletal problems vary by the horse's age and level of competition. A young futurity barrel horse may run up the fence, that is, the horse does not turn around the barrel but runs past it up the arena, or it may refuse to enter the arena. No lameness may be detectable, and the veterinarian has to determine whether the young horse is mentally stressed and showing behavioral problems or is responding to pain. Complaints about an older, experienced horse usually result from pain, but behavioral problems occur more often in young horses. Most barrel racers train their own horses, and the quality of training is inconsistent, and performance changes may be induced by the rider.

The teeth are evaluated to eliminate bitting problems as a cause of performance changes. Radiographic examination of the hocks is performed because of the high incidence of distal hock joint pain. The stifles also are examined to eliminate osteochondrosis as a potential source of pain. If no radiographic abnormalities are detected, several options are presented to the owner to help determine if the horse is responding to pain or is overtraining. One option is to administer phenylbutazone (2.2 mg/kg daily for 2 weeks and then 1.1 mg/kg daily for 2 weeks) for 30 days and to keep the horse in barrel-race training. If the horse returns to normal performance, then we conclude that the horse is most likely experiencing pain. If the problem does not resolve, then we try to address any behavioral problems. If problems persist, we often suggest giving the horse a 3- to 6-month break from barrel racing and have the horse work cattle or perform other less intense activities. A second option is to increase the workload and try to establish lameness that can be identified and then located with diagnostic analgesia, but few owners select this option. Because of high incidence of distal hock joint pain and the poor correlation between clinical signs and radiographic abnormalities, the centrodistal and tarsometatarsal joints can be medicated with hyaluronan, with or without corticosteroids, and the response assessed. Nuclear scintigraphic examination can be performed but often is unrewarding; however, owners may be encouraged then to increase the horse's work to see if overt lameness develops.

Fig. 121-6 A barrel horse turning a barrel. Note the pressure on the inside hindlimb. This horse is on the backside of the barrel coming out of the turn and is in correct position. At this point in the barrel turn a horse with hindlimb pain becomes uncollected and swings wide around the barrel.

An experienced horse may begin to have a change in behavior or performance rather than show an actual lameness. Behavioral problems occur more often than in other Western performance events, because the horse may experience pain at the same spot in relation to the barrel, regardless of arena size, and thus the horse begins to dread making the barrel turn.[3] A common complaint is that the horse is coming up out of the turn on the first barrel, meaning that the horse heads into the turn normally, but as the horse comes into the backside of the barrel turn, it does not want to stay in the ground or push off aggressively to the next barrel. Instead the horse comes uncollected, bounces out of the barrel, and makes a wide turn around the barrel that adds time to the run. Such behavior often is associated with distal hock joint pain, especially involving the hindlimb on the inside of the turn. The horse may not run between the barrels as it should or is slower, 3 or 4 tenths of a second off its time. Trotting the horse in hand in a small circle (1.5- to 3-m radius), mimicking the barrel turn, is helpful. This may be the only time the horse shows lameness. Determining which barrel is the problem barrel is helpful. An owner may complain that the horse will not stay in the ground for the first barrel but works fine for the second and third barrels. The horse may perform fine for the first barrel but does not make a good turn around the second barrel. The first barrel (usually going to the right) is the hardest barrel and most often a problem, because the horse is running at full speed when it reaches the barrel and must slow quickly to make the 360° turn.

When the horse is turning the barrel, the inside hindlimb appears to be under the greatest pressure (see Fig. 121-6). If the owner complains that the horse is swinging wide or pulling away from the first barrel, the horse does not want to turn to the right and is probably trying to avoid inside hindlimb pain. The outside forelimb is also under much stretching pressure as the horse goes into a barrel turn, but we also have seen horses that do not want to take the first barrel to the right and have right (inside) forelimb pain. Hindlimb lameness is more common than forelimb lameness, and less correlation exists between horses resisting a particular direction of the turn relative to a specific forelimb lameness.

DIAGNOSIS AND MANAGEMENT OF SPECIFIC LAMENESS

Distal hock osteoarthritis is the most commonly diagnosed problem, causing reduced performance or lameness. Diagnosis is based on intra-articular analgesia, radiography, response to treatment, and sometimes nuclear scintigraphy. The centrodistal and tarsometatarsal joints are treated using methylprednisolone acetate (40 to 60 mg per joint) or triamcinolone acetonide (6 mg per joint) alone, or in combination with hyaluronan (20 mg per joint). Ideally the horse should have 7 to 10 days of turnout or light exercise before returning to barrel racing, but often the competition schedule does not allow this. Response to treatment may take up to 3 weeks. If the horse does not respond to treatment, we re-evaluate the horse for lameness.

Hindlimb proximal suspensory desmitis is common in older, seasoned horses and can be a career-ending injury. Deep sand in arenas may contribute to the high incidence. Moderate lameness (grade 2 to 3 of 5) often is exacerbated by upper limb

flexion. The horse usually has no swelling or minimal swelling and no heat and pain. Local analgesia is essential to verify the source of pain. Radiography of the proximal metatarsal area is often negative, although if the condition is chronic, sclerosis or entheseous new bone may be present. Ultrasonographic examination may reveal an enlarged and hypoechoic SL, but some horses have no detectable structural abnormalities. The latter are treated by local infiltration of triamcinolone acetonide (9 to 12 mg) and reduced work. With acute, mild proximal suspensory desmitis horses often return to work in 2 to 4 weeks. We also recommend confining the horse to a small area to avoid further damage from excessive uncontrolled exercise. If ultrasonographic abnormalities are detected, the horse is confined to a small area with no riding for 60 to 90 days before reexamination. Complete healing often takes 6 to 12 months, and some horses never return to full athletic function.

Suspensory branch injuries are common in hindlimbs, especially the right, resulting in mild hindlimb lameness (grade 1 to 2 of 5), which is improved by a low plantar nerve block. Normally detectable ultrasonographic abnormalities are present, but radiographic abnormalities of the proximal sesamoid bones are unusual. Horses respond well to 60 to 90 days of small area confinement, followed by a gradual return to conditioning and resumption of competition after 4 months. We recommend the use of boots to protect the hindlimb soft tissues. If lameness is improved by a low plantar block but ultrasonographic and radiographic examinations are negative, intra-articular analgesia of the metatarsophalangeal joint and intrathecal analgesia of the digital flexor tendon sheath are performed. If the response is positive, the joint or digital flexor tendon sheath is treated with hyaluronan (20 mg) and triamcinolone acetonide (9 mg). These horses usually can continue competing but may have recurrent lameness.

QH and Appendix QHs make up most of the barrel horses. Sore feet, navicular disease, and palmar foot pain are the most frequent causes of forelimb lameness, with poor hoof conformation and farriery and hard arena surfaces being predisposing factors. Diagnosis and management are similar to those described for the team roping horse.

Proximal suspensory desmitis is also common in forelimbs. Deep arenas and long toes and low heels are predisposing factors. The prognosis for barrel racing horses with forelimb proximal suspensory desmitis is good, with most horses responding well to rest and controlled exercise for 3 to 4 months. Tendon protection boots are recommended.

Metacarpophalangeal joint synovitis results in mild lameness (grade 1 to 2 of 5) that is exacerbated by fetlock flexion. The horse often strongly resists fetlock flexion. Lameness and response to fetlock flexion are eliminated by intra-articular analgesia. Radiographic examination is usually negative. The horse is treated with intra-articularly administered triamcinolone acetonide (6 mg) and hyaluronan (20 mg). The problem may or may not recur. If recurrence is frequent, diagnostic arthroscopy is recommended.

Many times horses have undergone several types of alternative therapies (e.g., equipment changes, acupuncture, chiropractic, and herbal therapy) in an attempt to correct the perceived problems before being checked by a veterinarian. Often, for some inexplicable reason, an accurate diagnosis and conventional medical therapy is sought only after failure of these other treatments. Many owners rely on diagnosis from a fellow competitor, and request treatment that was successful in another horse. This makes client communication difficult.

SHOEING CONSIDERATIONS

Traction, especially in the deep and often muddy arenas in which horses compete, is critical. A rim shoe is used most commonly on all feet, with one rim higher than the other to provide added traction. The rounded toe provides easier breakover than a normal flat steel shoe. Hind shoes may have square toes.

Recently the natural balance shoe has gained popularity as owners are becoming more aware of good farriery principles and are trying to correct long-toe, low-heel problems. The natural balance shoe is available in steel or aluminum. The steel construction is preferred because of the added weight, which provides better traction than the aluminum shoe. The natural balance shoe has a rockered toe that eases breakover of the forelimb and is built with a wider web than a normal shoe, which benefits a sore-footed horse competing on hard surfaces.

OTHER CONSIDERATIONS

Exercise-induced pulmonary hemorrhage is common in barrel horses. The owner may complain that the horse has lost a step or has become slower. If a musculoskeletal reason for the performance change cannot be determined, a respiratory evaluation is indicated. Obvious bleeding from the nostrils rarely is seen, but endoscopic examination within 30 minutes of the barrel race often reveals tracheal hemorrhage. Presently no drug testing or rules prevent drug administration for competition. Most horses receive phenylbutazone or flunixin meglumine 4 to 6 hours before competition and furosemide (4 to 8 ml per horse).

THE EUROPEAN WESTERN PERFORMANCE HORSE

• Franco Ferrero

The Western performance sport horse has developed in Europe since the mid-1980s. Most horses are American QHs and are used for reining, a sport most popular in Germany and Italy. The Italian reining and cutting futurities for 3-year-olds offer the highest prize money. The rules governing competition usually are based on the American rules, with a few notable exceptions in Germany. Horses entered in the Reining Breeder's futurity must be 4 years of age. Strict rules govern which bits and harness are acceptable. Excessive use of force, spurs, or the whip may result in suspension of the rider.

Reining QHs usually are broken at 18 months of age and may undergo intense training in preparation for the snaffle-bit futurity at 3 years of age, but these horses rarely compete at high levels when older. Only a limited number of horses compete after 6 years of age.

TEN MOST COMMON LAMENESS CONDITIONS

The 10 most common causes of lameness in reining QHs 2 to 4 years of age are as follows:

1. Foot pain
2. Hock pain
3. Carpal pain

4. Fetlock pain
5. Stifle pain
6. Splints
7. Superficial digital flexor tendonitis
8. Desmitis of the accessory ligament of the deep digital flexor tendon
9. Suspensory ligament desmitis
10. Shoulder injury

Causes of foot pain include subsolar abscessation, solar bruising, osteoarthritis of the distal interphalangeal joint, fracture of the palmar process of the distal phalanx, osteitis of the palmar processes of the distal phalanx, and navicular syndrome.

Hoof tester examination is an essential diagnostic tool. Oblique radiographic views of the distal phalanx are invaluable for assessing the palmar processes. Poor foot conformation is often an important predisposing factor for the development of foot pain. The foot is often upright with overgrown angles of the walls and heels, flattening or convexity of the sole at the toe, and an underdeveloped frog. The shoes are often too small. Bar shoes also may prevent the heels from digging into the ground.

Osteoarthritis of the distal hock joints is common. Horses of 2 years of age have a high incidence of partial collapse of the central and third tarsal bones with secondary osteoarthritis. Carpal problems occur more commonly than in North America and include synovitis of the antebrachiocarpal and middle carpal joints, osteoarthritis, sagittal fracture of the third carpal bone, and chip fractures of the distal aspect of the radial carpal bone. Conformational abnormalities such as carpus valgus, calf knees (palmar deviation of the carpal joints), tied-in knees, and offset knees may be important predisposing factors. The limited number of blood lines available for breeding may influence the incidence of these conformational abnormalities. Bench or offset knees also may predispose horses to the high incidence of splints causing lameness, especially in 2-year-old horses.

CHAPTER • 122

The Tennessee Walking Horse

James T. Blackford and James C. Sternberg

DESCRIPTION OF THE SPORT

The Tennessee Walking Horse, commonly called the Walking Horse, is a light horse breed developed in middle Tennessee for use on southern plantations during the eighteenth century. The average Walking Horse is 15 to 16 hands tall and weighs 500 to 600 kg. The Tennessee Walking Horse is a composite breed, created by crossbreeding Canadian and Narragansett Pacers, Morgan, Standardbred, and Thoroughbred horses. The Tennessee Walking Horse Breeders' and Exhibitors' Association was formed in 1935. Because of the versatility of the Walking Horse, along with a characteristic racking gait within the breed, a second breed association was recognized in 1971, the Racking Horse Breeders' Association. This group of horses is commonly referred to as the Racking Horse.

The Walking Horse performs three gaits: the flat-foot walk, running walk, and canter. Both walks are four-beat gaits, with one foot up and three feet in various phases of striking the ground. The footfall sequence is left hind, left front, right hind, and right front. High-stepping forelimbs with an extended reach characterize the flat-foot walk. The hind foot overreaches the imprint of the front foot by 15 to 55 cm in a straight, smooth, gliding motion. This over-stride is unique to the breed and is referred to as the big lick. The horse's head and neck nod, and the ears flick forward and backward in rhythmical fashion with the rise and fall of the front feet. The appearance is that of pulling with the forelimbs and driving or pushing with the hindlimbs. The speed of the flat-foot walk is from 4 to 8 miles per hour. At the running walk, the gait is basically the same but faster (10 to 20 mph). The canter is a three-beat gait, with a left or right lead. In the canter the horse lifts the forehand, giving an easy rise and fall, in a rolling motion. The gait is referred to commonly as the rocking-chair canter because of the high, rolling movement of the horse's body.

The Racking Horse gait is a bilateral four-beat gait, with one foot striking the ground with the other three limbs in various phases of elevation. The gait often is referred to as the single-foot gait. When shown, the Racking Horse performs the show walk, slow rack, and fast rack. The show walk is a smooth, collected, slow and easy four-beat gait. At the slow rack the horse's head is held with the neck arched and ears erect. The fast rack is similar in form to the slow rack, but the horse displays speed and leg action. The natural head nod must not be exaggerated at the slow or fast rack.

In both breeds the collected gaits of the show horse shift the center of gravity caudally, compared with most other light breeds, with increased loads on the hindlimbs resulting in a high incidence of hindlimb lameness.

Both breeds are used for show, trail, and pleasure riding. Horses are shown at halter, harness, and under tack, with English or Western saddles. Horses that are shown wear a light shoe similar to a standard keg shoe, a plantation shoe, or a performance shoe, depending on the class. The plantation shoe cannot exceed 3.8 cm in width and 1.3 cm in thickness, and the heel calk cannot exceed 2.5 cm in height. The performance shoe, or stack, is a shoeing technique used to accentuate the show horse gaits. The shoe is constructed of several layers of flat or wedge pads, stacked one on top of another, placed between a nail pad at the solar margin and a metal shoe on the contact surface. Pads are made of leather, plastic, or hard rubber. The amount of height or extension the shoe provides must not exceed 50% of the natural hoof wall length, measured from the coronary band to the tip of the toe. Pleasure horses are commonly flat shod.

Although the highest population of Walking and Racking horses is presently in the southeast United States, they are becoming more popular across North America, especially for trail and pleasure riding, because of the physical endurance and

4. Fetlock pain
5. Stifle pain
6. Splints
7. Superficial digital flexor tendonitis
8. Desmitis of the accessory ligament of the deep digital flexor tendon

The Tennessee Walking Horse

James T. Blackford and James C. Sternberg

DESCRIPTION OF THE SPORT

The Tennessee Walking Horse, commonly called the Walking Horse, is a light horse breed developed in middle Tennessee for use on southern plantations during the eighteenth century. The average Walking Horse is 15 to 16 hands tall and weighs 500 to 600 kg. The Tennessee Walking Horse is a composite breed, created by crossbreeding Canadian and Narragansett Pacers, Morgan, Standardbred, and Thoroughbred horses. The Tennessee Walking Horse Breeders' and Exhibitors' Association was formed in 1935. Because of the versatility of the Walking Horse, along with a characteristic racking gait within the breed, a second breed association was recognized in 1971, the Racking Horse Breeders' Association. This group of horses is commonly referred to as the Racking Horse.

The Walking Horse performs three gaits: the flat-foot walk, running walk, and canter. Both walks are four-beat gaits, with one foot up and three feet in various phases of striking the ground. The footfall sequence is left hind, left front, right hind, and right front. High-stepping forelimbs with an extended reach characterize the flat-foot walk. The hind foot overreaches the imprint of the front foot by 15 to 55 cm in a straight, smooth, gliding motion. This over-stride is unique to the breed and is referred to as the big lick. The horse's head and neck nod, and the ears flick forward and backward in rhythmical fashion with the rise and fall of the front feet. The appearance is that of pulling with the forelimbs and driving or pushing with the hindlimbs. The speed of the flat-foot walk is from 4 to 8 miles per hour. At the running walk, the gait is basically the same but faster (10 to 20 mph). The canter is a three-beat gait, with a left or right lead. In the canter the horse lifts the forehand, giving an easy rise and fall, in a rolling motion. The gait is referred to commonly as the rocking-chair canter because of the high, rolling movement of the horse's body.

The Racking Horse gait is a bilateral four-beat gait, with one foot striking the ground with the other three limbs in various phases of elevation. The gait often is referred to as the single-foot gait. When shown, the Racking Horse performs the show walk, slow rack, and fast rack. The show walk is a smooth, collected, slow and easy four-beat gait. At the slow rack the horse's head is held with the neck arched and ears erect. The fast rack is similar in form to the slow rack, but the horse displays speed and leg action. The natural head nod must not be exaggerated at the slow or fast rack.

In both breeds the collected gaits of the show horse shift the center of gravity caudally, compared with most other light breeds, with increased loads on the hindlimbs resulting in a high incidence of hindlimb lameness.

Both breeds are used for show, trail, and pleasure riding. Horses are shown at halter, harness, and under tack, with English or Western saddles. Horses that are shown wear a light shoe similar to a standard keg shoe, a plantation shoe, or a performance shoe, depending on the class. The plantation shoe cannot exceed 3.8 cm in width and 1.3 cm in thickness, and the heel calk cannot exceed 2.5 cm in height. The performance shoe, or stack, is a shoeing technique used to accentuate the show horse gaits. The shoe is constructed of several layers of flat or wedge pads, stacked one on top of another, placed between a nail pad at the solar margin and a metal shoe on the contact surface. Pads are made of leather, plastic, or hard rubber. The amount of height or extension the shoe provides must not exceed 50% of the natural hoof wall length, measured from the coronary band to the tip of the toe. Pleasure horses are commonly flat shod.

Although the highest population of Walking and Racking horses is presently in the southeast United States, they are becoming more popular across North America, especially for trail and pleasure riding, because of the physical endurance and

gentle disposition of the breeds. The show season generally is considered to be year-round, picking up in the spring and peaking in the fall with the national championships. The Tennessee Walking Horse National Celebration is held in Shelbyville, Tennessee, each year and is an 11-day event ending with the crowning of the national champions on the Saturday before Labor Day. The Racking Horse Celebration is held each year in Decatur, Alabama, during the last 2 weeks in September.

LAMENESS EXAMINATION

Lameness evaluation of the gaited horse is best performed with the horse under complete tack with a rider. It is impossible to duplicate the head set, balance, and shifting of the horse's center of gravity caudally without a rider. The horses generally exercise in a large, oval arena, and to perform a good evaluation, one needs to provide a place where the horse has room to work in all gaits. The ground surface in this area should be firm. A veterinarian's impression when evaluating a show horse in performance shoes for the first time will be that the horse's problem must be in the forelimb and more specifically the foot. In light of the negative publicity the stacked shoe receives, focusing one's attention on this area is easy. Even as the horse is walked at halter, this impression may not change, because of the awkward nature of the horse handling the bulky shoe. In our experience, few problems are associated directly with the shoe, except hoof wall avulsions, when the shoe is accidentally pulled off in the show ring. Measures to control bleeding must be taken immediately, followed by good wound care. Hoof wall composites then can be used to restore hoof wall function. If an elevated shoe is removed completely and suddenly from an immature, developing horse early in training, removal causes a mechanical flexor contracture. The horse knuckles over at the fetlock joint because of the pain associated with pulling of the deep and superficial digital flexor tendons.

Unfamiliarity with the standard gaits of Walking and Racking horses, especially when shod with a stacked shoe, may result in confusion with ataxia, particularly at faster speeds. Anecdotally, our impression is that a high incidence of cervical vertebral malformation occurs in Tennessee Walking Horses, so this should be kept in mind.

Tennessee Walking Horses are stoical and seem to have a high pain tolerance. Problems encountered in the flat-shod Walkers or Rackers mirror the lameness problems seen in other light breeds; therefore the following discussion focuses on show horses in stacked shoes. The hoof tester evaluation is of limited value on the front feet of performance-shod horses. Careful palpation and manipulation of the limbs are performed routinely. Careful evaluation of the foot and shoe should not be overlooked. Pressure-shoeing techniques by unscrupulous owners and trainers, which causes soreness and increases the big lick, occasionally arise in a performance-shod horse and should not be overlooked. The technique is performed by over-trimming the hoof wall and thus increasing sole pressure. A carefully placed nail in the nail pad encroaching on the sole or the sensitive laminae may be noted. A foreign object, such as a stone inserted between the pad and the sole inflict discomfort. Digital pulses, tapping on the hoof wall with hoof testers or a shoeing hammer, and response to nerve blocks may determine the problem.

Problems seen in the forelimbs commonly are associated with imbalances in the shoeing, leading to an uneven height of the forelimb carriage. To evaluate the forelimb carriage, the observer should draw an imaginary line at the chest level, watching the carpal action to determine which leg is carried lower to the imaginary line as the limb advances, indicating the problem limb. When this problem is detected, careful evaluation of the shoeing technique and comparison between limbs are indicated. Correction of foot imbalance may resolve the problem. Osteoarthritis of the distal interphalangeal joint (low ringbone) frequently is seen in older horses but is not always correlated with lameness. Proximal suspensory desmitis usually is caused by slipping in an elevated shoe and may be associated with localized pain on palpation. Bicipital bursitis is seen occasionally. The horse may have asymmetry in shoulder motion and pain on palpation of the area, especially when the limb is raised. Abduction or adduction of the shoulder is performed. Like most breeds, sole abscesses are common in flat or performance-shod horses, as is laminitis.

The highest percentage of lameness seen in our practice with Walking and Racking horses is associated with the hindlimbs, because of loading of the hindlimbs during exercise. As each hindlimb strikes the ground and the horse's weight is carried through the stride, a rotational, twisting motion also is seen throughout the entire limb before the leg is advanced. This is especially noticeable in the Walking Horse at the faster gaits. The shifting weight and the twisting motion increase stress on the joints and surrounding support structures. Osteoarthritis of the distal hock joints and stifle is common. A positive response to the Churchill test is helpful in isolating pain to the distal hock joints. Careful palpation of the medial patellar ligament is particularly important in this type of sport horse, because at one time almost all of the show horses were subjected to medial patellar desmotomy with hopes of improving the over-reaching stride of the rear legs. Although the medial patellar desmotomy site only occasionally is found to be the origin of the lameness in these horses, the possibility should not be overlooked. The practice is not as common today as in the past; however, many trainers from the old school feel that having the desmotomy performed is important. Upper- and lower-limb flexion tests are performed. Local analgesia is used to define the source of pain. Trochanteric bursitis occurs in Walking and Racking horses and is related to the rotational, twisting motion of the hindlimbs. The horse has pain on deep palpation over the greater trochanter of the femur, during upper limb flexion tests, and when the hip is stretched forward or backward, abducted or adducted, and rotated.

Other conditions are encountered in these horses. Some have muscular weakness in the hindlimbs, especially in young unconditioned horses. When weakness is combined with straight hindlimbs, instability of the patella is common. Chronic hip and stifle soreness caused by a trailer on the outside of the shoe may be an underlying cause of lameness. Osteochondrosis occurs in the forelimbs and hindlimbs. We see a substantial number of horses that are thought to be lame but have equine protozoal myelitis.

CHAPTER • 123

Lameness in the American Saddlebred and Other Trotting Breeds with Collection

Scott D. Bennett

DESCRIPTION OF THE SPORT

The American Saddlebred, Morgan, Hackney Pony, National Show Horse, and Arabian (see Chapter 124) show horses are described as trotting breeds with collection. Lameness in disciplines such as dressage, road horses, and road ponies is similar. The American Saddlebred and National Show Horse have five gaits: walk, trot, canter, slow gait, and rack. The slow gait and rack are manmade gaits. These horses also perform in three gaited classes (walk, trot, and canter), fine harness classes, pleasure driving, pleasure-gaited classes, and equitation. Morgan and Arabian horses are shown similarly, but without the slow gait or rack. Hackney ponies are shown in harness, pleasure driving, and road pony classes. Show classes are further divided for professional, amateur, and juvenile riders. Equitation, hunt seat, Western, and numerous young horse and in-hand halter classes are available.

In road horse classes, Standardbreds, Morgans, American Saddlebreds, or Standardbred-cross horses are shown at the walk, trot, and road gait pulling a bike similar to a sulky used for Standardbred racehorses. These horses usually are more animated in gait than Standardbred racehorses and go both ways around the ring when performing. The road gait is a high-speed performance gait.

To understand lameness in the gaited show horse, the veterinarian must first understand the difference in locomotion between running and gaited horse disciplines. Concussion (impact) is a part of every gait. How the horse distributes concussion is related directly to athletic ability and the longevity of a horse's career. Better equine athletes are more efficient in the distribution of concussion through the limbs and body. The superior equine athlete appears capable of using energy of concussion efficiently and distributing it for dispersion and recovery. Normally kinetic or stored energy from proper distribution of concussion causes recoil of the tissues receiving the energy of concussion. Tissue injury results in an inability to disperse concussive energy properly. Maintaining healthy hoof wall, bone, cartilage, tendons, ligaments, and muscles in a good conditioning and gait management program is essential. The veterinarian must be familiar with the gaits, because gait analysis is an important part of evaluating poor performance and subtle lameness.

Gaits of the show horse are complex and must be synchronous to maintain distribution of concussion. Synchrony must be achieved in up to five gaits and is altered by the different gait specifications. The normal load distribution between forelimbs and hindlimbs in the show horse is about 35% and 65%, respectively (see Chapter 2). The show horse does not have to perform at speed. Compared with many sport horses, synchrony of concussion and weight distribution are totally different, and because much concussion is dispersed through the hindlimbs, hindlimb lameness is more important. In some other sports horses the head and neck are raised and lowered with the stride, a movement that assists in balance, energy distribution, and propulsion. The show horse, like the dressage horse, maintains a fixed and flexed head and neck carriage. This further shifts the balance and energy of concussion to the hindlimbs.

Show horses carry more body weight for a fleshier look than the greyhound-like racing counterparts. Riders of show horses, as a rule, also are heavier than racing jockeys.

Longevity of show horses compared with racehorses is related directly to speed of performance, which is dramatically less. Racehorses must change energy distribution at high speed quickly, potentially leading to catastrophic breakdown, but such actions and injuries in show horses are rare. A show horse often can remain competitive into the late teens and early twenties, but chronic wear and tear may result in lameness.

Although show horses do not perform at speed, high head carriage and high leg action and motion are strenuous. Show horses perform numerous gait changes and transitions going both directions of the ring, and for a high-level (stake class) five-gaited class to last from 30 to 40 minutes is not unusual.

Because five-gaited movements and transitions are complex and arduous, compensatory lameness is common. A methodical approach to lameness diagnosis must be used to differentiate primary and compensatory lameness. A superior show horse distinctly separates its different gait movements, raising each carpus above the horizontal, with a high hock action. The horse drives off its hindlimbs with a flexed high head and neck carriage. Responsiveness to the bit, with an alert expression and attitude, and forward placement of the ears are desirable. Just as racehorses are bred for speed, show horses are bred for animated motion.

AMERICAN SADDLEBRED

The American Saddlebred has a long history and aptitude for different gaits and is derived from many different lineages. The breed was developed by free men in a young free country where the best horses could be bred to the best. The American Saddlebred was developed as a horse of usefulness and beauty that could work in the field, pull a buggy or carriage, and have gaits that were smooth for travel under saddle.

The ability of the American Saddlebred to perform lateral gaits (slow gait and rack) came from the Narragansett pacers, which were among the earliest known easy-riding pacers. The Narragansett pacers were derived from French Canadian pacers of Arabian and Andalusian descent that were bred 100 to 200 years before the American Revolutionary War and had a comfortable saddle gait. Early settlers brought these horses, known as saddlers, to Kentucky. During the late 1830s and 1840s, many of these easy-riding saddlers were bred to the Thoroughbred foundation sires, Denmark and Montrose. These crossbreeds were then bred to horses of trotting blood, from which the Standardbred breed was developed. Offspring of these crosses became favorite mounts of cavalry during the

Civil War, because they had an easy gait, versatility, and an ability to withstand the pressures of war. On April 7, 1891, the American Saddlebred Breeders Association was founded in Louisville, Kentucky, and became the first all-American breed registry. In recent years the American Saddlebred has gained popularity in South Africa and has been crossed with European Warmblood and carriage bloodlines (e.g., Dutch Carriage Horse). During the 1980s, the National Show Horse was derived from American Saddlebred and Arabian lineage.

The American Saddlebred ranges in height from 152 to 178 cm (15 to 17.2 hands; average 160 cm [15.3 hands]) and varies in weight from 455 to 545 kg. Colors include chestnut, bay, black, gray, golden (palomino), and spotted (chestnut, black, or bay mixed with white). As described in *Modern Breeds of Livestock*,[1]

> *the American Saddlebred has a strikingly long neck and considerable arch to the neck. The American Saddlebred is refined in appearance; has long, sloping pasterns that give spring to the stride; has a long, level croup; is strong and short-coupled; and has a back with high, well-defined withers above the level of the hips. The American Saddlebred is famous for refinement, smoothness, proportion, and a beautiful and handsome presentation and projects an alert, curious, expressive personality.*

There are shows for American Saddlebreds throughout the United States and South Africa. The World Championship Horse Show is held each year in Louisville, Kentucky. Shows are run under the guidelines of USA Equestrian, which establishes rules, regulations, and drug-testing procedures. A veterinarian must be aware of current drug and medication rules, and failure to do so may result in fines and penalties to the horse, owner, and trainer.

SADDLEBRED GAITS

The five gaits of the American Saddlebred and other gaited horses are as follows[2]:

1. *Walk and flat walk*—The flat walk is a relaxed, elastic, ground-covering, and collected four-beat gait, maintaining proper form and consistency in stride. The gait is required in pleasure classes. The animated walk is a highly collected gait, exhibiting much primp at a slow, regulated speed, with good action and animation. The gait can be a two- or four-beat gait and is performed with great style, elegance, and airiness of motion.
2. *Trot*—The trot is a natural, two-beat diagonal gait. A balanced trot features coordinated motion with straight, true shoulder motion of forelimbs, with flexing hocks carried close together. The gait is executed in a highly collected manner and should display the horse's athletic ability.
3. *Slow gait*—The slow gait was developed from the pace to be a four-beat gait with each of the feet striking the ground separately. In the takeoff the ipsilateral front foot and hind foot start almost together, but the hind foot contacts the ground first. The slow gait is a highly collected gait with most of the propulsion coming from the hindquarters, whereas the forequarters assist in the pull of the final beats. The slow gait is not a medium rack. The slow gait is a restrained gait, executed slowly, but with true and distinct precision, and speed is penalized. The gait is high, lofty, brilliant, and restrained, denoting the style, grace, and polish of the horse.
4. *Rack*—The rack is a four-beat gait in which each foot meets the ground at equal, separate intervals. The gait is smooth and highly animated, performed with great action and speed in a slightly unrestrained manner. Desired speed and collection are determined by the maximum rate at which a horse can rack in form. Racking in form should include the horse remaining with a good set head and should be performed by the horse in an effortless manner from the slow gait, at which point all strides become equally rapid and regular. Any tendency to become trotty, pacey, or hitchy-gaited is penalized.
5. *Canter*—The canter is slow, lofty, and fluid, with a definite three-beat cadence. High action, a good way of going, and proper collection are paramount. The propulsion is in the hindquarters, with the leading forelimb sustaining the concussion of the final third beat. A brief interval occurs when all feet are off the ground. The gait is an ambidextrous gait, executed on the lead that is toward the center of the ring to relieve stress and aid in balance.

TEN MOST COMMON LAMENESS CONDITIONS

The 10 most common lameness conditions in show horses are the following:

1. Distal hock joint pain (tarsitis)
2. Gluteal myositis and back pain
3. Palmar heel pain, including contracted heels, sheared heels, quarter cracks, and navicular syndrome
4. Osteitis of the distal phalanx (pedal osteitis)
5. Osteoarthritis and osteochondrosis of the tarsocrural joint
6. Osteoarthritis and osteochondrosis of the fetlock joint
7. Osteoarthritis and osteochondrosis of the stifle joint
8. Suspensory desmitis
9. Tendonitis and desmitis, including deep digital flexor tendonitis, superficial digital flexor tendonitis, and desmitis of the accessory ligament of the deep digital flexor tendon
10. Splint exostosis

LAMENESS EXAMINATION

The history of lameness and poor performance must be discussed with the trainer and rider to seek their perception. This should include noting any problems with the bridle and the way a horse pulls on the bit and bridle. Show horses with hindlimb lameness often fight the bit and try to lower the head, an observation known as diving in the bit. Horses that become one-sided in the bit may have contralateral hindlimb or ipsilateral forelimb lameness. Faulty bit and bridle placement may cause gait abnormalities particularly of the hindlimbs. Keeping the head up and fixed in position in a horse that dives in the bit is difficult. A horse with forelimb lameness is more likely to raise up out of the bridle. A horse cannot produce a gait properly or do proper gait transitions when being pushed into an uncomfortable bridle or if the rider is using the bit improperly. It is important to determine if the rider is using the bit to balance the horse or themselves. A rider using the bit poorly can induce a gait abnormality. Bit and bridle responsiveness is often a wild card that must be played during examination of the show horse for gait abnormalities and lameness.

Problems with a particular gait may indicate the source of lameness. Back pain is seen in horses that have difficulty in the canter, a condition known as *being broke in the middle*. This occurs with asynchronous movement of the forelimbs and hindlimbs. Broke in the middle also can be caused by stifle pain that causes a reduction in the cranial phase of the stride. Most commonly, however, broke in the middle is caused by stringhalt. Stringhalt prevents the limb from moving forward

at a time when the forelimbs are required to go faster, causing a mismatch in synchronization between the forelimbs and hindlimbs. Distal hock joint pain and back pain can cause a hitching motion of the hindlimbs, jerking the lame limb caudally and leaving the hocks behind the motion.

Examination first begins in the stall before the horse is worked. Careful palpation with emphasis on the tendons, ligaments, joint capsules, and bulbs of the heels should be performed. Palpation of the back and gluteal muscles before working is important, because the horse can warm out of soreness in these areas. Digital pulse amplitudes should be assessed.

The horse should be evaluated during movement under tack. Harness horses, road horses, and ponies should be examined while working with and without the over-check (checked up and without the check). Five- and three-gaited horses should be examined performing each gait going in both directions. Often horses are only lame while going in one direction or only in the turns. Horses with lameness from the hock distally are often worse with the lame limb on the inside, whereas those with pain located more proximally are lame with the lame limb on the outside of the turn. Forelimb lameness is usually worse with the affected limb on the inside.

In most show horses flexion tests can be performed with a rider or in harness. The horse's temperament may make this difficult, but I find that the horse being ridden or jogged in the cart after flexion is helpful.

DIAGNOSTIC ANALGESIA

Diagnostic analgesia in show horses is similar to that described for other sport horses. I start distally and work proximally.

IMAGING CONSIDERATIONS

Conventional and computed radiography are used extensively. Scintigraphy is most useful in horses with complex lameness, because primary and compensatory issues are difficult to differentiate. The solar scintigraphic view is mandatory to evaluate horses with palmar heel pain in which radiographs are negative, because modeling of the navicular bone and distal phalanx should be assessed carefully. Areas of increased radiopharmaceutical uptake in the distal phalanx may indicate excessive pressure that can be relieved by corrective shoeing. Thermography is of value in diagnosing tendonitis, sole pressure, muscle inflammation, and suspensory desmitis. Ultrasonographic examination is useful to confirm and assess damaged soft tissues and healing. Diagnostic arthroscopy is used occasionally.

SHOEING GAITED HORSES

Shoeing gaited horses to assist with motion and gait transitions is an art form in itself. In general a long toe and high heel in front help to delay breakover and cause high knee action. In the past, weighted shoes and lead weights screwed into the bottom of shoe pads were used to induce animation. In recent years a transition to lighter is better has occurred, and now the focus is on fitness and training techniques to teach the horse to elevate its limbs to achieve animation. Shoeing depends to a great extent on the horse's ability, conformation, and desired gait performance (e.g., five-gaited, three-gaited, or harness). For example, a three-gaited horse may have a long foot with long toe and heel length to delay breakover in the forefeet and hindfeet. This gives the extreme highly animated knee and hock action expected from a top three-gaited horse. In contrast, in a five-gaited horse a lower hind heel angle is used to assist with a longer hindlimb stride needed for the slow gait and rack. Compared with three-gaited horses, lighter and shorter front feet are maintained in five-gaited horses to promote speed at the trot and rack.

Shoeing with high heels and long toes, with or without pads, predisposes the American Saddlebred to contracted heels, sheared heels, and quarter cracks. The recent use of cushion polymer compounds to maintain frog pressure is helpful, because frog pressure is lost with high heels and pads. Cushioned polymers placed in the collateral sulci (grooves) of the heel and over an atrophied frog have dramatically reduced hoof problems. Medial to lateral hoof balance is paramount.

SPECIFIC LAMENESS CONDITIONS

Distal Hock Joint Pain and Distal Tarsitis

There are two types of show horses, those that have distal hock joint pain and those that are getting it. Show horses with distal hock joint pain typically jerk the hindlimb caudally (hitching) and leave the hocks behind in motion. Many horses stab the toe, rather than landing normally with the heel first.

Distal hock joint pain without radiographic abnormality is common in 2- and early 3-year-olds just starting to rack. As training and showing proceed, radiographic evidence of osteoarthritis, such as loss of joint space, can become apparent as early as 5 years of age and may be severe by 12 years of age.

The tarsometatarsal joint is by far the most valuable point of intra-articular injection in show horses. Occasionally, injection of the centrodistal joint also is required. I prefer to use hyaluronan and a low-dose corticosteroid combination and recommend oral supplementation with glucosamine and chondroitin sulfate–containing products. Magnetic therapy appears beneficial. Horses with lameness that does not improve are considered candidates for shock wave therapy. Arthrodesis of the distal hock joints, using a drilling technique combined with laser ablation, is used in horses with severe pain. Although cunean tenectomy was once widely used, effects of the procedure are short-lived, and I do not recommend it. If the horse is hitching through the turns of a show ring, a 45° flat outside trailer is used on the hind shoe for support. The shoe is set back, and the toe is squared or rolled to improve breakover.

Gluteal Myositis and Back Pain

Show horses are prone to gluteal myositis and back pain, which are often secondary to primary distal hock joint pain. A willing horse hyperflexes its back to compensate for lower hindlimb pain. The middle gluteal muscle passes over the greater trochanter of the femur and the trochanteric bursa. Gluteal myositis and tendonitis are common sequelae to distal limb pain, but they can cause primary lameness. Trochanteric bursitis (whorl bone disease) can accompany gluteal myositis.

In horses with subacute gluteal myositis, upper limb flexion may stretch the gluteal muscles and produce a transient improvement in gait. Transient improvement may be seen by gently massaging the greater trochanter and gluteal muscles. However, in horses with chronic myositis with involvement of the trochanteric bursa, deep massage and pressure may make lameness worse. Horses with subacute primary gluteal myositis commonly have a tight-rope trot (plaiting). Plaiting is associated with distraction and rotation of the hindlimb, with subsequent lateral movement of the hip, motion that may cause gluteal muscle strain. Horses that plait usually have base-narrow conformation, and corrective trimming in the form of spreading the stance (lowering the outside hoof walls) may help.

Back pain is identified easily using digital pressure along the thoracolumbar region, abaxial to the spinous processes. Many horses are so painful that one can almost put them on the ground with digital pressure. Diagnostic analgesia usually

is not necessary. However, small amounts of local anesthetic solution injected at numerous sites along the affected muscles may give enough relief to allow evaluation for lameness that has been hidden by back or gluteal pain.

Management of horses with gluteal myositis and back pain requires a multifaceted approach, including local injection of Sarapin and corticosteroids. In most horses non-steroidal anti-inflammatory drugs (NSAIDs), methocarbamol, electrical stimulation, magnetic therapy, therapeutic ultrasound, and anti-concussion saddle pads are used in various combinations. Exercise regimens using stretching and flexing during the warm-up period are also beneficial. Acupuncture and chiropractic modalities often are used and can be of benefit if performed by skilled practitioners. Shock wave therapy may prove to be beneficial. Diagnosis and treatment of primary lameness problems, if present, are of utmost importance.

Palmar Heel Pain

Because show horses are shod intentionally with a high heel and long toe to produce high motion, they are prone to contracted and sheared heels. Full or wedge pads are often applied to achieve the desired motion, and the lack of frog pressure can cause atrophy of the soft tissues of the heel. Without proper frog support, the bulbs of the heel contract and sheared heels often develop. As the heels contract or sheared heels develop, more stress is applied to the quarters, predisposing the hooves to quarter cracks. Differentiation of causes of palmar heel pain is critical but difficult, because palmar digital analgesia affects these conditions and navicular syndrome similarly.

Recently more concern has arisen about maintaining frog pressure. Soft, acrylic polymers are now used for frog support in horses with frog atrophy. Turnout for several months, during which the horse is barefoot, may help. Expansion springs can be used to assist in re-establishing proper heel conformation. Severe quarter cracks are repaired using the techniques of lacing, applying screw compression plates, or nailing. Floating the heel and quarter located under the crack is important to reduce weight bearing, allowing showing to continue.

Navicular disease is not uncommon, but in horses without abnormal radiological findings the diagnosis should be confirmed using scintigraphy. The aforementioned conditions of the hoof capsule and supporting soft tissues are much more common.

Treatment of soft tissue causes of palmar heel pain involves maintaining comfort while proper anatomy is re-established. Corrective shoeing, NSAIDs, and long-term foot blocks often are used. If navicular disease is confirmed, intra-articular treatment of the distal interphalangeal joint using hyaluronan and corticosteroids is recommended. Drugs aimed at improving peripheral perfusion or decreasing intra-osseous pressure such as isoxsuprine may be useful with NSAIDs, long-term foot blocks, and corrective shoeing. Shock wave therapy appears promising in managing palmar heel pain.

Osteitis of the Distal Phalanx

In horses with high stepping gaits the distal phalanx is prone to injury. Trauma to the solar margin such as bruising and fracture occurs. A careful evaluation for improper sole pressure or medial to lateral hoof imbalance should be performed. Well-exposed and well-positioned radiographs are essential. Digital venography may reveal compression of blood vessels within the hoof capsule and is useful to pinpoint a location of trauma.

Fractures of the distal phalanx are rare. Palmar scintigraphic views are useful to diagnose fractures and other areas of distal phalanx trauma and can help to formulate a corrective shoeing plan. Thermography may be useful for diagnosis of distal phalanx trauma.

For horses without distal phalanx fracture, management includes corrective balancing and shoeing to relieve improper sole pressure and to provide support, NSAIDs, and isoxsuprine. If effusion of the distal interphalangeal joint is present, intra-articular treatment with hyaluronan and corticosteroids may help.

Osteoarthritis and Osteochondrosis of the Tarsocrural Joint

Lameness of the tarsocrural joint is not as common as distal hock joint pain. Osteochondrosis of the tarsocrural joint in show horses is similar to that described for other sport horses. The most common location is the distal intermediate ridge of the tibia. Although show horses with osteochondrosis lesions may compete successfully without surgical intervention, effusion and capsulitis are indications that surgery should be performed. Prognosis after arthroscopic surgery is favorable. However, prognosis for for show horses with trochlear ridge lesions is guarded. Osteophytes and small fragments of the distal, medial trochlear ridge are not a major source of lameness.

The diagnosis of osteoarthritis of the tarsocrural joint is derived from the results of physical examination, flexion tests, diagnostic analgesia, and radiography. Horses with early osteoarthritis of the tarsocrural joint are managed with intra-articular injections of hyaluronan, with or without corticosteroids. Oral supplementation with glucosamine and chondroitin sulfate-containing compounds appears beneficial. Intramuscular and intravenous administration of polysulfated glycosaminoglycans and hyaluronan, respectively, are helpful. NSAIDs may be necessary. Horses with chronically boggy hocks usually respond well to routine intra-articular medications, but if they are refractory, I add 0.5 ml atropine sulfate.

Osteoarthritis and Osteochondrosis of the Fetlock Joint

Conditions of the fetlock joint in show horses are essentially the same as seen in other sport horses. The most common conditions are osteochondral fragments of the proximal dorsal aspect of the proximal phalanx and sesamoiditis. Plantar process osteochondritic fragments are uncommon but are recognized. During prepurchase examinations, I obtain lateromedial radiographic views of each metatarsophalangeal joint specifically to evaluate for plantar process fragments. Fractures of the proximal sesamoid bones occur infrequently. Osseous cyst-like lesions of the distal aspect of the third metacarpal bone and osteochondritis dissecans lesions of the sagittal ridge of the third metacarpal bone occur infrequently and are less devastating than in racing breeds. Mineralized proliferative synovitis lesions are often confused with osteochondral fragments, but show horses with this condition have a favorable prognosis. Primary osteoarthritis of the fetlock joint is seen commonly in show horses that wing the lower limb while moving, but radiographs are often negative.

Diagnosis of lameness of the fetlock joint is routine. Nuclear scintigraphy is most useful in diagnosing sesamoiditis.

Arthroscopic removal of osteochondral fragments of the proximal phalanx is not always necessary, because many show horses compete well and require little maintenance therapy when fragments involve the front fetlock joints. When fragments involve the hind fetlock joints, arthroscopic removal is recommended, because these horses have gait abnormalities characterized by a skipping motion that are accentuated at the rack and slow gait.

Horses with sesamoiditis respond well to corrective shoeing (lowering the heel), NSAIDs, isoxsuprine, and injection of hyaluronan and corticosteroids into the fetlock joint. Shock wave therapy appears to be effective in managing horses with chronic sesamoiditis and collateral ligament damage.

Osteoarthritis and Osteochondrosis of the Stifle Joint

Osteoarthritis of the stifle joints is a common lameness in young horses, particularly in horses being pushed to perform

at a young age. Normal weight distribution favoring the hindlimbs, coupled with learning the slow gait and rack at a young age, predispose the horses to stifle pain. Horses with stifle lameness usually have a shortened cranial phase of the stride and are said to be humping up in the hip at the beginning of the caudal phase of the stride. Lameness often is pronounced with the limb on the outside of the ring and is worse in the turns. Diagnosis is made using gait analysis, diagnostic analgesia, radiography and, if necessary, nuclear scintigraphy. Subchondral bone cysts of the medial femoral condyles and osteochondritis dissecans of the trochlear ridges of the femur are commonly diagnosed in young show horses with stifle effusion. Arthroscopic surgery, debridement, and fragment removal are recommended in those horses with effusion and lameness. Prognosis for a five-gaited horse with osteochondritis dissecans of the stifle is guarded, even with surgery. Many of these horses can compete successfully in other divisions such as harness, pleasure driving, and equitation.

Distal patellar fragmentation and cartilage damage is seen in older horses, and horses respond well to intra-articular injections of hyaluronan and corticosteroids. Arthroscopic surgery is recommended in horses refractory to this therapy.

Lateral luxation of the patella occasionally is diagnosed in foals and has a guarded prognosis. Upward fixation of the patella is seen in young horses with under-developed quadriceps muscles. Most improve with training in a jog cart to build up the hindlimb musculature in lieu of intense riding and training. Trainers must be advised to be patient. Medial patellar desmotomy should be used as a last resort and should be done only if radiographs of the stifle are negative.

Horses with early osteoarthritis and negative radiographs are managed by decreasing training intensity and implementing a jogging program to develop the hindlimb musculature. A weighted drag behind the cart is added later, before the normal riding program resumes. Internal blisters are used commonly. Intra-articular injection of hyaluronan and corticosteroids alleviates clinical signs, but without modification of exercise the results are short-lived.

Horses with chronic osteoarthritis are maintained using intra-articular injections, oral supplements, intramuscularly and intravenously administered polysulfated glycosaminoglycans, and NSAIDs.

Suspensory Desmitis

Show horses with long pasterns and high heels are prone to suspensory desmitis because the fetlock drops excessively and stretches the suspensory ligament. Show horses trained in deep footing (sand or mud) are at increased risk for suspensory desmitis. Avulsion fracture of the third metacarpal bone may occur in association with suspensory desmitis. Suspensory desmitis is more common in the forelimb than in the hindlimb. Treatment of show horses with suspensory desmitis involves rest, NSAIDs, periligamentous injection of corticosteroids, leg sweating, magnetic therapy, and support wraps. Rest includes hand walking, because horses with suspensory desmitis appear to respond better to limited, controlled exercise than to stall rest alone. The heels should be lowered and a palmar or plantar extension applied.

Shock wave therapy has been extremely beneficial in show horses with suspensory desmitis, particularly those with proximal suspensory desmitis. I used to recommend bone marrow injection in horses with refractory suspensory desmitis, but the advent of shock wave therapy has decreased the need for surgery dramatically.

Tendonitis

Performing in deep, muddy, outdoor show rings and a long-toe, high-heel hoof conformation predispose horses to tendonitis of the superficial digital flexor and deep digital flexor tendons and desmitis of the accessory ligament of the deep digital flexor tendon. As a rule the tendonitis is not nearly as devastating in show horses as in racehorses.

Horses with tendonitis respond well to sweats, peritendonous injection of corticosteroids, NSAIDs, magnetic therapy, and shock wave therapy. Rarely, show horses require tendon splitting and desmotomy of the accessory ligament of the deep digital flexor tendon or the accessory ligament of the superficial digital flexor tendon. Serial ultrasonographic examinations are important to monitor healing.

Splint Exostoses

Splint exostoses are caused by lunging young horses in tight circles too fast and too long. Direct trauma from interference can cause splint exostosis or fracture. Once splints become inactive, they rarely cause lameness, unless the mineralization impinges on the suspensory ligament or if the exostosis is so large it repeatedly becomes traumatized. Diagnosis is made by palpation and radiographic assessment for fracture. Treatment consists of leg sweats, subcutaneous injections of corticosteroids over the exostosis, and shock wave therapy in horses refractory to sweating and injections. Surgical removal of distal splint bone fracture fragments, large exostoses, or nonunions that impinge on the suspensory ligament should be performed.

OTHER LAMENESS CONDITIONS

Stringhalt

Stringhalt is common in the show horse and needs to be differentiated from other hindlimb lameness conditions. Local anesthetic solution (5 ml at each of three sites) is injected into the lateral digital extensor muscle, and the horse is observed while ridden 10 minutes later. If gait is improved, I recommend lateral digital myotenectomy. Previous trauma to the lateral or common digital extensor tendons can predispose horses to stringhalt (see Chapter 44).

Semimembranosus/Semitendinosus Myositis

Myositis of semimembranosus or semitendinosus sometimes can mimic stringhalt and cause bizarre gait abnormalities. Horses and ponies (particularly road ponies) show restriction of the cranial phase of the stride. The hindlimb appears to hang up in a flexed position or the horse is short-strided. Typically a trainer says the horse cannot get underneath himself. This occurs particularly in gaited horses that cannot perform the slow gait or rack. This condition may be an early form of fibrotic myopathy.

Diagnosis involves injecting 5 ml of local anesthetic solution in three to four sites each in the semimembranosus and semitendinosus muscles. The horse is evaluated ridden in 10 minutes, and often the change is dramatic.

Short-lived benefit is seen by injecting the involved muscles with Sarapin and a corticosteroid and using electrotherapy. The best solution appears to be tenotomy of the medial branch of the semitendinosus muscle, the same procedure described for surgical management of horses with fibrotic myopathy.

Tibial Stress Fractures

Young show horses, particularly young, talented five-gaited prospects, can become suddenly difficult to gait. Typically the trainer says, "The horse was one of the best young prospects I ever had and then suddenly I lost him," or "Everything came undone." Tibial stress fractures are the show horse counterpart to bucked shins in the Thoroughbred. Diagnosis is difficult and usually involves ruling out everything else first and proceeding to nuclear scintigraphy, the most consistent and best method of diagnosis. Horses are given 60 days of jogging and are re-assessed.

Hindlimb Extensor Tenosynovitis

The common digital extensor tendon sheath at the level of the hock can become inflamed and distended, a condition that is particularly prevalent in talented gaited horses. There is usually an indentation of the distended sheath just below the hock, caused by constriction by the retinaculum. Although lameness is unusual, severe distention of the sheath may cause a stiff gait, because the horse cannot flex the hock normally. Tenosynovitis may be confused with bog spavin. If left untreated, synovium becomes hypertrophic, and movement of synovium under constricting retinaculum causes a hitch in hindlimb gait. Treatment consists of draining synovial fluid and injecting a combination of hyaluronan, corticosteroids, and 0.5 ml of atropine sulfate. Massaging with dimethylsulfoxide and a corticosteroid is also beneficial.

Cervical Myositis

The degree of neck flexion required in show horses often causes pain, particularly in young horses. Older horses may develop osteoarthritis of the facet joints. Horses with cervical myositis and pain often are observed to be fighting the bit. Diagnosis is made by palpation. Injection of Sarapin and corticosteroids in the affected muscles, methocarbamol, electrical stimulation, and NSAIDs are used. Acupuncture and chiropractic procedures also may be beneficial. Shock wave therapy may be beneficial in horses with osteoarthritis of the facet joints.

Lameness in the Arabian and Half-Arabian Show Horse

Jeffrey A. Williams and Bradley S. Root

HISTORY OF THE ARABIAN

The Arabian is one of the oldest breeds in the world. The horse originated in the deserts of the Middle East and was used by the Bedouins for transportation and in battle. The Arabian breed was noted for its speed and endurance. Three Arabian stallions (the Godolphin Barb, Byerley Turk, and Darley Arabian) imported to Europe during the late 1600s and early 1700s became the foundation of a new breed of horse, the Thoroughbred. Today, 93% of all modern Thoroughbreds can be traced to these three sires. In the 1800s many royal families of Europe established Arabian stud farms. Two of the most notable were the Polish National Arabian Stud in Poland and the Crabbet Arabian Stud in England. The Arabian is thought to have an influence on many of the light horse breeds that have developed throughout history. A typical Arabian ranges from 14.1 to 15.1 hands in height. The American Horse Show Association breed standards describe the Arabian as having a small, slightly dished face with large eyes set well apart, small ears, deep and wide jowls, a small muzzle, and large nostrils. The horse should have a long, arched neck; a long, sloping shoulder; well-sprung ribs; a short back with a relatively horizontal croup; and natural, high tail carriage. The limbs should have large, well-defined joints, short cannon bones, sloping pasterns of good length, and round feet of proportionate size.[1]

The Half-Arabian studbook originated with the U.S. Army Remount Service after World War II and was acquired by the International Arabian Horse Association in 1951. Half-Arabians must have a registered purebred Arabian sire or dam. The Anglo-Arabian is a cross between an Arabian and a Thoroughbred, whereas the more recently developed National Show Horse is a cross between an Arabian and a Saddlebred. Many Half-Arabians are double registered.

HISTORY OF THE SPORTING EVENT

The International Arabian Horse Association was created in 1950 to join the local and regional clubs across America into one united association. The International Arabian Horse Association promotes and coordinates all Arabian and Half-Arabian horse show activities and develops horse show rules. The International Arabian Horse Association also maintains the Half-Arabian and Anglo-Arabian registries, whereas the Arabian Horse Registry of America maintains the registry and pedigree records for purebred Arabian horses in the United States and Mexico.

The first U.S. National Arabian and Half-Arabian Show was held in 1966. The U.S. National Show is held in October and alternates yearly between Louisville, Kentucky, and Albuquerque, New Mexico. A separate Youth National show for riders under 18 years old is held in July of each year in Albuquerque. The Canadian National Horse Show is held in August in Regina, Saskatchewan. The United States and Canada are separated into 18 regions, each of which holds an annual show. Horses can qualify for the national show by placing in the top five at a regional show or by winning a championship or reserve championship at a Class A show. Some of the major shows other than the regionals and nationals are the Scottsdale Show (Arizona), the Buckeye Show (Ohio), the Pacific Slopes Show (California), the East Coast Championship (Pennsylvania), and the Pro-Am Challenge (Texas). Major international shows are held in England, France, South America, and Australia.

Performance classes for Arabian and Half-Arabian horses cover a broad spectrum and are listed in Box 124-1. Each of these classes is held separately for Arabians and Half-Arabians. They may be divided further into sections for junior owner, adult amateur owner, amateur owner, junior exhibitor, and

Box • **124-1**

Performance Classes for Arabian and Half-Arabian Horses

Park Horse
English Pleasure
Country English Pleasure
Hunter Pleasure
English Show Hack
Hunter
Jumper
Dressage
Formal Driving
Pleasure Driving
Country Pleasure Driving
Roadster
Combination (Driving and Riding)
Mounted Nature Costume
Ladies Side Saddle
Western Pleasure
Reining
Working Cow Horse
Trail
Cutting
Equitation (Hunter Seat, Saddle Seat, and Stock Seat): youth classes only
Western Horsemanship (youth only)

amateur. The Park horse has a strong animated trot, with the forearm horizontal and the leg extending fully forward. The hock has a well-raised driving action. The walk and canter are animated and collected. The English Pleasure horse is shown at a walk, trot, strong trot (faster and more animated than the normal trot), canter, and hand gallop. Its gaits are less animated than the Park horse although the forearm, at the trot, is horizontal. The same gaits are used in the Country English Pleasure class, but horses have lower leg action, and high action is penalized. The Country English Pleasure horse must also halt, stand quietly, back, and walk off on a loose rein. With all pleasure classes the horse must give the appearance of being a pleasure to ride. Park and English Pleasure horses are shown with the head carried high and considerable flexion at the poll. Saddle seat attire is required.

In the English Show Hack class the horse must perform each gait (walk, trot, and canter) in a normal, collected, and extended manner. A transition between gaits should be noticeable and high knee action is not expected. Horses in the Hunter Pleasure division are shown under saddle at the walk, trot, canter, and hand gallop. The neck should be carried lower, the head should be carried with less bend at the poll and the horse should be in a generally longer frame than the English Pleasure or Show Hack horse. Working Hunters are shown over a course of fences set at levels of 0.6 to 1 m and are judged on performance, manners, and soundness. Jumpers are shown over courses of jumps that vary in height from 0.9 to 1.05 m. The maximum width (spread) is 1.5 m.

Horses in driving classes are shown pulling a four-wheeled (Formal and Pleasure) or two-wheeled (Pleasure and Country Pleasure) vehicle. The gaits judged in the Formal, Pleasure, and Country Pleasure driving classes correspond to the Park, English Pleasure, and Country English Pleasure classes under saddle. The Roadster is a driving class, which focuses on the trot at three different speeds.

The Western Pleasure horse is shown at the walk, jog (trot), lope (slow canter), and hand gallop. Ideally, contact with the reins is light, the head is carried low (approximately at the level of the withers), and the jog and lope are slow, easy gaits. The Working Western horse classes include reining, working cow horse, trail, cutting, and Western riding.

TRAINING: IMPACT OF INDUSTRY

The Arabian and Half–Arabian are versatile breeds, as shown by the many sports in which they compete. When appropriate, differences between the two breeds are specified. These include halter, endurance (see Chapter 119), pleasure, jumping, dressage, reining, cutting, and racing (see Chapter 112). Young performance horses are not shown under saddle until they are 3 years old. They then compete in futurity classes for horses 3 years of age or junior horse classes for horses 5 years of age or younger. Because these horses do not compete in performance classes until 3 years of age, this allows more time for adequate skeletal development compared with racehorses and Quarter Horses that start training before 2 years of age. This and the lack of speed work help minimize injuries such as fractures, early osteoarthritis, and severe soft tissue injuries, which are common in the racehorse. The reason that training of Arabian show horses is started later than some other breeds may be partly because of smaller size and late maturation, but it is also related to the fact that no performance classes are available for 2-year-olds, and therefore no economic incentives exist to start intensive training early.

Early training and conditioning typically involve a substantial amount of work in a round pen or by lunging. Excessive training in small circles causes increased torque on the distal interphalangeal joint, the navicular bone, and the distal phalanx. Seeing young horses trained in this manner and developing bilateral forelimb lameness localized to the distal interphalangeal joint is not uncommon. This type of training also causes increased stress on the other joints and support structures of the forelimbs and hindlimbs. These problems tend to be exacerbated by uneven and hard footing.

Rules govern the shoeing of the Arabian and Half-Arabian show horses. A maximum shoe weight of 14 oz (392 g) excluding pads and nails is allowed. The maximum toe length including the shoe and any pads is 4½ inches (11.43 cm). Pads are allowed, as are normal packing materials such as tar, oakum, and silicone. No weights are allowed under the pad. Foot length, shoe weight and shape, and pad usage are individualized for each horse to optimize the height and arc of flight of the forelimbs and hindlimbs. In English Pleasure horses, a common shoe is the toe-weighted shoe constructed by forging more steel in the toe of the shoe. The long foot and weighted shoes are used to enhance forelimb motion. Unfortunately this can contribute to strain on the suspensory ligament (SL) and joints of the lower limb.

In all performance divisions horses are shown in a collected frame. In each division the type of work performed, the body position required, and the conformational defects of the individual horse contribute to the common lameness conditions. Differences are apparent in gaits, degrees of collection, and head and neck position in the various divisions. In the English Pleasure division, for example, the degree of collection, neck elevation, and poll flexion required shift weight to the hindlimbs and increases the work of the back and abdominal muscles. These positional factors can cause lameness of the hindlimbs (especially involving the stifle and SL) and back pain. In the Western Pleasure and Reining divisions, similar problems are seen because of the amount of collection required. These horses also incur a variety of lameness conditions because they commonly are worked for longer periods of

time than English Pleasure horses. In the Western Pleasure and Reining classes, because any departure from a quiet, steady position is penalized, fatigue is part of the class preparation.

CONFORMATION AND LAMENESS

Mild to moderate carpus valgus and toed-out conformation commonly are seen and do not appear to have a major impact on soundness (Fig. 124-1). One reason is that the carpus is not a common location for lameness. If these conformational faults are severe, horses are at risk of suspensory desmitis. Horses with long sloping pasterns, back-at-the-knee conformation, or offset knees are also predisposed to suspensory desmitis. These conformational faults are more common in the Half-Arabian and National Show Horse than in purebred Arabians and are more common in certain pedigrees.

Horses with low, underrun heels certainly are prone to lameness from palmar heel pain. This fault can be difficult to correct, even with careful attention to shoeing and trimming. A small, upright, contracted foot (club foot) can be a source of lameness and appears to be increasing in incidence. Inflammation of the soft tissues such as the SL, accessory ligament of the deep digital flexor tendon, and distal sesamoidean ligaments tends to be more common in horses with club foot conformation.

Fig. 124-1 A 4-year-old Half-Arabian with toed-out, carpus valgus, back-at-the-knee conformation. These are common conformation faults in the Arabian and Half-Arabian breeds and may predispose the horses to suspensory desmitis.

A long, weak (sway) back and a short croup may predispose horses to soreness in the thoracolumbar, sacroiliac, and gluteal areas. Because problems in these areas are a common cause of poor performance, this type of conformation is a serious fault. Horses with cow-hocked conformation are the rule rather than the exception, but this conformation seems to have little effect on soundness.

TEN MOST COMMON LAMENESS CONDITIONS

The 10 most common lameness conditions of the Arabian and Half-Arabian show horse are as follows:

1. Bruised and inflamed feet
2. Osteoarthritis of the distal interphalangeal joint and palmar heel pain
3. Suspensory desmitis
4. Osteoarthritis of the stifle joints
5. Thoracolumbar, sacroiliac, and gluteal pain
6. Osteoarthritis of the metacarpophalangeal and metatarsophalangeal joints
7. Distal hock joint pain
8. Splint bone injuries
9. Osteoarthritis of the proximal interphalangeal joint
10. Desmitis of the accessory ligament of the deep digital flexor tendon

LAMENESS EXAMINATION

History

When describing lameness, trainers often comment that problems occur or are more noticeable during the first direction or the second direction. This refers to the directional order in which rail classes are run. In the first direction horses enter the ring and travel counterclockwise, and in the second direction horses travel clockwise. Important questions regarding history include the division in which the horse competes, onset, degree and progression of the lameness, previous or current treatment and response to therapy. Additional information that can be helpful includes knowing which direction is harder for the horse at the trot (jog) and canter (lope), whether the horse pulls unevenly on the reins, whether the horse tracks straight in each direction, whether the horse falls out of leads behind (in the hindlimbs) in corners, and whether the rider rides the correct or incorrect diagonal in each direction.

The age of the horse is important, because osteochondrosis is more likely to affect young horses recently started into training than older animals, but in older horses osteoarthritis is common. It is important to find out when the horse was last shod, and if any recent shoeing changes have been made. Altering medial to lateral hoof balance or hoof angle may increase pressure in certain areas and lead to bruising of the heel or sole. Increasing the hoof angle by raising the heel may increase load on the SL, which may lead to suspensory desmitis. The type and condition of the footing the horse has been working on is important to consider. Often footing at shows is less than ideal and in many cases is too hard, leading to the development of bruised feet. Conversely, if footing is too deep, it may lead to tendon and ligament injuries.

Visual Examination

Stepping back and visually examining the horse for overall symmetry of the limbs and upper body is helpful. Asymmetry of upper limb muscle groups may be a sign of atrophy from denervation, chronic lameness, or neurological disease. Asymmetry in the height and position of the point of shoulder, the tubera sacrale, the tubera coxae, or the tubera ischii

can indicate subluxations or fractures. The size, shape, and symmetry of the feet are important to note. Abnormalities such as club feet, underrun or sheared heels, growth rings, dished dorsal hoof walls, and contracted heels are some of the more common problems. Joint swelling, soft tissue swellings, poor conformation, scars, and abnormal structures such as splints are recognized quickly.

Palpation

Thorough palpation of the lower limbs is performed with the horse in weight-bearing and non–weight-bearing positions. Degree of joint filling; abnormal contours of bones, tendons, and ligaments; and intensity of the digital pulses are best evaluated while the horse is bearing weight. With the limb elevated, painful response to palpation of tendons, ligaments (origins and insertions), and splints; pain on joint flexion; and range of motion of joints are assessed. In the Arabian and Half-Arabian show horses, in contrast to the racehorse, moderate filling of the metacarpophalangeal/metatarsophalangeal joint capsules is common and should not be over-interpreted. Effusion of the distal interphalangeal and stifle joints (especially the medial femorotibial joint) tends to be clinically relevant. To evaluate filling in the medial femorotibial joint, it is helpful to have the horse bearing weight with the limb being palpated slightly ahead of the opposite limb and perpendicular to the ground.

Response of the Arabian and Half-Arabian to palpation of the SL varies greatly, depending on the horse. Differences between limbs should be considered important, and change in the response of an individual over time is noteworthy. Many horses have a painful response to palpation of the SL but have primary lameness localized to the foot. Possibly the SL is painful because of a compensatory gait caused by a primary foot problem. In contrast, absence of inducible pain, especially in the proximal suspensory region does not rule out this area as a source of pain causing lameness.

Careful palpation of the thoracolumbar spine and upper body is useful in diagnosing the reason for poor performance and lameness. Asymmetry, abnormal contours, and painful response to palpation are important to assess. Particular attention should be given to the thoracolumbar musculature, the spinous process, and the sacral tuberosities, because these areas commonly are involved in horses that perform poorly.

Hoof Tester Examination

Many Arabian and Half-Arabian show horses wear full pads in front during training and showing. Although sometimes inconvenient, especially at a competition, removing the shoe and pad for a complete hoof tester examination is helpful if the veterinarian suspects a foot problem. Some indication of painful areas may be obtained with the shoe and pad on, but many areas can be missed. Bruised heels and soles are common, especially at shows where footing may be too hard and horses are being worked longer than normal. Bruised heels and soles are two of the most common sources of lameness. Improvement in lameness can be dramatic if areas of bruising can be trimmed to reduce pressure or if the shoe is modified to eliminate weight bearing on a bruised area. Many horses are painful when the hoof testers are applied across both heels, but show no pain on the individual heel, soles, or bar of the hoof. These horses are just as painful with the shoe and pad on, and therefore this situation may relate to structures deeper in the heel of the foot, rather than simply bruising of the sole.

Medial to lateral hoof imbalances may contribute to lameness and should be addressed whenever lower limb lameness exists and when sore feet have been identified with the hoof testers. In general, pain is associated with the high side of the foot or that area making ground contact first.

Pain in the toe region occurs less commonly than in the heel, especially for horses in the English and Park divisions, and likely is related to the way the foot is trimmed. These horses usually have a long toe and thick sole that may protect sensitive structures from bruising and exaggerate heel first landing in the forelimbs. When pain over the middle of the frog is detected, bruising, palmar heel pain, or navicular-related pain should be considered. Diagnostic analgesia should be performed to confirm the relevance of hoof tester examination, because false-positive reactions occur.

Flexion Tests

Flexion tests are important, but responses should be interpreted carefully. A painful response to flexion of joints and the degree of lameness should be assessed. Many false-positive lower limb flexion tests occur in Arabian and Half-Arabian show horses. Many horses without lameness show pain to static flexion and a positive response when trotted. In a lame horse a lower limb flexion test is not specific. For example, in lame horses positive to a lower limb flexion test lameness may be localized anywhere from the foot to the distal metacarpal region. Carpal flexion usually is performed only in the static situation because we do not feel that substantial additional information is gained by trotting the horse. Horses that resent carpal flexion may have proximal suspensory desmitis, superficial digital flexor tendonitis, or carpal tenosynovitis, because bony injury of the carpus itself is unusual in Arabian and Half-Arabian show horses.

Initially the entire hindlimb is held in flexion and then individual lower limb flexion and upper limb flexion tests are performed. We attempt to flex the stifle independently of the tarsus by holding the distal tibia upward and behind the horse for 60 seconds. These flexion tests are not specific, but they may increase the index of suspicion in a certain area. For example, horses with hindlimb proximal suspensory desmitis or distal tarsitis respond positively to upper limb flexion and must be differentiated based on the results of other tests. Mildly positive hindlimb flexion tests are seen in sound horses that are actively training and showing. These mildly positive flexion tests may be related to subtle lameness or could be a normal response. For horses that have been competing successfully to have a moderate to severe positive response to a lower limb flexion test after a lengthy show is not unusual. This fact needs to be taken into account when prepurchase examinations are performed directly after horses have competed.

Examination on the Lunge Line and Under Saddle

If possible, examining the horse on the lunge line (or long line) and under saddle is helpful. Multiple-limb lameness, especially contralateral forelimb and hindlimb lameness and bilateral front foot lameness, is common and is important to keep in mind. The possibility of subtle neurological deficits should be considered during all phases of the lameness examination. In some horses lameness may not be apparent unless the horse is under saddle and working near the higher end of its performance capabilities. This type of lameness is more difficult to diagnose, and localization frequently requires diagnostic analgesia. Subtle lameness can be masked by a rider restricting free head movement or by controlling body position. The diagonal on which the rider sits can alter the appearance of lameness. When riding the *left* diagonal, the rider sits when the left forelimb and right hindlimb bear weight, and on the *right* diagonal the rider sits when the right forelimb and left hindlimb bear weight. The correct diagonal is the *left* when trotting clockwise and the *right* when trotting counterclockwise. In general a horse appears lamer behind when the rider sits when the lame limb is bearing weight, and the horse may try to throw the rider to the opposite diagonal. A horse with right hindlimb lameness appears lamer when the rider

sits on the left diagonal, that is, the rider sits when the left forelimb and right hindlimb are bearing weight. In Park, English, or Country English Pleasure classes, where riders are not penalized for riding the incorrect diagonal, horses often are ridden on the diagonal that minimizes lameness. Often a lameness is involved when a horse is seen being ridden on the incorrect diagonal when traveling in one direction and on the correct diagonal going the other way. These horses are referred as right or left diagonal horses. An inconsistent relationship exists between the degree of forelimb lameness and the diagonal on which the rider sits, but lameness may be modified by switching diagonals.

It is important to note whether the observed lameness is constant regardless of direction or pattern. It is important to note if lameness varies, whether the involved limb is on the inside or outside of a circle, whether the horse is on the straight or in a turn, and whether lameness is worse when the horse is on hard or soft ground. The only gait deficit visible in horses with subtle forelimb lameness may be a slight difference in the height or arc of flight of the involved limb. Often a head nod is absent, but the horse appears unsteady in the face (movement of the nose from a fixed position) because of the discomfort of the limb from landing or from pushing off the ground.

DIAGNOSTIC ANALGESIA

If possible, it is important to perform diagnostic analgesia to confirm the source of pain. For example, many horses that appear to have foot pain because of sensitivity of hoof testers or pain on palpation of the SL actually have pain elsewhere. Under American Horse Show Association rules with a properly filed medication report, local anesthetic solution such as mepivacaine can be administered up to 24 hours before a class.

If lameness is to be re-assessed with the horse under saddle or in a cart, intra-articular rather than perineural nerve blocks are preferred, because of possible loss of proprioception, which may lead to tripping or stumbling. After perineural blocks, horses may pull shoes or show an altered or awkward gait regardless of the lameness. If perineual blocks are performed in horses under saddle or in a cart, the rider or driver should be cautioned. Hindlimb nerve blocks can be difficult in uncooperative horses, and a tranquilizer (10 to 15 mg acepromazine intravenously) may be administered to fractious horses. Lameness also may be more obvious, but the risk of permanent penile prolapse with the use of acepromazine in stallions or geldings should be considered. In some horses, diagnostic analgesia of the hindlimbs may be impossible, and the response to intra-articular medication, administered under heavy sedation, must then be assessed.

NEUROLOGICAL EXAMINATION

An Arabian or Half-Arabian show horse with neurological disease may show subtle to overt clinical signs of weakness and ataxia, which may be mistaken easily for signs of musculoskeletal pain. Watching the horse pivot in tight circles, back up, and walk a figure of eight can be performed quickly and may pinpoint subtle deficits that were not noted or were less noticeable earlier in the examination.

Traumatic injuries caused by fractious horses falling during handling and training, and equine protozoal myelitis, are the most common causes of neurological disease and dysfunction in the Arabian and Half-Arabian show horses in North America. Two rare neurological conditions that may be confused with lameness and are much more common in Arabians than in any other breed are cerebellar abiotrophy and occipito-atlantoaxial malformation. Cerebellar abiotrophy is a congenital neurological abnormality that may have an inherited susceptibility and has been reported only in the Arabian horse and Gotland pony. Typical signs occur around 2 to 4 months of age and include head tremor, incoordination, hypermetria, and proprioceptive deficits. Horses may live into adulthood, and anecdotal evidence suggests that the condition may stabilize or improve, although for these horses to improve sufficiently to be useful performance horses is unlikely. Occipito-atlantoaxial malformation is an inherited congenital malformation that has been reported most frequently in Arabians. The severity of clinical signs varies greatly, from splinting of the neck to progressive ataxia and weakness to congenital tetraparesis. Reduced atlanto-occipital movement and abnormal head carriage with the neck extended are common findings.[2] Diagnosis is confirmed radiographically (see Fig. 55-4, *B*). Developmental cervical vertebral anomalies also may cause ataxia.

UNDIAGNOSED LAMENESS

When a diagnosis of the cause of lameness cannot be made, the veterinarian should consider the following:

1. Tack problems: A poorly fitting saddle may create abnormal pressure on the withers or lumbar region and cause poor performance or lameness. A poorly fitted bit or bridle that causes the horse to flip its head or lean into or away from the bit also can affect performance greatly.
2. Dental problems (causing behavior that may lead to poor performance): Sharp enamel points, wolf teeth, and fractured or infected tooth roots may all cause abnormal head carriage and poor performance.
3. Painful skin lesions in the area of the girth, saddle, or bridle may affect performance.
4. A poorly skilled rider pulling on the horse while posting, or with poor balance, or timing may affect the horse's performance.
5. Recurrent exertional rhabdomyolysis affects performance.
6. Subtle neurological deficits may affect performance.

If these problems are ruled out and a diagnosis still cannot be made, the veterinarian should try empirical treatment including a period of rest, a course of non-steroidal anti-inflammatory drugs (NSAIDs), systemic corticosteroids, intravenously administered hyaluronan, oral or systemic polysulfated glycosaminoglycans (PSGAGs), acupuncture, or chiropractic manipulation.

DIAGNOSIS AND MANAGEMENT OF LAMENESS

Bruised and Inflamed Feet

Differential diagnoses for lameness in the foot of an Arabian or Half-Arabian show horse are sole bruising, osteitis of the distal phalanx, foot abscess, penetrating wounds, fractures, laminitis, navicular syndrome, osteoarthritis of the distal interphalangeal joint, and undiagnosed palmar heel pain. The most common foot problems are bruising, osteoarthritis of the distal interphalangeal joint, and palmar heel pain.

Bruising is diagnosed by finding localized or generalized pain in the sole and by ruling out other lameness conditions. Digital pulse amplitudes are usually normal unless bruising is severe. Discoloration of the sole by hemorrhage usually occurs later and may not be seen with acute sole bruising. The most common causes of bruising are hard footing or poor medial to lateral hoof balance. The high side (longer when viewed from the palmar aspect) is usually the bruised side, and treatment

may be as simple as balancing the hoof. If hoof balance is judged to be adequate, then a pad can be cut out or the shoe can be beveled to reduce pressure on the bruised area. A common problem is a low, underslung heel. One foot may be affected, while the other tends to be upright or club footed. Horses with low, underslung hoof conformation commonly develop bruised heels. Although raising the heel angle with a degree pad may appear desirable, this correction actually may cause further heel bruising by concentrating the force on the heel. We recommend the use of a heart bar shoe, frog pads, or an egg bar shoe and a pad cut out over both heels.

Horses with club foot conformation also may develop contracted heels. Treatment involves the use of a heart bar shoe or a frog pad, or beveling the branches of the shoe. Some horses with the low, underslung heel or with club foot conformation may not be lame, and therefore attempts at correction should be tempered.

In a flat-footed horse, sole bruising may occur in areas underlying the shoe, where the sole is not concave enough to prevent contact with the shoe or pad. In these horses a concave inner surface shoe should be used. Pads and packing material are important in treating and preventing bruised feet, but bruising can still be a problem. Silicone, tar, and oakum and newer products such as advanced cushion support are commonly used packing materials. However, if the packing is too firm, it may create rather than prevent sole bruising.

Osteitis of the distal phalanx refers to a non-infectious inflammation of the distal phalanx, which in many horses appears to occur secondary to chronic sole bruising. The diagnosis is made radiographically by observing radiolucent changes and remodeling along the margins and proliferative new bone growth along the dorsal aspect of the distal phalanx. Horses that have these radiographic changes in the toe region also may have chronic bruising, laminitis, solar margin fractures, or club footed conformation. In the heel the margins of the distal phalanx are normally irregular and less well defined radiographically, and a distinction between bruising and osteitis is harder, if not impossible, to make. In most horses, however, the treatment is similar.

Treatment of horses with acutely bruised feet also includes the administration of NSAIDs (phenylbutazone, 4.4 mg/kg bid for 3 days and then 2.2 mg/kg bid for 3 days) and physical therapy. If treatment is necessary during or close to a show in North America, NSAIDs must be given according to the American Horse Show Association rules for therapeutic medication under which the Arabian and Half-Arabian divisions operate. Currently (2001) the guidelines suggest horses can receive phenylbutazone at a dose of 4.4 mg/kg once daily for 5 days in a row no closer than 12 hours before a class. If 2.2 mg/kg phenylbutazone is given by mouth every 12 hours, then the drug can be dosed at any time before a class. Under American Horse Show Association rules, two NSAIDs from a list of five (flunixin meglumine, ketoprofen, naproxen, meclofenamic acid, and phenylbutazone) are allowed to be given at the same time, except that phenylbutazone and flunixin meglumine may not be given to the same horse within 7 days of a class. If bruising is severe and a second NSAID is required, intravenously administered ketoprofen (2.2 mg/kg sid) is helpful. This can be given up to 4 hours before a class. Isoxsuprine (400 mg PO bid) used to increase blood flow to the foot, although controversial, appears to be helpful in many horses.

Physical therapy includes standing the horse in ice (15 minutes in and 15 minutes out for 3 repetitions, repeated several times a day) for the first 24 hours, followed by soaks in hot water and Epsom salts (15 to 20 minutes, 3 times daily). After soaking, the bottom and sides of the foot can be packed with a poultice and wrapped. Before the poultice is applied, dimethylsulfoxide painted on the affected areas is helpful. If areas of the sole are particularly soft, painting on a mixture of formaldehyde and tincture of iodine hardens the sole.

Osteoarthritis of the Distal Interphalangeal Joint and Palmar Heel Pain

Synovitis or acute inflammation of the distal interphalangeal joint is common and likely represents an early form of osteoarthritis. Lameness is usually mild to moderate and frequently is bilateral. Lameness tends to be more obvious in circles or tight turns, frequently with the affected leg on the *outside* of a circle. When horses are affected bilaterally, the only signs may be a shortened cranial phase of the stride and reluctance to go forward. Effusion of the distal interphalangeal joint can be palpated just proximal to the coronary band on the dorsal aspect of the limb. Horses may show pain when hoof testers are applied across the heels, but examination of the sole of the foot is unremarkable, unless other problems such as bruising or navicular syndrome are present. Many young horses develop distal interphalangeal joint synovitis early in training and lameness improves with a short period (14 to 28 days) of rest and NSAIDs. Synovitis of the distal interphalangeal joint is also common in older show horses when it may be associated with poor foot conformation or a heavy show schedule.

No radiographic abnormalities are detected unless the condition is chronic and advanced osteoarthritis develops. Lameness is abolished by analgesia of the distal interphalangeal joint or a basisesamoid nerve block. Three milliliters of mepivacaine deposited over the medial and lateral palmar digital nerves just above the bulbs of the heel also significantly alleviates pain originating from the distal interphalangeal joint.[3] Analgesia of the distal interphalangeal joint is not specific, but use of a small volume (6 ml) of local anesthetic solution and evaluation of the response within 6 to 8 minutes may minimize the effects of diffusion into the digital nerves and inadvertent misdiagnosis.

It is important to remember that several problems may coexist in the foot, and sorting out a single specific diagnosis can be difficult. Horses with low, underrun heels often have bruising, osteitis of the distal phalanx, and osteoarthritis of the distal interphalangeal joint. Horses with navicular syndrome may have bruising in the toe area related to decreased weight bearing on the heel. A bone scan may be useful in differentiating these potential causes of lameness.

Horses with early, acute osteoarthritis of the distal interphalangeal joint should be evaluated clinically for abnormalities of hoof balance and hoof angle. Shortening and rolling the toe of the shoe to ease breakover can be helpful. Shortening the toe in English show horses may not be well accepted by trainers because they think it decreases the desired forelimb action. If the lameness is moderate or severe, the horse should be allowed to rest for 30 days or the workload should be reduced drastically. Intra-articular medication with hyaluronan (20 mg) and a corticosteroid (80 to 120 mg methylprednisolone acetate) and systemic phenylbutazone (2.2 mg/kg PO bid for 5 days) are recommended. If lameness is mild, training can resume 2 to 3 days after the injections. Treatment with systemic hyaluronan (40 mg intravenously once a week for 3 weeks) or PSGAGs (500 mg intramuscularly once every 5 days for 4 to 7 treatments) sometimes is used also, but it should not be a substitute for intra-articular therapy. These products frequently are used as maintenance medications (one dose every 2 to 4 weeks) and for pre-show medication (one dose 24 to 72 hours before a class) for joint-related lameness.

Palmar heel pain is a frequent cause of lameness. Horses may or may not show pain on hoof tester examination, but lameness is eliminated by palmar digital analgesia. Causes include navicular syndrome, deep digital flexor tendonitis, impar desmitis, navicular suspensory desmitis, inflammation of the navicular bone, fragmentation of the distal border of the

navicular bone, and congenital bipartate or tripartate navicular bones. Reaching a specific diagnosis in some horses may be difficult. Diagnosis and management of the navicular syndrome in the Arabian and Half-Arabian show horses are similar to that described for other horses, although this condition is less common than in Quarter Horses or Thoroughbreds.

Although it is important to identify the source of lameness as specifically as possible, the treatment options in horses with palmar heel pain are somewhat limited and similar regardless of the cause. Rest, systemic steroidal and NSAID administration, therapeutic shoeing, medication of the distal interphalangeal joint or navicular bursa in horses with navicular involvement, and palmar digital neurectomy are the most common treatments. The natural balance shoes are not used routinely for English and Park horses because they decrease forelimb motion.

Suspensory Desmitis

Proximal suspensory desmitis is one of the most common lameness conditions of the metacarpal and metatarsal regions. Although more prevalent in the forelimb, proximal suspensory desmitis is a common hindlimb problem and typically is an insidious lameness but may have an acute onset. Lameness is more obvious when the affected limb is on the outside of a circle and is worse on turns than in straight lines. Usually no swelling is detectable, and the response to palpation is unreliable. Definitive diagnosis is based on the response to diagnostic analgesia, combined with radiography and ultrasonography. Many treatments are available, including the use of systemic anti-inflammatory agents; local injections of anti-inflammatory agents or counterirritants; topical agents with support wraps; shock wave, magnetic, laser, and ultrasound therapies; and various surgical procedures. The effectiveness of radial shock wave therapy currently is being investigated.

A decision must be made whether the horse is sound enough to remain in work, as in horses with a chronic low-grade proximal suspensory desmitis, or whether the horse should be allowed to rest. If the horse is to remain in work and local injections are to be part of the treatment regimen, the veterinarian has two options. An anti-inflammatory agent such as a short-acting corticosteroid, possibly mixed with hyaluronan or a PSGAG, may be used, followed by a few days of hand walking, before the horse resumes work. Alternatively, a counterirritant such as 1 to 2 ml of 2% iodine in almond oil is injected, followed by continued work. In both instances the work is limited to graduated periods of walking and low-speed trotting for several weeks. The walking and trotting generally are performed in escalating timed intervals. The canter or lope is not recommended initially, because the affected limb is the only limb on the ground for a portion of the gait sequence. The weight of the shoes and pads may be reduced during the initial portion of the recovery period. If the injury is too severe for the horse to remain in work, the horse is confined and hand walked until recovery is sufficient enough to begin a regimen of low-impact, controlled exercise. These horses are not turned out, because they tend to re-injure themselves with free exercise.

Proximal suspensory desmitis tends to recur with prolonged intense exercise. Horses with bilateral club feet, low underrun heels, one club foot and one low heel, or substantial rotational and angular deformities are predisposed to proximal suspensory desmitis. Horses with a chronic lameness in the opposing limb or the diagonal limb also are predisposed to lameness because of compensatory loading. It is important to identify other problems, because resolution of lameness in another limb may be crucial to the long-term resolution of proximal suspensory desmitis.

Suspensory branch desmitis also occurs frequently. With an acute injury there is pain, heat, and swelling over the affected branch and a positive response to lower limb flexion. Usually some distention of the fetlock joint capsule occurs. Diagnosis is confirmed by ultrasonography, and the proximal sesamoid bones should be evaluated radiographically. Horses with acute injuries are treated symptomatically with ice, poultice, NSAIDs, and systemic corticosteroids. If sesamoiditis is present, isoxsuprine or pentoxifylline treatment may be helpful. The shoeing should be evaluated and imbalance (frequently a low heel on the affected side) corrected. If possible, the toe should be shortened, or a rolled toe shoe should be used to ease breakover. The branches of the shoe should be extended, or an egg bar shoe should be applied to support the SL. Horses with chronic active suspensory branch desmitis may benefit from injection of corticosteroids (methylprednisolone acetate and isoflupredone acetate) subcutaneously in the affected area. Most horses are managed with medical treatment, although surgical splitting of the branch or bone marrow injections are alternative treatment options. Suspensory branch desmitis tends to recur, can be difficult to manage successfully, and may be a career-ending injury.

Osteoarthritis of the Stifle Joints

The stifle is a common source of lameness, and apart from occasional acute injuries most horses have chronic, often low-grade lameness that may not be evident when examined in hand. Riders may complain that horses are hard on one side of the mouth, tracking with a shoulder or hip in or out, falling out of a hind lead in the corners, and bending poorly. Horses with stifle pain also have difficulties in downward transitions, because they cannot maintain a collected frame and tend to fall out behind. If forced to maintain collection, the head may be raised. Horses exhibit increased discomfort going downhill. If the work area has even a slight grade, an affected horse appears more comfortable going up the grade than down. Horses also fatigue easily in deep footing, with loss of collection, diving forward in the bridle (English divisions), raising out of the bridle (Western and Hunter divisions), and loss of hindlimb cadence at the trot. Lameness is worse in turns and improves in the straight portions of the arena.

The medial femorotibial and femoropatellar joint capsules may be distended and fibrous thickening from a previous medial patellar desmotomy and other abnormalities from previous injuries may be apparent. Various flexion tests, such as pulling the limb caudally, may exacerbate lameness, but these tests are not reliable and may be dangerous to perform. Intra-articular analgesia usually is required. The medial femorotibial joint, the femoropatellar joint, and the lateral femorotibial joint are affected with decreasing frequency and generally are blocked individually in that order. Radiography should include caudocranial, lateromedial, and oblique views. Ultrasonographic examination, nuclear scintigraphy, and diagnostic arthroscopy are sometimes required.

Most commonly lameness is improved by intra-articular analgesia of the medial femorotibial joint, but radiography is negative or equivocal. Affected horses are thought to have chronic inflammation of the soft tissues of the joint and synovitis. Some of these horses eventually develop an enthesophyte on the proximal medial aspect of the tibia. Lameness often recurs, because lameness reflects the type of work the horse performs, the collected frame required, and conformational weaknesses, such as lack of angulation in the hip, stifle, and hock, camped-out conformation, and weak hindquarters in general. The condition is managed by adapting the work level between shows and the show schedule of the horse to accommodate for lameness, by corrective shoeing, and by using systemic anti-inflammatory agents and intra-articular medication. Corrective shoeing is individualized but involves trimming the foot short and using a light shoe that assists breakover. Many horses break over the dorsomedial aspect of

Fig. 124-2 A left hind shoe indicating natural breakover medial to the toe area (medial is right). Future shoes will be formed to allow breakover in this area rather than directly at the center of the toe.

the toe, and that portion of the shoe can be rolled or shaped to ease breakover. A worn shoe can be examined for breakover location (Fig. 124-2). Some horses are more sound barefooted behind and compete that way. To maintain soundness at shows, horses are maintained at a work level between shows that does not require intra-articular treatment. Systemic administration of hyaluronan and a PSGAG may help. Systemic and intra-articular anti-inflammatory therapy is begun before competition to minimize lameness during the competition. If a horse requires frequent therapy between shows, it has a poor chance of enduring a competition in good form.

Counterirritant therapy in the form of 2% iodine in oil commonly is injected in various patterns along the patellar and collateral ligaments of young horses and horses with loose stifles and in horses that have been rested as the intensity of training increases and the horse exhibits non-specific pain or weakness in the stifle area. Counterirritants are not used as a replacement for intra-articular therapy but may be used concurrently. Injections usually are limited to 5 to 10 ml to reduce postinjection inflammation and to decrease scarring from multiple injections. Work is continued, but the intensity is reduced for a short time as the horse recovers.

Osteochondrosis is the second most common problem seen in the stifle. Osteochondral fragments from the femoral trochleas can be removed arthroscopically, usually with a favorable prognosis. Horses with lameness caused by subchondral bone cysts in the medial femoral condyle have a poorer prognosis. Some horses respond to intra-articular corticosteroids. Surgical treatment may fail to resolve the lameness.

Thoracolumbar (Back), Sacroiliac, and Gluteal (Croup) Pain

Work-related back and croup pain is common in horses because of working in a collected frame frequently or for extended periods of time, compensatory altered carriage caused by lower limb injuries, poor saddle fit, poor balance and timing of a rider, injuries from falling and weakness from immaturity, lack of conditioning, or poor conformation (long, weak back).

Back pain should be suspected when behavioral changes such as kicking out during lead changes and uncharacteristic bucking occur. The horse is observed for muscle asymmetry while it stands with the body straight and the limbs squared on a level surface. The back and croup are palpated for areas of pain, using gradual pressure with the flat surface of the digits. The lumbosacral junction should be evaluated by placing the heel of one hand on the left side of the loin and, with the other hand over the base of the tail, rocking the area back and forth. A normal horse allows this, but a horse with pain stiffens and steps away from the veterinarian. Unilateral abnormalities may indicate concurrent lower limb injuries. Unilateral lumbar pain often results from compensatory carriage of the hindlimbs to that side. Unilateral sacroiliac inflammation or dorsal ligamentous thickening often results from over-bearing on that side from a chronic contralateral or diagonal limb injury. For example, horses with a chronic left front or left hind lameness may have swelling and pain in the area of the right tuber sacrale. Rectal examination is used to evaluate pelvic symmetry and ventral lumbar muscular pain. Other diagnostic modalities include radiography, ultrasonography, nuclear scintigraphy, and thermography, but physical examination remains the most important and reliable method of diagnosis. Myositis also occurs commonly and is diagnosed by history, observation of altered gait, palpation, and serum enzyme assay.

A variety of treatments is used, and these are discussed thoroughly elsewhere. Usually a period of rest is indicated, along with resolution of any associated lameness, followed by a period of reduced exercise. Systemic and local anti-inflammatory agents are administered. Other therapies include cold and heat therapy, acupuncture, chiropractic therapy, massage therapy, and magnetic, electromagnetic, laser, and ultrasound therapy.

Successful treatment of horses with back and croup injuries depends on identification of initiating causes and making appropriate changes to alleviate these causes if possible. Educating the rider is also helpful, because changes in training routines or tack may be helpful in preventing recurrence.

Osteoarthritis of the Metacarpophalangeal and Metatarsophalangeal Joints

Synovitis of the metacarpophalangeal and metatarsophalangeal joints, an early form of osteoarthritis, causes effusion, pain on fetlock flexion, and a positive response to a lower limb flexion test. The condition is frequently bilateral. Because mild effusion in sound Arabian and Half-Arabian show horses is seen commonly, it is important to perform intra-articular or perineural analgesia to confirm the source of pain when osteoarthritis of the metacarpophalangeal or metatarsophalangeal joint is suspected. Radiography is performed to determine the extent of osteoarthritic abnormalities. Many Arabian and Half-Arabian show horses perform well in spite of mild osteoarthritis of the fetlock (Fig. 124-3). Treatment is similar to that recommended for osteoarthritis of the distal interphalangeal joint, except that a shorter-acting corticosteroid such as triamcinolone or betamethasone is used for intra-articular medication.

Distal Hock Joint Pain

Osteoarthritis of the centrodistal and tarsometatarsal joints or distal tarsitis is common. Tarsal lameness is often bilateral, although one limb usually is affected more severely. Affected

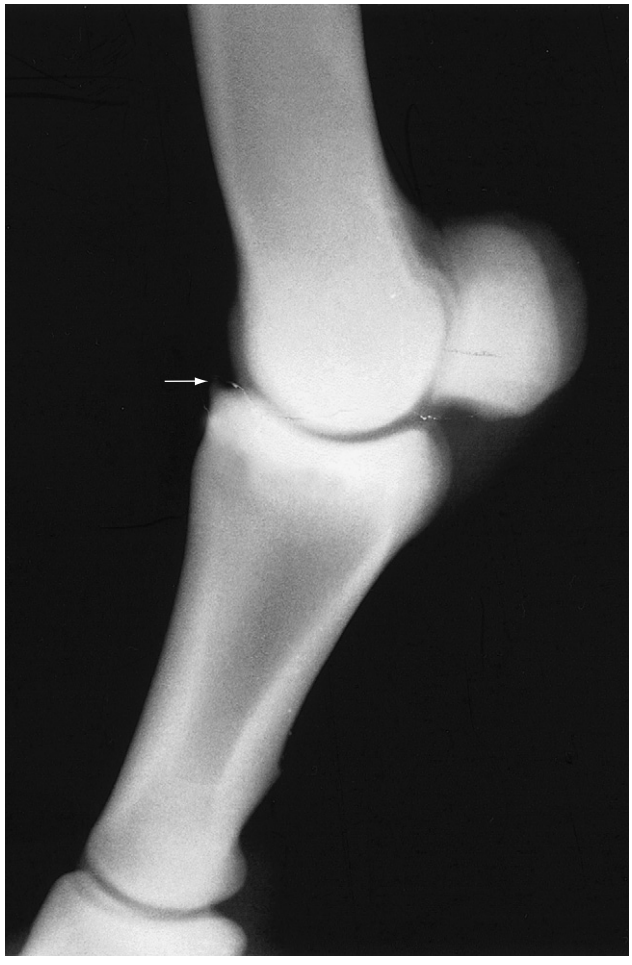

Fig. 124-3 Lateromedial radiographic view of a metacarpophalangeal joint of a sound Half-Arabian show horse. There is a moderately sized osteophyte *(arrow)* on the proximal dorsal aspect of the proximal phalanx, reflecting osteoarthritis.

horses have reduced hock flexion at the trot and tend to travel with a hip off to one side, especially in the corners (drift away from the lame limb). Rider complaints are similar to horses with stifle lameness. Western horses may tend to rate poorly and lope (canter) with a four-beat rather than a three-beat action. Reining horses tend to raise up in spins to the affected direction, bend poorly, stop unevenly or on the forehand, and change leads late behind. Diagnosis is based on palpation, including the Churchill test, flexion tests, diagnostic analgesia, radiography, and occasionally ultrasonography and nuclear scintigraphy. Treatment comprises systemic administration of anti-inflammatory agents and intra-articular medication with corticosteroids, possibly with hyaluronan (60 to 80 mg of methylprednisolone acetate and 10 mg of hyaluronan per joint), repeated as necessary, often 2 to 3 times during a show season. If medical therapy fails, chemical, laser, and surgical fusion techniques are available. Cunean tenectomy usually is not performed because the procedure commonly does not resolve lameness. Corrective shoeing involves inspecting the old shoe and squaring the new shoe to accommodate the breakover, setting the shoe back, shortening the toe, reducing the weight of the hind shoe, and occasionally using asymmetrical trailers.

Splint Bone Injuries

Proliferative periostitis, referred to as splints, and fractures of the second and fourth metacarpal bones and to a lesser extent fractures of the second and fourth metatarsal bones are common, especially in young horses. Diagnosis of splint-induced lameness is made using palpation, diagnostic analgesia, and radiography. Associated suspensory desmitis should be considered and assessed by ultrasonographic examination. Predisposing causes include conformational defects such as offset knees or base narrow and toed out. Heavy shoes and pads can exacerbate a tendency to wing in and cause interference. Poor footing that is excessively deep or hard can contribute to the development of splints. Immature horses in excessive work, or wearing shoes and pads that are too heavy for their level of fitness, are predisposed to splints. Shoeing with improper medial to lateral balance, obesity, and dietary imbalances can be contributory causes.

Proliferative periostitis originates from injury to the interosseous ligament, resulting in the development of proliferative fibrous connective tissue that subsequently mineralizes. Radiography is used to assess the injury and to determine the presence of fractures. Osteolysis of the third metacarpal or metatarsal bone and of the splint bone at the site of the injury is a sign of substantial inflammation and can indicate a prolonged recovery. Treatment includes rest (2 to 4 weeks), cold therapy, systemic and local administration of anti-inflammatory agents, topical agents with support wraps, and magnetic therapy. Large exostoses that interfere with surrounding soft tissue structures can be excised surgically.

Work-related fractures are predominantly distal, closed fractures and are thought to result from over-excursion of the SL during fetlock hyperextension. These fractures frequently are displaced, heal by non-union, and tend to irritate surrounding soft tissues. For these reasons they commonly are removed surgically. Mid-splint bone non-displaced fractures often resolve with conservative therapy. Initial therapy is similar to the treatment of a true splint, except that local administration of corticosteroids is not performed. If conservative therapy fails, surgical excision of the exostosis and distal portion of the splint bone may be performed. Horses with proximal fractures are evaluated on an individual basis, because some respond to conservative therapy, whereas others require surgical intervention.

Osteoarthritis of the Proximal Interphalangeal Joint

Incidental radiographic changes (lipping and spurring) indicating mild osteoarthritis of the proximal interphalangeal joint in Arabian and Half-Arabian show horses are not uncommon. Moderate to severe osteoarthritis, however, would be expected to cause chronic lameness. In most horses osteoarthritis of the proximal interphalangeal joint is caused by chronic repetitive trauma, although osteoarthritis secondary to a single severe injury is possible. In young horses osteochondrosis in the form of osseous cyst-like lesions and fragmentation may be involved. The importance of any radiographic changes should be validated using diagnostic analgesia. Lower limb flexion is usually positive, and lameness should improve with a basisesamoid or abaxial sesamoid block or analgesia of the proximal interphalangeal joint. Treatment is similar to that recommended for horses with osteoarthritis of the distal interphalangeal joint.

Desmitis of the Accessory Ligament of the Deep Digital Flexor Tendon

Desmitis of the accessory ligament of the deep digital flexor tendon occurs less frequently than does proximal suspensory desmitis, primarily in limbs with club feet or low, underrun heels. Footing that accumulates under the shoe, creating a rocking motion of the foot during the weight-bearing phase of the stride, may predispose horses to desmitis. Lameness is usually acute in onset, and palpation often reveals a painful

thickening along the length of the ligament that can be confused with the deep digital flexor tendon. If the condition is chronic and low grade, diagnostic analgesia may be required. Diagnosis is confirmed with ultrasonography. Treatment involves prolonged rest and systemic and local administration of anti-inflammatory agents. Adjuncts include cold therapy, topical agents with support wraps, and magnetic, laser, and ultrasound therapy. Because the predisposing conformational defect remains, the condition tends to recur.

CHAPTER • 125

Lameness in the Driving Horse

Kevin Keane and Graham Munroe

DESCRIPTION OF THE SPORT

This chapter deals with horses used for competitive driving purposes, those driven privately for pleasure, and those used as beasts of burden as a mode of transportation. The sport of driving horses in competition is relatively new and has many variations, requiring different types of horses performing different tasks. Certain breeds or breed types are perfectly suitable for one form of driving sport but not another, and variation in the size, type, and breed of horse used is considerable. Horses and ponies are used, and the term *horse* is used in this chapter to refer to both, except when specific reference to a pony is required.

In the United Kingdom and Europe there is a much greater availability of a variety of driving competitions than currently exists in North America. Pleasure driving includes presentation classes in the show ring and general driving on roads and tracks. Presentation classes are grouped broadly into hackney and non-hackney types, the difference being based on the phenotype of the animal as opposed to a breed registry. The competitor pays close attention to the harness, attire of the driver, and an appropriate carriage to suit the horse, because judging is subjective and based on strict adherence to tradition, based on a suitable match of horses and carriage. The horses perform movements requested by the judges, and style and quality of the gaits are scored subjectively. These horses compete at the walk and trot (a park pace being roughly equal to a slow working trot). Pleasure driving events also can include drives at the walk or trot on roads and tracks of up to 5 to 10 miles.

Competitive driving includes combined driving or horse driving trials and scurry driving. Scurry driving is seldom seen in North America but has a strong following in the United Kingdom and other parts of Europe. Scurry driving consists of a single pair, or more usually pairs, of mainly ponies competing over a tight, coned course in a show ring against the clock. The horses and carriages are often small to allow the narrow gates (the gap between a pair of cones) and corners to be negotiated at speed. Horse driving trials are a driven form of horse trials, or eventing, and like its ridden counterpart, driving is a highly athletic, physically demanding sport for the horse and driver.

Driving trials as an international equestrian sport started in 1968, when the Federation Equestre Internationale (FEI) international rules were drawn up under the instigation of HRH Prince Philip, who was then the President of the Federation. The first international horse driving trials event took place in 1971 in Hungary. Initially the competition was only for horse teams (four-in-hand). A team is four horses, two before two, and those in front are called *leaders* and those closer to the coach, *wheelers*. As the sport developed and individuals of more modest means entered the fray, competitions for singles (one horse), tandems (two horses harnessed one behind the other), and pairs (two horses harnessed side by side) rapidly blossomed. These classes were further divided into those for ponies (less than 148 cm or 14.2 hands high) and horses. The sport is now structured at various levels depending on the ability of the driver and horse(s). The FEI is responsible for the international rules that cover the world and European championships and selected international events such as the Royal Windsor International Driving Grand Prix. The national associations liaise with the FEI and are responsible for running the national events and championships and producing national rules. Local driving clubs (found in Europe, the United Kingdom, and the United States) also run local events that may differ substantially in standards and requirements of competitors, but they essentially mimic FEI rules. Important events include the following: Royal Windsor (United Kingdom), Aachen and Riesenbeck (Germany), Breda (Holland), Saumur (France), Waregem (Belgium), St. Gallen (Switzerland), and Fair Hill (United States). World championships are held every 2 years in singles, pairs, and teams in horses, and a European championship is held in pony teams. The first World Pony Championships (singles, pairs, and teams) will be held in Saumur in 2003. Competitions in Europe run from April to September, with championships held toward the end of this period.

Horse driving trials consist of three phases—dressage, marathon, and cones—usually spread over 3 days, but in lower standard competition all three may take place over 1 to 2 days.

thickening along the length of the ligament that can be confused with the deep digital flexor tendon. If the condition is chronic and low grade, diagnostic analgesia may be required. Diagnosis is confirmed with ultrasonography. Treatment involves prolonged rest and systemic and local administration of anti-inflammatory agents. Adjuncts include cold therapy, topical agents with support wraps, and magnetic, laser, and ultrasound therapy. Because the predisposing conformational defect remains, the condition tends to recur.

Lameness in the Driving Horse

Kevin Keane and Graham Munroe

DESCRIPTION OF THE SPORT

This chapter deals with horses used for competitive driving purposes, those driven privately for pleasure, and those used as beasts of burden as a mode of transportation. The sport of driving horses in competition is relatively new and has many variations, requiring different types of horses performing different tasks. Certain breeds or breed types are perfectly suitable for one form of driving sport but not another, and variation in the size, type, and breed of horse used is considerable. Horses and ponies are used, and the term *horse* is used in this chapter to refer to both, except when specific reference to a pony is required.

In the United Kingdom and Europe there is a much greater availability of a variety of driving competitions than currently exists in North America. Pleasure driving includes presentation classes in the show ring and general driving on roads and tracks. Presentation classes are grouped broadly into hackney and non-hackney types, the difference being based on the phenotype of the animal as opposed to a breed registry. The competitor pays close attention to the harness, attire of the driver, and an appropriate carriage to suit the horse, because judging is subjective and based on strict adherence to tradition, based on a suitable match of horses and carriage. The horses perform movements requested by the judges, and style and quality of the gaits are scored subjectively. These horses compete at the walk and trot (a park pace being roughly equal to a slow working trot). Pleasure driving events also can include drives at the walk or trot on roads and tracks of up to 5 to 10 miles.

Competitive driving includes combined driving or horse driving trials and scurry driving. Scurry driving is seldom seen in North America but has a strong following in the United Kingdom and other parts of Europe. Scurry driving consists of a single pair, or more usually pairs, of mainly ponies competing over a tight, coned course in a show ring against the clock. The horses and carriages are often small to allow the narrow gates (the gap between a pair of cones) and corners to be negotiated at speed. Horse driving trials are a driven form of horse trials, or eventing, and like its ridden counterpart, driving is a highly athletic, physically demanding sport for the horse and driver.

Driving trials as an international equestrian sport started in 1968, when the Federation Equestre Internationale (FEI) international rules were drawn up under the instigation of HRH Prince Philip, who was then the President of the Federation. The first international horse driving trials event took place in 1971 in Hungary. Initially the competition was only for horse teams (four-in-hand). A team is four horses, two before two, and those in front are called *leaders* and those closer to the coach, *wheelers*. As the sport developed and individuals of more modest means entered the fray, competitions for singles (one horse), tandems (two horses harnessed one behind the other), and pairs (two horses harnessed side by side) rapidly blossomed. These classes were further divided into those for ponies (less than 148 cm or 14.2 hands high) and horses. The sport is now structured at various levels depending on the ability of the driver and horse(s). The FEI is responsible for the international rules that cover the world and European championships and selected international events such as the Royal Windsor International Driving Grand Prix. The national associations liaise with the FEI and are responsible for running the national events and championships and producing national rules. Local driving clubs (found in Europe, the United Kingdom, and the United States) also run local events that may differ substantially in standards and requirements of competitors, but they essentially mimic FEI rules. Important events include the following: Royal Windsor (United Kingdom), Aachen and Riesenbeck (Germany), Breda (Holland), Saumur (France), Waregem (Belgium), St. Gallen (Switzerland), and Fair Hill (United States). World championships are held every 2 years in singles, pairs, and teams in horses, and a European championship is held in pony teams. The first World Pony Championships (singles, pairs, and teams) will be held in Saumur in 2003. Competitions in Europe run from April to September, with championships held toward the end of this period.

Horse driving trials consist of three phases—dressage, marathon, and cones—usually spread over 3 days, but in lower standard competition all three may take place over 1 to 2 days.

Table • **125-1**

Basic Format of the Five-Stage Marathon

	Length	Gait	Average Speed (kph)
Section A	≈ 10 km	Any type, usually trot	15
Section B	1 km	Walk	7
Section C	4 km	Fast trot	19
Section D	1 km	Walk	7
Section E	10 km	Trot/canter	14

The first phase is a driven dressage test, which consists of a set sequence of movements that are judged by a number of officials against a standard of absolute perfection. The test is designed to highlight the obedience, paces and suppleness of the horse(s), and the skill of the driver in handling of the reins. The second stage is the marathon, which tests the fitness and stamina of the horse(s) and the judgment of pace and horsemanship of the driver. The cross country marathon can be divided into three or five sections (depending on the level of competition) for which on each section a maximum and minimum time are allowed (Table 125-1).

The speeds and time allowances are adjusted for different classes, especially ponies. At the end of sections B and D are mandatory 10-minute halts. During the second of these, the animals are subjected to veterinary checks for lameness, injuries, and fitness (respiratory rate, pulse rate, dehydration, temperature, and speed of recovery). Section E has eight obstacles. Each obstacle is made up of a number of lettered gates. The aim is to drive through these gates (between white and red markers) within each obstacle in the correct alphabetical sequence in the shortest possible time. Most injuries occur on the marathon, although lameness may not become apparent until later, just before the third phase, the cones competition. The object of the cones phase is to test the fitness and suppleness of the horse after the marathon phase by driving through a course of narrowly spaced pairs of cones within an allotted time. Each cone has a ball balanced on top of it that is dislodged easily if the horse or carriage strikes the cone. The winner of the competition is the competitor with the fewest penalty points.

Veterinary inspections of horses taking part in an event also occur before the dressage day, at the end of the marathon, and at the beginning of the cones competition. Lameness at any of these inspections usually leads to elimination from the event, although considerable variation exists in the definition of working soundness among veternarians, particularly respecting hindlimb problems.

Horses used by Amish and Mennonite sects (United States) as beasts of burden are nearly always American Standardbreds or Saddlebred horses and are driven as singles. The horses are driven when needed, with no structured fitness training, and lameness is common.

TYPES OF HORSES USED

The type of horses used for driving varies considerably with the particular form of the sport or use to be undertaken. For pleasure and presentation driving the type of horse used is related mainly to the size and type of the carriage and the overall effect the driver is trying to convey to the judges (e.g., country or town turnout, meaning an informal or formal appearance of the coach, harness, and driver's attire). Horses used include Shires, Clydesdales, and Percherons in heavy horse turnouts such as drays; Hackneys (including crosses), Thoroughbreds, and Warmbloods in smart town turnouts; Cobs, larger pony types such as Welsh Cobs, Welsh Section C, Dales, Fells, Fiordlanders, and Friesians in country turnouts; and smaller pony types such as Welsh Mountain Section A, Shetlands, New Forest, and Dartmoor in small carriage turnouts. These aforementioned breeds primarily cover the variety seen in the United Kingdom and Europe. In the United States Warmblood, Warmblood crosses, Welsh, Hackney, Morgan, and Friesans are used most often for pleasure and driving trials. Most presentation and pleasure driving is undertaken with a single horse turnout. The horses range from 4 to 20 years of age and many have been or are used for other equestrian disciplines. Scurry driving usually involves single or pairs of small ponies or pony-type horses such as Shetlands, Welsh Mountain, New Forest, and Dartmoor. These ponies are often younger than pleasure-driving animals and are less likely to be used for other equestrian sports, except perhaps combined driving trials.

Driving trials horses must be older than 4 years before they can compete, and records show 19-year-old horses competing at world championship level. Many of the best driving trials horses are 12 to 19 years of age and have been used earlier for other purposes. This long working life and slow introduction to work at a young age, together with little high speed, more slow speed conditioning work, and regular winter breaks, has a considerable effect on the type of lameness seen in these animals. The types of horses and ponies used vary greatly. In continental Europe, Warmblood breeds are particularly popular; for example, Gelderlanders, Swedish Warmbloods, Dutch Warmbloods, Hanovarians, and Holsteiners, with a modern trait being an ever-increasing size. In the United Kingdom less uniformity occurs in the horses used; for example, Hackney crosses, Cobs, Welsh Cobs, Lipizzaners, Lusitanias, Orlovs, and some Warmbloods and Thoroughbred crosses. The most popular ponies used for driving trials in Europe are Welsh Sections A, B, and C, Haflingers, and New Forest crosses.

In the practice radius of one of the authors (K.K.) is a unique opportunity to observe, evaluate, and diagnose lameness conditions in driving horses used by members of the Mennonite and Amish religious sects as a mode of transportation. Several regions throughout North America have populations large enough to provide a reasonable number of horse owners for which to provide veterinary services. The incidence of lameness is influenced by the necessity of driving reasonably long distances on asphalt surfaces (up to 30 miles in one day), with sometimes a single horse pulling a Meadowbrook cart containing up to seven family members. Electricity is not used by the Amish sect and is consequently not available, so a veterinarian must be guided by the ability to palpate precisely and interpret the findings often without the adjunct diagnostic procedures relied on daily, such as radiography and ultrasonography. The veterinarian also faces great pressure because a lame horse may strand an Amish owner.

TRAINING

The training regimen for driving horses varies considerably depending on the type of driving to be undertaken and the level of competition to be attempted. Top-class horse driving trials horses require a regimented fitness program of up to several hours daily, with techniques for such fitness varying from trainer to trainer. In addition, some time is spent practicing cones and hazard training through schooling obstacles set up to mimic what is seen in competition. In pleasure or presentation driving, animals normally are worked intermittently, mainly on roads and tracks at the walk and trot, usually

in the summer months, with a rest or turnout to grass in the winter. In scurry driving the training required is more intense, with a combination of regular road work at the walk and trot to increase overall fitness, alongside school and field work concentrating on bending, suppleness, and turning at speed with accuracy. The scurry driving season can extend over longer periods of the year, when competition comes indoors. Amish horses attain a less quantitative level of fitness through irregular use and essentially no training.

Conditioning exercise tends to start in February, aiming for the first events in late April. Competitions are then available almost every weekend (Thursday to Sunday) throughout the summer, culminating in the national and international championships in August to October.

The type or breed of horse used in driving and the way the horse is trained have an important effect on the type and incidence of lameness. Differences in conformation, gait, and size have an influence. Generally, ponies are less likely to develop lameness, are easier to train to fitness, and are more agile. Pony conformation and foot shape are better and they carry less weight. Unfortunately, alongside this general toughness is all too frequently allied a cussed temperament. Cob types are similar to ponies in temperament and hardiness but are heavier and more powerful, often leading to low-grade osteoarthritis in later life. They often require considerable training to allow the necessary control and obedience to be obtained. Welsh Cobs and Hackney types and crosses have particularly exaggerated natural forelimb actions, which over long periods of use may increase wear and tear injuries in the forelimbs such as metacarpophalangeal joint problems. Some of the larger breeds, such as the Warmbloods, suffer from poor conformation, especially in the hindlimbs, such as straight in the stifle and hock, which has a major effect on the incidence of lameness. Most driving animals are not broken to harness until they are 3 to 4 years old and are not worked until they are 5 to 6 years old. Therefore conditions prominent at an earlier age, such as osteochondrosis of the tarsus and stifle, are uncommon.

The incidence of lameness in driving horses is much influenced by a long working life; the training, which is mainly flat work at the walk and trot; the different stresses and strains placed on them by the carriage (increased pressure on the hindlimbs, especially distally); the regular rest periods during the driving career; slow start in life; and whether they have been used for other purposes, previously or concurrently. All of these factors contribute to a low incidence of lameness, especially from fractures or acute soft tissue injuries seen in racing animals, but an increased incidence of low-grade wear and tear injuries, particularly of the hindlimb joints. In recent years the increasing competition and prestige at the top end of the sport, particularly internationally, has led to increased demands on horses, less patience to wait for horses to mature or to become seasoned, and consequently more lameness.

GROUND CONDITIONS

Training is usually carried out on roads or tracks of varying surfaces, depending on the region and country involved. In the United Kingdom this is mainly tarmacadam roads and firm tracks, whereas in the eastern United States, tarmacadam, dirt, and gravel roads and precut paths through agricultural fields predominate. Training for dressage and cones is usually in grass paddocks, although some drivers have access to all-weather areas. The variable, often hilly terrain in the United Kingdom and United States helps develop fitness. In Europe some of the competitions and areas for training are flat and have a sandy soil, which gives an even, absorbent, good surface for exercise. The firm surfaces on which many driving horses train and work tend to increase concussion to the feet and limbs, but they strengthen tendons and ligaments. Repeated concussion over many years may contribute to low-grade joint disease and does mean that good foot conformation and shoeing are imperative to help offset some of this constant trauma. The variable and unpredictable ground conditions present on marathon courses contributes to injuries to joints, such as the fetlock, and to ligaments and the digital flexor tendon sheath.

CONFORMATION

The huge variety of breeds and types of animals used in driving means that no particular traits of conformation have been established as representative of this type of work. Many of the Warmbloods, which are the most common breeds on the continent of Europe and are now becoming so popular elsewhere in the world for riding and driving, have a conformation that appears to predispose them to an increasing incidence of osteoarthritis of the distal hock joints. The hindlimbs are often straight through the hock and stifle, with increased body weight on small-boned legs. Some are also sickle hocked and cow hocked. Many Warmblood breeds have a high incidence of osteochondrosis, especially of the tarsocrural and stifle joints, which may manifest itself later in the working life of the horse. The headlong dash in recent years for bigger and stronger Warmblood driving horses has in our opinion lead to a heavier, less agile animal, often with small feet and limited bone, which cannot help the animal cope with work over the many years that the horse is driven. Foot conformation in some of the carriage breeds, such as the Hackney, Orlov, Gelderlander, and Lipizzaner, can be upright and boxy, which may decrease concussion protection by the foot and increase trauma reflected up the limb. Many of the native breeds or crosses have good conformation and inherent limb soundness, which is reflected in their low level of lameness. The exception to this statement is the pleasure or presentation pony that is worked irregularly and kept at grass in the summer. The overweight (show condition) nature of these ponies and the access to large amounts of grass predisposes them to laminitis, which reflects more on owner management than inherent unsoundness.

TEN MOST COMMON LAMENESS CONDITIONS

A 15-year retrospective study of the clinical practice of one of the authors (K.K.) led to the formation of the following list of common lameness conditions, in order of incidence. Some variation in incidence occurs from leaders to wheelers in four-in-hand teams and in other countries, such as the United Kingdom.

1. Suspensory desmitis
2. Foot lameness: palmar heel pain, corns, and navicular syndrome
3. Distal hock joint pain
4. Exertional rhabdomyolysis
5. Tenosynovitis of the digital flexor tendon sheath (DFTS)
6. Osteoarthritis of the proximal and distal interphalangeal and fetlock joints
7. Stifle lameness
8. Lesions associated with turnout: solar abscesses and bruising, mud fever, rain scald, cracked heels, and kick wounds
9. Interference and traumatic injuries of forelimbs and hindlimbs
10. Desmitis of the accessory ligament of the deep digital flexor tendon (ALDDFT) and superficial digital flexor tendonitis

LAMENESS EXAMINATION

Examination of lameness in the driving horse differs little from that of a standard approach. The major objectives are to decide if the animal is lame, which limb or limbs are affected, and which portion or portions of the limb(s) are affected and to determine a pathological process. This process is complicated in a driving horse, particularly as the horse ages, because of the possibility of old or insignificant lesions and the low-grade and often bilateral nature of some causes of lameness. Further problems are related to intermittent or variable lameness. Identification of lameness is more difficult in a driving animal when being driven, especially in the hindlimb, than in a ridden horse.

The history should consist of typical questions asked before any standard lameness evaluation: for example, how the lameness initially presented; what the duration of lameness is; whether lameness is worse on hard or soft ground; and whether the horse has responded to any treatments used. In addition, because driving horses are exercising between two poles that are parallel to the ground, straightness is generally fairly easy for the driver to observe. Is the horse resting one hip on the right or left shaft? Is the horse leaning more on one rein than the other? With pairs and four-in-hand is one horse taking more of the workload, indicating unwillingness of the other horse to pull an equal load? Have any changes in tack or harness been made? The veterinarian should observe the stance and attitude of the horse, areas of muscle atrophy, limb and foot conformation, and the presence of swellings before assessing the horse moving in hand at the walk and trot on a hard, flat surface. Examination in harness and carriage is rarely useful, because lameness is sometimes less evident while the horse is pulling, rather than moving freely and without restriction on a lunge line. When a driver or trainer feels that the demonstration of the lameness for which the horse is being presented is observed only when in work, that is, driven, seeing the horse in harness then may be necessary. Standard flexion tests of the forelimbs and hindlimbs are useful, but as a horse ages the likelihood of a positive result in an otherwise working, sound horse increases. Exercise on the lunge or in hand on a circle is helpful in bilateral or mild lameness. Exercise on different surfaces (hard and soft) and when possible on a slight incline up and down hill can be useful.

Identification of the affected lame limb(s) should be followed by detailed palpation and manipulation of the limb(s), with the limb bearing weight and in a flexed position. Assessment of any swelling by digital palpation and manipulation of the limb(s) to determine whether pain can be elicited can help to differentiate old, clinically insignificant lesions. In older horses distention of fetlock and tarsocrural joint capsules and DFTSs is a common, insignificant finding. Skin scars and areas of fibrosis from previous trauma may further complicate the localization of the site of lameness. Careful examination of the foot with hoof testers is important. The use of diagnostic analgesia is considered vital to rule out incidental lesions or previously managed chronic problems.

DIAGNOSTIC ANALGESIA

Many of the causes of lameness in driving horses are related to chronic wear and tear injuries in one or more joints. Distention of a joint capsule or DFTS can be an incidental finding. Localization of pain by a logical system of regional analgesia is central to our approach to lameness diagnosis and is particularly useful in horses with bilateral or multiple limb lameness, because such an approach allows the effect on the gait of one or more of the lame limbs to be removed, allowing identification of additional lame limb(s). In most horses localization of pain is initially undertaken by a sequence of perineural analgesic techniques beginning distally and moving proximally in a logical manner. In the forelimbs the sequence is palmar digital; abaxial sesamoid; low palmar and palmar metacarpal (four point); high palmar (subcarpal); and median/ulnar/musculocutaneous. In the hindlimb the sequence is abaxial sesamoid; low six point; and tibial/fibular. Nerve blocks of the antebrachium or crus are useful when the veterinarian is uncertain if the lesion is above or below mid-limb. Once that has been determined, more specific blocks may be planned proximally or distally as needed. If the veterinarian suspects a particular site, performing an intra-articular block at that site first may be more efficient. It may be necessary to perform intra-articular blocks after perineural analgesia. Sites for intrasynovial analgesia are prepared aseptically (with or with out clipping, at the discretion of the veterinarian), and fresh bottles of mepivacaine or bupivacaine, needles, and syringes are used. Gloves are mandatory for intrasynovial techniques. Assessment of response can be difficult in horses with mild or intermittent lameness or when several painful sites exist. The veterinarian should be as certain as possible of the degree of improvement in the lameness, but unfortunately this is sometimes equivocal. In a driving horse the most common intrasynovial structures injected are, in the forelimb, the distal interphalangeal, proximal interphalangeal, and metacarpophalangeal joints and the DFTS; and, in the hindlimb, the proximal interphalangeal, metatarsophalangeal, tarsometatarsal, centrodistal, and tarsocrural joints and the DFTS. Local infiltration of local anesthetic solution around areas of possible damage, such as periosteal reactions and ligament insertions, may be helpful in horses with specific injuries.

IMAGING CONSIDERATIONS

Many causes of lameness in the driving horse, especially in the older horses, are related to problems in the distal limb and the hock joints. Considerable variation in the radiological appearance of these structures can occur, representing normal anatomical variability, old injuries, incidental findings, or wear and tear. Only by localizing the site of pain to a particular joint by intra-articular analgesia is interpreting these findings possible. Standard radiographic views are obtained. Upper limb injuries are often induced by trauma, are not localized easily by diagnostic analgesia, and are difficult to examine with small x-ray machines. Ultrasonography is particularly useful in examining some of these injuries, not only to differentiate the soft tissue components (e.g., hematoma, muscle injury, edema, and wounds), but also to examine the cortical outline of the proximal limb bones in the shoulder and stifle regions for evidence of fractures or other damage. Comparison with the opposite limb is helpful in determining the normal in these areas.

Ultrasonography is essential for examining the DFTS and associated structures and for definitive diagnosis and monitoring of desmitis of the suspensory ligament (SL) or ALDDFT.

DIFFICULTIES IN DIAGNOSIS

The most difficult problem in diagnosing lameness in a driving horse is an intermittent, often low-grade lameness that may flare up with increased exercise or competition. Many lamenesses are bilateral hindlimb problems, often with several sites of pain contributing to lameness. If making progress in these horses by standard examination techniques is impossible, scintigraphic examination may be useful. The advantages of scintigraphy include the ability to cover many areas of the body (forelimbs and hindlimbs, back and pelvis) at one session,

the non-invasive nature of the technique, and its use to monitor healing. The disadvantages include cost, availability, and the lower sensitivity of the technique in localizing chronic sites of inflammation. Several sites may be detected as having increased radiopharmaceutical uptake, and other techniques, such as local analgesia, are necessary to assess clinical significance. Making a definitive diagnosis is not always possible, but it is important to treat what is diagnosable or visible and to monitor the horse's progress carefully during convalescence. A re-assessment of the horse at regular stages may cast further light on the problem. Rest may be easy to accomplish in driving horses because they have a long working life, and in pairs and teams a spare horse may be available to take the lame horse's place, allowing competition to be continued.

A problem occasionally encountered in lameness from harness and carriage use is an abnormal gait, often intermittent, seen only while the horse is working in harness, usually with the carriage. Lameness often is manifested at the collected trot in the forelimb, and an extra lift in the shoulder movement during protraction is apparent. Usually only one limb is affected. The horse appears normal at the walk and extended trot, and the problem is not exacerbated by exercise. The actual diagnosis of this condition remains obscure, but one possible theory revolves around the effect of the neck collar on the action of the scapula while the animal is in harness: a mechanical interference. In some horses, changing from a neck collar to breast band harness appears to stop the problem.

SHOEING

Most driving horses are shod conventionally, with few special techniques or shoes. Many are shod with flat, fullered shoes set rather short and tight at the heels to minimize interference injuries to the horse and other members in the pair or team. Other reasons for such shoeing given by farriers and owners include minimizing shoe loss in the varying surfaces of the competition and preventing inadvertent removal by the wearer or another horse by standing on the shoe. Short-shoeing a horse, with a tight fit in the heel, exacerbates poor foot conformation, whether the horse has upright, boxy feet or long-toed and low, weak-heeled feet.

The use of studs and occasionally calks, especially in the hind feet, is common in an attempt to increase grip in the marathon phase of competition. In the teams, the wheelers, where the power is mainly delivered, often have studs or calks. If they have to be used, we prefer to see studs only put in for the marathon and, if possible, only for the obstacles. The extra grip studs can give may lead to ligament or joint damage, particularly in the lower limb. The use of studs or calks all the time, especially on hard tracks and roads, increases heel trauma and changes the forces transmitted up the limbs. Unilateral studs and calks are not acceptable and should be actively discouraged.

DIAGNOSIS AND MANAGEMENT OF LAMENESS

Suspensory Desmitis

Desmitis of the SL, both body and branches, is common, particularly in Amish and Mennonite carriage horses. Seventy percent of the Amish carriage horses are Standardbreds, nearly all of which have raced previously and have pre-existing chronic, healed, or healing desmitis. Forelimbs (80%) and hindlimbs (20%) are affected. Body and branch lesions occur with similar prevalence in forelimbs, but branch injuries predominate in hindlimbs.

Suspensory desmitis may cause an acute onset, moderate lameness, but often a low-grade insidious lameness is reported by the owner or driver. There is often considerable swelling and inflammation associated with the SL. Horses with branch lesions especially are positive to a lower limb flexion test. Diagnosis usually is based on clinical examination and is confirmed by ultrasonography, but in some horses local analgesia is required to confirm that the SL is the source of pain.

With branch lesions radiographic examination of the proximal sesamoid bones and splint bones is required to identify concurrent fractures or sesamoiditis, which influence prognosis. Proximal sesamoid bone fractures usually are seen in Standardbred horses that have raced previously and were retired with a fracture that becomes apparent after a second career as an Amish driving horse. Amish and Mennonite horses with a less than good prognosis may be culled.

Rest is essential. The duration is determined by improvement in lameness, reduced sensitivity on palpation, and improvement in fiber pattern assessed by ultrasonography. In the initial, acute stages, cold hosing, icing for a few days, and support wrapping are recommended. The combined oral use of dexamethasone and a diuretic is helpful in decreasing inflammation and filling without masking pain. It is important to provide appropriate palmar support, and if necessary, an egg bar shoe is used to increase the weight-bearing surface.

In horses with the most severe injuries, and in those where economics does not play a role in selection of treatment, intralesional β-aminoproprionitrile fumarate injections or percutaneous ligament splitting can be performed. We currently have insufficient data to determine whether intralesional β-aminoproprionitrile fumarate improves the prognosis over conventional therapies and surgery and the drug has been taken off the market. Very good results have been obtained with surgical treatment of horses with large core lesions in the body of the SL. After perineural analgesia and localization of the core lesion by ultrasonography, we use a sharpened teat bistoury to enter the core lesion with the limb bearing weight.

Some clients prefer to turn out a horse with suspensory desmitis rather than adhere to a structured rehabilitation. Our impression is that lesions heal more slowly, often with less acceptable cosmetic results, compared with horses in which controlled exercise is used. Horses with branch injuries are treated conservatively with a long, slow progressive exercise schedule, with periodic ultrasonographic monitoring. Therapeutic ultrasound treatment also is recommended.

Prevention of suspensory desmitis is primarily by selecting well-conformed horses with a good hoof-pastern axis and good feet with continual re-assessment of hoof balance, the adequacy of heel support, and the angle of the pastern relative to the limb conformation.

Foot Problems

Foot lameness is common in driving horses and is traumatic, degenerative, or inflammatory. Lameness varies from simple trauma (puncture wounds and bruises) to infectious conditions such as thrush, degenerative conditions such as navicular syndrome, and a host of lesions caused or affected by quality of shoeing.

Carriage horses receive a moderate amount of direct trauma resulting in wounds of the digit. The lack of available prepared and manicured training surfaces often necessitates fitness work on gravel roads and through streams and wooded areas, and solar punctures by stumps or sharp objects are not uncommon. Injuries to the coronary region of horses in pairs and four-in-hand occur when driving conditions are difficult, as in the hazards, when one or more horses may be stepped on by an adjacent horse.

Although wounds of the coronary band are generally obvious, a puncture of the sole may not be readily apparent. A horse with a puncture may or may not be lame at the time

of injury. The excitement of competition allows horses to continue without overt signs of discomfort, even with frank injury to the sole. Once back in the stable or sometimes the following day, lameness becomes apparent. Many wounds of the sole and frog are difficult to see, and they can be missed easily. Frog and sole tissue tends to close over the entry site, particularly if the offending object was sharp. If foreign material remains in the foot, severe lameness is usually present. Most horses respond well to curettage and soaking in antiseptic solutions, but protracted lameness is usually a sign of infection. Contrast radiography is useful to detect direction and depth of a tract. When a veterinarian cannot determine if vital structures are involved, surgical exploration may be indicated.

Bruises and corns are diagnosed by localization of pain to the sole or heel, history, ruling out other causes of foot lameness, and identification of solar discoloration. Treatment for bruising is directed at protecting the sole. In the case of susceptible horses with a chronic tendency toward bruising, foot soaks or preferably packing gel with dimethylsulfoxide with an overwrap frequently are indicated for flare-ups. Horses with corns, in our experience, require changes in shoeing to relieve pressure on the heel and constant monitoring of the heel growth to discourage underrun, rolled in heels.

Synovitis of the distal interphalangeal joint occurs as an acute or, less commonly, as a recurrent condition. Effusion of the distal interphalangeal joint and lameness generally are exacerbated by distal limb flexion. Diagnosis is confirmed by intra-articular analgesia. Treatment comprises phenylbutazone (2 g sid) or flunixin meglumine (500 mg sid) for several days, icing of the digit, and intramuscular administration of a polysulfated glycosaminoglycan (PSGAG), with or without intra-articular administration of hyaluronan or corticosteroids.

Navicular syndrome may be more prevalent in carriage horses of certain breeds. The European Warmbloods, particularly the heavier horses, appear to be at risk. Navicular syndrome is nearly non-existent in driving ponies. Horses with navicular syndrome have an insidious lameness that usually resolves with palmar digital analgesia. Occasionally a horse has sudden onset of moderate to severe lameness without any history of a chronic problem. These horses may have dramatic lesions apparent radiographically without a reasonable explanation for why the lameness occurred suddenly rather than gradually. A critical evaluation of hoof balance is important, and we recommend using bar or egg bar shoes and oral isoxsuprine (400 mg bid). Horses with more pronounced lameness are also treated with phenylbutazone (1 to 2 gm PO sid).

The greatest number of foot lamenesses seen in carriage horses fit into a broad category of palmar heel pain. Lengthy drives on hard surfaces result in chronic contusions to the hoof capsule and subsequent lameness. Palmar heel pain often is correlated with the degree of work the horse is undertaking currently and may occur seasonally in susceptible individuals. Lameness varies from slight to moderate and is exacerbated by circling on hard ground with the affected leg on the inside of the circle. Hoof tester examination may reveal pain from the medial or lateral sulcus across to that quarter, but a large number of horses have no reaction. Lameness is eliminated by perineural analgesia of the palmar digital nerves. Intra-articular analgesia of the distal interphalangeal joint and intrathecal analgesia of the navicular bursa ideally should be performed to rule out these structures as sources of pain. Radiographic examination usually is unrewarding.

Assessment of hoof balance and shoeing is necessary, and until any imbalance has been corrected, recommending other therapies is pointless. We have had good results from increasing the length of support or ground surface in the dorsal/palmar direction of the hoof, without any other therapy. Many horse owners do not understand when instructed to move the weight bearing surface farther palmarly, and they simply raise the heel. Talking directly with the farrier and providing explanatory diagrams to the client is worthwhile. If the heels are too weak or inadequate to allow for corrective trimming, using egg bar shoes until heel growth is adequate may be necessary.

Distal Hock Joint Pain

Osteoarthritis of the distal tarsal joints is common, particularly in older and larger horses (>10 years old). Many of these horses are not presented by the owner or driver as overtly lame but with a history referring to lack of performance or action, stiffness, back problems, or poor bending. Some horses with osteoarthritis, especially from teams, are not identified until veterinary inspections at events. Many older driving horses, particularly those in horse driving trials at a high level, have an uneven hindlimb gait, especially when trotted in hand, and have positive upper limb flexion tests. The horse often is said to warm or work into its work (warm out of lameness), and owners do not request investigation. A high percentage of these horses have low-grade osteoarthritis of the distal tarsal joints. In some horses acute lameness or gradual worsening of lameness (often described as unilateral lameness by the driver) leads to lameness investigation. In the Warmblood breeds an earlier incidence of this problem has become apparent in recent years, with horses of 5 to 8 years old showing severe osteoarthritis and even ankylosis of affected joints. Many have poorly conformed and small hocks, and in some this osteoarthritis appears to be a sequel to developmental orthopedic disease in a young, growing animal.

Diagnosis is based on clinical examination, intra-articular analgesia, and radiography. Many horses have bilateral lameness, with one side worse than the other, and evidence of gluteal muscle atrophy. Poor hock conformation (sickle-hocked, straight, or cow-hocked) predisposes some horses to this condition. Shoe and hoof wear may indicate toe dragging or abnormal lateral breakover. Swelling may be palpable or visible at the seat of spavin. Tarsocrural joint distention is a common incidental finding, but it may indicate proximal intertarsal (talocalcaneal-centroquatral) joint involvement. The gait often is characterized by reduced foot flight arc and hock flexion, leading to toe dragging, and adduction of the limb medially underneath the body to land and then breakover laterally. On the lunge, lameness of the inside hindlimb may be worse, with shortening of the cranial phase of the stride and a tendency to fall toward the handler. Bilateral lameness is common, although one leg is often worse, leading to a choppy or stilted gait.

Flexion tests of the upper hindlimb are often positive bilaterally, but the response varies enormously depending on the stage and extent of the disease and the individual horse. Positive flexion tests in the hindlimb of older driving horses are common, even in the absence of lameness.

Initial localization of the lameness to the hock region can be accomplished by perineural analgesia, although intra-articular anesthesia is more specific Previously the centrodistal and tarsometatarsal joints were blocked separately, but more recently, only the tarsometatarsal is blocked, on the basis of recent research confirming the high rate of diffusion of mepivacaine between the two joints.

A poor correlation exists between the degree of lameness and the extent of radiological abnormalities. Scintigraphic examination may be indicated in the absence of radiological abnormalities.

Treatment depends on a variety of factors including the degree of lameness, other concurrent causes of lameness (e.g., back problems), the type and extent of radiological abnormalities, the age of the animal, the level of work, the competition undertaken, the time and cost constraints, and the response to previous treatment. Conservative treatments often are used when financial constraints exist, when lameness

is mild, when radiographically the disease is advanced, or simply to assess the effects of treatment before considering more radical therapy. Surgical treatments involve the willingness of the owner to make the financial investment and subject the horse to the risk of general anesthesia. We usually assess all aspects on an individual basis before embarking on a standard treatment plan, involving three monthly clinical and radiographic examinations.

In general, because of the low-grade and chronic nature of the complaint in driving horses, the horse initially is treated conservatively with corrective shoeing (graduated toe heel shoe, rolled at the toe, with or without lateral extension), a controlled graduated exercise program (up to 90 minutes) placing an emphasis on walking and trotting in a straight line (ridden or driven), and oral medication with variable levels of NSAIDs (usually phenylbutazone) to control pain and encourage a more normal action. Many driving horses make considerable clinical progress with this regimen, but few high-level driving trial horses are able to return to competition quickly. Healing may take up to 18 months, and in some healing never happens using conservative treatments. Predicting the course of the disease and ultimate result in any one horse is difficult early on and requires consideration of all the clinical and radiographic findings. Many horses improve, but they do not become sound, and have minimal progression of radiological abnormalities over 6 to 12 months. Horses with more obvious lameness, or those that are unable to cope with exercise with orally administered phenylbutazone, may be candidates for intra-articular injections with long-acting corticosteroid preparations (40 mg methylprednisolone acetate per joint). This may result in improvement for 3 to 6 months, and repeated injection usually is required. The use of NSAIDs or corticosteroids is not allowed in official competitions, and drugs must be withdrawn according to the manufacturers' recommendations before any competition.

Arthrodesis is used in horses that fail to respond to conservative treatment, are too painful to achieve ankylosis by exercise, and where time to return to performance soundness is important. In horses with minimal radiographic changes, intra-articular injection of sodium monoiodoacetate is performed under general anesthesia. In horses with more advanced radiological abnormalities or those in which monoiodoacetate has failed to achieve ankylosis, surgical treatment using three drill holes is used in each joint. Controlled exercise postoperatively is essential for success with either treatment. Although many driving horses with osteoarthritis of the distal tarsal joints are useable with treatment, complete resolution of lameness is unusual.

Exertional Rhabdomyolysis

Carriage horses have isolated episodes of tying up during competition or strenuous exercise, and this is a true exertional rhabdomyolysis. Competition horses may develop mild signs of muscle stiffness affecting the hindquarters, during or at the conclusion of an exertional session, such as the marathon. The condition may become apparent in the 10-minute box, during the formal veterinary examination section, or before the marathon course. Clinical signs are invariably subtle and may be interpreted as fatigue by an inexperienced competitor. Affected horses should be withdrawn from the competition to avoid further skeletal muscle damage. Treatment should include administration of anti-inflammatory drugs and low doses of acepromazine (5 to 25 mg total dose) and insuring adequate hydration. Horses should not be walked out of the stiffness and should be moved by trailer from the 10-minute box to a treatment stall.

To prevent further episodes, the feeding up to and including the competition and the horse's fitness program should be evaluated and amended as necessary. Teaching drivers how to assess the horse's fitness by measurement of temperature and pulse and respiratory rates on the stress days of training sessions is particularly valuable.

Acute, severe rhabdomyolysis (tying up) also occurs in horses driven by the Amish and Mennonites. These are frequently emergency situations. Horses have true, severe exertional rhabdomyolysis and are often in recumbency when examined. The clinical signs in non-recumbent horses are extreme muscle stiffness and swelling over the topline and gluteal muscle groups, increased heart rate, sweating, and colic-like symptoms. The history is consistent: the horse becomes stiff while being driven, but the driver needed to continue to a destination and may have been driven another 1 to 15 miles. The condition in colloquial Amish terminology is referred to as *kidney shot*.

Rehydration and controlling pain and shock are imperative. Tranquilizers are particularly helpful, and measurement of packed cell volume and total protein concentration is useful for monitoring hydration. Measurement of creatine kinase may be useful prognostically in recumbent horses, although the initial response to treatment and the ability to get the animal on its feet are primary factors in determining whether the horse can be saved. Creatine kinase concentrations are often 400,000 to 800,000 IU/L (normal 130 to 400 IU/L), and we have treated horses successfully with levels up to 600,000 IU/L. Without prompt emergency attention, nearly all of the more severely affected horses die or are ultimately humanely destroyed. Most horses that remain recumbent after 24 hours are lost.

Horses are viewed by Amish farmers as utilitarian and necessary for transportation, and prevention of fatal exertional rhabdomyolysis is not necessarily easy. Owners should be advised of the need to match exercise with the intake of concentrates. If possible, the horse's entire body can be clipped if the onset of summer or warm weather is sudden or the winter coat is still present. Clipping can be done using a gas-powered generator for the clippers. Clipped horses have less risk of severe dehydration, and a clipped horse apparently is less prone to rhabdomyolysis than a hirsute horse.

Tenosynovitis of the Digital Flexor Tendon Sheath

Tenosynovitis of the DFTS is a common cause of acute hindlimb lameness. Often extreme swelling of the DFTS occurs and is turgid and firm, which contrasts to chronic, benign distention of the DFTS in which fluid in an overly stretched sheath can be balloted from side to side.

With horses with acute tenosynovitis there is a substantial response to lower limb flexion, and in some horses (5%) a non–weight-bearing lameness develops. Using local analgesia is unnecessary, but intrathecal analgesia using 6 to 10 ml of mepivacaine can be used to confirm the source of pain. Synoviocentesis is best performed distal to the fetlock and is facilitated by applying a disposable elastic bandage around the distal metatarsal region to push the fluid into the distal projections of the sheath on the plantar aspect of the pastern (Fig. 125-1). Once the sheath has been entered, an assistant cuts off the bandage, and local anesthetic solution is injected.

Radiography is usually negative, but it is necessary to be certain that no unexpected lesion is missed. Ultrasonographic examination is essential to determine if tenosynovitis is associated with a lesion of the deep digital flexor tendon, which requires a longer convalescence and horses have a more guarded prognosis than those with primary tenosynovitis.

Treatment is based on reducing inflammation and controlling exercise. Uncontrolled turnout results in prolonged healing, and stall rest followed by walking in hand is preferable. A horse with an acute injury is treated with icing for 40 minutes twice a day, for 2 to 3 days, and orally administered NSAIDs. Intrathecally administered hyaluronan is beneficial. Caution should

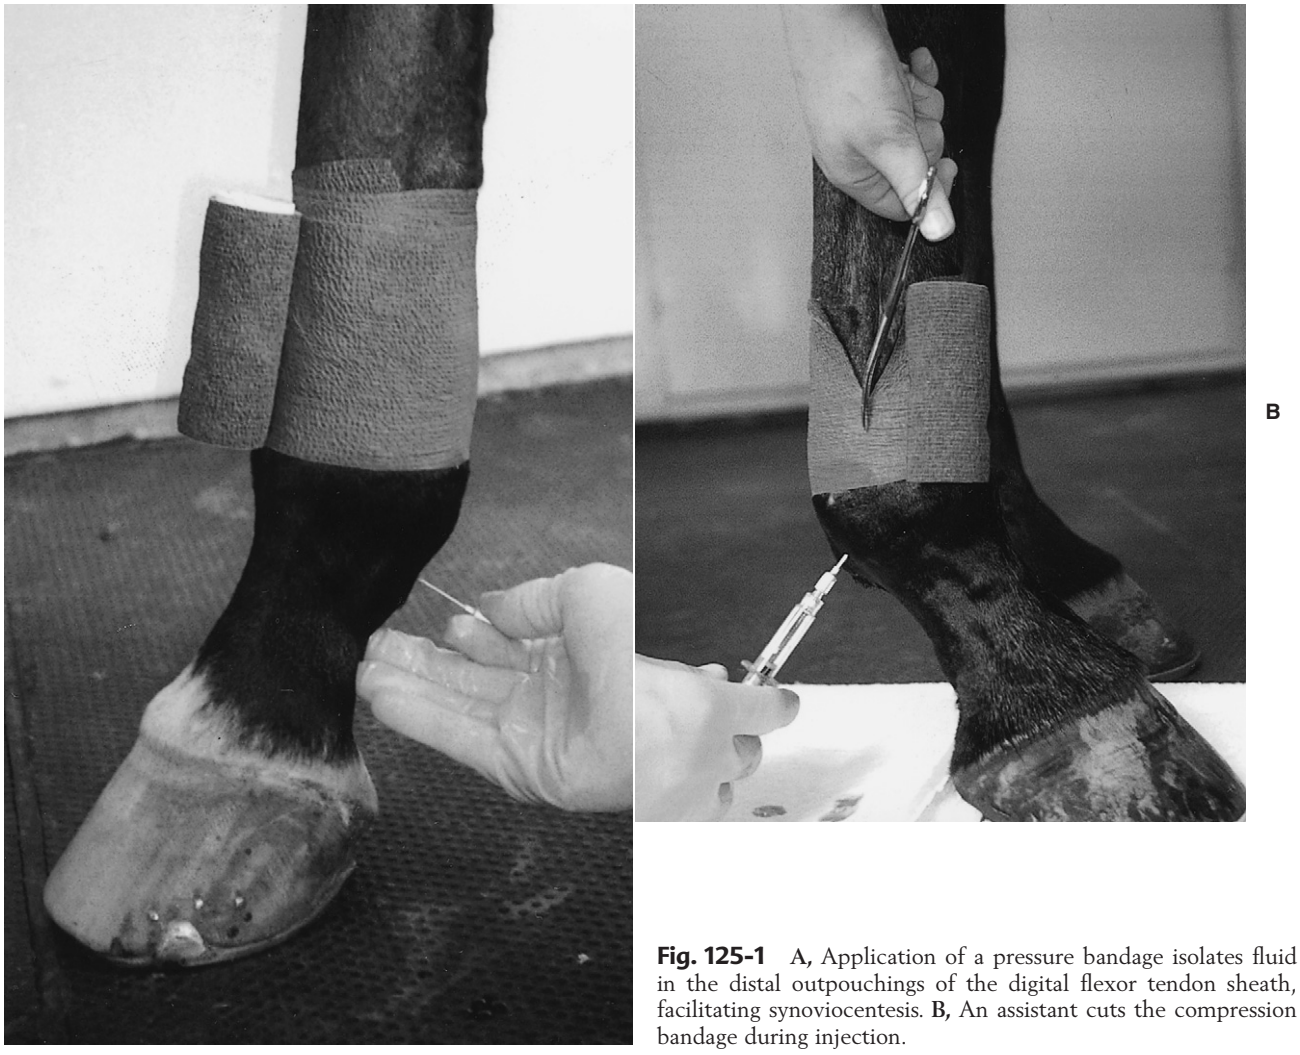

Fig. 125-1 **A,** Application of a pressure bandage isolates fluid in the distal outpouchings of the digital flexor tendon sheath, facilitating synoviocentesis. **B,** An assistant cuts the compression bandage during injection.

be exercised in the use of corticosteroids, which may provide temporary relief and often give the client a false sense of security regarding the rate of healing. Isoflupredone acetate is recommended, is short-acting, and may control the acute flare-up without any long-term affect that makes monitoring progress difficult. Methylprednisolone acetate lasts at least twice as long and may predispose the horse to develop dystrophic mineralization in the sheath. We have had better long-term results with conservative medical management than with surgical treatment by desmotomy of the plantar annular ligament.

Prevention of tenosynovitis and tears of the deep digital flexor tendon is difficult, because most injuries are acute and unforeseeable, occurring during strenuous exercise. A team horse previously used as a wheeler may be better placed as a leader. The foot should be kept well balanced, with a full-fitting shoe providing adequate plantar support.

Chronic Osteoarthritis of the Lower Limb Joints

Many driving horses develop chronic osteoarthritis of the distal interphalangeal, proximal interphalangeal, and metacarpophalangeal joints as a result of wear and tear because of the work they undertake, the length of time they are used, and other factors such as conformation, foot shape, and shoeing. Radiographic examination of these joints, especially in the hindlimbs and in larger animals, often reveals a variety of intra-articular and peri-articular abnormalities that may be associated with lameness. Older driving horses often live with low-grade hindlimb gait abnormalities associated with low-grade joint pain. This low-grade, chronic, and often multiple leg or multiple joint pain can be exacerbated by excessive or different exercise regimens, leading to acute flare-ups, increased lameness (often unilateral), joint flexion pain, peri-articular heat, and joint swelling. Radiographs obtained at this time reveal little more than the pre-existing abnormalities. Intra-articular analgesia may be essential to localize lameness, but multiple limb and joint involvement can make localization difficult. Nuclear scintigraphy may be helpful, but it is expensive, and often is used only after early treatment has proved unsuccessful.

Treatment of horses with acute flare-ups of osteoarthritis involves cold therapy such as cold hosing or ice packs, compression bandaging, systemic NSAIDs, topical applications of various anti-inflammatory substances and intra-articular or systemic medications such as corticosteroids, hyaluronan, and PSGAGs. Rest and a controlled, graduated return to exercise are important. Management of horses with chronic osteoarthritis involves a careful review and possible modification of the horse's work program, judicious use of NSAIDs, physiotherapy techniques such as laser or ultrasound treatment, and systemic medication with hyaluronan or PSGAGs. The prognosis varies enormously depending on the severity and extent of the problem, the way in which the individual horse responds to

pain and the level of work required to keep the horse sound and competing. In many horses, if the hindlimbs are affected and especially if the condition is bilateral and the horse is part of a pair or team, then the chronic low-level lameness is not observed, is undiagnosed, or is ignored. An acute flare-up may lead to recognition of the problem and diagnosis. Prognosis for horses with the first acute flare-up is reasonable, but those with further occurrences warrant a more guarded prognosis.

Stifle Lameness

A definitive diagnosis of the cause of stifle pain in driving horses is often difficult to determine. Most horses with stifle lameness are wheelers of four-in-hand or one of a pair. It is generally accepted that wheelers supply 60% of the workload in pulling, which may affect the incidence of stifle lameness. Lameness is usually acute in onset and unilateral, with no stifle effusion or other localizing clinical signs. Stifle flexion may cause more obvious accentuation of lameness than other hindlimb flexion tests. Lameness is improved by intra-articular analgesia.

Radiographs uniformly are negative. Ultrasonographic examination may sometimes reveal a lesion, but in more than 80% of horses no cause of pain can be identified. Arthroscopic exploration may be warranted, but this is expensive, and only a limited part of the stifle can be assessed. The prognosis generally is guarded for horses with a known meniscal or cruciate ligament injury and for those without a specific diagnosis. The best results have been achieved after intra-articular treatment with hyaluronan, combined with systemic administration of PSGAG and rest or rigidly controlled exercise, walking in hand.

We recommend that horses should not resume work until 60 days after complete resolution of lameness *and* when they do not respond to flexion of the stifle.

Direct Trauma

Traumatic injuries to the limbs and body of the driving animal are common.

Interference Injuries

Distal limb lacerations of varying severity are common, especially in horses that are part of a team, particularly in combined driving, and are caused by over-reaching (forelimbs) or by interference from other horses. The most common lesions involve the heels and coronary band (Fig. 125-2), although wounds to the mid-pastern and distal palmar (plantar) aspect of the metacarpal (metatarsal) region occur frequently. Many wounds are superficial and consist only of contaminated skin, but it is essential to check for injury to the flexor tendons and the DFTSs, joint integrity, and damage to the coronary band. The horse should be restrained properly, the affected area clipped and vigorously cleaned, and the damage assessed before medical or surgical treatment is initiated. In some horses detailed examination using digital palpation with sterile gloves, radiography, ultrasonography, and even surgical exploration may be necessary. Early and aggressive treatment may improve the prognosis considerably in the short and long term.

Injuries to the Brisket, Lower Neck, Antebrachium, Stifle, and Crus

Injuries usually occur during the marathon phase of driving trials, especially in the obstacles, or after runaways and accidents in any driven animal. The tendency of some drivers in combined driving in recent years to drive the carriage as a battering ram through the obstacles has increased the incidence of these injuries. Skin lesions occur, especially in the brisket and lower neck and upper forearm regions, and can range from full-thickness lacerations to mild hair loss and deeper bruising (Fig. 125-3). In some horses little is visible externally except mild swelling to suggest the site of impact. Stiffness or lameness often develops several hours later. Severe injuries, particularly involving broken shafts or obstacles, can lead to life-threatening injuries to the chest, abdomen, or vital vascular structures.

Fig. 125-2 A severe heel bulb laceration sustained by a driving horse during a team competition, probably caused by interference from another horse.

The injured area should be examined carefully, particularly when lacerations are present. In these, thorough lavage and cleaning, followed by digital exploration using sterile gloves to assess for additional deeper damage is essential. Surgical repair may be necessary. Horses with blunt soft tissue damage and bruising benefit from light walking in hand, cold therapy, topical and systemic anti-inflammatory medication, and physiotherapy techniques.

Desmitis of the Accessory Ligament of the Deep Digital Flexor Tendon

Desmitis of the ALDDFT is a common cause of forelimb lameness. Older horses, including ponies, are more likely to be affected, and injury can occur at exercise or during turnout. Onset is usually acute, with unilateral forelimb lameness occurring during or immediately after exercise. Swelling of the ALDDFT occurs with edematous swelling of the surrounding soft tissues. In horses with severe desmitis, periligamentous hemorrhage can occur. Palpable pain is rare, but heat usually is apparent.

Ultrasonographic examination is used to determine the extent of injury. Diffuse lesions are more common than focal core lesions. Damage to other tendon structures is uncommon, but adhesions to the SDFT or deep digital flexor tendon do occur, particularly in horses with chronic recurrent injuries.

Treatment of horses with acute injuries includes cold therapy, compression bandaging, box rest, and topical or systemic anti-inflammatory medications. We regularly recommend the use of systemic PSGAG therapy and therapeutic ultrasound physiotherapy from 7 days after injury. Graduated walking in hand is encouraged from 7 days after injury, increasing in duration up until 12 weeks, when limited free exercise is allowed. Ultrasonography is essential to determine when healing is sufficient to allow exercise to begin. A total convalescent period of 6 to 15 months may be required. Some injuries, particularly in older horses, do not heal satisfactorily. Occasionally horses with chronic injuries with adhesions have been treated by desmotomy of the ALDDFT, but the prognosis for return to full soundness is guarded.

Superficial Digital Flexor Tendonitis

Superficial digital flexor tendonitis is not common in the driving horse, although the condition is seen occasionally as a flare-up of a lesion sustained previously in another discipline, or in wheelers when the going during the marathon phase has been soft and deep. Most lesions are in the distal half of the metacarpal region and are generally mild. Diagnosis is based on clinical and ultrasonographic examinations. The prognosis for return to full work as a driving horse is generally good, because most of the injuries are mild and the type of work to be undertaken is usually slow.

CHAPTER • 126

Lameness in Draft Horses

Dallas O. Goble

The Draft horse today enjoys a position in the world far different from when it was considered primarily a work animal. Draft horses supplied power for farming, transportation of commodities, lumbering, road building, and all such tasks until the 1930s, when the gasoline engine essentially replaced the horse. Isolated areas still continued to use the Draft horse for farming and some lumbering activities until the early 1940s. After this period, Draft horses were used primarily for specialty areas such as movie production, theme parks, parades, and frontier celebrations. But in some communities, religion and family tradition mandated the continual use of Draft horses as a power source for farming. During the 1950s and 1960s, Draft horses decreased in numbers in the United States and subsequently, the genetic pool was decreased. Draft horses started gaining popularity in the late 1970s and early 1980s and have once again become a popular member of the horse industry.

Draft horses today are different from those of the early 1900s. They perform different functions and are owned for a different purpose. A Draft horse is far more likely to be simply a hobby than an economic part of the family income. Many horses are used strictly for show purposes in classes such as halter, fine harness, and equitation, or for parades and advertising. Draft horses are used for trail riding, pleasure riding, fox hunting (often crossbred with Thoroughbreds), and other pleasure use. In some mountain areas, where selective lumbering of individual trees is undertaken, Draft horses are still used today. With a resurgence of interest in mules, Draft horse mares often are used in the breeding programs. Draft horses frequently are crossed with Thoroughbreds to change the genetic pool for the breeding of large hunter, jumper, and Three Day Event horses. Pulling contests are popular in certain areas and represent an additional use of the modern-day Draft horse.

Treatment of horses with acute injuries includes cold therapy, compression bandaging, box rest, and topical or systemic anti-inflammatory medications. We regularly recommend the use of systemic PSGAG therapy and therapeutic ultrasound physiotherapy from 7 days after injury. Graduated walking in hand is encouraged from 7 days after injury, increasing in duration up until 12 weeks, when limited free exercise is allowed. Ultrasonography is essential to determine when healing is sufficient to allow exercise to begin. A total convalescent period of 6 to 15 months may be required. Some injuries, particularly in older horses, do not heal satisfactorily. CHAPTER • 126

Lameness in Draft Horses

Dallas O. Goble

The Draft horse today enjoys a position in the world far different from when it was considered primarily a work animal. Draft horses supplied power for farming, transportation of commodities, lumbering, road building, and all such tasks until the 1930s, when the gasoline engine essentially replaced the horse. Isolated areas still continued to use the Draft horse for farming and some lumbering activities until the early 1940s. After this period, Draft horses were used primarily for specialty areas such as movie production, theme parks, parades, and frontier celebrations. But in some communities, religion and family tradition mandated the continual use of Draft horses as a power source for farming. During the 1950s and 1960s, Draft horses decreased in numbers in the United States and subsequently, the genetic pool was decreased. Draft horses started gaining popularity in the late 1970s and early 1980s and have once again become a popular member of the horse industry.

Draft horses today are different from those of the early 1900s. They perform different functions and are owned for a different purpose. A Draft horse is far more likely to be simply a hobby than an economic part of the family income. Many horses are used strictly for show purposes in classes such as halter, fine harness, and equitation, or for parades and advertising. Draft horses are used for trail riding, pleasure riding, fox hunting (often crossbred with Thoroughbreds), and other pleasure use. In some mountain areas, where selective lumbering of individual trees is undertaken, Draft horses are still used today. With a resurgence of interest in mules, Draft horse mares often are used in the breeding programs. Draft horses frequently are crossed with Thoroughbreds to change the genetic pool for the breeding of large hunter, jumper, and Three Day Event horses. Pulling contests are popular in certain areas and represent an additional use of the modern-day Draft horse.

MODERN-DAY DRAFT HORSES

The most important physical change of the modern-day Draft horse is its size. In many modern breeding operations, size is the main criterion used for selection. When Draft horses were used predominantly as working horses, the average weight was 680 to 775 kg (1500 to 1700 lb) and the average height was 1.6 to 1.7 m (15.5 to 17 hands). This size was optimal for the multipurpose activities these horses performed on most farms and ranches. They pulled the plow, mowed and racked hay, helped round up cattle, and often took the family to church on Sunday. Draft horses today are more frequently in the range of 820 to 1000 kg (1800 to 2200 lb) and measure 1.8 to 2 m (17.5 to 19.5 hands) in height. As a result of selection based on size as the dominant characteristic, conformation and quality have suffered in some respects. Distribution of lameness also has changed. Foot size and quality have not increased proportionately with body size and weight. Osteoarthritis is common in Draft horses and likely is related to body size rather than the use of the horse. Hybrid vigor, once thought to be advantageous, has decreased by using the practice of line breeding for selected traits. The large size of a Draft horse sometimes misleads one to think the horse can withstand greater stress and disease than can light horses, but I have not found this to be true. Draft horses may not recover as well as light horses with the same injury or disease. Because Draft horses have a tendency to be stoic, recognizing a severe problem early in the disease process may be difficult. This tendency may cause a costly delay in diagnosis and management. The physical size of Draft horses today has hindered veterinary care and treatment. Veterinarians tend to be unsure of drug dosage and appropriate treatment schedules because of the large body size. Many hobby horse owners do not have facilities adequate to handle a 1000-kg horse and may not be knowledgeable in Draft horse care. Draft horses are not always well trained or easy to handle, and owners are sometimes unable to lend assistance when needed. These facts have curtailed the interest of many practicing veterinarians who have difficulty rationalizing being stepped on by a l000-kg Draft horse as fun. In addition, finding quality foot care for a Draft horse is sometimes difficult, because most farriers are experienced with light horses. Farriers feel similar to veterinarians: "Why hold up a 1000-kg horse twice as long as needed to hold up a 500-kg horse?" In addition, farriers who shoe Draft horses have to stock nails, shoes, and bar stock often on special order or low-volume items, a fact that dramatically increases overhead expenses. Thankfully, some veterinarians and farriers are willing to treat and specialize in Draft horse care.

The following discussions related to Draft horse lameness are my personal clinical experiences and do not necessarily reflect what may be in the equine literature. Lameness distribution may vary from my observations depending on the use, location, individual draft breed studied, or other factors associated with different populations of horses.

TEN MOST COMMON LAMENESS PROBLEMS

Over the last several years I have evaluated 745 Draft horses admitted with a chief complaint of lameness. The following list shows the top 10 lameness conditions that I have observed in order of decreasing frequency (33 horses had other problems):

1. Foot lameness (abscess, hoof cracks, laminitis, and sidebone) 260
2. Tarsal lameness (osteoarthritis, bog spavin, and osteochondrosis) 207
3. Splints 84
4. Tendonitis and suspensory desmitis 45
5. Osteoarthritis of the distal interphalangeal or proximal interphalangeal joints 44
6. Fetlock lameness (sesamoiditis, osteoarthritis, and osteochondrosis) 23
7. Thoroughpin 18
8. Carpal lameness (traumatic or infectious carpitis) 13
9. Stifle lameness (traumatic, upper fixation of the patella, and osteochondrosis) 10
10. Myopathy 8

LAMENESS EXAMINATION

Diagnosis and management of lameness in a Draft horse may seem more intimidating simply because of the large size of the horse and the infrequency with which requests are made for examination compared with light horses. In reality, Draft horses suffer from the same problems as do light horses, although the distribution is different, and the principles of diagnosis and management are the same. The lameness examination is the same as in light horses, and any deficiency of hands-on experience can be overcome by a systematic and thorough examination. Palpation of peripheral nerves (palmar and plantar digital nerve, in particular) can be difficult because of thick skin and hair, and veterinarians are sometimes reluctant to attempt perineural or intra-articular blocks. The anatomy is the same, but the ability to palpate the nerves is diminished by these factors and also by subcutaneous thickening that some Draft horses develop in the lower limb.

Draft horse lameness diagnosis and management lagged behind that of light horses for many years. First, as long as the horse could still accomplish farm work, less concern was shown for a horse that limped slightly. Possibly the person behind the plow or cultivator also limped and accepted it as part of doing the job. Second, economic considerations were a major factor in the farming operation. This does not reflect necessarily a lack of care, but it was simply an accepted part of working in that day and time. But today, Draft horses are afforded the same concerns and care given to the light horse, and only modification of most treatment protocols needs to be made.

Detailed description of the lameness examination can be found in earlier chapters. Special attention should be paid to several critical points, however. Draft horses are more stoical than light horses and, as a result, lameness may be advanced when first recognized. For example, Draft horses with osteoarthritis of the proximal interphalangeal or distal interphalangeal joints may have severe radiographic changes, but the owner may report that the horse only recently showed signs of lameness. Granted, many owners are inexperienced, but even the experienced owner may not recognize a problem until it is well advanced. This can be explained partially by the fact that a Draft horse often is used at a gait (walk) that makes lameness less obvious, and the horse frequently is hitched with one to seven additional horses, and an individual horse's problems are less discernible in a group.

When possible, observing the horse at a walk and trot on soft and hard surfaces is useful. Hoof tester examination, in my experience, is less reliable in Draft horses than in light horses. Small hoof testers are of questionable value. Even with long-handled hoof testers, it is difficult to apply enough pressure to produce a positive response in many horses. Foot lameness should be suspected if a horse shows grade 1 of 5 lameness on soft footing but grade 3 of 5 lameness on a hard surface. The examination always should include backing the horse at least two or three times and observing the horse at the walk and trot in a circle and in tight turns. Sometimes conditions such as shivers, stringhalt, or intermittent upward fixation of the patella are seen only during these maneuvers.

Lower limb flexion tests are less rewarding in Draft horses than in light horses. It is difficult to apply sufficient pressure during the flexion test to accentuate pain in this region. A Draft horse may be less willing to trot after a flexion test, making it difficult to determine a true positive response. Most light horses will trot after flexion, even when the reaction is highly positive, but a Draft horse will not trot off as readily without strong urging. In addition, Draft horses often are not accustomed to being trotted in hand routinely. Hindlimb upper limb flexion tests in a Draft horse are a more reliable indicator of hindlimb lameness than in a light horse.

I prefer to perform diagnostic nerve blocks with the horse in a standing position, rather than having an assistant elevate the limb. This is especially true when attempting the palmar digital nerve block or abaxial sesamoid block. Palpating anatomical landmarks in this area when a Draft horse is weight bearing is easier than when the limb is elevated. To maintain the limb in an elevated position or to restrain the limb in this position can be difficult. Adequate restraint usually can be achieved by the application of a nose twitch.

LAMENESS COMMON TO THE FORELIMB AND HINDLIMB

Foot

The foot is the most common source of pain causing lameness in Draft horses. A thorough and complete examination of the foot is paramount to diagnosis and management of lameness. Hoof quality and conformation have suffered in modern-day breeding selection, and as a result we tend to have large horses that are supported on feet that lack hoof size and quality. I suggest that breeders of Draft horses give strong consideration to hoof conformation when making critical selections for breeding programs.

Subsolar Abscess

The most common cause of foot lameness in a Draft horse is a subsolar abscess, a problem most frequently encountered in a forelimb. The high incidence of subsolar abscess formation in Draft horses can be related to several factors. First, obtaining consistent farrier care may be difficult in many locations, and foot care may be neglected. Second, Draft horses often have poor hoof quality and easily develop hoof cracks or severely chipped and broken hoof walls. Clydesdales often have poor hoof quality. Many Draft horses have dropped soles, predisposing them to bruising and subsolar abscess formation.

A pair of large, good quality hoof testers provides the simplest method of determining the location of the abscess. Tapping the hoof wall or sole with a hammer (or the hoof testers) can help locate the abscessed area. In horses that recently have been shod or reset, each nail should be examined. An abscess associated with a nail usually develops 5 to 11 days after shoeing. Hoof cracks causing instability of the hoof capsule can cause lameness even though the area of abscessation may have resolved. If a foreign body is lodged in the hoof (nail, glass, or other penetrating object), a fistulogram (contrast radiograph) should be performed. A subsolar abscess can become a life-threatening problem if osteitis of the distal phalanx develops or penetration of the distal interphalangeal joint, deep digital flexor tendon, or navicular bursa occurs. Proper diagnosis is mandatory; otherwise, the long-term prognosis becomes worse.

Once the abscess is located, the sole should be pared with caution, especially if the horse has a dropped sole or has a concomitant full-thickness hoof wall crack. Overzealous sole paring may result in extensive mechanical damage to laminae and loss of hoof wall strength. Adequate drainage is paramount, but removing a large amount of sole is not necessary, even when substantial undermining has occurred. In Draft horses, it is important to err toward a conservative approach, at least initially. Thorough flushing of the foot with povidone-iodine or chlorhexidine diacetate solutions should be done at least once a day for 3 days or until the drainage has stopped. The foot can be soaked in a saturated solution of magnesium sulfate for 3 to 5 days to reduce inflammation and to aid in drainage. Finding a soak boot large enough for Draft horse feet at a reasonable cost is difficult, and I have found an easy solution by using a 1 m length of truck tire inner tubing. The tubing is slipped half its length over the foot, and then up the leg, with the remaining half doubled back up the leg and secured in place by a wrap of choice (Fig. 126-1). The tube then can be filled with the soak solution. Draft horses with an uncomplicated subsolar abscess do not need to be treated with systemic antibiotics. However, if cellulitis of the coronary band and pastern region is present, the administration of antibiotics is indicated. Trimethoprim-sulfadiazine (15 mg/kg PO bid) or ceftiofur sodium (1 mg/kg IV bid or IM) is my usual choice. Judicious use of non-steroidal anti-inflammatory drugs (NSAIDs) is indicated, but theses drugs should not used for extended periods of time or at levels that may mask a more serious problem. Phenylbutazone, 4 g PO or 2 g IV, on the first day is sufficient. Thereafter, 3 g and then 1 g is given orally on the second and third days, respectively. A tetanus booster should be administered if the horse's vaccination status is not current or is unknown.

If the horse's condition is not improved in 3 days, the horse should be re-examined. Plain radiographs and positive contrast fistulography should be performed. A fistulogram is performed using contrast material administered through a Foley catheter. The foot should be held off the ground when contrast media is infused and held up for 2 minutes thereafter. The foot is then placed in a weight-bearing position, and radiographs are obtained immediately. During weight bearing, a fistulous tract

Fig. 126-1 Draft horse with rubber inner tube in place and used as a soak boot for a foot abscess.

often is closed by soft tissue compression. If deeper structures are involved (distal interphalangeal joint, deep digital flexor tendon, distal phalanx, or navicular bursa), an extensive treatment program is initiated, including bacterial cultures, surgical drainage or curettage, lavage of the affected area, and the administration of broad-spectrum intravenous antibiotics. The initial antibiotic treatment usually includes 20,000 IU/kg of potassium penicillin 4 times a day and 6.6 mg/kg of gentamicin once a day. Bacterial culture and sensitivity results may require changing the antibiotic regimen.

Hoof Wall Cracks

Forelimb hoof wall cracks were found in 67% of the 165 Draft horses examined for lameness, although not all were the primary cause of the horse's current problem. Full-thickness hoof wall cracks need to be stabilized when they cause lameness. The crack should be cleaned carefully and curetted, and normal hoof wall should be present on each side of the defect. The technique of dovetailing may provide additional support if hoof repair material is used. Dovetailing is accomplished most easily using a 1-cm (⅜-inch) round burr on an electric drill and undermining the hoof wall at about a 45° angle, leaving a shelf of hoof wall down to the white line on each side of the defect for the full length of the crack. This provides additional surface area for a stronger repair and reduces the likelihood that the repair material will come out. Care must be exercised to avoid damage to the sensitive laminae or to create bleeding during this procedure because these may predispose to abscess formation beneath the repair material. If the horse is initially unshod, a shoe with clips may be sufficient to provide support and to immobilize the defect. Radiator hose clamps and 1-cm long, No. 8 metal screws can be used to stabilize the crack. Because infection is often a problem, the radiator clamp method can be used initially, when filling the defect with repair material is contraindicated. Antibiotic-impregnated repair material has been used, but my success with this material in Draft horses has been limited, and my preferred method is a shoe and the radiator clamp/ screw combination. It is important to have at least two screws through each piece of clamp and on each side of the defect to add stability. The top clamp should be placed at the proximal limit of the crack. I generally space the clamps 1.9 cm (¾ inch) apart, and the number of clamps needed depends on the length, depth, and the amount of instability in the crack and on the size of radiator clamp used. The clamps are removed as the defect grows and replaced if broken. The clamps must be tightened carefully, because lameness from laminar pain will be worse if the clamps are too tight. This problem is corrected by adjusting the clamp with a screwdriver.

Laminitis

Laminitis in Draft horses is a serious lameness condition, and prognosis for complete resolution often is guarded to unfavorable. Regardless of the cause (grain overload, colitis, metritis, retained placenta, toxemia, and so on), once the pathophysiological process of laminitis is in motion, the end results are similar. The solution to the primary cause often is solved more easily than the secondary problem of laminitis. This is especially true in mares with retained placenta in which the retained placenta and metritis are solved easily, but secondary complications may be devastating. Many of these mares develop severe laminitis with distal displacement (sinking) of the distal phalanx.

I would like to contrast my observations of Draft horses with laminitis to similar conditions in light horses. Laminitis carries a more guarded or unfavorable prognosis in Draft horses for many reasons. Our ability to manage secondary problems is less satisfactory in Draft horses. Size, when we consider a 1000-kg as opposed to a 400- to 500-kg horse, is the most important factor. Slings are seldom big enough, and hoists or hoist support systems may not be available to lift a Draft horse safely. Locating a farrier who will work on a chronically lame Draft horse and forge therapeutic shoes on a consistent basis is often difficult. Management of Draft horses with myositis, decubital ulcers, infections, pneumonia, and other secondary complications is more difficult and costly. The owner must be informed clearly of cost, and a dedicated team (owner, farrier, and veterinarian) must be assembled to manage these complications. I generally tell clients that at least 1 year will pass before the horse's level of function can be assessed reasonably.

Classification of laminitis is confusing, and I make little attempt to classify laminitis based on chronicity or by using the Obel grading system (see Chapter 35). Regardless of classification used, prognosis for return to function is poor if lameness is severe and persists for longer than 10 days with intensive treatment. In my experience, two major differences exist between Draft horses and the light horses. First, Draft horses develop laminitis more frequently and severely in the hindlimbs. Second, Draft horses are more likely to develop distal displacement (sinking) of the distal phalanx once laminitis occurs (Fig. 126-2). This latter difference may be related to hoof quality or hoof care in general and the important role that body weight plays in causing distal displacement. In addition,

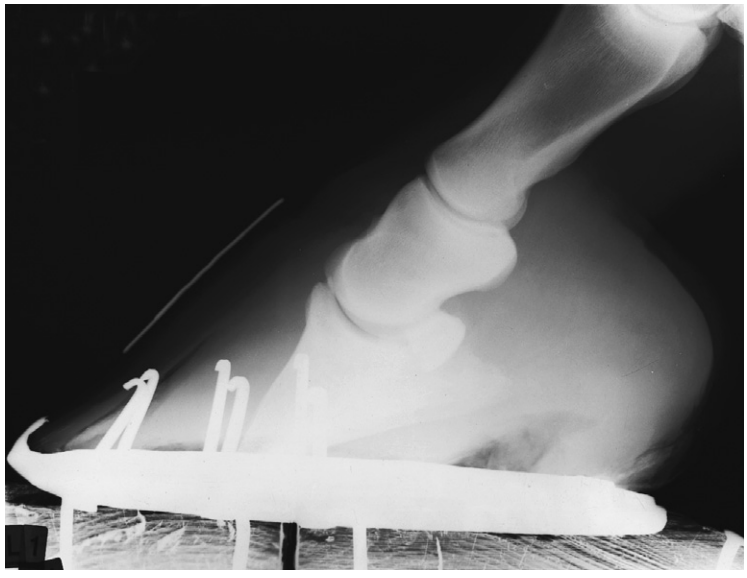

Fig. 126-2 Lateromedial radiographic view of the front foot of a Draft horse mare that had developed laminitis in all four limbs within 24 hours of foaling and retention of the placenta. The radiograph waas obtained 10 days after foaling. The proximal end of the radiopaque marker on the dorsal hoof wall is at the level of the coronary band. There is both extensive sinking and rotation of the distal phalanx. Note also the broad radiolucent line in the dorsal hoof wall, the result of laminar necrosis. The mare was managed until the foal was weaned but humane destruction was ultimately necessary.

shoeing methods that flair the hoof wall simply to give the impression of a large foot weaken laminar support. Distal displacement can occur in horses with traumatic laminitis without a traditional laminitic episode. Traumatic laminitis and sinking can occur unilaterally, only to then occur weeks to months later in the opposite foot. Traumatic laminitis caused by incorrect shoeing can be reduced greatly or eliminated when proper shoeing is provided on a regular basis.

Diagnosis of laminitis is not difficult except in Draft horses with traumatic laminitis that is slowly progressive, without an acute episode typically seen with laminitis in a light horse. These horses often have a dropped sole (including the frog in many horses), with the entire sole at a level below the hoof wall. Increased digital pulse amplitudes may be missed easily in a Draft horse, but hoof tester sensitivity and abnormal stance are important clinical signs. Initial and follow-up radiographs should always be obtained.

Management of Draft horses with laminitis is similar to that in light horses, but some precautions need to be taken. Pain amelioration is important but often difficult to achieve. Clydesdales, for instance, are susceptible to gastric and colonic ulcers when treated with phenylbutazone. The Belgian horses that I have treated with phenylbutazone seem less susceptible to ulcers than do Clydesdales. In Clydesdales I seldom if ever administer more than 4 g phenylbutazone orally daily, or do not exceed 3 g intravenously daily, unless no other alternative is available. The dose should be lowered as quickly as possible, and the high dose should be maintained for a maximum of 5 to 7 days. Although this dose is low based on milligrams per kilogram, Clydesdales have many gastrointestinal complications with higher doses. Flunixin meglumine, meclofenamic acid, and other NSAIDs can be used, but phenylbutazone is the most frequently used and cost-effective drug. Butorphanol tartrate (0.01 to 0.02 mg/kg) can be used with phenylbutazone to lower the necessary dose of NSAIDs. Butorphanol tartrate alone is not a satisfactory analgesic for Draft horses with laminitis, but it is useful with NSAIDs, and can be repeated 3 to 4 times each day.

To provide frog support initially, I use pieces of rubber stall matting, 1.9 cm (¾ inch) thick. The matting is cut to fit the foot and frog and then secured with fiberglass cast material. To increase thickness, two rubber pads can be glued together. To raise the heels in Draft horses with acute laminitis, a hand grinder can be used to make a wedge pad from the rubber mat. I believe raising the heels helps to reduce pain and rotation of the distal phalanx. Heels should be elevated 10° to 14°, however. The single most important factor in Draft horses with laminitis is to avoid excessive paring of the sole. Paring the sole away to make it look like a normal sole is putting the curse of death on Draft horses with laminitis. This practice removes natural protection from rotation or sinking, and the sole supports the foot better than anything we can apply externally.

Radical hoof wall resection should be avoided. I recall two horses that were referred after complete dorsal hoof wall resection. In both horses the remaining hoof wall lacked strength, and although one horse was shod and the other was unshod, the distal phalanx rotated and sank through the remaining hoof wall in both horses, which were euthanized. If hoof wall resection is indicated, a shoe with side or quarter clips is applied *before* the procedure is performed. The entire hoof wall should not be removed at one time, but resection should be staged over 2 to 3 weeks. If the hoof wall spreads and crowding of the side clips occurs or if further rotation or sinking of the distal phalanx is observed, any further resection is delayed. The coronary band should be assessed each day for signs of sinking (depression at the top of the coronary band). Radiography is helpful but does not replace careful physical examination. Horses with subsolar abscesses are treated by drilling small holes (3 to 5 mm) through the hoof rather than by resection of large portions of hoof wall and sole. Two or more holes may need to be placed in the hoof wall or sole to provide adequate drainage and to flush the site. Drilling small holes does not reduce hoof wall strength compared with paring or removing large portions using conventional methods.

Sidebone

Mineralization of the cartilages of the foot (sidebone) is a common radiographic finding in Draft horses, particularly in the forelimbs, but is an infrequent cause of lameness. Of 113 Draft horses with sidebones, 80 had the condition bilaterally in the forelimbs, and 28 horses had it bilaterally in the hindlimbs. Five horses had unilateral involvement. Draft horses with angular limb deformities are more likely to develop sidebone than are horses with normal bone structure. Sidebone is more common in Draft horses with poor hoof quality than in horses with normal hooves. Trauma to the heels and quarters and reduced palmar support are contributing factors. If sidebone is the cause of lameness, lameness grade is usually mild (1 to 2 of 5). Lameness is most common in horses 4 to 7 year of age. Sidebone fractures, occurring in older horses, can cause acute lameness. Lameness is usually most apparent when the horse is working on pavement or other hard surfaces. On soft surfaces the hoof can tip or angle, whereas on hard surfaces the bony column cannot move. Lameness is most obvious when the horses are working in circles or tight turns.

Lameness associated with sidebone can be difficult to confirm. Palmar or plantar digital nerve blocks usually greatly improved clinical signs, and abaxial sesamoid blocks abolish signs. Both nerve blocks provide analgesia to numerous other structures that are more frequent causes of lameness, however. Physical examination is more helpful than is diagnostic analgesia. Tapping on the upper one fourth of the hoof wall (while avoiding hitting the coronary band) with hoof testers or a hammer may elicit pain. A lateral or medial wedge test often causes lameness (see Chapter 8). Thermography is valuable in some horses, showing increased temperature in the area of the sidebone. Radiography is of limited value, because the mere presence of mineralization is not conclusive evidence for lameness diagnosis.

Treatment includes rest and hoof care. The hoof should be trimmed level. Hoof strike should be evaluated dynamically (how it strikes the ground) rather than by just viewing the hoof in a static position. Vertical and parallel grooving may allow the hoof wall to expand and may reduce pressure, but I have not found grooving highly rewarding. The horse should have stall rest or small paddock confinement for 4 to 8 weeks and NSAID therapy. The foot must be balanced properly before the horse resumes a normal exercise program. Fractures associated with large sidebones may be accompanied by osteoarthritis of the distal interphalangeal joint. Rarely the proximal interphalangeal joint is involved. Surgical management of Draft horses with sidebone fractures often is unrewarding, and I do not recommend it unless conservative management efforts have failed. Conservative management includes an extended period of stall rest (8 to 12 weeks) and then small, level paddock exercise for 6 to 8 months. Healing as shown on radiographs may require extensive time, and even then the fracture still may be evident, surrounded by proliferative exostosis. Unilateral palmar digital neurectomy also can be performed. This will provide relief in most horses unless there is concurrent osteoarthritis of the distal interphalangeal or proximal interphalangeal joints.

Quittor

Quittor is defined as a chronic infectious condition associated with one of the cartilages of the foot. A mixed bacterial infection causing chronic or recurrent drainage at or near the coronary band is most common (Fig. 126-3). Trauma is the most common cause of the condition referred to as necrosis of the

cartilage. Wire cuts and wounds incurred from large calks on the shoes when horses are working in harness or being transported are common histories. Quittor is considerably less common today than it once was.

Surgical management is the only option, because scar tissue and limited circulation preclude successful conservative management with local or systemic antibiotics. Excision of necrotic cartilage and scar tissue is best. Samples should be submitted for aerobic and anaerobic bacterial culture. Standing surgery can be performed, but I prefer to use general anesthesia, which reduces the chance of the distal interphalangeal joint being penetrated, improves the ability to provide hemostasis, and provides maximal restraint during surgery. A tourniquet at the level of the fetlock joint provides excellent surgical hemostasis, and as a precaution I always administer prophylactic broad-spectrum antibiotics before surgery. The distal interphalangeal joint occasionally is opened, and although penetration does not necessarily indicate surgical failure, an open joint alters the post-operative management protocol. If necrotic material (cartilage or scar tissue) extends distal to the coronary band, adequate distal drainage and flushing requires drilling a hole in the hoof wall.[1]

Osteitis of the Distal Phalanx

Many Draft horses have flat soles and bear significant weight on the sole, and thus are prone to sole bruising and osteitis of the distal phalanx. The condition is most prevalent in the forelimbs and often is associated with improper shoeing or lack of proper hoof care. Draft horses with osteitis of the distal phalanx may assume a stance similar to that seen with traumatic laminitis. Hoof tester examination may be helpful to differentiate these conditions. A laminitic horse is most sensitive immediately dorsal to the apex of the frog in line with the dorsal one third of the toe. With osteitis of the distal phalanx, hoof tester pain response usually is less severe and more likely involves the sole in general. Soles may be pink or red, showing indications of bruising, and lameness is worse on hard surfaces or gravel. Mildly affected horses warm out of the lameness, but in horses with severe pain lameness increases as exercise continues. Radiographs can be difficult to interpret, and a definitive diagnosis is best reached using nuclear scintigraphy, observing increased radiopharmaceutical uptake in the distal phalanx. Management includes the judicious administration of NSAIDs and corrective shoeing. The sole should be protected and minimally pared. Pads frequently are used initially but may be counterproductive in the long run, because the sole has a tendency to become soft and lose thickness. Pads are needed for the first few shoe changes but then should be removed, and the sole should be hardened. To harden the sole, a common mixture referred to as sole paint (comprised of equal parts of 7% iodine, buffered formalin, and liquid phenol) is applied. This solution is applied to the sole once each day for 3 to 5 days or until the sole becomes hard. Overzealous application can cause the sole to become too hard. Paddock rest for 45 to 60 days is given. If shorter rest periods are given, recurrence is common. Hard, frozen, or rough surfaces should be avoided.

Canker

Canker is not common but is a difficult problem to solve. Canker is proliferative pododermatitis of the frog that may extend to undermine the sole and heel bulbs. The condition can occur in one or all feet and has no predilection for forelimbs or hindlimbs. Often horses are thought to have nonresponsive thrush, but later when the problem persists, canker is diagnosed (Fig. 126-4). Canker is seen more commonly in Draft horses than in light horses, a fact that may reflect differences in hoof care and environment or simply may represent a breed predisposition. Two clinical signs that differentiate canker from thrush are a foul odor (necrotic) and the presence of granulation-like tissue that bleeds easily when manipulated (Fig. 126-5). Lameness is highly variable depending on the severity and number of feet involved. Once the superficial layer of tissue is removed, bleeding is often profuse. Creamy exudate is typical initially, especially if the owner has initiated treatment with caustic preparations.

Successful treatment of canker requires patience on the part of the owner and the veterinarian because recurrence is common. The application of a hospital plate shoe is critical,

Fig. 126-3 Draft horse foot showing chronic scar and granulation tissue associated with quittor.

Fig. 126-4 Draft horse foot showing the typical appearance of thrush complicated by canker beneath the superficial layer of the frog.

Fig. 126-5 Chronic canker with proliferative granulation tissue. Infected granulation tissue has undermined the sole and heels.

because this shoe allows for long-term treatment and protects the sole. Importantly, pressure on the sole appears beneficial to healing, similar to that seen with granulation tissue at any site. Hospital plate shoes reduce the cost associated with daily care and management of a bandage. The shoe allows the horse to be exercised. The hospital plate shoe is made and fitted to the foot, and then the foot is blocked. A tourniquet is placed at the level of the fetlock joint, because bleeding during debridement is often profuse. Complete debridement of all abnormal proliferative tissue is often not possible and in fact may be counterproductive, because aggressive debridement may expose uninvolved deep tissue. Dry gauze sponges are packed to apply pressure on the frog and sole when the plate is replaced. Metronidazole appears to be the best topical agent, but I have used tetracycline and sulfapyridine powder successfully. The dressing should be changed daily for the first 10 to 14 days and then as needed. Debridement often needs to be repeated several times. Long-term treatment is necessary, and the owner needs to be prepared to provide it. Caustic compounds are not effective and in fact may worsen the condition. In the final stages of healing, when cornification of the frog is complete, caustic agents may be applied. Sole paint is applied to the sole for 8 to 10 days before the hospital plate shoe is removed. Horses are administered trimethoprim-sulfamethoxazole (15 mg/kg) for 3 weeks starting the day before initial debridement. Penicillin (20,000 IU/kg IM) is also effective, but oral antimicrobial agents are administered more easily.

Osteoarthritis of the Proximal and Distal Interphalangeal Joints, Ringbone

Osteoarthritis of the proximal interphalangeal or distal interphalangeal joint was diagnosed in 26 Draft horses in my series.

Ringbone has been described classically as being peri-articular or articular in nature. The prognosis for Draft horses with articular ringbone is worse than for those with the peri-articular form. Pulling horses (heavy loads) are affected most commonly, especially in the hindlimbs. Osteoarthritis of the proximal interphalangeal and distal interphalangeal joints appears to occur with similar frequency, because in 26 horses, 11 had proximal interphalangeal, 10 had distal interphalangeal, and 5 had proximal interphalangeal and distal interphalangeal involvement. Horses with osteoarthritis of the proximal interphalangeal joint remained serviceably sound for 2.6 years, whereas horses with osteoarthritis of the distal interphalangeal joint or in both joints were serviceably sound for only 11 months. Early diagnosis appears to be an important criterion for an improved prognosis, and reducing workload, instituting corrective shoeing, and providing medical management can make a substantial difference in delaying the progression of osteoarthritis.

Draft horses with short, upright pasterns are predisposed to osteoarthritis of the proximal interphalangeal and distal interphalangeal joints, and other factors such as angular limb deformities, toed-in or toed-out conformation, hoof imbalance, and trauma may play a substantial role. Horses required to work on pavement are predisposed to osteoarthritis of the proximal interphalangeal and distal interphalangeal joints. Proliferative peri-articular changes often result from lacerations or wire cuts. Horses with moderate to severe lameness have obvious enlargement of the pastern or coronary band area and heat. The degree of lameness varies from grade 1 to 5, and it worsens with lower limb flexion or after rotation of the digit. Rotation causes a substantial positive response if collateral ligaments are involved in horses with the peri-articular form. In horses with osteoarthritis of the distal interphalangeal joint, a palmar digital nerve block generally results in substantial improvement in lameness score. Thorough examination of the foot must be done to eliminate other potential causes of lameness. If the diagnosis is unclear after radiography, intra-articular analgesia should be performed. In horses with osteoarthritis of the proximal interphalangeal joint, a palmar digital nerve block may provide some improvement in lameness score, but an abaxial sesamoid block is needed to improve lameness substantially. Intra-articular analgesia can also be used.

Management depends on when the diagnosis is first made. Horses with osteoarthritis and mild lameness should be given rest in a small level paddock for 4 months. I do not use stall rest unless horses are very active, because I have had greater success allowing the horse to walk in a confined area. Hoof balance should be corrected, and the horse should be shod with flat shoes without calks, toe grabs, or borium. I recommend oral glucosamine or chondroitin sulfate supplementation or intramuscular injection of a polysulfated glycosaminoglycan. I also inject the joints with a corticosteroid and hyaluronan. Initial and follow-up radiographic examination is recommended. If the horse is sound and radiographic changes do not progress, the horse is put back into a light exercise program, whereas if radiographic changes progress, additional rest and injections are given. Many horses with osteoarthritis perform for extended periods of time without recurrence of lameness. Horses with severe osteoarthritis of the proximal interphalangeal or distal interphalangeal joints have an unfavorable prognosis for athletic use. Medical management is of little benefit, and although spontaneous fusion of the proximal interphalangeal joint may occur, giving an accurate time estimate of when this may occur is difficult. Spontaneous fusion of the distal interphalangeal joint seldom occurs. Surgical arthrodesis of the proximal interphalangeal joint can be performed by using bone plates or the three-screw technique with 5.5-mm bone screws (see Chapter 36). A half-limb cast is placed for at least 4 to 6 weeks after surgery. In Draft horses the surgical procedure is difficult compared with light horses

because the joints are large, removing articular cartilage is difficult, and horses may have difficulty with anesthetic recovery. Draft horses in general do not recover well from extended periods (>2 hour) of general anesthesia. The surgical procedure can be long, in particular if there is substantial peri-articular bone formation and fibrosis. Implants can break because of the large size of a Draft horse. Because of this, I have used an alternative technique of drilling across the joint with a 4.5- or 5.5-mm drill bit and then applying a half-limb cast without using implants. In horses with substantial peri-articular bone proliferation or fibrosis, this technique is my method of choice. Intraoperative radiographs are mandatory to assure proper placement of the drill bit within the joint. I drill at three to five sites in a fan-shape pattern from each side of the joint to destroy as much articular cartilage as possible. Breaking a drill bit in the joint is possible, and if this happens, removing the bit generally is not worth the extra time required. The palmar digital artery, vein, and nerve must be avoided during this procedure. A half-limb cast encompassing the foot is applied and maintained for 12 to 16 weeks. Advantages of this technique over those involving implants are that this technique is faster, requires shorter anesthesia periods, and requires no major skin incisions, and implant failure is not a concern. Pain control must be used to maintain reasonable comfort to avoid contralateral laminitis, which is always a concern.

Metacarpophalangeal (Fetlock) Joint Lameness

Problems associated with the fetlock joint are less frequent in Draft horses than in other breeds, and most result from direct trauma. Fetlock joint problems plague horses that perform at speed, and therefore Draft horses seldom have lameness in this region. Sesamoiditis does occur in Draft horses and usually results from suspensory desmitis and insertional injury at the level of the proximal sesamoid bone. Sesamoiditis is more common in the hindlimbs. An unusual problem of the fetlock joint in young Draft horses is osteochondritis dissecans.

Splints

Exostoses of the second and fourth metacarpal or metatarsal bones (splints) most commonly affect the second metacarpal bone, similar to light horses. In 84 Draft horses diagnosed with splints, 71 horses had forelimb involvement. Lameness associated with true splint (tearing of the interosseous ligament) is not common in Draft horses. Lameness caused by splints is most prominent in the first 2 to 3 weeks after the condition is first recognized and usually resolves with 6 to 8 weeks of rest. Because Draft horses do not perform at speed or change direction quickly, splints do not cause long-term lameness. Splints can result from interference injury from the contralateral limb, a problem that usually is corrected by proper shoeing and trimming. Local infiltration of local anesthetic solution in the region of the splint may be performed if the diagnosis is in question. Although a splint may be painful during palpation, missing a more distal limb problem is easy; therefore diagnostic analgesia should be performed distal to the splint before local infiltration. Radiographs should be obtained to check for a fracture.

To manage a Draft horse with lameness resulting from a splint, I administer NSAIDs for 5 to 7 days and recommend stall rest. If the condition is acute, I use cold water therapy or ice boots for 20 to 30 minutes twice daily and apply support wraps. The horse should be hand walked for 10 minutes twice daily. In horses with chronic splints, I recommend a sweat (50/50 mixture of glycerine and alcohol) for 7 to 10 days. Paddock exercise can be given for 12 hours each day. A total rest period of 60 to 90 days is usually adequate. I avoid overzealous treatment with topical or internal blisters.

Fractures of the splint bones are rare but usually involve the fourth metatarsal bone, and they often occur from kick wounds. These fractures often are comminuted and usually infected, because owners do not seek veterinary attention until 2 to 3 weeks after injury. Severe lameness often is not seen or is short lived, so the owner usually is not concerned until drainage starts. If the tarsometatarsal joint is involved and infected, the prognosis for return to original use is unfavorable. Many of these fractures heal if horses are given rest and treated with antibiotics. If the articular surface of the tarsometatarsal joint is not involved, displacement of fragments is minimal, and if the horse is not an athlete, many times this injury can be treated conservatively. Standing curettage of a draining tract and removal of sequestra can be accomplished in many patients using sedation and local analgesia. A culture is performed, and the horse is placed on appropriate antibiotics for 3 to 4 weeks, and the outcome is often satisfactory. For economic reasons this method also is chosen by some owners for horses intended for athletic use. However, I believe the problem is best treated surgically in those horses that are expected to be athletes. Surgical removal of the distal fractured segment of the fourth metacarpal bone is recommended occasionally, and horses usually have a good prognosis. If greater than 80% of the total length of the fourth metacarpal bone is removed, I use a screw to stabilize the proximal fragment. I do not like placing a screw into an area of known infection if I can avoid doing so. In those horses with substantial displacement or a fracture involving the articular surface, internal fixation to realign the fracture is indicated, if the injury is less than 3 weeks old. Fractures older than 3 weeks can be difficult to realign because callus formation occurs quickly.

Tendonitis and Suspensory Desmitis

Flexor tendonitis and suspensory desmitis are not as common in the Draft horse as one might expect. Of 45 horses examined for these soft tissue problems, the distribution of these combined soft tissue injuries between the forelimbs and hindlimbs was similar, in contrast to most sport horses. Suspensory desmitis is more common in the hindlimb and often is seen with sesamoiditis. Tendonitis and suspensory desmitis are more common in horses that pull heavy loads or weighted sleds. Clinical signs include heat, pain, swelling, and lameness, and diagnosis is usually straightforward. Horses with hindlimb proximal suspensory desmitis may have more subtle clinical signs, and diagnostic analgesia is usually necessary. In horses with early forelimb superficial digital flexor tendonitis, the anastomosing branch of the palmar nerves may be enlarged and sensitive to palpation before the tendon itself shows clinical abnormalities. Ultrasonographic examination should be performed.

Management of Draft horses with tendonitis and suspensory desmitis is similar to that in light horses. Ultrasonographic examination, rest, and a staged return to work are important. I am an advocate of percutaneous tendon or suspensory ligament splitting under ultrasonographic guidance in Draft horses. The surgery can be accomplished in a standing horse, using local analgesia and sedation, thus avoiding the need for general anesthesia. Prognosis is guarded to favorable in Draft horses with forelimb tendonitis and suspensory desmitis. Draft horses with hindlimb injury, however, have a guarded to unfavorable prognosis, especially if horses are used for pulling heavy loads. Broodmares with chronic, severe suspensory desmitis must be given special attention during late pregnancy because of weight gain. These mares should be housed on level surfaces and alone. Situations that require the mare to move quickly to avoid an aggressive pasture mate, or to slip while going over rough terrain, should be avoided. Muddy or slick footing also should be avoided. Stall rest, while advantageous for healing of the suspensory ligament, is avoided, because these broodmares usually develop substantial ventral edema.

Other Forelimb Lameness

Other causes of forelimb lameness are unusual. Upper limb lameness usually is caused by direct trauma and is not the result of athletic use. Carpal, elbow, or shoulder joint lameness is not common. I have examined only 13 Draft horses with carpal lameness. Various manifestations of osteochondrosis are seen in the elbow and shoulder joints.

Sweeny, a neuromuscular disorder thought to be associated with injury of the suprascapular nerve, does occur with some frequency in Draft horses. Muscle atrophy may not be obvious for weeks to months, depending on the extent of the injury. Sweeny may result from acute direct trauma, but in Draft horses insidious trauma from a collar is the most common cause. This is especially true of poorly fitting collars, or old and worn collars in which the padding is no longer adequate. Collars of inadequate size often are used on today's large-sized Draft horses. Some Draft horses with sweeny continue to perform adequately despite muscle atrophy. Diagnosis is made by observing muscle atrophy over the scapula, especially affecting the supraspinatus muscle. Lameness is most likely functional and not related to pain, because horses cannot extend the shoulder joint normally. In some horses, however, the shoulder joint actually may subluxate, when the horse is walking or especially while turning in a circle. Subluxation results more frequently from external trauma from being kicked or from running into a solid object rather than from collar injury and may involve additional nerve injury.

Management of horses with acute trauma of the shoulder area includes the administration of NSAIDs, corticosteroids, and dimethylsulfoxide and by performing physical therapy. A water hose with a hard stream of water can be useful for physical therapy. Liniments, massage, handheld muscle stimulators, and heating pads can be useful physical therapeutic modalities as well. The administration of dimethylsulfoxide (0.3 g/kg sid IV for 3 to 5 days) is recommended in the acute phase. Prognosis is difficult to assess, but if improvement is not seen in the first 6 to 8 weeks after diagnosis, prognosis becomes less favorable. I have not attempted scapular notch resection in Draft horses, but knowing the complications associated with the procedure in light horses leads me to hesitate recommending it.

Unusual Signs Consistent with Lameness Caused by Mange Mites

In the United Kingdom a significant incidence of mange occurs in draft breed horses.[2] Draft horses often are presented for evaluation of presumed lameness because of a stiff, stilted gait and with abnormal stamping of the limbs to the ground. In these horses careful lameness evaluation reveals areas of dermatitis, but this condition can be confused easily with musculoskeletal pain. I have not seen this to be a problem in Draft horses in the United States.

Hindlimb Lameness

Hindlimb lameness occurs frequently in Draft horses, and the most common cause is lameness associated with the tarsus (hock joint). Draft horses in general have a predisposition to develop tarsitis, and lameness does not seem to be related to use. The custom of lowering the inside wall of the hoof and attempting to turn the hocks, a shoeing change thought to improve the horse's pulling ability, may predispose a Draft horse to tarsitis. To my knowledge, however, this has never been proved in a controlled study. Draft horse shoes often have a large calk on the heel of the lateral branch, increasing torque and shear stress on the entire limb. Heel calks are especially detrimental in horses that work on hard surfaces, because the calk does not sink into the surface, thus putting even greater stress on the limb. This method of shoeing causes a flaring of the lateral hoof wall and predisposes the hooves to separation and breakdown of laminae. Even if this method of shoeing is abandoned, at least 12 to 18 months are required for the foot to return to normal.

Tarsus

Draft horses with hock lameness show a variety of clinical signs. The perceived problems by the owner also vary considerably. The horse may stop pulling or may rest its butt on the stall wall when in the barn. Breeding stallions may be reluctant to mount a mare, and when mounted, they may be unable to maintain erection. Horses may be reluctant to back up, back in crooked fashion, and have difficulty going up and down inclines. The horse may take short strides in harness or may have a change in attitude, sometimes biting other horses. Because the prevalence of hock joint lameness is high, carefully considering this region when evaluating a Draft horse with hindlimb lameness is always wise.

Diagnosis may be straightforward, based on clinical signs, or may require diagnostic analgesia to pinpoint the problem. Upper limb flexion tests in Draft horses appear to be slightly more accurate as an indicator of hock lameness than the same test is in light horses, but false-negative results do occur. Pulling the medial splint bone with the fingers (Churchill test) with the limb in flexion also may be of value. The horse may show a positive response while standing, or lameness may be exacerbated after performing this maneuver. When the horse is trotting, careful attention is given to the vertical movement of the wings of the ilium (hip or pelvic hike), but if the problem is bilateral, a pelvic hike may not be obvious. Stride length may be shortened when viewed from the side, and when evaluated from behind or in front, horses have a tendency to swing the limb toward the midline and then place the limb laterally as it strikes the ground. Horses may scuff the toes because of the low arc of limb flight. Bony exostosis on the dorsal medial aspect of the hock joint may be obvious or absent.

Tarsocrural effusion, or bog spavin, is observed commonly in Draft horses. This clinical observation often does not correlate with the source of pain. Even if osteochondrosis is suspected or confirmed, intra-articular analgesia always should be performed (Fig. 126-6). Although present, osteochondritis dissecans fragments may not be causing the major source of pain, and surgical removal of these fragments may not resolve lameness. Arthroscopic removal of osteochondral fragments is often less rewarding in adult horses. In Draft horses less than 2 years of age, arthroscopic removal of osteochondritis dissecans fragments is more likely to resolve lameness, however. The decision to perform surgery is based on the level of performance, cosmetic considerations related to joint distention, location of the lesion, and most importantly, whether lameness resolves with tarsocrural analgesia. Horses with osteochondritis dissecans lesions located more distally on the trochlear ridges have a more favorable prognosis that those with lesions located on the proximal aspect. Horses with osteochondritis dissecans lesions associated with the cranial intermediate ridge of the distal tibia have a favorable prognosis if lesions are removed early before chronic synovitis or capsulitis occurs. With only a limited number of horses from which to draw experience, lesions seemingly occur more frequently on the lateral trochlear ridge of the talus (tibial tarsal bone) than in any other location in a Draft horse.

Lameness associated with osteoarthritis of the centrodistal and the tarsometatarsal joints is common. Intra-articular analgesia is often necessary, although some veterinarians medicate these joints and assess the clinical response to this treatment. I prefer to perform intra-articular analgesia and consider management options once a definitive diagnosis is made, however. In my opinion, conservative management should be attempted before using corticosteroids. I block the tarsometatarsal and the centrodistal joints first with the horse standing squarely on

Fig. 126-6 Dorsomedial-plantarolateral oblique radiographic view of a hock of a yearling Draft horse. The radiograph was deliberately underexposed to highlight the extensive osteochondritic lesion involving the distal half of the lateral trochlear ridge of the talus.

each limb. In Draft horses with exostoses on the medial aspect, confidently blocking the centrodistal joint may be difficult. Seven to 12 ml 2% mepivacaine hydrochloride is injected into each joint using a 20- to 22-gauge, 2.5- to 4-cm needle in the standard locations (see Chapter 10). In most Draft horses a twitch is adequate for restraint. Radiographs should be obtained, but unfortunately they are unreliable in confirming the diagnosis of osteoarthritis. In some Draft horses with substantial radiographic changes, lameness may originate elsewhere, whereas in some horses with minor or equivocal radiographic changes, severe lameness from early osteoarthritis of these joints is diagnosed. Radiographic examination helps to select management options and to determine prognosis, however.

Management of the Draft horse with osteoarthritis of the distal hock joints includes physical and medical and surgical options. Correction of any shoeing or trimming problems should be performed before any other treatment. The foot is balanced in a medial to lateral direction according to conformation to achieve a level foot strike. My definition of a level foot strike means that the foot lands evenly when contacting the ground during movement. I remove the large calks and trailers that often are placed on the lateral branch of the shoes. If the horse is not going to be worked for a period of time, I prefer to shoe the horse without any special trim (calks, toe grabs, or inside rims). The dorsal aspect of the shoe is placed at the white line, and the toe is rasped back to the level of the shoe. Squared-toe shoes also can be used. The heels of the shoe should extend far enough behind to support the plantar aspect of the heel completely. In some horses slight heel elevation improves breakover and comfort. If the lateral hoof wall is flared, it must be rasped at each shoeing, and the lateral branch of the shoe gradually must be adjusted to conform properly to a more normal hoof shape. If borium is needed for traction on hard surfaces, it should be placed so that it provides a level surface on the bottom of the shoe. Uneven stress from borium points may cause hoof wall cracks. Usually, using six to 10 spots of borium on the shoe adequately supports the foot and also provides adequate traction.

Medical management may include oral supplementation, intramuscular administration of polysulfated glycosaminoglycan, and intravenous administration of hyaluronan. NSAIDs are recommended at the time of shoeing changes, but long-term use of NSAIDs is usually not a solution in the management of chronic distal hock joint pain. Chronic administration often results in gastrointestinal ulceration and additional problems such as colic or colitis. Horses with distal hock joint pain can be given 2 to 3 g of phenylbutazone daily. Intra-articular injection with hyaluronan alone has limited value in Draft horses with osteoarthritis of the distal hock joints, and I prefer to use hyaluronan with methylprednisolone acetate. If treatment involves economic considerations, the corticosteroid is most important and can be injected alone. The dose of these compounds is similar to that used in the light horse and is not based necessarily on body weight. I increase the corticosteroid dose by about 25% using methylprednisolone acetate (100 mg) in each of the centrodistal and the tarsometatarsal joints. If treating bog spavin, I use methylprednisolone acetate (120 mg) and hyaluronan (40 mg). I seldom if ever use triamcinolone acetonide in Draft horses, because of a concern about laminitis induction and the fact that I often am injecting several joints simultaneously.

Cunean tenectomy is used in some horses, especially those that have obvious enlargement on the medial aspect of the hock (Fig. 126-7). Cunean tenectomy is accomplished in a standing horse using local analgesia and sedation. Horses often are put back into work once the skin sutures are removed, 12 to 14 days after surgery.

Stifle Joint

Draft horses have long been thought to have more stifle joint lameness than do light horses, but when reviewing the records of 745 Draft horse lameness examinations, only 10 horses had primary lameness of the stifle joint. Perhaps long ago, when Draft horses were used daily to pull heavy loads, the frequency of stifle lameness may have been far greater than it is today. Of these 10 horses, three had bilateral idiopathic effusion of the femoropatellar joint. One horse had bilateral subchondral bone cysts of the medial femoral condyles, one had upward fixation of the patella, and five had trauma from kick injuries. Poor conformation and extended stall confinement predispose some Draft horses to upward fixation of the patella. Emaciated horses or those with significant weight loss also are predisposed to the condition. I make every attempt to correct upward fixation of the patella by using conservative management including foot care, improving muscle tone or conditioning, and improving nutritional intake. Raising the heels often alleviates the problem, and block wedges to raise the angle of the foot 6° to 10° are needed. Heel elevation is reduced gradually as the problem is rectified. Improved muscle tone and exercise is beneficial, as is avoiding prolonged periods of stall confinement. Backing exercise strengthens the quadriceps muscles and is a useful form of physical therapy. Internal blisters, injected at the origin and insertion of the patellar ligaments, may cause mild fibrosis and thus tighten the joint. This treatment is used less frequently now than in the past because the preparations need to be special ordered. I seldom if ever elect medial patellar desmotomy as my initial treatment. If conservative management is unsuccessful, desmotomy needs to be performed. The procedure should be

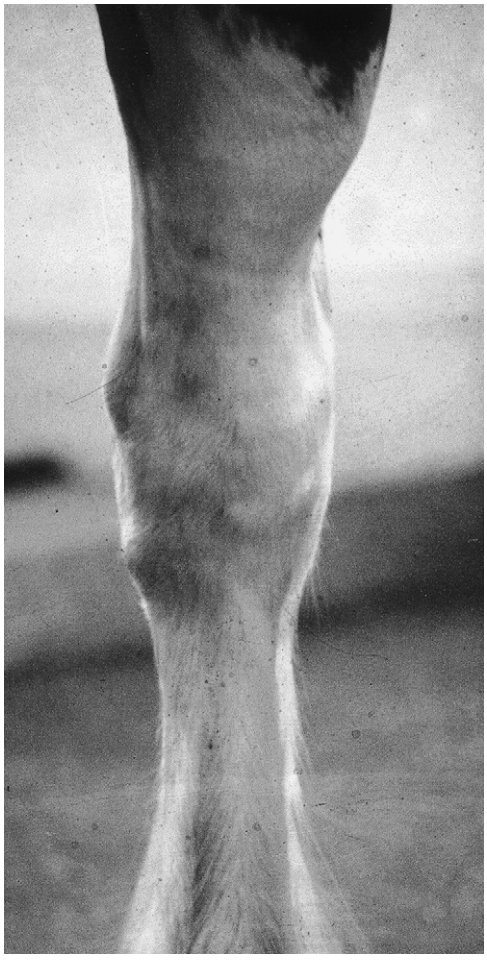

Fig. 126-7 The dorsal aspect of the left hock of Draft horse showing bony exostosis of the dorsal medial surface. If lameness were confirmed to originate from the lower hock joint region, this horse would be a candidate for cunean tenectomy.

done in the standing horse and not under general anesthesia and should be done with a sharp, strong-backed bistoury. This procedure should not be attempted in a Draft horse with an ordinary scalpel handle and blade, because the risk of the blade breaking during the surgery is real.

Shivers

Shivers is considered a progressive, degenerative neuromuscular disease predominantly affecting Draft horses or other large breed horses (see Chapter 49). Various causes have been suggested, including immune-mediated disease following viral infection or strangles and exposure to organophosphates. Presently, polysaccharide storage myopathy has been put forth as a possible cause, but like previous proposed causes, this one may go by the wayside. Clinical signs include an involuntary jerking or twitching most frequently affecting the hindlimbs and the tail. A reflex-like maximum degree of flexion can be seen. Clinical signs often are noticed first by the farrier, because manually picking up the hindlimb frequently stimulates the jerking movements. Signs may be most obvious when the horse first starts to walk, or is backed, or is turned sharply. On occasion, twitching of the muzzle, lips, and ears and forelimb involvement occurs. The condition may improve with rest but usually returns when the horse is put back into work.

Currently, no effective treatment is available. Shivers has been confused with stringhalt in some horses, and the surgical procedure, lateral digital flexor tenectomy, has been performed erroneously. Muscle biopsy to check for polysaccharide storage myopathy and treatment with high-fat, low-carbohydrate diets may be warranted, but definitive proof that polysaccharide storage myopathy is the cause of shivers may be difficult to substantiate. Horses still can be worked, but often owners elect to use them sparingly.

LAMENESS OF FOALS, WEANLINGS, AND YEARLINGS

Young Draft horses require careful monitoring and early attention to lameness conditions. Lameness is often multifactorial and is related to nutrition, genetics, and environment. Early diagnosis and management of lameness appears more critical in Draft horse foals than in light horse foals. Often the size and strength of Draft horse foals gives the erroneous impression that they can overcome many problems.

Infectious Arthritis

Infectious arthritis is common in Draft horse foals and may be related to a high frequency of umbilical problems. Umbilical hernias, umbilical infections, and patent urachus are more common in Draft horse foals than in light horses. Careful examination and treatment of the umbilicus at birth is mandatory, and the umbilicus should be monitored closely for a minimum of 3 weeks. Compared with light horse foals, Draft horse foals are often slower to stand and nurse after birth, leading to many infectious processes. Owner education is important, not only in assisting slow foals up to nurse but also in careful, daily evaluation of joints. Early and aggressive management of infectious arthritis and umbilical remnant infections should be performed (see Chapter 66).

Developmental Orthopedic Disease

Draft horses are affected by all of the various manifestations of developmental orthopedic disease, including flexural deformities, epiphysitis/physitis, osteochondrosis, angular limb deformities, and vertebral malformations (wobbler syndrome). A multifactorial cause is suspected, including nutrition (calcium/phosphorous ratios and trace mineral levels) and hereditary factors (certain bloodlines have a high prevalence). Hereditary factors are complex and include high growth rate, feed deficiency conversion, milk production, and individual horse size.

Physitis/Epiphysitis and Flexural Deformities

These conditions are closely related and seldom if ever a single problem. These conditions are seen over a wide age range from 6 weeks to 24 months, but peak occurrence is in foals 4 to 12 months of age. When raising large horses, owners have a tendency to overfeed, resulting in high-energy rations, fast growth, and nutritional stress, all of which include the possibility of developmental orthopedic disease. My experience with some 300 Draft horse foals suggests a distinct correlation between the frequency of developmental orthopedic disease and nutritional management. Foals having the highest frequency of developmental orthopedic disease were fed free choice high-quality alfalfa hay, approximately 0.015 kg feed/kg body weight/day, of a 16% protein grain ration and two vitamin/mineral supplements. Foals were fed in groups of six to 10 in 5- to 6-acre paddocks. Group feeding allowed the aggressive eater to consume far more than the prescribed amount of grain, and of course hay was fed free choice. None of the foals was thin or malnourished, but numerous foals were obese. Overweight foals, yearlings, or 2-year-olds do not exercise properly, a fact that exacerbates problems associated with excess ration. Under these conditions, two to four foals per group were affected with developmental orthopedic disease each year.

To correct this problem, the nutritional program was revamped. The owner accepted the fact that yearling size may

be slightly less than previously attained, but that developmental orthopedic disease would occur less frequently. Anecdotally, buyers of yearlings from this group had complained in previous years that 2-year-olds had become lame when training had started. The nutrition was changed as follows. The hay ration was given at a 50/50 mixture of alfalfa to timothy. Hay was fed at a rate of 0.015 kg/kg body weight/day, or the amount the foals could consume in about 16 hours. The grain ration was reduced to approximately 0.01 kg/kg body weight/day of a 14% protein ration. Only one vitamin/mineral supplement was given. Foals were grouped according to size, age, and disposition and were monitored closely and checked every 2 weeks by the farm veterinarian. Changes in conformation (becoming upright in the pastern and fetlock) or enlargement (heat and pain) of the growth plates were noted.

Any foal with a change in the pastern or fetlock angle (developing more upright conformation), joint effusion, or physitis was treated immediately. Stall rest was given for 7 to 10 days, the feed intake was reduced, and the foal subsequently was given controlled exercise in a small paddock. Foals were fed only timothy hay, and the grain ration was reduced to 0.002 kg/kg body weight/day. They were placed on phenylbutazone (2.2 mg/kg bid for 3 consecutive days and then every other day for 3 more days). They were maintained in this environment until the problem resolved. Any hoof imbalance or growth abnormality was treated. A 60% decrease in developmental orthopedic disease was noted the first year, and now that farm management has become more attentive to noticing early signs of developmental orthopedic disease, the frequency of this complex of diseases is now less than 10%.

Osteochondritis Dissecans and Osteochondrosis

In my experience, osteochondrosis is observed more commonly in Draft horse foals than in light horse foals. In Draft horse foals the tarsocrural and femoropatellar joints are affected most commonly. Any joint can be affected, including the cervical vertebrae. Horses affected with osteochondrosis show varying degrees of lameness from 1 to 4 of 5 degrees lame. Lameness is less frequent with osteochondrosis lesions of the tarsocrural joint than with osteochondrosis of the stifle. Loose osteochondral fragments in the femoropatellar joint should be removed as soon as possible. Arthroscopic surgery does not guarantee success but improves the prognosis for athletic use. In my experience, Draft horses have a more guarded prognosis for future soundness with osteochondrosis of the stifle than do light horses. I am unsure if this is related simply to the size of the horse or the amount of pulling many of these Draft horses are expected to do, but only about 50% of Draft horses are sound after surgery. Early diagnosis and surgical management improves prognosis considerably. In some foals, without loose fragments, conservative management has resulted in a favorable outcome. Large osteochondritis dissecans defects involving the lateral trochlear ridges have healed based on radiographic examination, but this process may take up to 6 months to occur.

CHAPTER • 127

Lameness in the Pony

Andrew McDiarmid

Horses under the height of 14 hands, 2 inches (148 cm) at the withers generally are recognized as ponies. Despite this classification some pony breeds are referred to as horses; for example, Icelandic (toelter) *horses*. Many native pony breeds occur throughout the world; for example, Asturian (Spain), Connemara (Ireland), Fell (England), Gerrano (Portugal), Highland (Scotland), M'Bayar (Senegal), Merens (Pyrenees), Ob (Russia), Pindos (Greece), and Welsh ponies. Several small island breeds also occur; for example, Barearic, Eriskay, Faeroe island *horse*, and Chincoteague ponies. The size and conformation of most pony breeds has evolved over centuries because of specific work requirements and geographical isolation. Several breeds are endangered, including the Yonaguni and Noma in Japan and Sorraia in Spain, and some have become extinct; for example, the Fen, Galloway, and Tarpan. Attempts are being made actively to prevent extinction for several breeds; for example, the Kerry bog pony in Ireland and the Taishuh in Japan. In recent times new breeds of pony have evolved, including the Welara and Pony of the Americas. Despite this, most ponies are crossbred.

Ponies have a considerable range of height, weight, and conformation and are involved in most spheres of equine work, including show jumping, eventing, dressage, driving, and general pleasure activities. Many ponies show great athletic ability and, when used for show jumping, they often jump heights similar to their own height at the withers. Ponies have a long life expectancy and can remain in athletic work well into the twenties. Although a small number of ponies are used for high-level competition work such as eventing and show jumping, most are used for general purpose work, when they may be ridden only in the summer months. General purpose ponies tend to be much less valuable than horses and are ridden predominantly by children, which may create emotional and financial conflicts for owners (parents) when deciding the appropriate treatment of a seriously injured pony. Many general purpose ponies remain at grass all year round and do not have access to a stable. Competition ponies often change ownership, at high prices, every 2 or 3 years, as children outgrow them.

Few reports in the literature describe orthopedic conditions specifically affecting the pony. In this chapter I hope to

be slightly less than previously attained, but that developmental orthopedic disease would occur less frequently. Anecdotally, buyers of yearlings from this group had complained in previous years that 2-year-olds had become lame when training had started. The nutrition was changed as follows. The hay ration was given at a 50/50 mixture of alfalfa to timothy. Hay was fed at a rate of 0.015 kg/kg body weight/day, or the amount the foals could consume in about 16 hours. The grain ration was reduced to approximately 0.01 kg/kg body weight/day of a 14% protein ration. Only one vitamin/mineral supplement was given. Several breeds are endangered, including the Yonaguni and Noma in Japan and Sorraia in Spain, and some have become extinct; for example, the Fen, Galloway, and Tarpan. Attempts are being made actively to prevent extinction for several breeds; for example, the Kerry bog pony in Ireland and the Taishuh in Japan. In recent times new breeds of pony have evolved, including the Welara and Pony of the Americas. Despite this, most ponies are crossbred.

Ponies have a considerable range of height, weight, and conformation and are involved in most spheres of equine work, including show jumping, eventing, dressage, driving, and general pleasure activities. Many ponies show great athletic ability and, when used for show jumping, they often jump heights similar to their own height at the withers. Ponies have a long life expectancy and can remain in athletic work well into the twenties. Although a small number of ponies are used for high-level competition work such as eventing and show jumping, most are used for general purpose work, when they may be ridden only in the summer months. General purpose ponies tend to be much less valuable than horses and are ridden predominantly by children, which may create emotional and financial conflicts for owners (parents) when deciding the appropriate treatment of a seriously injured pony. Many general purpose ponies remain at grass all year round and do not have access to a stable. Competition ponies often change ownership, at high prices, every 2 or 3 years, as children outgrow them.

Few reports in the literature describe orthopedic conditions specifically affecting the pony. In this chapter I hope to

give an overview of some of the conditions that are recognized as affecting the pony.

LAMENESS AFFECTING THE PONY

Ponies suffer from orthopedic problems similar to those horses suffer, but the overall prevalence of lameness in the pony is less than in the horse. This may be because of differences in temperament and body weight. With a relatively older population the incidence of some specific orthopedic conditions affecting older ponies may appear higher than in horses, but the prevalence is often unclear and may, for some conditions, be similar; for example, Cushing's disease.

LAMENESS EXAMINATION

Gait assessment in ponies can be challenging because they can have a higher limb speed than horses, and the larger, heavier pony breeds (e.g., Highland) often have a base-wide gait behind, which may make assessment of hindlimb lameness difficult. Several breeds also have gaits additional to walk, trot, and canter; these include the South African, Basotho pony, and Icelandic *horses*. In small ponies the handler may have to walk when leading a trotting pony, rather than run, to keep the limb speed to a rate at which the observer can detect low-grade lameness.

The low height of some ponies compared with most veterinary surgeons may create difficulties with assessment of the lower limb, and excessive force or torsion can be applied easily to the distal joints while performing a flexion test.

In small ponies, care should be taken not to apply excessive pressure with hoof testers and, if the veterinary surgeon is tall, not to flex or twist the lower limb excessively in an effort to raise the foot to a convenient height to use the testers. Paradoxically, in comparison with horses many ponies have harder hoof horn, making eliciting foot pain difficult, so care always should be taken when assessing the response to hoof testers. The use of small or adjustable hoof testers is advisable for ponies.

Ponies can have a positive response to lower limb flexion tests despite being sound and performing to the owner's expectations.

DIAGNOSTIC ANALGESIA

Some ponies are strong-willed, which can limit a conventional lameness evaluation using perineural or intrasynovial analgesia. Using a nose twitch or a low dose of an α_2-sedative may aid this (e.g., 40 to 60 µg/kg romifidine or 0.6 to 0.9 mg/kg xylazine intravenously). In some ponies the lower limbs may have thick skin and be very hairy, making accurate palpation of the structures difficult, particularly finding the site for a palmar digital nerve block. I am conscious that because of the relatively shorter limbs in ponies, local anesthetic solution may diffuse farther than in the horse, and a reduced amount of local anesthetic solution is used for perineural analgesia (e.g., 1 ml of mepivacaine hydrochloride for each nerve when performing a palmar digital or palmar [abaxial sesamoid] analgesia).

IMAGING CONSIDERATIONS

For most clinical situations a similar number of radiographic projections are required to examine the lower limb of a pony as for a horse. Although obtaining good-quality radiographs of the lower limb is generally easier, some important lesions may be more subtle than in the horse, particularly involving the distal interphalangeal joint and navicular bone. Conversely, one should note that a substantial amount of joint degeneration can be present in some sound ponies (Fig. 127-1). It is therefore important in the pony to undertake intrasynovial analgesia to confirm that any peri-articular and intra-articular abnormalities are associated with joint pain.

In some ponies, particularly those kept at grass, a prominent increased thickness of skin in the distal limbs, pelvis, and thoracolumbar areas can be present and reduces skin penetration by ultrasound waves, resulting in poor ultrasonographic images. I have found that shaving the hair and hosing the area to be scanned with warm water for 15 minutes often substantially improves the quality of the image.

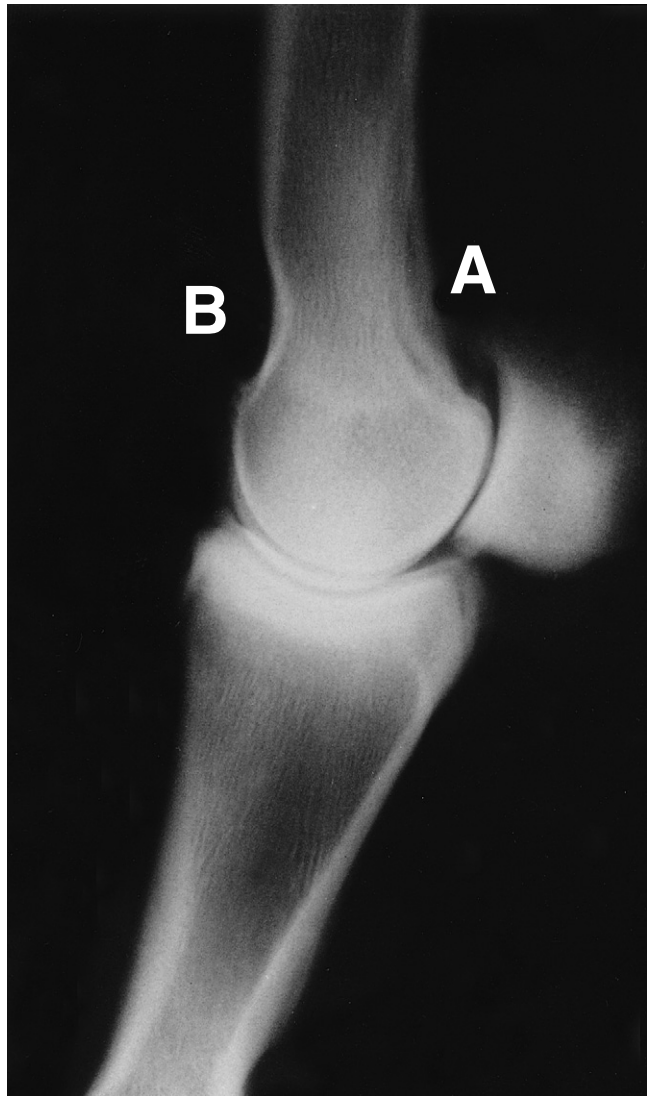

Fig. 127-1 Lateromedial radiographic view of the metacarpophalangeal joint of a 12-year-old jumping pony. Peri-articular osteophytes on the articular margins of the proximal and distal aspect of the proximal sesamoid bones reflect osteoarthritis. There is also evidence of supracondylar lysis (*A*) on the palmar aspect of the third metacarpal bone and villonodular (proliferative) synovitis (*B*) on the dorsal border. This pony had met the owners' expectation until 5 weeks before this examination.

MOST COMMON CONDITIONS AFFECTING COMPETITION PONIES

Competition ponies appear to have a reduced prevalence of lameness in comparison with horses, but the conditions that they suffer tend to mimic competition horses.

- Laminitis
- Distal hock joint pain—osteoarthritis of the distal tarsal joints (bone spavin)
- Desmitis of the accessory ligament of the deep digital flexor tendon (ALDDFT)
- Palmar and plantar annular desmitis
- Osteoarthritis of the metacarpophalangeal joint
- Superficial digital flexor tendonitis
- Exertional rhabdomyolysis
- Osteoarthritis of the carpus

LIMB DEFORMITIES

Mild angular limb deformities in ponies are common, but few affect performance or require medical or surgical correction. In many native breeds in the United Kingdom a small degree of carpus and fetlock valgus deviation is common. The persistence of a full-length ulna and fibula has been associated with the development of severe angular limb deformities in Shetland ponies.[1] This may be a form of atavism, the inheritance of a characteristic from remote rather than recent ancestors.

Congenital laxity of the flexor tendons in the hindlimb of Shetland ponies is not uncommon and can be associated with hyperextension of the distal interphalangeal joint. Treatment is similar to that in the horse.

Adactyly (absence of all or part of a normal digit) and polydactyly (duplication of all or part of a digit beyond the normal number) and other congenital musculoskeletal defects have been recorded in ponies.[2]

JOINT DISEASE

Osteochondrosis

Rarely do ponies have lameness associated with osteochondritis dissecans. Histopathological evidence of osteochondrosis specifically in ponies has been reported only in the lateral trochlear ridge of the femur.[3] Based on a limited number of ponies, in my opinion the most commonly affected joints are the tarsocrural and femoropatellar joints, and lesions are found at the same recognized sites as in the horse, that is, the cranial aspect of the distal intermediate ridge of the tibia, trochlear ridges of the talus, medial and lateral malleoli of the tibia, and lateral trochlear ridge of the femur. Osteochondrosis has been seen particularly in ponies bred for showing,[4] and this may be because these animals were receiving high feed intakes in an effort to improve their show ring appearance.

Lameness associated with a subchondral bone cyst in the medial femoral condyle in the stifle is not uncommon in the pony.

Osteoarthritis

Ponies suffer from osteoarthritis in similar joints as do horses. However, many ponies have mild to moderate joint degeneration, are clinically sound, and perform to the level of the owner's expectation (Fig. 127-1). Osteoarthritis in ponies tends to be primary rather than secondary to a previous intra-articular condition, such as intra-articular chip fractures, osteochondritis dissecans, osseous cyst-like lesions, or ligamentous damage.

Scapulohumeral Joint

Shetland ponies have a higher prevalence of osteoarthritis of the scapulohumeral joint than do other equine breeds. This typically occurs in young ponies; mean age in one survey was 5.2 years. The lameness is usually unilateral but can be bilateral and is sudden and severe (grade 4 to 5 of 5) in onset. Lameness is characterized by a reduction in the cranial phase of the stride and a low arc of foot flight. Radiographic abnormalities may not be present in the acute stage.[5] No reported treatment has resulted in successful resolution of the lameness. Shetland ponies have a flatter and shallower glenoid cavity of the scapula than other equine breeds, and this may be caused by a primary joint dysplasia that could predispose Shetland ponies to osteoarthritis of the scapulohumeral joint.[6]

Carpus

Older ponies appear to have an increased incidence of osteoarthritis of the carpometacarpal joint, often referred to as *carpal spavin*. The radiographic abnormalities found within the carpometacarpal joint are similar to osteoarthritis of the distal tarsal joints, and periosteal and enthesophyte formation on the abaxial margins of the second and fourth metacarpal bones also may be present.[7]

I have observed several lame ponies with restricted flexion of the carpus and radiographic evidence of carpal joint degeneration, but the lameness was abolished by perineural or intrasynovial analgesia in the more distal limb. Restricted carpal flexion, without overt lameness, may result in a pony being presented for a history of tripping and concern for the safety of a child rider.

Stifle

In a retrospective study of stifle lameness, a higher incidence of osteoarthritis of the femorotibial joints was noted in Highland ponies compared with the normal referral horse population at the University of Edinburgh.[8] The condition presents as sudden-onset, severe (grade 4 to 5 of 5) lameness associated with substantial damage to the menisci and collateral or cruciate ligaments. Ultrasonography and arthroscopy are useful to assess the extent of the soft tissue damage. In some of these ponies concurrent abnormalities in the surface of the medial femoral condyle, as described in horses, were present.[9] The extent of the meniscal and ligament damage was such that treatment was generally unsuccessful. Osteoarthritis of the femoropatellar joint can occur in Shetland and Miniature Shetland ponies secondary to chronic lateral luxation of the patella[10] (see following discussion).

Hock

Osteoarthritis of the distal tarsal joints (bone spavin) is a common cause of hindlimb lameness in ponies, but as in other joints, intrasynovial or perineural analgesia is advisable to confirm the relevance of any radiographic changes. Icelandic *horses* appear to be predisposed to osteoarthritis of the distal hock joints.[11] An epidemiological study showed that 23% of Icelandic *horses* in Sweden had radiographic signs of bone spavin.[12] A causal relationship has been found between hindlimb lameness and radiographic evidence of bone spavin and the animals' ages and hock angles. No relationship was found with environmental factors such as training and showing.[13] The lameness found in Icelandic *horses* is often mild, despite moderate to severe radiographic changes.[11]

Other Specific Joint Conditions

Luxation of the Coxofemoral Joint

Rupture of the coxofemoral ligaments and secondary luxation of the coxofemoral (hip) joint has a higher prevalence in the pony than in the horse (Fig. 127-2).[14] This may be because in the horse, unlike in ponies, the ilium tends to fracture before luxation of the hip occurs.[15] In the pony, ligament rupture usually occurs after trauma, and the head of the femur is often displaced in a craniodorsal direction. Affected ponies adopt a characteristic posture with outward rotation of the foot and stifle, inward rotation of the tarsus, and a pronounced shortening of the affected limb. Open or closed reduction has been

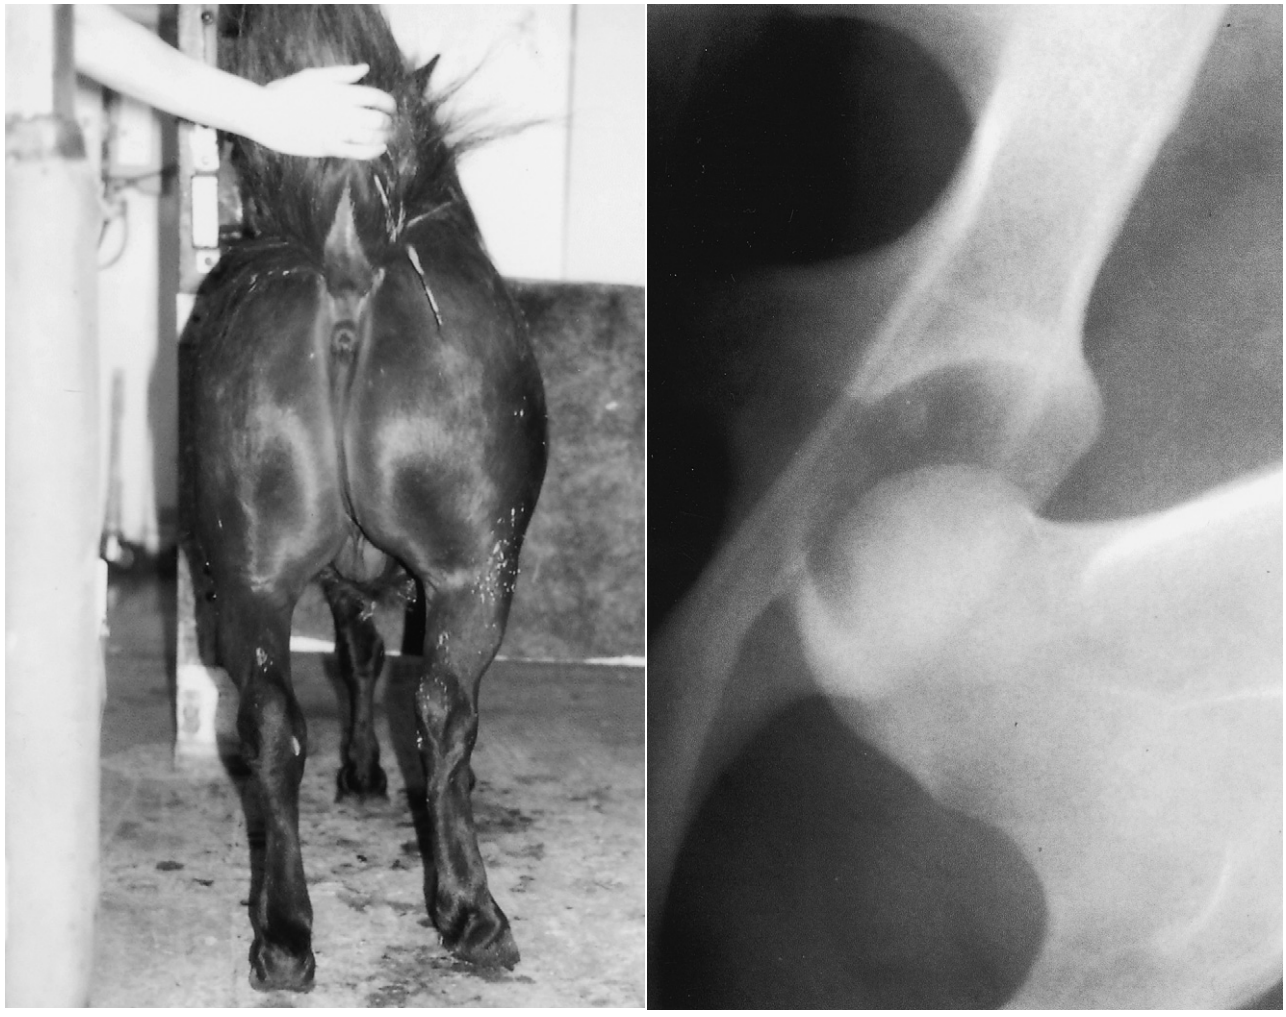

Fig. 127-2 **A,** Typical appearance of luxation of the coxofemoral joint in a pony. Note the outward rotation of the stifle and foot, inward rotation of the tarsus, and shortening of the right hindlimb. **B,** Ventrodorsal radiographic view of the right coxofemoral joint demonstrating the caudodorsal luxation of the head of the femur.

used to treat the luxation, but the prognosis for long-term soundness is poor.[14] Ponies with unsuccessful reduction or irreducible luxation can be salvaged for breeding or companion purposes by excision arthroplasty.[16] Coxofemoral luxation often is complicated by upward fixation of the patella.[15,16] Ligament rupture may occur without luxation of the coxofemoral joint, and the clinical signs are similar to luxation except for the absence of limb shortening.[15]

Dysplasia of the Coxofemoral Joint

Hip dysplasia has been reported in the Norwegian Dole and a Shetland pony colt.[17] In the Shetland pony, hip dysplasia was associated with the development of osteoarthritis in the coxofemoral joint.

Luxation of the Patella

Lateral (sub)luxation of the patella in Shetland ponies is common.[18] The condition is usually congenital, but can be acquired, and affects one or both hindlimbs. A distinction should be made between (sub)luxation and congenital permanent lateral luxation (see the following discussion). The cause of the condition is thought to be malformation of the trochlear ridges and groove, but rupture of the medial femoropatellar ligament has been reported in one pony.[19] Post-mortem examination usually reveals that (sub)luxation is associated with a broadening and flattening of the medial and lateral trochlear ridges, particularly the distal aspect of the medial trochlear ridge. Whether these changes are congenital or are caused by bone modeling is unknown. The clinical signs vary, but in most ponies the patella can be easily manipulated laterally and then replaced in the trochlear groove, and in some ponies the (sub)luxation can be observed during motion. The degree of (sub)luxation varies between ponies and can vary during an individual pony's life. Patellar luxation can be observed on lateromedial and caudocranial radiographs, but to confirm (sub)luxation a cranioproximal-craniodistal oblique (skyline) projection of the patella is required. In ponies with (sub)luxation the patella may appear an abnormal shape on the skyline projection, but this is caused by rotation and abnormal positioning and not by bone modeling.[18] Lateral luxation has been treated successfully by medial imbrication and lateral release incision,[10] or imbrication and recession sulcoplasty.[19] Hermans et al.,[18] using a limited breeding experiment with a group of Shetland ponies, found evidence to suggest monogenic autosomal recessive hereditary transmission of this defect.

Congenital permanent lateral luxation of the patella also is seen in Shetland ponies. Affected newborn foals are unable to extend the stifle fully and therefore have a crouched, squat-

ting position when standing. The lateral trochlear ridge in affected foals is often flat rather than convex.[18] The prognosis for successful treatment is poor.

Upward Fixation of the Patella

Intermittent upward fixation of the patella is a not uncommon condition in ponies, affecting young ponies (typically 2 to 3 years old), and older ponies secondary to an orthopedic problem in the limb. The clinical presentation is similar to that in the horse.

Hemarthrosis

A higher incidence of hemarthrosis has been noted in ponies than horses,[20] and this is often secondary to a systemic disease such as a blood clotting disorder or hepatopathy. Affected ponies have acute-onset lameness with a severely painful joint effusion(s).

Subluxation of the Proximal Interphalangeal Joint

Non-traumatic dorsal subluxation of the proximal interphalangeal (pastern) joint has been recorded in the hindlimbs of ponies.[21] The condition usually occurs bilaterally in young ponies (Fig. 127-3). Dorsal proximal interphalangeal joint subluxation is observed when the affected limb is not bearing weight. The subluxation is reduced as weight is borne on the affected limb, and an audible clink often accompanies joint reduction. Tenotomy of the medial head of the deep digital flexor tendon in the proximal metatarsal region has produced good results in treating this condition.[21] Unilateral proximal interphalangeal joint dorsal subluxation has been recorded in a 3-year-old pony secondary to infectious arthritis of the tarsocrural joint.[22] The subluxation resolved after successful treatment of the infectious arthritis.

Treatment of Joint Disease

Non-steroidal anti-inflammatory drugs should be used with care in lightweight ponies, because they may be more susceptible to phenylbutazone toxicity.[24] (Recommendations by some phenylbutazone-supplying drug companies in the United Kingdom state the maximum level of phenylbutazone in ponies is 4.4 mg/kg orally on alternate days compared with a maximum level of 4.4 mg/kg twice daily for horses.) The ulcerogenic properties of orally administered phenylbutazone are possibly more pronounced in ponies because of less efficient gut absorption. Systemic and intra-articular corticosteroid use in ponies also has to be undertaken with caution because of the potential for development of laminitis.[25]

If arthroscopy or arthrotomy is undertaken in the diagnosis or treatment of joint disease, one should note before giving a prognosis that ponies appear to accommodate greater cartilage degeneration than horses.

A Fell pony foal with infectious arthritis should be checked for immunodeficiency syndrome before treatment is initiated.[23]

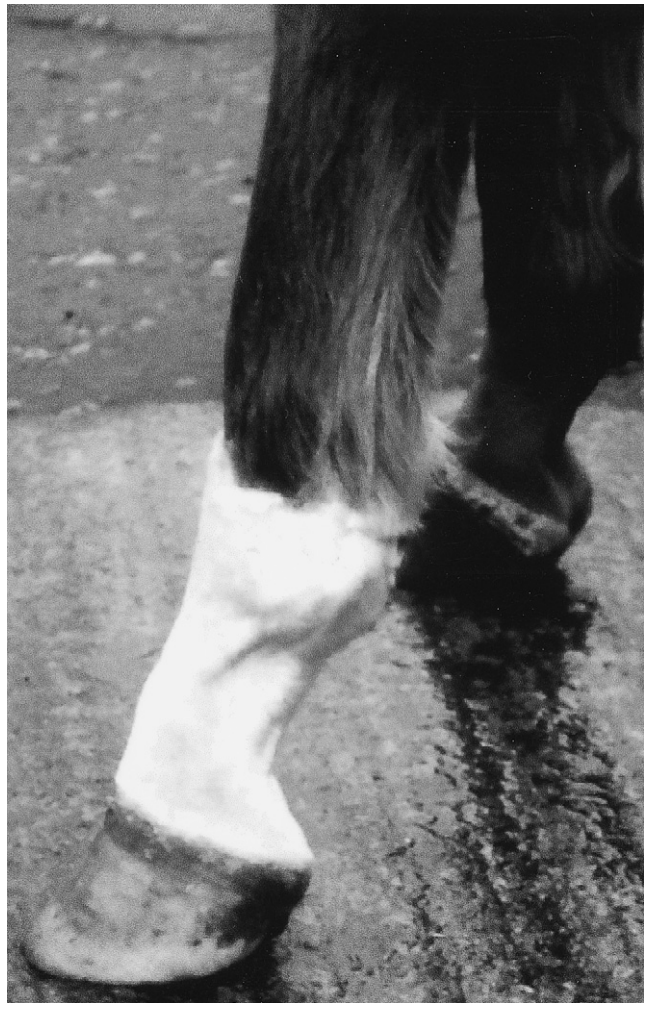

Fig. 127-3 Bilateral non-traumatic dorsal subluxation of the proximal interphalangeal joints in a 3-year-old Welsh pony. The condition resolved after tenotomy of the medial head of the deep digital flexor tendon.

FRACTURES

Common fractures seen in horses (i.e., third metacarpal/metatarsal bone condylar, proximal phalanx, and third carpal bone slab fractures) are rare in ponies. Most fractures are secondary to trauma. Hindlimb fractures, particularly involving the lateral splint bone (fourth metatarsal bone), often result from kicks from other horses. Because of the reduced value of ponies, owners may not opt for surgical intervention to repair fractures.

In some ponies, closed fracture reduction and using a cast alone may result in successful bony union in fractures that would require internal fixation in a horse. The lighter weight of most ponies also means that the use of internal or external fixation of long bone fractures is more successful than in a horse. Repair of some complete fractures of the humerus, tibia, and radius that would require euthanasia in a horse can be attempted in lightweight ponies (<300 kg).[26] Treatment may involve using intramedullary implants such as a single Steinmann pin, stacked pin fixation, or intramedullary interlocking nails. External fixation for comminuted lower limb fractures (e.g., proximal phalanx) is also more successful in the pony.[27] External fixation using a transfixation cast, with or without a U-bar,[28] or an equine modified type II external skeletal device may be successful.[29]

Many fractures of the splint bones (second and fourth metacarpal and metatarsal bones), including proximal fractures, heal satisfactorily with conservative management in the pony. I also have found in the pony that complete excision of the fourth metatarsal bone, as previously described,[30] to be successful in treating fractures of the proximal third of the fourth metatarsal bone.

In ponies with severe or multiple fractures of the carpus, pan-carpal or partial carpal arthrodesis also can be considered.[31] Arthrodesis of the scapulohumeral joint of a Miniature *horse* also has been described.[32]

It may be important when undertaking internal (or external) fixation in older ponies to assess whether the pony may be compromised systemically with Cushing's disease, because this potentially could result in delayed fracture healing and problems with implant failure.

Stress fractures in ponies are rare but have been recorded.[33]

FOOT-RELATED PROBLEMS

Ponies generally tend to have better foot conformation than do horses, and the prevalence of long-toe, low-heel foot conformation appears to be lower than in the Thoroughbred. Navicular disease does occur in ponies, but the incidence is considerably lower than in the horse.[34] Intrasynovial analgesia of the distal interphalangeal joint or navicular bursa should be undertaken to confirm any suspect radiographic changes in the flexor surface of the navicular bone.

Ossification of the cartilages of the foot (sidebone) commonly is observed radiographically in ponies.[35] As in horses, this rarely is associated with lameness.

Laminitis

The incidence of laminitis in ponies is high. Ponies may be more susceptible to laminitis because of an innate insulin insensitivity.[36] Reduction in insulin effectiveness may lead to elevation in thromboxane A_2 activity, causing vascular changes within the hoof. The incidence may be higher than in horses because ponies have a longer life span and insulin resistance may increase with age. In my opinion, the incidence of laminitis in fit, athletic ponies is considerably lower than in ponies that undertake minimal athletic work. This may be due to an improvement in insulin sensitivity.[37] In the United Kingdom many ponies used for showing are excessively overweight, and these animals have a high incidence of laminitis. Ponies often have repetitive annual bouts of laminitis, particularly in the spring, and many respond quickly to acute therapy within a matter of days. The quick response often leads to the feet of chronically laminitic ponies not receiving sufficient corrective farriery (Fig. 127-4), and in the subsequent months many secondary complications can occur, including recurrent subsolar hemorrhage, onychomycosis-induced white line disease,[38] and abscess formation within the dorsal wall.

Dorsal wall resection is indicated in treating some ponies with laminitis, and this can reduce the incidence of chronic problems.[39] Repetitive bouts of laminitis also can lead to hoof and distal phalanx deformation resulting in modified shoes having to be constructed for each foot.[40] The deformation also can result in substantial gait alterations. In a survey of horses and ponies suffering from laminitis, the prognosis for horses was found to be no different than for ponies.[41] Restricted access to grass may need to be enforced to prevent laminitis in general purpose ponies that are never stabled. This can involve mowing the field, strip grazing, or muzzling the pony for part of the day. Care should be taken, however, not to undernourish ponies to prevent laminitis because of the potential development of hyperlipemia.[42]

The incidence of Cushing's disease is higher in ponies than in horses, although no evidence suggests that prevalence is higher.[43] Cushing's disease always should be considered in an older pony with laminitis.

Fig. 127-4 Foot of pony with chronic laminitis that has not received any corrective farriery. Note the extremely long toe and laminitic rings.

SOFT TISSUE INJURIES

Superficial Digital Flexor Tendonitis

Superficial digital flexor tendonitis has a lower incidence in ponies than in horses. Tendonitis does occur in older animals, however, often associated with desmitis of the ALDDFT (inferior or distal check ligament).[44] Tendonitis may not occur necessarily after strenuous exercise, and the site of the superficial digital flexor tendon damage can be in the proximal metacarpal region or within the carpal canal.

Deep Digital Flexor Tendonitis

In my experience, deep digital flexor tendonitis within the digital sheath is also not an uncommon soft tissue injury in old ponies. Tendonitis presents as acute-onset lameness, with a painful digital sheath effusion. Diagnosis is confirmed by ultrasonography. Often a focal area of reduced echogenicity is seen. Dystrophic mineralization also can be evident. The lameness is often slow to resolve (8 to 12 months), treatment is prolonged (often 15 months), and the rate of re-injury is high after return to normal work.[45]

Desmitis of the Accessory Ligament of the Deep Digital Flexor Tendon

Desmitis of the ALDDFT has a higher incidence in ponies than horses.[46,47] An in vitro study has found that ALDDFT rupture occurs at lower forces in older horses and ponies, and this suggests that an age-related degeneration occurs within the ligament.[48] Because of the older pony population the prevalence of ALDDFT desmitis therefore may be similar to that in the horse. Clinically, desmitis presents as an acute-onset lameness and swelling in the proximopalmar metacarpal region. Ultrasonography may show a focal area of reduced echogenicity or disruption of the entire cross-sectional area of the ligament. The damage may occur for part or the entire length of the ALDDFT. Prompt aggressive anti-inflammatory therapy is required in the acute stage to prevent adhesion formation linking the ALDDFT to the superficial digital flexor tendon around the parietal layer of the carpal sheath.[47] Treatment recommended for ponites with desmitis of the ALDDFT is similar to that recommended for superficial digital flexor tendonitis in the horse.[45] If extensive adhesion formation occurs, an acquired flexural deformity of the metacarpophalangeal joint may develop, which is difficult to treat.[47]

Palmar (Plantar) Annular Desmitis

Desmitis of the palmar (or plantar) annular ligament of the fetlock joint is not uncommon in ponies and may be associated with tenosynovitis of the digital flexor tendon sheath and can cause secondary stenosis of the fetlock canal. I have noted a higher incidence of plantar annular desmitis in ponies with chronic or repetitive laminitis. The condition may develop because of the postural and gait changes occurring with laminitis that put greater strain on the plantar structures of the fetlock joint. In such a situation, plantar annular desmitis could be described as a repetitive strain injury. Treatment initially should include anti-inflammatory therapy and treatment of the laminitis. In ponies that are unresponsive or have chronic desmitis, annular desmotomy may be required to relieve fetlock canal stenosis. One should note that chronic enlargement of the annular ligament can occur without signs of lameness.[49]

WOUNDS

In ponies, second intention (contraction and epithelialization) wound healing has a reduced incidence of excessive granulation tissue (*proud flesh*), and wound contraction is faster compared with horses.[50] This appears to be because of better myofibroblast organization and a more effective acute inflammation phase.[51] An in vitro study also has found that horse limb fibroblasts have significantly less growth than in ponies.[52]

OTHER CONDITIONS

The results of nuclear scintigraphic examinations of a limited number of athletic jumping ponies I have treated are similar to those described in horses[53] (i.e., increased ^{99m}Tc uptake in the proximal and distal aspects of the proximal phalanx, dorsal spinous processes, and the distal hock joints). Similarly to the aforementioned study, not all of these lesions were associated with lameness and may represent bone adaptation to the act of jumping. In all ponies the results of scintigraphy should be confirmed by diagnostic analgesia.

Back Pain

Back injuries in ponies, particularly involving the sacroiliac joint, appear to have a lower prevalence than in horses.[54] Ponies, however, often demonstrate abnormal behavioral problems, such as bucking, secondary to hindlimb and occasionally forelimb lameness, that can be perceived by the owner as signs of primary back pain.

Recurrent Exertional Rhabdomyolysis

Recurrent exertional rhabdomyolysis (*azoturia* or *tying up*) does affect ponies, especially excitable types and ponies used for eventing. General purpose ponies often suffer from recurrent exertional rhabdomyolysis when the owner exercises an unfit pony. In one survey in the United Kingdom, ponies were the third most commonly affected group of horses suffering from recurrent exertional rhabdomyolysis.[55] A raised blood level of creatine kinase and aspartate aminotransferase confirms the diagnosis, and treatment is similar to that for the horse. Polysaccharide storage myopathy also has been reported in Welsh-cross ponies and in larger breeds of horses.[56]

Cerebellar Abiotrophy

Cerebellar abiotrophy has been recorded in Gotland[57] and Eriskay ponies.[58] The disease is inherited in the Gotland pony as an autosomal recessive gene.[57]

CHAPTER • 128

Lameness in Breeding Stallions and Broodmares

Benson B. Martin and Sue M. McDonnell*

Although maximal athletic fitness is typically not the goal for breeding stock, maintenance of musculoskeletal soundness is an important concern for breeding stallions and broodmares, especially because longevity is the usual expectation and a high percentage of these horses have existing musculoskeletal disease related to previous training and performance.

THE STALLION

Musculoskeletal fitness is critical to breeding efficiency of a stallion. The principal goals are to maintain adequate fitness for normal breeding behavior and to avoid conditions or treatments that may affect spermatogenesis or sperm viability adversely. Libido, mounting, thrusting, and ejaculatory dysfunction represent major causes of poor breeding performance in stallions.[1] Musculoskeletal and neurological disease have been estimated to account for as much as 50% of these problems.[1,2] The goal of managing a lame breeding stallion includes maintaining significant comfort and fitness to sustain libido and adequate copulatory agility.

Examination

Breeding stallions require skillful handling and should be examined in an area away from other stallions and mares, a secluded area if possible. An experienced breeding stallion handler with appropriate restraint aids is ideal. Sedation can be used, but care must be taken not to confound the examination or jeopardize fertility. Phenothiazine tranquilizers, although useful for lameness examinations, have been associated with an increased risk of paralysis of the retractor penis muscle. If acepromazine is used, we recommend a small dose (5 to 10 mg intravenously 30 minutes before the examination) well before the horse gets excited and diligent observation of the stallion for several hours to monitor its ability to retract the penis normally. Should the penis not retract with tactile stimulation once the horse is again otherwise normally alert and reactive, steps can be taken immediately for physical support and management to minimize loss of erectile function.[3] For further diagnostic procedures (e.g., radiography), xylazine or detomidine and butorphanol may be necessary.

History should include signalment, information about the performance career, duration and details of breeding experience, presenting problem and associated details, medical history, medication, nutrition, and environment including housing, breeding facilities (e.g., flooring and dummy), and breeding protocol (semen collection technique and stallion handling). Knowledge of old performance-related problems is useful. During the breeding season, the veterinarian should determine the breeding schedule, because this will influence the diagnostic and therapeutic strategy.

Complete musculoskeletal evaluation in a breeding stallion ideally begins with a routine breeding soundness examination, including a general physical examination, examination of the internal and external genitalia, evaluation of at least two ejaculates collected 1 hour apart, and evaluation of penile microflora, as outlined by the Society of Theriogenology.[4]

The veterinarian should observe the stallion at a walk and trot in hand, preferably on an even, hard, flat surface or on grass; perform upper and lower limb flexion tests of the forelimbs and hindlimbs, because osteoarthritis is common; examine the feet with hoof testers; and palpate the back. Manifestations of back pain include abnormal sinking, prolonged muscle fasciculation or guarding, or contraction of the epaxial muscles without touching the back. Back pain is common during the breeding season because of the work or secondary to lameness.

A simple neurological examination should include observation of the horse moving in small circles to the left and right, walking in a serpentine pattern with the head elevated, and assessment of hindlimb strength by pulling the tail as the horse walks. The veterinarian should look carefully for unusual patterns of muscle asymmetry, possibly indicative of equine protozoal myelitis (EPM).

A stallion often is examined because of difficulty in breeding and should be observed during teasing, mounting, thrusting, and dismounting. Specific findings suggestive of a musculoskeletal or neurological problem include failure to couple squarely and to thrust with smooth, rhythmic pelvic action; asymmetric hindlimb weight bearing, particularly one hindlimb dangling while thrusting with the other; failure to properly flex or use the neck or back; abnormal tail posture (spiked high) and anal tone (relaxed; voiding gas or feces) during thrusting; an anxious look in the eye or atypical ear postures suggesting discomfort or distraction; failure to grasp securely with the forelimbs; lateral instability; falling during thrusting or dismount; weak, thready, or irregular ejaculatory pulses (often variable from day to day); and lameness after breeding.[1] Other common manifestations of musculoskeletal pain are reluctance to mount or dismount, early dismount, squealing during dismount, or savaging the mare or handler during or immediately after mounting. Frame-by-frame videotape analysis may help to identify handling factors that enhance or impair performance. Diagnostic analgesia can be difficult to perform and is often unnecessary because of the obvious signs of osteoarthritis. Further investigation in selected stallions may include ultrasonography, nuclear scintigraphy, and measurement of creatine kinase before and 1 hour after breeding.

Specific Diagnostic Considerations and Therapy

Sore Back

A sore back is associated with inadequate coupling and thrusting during breeding. A stallion may fail to wrap the pelvis or neck around the mare or dummy and may tend to hold its head off the neck of the mare and paddle with the forelimbs. Thrusting is often of irregular depth and rhythm. An acutely sore back may become a chronic condition, exacerbated by

*With contributions from Roy Bergman, Herbert J. Burns, Wendell L. Cooper, Howard E. Gill, Thomas Little, John Steiner, and Norman Umphenour.

breeding and an increased number of unsuccessful mounts, unless treated aggressively.

It is important to determine the primary cause of lameness and initiate the appropriate treatment. Pain can be secondary to another musculoskeletal cause such as osteoarthritis, a heavy breeding schedule, poor footing, poor shoeing, poor fitting of the breeding dummy to the stallion, or allowing the stallion to advance up the side of a dummy mount so that it is thrusting with a curved back. Chronic back pain may be treated using acupuncture once weekly for 8 weeks, and repeated every 3 to 4 weeks, or as needed.[5] Acupuncture therapy may be combined with non-steroidal anti-inflammatory drug (NSAID) therapy, or NSAIDs may be used alone.[5,6]

Prognosis for normal breeding performance is guarded to good and varies with management factors. One key factor is ejaculatory efficiency. Once a stallion needs more than one or two mounts per breeding, expected performance diminishes rapidly.

Osteoarthritis

A stallion with osteoarthritis appears stiff and painful during breeding; stiffness is often worse after rest and improves with exercise. The carpus, front fetlocks, and hocks are affected most commonly. Diagnosis may be obvious on physical examination and is confirmed radiographically.

Pain control is essential to maintain adequate breeding performance. We recommend phenylbutazone (1.5 to 2 g orally bid for 4 to 5 days and then 1 g bid for 5 to 7 days)[7] combined with a period of sexual and general rest if possible. Significant improvement may not be evident for up to 5 to 10 days. Long-term, low-dose phenylbutazone treatment has no measurable effect on sperm production or testicular size,[8] but horses should be monitored for signs of toxicity including colic, loss of appetite, diarrhea, dependent edema, and mucosal ulceration or renal disease.[9] Other NSAIDs such as flunixin meglumine and ketoprofen, and intra-articular or systemic medication with corticosteroids, polysulfated glycosoaminoglycans, and hyaluronan may be useful in selected horses.

Arthrodesis may be warranted for severe osteoarthritis of the fetlock joint, but post-operative pain may persist, requiring long-term management. Pan-carpal arthrodesis may be considered for stallions with severe carpal osteoarthritis or after acute, severe carpal injury. With any lameness pain management must be used to prevent increased recumbency, which can compromise thermal regulation of the testes, especially in hot conditions, and reduce sperm viability and fertility.

Neurological Disease

Neurological disease (see also Chapter 11) is usually evident during mounting, intromission, and thrusting, with a stallion stepping on its hind feet, bearing weight on a toe rather than the sole, and sometimes knuckling over. The stallion may bear weight unevenly during thrusting, sometimes becoming high sided on the mare or dummy mount, or falling. The stallion may have reduced proprioceptive control of the penis in seeking and intromission and may have poor anal tone during thrusting. The horse may require extraordinary effort to ejaculate.

Treatment of cervical vertebral malformation in adult horses is challenging, and management methods are important, including good footing, proper shoeing, proper positioning of the mare or dummy mount, ground collection of semen, and pharmacological aids to ejaculation when necessary (Box 128-1).[1,10] Special precautions must be taken during collection of semen or breeding to protect the stallion, the mare, and the personnel working around the stallion. The mare or dummy mount should be positioned to minimize the risk of a stallion with poor lateral stability falling. Lateral support can be provided at the hips. For semen collection, a mare that does not wiggle from side to side should be used. A dummy mount may be better, but usually elicits less vigorous thrusting than a live mount and cannot be moved forward to assist the stallion with dismounting. Surgery occasionally is performed, with recovery taking many months.[11]

The management of horses with EPM is similar, together with daily pyrimethamine and sulfadiazine or sulfamethoxazole for at least 60 to 90 days (Table 128-1). To prevent anemia, supplementation with folate and vitamin E is advised.[12] This treatment does not affect sperm production adversely.[13]

Sore Feet

Signs of sore hind feet include shallow thrusting, failure to plant the feet securely during thrusting, thrusting on one leg, and early dismount. Signs of sore front feet or other forelimb pain include hesitancy to mount and dismount. If not resolved quickly, sore feet can lead to long-lasting psychogenic sexual behavior dysfunction.

Many breeding stallions that come from the racetrack have poor hoof quality, underrun heels, long toes, and thin soles, predisposing them to sore feet. The feet should be observed daily and trimmed every 4 to 6 weeks. Leaving stallions barefoot is best, but some may require front shoes to remain comfortable. These horses may be left barefoot during the off season to allow the feet to grow more normally. Provision of soft footing in the breeding shed and weight control are important. Pain control using NSAIDs may be necessary.

Fractures of the Distal Phalanx

Fractures of the distal phalanx can be acute or chronic injuries. Most are palmar process fractures and horses can be managed with a bar shoe with side clips reset every 6 weeks, stall rest, and NSAIDs. Sagittal fractures of the distal phalanx are more serious, but horses may be managed in the same way.

Laminitis

Common primary causes of laminitis include contralateral orthopedic injuries, colitis, Potomac fever, *Salmonella*, and other infectious diseases that predispose to the release of endotoxins. The treatment of horses with acute laminitis includes treating the primary disease, supporting the distal phalanx, decreasing blood pressure, treating inflammation, and managing pain (see Chapter 35).[14-16]

Chronic laminitis, with rotation of the distal phalanx, can be an important problem in breeding stallions, presenting as a stiff gait or more overt lameness in one or both front feet. Trimming, shoeing, and providing analgesia are important (see Chapter 35).

Rhabdomyolysis

Rhabdomyolysis is usually evident during or after thrusting. Inefficient thrusting on early mounts is followed by increasing discomfort, leading to rapid mounting and dismounting. The horse may sweat profusely and have an increased respiratory rate and obvious pain. Treatment of an acute episode includes administering acepromazine (10 to 20 mg IV) to control anxiety and 10 to 20 L balanced electrolyte solution intravenously, keeping the horse confined to a stall, monitoring progress, and evaluating the stallion closely for paraphimosis. In horses with chronic rhabdomyolysis, the diet should be altered to primarily hay and high-quality, low-protein, low-carbohydrate feed.[17] Methocarbamol (Table 128-1) is useful in some horses.

Injuries

Injuries in stallions, including lacerations, punctures, abrasions, and fractures or dislocations, are managed similarly as in other horses. A common injury is abrasion or contusion of the carpus during mounting, especially with dummy mounts. A stallion with a sore carpus may fail to grasp a mare with the forelimb and may stand up on the mare or dummy. Sexual rest until the wound heals is usually best. If continued breeding is necessary, emoliative topical analgesic ointment and skillful bandaging from the coronet to several centimeters above the carpus can relieve apparent discomfort, with the administration of NSAIDs if required.

Hyperextension injuries of a forelimb may occur at dismount but are usually not serious and resolve with NSAID treatment.

Box • **128-1**

Management and Pharmacological Aids to Enhance Libido and Facilitate Ejaculation

Management aids

To enhance sexual arousal

Prolonged teasing under conditions that yield the highest safe level of arousal
Breeding schedule for maximum arousal
Natural estrus stimulus and mount mare
Stable (no side to side movement) mount mare, or dummy is necessary
Minimal distractions in the breeding area
Established breeding routine rich with conditioned stimuli for maximum arousal
Encouragement and positive reinforcement

To reduce back and hindlimb pain and accommodate musculoskeletal deficiencies

Mount mare or dummy of appropriate height and conformation
Mare or dummy down grade from stallion to reduce weight on hindlimbs
Semen collection on the ground (artificial vagina or manual stimulation)
Weight loss to reduce work of hindlimbs, particularly during breeding
Pain treatment
Lateral support at the hips during mount
Good footing (grass or dry non-slip, synthetic surface)

To increase positive stimulation of the penis

Pressure and temperature of artificial vagina that yields best response
Hot compresses applied to the base of the penis

Pharmacological aids

To enhance sexual arousal

Gonadotropin-releasing hormone: 50 µg Cystorelin SC 1 and 2 hours before breeding[20]
Diazepam: 0.05 mg/kg slow IV administration[21,22]

To lower ejaculatory threshold (in copula)

Imipramine: 500 to 1000 mg PO in grain[28,29]

To induce ejaculation (ex copula)

Imipramine: 2.2 mg/kg PO followed 2 hours later by xylazine: 0.4 to 0.6 mg/kg IV[30,31]

Aortoiliac Thrombosis

Signs suggesting aortoiliac disease include delayed ejaculation in spite of good libido (multiple mounts and more than 12 thrusts); progressive hindlimb weakness or pain during thrusting resulting in camping under the mare or dummy; and difficulty backing up to dismount.[18] Erection aberrations are not as common as ejaculatory dysfunction, but they can include delayed or rapid tumescence or detumescence, or loss of erection during thrusting.

Comprehensive Management

The useful breeding career of a stallion with lameness problems often can be prolonged substantially with coordinated veterinary care and breeding management. Particular concerns and challenges include the following:

1. Controlling pain without adversely affecting libido or fertility
2. Maintaining a level of fitness adequate for the breeding work without exacerbating lameness
3. Using available management and veterinary techniques to enhance libido and ejaculatory function, to reduce the work of each breeding, and to reduce the total number of breedings required over the season
4. Managing the breeding book to maximize breeding value while not exacerbating the lameness

Table • **128-1**

Medications

DRUG	DOSE	ROUTE	FREQUENCY
Phenylbutazone	2.2 mg/kg	PO, IV	BID
Flunixin meglumine	1.1 mg/kg	IV, IM	BID
Ketoprofen	1.1 mg/kg	IV	SID
Aspirin	15-100 mg/kg	PO	SID
Isoxsuprine	1.2 mg/kg	PO	BID
Methocarbamol	40 mg/kg	PO	BID
Sulfamethoxazole	12.5 mg/kg	PO	BID
Sulfadiazine	12.5 mg/kg	PO	BID
Pyrimethamine	1 mg/kg	PO	SID
Folate	0.5 mg/kg	PO	SID
Vitamin E	5000 IU	PO	SID
Xylazine	150 mg	IV	AN
Detomidine	5-10 mg	IV	AN
Butorphanol	10-25 mg	IV	AN
Acepromazine	10-25 mg	IV	AN

PO, Orally; *IV*, intravenously; *IM*, intramuscularly; *BID*, twice daily; *SID*, once a day; *AN*, as needed.

Pain Management

Phenylbutazone is the most common NSAID used for breeding stallions. A 4-week oral treatment course (2.2 mg/kg twice daily) has no adverse effects on semen quality at the time of ejaculation, or after 24 and 48 hours stored at 4° C.[8] Although fertility trials have not been done, clinical experience suggests no adverse effects of chronic treatment with phenylbutazone at levels tolerated well by a stallion. We recommend orally administered phenylbutazone daily throughout the breeding season to keep the stallion comfortable and functioning with as little effort and pain as possible to avoid a potential downward spiral of delayed ejaculation, additional effort, and exacerbated lameness.

Complimentary pain management including acupuncture,[5,6] electrostimulation, and massage therapy may provide additional comfort, with no adverse effects on semen quality or fertility.

Fitness and Weight Management

Routine exercise is one of the most important management factors for maintaining cardiovascular and musculoskeletal physical and mental fitness of any breeding stallion. A general recommendation for exercise for a sound breeding stallion is daily paddock exercise for a minimum of 8 hours or a minimum of 30 minutes of supervised exercise or light work. Although the common tendency is to rest a lame horse, controlled exercise is probably even more important for breeding efficiency of a lame stallion. A daily exercise program, including turnout or supervised light work, appears to improve the breeding efficiency of a lame stallion significantly. The type of exercise is influenced by the degree of lameness and the temperament of the stallion. Controlled exercise may include daily riding, lunging, jogging, swimming, or exercise on a treadmill or mechanical walker.

Libido and breeding efficiency almost always improve with a stallion carrying less rather than more body weight, particularly for hindlimb lameness or incoordination. We have seen remarkable improvement in breeding efficiency and stamina after reduction in body weight in Quarter Horses with small sore feet or with aortoiliac thrombosis.

Breeding Management and Handling

Breeding schedule For any hand-bred stallion, and particularly for a stallion with lameness, an important goal of breeding management is to minimize the work of each breeding and the cumulative work of the season. For heavily booked stallions, total seasonal work and efficiency of each breeding often can be achieved by limiting services to one per mare cycle. This forces upgraded mare management so that she is close to ovulation when covered. This type of mare tends to be more stimulating to the stallion and to stand more solidly for breeding. For certain stallions with smaller books, availability for service often can be limited to one mare, 3 or 4 days weekly. In our experience, by shifting effort toward mare management and effectively increasing the sperm numbers per service, seasonal pregnancy rates are often as good or better than with more frequent services.

For stallions that are breeding by artificial insemination, with good to excellent longevity of sperm motility, a reasonable book of mares can be served with collection of semen limited to 2 or 3 times weekly. For stallions in registries permitting frozen semen, it is helpful to bank frozen semen for consideration for use during busy periods or to reduce pressure for obtaining fresh ejaculates when problems arise.

Maintaining ideal levels of libido It is important to maintain good to high libido to help a stallion to ejaculate more efficiently in the face of pain, neurological dysfunction, or musculoskeletal disability. Well-tested management schemes and pharmacological aids are available to enhance libido (Box 128-1). The most useful management tools in a stabled stallion are housing near mares and away from stallions, or ample daily teasing exposure to mares.[19] Treatment with gonadotropin-releasing hormone can be useful to boost libido via increased circulating testicular steroids.[20] Diazepam, by inhibiting the memory of pain associated with breeding, may be helpful.[21,22]

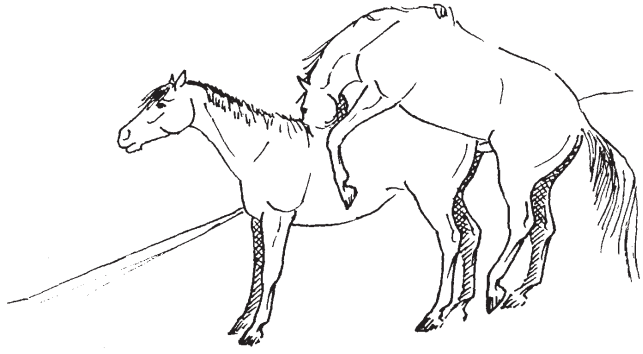

Fig. 128-1 Mare positioned down grade for breeding.

Occasionally, rowdy or over-enthusiastic breeding behavior complicates management and breeding of a lame stallion. The stallion handler should use judicious correction and guidance to establish and maintain organized control, without overcorrection that will diminish libido.[23] Medication is not recommended, because tranquilization at a level effective to control behavior makes the stallion unstable for breeding, and using progesterone or other endocrine-mediated treatments adversely affect spermatogenesis.

Breeding shed handling considerations Most disabled stallions benefit from having the mare or dummy mount slightly down grade. This can reduce the work of the hindlimbs in supporting the body weight. For a live mount mare, a down grade is achieved best with a sloping ramp extending at least 3 m behind, in front, and to each side of the mare (Fig. 128-1). A height differential between the stallion and the mare can be built with mats or by placing the mare in a pit. These work well if the mare remains stationary, but if the mare moves back, the grade may be reversed for the stallion. If the mare moves forward, the stallion can become trapped between the mare and the front edge of mats, or in the pit with the mare. When breeding a stallion with the mare downhill, it is important to avoid the peak of a knoll that slopes off to the sides, or behind the stallion, or in front of the stallion. This sets the stallion up to fall sideways should the mare move sideways, or to be at further disadvantage if the mare moves backward. Once the stallion mounts, restraint of the mare should be optimized to reduce movement in any direction. Disabled stallions that are tentative to mount also can be deterred by low ceilings, cornered mares, or dummy mounts.

When using a dummy mount for stallions with hindlimb, back, or neck problems, we find that greater heights are better. Most disabled stallions do better when guided to remain mounted squarely from the rear, as opposed to across the dummy, or traveling up the side. This is best accomplished by securing the artificial vagina at a physiological angle against the dummy for the stallion to serve, rather than taking the artificial vagina to the horse.

Excellent footing in the breeding area, that is customized to a stallion's particular needs, can improve breeding efficiency greatly (Table 128-2). The surface should be non-slip, even when wet; seamless and even, to avoid stumbling; and provide moderate cushion. Stallions with hindlimb weakness or incoordination tend to camp under the mare. For these stallions the footing behind the mare is critical to maximize the ability to correct the stance. Although some cushion is good, it should not be so spongy or deep that the stallion gets caught

Table • **128-2**

Flooring Materials for Breeding Sheds*

MATERIAL	FOOTING (NON-SLIP)	CUSHION	CLEAN (NO DUST OR KICK-UP)	EASE OF CARE AND CLEANING	COST	COMMENTS
Rubber composite bricks or mats	+++	+++	+++	+++	$$$$	Stable, highly durable

up or buried in the substrate. Stallions with sore feet, especially front feet, benefit from a softer footing, particularly a soft landing during dismount. Heavy sod on well-drained soil is often the simplest and best outdoor footing. Composite rubber athletic surfaces, particularly if poured and seamless, make ideal breeding surfaces.

A stallion should be given ample freedom about the head, particularly during mounting and thrusting, to allow postural adjustments. Enforcing routines that work well for sound stallions, such as always keeping the head on the left side of the mare or dummy mount, may discourage a disabled horse. For severely ataxic, weak, or uncomfortable stallions, thrusting and ejaculation can be facilitated with gentle stabilizing assistance or spotting during breeding. We recommend an assistant applying gentle pressure with the hands on one or both hips to support the stallion from falling (Fig. 128-2). Some stallions tolerate support from the rear, for example, with a wide strap held from either side behind the buttocks. Some resent this type of support, appearing to become trapped on the mare.

Gentle, guiding handling during dismount is important for all stallions but particularly for a disabled horse. For stallions with hindlimb weakness, pain, or incoordination, special consideration should be given to allowing the stallion as much recovery time as possible before dismount and to moving the mare slowly out from under the stallion rather than forcing the stallion to back off.

Ataxic stallions that tend to step on themselves and the mare while breeding can benefit from simple, well-secured protective boots or wraps for themselves and the mare.

Monitoring breeding performance Stallions with chronic musculoskeletal discomfort or disability usually deteriorate, and breeding performance should be monitored systematically so that adjustments can be made to maximize performance. A sensitive measure of improved comfort is the number, rhythmic pattern, and strength of pelvic thrusts from insertion to ejaculation. Normal, sound stallions typically require seven to nine thrusts at about 1 second intervals, with even sweep and strength, to ejaculate. The normal range of mount duration is 20 to 30 seconds, with insertion time 12 to 20 seconds. With discomfort, horses tend to require more thrusts, the sweeping pattern of the thrusts becomes less organized (irregular depth, rhythm, and strength), and the hindlimbs become more dancy as opposed to being planted with equal weight bearing on each. The head and ear positions of an uncomfortable stallion also suggest distraction (as if about to quit, fall, or dismount) as opposed to commitment. Horses with sore backs or necks tend to fail to couple closely. Thrusts may be jerky and shallow.

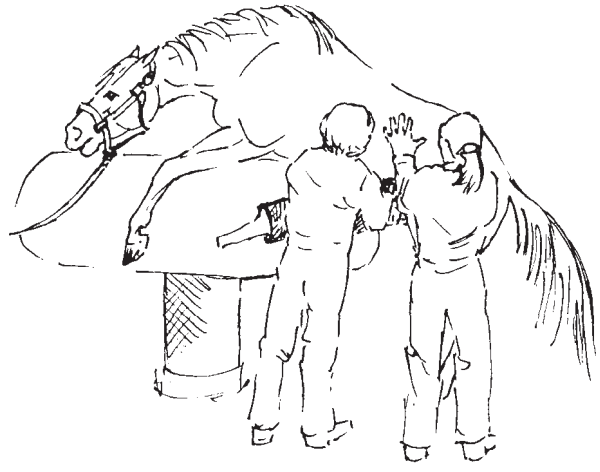

Fig. 128-2 Spotting a stallion on the left side during breeding.

Stallions with hindlimb neurological deficits may bear weight unevenly, become camped under, or become tipped toward the stronger side, with the weaker hindlimb dangling. They seem particularly unable to maintain lateral stability. We recommend developing a customized record sheet for daily grading of each abnormality. Videotaping each breeding from a direct lateral view that spans the entire mount and stallion and from the rear provides the most complete record.

One mount rule For longevity of a disabled stallion through a season or through a breeding career, we recommend that ejaculation should be achieved with one mount. If a horse does not ejaculate in one or at most two mounts, the horse should be taken back to the stall or paddock to rest and return fresh. This strategy often effectively yields a greater number of successful mounts, provided that conditions are optimized for the first mount. The horse should be at the highest level of arousal possible for safe handling, the mount well positioned and optimally restrained if it is a live mare, the artificial vagina at optimum pressure and temperature for semen collection, and the handling team in top form and focused. If particular procedures or medications (see Box 128-1) are known to make the horse more comfortable, enhance libido, or reduce the ejaculatory threshold, we recommend using these from the start.

Ground semen collections For stallions that breed by semen collection, a valuable alternative to mounting is ground semen collection. Most stallions with good to excellent libido are excellent candidates for semen collection while standing on the ground or even while supported in a sling. This technique is particularly useful in horses with aortoiliac thrombosis, cervical vertebral malformation, EPM, and other conditions with hindlimb instability or weakness.

Pharmacologically induced ex copula ejaculation For stallions that breed by artificial insemination, pharmacologically induced (or chemical) ejaculation can be used with the stallion at rest in his stall. Currently the generally most effective treatment (50% to 70% of attempts) is a combination of imipramine hydrochloride administered orally about 2 hours before intravenously administered xylazine hydrochloride (Box 128-1). For a particular stallion, best results can be achieved by titrating through a range of doses for each component drug.

BROODMARE

Soundness of a broodmare is important for the demands of pregnancy and lactation and for ongoing comfort for normal expression of estrus behavior, willingness to stand for natural service when necessary, conception, and normal interactive maternal behavior.[24] Diagnosis and treatment should not adversely affect fertility or the safety of the developing fetus, or nursing foal. As a population, broodmares tend to have a high rate of husbandry-related feet and leg problems. They may have old training or racing injuries. Broodmares coming and going tend to have herd social aggression and related injuries. Broodmares also suffer lameness secondary to foaling.

Specific Diagnostic Considerations and Therapy

Sore Feet

It is recommended that maiden mares should arrive on a breeding farm at least 8 to 10 weeks before the beginning of the breeding season. This allows time to assess and monitor condition of the feet and time for trimming as needed. Early arrival also affords time to acclimate the horse to the farm routine and social environment and for advanced photoperiod manipulation (under lights). Simple sore feet are a common problem in a maiden mare coming from the racetrack. The mare may have thin-walled feet and soles, underrun heels, long toes, bruised feet, quarter cracks, or corns. The mare may have been shod for a long time and not be accustomed to being barefoot. If sore feet are suspected as a cause of lameness, the feet should be examined with hoof testers. Baseline radiography may be indicated. Soaking, poulticing, sole painting, and the administration of phenylbutazone or flunixin meglumine (see Table 128-1) may be required for effective management of mares with foot soreness. Feet of broodmares should be trimmed every 6 to 8 weeks and ideally should be barefoot on all limbs and certainly for the hindlimbs.

A subsolar abscess is the most common cause of acute foot pain (see Chapter 28). Other causes include a sequestrum, laminitis, or a fracture of a palmar process of the distal phalanx. A sequestrum of the distal phalanx may be removed in a standing horse,[25] eliminating the risks of general anesthesia for a developing fetus.

Laminitis

Acute or chronic laminitis can be a management problem in mares and may be secondary to pleuritis, diarrhea, severe lameness, or most commonly after foaling followed by a retained placenta (more common in Draft breeds; see Chapter 126) or infectious metritis. Chronic laminitis also occurs in overweight mares, mares with a previous history of laminitis, or those that have ingested large amounts of feed or fresh pasture. Acute or chronic laminitis can have a negative effect on fertility secondary to pain.[24]

The treatment goals in broodmares with acute laminitis and chronic laminitis are similar to that described for the stallion. In our experience, some mares with chronic laminitis can be salvaged as successful broodmares with careful foot care, pain medication, good footing, separation from other broodmares and competition, and management similar to that described for the breeding stallion. In addition, some can conceive and deliver a normal foal, if these management techniques are successful. However, reproductive lives are often limited by laminitis.

Osteoarthritis

A broodmare with osteoarthritis may need confinement to a stall or small paddock and analgesic medication (see Table 128-1). With severe osteoarthritis of the fetlock or carpus, arthrodesis may be considered as a last resort in a broodmare that can no longer conceive or maintain a foal because of chronic pain.

Enlarged or Swollen Limbs

Palmar or plantar dermatitis of the pastern (scratches or mud fever) secondary to wet or muddy footing may cause lameness, particularly in hindlimbs. The mare should be removed from the wet area. Occasionally, local therapy may be necessary, including washing, drying, and clipping the affected area and local application of a steroid-triple antibiotic topical ointment.

Lymphangitis is seen most commonly in the hindlimbs, is worse in later pregnancy, and causes a reluctance to move, painful, pitting edema, and fever. Treatment includes stall rest, antibiotic therapy, and phenylbutazone.

A puncture wound and secondary cellulitis may cause lameness. Locating the original wound is often difficult. Aggressive antibiotic and anti-inflammatory therapy is necessary. Additional treatment may include surgical drainage, hot packs, warm water hosing, and bandaging.

Hindlimb lameness may be associated with mastitis. The udder is painful to touch, the mare may not allow the foal to nurse, her appetite may decrease, and she may be febrile. Lameness resolves with symptomatic treatment of the mastitis.

Rhabdomyolysis

Acute rhabdomyolysis occurs occasionally in late gestation after particularly vigorous exercise. The mare may not come in for normal feeding or night stables and is often anxious, has a stiff walk, and may have dark-colored urine. Diagnosis is confirmed by measurement of serum creatine kinase. Treatment includes stall rest and NSAIDs. A mare with a foal at foot can be treated with the foal present.

Foaling-Related Injuries

Obturator nerve paralysis secondary to dystocia can result in mild to severe lameness. The mare may show difficulty in abducting the hindlimb and standing immediately after foaling. Femoral nerve paralysis secondary to dystocia results in inability to fix the patella and therefore the hindlimb. This is seen immediately after foaling. Symptomatic therapy for either condition includes NSAIDs, supportive therapy, nursing care slinging if necessary, and adequate bedding and footing. The prognosis for full recovery is guarded, and a nurse mare may be needed for the foal.

Prepubic tendon rupture or ventral body wall hernias may occur during late gestation, apparently without reason. Ventral edema cranial to the udder is severe, unilaterally or bilaterally. An affected mare may have difficulty rising. It is difficult to obtain an accurate diagnosis before cessation of the edema after foaling. The body wall enlarges in the ventral flank. Diagnostic tests include palpation per rectum and diagnostic ultrasonography. Occasionally a tear in the ventral body wall can be palpated per rectum. Supportive treatment consists of NSAIDs, physical support of the enlarged area using large bandages, restricted exercise, close monitoring before and during foaling, a laxative diet, and assisted early induction of foaling. Successful surgical repair of ruptured prepubic tendons and large ventral body wall hernias is often unrewarding, but smaller defects can be repaired successfully. The prognosis for mares with large tears of a ruptured prepubic tendon and future use as broodmares is guarded to poor.[26] Embryo transfer may be a reasonable alternative in breeds that allow this form of management (the Editors).

Neurological Disease

The most common neurological disease of adult broodmares in the United States is EPM. Cervical vertebral malformation also occurs and should be distinguished because treatment is different. Treatment is as for a stallion, but folate supplementation is *not* recommended in broodmares receiving pyrimethamine because of the potential alteration in organogenesis.[27]

Old Injuries

Many broodmares have old superficial digital flexor tendon or suspensory ligament injuries that may deteriorate or sustain acute re-injury. Aged broodmares may have gradual thickening and lengthening of the hindlimb suspensory ligaments. Broodmares with acute re-injuries are treated by restricted exercise, analgesia if needed, local therapy, and ultrasonographic monitoring. Stall confinement with daily hand walking may be needed for 3 to 4 months, depending on ultrasonographic evidence of healing. Treatment of mares with hindlimb suspensory desmitis with a dropped fetlock consists of strict stall confinement, pain medication if needed, and application of an extended heel, egg bar shoe. This shoe should be removed just before foaling for safety.

Occasionally older broodmares develop extensive new bone, especially around the carpus, causing lameness. The mare should be separated from the normal herd to reduce competition for food and water, with restricted exercise and analgesia provided.

General Husbandry and Breeding Management Considerations

Simple management and handling may improve the comfort of an acutely lame broodmare and prolong the useful life of a chronically unsound broodmare. Attention to social groupings can reduce the chance of new injury and provide greater comfort for an older or lame broodmare. Many farms separate broodmares into compatible groups, including maidens, seasoned broodmares, barren mares, and older broodmares. The goals should be to limit competition for food and water and to minimize risk of encountering manufactured obstacles during aggressive interactions. Some farms follow a buddy system, in which compatible pairs are kept together as much as possible. Convalescent broodmares often do well grouped together for rehabilitation or special medical attention. Good footing, including breeding areas, pastures, alleyways, areas around hay bunks, loading ramps, and in stalls can prevent injury and provide comfort for a lame broodmare. Broodmares benefit from as much exercise as possible to maintain overall good musculoskeletal fitness, and obesity should be avoided.

Phenylbutazone is the most commonly used drug for the effective control of pain and has limited or no effect on organogenesis. Its use may be associated with gastric ulceration and concurrent treatment with omeprazole (4 mg/kg curative, or 2 mg/kg preventative) may be of value, although any effects on organogenesis have not been reported.

Emergency surgery to repair a fracture may be necessary to save the life of the mare and fetus. Ideally a pre-formed plan should be in place, especially close to gestation. Is the decision to save the mare and the foal or to consider a non-survival cesarean section to deliver the foal? If the decision is made to proceed to save the mare and fetus, administration of a synthetic progesterone (30 mg/kg orally bid) may be helpful, especially in the first trimester of pregnancy. Elective surgery should be delayed until the mare has foaled whenever possible.

For lame or otherwise disabled mares, artificial insemination should be considered whenever possible. For natural cover, we recommend excellent footing, a gentle approach, reduced restraint, and acute pain control. To reduce the stress in painful broodmares, maiden mares, or broodmares with a known volatile live cover breeding history, the use of 25 mg of acepromazine and 10 to 25 mg of butorphanol given together intravenously 15 to 20 minutes before breeding may increase safety without the ataxia or sudden outbursts seen with xylazine alone. When possible, medication including nutritional supplements should be avoided during gestation and early lactation, including detomidine and xylazine used alone.

CHAPTER • 129

Lameness in Foals

Robert J. Hunt

Like all horse, foals are prone to injury and lameness; however, considering the immature and fragile musculoskeletal system, the incidence of serious injury is surprisingly low. Exposure of a foal's naive immune system to the array of pathogens places the foal at high risk of infectious causes of lameness. Degree of lameness in foals ranges from subtle and nearly imperceptible to non–weight bearing. Although no published studies document the incidence of lameness in foals, the economic impact on the horse industry is substantial when factors such as cost of diagnosis and treatment, long-term morbidity and mortality, and the effect on athletic potential are considered. Economic and emotional losses may be substantial for horse owners and breeders, enough so that they may abandon the horse industry. Most lameness is self-limiting, however, and in many instances early recognition and prompt treatment makes a substantial difference in costly medical bills and improves the long-term soundness or survival. It is imperative that veterinarians learn to recognize the early clinical signs of these serious disorders and to initiate prompt treatment. Clients should be made aware of the potential danger of a wait-and-see approach and a delay in treatment.

EVALUATION OF A LAME FOAL

Foals often resist handling and limb manipulation, making assessing responses difficult and potentially confusing. It is imperative that the veterinarian is patient when evaluating foals. The basics of lameness localization are the same as in adult horses. The stance and any obvious swelling or sensitive areas on palpation should be noted. It is important to palpate the contralateral limb to gauge the foal's response to manipulation of that limb. Hoof and limb temperature (hot or cold) and amplitude of the digital pulses should be evaluated. Detailed assessment with hoof testers is invaluable in differentiating causes of hoof lameness. Any aberration in hoof development (club foot, deformed foot, unbalanced feet, or

Lameness in Foals

Robert J. Hunt

Like all horse, foals are prone to injury and lameness; however, considering the immature and fragile musculoskeletal system, the incidence of serious injury is surprisingly low. Exposure of a foal's naive immune system to the array of pathogens places the foal at high risk of infectious causes of lameness. Degree of lameness in foals ranges from subtle and nearly imperceptible to non–weight bearing. Although no published studies document the incidence of lameness in foals, the economic impact on the horse industry is substantial when factors such as cost of diagnosis and treatment, long-term morbidity and mortality, and the effect on athletic potential are considered. Economic and emotional losses may be substantial for horse owners and breeders, enough so that they may abandon the horse industry. Most lameness is self-limiting, however, and in many instances early recognition and prompt treatment makes a substantial difference in costly medical bills and improves the long-term soundness or survival. It is imperative that veterinarians learn to recognize the early clinical signs of these serious disorders and to initiate prompt treatment. Clients should be made aware of the potential danger of a wait-and-see approach and a delay in treatment.

EVALUATION OF A LAME FOAL

Foals often resist handling and limb manipulation, making assessing responses difficult and potentially confusing. It is imperative that the veterinarian is patient when evaluating foals. The basics of lameness localization are the same as in adult horses. The stance and any obvious swelling or sensitive areas on palpation should be noted. It is important to palpate the contralateral limb to gauge the foal's response to manipulation of that limb. Hoof and limb temperature (hot or cold) and amplitude of the digital pulses should be evaluated. Detailed assessment with hoof testers is invaluable in differentiating causes of hoof lameness. Any aberration in hoof development (club foot, deformed foot, unbalanced feet, or

mismatched sizes of feet) should be noted. Careful palpation of all structures of the skeletal system including all palpable surfaces of joints, bones, digital flexor tendons, and ligaments in a standing and flexed position is important. Swelling should be differentiated as intra-articular, peri-articular, or both.

Gait deficits in foals manifest like those in adult horses in that lameness is expressed as reduced time or weight on the lame limb.[1] The phase of the stride in which the gait is altered is the result of reducing loading of the limb during the painful portion of locomotion. Foals are more likely to show lameness in dramatic fashion by carrying the leg or exaggerating efforts to reduce load on the limb. It is important to observe the foal at a walk to discern subtle differences in stride and foot placement that may be missed at a trot.

Routine ancillary diagnostic tests used in foal lameness evaluation include diagnostic analgesia; radiographic, ultrasonographic, and nuclear scintigraphic examinations; and arthrocentesis and aspiration of other fluid pockets.[1-4] Diagnostic analgesia should be a routine component of lameness localization in foals just as in adults, unless a fracture is suspected. Any areas of suspect pathological bone conditions should be evaluated by radiography. Follow-up radiographic evaluation on a weekly basis may be required to recognize bony changes. Soft tissue evaluation is aided by ultrasonography, especially when the veterinarian is looking for fluid pockets or alterations in soft tissue architecture. Nuclear scintigraphy has limited applications for skeletal evaluation in foals, because normal radiopharmaceutical uptake in the physes can confuse or mask subtle abnormalities.

Fig. 129-1 Typical crouched stance of a foal with rupture of the left gastrocnemius muscle subsequent to overextension while chasing a mare. The foal is unable to extend the limb or support full weight on it. Note the excessive flexion of the hock.

NON-INFECTIOUS CAUSES OF LAMENESS

Non-infectious causes of lameness include external and internal traumatic injuries and developmental or metabolic musculoskeletal diseases. Lameness also may result as a sequella to vascular disorders or may be immune mediated secondary to an infectious problem.

Lameness resulting from external trauma varies with the area involved and the severity of the injury. Essentially any portion of the skeletal system is prone to injury. Traumatic injuries resulting in lameness are common but fortunately self-limiting in most instances. Boisterous activity, coupled with a hazardous environment places a foal at an increased risk of sustaining injury compared with an adult horse. Trauma from other horses (a mare kicking a foal or collision injuries with other foals) is a common cause of lameness. Impact with stationary objects while a foal is being chased may result in serious injury. Internal trauma includes over-exertion injuries, such as a foal running excessively with a mare or being chased, resulting in fracture of the proximal sesamoid bones (PSBs), or rupture of the suspensory apparatus or other soft tissue structures (Fig. 129-1). Common fractures in foals include those involving the long bones, physes, PSBs, carpal and tarsal cuboidal bones, and the distal phalanx.[1,2,5,6]

Fractures of Long Bones

Clinical evaluation may be diagnostic in foals with lameness of traumatic origin. Unstable fractures or severe soft tissue injuries cause obvious, immediate clinical signs. If a fracture is suspected, radiographs are necessary to confirm the diagnosis and determine the severity of the injury (Fig. 129-2).

Fractures of long bones most often result from external trauma such as a kick or having the limb pinned beneath an object while rolling. A limb mis-loaded while rearing may result in fracture of the tibia, femur, or pelvis. If a limb is unstable distal to the femur or humerus because of a fracture, the limb should be immobilized before transport. Surgical approaches and repair techniques for individual fracture types are described elsewhere.

Fig. 129-2 Slightly oblique lateromedial radiographic view of the femur of a foal. There is an unstable, displaced fracture of the distal femur, the result of trauma. This is a Salter-Harris type II fracture (see page 1086).

Prognosis for a foal after fracture depends on anatomical location of the fracture; the complexity, orientation, and degree of soft tissue injury around the fracture; and whether the fracture is open. Secondary problems associated with prolonged lameness, or confinement and immobilization, often dictate the degree of long-term soundness. These problems include excessive laxity of the metacarpophalangeal or metatarsophalangeal joint, varus deviation, or deformity of the foot such as underslung or crushed heels and overgrowth of the toe. Mechanical laminitis is not as common as in adult horses, but it does occur. Contracture or excessive laxity of the fractured limb associated with disuse may prevent future soundness.

Fractures of the radius, ulna, and tibia are generally more amenable to surgical repair than are femoral and humeral fractures. In my experience, conservative management of foals with femoral and humeral fractures by stall confinement is a feasible alternative to surgical intervention, if economics do not allow surgery. Complications encountered following surgery, such as implant failure or infection, are usually fatal. Without post-operative complications, however, the foal has a greater chance of soundness for light athletic use with surgical management. Fractures of the radius and tibia require surgical stabilization if any displacement of the fracture is present. Most foals have a fair to good prognosis for light to medium athletic use, or for breeding purposes. Foals with fractures of the ulna that have any displacement should undergo surgery, but those with non-displaced fissure fractures do not require surgical fixation. Foals with non-displaced fractures of the ulna should have stall confinement for a minimum of 8 to 10 weeks and undergo radiographic monitoring every other day for the first 2 weeks and then weekly to ensure displacement does not occur. Foals with displaced, unstable fractures of the metacarpal and metatarsal bones generally have a guarded to poor prognosis for future athletic use, with or without surgery. Foals with simple, stable fractures not requiring surgery have a good prognosis.

Fractures of the Pelvis

The occurrence of pelvic fractures is high and usually results from the foal mis-loading a hindlimb when rearing or from flipping over and landing on one side. Gait and degree of lameness depend on the portion of the pelvis involved and the amount of trauma to the surrounding tissue. Common sites of injury include the tuber coxae, tuber ischium, acetabulum, and the shaft of the ilium. Deep palpation of the area may elicit pain.

The characteristics of the lameness may reflect the site of injury. A foal with a fracture of the tuber ischium is reluctant to advance the limb and has a prolonged caudal phase of the stride. As with many pelvic injuries, the tail often is elevated and held to the opposite side, and the foal may carry the limb when running but bear full weight while walking. Foals with fractures of a tuber coxae have a shortened caudal phase of the stride, and the injured tuber coxae is often lower than the contralateral side.

Treatment for foals with pelvic fractures includes stall confinement for 8 to 12 weeks followed by a gradual return to controlled exercise. Improvement in the degree of lameness should be seen within 2 to 3 weeks, depending on the region of the pelvis injured. Foals with acetabular injuries may require a longer duration of confinement before improvement is seen.

Prognosis for foals with pelvic fracture not involving the acetabulum is fair to good for light use but guarded for competitive athletics. Some horses are able to race following healing of pelvic fractures. Most foals with pelvic fractures involving the acetabulum have a poor prognosis for an athletic future; however, they generally survive to make breeding animals. In the Editors' experience, the prognosis for athletic function is not invariably poor, because in contrast to adults, foals have a remarkable capacity for bone remodeling, and even severe articular fractures can heal satisfactorily, allowing normal athletic function.

Fractures of the Physes

Physeal fractures have been categorized and defined using the Salter-Harris classification scheme.[2,7] A type I fracture occurs through the physis and involves only the zone of hypertrophied chondrocytes; the adjacent epiphysis and the metaphysis are not involved. A type II fracture occurs across the physis and extends into a portion of the metaphysis. A type III fracture involves the physis and epiphysis and extends into the joint. A type IV fracture includes involvement of the physis, epiphysis, and metaphysis. A compression injury to the physis is referred to as a type V fracture. This classification scheme is applicable to pressure physes that contribute to the longitudinal growth of bone and are subject to compressive forces. Traction physes, such as the olecranon growth plate, are subject to tensile forces and are not included in this classification scheme.

Physeal fractures are common because physeal bone is weak compared with diaphyseal bone. Diagnosis of physeal injuries is made on clinical and radiographic findings (Fig. 129-3). Clinical signs include varying degree of lameness, pain on palpation of the injured area, swelling, and possibly instability of the limb or angular deviation of the limb distal to the fracture. The primary differential diagnosis for a stable physeal fracture is infectious physitis.

Surgical repair is necessary in foals with displaced, unstable physeal fractures. The major difficulty in surgical stabilization is the short section of epiphysis available for purchase. This shortcoming generally is overcome with the use of a form of T-plate, cross pins, transfixation pins, or tension-band wiring. If adequate reduction and stabilization are achieved, the prognosis for future soundness is good.

Cuboidal Bone Injury

Injury to the cuboidal bones of the tarsus or carpus often is associated with failure or delay of endochondral ossification in premature or dysmature neonates.[5,6] Crushing and malformation of the soft cartilaginous precursors of the cuboidal bones results in osteoarthritis and varying degrees of lameness (Fig. 129-4). Outwardly the limb may appear normal or have an angular deviation or, if a hindlimb is involved, it may be sickle hocked or curbed. Attempts at prevention of this condition are more effective than treatment after its onset, although these are limited in effectiveness. Prolonged stall confinement of premature neonates is recommended until signs of radiographic ossification of the cuboidal bones occur. Ossification generally requires 4 to 8 weeks but may vary. Foals affected with crushing of cuboidal bones rarely make competitive athletes, although most are suitable for light use, breeding, or as comfortable pasture animals.

Fractures of the Distal Phalanx

Non-articular fractures of the palmar processes of the distal phalanx occur with high frequency in Thoroughbred foals (Fig. 129-5). Other types of fractures of the distal phalanx occur but are not common. The forelimbs frequently are involved, and the lateral palmar process is more commonly fractured; bilateral and biaxial fractures occur occasionally. In the hindlimb, medial and lateral wing fractures occur evenly. Palmar process fractures may be detected on radiographs as incidental findings and may not necessarily cause lameness.

Salient clinical findings associated with a fracture of the palmar process of the distal phalanx include acute onset of lameness, which may be intermittent in nature, and lameness that is almost always more noticeable on sharp turns.

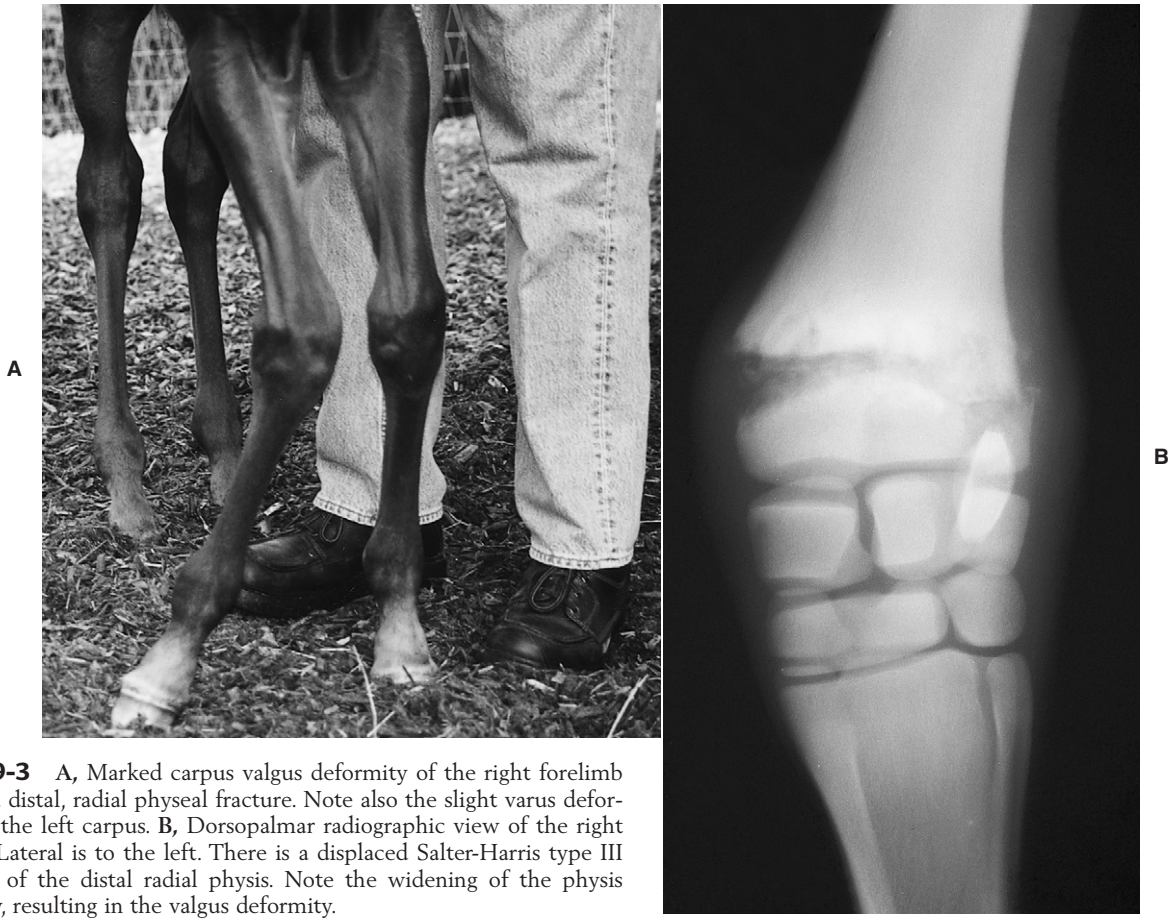

Fig. 129-3 **A,** Marked carpus valgus deformity of the right forelimb due to a distal, radial physeal fracture. Note also the slight varus deformity of the left carpus. **B,** Dorsopalmar radiographic view of the right carpus. Lateral is to the left. There is a displaced Salter-Harris type III fracture of the distal radial physis. Note the widening of the physis medially, resulting in the valgus deformity.

Fig. 129-4 Slightly oblique lateromedial view of the hock of a mature horse with crushing of the third tarsal bone and secondary osteoarthritis of the centrodistal and tarsometatarsal joints, the result of incomplete ossification of the third tarsal bone as a neonate. Note the wedge shape of the third tarsal bone and the abnormal dorsal contour.

Fig. 129-5 Dorsoproximal-palmarodistal oblique radiographic view of the foot of a foal. Lateral is to the right. There is a non-articular fracture of the lateral palmar process of the distal phalanx *(arrows)*.

Response to hoof tester evaluation is consistently painful when testers are applied across the heels. Atypically a response may be noticed with pressure at the toe. When diffuse pain is noted during hoof tester evaluation along, with an increased temperature of the foot, sub-solar abscessation should be considered.

Treatment includes confinement to a stall or small pen for 4 to 6 weeks. Lameness should improve dramatically in the first week. External coaptation such as a foot cast or glue-on shoe is contraindicated and may potentiate development of clubfoot conformation. Follow-up radiographs are not mandatory unless lameness persists or recurs. The prognosis is good. Differential diagnosis in foals suspect of fracture of the distal phalanx include subsolar bruising, subsolar abscessation, infectious osteitis of the distal phalanx, or infectious arthritis of the distal interphalangeal joint.

Fractures of the Proximal Sesamoid Bones

Fractures of the PSBs are common in young foals. Fractures usually are confined to one limb, but several limbs may be involved. Uniaxial (one) or biaxial (both sesamoids) fractures in a single limb can be found. PSB fractures occur most commonly in foals between 2 weeks and 2 months of age. Fractures most often involve the base or apex of the sesamoid (Fig. 129-6). Mid-body PSB fractures occur less commonly. Hindlimb PSB fractures are less common, but they generally occur in conjunction with PSB fractures in a forelimb.

Lameness varies from moderate to severe and is exaggerated on turns. Often an increased intensity in the digital pulse amplitudes is apparent, and palpation of the involved bone elicits a painful response. Depending on the fracture type and location, the fetlock joint capsule may be distended or regional swelling may occur over the fractured proximal sesamoid bone. Diagnosis is confirmed radiographically.

Conservative management is recommended and involves confinement to a small area for 6 to 8 weeks. If swelling is noticed, a lower limb bandage should be applied. Surgical repair is not beneficial in foals because of the lack of substance of the PSB. Prognosis depends on the type of fracture, number of PSBs involved, and the number of limbs involved. Most PSB fractures have an elongated appearance (megasesamoid) after healing, but foals may be suitable for athletic use if healing is complete (Fig. 129-7). The prognosis for athletic use is worse if both PSBs in one limb are affected, or if fractures occur in more than one limb, compared with a uniaxial fracture in a single limb.

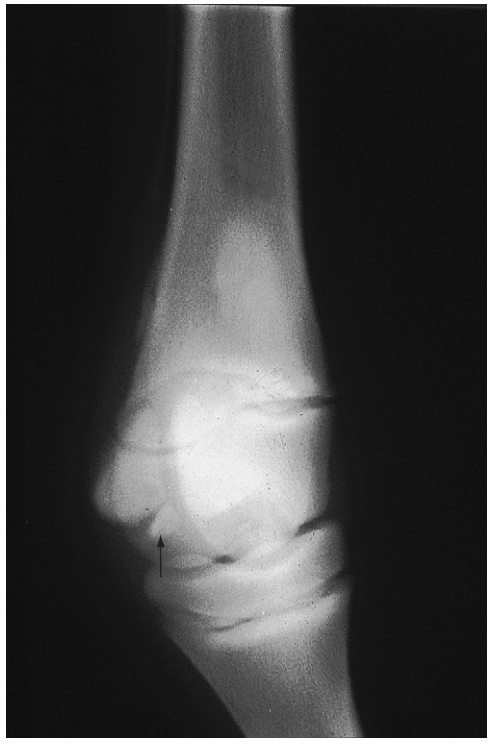

Fig. 129-6 Dorsolateral-palmaromedial oblique radiographic view of the metacarpophalangeal joint of a foal. There is a wedge-shaped basilar fracture *(arrow)* of the lateral proximal sesamoid bone.

Developmental Orthopedic Disease

Developmental orthopedic disease is an uncommon cause of lameness in foals less than 2 to 4 months old.[3,8] However, developmental orthopedic disease is a common skeletal disease in weanlings and yearlings and generally is considered self-limiting. Developmental orthopedic disease is complex and includes flexural deformity, osteochondrosis, physeal dysplasia (physitis), and cervical vertebral malformation. The pathogenesis, clinical manifestations, and management are discussed in Chapters 56, 58, 59, and 62.

Diagnosis of osteochondrosis is based on clinical evaluation and radiographic findings.[3,8] Clinical findings include synovial distention and varying degrees of lameness in the acute stage. Most young foals (less than 2 months old) afflicted with

Fig. 129-7 Dorsolateral-palmaromedial oblique radiographic view of the metacarpophalangeal joint seen in Fig. 129-6, obtained when the horse was a yearling. The basilar fracture of the lateral proximal sesamoid bone has healed, resulting in an elongated, distorted appearance of the bone.

osteochondrosis have several joints or bones involved. These foals are subsequently lamer than older foals and usually have severe osteochondrosis. The cause often is not found because individual foals usually are involved, although heredity likely plays a primary role. Radiographic findings may initially include osteochondral fragmentation or erosive changes in subchondral bone, or may be normal. Therefore, it is important to plan on serial radiographic studies to monitor the progression of changes.

Conservative management for young foals with osteochondrosis almost always is recommended and includes rest, anti-inflammatory drugs, systemic chondroprotective drugs, and occasionally joint lavage and injection with hyaluronan. If a free fragment is evident, surgical retrieval may be beneficial; however, one should keep in mind that surgery for osteochondrosis is an elective procedure that should be performed at a time optimal for the foal. If a non-displaced fragment occurs in a weanling or younger age foal, surgery may be delayed until the yearling period and monitored radiographically (Fig. 129-8). Time will allow maturation of the underlying bone so minimal debridement and curettage will be necessary. In many instances the extra time allows these fragments to remineralize, and surgical removal is not necessary. In a longitudinal study of 43 Dutch Warmblood foals osteochondritic lesions were found at the distal intermediate ridge of the tibia in 68% at 1 month of age, but at 11 months of age abnormalities were detected in only 18%.[9] Lesions in the lateral trochlear ridge of the femur developed later, with an incidence of 20% at 5 months of age, but by 11 months of age abnormalities were detected in only 3%.

Vascular Thrombosis

Vascular thrombosis is an unusual cause of lameness in foals. Usually a central focus provides emboli, the most common being a vegetative lesion on a heart valve. Clinical signs include a variable degree of lameness involving one or more limbs. The limb may feel cold during periods of lameness but normal at other times. Response to diagnostic analgesia is inconsistent. Ultrasonographic examination of the heart usually reveals a lesion on a heart valve. Although any valve may be involved, most commonly the aortic or mitral valves are affected. Bacterial blood cultures should be obtained, especially during febrile episodes, if present.

Treatment consists of long-term antimicrobial drugs, based on bacterial cultures if available, and optionally rheological agents such as pentoxifylline. Follow-up ultrasonographic examination is important to determine the effectiveness and duration of treatment. The prognosis is guarded and depends on the degree of ischemia in the distal extremity.

Fig. 129-8 Lateromedial radiographic view of a stifle. There is irregularity in outline of the cortex of the lateral trochlear ridge of the femur with subtle alteration of the subchondral bone opacity. This is the result of osteochondrosis. There are no displaced fragments, so surgery as a weanling is not required, although the foal should be monitored both clinically and radiographically.

Traumatic Nerve Injury

Collision injuries involving the proximal forelimb of foals may result in injury to the radial nerve or components of the brachial plexus. Most commonly a foal has a dropped shoulder, is unable to advance the limb, and drags the limb during ambulation. Differential diagnosis includes fracture of the humerus or scapula, and radiographic evaluation should be performed to differentiate these conditions. The condition may be transient, lasting only a few hours if attributable to neuropraxia, or may be permanent.

Treatment for nerve injury consists of anti-inflammatory drugs, including corticosteroids and non-steroidal drugs, and dimethylsulfoxide. Supportive care, such as physical manipulation of the limb and splinting, may aid in preventing flexural limb deformity. Acupuncture may be beneficial in some foals with nerve injury. In general, if no improvement is seen within 3 to 5 days of treatment, only 25% of foals recover.

INFECTIOUS CAUSES OF LAMENESS

Determining the location and cause of lameness in foals attributable to infection is crucial in deciding a course of therapy and assessing prognosis. As a general rule, assuming that all foal lameness is infectious in origin until proved otherwise is safest. In this instance, prompt appropriate treatment uniformly results in a more favorable outcome than if treatment is delayed.[10]

The clinical complex of infectious arthritis, tenosynovitis, infectious osteitis, or osteomyelitis occurs in foals commonly,[10-15] especially in foals less than 4 months of age, but occasionally occurs in older foals. The different forms of infection can be discussed together, because the pathogenesis is common. Bacteria may gain entry through the umbilicus, respiratory tract, or gastrointestinal tract, although direct penetration of a synovial structure from external trauma may result in synovial infection. Hematogenous dissemination of bacteria allows localization into metaphyseal, physeal, or epiphyseal cartilage and is believed to be associated with the rich vascular network comprised of metaphyseal loops, sinusoidal veins, and epiphyseal and transphyseal vessels that supply the end of the long bones and synovium (Fig. 129-9).[2,12] The sluggish blood flow and vascular stasis of nutrient vessels approaching a cartilage interface allows bacteria to proliferate and colonize. Bacterial colonization incites an acute inflammatory response associated with kinin, complement, and coagulation system activation, eventually leading to cartilage destruction. Vasoactive amines and prostaglandins acting as chemotactic agents result in rapid accumulation of inflammatory cells. Inflammatory products released from synoviocytes, fibroblasts, chondrocytes, neutrophils, and monocytes result in the degradation of articular cartilage proteoglycan, collagen, and hyaluronan. Mediators involved include collagenases, elastases, lysosomal enzymes, plasmin, prostaglandins, metalloproteases, monokines and free radicals. Extrinsic mediators include interleukins, bacterial lipopolysaccharides, and physical forces placed on the damaged cartilage, all of which further compound collagen degradation. Further compromise of cartilage occurs because of poor nutrition of the chondrocytes, caused primarily by fibrin clot formation over the

articular surface, and by thrombosis in the synovial membrane vasculature. The primary mediators of infectious arthritis and eventual cartilage destruction are toxic metabolites released from chondrocytes. Cartilage matrix degradation and proteoglycan loss may occur within 2 days and collagen loss by 9 days after bacterial inoculation.[2,16,17]

No explanation is apparent for disease localization in the epiphysis, metaphysis, physis, or joint. Certain joints do appear, however, to be affected more frequently than others. For example, the stifle, hock, metacarpophalangeal, and metatarsophalangeal joints are involved more often than the carpus or pastern. Infectious arthritis and osteomyelitis of hematogenous origin have been classified into five types based on location of the structure involved (Fig. 129-10).[12,18]

Infectious synovitis (S-type) affects foals usually within the first 10 days of life. Several joints are usually involved, and

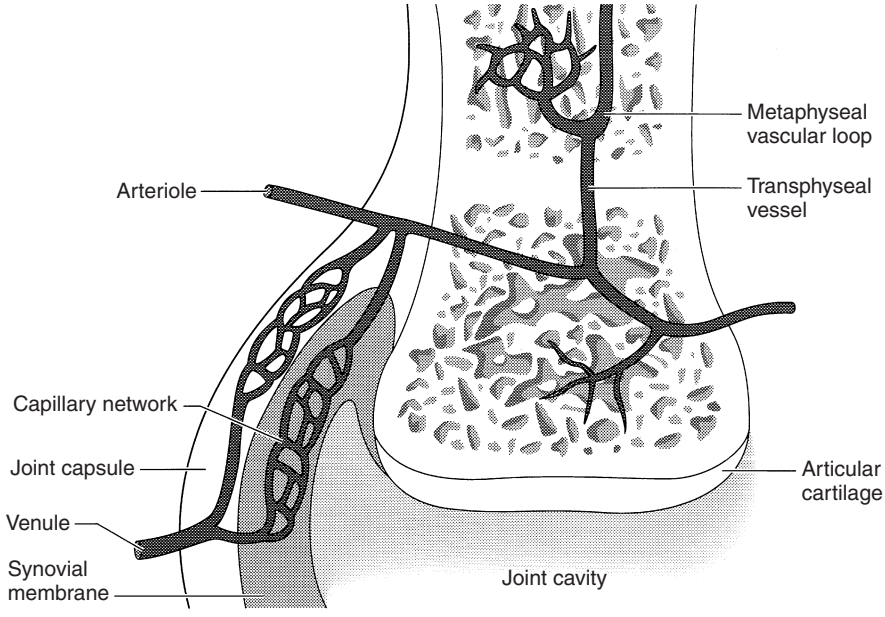

Fig. 129-9 Vascular supply to long bone and articular soft tissue. Blood-borne bacteria may colonize at the metaphyseal vascular loop and disseminate to the physis, epiphysis, or synovial membrane. (Modified from Kobluk CN, Ames TR, Geor RJ, editors: *The horse: diseases & clinical management*, Philadelphia, 1995, WB Saunders.)

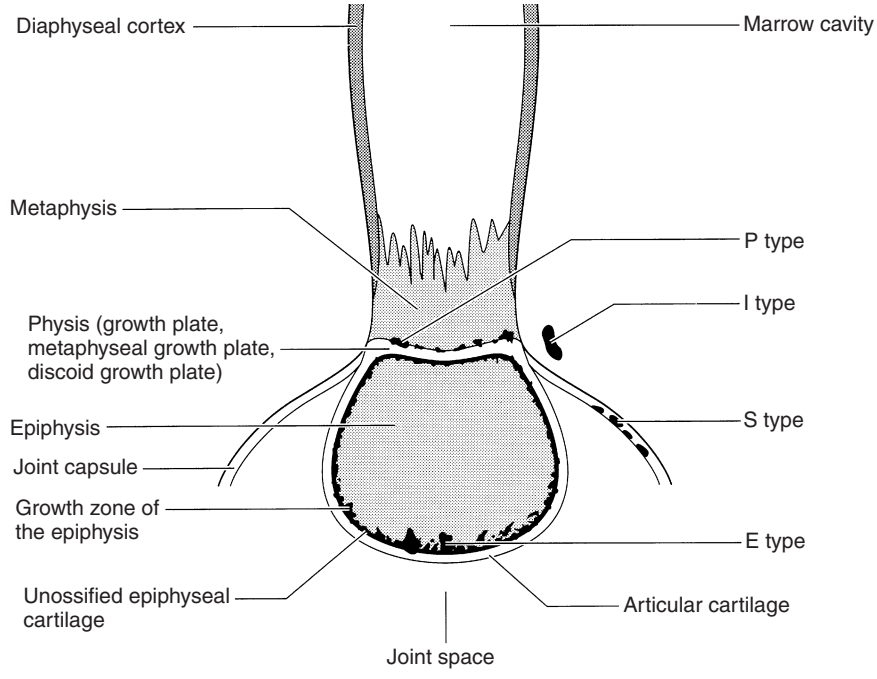

Fig. 129-10 Morphology of the long bone and types of S, E, P, and I infections. *P type,* Physeal-type infectious arthritis; *I type,* bacterial invasion into a physis or joint from a peri-articular abscess; *S type,* infectious synovitis; *E type,* epiphyseal-type infectious arthritis. (Modified from Kobluk CN, Ames TR, Geor RJ, editors: *The horse: diseases & clinical management,* Philadelphia, 1995, WB Saunders.)

few if any radiographic changes are seen. Predominant clinical signs include peri-articular soft tissue swelling, effusion, and lameness. Arthrocentesis reveals an elevation in nucleated cell count (usually >50,000/µl), and degenerate neutrophils predominate.

Epiphyseal type (E-type) infectious arthritis involves the joint and adjacent epiphysis. Foals are generally several weeks of age or older. One or more joints may be infected, and other systemic illnesses may occur concomitantly. Radiographic evidence of epiphyseal involvement commonly is seen.

Physeal type (P-type) may occur in foals from 1 week to 4 months of age. Degrees of soft tissue swelling and lameness may vary, and generally only one site is involved. Sympathetic effusion eventually may occur in a nearby joint (articular structure in close proximity). Lesions may be seen radiographically in the metaphysis, physis, or epiphysis (Fig. 129-11). Pathological fracture may result because of weakening of the involved structure.

Small tarsal or carpal cuboidal bone (T-type) osteomyelitis may result in collapse of the central or third tarsal bones (Fig. 129-12). Several joints commonly are affected.

Invasion into a physis or joint from a peri-articular soft tissue abscess is called I-type infection. Most commonly, joints of the upper limb such as the hip or stifle are involved. If soft tissue abscessation is detected early, infectious arthritis often can be avoided.

Most commonly foals with osteomyelitis have acute onset lameness, diffuse regional swelling, heat, and detectable pain of the involved area. Fever is generally present before and at the onset of lameness but may go undetected. Degree of lameness depends on what bone is involved, the time frame, and stage of detection. Owners often erroneously assume lameness results from trauma because signs occur acutely. A common assumption is that the mare stepped on the foal (the Editors).

Diagnosis of complex infection is based on physical examination findings and the results of arthrocentesis (if intrasynovial involvement occurs) and radiographic examination.[2,10,12,14,15] Foals with infectious osteitis or early osteomyelitis may have no or subtle radiographic changes, but within 1 to 2 weeks radiographic changes consist of erosive, radiolucent changes with sclerosis and eventual proliferation of new bone. It is therefore important to perform follow-up radiographic evaluation to monitor the progression of the disease.

Other imaging modalities are of limited value. Sensitivity of nuclear scintigraphy alone is questionable in young foals because of the high metabolic activity of developing bone.[10] White cell imaging using nuclear medicine techniques is useful, but adds expense and radiation exposure, and has not gained widespread acceptance in private practice.

Ultrasonographic examination is most helpful in identifying soft tissue injury or inflammatory processes of the upper limb. Abscessation of the soft tissue adjacent to the infected bone is a common finding in foals with physeal infection. Using ultrasonographic guidance, abscesses can be aspirated for culture and susceptibility testing and opened, drained, and lavaged.

Arthrocentesis is the key in diagnosing infectious arthritis, but a negative culture does not rule out infection.[4,10-14,19] Joint fluid should be obtained in EDTA tubes to evaluate the differential and total nucleated white blood cell count and protein concentration and for cytological evaluation. Anaerobic and aerobic culture and susceptibility tests should be performed. Using an antimicrobial removal device may be of benefit to potentiate a positive culture if the foal is receiving antimicrobial drugs. Blood cultures should be collected.

Fig. 129-11 Dorsopalmar radiographic view of the carpus of a foal with P-type osteomyelitis of the distal radial physis. Lateral is to the right. Note the soft tissue swelling and the extensive lytic areas in the physis, metaphysis, and epiphysis. Infection has caused fragmentation of the lateral aspect of the metaphysis.

Fig. 129-12 Dorsoplantar radiographic view of a hock of a young foal with type T osteomyelitis involving the cuboidal bone of the tarsus. Lateral is to the right. Note the mottled opacity of the central and third tarsal bones and the proximolateral aspect of the third and fourth metatarsal bones. These extensive lesions warrant a grave prognosis.

In horses suspected of having infectious arthritis, synovial fluid cultures are positive 64% of the time.[11,13,16,17,19] In our practice, of 158 synovial samples submitted in 1 year, there were only 64 (40%) positive isolates. Reasons for low positive culture results include previous administration of antimicrobial agents, partial success of the immune system, the intrinsic bacteriocidal properties of infected synovial fluid, poor storage, or no bacteria present in the synovial fluid.

If there is radiographic evidence of osteomyelitis well away from a joint, a sample of bone and debris may be obtained using a Michelle's trephine. An alternative technique is to use a 2.5- or 3.2-mm drill bit and collect the shavings for culture and sensitivity testing.[10] This tract then may be used for intraosseous infusion of an antimicrobial agent.

The results of hematological testing can be confusing. Complete blood count and fibrinogen level should be assessed, but results are often within normal limits initially because infection is localized. Serial hemograms should be performed in this instance. Any elevation in the white blood cell count or fibrinogen level in a lame foal with fever should be assumed to reflect bone or joint infection until proved otherwise. A normal hemogram does not rule out infectious arthritis or osteomyelitis. Foals less than 1 month of age should have immunoglobulin G levels checked to evaluate for failure of passive transfer.

Treatment of foals with infectious arthritis consists of joint lavage with sterile polyionic fluids through large-bore needles or by using an arthroscope. If a large amount of fibrin and cellular debris is in the synovial fluid, arthrotomy and lavage with or without primary closure of the joint may be indicated. Joint lavage may be repeated every 1 to 3 days depending on the clinical response. A long-term closed suction drainage system may be used as well.[10] Broad-spectrum systemic antimicrobial drugs should be started immediately and adjusted accordingly based on the clinical progression and culture and sensitivity testing.

Other treatments for joint and bone infection include local intraosseous injection or regional hyperperfusion with antimicrobial agents. To perform intraosseous injection, an 18- or 20-gauge needle is inserted into the physis or adjacent bone. An aminoglycoside such as amikacin (250 to 500 mg) may be used. To perform regional hyperperfusion, a site over the abaxial digital neurovascular bundle is prepared aseptically and a rubber tourniquet is placed in the proximal metacarpal region. A 23-gauge butterfly catheter is inserted in the digital vein. An antimicrobial solution (500 mg amikacin diluted in 10 ml sterile water) is infused into the digital vein (Fig. 129-13). The tourniquet is removed after 15 minutes, and a lower-limb bandage is applied. The procedure may be repeated as necessary. Regional digital hyperperfusion is especially useful in treating infectious osteitis of the distal phalanx and distal limb infectious arthritis or osteomyelitis. I have not encountered complications from tourniquet application such as distal limb ischemia.

Foals with infectious arthritis should be allowed to rest for a minimum of 3 to 4 weeks to prevent further traumatic cartilage damage.[2] Systemic administration of chondroprotective agents or intra-articular administration of hyaluronan may be of benefit.

Severe erosive lesions of the physis and metaphysis may result in pathological fracture and collapse of the bony column, resulting in an unstable fracture or severe angular deviation. Surgery may be indicated, but prognosis is poor for soundness if this occurs.

The prognosis for foals with infectious arthritis and osteomyelitis depends on the antimicrobial susceptibility of the organism and how early effective treatment is instituted.[11-19] In general, foals treated early for articular infections have a good prognosis for full recovery. Foals with articular infection with subchondral bone involvement have a poor prognosis, and the clinical course of disease and treatment are prolonged. Foals with focal bony lesions, involving only the physis without bone instability, have a good prognosis. Those with a pathological fracture or severe angular limb deformities have a poor prognosis and may be candidates for humane destruction.

Fig. 129-13 Regional intravenous hyperperfusion of an antimicrobial solution for treatment of infection of the digit. A needle has been placed into the lateral digital vein. There is a tourniquet around the proximal metacarpal region.

Immune-Mediated Synovitis

Immune-mediated synovitis is a sequella to a primary inflammatory focus such as pneumonia, umbilical remnant infection, or a peripheral abscess.[10,20] *Rhodococcus equi* pneumonia is the most common primary focus of infection. The syndrome results from the deposition of immune complexes in the synovial lining and complement activation, resulting in synovitis. The condition usually involves more than one synovial structure. Foals usually have a stiff gait resulting from the synovial distention, and severe lameness is unusual.

The primary rule out for immune-mediated synovitis is early infectious polyarthritis, causing only moderate lameness and mild synovial fluid distention. Cytological evaluation of joint fluid in foals with immune-mediated synovitis commonly reveals nucleated cell counts of less than 20,000 nucleated cells/µl. The cells are well-preserved neutrophils and large mononuclear cells. Foals with infectious arthritis generally have nucleated cell counts greater than 50,000 nucleated cells/µl, and neutrophils are degenerative.

Therapy for foals with immune-mediated synovitis is based on identifying and resolving the underlying disease. Synovitis is self-limiting once the offending cause is removed. Systemic chondroprotective agents may be of benefit to the health of the joint, because prolonged inflammation may cause cartilage damage.

Infection of the Digit

Infection of the digit is a frequent cause of substantial lameness in foals. Infection may be contained to the subsolar or hoof wall regions, or it may involve the distal phalanx or the distal interphalangeal joint. It is critical to differentiate between these sites as soon as possible. Infection at all sites causes increased intensity of the digital pulse amplitudes and, at some stage, increased temperature of the hoof capsule. With subsolar or wall abscessation, pressure applied with hoof testers usually produces a painful response along the toe and sole, unless overlying horn is separated from the sensitive tissue caused by accumulation of purulent material. Radiographs in these foals reveal gas accumulation in the involved area. If the distal phalanx is infected, radiolucency or sequestration may be evident. Diffuse swelling at the coronary band usually means involvement of the distal interphalangeal joint, and arthrocentesis should be performed in an area remote from the swelling.

Subsolar abscesses should be drained early to prevent involvement of deeper tissues. To facilitate drainage, the foot can be soaked in hot water and bandaged with an Animalintex pack (3M Animal Care Products, St. Paul, MN). Both procedures soften the horn. Surgical curettage of the distal phalanx and lavage of the infected bone should be performed in foals with sequestration. A sterile, antiseptic bandage should be maintained after surgery for a minimum of 3 to 4 weeks or until a healthy keratin covering has grown over the exposed bone. Ancillary treatment includes regional digital hyperinfusion using a dilute antimicrobial solution. A good prognosis is warranted in foals with infection of the distal phalanx if the disease is detected and treated early. If more than 25% of the distal phalanx is involved, prognosis for future soundness worsens. Recurrence of infection after initial curettage requires additional surgery. Because of the limited surface area and porous nature of the distal phalanx in the foal, recurrence worsens the prognosis considerably.

CHAPTER • 130

Pleasure Riding Horse

Herbert J. Burns

Pleasure riding horses are a vital part of the equine industry and many owners devote great amounts of time, money, and emotion to them. Although pleasure riding horses are of far less monetary value than competition horses, the overall importance to the owner should never be underestimated.

Pleasure riding horses often tend to be used seasonally and somewhat episodically. Uses include trail riding, hunting, gymkhana-type activities, showing, lesson horses (teaching horses), the pasture pet, and eating grass. Pleasure riding horses can be divided loosely into two categories, ex-professionals and others. The ex-professionals are horses that formerly were used for a specific athletic use such as racing, but are no longer able to perform in the sport, and have been demoted. The others include potential athletes that were unable to be used for the intended purpose because of lack of ability, poor conformation, or temperament and horses and ponies that were bred casually as pets. The common causes of lameness in these two groups differ to some extent.

It is vital to be able to relate to the owners of pleasure riding horses, who often are inexperienced with horses, have little veterinary knowledge, but have tremendous emotional involvement with the horse and are often anxious. It is vital to first establish communication with the owner and try to relieve any anxieties. The veterinarian should explain the intended examination and treatment and why in straightforward, non-technical language. Facilities for examination may be far from ideal and may complicate the examination. The veterinarian should not over-interpret a short striding gait shown by a horse trotting on an uneven paddock or a rocky driveway. The clinician should start from the basics and evaluate left-right symmetry, with the horse standing on a flat, level surface, if available, and then assess the horse moving in straight lines and circles. The veterinarian should be aware that the horse may have been living with a low-grade lameness, unrecognized by the owner, for a considerable time. If the owner is concerned about a severe left forelimb lameness, the veterinarian would be prudent to avoid mentioning a low-grade left hindlimb lameness observed concurrently, because the lameness is probably not of material relevance and will only further worry the owner.

Interpretation of findings is in part dictated by the age and previous occupation of the horse. Many ex-professional horses have previous soft tissue injuries or show lameness after flexion of a variety of joints, and it is important to try to establish which is the current active disease process causing lameness. Many clinical observations reflect previous injuries and are unrelated to the current lameness.

Local analgesic techniques are useful in some situations, but the temperament of the horse, difficulties in adequate restraint, or examination facilities available may mitigate against them. Owners of pleasure riding horses may resist techniques that are invasive or potentially painful to the horse, whereas they may be fully prepared to pay large sums for advanced diagnostic techniques. The clinician should bear in mind that a twitch in the inexperienced hands of an owner may be dangerous and should consider using tranquilization (e.g., 1 ml of acepromazine) in the horse to facilitate local analgesic techniques.

In some situations an owner prefers a step-by-step diagnosis reached by assessing the response to treatment, even without a definitive diagnosis. This can provide the slow acquisition of useful information. For example, assessment of the response to non-steroidal anti-inflammatory drug treatment can be helpful. Lameness associated with a subsolar abscess is likely to deteriorate, whereas lameness from navicular disease or osteoarthritis of the proximal interphalangeal joint is likely to improve.

In ex-professional horses, osteoarthritis and previous tendon and ligament injuries are common. Minor trauma to a joint in a horse with pre-existing osteoarthritis may result in severe, persistent lameness, whereas similar trauma to a normal joint probably would not result in chronic lameness. Commonly injured joints include the carpus, fetlock, hock, and stifle. Superficial digital flexor tendonitis, suspensory desmitis, and distal sesamoidean ligament injuries are common chronic injuries in ex-professional horses, but re-injury is comparatively unusual unless the horse is subjected to a sudden and substantial increase in exercise intensity; for example, a horse is ridden hard for 2 hours after 3 months of little or no exercise. Previous sites of chronic inflammation may become a long-term problem. For example, a horse may lose a shoe and then gallop about on hard ground, resulting in solar bruising. However, lameness may persist and radiographs may reveal osteitis of the palmar processes of the distal phalanx. A horse with toed-out conformation may traumatize the medial proximal sesamoid bone, resulting in acute lameness, but radiographic examination may reveal pre-existing abnormalities.

Many causes of lameness in pleasure riding horses relate to the lifestyle of pampered pets, and the environment in which they are kept. Subsolar abscesses are common and often result in a severe lameness, creating panic for an owner, who assumes the horse must have sustained a fracture. Managing the owner is equally as important as treating the horse. Subsolar abscesses also may be sequelae to previous laminitis.

Creation of effective drainage is essential for successful management of subsolar abscesses. Without drainage the use of systemic antimicrobial drugs is contraindicated in my experience, because such drugs may prolong the course of the infection. In some pleasure riding horses with a hard hoof capsule, determining accurately the site of abscess may not be possible initially. I recommend intensive soaking with Epsom salts and warm water and poultice at night. Periodic survey radiographs can be useful. Up to 30 days may pass before the abscess can be located accurately and drainage can be established. Once the abscess has opened or been opened, systemic antimicrobial drugs may be useful, especially if a large area of the foot is damaged.

Pleasure riding horses are at high risk for sustaining lacerations or puncture wounds, often resulting from impact with less than ideal fencing such as barbed wire or a jagged post. Injuries vary from minor to severe, resulting in long-term lame-

ness. Injuries may go unrecognized for several days because not all pleasure riding horses are inspected carefully and regularly. Many pleasure riding horses are kept in groups at pasture, and the introduction of a new horse can result in disruption of the hierarchy and the risk of horse-induced injury.

The veterinarian also should recognize that many pleasure riding horses have major conformational abnormalities that predispose them to the early development of osteoarthritis. Many pleasure riding horses live to an old age, and age-related osteoarthritis is not uncommon. Farrier care may be less than ideal and may predispose the horses to chronic foot pain and osteoarthritis of the distal limb joints. Nail bind and excessive shortening of the toe are common farriery-related causes of lameness. It is important to establish the time of onset of lameness relative to when the horse was last shod. These problems are usually apparent within 48 hours. If a nail was driven inside the white line and immediately removed, this may predispose the horse to a subsolar abscess, which usually causes lameness within 7 to 10 days. If foot lameness develops more than 2 weeks after trimming and shoeing, the lameness is unlikely to be related to the farrier. Other primary foot problems include solar bruising, sheared heels, puncture injuries, and thrush. The relative incidence of these problems may be related to the ground conditions if the horse lives out. Early, wet springs increase the incidence of thrush. Long, dry summers resulting in hard ground are associated with an increased incidence of bruising and sore feet.

Laminitis is a problem seen most commonly in two types of pleasure riding horse, obese ponies and older horses and ponies with a pituitary adenoma. Laminitis is often seasonal, occurring most in the spring and early summer and also in the autumn, if a flush of grass occurs late. Navicular disease is not uncommon, and an irregular exercise history may be a predisposing factor. Navicular disease is less common in horses that have never been shod.

Cellulitis can create an acute-onset, non–weight-bearing lameness associated with pyrexia and inappetence. In some horses minor skin abrasions can be identified through which infection was initiated, but in others the primary cause may not be identified.

The incidence of tendon and ligament injuries is low and may be related to the weather and environmental conditions, or to the age of the horse. Excessively deep, muddy pastures and extremely icy conditions may predispose horses to tendonitis or desmitis. Age-related degenerative changes take place in some tendons and ligaments, and in older pleasure riding horses, even those receiving no ridden exercise, sudden onset of a severe, progressive tendonitis of the forelimb superficial digital flexor tendons may develop. Progressive stretching of the hindlimb suspensory apparatus, resulting in dropping of the fetlocks, also occurs in older horses.

Neurological problems such as radial nerve paralysis may result from trauma induced by a kick from another horse in the same field or from a collision with another horse or a static object such as a gate post. In older horses neoplastic lesions may result in secondary lameness. For example, a large melanoma in the gluteal region in a horse I examined created pressure on the sciatic nerve and thus lameness.

Pleasure riding horses are often kept at pasture in a group, with access to field shelters of variable design. Long bone fractures, the result of a kick from a companion horse, are not uncommon, especially during the winter months. Splint bone fractures are also common.

Treatment of many of these conditions is no different than in other athletic sport horses; however, certain constraints may apply that must be considered. No facilities may be available to restrict the horse's exercise or to keep it on its own. Some facilities are completely inadequate for performing clean procedures, such as intra-articular medication, in a safe manner. However, owners often are prepared to spend a disproportionate amount of their income on treating a condition in their much loved horse, despite a guarded prognosis, so it is important to describe all available treatment options. It is also critically important to explain carefully the treatment protocol, and writing it down can be useful to ensure owner compliance. The veterinarian can create a chart that the owner should complete as medication is administered.

In managing osteoarthritis, the fact that a pleasure riding horse lives out and is constantly exercising actually may be of benefit. I prefer to start with the least invasive therapy first and only use alternative methods if that does not work. Some oral nutraceutical agents may be of benefit, as may be intramuscular administration of polysulfated glycosaminoglycans.

Management of wounds can be difficult because client compliance is often poor. I treat wounds in anticipation of the worst-case scenario, using non-steroidal anti-inflammatory drugs, broad-spectrum antimicrobial drugs, and confinement. Complete stall rest is often impossible, and restricted area turnout is a frequent compromise. If a penetrating injury possibly may have entered a joint or tendon sheath, I recommend referral for intensive therapy, stressing to the owner that this injury is potentially life threatening.
