Preface

Multiphase flow is the flow of heterogeneous mixtures of two or more phases, such as gas–liquid, solid–liquid, or gas–solid. Multiphase flow is encountered in numerous industrial and scientific applications, such as boiling and condensation processes, aerosol flows in the environment, gas and petroleum flows, gas–solid and slurry flows in pipelines, particle and fiber flows in airways, fluidized bed reactors, and nanofluids.

The first edition of the *Multiphase Flow Handbook* was published ten years ago with the late professor C.T. Crowe as the editor. The handbook provided a plethora of scientific and practical information to scientists, engineers, researchers, and students and has been useful to many. A great deal of research and development in multiphase flow occurred since the first edition of the handbook, and a lot of additional information is now available, especially in the area of computational modeling. The purpose of this second edition is to provide the reader with the fundamental principles of multiphase flow and useful current information for research, engineering design, and the classroom.

The structure of the second edition is different from that of the first: Several new chapters have been added, primarily on the applications. The material is divided into three sections: (1) fundamentals, (2) descriptions of specific types of multiphase flow and processes, and (3) significant applications. Chapters 1 and 2 pertain to fundamental concepts and numerical methods that are used in all types and applications of multiphase flow. Chapters 3 through 13 describe general types of multiphase flow, such as gas–solid, compressible multiphase flow, flow in porous media, bubble formation and cavitation, etc. Chapters 14 and 15 cover the processes of aggregation and industrial separation of particles, bubbles, and drops. Chapters 16 through 21 examine significant applications of multiphase flow from fluidized bed reactors to nanofluids to multiphase flow with non-Newtonian fluids.

I am grateful to the many distinguished contributors who lent their expertise and spent significant time and effort writing the chapters of this handbook within the time constraints of a publication. Jonathan Plant of Taylor & Francis Group/CRC Press was always there to provide managerial support and advice. Jessica Vakilli put together three of the sections from edited material supplied by the contributors. She and Kyra Lindholm completed all the administrative work such a big undertaking requires. Dr. John Schwarzkopf assisted in the early stages of the project. I am also indebted to Mr. Aranganathan Arunkumar of the production team of this publication, who spent many hours putting together the chapters and sections of this handbook. Last, but not least, I am thankful to my family, Laura, Emmanuel, Dimitri, and Eleni, for their continuous support and encouragement for such ambitious projects.

Editors

Efstathios E. Michaelides holds the Tex Moncrief Chair of Engineering at Texas Christian University (TCU), Fort Worth, Texas. Prior to this, he was chair in the Department of Mechanical Engineering at the University of Texas in San Antonio, where he also held the Robert F. McDermott Chair in engineering and was the founder and director of the NSF-supported Center on Simulation, Visualization and Real Time Computing (SiViRT). He was also the founding chair of the Department of Mechanical and Energy Engineering at the University of North Texas (2006–2007); the Leo S. Weil professor of mechanical engineering at Tulane University (1998–2007); director of the South-Central Center of the National Institute for Global Environmental Change (2002–2007); associate dean for graduate studies and research in the School of Engineering at Tulane University (1992–2003); head of the Mechanical Engineering Department at Tulane University (1990–1992). Between 1980 and 1989, he was on the faculty of the University of Delaware, where he also served as the acting chair of the Mechanical Engineering Department (1985–1987).

Professor Michaelides was awarded an honorary MA from Oxford University (1983); the Casberg and Schillizzi scholarships at St. Johns College, Oxford; the student chapter ASME/Phi, Beta, Tau excellence in teaching award (1991 and 2001); the Lee H. Johnson award for teaching excellence (1995); a senior Fulbright fellowship (1997); the ASME Freeman Scholar award (2002); the Outstanding Researcher award at Tulane (2003); and the ASME Fluids Engineering award (2014).

Professor Michaelides was a member of the executive committee of the Fluids Engineering Division of the ASME (2002–2008) and served as the chair of the Division in 2005–2006. Prior to this, he served as the chair (1996–1998) of the Multiphase Flow Technical Committee. He also served as the president of the ASEE Gulf-South Region (1992–1993 and 2015–2016); he chaired the *Fourth International Conference on Multiphase Flows* (New Orleans, Louisiana, May 27 to June 1, 2001) and was the vice-chair of the *Fifth International Conference on Multiphase Flows* (Yokohama, Japan, May 2004). He has published more than 140 journal papers and has contributed more than 250 papers in national and international conferences. He has also published four books: *Particles, Bubbles and Drops—Their Motion and Heat Transfer* (World Scientific, 2006); *Alternative Energy Sources* (Springer, 2012); *Heat and Mass Transfer in Particulate Suspensions* (Springer, 2013); and *Nanofluidics—Thermodynamic and Transport Properties* (Springer, 2014). Professor Michaelides earned a bachelor's degree (honors) from Oxford University and master's and doctorate degrees from Brown University.

Clayton T. Crowe was a professor of mechanical and materials engineering at Washington State University in Pullman, Pullman, Washington. He is recognized as a leading scholar and author in fluid mechanics, and, in particular, the area of multiphase flows. Among his achievements was the development of the particle-source-in-cell (PSI-Cell) method for the numerical simulation of multiphase flow that has been used extensively in industry and in commercial simulation software. He was the author of numerous technical articles and of *Engineering Fluid Mechanics*, a widely used college textbook now in its eleventh edition. His other publications include *Multiphase Flows with Droplets and Particles, Second Edition* (CRC Press, 2012), and *Multiphase Flow Handbook, First Edition* (CRC Press, 2005). He received many honors for his work, including ASME fellow, the ASME Fluids Engineering Award, and the Senior International Prize for Multiphase Flows. Dr. Crowe passed away in 2012.

John D. Schwarzkopf is a staff scientist within the Theoretical Design Division at Los Alamos National Laboratory, Los Alamos, New Mexico. He has more than 10 years of experience in the application of multiphase flows and computational code development. His work contributed to two patents and several technical articles on the topic of multiphase and multicomponent flow applied to electronics cooling, atomization, and turbulence modeling. He is a coauthor of the book *Multiphase Flows with Droplets and Particles, Second Edition* (CRC Press, 2012).

Nomenclature

Latin Symbols

a	Acceleration
A	Area
A_{eff}	Hamaker constant
B	Blowing factor
Bo	Bond number
Boi	Boiling number
c	Specific heat capacity
c_A, c_B,…	Mass concentration of species A, B,…
c_l	Speed of sound in liquid
C	Coefficient (dimensionless)
Ca	Capillary number
Co	Convection number
C_A	Added mass coefficient
C_D	Drag coefficient
C_H	History term coefficient
d	Diameter of small-scale features (particles, droplets, bubbles, etc.)
d_{32}	Sauter mean diameter (SMD)
D	Diameter of large-scale features (pipes, bends, etc.)
$\mathfrak{D}_{(\ )}$	Diffusion coefficient
e	Internal energy
E	Young's modulus
$E(\kappa)$	Energy intensity (for spectra)
Eo	Eötvös number
Eu	Euler number
f	Friction factor
$\mathfrak{F}$	Frequency
$F(D)$	Cumulative distribution
F_i	Force vector
Fo	Fourier number
Fr	Froude number
g	Gravitational acceleration
g_I	(i = 1, 2, 3,…) Gibbs free energy (molar)
G	Mass flux
Gr	Grashoff number
h	Enthalpy
h_c	Convective heat transfer coefficient
h_{fg}	Latent heat of evaporation
h_m	Convective mass transfer coefficient

H	Head
He	Hedstrom number
I	Intensity
Ja	Jakob number
$J_A, J_B,\ldots$	Mole fluxes of species A, B,…
k	Thermal conductivity
k_B	Boltzmann constant
k_s	Pipe roughness
k_w	Wave number
K	Turbulent kinetic energy
K_{nu}	Knudsen number
Ki	Kirpichev number
Ku	Kutateladze number
l	Length scale
L	Characteristic length
m	Mass
M	Mass flux
$\mathfrak{M}$	Molecular weight
M_a	Mach number
n	Power-law factor, number or number density
$n_A, n_B,\ldots$	Mole concentration of species A, B,…
n_i	Unit normal vector
N	Total number
N_{av}	Avogadro number
Nu	Nusselt number
Oh	Ohnesorge number
P	Pressure
p	Perimeter
P_{ij}	Collision frequency
Pe	Peclet number
q_e	Electric charge
$\dot{Q}$	Heat rate
q''	Heat flux
r, θ, φ	Spherical coordinates
r, θ, z	Cylindrical coordinates
$\mathfrak{R}_u$	Universal gas constant
Ra	Rayleigh number
Re	Reynolds number
R_{ij}	Turbulence Reynolds stress tensor
$R(\tau)$	Velocity correlation function
S	Surface
S_w	Swirl parameter
Sh	Sherwood number
Sha	Shannon number
St	Stokes number
St_h	Strouhal number
S_{ij}	Stress tensor
S_{mass}	Mass source term
S_{mom}	Momentum source term
t	Time
T	Temperature
$T(\kappa)$	Spectral energy transfer rate
U, u	Continuous phase velocity
u_i, v_i, w_i	Velocity vectors
v	Dispersed phase velocity

v_T	Terminal velocity
V	Volume
$\dot{V}$	Volumetric flow rate
We	Weber number
x, y, z	Cartesian coordinates
X	Lockhart–Martinelli parameter
Y	Mass fraction
Y_{mol}	Mole fraction
Z	Loading
z	Length scale

Greek Symbols

a	Particle radius
α_f	Thermal diffusivity of fluid
α_s	Absorptivity
β	Slip parameter
β_P	Expansion coefficient at constant pressure
β_T	Expansion coefficient at constant temperature
γ	Specific gravity
Γ	Torque
δ	Distance or spacing
δ_{ij}	Kronecker delta
ε	Turbulence energy dissipation rate
ε_0	Electric permeability of vacuum
ε_p	Porosity
ϵ	Emissivity
ζ	Dimensionless parameter
η	Kolmogorov length scale, amplitude
θ	Angle
Θ	Granular temperature, dimensionless temperature, wall scattering function
κ	Wave number, ratio of specific heats
κ_p	Permeability
κ_T	Expansion coefficient
λ_{m}	Molecular mean free path
λ	Factor of ratio
μ	Chemical potential, dynamic viscosity
ν	Kinematic viscosity
ρ	Density
Π	Coupling parameter
σ	Surface tension, standard deviation, Stefan–Boltzmann constant
$\sigma_n, \sigma_1, \sigma_2, \sigma_3$	Normal or principal stresses
τ	Response time, time scale
τ_s	Shear stress
φ	Velocity ratio
ϕ	Porosity
Φ	Two-phase flow multiplier, potential
ϕ_c	Volume fraction of continuous phase, void fraction
ϕ_d	Volume fraction of dispersed phase
χ	Gas mass quality
ψ	Stream function
ψ_s	Surface potential
Ψ	Shape factor
ω	Frequency
ω_i	Chemical source for species "i"
ω_n	Natural frequency
Ω	Angular velocity

Subscripts

,	Derivative
an	Annular
avg	Average
agg	Agglomeration
b	Bubble
B	Bulk
c	Continuous phase
ch	Characteristic
cr	Critical
co	Core
coag	Coagulation
coll	Collision
conv	Convective
d	Dispersed or dense phase
D	Drag
e	Eddy or equilibrium
eff	Effective
eq	Equivalent
f, *F*	Fluid
fg	Latent heat/enthalpy
fr	Friction
gas, *G*	Gas
gs	Superficial gas

Fundamentals of Multiphase Flow

Efstathios E. Michaelides and Zhi-Gang Feng

1.1 General Features of Multiphase Flows
1.2 Fundamental Definitions
1.3 Size of Particles, Drops, and Bubbles
1.4 Interactions of Fluids with Particles, Drops, and Bubbles

1.1 General Features of Multiphase Flows

Solid, liquid, and vapor are the three natural phases of materials. Gases and ideal gases are parts of the vapor phase where specific constitutive equations, for example, the ideal gas equation, apply. A multiphase system contains materials of two or more phases. Multiphase flow is the flow of a mixture of phases such as gases (bubbles) in a liquid or liquid (droplets) in gases. Liquids of different densities and solids of different crystalline systems are often considered as separate phases. Thus, the flow of oil droplets in water is considered multiphase flow.

1.1.1 Dispersed Phase and Separated Flows

In dispersed phase flows, one phase consists of discrete, noncontinuous elements and the second phase consists of a continuous fluid matrix. Examples of dispersed multiphase flows are the flow of bubbles in a liquid and the flow of particles or droplets in a gaseous matrix. In a separated flow, the two phases are separated by a single surface of contact. For example, the annular flow in a pipe, which includes a liquid layer on the pipe wall and a vapor core, is a separated flow.

1.1.2 Gas–Liquid Flows

The motion of bubbles in liquids and the motion of droplets in gas streams are examples of gas–liquid flows. Bubble columns are commonly used in several process industries including chemical reactions and fluid purification processes. The atomization of a liquid to generate small droplets for combustion is important in power generation and automotive systems. Droplet formation and impaction are important in spray forming for materials processing. Steam–water flows in pipes and heat exchangers are very common in power systems with vapor cycles, such as fossil fuel plants and nuclear reactors. Gas–liquid flows in pipes can assume several geometric configurations ranging from bubbly flow to churn and annular flow.

1.1.3 Gas–Particle Flows

The particles in this case are either solid particles or liquid droplets. This type of multiphase flow includes the pneumatic transport of solids, fluidized beds for solids combustion, and the burning of fuel droplets.

The operation of pollution control devices, such as cyclone separators and electrostatic precipitators, is based on the principles of gas–solid flows. The combustion process of coal in fossil fuel power systems depends on the dispersion and burning of coal particles. The micron-size particles in a solid propellant rocket exhaust affect the performance of the rocket. Another type of a gas–solid flow is the motion of particles down a chute or an inclined plane. These are known as granular flows where particle–particle and particle–wall interactions determine the transport of the solid phase. In the extreme case, where the particulate phase is motionless, the flow becomes flow through a porous medium as, for example, in a pebble-bed heat exchanger or a stationary bed reactor.

1.1.4 Liquid–Solid Flows

Liquid–solid flows are flows where solid particles are carried by the liquid. Oftentimes, such flows are referred to as slurry flows. Slurries cover a wide spectrum of applications ranging from the transport of minerals (including coal) to the flow of toothpaste. Several environmental flows and processes, such as the removal of sediment from water and waterways, involve slurry transport. Typically, the solid particles are discrete and for this reason, slurry flows are classified as dispersed flows. When the solids are stationary, the flow of liquid through the solid is another example of flow in a porous medium.

1.1.5 Three-Phase Flows

Three-phase flows are also encountered in a few engineering systems. For example, gaseous bubbles rising in slurry are three phases flowing together. Three-phase flows are met in specialized systems and have a high degree of complexity. For this reason, not much research work has been reported in the literature on these flows.

1.1.6 Scope of This Handbook

Before the 1980s, the design of multiphase systems was based primarily on empirical observations and correlations of experimental data. Since the early 1980s, the design of more advanced instruments and the application of more scientific measurement techniques have led to the measurement and quantification of fundamental parameters that improved our understanding of multiphase systems and processes. In parallel, the tremendous improvement of computational capacity and numerical techniques has enabled the development of numerical models that are now reliably used to complement engineering design. The improvements of the experimental instruments and the numerical models for multiphase flows are rapidly growing areas of technology, which have far-reaching benefits in upgrading the operation and efficiency of current engineering systems and processes and in supporting the development of new and innovative technologies.

This handbook is designed to provide a background for engineers and scientists and to serve as a source of information on current technology. This chapter introduces fundamental definitions of dispersed multiphase flows, including size distributions and fundamental interactions of particles, bubbles, and drops with fluids. This chapter also addresses the current state of the art and examines commonly used instruments and processes for measuring multiphase flows. Chapter 2 deals with the numerical modeling of multiphase flows. It includes numerical modeling methods such as direct simulation, Lagrangian modeling, two-fluid modeling, and PDF modeling, as well as specific numerical techniques, such as the discrete element, the immersed boundary, and the lattice Boltzmann techniques. Chapters 3 and 4 cover the fundamentals of multiphase flow in ducts and apply to engineering systems for the transport of gas–liquid mixtures, pneumatic transport, and slurry transport. Chapter 5 addresses a more recently researched area, the area of compressible multiphase flow, and includes the interactions of particles, bubbles, and drops in compressible fluids. Chapter 6 addresses the subject of chemical reactions and combustion with drops and particles. The subject of Chapter 7 is multiphase flow and heat transfer under microgravity and zero-gravity conditions. Chapters 8 and 9 address the boiling and condensation processes in multiphase systems and include the local and global heat transfer processes in industrial boiling and condensation equipment. Chapter 10 addresses powder and granular flows, where the forces between the solid particles or between the solid particles and the boundaries are by far greater than the hydrodynamic forces between the particles and the interstitial fluid. The subject of multiphase flow in porous media, such as the flow of oil and gas in rock formations and cracks, is surveyed in Chapter 11. The complex interactions between the dispersed phase (bubbles, particles, and drops) and

the turbulence of the continuous fluid phase are the subject of Chapter 12. Chapter 13 addresses the dynamics of deformable bubbles and the process of bubble cavitation, which is of paramount importance in the shipping industry. Chapter 14 addresses the fundamentals of the collision process, which may result in the aggregation of particles and the formation or breakup of clusters. Chapter 15 addresses the separation processes and equipment, including the removal of dust and droplets from gaseous streams. Chapter 16 covers the flow of particles in biological systems, such as the blood stream and the respiratory tract. Chapter 17 is devoted to the industrial systems known as fluidized bed reactors that are increasingly used for chemical and combustion processes. Chapter 18 is devoted to the new application of multiphase fluids, which are known as nanofluids. Nanofluids exhibit very high heat and mass transfer characteristics. The formation and dynamics of spray systems is addressed in Chapter 19. The flow and processes of aerosols, with particular emphasis on aerosol deposition, are covered in Chapter 20. Finally, Chapter 21 addresses the fundamentals of flow and heat transfer characteristics of a dispersed phase in a non-Newtonian fluid.

1.2 Fundamental Definitions

This section introduces parameters that are fundamental to multiphase flows. For brevity and convenience, the terms *discrete phase* and *dispersed phase* will be used for the particles, drops, or bubbles, while the terms *carrier fluid* and *continuous phase* will be used for the fluid that carries the dispersed phase.

1.2.1 Volume Fraction and Densities

The continuum hypothesis enables one to define material properties at any point (x, y, z) despite the fact that matter is discontinuous at the molecular level. According to the continuum hypothesis, all properties, variables, and derivatives of the variables are defined within a limit volume, V_{lim}, that is big enough and contains a sufficient number of molecules so that all the variables and their derivatives have stationary values. An extension of the continuum hypothesis may be used with dispersed multiphase systems to define their properties (Michaelides, 2014). The extension defines the property of an inhomogeneous mixture at a point (x, y, z) by considering a volume, V, around the point (x, y, z). This volume must be greater than a limit volume, V_0, which is defined so that the calculated or measured values of the properties of the dispersed phase are stationary and independent of the motion of the dispersed phase elements (Michaelides, 2014).

Under this extension of the continuum hypothesis, the volume fraction of the dispersed phase is defined as

$$\alpha_d(x,y,z) = \frac{V_d}{V} \quad \text{with } V > V_0, \tag{1.1}$$

where V_d is the volume of the dispersed phase within the volume V. The volume V_0 is the limit volume that ensures a stationary average of the volume fraction despite the motion of the elements of the dispersed phase (particles, bubbles, or drops).

Similarly, the volume fraction of the continuous phase is

$$\alpha_c(x,y,z) = \frac{V_c}{V} \quad \text{with } V > V_0, \tag{1.2}$$

where V_c is the volume of the continuous phase in the volume under consideration.

In gas–liquid flows, the volume fraction is sometimes referred to as the "void fraction." From the volume conservation principle, the total volume is occupied either by the dispersed or by the continuous phase. This implies that, at any point of the continuum, the sum of the two volume fractions equals 1:

$$\alpha_c(x,y,z) + \alpha_d(x,y,z) \equiv 1. \tag{1.3}$$

The *density* or *apparent density* of the dispersed phase is equal to the mass of the dispersed phase per unit volume of the mixture. Similarly, the apparent density of the continuous phase is equal to the mass of the

continuous phase per unit volume of the mixture. If the dispersed material is composed of a single chemical substance with material density ρ_d and the material density of the continuous phase is ρ_c, the apparent densities of the two phases are

$$\bar{\rho}_d = \rho_d \alpha_d \quad \text{and} \quad \bar{\rho}_c = \rho_c \alpha_c. \tag{1.4}$$

Finally, the *mixture density*, which is defined as the total mass of the mixture divided by the total volume, is equal to the sum of the two apparent densities:

$$\rho_m = \bar{\rho}_c + \bar{\rho}_d. \tag{1.5}$$

1.2.2 Phase Velocities and Superficial Velocities

The *phase velocity* of a phase—u_c and u_d for the continuous and dispersed phases, respectively—is the actual velocity of each phase of a multiphase flow mixture and may be defined and measured at any point of the mixture. The *superficial velocity* of a phase is oftentimes used for calculations in channel flows and is defined as the mass flow rate of the phase divided by the total channel area and the material density of the phase:

$$U_d = \frac{\dot{m}_d}{A\rho_d} \quad \text{and} \quad U_c = \frac{\dot{m}_c}{A\rho_c} \tag{1.6}$$

It is apparent that the superficial velocity is the velocity of the phase if that phase were flowing alone and occupied the entire channel area. The phase velocities and the superficial velocities are related through the following volume fractions:

$$u_d = \frac{U_d}{\alpha_d} \quad \text{and} \quad u_c = \frac{U_c}{\alpha_c} \tag{1.7}$$

1.2.3 Quality, Concentration, and Loading

The quality, which is primarily used in vapor–liquid flows, is the ratio of the mass of the gas to the mass of the mixture. If the gas is the dispersed phase, the quality is defined as follows:

$$x = \frac{m_d}{m_c + m_d} = \frac{\bar{\rho}_d}{\bar{\rho}_m}. \tag{1.8}$$

The *mass concentration* or simply *concentration* of the dispersed phase is used in fluid–solid mixtures. This is a local variable defined at every point and is equal to the ratio of the apparent densities:

$$C = \frac{\bar{\rho}_d}{\bar{\rho}_c}. \tag{1.9}$$

The volume fraction, α_d, is used by some authors as an alternative definition of the concentration. A third variable, the loading, is often used in fluid–solid flows. The loading is the ratio of the two mass flow rates and is defined as follows:

$$Z = \frac{\dot{m}_d}{\dot{m}_c}. \tag{1.10}$$

1.2.4 Response Times

The response times of particles, bubbles, and drops are pertinent to their interactions with fluids and the interfacial transfer of momentum, energy, and mass. Oftentimes, the response times are called characteristic times. The momentum response time, τ_v, is of the order of magnitude of the time required for a sphere

to respond to a change in velocity. A measure of the momentum response time for a sphere may be derived from the equation of motion of a sphere in a fluid, which, in the absence of the transient terms, may be written as

$$\frac{\pi d^3}{6}\rho_d \frac{dv}{dt} = \frac{1}{2} C_D \frac{\pi d^2}{4}\rho_c (u-v)|u-v|, \tag{1.11}$$

where v is the particle velocity in the direction of the carrier fluid velocity u. The drag coefficient C_D is a function of the Reynolds number of the sphere, which is defined in terms of the relative velocity

$$Re_r = \frac{\rho_c d|u-v|}{\mu_c}, \tag{1.12}$$

where μ_c is the viscosity of the continuous phase. Rearranging the terms of Equation 1.11, one obtains

$$\frac{dv}{dt} = \left(\frac{C_D Re_s}{24}\right)\left(\frac{18\mu_c}{\rho_d d^2}\right)(u-v). \tag{1.13}$$

At the limit of vanishingly small Re_r, the so-called Stokes flow, the factor in the first parenthesis, $C_D Re_s/24$, is equal to 1. The factor in the second parenthesis has the dimension of (time)$^{-1}$. The inverse of this variable defines the momentum response time

$$\tau_V = \frac{d^2\rho_d}{18\mu_c}. \tag{1.14}$$

With this definition of the response time, the equation of motion is simplified to

$$\frac{dv}{dt} = \frac{1}{\tau_V}(u-v). \tag{1.15}$$

When the (uniform) fluid velocity undergoes a step from 0 to U, the solution to the last equation is

$$v = U\left[1-\exp\left(-\frac{t}{\tau_V}\right)\right]. \tag{1.16}$$

Therefore, the momentum response time is the time required for a particle released from rest to reach 63% or $(1 - 1/e)$ of the free-stream velocity under Stokes flow conditions.

The thermal response time, τ_T, is defined in a similar way, using a simplified form of the energy equation of a solid sphere at the limit of vanishingly small Peclet numbers:

$$\frac{dT_d}{dt} = \frac{Nu}{2}\left(\frac{12k_c}{\rho_d c_d d^2}\right)(T_c - T_d). \tag{1.17}$$

Since at vanishingly small Peclet numbers $Nu = 2$, the last equation defines the thermal response time

$$\tau_T = \frac{\rho_d c_d d^2}{12k_c}, \tag{1.18}$$

where c_d is the specific heat (at constant pressure) of the dispersed phase. When the fluid temperature undergoes a temperature step, τ_T is the time required for a particle's temperature to reach 63% or $(1 - 1/e)$ of this temperature step.

A third response time may be defined for the mass transfer process from a sphere. Since the mass transfer process is analogous to the heat transfer, the characteristic time for the mass transfer is

$$\tau_M = \frac{d^2}{12D_c}, \tag{1.19}$$

where D_c is the diffusion coefficient of the dispersed phase species inside the continuous phase. The three response times are related as follows:

$$\frac{\tau_V}{\tau_T} = \frac{2}{3}\frac{c_c}{c_d}\frac{1}{Pr}, \quad \frac{\tau_V}{\tau_M} = \frac{12D_c\rho_d}{18\mu_c} = \frac{2\rho_d}{3\rho_c}Sc, \quad \frac{\tau_T}{\tau_M} = \frac{Pr}{Sc}\frac{\rho_d}{\rho_c}\frac{c_d}{c_c}. \tag{1.20}$$

The Prandtl and Schmidt numbers pertain to the properties of the continuous phase. The order of magnitude considerations of the two dimensionless numbers proves that the mass transfer process is by far the slowest of the three transfer processes (Michaelides, 2014).

1.2.5 Dimensionless Numbers

The carrier fluid also has characteristic times and length scales that depend on the process under consideration and the domain geometry. The ratios of the particle to fluid characteristic times and length scales define several dimensionless numbers. These numbers are classified here according to the pertinent effects (Michaelides, 2013a,b, 2014):

1. *Viscosity effects*: Three Reynolds numbers for the particles are defined with respect to the rectilinear velocity, the rotational velocity, and the local fluid shear. In addition, a separate Reynolds number is defined for the carrier fluid. The first three dimensionless groups are based on the particle diameter. The last is defined with respect to the characteristic length scale of the fluid, L, and pertains to the entire suspension. The four Reynolds numbers are defined as follows:

$$Re_r = \frac{d\rho_c|\vec{u}-\vec{v}|}{\mu_c}, \quad Re_\gamma = \frac{d^2\rho_c\gamma}{\mu_c}, \quad Re_{rot} = \frac{d^2\rho_c|\vec{\Omega}|}{\mu_c}, \quad Re_c = \frac{L\rho_c|\vec{u}|}{\mu_c}. \tag{1.21}$$

2. *Heat and mass transfer effects:* Four Peclet numbers that correspond to the four Reynolds numbers ($Pe = Re * Pr$), the Nusselt number, the Biot number, and the Sherwood number of the particles and the suspension are defined as follows:

$$\begin{aligned} &Pe_r = \frac{d\rho_c c_c|\vec{u}-\vec{v}|}{k_c}, \quad Pe_\gamma = \frac{d^2\gamma\rho_c c_c}{k_c}, \quad Pe_M = \frac{d|\vec{u}-\vec{v}|}{D_c}, \\ &Pe_c = \frac{L\rho_c c_c|\vec{u}|}{k_c}, \quad Nu = \frac{2\alpha h_c}{k_c}, \quad Bi = \frac{dh_c}{k_c}, \quad Sh = \frac{dh_M}{D_c}. \end{aligned} \tag{1.22}$$

3. *Surface tension effects*: These are characterized by the Bond number, the capillary number, the Eötvos number, the Morton number, and the Weber number:

$$\begin{aligned} &Bo = \frac{gd^2|\rho_d-\rho_c|}{\sigma}, \quad Ca = \frac{\mu_c|\vec{u}-\vec{v}|}{\sigma} = \frac{We}{Re_r}, \quad Eo = \frac{d^2g\rho_c}{\sigma}, \\ &Mo = \frac{g\mu_c^4}{\rho_c\sigma^3}, \quad We = \frac{d\rho_c|\vec{u}-\vec{v}|^2}{\sigma} = Re_rCa. \end{aligned} \tag{1.23}$$

4. *Dimensionless property numbers*: The Prandtl number, the Lewis number, and the Schmidt number, which are pertinent to the transport properties of the fluid, are defined as follows:

$$Pr = \frac{c_c \mu_c}{k_c}, \quad Le = \frac{k_c}{\rho_c D_c c_c}, \quad Sc = \frac{\mu_c}{\rho_c D_c}. \tag{1.24}$$

5. *Other effects*: Molecular or rarefaction effects are quantified by the Knudsen number, phase-change effects by the Stefan number, and oscillatory and transient effects by the Strouhal number:

$$Kn = \frac{L_{mol}}{d}, \quad Ste = \frac{c_c \Delta T}{h_{fg}}, \quad Sl = \frac{df}{|\vec{u} - \vec{v}|}. \tag{1.25}$$

Of particular significance in the literature of dispersed multiphase flow is the Stokes number, *St*. The Stokes number characterizes the inertia of the particle and is defined as the ratio of the momentum timescale of the sphere to the characteristic timescale of the carrier fluid:

$$St = \frac{\tau_V}{\tau_c}. \tag{1.26}$$

The characteristic time of the fluid, τ_c, related to a spherical particle is defined as the diameter of the particle divided by the pertinent fluid velocity or by the rms of the velocity fluctuations in the case of turbulence. When $St \ll 1$, the particle has ample time to respond to changes in the flow velocity and follows closely the fluid velocity changes. When $St \gg 1$, the particle has no time to respond to the fluid velocity and does not follow the carrier fluid changes or fluctuations. The Stokes number is frequently used in turbulent flows to determine the response of particles, drops, and bubbles to the turbulent velocity fluctuations.

1.3 Size of Particles, Drops, and Bubbles

While drops and bubbles are largely spherical or ellipsoidal, most particles have irregular shapes that may not be described by one or two easily measurable dimensions. Despite this, it is often advantageous to include in calculations the characteristic length or *size* of the elements of the dispersed phase. The *size* of a spherical particle is equal to its diameter. The *size* of a nonspherical particle is subject to interpretation and must be well defined. Following the practice of spherical particles—for which most of the analytical and experimental work has been performed in the past—fan *equivalent diameter* may be defined for nonspherical particles, drops, and bubbles. The practical usefulness of the equivalent diameter is that one may correlate the transport coefficients of irregularly shaped particles, for example, drag coefficients and heat/mass transfer coefficients, with the known transport coefficients for spheres. Several equivalent diameters have been proposed in the past for nonspherical particles including the diameter of a sphere that would have the same volume, *V*; the diameter of a sphere that would have the same area, *A*; and the diameter of a sphere that would have the same perimeter, *P*, projected in the direction of the motion of the nonspherical particle. These three equivalent diameters are defined as follows:

$$d_V = \sqrt[3]{\frac{6V}{\pi}}, \quad d_A = \sqrt{\frac{4A}{\pi}}, \quad \text{and} \quad d_P = \frac{P}{\pi}. \tag{1.27}$$

For a sphere, the three equivalent diameters are the same and equal to the actual diameter, *d*. A fourth equivalent diameter, which is frequently used with irregular particles and aggregates, is the diameter of the minimum sphere, in which the irregular particle will fit in. Typically, this is the longest dimension of the particle, d_L. While d_P depends on the direction of the particle movement and its magnitude may vary in an arbitrary way, for all the other measures of the *size* of a particle, the inequality $d_V \leq d_A \leq d_L$ holds, with the equal sign applying to spheres only. Figure 1.1 shows schematically the last three diameters or *sizes* for a particle that appears as an elongated parallelepiped. It may be seen in this figure that the three equivalent

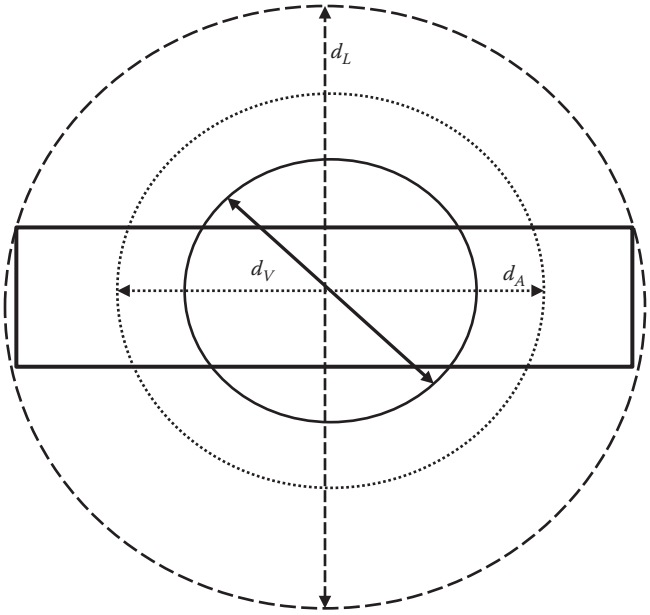

Figure 1.1

A schematic diagram of the three equivalent diameters, d_V, d_A, and d_L, for a particle with the shape of a parallelepiped.

diameters, which are also depicted, vary significantly in magnitude. Because of the significant variability, a precise definition or measurement of the *size* of particles, bubbles, and drops must include how this *size* has been defined or measured (Michaelides, 2014).

Another definition of an equivalent diameter that is extensively used with sediments and sedimentary suspensions of particles is the "sieve diameter." This is obtained from a sieve mesh analysis and is defined as the maximum standard sieve mesh size (or minimum sieve aperture) through which the particles may pass through (Leeder, 1982). Since the standard sieves do not extend to the micrometer and nanometer sizes, this method is not applicable to micro- and nanosize particles.

Regarding shapes, the *Corey shape factor* has been defined as the ratio of the shortest principal axis of the particle to the square root of the product of the longest two principal axes. The Corey factor, although widely used in the past with ellipsoidal particles, is not related to volume or area calculations, which are important in the calculations of the transport coefficients. In addition, it is difficult to apply this factor to irregular particles, where the principal axes are not well defined.

1.3.1 Fractal Dimensions of Particles and Aggregates

Fractal geometry is a recent tool that is often used to analyze the structure of irregular patterns of lines, surfaces, and volumes. The fractal shapes are composed of self-similar parts when viewed or measured by different length scales. For example, if we take photographs of a fractal object at different scales, as the scale changes, we will observe that the shapes in the photographs remain the same. When viewed and measured at the different length scales, the length and area of the fractal shape are different and, actually, increase when the scale of measurement decreases. The classical example of a fractal shape is the coastline of a country (Mandelbrot, 1967): one may measure the length of the coastline using a map, using aerial photographs, using a 1 m ruler on the ground, or using a smaller ruler, whose length is one grain of sand. The length of the coastline increases as the unit of measurement becomes smaller, and more details are revealed and counted. Figure 1.2 illustrates an example of this concept using the so-called Koch curve. The Koch curve is a complex, self-similar curve that evolves from a single straight segment according to the following rule: at each stage of evolution, every straight segment of the curve is substituted by four other straight segments of length 1/3 the length of the old segment. Two of the new segments span the ends of the old segment. The other two segments, which occupy one-third of the old segment's length, form the sides of an equilateral triangle and make up the inner part of the new segment. The process of evolution of the curve may produce an infinite number of stages, three of

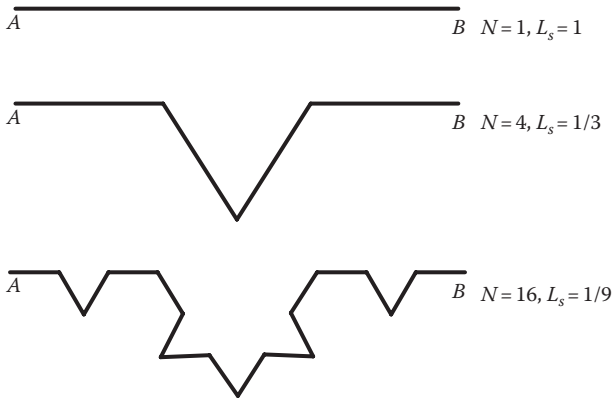

Figure 1.2

The length of a complex, fractal curve increases as the unit of measurement decreases.

which are shown in Figure 1.2. The end points of all the stages, A and B, are at the same distance apart in all the stages of the pattern evolution.

Without loss of generality, we may stipulate that the segment AB is of unit length. The measure of the length in the first stage of the curve is $N = 1$. In the second stage, the length scale is $L_s = 1/3$ and the number of segments $N = 4$. In the third stage, the length scale is $L_s = 1/9$ and the number of segments $N = 16$. In terms of the original units, the total length of the curve is 4/3 units in the second stage, 16/9 in the third stage, and so on. For self-similar objects, such as this curve, there is a fundamental dimension, the *fractal dimension*, L_f, which does not change with the scale of measurement. The fundamental dimension is related to the fundamental equation of self-similar patterns:

$$N = \left(L_s\right)^{-L_f}, \tag{1.28}$$

where N is the number of straight line segments of the scale length, L_s, that spans the entire length of the curve. From the definition of the fractal shapes, N is a strong function of the scale length. The value of L_f for a straight line is 1 and for a sphere 3. All other shapes have fractal dimensions between the two limits.

It must be noted that fractal dimensions describe a shape or a surface in very general terms. They do not define shapes and patterns and they do not contain enough information to construct them. In the case of the Koch curve, which has $L_s = 1.2619$, there are several other complex patterns that have the same fractal dimension but are dramatically different in shape and complexity.

Single particles have irregular but not self-similar shapes. The fractal dimension, L_f, of single particles is meaningless in most cases. Aggregates of primary particles, and especially very large aggregates of spheres, have been observed to have complex shapes, surfaces, and perimeters, which are oftentimes approximated as self-similar surfaces and lengths. In these cases, a fractal dimension of the aggregates, L_f, may be defined using the limit of Equation 1.28 as the length scale, L_s, vanishes (Vicsek, 1999):

$$L_f = -\lim \frac{\ln\left(N\right)}{\ln\left(L_s\right)} \quad \text{as } L_s \to 0. \tag{1.29}$$

For particle aggregates, L_f is typically calculated by taking microscopic images of the aggregates at different scales and using Equation 1.29 with the measuring length scale, L_s, taking several different values. Oftentimes, optical image software performs this task (Lee and Kramer, 2004, Wang and Chau, 2009). A simpler, albeit not as accurate method, is to measure the fractal dimension from light scattering (Bushell et al., 2002).

It must be noted that in the determination process of the fractal dimension of aggregates, the scale L_s cannot attain values that are smaller than the dimension of the largest primary particle of the aggregate. Therefore, the determination of the fractal dimension of particle aggregates is only an approximation to Equation 1.29. Also that for any measurement of L_f to be meaningful, the variation of the measurement length scale, L_s, must span at least two orders of magnitude. This implies that the method may only be used with big aggregates that contain a very large number of primary particles (at least 500).

The fractal dimension of the aggregates is often used to give an estimate of the porosity, ε_p, of the aggregate (Li and Logan, 2001):

$$\varepsilon_p = 1 - \left(\frac{d_a}{d}\right)^{3-L_f}, \tag{1.30}$$

where

d is the diameter of the primary particles

d_a is the *diameter* of the aggregate

The latter is typically assumed to be equal to the longest dimension of the aggregate, that is, $d_a = d_L$.

Several authors have used the fractal dimension to describe the structure and morphology of particles or aggregates of particles. Two conditions must be explicitly satisfied when one uses the fractal dimension in a quantitative manner:

1. The original object must have a self-similar shape to make the fractal dimension, L_f, meaningful.
2. The 2D microscopic images or the light scattering method must be adequate for the determination of the fractal dimension, L_f, of particles that are inherently three dimensional.

Because the second condition is not always satisfied, it has been observed that measurements of L_f by 2D photographic images may be laden with high measurement errors. The measurement error becomes significantly high if the *measured* fractal dimension is close to or greater than 2 (Vicsek, 1999).

1.3.2 Size Distributions

The sizes of particles, drops, and bubbles are important parameters that govern the flow of a dispersed multiphase mixture. In most cases, there is not a single size of these elements of dispersed flows but several sizes, which constitute the size distribution. Because of this, it is important to have a basic knowledge of the statistical parameters of the size distributions. A general characterization of particle size distribution is *monodisperse* and *polydisperse*. In a monodisperse mixture, the particles' sizes are close to a single size and typically, the standard deviation of the sizes is less than 10% of the mean size. In a polydisperse mixture, there is a wide range of particle sizes. Particle, drop, and bubble size distributions can also be classified as discrete or continuous. The continuous size distribution derives from the discrete distribution as the sampling interval approaches zero.

1.3.2.1 Discrete Size Distribution

For the size measurements of particles, one chooses a measuring technique, such as photography or sieve measurements, and also chooses size intervals, Δd, which are not necessarily of equal magnitude. The size intervals are large enough to contain a significant fraction of particles, yet small enough to yield sufficient detail. The representative size of the particles in each interval may be defined as the diameter corresponding to the midpoint of the interval. For the size measurements, the number of particles in each interval is counted, recorded, and divided by the total number of particles in the sample. The results are plotted in the form of a histogram (bar chart) as shown in Figure 1.3. Such histograms are identified as the *discrete number frequency distribution* for the particle size. For large samples of particles, the distribution is also referred to as the "probability density function" or "pdf." The ordinate of the histogram is the number frequency of the particles, $\tilde{f}_n$, within a size interval. The sum of the number frequency over all the size categories is equal to 1.

The number-average particle diameter of this distribution is defined as

$$\bar{d}_n = \sum_{i=1}^{N} d_i \tilde{f}_n(d_i), \tag{1.31}$$

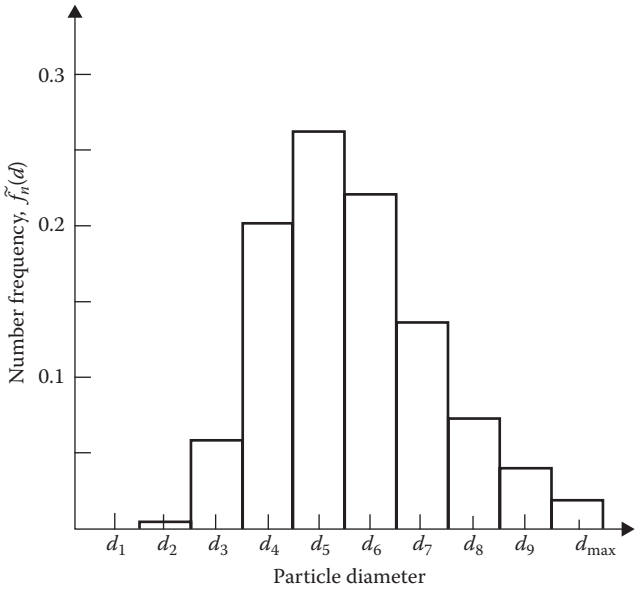

Figure 1.3

Histogram of the number frequency distribution of a sample of particles. The sum of the nine values of the frequency distribution is equal to 1.

where N is the total number of intervals. The number variance is

$$\sigma_n^2 = \frac{N}{N-1}\sum_{i=1}^{N}\left(d_i - \bar{d}_n\right)^2 \tilde{f}_n(d_i) = \frac{N}{N-1}\sum_{i=1}^{N} d_i^2 \tilde{f}_n(d_i) - \bar{d}_n^2 . \tag{1.32}$$

The standard deviation, σ_n, is the square root of the variance of the sizes. Oftentimes, the ratio of the standard deviation to the average diameter is used as a measure of the spread of the distribution. A narrow distribution is characterized by the relationship $\sigma_n / d_n < 0.1$, and the mixture is characterized as monodisperse.

Two other approaches are used to describe the size distribution using the particle mass and volume *in lieu* of the particle number as the dependent variable. Thus, for the mass distribution, the mass of each particle is measured or inferred from measurements, and the fraction of mass associated with each size interval is used to construct the distribution. This is known as the discrete mass frequency distribution, $\tilde{f}_m$. Using this distribution, one may calculate the mass-averaged particle diameter and mass-averaged variance as follows:

$$\bar{d}_m = \sum_{i=1}^{N} d_i \tilde{f}_m(d_i), \tag{1.33}$$

and

$$\sigma_m^2 = \frac{N}{N-1}\sum_{i=1}^{N}\left(d_i - \bar{d}_m\right)^2 \tilde{f}_m(d_i) = \frac{N}{N-1}\sum_{i=1}^{N} d_i^2 \tilde{f}_m(d_i) - \bar{d}_m^2 \tag{1.34}$$

The volume-averaged particle diameter and volume-averaged variance are calculated in a similar manner. If the material density of the particles is constant, the volume- and mass-averaged distributions are identical. It must be noted that in order to achieve a reasonably smooth frequency distribution function, a very large number of particles must be counted. Several modern optical experimental techniques make this task feasible with relatively low effort.

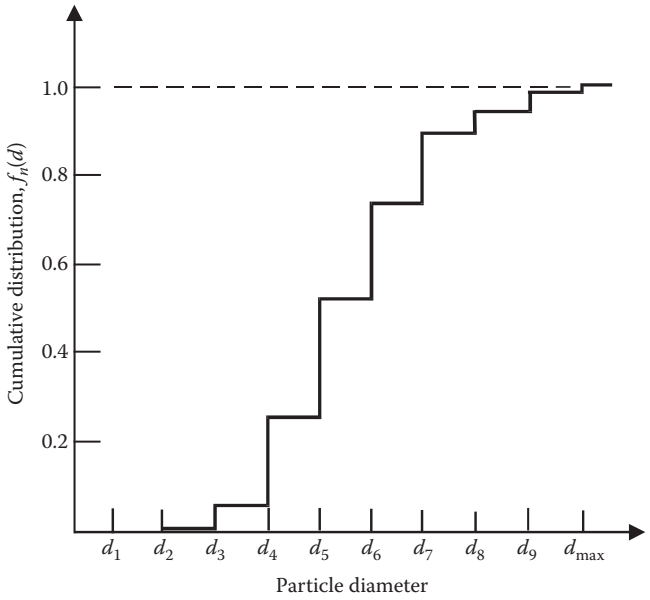

Figure 1.4

The cumulative number distribution that corresponds to the number frequency distribution of Figure 1.3.

Another commonly used method to quantify particle size is using the *cumulative* distribution, which is the sum of the components of the frequency distribution. The cumulative number distribution associated with size d_k is

$$\tilde{F}_n(d_k) = \sum_{i=1}^{k} \tilde{f}_n(d_i). \tag{1.35}$$

The numerical value of $\tilde{F}_n$ is the fraction of particles with sizes less than d_k. It is apparent that the cumulative number distribution is equal to 0 at the very fine sizes and close to 1 at the higher end of the sizes of the particles. The cumulative number distribution that corresponds to the number frequency distribution of Figure 1.3 is shown in Figure 1.4. Both cumulative number and cumulative mass distributions may be determined from the data of the corresponding frequency distribution.

1.3.2.2 Continuous Size Distributions

If the size intervals in a discrete distribution are made progressively smaller, in the limit as Δd approaches very small values, one obtains the continuous number frequency function

$$f_n(d) = \lim_{\Delta d \to 0} \left(\frac{\tilde{f}_n(d)}{\Delta d} \right). \tag{1.36}$$

The number fraction of particles with diameters between d and $d + d(d)$ is given by the differential $f_n(d)\, d(d)$. The function of the continuous frequency distribution is a continuous function of the diameter as shown in Figure 1.5. In a similar manner, one obtains the mass frequency function based on the mass distribution $\tilde{f}_m$. If the continuous distribution is normalized, as in Figure 1.5, then the area under the continuous frequency distribution curve is equal to 1.

The continuous cumulative distribution is obtained from the integral of the continuous frequency distribution as follows:

$$F_n(d) = \int_0^d f_n(\xi) d\xi. \tag{1.37}$$

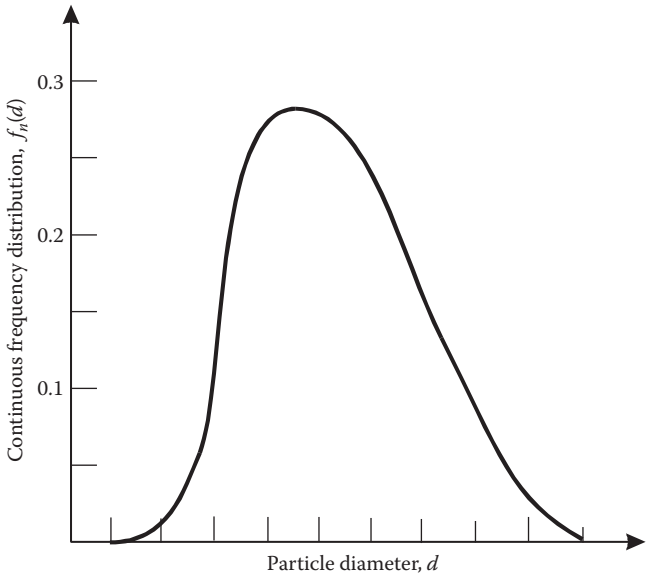

Figure 1.5

Continuous number frequency distribution of a sample of particles.

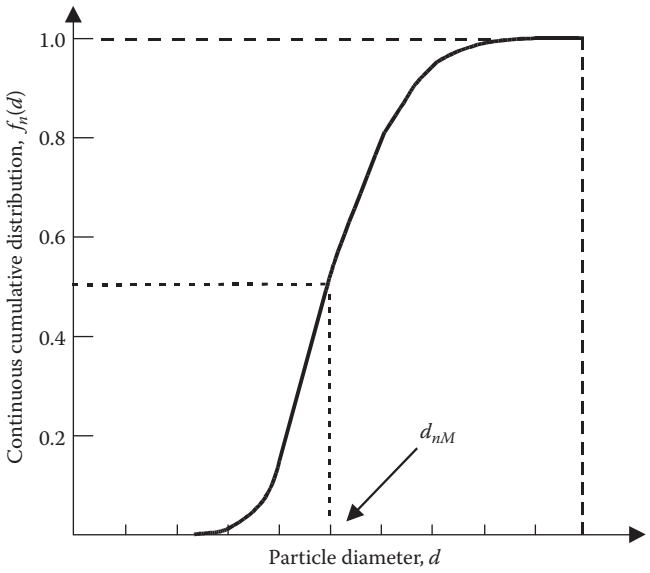

Figure 1.6

The cumulative distribution function that corresponds to the continuous distribution function of Figure 1.5.

The cumulative distribution function associated with the continuous distribution function of Figure 1.5 is an S-shaped curve, which is shown in Figure 1.6. The cumulative distribution of a uniform (constant) continuous distribution is a straight line. All cumulative distribution functions approach the value 1, as the particle size approaches the maximum size.

It must be noted that measurements of size data for particles generate discrete distributions. Continuous distributions may be obtained for convenience by fitting empirical functions to the discrete size data.

1.3.3 Statistical Parameters of the Size Distributions

Several parameters are used with discrete and continuous size distributions. We present here the most commonly used parameters in dispersed multiphase flow. Typically, these parameters have different values for the number, mass, and volume distributions.

1.3.3.1 Mode

The mode is the size that corresponds to the maximum of a continuous frequency function. A distribution that has two local maxima is referred to as a bimodal distribution and it has two modes. Similarly, trimodal and multimodal distributions may be defined, but they are seldom met in dispersed multiphase flows. The corresponding mode for a discrete size distribution is the size that corresponds to the highest value in the frequency histogram. For example, d_5 is the mode of the discrete distribution depicted in Figure 1.3.

1.3.3.2 Mean

For a discrete distribution, the mean is equal to the average and is given by Equations 1.31 and 1.33. The mean of a continuous distribution is obtained from the integral of the size, d, multiplied by the pertinent frequency distribution. For the continuous number distribution function, the corresponding mean is

$$\mu_n = \int_0^{d_{\max}} d\tilde{f}_n d(d). \tag{1.38}$$

A similar expression applies to the continuous mass distribution mean, μ_m. Sometimes, this mean is called the arithmetic mean diameter d_{AM}. Other mean diameters that are used in dispersed multiphase flows are the surface mean diameter

$$d_{SM} = \left[\int_0^{d_{\max}} d^2 \tilde{f}_n d(d) \right]^{1/2} \tag{1.39}$$

and the volume mean diameter

$$d_{VM} = \left[\int_0^{d_{\max}} d^3 \tilde{f}_n d(d) \right]^{1/3}. \tag{1.40}$$

1.3.3.3 Sauter Mean Diameter

The Sauter mean diameter (SMD) is encountered frequently in the spray and atomization literature and is defined as follows:

$$d_{32} = \frac{\int_0^{d_{\max}} d^3 f_n(d) d(d)}{\int_0^{d_{\max}} d^2 f_n(d) d(d)}. \tag{1.41}$$

The SMD is a measure of the volume-to-surface area ratio for particles, bubbles, and drops.

1.3.3.4 Variance

The variance of the continuous distribution with mean μ is calculated from the expression

$$\sigma^2 = \int_0^{d_{\max}} (d-\mu)^2 f(d) d(d) = \int_0^{d_{\max}} d^2 f(d) d(d) - \mu^2. \tag{1.42}$$

As with the mean, a variance may be defined to the number, the mass, or the volume distributions of particle sizes. As with the discrete distributions, the variance is a measure of the spread of the distribution and the square root of the variance is the standard deviation. A continuous distribution may be classified as monodisperse if $\sigma/\mu < 0.1$.

1.3.3.5 Median

The median diameter, d_M, corresponds to the diameter for which the cumulative distribution has the value 0.5. The number median diameter, d_{nM}, is shown in the cumulative distribution of Figure 1.6. A corresponding value for the mass median diameter, d_{mM}, may be determined from the cumulative mass distribution function.

1.3.4 Size Distributions

While there is a multitude of distributions in the literature of statistics, this section presents the statistical distributions that are most often used in the literature of dispersed multiphase flow.

1.3.4.1 Log-Normal Distribution

The number frequency function of the log-normal distribution is (Marshall, 1954)

$$f_n(d) = \frac{1}{\sqrt{2\pi} d\sigma_G} \exp\left[-\frac{1}{2}\left(\frac{\ln(d) - \ln(d_{nM})}{\sigma_G} \right)^2 \right], \tag{1.43}$$

where

d_{nM} is the median diameter of the number distribution
σ_G is the geometric standard deviation

The corresponding expression for the mass frequency distribution is

$$f_m(d) = \frac{1}{\sqrt{2\pi} d\sigma_G} \exp\left[-\frac{1}{2}\left(\frac{\ln(d) - \ln(d_{mM})}{\sigma_G} \right)^2 \right], \tag{1.44}$$

where d_{mM} is the mass median diameter. The geometric standard deviation is determined by plotting the cumulative distribution on logarithmic coordinates. The plot is a straight line with a positive slope, and the value for σ_G may be determined from the relationship

$$\sigma_G = \ln \frac{d_{84}}{d_M}, \tag{1.45}$$

where

d_{84} is the diameter corresponding to the 84th percentile on the logarithmic plot
d_M is the median diameter, which is the diameter corresponding to the 50th percentile

The same value for σ_G is used for the mass and number distributions. For the calculation of the several statistical parameters in this distribution, a useful mathematical relationship is

$$d_M^k \exp\left(\frac{k^2 \sigma_G^2}{2} \right) = \frac{1}{\sqrt{2\pi}\sigma_G} \int_0^\infty \left[d^k \exp\left[-\frac{1}{2}\left(\frac{\ln(d) - \ln(d_{mM})}{\sigma_G} \right)^2 \right] \right] \frac{d(d)}{d}, \tag{1.46}$$

or

$$d_M^k \exp\left(\frac{k^2 \sigma_G^2}{2} \right) = \int_0^\infty d^k f(d) d(d). \tag{1.47}$$

These relationships may be readily used to calculate the various statistical parameters of the distribution.

1.3.4.2 Upper-Limit Log-Normal Distribution

A derivative of the log-normal distribution is the upper-limit log-normal distribution (Mugele and Evans, 1951), which is frequently used to model droplet data from spray nozzles. The distribution makes use of a maximum particle size as the upper limit of the distribution and its number frequency function is defined as

$$f_n(d) = \frac{1}{\sqrt{2\pi} d \sigma_G} \exp\left[-\frac{1}{2} \left(\frac{\ln(\alpha d) - \ln\left(d_{\max} - d_{nM}\right)}{\sigma_G} \right)^2 \right], \tag{1.48}$$

where

$d_{\max}$ is the maximum diameter in the distribution
a is a constant equal to

$$\alpha = \frac{d_{\max}}{d_M} - 1. \tag{1.49}$$

As with the log-normal distribution, the standard deviation may be calculated from the slope of the logarithmic plot of the data.

1.3.4.3 Square-Root Normal Distribution

The number frequency function for the square-root normal distribution is given by the expression (Tate and Marshall, 1953)

$$f_n(d) = \frac{1}{2\sqrt{2\pi\sigma} d} \exp\left[-\left(\frac{\left(\sqrt{d} - \sqrt{\bar{d}}\right)}{2\sigma} \right)^2 \right], \tag{1.50}$$

where σ is the variance of the square-root normal distribution. This distribution appears to fit well empirical data from vane-type atomizers and does not have the end "tails" of a normal distribution. When using this distribution, one must be cognizant that several relationships that were derived for the other types of normal distributions are not applicable to the square-root normal distribution.

1.3.4.4 Rosin–Rammler Distribution

The Rosin–Rammler distribution (Mugele and Evans, 1951) is frequently used to model droplet size distributions in sprays. It is expressed in terms of the cumulative mass distribution

$$F_m(d) = 1 - \exp\left[-\left(\frac{d}{\delta} \right)^n \right]. \tag{1.51}$$

where δ and n are two empirical constants, which are determined by plotting the cumulative distribution on logarithmic coordinates. By taking twice the logarithm of Equation 1.51, one obtains

$$\ln\left[-\ln\left(1 - F_m(d)\right) \right] = n\left(\ln(d) - \ln(\delta)\right). \tag{1.52}$$

Therefore, n is the slope of this line and δ can be obtained from the expression

$$\delta = \frac{d_{mM}}{0.693^{1/n}}. \tag{1.53}$$

The mass frequency function of this distribution may be obtained by taking the derivative of the cumulative distribution of Equation 1.51:

$$f_m(d) = \frac{dF_m(d)}{d(d)} = \frac{n}{\delta}\left(\frac{d}{\delta}\right)^{n-1} \exp\left(\left[-\left(\frac{d}{\delta}\right)^n\right]\right). \tag{1.54}$$

When using the Rosin–Rammler distribution, the gamma function,

$$\Gamma(x) = \int_0^\infty \lambda^{x-1} \exp(-\lambda) d\lambda, \tag{1.55}$$

is a useful tool to calculate the moments of the distribution because

$$\int_0^\infty n d^\alpha \left(\frac{d}{\delta}\right)^{n-1} \exp\left[-\left(\frac{d}{\delta}\right)^n\right] d\left(\frac{d}{\delta}\right) = \delta^\alpha \Gamma\left(\frac{\alpha}{n}+1\right), \tag{1.56}$$

which leads to the relationship for the statistical parameters of this distribution

$$\int_0^\infty d^\alpha f_m(d) d(d) = \delta^\alpha \Gamma\left(\frac{\alpha}{n}+1\right). \tag{1.57}$$

1.3.4.5 Nukiyama–Tanasawa Distribution

The Nukiyama–Tanasawa distribution is a more general distribution from which the Rosin–Rammler distribution is a special case. The frequency function of this distribution is

$$f_n(d) = Bd^2 \exp\left(-Cd^q\right), \tag{1.58}$$

where B, C, and q are empirical parameters. For spray distributions, q typically varies from 1/6 to 2 with the higher values corresponding to narrower distributions.

1.3.4.6 Log-Hyperbolic Distribution

Some empirical studies on sprays showed that neither the log-normal nor the Rosin–Rammler distribution fits the data sufficiently well. Two droplet size distributions fitted with a Rosin–Rammler distribution may have the same parameters, but the actual distribution may be quite different. This happens because one of the shortcomings of both the log-normal and Rosin–Rammler distributions is the representation of the tails of the distribution—the values of the frequency function for very large and very small values of the sizes. A better fit for the tails of the distributions is the log-hyperbolic distribution proposed by Barndorff-Nielsen (1977). The form of the number frequency function for this distribution is

$$f_n(d) = A \exp\left[-\alpha\sqrt{\delta^2 - \left(\ln(d)-\mu\right)^2} + \beta\left(d-\mu\right)\right], \tag{1.59}$$

where α, β, δ, and μ are empirical parameters. It is apparent that the random variable of this distribution is the logarithm of the particle diameter. The coefficient A is a normalization factor related to the other parameters by the expression

$$A = \frac{\sqrt{\left(\alpha^2-\beta^2\right)}}{2\alpha\delta K_1\left(\delta\sqrt{\left(\alpha^2-\beta^2\right)}\right)}, \tag{1.60}$$

where K_1 is the third-order Bessel function of the third kind. The logarithm of the frequency function yields the equation of a hyperbola:

$$\ln(f_n) = \ln(A) - \alpha\sqrt{\delta^2 - (\ln(d) - \mu)^2} + \beta(d - \mu). \tag{1.61}$$

For $[\ln(d) - \mu]/\delta < 0$, the slope of the asymptote is $\alpha + \beta$, while for $[\ln(d) - \mu]/\delta > 0$, the slope of the asymptote is $-\alpha + \beta$. Thus, when the logarithm of the frequency data is plotted versus $\ln(d)$, the slopes of the two asymptotes may be measured to determine the parameters α and β. It may be proven that the parameter μ is the mode of the distribution. The value of this parameter may be determined from data fitting. A practical problem of the log-hyperbolic distribution for particle or drop size distributions is that if the tails are not long enough to generate accurate values of the slopes, there is a great deal of inaccuracy in the determination of the parameters α and β. A three-parameter log-hyperbolic distribution may be used in such cases to alleviate this problem.

1.4 Interactions of Fluids with Particles, Drops, and Bubbles

1.4.1 Introduction

Because the sphere is the simplest, 3D shape, mass, momentum, and heat transport problems pertaining to spheres have been the subjects of the first analytical methods as well as of the intellectual curiosity of scientists. These problems belong to the class of the most fundamental problems in fluid dynamics, heat transfer, and mass transfer and have attracted the attention of many mathematicians, physicists, and engineers. They are also subjects that have numerous practical applications including combustion and propulsion, chemical reactions and catalysis, mixing and separation, boiling and condensation, environmental sedimentation and resuspension, and biological flows. The transport of momentum, heat, and mass is of primary interest in all of these processes, which are often expressed in terms of *transport coefficients* or in terms of dimensionless parameters that are pertinent to these coefficients. For example, the instantaneous loss or gain of mass of a sphere during any process may be expressed in terms of the mass transfer coefficient, h_M, or its dimensionless representation, the Sherwood number, Sh, and the material properties of the sphere and the carrier fluid:

$$\dot{m}_s = \frac{dm_s}{dt} = -\pi h_M d^2 \rho_c (Y_s - Y_\infty) = -\pi (Sh) d D_c \rho_f (Y_s - Y_\infty), \tag{1.62}$$

where D_c is the diffusivity of the material of the sphere inside the carrier fluid. Similarly, the instantaneous temperature change of the sphere, in the case of convective heating (when radiation is negligible), may be expressed in terms of the heat transfer coefficient, h, or its dimensionless representation, the Nusselt number:

$$m_s c_{ps} \frac{dT_s}{dt} = \dot{Q} = -\pi h d^2 (T_s - T_\infty) = -\pi d Nu k_c d (T_s - T_\infty). \tag{1.63}$$

Finally, the equation of motion of a sphere may be expressed by Newton's second law in terms of all the instantaneous forces that act on the sphere. These forces are the hydrodynamic force on the sphere, F_H (which is composed of two parts, the drag and lift, F_D, and, F_L), and the body or volume force, F_B. The latter is normally the gravity/buoyancy force, and the former may be written in terms of two dimensionless factors: the drag coefficient, C_D, and the lift coefficient, C_L:

$$\begin{aligned} m_s \frac{dv_i}{dt} = F_{Di} + F_{Li} + F_{Bi} + F_{AMi} + F_{Hi} &= \frac{1}{8}\pi d^2 \rho_c C_D (u_i - v_i)\left|u_m - v_m\right| \\ &+ \frac{1}{8}\pi d^2 \rho_c C_L \left|u_m - v_m\right| \frac{e_{ijk}(u_k - v_k)\Omega_j}{\sqrt{\Omega_l \Omega_l}} + \frac{1}{6}\pi(\rho_s - \rho_c) d^3 g_i + F_{AM} + F_H, \end{aligned} \tag{1.64}$$

where e_{ijk} is the permutation symbol. The added mass force, F_{AM}, and the history term, F_H, emanate from the transient response of the particle and the surrounding fluid. Functional forms for the two terms are given in

Section 1.4.3.6. For the performance of any calculations on the motion of the sphere, one would need accurate information for the *transport coefficients*: drag coefficient, lift coefficient, heat transfer coefficient, and mass transfer coefficient. The numerical values of these coefficients emanate from analytical or numerical results and from experimental data.

This section intends to be a succinct presentation of analytical, experimental, and numerical results that pertain to the transport processes involving a carrier fluid and bubbles, drops, or particles and are useful for the performance of engineering calculations. In particular, mass transfer, momentum transfer, and heat transfer from a particle, bubble, or drop with the carrier fluid will be examined. For a historical background and a more extensive description of the development of these subjects, one may consult the review article by Michaelides (2003). Of the other recent studies, the main results on the momentum transfer from a sphere to a fluid as well as the energy and mass transfer at wide ranges of Reynolds and Peclet numbers may be found in several treatises and monographs, such as those by Leal (1992), Kim and Karila (1991), Crowe et al. (1998), Sirignano (1999), Michaelides (2006), and Michaelides (2014).

1.4.2 Mass Transfer

1.4.2.1 Thermodynamic Relations of Evaporation, Sublimation, and Condensation

In this section, we seek to determine the thermodynamic equilibrium relations between the carrier fluid and a sphere that undergoes phase change. For this reason, the thermodynamic properties are assumed to be equilibrium properties and this implies no (or very weak) heat and mass transfer within the system. Consider a sphere of radius a, inside a carrier gas of density ρ_f, in a spherical system of coordinates that follow the center of the sphere. The carrier gas and the sphere have different chemical composition, and their species will be denoted by c and l, respectively. Mass is allowed to cross the boundary of the sphere due to one of the processes of sublimation, evaporation, or condensation. Because of this, the gaseous phase is composed of both the species l and c, while the sphere, which may be either solid or liquid, is composed solely of the species l. Figure 1.7 is a schematic diagram of such a process. The directions and numerical signs of the pressure and temperature gradients in this figure are such that they correspond to the case of condensation. The total pressure in the gaseous mixture is constant and equal to p_T. The total pressure comprises two parts: the partial pressure, or vapor pressure, of the species l, p_l, and the partial pressure of the carrier gaseous species c, p_c. In all the transport processes that are pertinent to mass transfer, both the partial pressures are functions of the radial direction, r:

$$p_T = p_c(r) + p_l(r). \tag{1.65}$$

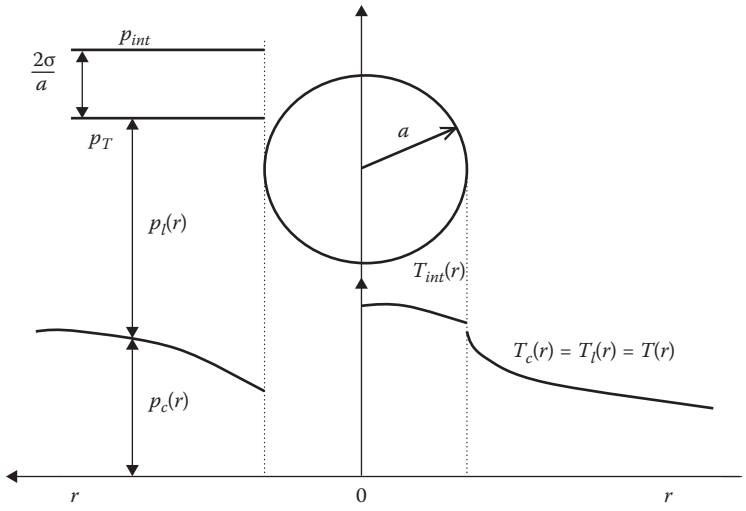

Figure 1.7

Pressure and temperature fields developed in the vicinity of a drop carried by the fluid of different compositions.

If the carrier phase is composed of a number of species, $c1$, $c2$, $c3$, … as, for example, in the case of air, then the total pressure is the sum of all the partial pressures of these species:

$$p_T = \sum_i p_{ci}(r) + p_l(r). \tag{1.66}$$

When the sphere is a liquid drop, the pressure in the interior of the drop would be higher than p_T by the amount contributed by the surface tension:

$$p_{int} = p_T + \frac{2\sigma}{a}. \tag{1.67}$$

In most practical applications, the radius of the sphere, a, is large enough to satisfy the condition $p_T \gg 2\sigma/a$. Hence, the internal pressure, p_{int}, is approximately equal to the total pressure in the gas phase, p_T. Thermodynamic equilibrium implies that the temperatures of the species l and c at the surface anywhere in the gaseous mixture are equal, that is, $T_c(r) = T_l(r) = T(r)$, where $r > a$. The temperature inside the sphere may be nonuniform and hence a function of the radial distance. This temperature will be denoted as $T_{int}(r)$, where $r < a$.

At the surface of the sphere, there is a phase transition, for example, liquid–vapor or solid–vapor, that normally occurs within a very short layer of molecular dimensions. The phase of the matter in this film layer is not well defined. Hence, the material and thermodynamic properties within this molecular layer are not well defined too. For this reason, they are depicted by the dashed lines in Figure 1.7. It is known that the specific properties of matter exhibit a jump discontinuity within this layer, for example, from liquid-specific enthalpy to vapor-specific enthalpy. The intensive properties of matter, temperature, and pressure exhibit a discontinuity of lower magnitude. The discontinuity of the intensive properties is not noticeable unless the Knudsen number of the flow is higher than 0.01 (see Section 1.4.3.5. for more details) where the molecular effects play an important role in the behavior of the sphere.

With the exception of very fast combustion processes, in most of the practical applications involving drops and particles that undergo mass, momentum, and heat transfer with a carrier fluid, the thermodynamic relaxation time is much shorter than all the response times of the sphere. For this reason, thermodynamic equilibrium is normally established fast at the interface and does not affect significantly the transport processes. When the interface may be considered sufficiently flat for the surface tension to have negligible impact, the partial pressure of the vapor and the temperature of the vapor at the interface are related via the Clausius–Clapeyron equation

$$\frac{dp_l}{dT}\Big|_a = \frac{h_{fg}}{T(a)\left[\dfrac{1}{\rho_v(a)} - \dfrac{1}{\rho_s(a)}\right]}, \tag{1.68}$$

where the symbols in parentheses denote arguments of functions and the derivative must be evaluated at the conditions of the interface $r = a$. Thus, $T(a)$ is the temperature at the interface, $\rho_v(a)$ is the density of the species l in its vapor phase at the interfacial pressure and temperature, and $\rho_s(a)$ is the density of the material in the sphere, evaluated also at the interfacial pressure and temperature. Therefore, the temperature and vapor pressure at the interface of the sphere are related by the so-called saturation relation, $p_l = p_{sat}(T)$. The function $p_{sat}(T)$ for any of the commonly used materials may be obtained in tabular form from thermodynamics texts or in tables of properties. It must be emphasized that this thermodynamic relationship between the prevailing pressure and temperature applies only at the surface of the sphere $r = a$. In general, $p_l(r)$ and $T_l(r)$ are two independent functions that are only related at $r = a$.

As in the case of the pressure (Equation 1.67), the surface tension may have an influence on the saturation relation. In this case, the value for the partial pressure of the vapor at the interface must be corrected as follows:

$$p_l(a) = p_{sat}(T(a))\exp\left[\frac{2\sigma(T(a))}{a\rho_s(a)R_vT(a)}\right]. \tag{1.69}$$

where the parentheses denote arguments of functions and R_v is the specific gas constant for the material species of the vapor, l, that is, $R_v = R/\mathcal{M}_l$ and $R = 8.314$ kJ/kg > K. The term in the square brackets is sometimes called the "Kelvin number," *Ke*, and in most practical applications its value is very low ($Ke \ll 1$). Hence, in most practical applications, $p_l(a) \approx p_{sat}(T(a))$. A glance at Equation 1.69 proves that the Kelvin number and hence the effects of surface tension become significant when $a \to 0$, a condition that is met at the last stages of combustion, evaporation, or sublimation of a sphere.

Within the gaseous phase that comprises the vapor of the sphere and the carrier fluid, the mole fraction of the vapor and the mole fraction of the components of the carrier fluid at any distance $r > a$ are defined in terms of their partial pressures as follows:

$$X_v(r) = \frac{p_l(r)}{p_T} \quad \text{and} \quad X_{ci}(r) = \frac{p_{ci}(r)}{p_T}. \tag{1.70}$$

Obviously, at any point, the condition applies that the sum of all the mole fractions in the gaseous mixture is equal to one. At the surface of the sphere, the pressure $p_l(a)$ is equal to the saturation pressure at the prevailing temperature, $T(a)$. Hence, the mole fraction of the vapor at the interface is determined from the knowledge of the total pressure and the temperature of the sphere.

The mole fraction of any species, denoted by the letter X_j, and the mass fraction of this species, Y_j, are related via the molecular weights, M_i, of the species that are present in the gaseous mixture:

$$Y_j = \frac{X_j M_j}{\sum_i X_i M_i} \quad \text{and} \quad X_j = \frac{Y_j/M_j}{\sum_i Y_j/M_j}, \tag{1.71}$$

where the sum in the denominator is over all the species that are present in the gaseous phase, namely, the carrier gas and the vapor. As in the case of the mole fractions, at any point outside the sphere, the sum of all the mass fractions is equal to one.

In the cases of sublimation and evaporation, the variation of the intensive vapor properties $T_v(r)$ and $p_v(r)$ is in the opposite direction from the one shown in Figure 1.7. In such processes, any mass flow rate from the sphere to the gas results in a radial velocity w from the surface of the sphere to the gas, which is described by the following mass conservation equation:

$$d^2 \frac{d\rho_f}{dt} + \frac{d(\rho_f d^2 w)}{dr} = 0. \tag{1.72}$$

where d, when it is not part of a differential operator such as d/dt or d/dr, is the diameter of the sphere and r is the radial coordinate. In a quasi-steady case, where the density of the carrier fluid may be considered to be constant, the aforementioned equation may be integrated on the surface of the sphere to yield the mass flow rate from the sphere to the fluid:

$$\frac{dm}{dt} = -\pi d^2 \rho_f w\big|_s. \tag{1.73}$$

The velocity w is evaluated with respect to the surface of the sphere at the gas side. Since the radial velocity w is an outward velocity with respect to a control volume that encloses the sphere, the negative sign signifies that mass is transferred from the sphere to the fluid when w is positive.

Evaporation, condensation, sublimation, and chemical reactions are the basic processes for the mass transfer to or from a sphere. Processes without chemical reactions will be examined in this section, while processes with chemical reactions, such as combustion, will be mentioned briefly in the next section and will be examined in more detail in Chapter 6. It must be recalled that when mass transfer occurs without chemical reactions, the driving force for the process is the difference of the concentration of the species the sphere is composed of (evaluated at the surface of the sphere) and the concentration of the same species in the carrier fluid (evaluated far from the sphere). For example, in the case of an evaporating water droplet in air, the driving force is the difference of the specific humidity at the surface of the sphere and

the specific humidity of the carrier fluid, far from the sphere. The former is a function of the temperature and pressure at the surface of the sphere, while the latter is a property of the carrier fluid. If the carrier fluid becomes completely saturated with water vapor, there is no such difference, and hence, no evaporation takes place.

The mass flux at the surface of an evaporating or condensing droplet in a binary mixture is given by Fick's law:

$$\rho_f w = -\rho_f D_c \frac{\partial Y_s}{\partial r}\Big|_s, \tag{1.74}$$

where D_c is the diffusion coefficient of the species the drop is composed of in the carrier fluid.

At the surface, we also require the following condition:

$$D_c \frac{\partial Y_s}{\partial r} = h_M (Y_s - Y_c), \tag{1.75}$$

where h_M is the convective mass transfer coefficient, which is analogous to the convective heat transfer coefficient. For a droplet of diameter $d = 2a$, the gradient of the mass fraction of any species at the droplet surface is proportional to the difference between the mass fraction at the surface and in the free stream and inversely proportional to the droplet diameter. Therefore,

$$\frac{\partial Y_s}{\partial r}\Big|_s \sim \frac{Y_s - Y_\infty}{d}, \tag{1.76}$$

where Y_∞ is the mass faction of the species in the free stream far from the droplet. A combination of the last two equations yields

$$\frac{dm}{dt} \sim \pi \rho_f D d (Y_\infty - Y_s). \tag{1.77}$$

The parameter that makes this expression an equation is the Sherwood number, *Sh*, which is often determined by experiment. Thus, the following expression may be derived for the rate of mass transfer from a sphere:

$$\frac{dm}{dt} = Sh \pi \rho_f D_c d (Y_\infty - Y_s). \tag{1.78}$$

Without mass advection caused by forced or free convection processes, the pure molecular diffusion dominates the mass transfer process, and hence, $Sh = 2$. The effect of fluid advection and relative velocity between the droplet and the carrier fluid is frequently represented by the so-called "Ranz–Marshall relation" (Ranz and Marshall, 1952):

$$Sh = 2 + 0.6 Re_r^{1/2} Sc^{1/3}, \tag{1.79}$$

where

Re_r is the Reynolds number based on the relative velocity
Sc is the Schmidt number

Since the mass transfer process from a sphere is closely related to the heat transfer process via the well-known heat/mass transfer analogy, one may also use alternative expressions for the Sherwood number, which are given as expressions for the Nusselt number in Section 1.4.4. In particular, one may use the *Sh*–*Nu* analogy and obtain expressions for the Sherwood number based on the numerical correlations of Section 1.4.4.2 for the heat and mass transfer from viscous spheres at finite Reynolds numbers.

1.4.2.2 Chemical Reactions

When chemical reactions take place, the mass transfer from the sphere is related to the reaction rate of the fuel, ξ. This is expressed in units of the reaction per unit time, which are sometimes referred to as DeDonder/second. If we assume that the spherical symmetry of the drop is retained during the processes of mass transfer and chemical reaction, the mass conservation equation for the fuel, the oxidant, and an inert component, such as nitrogen, which may be present in the reaction, may be written as follows:

1. For the fuel, whose mass fraction is denoted by the subscript *F*:

$$\frac{\partial}{\partial t}(\rho d^2 Y_F) + \frac{\partial}{\partial r}(\rho u d^2 Y_F) - \frac{\partial}{\partial r}\left(\rho d^2 D_F \frac{\partial Y_F}{\partial r}\right) = \rho d^2 \xi. \tag{1.80}$$

   The last term in this equation is a measure of the mass of the fuel that is consumed by the reaction.
2. For an oxidant, whose mass fraction is denoted by the subscript *O*:

$$\frac{\partial}{\partial t}(\rho d^2 Y_O) + \frac{\partial}{\partial r}(\rho u d^2 Y_O) - \frac{\partial}{\partial r}\left(\rho d^2 D_O \frac{\partial Y_O}{\partial r}\right) = \rho d^2 F_{OF} \xi, \tag{1.81}$$

   where FOF is the stoichiometric ratio of oxidant to the fuel that is consumed by the reaction.
3. For an inert component, such as nitrogen, the total mass is conserved and the right-hand side of the corresponding equation is equal to zero:

$$\frac{\partial}{\partial t}(\rho d^2 Y_N) + \frac{\partial}{\partial r}(\rho u d^2 Y_N) - \frac{\partial}{\partial r}\left(\rho d^2 D_N \frac{\partial Y_N}{\partial r}\right) = 0. \tag{1.82}$$

4. The mass conservation equation for any product, denoted by the subscript *P*, which appears as a result of the reaction, is

$$\frac{\partial}{\partial t}(\rho d^2 Y_P) + \frac{\partial}{\partial r}(\rho u d^2 Y_P) - \frac{\partial}{\partial r}\left(\rho d^2 D_P \frac{\partial Y_P}{\partial r}\right) = -\rho d^2 (F_{OF} + 1)\xi. \tag{1.83}$$

From the definition of the mass fractions for all the components of the reaction, one may also derive the following identity, which is useful as a closure equation:

$$Y_F + Y_O + Y_N + Y_P = 1. \tag{1.84}$$

The mass balance for any species at the surface of an evaporating or reacting droplet may be imposed on all the species that are present in the droplet and the gas. Because of the loss of liquid mass, there is a radial convection at the surface that is often called "Stefan convection." The rate of mass convection on the side of the gas is equal to the rate of mass convection on the liquid side:

$$\dot{M} Y_{is} - \rho \pi d^2 D_c \frac{\partial Y_i}{\partial r}\Big|_s = \dot{M} \delta_{iF} \quad i = O, F, N, P, \tag{1.85}$$

where

the left-hand side represents the advection and diffusion at the gas side
$\dot{M}$ is the rate of mass vaporization or reaction of the droplet
the subscript *i* extends over the species of fuel, oxidant, inert, and products
δ_{iF} is the Kronecker delta

More details on the combustion processes and methods for calculating the mass transfer from a burning drop are presented in Chapter 6. Since the subject of mass transfer from a sphere is closely connected to the processes of evaporation and sublimation and since the corresponding mass transfer or *blowing effect*

influences significantly the momentum transfer and the hydrodynamic forces exerted on the droplet, the relevant correlations and useful information on engineering computations will be presented in Sections 1.4.3.4 and 1.4.4.4.

1.4.3 Momentum Transfer

The functional form and expressions for the steady and transient hydrodynamic force exerted by a fluid on a sphere will be presented in this section. The hydrodynamic force is a surface force. The body forces (gravity, magnetic, electric, etc.) that may act on the sphere will not be included in the analysis for brevity. These forces are added to the hydrodynamic force and all the other forces acting on the sphere to generate the Lagrangian equation of motion.

We consider the rectilinear flow of a viscous fluid around a sphere of radius $a(d = 2a)$. The fluid velocity field is nonuniform and given by the function $u_i(x_i, t)$ outside the volume occupied by the sphere. If the sphere is solid that does not rotate,* its velocity is only a function of the time, $v_i(t)$. If the sphere is composed of a viscous fluid (as in bubbles and drops), its velocity is $v_i(x_i, t)$, which signifies that there is fluid motion inside the fluid sphere. In both cases, the governing equations for the process of mass and momentum exchange are the continuity, or mass conservation, equation

$$\frac{\partial \rho_f}{\partial t} + \rho_f \vec{\nabla} \cdot \vec{u} = 0, \tag{1.86}$$

and the momentum conservation equation

$$-\vec{\nabla} p + \mu_f \nabla^2 \vec{u} = \rho_f \left(\frac{\partial \vec{u}}{\partial t} + \vec{U} \cdot \vec{\nabla} \vec{u} \right), \tag{1.87}$$

where U is the fluid velocity at the surface of the sphere. The last equation may be rendered dimensionless by using the diameter, $2a$, as the characteristic dimension of the problem and the characteristic time $\tau_s = 4\alpha^2 \rho_f / \mu_f$. This yields the following dimensionless expression:

$$-\vec{\nabla}^\star p^\star + \nabla^{\star 2} \vec{u}^\star = \frac{\partial \vec{u}^\star}{\partial t^\star} + Re\left(\vec{U}^\star \cdot \vec{\nabla}^\star \vec{u}^\star \right). \tag{1.88}$$

Depending on the details of the process, the characteristic velocity for the definition of $u^\star$ is either the characteristic velocity of the fluid itself or the relative velocity of the sphere with respect to the fluid. This defines two Reynolds numbers for the flow, Re and Re_r:

$$Re = \frac{2a\rho_f |\vec{u}|}{\mu_f} \quad \text{and} \quad Re_r = \frac{2a\rho_f |\vec{u} - \vec{v}|}{\mu_f} \tag{1.89}$$

When applied to particulate flows, Equations 1.87 and 1.88 are sometimes referred to as the "Oseen equations." They contain the velocity at the surface of the sphere and the nonlinear advection term of the fluid flow, which is the last term in the two equations (Oseen, 1913). When $Re \ll 1$, the nonlinear advection term may be neglected in comparison to the viscous term. Then the momentum equation becomes linear and reads as follows:

$$\rho_f \frac{\partial \vec{u}}{\partial t} = -\vec{\nabla} p + \mu_f \nabla^2 \vec{u} \tag{1.90}$$

or in dimensionless form

$$-\vec{\nabla}^\star p^\star + \nabla^{\star 2} \vec{u}^\star = \frac{\partial \vec{u}^\star}{\partial t^\star}. \tag{1.91}$$

* If the solid sphere rotates, its interior points move according to the solid body rotation principles.

This flow is often called "Stokes flow" or "creeping flow" (Stokes, 1851) and the last two equations *Stokes equations*. Creeping or Stokes flow basically implies that the relative Reynolds number of the flow, Re_r, is very small, the viscous effects dominate the hydrodynamic force on the sphere, and the inertia effects, which are represented by the nonlinear term of the governing equation, may be neglected. Micron-size and nanoparticles satisfy this condition as well as larger particles in fluids of high viscosity and low relative velocity.

1.4.3.1 Stokes or Creeping Flow

The steady-state solution of Equation 1.90 yields the *Stokes drag* for the hydrodynamic force ($F_D = 6\pi a v \mu_f$). The full, transient solution of the equation is the so-called Boussinesq–Basset expression (Maxey and Riley, 1983, Boussinesq, 1885, Basset, 1888a, Michaelides, 2003), which is elucidated in Section 1.4.3.6. Although the Stokes drag is obtained for $Re_r \ll 1$, the expression for it is accurate up to $Re_r = 0.5$ (see Table 1.1). Because many industrial applications with small particles and drops in viscous fluids occur at $Re_r < 1$, this type of flow is of immense interest to engineers and scientists.

Consider the motion of a viscous fluid sphere inside the fluid of different viscosities at $Re_r \ll 1$. The fluid velocity is uniform and equal to U, far from the sphere and the no-slip condition applied on the surface of the sphere. The center of coordinates is coincident with the center of the sphere, and the flow domain is much larger than the diameter of the sphere. This is referred to sometimes as an "infinite domain." The viscous sphere problem in a fluid was solved independently by Hadamard (1911) and Rybczynski (1911) who obtained the following analytical expressions for the stream functions inside and outside the sphere:

$$\psi_i = \frac{Ur^2(a^2 - r^2)\sin^2\theta}{4(\lambda+1)a^2} \tag{1.92}$$

and

$$\psi_o = \frac{Ur^2\sin^2\theta}{2}\left[1 - \frac{(3\lambda+2)a}{2(\lambda+1)r} + \frac{\lambda a^3}{2(\lambda+1)r^3}\right], \tag{1.93}$$

where λ is the ratio of the dynamic viscosities, μ_s/μ_c. The case of a solid sphere is given at the limit $\lambda \to \infty$, and the case of an inviscid sphere (a bubble) is given at the limit $\lambda \to 0$. It is apparent that even at this very low relative velocity, the presence of the sphere in a flow field creates a disturbance in the velocity field of the fluid, which is determined in the radial and transverse directions from the following last two equations:

$$u_r = U\cos\theta\left[1 - \frac{(3\lambda+2)a}{2(\lambda+1)r} + \frac{\lambda a^3}{2(\lambda+1)r^3}\right] \tag{1.94}$$

and

$$u_\theta = -U\sin\theta\left[1 - \frac{(3\lambda+2)a}{4(\lambda+1)r} - \frac{\lambda a^3}{4(\lambda+1)r^3}\right]. \tag{1.95}$$

Table 1.1 Drag Coefficients of Spherical Particles Calculated by Four Different Expressions

Re_r	Stokes	Equation 1.103	Equation 1.104	Equation 1.105
0.05	480.0	484.5	484.3	489.2
0.1	240.0	244.5	244.1	247.4
0.2	120.0	124.5	123.9	126.0
0.5	48.0	52.5	51.6	52.5
0.8	30.0	34.5	33.5	33.9
1.0	24.0	28.5	27.6	27.6
1.2	20.0	24.5	23.7	23.4
1.5	16.0	20.5	19.9	19.2
1.8	13.3	17.8	17.6	16.3
2.0	12.0	16.5	16.5	14.9

It is evident that the velocity field described by these equations yields $u_r = 0$ on the surface of the sphere and $u = U$ far away from the sphere. These velocity solutions can be used to determine the pressure field and the fluid stress tensor.

Integration of the normal and shear stresses on the surface of the fluid sphere yields the total hydrodynamic force exerted by the fluid on the viscous sphere as follows:

$$F_D = 2\pi a U \mu_c \frac{3\lambda + 2}{\lambda + 1}. \tag{1.96}$$

The corresponding drag coefficient for the viscous sphere in Stokes flow becomes

$$C_D = \frac{2F_D}{\pi \rho U^2 a^2} = \frac{8(3\lambda + 2)}{Re_r(\lambda + 1)}. \tag{1.97}$$

The last expression yields the so-called Stokes drag for a solid sphere $C_D = 24/Re_r$ and for an inviscid bubble $C_D = 16/Re_r$. The corresponding expressions for the drag force are $F_D = 6\pi a U \mu_c$ for the solid sphere and $F_D = 4\pi a U \mu_c$ for the inviscid bubble. The latter is sometimes referred to as the "form drag," while the difference of the two expressions, which is equal to $2\pi a U \mu_c$, is referred to as the "friction drag." The form drag or pressure drag is due to pressure distribution over the surface of the sphere, while the friction drag results from the viscous stress at the surface of the sphere. While several authors make this distinction between the two parts of the drag force, it must be noted that the drag force is a single entity that arises from the interactions between the fluid and the sphere and not two different forces.

Spheres settling or rising under gravity at Stokes flow conditions are subjected to the gravity and buoyancy force and the hydrodynamic/drag force. At steady flow, the two opposing forces are equal in magnitude and the spheres move at constant velocity. Depending on the actual application, this velocity is known as the "terminal, rising, or settling velocity" of the sphere. An expression for the terminal velocity of a viscous sphere in Stokesian flow is

$$V_t = \frac{2}{3} \frac{g a^2 (\rho_c - \rho_s)}{\mu_c} \frac{\lambda + 1}{3\lambda + 2}. \tag{1.98}$$

In some industrial applications, bubbles and drops do not follow the predictions of the Hadamard–Rybczynski analysis, because of the presence of impurities that act as surfactants in the fluid. The surfactants, in general, dampen the internal velocity field, thus increasing the effective viscosity of the internal fluid. In this case, the viscous sphere behaves as a solid sphere. When the bubble or drop is in motion, the surfactants are swept to the aft, leaving the forward surface relatively uncontaminated. This establishes a concentration gradient on the surface of the sphere, which results in a surface tension gradient and, subsequently, in a tangential stress that opposes the motion of the surface. The net result of this phenomenon is an increase in the total drag force, which is manifested in the retardation of the terminal velocity of the viscous sphere (Levitch, 1962). In practical cases of bubble and droplet flows, one must consider the drag given by Equation 1.96 as the lower limit of the hydrodynamic force, which is reached under conditions of exceptional carrier fluid purity. Similarly, the terminal velocity given by Equation 1.98 is the upper limit of the velocity that can be attained by a bubble or drop under Stokes flow (or creeping flow) conditions.

The work by Bond and Newton (1928) and similar more recent studies suggest that as long as the flow may be characterized as Stokes flow and $Re_r \ll 1$, the viscous spheres behave as solid spheres in the range $Eo < 4$. This Eötvos number is based on the density difference between the two fluids:

$$Eo = \frac{(\rho_c - \rho_s) g d^2}{\sigma}. \tag{1.99}$$

In the range $Eo > 4$, the spheres follow more closely the Hadamard–Rybczynski analysis and Equations 1.97 through 1.99. It must be noted that in the Stokes flow regime ($Re_r \ll 1$), all viscous spheres (bubbles and drops) remain spherical, regardless of the value of the Eötvos number (for more details see Section 1.4.3.8).

1.4.3.2 Reynolds Number Effects

1.4.3.2.1 Solid Spheres At finite Re_r, the fore-aft symmetry of the flow around the sphere, which is implied by the Stokes flow conditions, breaks down and the equations of the last section do not apply. Experimental observations have proven that, even at low Re_r, a wake is formed behind the sphere. This is a steady wake that becomes stronger as the Reynolds number increases and the inertia of the flow around the sphere overcomes the viscosity effects on the surface of the sphere. Experimental observations (Taneda, 1956, Achenbach, 1974, Seeley et al., 1975), as well as numerical computations, give sufficient evidence that the following flow descriptions or *regimes*, related to the presence and behavior of the wake, are observed around a sphere:

1. *Attached flow*: In the range $0 < Re_r < 20$, the flow is attached to the sphere and there is no visible recirculation behind it. There is a *velocity defect* region behind the sphere, which is the characteristic of a weak wake. The fore-aft asymmetry of the flow becomes progressively more pronounced as Re_r increases.
2. *Steady wake*: The onset of wake separation occurs at approximately $Re_r = 20$ and a very weak recirculating wake becomes visible. The wake is very small in volume and is attached to the aft of the sphere. As the Re_r increases, the wake becomes wider and longer and its point of attachment on the sphere moves forward. The wake is steady up to approximately $Re_r = 150$. With the steady wake, the separation angle is a monotonically decreasing function of Re_r, while the wake length and volume increase with Re_r. An approximate correlation for the length of the wake in this flow regime is

$$L_W = 2a\left[0.0203\left(Re_r - 20\right) + 0.00012\left(Re_r - 20\right)^2\right]. \tag{1.100}$$

3. *Unsteady wake regime in laminar flow*: The onset of the wake instability occurs in the range $130 < Re_r < 150$, where a weak, long-period, laminar oscillation appears at the tip of the wake and its amplitude increases with Re_r. Pockets of vorticity begin to shed from the tip of the sphere and influence the flow field downstream. The unsteady wake regime has been observed in experiments in the range $(130–150) < Re_r < 270$.
4. *High subcritical range*: This regime covers the range $270 < Re_r < 3 * 10^5$. As Re_r increases, vortices are shed regularly from alternate sides of the sphere. At the lower end of this regime, the Strouhal number, *Sl*, of the vortices is a monotonic function of Re_r and ranges from 0.1 at $Re_r = 400$ to approximately 2 at $Re_r = 6000$. The following relationship between the *Sl* and Re_r shows the best fit with the data in the range $400 < Re_r < 4000$:

$$Sl = 1.89 * 10^{-5} Re_r^{1.43}. \tag{1.101}$$

   In the range $4000 < Re_r < 6000$, there is too much scatter in the experimental data, with *Sl* appearing to level at the value 0.21. In the range $Re_r > 6000$, separation occurs at a point that rotates around the sphere with frequency equal to the shedding frequency. The result of the wake separation above $Re_r = 6000$ is the drastic reduction of *Sl* to 0.125. In the range $6000 < Re_r < 3 * 10^4$, *Sl* rises from 0.125 to 0.18, while in the range $3 * 10^4 < Re_r < 2 * 10^5$ *Sl* only rises to 0.19 (Achenbach, 1974). All the studies indicate that in this flow regime, the wake is periodic but not turbulent. The observations by Seeley et al. (1975) have shown that at values of Re_r above 1300 small jets and eddies appeared, signifying 3D rotation of the flow. The observations confirm that, in the subcritical range, the separation point moves forward and the angle where separation occurs is

$$\theta_S = 83 + 660 Re_r^{-0.5}. \tag{1.102}$$

5. *Supercritical flow*: The onset of the transition to a turbulent wake occurs at $Re_r = 2 * 10^5$, and the transition is completed at $Re_r = 3.7 * 10^5$. In this range, changes in the flow pattern occur that are referred to as "critical transition." At $Re_r > 3.7 * 10^5$, the separation begins to move downstream and fluctuations in the position of the separation point become evident. The free shear layer becomes turbulent and attaches to the surface of the sphere. The most evident result of the transition is a

sharp drop of the drag coefficient from approximately 0.44 to approximately 0.07. It must be noted that the transition to a turbulent boundary layer is sensitive to the intensity of the free-stream turbulence and it may be accelerated by "tripping" the flow with a thin wire, a devise that has often been used in experimental studies of turbulent boundary layers (Maxworthy, 1969). The effects of the free turbulence on the flow field and other transient effects are presented in Sections 1.4.3.3 and 1.4.3.6, respectively.

The first accurate determination of the hydrodynamic force on a sphere at finite Reynolds numbers is attributed to Oseen (1913). He used a simple perturbation method to calculate a first-order correction for the steady drag coefficient. His expression

$$C_D = \frac{24}{Re_r}\left(1+\frac{3}{16}Re_r\right) \tag{1.103}$$

is valid for finite but small values of Re_r. Maxworthy (1975) verified experimentally that the Oseen correction is accurate up to $Re_r = 0.45$. This range covers many practical applications in the chemical industry, where particles are very small and the fluids have high viscosity.

At finite values of Re_r, the nonlinear advection term in the governing momentum equation (1.87) or (1.88) is retained in the solution of the equations. This implies that the vorticity and vorticity gradients around the sphere are transported by the advection of the fluid as well as by the molecular diffusion processes. An analysis of the governing equations reveals that the diffusion part of the process is dominant in an inner region surrounding the sphere with radius aRe_r^{-1}, while the advection process is dominant at distances far from this region. At the overlap of the two regions, $r \sim aRe_r^{-1}$, the two processes, advection and diffusion, are of the same order of magnitude, and their effects must be calculated simultaneously. In this case, the characteristic time of the advection process is a/U, while that of the diffusion process is equal to a^2/ν_f. Because the characteristic times are of different orders of magnitude, an analytic solution for the problems of the transport of momentum and energy at finite Reynolds and Peclet numbers may be solved asymptotically, usually by a singular perturbation method.

Proudman and Pearson (1956) used an asymptotic method to calculate the velocity field around a solid sphere and around a cylinder at steady flow. This approximation enabled them to extend the Oseen result and to calculate the steady drag coefficient to $O(Re_r^2 \ln Re_r)$. Their expression for the drag coefficient is

$$C_D = \frac{24}{Re_r}\left[1+\frac{3}{16}Re_r+\frac{9}{160}Re_r^2\ln\left(\frac{Re_r}{2}\right)+O\left(Re_r^2\right)\right]. \tag{1.104}$$

Expressions such as this may be used with accuracy in applications of finite but small Re_r in the range from 0 to 1.5. At higher values of Re_r it is advisable to use one of the empirical or semiempirical expressions for the steady drag coefficient that abound in the literature. One of them is the Schiller and Nauman (1933) correlation, which is relatively simple and accurate:

$$C_D = \frac{24\left(1+0.15Re_r^{0.687}\right)}{Re_r}. \tag{1.105}$$

This expression is recommended in the range $1 < Re_r < 800$. The similar and simpler expression

$$C_D = \frac{24}{Re_r}\left(1+\frac{1}{6}Re_r^{2/3}\right) \tag{1.106}$$

is easier to integrate analytically and is also recommended in the same range $1 < Re_r < 800$.

Of interest to several engineering applications is the range $Re_r < 2$, and Table 1.1 gives the numerical values of the drag coefficients calculated by the Stokes equation, the Oseen equation (Equation 1.103), the Proudman and Pearson equation (1.104), and the Schiller and Nauman correlation (Equation 1.105).

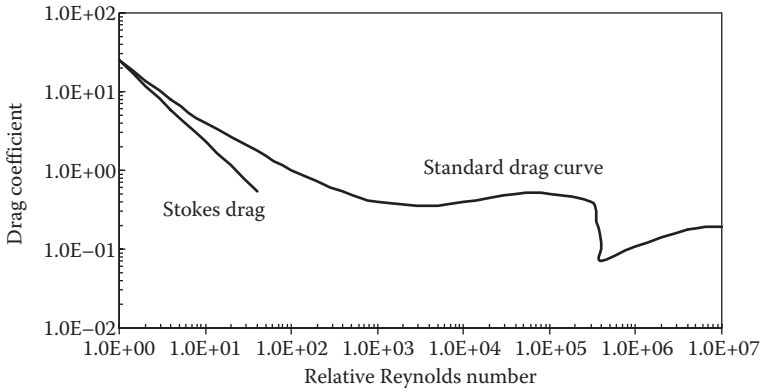

Figure 1.8

The standard drag coefficient curve for a solid sphere in steady flow.

It is observed in Table 1.1 that the Stokes drag agrees within 10% with the values of the other expressions up to $Re_r = 0.5$ and that the other three expressions agree within 10% up to $Re_r = 2$ despite the fact that the analytical equations were derived under the condition $Re_r < 1$.

The empirical equations give rise to the *standard*, *steady drag coefficient curve*, which is depicted in Figure 1.8 and extends to $Re_r = 10^7$. It is apparent in this figure that the steady drag coefficient of a sphere becomes constant and approximately equal to 0.44 in the range $10^3 < Re_r < 3 * 10^5$. In this range, the friction part of the drag force is insignificant and all the contribution comes from the form drag.

A key determinant of the magnitude of the drag coefficient is the type of the boundary layer that is formed outside the sphere and the separation point of the flow field behind the sphere. At $Re_r = 3 * 10^5$, this boundary layer becomes turbulent and the separation point of the flow moves downstream. The result is a sharp reduction of the form drag and hence a drastic reduction of the drag coefficient from 0.42 to 0.07, which is typical of laminar-to-turbulent transitions. At these high values of Re_r, the flow becomes inherently unsteady because vortices are shed regularly behind the sphere. In this case, as well as in all transient flows, the standard hydrodynamic drag on a sphere may be used (instead of the transient expressions that are presented in Section 1.4.3.6) only if the timescale of the sphere ($\tau_s = 4\alpha^2\rho_f/\mu_f$) is much smaller than the timescale of the transients in the carrier fluid, $\tau_s \ll \tau_f$. This condition implies that $St \ll 1$.

1.4.3.2.2 Viscous Spheres At higher Re_r, internal circulation creates a flow field inside the viscous spheres. This modifies the external flow field and hence the drag coefficient. Figure 1.9 (from Feng and Michaelides, 2001a) shows the streamlines (a) and vorticity (b) of these flow fields for $\lambda = 7$ and $Re_r = 10$, 100, and 500. At first, it is evident from the streamlines that there is a fore-aft asymmetry, which is also seen in the case of rigid spheres. Even though at $Re_r = 10$ the recirculation region behind the sphere has not been formed, there is an obvious velocity defect region. At $Re_r = 100$, there is a well-defined recirculation region, and at $Re_r = 500$, this region expands considerably and extends to a distance more than one diameter downstream. Second, at $Re_r = 500$, there are sharp gradients of vorticity in the outer field of the sphere, which indicate the formation of a boundary layer. This boundary layer is characteristic of flows with $Re_r > 400$, and its thickness is of the order of $Re_r^{-1/2}$. Third, there are two counterrotating vortices inside the sphere (sometimes referred to as "Hill's vortices") whose strength increases with Re_r. An internal recirculation region at the aft end of the sphere may also be formed at higher values of Re_r or at lower values of λ. The formation of the internal flow in viscous spheres modifies the whole velocity field and results in the lower drag on the spheres.

LeClair and Hamielec (1972), Rivkind et al. (1976), and Oliver and Chung (1987) used analytical and numerical studies to derive expressions for the drag coefficients of viscous spheres (bubbles and drops) at relatively low Re_r. Feng and Michaelides (2001a) used a two-layer concept for the computational grid and were able to perform more accurate computations that extend to higher values of Re_r, where the boundary layer is well formed on the outside of the viscous sphere. They used their computational results to derive simple engineering correlations for the drag coefficients in terms of the viscosity ratio up to $Re_r = 1000$. Figure 1.10 depicts these results for several values of the viscosity ratio, λ. The standard drag coefficient

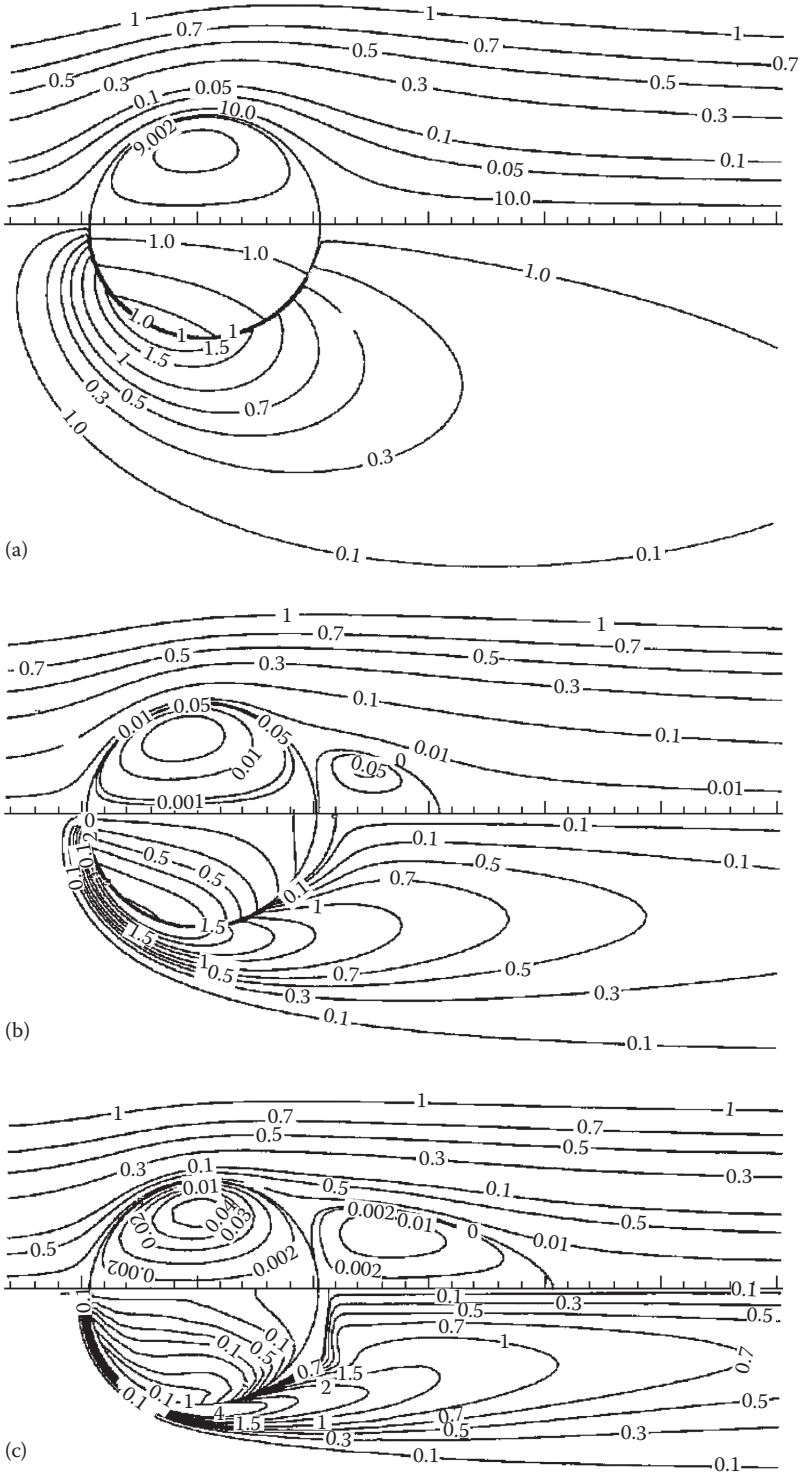

Figure 1.9

Streamlines and vorticity around a viscous sphere with viscosity ratio 7 at *Re* = 10 (a), 100 (b), and 500 (c).

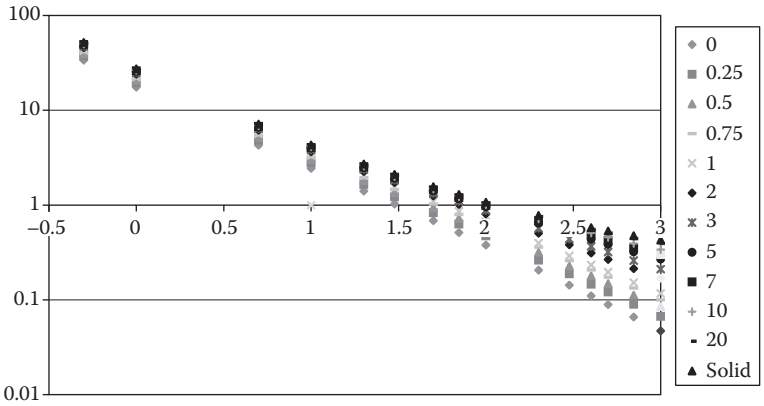

Figure 1.10

Drag coefficients for viscous spheres at different values of λ.

curve for solid spheres in this figure corresponds to the limit $\lambda \to \infty$. When expressed in terms of Re_r, the correlations derived by Feng and Michaelides (2001a) may be written as follows:

$$C_D\left(Re_r,\lambda\right)=\frac{2-\lambda}{2}C_D\left(Re_r,0\right)+\frac{4\lambda}{6+\lambda}C_D\left(Re_r,2\right) \quad \text{for } 0\le\lambda\le 2 \quad \text{and} \quad 5<Re_r\le 1000 \tag{1.107}$$

and

$$C_D\left(Re_r,\lambda\right)=\frac{4}{\lambda+2}C_D\left(Re_r,2\right)+\frac{\lambda-2}{\lambda+2}C_D\left(Re_r,\infty\right) \quad \text{for } 2\le\lambda\le\infty \quad \text{and} \quad 5<Re_r\le 1000 \tag{1.108}$$

The functions $C_D(Re_r, 0)$, $C_D(Re_r, 2)$, and $C_D(Re_r, \infty)$ are the drag coefficient for inviscid bubbles, for viscous drops with $\lambda = 2$, and for solid spheres, respectively. The following functions are recommended to be used with the two aforementioned correlations:

$$C_D\left(Re_r,0\right)=\frac{48}{Re_r}\left(1+\frac{2.21}{\sqrt{Re_r}}-\frac{2.14}{Re_r}\right), \tag{1.109}$$

$$C_D\left(Re_r,2\right)=17.0Re_r^{-2/3}, \tag{1.110}$$

and

$$C_D\left(Re_r,\infty\right)=\frac{24}{Re_r}\left(1+\frac{1}{6}Re_r^{2/3}\right). \tag{1.111}$$

In the lower range of Re_r, which is not covered by these equations, the following expression is recommended:

$$C_D=\frac{8}{Re_r}\frac{3\lambda+2}{\lambda+1}\left(1+0.05\frac{3\lambda+2}{\lambda+1}Re_r\right)-0.01\frac{3\lambda+2}{\lambda+1}Re_r\ln\left(Re_r\right) \quad 0\le Re_r\le 5. \tag{1.112}$$

The last expression has been derived from the results of the numerical computations in a way that it reduces asymptotically to the Hadamard–Rybczynski solution at $Re_r = 0$ and to the Oliver and Chung expression for very small Re_r.

The density ratio ρ_f/ρ_s does not influence significantly the drag coefficient of viscous spheres. Feng and Michaelides (2001a) observed that the variation of the density ratio by two orders of magnitude had an effect of less than 2% on the values of the drag coefficients. The maximum fractional difference of the correlations from the pertinent computational results is 4.6%, and the standard deviation of all the fractional differences is 2.1%. It must be noted that at the high range of Re_r the wake behind the spheres is unsteady and a transient expression for the total drag force should be used, if one is known. In such cases, the aforementioned expressions may be used for the steady part of the total hydrodynamic force.

It is well known that viscous spheres at higher Re_r become elongated. The drag coefficient of elongated viscous spheres is a function of the variables that appear in the aforementioned correlations as well as of the amount of deformation, which is characterized by the elongation or eccentricity. Correction functions must be used with these correlations, such as the ones presented in Sections 1.4.3.7 and 1.4.3.8. Experimental results by Winnikow and Chao (1966) and others on the free fall or rise of drops in liquids show that a liquid drop will remain spherical when the dimensionless Bond number, *Bo*, is less than or equal to 0.2, that is, when

$$Bo = \frac{We}{Fr} = \frac{gd^2|\rho_s - \rho_f|}{\sigma} \leq 0.2. \tag{1.113}$$

Accordingly, water droplets in air will maintain their spherical shape at values of Re_r up to 470. In the case of substances with high surface tension (liquid metals), the corresponding Re_r is much larger (up to $Re_r = 1150$ for mercury droplets in air).

1.4.3.2.3 Effect of Interfacial Velocity Slip All the aforementioned results and expressions for the drag force and the drag coefficient pertain to applications where the no-slip boundary condition applies at the interface of the carrier fluid and the bubble, particle, or drop. It has been observed that when the size of the elements of the dispersed phase is very small, of the order of 1000 nm and lower, there is velocity slip at the interface that modifies significantly the drag coefficient. This modification of the drag is of immense interest in flows of nanoparticles and nanodroplets. Several authors, starting with Basset (1888b), derived expressions for the drag modification due to interfacial slip. Basset (1888b) stipulated that the shear stress on the sphere is proportional to the tangential slip: $\tau = \beta \Delta u_t$. The coefficient β is often referred to as the "slip parameter" and the dimensionless ratio $\mu_c/a\beta$ as the "slip ratio." Feng et al. (2012) derived a comprehensive correction to the steady drag force with slip, which applies to viscous as well as inviscid spheres:

$$\frac{F_D}{6\pi\alpha\mu_c U} = \frac{1}{3}\frac{2\beta\alpha + 3\lambda\beta\alpha + 6\lambda\mu_c}{\beta\alpha + \lambda\beta\alpha + 3\lambda\mu_c} + \frac{1}{24}\left(\frac{2\beta\alpha + 3\lambda\beta\alpha + 6\lambda\mu_c}{\beta\alpha + \lambda\beta\alpha + 3\lambda\mu_c}\right)^2 \frac{Re_r}{2} + \frac{1}{120}\left(\frac{2\beta\alpha + 3\lambda\beta\alpha + 6\lambda\mu_c}{\beta\alpha + \lambda\beta\alpha + 3\lambda\mu_c}\right)^3 \frac{Re_r^2}{4}\ln\left(\frac{Re_r}{2}\right) + O\left(Re_r^2\right). \tag{1.114}$$

For a solid sphere, $\lambda \to \infty$, the last equation yields

$$\frac{F_D}{6\pi\alpha\mu_c U} = \frac{\beta\alpha + 2\mu_c}{\beta\alpha + 3\mu_c} + \frac{3}{8}\left(\frac{\beta\alpha + 2\mu_c}{\beta\alpha + 3\mu_c}\right)^2 \frac{Re_r}{2} + \frac{9}{40}\left(\frac{\beta\alpha + 2\mu_c}{\beta\alpha + 3\mu_c}\right)^3 \frac{Re_r^2}{4}\ln\left(\frac{Re_r}{2}\right) + O\left(Re_r^2\right). \tag{1.115}$$

By using dimensionless slip ratio $S = \mu_c/a\beta$, this equation can be expressed as the drag coefficient of the solid sphere:

$$C_D = \left(\frac{1+2S}{1+3S}\right)\frac{24}{Re_r}\left(1 + \frac{3}{16}\left(\frac{1+2S}{1+3S}\right)Re_r + \frac{9}{160}\left(\frac{1+2S}{1+3S}\right)^2 Re_r^2 \ln\left(\frac{Re_r}{2}\right) + O\left(Re_r^2\right)\right). \tag{1.116}$$

The last equation reduces to the expression (Equation 1.104) derived by Proudman and Pierson (1956) when there is no slip at the interface ($S \to 0$).

Under rarefied conditions, interfacial slip may occur at higher values of the Re_r. Feng et al. (2012) performed extensive numerical simulations at higher Re_r and derived a correlation for the drag coefficient with slip flow, for S between 0 and ∞, at Reynolds number up to 150:

$$C_D = \frac{1+2S}{1+3S}\frac{24}{Re_r}\left(1+0.1509\sqrt{\frac{1+2S}{1+3S}}Re_r^{0.678} - 0.0254\frac{S}{1+3S}Re_r^{1.104}\right). \tag{1.117}$$

1.4.3.3 Effects of Flow Turbulence

Turbulence in the carrier fluid (free-stream turbulence) implies an unsteady flow field and unsteady motion of particles, bubbles, and drops. For this reason, the effects of the free-stream turbulence are transient flow effects. Numerous experiments on the drag for solid spheres proved that the free-stream turbulence modifies the drag coefficient of particles, sometimes significantly. Typical results of such experiments are reproduced in Figure 1.11 from Clift et al. (1978). It is observed in this figure that when the relative Reynolds number is in the range $10 < Re_r < 500$, the drag coefficient of solid spheres in a turbulent flow is almost always higher than the values of the standard curve. The influence of the free-stream turbulence on the boundary layer around the sphere and the wake behind the sphere is manifested by the sharp changes observed at approximately $Re_r = 50$ and the leveling of the drag coefficient curves at values that are 2–4 times higher than the corresponding values of the standard drag curve. In the range $500 < Re_r < 20{,}000$, the drag coefficient of a sphere is first reduced dramatically in a short range of Reynolds numbers, often reaching a value 50% lower than the value of the standard curve (Clamen and Gauvin, 1969). Then, C_D increases gradually and may reach a maximum, which is two to five times higher than the values predicted by the standard curve. Thereafter, C_D decreases to the values of the standard curve. The sudden dip of the drag coefficients is often attributed to the formation of a turbulent boundary on the surface of the particle. Apparently, the transition, which in the standard drag curve occurs at $Re_r = 3 * 10^5$, is accelerated and occurs earlier when the free stream is turbulent. Clift and Gauvin (1970) introduced the critical Reynolds number for the gaseous boundary layer. This is the relative Reynolds number at which the turbulent transition happens and is given by the following expressions:

$$\begin{aligned} Re_{cr} &= 10^{5.477-15.8I_r} \quad \text{for } I_r \le 0.15 \\ Re_{cr} &= 10^{3.371-1.75I_r} \quad \text{for } I_r > 0.15 \end{aligned}, \tag{1.118}$$

where I_r is the turbulence intensity based on the relative velocity of the sphere. As with all the correlations that involve exponential expressions, the results of the two aforementioned equations must be strictly used within the range of the experimental conditions (Re_r and I_r) for which they were derived.

It must be noted that the experimental uncertainty associated with the results of Figure 1.11 and Equation 1.118 is significant and that there is a considerable discrepancy with the data emanating from the different experimental studies. Part of this uncertainty is inherent in the measurements of unsteady turbulent flows.

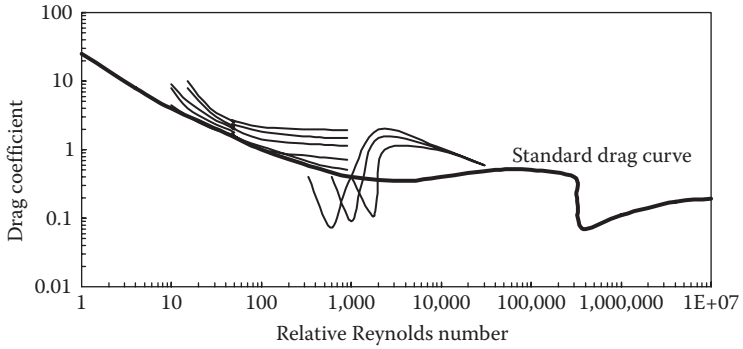

Figure 1.11

The effect of the free-stream turbulence on the standard drag coefficient for a solid sphere.

Another part of the uncertainty stems from the fact that the response of particles in a turbulent flow has been implicitly treated as steady and not as transient process, while it is evident that the response of particles to the turbulent eddies depends strongly on the frequency of the eddies and that the particle movement is transient.

The presence of particles, bubbles, and drops in turbulent flows also has an effect on the intensity and characteristics of the carrier fluid turbulence. This was observed in many relatively recent experimental studies and is called "modulation" or "modification" of the turbulence, regardless of any transition in the boundary layer of the particles. A great deal of work was devoted in the last 30 years on this subject, which is treated extensively in Chapter 12.

1.4.3.4 Blowing Effects

The mass transfer from the surface of a sublimating particle or an evaporating droplet causes an outward radial flow and hence a drastic change in the gaseous boundary layer around the sphere. This flow modification reduces the drag coefficient from the steady value as it is given by the standard curve. The exchange of mass from the particle or droplet to the surrounding fluid causes two significant effects:

1. The change in the viscosity of the surrounding fluid, because of temperature and composition changes
2. A regression of the surface of the droplet, which is associated with the flow of the vapor from the surface to the carrier fluid (Stefan convection)

Yuen and Chen (1976) conducted experiments on the drag force of evaporating drops and on the effect of the change of the transport properties of the carrier fluid as a result of the transfer of mass from the surface of the droplet. They concluded that their results are well represented when a reference viscosity for the carrier fluid is used, the *film viscosity*, which is defined as follows:

$$\mu_m = \mu_s + \frac{1}{3}(\mu_\infty - \mu_s), \tag{1.119}$$

where

μ_∞ is the viscosity of the fluid far from the sphere
μ_s is the gas viscosity on the surface of the sphere

This equation is sometimes referred to as the 1/3 *rule* for the film properties. The experimental data and analysis on the density and viscosity averages by Lerner et al. (1980) confirmed this relationship. The data also suggested that the standard drag curve with the aforementioned correction for the viscosity may be applied to slightly ellipsoidal drops if the equivalent diameter of the ellipsoid, d_V, is used and the two axes of the ellipsoid are within 10% of each other.

Eisenklam et al. (1967) and later Renksizbulut and Yuen (1983) examined the effects of the radial flow and Stefan convection process away from the surface of an evaporating droplet. They recommend that the following correction for the effect of the Stefan convection on the drag coefficient be used in calculations:

$$C_D = \frac{C_{D,0}}{1 + B_M}, \tag{1.120}$$

where $C_{D,0}$ is the value of the drag coefficient in the absence of mass transfer, which is calculated from the correlations presented in Section 1.4.3.2.

The coefficient B_M is the *blowing coefficient* and is based on the mass transfer from the surface of the sphere.

It is defined in terms of the mass fractions of the vapor on the surface and far away from the sphere:

$$B_M = \frac{Y_s - Y_\infty}{1 - Y_s}. \tag{1.121}$$

Chiang et al. (1992) conducted a numerical study of evaporating droplets with variable transport properties and derived a correlation for their drag coefficients, which is valid in the range $30 < Re_r < 200$:

$$C_D = \frac{24.432}{\left(1+B_H\right)^{0.27}\left(Re_m/2\right)^{0.721}}. \tag{1.122}$$

The relative Reynolds number in this case, Re_m, is defined in terms of the gas-film viscosity (Equation 1.119) and the free-stream gas density, $\rho_{f\infty}$. In the last equation, B_H is another blowing coefficient, which is based on the thermodynamic enthalpy of the evaporating fluid:

$$B_H = \frac{h_\infty - h_s}{h_{fg}^{eff}}. \tag{1.123}$$

The effective latent heat of vaporization, in the denominator of the last expression, is the sum of the latent heat of the vapor at the drop surface and the sensible heat conducted to the interior of the drop.

When the radial velocity of blowing, V_n, is known or may be calculated from mass flow rate data, Clift and Lever (1985) used a numerical analysis and derived the following relationship for the drag coefficient:

$$C_D = \frac{24}{Re_r}\frac{1+0.545Re_r+0.1Re_r^{0.5}\left(1-0.03Re_r\right)}{1+ARe_n^B}, \tag{1.124}$$

where Re_n is the blowing Reynolds number based on the radial (normal to the surface) velocity, $Re_n = \rho d V_n/\mu$, and the functions A and B are correlated to Re_r:

$$A = 0.09 + 0.077\exp\left(-0.4Re_r\right) \quad \text{and} \quad B = 0.4 + 0.77\exp\left(-0.04Re_r\right). \tag{1.125}$$

The last two expressions are valid in the ranges $10 < Re_r < 200$ and $1 < Re_n < 20$. At lower values of the Reynolds numbers, $Re_r < 10$ and $Re_n < 1$, the following modification in the function $A(Re_r)$ has been recommended:

$$A = 0.06 + 0.077\exp(-0.4Re_r). \tag{1.126}$$

These correlations and the pertinent studies suggest that the drag coefficient of burning and evaporating droplets departs only slightly from the corresponding values without mass transfer. The blowing effects may be perceived as corrections to the standard drag curve for spheres, caused by the different composition of the gaseous boundary layer and by mass convection from the sphere.

1.4.3.5 Compressibility and Rarefaction Effects

When the carrier gas is rarefied, for example, under conditions that are prevalent in the upper atmosphere, the length of the molecular free path, L_m, is comparable or even greater than the size of the particles or drops. Therefore, the medium surrounding the particle/drop may not be considered to be a continuum, and hence, the hydrodynamic force is not the same as in the case of continuum flows. The Knudsen number,

$$Kn = \frac{L_m}{d}, \tag{1.127}$$

is a dimensionless measure of the relative magnitude of the two length scales. Continuum flows imply that $Kn \ll 1$. Since the molecular free path of a gas is proportional to the ratio of the viscosity divided by the

product of the speed of sound and the gas density ($L_m \sim \mu/c\rho$), it follows that Kn is proportional to the ratio of the Mach number and the Reynolds number ($Kn \sim M/Re$). Schaaf and Chambre (1958) identified four flow regimes to characterize rarefaction flows, and Crowe et al. (1969) showed that, in the case of rocket nozzles, a burning particle or droplet is subjected to all four flow regimes:

1. The *free molecule flow*, where there are no interactions among the molecules and individual molecules collide with the particles exchanging momentum ($Kn > 10$ and $M > 3Re_r$). In this regime, the drag coefficient of a sphere is equal to 2, regardless of the value of the Reynolds number.
2. The *transitional flow*, where the size of the particles is comparable to the size of the mean free path. Since molecules interact by collisions, the collisions between the particles and the molecules create a distinct flow field around the particles. The effect of this flow field and the collisions is manifested on the force exerted by the gas on the particles ($0.25 < Kn < 10$, $0.1\, Re_r^{1/2} < M < 3Re_r$).
3. In the *slip flow* regime, there is a distinct flow field around the particles. The temperature and velocity at the surface of the particle are different from the temperature and velocity on the side of the gas close to the surface ($0.001 < Kn < 0.25$ and $0.01\, Re_r^{1/2} < M < 0.1\, Re_r^{1/2}$). This gives rise to a velocity difference (slip) between the gas and particle velocities at the particle surface. When $Kn < 0.01$, the flow field around the particles may be obtained from the solution of the Navier–Stokes equations with the stipulation of a suitable closure equation for the slip. Equations 1.114 and 1.115 were obtained using the stipulation for the slip velocity $\tau = \beta \Delta u_t$.
4. The *continuum flow* is characterized by the absence of velocity slip on the surface of the particles ($Kn < 0.01$, $M < 0.1\, Re_r^{1/2}$). The no-slip boundary condition applies to the surface of the particles, and the flow field is obtained by the analytical or numerical solution of the Navier–Stokes equations.

It is intuitive that an evaporating droplet or a sublimating particle will pass sequentially through all these flow regimes, starting in continuum flow and ending in the free molecular flow regime. However, under ambient conditions, when $Kn > 0.001$, there is very small mass remaining in the particle or droplet. Under these conditions and typical rates of evaporation, sublimation, and burning, the process passes rapidly through the first three regimes. When treating these processes by a numerical scheme, one has to be cognizant of this fact and to use the timescales and time steps that are appropriate to the processes.

At high Reynolds numbers, the effects of the Mach number on the drag coefficient become significant when $M > 0.6$. This is sometimes called the critical Mach number, and the flow around the particle is characterized by the formation of a shock wave, which increases significantly the form drag of the particle. Hence, the drag coefficient, which does not vary with the Mach number in the range $0 < M < 0.6$, increases rapidly beyond $M = 0.6$; reaches a maximum, which depends on the value of Re but is always greater than 2; and, thereafter, decreases gradually and approaches asymptotically the theoretically predicted value of 2 for free molecular flows (Schaaf and Chambre, 1958). At low Reynolds numbers, an increased Mach number signifies that the flow is rarefied. In this case, there is a shock wave associated with the presence of the particle and the drag coefficient decreases monotonically with M.

In general, the effect of the Knudsen number and the Mach number on the drag coefficient is given by correction factors $f(M)$ and $f(Kn)$. The classic experiment by Millikan (1923) yields the following correction factor for drops in rarefied flows, which is valid in the Stokesian flow regime:

$$f\left(Kn\right) = \frac{24C_D}{Re_r} = \left[1 + Kn\left[1.209 + 0.406\exp\left(-\frac{0.447}{Kn}\right)\right]\right]^{-1}. \tag{1.128}$$

The coefficients in the last equation appear with the corrections made for the more accurate knowledge of the molecular free path for air by Kim et al. (2005). The latter suggests that the three coefficients in the square bracket be 1.165, 0.483, and 0.449, respectively. An assessment of several studies on the subject reveals that these coefficients are approximately 1.15, 0.5, and 0.5 (Michaelides, 2014).

An equation for the drag coefficient, proposed by Crowe et al. (1973) and later simplified by Hermsen (1979), has been applied successfully to burning particles in solid propellant rocket nozzles:

$$C_D = 2 + \left(C_{D,0} - 2\right)\exp\left[-\frac{3.07\sqrt{k}\,g\left(Re_r\right)M}{Re_r}\right] + \frac{h\left(M\right)}{M\sqrt{k}}\exp\left(-\frac{Re_r}{2M}\right), \tag{1.129}$$

where

k is the ratio of the specific heats of the gas

$g(Re)$ and $h(M)$ are the empirical functions

$$g\left(Re\right) = \frac{1 + Re_r\left(12.278 + 0.548Re_r\right)}{1 + 11.278Re_r} \quad \text{and} \quad h\left(M\right) = \frac{5.6}{1+M} + 1.7\sqrt{\frac{T_p}{T_c}}. \tag{1.130}$$

In the last expressions

T_c is the mean temperature of the carrier gas far from the particle

T_p is the temperature of the particle

Alternatively, Carlson and Hoglund (1964) derived the following empirical relationship for the function $f(M)$, which is used in some computations pertaining to particles in shock waves and other compressible flow fields:

$$f\left(M\right) = \frac{1 + \exp\left(-\dfrac{0.427}{M^{4.63}} - \dfrac{3}{Re_r^{0.88}}\right)}{1 + \dfrac{M}{Re_r}\left[3.82 + 1.28\exp\left(-1.25\dfrac{Re_r}{M}\right)\right]}. \tag{1.131}$$

It must be noted that the last three equations are correlations of experimental data and must be used within the range of the independent variables for which the original data have been derived.

1.4.3.6 Transient Flow Effects

Most of the practical applications of dispersed multiphase flows involve time-dependent flows. When the characteristic time of the flow transients is of the same order of magnitude as the response time of bubbles, drops, or particles, a transient equation should be used for the exchange of momentum between the carrier fluid and the dispersed phase. Exact analytical expressions for transient flows have been derived for creeping flow (Stokes flow) conditions ($Re \ll 1$), and asymptotic expressions have been derived for finite but small Reynolds numbers ($Re_r < 1$). Semiempirical expressions, which emanate from a combination of experimental data and analyses, have also been developed and frequently used at high Re_r.

1.4.3.6.1 Creeping Flow ($Re \ll 1$) The so-called Boussinesq–Basset equation,

$$F_i(t) = -6\pi\alpha\mu_c(v_i - u_i) - \frac{1}{2}m_c\frac{d}{dt}(v_i - u_i) - 6\alpha^2\sqrt{\pi\mu_c\rho_c}\int_0^t \frac{d/d\tau(v_i - u_i)}{\sqrt{t-\tau}}d\tau, \tag{1.132}$$

which was independently derived by Boussinesq (1885) and Basset (1888a), is the first equation for the transient hydrodynamic force acting on a solid sphere. The expression applies to creeping flow conditions ($Re \ll 1$), where the inertia terms in the momentum equation of the fluid may be neglected in

comparison to the viscous effects. Maxey and Riley (1983) performed a more detailed analysis for a rigid sphere in an arbitrary nonuniform flow field, whose velocity is given by the functional relationship $u_i(x_i, t)$. The latter is not an arbitrary function, since it must be a solution of the Navier–Stokes equations. Maxey and Riley (1983) obtained the following expression for the equation of motion of a sphere:

$$m_s\frac{dv_i}{dt} = -\frac{1}{2}m_c\frac{d}{dt}\left(v_i - u_i - \frac{a^2}{10}u_{i,jj}\right) - 6\pi a\mu_c\left(v_i - u_i - \frac{a^2}{6}u_{i,jj}\right)$$
$$-\frac{6\pi a^2\mu_c}{\sqrt{\pi\nu_f}}\int_0^t \frac{d/d\tau\left(v_i - u_i - \frac{a^2}{6}u_{i,jj}\right)}{\sqrt{t-\tau}}d\tau + (m_s - m_c)g_i + m_c\frac{Du_i}{Dt}. \tag{1.133}$$

In the last equation

m_s is the mass of the sphere

m_c is the mass of the carrier fluid that occupies the same volume as that of the sphere

The repeated index with comma ($,jj$) denotes the Laplacian operator and the derivative D/Dt is the total Lagrangian derivative following the center of the sphere

All the spatial derivatives are evaluated at the center of the sphere. The left-hand side in this equation represents the acceleration of the sphere. Of the terms on the right-hand side, the first is the steady drag, the second is the added mass (or virtual mass) of the fluid, and third term is the history term. The remaining terms on the right-hand side are the net gravitational or body force and the Lagrangian acceleration term of the fluid. The Laplacian terms in all the parentheses account for the nonuniformity of the fluid velocity field. They are second-order corrections for the curvature of the flow field and are called sometimes the "Faxen terms." These derivatives become zero when the fluid velocity field is uniform. The Faxen terms scale as a^2/L^2, where L is the macroscopic characteristic length of the fluid velocity field, and in most applications of dispersed multiphase flows, where $a/L \ll 1$, they are small enough to be neglected.

It must be noted that the derivation of the last equation is based on the following assumptions:

- Spherical shape
- Infinite fluid domain initially undisturbed
- No rotation
- Rigid sphere ($\mu_f/\mu_s \ll 1$)
- Zero initial relative velocity
- Negligible inertia effects ($Re_r \ll 1$)

If the initial relative velocity is different than zero, the following expression/correction replaces the history term (Michaelides, 2003, 2006):

$$\frac{6\pi a^2\mu_c}{\sqrt{\pi\nu_c}}\int_0^t \frac{d/d\tau\left[v_i - u_i - \frac{a^2}{6}u_{i,jj}\right]}{\sqrt{t-\tau}}d\tau + \frac{6\pi a^2\mu_c[v_i(0) - u_i(0)]}{\sqrt{\pi\nu_c t}}, \tag{1.134}$$

where the quantity $v_i(0) - u_i(0)$ represents the initial relative velocity at time $t = 0$.

Integrodifferential equations, such as (1.133), do not have an explicit analytical solution for the dependent variable (v_i). Since they are implicit in their dependent variable, they must be solved numerically by an iteration method and this requires a great deal of computational resources in both memory and CPU time with repetitive calculations, such as the Lagrangian computations of a large group of particle trajectories. Michaelides (1992) and later Vojir and Michaelides (1994) devised an analytical method to convert such first-order implicit integrodifferential equations to second-order integrodifferential equations, which are explicit in the dependent variables v_i (or T_s in the case of temperature).

For viscous spheres (drops and bubbles) in a carrier fluid, there are two timescales for the motion of the fluid inside the sphere and the motion of the external fluid. For this reason, an analytical expression for the equation of motion, similar to Equation 1.133, is impossible to be derived in the time domain. Galindo and Gerbeth (1993) derived an expression for the hydrodynamic force on a viscous sphere under creeping flow conditions in the Laplace domain, which is as follows:

$$\overline{F_i} = -6\pi a \mu_c \left[\overline{v_i} - \overline{u_i}\right] \left\{ \frac{\chi_c^2}{9} + (\chi_c + 1) - \frac{(\chi_c + 1)^2 f(\chi_s)}{[\chi_s^3 - \chi_s^2 \tanh(\chi_s) - 2f(\chi_s)]\lambda + (\chi_c + 3) f(\chi_s)} \right\}. \tag{1.135}$$

The overbar in the last expression denotes functions in the Laplace domain; χ represents the two dimensionless timescales, also in the Laplace domain,

$$\chi_c = \sqrt{\frac{s\alpha^2}{\nu_f}} \quad \text{and} \quad \chi_s = \sqrt{\frac{s\alpha^2}{\nu_s}} \tag{1.136}$$

and the function $f(\chi)$ is defined as follows:

$$f(\chi) = (\chi^2 + 3)\tanh(\chi) - 3\chi. \tag{1.137}$$

Transient flow with tangential slip at the interface occurs with nanoparticles, submicron-sized drops, and colloidal particles, as well as larger drops and particles in rarefied gases. Michaelides and Feng (1995) performed a study that included the effect of the viscosity ratio, λ, and also allowed for the existence of a finite tangential velocity slip at the interface. The analysis proved that an expression for the complete hydrodynamic force may only be obtained Laplace domain:

$$\begin{aligned} \overline{F^i} = &-6\pi a \mu_c \left[\overline{v_i}(s) - \overline{u_i}(\vec{Y}(t), s)\right] \\ &\times \left\{ \frac{\chi_c^2}{9} + \chi_c + 1 - \frac{(\chi_c + 1)^2 < [\chi_s^3 - \chi_s^2 \tanh(\chi_s) - 2f(\chi_s)]\lambda(\mu/\alpha\beta) + f(\chi_s) >}{[1 + (\mu/\alpha\beta)(\chi_c + 3)][\chi_s^3 - \chi_s^2 \tanh(\chi_s) - 2f(\chi_s)]\lambda + (\chi_c + 3) f(\chi_s)} \right\}, \end{aligned} \tag{1.138}$$

where the variables χ_c and χ_s are the same as in expression (1.134) and β is the same slip parameter that was defined earlier in Equation 1.114 for the steady drag coefficients.

When there is no slip on the surface of the sphere, that is, $\beta \to \infty$, Equation 1.136 reduces to the Galindo and Gerbeth equation (1.133). Remarkably, the case of a sphere with perfect slip, $\beta = 0$, and the case of an inviscid sphere, $\lambda = 0$, are equivalent and result in the same equation of motion. This equation was first derived for an inviscid bubble by Morrison and Stewart (1976) in an implicit integrodifferential form. Therefore, if extremely small particles and drops in the last stages of vaporization/combustion are to be modeled by a continuum approach with finite velocity slip at their interface, then the values of their drag coefficients would be between the theoretical values for the drag coefficients of bubbles and the drag coefficients of rigid particles.

Parmar et al. (2011) examined the effects of fluid compressibility on the transient motion of a solid sphere in a compressible flow. They performed an analytical study at $Re_r \ll 1$ and expressed the effects of the fluid compressibility by a correction function, which depends on Kn and the ratio of the bulk to the dynamic viscosities. In a companion study, Ling et al. (2011a,b) determined the effects of the unsteady terms on the dispersion of small particles in shock waves. The results of the two studies show that the transient term contributions to the hydrodynamic force and heat transfer coefficients of the particles are significant. At the early stages of the blast wave, when particles are traveling in the expansion fan, the gas density surrounding the particles is larger. This makes the transient components of the hydrodynamic force and the rate of heat transfer to be of the same order of magnitude as the steady terms. Consequently, the error from neglecting the transient terms in such applications may become significant.

1.4.3.6.2 Finite but Small Reynolds Numbers Sano (1981) used an asymptotic analysis to derive an expression for the transient hydrodynamic force acting on a rigid sphere at small but finite values of Re_r, when the sphere undergoes a step change in its velocity, from 0 to v_i:

$$F_i(t)=3\pi d\mu_f v_i\left\{H(t^\star)+\frac{1}{3}\delta(t^\star)+\frac{1}{2\sqrt{\pi t^\star}}+\frac{3}{16}Re_r\left[\left(1+\frac{16}{Re_r^4 t^{\star 2}}\right)\operatorname{erf}\left(0.5Re_r t^{\star 1/2}\right)\right.\right.$$
$$\left.\left.+\frac{2}{(\pi t^\star)^{1/2}Re_r}\left(1-\frac{2}{Re_r^2 t^\star}\right)\exp\left(-\frac{1}{4}Re_r^2 t^\star\right)-\frac{8}{3(\pi t^\star)^{1/2}Re_r}\right]+\frac{9}{160}Re_r^2\ln\left(\frac{1}{2}Re_r\right)\right\}+O\left(Re_r^2\right). \quad (1.139)$$

The time variable in this equation is made dimensionless by dividing with a characteristic time based on the properties of the viscous fluid, $\tau_f = a^2\rho_f/\mu_f$. The expression in the square brackets results from the contribution of the outer velocity field and is a consequence of the advective terms in the Oseen equations. For this reason, it has been referred to as the "Oseen contribution." It appears that the most important effect of the higher Re_r on the hydrodynamic force is on the history term. The last term of the Oseen contribution cancels the third term in the right-hand side, $(\pi t)^{-1/2}$. The remaining transient history terms decay exponentially. This rate of decay is faster than the decay of the transient terms of the creeping flow equation. From the physical point of view, this occurs because the finite velocity difference allows for the faster advection and evolution of the vorticity field around the sphere. While in the creeping flow case the vorticity field around the sphere was transported by viscous diffusion alone, which is a slower molecular process, in the case of advection, the finite velocity "carries" the vorticity field far from the sphere with the characteristic velocity of advection. With the faster decay of the transient terms, a spherical particle does not retain any "memory" of its initial velocity, which is characteristic of the $t^{-1/2}$ rate of decay.

Mei et al. (1991) conducted such a numerical study on the motion of a rigid spherical particle in the range $0 < Re_r < 50$ when the free-stream velocity fluctuates with a small amplitude. The results of this study show that, in the low-frequency limit, the history term of the hydrodynamic force decays faster than the conventional $t^{-1/2}$ rate. Subsequently, Mei and Adrian (1992) obtained an analytical solution for the motion of a solid sphere, which is valid at very low frequencies ($Sl \ll Re_r < 1$). Their results revealed a different history term for the hydrodynamic force acting on the particle, which may be written as follows:

$$\int_0^t \frac{(dv_i/d\tau)-(du_i/d\tau)}{\left[\left(\frac{\pi\nu_c}{a^2}(t-\tau)\right)^{1/4}+\left(\frac{\pi}{2a\nu_c}\left(\frac{|u_i(\tau)|}{f_H}\right)^3(t-\tau)^2\right)^{1/2}\right]^2}d\tau, \quad (1.140)$$

where f_H is a function, which has been correlated from the numerical data

$$f_H = 0.75 + 0.105Re_r. \quad (1.141)$$

It is evident that, at short times, this history term matches the asymptotic behavior of the typical history term at creeping flow, $t^{-1/2}$, while at long times the term decays asymptotically as t^{-2}. With this functional form of long-term decay, the sphere does not retain any memory of its initial velocity. Lovalenti and Brady (1993) confirmed this in a more general study on the transient flow of particles.

1.4.3.6.3 High Reynolds Numbers: The Semiempirical Equations While all the known analytical expressions for the transient hydrodynamic force on particles, bubbles, or drops apply to low Re_r, many engineering applications occur at higher ranges of this parameter: slurry transport and practical pneumatic conveying systems operate in the range $10^1 < Re_r < 10^3$; drops in combustion processes may reach Re_r up to 10^3; bubble columns in chemical processes operate in a range of Re_r from 0 to 10^3, depending on the properties of the

carrier fluid; and particulate flows in the environment may reach relative, Re_r, up to 10^4. Since there is no applicable theory, other than some asymptotic studies that only lead to approximate analytical expressions for the hydrodynamic force at $Re_r > 1$, experimental data and empirical correlations have been used for the calculation of the steady as well as for the transient hydrodynamic force and the corresponding drag coefficient.

The steady flow empirical relations for the drag coefficients of a solid or a viscous sphere have been presented in Section 1.4.3.2 and are summarized in the standard drag curve of Figure 1.8. Following the practice used for the steady term, Odar and Hamilton (1964) proposed modifications and correlation functions that extend to the transient terms of the hydrodynamic force. They essentially treated the three terms of the Boussinesq–Basset expression as separate forces and associated each one of them with a correction factor or function that accounts for the higher Re_r. Their equation is

$$F_i = C_1 6\pi a \mu_f (v_i - u_i) + \Delta_A \frac{1}{2} m_f \frac{d(v_i - u_i)}{dt} + \Delta_H a^2 \sqrt{\pi \rho_f \mu_f} \int_0^t \frac{\frac{d(v_i - u_i)}{d\tau}}{\sqrt{t - \tau}} d\tau, \tag{1.142}$$

where the functions C_1, Δ_A, and Δ_H are the empirical functions determined by experiments. Odar and Hamilton used the Schiller and Nauman (1933) correlation for the coefficient C_1 (Equation 1.104) and reduced their experimental data to derive the following expressions for the added mass and history term coefficients:

$$\Delta_A = 1.05 - \frac{0.066}{0.12 + Ac^2} \quad \text{and} \quad \Delta_H = 2.88 + \frac{3.12}{(1 + Ac)^3}, \tag{1.143}$$

where Ac is the dimensionless acceleration number

$$Ac = \frac{|u_i - v_i|^2}{2a\left|\frac{dv_i}{dt}\right|}. \tag{1.144}$$

Bataille et al. (1990) measured independently the added mass coefficient for bubbles and concluded that, within the experimental error of the measurements, the added mass coefficient Δ_A is consistently equal to 1 up to $Re_r = 1000$, even when some of the bubbles are not exactly spherical. Also Auton et al. (1988) and Mei et al. (1991) confirmed analytically that the potential flow solution, which yields the value $\Delta_A = 1$ for the added mass coefficient, is correct and that neither the Reynolds number nor the acceleration number has a significant impact on this term. Based on these analytical and experimental observations, Michaelides and Roig (2011) reinterpreted and recorrelated the original data by Odar and Hamilton (1964) and determined that for $\Delta_A = 1$, the correct expression for the history coefficient is

$$\Delta_{HNEW} = 6.00 - 3.16\left[1 - \exp\left(-0.14 Re_r Sl^{0.82}\right)^{2.5}\right]. \tag{1.145}$$

A more thorough discussion on the use of the semiempirical expressions as well as the results of several other analytical, computational, and experimental studies is that by Michaelides (2003, 2006).

1.4.3.7 Deformable and Irregular Particles

Simple experiments based on sedimentation have shown that the drag coefficients for nonspherical particles are significantly different from those of spheres. Shape factors have been proposed for the quantification of the effect of nonsphericity of particles, bubbles, and drops. Wadell (1933) suggested that the volume-equivalent diameter of a sphere, d_V, or the area-equivalent diameter be used as the characteristic length of

the particles for the determination of the drag coefficient. These two diameters may be given in terms of the volume and the projected area of the irregular particle as follows:

$$d_V = \sqrt[3]{6V/\pi} \quad \text{and} \quad d_p = \sqrt{4A_p/\pi} \tag{1.146}$$

where

V is the total volume of the particle

A_p is the projected area of the particle in the direction of the flow

For the determination of d_p, one must have information on the orientation of the particle during the flow. Wadell (1933) suggested that a shape factor, Ψ, may be defined as a dimensionless measure of the irregularity of the particle:

$$\Psi = \frac{d_V^2}{d_p^2} = \frac{\pi^{1/3}(6V)^{2/3}}{A_p}. \tag{1.147}$$

Since the drag coefficient is defined in terms of the projected area of the particle, the shape factor may be used to correct for the irregular shape of particles according to the following expression:

$$\Psi C_D A = (C_D A)_s. \tag{1.148}$$

The quantity in the parenthesis in the last expression pertains to the characteristics of a sphere, defined in terms of the volume-equivalent diameter, d_V.

While Equation 1.148 may be used as a first approximation for a correction to the steady drag coefficient for particles that are nearly spherical, several other researchers (Haider and Levenspiel, 1989, Hartman and Yates, 1993) determined that when particles are very elongated and the correction factors are very large, this equation introduces significant errors in the determination of the drag coefficient. For this reason, another quantity, the circularity, which is also called surface sphericity, c, was introduced:

$$c = \frac{\pi d_A}{P_p}, \tag{1.149}$$

where P_p is the projected perimeter of the particle in its direction of motion, which is an easier parameter to measure in particles than the projected area. The circularity suffers from the drawback that it yields the same value for some 3D and 2D objects. For example, spheres and disks that fall on their flat sides have the same circularity, while their drag coefficients differ significantly.

Expressions for the drag coefficients of irregular particles have been derived by several researchers for different types and shapes of particles, including Pettyjohn and Christiansen (1948), Masliyah and Epstein (1970), Lasso and Weidman (1986), Haider and Levenspiel (1989), and Hartman and Yates (1993). Each one of these correlations applies to a specific type of particles (e.g., disks, pyramids, prisms) or to a group of shapes. Chhabra et al. (1995) conducted an experimental study and determined the drag coefficients of chains of agglomerates of spheres in viscous fluids at relatively low Reynolds numbers ($Re_r < 2.5$). They concluded that in all cases the drag of the irregular agglomerate is higher (up to 50%) than the drag of a sphere with diameter d_V. Madhav and Chhabra (1995) presented experimental data for the terminal velocity and the drag coefficients of spheres, cylinders, needles, and prisms in the range $1 < Re_r < 400$.

More recently, Tran Cong et al. (2003) performed an experimental study that included several types of irregular particles: spheroids; prisms; star-shaped; H-shaped; elongated bars and cylinders; X-shaped; and cross-shaped. They correlated their data using several suitable functional forms and concluded that the following expression not only correlates the data best but also agrees very well with the correlations of the others:

$$C_D = \frac{24}{Re_r}\frac{d_A}{d_V}\left[1 + \frac{0.15}{\sqrt{c}}\left(\frac{d_A}{d_V}Re_r\right)^{0.687}\right] + \frac{0.42}{\sqrt{c}\left[1 + 4.25\times10^4\left(\frac{d_A}{d_V}Re_r\right)^{-1.16}\right]}. \tag{1.150}$$

This is valid in the ranges $0.15 < Re_r < 1500$, $0.80 < d_A/d_V < 1.50$, and $0.4 < c < 1.0$. These ranges cover most of the irregularly shaped particles in engineering applications.

1.4.3.8 Deformable Bubbles and Drops

Oftentimes, bubbles and drops become spheroidal. Lawrence and Weinbaum (1986, 1988) conducted an analytical study on the transient motion of a rigid spheroid of revolution with small eccentricity, under creeping flow conditions. The results of this study are applicable to bubbles and drops if the internal circulation has negligible effect. The study used essentially the method employed by Maxey and Riley (1983) with the added complexity of domain decomposition to account for the eccentricity and extended to the second-order expansion in terms of ε. The resulting expression for the transient hydrodynamic force on the spheroid is

$$F_i = -6\pi\mu_f a\left[\left(v_i-u_i\right)\left(1-\frac{\varepsilon}{5}+\frac{37\varepsilon^2}{175}\right)+\frac{a}{\sqrt{\nu\pi}}\left(1-\frac{2\varepsilon}{5}+\frac{81\varepsilon^2}{175}\right)\int_0^t \frac{d\left(v_i-u_i\right)/d\tau}{\sqrt{t-\tau}}d\tau\right.$$
$$\left.+\frac{a^2}{9\nu}\left(1+\frac{\varepsilon}{5}-\frac{26\varepsilon^2}{175}\right)\frac{d\left(v_i-u_i\right)}{dt}+\frac{8a\varepsilon^2}{175\sqrt{\pi\nu}}\int_0^t \frac{d\left(v_i-u_i\right)}{d\tau}G\left(t-\tau\right)d\tau\right] \tag{1.151}$$

The function G of the last term is a frequency-dependent term:

$$G\left(t\right) = Im\left[\sqrt{\frac{\pi\phi}{3}}e^{\phi t}erfc\sqrt{\phi t}\right],\ \text{with}\ \phi=\frac{3}{2}\left(1+i\sqrt{3}\right). \tag{1.152}$$

The first three terms of (1.149) are similar to the steady drag, the history, and the added mass term of the Boussinesq–Basset equation. Their form is the same as the form of the corresponding terms of Equations 1.132 and 1.133 with the correction terms due to the eccentricity of the spheroid. However, the last term of Equation 1.151 does not have a counterpart in the Boussinesq–Basset expression. The term depends on the eccentricity as well as the frequency of variation of the velocity of the fluid and vanishes asymptotically as ε^2. This is a new history integral term, which emanates from the elongated shape of the immersed object. The presence of such terms in an equation derived under the creeping flow assumption is another indication that the transient Boussinesq–Basset and Maxey–Riley expressions are significantly modified when there are departures from the assumptions these equations were derived from and which were listed in Section 1.4.3.6. Given that the modifications are on the functional form of these expressions, simple empirical corrections of the three terms of the hydrodynamic force would not be sufficient for the development of the correct transient expressions.

The motion of bubbles and drops in viscous fluids at finite Re_r creates surface stresses that deform the spherical symmetry of these objects. This has a very important effect on the transport coefficients, because the shape of an object is one of the primary determinants of the hydrodynamic force, the heat, and the mass transfer coefficient. The physical properties of the bubbles/drops and the carrier fluid, such as surface tension and viscosity, play an important role in the deformation of the bubbles and drops as well as in the determination of their shapes. For bubbles freely rising in a column of water under the action of gravity, Haberman and Morton (1953) concluded that the following variables determine their shape:

1. The terminal velocity, v
2. The characteristic length, defined as the diameter of the volume-equivalent sphere, d_V
3. The density of the carrier fluid, ρ_f
4. The viscosity of the carrier fluid, μ
5. The surface tension, σ
6. The gravitational acceleration, g

Three independent dimensionless groups may be derived from these six variables:

1. The Reynolds number, $Re = \rho_f d_V v/\mu$, or, equivalently, the relative Reynolds number, Re_r
2. The Eötvös number, $Eo = g\rho_f d_V^2/\sigma$
3. The Morton number, $Mo = g\mu_f^4/\rho_f\sigma^{\,3}$

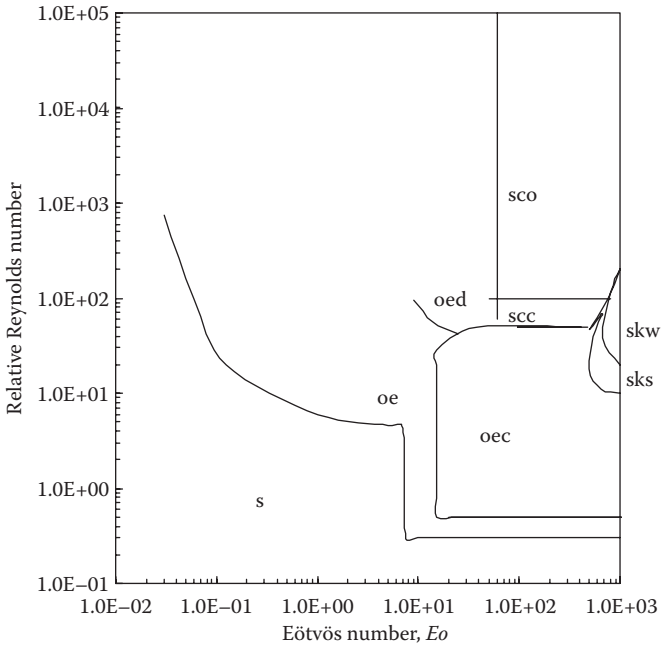

Figure 1.12

The shape map of the deformed bubbles. (Reproduced from the data of Bhaga, D. and Weber, M.E., *J. Fluid Mech.*, 105, 61, 1981.)

Another dimensionless group that appears often in the literature, the Weber number, is defined by the relationship $We = \rho_f v^2 d_V/\sigma$, or $We = Re^2(Mo/Eo)^{-1/2}$.

When experiments are carried in a constant gravitational field, such as laboratories on the Earth's surface, the list of the important variables is reduced to five. This leaves only 2D groups that would determine the shape of bubbles. This pair may be one of the combinations (*Re*, *Eo*), (*Re*, *Mo*), or (*Eo*, *Mo*).

It is standard practice to reduce experimental observations on the shape of bubbles and drops in the so-called shape maps with two of the aforementioned dimensionless groups as coordinates. Such a shape-map has been constructed from the data by Bhaga and Weber (1981) and is reproduced in Figure 1.12. The acronyms on the map are

- s: spherical
- scc: spherical cap with steady, closed wake
- sco: spherical cap with open unsteady wake
- oe: oblate ellipsoidal
- oed: oblate ellipsoidal disk (very elongated and wobbling in motion)
- oec: oblate ellipsoidal with cap in the bottom
- sks: skirted with steady skirt
- skw: skirted with wavy unsteady skirt

It is apparent in this figure that while there is a complexity with the conditions on the shapes of bubbles, in general, bubbles assume the spherical shape at low Reynolds numbers, regardless of the value of the Eötvös number. Also, bubbles are spherical at intermediate values of Re_r, when $Eo < 1$. Bubbles become ellipsoidal at intermediate values of Eötvös numbers and high Re_r. Finally, bubbles assume the shape of a spherical cap at high *Eo* and at relatively high Re_r.

While a shape map, such as that given earlier, which represents static or steady conditions, is useful in determining the shape of flowing bubbles, recent experimental studies on the subject suggest that the method of the creation and release of bubbles also affects their shape, their drag coefficients, and their trajectories. Tomiyama (2001) observed that when bubbles are released with small initial deformation, their shape remains very close to spherical, their drag coefficient is higher than expected, and their motion is rectilinear or zigzag on a plane. However, when the bubbles are released with high initial deformations as ellipsoids,

their shape continues to be ellipsoidal, their drag coefficient is higher, and their motion is helical or rectilinear. In a similar study, Wu and Gharib (2002) also concluded that the initial method of the release of bubbles (whether they are released from a narrow or from a wide tube) plays a role in the eventual shape, the rise velocity, and the drag coefficient. Apparently, the shape oscillations that occur after a bubble is detached from the nozzle are strong enough to disperse the contaminants and to render the bubble surface clean, at least in the initial stage of the bubble trajectory. In most practical cases, the surrounding water contains a sufficient concentration of contaminants for the bubble surface to become immediately contaminated. However, in the case of very pure systems such as the ones used in the study by Wu and Gharib (2002), the recontamination process of the surface was very slow, the bubbles' surface remained clean for the duration of the experiment, and the bubbles remained spherical at significantly higher values of Re_r.

The drag coefficient of inviscid spheres (bubbles) is of importance in practical applications, such as boiling, aeration, and water purification. In this case, the surfactants and contaminants in the water that finally line up on the interface of the bubble and the carrier fluid also play an important role in the determination of the drag coefficient of bubbles. Among the various studies on the drag coefficients, Tomiyama et al. (1998) studied the rise of bubbles in a wide range of Reynolds and Eötvös numbers and derived the following expression for the drag coefficients of clean uncontaminated bubbles:

$$C_D = \max\left\{\min\left(\frac{16}{Re_r}\left(1+0.15Re_r^{0.687}\right), \frac{48}{Re_r}\right), \frac{8Eo}{3Eo+12}\right\}. \tag{1.153}$$

This expression is consistent with the correlations of the numerical data that were given in Section 1.4.3.2, Equations 1.107 through 1.112. It must be noted that when the bubbles become bigger, their shape becomes ellipsoidal. Consequently, the drag coefficient of bubbles depends strongly on the surface tension, which is a determinant of their shape. In the case of elongated bubbles, their drag coefficient is independent of Re_r and is given by the last expression in Equation 1.153, which is a simple function of the Eötvös number. This expression is valid for fairly large hemispherical bubbles, up to 3 cm in diameter.

Because the surfactants in the gas–fluid interface play a major role in the friction part of the drag force and contaminants/surfactants accumulate on this interface, the degree of contamination of the liquid is an important factor in the determination of the drag coefficient of bubbles. The data by Sridhar and Katz (1995) suggest that small bubbles in filtered water, which may be characterized as *contaminated*, behave as solid spheres, and their drag coefficients are very well correlated by the Schiller and Nauman (1933) expression (Equation 1.104) up to $Re_r = 85$. In the case of *grossly contaminated* bubbles, such as those involving tap or industrial water, Loth (2000) recommends the Oseen expression (Equation 1.102) for $Re_r < 1$ and the following expressions, which are based on data from Clift et al. (1978):

$$C_D = \frac{24}{Re_r}\left(1+0.1935Re_r^{0.6305}\right), \quad 1 < Re_r < 78 \quad \text{and} \quad C_D = \frac{24}{Re_r}\left(1+0.03875Re_r\right), \quad 78 < Re_r < 300. \tag{1.154}$$

Beyond this range of Re_r, it is very likely that the bubbles are not spherical, and hence, their shape is the major factor that influences the drag coefficient. It must be noted that the drag coefficient expressions for *clean* and *grossly contaminated* conditions may be considered as the lower and the upper limits for the drag coefficients of bubbles. The actual value of the drag coefficient of bubbles is expected to be between these two limits.

1.4.3.9 Lift Effects and Transverse Forces

The drag force is always acting in the direction of the motion of the particle, and its magnitude is monotonically increasing with the relative velocity of the sphere. Particle rotation combined with finite relative velocity or fluid velocity gradients (shear) induces a transverse component in the hydrodynamic force on the sphere, which is often called the "lift force."

When the rigid, spherical particle travels in an inviscid fluid with a relative velocity and also rotates with respect to the far field of the flow, the velocity asymmetry around the particle induces a transverse pressure difference on the surface of the sphere, which generates the *Magnus force* (Magnus, 1861):

$$F_{LMi} = \pi\alpha^3\rho_f[e_{ijk}\Omega_j(u_k - v_k)], \tag{1.155}$$

where Ω_j is the relative rotation of the particle with respect to the inviscid fluid. The term in the square brackets represents the vector product of the relative rotation and the relative velocity vectors. It is apparent that the direction of the Magnus force is perpendicular to the plane of the relative velocity and the axis of rotation.

The functional form of the lift force in a viscous fluid is influenced by the Reynolds number. In this case, the magnitude of the lift force is often expressed as a function of a dimensionless *lift coefficient*, C_{LM}, which is correlated with experimental data. While many expressions have appeared in the past, the investigation by Oesterle and Bui-Dinh (1998) appears to be based on accurate data and is recommended to be used for the lift coefficient of a sphere rotating in an infinite fluid:

$$C_{LM} = \frac{\left|\vec{F}_{LM}\right|}{\pi\alpha^3\rho_c\left|\vec{\Omega}\right|\left|\vec{u}-\vec{v}\right|} = 0.45 + \left(\frac{Re_R}{Re_r} - 0.45\right)\exp\left(-0.05684 Re_R^{0.4} Re_r^{0.3}\right) \quad \text{for } Re_R < 140, \tag{1.156}$$

where Re_R is the Reynolds number based on the relative rotational speed of the sphere

$$Re_R = \frac{\rho_f d^2\left|\vec{\Omega}\right|}{\mu_c}. \tag{1.157}$$

The lift coefficient is, in general, a monotonically decreasing function of Re_R and increases with the dimensionless *rotation parameter*, $(|\vec{\Omega}|d)/(|\vec{u}-\vec{v}|)$. This is a dimensionless measure of the rotational speed of the particle. Experiments at low values of the rotation parameter suggest that C_{LM} may become negative (Tanaka et al., 1990). This is most likely due to a higher relative velocity on one side of the sphere and a premature transition to turbulence of the boundary layer on that side. As a consequence, the wake behind the sphere deflects in a direction that is opposite to what is expected in rotating flow. This reverses the direction of the lift force.

Saffman (1965, 1968) considered the case of a very small sphere in a shear flow at the limit of vanishing Reynolds numbers (creeping flow). He derived an expression for the lift force due to shear, which is

$$\vec{F}_{LS} = \frac{6.46\alpha^2\sqrt{\rho_c\mu_c}}{\sqrt{|\vec{\gamma}|}}\left(\vec{u}-\vec{v}\right)\times\vec{\gamma}, \tag{1.158}$$

where $\vec{\gamma}$ is the fluid velocity shear evaluated at the center of the sphere. The direction of this force is the perpendicular direction to the plane defined by the relative velocity vector and the shear vector. Sufficient conditions for the validity of the aforementioned expression are very low Re_r as well as:

$$\left|\vec{v}-\vec{u}\right| \ll (\gamma\nu)^{1/2}, \quad \gamma a^2/\nu \gg 1 \quad \text{and} \quad a^2\left|\vec{\Omega}\right|/\nu \ll 1. \tag{1.159}$$

The last three conditions imply one of the following alternatives:

- **a.** Either very low particle velocity, shear, and angular rotation for the particle
- **b.** Extremely high kinematic viscosity for the fluid if the particle has finite velocity, shear, or angular rotation

The first alternative is compatible with the assumptions implied in the derivation of the transient Basset–Boussinesq equation. The second alternative implies very high viscosity in combination with finite shear or rotation and is not strictly compatible with the implied conditions of the transient equation. It must be noted that although Saffman's result (Equation 1.158) is occasionally referred to as the "Saffman force," it is not a separate force from the *Magnus force* but a special case of the latter at the limit $Re_r \to 0$. For this reason, the lift force must be only accounted once in computations of particle dynamics.

The lift force developed on a sphere is very much weaker than the longitudinal drag force. However, the transverse lift plays a dominant role in the lateral migration of bubbles, drops, and particles toward the walls

of cylindrical pipes as well as in dispersion processes. This occurs because in most engineering systems particles, bubbles, and drops have to travel relatively very short distances in order to approach the walls of a pipe or a channel and, hence, a weak force would be sufficient to induce a lateral motion that covers such short distances. These weak transverse forces contribute significantly to radial diffusion and dispersion, wall deposition, mixing, and separation processes.

Tsuji et al. (1985) measured experimentally the shear-induced lift on bubbles and concluded that the expression by Saffman yields satisfactory results for the magnitude of the force. McLaughlin (1991) extended the theoretical analysis by Saffman to higher Re_r and derived a correction to the expression by Saffman, which shows that the magnitude of F_{LS} decreases with the increase of Re_r. McLaughlin's expression for the lift force is as follows:

$$F_{LS} = \frac{9}{\pi}\mu_f a^2 |\vec{v} - \vec{u}| \sqrt{\frac{\gamma \rho_f}{\mu_f}} J(\varepsilon), \tag{1.160}$$

where ε is the dimensionless velocity ratio $\varepsilon = \sqrt{\gamma \mu_f / \rho_f} / |\vec{v} - \vec{u}|$ and the function $J(\varepsilon)$ is given in tabular form by McLaughlin (1991). Two approximate asymptotic expressions for this function are $J(\varepsilon) = 2.255 - 0.6463/\varepsilon^2$ for $\varepsilon \gg 1$ and $J(\varepsilon) = 32\pi^2\varepsilon^5 \ln(\varepsilon^{-2})$ for $\varepsilon \ll 1$.

The numerical results for the shear lift force exerted on a sphere obtained by Dandy and Dwyer (1990) were reduced to a useful correlation by Mei (1992):

$$\begin{aligned} &C_{LS} = \frac{F_L}{6.44\rho_f a^2 \gamma^{1/2} \nu^{-1/2}} = \left(1 - 0.3314\sqrt{\beta}\right)\exp\left(-\frac{Re_r}{10}\right) + 0.3314\sqrt{\beta} \quad \text{for } Re_r \le 40 \\ &C_{LS} = 0.0524\sqrt{\beta Re_r} \quad \text{for } Re_r > 40, \\ &\text{where} \quad \beta = \frac{d|\nabla \times \vec{u}|}{2|\vec{u} - \vec{v}|}. \end{aligned} \tag{1.161}$$

The parameter β in the last equation is a dimensionless measure of the shear. The recommended range of this correlation is $0.005 < \beta < 0.4$, and Mei (1992) showed that this empirical equation fits well McLaughlin's results.

There is no widespread agreement on the magnitude of the lift coefficients. The experimental results by Sridhar and Katz (1995) suggest that at least for bubbles, the magnitude of the lift component of the hydrodynamic force is higher than the values predicted by the two aforementioned expressions. Another experimental study by Tomiyama et al. (1999) for bubbles in shear flows concluded that the lift coefficient of larger bubbles depends on the surface tension too and included the Eötvös number in the correlation. Tomiyama et al. (1999) also concluded that rising bubbles tend to accumulate close to the walls if their radii are less than 6 mm, while bigger bubbles with $a > 6$ mm migrate toward the center of the apparatus.

The lift of growing or receding bubbles and drops close to a wall is very important in the boiling, condensation, and evaporation processes, because the global rate of the heat transfer greatly depends on the amount of vapor in contact with the wall or in the immediate vicinity of the wall. In convective boiling systems, such as heated pipes, the lift due to shear facilitates the detachment of small spherical bubbles from the wall and subsequently the nucleation and the commencement of the growth process of other bubbles. Thorncroft et al. (2001) studied the growth and detachment of bubbles from a surface and concluded that the growth of a bubble, whose radius is a function of time, $a(t)$, close to a wall enhances the lift force exerted by the shear. In their analytical and computational study, Thorncroft et al. (2001) derived the following expression for the lift, due to the shear:

$$F_{SLi} = \frac{1}{2}|\vec{u} - \vec{v}|(u_i - v_i)\pi\rho_f a^2(t)\gamma^{1/2}\left\{\left[\frac{1.46J}{Re_r^{1/2}}\right]^2 + \left[\frac{3}{4}\gamma^{1/2}\right]^2\right\}^{1/2}, \tag{1.162}$$

where J is a scalar function of the dimensionless shear rate and Re_r. The augmented lift force in this case facilitates the detachment of the bubble from the wall, reduces the amount of vapor close to this wall, and thus contributes to the enhancement of the heat transfer from the wall to the bulk fluid.

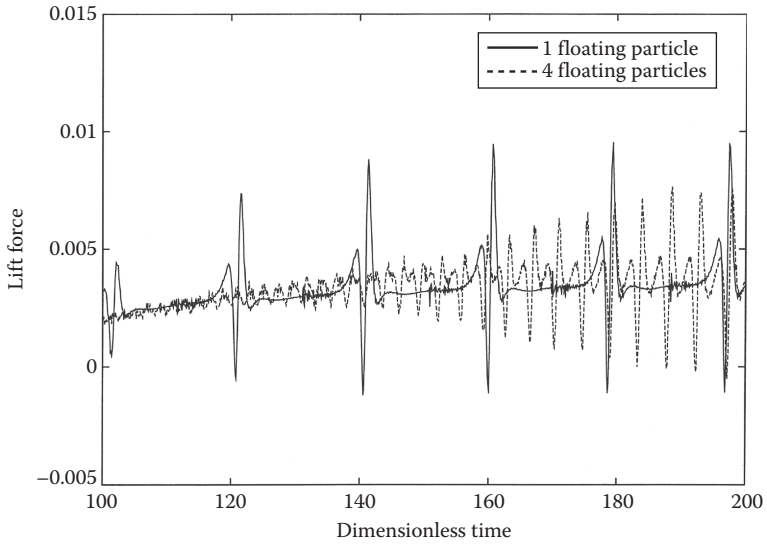

Figure 1.13

The effect of the flow of suspended particles on the lift and drag on a stationary particle.

The transverse force on particles is also influenced by the advection of other particles in the flow. The shear-induced lift on solid spheres attached or deposited on a boundary, in the presence of other spheres in the flow field, known as suspension flow, was studied numerically by Feng and Michaelides (2002a). Their results show that the instantaneous hydrodynamic force exerted by the suspension flow on a solid particle attached to a wall is increased by a factor of 2–4 by the presence of similar particles, which are carried by the fluid. This effect is depicted in Figure 1.13, which shows the instantaneous lift on an embedded sphere, when other spheres in the suspension pass by it. This augmentation includes both the lift and the drag components of the hydrodynamic force and is caused by the interactions of the suspended spherical particles with the stationary particle when they are in the range of 0–5 diameters. As a result of this type of hydrodynamic interaction, a particle that lies on a horizontal plane may be lifted and become part of the suspension flow without any physical collisions with other particles.

Regardless of the method of evaluation of the lift component, the ratio of the transverse component to the longitudinal component of the hydrodynamic force, F_L/F_D, is of the order of $d(\gamma/\nu)^{1/2}$, which is typically a very small number. Despite this, the transverse component of the hydrodynamic force is important in engineering because it causes the lateral migration and dispersion of spheres and plays an important role in several applications, such as bubble detachment from the pipe walls during boiling, particle sedimentation, and resuspension in water as well as particulate and aerosol dispersion in the atmosphere. The accurate knowledge of the transverse component of the transient hydrodynamic force is of importance in calculations that pertain to such processes, even though the method of the determination of the drag component is not fully compatible with the assumptions used for the determination of the lift. It is common practice in such calculations to superpose an expression for the transverse or lift component, such as Equation 1.153 or Equation 1.158 with an expression for the transient hydrodynamic force in the longitudinal direction, such as Equation 1.133, and compute the longitudinal and transverse motion of particles, bubbles, and drops. The result of such a superposition is that the transient hydrodynamic force on a sphere appears to have a lateral, albeit steady, component in addition to the longitudinal component. Although the superposition is not justified on analytical grounds, it is very convenient to use and the results obtained appear to be accurate. When one uses this superposition, it is important to ensure that the necessary conditions for the validity of the expressions used for the several components of the hydrodynamic force are not violated. This implies that there is very low relative velocity and that the local shear is low.

The influence of mass transfer from the sphere (evaporation or sublimation) on the lift has been investigated experimentally and numerically. A numerical study by Kurose et al. (2003) determined that in linear shear flow, the outflow from a sphere acts in a way to push the sphere toward the lower flow velocity side. Thus, a negative lift is developed at high Reynolds numbers. This counteracts the positive lift on the sphere, which is directed toward the higher velocity side. According to Kurose et al. (2003), the diffusion

and reaction rates are strongly affected by the outflow velocity and the fluid shear because of the deformation of the vortices that appear behind the evaporating sphere. This suggests that surface evaporation and/or reaction influences significantly the lateral motion of drops and hence the concentration field of the drops.

1.4.3.10 Effects of the Boundaries

The effect of a wall, in general, is to retard the motion of particles in both the parallel and the perpendicular direction to the wall, thus reducing the rate of mass transport. In addition, the presence of particles and bubbles in boundary layers and mixing layers significantly modifies the stability and transport properties of these layers. The motion of particles, bubbles, and drops in the vicinity of a boundary is important in many practical applications especially those related to boiling of liquids and the transport of particulates and slurries. In particulate transport processes, particle collisions with the walls cause pipeline erosion and particle adhesion to the walls, scale buildup, and oftentimes pipeline clogging.

Faxen (1922) was the first to consider the motion of a particle in rectilinear motion parallel to a wall and to derive an expression for the hydrodynamic force on a spherical particle. He used the method of reflections for the movement of the sphere under creeping flow conditions and obtained an asymptotic solution for the total force acting on a sphere, which settles along the centerline of an orthogonal cylinder. The ratio, Ξ, of the particle diameter, d, to the diameter of the cylinder, D, ($\Xi = d/D$) is the most important parameter that affects the hydrodynamic force. Faxen's expression for the hydrodynamic force is given in terms of a wall drag multiplier, K_{wall}. This is the ratio of the steady hydrodynamic force to the Stokesian force the same sphere experiences in an unbounded flow. By using the same method, Bohlin (1960) obtained a higher-order approximation for the wall drag multiplier, which may be written as follows:

$$K_{wall} = \frac{1}{1 - 2.01443\Xi + 2.088777\Xi^3 - 6.94813\Xi^5 - 1.372\Xi^6 + 3.87\Xi^8 - 4.19\Xi^{10} + \cdots}. \tag{1.163}$$

Haberman and Sayre (1958) developed a theoretical method to compute the wall correction factor, K_{wall}, for spheres settling in cylinders up to very high values of Ξ, and later Paine and Scherr (1975) computed the values for K_{wall}. Their results are tabulated in the range $0 \leq \Xi \leq 0.9$. A comparison between the expression by Bohlin (Equation 1.160) and the exact theory by Haberman and Sayre (1958) shows that the last equation yields accurate results only up to $\Xi = 0.6$. There are also several experimental studies pertaining to the settling of a sphere along the centerlines of orthogonal circular cylinders or plane walls. Among them, the experimental studies by Iwaoka and Ishii (1979) and Miyamura et al. (1981) demonstrate good agreement with the theoretical predictions by Faxen (1922), Bohlin (1960), and Paine and Scherr (1975).

Happel and Brenner (1986) considered creeping as well as inertia flows for the settling of a sphere in a cylinder and stipulated that the total effect on the hydrodynamic force is a simple linear combination of the separate effects of proximity to the outside boundary and inertia:

$$K = K_{wall} + K_{inertia} - 1, \tag{1.164}$$

where

K_{wall} is the effect of the wall at creeping flow conditions as calculated by an expression similar to (1.160)
$K_{inertia}$ is the additional correction factor due to inertia at higher Re_r

The last equation simply implies that the drag on a sphere is composed of two additive terms: one term is due to the effect of the cylindrical boundary and the other to flow inertia. The latter is usually obtained from one of the empirical correlations for the drag coefficient at higher Re_r, such as the one by Schiller and Nauman (1933). Equation 1.164 is a conjecture, partly based on the experimental data by Fayon and Happel (1960). The data set pertains to a diameter ratio, Ξ, in the range of 0.1250–0.3125 and the Reynolds numbers in the range 0.1–40.

Feng and Michaelides (2002b) conducted a more general numerical study in the ranges $0.1 < \Xi < 0.8$ and $0 < Re_r < 35$ for cylindrical as well as for prismatic enclosures. They concluded that the two effects of inertia and of flow confinement are not additive and may not be linearly combined as Equation 1.164 implies. Because of this, in calculating the hydrodynamic force on a sphere, it is more accurate to use computational and experimental results, which are not restricted by the conjecture (1.161). One of the significant results by Feng and

Table 1.2 Wall Correction Factors for Various Orthogonal Rectangular Prisms

$L/W = 1.0$								
$\Xi(=d/W)$	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9
K	1.72	2.30	3.18	5.01	8.03	13.98	27.9	61.8
$L/W = 1.5$								
$\Xi(=d/W)$	0.3	0.4	0.5	0.6	0.7	0.8		
K	1.90	2.47	3.32	4.46	6.11	9.24		
$L/W = 2.0$								
$\Xi(=d/W)$	0.3	0.4	0.5	0.6	0.7	0.8		
K	1.73	2.12	2.67	3.33	4.37	5.76		
$L/W = 5.0$								
$\Xi(=d/W)$	0.3	0.4	0.5	0.6	0.7	0.8		
K	1.53	1.75	2.11	2.48	3.06	3.78		

Michaelides (2002b) is that at the higher values of the parameter, $\Xi > 0.5$, the effect of inertia is less than 10% of the total correction factor, K. Table 1.2, which is reproduced from this study, shows the total correction factor, K, for a sphere of diameter, d, when it falls in a rectangular prismatic enclosure whose cross section has length, L, and width, W. The results shown are for $Re_r \ll 1$.

It must be noted that the effect of boundaries on settling spheres is different in the case of prismatic enclosures than in circular cylinders, because secondary flows are induced in the corners of the prisms. Even though the secondary flows are relatively weak, they affect considerably the hydrodynamic force on the spheres.

The asymmetrical velocity and pressure fields due to walls cause the radial migration of particles in pressure-driven flows in pipes and small capillaries away from the wall. Cox and Brenner (1967) expressed the effect of a vertical wall on a particle using the concept of a *migration velocity* of a sphere that is falling freely close to a wall. An analytical expression for the migration velocity is as follows:

$$V_r = \frac{6\pi V_t^2}{\nu} I_h, \tag{1.165}$$

where

V_t is the terminal velocity of the sphere in a stagnant, unbounded fluid

I_h is an integral of Green's function for the point force representing the sphere

The last expression is valid under the conditions $Re_r \ll a/l_w \ll 1$, where l_w is the distance of the center of the sphere from the wall. The implications of this condition are that the sphere is relatively far from the wall and the flow field is Stokesian (creeping flow). Later, Cox and Hsu (1977) calculated analytically the integral, I_h, for spheres and derived the following expression for the migration velocity:

$$V_r = \frac{3}{64} Re_r V_t, \tag{1.166}$$

which is also valid under the condition $Re_r \ll a/l_w \ll 1$. A close look at the last expression reveals that the migration velocity of the sphere is independent from its distance from the wall. This does not constitute a paradox, because the expression is valid only at distances sufficiently far from the wall as required by the condition $a/l_w \ll 1$.

Vasseur and Cox (1976) derived analytically another expression for the lateral migration velocity of a sphere:

$$V_r = \frac{3}{8}\frac{\alpha v_s^2}{\nu}\left[\left(\frac{\nu}{l_w V_t}\right)^2 + 2.219\left(\frac{\nu}{l_w V_t}\right)^{5/2}\right]. \tag{1.167}$$

The terms in the two parentheses are obviously the inverse of a Reynolds number, which is based on the distance of the center of the sphere from the wall. The last expression was later confirmed by the experimental data of Cherukat and McLaughlin (1990) to be valid up to $Re_r = 3.0$.

The repulsive effect of the wall on particles is very important in the distribution of phases in dispersed flows in pipes as well as in sedimentation–resuspension processes with particles. The effect has been demonstrated in a number of experimental and numerical studies, such as the one by Segre and Silberberg (1962) with neutrally buoyant spheres. They concluded that neutrally buoyant particles in a pressure-driven Poiseuille flow (pipe flow) experience a radial force and tend to align at 0.6 pipe radii away from the centerline. This shows that there exists an equilibrium position, where the radial force is zero and where particles tend to accumulate. Two-dimensional numerical studies have also concluded that there is an equilibrium position for cylinders at a distance of 0.4234 half-channel width away from the centerline. Inamuro et al. (2000) concluded that this distance is the same for both a single cylinder and a group of naturally buoyant cylinders in pressure-driven channel flows. Mortazavi and Tryggvason (2000) also studied the lateral migration of 2D drops in Poiseuille flows and determined that drops either move halfway between the pipe centerline and the wall, as Segre and Silberberg (1962) also observed, or they oscillate around an off-center equilibrium position. In a study involving the resuspension of particles in simple shear flow over a flat plate, Feng and Michaelides (2003) concluded that particles, which are slightly heavier than the fluid, do not settle down on a flat surface, but reach an equilibrium position at a certain height from the plane and then drift with the main flow at this vertical position without settling. Their numerical results are shown in Figure 1.14, where the lower facing triangles denote particles that settled under gravity and the upper facing triangles denote particles that drifted at a vertical equilibrium distance. The dividing line separates the settled particles from the particle that reach the equilibrium position, which is usually at a height less than a single diameter from the flat surface. Feng and Michaelides (2003) derived the following expression for the line that separates the settled from the suspended particles:

$$Re_\gamma = \frac{\rho_f \gamma d^2}{\mu_f} = 58\left[\frac{\rho_s}{\rho_f} - 1\right]^{0.59}. \tag{1.168}$$

At a given shear Reynolds number heavier particles settle, while lighter particles move to an equilibrium position and stay suspended in the flow, even though they may be heavier than the fluid. Patankar et al. (2001) also examined the behavior of particles close to the wall in a Poiseuille flow and observed a similar

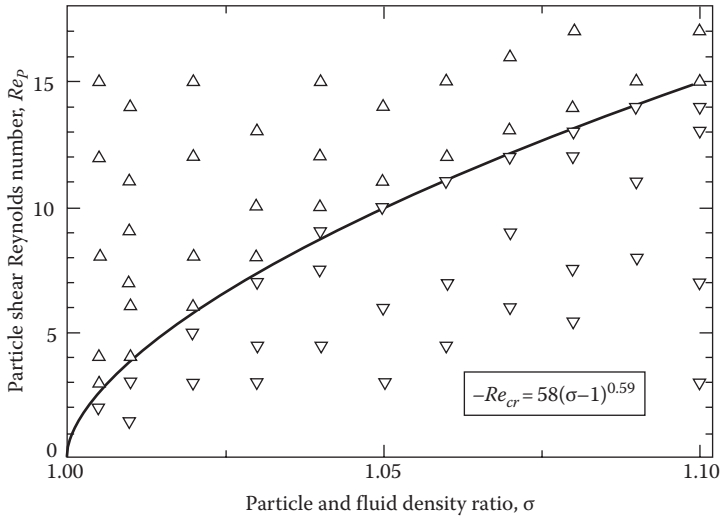

Figure 1.14

Settling or suspended particles with the density ratio and Reynolds number as parameters. The symbol Δ is for suspended and ∇ is for settled particles.

behavior for the particles. They developed a corresponding expression for Re_γ and the density ratio, which may be written as follows:

$$\frac{\rho_s}{\rho_f} - 1 = 2.3648 \frac{\mu_f^2}{d^3 \rho_f^2 g} Re_\gamma^{1.3904}. \tag{1.169}$$

Equation 1.168 applies to shear flows over flat plates, while (1.167) applies to pipes and channels, where Poiseuille flows are more likely to occur. It must be noted that neither of the last two equations takes into account turbulence in the flow nor turbulent bursts that result in the advection of particles and the resuspension of groups of particles.

Walls also retard the movement of spheres that travel perpendicular to them. Regarding these flows, Brenner (1961) obtained asymptotically a first-order correction for the drag coefficient of a small rigid sphere moving toward the wall and concluded that the Stokes drag coefficient, f, increased by a factor:

$$f = \frac{C_D}{24/Re_r} = 0.625 \left(\frac{d}{l_w} \right)^{-1}, \tag{1.170}$$

where l_w is the distance from the center of the sphere to the wall. Brenner's results indicate that the hydrodynamic force on the particle increases dramatically when the particle approaches very closely the wall. This is related to the thin fluid layer that develops between the particle and the wall. Draining such thin layers, where viscous effects dominate, is a very slow process. In this case, the hydrodynamic force opposing the motion of the sphere becomes very large and the particle velocity drops significantly. The study by Kalio (1993) indicates that the influence of the wall on the drag of the particles is important when the particle is within 20 diameters from the wall. The experimental and computational study by ten Cate et al. (2002) confirmed this rapid and significant increase in the drag coefficient of settling spheres, which are within one diameter from a horizontal wall.

It must be pointed out that the analytical expressions of all transverse components of the hydrodynamic force and of the effect of the walls on the motion of a sphere are not based on a rigorous derivation of the transient equation of motion, but on specific analytical, experimental, and numerical studies, most of which were performed at steady flow conditions. One has to be aware that the rectilinear transient equations of motion mentioned in Section 1.4.3.6 implicitly assume that there is no rotation of the sphere, no significant shear in the flow, and the sphere is in an unbounded fluid, which essentially means far from any wall or other boundary. The addition of the lift or of any wall effect on a rigorously derived transient equation for the rectilinear motion of a particle must be viewed as an *ad hoc* assumption. Such assumptions are frequently used, because practice has shown that they produce reliable results on the average movement of particles. It must be remembered, however, that such assumptions, even though justified by validation with experiments or other means, have practical limitations.

1.4.3.11 Thermophoresis and Turbophoresis

When particles, bubbles, or drops are present in a fluid where a temperature gradient is applied, they experience molecular impulses that are stronger on the side of higher temperatures. This induces stronger Brownian motion in the hotter regions of the flow domain than in the colder ones. As a result, the particles, on the average, migrate to the colder regions of the flow domain, as was first observed by Tyndal (1870). A constant temperature gradient creates the steady average movement of an ensemble of particles, bubbles, and drops to the colder regions of the flow domain, a phenomenon called "thermophoresis." The latter is expressed quantitatively in terms of a thermophoretic velocity, v_{tp}, or of a thermophoretic force, F_{tp} (Epstein, 1929, Brock, 1962, Talbot et al., 1980). The directions of the thermophoretic force and thermophoretic velocity are opposite to the temperature gradient, and their magnitudes are

$$v_{tp} = -K_{tp} \frac{\mu_f}{\rho_f} \frac{\nabla T}{T_\infty} \quad \text{and} \quad F_{tp} = -6\pi\mu_f^2 \alpha K_{tp} \frac{\nabla T}{\rho_f T_\infty}. \tag{1.171}$$

The function K_{tp} depends on the Knudsen number, $K_{tp}(Kn)$, and on the properties of the fluid and the solid particles. By considering the velocity slip as well as a temperature slip of particles in gases, the

following expression for K_{tp}, in terms of the thermal conductivities, and the Knudsen number, Kn, was derived by Brock (1962):

$$K_{tp} = \frac{2C_s\left(k_f + 2k_s Kn\right)}{(1+6C_m Kn)(2k_f + k_s + 4k_s C_t Kn)}. \tag{1.172}$$

The parameters C_s, C_m, and C_t are determined empirically from the flow field around the particles and the discontinuities on the fluid–particle interface. Talbot et al. (1980) used the velocity slip expression that was recommended by Millikan (1923) and derived empirical correlations for these parameters. Experimental data and engineering practice have shown that reasonable results may be obtained by treating these parameters as constants with the numerical values for gases $C_s = 1.17$, $C_m = 1.14$, and $C_t = 2.18$ in the range $Kn < 0.1$. For liquids, McNabb and Meisen (1973) showed that the magnitude of the thermophoretic force is much lower, approximately 17% of the values predicted by Equations 1.171 and 1.172.

However, a disadvantage of the last two equations becomes obvious: when the equations are used for liquids with highly conducting particles (nanofluids), the thermophoretic velocity becomes vanishingly small, because $K_n \ll 1$ and $k_f \ll k_s$ for typical nanofluids. Since thermophoresis is a consequence of the Brownian movement, its effects are significant in very small particles, bubbles, and drops in the submicron range and becomes insignificant for larger particles of mm sizes. Michaelides (2015) used a stochastic Lagrangian method to derive the functional relationship for the dimensionless thermophoretic coefficient of spherical particles K_{tp} that appears in the last two equations:

$$K_{tp} = A\left(\frac{\alpha}{\alpha_0}\right)^{-B} \Rightarrow v_{tp} = -A\left(\frac{\alpha}{\alpha_0}\right)^{-B} \frac{\mu_f}{\rho_f T_\infty}\nabla T, \tag{1.173}$$

where $\alpha_0 = 1$ nm appears to correlate well all the combinations of particle types and base fluids. One of the advantages of the last expression is that it has been derived specifically for liquids, where typically $K_n \ll 1$ and applies to all types of spheres including the highly conducting spheres of nanofluids. The pairs of coefficients (A, B) for 20 common combinations of particles and fluids used in nanofluids are given in Table 1.3.

It must be noted that an implicit assumption of Equation 1.171 and all similar expressions of thermophoresis is that the effect of a temperature gradient on the motion of the particle is decoupled from all the other forces that act on the particle, such as lift forces and effects of boundaries. Also, although the thermophoretic force is a weak force and has a vanishing effect on larger particles, it may become the dominant force for very small nanoparticles, where gravity—as well as all other volume/body forces—is very weak. A glance at Equation 1.171 proves that the ratio of the thermophoretic to the force of gravity varies as α^{-2} and that the thermophoretic force would be dominant on nanoparticles in a gravitational field with a strong temperature gradient. Because of this, thermophoresis has often been used for the collection of nanoparticles on collection surfaces (Leung and Crowe, 1993). Nevertheless, the thermophoretic force is weak and this collection method takes very long time. It also requires precise equipment and suppression of any flow instabilities. Artificial centrifuging is a more effective method to concentrate and collect nanoparticles (Michaelides, 2014).

It must be emphasized that the thermophoretic force is a consequence of the molecular collisions, which also cause the Brownian motion. The thermophoretic and Brownian forces are not independent forces to be accounted separately in the Lagrangian simulations of particle motion. The simple inclusion of the Brownian

Table 1.3 Pairs of Coefficients (A,B) for the Correlation of Equation 1.173 for Several Spherical Particles in Common Fluids

force in the Lagrangian simulations of particle motion in fluids with temperature gradients will reproduce the thermophoretic velocity as the steady *drift velocity* of the particles toward the colder regions of the system.

Turbophoresis is a phenomenon similar to thermophoresis and results from the gradients of turbulence intensity, which develop in boundary and shear layers. In this case, the particle is subjected to a higher force on the side where turbulence is higher. Thus, the net turbophoretic force acts in the direction opposite to $\nabla\overline{u'^2}$. Analysis and experiments have shown that in a wall boundary layer, the process of turbophoresis tends to bring the particles closer to the wall, where the turbulent fluctuations are weaker. However, when the particle concentration at the wall becomes high, the accumulation of particles and the more frequent interparticle collisions cause a *drift velocity* away from the high particle concentrations. The balance of the two driving forces, turbulence and concentration, leads to an equilibrium condition. Portela et al. (2002) concluded that the local equilibrium predict well the particulate concentration, except when very close to the wall ($y^+ < 20$) where the turbulent fluctuations are very weak and turbophoresis cannot even be defined in a physically meaningful way.

1.4.4 Heat Transfer

While the development of the equation of motion for a sphere was based predominantly on analytical work followed by corrections derived from experiments, most of the analyses on the subject of heat transfer are based on Fourier's work (Fourier, 1822). His treatise, which was preceded by his seven shorter articles on heat conduction, has been subsequently supplemented by numerous experimental studies that have provided semiempirical correlations for the rate of heat transfer or, equivalently, for the Nusselt number. For this reason, the subject of heat transfer from spheres is based primarily on correlations that stem from experiments or, in the recent past, from numerical studies.

The governing equations for the heat transfer and for the mass transfer are strictly similar. For this reason, the solution of one equation also yields the solution of the other equation by simple substitution of the corresponding dimensionless numbers. Therefore, all the results, analytical, experimental, or computational, for the heat transfer coefficients are also applicable to the pertinent mass transfer coefficients.

An important parameter in the study of convective heat and mass transfer from spheres is the Peclet number (for heat or mass transfer), which accounts for the heat or mass advected by the fluid. The Peclet number is analogous to the Reynolds number in the equation of motion and is defined as follows for the cases of heat transfer and mass transfer, respectively:

$$Pe = d\rho_f c_{pf} U/k_f \left(\text{or } Pe = Re^* Pr\right) \quad \text{and} \quad Pe_M = \frac{dU}{D}, \tag{1.174}$$

where

U is the characteristic velocity of the fluid
c_{pf} is the specific heat capacity of the fluid
k_f is the conductivity of the fluid
D is the diffusivity of the fluid

The Prandtl number, Pr, is the dimensionless group of the fluid properties, $Pr = \mu_f c_{pf}/k_f$. When there is relative motion between the sphere and the fluid, which is characteristic of most advection processes, the magnitude of the relative velocity is used as the characteristic velocity U in the expressions for the Peclet number as in Equation 1.22. The Nusselt number, the Sherwood number, and the Biot number, which are also given in Equation 1.22, are other dimensionless groups frequently used in heat transfer from particles, bubbles, and drops.

1.4.4.1 Creeping or Stokes Flow

As in the case of momentum transfer, creeping flow or Stokes flow implies $Re_r \ll 1$. Since $Pe_r = Re_r{}^* Pr$, unless Pr for the sphere is very large, as is the case of some organic oils, this condition also implies that $Pe_r \ll 1$, or at least that $Pe_r < 1$. Heat convection comprises two parts, conduction and advection. Since in creeping flows the advection is negligible, the conduction part dominates in the convection process. Therefore, studies that implicitly or explicitly assume that $Pe_r \ll 1$ or $Re_r \ll 1$ essentially neglect the effects of the advection part of the process and are treating the conduction part of the process alone.

The solution of the conduction equation (or $Pe_r \ll 1$) yields the following expression for the steady flow Nusselt number:

$$Nu = 2. \tag{1.175}$$

Acrivos and Taylor (1962) conducted a study on the heat transfer from a solid sphere, analogous to the study by Proudman and Pierson (1956) for the equation of motion. They implicitly assumed a Stokesian flow around a sphere and derived an asymptotic heat transfer solution, which is valid at higher order of Pe_r. With the corrections in the coefficients (Acrivos, 1980), their expression for the steady Nu, which is applicable in the ranges $Re_r \ll 1$ and $Pe_r < 1$, is

$$Nu = 2 + \frac{Pe_r}{2} + \frac{1}{4} Pe_r^2 \ln \frac{Pe_r}{2} + 0.2073 Pe_r^2 + \frac{1}{16} Pe_r^3 \ln \frac{Pe_r}{2}. \tag{1.176}$$

Acrivos and Taylor (1962) also proved that the functional relationship $Nu(Pe_r)$ obtained for creeping flow is less sensitive to an increase of Re_r than the corresponding functional relation for the drag coefficient, $C_D(Re_r)$, of solid spheres. Therefore, it is generally accepted that the last equation is valid not only under creeping flow conditions but also when Re_r is finite but small.

Acrivos and Goddard (1965) also derived an asymptotic solution for high Pe_r assuming a Stokesian velocity distribution. Their expression, which is valid for $Pe_r > 5$, is

$$Nu = 1.249 \left(\frac{Pe_r}{2} \right)^{1/3} + 0.922 \tag{1.177}$$

In the case of viscous spheres, with viscosity ratio, λ, Levich (1962) derived an asymptotic first-order solution for a liquid sphere at very large Pe_r and $Re_r \ll 1$:

$$Nu = \sqrt{\frac{4 Pe_r}{3\pi(1+\lambda)}}. \tag{1.178}$$

Feng and Michaelides (2000b) under the assumption of a Stokesian velocity profile around a viscous sphere (drop or bubble) solved numerically the energy equation and derived the following correlation for the heat transfer coefficients:

$$Nu = 1.49 Pe_r^{0.322 + \frac{0.113}{0.361\lambda + 1}}. \tag{1.179}$$

It must also be pointed out that the implicit conditions for the use of the last three expressions are as follows: $Re_r < 1$ and $Pe_r \gg 1$. These conditions are satisfied for spheres with $Pr \gg 1$. Several organic liquids, including gasoline and engine oil, satisfy these conditions.

More recently, Feng (2014) used a combined regular and singular perturbation method to solve the heat and mass transfer from a slightly deformed sphere at low but finite Peclet numbers in Stokes flow. The deformed sphere was assumed to be axisymmetric, and its shape is described in the spherical coordinates (r, θ, ϕ) by a power series of a small parameter ε ($|\varepsilon| \ll 1$) as follows:

$$r = 1 + \varepsilon \sum_{n=0}^{\infty} b_n P_n(\cos\theta) + O(\varepsilon^2). \tag{1.180}$$

Here, the origin of the spherical coordinate system is at the center of the undeformed sphere, $P_n(\cos\theta)$ is the Legendre polynomial of nth order, and b_n are constants of order $O(1)$. The correction to the Nusselt number due to the deformation of the sphere was obtained through a regular perturbation method, while the correction to Nu number due to the small Peclet number was obtained through a singular perturbation method.

The analytical solution for the averaged Nusselt number in terms of the Peclet number and the deformation parameter is

$$Nu = 2 + \frac{1}{2}Pe_r + \frac{1}{4}Pe_r^2 \ln Pe_r + 0.03404Pe_r^2 + \frac{1}{16}Pe_r^3 \ln Pe_r + \varepsilon\Delta(Pe_r) + O(\varepsilon^2) + O(Pe_r^3), \tag{1.181}$$

where

$$\Delta(Pe_r) = 2b_0 + b_0 Pe_r + \left(\frac{3}{4}b_0 - \frac{1}{20}b_2\right)Pe_r^2 \ln Pe_r + \left[\left(\frac{1721}{2400}b_0 + \frac{1}{16}b_1 + \frac{611}{8400}b_2\right) - \left(\frac{3}{16}b_0 - \frac{1}{80}b_2\right)\ln 2\right]Pe_r^2$$
$$+ \left(\frac{3}{16}b_0 - \frac{1}{80}b_2\right)Pe_r^3 \ln Pe_r. \tag{1.182}$$

In the case of a spheroid with its surface described in Cartesian coordinates by,

$$\frac{x^2 + y^2}{[(1+\varepsilon)c]^2} + \frac{z^2}{c^2} = 1. \tag{1.183}$$

If we choose the semiaxis c as the reference length ($c = 1$), the surface points of the spheroid are described by the equation

$$r = 1 + \varepsilon\left[\frac{2}{3}P_0(\cos\theta) - \frac{2}{3}P_2(\cos\theta)\right] + O(\varepsilon^2). \tag{1.184}$$

If $\varepsilon > 0$, the spheroid is an oblate; if $\varepsilon < 0$, it is a prolate; if $\varepsilon = 0$, it reduces to a sphere. By letting $b_0 = 2/3$ and $b_2 = -2/3$, the Nusselt number becomes

$$Nu = 2 + \frac{1}{2}Pe + \frac{1}{4}Pe^2 \ln Pe + 0.03404Pe^2 + \frac{1}{16}Pe^3 \ln Pe$$
$$+ \varepsilon\left[\frac{4}{3} + \frac{2}{3}Pe + \frac{8}{15}Pe^2 \ln Pe + 0.33714Pe^2 + \frac{3}{15}Pe^3 \ln Pe\right] + O(\varepsilon^2) + O(Pe^3). \tag{1.185}$$

1.4.4.2 Reynolds Number Effects

1.4.4.2.1 Solid Spheres Among the correlations of experimental data that have been used for the steady heat transfer from a solid sphere due to forced convection without mass transfer on the surface, for example, in the absence of evaporation, sublimation, or chemical reactions, are the expressions derived by Ranz and Marshal (1952) and Whitacker (1972), which may be written, respectively, as follows:

$$Nu = 2 + 0.6Re_r^{0.5}Pr^{0.33} \tag{1.186}$$

and

$$Nu = 2 + (0.4Re_r^{1/2} + 0.06Re_r^{2/3})Pr^{0.4}. \tag{1.187}$$

These correlations are valid for solid spheres only and may be used up to $Re_r = 10^4$.

In many heating and cooling applications involving dispersed flows, the convective heat transfer is of a mixed type, with the free convection part induced by the different temperature of particles. Since the free convection takes place in the direction of gravity and the forced convection is arbitrary, the directions of the free and forced convection are not necessarily the same. The overall heat transfer of a sphere resulting from the mixed flow is significantly influenced by the direction of the forced flow. Musong and Feng (2014) examined numerically the mixed convection from a heated sphere at an arbitrary incident flow angle in laminar

flows at moderate Reynolds numbers ($1 \le Re_r \le 100$) and Richardson numbers ($1 \le Ri \le 5$). Based on the simulation results, they developed a correlation for the mixed convection with incident angles in the range $0 \le \theta < \pi/2$:

$$Nu = aRe^{b}Ri^{0.5b}\theta^{2} + cRe^{d}Ri^{0.5d}\theta + nRe^{f}Ri^{0.5f} - gRe^{1+h}Ri^{0.5} - kRe^{m}, \tag{1.188}$$

where $a = -0.0208$, $b = 0.4851$, $c = 0.0250$, $d = 0.05$, $n = 1.436$, $f = 0.3642$, $g = 0.2534$, $h = -0.722$, $k = -0.2602$, and $m = 0.2412$. The units of the incident angle θ are radians.

1.4.4.2.2 Viscous Spheres Feng and Michaelides (2000a, 2001b) conducted two numerical studies on the subject of heat transfer from viscous spheres without mass transfer at the interface and derived useful and accurate correlations, with Re_r and Pe_r as independent variables. The first study pertains to high Re_r and any Pe_r and the second to any values of Re_r and Pe_r. Their results in correlation form are summarized in the following equations:

1. At small but finite values of Re_r ($0 < Re_r < 1$) and $Pe_r > 10$, the expression for the Nusselt number is

$$Nu(\lambda, Pe_r, Re_r) = \left(\frac{0.651}{1+0.95\lambda}Pe_r^{1/2} + \frac{0.991\lambda}{1+\lambda}Pe_r^{1/3}\right)\left(1+\alpha(Re_r)\right) + \left(\frac{1.65\left(1-f(Re_r)\right)}{1+0.95\lambda} + \frac{\lambda}{1+\lambda}\right), \tag{1.189}$$

where the function $f(Re_r)$ is defined as

$$f(Re_r) = \frac{0.61Re_r}{Re_r + 21} + 0.032. \tag{1.190}$$

2. As with the drag coefficient in Section 1.4.3.2, for higher Re_r and Pe_r, the analysis of numerical data revealed that the most accurate correlations of the numerical data are obtained when the general expression for Nu is given in terms of the following three functions, which pertain to specific values of the viscosity ratio λ:

a. The correlation for an inviscid sphere ($\lambda = 0$), which is given by the following expression:

$$Nu(0, Pe_r, Re_r) = 0.651Pe_r^{1/2}\left(1.032 + \frac{0.61Re_r}{Re_r + 21}\right) + \left(1.60 - \frac{0.61Re_r}{Re_r + 21}\right). \tag{1.191}$$

b. The Nusselt number expression for a solid sphere ($\lambda = \infty$):

$$Nu(\infty, Pe_r, Re_r) = 0.852Pe_r^{1/3}\left(1 + 0.233Re_r^{0.287}\right) + 1.3 - 0.182Re_r^{0.355}. \tag{1.192}$$

c. The corresponding function for a sphere with $\lambda = 2$, which was derived from the numerical results:

$$Nu(2, Pe_r, Re_r) = 0.64Pe_r^{0.43}\left(1 + 0.233Re_r^{0.287}\right) + 1.41 - 0.15Re_r^{0.287}. \tag{1.193}$$

Accordingly, the final correlations for the heat transfer coefficients are given by the following expressions in the two ranges of the viscosity ratio, $0 \le \lambda < 2$ and $2 < \lambda \le \infty$:

$$Nu(Pe_r, Re_r, \lambda) = \frac{2-\lambda}{2}Nu(Pe_r, Re_r, 0) + \frac{4\lambda}{6+\lambda}Nu(Pe_r, Re_r, 2)$$
$$\text{for } 0 \le \lambda \le 2 \quad \text{and} \quad 10 \le Pe_r \le 1000 \tag{1.194}$$

and

$$Nu\left(Pe_r,Re_r,\lambda\right)=\frac{4}{\lambda+2}Nu\left(Pe_r,Re_r,2\right)+\frac{\lambda-2}{\lambda+2}Nu\left(Pe_r,Re_r,\infty\right)$$
$$\text{for } 2\le\lambda\le\infty \quad \text{and} \quad 10\le Pe_r\le 1000. \tag{1.195}$$

For smaller values of $Pe_r < 10$, it was not possible to obtain a simple correlation of the numerical results, $Nu(Pe_r, Re_r, \lambda)$, with any satisfactory degree of accuracy. For this reason, for applications in the range $0 < Pe_r < 10$, it is recommended that one uses the numerical results in the original publication (Feng and Michaelides, 2001b), which are given in tabular form and their accuracy is only limited by the numerical accuracy of the method.

As in the case of the hydrodynamic force on a viscous sphere, it was determined that for a fixed value of Re_r and viscosity ratio, λ, the variations of the density ratio, ρ_s/ρ_f, have only a minimal effect on the external flow field. When one considers the governing equation for the heat or mass transfer processes and the pertinent boundary conditions, one will conclude that the density ratio (as well as the internal Reynolds number, Re_i) does not affect appreciably the corresponding transport coefficients, h and h_M, and, consequently, the Nusselt and Sherwood numbers. This was verified numerically by Feng and Michaelides (2001a,b) for both the hydrodynamic force and the rate of heat transfer: the influence of the density ratio on the heat transfer coefficient is less than 0.1%. This is of the same order of magnitude as the numerical uncertainty of the computations and much lower than the required accuracy for engineering calculations.

1.4.4.2.3 Interfacial Velocity Slip and Temperature Difference All the aforementioned expressions for Nu are based on the no-slip velocity condition at the interface as well as on the assumption that the temperatures of the sphere and the fluid at their interface are equal. It has been experimentally observed that when the size of particles is comparable to the mean free path of the base fluid, there is a significant discontinuity of both the velocity and the temperature at the solid–fluid interface. The effect of the two discontinuities is to decrease the magnitude of the convective heat transfer. The velocity discontinuity at the interface is modeled as in Equations 1.114 and 1.115. The discontinuity at the solid–liquid interface is usually modeled in terms of an *accommodation coefficient*, $\zeta = f(T)$, defined in terms of the molecular collisions on the surface of the sphere. Accordingly, the temperature discontinuity at the solid–liquid interface is expressed by the following boundary condition:

$$T_f-T_s\big|_{r=\alpha}=\left(\frac{c_p}{c_v}\right)\frac{2\left(2-\zeta\right)L_{mol}}{\left(\frac{c_p}{c_v}+1\right)\zeta Pr}\frac{\partial T_f}{\partial r}. \tag{1.196}$$

In most cases with liquids, the ratio of the specific heats of the fluid, c_p/c_v, is approximately equal to 1. When the mean free path is expressed in terms of the Knudsen number, the last equation becomes

$$T_f-T_s\big|_{r=\alpha}=\frac{2\left(2-\zeta\right)aKn}{\zeta Pr}\frac{\partial T_f}{\partial r}. \tag{1.197}$$

Brun (1982) also derived an expression for the heat transfer from a sphere using this thermal boundary condition and verified his solution with experimental data and other analytical results. Feng and Michaelides (2012) used an asymptotic method and derived a solution to the more general problem of heat transfer from solid spheres with velocity and thermal slip at the interface. Their expression agrees with the expression by Brun (1982) for a solid sphere with thermal slip only and with the experimental data by Mikami et al. (1966) in the range $0.01 < Kn < 2$. This general expression for the viscous spheres is

$$Nu=\frac{2}{1+\lambda_t}+\frac{1}{2\left(1+\lambda_t\right)^2}Pe_r+\frac{f_s}{4\left(1+\lambda_t\right)^2}Pe_r^2\ln\left(Pe_r\right)+\frac{1}{2\left(1+\lambda_t\right)^2}$$
$$\times\left[\frac{-156+148f_s-152\lambda+341\lambda f_s+129f_s^2+528\lambda f_s^2}{960\left(1+2\lambda_t\right)}-0.06+0.58\lambda_t\right]Pe_r^2+\frac{1}{16\left(1+\lambda_t\right)^3}Pe_r^3\ln\left(Pe_r\right)+O\left(Pe_r^3\right), \tag{1.198}$$

where f_s is a dimensionless parameter related to the dimensionless velocity slip, $S = 2\mu_c/\beta\alpha$:

$$f_s = \frac{\beta\alpha + 2\mu_c}{\beta\alpha + 3\mu_c} = \frac{1+2S}{1+3S}. \tag{1.199}$$

This parameter is evident in the expression for the drag force on a solid sphere with slip, Equation 1.114. λ_t is another dimensionless parameter that characterizes the thermal slip as modeled by Equation 1.197:

$$\lambda_t = \frac{2(2-\zeta)}{\zeta}\frac{Kn}{Pr}. \tag{1.200}$$

Because λ_t is always positive, the effect of the thermal slip is to reduce *Nu* and by extent the convective heat transfer coefficient of the solid sphere. Equation 1.198 reveals that the velocity slip affects the heat transfer process only at the higher values of Pe_r. Since velocity and temperature discontinuities are observed only with very small spheres of submicron dimensions, where the internal circulation effects are restricted, Equation 1.200 is also a good approximation to the heat (and mass) transfer from viscous spheres as well.

1.4.4.3 Effects of Rotational Motion

The problem of convection heat (or mass) transfer over a heated rotating sphere in a fluid is a classical problem that has been studied extensively in the past. There are several studies found in the literature focusing on the development of experimental techniques to measure the mean heat transfer rate or the average Nusselt number. Kreith et al. (1965) studied the cooling and heating of a solid sphere in several fluids including oil, water, and air. They correlated their measurements for the forced convection heat transfer with the following equation:

$$Nu = 0.43 Pr^{0.4} Re_{rot}^{0.5}. \tag{1.201}$$

Tieng and Yan (1993) studied the mixed convection of a rotating sphere in air. They considered the mixed convection as a resultant effect composed of both free and forced convections. Their results for forced convection at large Reynolds numbers also supported this correlation. However, for smaller Re they suggested a new correlation:

$$Nu = 2 + 0.175 Re_{rot}^{0.583}, \quad Re_{rot} < 33{,}320, \quad Pr = 0.71. \tag{1.202}$$

This is a similar expression as the one initially proposed by Farouk (1985) for the Nusselt number of forced convective heat transfer of a rotating sphere in air. Dorfman and Serazetdinov (1973) used boundary layer theory and derived analytically a similar relation to Equation 1.201, but with a smaller coefficient of 0.33.

The correlations in Equations 1.201 and 1.202 were obtained for flows of Reynolds number above 1000, where a boundary layer is formed at the surface of the sphere. These correlations show that the Nusselt number is proportional to $Re_{rot}^{1/2}$, a characteristic arising from laminar boundary layer theory. For flows of small to moderate Reynolds numbers where the boundary layer theory may not be valid, these correlations are not applicable.

Feng (2014) employed a direct numerical simulation approach combined with immersed boundary method (IBM) to study the convective heat transfer of a heated rotating sphere in otherwise stationary air at low to moderate Reynolds numbers. The sphere is assumed to have a constant temperature; the Prandtl number of air is chosen to be 0.72; the flow Reynolds numbers in study range from 0 to 1000. Figure 1.15 shows the relationship between the mean Nusselt numbers and Reynolds numbers. The correlations by Kreith et al. (1965), by Tieng and Yan (1993), and by Dorfman and Serazetdinov (1973) are also plotted in the figure. It can be seen that these correlations fail to predict the mean Nusselt numbers correctly at $Re < 500$. At Reynolds number between $0 \le Re \le 500$, the simulation data are best fit by the following correlation, as seen in Figure 1.15:

$$Nu = 2 + 0.00051 Re_{rot}^{1.5}, \quad Pr = 0.72, \quad 0 \le Re_{rot} \le 500. \tag{1.203}$$

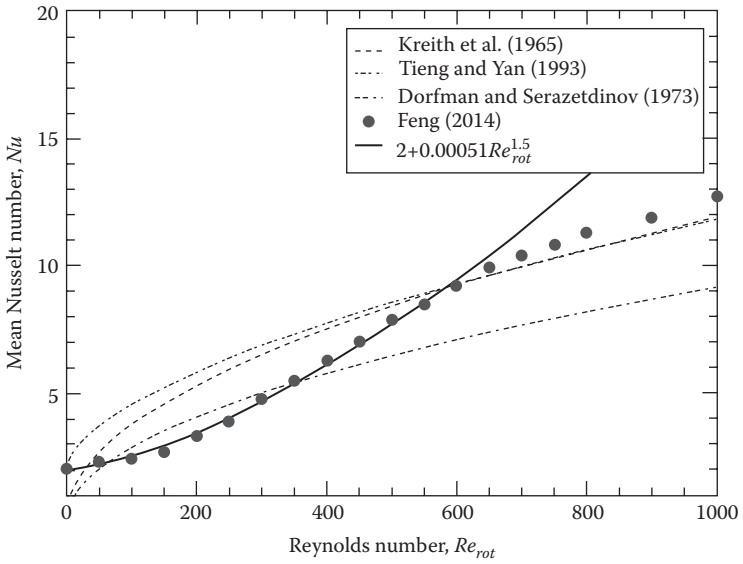

Figure 1.15

Mean Nusselt number versus Reynolds number of rotation for $0 \le Re_{rot} \le 1000$.

1.4.4.4 Effects of Flow Turbulence

As in the case the drag coefficient of particles, free-stream turbulence causes an increase in the heat transfer coefficients. Early experimental studies by Raithby and Eckert (1968) in grid-generated turbulence show that Nu increases rapidly with the turbulence intensity up to $I_r = 1\%$ when Re_r is of the order of 10^3. The Nusselt number subsequently increases, but only linearly with I_r. When Re_r is of the order of 10^4, Nu is proportional to I_r in the whole range of the investigations. Based on several sets of available experimental data, Clift et al. (1978) suggest the following correlation for the increase in the heat transfer coefficient:

$$\frac{Nu}{Nu_0} = 1.0 + 4.8 * 10^{-4} \frac{I_r}{I_{rc}} Re_r^{0.57}, \tag{1.204}$$

where

Nu_0 is the Nusselt number in the absence of free-stream turbulence
I_r is the turbulence intensity
I_{rc} is the critical turbulence intensity

The latter is defined in a way that it makes the Reynolds number of the particle, Re_r, equal to the critical Reynolds number, which was defined in Equation 1.118. From that expression, one may derive the following expression for the critical turbulence intensity, I_{rc}:

$$\begin{aligned} I_{rc} &= \left[5.477 - \log_{10}\left(Re_r\right)\right]/15.8 \quad \text{for } I_r \le 0.15 \\ \text{and} \quad I_{rc} &= \left[3.71 - \log_{10}\left(Re_r\right)\right]/1.75 \quad \text{for } I_r > 0.15. \end{aligned} \tag{1.205}$$

A more recent study on the effect of free-stream turbulence by Yearling and Gould (1995) conducted with evaporating droplets of water, ethanol, and methanol yields the following dependence of Nu on the intensity of turbulence:

$$\frac{Nu}{Nu_0} = 1 + 3.4 I_r^{0.843}. \tag{1.206}$$

Since Yearling and Gould (1995) considered evaporating droplets, Nu_0 is the Nusselt number with the blowing effects, which is given by Equation 1.210. The film properties must be used for all the properties of the materials in the last equation.

1.4.4.5 Blowing Effects

Blowing effects are important for burning droplets when the timescale of burning (mass transfer from the droplet) is of equal or lesser order of magnitude than the timescale for energy transfer. As in the case of momentum transfer, corrections to the heat transfer coefficient have been developed. These corrections take into account the change of the properties of the gaseous boundary layer and the phase change on the surface of the sphere. The two dimensionless numbers, *blowing factors or transfer numbers*, B_H and B_M, which were defined in Equations 1.121 and 1.123, account for the heat and mass transfer effects on the surface of the sphere. These factors are used in corrections for the empirical and analytical correlations on heat and mass transfer from the surface of a constant volume sphere.

Since the origin of the two blowing factors is the radial mass transfer from the surface of the sphere to the carrier fluid, it is evident that the two are not independent. Abramzon and Sirignano (1989) conducted an analytical study on the evaporation of drops and derived expressions for these blowing factors to be used in engineering calculations. In the case of a fuel droplet that burns in air, they derived the following relationship between the two blowing factors:

$$B_H = (1 + B_M)^n - 1. \tag{1.207}$$

The exponent n represents the ratio

$$n = \frac{c_{pF}}{c_{pf}} \frac{1}{Le} \frac{1 + \frac{k}{2} \frac{\sqrt{Re_r/2}}{F(B_M)}}{1 + \frac{k}{2} \frac{\sqrt{Re_r/2}}{F(B_H)}}. \tag{1.208}$$

In the last equation

c_{pF} is the specific heat of the fuel vapor
c_{pf} is the specific heat of the carrier gas
Le is the dimensionless Lewis number
k is an empirical coefficient equal to 0.848
F is a function of the corresponding blowing factor

$$F(B) = (1 + B)^{0.7} \frac{\log(1 + B)}{B}. \tag{1.209}$$

When there is thermodynamic equilibrium and the properties of the material satisfy the conditions $Pr = Sc = 1$, the two transfer coefficients are equal: $B_H = B_M$ (Sirignano, 1999).

Abramzon and Sirignano (1989) obtained semianalytical expressions for the Nusselt and Sherwood numbers for a drop with mass transfer on its surface. Chiang et al. (1992) improved on that study by relaxing some of the most restrictive assumptions and conducting numerical computations on the vaporization of drops. They derived a more general and, very likely, more accurate correlations for the heat and mass transfer coefficients:

$$Nu = 1.275\left(1 + B_H\right)^{-0.678} Re_m^{0.438} Pr_m^{0.619} \tag{1.210}$$

and

$$Sh = 1.224\left(1 + B_M\right)^{-0.568} Re_m^{0.385} Sc_m^{0.492}. \tag{1.211}$$

Both the Reynolds and Schmidt numbers, Re_m and Sc_m, must be calculated using the film transport coefficients, defined by Equation 1.119 and, in the case of Re_m, the free-stream gas density, $\rho_{f\infty}$, far from the droplet. One may use the aforementioned correlations with the heat and mass transport equations to derive the following expressions for the rate of heat and mass transfer of vapor from the surface of a spherical drop:

$$\begin{aligned} \dot{Q} &= 1.275\pi k_f d\left(T_s - T_\infty\right)\left(1 + B_H\right)^{-0.678} Re_m^{0.438} Pr_m^{0.619} \\ \dot{m} &= 1.224\pi d\rho_f D\left(Y_s - Y_\infty\right) B_M \left(1 + B_M\right)^{-0.568} Re_m^{0.385} Sc_m^{0.492}. \end{aligned} \tag{1.212}$$

An alternative method to calculate the heat and mass transfer from a drop is to use another empirical relationship, which is derived from the experimental results by Renksizbulut and Yuen (1983). They correlated their experimental data on the heat transfer from a sphere with mass transfer at its surface by the expression

$$Nu = \frac{2 + 0.584 Re_m^{0.5} Pr^{0.33}}{\left(1 + B_M\right)^{0.7}}. \tag{1.213}$$

This yields the following expressions for the rates of heat and mass transfer from the surface of the spherical drop:

$$\dot{Q} = \pi k_f d\left(T_s - T_\infty\right) \frac{2 + 0.584 Re_m^{0.5} Pr^{0.33}}{\left(1 + B_M\right)^{0.7}} \tag{1.214}$$

and

$$\dot{m} = \pi d \rho_f D (Y_s - Y_\infty) \frac{2 + 0.584 Pe_m^{0.5} Sc^{0.33}}{(1 + B_M)^{0.7}}. \tag{1.215}$$

All the fluid properties in the last four equations that define the Nusselt, Prandtl, and Schmidt numbers are the film properties defined by Equation 1.119. In addition, the relative Reynolds and Peclet numbers Re_m and Pe_m are defined in terms of the gas-film viscosity as in Equation 1.119 and the free-stream gas density, $\rho_{f\infty}$, which is far from the droplet. It is evident from an inspection of these equations that their functional form and coefficients are very similar. It has been confirmed (Sirignano, 1999) that the results of the two expressions do not differ substantially.

1.4.4.6 Transient Effects

Michaelides and Feng (1994) conducted a study on the transient energy equation for spheres, which is analogous to the one by Maxey and Riley (1983) for the equation of motion. The implicit and explicit assumptions for this study are similar to the assumptions for the derivation of the equation of motion and may be summarized as follows:

- **a.** Spherical shape
- **b.** Infinite fluid domain
- **c.** No rotation
- **d.** Highly conducting ($Bi \ll 1$ or $k_f/k_s \ll 1$)
- **e.** Zero initial relative temperature
- **f.** Negligible advection ($Pe_r \ll 1$)

For a rigid, isothermal sphere in a time-variable, nonuniform fluid temperature field $T_f(x_i, t)$, the final form of the transient Lagrangian energy equation is

$$m_s c_{ps} \frac{dT_s}{dt} = -m_f c_{pf} \frac{DT_f}{Dt} - 4\pi a k_f \left[T_s - T_f - \frac{1}{6} a^2 T_{f,jj} \right] - 4\pi a^2 k_f \int_0^t \frac{d/d\tau \left[T_s - T_f - \frac{1}{6} \alpha^2 T_{f,jj} \right]}{\left[\pi \alpha_f (t - \tau) \right]^{1/2}} d\tau, \tag{1.216}$$

where

c_{pf} and c_{ps} are the specific heat capacities of the fluid and the sphere, respectively

α_f in the denominator of the last term is the thermal diffusivity of the fluid, which is equal to $k_f/\rho_f c_{pf}$

The differential operator D/Dt represents the Lagrangian derivative with a reference system of coordinates at the center of the sphere

The temperature T_f is the temperature function of the fluid far from the sphere

The left-hand side of the aforementioned equation denotes the change in the temperature of the sphere due to the heat transfer

The first term in the right-hand side is analogous to the inertia term in the momentum equation and accounts for the (Lagrangian) change in temperature of the mass of displaced fluid. The second term is the usual conduction term from the sphere to the fluid and is analogous to the steady drag term of the equation of motion. This term represents the rate of heat transfer due to the bulk temperature difference between the fluid and the sphere. It is similar to the well-known conduction term that appears in texts, with the inclusion of the Laplacian derivative, which accounts for any nonuniformities of the temperature field. The Laplacian terms are analogous to the Faxen terms of the equation of motion and scale as a^2/L^2. In most of the practical applications where the particle radius is significantly smaller than the characteristic dimension of the fluid and $a^2/L^2 \ll 1$, these corrections are insignificant and may be neglected. The last term in the energy equation is a history integral, which results from the diffusion of the temperature gradients in the fluid temperature field and is also corrected for the nonuniformity (curvature) of the temperature field. It is apparent that this history term depends on the temporal as well as the spatial variation of the temperature field and is exactly analogous to the history term of the equation of motion. This history term may account for a significant part of the transient heat transfer to a sphere, as it may be seen in Figure 1.16.

It must be pointed out that the added mass term in the equation of motion derives from the pressure gradient term in the momentum equation. Since the governing equation for the energy transfer does not have a term equivalent to ∇p, there is no term corresponding to the added mass term in the transient energy equation. The absence of the added mass term is the main difference in the functional forms of the equations of motion and temperature variation under creeping flow conditions as well as at finite Reynolds numbers. It is apparent that there is not a mathematical similarity between the transient equations of motion and energy for particles, drops, or bubbles. However, there are several analogous results in the momentum and heat exchange processes for viscous and solid spheres.

As with the equation of motion, the assumption of equal temperatures at the interface may be relaxed. In this case, the history term is substituted by the expression

$$4\pi a^2 k_f \int_0^t \frac{d/d\tau\left[T_s - T_f - \frac{1}{6}a^2 T_{f,jj}\right]}{\left[\pi\alpha_f (t-\tau)\right]^{1/2}} d\tau + 4\pi a^2 k_f \frac{T_s(0) - T_f(0)}{\sqrt{\pi a_f t}}. \tag{1.217}$$

Gay and Michaelides (2003) conducted a numerical study to compute the effect of the history term on the heat transferred to a sphere at creeping flow conditions by considering three types of variation of the carrier fluid temperature: (1) a step change, (2) a ramp change, and (3) a sinusoidal variation. The main parameters for this

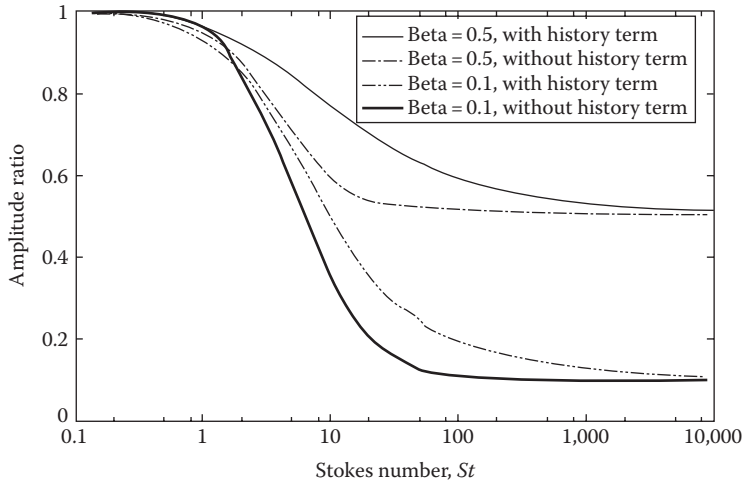

Figure 1.16

The effect of the thermal Stokes number on the heat transfer from rigid particles with and without the history term.

study are the volumetric heat capacity ratio $\beta = \rho_f c_{pf}/\rho_s c_{ps}$ and a thermal Stokes number, St_t, which is defined as the ratio of the thermal timescale of the particle $\tau_s = a^2\rho_f c_f/k_f$ to the characteristic timescale of the fluid:

$$St_t = \frac{a^2 \rho_f c_f \omega}{k_f}. \tag{1.218}$$

The history term is of importance in the computations of the heat flux when the ratio of the volumetric heat capacities, β, is between 0.002 and 0.5. This is the range of liquid–solid flows and droplet flows in heavier gases. The study found almost no effect of the history term on the heat transfer for bubbles, which are in the range $\beta > 10$. Typical result of these computations for a sinusoidal oscillation of the fluid temperature field with frequency ω is depicted in Figure 1.16 (from Gay and Michaelides, 2003). This figure demonstrates that neglecting the history term in the energy equation may lead to an underestimation of the instantaneous rate of heat transfer by as much as 35%, a significant fraction for most engineering computations.

Feng and Michaelides (1997) performed a study on the transient energy equation for a spheroid of eccentricity ε, which is analogous to the study by Lawrence and Weinbaum (1986) for the drag on a spheroid. They derived the following equation for the heat transfer from a spheroid:

$$Q(t^\star) = -4\pi\left\{\left(1+\frac{2}{3}\varepsilon-\frac{1}{45}\varepsilon^2\right)(T_s^\star - T_\infty^\star)+\left(1+\frac{4}{3}\varepsilon-\frac{2}{3}\varepsilon^2\right)\int_0^t \frac{d/d\tau^\star (T_s^\star - T_\infty^\star)}{\sqrt{\pi(t^\star-\tau^\star)}}d\tau^\star + \right.$$
$$\left. +\frac{1}{3}\left(1+\frac{2}{9}\varepsilon+\varepsilon^2\right)\frac{DT_\infty^\star}{Dt^\star}+\varepsilon^2\frac{4}{45}\sqrt{\frac{\pi}{3}}\int_0^t\left[\frac{d}{dt^\star}(T_s^\star - T_\infty^\star)\right]G'(t^\star-\tau^\star)d\tau^\star\right\}, \tag{1.219}$$

where all the variables are in dimensionless form and the function $G'(t)$ depends on the frequency of variation of the fluid temperature field

$$G'(t) = Im\left[\sqrt{\pi\Phi}e^{\Phi t^\star}erfc\left(\sqrt{\Phi t^\star}\right)\right] \quad \text{and} \quad \Phi = 3e^{i\frac{\pi}{3}}. \tag{1.220}$$

The last term in Equation 1.219 depends entirely on the eccentricity and the frequency of variation of the external temperature field. The kernel of this term does not necessarily follow the $t^{-1/2}$ decay of the typical history term in creeping flows and depends on the frequency of the variation of the velocity of temperature fields. Feng and Michaelides (1997) showed that when the frequency of variation of the velocity and temperature fields is not high, the contribution of this new history term to the total heat flux is much smaller than the contributions of the other transient terms.

Feng and Michaelides (1998a) also performed a study on the energy equation of a particle with arbitrary motion and in an arbitrary temperature field with finite but small inertia. This study is analogous to the one performed by Lovalenti and Brady (1993) for the equation of motion, and its results are expressed in terms of Pe_r and *Sl*. Details of the transient hydrodynamic force and heat transfer of particles, bubbles, and drops at finite Re_r and Pe_r may be found in Michaelides (2006).

1.4.4.7 Radiation Effects

Thermal radiation is the mode of heat transfer through which electromagnetic energy is continuously emitted and absorbed by a system. This energy exchange applies to the system under observation as well as all the other systems in its surroundings. For a sphere whose surface temperature is T_s, the emitted radiation energy is equal to

$$\dot{Q}_{rad}^{em} = \sigma\varepsilon\pi d^2 T_s^4, \tag{1.221}$$

where

σ is the Stefan–Boltzmann constant, $5.669 * 10^{-8}$ W/m^2 K^4

ε is the emissivity of the sphere

The emissivity of a blackbody is equal to one. Similarly, the sphere absorbs heat from all the objects in its surroundings. In the simple case where the sphere is enclosed by a single medium of temperature T_∞, the sphere absorbs thermal radiation equal to

$$\dot{Q}_{rad}^{ab} = \sigma\alpha\pi d^2 T_\infty^4, \tag{1.222}$$

where α is the absorptivity of the sphere. In general, the absorptivity and the emissivity of a material are functions of its temperature and are equal in magnitude: $\alpha(T_s) = \varepsilon(T_s)$.

The net rate of energy that enters the sphere as a result of thermal radiation is equal to the difference of the two aforementioned equations and, in analogy with the convection mode of heat transfer, may be given in terms of a radiation coefficient, h_{rad}:

$$\dot{Q}_{rad}^{ab} - \dot{Q}_{rad}^{em} = \sigma\varepsilon\pi d^2 (T_\infty^4 - T_s^4) = \pi d^2 h_{rad} (T_\infty - T_s). \tag{1.223}$$

The radiation coefficient is a strong function of temperature. It is obvious that when the temperature difference of the sphere and its surroundings is sufficiently high, the net energy exchanged by radiation is significant and may actually surpass the energy exchange due to the other two modes of heat transfer, conduction and convection. The total rate of heat entering the sphere is the sum of the convection and radiation:

$$\dot{Q}_T = \pi d^2 (h_{rad} + h)(T_\infty - T_s). \tag{1.224}$$

It must be pointed out that in the case of radiation one has to account not only for the carrier gas but also for all the boundaries and other objects in the vicinity of the sphere. The sphere exchanges radiation with any other object or surface that it "sees." In the general case, when this body is surrounded by many objects, including other similar bodies in the same carrier fluid, the determination of the net thermal radiation or the thermal radiation coefficient must be carried out by carefully evaluating the effects of all the surfaces in the surroundings and the shape factors of these surfaces. This may become a challenging task. A more extensive description of the processes and the methods used for the determination of radiative heat transfer may be found in a specialized treatise on the subject, such as the one by Siegel and Howel (1981).

An interesting consequence of radiation heat transfer with particles is that radiation may cause a significant deviation of the temperature of the particle from that of the surrounding fluid and in extreme cases natural convection from a particle. Let us consider a spherical particle in a fluid stream of temperature T_f and velocity u, inside a long channel whose walls are at a different temperature T_w. The particle reaches an equilibrium temperature, which is defined by a zero net heat gain at its surface and is characterized by equal and opposite magnitudes of the convection and radiation. In the simplest case of blackbody radiation and a nonabsorbing gas, this equilibrium yields the following expression for the temperature of the particle:

$$h_c (T_f - T_s) = h_{rad} (T_{th} - T_w) \Rightarrow T_s = \frac{h_c T_f + h_{rad} T_w}{h_c + h_{rad}}. \tag{1.225}$$

This analysis implies that the particle temperature will be close to the temperature of the gas, T_f, only when $h_c \gg h_{rad}$. On the contrary, the particle temperature will be close to that of the surrounding boundaries, T_w, when $h_c \ll h_{rad}$. In all cases, the particle will reach an intermediate temperature, which is not equal to the temperature of the fluid, T_f, that surrounds it. Several interesting effects may occur if the temperature difference between fluid and particles, $T_s - T_f$, becomes significant: natural convection and buoyancy effects will develop around the particles and the particles will experience an upward draft. The draft affects both the particle motion and the heat transfer from it. If this natural convection is strong enough, the particles may even be carried upward with the locally buoyant fluid (Feng and Michaelides, 2008, 2009).

1.4.5 Effects of Concentration

Most of the analytical, experimental, and numerical results presented in the previous sections were derived for single particles, bubbles, and drops. However, the majority of practical applications involve the flow of groups of interacting particles, bubbles, or drops. Interactions of these objects and the formation of clusters

and aggregates with correlated motions play an important role on the value of the hydrodynamic force and heat transfer. It is accepted, in general, that one may use the results and apply the theory of single particles, bubbles, and drops in a flowing mixture if the mixture is *dilute*, that is, if the concentration of the mixture is less than 6.5%. In dispersed mixtures like this, spheres are separated on the average by one diameter. Intermediate concentrations are in the range $6.5\% < C < 30\%$. In this range, particle-to-particle interactions are as important in the determination of all the transport coefficients as particle-to-fluid interactions. In applications with very dense concentrations, $C > 30\%$, particle interactions are the main mechanism for the transport processes and particle–fluid interactions are of lesser importance. Therefore, the effect of concentration on the transport coefficients is of paramount importance in engineering processes.

Regarding the steady hydrodynamic force, Richardson and Zaki (1954) carried one of the earlier series of experiments on the sedimentation of particles in a quiescent fluid, which is bounded by a channel of diameter D. By correlating the settling velocity of the particles to the concentration of the mixture, they concluded that the drag coefficient of a single sphere must be multiplied by a correction factor equal to

$$(1 - C)^{-K}, \tag{1.226}$$

where

C is the concentration of solids

exponent K is a weak function of the Reynolds number

K was correlated as follows:

$$\begin{array}{ll} Re_r \le 0.2 & K = 4.65 + 19.5 d/D \\ 0.2 < Re_r \le 1 & K = (4.35 + 17.5 d/D) Re_r^{-0.03} \\ 1 < Re_r \le 200 & K = (4.45 + 18 d/D) Re_r^{-0.1} \\ 200 < Re_r \le 500 & K = 4.45 Re_r^{-0.1} \\ Re_r > 500 & K = 2.39. \end{array} \tag{1.227}$$

It is apparent that the exponent K may attain any value in the range 2.4–5.7. Later experimental data by Rowe (1961) with arrays of solid spheres in water and air determined that the drag coefficients are better correlated with the single constant $K = 3$.

Another correlation, which is widely used in fluidization systems, is the one by Wen and Wu (1966). They included the effects of Re_r on the terminal velocity of a single particle and derived a correlation for the effect of concentration that is independent of the Reynolds number:

$$C_D = C_{D0}(1-C)^{-K} \quad \text{with } K = 3.7\,. \tag{1.228}$$

Wen and Wu (1966) recommend the Schiller and Nauman expression for the drag coefficient at zero concentration, $C_{D0} = 24(1 + 0.15 Re_r^{0.687})/Re_r$.

Di Felice (1994) used several sets of data available in the literature, including those by Richardson and Zaki (1954) and Wen and Wu (1966), to develop a more general and probably more accurate expression for the drag coefficient. He derived the following correlation, which is applicable in the range $10^{-2} < Re_r < 10^4$:

$$C_D = C_{D0}\left(1-C\right)^{-K} \quad \text{with } K = 3.7 - 0.65 \exp\left[-\frac{\left(1.5 - \log Re_r\right)^2}{2}\right]. \tag{1.229}$$

The subject of interacting particles, bubbles, and drops is rather difficult to investigate experimentally, but ideally suited for computational simulations, where different initial conditions may be examined and statistical results are relatively easy to derive. Modern computational techniques and more powerful computers have allowed the accurate modeling of groups of spheres with the flow properties of solid particles, bubbles, or drops to be studied in numerical experiments. Finite element methods and the lattice

Boltzmann method (LBM) have enabled scientists and engineers to perform *thought experiments* of groups of interacting spheres and, thus, to obtain the effect of interactions on the hydrodynamic force exerted on individual spheres under specific and well-defined conditions. In particular, the LBM and its derivative, the IBM (Feng and Michaelides, 2004b, 2005), are ideally suited methods for the determination of the interaction of groups of particles, drops, and bubbles of any shape and material properties. These recently developed methods have enabled the simulation of processes involving very large groups of particles, of the order of tens of thousands.

Kaneda (1986) used an asymptotic method to derive the steady component of the hydrodynamic force on an array of solid spheres at small but not vanishing Re_r and very low concentrations. He developed the following relationship for the average drag coefficient, C_D:

$$C_D = 1 + (\sqrt{2}/3)C^{1/2} + (\sqrt{2}/40)C^{-1/2}Re_r^2, \tag{1.230}$$

which is valid at distances where the inertia of the sphere is important. In the case of flows with several interacting objects, inertia becomes important at distances far from the *Brinkman screening length*. In the case of an array of spheres, the Brinkman screening length is equal to $C^{1/2}$, and hence, the range of applicability of this expression is $C^{1/2} \gg Re_r$. Kaneda (1986) also concluded that in the opposite limit, ($C^{1/2} \ll Re_r$), the Oseen correction to the Stokes drag ($1 + 3/16Re_r$) should be used for the average drag coefficient of the spheres. Working with arrays of two-dimensional particles in flows at small but finite Re_r and using the LBM, Koch and Ladd (1997) and Rojas and Koplik (1998) also confirmed that the Oseen relationship for the steady component of the hydrodynamic force applies to particles at small but finite Re_r.

Koch and Sangani (1999) used the LBM for a packed bed of particles and performed calculations on the rectilinear drag coefficients with fixed arrays of spheres. Their system is essentially a well-organized porous medium. They found out that the steady drag component may be scaled as Re_r^2 in high-concentration suspensions and depends on the concentration. Koch and Sangani (1999) obtained the following relationship for the steady hydrodynamic force in dense concentrations, $C > 40\%$, applicable to finite but small values of Re_r:

$$C_D = C_{D0}(C) + C_{D1}(C)Re_r^2. \tag{1.231}$$

The first function of this expression, which is the equivalent of the dimensionless Stokes drag force, is

$$C_{D0}(C) = \frac{1 + 3(C/2)^{1/2} + 2.11C\ln C + 16.14C}{1 + 0.681C - 8.48C^2 + 8.16C^3}. \tag{1.232}$$

The ratio of the functions C_{D1}/C_{D0} in this study diminishes with the increasing concentration of the solid particles. Hence, the second term in Equation 1.231 is very small in comparison to the first term at sufficiently high values of C. Because of this, Koch and Sangani (1999) claimed that the nonlinear behavior of the steady part of the average hydrodynamic force for close-packed arrays is difficult to be observed with the currently available experimental means.

Koch and Hill (2001) also performed computational studies using the LBM at higher Reynolds numbers and concluded that the steady component of the hydrodynamic force increases linearly with Re_r according to the following correlation:

$$C_D = C_{D0}(C) + \left[0.0673 + 0.212C + 0.0232(1 - C)^{-5}\right]Re_r, \tag{1.233}$$

where the function $C_{D0}(C)$ is the same as in Equation 1.231. Koch and Hill (2001) concluded that this expression agrees very well with experimental results and empirical relations derived in the past for packed beds of particles.

Bubbles are modeled as inviscid and weightless spheres moving in a medium, which is often idealized as an inviscid fluid. Because in the case of bubbles the added mass term is by far greater than the other components of the hydrodynamic force, such spheres accelerate as if their masses were equal to the mass of the

fluid occupying half of their volume, that is, fluid of mass $m_s = 2/3\pi\rho_f a^3$. For swarms of bubbles moving in a fluid with concentration C, the added mass coefficient, Δ_A, is a function of the concentration of the bubbles. Zuber (1964) used the simple theory of a bubble in a cell model for the flow of groups of bubbles to obtain analytically the following correction to the added mass coefficient:

$$\Delta_A = \frac{1+2C}{1-C}. \tag{1.234}$$

This expression is very simple to use in repetitive computations, and according to Sangani et al. (1991), it is sufficiently accurate and applies to a wide variety of conditions. Van Wijngaarten (1976) performed an asymptotic analytical study in the case of a swarm of bubbles that are impulsively accelerated and concluded that, with accuracy of the order of C^2, the added mass coefficient of a group with concentration C is equal to

$$\Delta_A = 1 + 2.76C + O(C^2). \tag{1.235}$$

A great deal of knowledge on the behavior of interacting bubbles has been recently developed as a result of computer simulations. Spelt and Sangani (1998) performed such a simulation to determine the influence of the fluid pseudo-turbulence—the velocity fluctuations in the carrier fluid, due to the motion of particles and bubbles—on the hydrodynamic force and the drag coefficient of a swarm of bubbles. They concluded that there is a weak dependence of the added mass coefficient on the fluid velocity fluctuations, but a significant dependence of the added mass on the bubble concentration. Their final expression, valid for $C < 0.3$, is

$$\Delta_A = \frac{1+2C+0.225CJ_A}{1-C}, \tag{1.236}$$

where J_A is a dimensionless measure of the temporal velocity fluctuations of the fluid. With a similar analysis, Spelt and Sangani (1998) obtained the following expression for the steady viscous drag coefficient for a swarm of bubbles in a viscous fluid:

$$C_D = \frac{1+0.15CJ_A}{(1-C)^2}. \tag{1.237}$$

1.4.5.1 Porous Particles

Large groups of interacting particles, clusters, and aggregates in dense flows may be approximated and treated as porous media. The permeability and porosity of such a porous media depend on the concentration. Similarly, clouds or large groups of smaller spheres may be approximated as larger porous spheres that are transported in a fluid medium. Jones (1973) obtained an expression for the steady hydrodynamic force on a porous sphere at creeping flow conditions:

$$F_i = 6\pi a\mu_f(u_i - v_i)\frac{2\zeta^2(1+2\eta\zeta^{-1})}{2\zeta^2+3+6\eta\zeta+6\eta\zeta^{-1}}, \tag{1.238}$$

where

ζ is the inverse of the dimensionless permeability of the sphere ($\zeta = a/\kappa^{1/2}$, with κ being the permeability of the sphere)

η is a dimensionless constant that depends on the properties of the porous medium

The permeability, κ, of a group of particles that form a porous medium is related to the porosity and, by extent, to the concentration, C, by the so-called Carman–Kozeny equation:

$$\kappa = \frac{(1-C)^3}{180C^2}d^2. \tag{1.239}$$

Feng and Michaelides (1998b) used an asymptotic expansion and extended this result to finite Reynolds numbers, Re_r, by developing corrections for Re_r up to the order Re_r^2. Their final expression for the drag force of such porous spheres is

$$F_i = 6\pi a\mu_f\left(u_i - v_i\right)\frac{2\left(1+\frac{\eta}{\zeta}\right)\zeta^2}{4\eta\zeta+2\zeta^2+3\frac{\eta}{\zeta}+1}\left[1+Re_r\frac{3\left(1+\frac{\eta}{\zeta}\right)\zeta^2}{4\left(4\eta\zeta+2\zeta^2+3\frac{\eta}{\zeta}+1\right)}+Re_r^2\ln\left(Re_r\right)\frac{9\left(1+\frac{\eta}{\zeta}\right)^2\zeta^4}{10\left(4\eta\zeta+2\zeta^2+3\frac{\eta}{\zeta}+1\right)^2}\right]. \tag{1.240}$$

$$C_D = \frac{24}{Re_r}\frac{2\left(1+\frac{\eta}{\zeta}\right)\zeta^2}{4\eta\zeta+2\zeta^2+3\frac{\eta}{\zeta}+1}\left[1+Re_r\frac{3\left(1+\frac{\eta}{\zeta}\right)\zeta^2}{4\left(4\eta\zeta+2\zeta^2+3\frac{\eta}{\zeta}+1\right)}+Re_r^2\ln\left(Re_r\right)\frac{9\left(1+\frac{\eta}{\zeta}\right)^2\zeta^4}{10\left(4\eta\zeta+2\zeta^2+3\frac{\eta}{\zeta}+1\right)^2}+O\left(Re_r^2\right)\right]$$

Re_r is based on the diameter of the whole cloud of small spheres and on the average relative velocity of the cloud. The last equation yields the correct behavior in the extreme cases of zero and infinite permeability: for a solid sphere ($\kappa \to 0$), this expression yields the hydrodynamic force expression obtained by Proudman and Pearson (1956) (Equation 1.103), while at low permeability ($\kappa \to 0$), it yields the result by Joseph and Tao (1964). At creeping flow, it yields the expression for the drag force that was first predicted by the study of Saffman (1971).

Looker and Carnie (2004) studied the transient hydrodynamic force of an oscillating porous sphere with velocity slip at its interface (a condition that was also studied by Saffman, 1971). They derived an asymptotic expression for the transient hydrodynamic force on the porous sphere with slip, valid up to the order of $\kappa^{1/2}$. Most of the results of this study may also be derived from the fundamental equation of a sphere with slip at its interface, Equation 1.138.

Nomenclature

Latin

a	Particle, droplet radius (m)
A	Area (m^2)
B_H	Blowing factor
B_M	Blowing parameter
c	Specific heat
c_p	Specific heat at constant pressure (J/kg·K)
c_v	Specific heat at constant volume (J/kg·K)
C	Concentration
C_D	Drag coefficient
C_L	Lift coefficient
d	Particle, droplet diameter (m)
d_A	Area-equivalent diameter (m)
d_V	Volume-equivalent diameter (m)
D	Diffusion coefficient (m^2/s)
D	Pipe/channel diameter (m)
f	Frequency distribution (continuous)
$f,$	Frequency distribution (discrete)
$F,$	Cumulative distribution
F	Force (N)
F_D,$F_{D,i}$	Drag force vector (N)
F_L,$F_{L,i}$	Lift force vector (N)
g,g_i	Gravity vector (m/s^2)
h	Specific enthalpy (J/kg), heat transfer coefficient (J/m^2-K)
h_{fg}	Latent heat of evaporation (J/kg)

h_M	Mass transfer coefficient
ΔH	Heat of combustion
I	Turbulence intensity
k	Thermal conductivity (J/m-K)
k	Ratio specific heats
l_m	Molecular mean free path
l_w	Distance to wall
L	Characteristic length (m)
m	Mass (kg)
$\dot{m}$	Mass flow rate (kg/s)
M	Molecular weight (kmol/kg)
n	Number density ($1/m^3$)
p	Pressure (Pa)
$\dot{Q}$	Heat transfer rate (W)
r, r_i	Radius vector
R	Gas constant (kJ/kg·K)
R_u	Universal gas constant (kJ/kmol K)
S	Dimensionless slip
T	Temperature (K)
t	Time (s)
u	Phase velocity of fluid (m/s)
U_a	Superficial velocity of phase "a" (m/s)
u	Velocity component in x-direction (m/s)
u_i,u	Velocity vector, continuous phase (m/s)
U	Characteristic velocity (m/s)
v_i,v	Velocity vector, dispersed phase (m/s)
V	Volume (m^3)
V_r	Migration velocity (m/s)
V_s	Settling velocity (m/s)
V_t	Terminal velocity (m/s)
w	Relative velocity (m/s)
w_i	Relative velocity vector (m/s)
x_i	Coordinate vector (m)
x	Quality, coordinate direction (m)
X	Mole fraction
y	Coordinate direction (m)
Y	Mass fraction
z	Vertical coordinate direction (m)
Z	Loading

Greek

α	Absorptivity
α_a	Volume fraction of phase "a"
β	Density ratio
β	Slip parameter
γ	Shear, rate of strain
Δ	Additional term of the Nusselt number
Δ_A	Added mass coefficient
Δ_H	History term coefficient
ε	Emissivity
ζ	Inverse of the dimensionless permeability
η	Dimensionless constant
θ	Angle, azimuthal angle (°)
κ	Permeability
λ	Viscosity ratio
μ	Dynamic viscosity (N/m-s), mean value

ν	Kinematic viscosity (m^2/s)
Ξ	Particle–cylinder diameter ratio
ρ	Density (kg/m^3)
ρ_m	Mixture density (kg/m^3)
σ	Surface tension (N/m)
σ	Standard deviation
σ	Stefan–Boltzmann constant
τ_V	Velocity response time (s)
τ_T	Thermal response time (s)
τ_c	Collision time (s)
ϕ	Velocity ratio
ψ	Stream function
Ψ	Shape factor for particles
Ω	Angular velocity (1/s)

w	Wall
θ	Circumferential, tangential direction
∞	Free stream

Dimensionless Numbers

Ac	Acceleration number
Bo	Bond number
Eo	Eötvös number
Kn	Knudsen number
Le	Lewis number
Ma	Mach number
Mo	Morton number
Nu	Nusselt number
Pe	Peclet number
Pr	Prandtl number
Re	Reynolds number
Re_γ	Shear Reynolds number
Re_r	Relative Reynolds number
Re_R	Rotation Reynolds number
Sc	Schmidt number
Sh	Sherwood number
Sl	Strouhal number
St	Stokes number
We	Weber number

2.1 Overview of Numerical Approaches

Eric Loth

2.1.1 Classification by Particle Reference Frame

While continuous-flow computational fluid dynamics (CFD) formulations are generally considered in an Eulerian reference, the dispersed-phase characteristics (velocity, concentration, diameter, etc.) can be treated with either Lagrangian or Eulerian representations. This difference of the reference frame for dispersed phase is the key division between the different multiphase numerical methods. The Lagrangian representation for particles is a natural approach since the particle positions are declared and updated along the particle paths. These paths are defined by the center of mass of the particle (or center of mass for a cloud of particles) as shown in Figure 2.1a. This approach can include wall collisions and other trajectory information in a straightforward manner. In contrast, the Eulerian approach for the particles considers cell-averaged particle characteristics based on the continuous-phase grid nodes (Figure 2.1b). This approach is efficient in terms of predicting particle concentration.

The two different approaches (Lagrangian and Eulerian) lead to significantly different formulations and numerical constraints. The Lagrangian approach leads to ordinary differential equations (ODEs) along the particle path but requires interpolation of the continuous-phase properties to the particle centroids. In contrast, the Eulerian approach leads to partial differential equations (PDEs) for the particle characteristics on an Eulerian grid but requires a continuum assumption for the particle characteristics. These two approaches are, respectively, discussed in the following two sections.

2.1.1.1 Lagrangian Approach for the Dispersed Phase

2.1.1.1.1 Lagrangian Particle Equation of Motion Since the dispersed phase is treated in terms of individual particle paths (or a group of particles), the Lagrangian method is also sometimes referred to as the "discrete" approach. When coupled with an Eulerian representation of the continuous phase, this combined treatment is termed the "Eulerian–Lagrangian" approach.

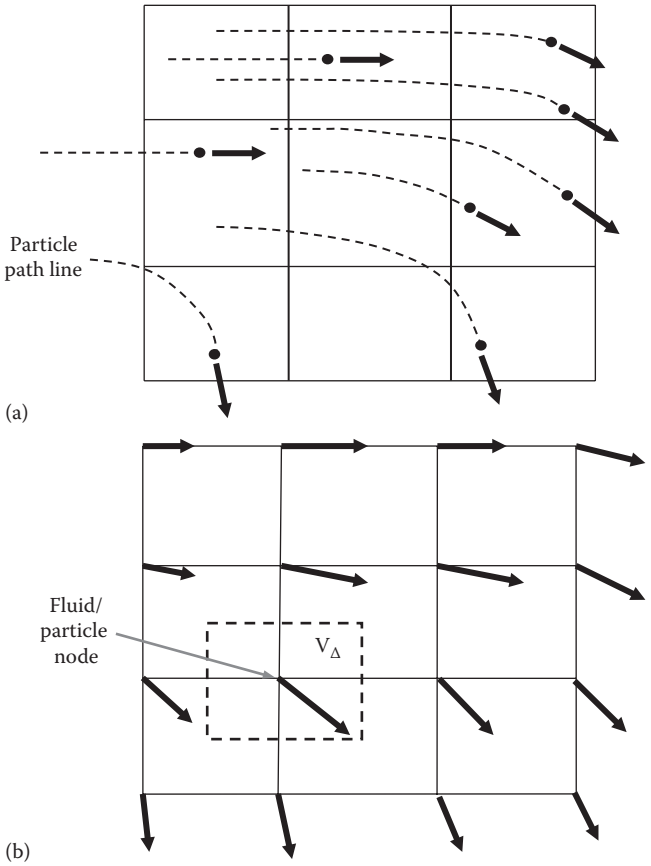

Figure 2.1

Particle velocity vectors in different reference frames in the context of an Eulerian continuous-phase grid: (a) Lagrangian vectors based on particle positions and (b) Eulerian particle velocity vectors based on average over a control volume centered at a discrete grid node used to store fluid properties and particle properties.

In the Lagrangian methodology, ODEs for the particle properties are based on particle path derivatives. The differential equations for particle position ($\mathbf{x}_p$), velocity ($\mathbf{v}$), mass (m_p), and internal energy (e_p) are summarized as follows:

$$\frac{d\mathbf{x}_p}{dt} \equiv \mathbf{v} \tag{2.1}$$

$$m_p \frac{d\mathbf{v}}{dt} = \mathbf{F}_{body} + \mathbf{F}_{sur} + \mathbf{F}_{coll} \tag{2.2}$$

$$\frac{dm_p}{dt} \equiv \dot{m}_p \tag{2.3}$$

$$m_p \frac{de_p}{dt} = \dot{Q}_p + \dot{m}_p h_{phase} \tag{2.4}$$

The RHS of Equation 2.2 contains the body force ($\mathbf{F}_{body}$), the fluid dynamic surface force ($\mathbf{F}_{sur}$), and the collision force with other particles or walls ($\mathbf{F}_{coll}$). The RHS of Equation 2.3 contains the mass transfer rate to the particle ($\dot{m}_p$, which is positive when the particle mass is increasing). The RHS of Equation 2.4 contains the heat transfer to the particle ($\dot{Q}_p$, which is positive when the particle temperature is increasing) and enthalpy for phase change (h_{phase}). The particle specific energy is equal to the product of the particle specific heat at constant pressure and particle temperature ($e_p = c_{p,p}T_p$). If there is negligible mass

or heat transfer (e.g., if temperature variations are small), the last two ODEs are not needed. The models for these RHS terms are listed as follows.

For a steady uniform continuum surrounding fluid moving past a single solid spherical particle at finite Reynolds numbers, the momentum RHS term (of Equation 2.2) neglecting collision effects can be modeled as

$$\mathbf{F}_{\text{body}} + \mathbf{F}_{\text{sur}} = -3\pi d\mu_f f \mathbf{w} + \rho_f \forall_p \left[\left(\frac{\rho_p}{\rho_f} - 1 \right) \mathbf{g} + \frac{3}{2} \frac{\mathcal{D}\mathbf{u}_{@p}}{\mathcal{D}t} - \frac{1}{2} \frac{d\mathbf{v}}{dt} \right] \tag{2.5}$$

$$\mathbf{w}(t) \equiv \mathbf{v}(t) - \mathbf{u}_{@p}(t) \tag{2.6}$$

$$f = 1 + \frac{Re_p/4}{1 + \sqrt{Re_p}} + \frac{Re_p}{60} \tag{2.7}$$

$$Re_p = \frac{\rho_f w d}{\mu_f} \tag{2.8}$$

In these expressions,

- d is the particle diameter
- μ_f is the fluid viscosity
- $\mathbf{w}$ is the particle relative velocity
- ρ_f is the fluid density
- $\forall_p$ is the particle volume
- ρ_p is the particle density
- $\mathbf{g}$ is the gravitational acceleration
- $\mathbf{u}_{@p}$ is the undisturbed fluid velocity (seen by the particle and interpolated to the particle centroid)
- Re_p is the particle Reynolds number

The RHS terms for mass and energy transfer (of Equations 2.3 and 2.4) can be modeled as

$$\dot{m}_p = -\pi d \rho_f Sp \Theta_{p@f} Sh \tag{2.9}$$

$$Sh = \left(2 + 0.6 \cdot Re_p^{1/2} \cdot Sc_f^{1/3} \right) \frac{\ln(1+Sp)}{Sp} \tag{2.10}$$

$$\dot{Q}_p = \pi d \kappa_f \left(T_{f@p} - T_p \right) Nu \tag{2.11}$$

$$Nu = \left(2 + 0.6 \cdot Re_p^{1/2} \cdot Pr_f^{1/3} \right) \frac{\ln(1+Sp)}{Sp} \tag{2.12}$$

In these expressions,

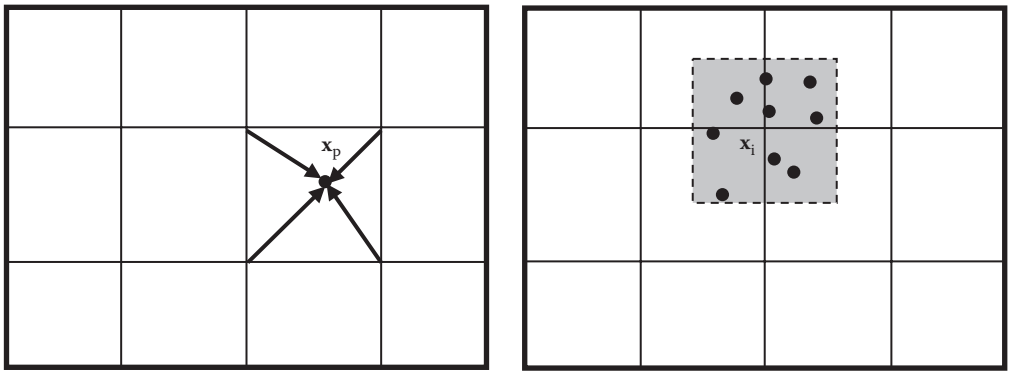
- Sp is the Spalding number
- $\Theta_{p@f}$ is the mass diffusivity of the particle matter into the surrounding fluid
- Sh is the Sherwood number
- Sc_f is the Schmidt number
- κ_f is the fluid thermal diffusivity
- $T_{f@p}$ is the fluid temperature extrapolated to the particle centroid
- Nu is the Nusselt number

These RHS terms neglect effects of lift, history force, collisions, internal recirculation, turbulence, and three-way coupling. Additions and corrections for these effects are described by Crowe et al. (1998, 2012), Loth (2000), and Michaelidis (2006, 2014).

2.1.1.1.2 Numerical Interpolation from Eulerian Grid To numerically integrate the particle ODEs, one must obtain the fluid properties interpolated to the particle centroid, for example, $\mathbf{u}_{@p}$ and $T_{f@p}$. These properties can be interpolated numerically from the Eulerian nodes of the continuous phase. For example, if the continuous-phase discretization is based on grid shape functions Φ, then the "unhindered" fluid velocity extrapolated to the particle centroid is given by

$$\mathbf{u}_{@p}(\mathbf{x}_p, t) = \sum_{j=1}^{N_\Phi} \mathbf{u}_j(t)\Phi_j(\mathbf{x}_p) \tag{2.13}$$

In this equation, N_Φ is all the number of computational cells associated with a particle location. The use of the shape function allows the velocity of all surrounding nodes to be included in the evaluation of $\mathbf{u}_{@p}$. This is shown schematically in Figure 2.2a for a 2D grid.



To predict particle concentration with a Lagrangian particle approach, the distribution of discrete particle positions must be translated into discrete volume averages. This can be accomplished by averaging all the respective particle volumes ($V_{p,j}$) whose centroids are within a discrete cell volume (V_Δ). Denoting this sum of particles in a cell as $N_{p\Delta}$, the particle number density (n_p) and particle volumetric fraction (ϕ_d) can be given as

$$n_p = \frac{N_{p\Delta}}{V_\Delta} \tag{2.14}$$

$$\phi_d = \frac{1}{V_\Delta}\sum_{j=1}^{N_{pD}} \forall_{p,j} = \frac{N_{p\Delta}\langle V_p \rangle}{V_\Delta} \tag{2.15}$$

The RHS of Equation 2.15 uses angled brackets, that is, <..>, to indicate a cell-based ensemble average. This cell-based ensemble averaging is illustrated in Figure 2.2b, and similar equations can convert Lagrangian particle velocities and temperatures to cell-averaged Eulerian particle velocities and temperatures. To ensure that ϕ_d can vary spatially as a continuum, the mixed-fluid volume should encompass many particles so that the concentration is continuously differentiable in space, that is,

$$N_{p,\Delta} \gg 1 \quad \text{for a well-posed continuum particle concentration} \tag{2.16}$$

(a) Interpolate $\mathbf{u}_{@p}$ at particle location (b) Collect ϕ_d for cell volume associated with a node

Figure 2.2

Schematic of Lagrangian point-force particles in a 2D Eulerian continuous-phase grid showing (a) interpolation of fluid velocity of the surrounding nodes to the particle position at $\mathbf{x}_p$ and (b) summation of particle volumes in a computational volume to compute volume fraction associated with a node $\mathbf{x}_i$.

If a continuum of particle concentration is not required, a more relaxed discrete concentration requirement can be imposed specifying that $\phi_d < 1$. Using the particle diameter (d) and assuming an isotropic grid ($\Delta x = \Delta y = \Delta z$), this inequality can be roughly expressed as

$$d < \Delta x \quad \text{for a well-posed discrete particle concentration} \tag{2.17}$$

If the grid is anisotropic, the RHS of this inequality can be replaced with grid length scale, for example, $(\Delta x \Delta y \Delta z)^{1/3}$ or the minimum of the three grid scales. This criterion ensures that the interpolation used in Equation 2.13 is reasonable assuming that the flow gradients within a given computational cell are small. Thus, the particle size is limited for a given discretization of the continuous phase. Approaches not bound by this constraint will be discussed in Section 2.1.3.

If the number of physical particles is very high (e.g., hundreds of particles per computation cell), it may be impossible or inconvenient to track all of the particles with individual Lagrangian ODEs. An alternative approach is to use representative Lagrangian particles called "parcels." These representative particle groups are essentially a small cloud of particles that are all modeled with the same Lagrangian trajectory and are also sometimes called "computational particles" or "superparticles." If we denote N_{pP} as the number of physical particles in a parcel and $N_{P\Delta}$ as the number of parcels in a cell, the particle concentration can be evaluated as

$$\phi_d = \frac{1}{V_\Delta}\sum_{j=1}^{N_{P\Delta}} N_{pP,j} V_{p,j} = \frac{N_{P\Delta}\left\langle N_{pP} V_p \right\rangle}{V_\Delta} \tag{2.18}$$

Further denoting $\mathbf{v}_P$ as the velocity of the parcel, the corresponding ODEs for the trajectory and momentum are given as

$$N_{pP}\left(\frac{d\mathbf{x}_P}{dt}\right) = N_{pP}\mathbf{v}_P \tag{2.19}$$

$$N_{pP} m_p \left(\frac{d\mathbf{v}_P}{dt}\right) = N_{pP}\left(\mathbf{F}_{body} + \mathbf{F}_{sur} + \mathbf{F}_{coll}\right) \tag{2.20}$$

$$\frac{N_{pP} dm_p}{dt} = N_{pP}\dot{m}_p \tag{2.21}$$

In this expression, all the particles in a parcel are assumed to have the same properties (i.e., diameter, temperature, and mass). If there is no mass transfer, breakup, or coalescence, the number of particles per parcel will be constant along its trajectory. In this case, the aforementioned trajectory and momentum equations for a single parcel are the same as those for a single particle (i.e., Equations 2.19 through 2.21 normalized by N_{pP} is the same as Equations 2.1 through 2.4). Thus, the parcel approach is much more computationally efficient as the number of equations reduces as the number of particles per parcel increases, for example, $N_{pP} = 100$ allows the number of computed trajectories to be reduced 100-fold. This is the key benefit of the parcel approach. However, there is an upper limit to how many particles per parcel can be used. In particular, if the parcel cloud is too large, there can be a substantial variation of continuous-phase flow variables across its length so that Equations 2.13 and 2.18 are not reasonable.

The parcel cloud volume (V_p) is the mixed-fluid volume occupied by the particles and the surrounding fluid. If the particle and surrounding fluid are both incompressible and there is no loss of particles (N_{pP} remains constant), the parcel "cloud" volume will stay fixed along its trajectory and be initialized based on the initial particle concentration prescription ($\phi_{d,inj}$)

$$V_P \equiv \text{volume occupied by particles and fluid for a parcel} = \frac{V_p N_{pP}}{\phi_{d,inj}} \tag{2.22}$$

To ensure that particles associated with a parcel will, on average, be physically within the computational cell (to be consistent with Equation 2.18), the parcel cloud volume should be smaller than the host computational cell volume, that is,

$$V_P < V_\Delta \quad \text{for a well-posed continuum particle concentration} \tag{2.23}$$

If particle concentration is needed, this criterion (combined Equation 2.22) places an upper bound on the number of particles per parcel (N_{pP}) at the point of injection as well as anywhere the parcel will travel.

2.1.1.2 Eulerian Approach for the Dispersed Phase

2.1.1.2.1 Eulerian Dispersed-Phase Equations of Motion In the Eulerian approach, the particle concentration and momentum are solved with transport equations in a manner similar to the density and momentum for the continuous phase. To allow this, we assume that the particle concentration (n_p or ϕ_d) can be described as a continuum (the requirements for this will be discussed later). Based on this assumption, the conservation equations for the Eulerian dispersed-phase mass, momentum, and energy can be derived. For continuity, the rate of mass change in a control volume is equal to the mass flux through its boundaries and any mass source term within the control volume. Written in PDE form and ignoring particle collisions, the governing equations for particle mass, momentum, and energy (per unit volume of the mixed-volume fluid) can be obtained in conservative form (Crowe et al., 1998) as

$$\frac{\partial\left(m_p n_p\right)}{\partial t} + \nabla\left(m_p n_p \mathbf{v}\right) = n_p \dot{m}_p \tag{2.24}$$

$$\frac{\partial\left(m_p n_p \mathbf{v}\right)}{\partial t} + \nabla\cdot\left(m_p n_p \mathbf{v}\mathbf{v}\right) = n_p\left(\mathbf{F}_{body} + \mathbf{F}_{sur} + \dot{m}_p \mathbf{v}\right) \tag{2.25}$$

$$\frac{\partial\left(m_p n_p e_p\right)}{\partial t} + \nabla\left(m_p n_p e_p \mathbf{v}\right) = n_p\left[\dot{Q}_p + \dot{m}_p h_{phase} + \dot{m}_p e_p\right] \tag{2.26}$$

Note the conservative form results in a RHS mass transfer term for the momentum and energy equations. These Eulerian equations can be rewritten in terms of particle volume fraction as

$$\frac{\partial\left(\phi_d \rho_p\right)}{\partial t} + \nabla\left(\phi_d \rho_p \mathbf{v}\right) = \frac{\phi_d}{V_p}\dot{m}_p \tag{2.27}$$

$$\frac{\partial\left(\phi_d \rho_p \mathbf{v}\right)}{\partial t} + \nabla\cdot\left(\phi_d \rho_p \mathbf{v}\mathbf{v}\right) = \frac{\phi_d}{V_p}\left(\mathbf{F}_{body} + \mathbf{F}_{sur} + \dot{m}_p \mathbf{v}\right) \tag{2.28}$$

$$\frac{\partial\left(\phi_d \rho_p e_p\right)}{\partial t} + \nabla\left(\phi_d \rho_p e_p \mathbf{v}\right) = \frac{\phi_d}{V_p}\left[\dot{Q}_p + \dot{m}_p\left(h_{phase} + e_p\right)\right] \tag{2.29}$$

The RHS values for these equations are given by Equations 2.5 through 2.8.

Once the Eulerian conservation equations are discretized, each (cell-averaged) node in the computational domain will include cell-averaged particle-phase variables. When coupled with an Eulerian representation of the continuous phase, this overall multiphase treatment is termed the "Eulerian–Eulerian" or "two-fluid" approach. Importantly, this approach allows the dispersed-phase PDEs to be treated with the same discretization techniques as used for the continuous-phase PDEs. It also conveniently allows the same grid for both phases so that the grid resolution is equivalent ($\Delta x_f = \Delta x_p$). Because of this, the average interphase coupling terms are treated in the same manner for both phases so that Eulerian–Eulerian approaches are especially efficient and accurate when two-way coupling effects are present (to be discussed in Section 2.1.1.2.2).

2.1.1.2.2 Dispersed-Phase Continuum Approximation A formal derivation of the Eulerian dispersed-phase equations requires careful consideration of the spatial and temporal averaging limits and the assumption of small but finite particle size. As such, the reader is particularly referred to details given by Drew (1983), Zhang and Prosperetti (1994), Crowe et al. (1998), and Prosperetti (2007). There are subtle differences among these derivations in these sources that are particular to different assumptions. However, a key tenant for the Eulerian description of the dispersed phase is that the particle properties (such as concentration, velocity, or temperature) can be approximated as a continuum at the grid scale. This is generally known as the "particle-phase continuum" assumption (Drew and Passman, 1999) and requires that changes in grid cell position or further refinements in grid cell do not fundamentally alter the predicted particle concentration distribution.

The particle-phase continuum assumption is related to the number of physical particles per computational cell ($N_{p\Delta}$). To demonstrate this, consider two neighboring control volumes with a particle concentration defined as $n_{p,i}$ and $n_{p,i+1}$ as shown in Figure 2.3a. In this case, one may apply a Taylor series expansion to express the number concentration at node i + 1 in terms of the value and gradients at node i + 1/2 using a forward shift ($\Delta x/2$) as

$$n_{p,i+1} = n_{p,i+1/2} + \frac{\Delta x}{2}\left(\frac{\partial n_p}{\partial x}\right)_{i+1/2} + \frac{1}{2!}\left(\frac{\Delta x}{2}\right)^2\left(\frac{\partial^2 n_p}{\partial x^2}\right)_{i+1/2} + O(\Delta x)^3 \ldots \tag{2.30}$$

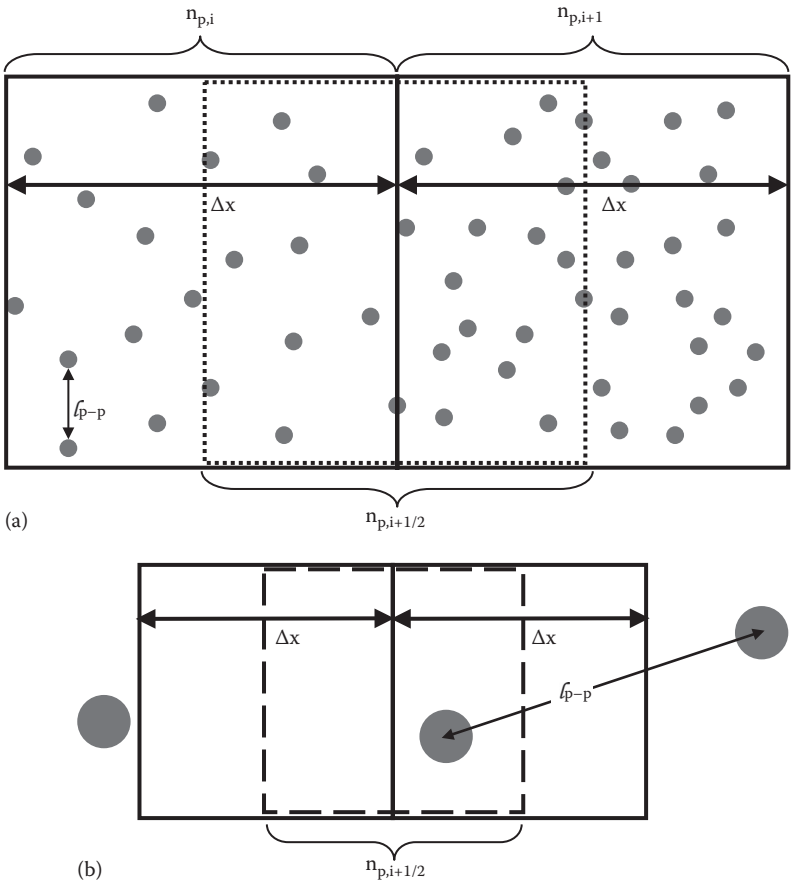


Figure 2.3

Two-dimensional Eulerian grid that contains discrete particles in adjoining computational control volumes: (a) $N_{p,\Delta} \gg 1$ allowing a continuum approximation and (b) $N_{p,\Delta} \sim 1$ so that a continuum approximation is *not* appropriate.

The last term on the RHS term corresponds to all terms of Δx^2 or higher. Comparing this result to a similar expansion for $n_{p,i}$ but with a backward shift ($-\Delta x/2$) yields

$$\left(\frac{\partial n_p}{\partial x}\right)_{i+1/2} = \frac{n_{p,i+1} - n_{p,i}}{\Delta x} + O\left(\Delta x\right)^2 \tag{2.31}$$

By dropping the second RHS term (which corresponds to terms of order Δx^2 or higher), we obtain a second-order finite difference expression. Such expressions can be used to discretize the spatial gradients for the Eulerian approach, for example, Equations 2.24 through 2.26. If the computational cell volume contains many particles as shown in Figure 2.3a, the number density will vary smoothly between cells and will not depend significantly on the exact volume position, that is, it will be continuously differentiable. A much different result arises if $N_{p\Delta}$ is no longer large. In this case, the grid resolution is on the order of the local interparticle spacing ($\Delta x \sim \ell_{p-p}$), which leads to discontinuities in particle concentration depending on where the grid cell is taken. For example, $n_{pi+1} = 1$ while $n_{p,i} = 0$ as in Figure 2.3b. This leads to uncertainty with respect to the spatial gradient of particle concentration. This uncertainty can be quantified for uniformly or randomly space particle positions. If the particles are uniformly spaced, the error of number density ($\mathcal{U}n_p$) is proportional to the number of particles

$$\frac{\mathcal{U}n_p}{n_p} \sim \frac{1}{N_{p\Delta}} \tag{2.32}$$

Thus, 10 particles are needed to achieve 10% accuracy. For a random Gaussian distribution of particle positions, the error is proportional to the square root of the sample size

$$\frac{\mathcal{U}n_p}{n_p} \sim \frac{1}{\sqrt{N_{p\Delta}}} \tag{2.33}$$

Thus, 100 particles per cell are needed for an uncertainty of 10%. In either case, if $N_{p\Delta}$ is order unity, the error in n_p will be on the order of 100% as shown in Figure 2.3b.

Therefore, a large number of particles per cell are needed for an accurate instantaneous Eulerian representation of n_p or ϕ_d, that is,

$$N_{p\Delta} \gg 1 \quad \text{for approximate Eulerian particle concentration “continuum”} \tag{2.34}$$

Thus, 10 or more particles in a cell are a practical lower bound for this approximation. Concentration continuum can be more rigorously specified by stating that the grid spacing should be much larger than the particle–particle spacing, that is,

$$\Delta x \gg \ell_{p-p} \quad \text{for an Eulerian particle concentration “continuum”} \tag{2.35}$$

This requirement reflects a lower bound for the computational grid size for which the concentration and its gradients are well defined.

In a sense, the requirement of Equation 2.35 is similar to the continuum assumption for a single-phase flow that requires a large number of molecules within a fluid control volume, that is,

$$\Delta x \gg \ell_{f-f} \quad \text{for a fluid “continuum” on an Eulerian grid} \tag{2.36}$$

Since the mean free path for most fluids is extremely small (e.g., on the order of nanometers), the requirement of Equation 2.36 is readily met for most CFD grids while that of Equation 2.35 is more conservative and more likely to be constraining.

It should be noted that the continuum approximation constraint for instantaneous concentration (Equation 2.35) may be relaxed if just the *mean* or properties are of interest. For example, consider the time-averaged number density obtained from an unsteady simulation over a number of time steps ($N_{\Delta t}$) as

$$\bar{n}_p = \frac{\bar{N}_{p\Delta}}{V_\Delta} = \frac{1}{V_\Delta N_{\Delta t}} \sum_{k=0}^{N_{\Delta t}} N_{p\Delta}(t_o + k\Delta t) \tag{2.37}$$

If the total number of particles considered all times (the summation on the RHS) is large, then $\bar{n}_p$ can be considered as a continuum in the mean sense, even if $N_{p\Delta}$ at a given instant is small or even zero. For example, a mean can be based on 0.1 particles in a cell (equivalent to a 10% probability that one particle is in the cell at any given time). Similar reasoning can be used if a time-averaged Reynolds-averaged Navier–Stokes approach is employed. As such, the uncertainty of Equation 2.33 only arises if one wishes to convert this probability into an instantaneous realization. Using a time average such as this allows the constraints of Equations 2.18 and 2.34 to be relaxed, but the continuum approximation still requires that the cell volume be well posed (Equation 2.17) so that

$$d < \Delta x \quad \text{for a mean particle concentration "continuum"} \tag{2.38}$$

This more relaxed criterion allows a smaller computational grid size as compared to Equation 2.35.

2.1.1.3 Eulerian Approach for the Continuous Phase

For two-way and three-way coupling, the continuous-phase mass, momentum, and energy must incorporate interphase transfer of mass, momentum, and energy interphase to the particles as sinks into the single-phase equations. In particular, these conservation equations must also take into account that the continuous-phase mass only occupies part of the mixed-fluid volume, for example, the continuous-phase fluid mass per mixed-fluid volume is $(1 - \phi_d)\rho_f$. Application of the Reynolds transport theorem to this quantity yields the continuous-phase continuity equation, where the interphase mass transfer is included as a sink term

$$\frac{\partial\left[(1-\phi_d)\rho_f\right]}{\partial t} + \nabla\left[(1-\phi_d)\rho_f \mathbf{u}\right] = -\frac{\phi_d}{V_p}\dot{m}_p \tag{2.39}$$

The RHS is thus equal and opposite to the source term used for the particle-phase Eulerian transport of Equations 2.27 through 2.29.

2.1.1.3.1 Continuous-Phase Momentum Conservation with Two-Way Coupling The same principle applied to mass conservation for Equation 2.39 can be applied to the continuous-phase momentum by defining the interphase force ($\mathbf{F}_{int}$) as the interphase momentum transfer from the continuous fluid to a single particle. This force is equal but opposite to the force that a particle exerts on the fluid ($-\mathbf{F}_{int}$), which is the sink term for continuous-phase equation. However, the fluid stress acts on a volume regardless of whether the volume is occupied by a particle or by fluid element. As such, it is not part of the interphase force, which can then be written as

$$\mathbf{F}_{int} = \mathbf{F}_{surf} - V_p\left(-\nabla p + \nabla \cdot \tau_{ij}\right) \tag{2.40}$$

$$\tau_{ij} = \mu_f\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} - \frac{2}{3}\delta_{ij}\nabla \cdot \mathbf{u}\right) \tag{2.41}$$

The fluid stress term on the RHS of Equation 2.30 is the sum of the pressure gradient and that of the viscous stress. A rigorous derivation and discussion of the term is given by Prosperetti (2007).

Applying the Reynolds transport theorem to describe the change in continuous-phase momentum per unit volume yields

$$\frac{\partial\left[(1-\phi_d)\rho_f \mathbf{u}\right]}{\partial t} + \nabla \cdot \left[(1-\phi_d)\rho_f \mathbf{u}\mathbf{u}\right] = (1-\phi_d)\rho_f \mathbf{g} + (1-\phi_d)\left[\nabla \cdot \tau_{ij} - \nabla p\right] - \frac{\phi_d}{V_p}\left(\mathbf{F}_{int} + \dot{m}_p \mathbf{v}\right) \tag{2.42}$$

The first and second terms on the RHS are the body and fluid stress forces applied to the continuous-phase mass per unit volume, while the third term stems from Equations 2.40 and 2.41.

A coupled continuous-phase energy equation can be similarly obtained by employing the same assumptions used for particle energy transport (Equations 2.9 through 2.12) and by neglecting effects associated with particle volume or shape changes

$$\frac{\partial\left[(1-\phi_d)\rho_f e_{tot}\right]}{\partial t}+\nabla\left[(1-\phi_d)\rho_f e_{tot}\mathbf{u}\right]=(1-\phi_d)\rho_f\mathbf{u}\cdot\mathbf{g}-\frac{\phi_d}{V_p}\left(\mathbf{F}_{int}\cdot\mathbf{v}\right)$$
$$+\frac{\partial\left[(1-\phi_d)\tau_{ij}u_i\right]}{\partial x_j}-\nabla\cdot\left[(1-\phi_d)p\mathbf{u}\right]+\tau_{ij}\frac{\partial\left(\phi_d v_i\right)}{\partial x_j}-p\nabla\cdot\left(\phi_d\mathbf{v}\right)$$
$$-\frac{\phi_d}{V_p}\left[\dot{Q}_p+\dot{m}_p\left(h_{phase}+e_p\right)+\left(\dot{m}_p\mathbf{v}\cdot\mathbf{v}\right)\right]+\nabla\cdot\left[k_{eff}\nabla T\right] \tag{2.43}$$

The LHS terms on the first line include the Eulerian and convective changes in the total fluid energy, while the RHS terms on this first line include the work associated with moving the fluid against the body force and against the particle interphase force. The RHS terms on the second line include work against the fluid stress forces, while those on the third line arise from heat and mass transfer as well as the thermal diffusion within the continuous-phase volume. The thermal diffusion is based on an effective conductivity (k_{eff}), typically taken to be the mixed-fluid conductivity (k_m). This mixed-fluid conductivity is based on the volume fraction weighted values from the particles and from the continuous phase:

$$k_{eff}\approx k_m\equiv\phi_d k_p+(1-\phi_d)k_f \tag{2.44}$$

This approximation is appropriate if the particles have a small thermal response time compared to the timescale of temperature changes in the fluid. On the other hand, a very long particle thermal response time will limit the thermal diffusivity to only that conducted through the continuous phase, that is, $k_{eff}\rightarrow(1-\phi_d)k_f$. Since the differences in thermal conductivities for most substances do not vary widely, the difference between these two limits is small for most dispersed flows ($\phi_d < 10\%$). As such, Equation 2.44 is both common and generally reasonable (Crowe et al., 1998, Elghobashi, 2006).

Finally, the terms in the third line include interphase energy coupling due to heat and mass transfer, the kinetic energy losses due to generation of particle mass, and the work required to move the particles based on interphase force and fluid stress force. A more detailed derivation and accounting of these terms is given by Crowe et al. (1998).

2.1.1.3.2 Influence of Dispersed-Phase Reference Frame The Eulerian transport equation given earlier for the continuous phase can be paired with dispersed-phase equations in the form of either the Lagrangian ODEs or Eulerian PDEs. In both cases, the key is determining the cell-averaged volume fraction at the continuous-phase nodes. If the particles are treated with an Eulerian approach, the interphase coupling terms can be obtained directly via the particle concentration predicted from Equations 2.27 through 2.29. For example, the interphase force per unit volume evaluated at the fluid node i is simply

$$\left(\frac{\phi_d}{V_p}\mathbf{F}_{int}\right)_i=\frac{\phi_d\left(\mathbf{x}_i,t\right)\mathbf{F}_{int}\left(\mathbf{x}_i,t\right)}{V_{p,i}} \tag{2.45}$$

This Eulerian–Eulerian formulation is numerically convenient since communication of data between the phases occurs at coincident node locations so that there is no interpolation error.

For Lagrangian particles, the coupling to a continuous-phase node can be computed based on the computational volumes associated with the nodes as shown in Figure 2.2b. For example, the interphase force coupling term for particle and parcel approaches can be given as

$$\left(\frac{\phi_d}{V_p}\mathbf{F}_{int}\right)_i=\frac{1}{V_{\Delta,i}}\sum_{j=1}^{N_{p\Delta}}\mathbf{F}_{int,j}=\frac{1}{V_{\Delta,i}}\sum_{j=1}^{N_{p\Delta}}N_{pP,j}\mathbf{F}_{int,j} \tag{2.46}$$

In this expression, $V_{\Delta,i}$ is the volume associated with node $\mathbf{x}_i$ that contains $N_{p\Delta}$ number of particles per cell if individual trajectories are followed or (as given by the RHS) contains $N_{p\Delta}$ parcels per cell with N_{pP} particles per parcel. To ensure that the coupling to the continuous phase can be described as a continuum, the constraint of Equation 5.14 must be placed on the number of Lagrangian particles or a similar constraint based on the number of parcels as

$$N_{p\Delta} \gg 1 \quad \text{for Lagrangian parcels with two-way or three-way coupling} \tag{2.47}$$

For example, four or more particles or parcels per element are typically needed for accurate two-way coupling. As a result, the Eulerian–Lagrangian approach can be an order of magnitude less efficient for two-way coupling as compared to the Eulerian–Eulerian approach (Druzhinin and Elghobashi, 1998, 1999).

2.1.2 Classification by Relative Velocity Magnitude

There is a second type of classification that is based on increasing particle relative velocity and includes mixed-fluid, weakly separated, and separated-fluid treatments. The separated-fluid treatment generally assumes that the continuous phase and dispersed phase have distinct transport equations and is described earlier for the Eulerian–Lagrangian approach and the Eulerian–Eulerian approach. The separated-fluid approach places no restriction on the magnitude of the relative velocity but can require significant computation to compute the associated surface forces. In contrast, the mixed-fluid approach assumes that the relative velocity be negligible compared to the fluid velocity ($w/u \to 0$). Finally, the weakly separated approach is intermediate to the other two approaches as it assumes a small but finite relative velocity ($w/u \ll 1$). These mixed-fluid and weakly separated approaches are discussed later and are advantageous to use when the test conditions are appropriate because they generally only require one momentum PDE for both phases.

2.1.2.1 Mixed-Fluid Approach

The mixed-fluid approximation assumes that the dispersed phase and the continuous phase are in local kinetic and thermal equilibrium, that is, the relative velocities and temperatures between the two phases are negligible in comparison to variations of the overall flow field

$$\frac{w}{u} \to 0 \tag{2.48}$$

for kinetic and thermal equilibrium assumption

$$\frac{(T_p - T)}{T_p} \to 0 \tag{2.49}$$

Using these assumptions, the mixed-fluid values are set equal to the respective continuous phase and particle values at the centroid locations for the mixed-fluid approach, that is,

$$\mathbf{u}_m(\mathbf{x},t) \equiv \left[\mathbf{u}_{@p}(\mathbf{x},t) = \mathbf{v}(\mathbf{x},t)\right] \tag{2.50}$$

mixed-fluid treatment

$$T_m(\mathbf{x},t) \equiv \left[T(\mathbf{x},t) = T_p(\mathbf{x},t)\right] \tag{2.51}$$

This is equivalent to assuming negligible momentum and thermal inertias (zero response times), which is consistent with particles for which all the relevant Stokes numbers are much less than unity, for example, $St_D \ll 1$ for the macroscopic flow or $St_\lambda \ll 1$ for turbulent flow. Therefore, the mixed-fluid approach is only reasonable for very small particles (equivalent to an *immiscible* mixture distributed throughout a domain). Since the velocities and temperatures of both phases are now assumed to be represented by single values, this mixed-fluid approach has also been termed the *locally homogeneous flow* approach (Faeth, 1987), the *single-fluid scalar transport* approach, and the *modified-density* approach.

Since both phases move at the same velocity, the overall mixture can be described to have a mixed-fluid density that is simply the mass of all phases per unit volume and can be related to the volume fraction as

$$\rho_m \equiv \rho_p \phi_d + \rho_f (1 - \phi_d) \tag{2.52}$$

As a result, the mixed-fluid approximation results in a single set of conservation equations for the flow mixture (as opposed to one set for the continuous phase and one set of the dispersed phase). In particular, the transport of mass, momentum, and energy can be obtained by applying Equations 2.50 and 2.51 to both the Eulerian dispersed-phase and continuous-phase equations and then summing the two sets of equations together

$$\frac{\partial \rho_m}{\partial t} + \nabla\left(\rho_m \mathbf{u}_m\right) = 0 \tag{2.53}$$

$$\frac{\partial\left(\rho_m \mathbf{u}_m\right)}{\partial t} + \nabla \cdot \left(\rho_m \mathbf{u}\mathbf{u}\right) = \rho_m \mathbf{g} - \nabla p + \nabla \cdot \tau_{m,ij} \tag{2.54}$$

$$\frac{\partial\left(\rho_m e_m\right)}{\partial t} + \nabla\left(\rho_m e_m \mathbf{u}\right) = \left(\tau_{m,ij} - p\delta_{ij}\right)\frac{\partial u_{m,i}}{\partial x_j} + \nabla \cdot \left(k_m \nabla T_m\right) \tag{2.55}$$

The second and third equations include a mixed-fluid viscous stress tensor ($\tau_{m,ij}$) that can be written in terms of a mixed-fluid viscosity

$$\tau_{m,ij} = \mu_m\left(\frac{\partial u_{m,i}}{\partial x_j} + \frac{\partial u_{m,j}}{\partial x_i} - \frac{2}{3}\delta_{ij}\nabla \cdot \mathbf{u}_m\right) \tag{2.56}$$

A key benefit for this approach is that the relative velocity and momentum ODE need not be employed (the same is true for the relative particle temperature and energy transfer ODE). Thus, the presence of the particle is only realized through the modification of the mixture density (ρ_m).

These aspect differences between the mixed-fluid and separated-fluid approaches are illustrated in Figure 2.4. Some key aspects of the mixed-fluid approach are especially relevant. First, the mixed-fluid set of equations is inherently a two-way coupled system since all phases act in concert and collision effects are ignored since **u** = **v**. Second, a single set of equations (without interphase momentum and energy transfer formulations) allows significant numerical simplicity, which should be used whenever appropriate (Equations 2.48 and 2.49). Third, the mixed-fluid approach generally uses the Eulerian reference frame for both phases, that is, an Eulerian–Eulerian approach. Figure 2.4 shows that the mixed-fluid method and the separated-fluid method are quite different. However, there is an intermediate method, as described later, which retains some of the features of each of these two distinct approaches.

2.1.2.2 Weakly Separated Approach

A hybrid approach between that of separated flow and mixed-fluid flow is the weakly separated approach or also called the "partially mixed" method. This approach is useful to describe motion of small particles whose dynamics are primarily controlled by the surrounding flow but which have a small but significant settling velocity. The simplest and most common version of the weakly separated method assumes that the particle relative acceleration is negligible in comparison to the fluid acceleration. This assumption allows a finite relative velocity that can be approximated by the terminal velocity

$$\mathbf{v}(\mathbf{x},t) = \mathbf{u}_{@p}(\mathbf{x},t) + \mathbf{w}_{term} \tag{2.57}$$

This is also called the "terminal velocity" approach and can be used for flows with slow sedimentation or rise. If the particle is considered to be in thermal equilibrium $T_p = T$, the dispersed phase only requires a mass transport equation given by either the Eulerian particle concentration PDE or a Lagrangian position ODE

$$\frac{\partial\left(\phi_d \rho_p\right)}{\partial t} + \nabla\left[\phi_d \rho_p\left(\mathbf{u}_{@p} + \mathbf{w}_{term}\right)\right] = \frac{\phi_d}{V_p}\dot{m}_p \tag{2.58}$$

$$\frac{d\left(\mathbf{x}_p\right)}{dt} = \mathbf{u}_{@p} + \mathbf{w}_{term} \tag{2.59}$$

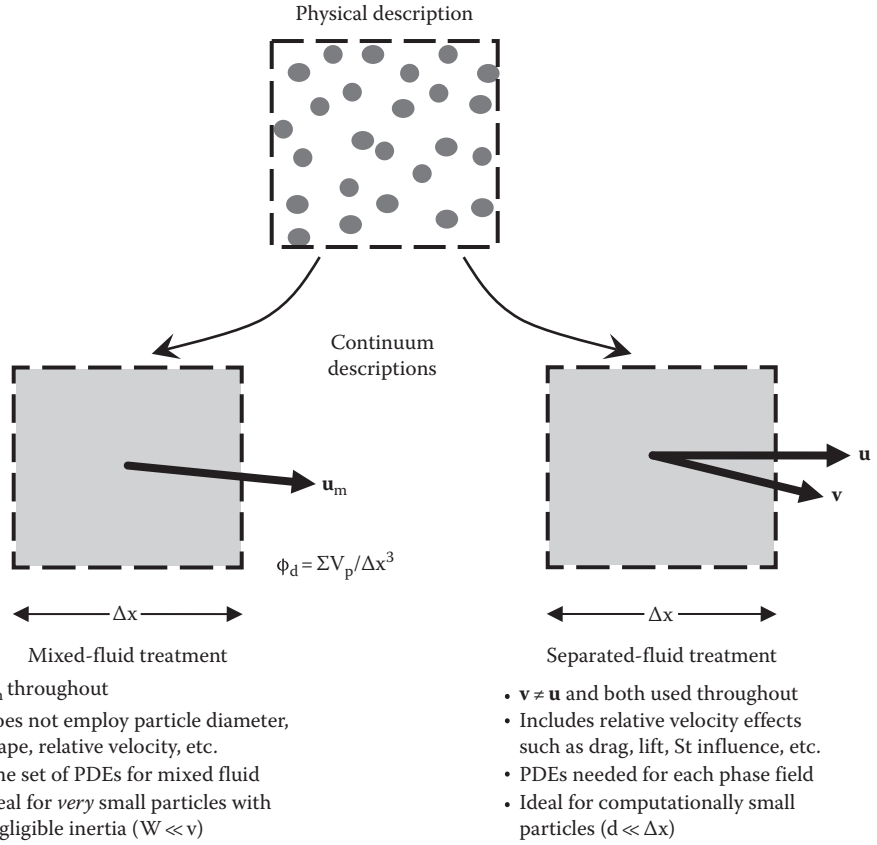

Figure 2.4

Comparison of mixed-fluid and separated-fluid treatments for a computational cell based on an Eulerian–Eulerian approach.

Thus, Equation 2.57 effectively serves as the momentum equation for the particles. This method is thus nearly as efficient as the mixed-fluid method but captures mean relative velocity effects. However, this approach cannot capture any effects associated with an initial particle velocity or due to a collision with a wall or another particle.

2.1.3 Classification by Particle Size Relative to Grid Size

As discussed earlier, there are three main approaches for multiphase numerical treatments based on particle size: point force, distributed force, and resolved surface. The choice is related to the capability in predicting the surface forces acting on the particle ($\mathbf{F}_{surf}$), which is needed for the separated-fluid treatment as discussed earlier. These forces are also needed if two-way and three-way coupling effects are to be included for the continuous-phase fluid solution. In determining $\mathbf{F}_{surf}$, there are three primary approaches: the "point-force" representation for particles smaller than the grid scale ($d < \Delta x$), the "distributed-force" representation for particles on the order of the grid scale ($d \sim \Delta x$), and the "resolved-surface" representation for particles much larger than the grid scale ($d \gg \Delta x$). These are discussed in the following three subsections.

2.1.3.1 Point-Force Approach

The point force (also referred to as the "point mass" or "point volume") has the advantage of eliminating the need to simulate the detailed flow around the particle. For an Eulerian treatment of the dispersed phase, the relative velocity is defined at the grid nodes

$$\mathbf{w}(\mathbf{x}_i, t) = \mathbf{v}(\mathbf{x}_i, t) - \mathbf{u}(\mathbf{x}_i, t) \tag{2.60}$$

Once the unhindered flow characteristics are known, a point-force equation can be used to describe the surface forces based on a linear combination of drag, lift, added mass, history, fluid stress, and so on. The fluid dynamic forces on the particle can be obtained with empirical or theoretical treatments.

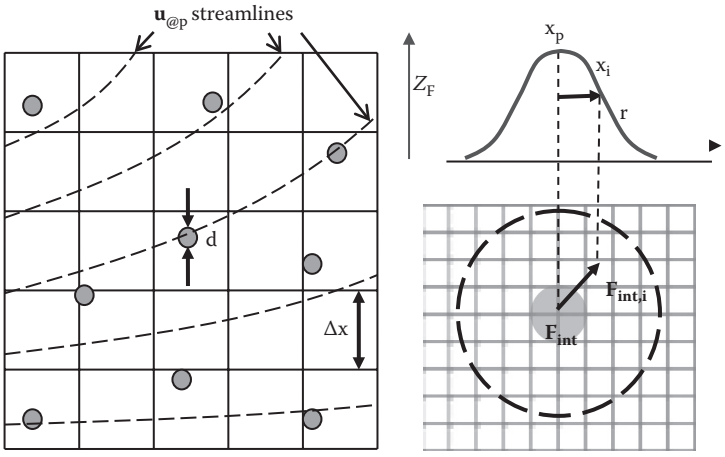

Figure 2.5

Different representations for particle treatment based on particle size in relation to continuous-fluid grid resolution for (a) a point-force representation and (b) a distributed-force representation.

The continuous-phase characteristics in either case do not include the fluid disturbances associated with individual particles. This indicates that the particle should be smaller than the length scales associated with continuous-phase gradients. Since this is also true for the discretization of the continuous phase, it yields a size criterion based on computational resolution

$$d < \Delta x \quad \text{for point force with one-way coupling} \tag{2.61}$$

A more rigorous criterion would be $d \ll \Delta x$ (Figure 2.5a) such that the particle will see only very weak continuous-fluid gradients over the length scale associated with its diameter. Since the continuous-phase computational resolution must be small enough to provide grid-independent results, the point-force technique is limited to particles that are smaller than any spatial features to be resolved in the computational domain. For example, a direct numerical simaultion (DNS) description of turbulent flow requires that the particle diameter be smaller than the friction length scale if in the laminar sublayer ($d^+ < 1$) or less than the Kolmogorov turbulent microscale ($d < \lambda$) if in the outer portion or above the boundary layer.

2.1.3.2 Distributed-Force Approach

The distributed-force technique is employed when the particle diameter is on the order of the spatial resolution of the continuous phase, that is,

$$d \sim \Delta x \quad \text{for distributed-force treatment} \tag{2.62}$$

In this case, the variations in the flow properties in the region of the particle should be considered since the fluid interactions between the two phases occur over distances extending several particle diameters. As such, the coupling should extend over a region larger than a single grid cell (Figure 2.5b). To include the surface force on the particle, there are two distributed-force methods: "spatially averaged" and "semiresolved." The spatially averaged approach approximates the unhindered conditions (e.g., $\mathbf{u}_{@p}$) by surface and volume averages in the vicinity of the particle as opposed to using a single interpolated point at the centroid. This approach is generally limited to $d < 3\Delta x$ without two-way coupling but $d < \Delta x$ with two-way coupling.

In contrast, the semiresolved approach directly integrates two-way coupling effects and thus allows for larger particles (or finer resolutions) based on $3\Delta x < d < 10\Delta x$. Note that both techniques share a similar approach for distributing the interphase force on the fluid.

For two-way coupling, there are many variants of the distributed-force technique. To impart $\mathbf{F}_{int}$ over a region (instead of at a point), a force distribution function ($\mathcal{Z}_F$) can be used about the vicinity of the particle as illustrated in Figure 2.5b. Similar distributions can be applied for mass and heat transfer. The distributed-force technique is thus a hybrid between the point-force approach and the resolved-surface approach, the latter of which is discussed later.

2.1.3.3 Resolved-Surface Approach

For very large particles, the resolved-surface approach can be used if the detailed local flow over the particle surface is numerically discretized and computed. This approach resolves the fluid surface stresses so that they may be computationally integrated to compute the resulting fluid dynamic forces on the particle. This method is also called the "full DNS" approach and requires the computational resolution to sufficiently describe the detailed stress distribution over the particle surface, for example,

$$d \gg \Delta x \quad \text{for resolved-surface treatment} \tag{2.63}$$

This criterion requires many fluid nodes per individual particle, for example, hundreds or thousands depending on the particle geometry, Reynolds number, and so on. As such, this technique is only reasonable when there are few particles in the computational domain. However, this technique has the advantage of allowing complex particle geometries and incorporating detailed nonlinear flow fields around the particles (Figure 2.6).

Since the surface force is obtained from the surrounding flow, it does not require any force decomposition in terms of lift, drag, added mass, history, fluid stress, and so on since all these effects are directly incorporated by the discrete surface integration. In particular, no assumptions of particle shape, particle Reynolds number, particle or flow acceleration, surface conditions, flow gradients, and so on are required for the use of this formulation. Thus, there is no need to determine $\mathbf{u}_{@p}$, and no empirical or analytical force expressions for $\mathbf{F}_{sur}$ are required. Furthermore, in the case of a fluid particle (e.g., drop or bubble), the internal fluid dynamics may also be directly simulated using internal discretization (this can be important since the recirculation can affect the surface stresses). Also note that two-way coupling, three-way coupling, and four-way coupling are automatically included in the resolved-surface approach since the interstitial fluid and contact dynamics can be fully resolved as well. As such, the resolved-surface technique is the most desirable in terms of accuracy as it allows the most physically realistic surface force method but is also the most computationally intensive approach.

There are two primary treatments for the resolved-surface method that depend on how the interface between the particle and the continuous phase is treated: the "gridded interface method" (GIM) and the "immersed interface method" (IIM). These two approaches are illustrated in Figure 2.6 (where the outward normal of the interface is $\mathbf{n}$) and are overviewed in the following sections.

2.1.3.3.1 Gridded Interface Method The GIM approach is typically used when the particle shape is simple (e.g., a sphere or an ellipsoid) so that the grid resolution over the surface is straightforward. In this case, the interface between the particle and the surrounding fluid is discontinuous, that is, infinitely thin (Figure 2.6b). The boundary condition on a solid particle surface is typically specified as *a no slip for continuum conditions*. For an uncontaminated fluid particle with significant recirculation, the particle interior should also be discretized.

Once the flow field around the particle surface is known and described by the resolved velocity and pressure ($\mathbf{U}$ and P), the surface force can be determined by numerically integrating the pressure and the continuous-phase shear stress over the discretized surface elements

$$\mathbf{F}_{sur} = \sum_{k=1}^{N_k} \left(-P\mathbf{n} + \tau_{resolved,ij} n_j \right)_k \Delta A_{p,k} \tag{2.64}$$

$$\tau_{resolved,ij} = \mu_f \left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i} - \frac{2}{3}\delta_{ij} \nabla \cdot \mathbf{U} \right) \tag{2.65}$$

In this equation, ΔA_p is a discrete particle surface area element, while $\mathbf{U}$ and P are the resolved velocity and pressure, that is, the values on the particle surface that take into account the particle's volume and impact

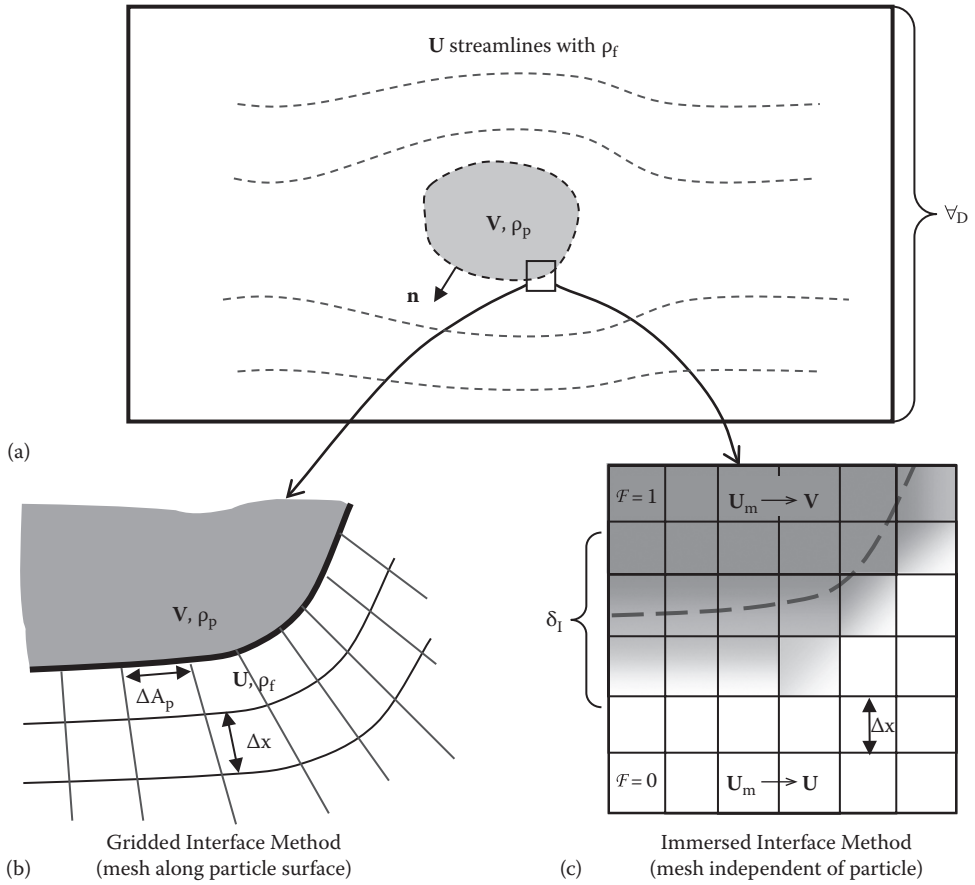

Figure 2.6

Resolved-surface approaches showing (a) schematic of particle in a computational domain along with (b) near-surface close-ups of a GIM mesh, and (c) that of an IIM mesh superimposed on the marker function distribution.

on the flow. This resolved-surface force can be combined with Equation 2.1 to move the particle to the next position with a new velocity and acceleration.

2.1.3.3.2 Immersed Interface Method The IIM is fundamentally based on a structured Eulerian grid for the computational domain that does not need to coincide with the particle surface. This allows the flow PDEs to be solved efficiently on simple Cartesian grids. A popular IIM category is the continuous interface methods that can be applied if the particle is a fluid. The approach introduces a nonphysical interface thickness (δ_I) as shown in Figure 2.6c. Instead of letting the flow properties between the particle and the surrounding fluid jump discontinuously (as is physically appropriate) across the molecularly thin interface, the CIM smoothly distribute these flow properties of velocity, density, and viscosity across a finite thickness interface that is several grid cell thick. This smooth distribution is accomplished with a "marker function" ($\mathcal{F}$) that is defined as the fraction of the computational cell occupied by particle matter. This function $\mathcal{F}$ equals 0 outside of the particle, varies smoothly from 0 to 1 across this interface, and equals 1 inside the particle. This function assumes that a computational cell volume is much smaller than the particle diameter. This function is distinct from the continuum-based volume fraction that assumes a computational volume much larger than the particle diameter. This marker function can then be used to define the "one-fluid" density that tends to the physical values outside the interface as

$$\rho = (1-\mathcal{F})\rho_f + \mathcal{F}\rho_p \tag{2.66}$$

Similarly, the velocity fields of both phases are represented by a one-fluid velocity ($\mathbf{U}_m$) that reverts to the correct physical limits outside of the interface but takes on a nonphysical (numerically convenient) value within the interface

$$\mathcal{F} = 0 \quad \mathbf{U}_m \rightarrow \mathbf{U} \text{ (outside of the particle)} \tag{2.67}$$

$$0 < \mathcal{F} < 1 \quad \mathbf{U}_m \rightarrow \mathbf{V}_I \text{ (within particle interface)} \tag{2.68}$$

$$\mathcal{F} = 1 \quad \mathbf{U}_m \rightarrow \mathbf{V} \text{ (inside of the particle)} \tag{2.69}$$

This formulation provides a single set of continuum PDEs for the entire domain based on $\mathbf{U}_m$ using the one-fluid density and viscosity. This allows for solutions on a simple Cartesian grid (which generally allows the fastest computation for a given number of grid points). Note that the finite interface thickness is nonphysical but is constructed to be as thin as possible while still allowing a stable continuum variation of velocity, density, and viscosity across the grid. This typically results in a prescribed thickness of 2–4 computational cells depending on the magnitude of the density ratio (although specialized sharp interface methods can reduce this thickness to one computational cell). A distinct advantage of the one-fluid approach is that the surface force of Equations 2.64 and 2.65 is satisfied (in contrast to the GIM). As such, this one-fluid approach avoids the ODEs needed to update particle velocity and rotation and complexities associated with gridding along the particle surface.

2.2 Direct Numerical Simulations of Gas–Liquid Flows

Gretar Tryggvason

An analytical solution of the equations governing multiphase flows is the ultimate reference to which experimental results and approximate models can be compared to. Unfortunately, analytical solutions for multiphase flows are few and limited to very simple systems. Solutions of the equations using numerical methods have, since the latter part of the last century, come to the rescue, and it is now possible to obtain accurate solution for a wide range of parameters, where analytical solutions, even approximate ones, cannot be found. Numerical solutions have, however, done much more than simply provide solutions where analytical

techniques do not work. It is now possible to solve the governing equations for the unsteady motion of systems that approach the complexity that was only addressable by experiments earlier. The emergence of direct numerical simulations (DNS) has changed multiphase flow research in fundamental ways, and yet, it is clear that so far we have only started to explore the full potentials of this approach. It is useful for the purpose of the present discussion to define DNS as simulations of unsteady complex flow with a large range of scales where every continuum spatial and temporal scale is fully resolved. The early computations of the Rayleigh–Taylor instability, gravity currents, and droplet splatting by the marker-and-cell (MAC) method—impressive as those were—are therefore not DNS by the present definition, since the range of length and timescales was so limited. For single-phase flows, DNS generally require the flow to be turbulent, but for multiphase flows the unsteady motion of different phases can lead to the expected range of scales.

In many industrial and natural processes, multiphase gas–liquid flows consist of one phase in the form of well-defined bubbles or drops dispersed in another continuous phase. Bubbly flows occur in boiling heat transfer, cloud cavitation, aeration and stirring of reactors in water purification and wastewater treatment plants, bubble columns and centrifuges in the chemical industry, cooling circuits of nuclear reactors, the exchange of gases and heat between the oceans and the atmosphere, and explosive volcanic eruptions, just to name a few examples. Similarly, drops are found in sprays used in atomization of liquid fuels, painting and coating, emulsions, and rain. Understanding the evolution and properties of *dispersed* flows is therefore of major technological as well as scientific interest.

For engineering applications involving a large number of bubbles and drops, computational modeling usually relies on equations that describe the average flow field. The two-fluid model, where separate equations are solved for the dispersed and the continuous phase, is the most common approach. Since no attempt is made to resolve the unsteady motion of individual particle, closure relations are necessary for the unresolved motion and the forces between the particle and the continuous phase. Closure relations are usually determined through a combination of dimensional arguments and correlation of experimental data. The situation is analogous to computations of turbulent flows using the Reynolds-averaged Navier–Stokes equations where momentum transfer due to unsteady small-scale motion must be modeled. For details of two-fluid modeling, see Drew (1983), Ishii (1975), Drew and Lahey (1993), and Zhang and Prosperetti (1994). For the turbulent motion of single-phase flows, DNS, where the unsteady Navier–Stokes equations are solved on fine enough grids to fully resolve all flow scales, have had a major impact on closure modeling. The goal of DNS of multiphase flows is similar. In addition to information about how the drift Reynolds number, velocity fluctuations, and bubble dispersion change with the properties of the system, the computations should yield insight into how bubbles and drops interact, both with each other and with the continuous phase. The simulations should show whether there is a predominant microstructure and/or interaction mode, and if the flow forms structures that are much larger than the size of the dispersed particles. Information about the microstructure is essential for the construction of models of multiphase flows and can also help to identify what approximations can be made.

In this section, we first review briefly the various numerical techniques developed for the DNS of multiphase flows and then discuss a few results, focusing mostly on disperse flows of gas bubbles in liquids. Although the focus is on simulations of complex systems with a broad range of scales, most of the methods used are applicable to much simpler systems and, indeed, the methods have been developed and tested for such problems. Thus, some references to computations of simple problems—even if they are not DNS by the definition used here—are unavoidable.

2.2.1 Simple Flows (Re = 0 and Re = ∞)

In the limit of high and low Reynolds numbers, it is sometimes possible to simplify the flow description considerably either by ignoring inertia completely (Stokes flow) or by ignoring viscous effects completely (inviscid, potential flow). Early attempts to understand the collective motion of bubbles, drops, and solid particles therefore focused on these limits. For undeformable spheres, it is, in both these limits, possible to reduce the governing equations to a system of coupled ordinary differential equations for the particle positions. For Stokes flows, several authors have examined the properties of suspensions of solid particles in shear flows (see Brady and Bossis, 1988, for a review of early work), but studies of inviscid systems are more limited. Sangani and Didwania (1993) and Smereka (1993) examined the behavior of many bubbles in periodic domains, specifying the rise velocity to prevent continuing acceleration. They observed that the bubbles tended to form horizontal "rafts," particularly when the variance of the bubble velocities was small. As this "rafting" is generally not observed experimentally, the results cast considerable doubt on the utility of the potential flow approximation for the interactions of many bubbles. This is somewhat unexpected since for single bubble this approximation is rather good (see, however, Harper, 1997) for a discussion of bubbles

rising in-line). Deformable bubbles and drops can be simulated using boundary integral techniques in both the Stokes and the inviscid limits. Several authors have examined suspensions of very viscous drops, including Li and Pozrikidis (2000) and Zhou and Pozrikidis (1993), who followed the dynamics of 2D drops in a channel, and Loewenberg and Hinch (1996) and Zinchenko and Davis (2000) have examined fully 3D drops. The boundary integral method for Stokes flow has been described in detail in the book by Pozrikidis (1992), and Pozrikidis (2001) gives a detailed summary of various applications. Unlike Stokes flow, inviscid models are generally only suitable for a transient short-time evolution since eventually viscous dissipation becomes important (see Chahine and Duraiswami, 1992, for early work). Although studies of flows in the limits of zero and infinite Reynolds number played an important role in early work on multiphase flows, their role is now much diminished, although there are situations where they constitute important limiting cases.

2.2.2 Methods for Finite Reynolds Number Flows

For intermediate Reynolds numbers, it is necessary to solve the full Navier–Stokes equations. The first method to allow computations of multifluid flows was the MAC method developed at Los Alamos by Harlow and collaborators. In Harlow and Welch (1965), the method was introduced and two sample computations of the so-called dam breaking problem shown. Several papers quickly followed: Harlow and Welch (1966) examined the Rayleigh–Taylor problem and Harlow and Shannon (1967) studied the splash when a drop hits a liquid surface. As originally implemented, the MAC method assumed a free surface, so there was only one fluid involved. This required boundary conditions to be applied at this surface and the fluid in the rest of the domain to be completely passive. The Los Alamos group quickly realized, however, that the same methodology could be applied to two-fluid problems. Daly (1969b) computed the evolution of the Rayleigh–Taylor instability for finite density ratios, and Daly and Pracht (1968) examined the initial motion of density currents. Surface tension was then added by Daly (1969a), and the method was again used to examine the Rayleigh–Taylor instability. The MAC method quickly attracted a small group of followers that used it to study several problems: Chan and Street (1970) applied it to free surface waves, Foote (1973) and Foote (1975) simulated the oscillations of an axisymmetric drop and the collision of a drop with a rigid wall, and Chapman and Plesset (1972) and Mitchell and Hammitt (1973) simulated the collapse of a cavitation bubble. Although the MAC method was designed specifically for multifluid problems (hence the M for Markers!), it was also the first method to successfully solve the Navier–Stokes equation using the primitive variables (velocity and pressure). The staggered grid used was a novelty, and today, it is common practice to refer to any method using a projection-based time integration on a staggered grid as a MAC method.

The next generation of methods for multifluid flow evolved gradually from the MAC method. It was already clear in the Harlow and Welch (1965) paper that the marker particles could cause inaccuracies, and among the number of algorithmic ideas explored by the Los Alamos group, the replacement of the particles by a marker function soon became the most popular alternative. Thus, the volume-of-fluid (VOF) method was born. VOF was first discussed in a refereed journal article by Hirt and Nichols (1981), but the method apparently originated a few years earlier. While the results were generally superior to those of the MAC method, early VOF results showed considerable irregularities at the interface between the different fluids. In the 1980s and early 1990s, better advection methods (Youngs, 1982) and new ways to find surface tension (Brackbill et al., 1992) improved the results significantly. Fairly advanced VOF methods are now available, and many commercial CFD codes include the option of simulating free surface or multiphase flows using the VOF method. For a review of VOF methods, see Scardovelli and Zaleski (1999) and Tryggvason et al. (2011). Other methods, based on similar ideas but advecting the marker function in a different way, include the level set method (reviewed by Osher and Fedkiw, 2001, and Sethian, 2001) and the CIP method of Yabe and collaborators (see Yabe et al., 2001).

While the MAC methodology and its successors were being developed, other techniques were also being explored to capture fluid interfaces. Hirt et al. (1970) describe one of the earliest use of structured boundary-fitted Lagrangian grids. This approach is particularly well suited when the interface topology is relatively simple and no unexpected interface configurations develop. In a related approach, a grid line is aligned with the fluid interface, but the grid away from the interface is generated using standard grid generation techniques such as conformal mapping or other more advanced elliptic grid generation schemes. Such a method was used by Ryskin and Leal (1984) to compute the steady rise of buoyant, deformable, axisymmetric bubbles. Ryskin and Leal assumed that the fluid inside the bubble could be neglected, but Dandy and Leal (1989) and Kang and Leal (1987) extended the method to two-fluid problems and unsteady flows. Several authors have used this approach to examine relatively simple problems such as the steady-state motion of single particles or moderate deformation of free surfaces. Fully 3D simulations are relatively rare, and it is probably fair to say that it is unlikely that this approach will be the method of choice for very complex problems such

as the 3D unsteady motion of several particles. Similar comments apply to methods based on resolving the fluid by unstructured grid that are updated to ensure that the interface coincides with a grid line.

Several hybrid methods combine the ideas discussed earlier in a variety of ways. Front tracking, where the interface is marked by connected marker points but a fixed grid is used for the fluid within each phase has been particularly successful. In the method of Tryggvason and collaborators (Unverdi and Tryggvason, 1992, Tryggvason et al., 2001), the tracked front is used to advect a smoothed marker function and to compute the surface tension. The method is therefore very similar to methods that work directly with a grid-marker function, but the advection of the interface is greatly improved. For other implementation of similar ideas, see van Sint Annaland et al. (2006), Hao and Prosperetti (2004), Hua and Lou (2007), and Muradoglu and Kayaalp (2006). Other methods have been designed to capture the interface more accurately. These include the method of Glimm and collaborators (Glimm and McBryan, 1985) where the fixed grid is modified near the front to make a grid line follow the interface, as well as more recent "sharp-interface methods" (such as Fedkiw et al., 1999, Ye et al., 1999, Lee and LeVeque, 2003). The increased accuracy does, however, come at the cost of a considerably increased complexity, and it is not clear at the time of this writing what the impact of these new methods will be on the DNS of finite Reynolds numbers flows.

The most recent addition to the collection of methods capable of simulating finite Reynolds number multiphase flows is the lattice Boltzmann method (LBM). Although there have been some doubts about the accuracy and correctness of the LBM, it seems now clear that they can be used to produce results of accuracy comparable to more conventional methods. It is still not clear whether the LBM is significantly faster or simpler than other methods (as sometimes claimed), but most likely these methods are here to stay. For a discussion see, for example, Shan and Chen (1993).

Although there are many possible ways to solve the Navier–Stokes equations for multiphase flows, the most successful approaches have been based on the so-called one-fluid formulation, where one set of equations are solved for the whole flow field and the phase boundary is treated as an embedded interface by adding the appropriate source terms. These source terms are in the form of delta functions localized at the interface and are selected to provide the correct matching conditions at the phase boundary. Although the integral form is often used as a starting point, here we write the "one-fluid" Navier–Stokes equations for incompressible flows in the following differential form:

$$\frac{\partial \rho \mathbf{u}}{\partial t} + \nabla \rho \mathbf{u}\mathbf{u} = -\nabla p \cdot \rho \mathbf{g} + \nabla \cdot \mu(\nabla \mathbf{u} + \nabla \mathbf{u}^T) + \int_f \sigma \kappa \mathbf{n} \delta(\mathbf{x} - \mathbf{x}_f) ds. \tag{2.70}$$

Here,

u is the velocity
p is the pressure
ρ and μ are the discontinuous density and viscosity fields, respectively
σ is a 3D delta function constructed by repeated multiplication of 1D delta functions
κ is twice the mean curvature
n is a unit vector normal to the front

Formally, the integral is over the entire front, thereby adding the delta functions together to create a force that is concentrated at the interface, but smooth along the front. **x** is the point at which the equation is evaluated and $\mathbf{x}_f$ is the position of the front. In most cases, the flow is assumed to be incompressible, so Equation 2.70 is supplemented by

$$\nabla \cdot \mathbf{u} = 0. \tag{2.71}$$

When combined with the momentum equation, this leads to an elliptic equation for the pressure. The single field formulation naturally incorporates the correct mass, momentum, and energy balances across the interface and integration of the conservation equations across the interface directly yields the standard jump conditions.

Equations 2.70 and 2.71 are usually solved on a regular staggered grid using a projection method for the time integration. The spatial and temporal accuracy are usually of second order, although sometimes higher-order time integration is used and the advection terms are treated by methods that are more robust than centered differences such as QUICK, ENO, or WENO. The elliptic pressure equation is generally solved by a multigrid iteration or Krylov subspace methods.

This solution strategy is, in particular, used in most implementations of VOF, level set, and front-tracking methods. What distinguishes between the various methods is how the marker function identifying the different fluids is updated. For flows where the material properties are constant in each fluid, a marker function is usually used to identify the different fluids. The marker moves with the fluid velocity:

$$\frac{DH}{Dt} = \frac{\partial H}{\partial t} + \mathbf{u} \cdot \nabla H = 0, \tag{2.72}$$

where

$$H(\mathbf{x}) = \begin{cases} 1 \text{ in fluid } 1 \\ 0 \text{ in fluid } 2 \end{cases}. \tag{2.73}$$

The density and viscosity are then set as functions of H, usually by

$$\rho = \rho_2 + (\rho_1 - \rho_2)H(\mathbf{x}) \quad \text{and} \quad \mu = \mu_2 + (\mu_1 - \mu_2)H(\mathbf{x}) \tag{2.74}$$

Other material properties are set similarly, when needed. Sometimes, the density is used as a marker function and other variables set as functions of the density.

In the VOF method, the marker function is advected directly, using specialized techniques to ensure that the interface stays sharp and well defined. In level set methods, a smooth function is advected and the interface identified by the zero contour line. The marker function is then constructed by mapping the smooth function into a function that transitions relatively sharply from one value to the other. To keep the mapping well behaved, the smooth function is readjusted periodically to keep it close to a distance function in the vicinity of the interface. In both VOF and level set methods, surface tension must be computed from the marker function on the fixed grid. In front-tracking methods, the phase boundary is tracked by connected marker points (the "front") that are advected by the flow velocity, interpolated from the fixed grid. The gradient of the marker function becomes a delta function when the change is abrupt across the boundary. To transfer the front singularities to the fixed grid, the delta functions are approximated by smoother functions with a compact support on the fixed grid. At each time step, after the front has been advected, the marker function is reconstructed by integration of the smooth grid-delta function. The surface tension is computed on the front, distributed to the grid, and then added to the nodal values of the discrete Navier–Stokes equations.

Many reviews are available that discuss computational methods for multiphase flows. Early reviews that discuss the many possible approaches include Hyman (1984) and Floryan and Rasmussen (1989), and more specialized treatment can be found in Scardovelli and Zaleski (1999) for VOF methods, Anderson et al. (1998) for phase field methods, and Osher and Fedkiw (2002) who discuss level set methods. The book by Shyy et al. (1996) also covers several aspects of computations of multiphase flows. Several articles about various aspects of computations of multiphase systems and related problems can be found in a special issue of the *Journal of Computational Physics* (volume 169, 2001). More recent coverage, focusing on VOF and front-tracking method, can be found in Tryggvason et al. (2011).

2.2.3 Bubbly Flows

One of the major applications of DNS of multiphase flows has been of bubbly flows. Studies of many interacting bubbles in periodic domains can be found in Esmaeeli and Tryggvason (1998, 1999) who simulated the unsteady motion of several 2D and 3D bubbles and Bunner and Tryggvason (1999, 2002a,b) who examined 3D systems with a much larger number of bubbles. The results of these simulations have helped clarify various aspects of the bubble interactions. One of the fundamental questions was, in particular, if relatively modest number of bubbles in fully periodic domains could be used to model homogeneous bubbly flows. The simulations showed that relatively low-order statistics, such as the average rise velocity of the bubbles and the pair probability distribution, converge rapidly with increasing size of the simulated domain, but other quantities, like the self-diffusion coefficient, converge much more slowly. The results also showed that for nearly spherical buoyant bubbles at modest Reynolds numbers that the dominant interaction mode is the "drafting, kissing, and tumbling" mechanism described by

Fortes et al. (1987). Thus, a bubble behind another bubble is drawn into the wake of the bubble in front, once in the wake it catches up and collides with the one in front and the two bubbles then "tumble" and move apart. This collision mode is inherently a finite Reynolds number effect, since two buoyant bubbles in Stokes flow do not change their orientation unless acted on by the third bubble and bubbles in potential flow repel each other if they are rising in an in-line configuration. The results also helped clarify the very different dynamics of nearly spherical bubbles that tender to line up side by side and more deformable ones that often rose one behind the other.

A number of recent studies have also focused on bubbles in laminar and turbulent flows in channels (Lu et al., 2005, 2006, Lu and Tryggvason, 2006, 2008, 2013). The results show that for clean bubbles in vertical channels, the flow structure is determined by the lift force on the bubbles. Nearly spherical bubbles in upflow are pushed to the walls, resulting in a bubble-rich wall layer and a lower void fraction in the middle, while in downflow the bubbles move away from the wall and the void fraction in the middle increases. For steady-state flow, this results in a very simple model for the void fraction. The removal of bubbles from the core region in upflow decreases the mixture density, and eventually, the weight of the mixture balances the imposed pressure gradient and the transfer stops. For downflow, the addition of bubbles to the core decreases the mixture density and again, the transfer continues until the buoyancy of the mixture matches the weight of the mixture. Thus, in both cases, the void fraction at steady state in the channel core is easily found, and if the average void fraction is known, then the void fraction in the wall layer for upflow and the thickness of the bubble free wall layer for downflow can be computed. The lift on deformable bubbles is generally either small or in a direction opposite to nearly spherical bubbles, so bubble-rich wall layers are not seen, in agreement with experimental studies. Simulations of the transient evolution toward the steady state have shown that while the lateral migration of bubbles occurs relatively fast, the velocity takes longer to adjust to the changes in the void fraction distribution.

As computer power increases, it is possible to examine both larger and more complex systems. In Figure 2.7, one example of a relatively large-scale simulation of bubbles in a turbulent channel flow is shown. The domain size is $2\pi \times 4 \times \pi$ computational units in the streamwise, wall-normal, and spanwise direction, respectively, resolved by about 0.4 billion grid points. The physical parameters are selected such that the Morton number is equal to 5.75×10^{-10} and the void fraction is about 3%. The bubbles come in four sizes, with the smallest bubbles having a diameter of 0.16 in computational units, and the largest one with a diameter of 0.44. The majority of the bubbles are small, and we expect the smallest bubbles to accumulate at the wall. The flow is driven upward by an imposed pressure gradient, giving a friction Reynolds number of $Re^+ = 500$. The bubbles are initially distributed nearly uniformly across the domain but as they start to rise, the smaller bubbles start to migrate toward the walls and form a dense wall layer. In the figure, the bubbles are shown at a relatively early time, where many of the small bubbles have moved to the wall, but there are still several small bubbles in the middle, along with most of the larger bubbles. The bubbles are shown along with the vorticity, visualized using the λ_2 method (Jeong and Hussain, 1995), where dark and light color indicates rotation in the opposite direction. Near the wall, most of the vortices are aligned with the flow and usually come in pairs, where nearby vortices have opposite rotation. Although bubbles moving toward the walls disrupt the vortices there, some have survived, at least at the time plotted here. The figure also shows that the vorticity shed by the large bubbles is responsible for the majority of the vorticity in the interior of the channel. Figure 2.8 shows a close-up of the bubbles and the vortices near the right wall, where we have selected a different value for the isocontour of λ_2.

For other simulations of various aspects of bubbly flows, see, for example, the LBM studies by Takada et al. (2000, 2001) and Sankaranarayanan et al. (2002); VOF simulations by Rabha and Buwa (2010); and computations using a front-tracking method similar to the one used for the results in Figure 2.7 by Dijkhuizen et al. (2010a,b). Large-scale simulations using a finite element flow solver coupled with a level set method to advect the phase boundary can be found in Bolotnov et al. (2011) and Bolotnov (2013).

Although bubbly flows have received considerable attention, the interface topology is often much more complex, particularly if the void fraction is high. Not only can the interface topology be very complex, but the interfaces may undergo repeated coalescence and breakup. Modeling such flows is still very primitive, but DNS should be able to provide considerable light on the various processes governing the flow. Topology changes in multiphase flows occur through two primary mechanisms: films that rupture and threads that break. Methods that track the indicator function identifying the different fluids directly on an Eulerian grid (such as VOF or level set methods) lead to coalescence or breakup whenever the film or the thread is underresolved, but front-tracking methods will generally not allow a change in topology. If the interface is tracked, it is possible to either prevent or allow topology changes. Generally, threads that

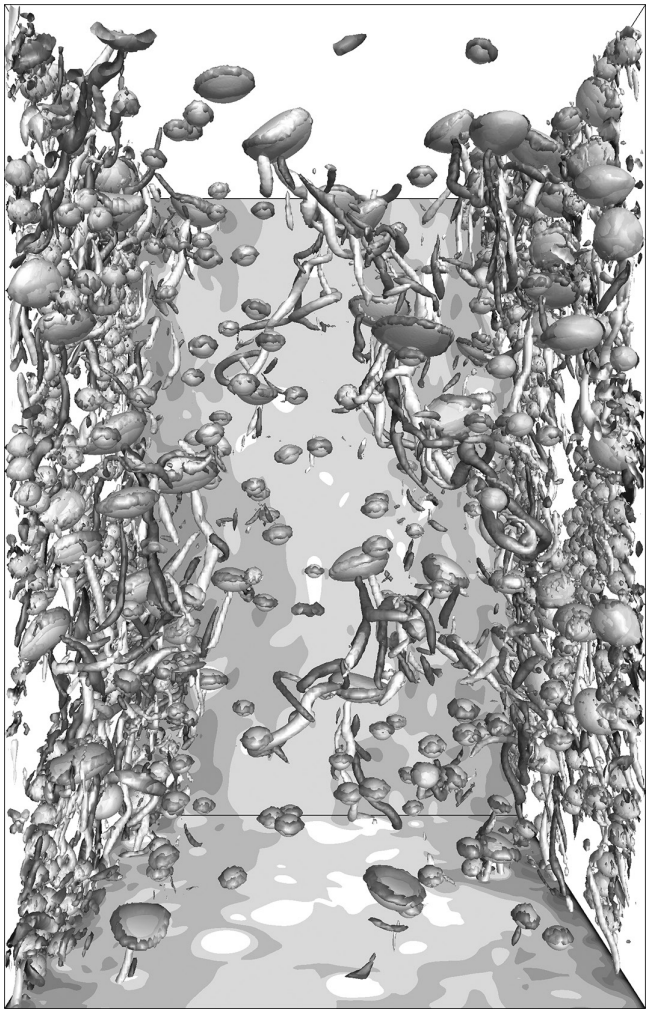

Figure 2.7

One frame from a simulation of many bubbles of different sizes in a turbulent channel flow. The bubbles and the vortical structures, visualized by $\lambda_2 = -2$, along with contours of the vertical velocity in the bottom horizontal plane and the back vertical plane. (Courtesy of Dr. Jiacai Lu, University of Notre Dame, Notre Dame, IN.)

break are by far the easier to deal with than the rupture of thin films. The diameter of threads goes to zero in a finite time, and the evolution is governed by the Navier–Stokes equations so that no additional physical modeling needs to be included. In addition, the breakup is very fast, so even if the final stage is not well resolved, that often does not have a significant effect on the overall flow dynamics. Thus, thread breakup is generally handled easily by most methods. Film draining and rupture are more complex, since the topology change takes place due to short-range attractive forces that are usually not included in the simulations. The attractive forces lead to an instability that results in holes that are then enlarged either by the formation of other holes that merge with the first one or by the enlargement of the original hole by rim breakup involving the formation of very small drops that are difficult to resolve. While methods that track the indicator function directly often produce ruptures that look plausible, the rupture is an artifact of the finite resolution, and in some cases, it is found that refining the grid postpones the rupture and prevents the solution from converging. It is possible that in some cases it does not make a big difference whether the rupture is physical or due to the resolution, but, in general, the importance of capturing the rupture accurately is not well understood. When the interface is tracked by connected marker points, it is necessary to explicitly add a strategy to rupture the interfaces when they are close enough, but at least it is possible to control when rupture takes place and when it does not. Thus, it should be possible to examine how sensitive the overall evolution of the flow is to how the rupture takes place, even if a complete rupture model is not included.

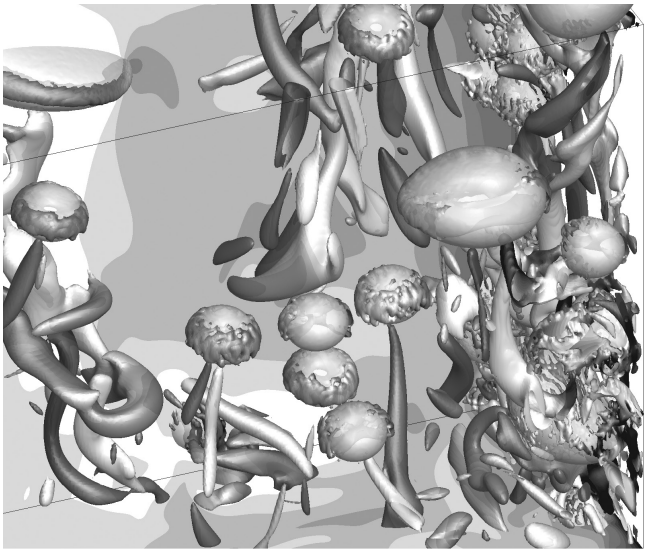

Figure 2.8

A close-up for the results shown in Figure 2.7, showing bubbles and vortical structures near the right wall. Here, $\lambda_2 = -1$. (Courtesy of Dr. Jiacai Lu, University of Notre Dame, Notre Dame, IN.)

Figure 2.9 shows results from two simulations of 40 bubbles in a channel flow. The bubbles are initially placed in a rectangular channel of size $\pi \times 2 \times \pi/2$ computational units in the streamwise, wall-normal, and spanwise direction, respectively, resolved by a $192 \times 128 \times 96$ grid. The bubble diameter is selected such that the void fraction is 13.6%. The flow is initially turbulent, with a friction Reynolds number of 128. All parameters except the surface tension are the same for both runs, giving a Morton number of 2.41×10^{-12} for the high surface tension case and 1.54×10^{-7} for the low surface tension case. The initial Eötvös

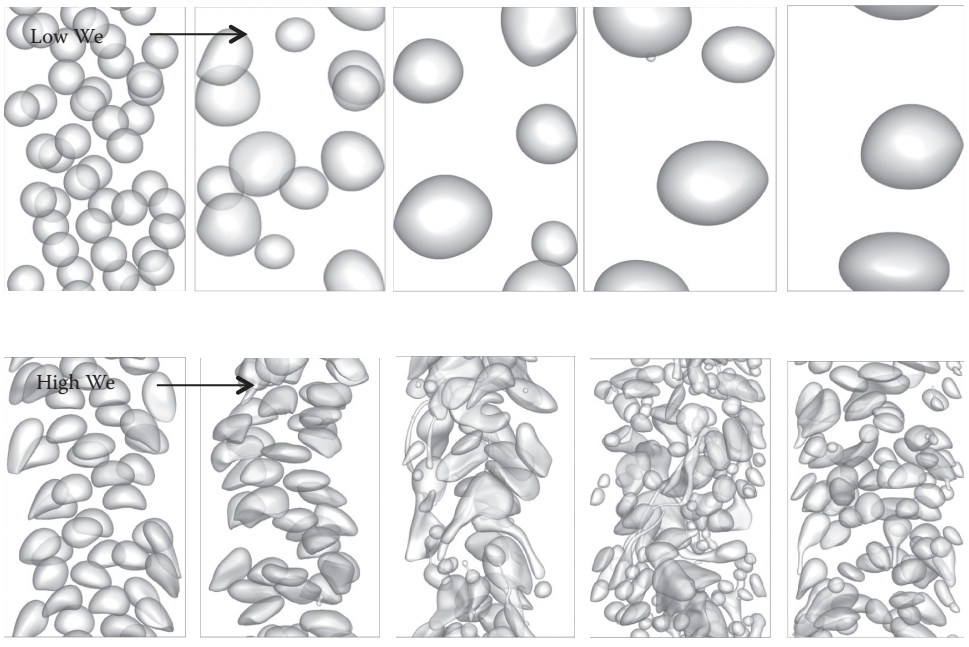

Figure 2.9

A few frames from two simulations of the evolution of several bubbles placed in an initially turbulent channel flow, when the bubbles are allowed to coalesce. In the top frames the surface tension is high and in the bottom frames the surface tension is low, so the bubbles break up after the initial coalescence. (Courtesy of Dr. Jiacai Lu, University of Notre Dame, Notre Dame, IN.)

number is 0.2 for the first case and 8.0 for the second case. As the bubbles rise, they collide and coalesce if the liquid film between them becomes sufficiently thin. For the high surface tension case, the bubbles keep coalescing until there is only one large bubble left (the two bubbles in the last frame will eventually become one), but for the high Weber number the bubbles first coalesce and then breakup again, eventually leading to a mixture of bubble sizes. Here, the thin films are ruptured if they become thinner than a third of a grid spacing, thus making the results similar to what we would expect from a VOF or level set computation.

While simulations of bubbles undergoing topology changes are just starting, many authors have examined the atomization of liquid jets, where the topology changes are critical for the formation of drops. Such studies include air-assisted breakup due to the coinjection of air as well as the breakup due to cross flow (Ménard et al., 2007, Desjardins et al., 2008, Gorokhovski and Herrmann, 2008, Lebas et al., 2009, Desjardins and Pitsch, 2010, Herrmann, 2011). The breakup remains the main challenge in these simulations and in spite of very large grids (Shinjo and Umemura, 2010, 2011) or the use of locally refined grids (Fuster et al., 2009), the breakup is generally dependent on the grid resolution and the smallest drops are underresolved. Thus, several authors have proposed hybrid approaches, where very small drops are modeled as point particles whose motion is modeled by empirical correlations for the drag force and ordinary differential equations are solved for the velocity and location (Herrmann, 2010, Tomara et al., 2010). The challenge is when to convert a fluid blob resolved on a grid to a point particle, and sometimes back again, in such a way that all conservation principles are satisfied.

2.2.4 Outlook

DNSs of multiphase flows have come a long way during the last decade. It is now possible to follow the motion of hundreds of bubbles, drops, and particles at finite Reynolds numbers in simple geometries for sufficiently long time so that meaningful averages can be computed. Much remains to be done, however. At higher Reynolds numbers, the number of grid points required to resolve each bubble and the flow around them increases and the cost of doing simulations with many bubbles increases. With larger computers, such simulations will become increasingly more feasible. The formation of bubbles and drops, as well as coalescence, must also be addressed and except for a few simulations of the breakup of drops in well-defined flows, little has been done. These problems are, nevertheless, well within reach.

As DNS of multiphase flows become more common, the need for advances in the development of the theoretical framework for modeling such flows is also becoming more urgent. Current models have mostly been developed in an environment where relatively little has been known about the details of the flow, and for the most part, these models are far behind what is available for single-phase turbulent flows. While our abilities to simulate directly more and more complex multiphase systems will certainly increase dramatically in the next few years, it is important to realize that our desire to compute will always be ahead of what we can do by DNS. Thus, the condensation of knowledge obtained by DNSs into reduced or averaged models that allow faster predictions will remain at the core of multiphase flow research for a long time to come. Given the experience from modeling turbulent single-phase flows, it is likely that many such models will involve resolving the large-scale motion but modeling the smallest scales. Efforts to develop such large eddy simulation–like model have just started (Labourasse et al., 2007, Toutant et al., 2008, 2009, Vincent et al., 2008).

Although much more can be done for two-fluid disperse systems, it is the longer-term development of the ability to compute the coupled motion of complex systems that will bring about the full impact of DNS. Most engineering fluid systems include a large number of physical phenomena such as fluid flow, evaporation, solidification, and chemical reactions, and simulations of the full systems will allow unprecedented insight. Real bubbles are, for example, rarely clean, and it is well known that surfactants change the behavior of a single bubble significantly. Extensions of various of methods to include surfactants can be found in James and Lowengrub (2004), Muradoglu and Tryggvason (2008), Booty and Siegel (2010), and Muradoglu and Tryggvason (2014), and results for a single bubble show significant effects, including changes in the lift force. However, DNS studies of the collective dynamics of many contaminated bubbles remain to be done. Heat transfer has been examined by Deen and Kuipers (2013), who showed that the passage of a small group of bubbles generally increases the local heat transfer, and by Tanaka (2011) and Dabiri and Tryggvason (2015) examined the motion of many bubbles in turbulent channel flows and showed that the bubbles enhance the overall heat transfer, both for nearly spherical bubbles that form wall layers and for more deformable ones that stay away from the walls. Mass transfer and reactions require us to solve additional advection/diffusion equations that include source terms when there are reactions, but the large range of scales, due to low mass diffusivities and fast reactions, introduce significant challenges. Similarly, several authors have simulating

boiling flows (for early work for relatively simple systems, see Juric and Tryggvason, 1998, Son and Dhir, 1998, Shin and Juric, 2002, and Esmaeeli and Tryggvason, 2003). The main challenge for most of these systems is that the different physical processes take place on very different temporal and spatial scales. While adaptive grid refinement can, in principle, be used for most of those cases, the reality is that that approach will quickly consume all the available grid points. In some cases, the small-scale motion is relatively simple, because surface tension and viscosity are significant, and the dynamics is well described by analytical models. When applicable, it is tempting to couple an analytical model of the small-scale motion with a full simulation of the larger-scale motion. The point particle approximation for small bubbles and drops is perhaps the best example, but a similar approach has also been used for nucleate boiling (Son and Dhir, 1998) and mass transfer (Aboulhasanzadeh et al., 2012). Although we defined DNS as simulations where all continuum length and timescales are fully resolved, and one can argue that we do not really have a DNS if some scales are treated differently, it is likely that as our problems become more complex, our numerical strategies must allow for more flexible approaches. As additional physical processes are incorporated into our mathematical models, we are also likely to be faced with increased uncertainty in the mathematical models used to describe the new physics, rendering traditional DNS less applicable.

2.3 The Lattice Boltzmann Method

Cyrus K. Aidun, Dennis E. Oztekin, Yuanzheng Zhu, Tomas Rosén, and Fredrik Lundell

2.3.1 Introduction and Basics of Lattice Boltzmann Method

The lattice Boltzmann method (LBM) is a computational tool that has been growing in popularity since its development due to the simplicity with which it is implemented and the ease with which it can be scaled to parallel processing systems. The method was introduced in the late 1980s (Higuera and Jimenez, 1989) and addressed a number of problems with its predecessor, the lattice gas automation method (Frisch et al., 1987). New variations of the method are being developed constantly, extending range of applicable problems for LBM. This constant development creates opportunities for new investigations on a variety of fronts.

This chapter will focus primarily on four areas that have been under intense study recently as fields of research that lend themselves well to newer lattice Boltzmann variants. The first section will focus on fluid–solid interaction. Here, the bounce-back boundary condition will be discussed, along with the newer external boundary force (EBF) method for treating solid interfaces. Following this, there will be a section about the suspension of deformable capsules and then a section about the suspension of deformable fibers. Finally, there will be a section on the methods by which lattice Boltzmann deals with liquid–gas problems.

2.3.1.1 Brief Background

All of lattice Boltzmann research is based on the Boltzmann equation, which states

$$\frac{\partial f}{\partial t} + \boldsymbol{\zeta} \cdot \nabla f + \frac{\boldsymbol{F}}{m_p} \cdot \frac{\partial f}{\partial \boldsymbol{\zeta}} = \left\{ \frac{\partial f}{\partial t} \right\}_{collision} \tag{2.75}$$

In this equation,

$\boldsymbol{F}$ is the term of body forces

m_p is the particle mass

$\boldsymbol{\zeta}$ is the velocity of the particle

f is the density distribution function, that is, for some position and some time, the number of particles per volume, or density ρ, with a velocity between $\boldsymbol{\zeta}$ and $\boldsymbol{\zeta} + d\boldsymbol{\zeta}$. From this definition, we can write

$$\rho = \int f d\boldsymbol{\zeta} \tag{2.76}$$

The moment of this equation can be taken to get a very important relationship in recovering the conservation of momentum:

$$\rho \boldsymbol{u} = \int \boldsymbol{\zeta} f d\boldsymbol{\zeta} \tag{2.77}$$

Here, it is very important to distinguish $\boldsymbol{u}$, the macroscopic fluid velocity, from $\boldsymbol{\zeta}$, the particle velocity. The macroscopic fluid velocity is the property that is commonly utilized in fluid mechanics; as such, this is the property that is typically solved for in the following sections. The particle velocity is only the velocity of a single particle; if it is assumed that the individual particles only move along a discretized grid, this will be reduced to the aptly named lattice velocity, $\boldsymbol{e}_k$. This will be presented later. Before any discretization can occur, the Boltzmann equation needs to be reduced to a usable form. First, the forcing term is dropped. Later in the chapter, more numerically friendly methods of including the force will be discussed. The next term that needs to be addressed is the rate of change of the density distribution due to the collision of particles. This is the right-hand side of the Boltzmann equation displayed earlier. To address this term, the Lattice Bhatnagar-Gross-Krook, LBGK, approximation (Bhatnagar et al., 1954) is applied. This approximation

introduced an equilibrium density distribution function f^{eq}, which is a function of velocity and density, and a relaxation time τ, which is a function of viscosity. The approximation becomes

$$\left\{\frac{\partial f}{\partial t}\right\}_{collision} = \frac{f^{eq} - f}{\tau} \tag{2.78}$$

With this, the Boltzmann equation is put into a usable form and is ready for discretization.

2.3.1.2 Discretization

The most immediate effect of the discretization is allowing the expansion of the derivative term remaining on the left-hand side of the Boltzmann equation. With these simplifications, the Boltzmann equation is reduced to

$$f_k(\boldsymbol{x}+\boldsymbol{e}_k, t+1) - f_k(\boldsymbol{x},t) = -\frac{1}{\tau}\left[f_k(\boldsymbol{x},t) - f_k^{eq}(\boldsymbol{x},t)\right] = \boldsymbol{C}\left(f_k(\boldsymbol{x},t)\right) \tag{2.79}$$

where the subscript k denotes the lattice direction and $\boldsymbol{C}$ is the collision operator. The lattice direction represents which path from the lattice node a given particle might be taking. For reference, the lattice arrangements used in this study are D2Q9 and D3Q19. Where the notation DxQy means there are x dimensions and y lattice arrangements. D2Q9 is commonly used two dimensional arrangement which includes the node itself, the four cardinal direction, and its four diagonals. D3Q19 is a common three dimensional arrangement which includes the node itself, its six cardinal directions, and the twelve diagonals that lie on the three planes normal to the cardinal directions. From this equation, commonly called the evolution equation, the equilibrium density distribution function can be determined in a number of ways; however, the most general way is demonstrated by He and Luo (1997). This derivation starts with a Maxwell–Boltzmann distribution and takes a Taylor expansion about the macroscopic velocity. The result is

$$f_k^{eq}(x,t) = \frac{3\rho}{(2\pi c^2)^{D/2}}\left\{1 + \frac{6\boldsymbol{e}_k\boldsymbol{u}}{c^2} - \frac{3\boldsymbol{e}_k^2}{c^2} + \frac{9\boldsymbol{e}_k\boldsymbol{u}^2}{c^4}\right\} \tag{2.80}$$

Here,

D is the number of dimensions being modeled

c is called the lattice speed, which is the distance between two adjacent nodes divided by the time of a single time step.

2.3.2 Fluid–Solid Interaction

In this section, we will discuss how fluid–solid interaction can be modeled in Lattice Boltzmann, LB, simulations. As an example, we will consider a single solid particle suspended in the fluid domain and describe two methods for coupling the solid and fluid motion.

2.3.2.1 Standard Bounce-Back Method

The standard bounce-back (SBB) method for simulating particles in flows was described by Aidun et al. (1998) and will be summarized in this section.

Consider a particle at a position $\boldsymbol{X}(t)$ with a certain velocity $\boldsymbol{U}(t)$ and angular velocity $\Omega(t)$ at time instance t. The particle has mass m and inertial tensor $\boldsymbol{I}$. The position, orientation, and geometry of the particle determine the location of the particle boundary $\Gamma(t)$. Using the SBB method, the following steps are performed:

1. Each link k is classified according to the boundary $\Gamma(t)$ (see Figure 2.10). The link in the opposite direction of k is denoted k'. The link is
   a. A boundary link (*BL*) if it is crossing the particle boundary
   b. A regular link (*RL*) otherwise

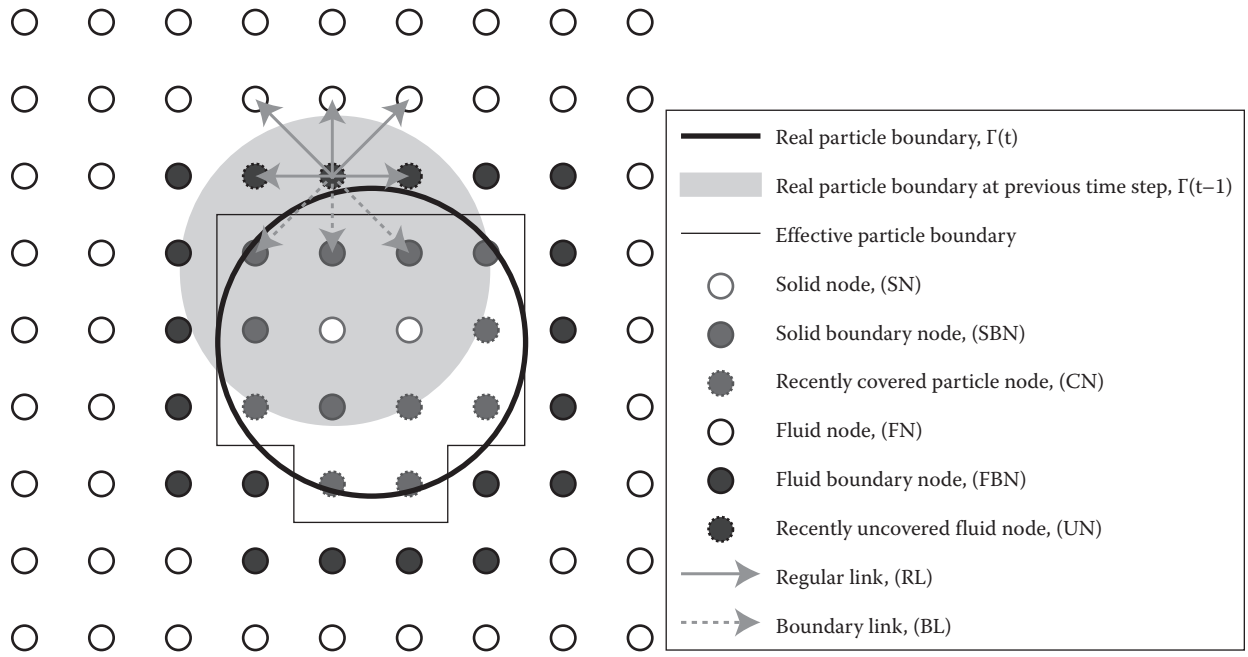

Figure 2.10

Definitions and classifications of the standard bounce-back method for a D2Q9 arrangement.

Note that the effective boundary of the particle is defined by the halfway point of the BLs and thus gets a staircase shape.

2. The lattice nodes are classified according to the boundary $\Gamma(t)$ (see Figure 2.10). The node is
   - **a.** A fluid node (*FN*) if the node is outside $\Gamma(t)$ and all links are RLs
   - **b.** A fluid boundary node (*FBN*) if the node is outside $\Gamma(t)$ and has one or more BLs
   - **c.** A recently uncovered node (*UN*) if the node is outside $\Gamma(t)$ but was inside $\Gamma(t-1)$
   - **d.** A solid node (*SN*) if the node is inside $\Gamma(t)$ and all links are RLs
   - **e.** A solid boundary node (*SBN*) if the node is inside $\Gamma(t)$ and has one or more BLs
   - **f.** A recently covered node (*CN*) if the node is inside $\Gamma(t)$ but was outside $\Gamma(t-1)$.
3. Density and velocity are corrected for UNs:

$$\rho(\boldsymbol{x},t)=\frac{1}{N_b}\sum_{k\in RL}\rho(\boldsymbol{x}+\boldsymbol{e}_k,t) \tag{2.81}$$

$$\boldsymbol{u}(\boldsymbol{x},t)=\boldsymbol{U}(t)+\boldsymbol{\Omega}(t)\times[\boldsymbol{x}-\boldsymbol{X}(t)] \tag{2.82}$$

where N_b is the amount of RLs for the UN and $\boldsymbol{x}\in UN$.

4. Collision step:

$$f_k(\boldsymbol{x},t_+)=\boldsymbol{C}f_k(\boldsymbol{x},t) \tag{2.83}$$

where $\boldsymbol{C}$ is the collision operator described in the previous section.

5. Propagation step:

$$\tilde{f}_k(\boldsymbol{x},t+1)=\begin{cases} f_{k'}(\boldsymbol{x},t_+) & \text{if } k'\in BL \\ f_k(\boldsymbol{x}+\boldsymbol{e}_{k'},t_+) & \text{otherwise} \end{cases} \tag{2.84}$$

6. The correct fluid density is obtained at each node through

$$\rho(\boldsymbol{x},t+1)=\frac{\sum_k \tilde{f}_k(\boldsymbol{x},t+1)}{1-2\sum_{k'\in BL} B_k \boldsymbol{u}_{k'}(t)\cdot \boldsymbol{e}_k} \tag{2.85}$$

where $B_0 = 1/3$, $B_{1-6} = 1/6$, and $B_{7-18} = 1/12$ in the D3Q19 lattice arrangement. The velocity of the wall $\boldsymbol{u}_k$, crossing the BL $k' \in BL$, is obtained through

$$\mathbf{u}_{k'}(t)=\mathbf{U}(t)+\boldsymbol{\Omega}(t)\times\left[\boldsymbol{x}+\frac{1}{2}\boldsymbol{e}_{k'}-\boldsymbol{X}(t)\right] \tag{2.86}$$

7. The modification of the distribution function components is obtained through

$$f_k(\boldsymbol{x},t+1)=\begin{cases}\tilde{f}_k(\boldsymbol{x},t+1)+2\rho(\boldsymbol{x},t+1)B_k\boldsymbol{u}_{k'}(t)\cdot\boldsymbol{e}_k & \text{if } k'\in BL\\ \tilde{f}_k(\boldsymbol{x},t+1) & \text{otherwise}\end{cases} \tag{2.87}$$

8. The force and torque contributions on the particle from the BLs are obtained through

$$\boldsymbol{F}_k^{BL}\left(\boldsymbol{x}+\frac{1}{2}\boldsymbol{e}_{k'},t+\frac{1}{2}\right)=2\boldsymbol{e}_{k'}[f_k(\boldsymbol{x},t+1)+\rho(\boldsymbol{x},t+1)B_k\boldsymbol{u}_{k'}(t)\cdot\boldsymbol{e}_{k'}] \tag{2.88}$$

$$\boldsymbol{T}_k^{BL}\left(\boldsymbol{x}+\frac{1}{2}\boldsymbol{e}_{k'},t+\frac{1}{2}\right)=\left[\boldsymbol{x}+\frac{1}{2}\boldsymbol{e}_{k'}-\boldsymbol{X}(t)\right]\times\boldsymbol{F}_k^{BL}\left(\boldsymbol{x}+\frac{1}{2}\boldsymbol{e}_{k'},t+\frac{1}{2}\right) \tag{2.89}$$

where $k' \in BL$.

9. The force and torque contributions on the particle from the recent CNs are obtained through

$$\boldsymbol{F}^{CN}\left(\boldsymbol{x},t+\frac{1}{2}\right)=\sum_k f_k(\boldsymbol{x},t)\boldsymbol{e}_k \tag{2.90}$$

$$\boldsymbol{T}^{CN}\left(\boldsymbol{x},t+\frac{1}{2}\right)=[\boldsymbol{x}-\boldsymbol{X}(t)]\times\boldsymbol{F}^{CN}\left(\boldsymbol{x},t+\frac{1}{2}\right) \tag{2.91}$$

where $\boldsymbol{x} \in CN$.

10. The force and torque contributions on the particle from the recent UNs are obtained through

$$\boldsymbol{F}^{UN}\left(\boldsymbol{x},t+\frac{1}{2}\right)=-\rho(\boldsymbol{x},t)\boldsymbol{u}(\boldsymbol{x},t) \tag{2.92}$$

$$\boldsymbol{T}^{UN}\left(\boldsymbol{x},t+\frac{1}{2}\right)=[\boldsymbol{x}-\boldsymbol{X}(t)]\times\boldsymbol{F}^{UN}\left(\boldsymbol{x},t+\frac{1}{2}\right) \tag{2.93}$$

where $\boldsymbol{x} \in UN$.

11. The force and torque contributions are summed together according to

$$\boldsymbol{F}\left(t+\frac{1}{2}\right)=\sum_{\boldsymbol{x}\in FBN}\sum_{k'\in BL}\boldsymbol{F}_k^{BL}\left(\boldsymbol{x}+\frac{1}{2}\boldsymbol{e}_{k'},t+\frac{1}{2}\right)+ \\ +\sum_{\boldsymbol{x}\in CN}\boldsymbol{F}^{CN}\left(\boldsymbol{x},t+\frac{1}{2}\right)+\sum_{\boldsymbol{x}\in UN}\boldsymbol{F}^{UN}\left(\boldsymbol{x},t+\frac{1}{2}\right) \tag{2.94}$$

$$\boldsymbol{T}\left(t+\frac{1}{2}\right)=\sum_{\boldsymbol{x}\in FBN}\sum_{k'\in BL}\boldsymbol{T}_k^{BL}\left(\boldsymbol{x}+\frac{1}{2}\boldsymbol{e}_{k'},t+\frac{1}{2}\right)+ \\ +\sum_{\boldsymbol{x}\in CN}\boldsymbol{T}^{CN}\left(\boldsymbol{x},t+\frac{1}{2}\right)+\sum_{\boldsymbol{x}\in UN}\boldsymbol{T}^{UN}\left(\boldsymbol{x},t+\frac{1}{2}\right) \tag{2.95}$$

12. Force $\boldsymbol{F}(t)$ and torque $\boldsymbol{T}(t)$ on the particle are found through averaging with the previous time step:

$$\boldsymbol{F}(t)=\frac{1}{2}\left[\boldsymbol{F}\left(t+\frac{1}{2}\right)+\boldsymbol{F}\left(t-\frac{1}{2}\right)\right] \tag{2.96}$$

$$\boldsymbol{T}(t)=\frac{1}{2}\left[\boldsymbol{T}\left(t+\frac{1}{2}\right)+\boldsymbol{T}\left(t-\frac{1}{2}\right)\right] \tag{2.97}$$

13. The new particle position $\boldsymbol{X}(t+1)$, velocity $\boldsymbol{U}(t+1)$, angular velocity $\boldsymbol{\Omega}(t+1)$, and orientation are found through numerical integration of the particle equations of motion:

$$m\frac{d\boldsymbol{U}(t)}{dt}=\boldsymbol{F}(t) \tag{2.98}$$

$$\boldsymbol{I}\cdot\frac{d\boldsymbol{\Omega}(t)}{dt}+\boldsymbol{\Omega}(t)\times[\boldsymbol{I}\cdot\boldsymbol{\Omega}(t)]=\boldsymbol{T}(t) \tag{2.99}$$

14. The particle boundary $\Gamma(t+1)$ is updated according to the new particle position and orientation.

2.3.2.2 External Boundary Force Method

The EBF method is an improved way of simulating particles in flows using LBM and was described by Wu and Aidun (2010a). Instead of having the particle defined on the fixed Eulerian fluid grid, the particle is defined by an overlapping Lagrangian grid that can move freely in the domain. The nodes in the fluid domain are denoted as $\boldsymbol{x}^e \in \Pi_f$ and the nodes in the particle grid are denoted (for the jth node) $\boldsymbol{x}_j^l \in \Gamma_s$. Each node in the particle grid is associated with an area element of size ΔA_j and gets a characteristic volume $\Delta v_j = \Delta A_j^{3/2}$. The best results are obtained by keeping $\Delta A_j \approx (\Delta x)^2$, with Δx as the node spacing in the fluid grid.

Fluid quantities are mapped onto the particle grid by using a discrete delta function as defined by Peskin (2002):

$$D(\boldsymbol{x})=\begin{cases}\dfrac{1}{64\Delta x^3}\left(\left(1+\cos\left(\dfrac{\pi x}{2\Delta x}\right)\right)\left(1+\cos\left(\dfrac{\pi y}{2\Delta x}\right)\right)\left(1+\cos\left(\dfrac{\pi z}{2\Delta x}\right)\right)\right), & |\boldsymbol{x}|\le 2\Delta x \\ 0, & |\boldsymbol{x}|>2\Delta x.\end{cases} \tag{2.100}$$

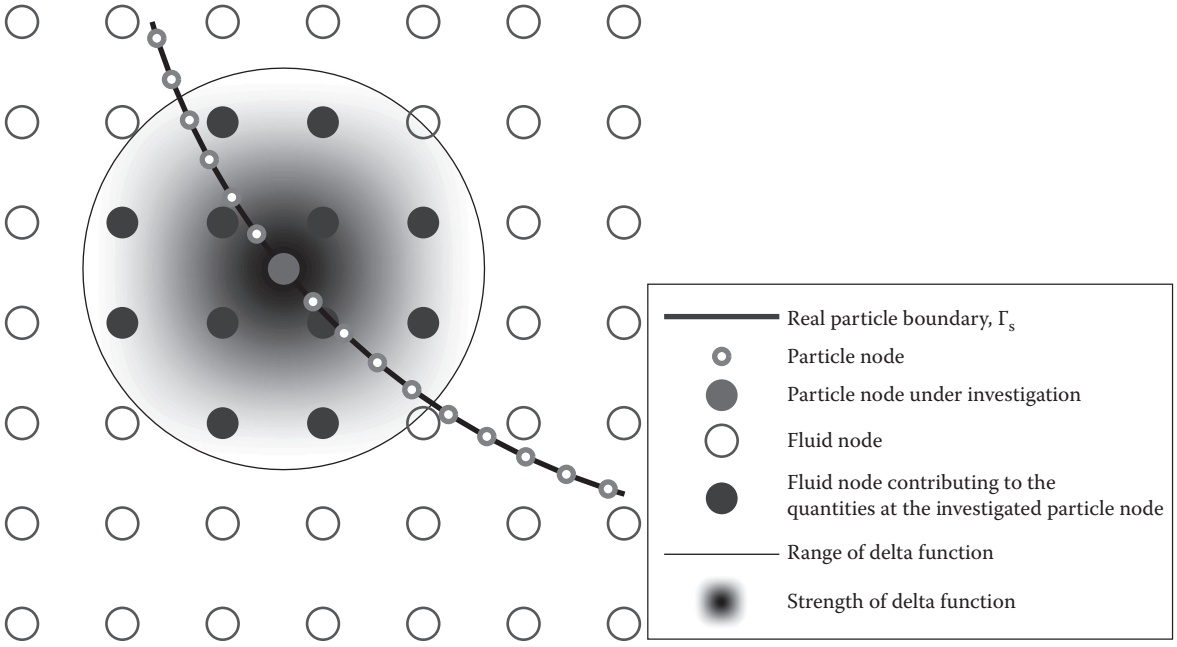

Figure 2.11

Illustration of the principle of the external boundary force method; the mapping of fluid quantities onto a particle node of investigation is done through a discrete delta function.

Again, we consider a particle with mass m, inertial tensor $\boldsymbol{I}$, position $\boldsymbol{X}(t)$, velocity $\boldsymbol{U}(t)$, and angular velocity $\boldsymbol{\Omega}(t)$ at time instance t. The following steps are performed when using the EBF method:

1. Propagation step:

$$\tilde{f}_k(\boldsymbol{x}^e,t) = f_k(\boldsymbol{x}^e + \boldsymbol{e}_{k'}, t-1) \tag{2.101}$$

2. The precollisional distributions $\tilde{f}_k(\boldsymbol{x}^e,t)$ are used to calculate the fluid velocity $\boldsymbol{u}(\boldsymbol{x}^e,t)$, which is then mapped to the particle grid through (see Figure 2.11):

$$\boldsymbol{u}(\boldsymbol{x}_j^l,t) = \sum_{\boldsymbol{x}^e \in \Pi_f} \boldsymbol{u}(\boldsymbol{x}^e,t) D(\boldsymbol{x}^e - \boldsymbol{x}_j^l)(\Delta x)^3. \tag{2.102}$$

3. The force acting on the particle node is calculated through

$$\boldsymbol{F}^{fsi}(\boldsymbol{x}_j^l,t) = \boldsymbol{f}^{fsi}(\boldsymbol{x}_j^l,t)\cdot\Delta v_j = \rho_0[\boldsymbol{u}(\boldsymbol{x}_j^l,t) - \boldsymbol{U}_p(\boldsymbol{x}_j^l,t-1)]\cdot\Delta v_j \tag{2.103}$$

with $\boldsymbol{f}^{fsi}(\boldsymbol{x}_j^l,t)$ as the force density at the jth particle node, ρ_0 as the reference fluid density, and $\boldsymbol{U}_p(\boldsymbol{x}_j^l,t-1)$ as the jth particle node velocity at time $t-1$.

4. The particle force $\boldsymbol{F}(t)$ and torque $\boldsymbol{T}(t)$ are determined by summing the contributions from the nodes:

$$\boldsymbol{F}(t) = \sum_{\boldsymbol{x}_j^l \in \Gamma_s} \boldsymbol{F}^{fsi}(\boldsymbol{x}_j^l,t) \tag{2.104}$$

$$\boldsymbol{T}(t) = \sum_{x_j^l \in \Gamma_s} (\boldsymbol{x}_j^l - \boldsymbol{x}^{lc}) \times \boldsymbol{F}^{fsi}(\boldsymbol{x}_j^l,t) \tag{2.105}$$

where $\boldsymbol{x}^{lc}$ is the center of gravity of the particle.

5. The new particle position $\boldsymbol{X}(t+1)$, velocity $\boldsymbol{U}(t+1)$, angular velocity $\boldsymbol{\Omega}(t+1)$, and orientation are found through numerical integration of the particle equations of motion:

$$m\frac{d\boldsymbol{U}(t)}{dt} = \boldsymbol{F}(t) \tag{2.106}$$

$$\boldsymbol{I}\cdot\frac{d\boldsymbol{\Omega}(t)}{dt} + \boldsymbol{\Omega}(t)\times[\boldsymbol{I}\cdot\boldsymbol{\Omega}(t)] = \boldsymbol{T}(t) \tag{2.107}$$

6. The force acting on the FNs from the particle is determined by

$$\boldsymbol{g}(\boldsymbol{x}^e,t) = -\sum_{\boldsymbol{x}_j^l\in\Gamma_s} \boldsymbol{f}^{fsi}(\boldsymbol{x}_j^l,t)D(\boldsymbol{x}^e-\boldsymbol{x}_j^l)\Delta v_j \tag{2.108}$$

7. Collision step:

$$f_k(\boldsymbol{x},t) = \boldsymbol{C}\tilde{f}_k(\boldsymbol{x},t) + 3w_k\boldsymbol{g}(\boldsymbol{x}^e,t)\cdot\boldsymbol{e}_k \tag{2.109}$$

where $\boldsymbol{C}$ is the collision operator, $w_0 = 1/3$, $w_{1-6} = 1/18$, and $w_{7-18} = 1/36$.

Even though the EBF method has many advantages over the SBB method, one drawback of EBF is that the code gets unstable as the particle density becomes significantly lighter than the density of the surrounding fluid. For simulating a particle with $\rho_p < \rho_f$, the SBB method is a better choice.

2.3.2.3 Example: Single Prolate Spheroid in Linear Shear Flow

One of the several advantages of the SBB and EBF methods is the ability to efficiently study nonspherical particles in flows with inertia. In many industrial applications, for example, in papermaking, the particles of interest are elongated and thus highly nonspherical fibers. The quality of the final product is dependent not only on the spatial distribution but also on the orientation distribution of fibers. This, in turn, is dependent on the orientational dynamics of the fibers due to local velocity gradients in the flow of paper pulp. Consequently, it is important to understand how a single fiber behaves in a linear shear flow. The easiest way of going from a spherical particle to a fiber is to consider a prolate spheroid, which can be seen as a sphere that is elongated along a line. This line is thus an axis of rotational symmetry $\boldsymbol{s} = (s_x, s_y, s_z)$ and also determines the particle orientation. The aspect ratio of the particle is given by $r_p = l/w$, where l is the particle length and w is the equatorial diameter.

Considering a single prolate spheroid in a linear shear flow (illustrated in Figure 2.12a), there are two dimensionless quantities governing the orientational dynamics. The fluid inertia is quantified by the particle Reynolds number $Re_p = \dot{\gamma}l/\nu$ ($\dot{\gamma}$ is the shear rate and ν is the kinematic viscosity), and the particle inertia is quantified by the Stokes number $St = (\rho_s/\rho_f)\,Re_p$ (ρ_s and ρ_f are the solid and fluid densities, respectively).

Without any inertia ($Re_p = St = 0$), Jeffery (1922) found that the prolate spheroid is rotating in one of an infinite amount of periodic orbits determined by the initial orientation (see trajectories of (s_x, s_y) in Figure 2.12b). Using the EBF method, the flow problem was investigated by Rosén et al. (2014, 2015). It was found that there are several dynamical transitions that occur when increasing Re_p, which leads to different stable rotational states as described in Table 2.1 and illustrated in Figure 2.12c. Depending on the choice of Re_p and St, certain rotational states are stable, and it is found that there are 13 distinct regimes in the Re_p/St parameter space according to Figure 2.13. This parameter space furthermore looks qualitatively the same (i.e., the same sequence of transitions with increasing Re_p and/or St, but quantitative values are different) for any prolate spheroid with $r_p = 2$–6 but is believed to be even qualitatively valid for a wider range of r_p.

In regimes II–IV, the planar states (rotating or tumbling) coexist with a nonplanar state (Log-rolling, inclined rolling, inclined kayaking, or kayaking). In these regimes, there is an unstable limit cycle that separates the initial orientations leading to the planar and nonplanar rotation, respectively (see Figure 2.12), for example, a particle initialized at rest with an orientation inside the unstable limit cycle will enter a nonplanar rotation.

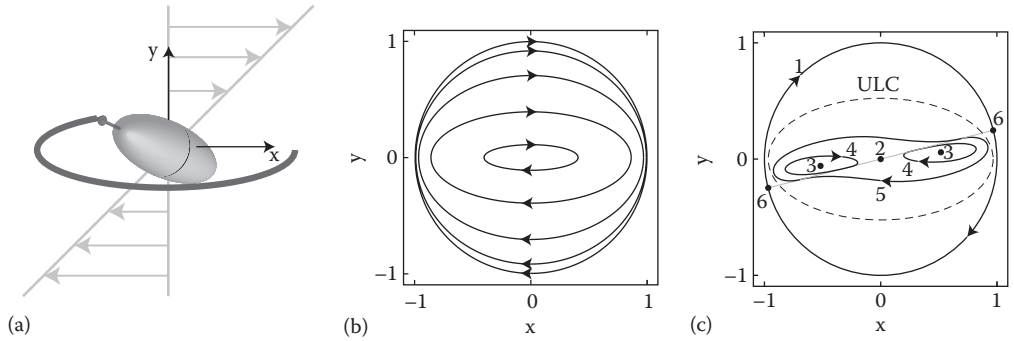

Figure 2.12

(a) A prolate spheroid is placed in a linear shear flow. The particle orientation is given by the direction of its symmetry axis, $\boldsymbol{s}$. (b) Trajectories of (s_x, s_y) at $Re_p = St = 0$ for a particle with $r_p = 4$ given by Jeffery (1922). (c) Schematic trajectories of (s_x, s_y) of stable rotational states at $Re_p > 0$. (1) Tumbling or rotating. (2) Log-rolling. (3) Inclined rolling. (4) Inclined kayaking. (5) Kayaking. (6) Steady state; An unstable limit cycle separates the nonplanar states (2–5) with the coexisting planar state (1).

Table 2.1 Description of the Rotational States of the Prolate Spheroid in Shear Flow

Rotational State	Rotational State (Abbr.)	Definition
Tumbling	T	$s_z = 0, \boldsymbol{s} = \boldsymbol{s}(t), \tau_p > \tau_c$
Rotating	R	$s_z = 0, \boldsymbol{s} = \boldsymbol{s}(t), \tau_p < \tau_c$
Steady state	S	$s_z = 0, \boldsymbol{s} = const.$
Log-rolling	LR	$s_z = 1, \boldsymbol{s} = const.$
Inclined rolling	IR	$0 < s_z < 1, \boldsymbol{s} = const.$
Inclined kayaking	IK	$0 < s_z < 1, \boldsymbol{s} = \boldsymbol{s}(t), \langle s_x \rangle \neq 0$
Kayaking	K	$0 < s_z < 1, \boldsymbol{s} = \boldsymbol{s}(t), \langle s_x \rangle = 0$

τ_p is the period of the rotation and $\tau_c = (\pi/\dot{\gamma}) \cdot (r_p + r_p^{-1} + 2)$.

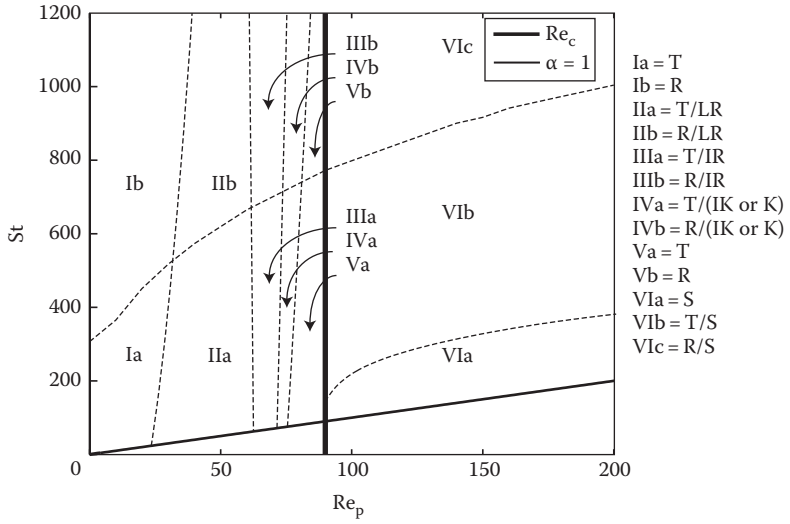

Figure 2.13

Stable rotational states of a prolate spheroid of $r_p = 4$ in a linear shear flow as found by Rosén et al. (2014, 2015); in regions with two stable states, the final state depends on initial conditions; and the steady state is created in a saddle-node bifurcation at $Re_p = Re_c$. The abbreviations of rotational states are found in Table 2.1.

At $Re_p = Re_c$, a steady state is created through a saddle-node bifurcation. This state will exist at all $Re_p > Re_c$. However, if St is high enough, the particle can gain enough angular momentum for a planar rotation to coexist with the steady state.

One of the main difficulties with the presented methods in this section (SBB and EBF) is the fact that there is no local grid refinement close to the particle surface. At higher Re_p, boundary layers need to be resolved around the particle to get quantitative results of critical Reynolds numbers (e.g., Re_c) that are independent of grid resolution. On the other hand, increasing resolution to fulfill the desired accuracy might be computationally unfeasible due to the uniform grid. Fortunately, the qualitative dynamics and the sequence of bifurcations are independent of resolution using the EBF method as long as $w \geq 6\Delta x$ (Rosén et al., 2015). The conclusion is that these methods are excellent tools for exploring unknown qualitative features of non-spherical particles in flows, but methods with local grid refinement are desirable for obtaining quantitative results at higher Re_p.

2.3.3 Suspension of Deformable Particles and Capsules

The dynamics of deformable capsules, vesicles, and soft particles have been of continued interest to the scientific community. Deformable particles exhibit much more complex dynamic behavior than rigid particles. Also, treating them as rigid solids will not properly capture the micro and macroscopic properties.

In suspensions, these complex dynamics affect the rheology of the bulk flow, creating non-Newtonian flow characteristics. For example, one of the most intensely studied deformable capsules, the red blood cell (RBC), is the major constituent of blood. As the local shear increases, so does the deformation of RBC, which results in a decreased suspension viscosity. This effect causes the shear-thinning behavior of blood.

2.3.3.1 Coupling Lattice Boltzmann with Finite Element Method

MacMeccan et al. (2009) introduced a method to simulate both deformable solid particles and deformable fluid-filled membranes, namely, capsules. This method couples the LBM for the fluid phase to a linear-elastic finite element analysis (FEA) describing particle deformation.

For deformable solid particles, the shear elastic number (Goddard Miller, 1967, Pal, 2003), $N_s e = \mu\gamma \cdot /G_S$, governs particle deformation, where μ is the fluid dynamic viscosity, γ is the fluid shear rate, and G_S is the particle shear modulus. For fluid-filled elastic capsules, the capillary number, $Ca_G = \mu\gamma \cdot R/G_M$, governs particle deformation, where R is the particle radius and G_M is the effective membrane shear modulus ($G_M = G_S \cdot t_M$ for membranes with thickness, t_M).

In both cases, deformable solid particle and fluid-filled elastic capsules, the trajectory and deformation of an elastic deformable particle are governed by Cauchy's equation,

$$\frac{D\rho_s \boldsymbol{u}_s}{Dt} = \nabla \cdot \boldsymbol{T} \tag{2.110}$$

in which the left-hand side is the material derivative of solid momentum and $\boldsymbol{T}$ is the elastic stress tensor. A transient FEA is chosen to calculate the time evolution of deformable particles in suspension, which integrates virtual work over the volume of the element:

$$\int tr(\bar{\varepsilon} \otimes \boldsymbol{T}) dV = \int \bar{\boldsymbol{X}} \cdot \boldsymbol{F}^{tr} dA + \int \bar{\boldsymbol{X}} \cdot \boldsymbol{F}^{b} dV \tag{2.111}$$

where

$\bar{\boldsymbol{X}}$ is the elemental virtual displacements
$\bar{\varepsilon}$ is an elemental virtual strain due to virtual displacements
$\boldsymbol{F}^{tr}$ are the traction stresses on the surface
$\boldsymbol{F}^{b}$ is the body stresses
A is the surface area
V is the volume

In this method, linear-elastic solid elements are used to model solid deformable particles such as platelets, and linear-elastic shell elements are used to model deformable fluid-filled membranes such as RBCs. The linear-elastic solid element is shown in Figure 2.14a with four nodes, and the linear-elastic shell element is shown in Figure 2.14b with three nodes.

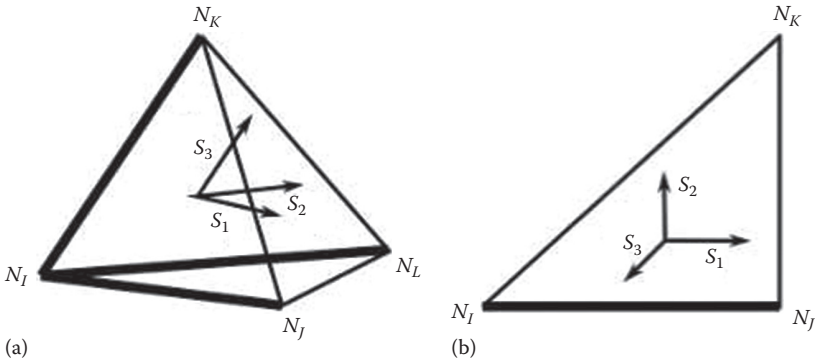

Figure 2.14

(a) Linear-elastic solid element with four nodes (tetrahedron) and (b) linear-elastic shell element with three nodes (triangle). Shell elements have a constant thickness and rotational degrees of freedom along elemental coordinates at each node for bending stiffness.

Through an interpolation or shape function, nodal displacements and positions can be related to elemental displacements and positions (for details, see MacMeccan et al., 2009, and Clausen, 2010). The integrals in 37 are evaluated in terms of nodal virtual displacements; elemental stiffness and mass matrices are constructed from elemental material properties such as density and elasticity. A detailed derivation of this process can be found in Bathe (1996). On summing over all elements in the object, the resulting transient finite element equation is obtained:

$$\boldsymbol{M}\ddot{x} + \boldsymbol{C}\dot{x} + \boldsymbol{K}x = \boldsymbol{F} \tag{2.112}$$

which determines the time evolution of the nodal displacement vector, x, and its time derivatives, $\dot{x}$ and $\ddot{x}$, where the nodal displacement vector is defined as the deformed node location minus the undeformed node location. The global mass, M, and stiffness, K, matrices are constructed from summing the elemental matrices, and the force vector, F, is calculated from traction forces resulting from the fluid–solid coupling. This transient finite element equation, 38, is solved using Newmark's integration method (for details, see MacMeccan et al., 2009, and Clausen, 2010).

In order to simulate large numbers of deformable particles in suspension, it is necessary to improve the efficiency of FEA by making the assumption of small body-fixed deformation. To comply with this assumption, a particle coordinate system is fixed on a particle's center of mass and oriented using the average angular displacement of the finite element nodes. Although elemental corotational procedures are typically used for large rotation problems (Rankin and Brogan, 1986, Campanelli et al., 2000), when averaged, the corotational procedure gives less consistent results than a simple average angular displacement. The use of a body-fixed coordinate system for the solid particles results in invariant linear-elastic stiffness, mass, and damping matrices that may be determined a priori for each type of particle.

Coupling between fluid and solid is based on lattice links crossing the solid boundary. These lattice links lie along lattice direction vectors and have endpoints on lattice nodes on either side of the particle boundary (Aidun et al., 1998). Lattice links are found on the discretized finite element surface using a ray-tracing algorithm commonly used in computer graphics. In this method, rays are projected along the lattice directions and tested for intersection with the triangles comprising the solid surface using a fast and minimum storage algorithm. The intersection is found through direct 3D calculation using barycentric coordinates, which eliminate the need for 2D projections or calculation of the plane equation for the triangle. For more details on this method, see the implementation by Moller and Trumbore (1997).

This LB–FEA hybrid method is capable of simulating $O(10^2)$ particles at high volume fraction (40%) on a desktop workstation. A snapshot from a wall-bounded shear simulation of 2472 RBCs at 40% volume fraction is shown in Figure 2.15 (Aidun and Clausen, 2010).

2.3.3.2 Coupling Lattice Boltzmann with Coarse-Grained Spectrin-Link Method

The spectrin-link (SL) method models the RBC membrane as a surface consisting of a triangular network. High-resolution studies using SL modeling were conducted by Li et al. (Li et al., 2005). This study set the SL

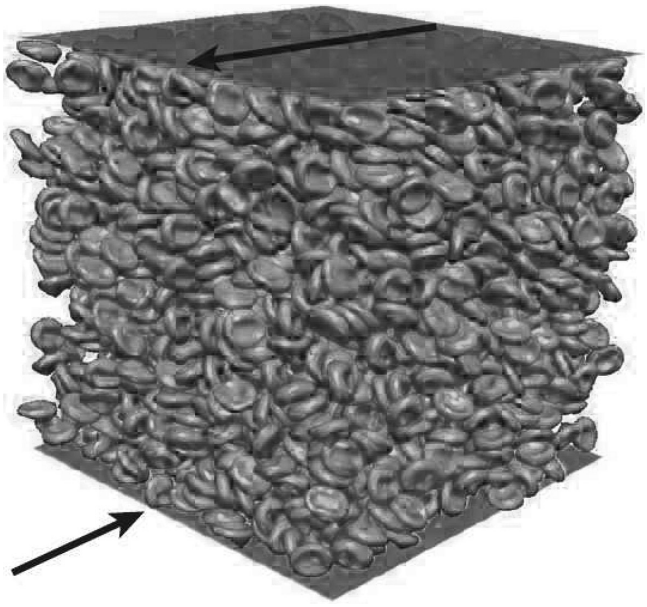

Figure 2.15

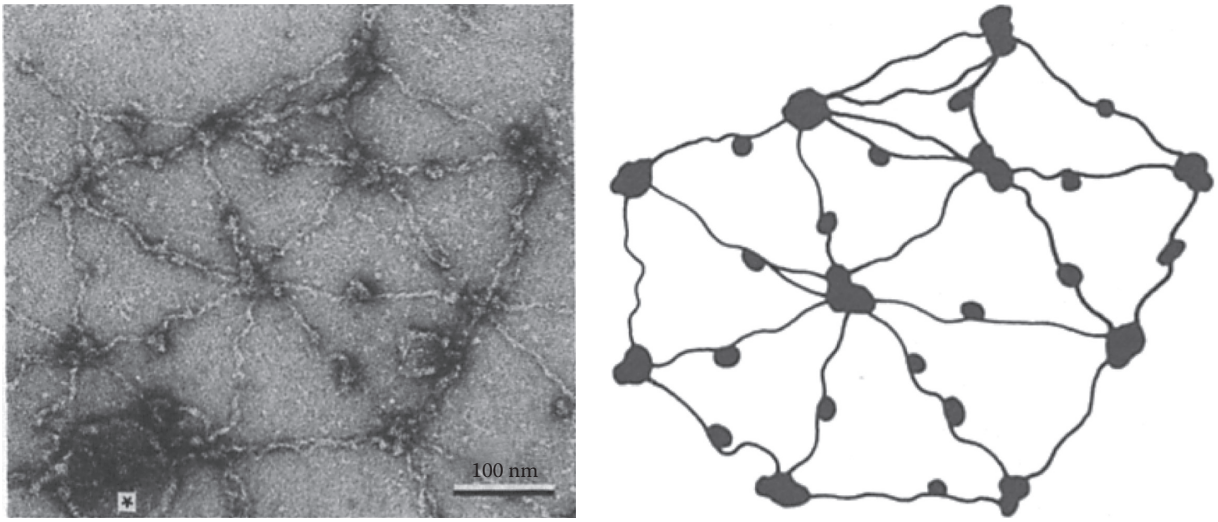
Wall-bounded simulation of 2472 deformable RBCs in shear at 40% concentration.

length scale to the same order of magnitude as the lengths of the proteins found in an actual RBC, see Figure 2.16 for a demonstration of this scale. While this method of modeling is incredibly realistic, it required the use of >25,000 vertices per RBC. This level of fidelity is not suitable for simulations of blood flow with realistic hematocrit. The use of a coarse-graining SL approach (Pivkin and Karniadakis, 2008, Fedosov et al., 2009) allows for the extension of the SL method to flows with thousands of deformable RBCs. One such benefit of the coarse-grained SL approach is the ability to resolve RBC deformation in capillary and shear flows (Pivkin and Karniadakis, 2008) where the high-resolution models are too expensive.



SL models, with the same number of vertices per RBC as linear finite element methods (MacMeccan et al., 2009) use less computer memory and expense but slightly more MPI communication. The SL method also does not require storage of a $(3N)^2$ (where N is the number of surface nodes with 3 degrees of freedom)-sized effective stiffness matrix inverse for updating RBC membrane deformation.

In the SL model, each RBC membrane consists of a network of points $\{\mathbf{x}_n, n \in 1\ldots N\}$, which are the vertices of the RBC surface triangulation. The area of a triangle $\alpha \in 1\ldots\prod$ formed by the vertices (l, m, n) is given by $A_\alpha = 1/2|(\mathbf{x}_m - \mathbf{x}_l) \times (\mathbf{x}_n - \mathbf{x}_l)|$. The total area of the RBC surface is given by, $A_{\text{total}} = \sum_{\alpha\in\prod} A_\alpha$, and the total volume is given as $\Omega_{\text{total}} = \sum_{\alpha\in\prod} (\mathbf{x}_\alpha \cdot \mathbf{n}_\alpha) A_\alpha/3$, where $\mathbf{x}_\alpha = 1/3(\mathbf{x}_m + \mathbf{x}_n + \mathbf{x}_l)$ is the center of triangle α. The length of the link $i \in 1\ldots S$ connecting two vertices m and n is given by $L_i = |\mathbf{x}_m - \mathbf{x}_n|$. The lists of unique links and unique triangle pairs are established prior to simulations. The Helmholtz free energy of the system is given as

$$E\{\mathbf{x}_n\} = E_{\text{in-plane}} + E_{\text{bending}} + E_{\text{volume}} + E_{\text{area}}. \tag{2.113}$$

The in-plane contribution relevant to shear properties is a force–length relationship rooted in DNA mechanics (Marko and Siggia, 1995, Bustamante et al., 2003). The bending contribution takes into account the spontaneous and instantaneous angles between adjacent pairs of triangles (Fedosov et al., 2009). The constraint on volume ensures the volume of the RBC enclosed by the triangulated membrane remains constant, with a similar constraint on the surface area. This conservation of area is essential in a realistic model of blood cells. Each of the vertices combines to form the triangulated RBC membrane surface advances according to Newton's equations of motion:

$$\frac{d\mathbf{x}_n}{dt} = \mathbf{v}_n; \quad M\frac{d\mathbf{v}_n}{dt} = \mathbf{f}_n + \mathbf{f}_n^{\text{LB}} + \mathbf{f}_n^{\text{PP}} \tag{2.114}$$

(a) (b)

Figure 2.16

(a) A highly magnified image of a spread membrane skeleton derived from normal red cell ghosts. Displayed to provide a scale to the order of the proteins in an actual red blood cell. (b) A diagram demonstrating the structure of the proteins in a red blood cell (Liu et al., 1987).

where $\mathbf{v}_n$ is the velocity of vertex n and M is taken to be a fictitious mass at each point chosen to yield the same membrane mass as previous linear finite element studies (MacMeccan et al., 2009). The external forces $\mathbf{f}_n^{\mathrm{LB}}$ are forces on the vertex due to fluid–structure interaction and $\mathbf{f}_n^{\mathrm{PP}}$ are forces due to particle–particle interactions. The forces due to the SL model via Helmholtz free energy contributions are denoted by $\mathbf{f}_n$ and are given as

$$\mathbf{f}_n = -\frac{\partial E\{\mathbf{x}_n\}}{\partial \mathbf{x}_n} \tag{2.115}$$

This method uses analytic forms obtained by using Mathematica's symbolic manipulation capabilities as was the case in Pivkin and Karniadakis (2008). This method aims to minimize the total energy given from Equation 2.113. In the absence of bending energy, the equilibrium shape will be a sphere with the volume specified by a desired RBC volume. When bending energy is present, the equilibrium shape is a biconcave disk representative of a RBC. As a result, spherical membrane meshes can be used as a starting point for RBC simulations. Equation 2.114 are solved using a first-order accurate time integration scheme.

2.3.4 Suspension of Deformable Fibers

Modeling suspensions of deformable fibers are of interest in many material processing applications, for example, papermaking (Lundell et al., 2011). Fibers are characterized by the fact that they have a large aspect ratio: the smallest length scale is very small compared to the fiber length. Thus, the resolution needs to be very high if the flow on the length scale of the fiber diameter is to be resolved and systems much larger than the fiber length cannot be simulated. Furthermore, the deformation of the fibers needs to be modeled.

Wu and Aidun (2010b) used LBM with EBF together with a flexible fiber model and showed that suspensions with deformable fibers could be modeled without totally resolving the flow on the fiber diameter scale and the resolution is approximately one lattice per fiber diameter. The simulation results obtained from the model agree well with available measurements, both in terms of fiber deformation and rheological data. This method has been used to investigate the effect of fiber stiffness on the rheology of sheared fiber suspensions (Wu and Aidun, 2010c).

2.3.4.1 Flexible Fiber Model and Fluid–Solid Interaction

The fibers are assumed to have elastic and shear moduli of E_γ and E_G, respectively, and each fiber is modeled as a chain of rods connected by hinges (see Figure 2.17). A fiber bends and twists at the hinges and changes length by the elasticity of the rods, which remain straight. The resistances to elongation, bending, and twisting are given by E_γ and E_G. The fiber is exposed to forces and the total force on a fiber determines its acceleration whereas the distribution of this force among its hinges determines its deformation.

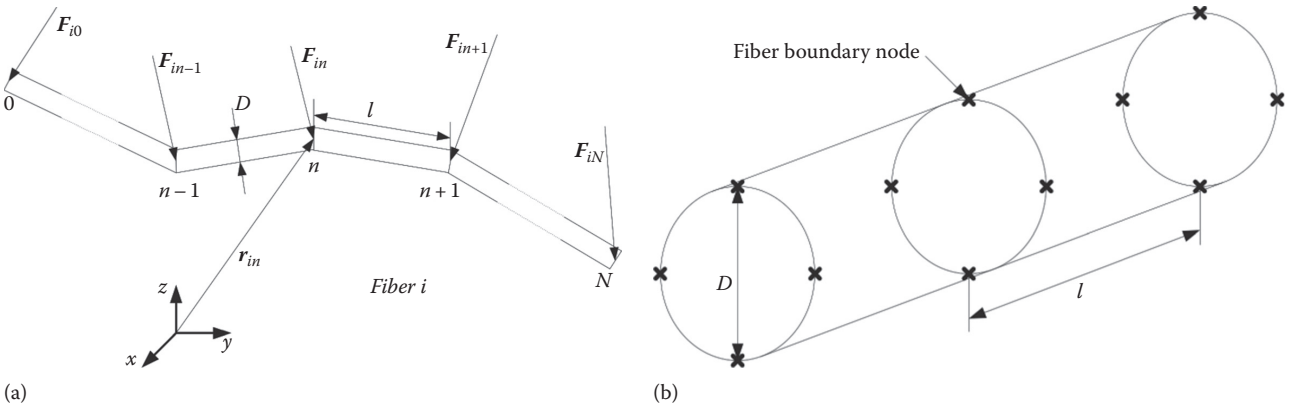


Figure 2.17

(a) Illustration of a fiber consisting of rods and hinges with external forces acting on the hinges. (b) Two rods and three hinges with the fiber boundary nodes are indicated (Wu and Aidun, 2010b).

There are several sources of forces on a fiber. The fluid–structure interaction forces $\mathbf{F}^{fsi}$ can be complemented with gravity $\mathbf{F}^{gra}$ and other forces due to external fields. There are also interparticle forces (electrical $\mathbf{F}^{ele}$, contact $\mathbf{F}^{con}$, or lubrication $\mathbf{F}^{lub}$). The fibers are assumed to be large enough so that Brownian forces can be neglected.

In a model used by previous investigators (Wu and Aidun, 2010b,c), all forces on the fiber are exerted on the hinges. Since buoyant fibers with no external field are only exposed to the fluid–solid interaction forces $\mathbf{F}^{fsi}$, they are calculated according to equation 3 at the four boundary nodes of each hinge. In order to prevent fibers from crossing each other and avoid singularities, a lubrication force (Yamane et al., 1994) proportional to the relative velocity between two hinges is used if the hinges are closer to each other than 0.25D. In order to ensure stability, the hinge velocities are reset to nonapproaching values if the hinges come very close to each other in spite of the lubrication force (which is repelling for approaching hinges).

2.3.4.2 Example Results

A model of suspensions of flexible fibers should be evaluated by its ability to predict both single fiber motion and suspension rheology. In Figure 2.18a, it is shown that the calculated flipping period of a fiber in linear shear flow from the LBM-EBF model agrees with previous results. For the flexible fibers, Figure 2.18b shows that the position of the fiber endpoints agrees well with the experiments of EMBC (2009) who took photographs of a long nylon filament (with an aspect ratio of 170) at short time intervals during rotation in shear.

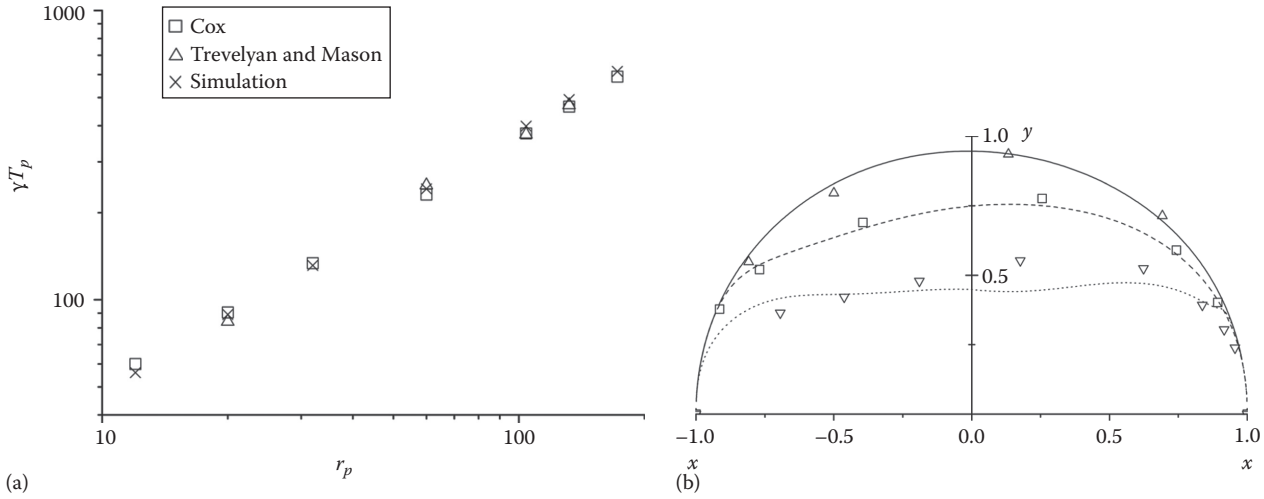

Figure 2.18

(a) Period for one rotation in creeping shear flow as a function of fiber aspect ratio r_p for a stiff fiber compared with theoretical (Cox, 1971) and experimental (Trevelyan and Mason, 1951) results. (b) Trajectory of a fiber endpoint during one flip of elastic fibers; the full, dashed, and dotted lines are present simulations and markers are (EMBC, 2009) at different shear rates. The physical properties of the liquid and fibers are matched. (From Wu, J. and Aidun, C.K., *Int. J. Multiphase Flow*, 36, 202, 2010b.)

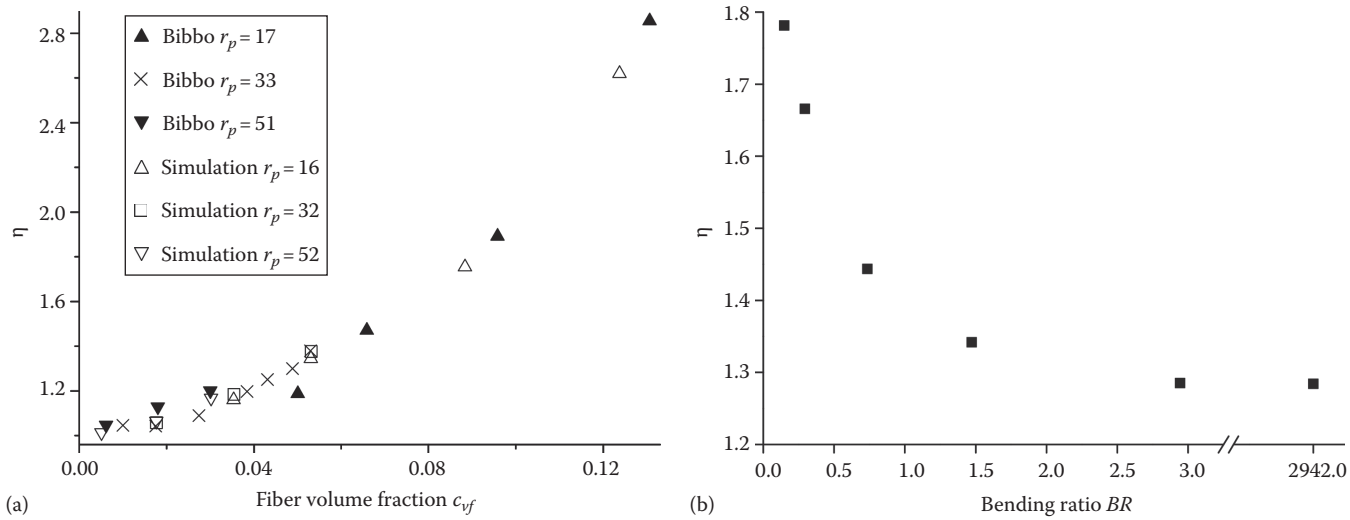

Figure 2.19

(a) Relative shear viscosity as a function of fiber volume fraction from present simulations (open symbols) and previous experiments (Bibbo, 1987). The bending ratios are 2942, 248, and 42 for r_p = 16, 32, and 52, respectively. (b) Relative viscosity as a function of bending ratio for an aspect ratio of r_p = 16 and a fiber volume fraction of c_{vf} = 0.053. (From Wu, J. and Aidun, C.K., *Int. J. Multiphase Flow*, 36, 202, 2010b.)

The stiffness of fibers is often characterized by the nondimensional bending ratio

$$BR = \frac{E_\gamma(\ln 2r_e - 15)}{2\mu\dot{\gamma}r_p^4}$$

where

r_p is the aspect ratio of the cylindrical fiber

$r_e = 1.24r_p/\sqrt{\ln r_p}$ is an equivalent aspect ratio relating results for ellipsoids with results to circular cylinders

μ is the dynamic viscosity of the fluid

$\dot{\gamma}$ is the shear rate

Rheological verification for elastic fibers is demonstrated in Figure 2.19a where the relative shear viscosity obtained from the LBM-EBF method as a function of volume fraction is shown to agree with experiments (Bibbo, 1987) for r_p = 16, 32, and 52 (BR = 2942, 248, and 42). The LBM-EBF simulations can also be used to study the decay of relative shear viscosity as BR is increased; see Figure 2.19.

2.3.5 Liquid–Gas Flow

Since very early into the development of LB models, investigators have been attempting to develop a method of studying multiphase flow problems. At first glance, it would seem that LB lends itself quite naturally to these problems. Because of the way the model works, the fluids in question can be modeled individually with some manner of separating influence acting between them. Building on this idea, the earliest idea in LB multiphase modeling was formed. The R–K model, developed by Rothman and Keller (1988), was later refined into the color fluid model proposed by Gunstensen et al. (1991). This method worked on the idea described earlier. It introduces a distribution function for each fluid and then added a segregation step that forced particles of each fluid into their own regions. Soon after, another idea, following the same premise of modeling the two fluids independently and interacting them, was developed. This was the Shan and Chen method (Shan and Chen, 1993). Rather than interacting the fluids by forcing them apart with a separation step, the S–C method introduced an external force acting on both fluids. This was the interaction force between the two fluids. The S–C model is the most popular LB variant for the modeling of multiphase problems; most likely because of the ease with which it is implemented. However, the S–C model has a number of problems that will be detailed later in this section. In response to these problems a couple of new methods arose: the free energy method and the mean field theory model. These two models operate on completely different theories than the R–K and S–C models. The previous

two models were very intuitive. When there was a single fluid, there would be a density distribution function for it. So, if there are two fluids, then there should be a density distribution for each fluid. Afterward, some manner of interaction is added to ensure that all the fluids involved are affected by one another. However, the next two models operate very differently. They take advantage of the fact that density is not the only property that can be expressed as a distribution function and modeled with an evolution equation. The free energy model, developed by Swift et al. (1995), solves an evolution equation with a distribution function of the total density and another evolution equation with a distribution function of the difference in the densities. Next, the mean field theory model was proposed by He et al. (1999). This model introduces a distribution function for pressure and a distribution function for an index function, which is function of the two densities.

2.3.5.1 The R–K (Rothman and Keller) Model

This model begins by creating a density distribution function for each fluid:

$$f_k^i(\boldsymbol{x}+\boldsymbol{e}_k,t+\delta_t)-f_k^i(\boldsymbol{x},t)=-\frac{1}{\tau^i}\left[f_k^i(\boldsymbol{x},t)-f_k^{i,eq}(\boldsymbol{x},t)\right]+\Omega^i, \tag{2.116}$$

Here, the superscript *i* denotes which fluid is being studied and ranges from 1 to the total number of fluids, α. Also immediately noticeable is the presence of an extra term, Ω^i, added to the LBGK collision term. This extra term in the collision operator has been modified by several investigators in the past; the extension for D2Q9 proposed by Grunau et al. (1993) had it in the form

$$\Omega^i=\frac{A^i\,|\boldsymbol{Co}|}{2}\frac{\boldsymbol{e}_k\cdot\boldsymbol{Co}}{|\boldsymbol{Co}|^2}-\frac{3}{4} \tag{2.117}$$

Here, ***Co*** is an approximation of the gradient of the density difference, written for two fluids as

$$\boldsymbol{Co}(\vec{x})=\sum_{k=1}^{8}\boldsymbol{e}_k(\rho^1(\boldsymbol{x}+\boldsymbol{e}_k)-\rho^2(\vec{x}+\vec{e}_k)) \tag{2.118}$$

One more important change to the collation operator is in the equilibrium density distribution function itself. In order to ensure a stable interface, a modified version of the pressure-corrected equilibrium distribution function proposed by Chen et al. (1991) is used. The details of the modification to this single-phase function can also be found in Grunau et al. (1993).

2.3.5.2 Shan and Chen Model

As mentioned earlier, the S–C model keeps with the theme introduced by the R–K model of simply adding another density distribution function for each fluid and allowing for some interaction. As with R–K, we first introduce an evolution equation for the density distribution of each fluid; in this model, we use

$$f_k^i(\boldsymbol{x}+\boldsymbol{e}_k,t+\delta_t)-f_k^i(\boldsymbol{x},t)=-\frac{1}{\tau^i}\left[f_k^i(\boldsymbol{x},t)-f_k^{i,eq}(\boldsymbol{x},t)\right] \tag{2.119}$$

and as earlier

$$\sum_{k=1}^{8}f_k^i=\rho^i\quad\text{and}\quad\sum_{k=1}^{8}f_k^i\boldsymbol{e}_k=\rho^i\boldsymbol{u}^i \tag{2.120}$$

The S–C model differs from the R–K model in how the fluids in question are allowed to interact. To allow for the interaction, a modified velocity term is included in the calculation of the equilibrium density distribution function. To calculate this modified velocity, first, a common velocity term, $\bar{\boldsymbol{u}}^i$, is needed. This is calculated by what is effectively mass averaging

$$\bar{\boldsymbol{u}}^i=\frac{\sum_{i=1}^{\alpha}\frac{\rho^i\boldsymbol{u}^i}{\tau^i}}{\sum_{i=1}^{\alpha}\frac{\rho^i}{\tau^i}} \tag{2.121}$$

Now, the modified velocity, sometimes called the equilibrium velocity, can be determined by

$$\rho^i \boldsymbol{u}^{ieq} = \rho^i \bar{\boldsymbol{u}}^{ieq} + \tau^i \boldsymbol{F}^i \tag{2.122}$$

Here, the force term, $\boldsymbol{F}^i$, is the sum of the forces acting on the fluid i at the node; this means other forces can be added to the model as well. A good example, demonstrated by Huang et al. (2009), is the inclusion of external forces and adhesion forces. For simplicity, in this demonstration, only the interparticle forces will be considered. The derivation of the interparticle forces, demonstrated in Martys and Chen (1996), is rather simple. Start with the interaction potential

$$V(\boldsymbol{x}, \dot{\boldsymbol{x}}) = G^{i,\dot{l}} \psi^i(\boldsymbol{x}) \psi^{\dot{l}}(\dot{\boldsymbol{x}}) \tag{2.123}$$

This is the equation for the interaction potential between a fluid i at a position $\boldsymbol{x}$ and a fluid l at a position $\dot{x}$. ψ^i is the effective mass of fluid i at position $\boldsymbol{x}$. The effective mass is a function of density derived from the equation of state. It is shown by Yuan and Schaefer (2006) that with pressure as a function of density known, an expression for the effective mass can be derived. Finally, G controls the strength of the interaction between the two points in question. At this point, the model makes a key simplification. It assumes that only the neighboring nodes affect the interaction. This allows the description of the rate of change of momentum to be simplified, which in turn allows for an expression for the interparticle force as

$$F^i_{int}(\boldsymbol{x}) = -\psi^{\dot{l}}(\boldsymbol{x}) \sum_{\dot{x}} \sum_{\dot{l}=1}^{\alpha} G^{i\dot{l}}(\boldsymbol{x}, \dot{\boldsymbol{x}}) \psi^{\dot{l}}(\dot{\boldsymbol{x}}) (\dot{\boldsymbol{x}} - \boldsymbol{x}) \tag{2.124}$$

Again, it should be emphasized that this G is assumed to be 0 for any two nodes, except when they are directly adjacent. With this, it is possible to calculate the equilibrium velocity, and the equilibrium velocity can be used to calculate the equilibrium density distribution function. This part of the method is identical to the process in the single relaxation time lattice Boltzmann.

2.3.5.3 Free Energy Model

The free energy model is immediately different from the previous two models. It introduces three new variables: total density, ρ^t; mean fluid velocity, $\boldsymbol{u}$; and the density difference, $\Delta\rho$. For two fluids

$$\rho^t = \rho^1 + \rho^2 \quad \text{and} \quad \Delta\rho^t = \rho^1 - \rho^2 \tag{2.125}$$

The density distribution function of ρ^t is called f, due to it similarity to the density distribution function in single-fluid lattice Boltzmann. The density distribution function of $\Delta\rho$ is called Δ. These distribution functions can be related to their physical counterparts by

$$\sum_k f_k = \rho, \quad \sum_k f_k \boldsymbol{e}_k = \rho \boldsymbol{u}, \quad \text{and} \quad \sum_k \Delta_k = \Delta\rho \tag{2.126}$$

Now the two evolution equations can be introduced:

$$f^i_k(\boldsymbol{x} + \boldsymbol{e}_k, t + \delta_t) - f^i_k(\boldsymbol{x}, t) = -\frac{1}{\tau_t}\left[f^i_k(\boldsymbol{x}, t) - f^{i,eq}_k(\boldsymbol{x}, t) \right] \tag{2.127}$$

$$\Delta^i_k(\boldsymbol{x} + \boldsymbol{e}_k, t + \delta_t) - \Delta^i_k(\boldsymbol{x}, t) = -\frac{1}{\tau_\Delta}\left[\Delta^i_k(\boldsymbol{x}, t) - \Delta^{i,eq}_k(\boldsymbol{x}, t) \right] \tag{2.128}$$

The equilibrium functions and their derivations can be found in the original paper by Swift et al. (1995).

2.3.5.4 The Mean Field Theory Model

Like the free energy model, the mean field theory model operates with distributions of new variables. The first distribution function is g, where g is related to the density distribution function f by

$$g = fRT + \psi(\rho)\Gamma(\mathbf{0}) \tag{2.129}$$

As earlier, the function, $\Psi(\rho)$, is the effective mass and can be determined from the equation of state. R is the gas constant and T is the temperature. The function, $\Gamma(\boldsymbol{u})$, is dependent on the velocity by

$$\Gamma(\boldsymbol{u}) = \frac{1}{(2\pi RT)^{D/2}} exp^{-\frac{(\boldsymbol{e}_k - \boldsymbol{u})}{2RT}} \tag{2.130}$$

where D is the dimension of the problem. From what is known about the density distribution function and the definition of incompressible fluids, He et al. (1999) derive an evolution equation for g as

$$g_k^i(\boldsymbol{x} + \boldsymbol{e}_k, t + \delta_t) - g_k^i(\boldsymbol{x}, t) = -\frac{1}{\tau_t}\left[g_k^i(\boldsymbol{x}, t) - g_k^{i,eq}(\boldsymbol{x}, t)\right] + (\boldsymbol{e}_k - \boldsymbol{u}) \cdot (\Gamma(\boldsymbol{u})(\boldsymbol{F}_s + \boldsymbol{F}_b) - (\Gamma(\boldsymbol{u}) - \Gamma(\mathbf{0}))\nabla\Psi(\rho)) \tag{2.131}$$

Here,

F_b is an external body force

F_s is a force associated with the surface tension

From g, the total density and total velocity can be recovered by

$$\sum_k g_k = \rho \quad \text{and} \quad \sum_k g_k \boldsymbol{e}_k = \rho RT\boldsymbol{u} \tag{2.132}$$

This alone cannot close the equations in multiphase problems. Another variable is introduced, an index function, ϕ, such as the ones introduced in the level set approaches used by Osher and Sethian (1988). Its distribution function h is defined by

$$\sum_k h_k = \phi \tag{2.133}$$

And the evolution equation for h comes to

$$h_k^i(\boldsymbol{x} + \boldsymbol{e}_k, t + \delta_t) - h_k^i(\boldsymbol{x}, t) = -\frac{1}{\tau_t}\left[h_k^i(\boldsymbol{x}, t) - h_k^{i,eq}(\boldsymbol{x}, t)\right] + \frac{(\boldsymbol{e}_k - \boldsymbol{u}) \cdot \nabla\Psi(\phi)}{RT}\Gamma(\boldsymbol{u}) \tag{2.134}$$

It can be shown that g and h have simple equilibrium equations of the form

$$h^{eq} = \phi\Gamma(\boldsymbol{u}) \tag{2.135}$$

$$g^{eq} = \rho RT\Gamma(\boldsymbol{u}) + \Psi(\rho)\Gamma(0) \tag{2.136}$$

2.3.5.5 Front Tracking in Lattice Boltzmann

There exist a number of problems with each of these methods of treating multiphase problems with lattice Boltzmann. Since the S–C method is the most popular method, its problems have been discussed the most. In particular, the S–C method has difficulty in producing a sharp boundary. The method produces a great deal of unphysical diffusion that blurs the interface between fluids. This problem can be eliminated by switching to another method; the mean field theory method in particular produces a very sharp interface by virtue of how the index function works. However, no other method can match S–C in the ease with which it is implemented. In recent years, research has been done in using front tracking with

the S–C model. The aim is to maintain the simplicity of the S–C method and produce a sharp interface. In the past, Popinet and Zaleski (1999) used the idea of placing a large number of particles on an interface and tracking the movements of these particles to get a more accurate representation of the evolution of the interface. The idea has since also been used by Shin et al. (2005). This method works by placing a dense line of particles over the initial fluid interface. These particles do not interact with one another and they only interact with the fluid. The idea is that the particles should be moving with the fluid flow. Any deviation between the location of the interface and the location of the particles must be a numerical error and needs to be corrected.

2.4 Immersed Boundary Method

Zhi-Gang Feng and Efstathios E. Michaelides

2.4.1 Introduction

The prescription of the interfacial boundary conditions is a rather peculiar feature within the framework of the governing equations the numerical codes solve. In our Newtonian scientific framework, the governing equations that are solved for the transport of momentum are given in terms of forces (rates of change of momentum), while velocity interfacial conditions need to be prescribed at the interface by a commonly agreed convention or experimental data. A more consistent approach within the Newtonian framework would be to describe the interfaces and other boundaries in terms of interfacial forces. Peskin (1977) used such an approach and developed the immersed boundary method (IBM) in order to model the flow of blood in the heart. The method uses a fixed Cartesian mesh for the fluid, which is composed of Eulerian nodes. For the solid boundaries, which are immersed in the fluid, the IBM uses a set of Lagrangian points that are advected according to the rules of fluid–solid interactions. The boundaries are modeled as continuous force fields acting on the fluid.

Feng and Michaelides (2004) combined the IBM and the lattice Boltzmann method (LBM) for the first time to model the flow and interactions of groups of particles in flow systems. They computed the boundary surface force at the interfaces using a numerical penalty method. The advantage of the IBM is that instead of remeshing the fluid domain to account for the flow of particles, the method uses a fixed mesh to represent the fluid field. The moving boundaries of the particles are represented by a set of Lagrangian boundary points, which are advected by the fluid. Feng and Michaelides (2005) developed the *Proteus* code, using a numerical method that combines direct forcing (DF) scheme (Mohd-Yusof, 1997) and the IBM. *Proteus* makes use of Eulerian lattice nodes for the fluid flow field and Lagrangian boundary nodes to represent particles or moving boundary surfaces. A few months later, Uhlmann (2005) also developed a similar computational method that combines the IBM with a finite-difference-based fluid solver. This section describes in more detail the implementation of the IBM in isothermal particulate flows as well as particulate flows with interfacial heat and mass transfer. A recent extension of the IBM has been developed in combination with the resolved discrete particle model (RDPM) to be used primarily with heat and mass interaction in the particulate flow systems. This numerical scheme has also received significant attention (Gan et al., 2003, Yu and Shao, 2007, Feng and Michaelides 2008, 2009a, Tavassoli et al., 2013, Tenetti et al., 2013) and is briefly described at the end of this section.

2.4.2 Fundamentals of the Immersed Boundary Method

The key characteristic of the IBM is that the existence of a solid body is represented by its effect on the fluid as a force field. This is implemented by introducing a *body force density* term into the fluid momentum equations. Let us consider a particle with a boundary surface, Γ, immersed in a 3D incompressible viscous fluid with a domain, Ω. The particle boundary surface, Γ, is represented by the Lagrangian parametric coordinates, $\boldsymbol{s}$, and the flow domain, Ω, is represented by the Eulerian coordinates $\boldsymbol{x}$. Hence, the positions of the surface may be written as $\boldsymbol{x} = \boldsymbol{X}(\boldsymbol{s},t)$. The no-slip boundary condition at the particle surface is satisfied by enforcing the velocity at all interfaces to be equal to the velocity of the fluid at the same location:

$$\frac{\partial X(s,t)}{\partial t} = \boldsymbol{u}(\boldsymbol{X}(\boldsymbol{s},t),t), \tag{2.137}$$

where $\boldsymbol{u}$ is the fluid velocity. Let $\boldsymbol{F}(\boldsymbol{s},t)$ and $\boldsymbol{f}(\boldsymbol{x},t)$ represent the particle surface force density and the fluid body force density, respectively. In this treatment of the particulate system, the entire domain, Ω, can be regarded to be filled with fluid, and its velocity field is described by

$$\rho\left(\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u}\cdot\nabla\boldsymbol{u}\right) = \mu\nabla^2\boldsymbol{u} - \nabla p + \boldsymbol{f}. \tag{2.138}$$

$$\nabla\cdot\boldsymbol{u} = 0. \tag{2.139}$$

with

$$\boldsymbol{f}(\boldsymbol{x},t) = \int_{\Gamma} \boldsymbol{F}(\boldsymbol{s},t)\delta\big(\boldsymbol{x} - \boldsymbol{X}(\boldsymbol{s},t)\big)d\boldsymbol{s}, \tag{2.140}$$

and

$$\frac{\partial X}{\partial t} = \int_{\Omega} \boldsymbol{u}(\boldsymbol{x},t)\delta\big(\boldsymbol{x} - \boldsymbol{X}(\boldsymbol{s},t)\big)d\boldsymbol{x}, \tag{2.141}$$

where

$p(\boldsymbol{x},t)$ is the fluid pressure
ρ is the fluid density
μ is the fluid viscosity

Equations 2.138 and 2.139 are the governing equations for viscous, isothermal, incompressible flow, which include the effect of the particle interface as a force density. Equation 2.140 shows how the force density of the fluid, $\boldsymbol{f}(\boldsymbol{x},t)$, may be calculated from the immersed boundary surface force density, $\boldsymbol{F}(\boldsymbol{s},t)$. Equation 2.141 is essentially the no-slip condition at the interface, since the particle moves at the same velocity as the neighboring fluid.

In its original development, the IBM theory was tailored for solving the interaction between elastic fibers and fluid. To model a particle, the density force is only defined on the particle surface, as indicated by Equation 2.140. This force field is set to be zero inside the particle. In the numerical implementation of the IBM, the entire fluid domain, including the parts that are occupied by immersed bodies, is divided into a set of fixed regular nodes. The fixed nodes are not moving with the flow and are simple Eulerian nodes. The immersed fiber is discretized by a set of segments with each segment represented by a boundary point that moves under the action of the fluid. We will call these boundary Lagrangian nodes. It must be noted that the Lagrangian nodes do not necessarily coincide with the Eulerian nodes.

There are several schemes to compute the surface force density associated with the Lagrangian nodes that represent the fluid–particle interface. For example, the penalty method considers the particle boundary as an elastic fiber with high stiffness in the case of modeling solid particles (Feng and Michaelides, 2004). In this case, we define a set of reference nodes and a set of boundary nodes for each particle. We use a template that is undergoing a rigid body motion consisting of the reference nodes. Before the particle deforms, the reference nodes are coincident with the particle boundary nodes. Once the particle has deformed under particle–fluid interaction, the particle boundary nodes are compared to the reference nodes. During one time step, the reference nodes are following the motion of a template that is a rigid particle, while the boundary nodes are following the motion of fluid, thus resulting in a distortion. Such a distortion between the boundary nodes and reference nodes causes an elastic restoration force on the particle boundary node. This method requires the input in the computational scheme for the stiffness of the fiber or particle. A very large value for the stiffness is used for modeling solid particles.

Figure 2.20 is a schematic diagram of the main steps that constitute the IBM. Part (a) shows the boundary of an ellipsoidal particle, which is carried by the fluid, within the Eulerian grid where the fluid computations take place. Part (b) shows the discretization of the fluid–particle interface using a fixed number of points. If the interface is deformable, these interfacial points are connected by springs with finite spring constants (Feng and Michaelides, 2004). If the interface is rigid, the spring constant value is set to be very large. Part (c) depicts the substitution of the ellipsoidal particle surface and its effect on the fluid domain by a system of forces acting on the nodes of the Lagrangian grid. Part (d) is the final step in the interface modeling and shows the spreading of the forces from the Lagrangian points that move with the particle to the nodes of the Eulerian grid, which are stationary and where the flow computations take place.

In modeling the interactions between a rigid body and a fluid, the IBM can be extended by replacing the surface force $\boldsymbol{F}$ with a body force $\boldsymbol{f}$ that acts only in the region occupied by the solid. The body force in the region of the particles is determined in a way to enforce that this region moves exactly like a solid.

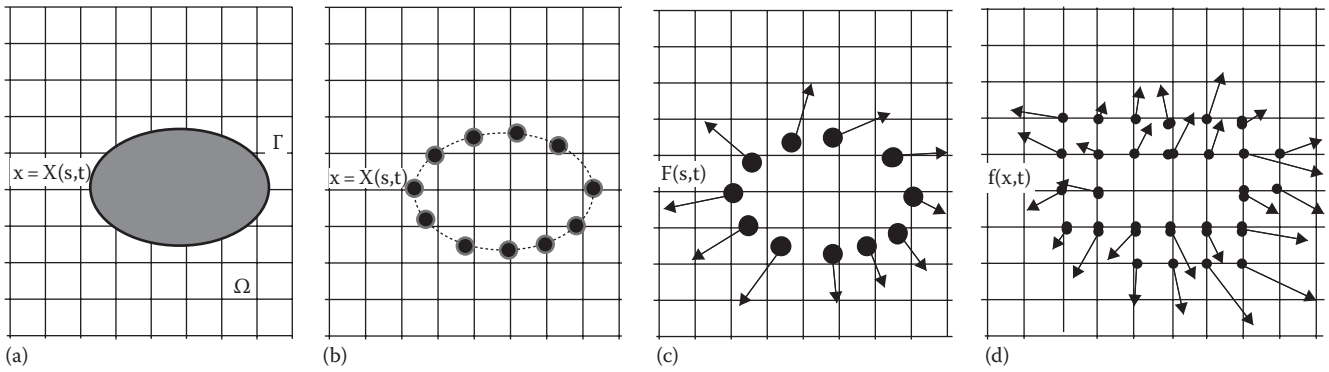

Figure 2.20

The four main steps in the implementation of the IBM. From left to right: (a) The Eulerian grid and the (ellipsoidal) particle whose surface is described by the parameter s, $\boldsymbol{X}(\boldsymbol{s},t)$, (b) discretization of the particle surface into Lagrangian points, (c) substitution of the particle surface with a system of forces at the Lagrangian points that enforce the no-slip velocity condition, and (d) spreading of the forces in the Eulerian grids in the form of force density.

This method is called DF scheme and provides a very good way to compute the velocity field. Unlike the penalty method, this method does not require another artificial input. If we consider the entire geometric domain as being occupied by fluid, with the body density force acting in regions that are known to be occupied by a solid particle, the fluid motion can be described by Equations 2.138 and 2.139.

Let us assume that the velocity in the regions occupied by a solid particle represents/mimics the motion of a solid particle is $\boldsymbol{u}$. Then the force density must satisfy the following equation:

$$\boldsymbol{f} = \rho\left(\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u}\cdot\nabla\boldsymbol{u}\right) - \mu\nabla^2\boldsymbol{u} + \nabla p. \tag{2.142}$$

Therefore, the body force at a point $\boldsymbol{X}_\mathrm{P}$ can be computed by replacing the fluid velocity $\boldsymbol{u}$ in Equation 2.142 with the expected velocity of that point attached to the particle, $\boldsymbol{U}_\mathrm{P}$. With known velocity and pressure fields at the time step $t = t_n$, we then have an explicit scheme to determine the force term at the Lagrangian boundary point L at time $t = t_{n+1}$:

$$\boldsymbol{f}_P^{(n+1)} = \rho\left(\frac{\boldsymbol{U}_P^{(n+1)} - \boldsymbol{u}_P^{(n)}}{\Delta t} + \boldsymbol{u}_P^{(n)}\cdot\nabla\boldsymbol{u}_P^{(n)}\right) - \mu\nabla\cdot\nabla\boldsymbol{u}_P^{(n)} + \nabla p_P^{(n)}. \tag{2.143}$$

For a rigid particle, some of the terms in this Equation 2.143 can be further simplified. For example, the viscous force can be dropped because of the zero strain rate when the fluid is within the solid boundary and undergoes a rigid body motion. However, in order to reduce computational complexity, the force density is typically set to zero inside the boundaries of particles and the inside fluid is not strictly in rigid body motion.

Mohd-Yusof (1997) proposed this scheme to compute the body force directly at the Eulerian nodes with interpolation. In the case of particulate flows, where the particle interfaces are constantly moving, the task to directly compute these forces at the Eulerian nodes becomes formidable, and for this reason, Feng and Michaelides (2005) computed the force density at a Lagrangian point, *P,* using Equation 2.143. The velocity at *P* can be obtained using Equation 2.141 with a delta function. Alternatively, one may employ a bilinear interpolation using the velocity values of four neighboring grid points for 2D flows or eight neighboring grid points for 3D flows. This scheme was adopted in the *Proteus* code and is obtained through interpolations based on their values at the surrounding Eulerian nodes. The calculated force density is then spread from the Lagrangian points to the neighboring Eulerian points, where the computations take place. Goldstein et al. (1993) explained this spreading as the smoothing of the boundary surface and used a Gaussian function to smoothen the boundary within one grid spacing. In the *Proteus* code, a delta function was used to spread the force density to the nearby Eulerian nodes.

When the fractional step method is used in a Navier–Stokes solver, let $\boldsymbol{u}^\star$ be the intermediate velocity without including the body force:

$$\rho\frac{\partial \boldsymbol{u}}{\partial t} = \rho\left(\frac{\boldsymbol{u}^\star - \boldsymbol{u}^{(n)}}{\Delta t}\right) = -RHS(\boldsymbol{u}^\star). \tag{2.144}$$

$-RHS\,(\boldsymbol{u}^\star)$ is the sum of all the terms in Equation 2.138 other than $\rho\dfrac{\partial \boldsymbol{u}}{\partial t}$ and the body force f after they are moved to the right hand side of the equation.

When the force term is included, we use the expression

$$\rho\left(\frac{\boldsymbol{U}_P^{(n+1)} - \boldsymbol{u}^{(n)}}{\Delta t}\right) = -RHS\left(\boldsymbol{u}^\star\right) + \boldsymbol{f}^{(n+1)}. \tag{2.145}$$

From these two equations and by replacing the flow velocity at $t = t_{n+1}$ with the particle velocity, the density force can be easily computed as follows:

$$\boldsymbol{f}^{(n+1)} = \rho\left(\frac{\boldsymbol{U}_P^{(n+1)} - \boldsymbol{u}^\star}{\Delta t}\right). \tag{2.146}$$

When the DF scheme is used, the force acting on the particle can be obtained by integrating the fluid stress over the particle surface:

$$\boldsymbol{F} = \oint_{\Gamma} \boldsymbol{\sigma} \cdot \boldsymbol{n} dS = -\int_{\Omega} \boldsymbol{f} dV + \rho \frac{d}{dt} \int_{\Omega} \boldsymbol{u} dV = -\int_{\Omega} \boldsymbol{f} dV + \rho_f V_s \frac{d\boldsymbol{U}_s}{dt}. \tag{2.147}$$

where

ρ_f is the fluid density
$\boldsymbol{V}_s$ is the volume of the particle
$\boldsymbol{U}_s$ is the particle velocity
$\boldsymbol{\sigma}$ is the fluid stress tensor at the particle–fluid interface
$\boldsymbol{n}$ is the outward normal unit vector

When the particle is fixed, one can calculate the particle drag from first principles as follows:

$$\boldsymbol{F}_D = -\int_{\Omega} \boldsymbol{f} dV. \tag{2.148}$$

The volume integral is taken only over the external layer where the force density is nonzero.

When the Lagrangian nodes of the external layer or the boundary nodes are placed exactly at the particle–fluid interface, the use of a delta function to spread the body force field results the distributed forces cover a volume that is larger than the volume of the particle. Consequently, the size of the particle that influences the flow field is larger, and this may introduce errors in the interfacial transport of mass, momentum, and energy. To achieve better accuracy, each boundary node has to be placed at the centroid of the small volume associated with the body force (typically, it is beneath the particle surface by about 0.5 grid steps when a very fine grid is used) rather than on the particle surface (Feng and Michaelides, 2009b).

2.4.3 Numerical Implementation of the IBM in 3D Isothermal Flows

This section contains details of the numerical implementation of the IBM in 3D isothermal flows when the DF scheme is used to determine the density force. Consider solid particles suspended in a Newtonian flow. The entire flow domain is discretized with a fixed regular grid or Eulerian grid. At time step t_n a solid particle whose mass center is at point C and has a translational velocity $\boldsymbol{U}_s^{(n)}$ at C and angular velocity $\boldsymbol{\omega}_s^{(n)}$. In order to obtain the particle drag, determine the particle motion, and solve the flow velocity at the next time step t_{n+1}, we need to compute the force density due to the momentum interactions between the particle and fluid.

The first issue arising in the implementation of the IBM is how to set up the Lagrangian boundary nodes in order to accurately represent the particle surface. For a spherical particle in three dimensions, it is impossible to find evenly distributed boundary nodes that represent the surface of the sphere. Feng and Michaelides (2005, 2009b) used a number of strips, with the width of a strip being comparable to the grid spacing. Each strip is composed of a number of evenly distributed points. The number of the points in each strip is chosen in a way that the spacing between two neighboring points is approximately equal to the width of the strips. The boundary nodes are placed slightly beneath the actual particle–fluid interface, as discussed at the end of the previous subsection.

After outlining the particle with a set of boundary nodes, the velocity at a boundary node $\boldsymbol{X}_P$ can be determined by the expression

$$\boldsymbol{U}_P^{(n+1)} = \boldsymbol{U}_s^{(n+1)} + \boldsymbol{\omega}_s \times (\boldsymbol{X}_P - \boldsymbol{X}_C). \tag{2.149}$$

To force the fluid velocity at the next time step t_{n+1} to be equal to the predicted particle velocity at the Lagrangian boundary node, $\boldsymbol{U}_P^{(n+1)}$, the force can be computed at each Lagrangian boundary node using the

DF scheme, Equation 2.143 or 2.146. These forces are then spread in the Eulerian nodes, where the computations for the fluid motion take place.

The force corresponding to each Lagrangian boundary node is spread into all its neighboring Eulerian nodes. The choice of the spreading function must meet certain criteria, which were discussed by Peskin (2002). For the 3D simulations on a regular Eulerian grid of grid spacing h, the following expressions can be used:

$$\delta(r)=\begin{cases}\dfrac{1}{4}\left[1+\cos\left(\dfrac{\pi r}{2h}\right)\right], & |r|\le 2h\\ 0, & |r|>2h\end{cases}, \tag{2.150}$$

and

$$D(\boldsymbol{x}-\boldsymbol{x}_{mn})=\delta(x-x_{mn})\delta(y-y_{mn})\delta(z-z_{mn}). \tag{2.151}$$

With the use of these expressions, the spreading occurs within a distance of two units of the Eulerian grid spacing from each Lagrangian node. The spreading process is performed for each Lagrangian boundary node. The force on each Eulerian node is the summation of all the contributions from the surrounding Lagrangian boundary nodes. The spreading process can be stated succinctly as follows: For a system of N number of particles, with M Lagrangian boundary nodes used to represent each particle, and the force density at these Lagrangian boundary nodes $f(x_{mn}(t),t)$, the flow force density at an Eulerian node $\boldsymbol{x}_i$ is computed as follows:

$$\boldsymbol{f}(\boldsymbol{x}_i,t)=\sum_{n=1}^{N}\sum_{m=1}^{M}\boldsymbol{f}(\boldsymbol{x}_{mn}(t),t)(\delta V)_{mn}D(\boldsymbol{x}_i-\boldsymbol{x}_{mn}(t))\frac{1}{h^3}, \tag{2.152}$$

where

$\boldsymbol{x}_{mn}$ is the position of the mth Lagrangian boundary point for the nth particle at the time t

δV_{mn} is the volume represented by boundary point, $\boldsymbol{x}_{mn}$; and the function $D(\mathbf{r})$ is given by Equation 2.151

It must be pointed out that in the original concept of IBM proposed by Peskin (1977), the surface force is used for mimicking a solid boundary. In this case, the volume associated with Lagrangian point, δV_{mn}, should be replaced by the surface area associated with the boundary point, δA_{mn}. This applies to the case when the penalty method is used. However, when DF scheme is used, the surface force can be converted to volume force based on the Cauchy theorem, which will be seen in Equation 2.158.

In general, the spreading of forces from the Lagrangian nodes to Eulerian nodes may deteriorate the accuracy of the results, especially when flow Reynolds number becomes high. Several authors proposed schemes such as sharp immersed boundary to improve the accuracy (Cristallo et al., 2006) in the case of fixed boundary. However, some of these methods are cumbersome to be used for particles in motion.

Once the force is transferred onto Eulerian nodes as a body force, the fluid velocity can then be determined. This is done by either solving the Navier–Stokes equation with an added body force or using other fluid solvers, such as the LBM. In the original implementation of the IBM (Feng and Michaelides, 2004, 2005), the fluid velocity was solved using the LBM. The latter originates from the Boltzmann equation, which describes the statistical behavior of a very large number of particles moving in a space:

$$\frac{\partial f}{\partial t}+\boldsymbol{\xi}\cdot\nabla_{\mathbf{x}}f+\boldsymbol{F}\cdot\nabla_{\boldsymbol{\xi}}f=\left(\frac{\partial f}{\partial t}\right)_{col}, \tag{2.153}$$

where

f is the particle probability density function

$\boldsymbol{\xi}$ is the particle's velocity

$\boldsymbol{F}$ is the external force exerted on a particle

$\nabla_{\mathbf{x}}$ and $\nabla_{\boldsymbol{\xi}}$ are gradient operators with respect to the position space $\boldsymbol{x}$ and the velocity space $\boldsymbol{\xi}$, respectively

The term on the right side accounts for the particle collision effect. The Boltzmann equation can be discretized in time, position space, as well as velocity space. Therefore, there are various schemes to solve Equation 2.153 based on the ways of discretization and the number of relaxation times. The most commonly used scheme is the explicit scheme that is commonly called the LBM.

In LBM, the fluid motion is modeled by the transport of imaginary fluid particles on the lattice sites of a Cartesian grid. These fluid particles move from one lattice site to another site along a limited number of specified directions to a neighboring site at discrete velocity per time step in two steps: first streaming to the neighboring sites and then colliding with imaginary fluid particles at the local site. A discretized distribution function, $f_i(\boldsymbol{x},t)$, is used to represent the populations of the particles residing at the node $\boldsymbol{x}$ and moving in the ith direction. The evolution of the imaginary fluid particle distributions resulting from the collision and streaming processes is modeled using the single-relaxation time (SRT) *Bhatnagar–Gross–Krook* model (BGK),

$$f_i\left(\boldsymbol{x}+\boldsymbol{c}_i\delta t,t+\delta t\right)=f_i\left(\boldsymbol{x},t\right)-\frac{1}{\tau}\left[f_i\left(\boldsymbol{x},t\right)-f_i^{(eq)}\left(\boldsymbol{x},t\right)\right]+\frac{3}{2}w_i\boldsymbol{f}\cdot\boldsymbol{c}_i. \tag{2.154}$$

where

$\boldsymbol{c}_i$ is the fluid particle velocity along ith direction
τ is a relaxation time, which can be related to the fluid viscosity
w_i is the weighting factor
the vector $\boldsymbol{f}$ is the body force term

When the IBM is used for enforcing the no-slip boundary condition on particle surface, the force density can be treated as a body force term and added on the right side to account for the effect of the presence of the particle. The fluid density, ρ, and velocity field, $\boldsymbol{u}$, are obtained from $f_i(\boldsymbol{x},t)$ as follows:

$$\rho\left(\boldsymbol{x},t\right)=\sum_i f_i\left(\boldsymbol{x},t\right), \tag{2.155}$$

and

$$\rho\left(\boldsymbol{x},t\right)\boldsymbol{u}\left(\boldsymbol{x},t\right)=\sum_i f\left(\boldsymbol{x},t\right)\boldsymbol{c}_i. \tag{2.156}$$

There are other numerical schemes in the literature for adding a body force term in Equation 2.154. Mohamad and Kuzmin (2010) reported that there are no significant differences in the results obtained from these schemes in most applications.

During the simulations of the particle motion, it is necessary to compute the total force and torque acting on each particle. The force on a particle includes the gravity; the buoyancy; the particle collision forces, $\boldsymbol{F}^{\text{col}}$; as well as the hydrodynamic force exerted by the fluid. Hence, the total force exerted on the ith particle is

$$\boldsymbol{F}=\left(1-\frac{\rho_f}{\rho_s}\right)\rho_s V_s\boldsymbol{g}+\oint_\Gamma\boldsymbol{\sigma}\cdot\boldsymbol{n}dS+\boldsymbol{F}^{col}, \tag{2.157}$$

where

V_s is the volume of the particle
ρ_f is the fluid density
ρ_s is the particle density

When the DF scheme is used, it is more convenient to replace the surface integral with a volume integral of the body force within the particle. Utilizing the Gauss integral and the Cauchy theorem, we have

$$\oint_\Gamma\boldsymbol{\sigma}\cdot\boldsymbol{n}dS=-\int_\Omega\boldsymbol{f}dV+\rho\frac{d}{dt}\int_\Omega\boldsymbol{u}dV=-\int_\Omega\boldsymbol{f}dV+\rho_f V_s\frac{d\boldsymbol{U}_s}{dt}. \tag{2.158}$$

Thus, the conservation of linear momentum, $\boldsymbol{P} = \rho_s V_s \boldsymbol{U}_s$, follows

$$\frac{d\boldsymbol{P}}{dt} = \rho_s V_s \frac{d\boldsymbol{U}_s}{dt} = \left(1 - \frac{\rho_f}{\rho_s}\right)\rho_s \boldsymbol{V}_s \boldsymbol{g} - \int_V \boldsymbol{f} dV + \rho_f V_s \frac{d\boldsymbol{U}_s}{dt} + \boldsymbol{F}^{col}. \tag{2.159}$$

When a first-order forward finite difference numerical scheme is used to solve the earlier ODE, the term $\rho_f V_s (d\boldsymbol{U}_s/dt)$ is evaluated at the current time step t_n. Without combining $\rho_f V_s (d\boldsymbol{U}_s/dt)$ with $\rho_s V_s (d\boldsymbol{U}_s/dt)$, this scheme is able to resolve the instability issue for low particle-fluid density ratio, as demonstrated by Feng and Michaelides (2009b).

The torque on a particle is computed using the following expression:

$$\boldsymbol{T} = \oint_\Gamma \left(\boldsymbol{x} - \boldsymbol{X}_C\right) \times (\boldsymbol{\sigma} \cdot \boldsymbol{n}) dS. \tag{2.160}$$

In the case of a spherical particle, its rotational motion can be described by the following equation:

$$\frac{d\boldsymbol{L}}{dt} = \frac{d\left(\boldsymbol{I}_s \cdot \boldsymbol{\omega}_s\right)}{dt} = -\int_\Omega (\boldsymbol{x} - \boldsymbol{X}_C) \times \boldsymbol{f} dV + \frac{d(\boldsymbol{I}_f \cdot \boldsymbol{\omega}_s)}{dt} + \boldsymbol{T}^{col}, \tag{2.161}$$

where

$\boldsymbol{L}$ is the angular momentum

$\boldsymbol{I}_s$ and $\boldsymbol{I}_f$ are the moment of inertia matrices of the solid particle and fluid particle, respectively

We add a $\boldsymbol{T}^{\text{col}}$ to include additional torques that may arise, such as the torque due to the tangential collision force component when the soft-sphere collision model is used.

In order to minimize the skewing effect (drift) due to the accumulation of the numerical error when one uses the rotational matrix of the particle, a unit quaternion is used to represent the rotation of the particles. In the 3D implementation of the method, the following set of differential equations are solved to get the equation of motion of a particle:

$$\frac{d}{dt}\begin{bmatrix} \boldsymbol{x}(t) \\ \boldsymbol{q}(t) \\ \boldsymbol{P}(t) \\ \boldsymbol{L}(t) \end{bmatrix} = \begin{bmatrix} \boldsymbol{U}_s(t) \\ \frac{1}{2}\Xi\left[\boldsymbol{\omega}_s(t)\right] \cdot \boldsymbol{q}(t) \\ \boldsymbol{F}(t) \\ \boldsymbol{T}(t) \end{bmatrix}. \tag{2.162}$$

with the prescribed initial conditions. Here, $\boldsymbol{q}(t)$ is the unit quaternion form for the rotation matrix of the particle with its initial value determined from the initial rotation matrix, $\Xi(\omega_s(t))$ is the rotational tensor associated with $\boldsymbol{\omega}_s(t)$, which can be expressed as

$$\Xi_{ij} = -\epsilon_{ijk}\omega_k \tag{2.163}$$

where ϵ_{ijk} is the permutation tensor.

At any given time, the translational and rotational velocities of particles are computed by the following expressions:

$$\dot{\boldsymbol{U}}_s(t) = \frac{\boldsymbol{P}(t)}{m_s}, \tag{2.164}$$

and

$$\dot{\boldsymbol{\omega}}(t) = \boldsymbol{I}_s^{-1}(t)\boldsymbol{L}(t), \tag{2.165}$$

where $m_s = P_s V_s$ is the mass of the particle, $\boldsymbol{I}_s(t)$ is the moment of inertia matrix of the particle in the current coordinate system. This is related to the moment of inertia matrix I_{s0} at the initial coordinate system and the rotation matrix of the particle, $\boldsymbol{R}_s(t)$, by the expression

$$\boldsymbol{I}_s(t) = \boldsymbol{R}(t)\boldsymbol{I}_{s,0}\boldsymbol{R}(t)^T. \tag{2.166}$$

This numerical scheme is capable of simulating the motion and rotation not only of spherical particles but also of particles with irregular shapes. In the special case of spherical particles, $\boldsymbol{I}_i(t)$ is a constant diagonal matrix:

$$I_s = \begin{bmatrix} \frac{2}{5}m_s a^2 & & \\ & \frac{2}{5}m_s a^2 & \\ & & \frac{2}{5}m_s a^2 \end{bmatrix}. \tag{2.167}$$

where a is the radius of the particle.

It must be noted that many times the rigid body motion inside the particle is not enforced *a priori*. Therefore, the problem that is actually solved with these techniques is the interaction between a fluid and a solid shell filled with the same fluid. The solid shell has the same boundary as the particle and carries the total mass of the particle. The contribution of the interior fluid mass is typically ignored. In general, the contribution from the internal flow to the resulting motion of the particle is not significant for low-frequency flows.

One may enforce the rigid body motion for the internal fluid by setting up a few internal Lagrangian points in order to remedy this deficiency. The velocity at these points is determined by the rigid body motion of the particle. With this addition to the numerical scheme, an advantage of the DF scheme is that it enforces the rigid body motion in the interior of the particles in a straightforward way.

There are a few recent developments in improving the accuracy and stability of the original implementation of the SRT-LBM-based explicit IBM. For example, Wu and Shu (2009) pointed out that the explicit IBM method can only approximately satisfy the no-slip boundary condition at the Lagrangian nodes. They proposed an implicit velocity correction-based IBM that provides better accuracy. Lu et al. (2012) applied the IBM with a multirelaxation time scheme LBM. Seta et al. (2014) developed a two-relaxation-times (TRT)-based IBM and compared the simulation results between the SRT-LBM, the TRT-LBM, and the MRT-LBM.

2.4.4 Implementation of the IBM with Heat Transfer

In the case of nonisothermal flow due to the presence of hotter or colder particles suspended in a viscous fluid or of particulate flow with heat transfer, a similar IB-based method can be proposed. Kim and Choi (2004) proposed a method based on the IBM for the solution of 2D heat flow problems with complex geometries. Pacheco et al. (2005) presented a finite volume IBM to study the heat transfer between a fixed solid and a fluid.

A glance at the implementation of the IBM proves that the method is ideally suited for the solution of applications involving simultaneous multiphase flow with mass and energy transfer. While for the momentum exchange the boundaries of particles are substituted with a system of forces, for the energy interactions the boundaries of particles may be substituted by a system of heat sources or heat sinks. Feng and Michaelides (2008, 2009a) recognized this analogy and extended the IBM from isothermal systems of particulate flows to systems that included heat transfer. They used a DF scheme for the computations.

Similar to the momentum interaction equations, the temperature field in the Eulerian domain of the fluid is governed by the following modified energy equation:

$$\rho_f c_f \left(\frac{\partial T}{\partial t} + \boldsymbol{u} \cdot \nabla \mathrm{T} \right) = k_\mathrm{f} \nabla^2 T + \lambda, \tag{2.168}$$

where c_f and k_f are the specific heat and thermal conductivity of the fluid, respectively. The additional term, λ, is an energy density term that is added to enforce the temperature field in the region occupied by

the particles. As in the case of the momentum balance equations, this term is equal to zero in the field occupied by the fluid. In the solid region, this term is computed by the following equation:

$$\lambda = \rho_f c_f \left(\frac{\partial T}{\partial t} + \boldsymbol{u} \cdot \nabla T \right) - k_f \nabla^2 T, \tag{2.169}$$

In the original publications, the temperature of each particle was assumed to be uniform, that is, $T = T_s(t)$, which essentially implies that the Biot number vanishes ($Bi \ll 1$). This assumption may be relaxed by solving the energy equation inside the particles to obtain the temperature field, $T_s(\boldsymbol{x},t)$, though the computational cost could be prohibitive for a large number of particles.

The transient temperature of the particles, $T_s(t)$, is determined by solving the following differential equation, which is obtained from the energy balance for each particle:

$$\rho_s V_s C_s \frac{dT_s}{dt} = \oint_\Gamma k_f \nabla T_f \cdot \boldsymbol{n} ds = -\int_\Omega \lambda dV + \rho_f V_s C_f \frac{dT_f}{dt} dV. \tag{2.170}$$

The last term in the last equation is the rate of heat that would have entered the control volume occupied by the sphere in the absence of the latter (Michaelides and Feng, 1994). In the case of constant particle temperature, the heat transfer rate between the particle and its surrounding fluid may be calculated by the volume integral of energy density λ instead of a surface integral.

Whenever particles have different temperatures than the fluid, the term λ creates a temperature gradient within the fluid, which would modify the fluid properties. This effect may be computed in a conceptually easy manner by using empirical equations for the properties of the fluid at every point of the Eulerian grid. For relatively small temperature differences between the particles and the fluid, the Boussinesq approximation is typically used successfully for the coupling of the energy and momentum equations. Hence, the momentum equation of the fluid is written as follows:

$$\rho_{f0} \left(\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u} \cdot \nabla \boldsymbol{u} \right) = -\nabla p + \mu_f \nabla^2 \boldsymbol{u} + \beta_f \left(T - T_{f0} \right) \boldsymbol{g} + \boldsymbol{f}, \quad x \in \boldsymbol{\Omega}. \tag{2.171}$$

where

the subscript 0 denotes values far from the particles

β_f is the thermal expansion coefficient of the fluid

The fluid velocity and temperature fields can also be solved using the LBM (Kang et al., 2011). More recently, a variation of this method, the IBM-based resolved discrete particle method (IBM-RDPM), has been used to study the convective heat transfer of particulate flows. An example of the application of this method is given in the last part of this section.

2.4.5 Particle–Particle and Particle–Wall Interactions

When a Lagrangian–Eulerian method such as the RDPM is used in modeling particulate flows of large groups of particles, interparticle collisions and collisions between particles and flow boundaries are unavoidable and need to be modeled appropriately. In general, even at low Reynolds numbers, the Eulerian grid used in a RDPM study is not fine enough to handle the lubrication force that develops between the particles or between particles and a solid boundary, when the boundaries almost touch. Therefore, a mechanism is necessary to be introduced in the IBM numerical scheme in order to account for the repulsive forces that develop before and during the collision processes. In the absence of such a mechanism, the motion of the particles will result in the partial penetration of the particle surfaces. When significant boundary penetrations occur, the computational results may become meaningless. Therefore, the prescription of a definitive collision scheme is necessary for any discrete particle method. This becomes even more important when the particle phase is dense.

There are several collision schemes that have been reported in the literature. We will introduce three of the most commonly used schemes: the soft-sphere scheme, the repulsive force scheme, and the lubrication scheme. Notwithstanding, it must be pointed out that the general consensus is that the use of a particular collision model will not significantly alter the simulation results for dilute particulate flows (Abdelsamie et al., 2014).

2.4.5.1 Soft-Sphere Collision Scheme

The soft-sphere scheme is the most common collision model used in Eulerian–Lagrangian particulate flow simulations. It allows particles to deform during a contact. However, the deformation is only used to determine collision force and particles remain geometrically rigid. This model is suitable for fixed time step simulations since it allows multiple collisions within one time step. It is composed of a spring-dashpot system. The spring provides the elastic rebound while the dashpot dissipates energy. The collision force when two spheres are in contact is composed of normal and tangential force components, which are calculated from the overlapping displacement and their relative velocities. However, the spring can be a linear spring, Hertzian spring, or other nonlinear spring. For small length and timescale simulations such as nanoparticles suspended in a fluid, the Hertzian spring model can be applied (Sloan et al., 2012). For most other engineering applications, a linear spring model is sufficient to produce satisfactory results.

In the linear spring-dashpot model, the normal contact force between two particles, i (located at $\boldsymbol{X}_i$) and j (located at $\boldsymbol{X}_j$), can be computed by the following expression:

$$f_{ij}^n = -k_n \delta_{ij}^n - \eta_n u_{ij}^n, \tag{2.172}$$

with

$$\delta_{ij}^n = R_i + R_j - \left|\boldsymbol{X}_i - \boldsymbol{X}_j\right|, \tag{2.173}$$

and

$$u_{ij}^n = \boldsymbol{u}_{ij} \cdot \frac{\boldsymbol{X}_i - \boldsymbol{X}_j}{\left|\boldsymbol{X}_i - \boldsymbol{X}_j\right|}, \tag{2.174}$$

where

δ_{ij}^n is the normal overlapping displacement
k_n and η_n are the normal spring stiffness and damping coefficient
u_{ij} is the relative velocity of particle j with respect to particle i

Here,

$$\boldsymbol{u}_{ij} = \boldsymbol{U}_j - \boldsymbol{U}_i \tag{2.175}$$

where u_{ij}^n is the relative normal velocity component of particle j with respect to particle i.

When one considers the friction at contact, the tangential contact force can be calculated from the following equation:

$$f_{ij}^t = \begin{cases} -k_t \delta_{ij}^t - \eta_t u_{ij}^t & \text{if } \left|f_{ij}^t\right| \le \mu_s \left|f_{ij}^n\right| \\ \mu_k \left|f_{ij}^n\right| \dfrac{\delta_{ij}^t}{\left|\delta_{ij}^t\right|} & \text{if } \left|f_{ij}^t\right| > \mu_s \left|f_{ij}^n\right| \end{cases}. \tag{2.176}$$

where

μ_s and μ_k are the coefficients of static and dynamic friction, respectively
δ_{ij}^t is the tangential overlapping displacement
$\mathbf{k}_t$ and η_t are the tangential spring stiffness and damping coefficients, respectively

The relative tangential velocity component at the contact point is given as

$$\boldsymbol{u}_{ij}^t = \boldsymbol{u}_{ij} - \boldsymbol{u}_{ij}^n. \tag{2.177}$$

The slider distance or tangential displacement can be computed by integrating the relative tangential velocity within the contact time.

However, most studies do not differentiate between μ_k and μ_s and use a single coefficient of friction, μ. The following damping coefficient is obtained based on the following dry collision assumption (Tsuji et al., 1998):

$$\eta_n = \begin{cases} \dfrac{-2\ln(e_n)\sqrt{m_{ij}k_n}}{\sqrt{\pi^2+\ln^2(e_n)}} & \text{if } e_n \neq 0 \\ 2\sqrt{m_{ij}k_n} & \text{if } e_n = 0 \end{cases}. \tag{2.178}$$

The particle–wall collision may be considered as a special case of the interparticle collision when the radius of one of the particles becomes approaches infinity, thus applying also the method described earlier. In the case of particle collisions in a viscous flow, the collision parameters must be modified to account for the flow viscous effects as noted in the study by Feng et al. (2010).

2.4.5.2 Repulsive Force Scheme

Glowinski et al. (2003) suggested an artificial collision technique by introducing a repulsive force when the gap between two particles is lower than a given threshold, the so-called safe zone. This artificial short-range repulsive force is added as an external force in the IBM. Thus, when two particles with radii R_i and R_j approach very closely, the collision force exerted on each particle is

$$\boldsymbol{F}_{ij}^{P} = \begin{cases} 0, & \|\boldsymbol{x}_i - \boldsymbol{x}_j\| > R_i + R_j + \xi \\ \dfrac{c_{ij}}{\epsilon_P}\left[\dfrac{\|\boldsymbol{x}_i - \boldsymbol{x}_j\| - R_i - R_j - \xi}{\xi}\right]^2 \left(\dfrac{\boldsymbol{x}_i - \boldsymbol{x}_j}{\|\boldsymbol{x}_i - \boldsymbol{x}_j\|}\right), & \|\boldsymbol{x}_i - \boldsymbol{x}\|_j \leq R_i + R_j + \xi \end{cases} \tag{2.179}$$

where

$\boldsymbol{x}_i$ is the position of the particle i

ε_P is the stiffness parameter for collisions

ζ is the threshold or safe zone, which is specified in advance and typically chosen to be one or two units of grid spacing

c_{ij} is the force scale in the problem that is studied, for example, a good choice for this scale in sedimentation problems is the net gravity force on a single particle

Similarly, the repulsive force between a particle and a wall is given by the reflection method assuming that an identical, fictitious particle approaches the wall from the other side with a normal velocity that is equal and opposite to that of the particle under consideration. Glowinski et al. (2001) provide an extensive discussion on the choice of the stiffness parameters.

This collision technique allows particles to interpenetrate when the stiffness parameter ε_P is very large. In this case, it is said that the particles undergo soft collisions. Depending on the type of flow and the particle density, the partial overlapping of particles may be significant. This phenomenon is accentuated when a large number of particles undergo a packing process: the particles at the bottom, which have to bear the load of the particles above, overlap significantly. To counteract this overlapping, one has to choose a higher value for the repulsive force when the collision scheme of Equation 2.179 is used. Feng and Michaelides (2005) employed a novel collision scheme with the *Proteus* code: before the contact of the two particles, a repulsive force given by Equation 2.179 is used. If the particles start overlapping, a higher spring force is applied. The spring force is proportional to the overlapping distance of the two particles and typically is much larger than the repulsive force before the overlapping process. Thus, the functional form of this collision force scheme is

$$\boldsymbol{F}_{ij}^{P} = \begin{cases} 0, & \|\boldsymbol{x}_i - \boldsymbol{x}_j\| > R_i + R_j + \xi \\ \dfrac{c_{ij}}{\epsilon_P}\left[\dfrac{\|\boldsymbol{x}_i - \boldsymbol{x}_j\| - R_i - R_j - \xi}{\xi}\right]^2 \left(\dfrac{\boldsymbol{x}_i - \boldsymbol{x}_j}{\|\boldsymbol{x}_i - \boldsymbol{x}_j\|}\right), & R_i + R_j \leq \|\boldsymbol{x}_i - \boldsymbol{x}_j\| \leq R_i + R_j + \xi, \\ \dfrac{c_{ij}}{\epsilon_P}\left\{\left[\dfrac{\|\boldsymbol{x}_i - \boldsymbol{x}_j\| - R_i - R_j - \xi}{\xi}\right]^2 + \dfrac{c_{ij}}{E_p}\dfrac{\left(R_i + R_j - \|\boldsymbol{x}_i - \boldsymbol{x}_j\|\right)}{\xi}\right\}\left(\dfrac{\boldsymbol{x}_i - \boldsymbol{x}_j}{\|\boldsymbol{x}_i - \boldsymbol{x}_j\|}\right), & \|\boldsymbol{x}_i - \boldsymbol{x}_j\| \leq R_i + \boldsymbol{R}_j \end{cases} \tag{2.180}$$

where E_P is a smaller parameter than ε_P to ensure that the spring force after the overlapping is significantly larger. It was observed that when this type of force was applied, the overlapping of two particles and the overlapping of particles and walls become very low and do not affect significantly the computational results. It must be noted that the first term of the last function of Equation 2.180 is present so that the collision force is continuous before and after penetration. The implementation of this collision scheme enables one to use smaller repulsive forces that keep the particles from overlapping under normal flow conditions. The additional spring force is added that separates the particles quickly when overlapping occurs.

2.4.5.3 Hybrid Lubrication Force Scheme

An early lubrication force model was developed by Ladd (1994) to be applied to low Reynolds and Stokes numbers. The model can be extended to higher Reynolds numbers by permitting a possible overlap between the colliding particles, after the particles contact. In a similar manner as the modified repulsive force scheme, we consider two particles approaching each other along their line of centers (Musong and Feng, 2012). The drag force and buoyancy of the particles then become characteristics of this lubrication model. The gap width between the surfaces of the two spheres at the tangents normal to the line of their centers has a threshold value $\xi_0 = \delta$, where δ can be the Eulerian grid spacing. The normal lubrication force exerted when the viscous fluid is squeezed or compressed by the two approaching particles before contact and when they start to overlap is given by

$$f_{ij}^{n} = \begin{cases} 0 & \xi > \delta \\ -F_d\left(\dfrac{\delta}{\max(\xi,\delta_s)} - 1\right) & 0 \le \xi < \delta \\ -F_d\left(\dfrac{\delta}{\max(\xi,\delta_s)} - 1\right) - k_n(-\xi) & \xi < 0 \end{cases}. \tag{2.181}$$

In the last equation, F_d is the effective drag force that can be calculated by several drag force models and δ_s is a small positive gap (e.g., $\delta_s = (1/10)\delta$) to prevent singular value at $\xi = 0$. If the particles continue to approach and overlap, a force proportional to the overlapping distance is applied on top of the modified lubrication force with a spring stiffness k_n.

2.4.6 Examples on the Application of IBM

In this subsection, we provide two examples on two types of problems to demonstrate that the IBM-based method may be used to obtain needed data for engineering and scientific applications. The first application pertains to the fundamental problem of calculating the drag and heat transfer for a pair of particles and the second to an engineering application of heat transfer in a smaller-scale fluidized bed.

2.4.6.1 Drag and Heat Transfer Rate of a Pair of Heated Spheres

The drag and heat transfer rate of a spherical particle is significantly changed by the presence of neighboring particles. We consider a uniform flow over a pair of spheres aligned along the flow direction and separated by a distance δ, ranging from 1 to 6 sphere diameters, at different Reynolds numbers. The Prandtl number is chosen to be Pr = 7 (approximately that of water). Periodic boundary conditions are applied at the two directions other than the flow direction. The size of simulation domain is $6D \times 6D \times 20D$, where D is the diameter of the sphere. One sphere is outlined by a number of grid points ranging from 13 to 27 depending on the chosen Reynolds numbers.

Table 2.2 shows the computed drag coefficients of a pair of spheres at different Reynolds numbers and different separation distances. It also lists the drag coefficients of a single sphere in uniform flow obtained from the numerical simulations by Feng and Michaelides (2001a) and from the following correlation (Clift et al., 1978):

$$C_D = \frac{24}{Re}(1 + 0.15Re^{0.687}) \tag{2.182}$$

It is observed in this table that the present simulation results for a single sphere case agree very well with those found in the literature at Re = 10 and 100, with an overall difference of a few percentages. However, more

Table 2.2 Drag Coefficient of Spheres

		Re = 10		Re = 100		Re = 400	
Single sphere	Clift et al. (1978)	4.15		1.092		0.612	
	Feng and Michaelides (2001a)	4.30		1.103		0.579	
	Present	4.50		1.124		0.711	
A pair of spheres at δ/D		Sphere 1	Sphere 2	Sphere 1	Sphere 2	Sphere 1	Sphere 2
1		3.81	2.23	1.061	0.247	0.734	−0.064
2		4.19	2.94	1.054	0.430	0.710	0.028
3		4.28	3.34	1.081	0.548	0.690	0.190
4		4.45	3.51	1.105	0.620	0.679	0.331
5		4.47	3.71	1.117	0.671	0.702	0.382
6		4.49	4.00	1.121	0.709	0.710	0.421

than 15% difference is observed at Re = 400. Two factors contribute to this deviation. The first is that the current simulation domain is much smaller compared to those used in the literature where the sphere is isolated. The second is that the grid used for Re = 400 is not sufficiently fine to fully resolve the laminar boundary layer near the surface of the sphere (Feng and Musong, 2014). Nevertheless, the simulation is able to capture the principal flow structures behind spheres.

Table 2.2 clearly shows that the drag of the trailing sphere is considerably reduced. In general, the influence of the second sphere on the drag of the leading sphere is not significant, especially when the separation distance is more than 3D. However, the influence of the leading sphere on the drag of the trailing sphere can be very large and increases as the Reynolds number increases, even when the separation distance remains the same. Thus, at a separation distance of 2D, the drag on the trailing sphere is 70% that of the leading sphere at Re = 10, 41% at Re = 100, and only 4% at Re = 400. At a separation distance of 5D, the drag on the trailing sphere is 83% at Re = 10, 60% at Re = 100, and 54% at Re = 400. At Re = 400, the drag of the leading sphere is largest when it is almost in contact with the trailing sphere, and it gradually decreases as the separation distance increases. However, after the separation distance exceeds 4D, the drag starts to increase again because the trailing sphere is out of the main wake of the leading sphere. This nonmonotonic behavior is also observed in the case of two cylinders placed in tandem at moderate Reynolds numbers between 1 and 40 in a recent study by Vakil and Green (2013).

Figure 2.21 shows the temporal behavior of the drag coefficient at Re = 400 for a single sphere and a pair of spheres with a separation distance of 1D, 3D, and 6D. The accompanying vortex structures are shown in Figure 2.22 using the λ_2 method of vortex identification. There are a few interesting observations in these Figures. In the case of a single sphere, periodical vortex loops or hairpin vortices are constantly shed from the surface of the sphere at a period of 0.87 s, with a constant Strouhal number, St = 0.12. This observation agrees very well with the data by Wu and Faeth (1994) who observed Strouhal numbers around 0.13 for $335 \leq \text{Re} \leq 620$.

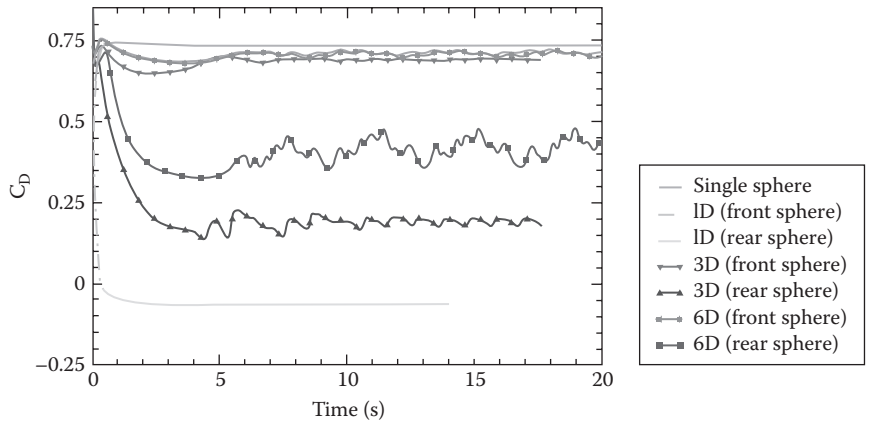

Figure 2.21

Drag coefficients of spheres versus time.

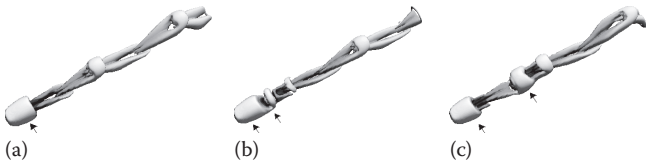

Figure 2.22

Vortex structures behind spheres at Re = 400 identified by $\lambda_2 = -0.002$: (a) a single sphere, (b) two spheres separated by 3D, (c) two spheres separated by 6D. Arrows indicate the position of a sphere; gray scale indicates fluid velocity magnitude.

In the case of two spheres placed along the flow direction, a slight increase in the drag coefficient of the leading sphere and a negative drag coefficient on the trailing sphere are observed when they are in contact (separation distance $\delta = D$). The negative drag coefficient on the trailing sphere implies a "push" effect on the leading sphere. It is due to the recirculation or wake behind the leading sphere that explains the higher drag coefficient of the leading sphere. It is also observed that the trailing sphere stabilizes the flow when placed closely with a gap of one or two diameters. In these cases, no hairpin vortex shedding was observed. However, as the gap increases to 3D or more, the vortex shedding occurs again. At $\delta = 3D$, the wake of the leading sphere induces vortex hairpins, which are interrupted by the presence of the trailing sphere. At $\delta = 6D$, the wake of the leading sphere is almost fully developed before it is interrupted by the trailing sphere. In this case, in addition to the Strouhal number of 0.12 that is due to the leading sphere vortex shedding, an additional higher Strouhal number of 0.5 is also observed, which is most likely due to the flow instability of the trailing sphere.

Table 2.3 shows the Nusselt numbers for a single sphere and a pair of spheres at different separation distances. In the case of forced convection of an isolated sphere in a large flow domain, Ranz and Marshall (1952) developed the following correlation experimentally:

$$Nu = 2 + 0.6Re^{0.5}\,\mathrm{Pr}^{0.33} \tag{2.183}$$

Feng and Michaelides (2001b) also proposed the following correlation based on their numerical results:

$$Nu = 0.852\left(PrRe\right)^{0.333}\left(1 + 0.233Re^{0.287}\right) + 1.3 - 0.182Re^{0.355} \tag{2.184}$$

The results of Table 2.3 show that the momentum and thermal wakes created by the leading sphere also have a significant effect on the heat transfer rate of the trailing sphere. Even at $\delta = 6D$ away from the leading sphere, the Nusselt number of the trailing sphere is only 60% compared to the leading sphere. However, it is seen that the trailing sphere has an insignificant effect on the heat transfer rate of the leading sphere. In the conduct of these calculations, the simulation results were significantly improved using the centroid of a control volume associated with the body force as the boundary node.

Table 2.3 Nusselt Number of Spheres

		Re = 10		Re = 100		Re = 400	
Single sphere	Ranzand Marshal (1952)	5.61		13.40		24.8	
	Feng and Michaelides (2001b)	5.98		14.54		27.4	
	Present	5.43		12.70		29.8	
A pair of spheres at δ/D		Sphere 1	Sphere 2	Sphere 1	Sphere 2	Sphere 1	Sphere 2
1		4.97	3.00	12.04	4.98	29.3	5.2
2		5.31	3.52	12.34	6.26	29.3	9.9
3		5.39	3.83	12.56	6.85	29.3	13.8

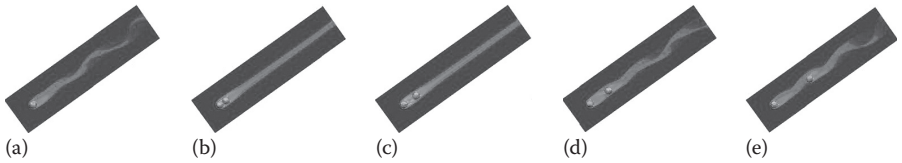

Figure 2.23

Temperature contours at Re = 400. (a) A single sphere, (b) δ = 1D, (c) δ = 2D, (d) δ = 3D, (e) δ = 6D.

The temperature contours for the cases of a single sphere and of a pair of spheres with separation distances 1D, 2D, 3D, and 6D are plotted in Figure 2.23. The vortex shedding for a single sphere and of a pair of spheres at δ = 3D and 6D causes nonsymmetric temperature distributions behind both spheres. However, at a separation distance of 1D and 2D, the flows remain stable and symmetric even after a long period of time.

In summary, the results presented in this subsection show that the drag and heat transfer rate of a sphere is significantly affected by its neighboring spheres. A simple influencing factor that depends only on the solid fraction may not be sufficient to account for the effect from the neighboring particles. In order to obtain accurate representations of drag and heat transfer rate in a complex flow filled with many neighboring particles, the RDPM or DNS must be applied as elucidated further in the next subsection.

2.4.6.2 Fluidization of 1204 Spheres by a Jet Flow Using a RDPM

In this example, we study the fluidization of 1204 spheres by a jet flow using an IBM-based RDPM. The bed setup and fluid and particle properties are the same as the one used by Pan et al. (2002) who studied the particle fluidization by a uniform flow in a slit bed using a fictitious domain method. The bed geometry is 20.3 cm × 0.6858 cm × 70.22 cm, the sphere diameter is 0.635 cm, the particle density is 1.14 g/cm^3, the fluid density is 1 g/cm^3, the viscosity is 0.01 g/(cm·s), and the Prandtl number is 7.

The high-velocity jet is placed at the center of the inlet. The jet orifice has a width of 2.03 cm and a depth of 0.6858 cm. The jet velocity is 40 cm/s, resulting in the same mass flow rate as that of a uniform flow across the entire bed at V = 4 cm/s. A time step Δt = 0.0002 s is used in the simulation because of the much higher maximum flow velocity in a jet flow fluidized bed.

Figure 2.24 shows the distribution of 1204 spherical particles at five different time instants: 1, 3, 5, 7, and 10 s. For better visualization, the particles are colored with four different colors based on their initial locations. From these snapshots, it is clearly seen that the particles are well mixed during the fluidization. The bottom region, where the particles are dense (the so-called dead zone), accounts for roughly a quarter of the entire bed. It is observed that the particles inside the "dead zone" are not stationary. During the

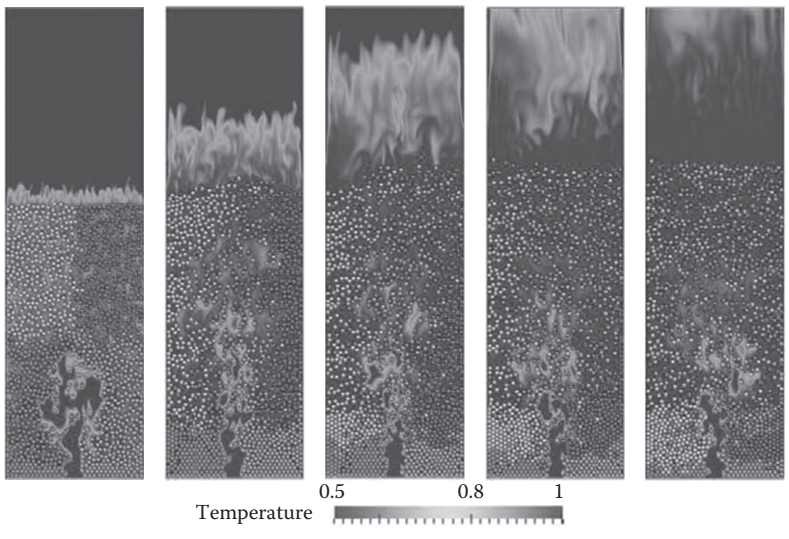

Figure 2.24

Snapshots of particle positions and flow temperature contours in a jet flow fluidized bed. From left to right, t = 1, 3, 5, 7, and 10 s.

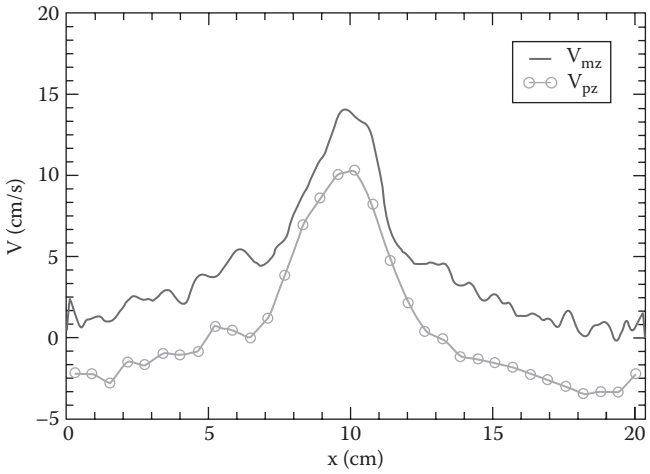

Figure 2.25

Time- and space (z-direction)-averaged particle velocity V_{pz} and fluid–particle composite velocity V_{mz} for a jet flow fluidized bed.

fluidization, some of the particles originally trapped in the dead zone are being fluidized, while "fresh" particles fall down and are entrained into the dead zone.

The time- and space-averaged particle velocity (in the z-direction) and fluid–particle composite velocity when the bed reaches a quasi-steady condition are computed, and their results are shown in Figure 2.25. The space averaging in the z-direction is achieved by averaging all the vertical velocity components of each node or each particle within a vertical column (Feng et al., 2014). As expected, the particles in the middle of the bed are entrained into the jet and move upward. However, as the jet's momentum is dissipated, the entrained particles start to fall downward near the left and right walls of the bed. With the particles rising in the central region and falling at the sides, the x-averaged particle velocity approaches zero, while the x-averaged mixture velocity approaches V = 4 cm/s as the bed becomes quasi-stable.

We also studied the fluidization by a uniform flow and compared its results with those from jet flow fluidization (Feng and Musing, 2014). There are a few interesting findings that are worth mentioning: The simulation results show that the bed is slightly higher when uniform flow is used for fluidization. However, the wall pressure gradient, which is an indication of wall friction, is much lower in the jet flow fluidized bed. This can be explained by the much smaller velocity gradient of the mixture in the jet flow fluidized bed compared to a higher velocity gradient of mixture in the uniform flow fluidized bed near the wall. As a result, the pressure drop over the jet flow fluidized bed is much lower than that of the uniform flow fluidized bed. Another observation is that the particle-averaged Nusselt number in the jet fluidized bed is significantly higher than that of the uniform flow fluidized bed. One plausible explanation is that the fluid warms up quickly as it moves upward in the case of the uniform flow fluidized bed. This reduces the temperature differences and the heat transfer rate of particles. However, in the case of the jet flow fluidized bed, the high jet stream forces cold fluid to penetrate deeper into the bed, resulting in a higher heat transfer rate when it interacts with particles along its path.

2.5 Pdf Models for Particle Transport Mixing and Collisions in Turbulent Flows

Michael W. Reeks, Olivier Simonin, and Pascal Fede

2.5.1 Introduction

Probability density function (pdf) equations have proved very useful in studying the behavior of stochastic systems. Obvious examples of their usage occur in the study of Brownian motion (Chandrasekhar, 1943) and in the kinetic theory of gases (Chapman and Cowling, 1952). In more recent times, they have been used extensively by Pope and others to model both turbulence (Pope, 1985) and turbulence-related phenomena such as combustion (Pope, 1991) and atmospheric dispersion (MacInnes and Bracco, 1992). In this section, we review how this approach has been used to model the behavior of a particle-laden turbulent gas: in particular how in a two-fluid model it has been used to derive the continuum equations and constitutive relations of the dispersed particle phase and deal with the near-wall behavior when the natural boundary conditions (bc's) and strong inhomogeneity lead to a breakdown of the traditional form of the two-fluid model equations.

As in other approaches, the independent variables that describe the system are the phase space variables and the pdf equation describes the transport of the average phase space density in terms of those variables in phase space: the solution of the equation is the pdf that the system will be in any particular state as it evolves randomly in time. In the particular case of gas–particle flows, the phase space variables are taken to be the particle velocity and position.

The approach we consider here has much in keeping with the kinetic theory of gases: that is, the pdf equation is an analogue of the Maxwell–Boltzmann equation and can be used in precisely the same way to generate the continuum equations and constitutive relations from known solutions under the so-called equilibrium conditions. Likewise, the pdf equation may be regarded as a more exact description of the behavior of a gas–particle flow than that given by the continuum equations (with constitutive relations, especially, as we have said, near the wall when the inhomogeneity and natural boundary cause significant departures from the so-called equilibrium solutions upon which the constitutive relations are based). To emphasize its similarity to the kinetic theory, we have in the past referred to this approach as the pdf–kinetic approach. Like the kinetic theory, it can be regarded as a rational approach to two-fluid modeling; by this we mean that the equation and in particular the terms it contains can be traced back in a rational manner to the underlying equations of motion of the individual particles themselves. In the case of certain simple but generic flows, the solutions of the pdf equations are exact solutions and can be made the basis of approximate solutions of more complex flows in a formal and precise way.

This is different from what has gone before. In the past, for instance, it has been traditional to assume that the particle phase behaves as a simple Newtonian fluid (e.g., Elghobashi and Abou-Arab, 1983): that is, the particle Reynolds stresses are proportional to the mean symmetric rate of strain of the particle flow via

some particle eddy viscosity that is related to that of the carrier flow in some empirical way. Now, we can examine the validity of these assumptions within the context of a more reliable and complete framework using techniques that are well tested and understood and ultimately replace them with more legitimate relationships that do not rely on intuition and empiricism. Perhaps more importantly, we have an approach that is crucial to the formulation of particle–wall interactions (which is referred to as the natural boundary conditions (bc's) of a gas–particle flow).

In this section, we will show how the pdf–kinetic approach deals with both aspects of a two-fluid model; how it generates the equations for mass, momentum, and energy (so-called continuum equations) and constitutive relations for the dispersed phase (which would be appropriate for the far-wall solution of a gas–particle flow); and how it generates near-wall solutions that take account of the inhomogeneity of the flow and the natural bc's. Throughout the chapter, we will concentrate on dilute gas–particle flow where interparticle collisions can be safely ignored. For the application of the pdf approach to dense flows, see the recent work of Boëlle et al. (1995). Though we will consider the form of the momentum coupling between phases, specific examples will be taken from situations where that coupling is sufficiently small to not influence the underlying carrier gas flow itself.

In Section 2.5.1, we will present the pdf equation itself and discuss about how it is derived from the underlying particle equations of motion. In Section 2.5.2, we will consider analytic solutions of the equation for simple flow in which the turbulence is homogeneous and stationary and the mean flow is uniform or is a simple shear or a rotational flow. These solutions have important implications for the behavior of the particle phase as a simple Newtonian flow. In Section 2.5.3, we will present the continuum equations as derived from the pdf equation and the constitutive relations for the particle Reynolds stress flux as derived using the Chapman–Enskog (C–E) approximation and show some predictions using these equations compared with those of a random walk simulation. Section 2.5.4 is concerned with the application of the pdf approach to the prediction of near-wall behavior. In particular, we will consider natural bc's involving partial absorption and both specular and diffuse reflection, and finally, we will consider solutions for the well-known problem of particle deposition in a turbulent boundary layer with perfectly absorbing walls (this is a much–studied system both theoretically and experimentally) and highlight the breakdown of the so-called gradient transport due to both the strong inhomogeneity of the flow near the wall and the strong departure of the velocity distribution at the wall compared with that in the far wall (bulk flow). In the final section, we will draw some comparison between the pdf approach used by Simonin (1991), for which there are strong similarities, and a practical point of view identical as far as dilute gas–particle flows).

2.5.2 Formulations of pdf Equations

There are currently two forms of the pdf equation in use. In the first form, the pdf, as in the kinetic theory, refers to the probability density that a particle has a certain velocity and position at a given time. We will refer to this pdf approach as the kinetic method (KM). This approach was originated by Buyevich (1971, 1972a,b) and developed since then by a number of workers most notably Reeks (1980, 1983, 1991, 1992), Swailes and Darbyshire (1997), Derevich and Zaichik (1988), Zaichik (1991), Pozorski and Minier (1998), and more recently Li and Zhou (1996). In all these developments, the pdf approach was restricted to inert nonreactive particles. More recently, Pandya and Mashayek (2001) extended the approach to reactive condensing or evaporating particles in a turbulent gas. In contrast, the second form of pdf equation, first proposed by Simonin et al. (1993), is for a more general pdf that includes the velocity of the carrier flow local to the particle as a phase space variable as well as the particle position and velocity. As an example of how pdfs and pdf equations are obtained, consider the motion of evaporating/condensing particles (droplets) in a dilute suspension in which there are no interparticle collisions. Let $\mathbf{X}(t)$ be the phase space vector at time t of a single particle as it moves through phase space. So, in this case,

$$\mathbf{X} = \left[m, T, \boldsymbol{v}, \boldsymbol{x}\right] \tag{2.185}$$

where

m is the mass of the particle
T is its temperature
$\boldsymbol{v}$ is its velocity
$\boldsymbol{x}$ is the position of its center of mass at time t

The n number of independent variables that defines the phase space dimension is thus $n = 8$. For a single realization of the underlying carrier flow velocity field $\boldsymbol{u}(\boldsymbol{x}, t)$ and temperature field $T(\boldsymbol{x}, t)$, the number of

particles in an elemental volume $d^n\mathbf{X}$ of phase space located at $\mathbf{X}$ is given by $W(\mathbf{X}, t)d^n\mathbf{X}$, where $W(\mathbf{X}, t)$ is the phase space density, that is, the number of particles per unit volume in phase space. So, if we consider conservation of particle number within that elemental volume at $\mathbf{X}$, then with respect to P, we have

$$\frac{\partial W}{\partial t}+\frac{\partial}{\partial \mathbf{X}}\cdot\left[W\dot{\mathbf{X}}\right]=0 \tag{2.186}$$

So, for the case of the evaporating droplet, we have explicitly

$$\dot{\mathbf{X}}=\left[\dot{m},\dot{T},\dot{\boldsymbol{v}},\dot{\boldsymbol{x}}\right] \tag{2.187}$$

where the equations for components of $\dot{\mathbf{X}}$ represent the *particle equations of motion* in the most general sense and are derived from the mass, momentum, and energy conservation equations for an individual particle/droplet (see, e.g., Crowe et al., 2012). However, because the underlying carrier flow field is turbulent, $\dot{\mathbf{X}}$ has a random component, so we can only usefully refer to the pdf that a particle has a set of values $\mathbf{X}$ at any given time. This is represented by the ensemble average of W over all realizations of the system, symbolically $\langle W\rangle$. The equation for $\langle W\rangle$ (the pdf equation) can be found by ensemble averaging the conservation equation for W (the Liouville equation). For convenience, we use Reynolds decomposition, whereby the instantaneous components of $\dot{\mathbf{X}}$ are decomposed into their mean components $\langle\dot{\mathbf{X}}\rangle$ and fluctuating (zero mean) components $\dot{\mathbf{X}}'$, noting that $\dot{\boldsymbol{x}}=\boldsymbol{v}$, so that explicitly the pdf equation for the evaporating/condensing particle is

$$\begin{aligned}&\frac{\partial\langle W\rangle}{\partial t}+\left(\frac{\partial}{\partial m}\langle\dot{m}\rangle+\frac{\partial}{\partial T}\langle\dot{T}\rangle+\boldsymbol{v}\cdot\frac{\partial}{\partial\boldsymbol{x}}+\frac{\partial}{\partial\boldsymbol{v}}\cdot\langle\dot{\boldsymbol{v}}\rangle\right)\langle W\rangle\\&\quad=-\frac{\partial}{\partial m}\langle\dot{m}'W\rangle-\frac{\partial}{\partial T}\langle\dot{T}'W\rangle-\frac{\partial}{\partial\boldsymbol{v}}\cdot\langle\dot{\boldsymbol{v}}'W\rangle\end{aligned} \tag{2.188}$$

where on the left-hand side (LHS) we have the convective part (the transport in the absence of the turbulence) and on the right-hand side (RHS) the dispersive part involving the gradients of the net fluxes due to the turbulence. To close the equation, we need to relate the turbulent fluxes in some way, directly or indirectly, to $\langle W\rangle$ and its derivatives. That is, we have a closure problem to resolve, which is the most important element of the pdf approach.

To illustrate the way in which the values of $\dot{\mathbf{X}}$ depend upon the properties of the particle and the underlying carrier flow, let us consider the case of the evaporating droplet in more detail. From mass conservation of a spherical droplet of diameter d_p evaporating in a gas of mass density ρ_g, we have the general relationship

$$\dot{m}=\pi\rho_g d_p D_g Sh(Re_p,S_c)\ln\left[\frac{1-\alpha_v}{1-\alpha_{vs}}\right] \tag{2.189}$$

where

α_v is the mass fraction of vapor emitted by the particle in the locally undisturbed gas flow

α_{vs} is the (saturated) vapor mass fraction at the droplet/particle–surface assumed to be in equilibrium with the particle (so it depends directly on the temperature T of the particle)

D_g is the molecular diffusion coefficient of the vapor

Sh is the droplet Sherwood number for the mass transfer of vapor to or from the droplet that is a function of the vapor Schmidt number S_c and the local particle Reynolds number Re_p given by

$$Re_p=\frac{d_p|\boldsymbol{v}-\boldsymbol{u}|}{\nu_g};\quad Sc=\frac{D_v}{\nu_g} \tag{2.190}$$

where

$\boldsymbol{u}(\boldsymbol{x}, t)$ is the gas flow velocity local to the droplet at $\boldsymbol{x}$ at time t

ν_g is the kinematic viscosity of the gas

From momentum conservation (Crowe et al., 2012), we have

$$m\dot{\boldsymbol{v}} = mg - V\frac{\partial \cdot \underline{\sigma}}{\partial x} + \mathbf{F}_A + (\boldsymbol{u} - \boldsymbol{v})\dot{m} \tag{2.191}$$

The first term on the RHS of this equation is the gravitational force. The second and third terms represent the force exerted by the surrounding gas flow from the external stresses $\underline{\sigma}$ and the aerodynamic force $\mathbf{F}_A$ that has both lift and drag components $\mathbf{F}_L$ and $\mathbf{F}_D$ arising from the locally disturbed gas flow field due to the presence of the particle that has a volume V. For a spherical particle, this is well represented by the drag force in most cases so that

$$\mathbf{F}_A \cong \mathbf{F}_D = -\frac{1}{2}\rho_g A C_D(Re_p)\left|\boldsymbol{v} - \boldsymbol{u}\right|(\boldsymbol{v} - \boldsymbol{u}) \tag{2.192}$$

where

C_D is the drag coefficient

A is the projected area of the particle normal to the flow

From energy conservation, we would have an equation of the form

$$mC_p\dot{T} = S_r - \pi k_f d_p Nu(Re_p, Pr) + \Delta H\dot{m} \tag{2.193}$$

where C_p is the specific heat of the particle/droplet and, on the RHS of the equation, the first term S_r is the heat source due to the external field (radiation), the second term is the particle to surrounding gas heat transfer rate where Nu is the Nusselt number (depending upon the local particle Reynolds number and the Prandtl number of the gas/vapor mixture), and the third term is energy exchange during the evaporation/condensation that depends upon ΔH (the difference in enthalpy between the droplet and the vapor mass flux).

The point to note here is that the equations of motion are all coupled and all depend upon the instantaneous particle Reynolds number based upon the relative velocity between particle and locally undisturbed gas.

2.5.2.1 Pdf Equation for Inertial Particles

As we have said earlier, there are currently two pdf approaches in use that we refer to as the kinetic method (KM) and the generalized Langevin method (GLM), respectively. To illustrate the differences and similarities between these approaches, we consider here the simplest case of transport of inertial nonreacting solid particles in a turbulent gas flow that we will assume all to be identical to one another. To simplify the situation still further, we will linearize the drag acting on the particle with respect to the relative velocity, that is,

$$\mathbf{F}_A \cong \eta\left(\boldsymbol{u} - \boldsymbol{v}\right) \tag{2.194}$$

where η is the net friction coefficient and is given by

$$\eta = \frac{1}{2}\rho_g A C_D(\overline{Re}_p)\left|\bar{\boldsymbol{u}} - \bar{\boldsymbol{v}}\right| \tag{2.195}$$

where

$\bar{\boldsymbol{v}}$ is the net particle velocity

$\overline{Re}_p$ is the value of the particle Reynolds number based on the net relative velocity between particle and local carrier flow

The equations of motion for an identical particle are thus

$$\frac{d\boldsymbol{x}}{dt} = \boldsymbol{v} \tag{2.196}$$

$$\frac{d\boldsymbol{v}}{dt} = \beta\left(\boldsymbol{u} - \boldsymbol{v}\right) \tag{2.197}$$

where β is the inverse particle response time and is given by $m^{-1}\eta$ for a particle of mass m: in the case $Re_p \ll 1$ corresponding to Stokes drag, β is a constant of the motion. To the particle equations of motion, we add an equation of motion of the carrier flow velocity **u** along a particle trajectory, namely,

$$\frac{du_i}{dt} = F_i\left(\boldsymbol{v}, \boldsymbol{u}, \boldsymbol{x}, t\right) \tag{2.198}$$

In the KM approach, we consider continuum equations derived from an equation for the phase space density $W(\mathbf{v}, \mathbf{x}, t)$ in which $\mathbf{u}(\mathbf{x}, t)$ is a random function of **x** and t and **v** and **x** are independent random variables. In the GLM approach, the continuum equations are derived from a conservation equation for the phase space density $P(\boldsymbol{v}, \boldsymbol{u}, \boldsymbol{x}, t)$ where $\boldsymbol{v}, \boldsymbol{u}, \boldsymbol{x}$ form a set of independent variables. The transport/conservation equations for $W(\boldsymbol{v}, \boldsymbol{x}, t)$ and $P(\boldsymbol{v}, \boldsymbol{u}, \boldsymbol{x}, t)$ are, respectively,

$$\left\{\frac{\partial}{\partial t} + \frac{\partial}{\partial x_i}v_i + \frac{\partial}{\partial v_i}\beta\left(u_i(\boldsymbol{x}, t) - v_i\right)\right\}W\left(\boldsymbol{v}, \boldsymbol{x}, t\right) = 0 \tag{2.199}$$

$$\left\{\frac{\partial}{\partial t} + \frac{\partial}{\partial x_i}v_i + \frac{\partial}{\partial v_i}\beta_i\left(u_i - v_i\right) + \frac{\partial}{\partial u_i}F_i\left(\boldsymbol{v}, \boldsymbol{u}, \boldsymbol{x}, t\right)\right\}P\left(\boldsymbol{v}, \boldsymbol{u}, \boldsymbol{x}, t\right) = 0 \tag{2.200}$$

Note that integrating the equation for P over all $\boldsymbol{u}$ gives the equation for W. We resolve $u_i(\boldsymbol{x}, t)$ and $F_i(\boldsymbol{v}, \boldsymbol{u}, \boldsymbol{x}, t)$ into mean and fluctuating parts:

$$u_i = \langle u_i \rangle + u_i''; \quad F_i = \left\langle F_i \right\rangle + F_i'' \tag{2.201}$$

where $\langle \ldots. \rangle$ represents an ensemble average. Then the transport equations for mean values of W and P, namely, $\langle W \rangle$ and $\langle P \rangle$, are

$$\left\{\frac{\partial}{\partial t} + \frac{\partial}{\partial x_i}v_i + \frac{\partial}{\partial v_i}\beta\left(\left\langle u_i \right\rangle - v_i\right)\right\}\left\langle W \right\rangle = -\frac{\partial}{\partial v_i}\beta\left\langle u_i'' W \right\rangle \tag{2.202}$$

$$\left\{\frac{\partial}{\partial t} + \frac{\partial}{\partial x_i}v_i + \frac{\partial}{\partial v_i}\beta\left(u_i - v_i\right) + \frac{\partial}{\partial u_i}\left\langle F_i \right\rangle\right\}\left\langle P \right\rangle = -\frac{\partial}{\partial u_i}\left\langle F_i'' P \right\rangle \tag{2.203}$$

when suitably normalized $\langle W \rangle$ and $\langle P \rangle$ represent the probability density at time t that a particle has $(\boldsymbol{v}, \boldsymbol{x})$ and $(\boldsymbol{v}, \boldsymbol{x}, \boldsymbol{u})$, respectively. To solve these equations, closure relations for $\left\langle u_i'' W \right\rangle$ and $\left\langle F_i'' P \right\rangle$ are required. For simplicity, we will just deal with the case where $\beta_{ij} = \beta\delta_{ij}$.

2.5.2.2 Closure Approximation for a Nonreactive Gas–Particle Flows

2.5.2.2.1 Kinetic Model A range of strategies for closing the turbulent flux can be found in the literature. The methodologies underpinning these approaches can be divided into three distinct categories: (1) Furutsu–Novikov-based (EN) methods (Furutsu, 1963, Novikov, 1965, Derevich and Zaichik, 1990, Swailes and Darbyshire, 1997, Zaichik, 1997, Hyland et al., 1999a, Zaichik, 1999, Derevich, 2000, Zaichik et al., 2004), (2) Lagrangian history direct interaction (LHDI) methods (Reeks, 1992), and (3) Van Kampen (VK) operator representation methods (Pozorski and Minier, 1998, Pandya and Mashayek, 2001). These different approaches have been reviewed and analyzed recently by Bragg et al. (2012a). Recent work has suggested that the corresponding kinetic equations are essentially equivalent (Pandya and Mashayek, 2001). However, while the three closure expressions exhibit superficial similarities, Bragg et al. have shown that there are fundamental differences that have an important bearing on their validity in inhomogeneous turbulence. What all three

methods do have in common is that they represent the net force due to the turbulence $\langle \beta u' W \rangle$ by gradient diffusion contributions both in velocity and position and in body force (per unit mass) dependent on the statistical inhomogeneity of the turbulence, that is, it is zero in statistically stationary homogeneous turbulence. Thus, in general,

$$\langle f_i W \rangle = -\left(\frac{\partial}{\partial x_j} \langle W \rangle \lambda_{ji} + \frac{\partial}{\partial v_j} \langle W \rangle \mu_{ji} - \kappa_i \langle W \rangle \right) \tag{2.204}$$

where for convenience we have written f_i for $\beta u_i'$. Note that dispersion coefficients appear on the other side of the gradients in velocity and position than is normal. So, in this context, they are more appropriately the components of stress tensors $\boldsymbol{\lambda}$ and $\boldsymbol{\mu}$ (per unit particle mass) rather than diffusion coefficients. Reeks (1991) has shown that this form is a general requirement of random Galilean transformation invariance. Taking the forms for $\boldsymbol{\lambda}$ and $\boldsymbol{\mu}$ and $\boldsymbol{\kappa}$ given by the Furutsu–Novikov (FN) method,

$$\begin{aligned}
\lambda_{ji} &= \int_0^t \langle \mathcal{G}_{jk}(t|s) R_{ki}(\boldsymbol{x}^p(t|s), s; \boldsymbol{x}, t) \rangle ds \\
\mu_{ji} &= \int_0^t \langle \dot{\mathcal{G}}_{jk}(t|s) R_{ki}(\boldsymbol{x}^p(t|s), s; \boldsymbol{x}, t) \rangle ds \\
\kappa_i &= \int_0^t \left\langle \mathcal{G}_{jk}(t|s) \frac{\partial}{\partial x_j} R_{ki}\left(\boldsymbol{x}^p(t|s), s; \boldsymbol{x}, t\right) \right\rangle ds
\end{aligned} \tag{2.205}$$

$\boldsymbol{R}$ denotes an Eulerian two-point, two-time correlation tensor of the turbulent force field $\boldsymbol{f}$, that is,

$$R_{ki}(\boldsymbol{y}, s; \boldsymbol{x}, t) = \langle f_k(\boldsymbol{y}, s) f_k(\boldsymbol{x}, t) \rangle \tag{2.206}$$

where $\boldsymbol{x}^p(t|s)$ is the particle position evaluated at time s along all particle trajectories passing through $\boldsymbol{x}$ and v at time t, that is, in Equation 2.206 $\boldsymbol{y} = \boldsymbol{x}^p(t|s)$, with $\boldsymbol{x}^p(t|t) = \boldsymbol{x}$ and $\dot{\boldsymbol{x}}^p(t|t) = \boldsymbol{\upsilon}$. $\mathcal{G}_{jk}(t \mid s)$ are the components of a response tensor $\mathcal{G}$ given formally by the functional derivative

$$\mathcal{G}_{jk}(t|s) = \frac{\delta x_j^p(t|t)}{\delta f_k(\boldsymbol{x}^p(t|s), s) ds} \tag{2.207}$$

That is, they describe the effect of a perturbation in the field $\boldsymbol{f}(\boldsymbol{x}, s)$ applied at the particle position $\boldsymbol{x}^p(t|s)$ at time s upon the position of the particle at time t. This can be obtained by taking the functional derivative with respect to $\boldsymbol{\delta f}(\boldsymbol{x}, s)$ of the particle equation of motion Equation 2.197 so that

$$\ddot{\mathcal{G}}_{jk} + \beta \dot{\mathcal{G}}_{jk} - \beta \left(\frac{\partial \langle u_j \rangle}{\partial x_k} + \frac{\partial u_j''}{\partial x_k} \right) \mathcal{G}_{jk} = 0 \tag{2.208}$$

with the "initial" conditions $\mathcal{G}_{jk}(s|s) = 0$ and $\dot{\mathcal{G}}_{jk}(s|s) = \delta_{jk}$. In Equation 2.208, the spatial derivatives of $\boldsymbol{u}$ and $\boldsymbol{u}'$ are evaluated along the particle trajectories $\boldsymbol{x}^p(t|s)$. The closure term given by Equation 2.204 based on the forms for $\boldsymbol{\lambda}$ and $\boldsymbol{\mu}$ and $\boldsymbol{\kappa}$ given by Equation 2.205 is *exact* if the flow field $\boldsymbol{f}(\boldsymbol{x}, t)$ is Gaussian. We note that in the case of high-inertia particles, $\beta \to \infty$, the velocity gradient term in Equation 2.204 dominates and the kinetic equation reduces to the well-known Fokker–Planck equation. The forms $\boldsymbol{\lambda}$ and $\boldsymbol{\mu}$ and $\boldsymbol{\kappa}$ based on the LHDI approach (Reeks, 1992) are the same as those based on the Furutsu–Novikov method except that the Eulerian correlation R is replaced by $f_k(\boldsymbol{x}^p(s), s) f_i(\boldsymbol{x}, t)$. Thus, it is Lagrangian correlations that are involved rather than Eulerian correlations. In addition, the stochastic response functions $\mathcal{G}_{jk}$ are replaced by its deterministic components $\langle \mathcal{G}_{jk} \rangle$ so that the equation for $\langle \mathcal{G}_{jk} \rangle$ is given by

$$\langle \ddot{\mathcal{G}}_{jk} \rangle + \beta \langle \dot{\mathcal{G}}_{jk} \rangle - \beta \frac{\partial \langle u_j \rangle}{\partial x_k} \langle \mathcal{G}_{jk} \rangle = \delta(t - s) \delta_{jk} \tag{2.209}$$

In the LHDI case, then

$$\lambda_{ji} = \langle \Delta x_j(t) f_i(\boldsymbol{x},t) \rangle \quad \mu_{ji} = \langle \Delta v_j(t) f_i(\boldsymbol{x},t) \rangle \quad \kappa_i = \left\langle \Delta x_j(t) \frac{\partial f_i(\boldsymbol{x},t)}{\partial x_j} \right\rangle \tag{2.210}$$

where explicitly $\Delta x_j(t)$ and $\Delta v_j(t)$ are shorthand for $\Delta x_j(\boldsymbol{x}, \boldsymbol{v}, t|0)$ and $\Delta v_j(\boldsymbol{x}, \boldsymbol{v}, t|0)$ denoting changes in the particle position and velocity for a particle starting somewhere in the particle phase space at some initial time $s = 0$ and arriving at the point $\boldsymbol{x}$, $\boldsymbol{\upsilon}$ at time $s = t$. In terms of the deterministic response functions $\langle \mathcal{G}_{jk} \rangle$, these changes are given by

$$\begin{aligned} \Delta x_j(\boldsymbol{x},\boldsymbol{v},t\,|\,0) &= \int_0^t ds \langle G_{jk} \rangle (t|s) f_k(\boldsymbol{x}^p(t|s),s) \\ \Delta v_j(\boldsymbol{x},\boldsymbol{v},t\,|\,0) &= \int_0^t ds \langle \dot{\mathcal{G}}_{jk} \rangle (t|s) f_k(\boldsymbol{x}^p(t|s),s) \end{aligned} \tag{2.211}$$

It is claimed that the result is exact for a process in which the displacements $\Delta x_j(\boldsymbol{x}, \boldsymbol{v}, t|0)$, $\Delta v_j(\boldsymbol{x}, \boldsymbol{v}, t|0)$ form a Gaussian process. While both LHDI and FN closures would both claim to be exact for Gaussian processes, the Gaussian processes to which they refer are not the same: in the case of LHDI, the Gaussian process refers to the Lagrangian statistics of $\boldsymbol{f}(\boldsymbol{x}^p(s), s)$ along a particle trajectory in phase space, while in the FN case, it refers to the field $\boldsymbol{f}(\boldsymbol{x}, t)$. Given that one process is prescribed as Gaussian, it does not imply that the other is Gaussian. Bragg et al. (2012a) pointed out that in the previous FN formulations, the deterministic response functions $\langle \mathcal{G}_{jk} \rangle (t|s)$ were used in place of $\mathcal{G}_{jk}$ so that the contribution of the fluctuations in the spatial gradient of $\boldsymbol{f}(\boldsymbol{x}, t)$ was omitted. While using this nonrandom form for $\mathcal{G}$ formally closes the equation for $\langle f_i W \rangle$, Bragg et al. (2012b) have shown that the inclusion of this random term ensures the fully mixed criterion for a passive scalar (particle Stokes number $St \to 0$),* that is, the absence of spurious drift. We need to refer to this feature in more detail later on (see Section 2.5.4.1.1). There is good reason, however, to use $\langle \mathcal{G}_{ji} \rangle$ instead of $\mathcal{G}_{ji}$ other than for practicality. Calculations of the value of the dispersion coefficients by Bragg et al. (2012a) in a fully developed KS of a turbulent boundary using both $\langle \mathcal{G}_{ji} \rangle$ and $\mathcal{G}_{ji}$ show little difference for $St = 0.3$, negligible difference at $St = 0.8$, and an imperceptible difference at $St = 3$. Using the deterministic response $\langle \mathcal{G}_{ji} \rangle$ shows a resemblance between the FN and LHDI approaches that is reminiscent of Corrsin's independence hypothesis (Corrsin, 1974) that gives an approximate relationship between Lagrangian and Eulerian timescales. So, the Lagrangian correlation is given as

$$\begin{aligned} \left\langle f_j(\boldsymbol{x},\boldsymbol{v},t\,|\,t') f_i\big(\boldsymbol{x},t\big) \right\rangle &\simeq \int R_{ji}(\boldsymbol{x}',t';\boldsymbol{x},t) \left\langle \delta(\boldsymbol{x}' - \boldsymbol{x}^p(t\,|\,t')) \right\rangle d^3\boldsymbol{x}' \\ &= \int d^3\boldsymbol{x}' R_{ki}(\boldsymbol{x}',t';\boldsymbol{x},t) G(\boldsymbol{x}' - \boldsymbol{x}, t - t') \end{aligned} \tag{2.212}$$

where $G(\boldsymbol{x}' - \boldsymbol{x}, t - t')$ is Green's function solution for an instantaneous point source $\delta(\boldsymbol{x}' - \boldsymbol{x})\delta(t' - t)$. This relationship arises naturally through the comparison between between LHDI and FN approaches without the necessity of invoking Corrsin's hypothesis.

Finally, we mention briefly the operator representation of VK that was used by Pozorski and Minier (1998) to obtain a pdf–kinetic equation. This third form of the kinetic equation is formally consistent with the fully mixed condition but fails to account for a nonzero scalar flux contribution associated with nonuniform scalar distributions in inhomogeneous, incompressible flows. Furthermore, this VK closure is based on an expansion in terms of a small parameter reflecting the magnitude of turbulence intensity relative to a rate scale for the decorrelation of turbulent flow velocities (weak turbulence approximation). Correlations are based on mean trajectories, that is, due to the mean flow, ignoring the influence of the turbulence, and while this affords a significant simplification to the closure problem, removing conditional averages within the dispersion tensors makes the validity of such an approximation in strongly inhomogeneous flows

* For Stokes number St, we mean the ratio of β^{-1}/τ_f where τ_f is the typical timescale of the turbulence encountered by a particle.

highly questionable. In addition, as Bragg et al. (2012a) pointed out, even for the simpler case of dispersion in isotropic turbulence, there seems to be a serious issue with the VK formulation. The VK diffusion coefficients for fluid point dispersion in isotropic turbulence suggest that the dispersion rate should be proportional to the Eulerian integral timescale rather than the Lagrangian integral timescale. This is clearly incorrect and arises precisely because the VK dispersion tensors contain correlations of the fluid velocity field evaluated along mean trajectories. Therefore, the question of the validity of the VK closure relates not only to inhomogeneous flows but also to homogeneous, isotropic flows. This is not as we will see the case with FN and LHDI formulations.

2.5.2.2.2 GLM SDM (Simonin et al., 1993) derived an equation of motion for the fluid velocity along a particle trajectory by starting from the Langevin equation that Pope (Haworth and Pope, 1986) has used as the analogue of the Navier–Stokes equation for fluid point motion. Thus, along a fluid point trajectory,

$$\frac{du_i}{dt} = -\alpha_{ij}(\boldsymbol{x})u_j'' + f_i(\boldsymbol{x}) + f_i''(t) \tag{2.213}$$

where

$f_i(\boldsymbol{x})$ is the net viscous and pressure force per unit mass of fluid
$f_i''(t)$ is a white noise function of time.

Both SDM and Pope consider the equation of motion in differential form because the white noise is assumed nondifferentiable. For convenience, we have assumed that the white noise, like all turbulence-related functions, is differentiable: it has white noise properties simply because it has a timescale much shorter than the timescale over which $\boldsymbol{u}(t)$ varies along a fluid point trajectory $O(\alpha^{-1})$. For future reference, we note that

$$f_i(\boldsymbol{x}) = \frac{D_f \langle u_i \rangle}{Dt} + \frac{\partial \langle u_j'' u_i'' \rangle}{\partial x_j} \tag{2.214}$$

where

$$\frac{D_f}{Dt} = \frac{\partial}{\partial t} + \langle u_j \rangle \frac{\partial}{\partial x_j}. \tag{2.215}$$

SDM use this equation to generate an equation of motion for the fluid velocity along a particle trajectory. That is, if d_p/dt is the time derivative of the fluid velocity along a particle trajectory and similarly d_f/dt along a fluid point trajectory, then we have

$$\begin{aligned}
\frac{d_p u_i}{dt} &= \left(\frac{\partial}{\partial t} + v_j \frac{\partial}{\partial x_j} \right) u_i(\boldsymbol{x},t) \\
&= (v_j - u_j)\frac{\partial u_i(\boldsymbol{x},t)}{\partial x_j} + \frac{d_f u_i}{dt} \\
&= (\boldsymbol{v}_j - u_j)\frac{\partial u_i(\boldsymbol{x},t)}{\partial x_j} \\
&= -\alpha_{ij}u_j'' + f_i(\boldsymbol{x}) + f_i''(t)
\end{aligned} \tag{2.216}$$

SDM consider only the contribution from the gradient of the mean fluid velocity in this equation of motion for the fluid velocity along a particle trajectory. That is, they consider the equation

$$\frac{d_p u_i}{dt} = (v_j - u_j)\frac{\partial \langle u_i(\boldsymbol{x},t) \rangle}{\partial x_j} - \alpha_{ij}u_j'' + f_i(\boldsymbol{x}) + f_i''(t) \tag{2.217}$$

In effect, this is equivalent to assuming that the contribution of the fluctuating fluid velocity gradient is absorbed into the white noise function $f_i''(t)$. In the case of the white noise function, the equation for $\langle P\rangle$ can be closed exactly, namely,*

$$\begin{aligned}\left\langle F_i''(\boldsymbol{x},t)P(\boldsymbol{v},\boldsymbol{u},\boldsymbol{x},t)\right\rangle &= \left\langle f_i''(t)P(\boldsymbol{v},\boldsymbol{u},\boldsymbol{x},t)\right\rangle \\ &= -\int_0^\infty \left\langle f_i''(0)f_j''(s)\right\rangle ds\frac{\partial\langle P\rangle}{\partial \boldsymbol{u}_j}\end{aligned} \tag{2.218}$$

Then from Equation 2.203, the equation for $\langle P\rangle$ used by SDM is

$$\begin{aligned}&\frac{\partial\langle P\rangle}{\partial t}+\frac{\partial}{\partial x_i}v_i\langle P\rangle+\frac{\partial}{\partial v_i}\beta\left(u_j-v_j\right)\langle P\rangle+\frac{\partial}{\partial u_i}\left[-\alpha_{ij}u_j''+f_i(\boldsymbol{x})+(v_j-u_j)\frac{\partial\langle u_i\rangle}{\partial x_j}\right]\langle P\rangle \\ &=\int_0^\infty \left\langle f_i''(0)f_j''(s)\right\rangle ds\frac{\partial^2\langle P\rangle}{\partial u_i u_j}\end{aligned} \tag{2.219}$$

which are spatially independent but varying in time.

2.5.3 Analytic Solutions in Simple Flows

In cases where the turbulence is homogeneous and stationary and the mean carrier flow is a linear flow field, the pdf equations for both KM and GLM have analytic solutions. Moreover, when the fluctuating aerodynamic force is a Gaussian random force, both pdf approaches, given the same form for the carrier flow correlation along a particle trajectory, will give identical results (Reeks, 2005). Furthermore, these solutions can be used as a basis for dealing with more complex flow fields (e.g., in constructing appropriate constitutive relations), can give some insights into the basic diffusion process, and can be used as test cases to check out numerical methods that are appropriate in more general cases. In this section, we will present some results for dispersion of point sources in mean flows that are (1) uniform, (2) simple shear, and (3) rotational. The results are taken from Hyland et al. (1999b), Swailes and Darbyshire (1997), and Reeks (2005). As a preliminary, we note as in the work by Swailes and Darbyshire (1997) that if for convenience we introduce the phase space variable $\wp = (\boldsymbol{x}, \boldsymbol{v})$, then the solution of the pdf equation for an instantaneous point source is a Gaussian $G(\wp, t)$ given by

$$G(\wp,t)=(2\pi)^{-n}\det\left\{\underline{\Theta}\right\}^{-\frac{1}{2}}\exp\left\{-\frac{1}{2}(\wp-\boldsymbol{m})\cdot\underline{\Theta}^{-1}(\wp-\boldsymbol{m})\right\} \tag{2.220}$$

where $\underline{\Theta}$ is the matrix of ensemble covariances of $\wp$ as a function of time t and $\boldsymbol{m}=(\hat{\boldsymbol{x}},\hat{\boldsymbol{v}})$ where $\hat{x}$ and $\hat{\boldsymbol{v}}$ are the solutions of $\boldsymbol{x}(t)$ and $\boldsymbol{v}(t)$, respectively, without the turbulence starting from some initial values $\boldsymbol{x}^0$ and $\boldsymbol{v}^0$ at time zero (the point of release) and $\det\underline{\Theta}(0) = 0$. The solution for the particle spatial concentration at $\boldsymbol{x}^*$ in a frame of reference moving with velocity $\hat{\boldsymbol{v}}(t)$ whose origin coincides with the point of release $\boldsymbol{x}^0$ at time zero satisfies the following simple diffusion equation:

$$\frac{\partial\langle\rho\rangle}{\partial t}=\frac{\partial}{\partial x_i^*}D_{ij}(t)\frac{\partial}{\partial x_j^*}\langle\rho\rangle+\delta(\boldsymbol{x}^*)\delta(t) \tag{2.221}$$

where the diffusion coefficients $D_{ij}(t)$ are the particle ensemble covariances $\langle x_i^*(t)v_j^*(t)\rangle$. The solution is a Gaussian in $\boldsymbol{x}^*$ of the general form

$$G(\boldsymbol{x}^*,t)=(2\pi)^{-3/2}\det\left(\langle\boldsymbol{x}^*\,\boldsymbol{x}^*\rangle\right)^{-1/2}\times\exp\left(-\frac{1}{2}\boldsymbol{x}^*\langle\boldsymbol{x}^*\,\boldsymbol{x}^*\rangle^{-1}\boldsymbol{x}^*\right) \tag{2.222}$$

* Note that the closure is also exact if $f''(t)$ is Gaussian nonwhite but will include gradients of $\langle P\rangle$ in $\boldsymbol{x}$ and $\boldsymbol{v}$ as well.

That is, in the fixed frame of reference, the contours of constant concentration will be concentric ellipses (in 2D) centered at $\hat{\boldsymbol{x}}(t)$. For the mean density-weighted particle velocity, we have

$$\bar{\boldsymbol{v}} = \hat{\boldsymbol{v}} + \langle \boldsymbol{v}^* \boldsymbol{x}^* \rangle \langle \boldsymbol{x}^* \boldsymbol{x}^* \rangle^{-1} \boldsymbol{x}^* \tag{2.223}$$

that is, the mean particle flow field is linear in x, and for the density-weighted particle velocity covariances, we have

$$\overline{\boldsymbol{v}'\boldsymbol{v}'} = \langle \boldsymbol{v}^* \boldsymbol{v}^* \rangle - < \boldsymbol{v}^* \boldsymbol{x}^* \rangle \langle \boldsymbol{x}^* \boldsymbol{x}^* \rangle^{-1} \langle \boldsymbol{x}^* \boldsymbol{x}^* \rangle \tag{2.224}$$

which are spatially independent but varying in time.

2.5.3.1 Uniform Flows

The features of dispersion in this flow have been extensively simulated and measured, particularly the particle diffusion coefficient and particle velocity covariances (see Stock, 1996). Forms for the long-time particle diffusion coefficient $D_p(\infty)$ have been much quoted in isotropic turbulence both with and without gravity (e.g., Reeks, 1977). The pdf equation reproduces the right result, namely, for Stokes drag

$$D_p(\infty) = \frac{1}{3} \int_0^\infty \langle \boldsymbol{u}(0) \boldsymbol{u}(s) ds \tag{2.225}$$

where we have used $\boldsymbol{u}(s)$ as shorthand for $\boldsymbol{u}(\boldsymbol{x}|s)$, that is, the carrier flow velocity along a particle trajectory measured at time s with $\boldsymbol{u}(\boldsymbol{x}|0) = \boldsymbol{u}(0)$. The absence of $\boldsymbol{x}$ in Equation 2.225 is meant to imply an independence on the initial position at $s = 0$. It is a result we will deduce later from the momentum equation, which shows that the particle response time (inertia) dependence is reflected only in the way this quantity determines the timescale of $\boldsymbol{u}(s)$ along a particle trajectory: whether the carrier flow timescales along a particle trajectory are bigger or smaller than those along a fluid element trajectory. In fact, particles with more inertia appear to have a long-time diffusion coefficient that is greater than that for a fluid element or passive tracer. This is shown in Figure 2.26 based on the results obtained by Squires and Eaton (1991) for particle diffusion in a direct numerical simulation (DNS) of statistically stationary isotropic homogeneous turbulence.

The vertical axis is the ratio of the particle diffusion coefficient compared to that of the fluid or passive scalar. The calculations were done for a range of particle Stokes numbers St from 0.06 to 0.35 where Stokes number is the ratio of the particle response time τ_p to integral timescale of the flow T_f. You can see that for all

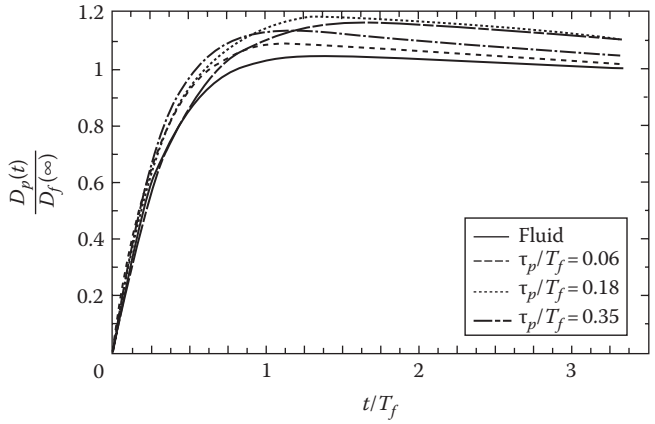

Figure 2.26

Ratio of particle diffusion coefficient to long-term fluid element diffusion coefficient in homogeneous isotropic turbulence: direct numerical simulation and experimental measurements, the influence of inertia (Stokes number St) τ_p/T_f, and settling v_g/u'. (Taken from Squires, K.D. and Eaton, J.K., *J. Fluid Mech.*, 226, 135, 1991.)

the Stokes numbers, the long-time values of the diffusion coefficient are greater than that of the carrier flow, the greatest value being for St =.35 but with little difference between this value and the value for St = 1.09. The formula in Equation 2.225 is also appropriate for particles settling under gravity or in an electric field as with the measurements of Wells and Stock (1983). The timescales of fluid motion along a particle trajectory depend upon the time it takes for a particle to move from one eddy to another in the flow field. The faster the particle moves, the shorter the timescale of the fluid motion it encounters, assuming that the eddy lifetime is much longer than the transit time of the particle. If v_g is the settling velocity and l_e the spatial length scale, then $l_e/v_g \ll \tau_e$, where τ_e is the eddy decay time. Since $\tau_e \sim l_e/u'$, this implies $u'/v_g \ll 1$ in which case

$$D_p(\infty) = \int_0^\infty R_E(0, \boldsymbol{v}_g t)\, dt \tag{2.226}$$

where $R_E(t, \boldsymbol{x})$ is the carrier flow spatial velocity correlation (in a frame moving with the settling velocity $\boldsymbol{v}_g$ with a separation $\boldsymbol{x}$ measured in the direction of gravity). ϵ in this case refers to the diffusion coefficient for diffusion in the direction of gravity. Reeks (1991) shows how the phase space density changes with time as it moves toward its long-term form, in which case the velocity distribution is a Maxwell–Boltzmann distribution with a mean square velocity given by

$$\langle v^2(\infty)\rangle = \beta \int_0^\infty e^{-\beta s} \langle \boldsymbol{u}(0) \cdot \boldsymbol{u}(s)\rangle\, ds \tag{2.227}$$

where $v = |\boldsymbol{v}|$.

2.5.3.2 Simple Shear and Rotational Flows for KM and GLM

While the KM and GLM approaches are compatible with one another for a Gaussian process, there is an important difference between the two approaches, namely, the GLM approach provides a model for particle transport and at the same time a model for the turbulence encountered by the particle, which encompasses in the limit of very small particles, the turbulence of the carrier flow itself. In the KM approach, this information must be prescribed independently, either on the basis of experiment or from a separate model like the GLM.

2.5.3.2.1 Analytic Solutions Based on KM Using the general result in Equations 2.204 and 2.206, Swailes et al. (1995) have evaluated the particle spatial concentration and mean velocity fields in a simple shear and rotational mean carrier flow fields and compared them with results obtained from a random flight simulation in which the turbulence is Gaussian with an exponential decaying autocorrelation. Results were obtained for both Stokes drag and a combination of drag and lift appropriate for low particle Reynolds numbers. In all these cases, the equation of motion of the particle is given by

$$x = \dot{v} = \underline{\beta} \cdot (\boldsymbol{S} \cdot \boldsymbol{x} - \boldsymbol{v} + \boldsymbol{u}''(t))$$

where **S** is the strain rate tensor. Some of their results are reproduced in Figure 2.27 for the case of Stokes drag with the particle response times and shear rates normalized on the fluid integral timescale along a particle trajectory. For the simple shear and rotating flow, we have, respectively,

$$\mathbf{S} = \begin{bmatrix} 0 & S \\ 0 & 0 \end{bmatrix} \quad \mathbf{S} = \begin{pmatrix} 0 & \omega \\ -\omega & 0 \end{pmatrix}$$

For the sake of brevity, we show in Figure 2.27 only analytic solutions for the form of the underlying mean particle flow for both these types of dispersion at some time after releasing the particles from the origin. Normalizing timescales on the integral timescale of the turbulence, the cases shown in Figure 2.27 correspond to t = 1, β = 1, S = 1, and ω = 1. We will consider the results for particle concentration in the simple shear when we consider solutions based on the GLM in the next section for which KM using the same carrier flow autocorrelation along particle trajectories would give identical results. We note that for the simple shear flow the concentration contours are ellipses concentric about the origin of the shear whose principal axes rotate in time as the concentration decays until they align with the carrier mean shear. In contrast to

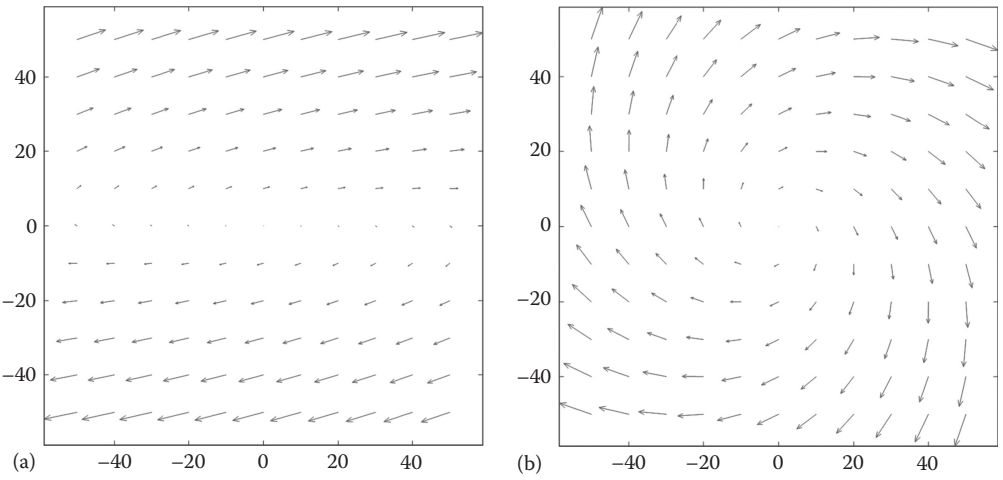

Figure 2.27

Analytic solutions for the mean particle velocity field for an instantaneous point source at the center of a simple shear flow and a rotating flow: β = 1, S = 1, and ω = 1, t = 1. (a) Simple shear flow, (b) rotating flow. (From Swailes, D.C. et al., Analysis of particle dispersion using a pdf equation: Results for simple shear and rotating flows, in *Gas-Particle Flows ASME Summer Meeting*, Hilton Head Island, SC, ASME FED-Vol. 228, August 1995, pp. 257–263.)

the rotating flow, the concentration contours, like those in uniform flow, are all circles centered about the origin. The rate of diffusion outward is greater than that in uniform flow because the mean spatial variation of the flow enhances the diffusion (the spreading of the particles).

2.5.3.2.2 GLM for a Simple Shear In this regard, a more detailed analysis has been performed for particle dispersion in simple shear based on the GLM approach that demonstrates the compatibility of the two approaches while at the same time highlighting the extra information that the GLM approach provides relating to the underlying carrier flow encountered by the particle. In this simple case, Pope's analogue equation is

$$\frac{du_i}{dt} = \alpha\left(S_{ij}x_j - u_i\right) + f_i''(t)$$
$$S_{ij} = S\delta_{i1}\delta_{j2} \tag{2.228}$$

where α in this simple case is assumed constant.

Using a simple model for the Reynolds shear stresses based on Pope's GLM model (Haworth and Pope, 1986), exact solutions have been obtained for the particle kinetic stresses (velocity covariances) and the particle diffusion coefficients associated with an instantaneous point source located at the center of the shear (Reeks, 2005). The results for the particle kinetic stresses are shown in Figure 2.28a as a function of the particle response time suitably normalized on the timescale of the turbulence that is homogeneous and stationary (effectively the particle Stokes number St). x_1 is the streamwise direction and x_2 cross-streamwise direction. What is plotted is the difference between the streamwise and cross-streamwise components for the normal stresses normalized on $S^2\langle u'^2\rangle$, where S is the strain rate normalized on the timescale of the turbulence. What is noticeable is that the difference is positive and increases with the Stokes number. As the particles cross the shear, they extract turbulent energy from the mean flow—it is the work done by shear stresses in the streamwise direction that appears as an increase of turbulent kinetic energy in the streamwise direction. The second graph in Figure 2.28b is even more revealing. A calculation is made of the diffusion coefficients ϵ_{ij}^S that relate the diffusion current j_i to the gradients of the concentration gradient, that is,

$$j_i = \langle u_i\rangle\langle\rho\rangle - \epsilon_{ij}^S\frac{\partial}{\partial x_j}\langle\rho\rangle \tag{2.229}$$

Here, we see the particle current composed of a convective term proportional to the local mean carrier flow and a long-term diffusive current. What is most interesting is the particle diffusion coefficient in the

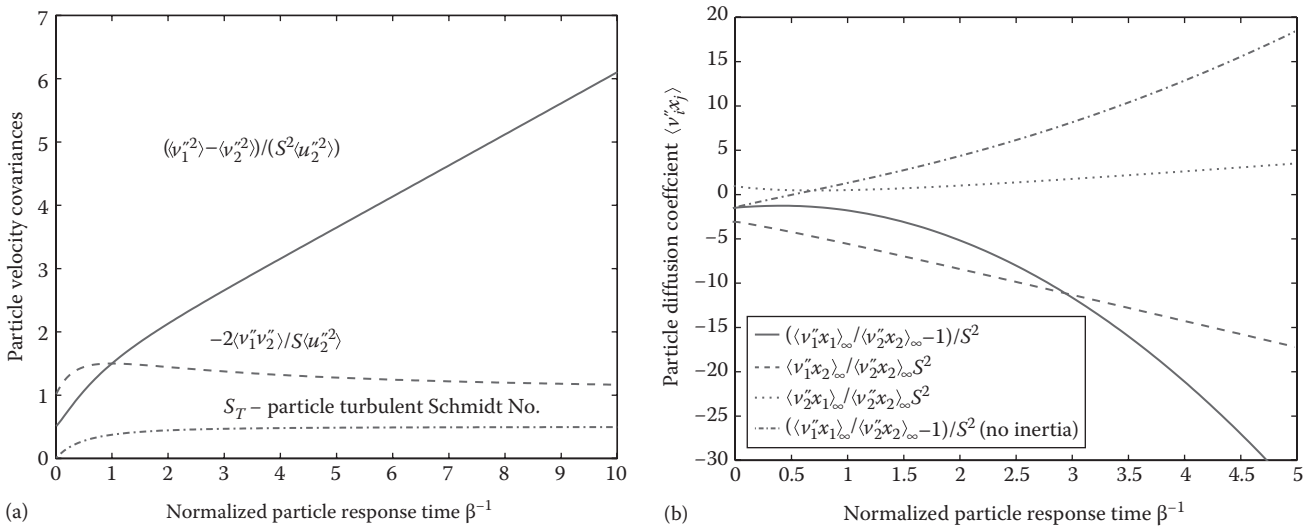

Figure 2.28

Dispersion of particles in a simple shear based on Pope's generalized Langevin method versus Stokes number β^{-1}. S is the strain rate normalized on turbulence integral timescale versus Stokes number β^{-1}. In the graphs $\epsilon_{ij}^S = \langle v_i'' x_j\rangle$. (a) Particle covariance (kinetic stresses) (b) Long-time particle dispersion coefficients ϵ.

streamwise direction compared to that in the cross-streamwise direction. We note that for all Stokes numbers it is *−ve*, which includes that for a passive scalar! This does not imply, however, that contrary to the second law a blob of particles will always contract rather than expand. These diffusion coefficients make a small contribution to the way a blob will diffuse. Particles will diffuse in the streamwise direction because as they move upward or downward, they will experience larger positive or negative velocities according to how far they are away from the origin. And that displacement is randomly positive or negative because it is determined by dispersion in the cross-streamwise direction. So, it is this process that makes the blob stretch in the streamwise direction. The *−ve* diffusion coefficients reduce this process but never reverse it.

Figure 2.29 shows a picture of the concentration contours and the mean particle velocities at a time on an integral timescale after they were released from the center of the shear where the mean velocities are almost

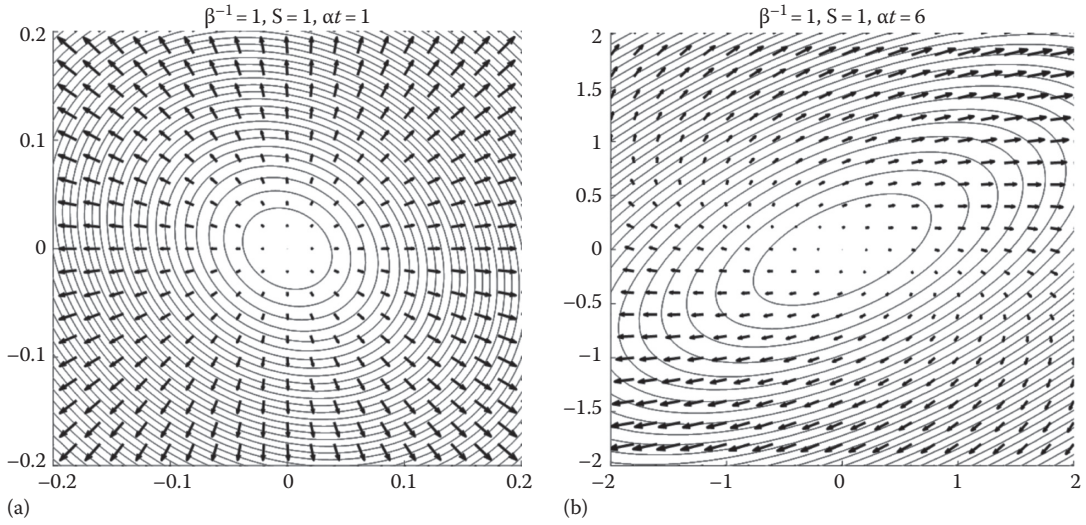

Figure 2.29

Concentration contours and particle mean velocity for St = 1 and normalized strain rate S =1, at (a) t = 1 and (b) t = 6, where t is in units of the integral timescale. Concentration contours represent a constant fraction f of the concentration at the center of the shear, $f = 1 - 0.02n$, $n = 1, 2, \ldots, k$.

radial and later where they have rotated to align with the velocities of the shear during which time the contours have expanded. As noted earlier, the mean concentration contours at any given time are expanding ellipses possessing the same principal axes centered at the origin, which rotate first anticlockwise and then clockwise until the major principal axis aligns with the streamwise direction. The rotational component of the particle mean velocity follows a similar behavior though the changeover from anticlockwise to clockwise is much more gradual. Although one of the principal strain rates of the mean particle velocity field becomes compressional during the approach to equilibrium, the divergence of the mean particle velocity field is always positive, ensuring the mean particle concentration decreases everywhere and for all time consistent with the second law of thermodynamics. See Figure 2.29 for the corresponding concentration and mean velocity vectors during the dispersion.

The possibility of this occurring has been noted earlier for passive scalar diffusion.

2.5.4 Continuum Equations and Constitutive Relations for the Dispersed Phase (without Collisions)

Continuum equations refer to the equations that describe the net transport of mass, momentum, and kinetic stress of the particle phase and can be generated from the pdf equations for $\langle P\rangle$ or $\langle W\rangle$ by multiplying them by an appropriate power of $mv_i'^p v_j'^q v_k'^r \ldots$ and then integrating over all $\boldsymbol{u}$ and $\boldsymbol{v}$ (for $\langle P\rangle$) and over all $\boldsymbol{v}$ (for $\langle W\rangle$), where m is the mass of a particle (assuming that all the particles for the sake of simplicity have the same mass m) and $\boldsymbol{v}'$ is the fluctuating value of $\boldsymbol{v}$ relative to its mean density-weighted value $\bar{\boldsymbol{v}}$. Thus, the following equations are derived:

$$\text{Mass } (\langle\rho\rangle) = m\int \langle P\rangle(\boldsymbol{v},\boldsymbol{u},\boldsymbol{x})d\boldsymbol{v}d\boldsymbol{u} \tag{2.230}$$

$$\text{Momentum } \langle\rho\rangle\bar{v}_i = m\int \langle P\rangle(\boldsymbol{v},\boldsymbol{u},\boldsymbol{x})v_i d\boldsymbol{v}d\boldsymbol{u} \tag{2.231}$$

$$\text{Kinetic stress } \langle\rho\rangle\overline{v_i v_j} = m\int \langle P\rangle(\boldsymbol{v},\boldsymbol{u},\boldsymbol{x})v_i' v_j' d\boldsymbol{v}d\boldsymbol{u} \tag{2.232}$$

So, the quantities $\bar{v}_j$ and $\overline{v_i'v_j'}$ are the particle mass density-weighted mean and covariance* of the particle velocities at $(\boldsymbol{x}, t)$. The continuum equations are from Equation 2.202:

$$\frac{\partial\langle\rho\rangle}{\partial t} + \frac{\partial}{\partial x_i}\langle\rho\rangle\bar{v}_i = 0 \tag{2.233}$$

$$\langle\rho\rangle\frac{D_p}{Dt}\bar{v}_i = -\frac{\partial}{\partial x_j}\langle\rho\rangle\overline{v_i'v_j'} + \langle\rho\rangle\beta(\langle u_i\rangle - \bar{v}_i) + \beta\langle\rho\rangle\overline{u_i''} \tag{2.234}$$

$$\begin{aligned}\langle\rho\rangle\frac{D_p}{Dt}\overline{v_i'v_j'} = &-\frac{\partial}{\partial x_k}\langle\rho_i\rangle + \langle\rho\rangle\overline{v_j'v_k'}\frac{\partial\bar{v}_i}{\partial x_k} + \langle\rho\rangle\overline{v_i'v_k'}\frac{\partial\bar{v}_j}{\partial x_k}\\ &-\langle\rho\rangle\beta\left(2\overline{v_i'v_j'} - \left\{\overline{v_i'u_j'} + \overline{v_j'u_i'}\right\}\right)\end{aligned} \tag{2.235}$$

where D_p/Dt is the particle substantial derivative, that is,

$$\frac{D_p}{Dt} = \frac{\partial}{\partial t} + \bar{v}_j\frac{\partial}{\partial x_j}$$

* Alternatively the particle kinematic kinetic stresses.

So, we require closed expressions for

1. $\overline{\boldsymbol{u}'}$, the average fluid velocity relative to $\langle \boldsymbol{u} \rangle$ encountered by a particle
2. $\overline{u_k' v_j'}$, the carrier–particle velocity covariances
3. $\langle \rho v_k' v_j' v_i' \rangle$, the turbulent kinetic energy flux

Note the distinction here between variables u_i'' and u_i'. Here and throughout, we will use superscripts $''$ and $'$ to refer to random variables relative to $\langle \boldsymbol{u} \rangle$ and particle density-weighted averages, respectively, for example, $\boldsymbol{v}'' = \boldsymbol{v} - \langle \boldsymbol{u} \rangle; \boldsymbol{v}' = \boldsymbol{v} - \bar{\boldsymbol{v}}$.

2.5.4.1 Constitutive Relations Based on Kinetic Model

Using the kinetic Equation 2.202 with Equation 2.204, together with the simpler LHDI forms for the phase space dispersion coefficients given in Equation 2.210 and suitably integrating Equation 2.202 over all particle velocities to form transport equations for the particle phase momentum and particle kinetic stresses and then comparing the resulting equations with Equations 2.234 and 2.235, we obtain the following identities:

$$\overline{u_i''}\langle \rho \rangle = -\frac{\partial}{\partial x_j}\left(\Delta x_j(\boldsymbol{x}, t \,|\, 0) \langle u_i''(\boldsymbol{x}, t) \rangle \langle \rho \rangle \right) - \left\langle \Delta x_j(\boldsymbol{x}, t \,|\, 0) \frac{\partial u_i''}{\partial x_j} \right\rangle \langle \rho \rangle \tag{2.236}$$

$$\overline{u_i' v_j'} = \langle \Delta v_j(\boldsymbol{x}, t \,|\, 0) u_i''(\boldsymbol{x}, t) \rangle - \frac{\partial \overline{v_j}}{\partial x_m} \langle \Delta x_m(\boldsymbol{x}, t \,|\, 0) u_i''(\boldsymbol{x}, t) \rangle \tag{2.237}$$

where

the displacements $\Delta \boldsymbol{v}$ and $\Delta \boldsymbol{x}$ refer to all particle trajectories arriving at $\boldsymbol{x}$ at time t irrespective of their velocity

$\langle u_i''(\boldsymbol{x}, t) \Delta v_j(\boldsymbol{x}, t \,|\, 0) \rangle$ is the fluid–particle velocity diffusion coefficient

$\langle u_i''(\boldsymbol{x}, t) \Delta x_j(\boldsymbol{x}, t \,|\, 0) \rangle$ is the fluid–particle spatial diffusion coefficient

It is noticeable from Equation 2.236 that the turbulent interfacial momentum transfer term $\beta \overline{\boldsymbol{u}''} \langle \rho \rangle$ will contribute an interfacial surface force to the particle phase momentum equation that combines with the particle Reynolds stresses to give a pressure tensor $\boldsymbol{p}$ whose components are expressible in terms of an equation of state, namely, at $\boldsymbol{x}$

$$\frac{p_{ij}}{\langle \rho \rangle} = \langle v_i' v_j' \rangle + \beta \langle \Delta x_j(\boldsymbol{x}, t \,|\, 0) u_i''(\boldsymbol{x}, t) \rangle \tag{2.238}$$

where $\boldsymbol{v}'$ is the particle velocity fluctuation relative to the mean velocity $\bar{\boldsymbol{v}}$ at ($\boldsymbol{x}$, t). Equation 2.238 in turn encapsulates a fundamental relationship between the components of $\boldsymbol{p}$ and a set of coefficients ϵ_{ij}:

$$\frac{p_{ij}}{\langle \rho \rangle} = \beta \epsilon_{ij}^{\dagger} \tag{2.239}$$

$$\epsilon_{ij} = \beta^{-1} \langle v_i' v_j' \rangle + \langle u_i''(\boldsymbol{x}, t) \rangle \Delta x_j(\boldsymbol{x}, t | 0) \tag{2.240}$$

where $\epsilon_{ij}^{\dagger}$ is the transpose of ϵ_{ij}. Expressing the RHS in the way we have done earlier demonstrates a close relationship to the particle diffusion coefficients associated with particle dispersion in generic flows like those considered in Section 3. We note that it is these coefficients that are the analogue of temperature, not the particle kinetic energy. These results have also been derived independently using the Clausius virial theorem of the classical kinetic theory (Reeks, 1991).

2.5.4.1.1 Particle Momentum Equation Interpreted as an Advection–Diffusion Equation It is clear from the momentum equation that when the inertial term $D\bar{v}_i/Dt$ is small compared to the other terms, the transport is described by a simple advection gradient diffusion equation with the components of the particle mass flux $\boldsymbol{j}$:

$$j_i = -\epsilon_{ij} \frac{\partial \langle \rho \rangle}{\partial x_j} + \boldsymbol{v}_D \tag{2.241}$$

in which the diffusion coefficients ϵ_{ij} are identical to those given in Equation 2.239 and the convection velocity is given by

$$\underline{v}_D = \langle \boldsymbol{u} \rangle + \boldsymbol{v}_d \tag{2.242}$$

$$\boldsymbol{v}_d = -\beta^{-1}\left\{\frac{\partial}{\partial \boldsymbol{x}} \cdot \overline{\mathbf{v}'\mathbf{v}'}\right\} - \left\langle \left(\frac{\partial}{\partial \boldsymbol{x}} \cdot \Delta \boldsymbol{x}(\boldsymbol{x}, t \,|\, 0)\right) \boldsymbol{u}''(\boldsymbol{x}, t) \right\rangle \tag{2.243}$$

The first term on the RHS of Equation 2.243 has been referred to as the turbophoretic velocity (Reeks, 1983); the additional contribution from the second term is entirely due to the structure of the flow. It should be zero for inertialess particles that follow the flow (Bragg et al., 2012a). According to this approach, gradient diffusion is always the case for particles that follow the flow: indeed, the set of diffusion coefficients ϵ_{ij} reduce to the local average

$$\epsilon_{ij} = \langle u_i''(\boldsymbol{x}, t) \Delta x_j(\boldsymbol{x}, t|0) \rangle \tag{2.244}$$

In the case of statistical stationary homogeneous turbulence, advection–diffusion applies to the case for inertial particles in the long term for dispersion in an unbounded flow when $\beta t \gg 1$ or when the particles are confined and the system approaches equilibrium, in which case $\partial \rho / \partial \boldsymbol{x} \to 0$. In this case, substituting the formulae $\left\langle v'_i v'_j \right\rangle = \beta \int_0^\infty e^{-\beta s} u_i''(0) u''(s) ds$ and $\Delta x_j(\boldsymbol{x}, t \,|\, 0|) = \int_0^\infty (1 - e^{-\beta s}) u_j''(s) ds$ into the formula for ϵ_{ij} in Equation 2.240, we would obtain the result in 2.225 for statistically stationary isotropic homogeneous turbulence.

It is very interesting to point out that similar arguments were used by Einstein (1905) to evaluate the diffusion coefficient of Brownian particles. Here, we have an almost identical particle equation of motion except that the driving force (due to the turbulence carrier flow) in our case is not limited to white noise as it is in the case of Brownian motion due to molecular bombardment of the suspended particles. What Einstein recognized was that the momentum equation (in his case the balance of the pressure gradient with the weight of the particles) implies a diffusion equation for the suspended particles as they approached their long-term equilibrium state and in particular as the gradient of the average particle concentration $\nabla \langle \rho \rangle \to 0$. So, instead of an isothermal system, what we have is a statistical stationary homogeneous isotropic turbulent flow and we consider an equilibrium state in which there is a balance between the pressure gradient and a body force acting on the particles, the obvious one being the weight of the particles. So in effect we are considering the weight of an elemental volume of particles balanced by the pressure gradient acting across it as Einstein did.

We note, however, that the coefficients ϵ_{ij} defined in general in Equation 2.240 are not the same as the diffusion coefficients ϵ_{ij}^S for particle dispersion in a simple linear shear flow referred to in Equation 2.229 except in the case of inertialess particles that follow the flow $\beta^{-1} = 0$. In general,

$$\epsilon_{ij}^S = \langle v_i'' x_j \rangle \tag{2.245}$$

The reason for the discrepancy between ϵ_{ij} and ϵ_{ij}^S for particles with inertia is that while the process is still diffusive (for particles released from the center of the shear), the inertial acceleration term $D\bar{v}_i/Dt$ in the particle momentum in Equation 2.234 also makes a finite contribution to ϵ_{ij}^S along with normal gradient diffusion term in the momentum equation from which ϵ_{ij} is derived.

2.5.4.1.2 Particle–Carrier Velocity Covariances Referring to the transport equation Equation 2.235 for the particle kinetic stresses (which includes the particles' turbulent kinetic energy), the particle-carrier flow velocity covariances are given in KM by

$$\overline{u'_i v'_j} = \langle u_i''(\boldsymbol{x}, t) \Delta v_j(\boldsymbol{x}, t|0) \rangle - \langle u_i''(\boldsymbol{x}, t) \Delta x_m(\boldsymbol{x}, t|0) \rangle \frac{\partial \overline{v_j}}{\partial x_m} \tag{2.246}$$

where the displacements $\Delta \boldsymbol{v}$ and $\Delta \boldsymbol{x}$ refer to all particle trajectories arriving at $\boldsymbol{x}$ at time t irrespective of their velocity. Substituting these expressions for the carrier flow–particle velocity covariances into the transport equation (2.235) for the particle kinetic stresses gives

$$\langle \rho \rangle \frac{D}{Dt} \overline{v'_m v'_n} = -\frac{\partial}{\partial x_i} \langle \rho v'_i v'_m v'_n \rangle - \langle \rho \rangle \left[\frac{\partial \bar{v}_n}{\partial x_l} p_{lm} + \frac{\partial \bar{v}_m}{\partial x_l} p_{ln} \right] + 2 \langle \rho \rangle \beta \left\{ \mu^S_{mn} - \overline{v'_m v'_n} \right\} \tag{2.247}$$

where μ^S_{mn} refers to the components of the symmetric part of $\mu = \langle \boldsymbol{u}''(\boldsymbol{x}, t) \Delta \boldsymbol{v}(\boldsymbol{x}, t|0) \rangle$.

So, we refer to the terms on the RHS of the aforementioned equation:

1. The first term is a third-order velocity moment of the particle pdf, which can be referred to as the turbulent kinetic stress flux, which for $m = n$ includes the turbulent kinetic energy flux and is a term that requires closure. In this case, one can use the methods developed in kinetic theory to approximate this term. In particular, applying the Chapman–Enskog (C–E) approximation gives the following relationship involving the gradients of the velocity covariance and the particle diffusion coefficients ϵ_{ij}, a result obtained by Swailes et al. (1998), among others:

$$\overline{v'_i v'_j v'_k} = -\epsilon_{li} \frac{\partial}{\partial x_l} \overline{v'_j v'_k} - \epsilon_{lj} \frac{\partial}{\partial x_l} \overline{v'_i v'_k} - \epsilon_{lk} \frac{\partial}{\partial x_l} \overline{v'_i v'_j} \tag{2.248}$$

Compare their result with the form used for third-order moment in single-phase flow by Daly and Harlow (1970). The answers to the questions how accurate it is and how important it is to take it into account are illustrated by the two graphs in Figure 2.30, giving a comparison with the results from tracking many particles in a channel flow and then averaging. Figure 2.30a shows the particle tracking result for the triple moment in the normal streamwise direction by comparing that obtained from the C–E approximation and those based on an approximation derived from a transport equation for the triple moments where fourth-order moments are closed, assuming a Gaussian distribution known as the quasi-normal approximation. The C–E approximation does

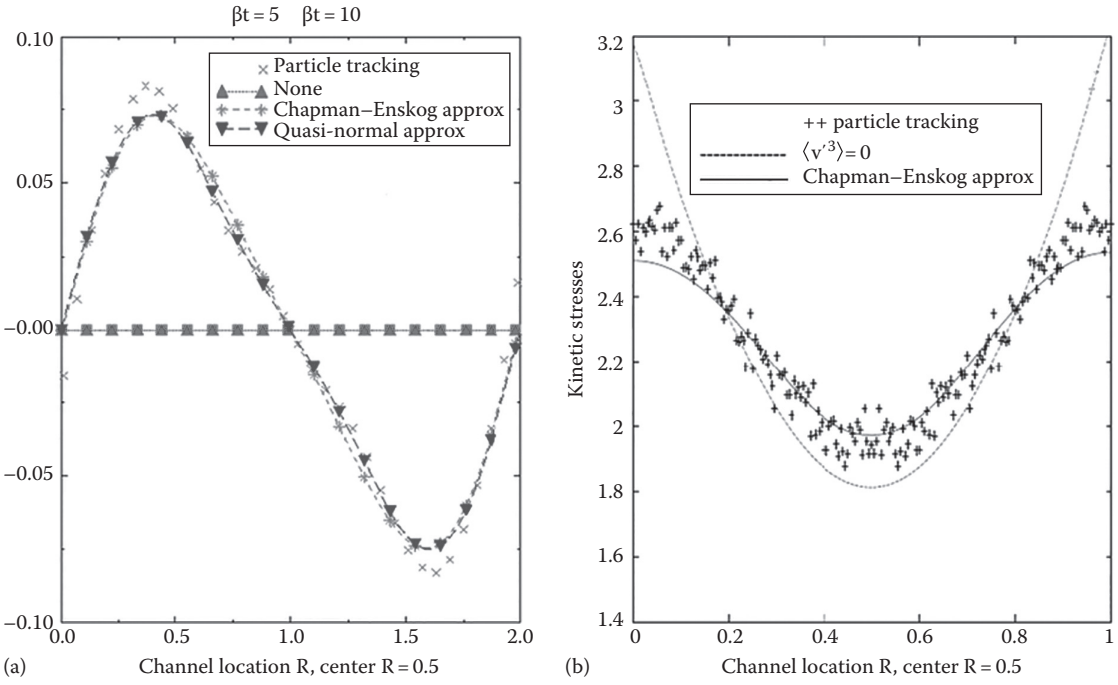

Figure 2.30

Simulation (particle tracking) and kinetic method predictions using Chapman–Enskog approximation in Equation 2.248 for turbulent pipe flow. (a) Particle triple correlation, (b) particle kinetic stresses.

well but underpredicts the maximum. The center of the channel is at R = 1 and the walls at R = 0. Figure 2.30b shows the contribution the triple correlation makes to the particle velocity covariance or kinetic stresses, thus clearly indicating the significant contribution they make near the walls.

2. The second term in brackets represents "viscous"* losses from the action of surface forces p (as defined in Equation 2.239) in changing the shape and size of an elemental volume of the dispersed flow as it moves through the mean shear gradients of that flow. So, this term acts as a source of production of turbulent kinetic energy for the suspended particles. We recall that in the case of particle dispersion in a simple shear flow, the particle rms velocity in the streamwise direction (in the direction of the straining flow) is greater than that in the cross-streamwise direction by an amount that is proportional to the strain rate (see Figure 2.28a).
3. The third and fourth terms are net loss and production terms arising from an internal volume dissipative force $-\beta \boldsymbol{v}'$ and a driving force $\beta \cdot \boldsymbol{u}''(\boldsymbol{x}, t)$, respectively. Here, $v' = |\boldsymbol{v}'|$. We note that at equilibrium in homogeneous turbulence

$$\overline{v'^2} = \langle \boldsymbol{u}''(\boldsymbol{x},t) \cdot \Delta \boldsymbol{v}(\boldsymbol{x},t|0) \rangle$$

with all other terms being zero. Using the appropriate form for $\Delta v_i(\mathbf{x}, t|0)$ gives the correct analytic form of Equation 2.227:

$$\overline{v'^2} = \beta \int_0^\infty e^{-\beta s} \langle u''(0) \cdot \boldsymbol{u}''(s) \rangle ds$$

where *vecu″*(*s*) is the fluctuating carrier flow velocity along a particle trajectory;

2.5.4.1.3 Form for Kinetic Stresses for $\beta^{-1} \ll 1$ The particle kinetic stresses depend explicitly on the shearing of the dispersed phase (the term in square brackets in Equation 2.247) and the shearing of the carrier flow (the terms involving $\langle \boldsymbol{u}_i''(\boldsymbol{x},t) \Delta \boldsymbol{v}_n(\boldsymbol{x},t\,|\,0) \rangle$ in Equation 2.247).

To illustrate this behavior still further, let us refer to $\langle \boldsymbol{u}''(\boldsymbol{x}, t) \Delta \boldsymbol{v}(\boldsymbol{x}, t|0) \rangle$ by $\underline{\zeta}$ composed of a part $\underline{\zeta}^{(0)}$ (as if the flow was uniform and independent of the shearing of the carrier flow) and a deviatoric part $\delta\underline{\zeta}$ that is linear in the local shearing of the carrier flow. Likewise, we divide the particle kinetic stress into similar components. Consider thus the case when β^{-1} is very small (almost fluid point motion). Only a balance of the terms of order β is important in the kinetic stress equation so that we have

$$-2\delta\overline{v_n' v_m'} + \{\delta\zeta_{mn} + \delta\zeta_{nm}\} - \epsilon_{mi} \frac{\partial \bar{v}_n}{\partial x_i} - \epsilon_{ni} \frac{\partial \bar{v}_m}{\partial x_i} = 2\overline{v_n' v_m'}^{(0)} - \{\zeta_{mn}^{(0)} + \zeta_{nm}^{(0)}\}$$

The terms on the LHS contain all the deviatoric terms and the terms on the RHS all the homogeneous terms. The whole equation must express the fact that in this limit, the particle velocity covariances are the same as the carrier flow covariances: this is consistent with the bracketed terms containing all the homogeneous forms and the deviatoric terms being both zero. The implication for the sum of the deviatoric terms being zero is that

$$\delta\overline{v_n' v_m'} = -\epsilon_{mi} \frac{\partial}{\partial x_i}(\bar{v}_n - \bar{u}_n) - \epsilon_{ni} \frac{\partial}{\partial x_i}(\bar{v}_m - \bar{u}_m) \quad \beta^{-1} \to 0 \tag{2.249}$$

That is, the particle deviatoric kinetic stresses in the limit of very small particles are linear in the relative shearing between the carrier and dispersed phases. For the case of very large particles, the contribution from the interfacial momentum transfer term to the deviatoric particle Reynolds stresses drops to zero with no explicit dependence on the shearing of the carrier flow: the contribution is entirely viscous.

* Equivalent to viscous losses; increases the temperature in a flowing gas.

2.5.4.2 Constitutive Relations Based on GLM

The closure expressions in this case are transport equations for $\overline{\boldsymbol{u}''}$ and $\overline{u_k'v_j'}$, which are derived from the GLM pdf equation for $\langle P\rangle$, that is, Equation 2.219. Multiplying Equation 2.219 by u_i and integrating over all $\boldsymbol{v}$ and $\boldsymbol{u}$, we have

$$\frac{\partial}{\partial t}\langle \rho u_i\rangle + \frac{\partial}{\partial x_j}\langle \rho v_j u_i\rangle = \left\{ f_i(\boldsymbol{x}) - \alpha_{ij}\overline{u_j''} + (\bar{v}_k - \bar{u}_k)\frac{\partial \langle u_j\rangle}{\partial x_k}\right\}\langle \rho\rangle$$

Recognizing that we can rewrite the LHS as

$$\frac{\partial}{\partial t}\langle \rho u_i\rangle + \frac{\partial}{\partial x_j}\langle \rho v_j u_i\rangle = \langle \rho\rangle \frac{D_p}{Dt}\langle u_i\rangle + \langle \rho\rangle \frac{D_p}{Dt}\overline{u_i''} + \frac{\partial}{\partial x_j}\overline{v_j'u_i'}\langle \rho\rangle \tag{2.250}$$

and that from Equation 2.215 to 2.201

$$\left(\frac{\partial}{\partial t} + \bar{u}_j\frac{\partial}{\partial x_j}\right)\langle u_i\rangle = \left(\frac{D_f}{Dt} + \overline{u_j''}\frac{\partial}{\partial x_j}\right)\langle u_i\rangle$$

and using the relationship given in Equation 2.214, we finally derive the following transport equation for $\overline{u_i''}$:

$$\langle \rho\rangle \frac{D_p}{Dt}\overline{u_i''} = -\frac{\partial}{\partial x_j}\overline{v_j'u_i'}\langle \rho\rangle + \langle \rho\rangle \frac{\partial}{\partial x_j}\left\langle u_j''u_i''\right\rangle - \left\{\frac{\partial \langle u_i\rangle}{\partial x_j} + \alpha_{ij}\right\}\overline{u_j''}\langle \rho\rangle \tag{2.251}$$

A transport equation can also be obtained for $\overline{u_k'v_j'}$ by transforming the GLM pdf equation into an equation for $P(\boldsymbol{v}', \boldsymbol{u}', \boldsymbol{x}, t)$, multiplying the resulting equation by $u_i'v_j'$, and then integrating over all $\boldsymbol{u}'$ and $\boldsymbol{v}'$. This gives

$$\langle \rho\rangle \frac{D_p}{Dt}\overline{u_i'v_j'} = -\frac{\partial}{\partial x_k}\langle \rho\rangle \overline{u_i'v_j'v_k'} - \langle \rho\rangle \overline{v_j'v_k'}\frac{\partial \overline{u_i''}}{\partial x_k} - \left(\langle \rho\rangle \overline{u_i'v_k'}\frac{\partial \bar{v}_j}{\partial x_k} + \overline{v_j'u_k'}\frac{\partial \overline{u_j}}{\partial x_k}\right) - \langle \rho\rangle \beta\left(\overline{u_i'v_j'} - \overline{u_i'u_j'}\right) + \langle \rho\rangle \alpha_{ik}\overline{u_k'v_j'} \tag{2.252}$$

2.5.4.2.1 Fluid–Particle Velocity Correlation Models The general form of α in Pope's GLM model is assumed to be linear in the local strain rates of the carrier flow, that is,

$$\alpha_{ij} = \alpha_{ij}^{(0)} + \beta_2\frac{\partial \overline{u_i}}{\partial x_j} \tag{2.253}$$

where $\alpha_{ij}^{(0)}$ is the homogeneous (strain rate independent) component and β_2 a constant whose value is obtained from measured values of one-point statistics. In the case of the SDM model, the values of $\alpha_{ij}^{(0)}$ are dependent on the particle itself since they refer to fluid timescales viewed by the particle. In particular, SDM account for the influence of crossing trajectories by choosing the following form for $\alpha_{ij}^{(0)}$:

$$\alpha_{ij}^{(0)} = \frac{\delta_{ij}}{\tau_{pf,\perp}} + \left[\frac{1}{\tau_{pf,\parallel}} - \frac{1}{\tau_{pf,\perp}}\right]n_i n_j$$

where $\tau_{pf,\perp}$ and $\tau_{pf,\parallel}$ are the turbulent characteristic timescales of the fluid velocity fluctuations viewed by the particles in the direction normal and parallel to the mean relative velocity vector $\bar{\mathbf{V}}_r$ between particle and

carrier flow that has direction cosines n_i. Thus, by adopting the same approach as that of Csanady (1963) for gravitational settling, $\tau_{pf,\perp}$ and $\tau_{pf,\parallel}$ are given by

$$\tau_{pf,\parallel} = \tau_f (1 + C\zeta_r^2)^{-1/2} \tau_{pf,\perp} = \tau_f (1 + 4C\zeta_r^2)^{-1/2}$$

where

$$\zeta_r^2 = \frac{3\left|\bar{\mathbf{V}}_r\right|^2}{\langle \boldsymbol{u}' \cdot \boldsymbol{u}' \rangle}$$

and C is a given parameter characterising the Eulerian to Lagrangian integral time scale ratio.

For the closure of the transport equation for the fluid–particle covariances in Equation 2.252, we need finally a closed expression for the fluid–particle velocity $\overline{\rho u_i' v_j' v_k'}$ for the particle fluid covariance flux. In the case of the scalar particle fluid covariance $\langle \mathbf{u}' \cdot \mathbf{v}' \rangle$, Simonin (1996a) has used a Boussinesq approximation

$$\langle \rho \boldsymbol{u}' \cdot \boldsymbol{v}' \boldsymbol{v}_i' \rangle = -\langle \rho \rangle \nu_{pf}^t \frac{\partial}{\partial x_i} \langle \boldsymbol{u}' \cdot \boldsymbol{v}' \rangle$$

where ν_{pf}^t is referred to as the fluid–particle turbulent viscosity written in terms of the timescale of the fluid along a particle trajectory τ_{pf}, namely,

$$\nu_{pf}^t = \frac{1}{3} \langle \boldsymbol{u}' \cdot \boldsymbol{v}' \rangle \tau_{pf}$$

Using this gradient approximation of the particle fluid velocity fluxes and the expressions for α_{ij}, the transport equation can, in principle, be solved for the linear form for α_{ij} in Equation 2.253. Fevrier and Simonin (1998), from a computational point of view, have derived an algebraic model for the off-diagonal particle–fluid covariances, which they then use in conjunction with a transport model for the scalar fluid–particle covariance $\langle \boldsymbol{u}' \cdot \boldsymbol{v}' \rangle$. This algebraic model is derived from Equation 2.252, assuming equilibrium of the fluid–particle turbulent velocity correlation tensor in single-phase flow, namely,

$$\langle u_m' v_m' \rangle \left[\frac{d}{dt} \langle u_i' v_j' \rangle - D_{ij} \right] = \langle u_i' v_j' \rangle \left[\frac{d}{dt} \langle u_m' v_m' \rangle - D_{mm} \right]$$

where D_{ij} refers to the diffusive component (gradient of the fluid–particle velocity flux) in the transport equation for the fluid–particle covariance. Then from the fluid–particle correlation transport (Equation 2.252), one obtains the following models:

2.5.4.2.2 Algebraic Model

$$\begin{aligned} \langle u_i' v_j' \rangle = {} & \frac{1}{3} \langle \boldsymbol{u}' \cdot \boldsymbol{v}' \rangle \delta_{ij} + \frac{\langle \boldsymbol{u}' \cdot \boldsymbol{v}' \rangle}{\langle u'^2 \rangle} \left[\langle u_i' u_j' \rangle - \frac{1}{3} \langle u'^2 \rangle \delta_{ij} \right] - \frac{1}{2\beta \langle u'^2 \rangle} \left[\langle \boldsymbol{u}' \cdot \boldsymbol{v}' \rangle \left\{ \langle u_i' v_k' \rangle \frac{\partial \overline{v_j}}{\partial x_k} + (1 - \beta_2) \langle u_i' v_k' \rangle \frac{\partial \overline{u_j}}{\partial x_k} \right\} \right. \\ & \left. - \langle u_i' v_j' \rangle \left\{ \langle u_m' v_n' \rangle \frac{\partial \overline{v_m}}{\partial x_n} + (1 - \beta_2) \langle v_m' u_n' \rangle \frac{\partial \overline{u_m}}{\partial x_n} \right\} \right] \end{aligned} \tag{2.254}$$

where $\langle u'^2 \rangle = \langle \boldsymbol{u}' \cdot \boldsymbol{u}' \rangle$. For practical application, this algebraic expression may be used with the transport equation of the fluid–particle covariance $\langle \boldsymbol{u}' \cdot \boldsymbol{v}' \rangle$ obtained directly from Equation 2.252. Fevrier and

Simonin (1998) go further and derive an even simpler model than the algebraic model by assuming that the fluid–particle covariance tensor anisotropy is small so that, for instance, certain ratios in the algebraic model equation can be replaced by their local quasi-homogeneous value. Thus,

$$\frac{\langle \boldsymbol{u}' \cdot \boldsymbol{v}' \rangle}{\langle u'^2 \rangle} = \frac{\beta \tau_f}{1+\beta \tau_f}$$

This sort of approximation gives a Boussinesq or eddy viscosity model for the fluid–particle velocity covariance as follows:

2.5.4.2.3 Eddy Viscosity Model

$$\langle u_i' v_j' \rangle = \frac{1}{3}\langle \boldsymbol{u}' \cdot \boldsymbol{v}' \rangle \delta_{ij} + \frac{\beta \tau_f}{1+\beta \tau_f}\left\{ \langle u_i' u_j' \rangle - \frac{1}{3}\langle \boldsymbol{u}' \cdot \boldsymbol{v}' \rangle \right\} - \frac{\nu_{pf}^t}{1+\beta \tau_f}\left\{ \frac{\partial \overline{v_j}}{\partial x_i} - \frac{1}{3} div \bar{\boldsymbol{v}} \right.$$

$$\left. + (1-\beta_2)\left(\frac{\partial \overline{u_i}}{\partial x_j} - \frac{\delta_{ij}}{3} div \bar{\boldsymbol{u}} \right) \right. \tag{2.255}$$

In Section 2.5.4.3, we compare the predictions for the dispersion of particles in a particle-laden jet and a vertical channel flow.

2.5.4.3 Comparison of Predictions with Experimental Results for Nonuniform Unbounded Flows

Here, we briefly consider the application of the pdf approach for predicting the concentration, mean velocity, and velocity covariances of a dilute suspension of particles in nonuniform flows where near-wall behavior is not a feature. In particular, in Figure 2.31, we show the predictions of Simonin and Fevrier (1996a,b) using a particle kinetic stress transport model of the particle mean and rms velocities in a vertical channel flow and in a turbulent round jet in comparison with the experimental measurements of Rogers and Eaton (1963)

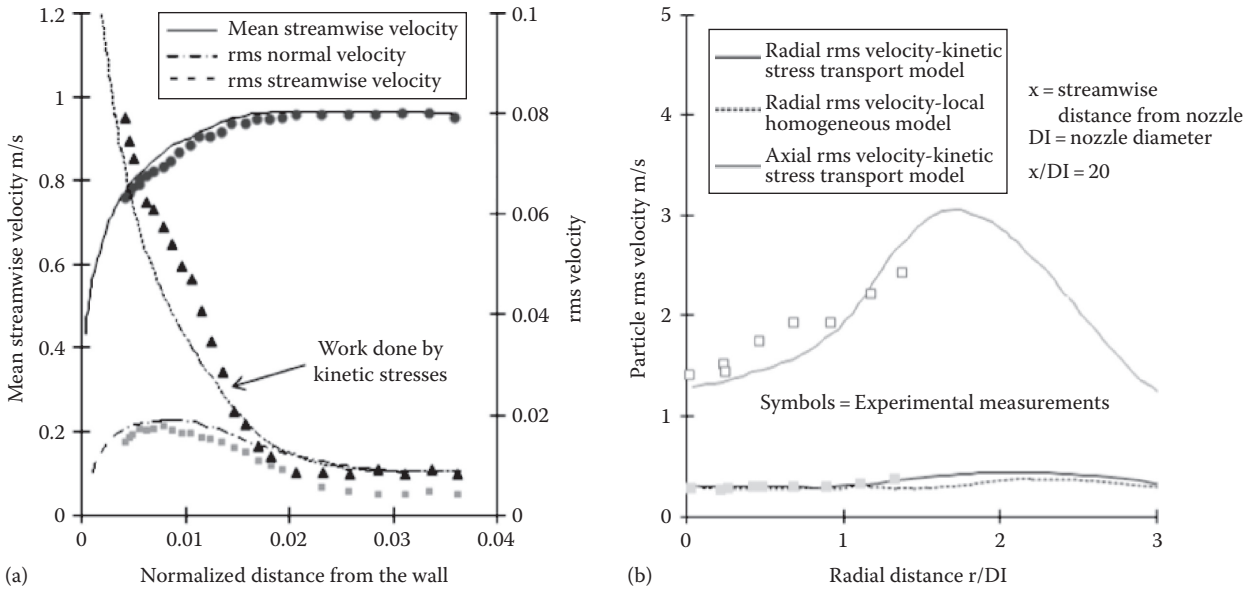

Figure 2.31

(a) Particle rms velocity predictions of Simonin (1996b) using kinetic stress transport compared to experimental measurements in a vertical channel flow. (From Rogers, C.B. and Eaton, J.K., Int. J. Multiphase Flow, 16(5), 819, 1963.) and (b) a turbulent round jet. (From Hishida, K. and Maeda, M., Turbulent characteristics of gas-solid two-phase confined jet: Effect of particle density, in *Fifth Workshop on Two Phase Flow Predictions: Proceedings*, Erlangen, Germany, March 19–22, 1990.)

for the vertical channel flow and that of Hishida and Maeda (1990) for the round jet. The results show the significant difference between the streamwise and normal streamwise rms particle velocities in the case of channel flow and between the axial and radial rms velocities for the round jet. You can see the greatest difference near the walls in the vertical channel flow where the shear stresses are greatest and also near the nozzle in the case of the round jet. In both cases, this is due to the work done by the kinetic stresses as the mean shearing of the particle flow compresses or dilates the particle flow in the streamwise direction or axial direction (see the terms proportional to the mean shearing (Equation 2.235), which are responsible for the difference). Note that in the case of the jet, the kinetic stress transport model gives slightly better predictions for the radial rms velocities than the quasi-homogeneous model due to the contribution of the gradients of the triple correlation. This is one of the many examples where comparison between model predictions and experimental measurements has been made. However, it does provide very good examples of the application of the transport equation for the particle kinetic stresses (Equation 2.232) where the work done by the mean shear of either phase introduces a significant anisotropy into the particle velocity covariance as is also the case of dispersion in a simple shear.

Figure 2.32 shows the axial and radial particle rms velocities for the turbulent round jet as a function of radial location for a range of axial distances from the jet nozzle. While showing the same anisotropy in the axial and radial rms velocities as in Figure 2.32, the figure also indicates the contribution of

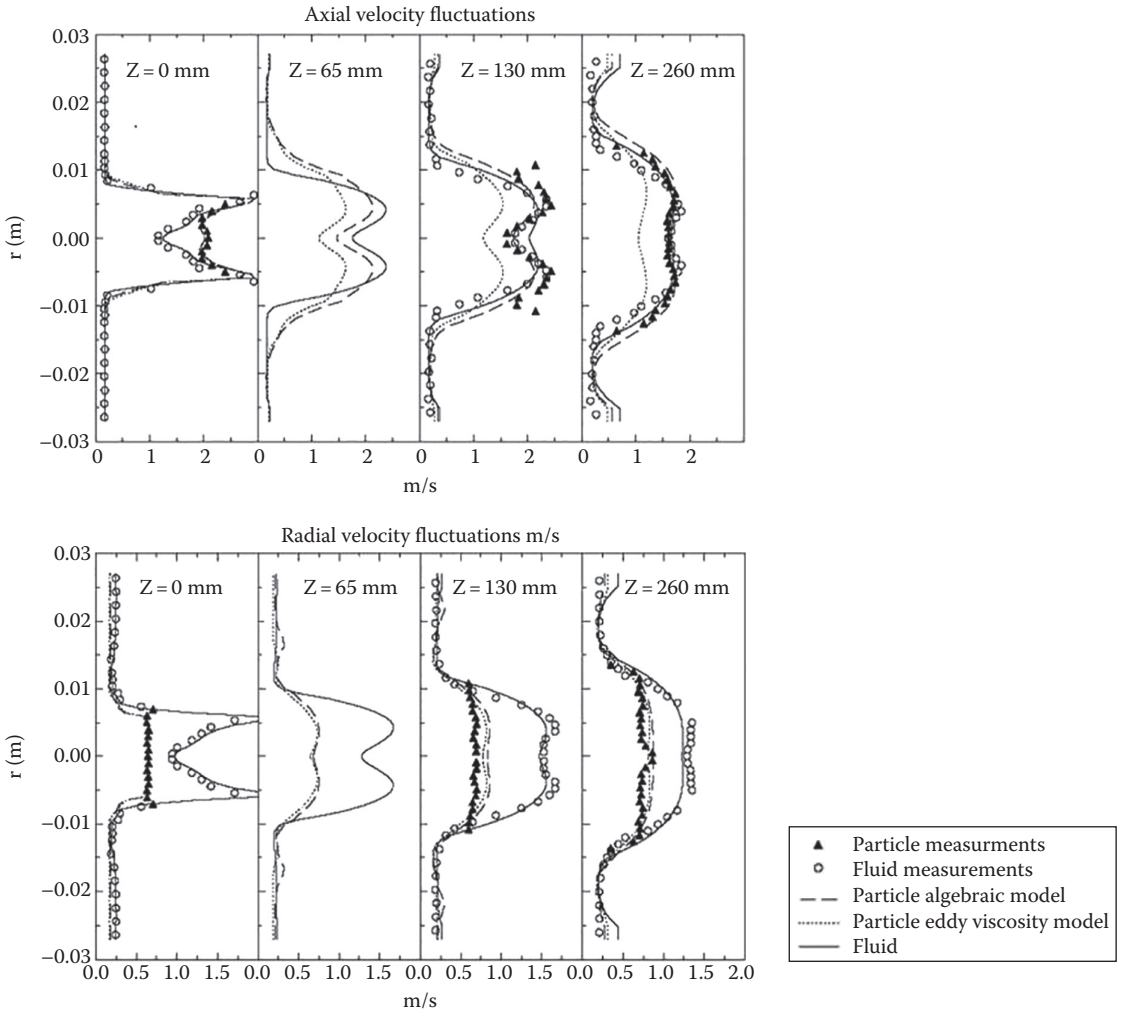

Figure 2.32

Turbulent round jet. Further generalized Langevin method probability density function predictions versus experimental measurements of the radial and axial particle rms velocities as a function of radial location for a range of axial distances (Simonin [1996a]).

the particle fluid covariances based on the algebraic model (Equatin 2.254) and the eddy viscosity model (Equation 2.255). Application of the algebraic model accurately predicts the values in the particle velocity fluctuations in both the axial and radial directions for all measured axial locations. The fluid–particle eddy viscosity model is reasonably accurate in predicting the radial velocity fluctuations but clearly underpredicts the axial values.

2.5.5 Particle–Wall Interactions and Transport in Turbulent Boundary Layers

Not only does the pdf approach provide a formal way of deriving the continuum equations and constitutive relations of the dispersed phase, but it also correctly deals with the near-wall behavior and particle–wall interactions that form the natural bc's of the dispersed phase. Applying bc's to the continuum equations themselves, as is done for the continuous-phase two-fluid modeling, is inappropriate because such bc's imposed are artificial. In reality, the natural bc's have to do with the particles' response to the surface molecular forces that, for an impacting particle at a solid surface, express a relationship between the distribution of particle velocity before and after impact and the possible deposition/absorption and subsequent resuspension of the deposited particles sometime later. So while the velocity distribution at the wall is an important feature of the bc's, it is not known a priori but is an intrinsic part of the calculation.

In this section, we briefly review the work of Swailes et al. (Swailes and Reeks, 1994, Darbyshire and Swailes, 1996, Reeks and Swailes, 1997, Devenish et al., 1999) on the application of the pdf approach to near-wall behavior in a turbulent boundary and the influence of natural bc's. We note that the steep change in the level of turbulence at the wall means that only for very small particles are the two-fluid equations (mass, momentum, and energy) likely to apply, that is, the particle distribution of velocities at any position within the turbulent boundary layer will not be locally related to the turbulence: depending on its size, a particle will retain some memory of its behavior in the far wall or bulk flow. More precisely, this depends on the variation of the turbulence over a particle mean free path, which is defined as the distance a particle travels in a time equal to its correlation time ϵ/v': the same sort of conditions apply in a gas at low pressure when the dimensions of the container are comparable to the molecular mean free path. Under such circumstances, the so-called continuum theory no longer applies. It is to be noted that even without the steep change in turbulence, the bc's at the wall are in themselves likely to cause a lack of validity of two-fluid model equations simply because the particle–wall distribution will be so very much different from the distribution away from the wall (one mean free path away) and far from the assumption that it is close to Gaussian.

However, to begin with, we consider particles whose inertia is sufficiently large that their transport through the turbulent boundary layer is ballistic, that is, they are unaffected by the turbulent boundary layer adjacent to the wall and the effective mean free path of the particles is comparable to the dimensions of the containment. We consider first the interesting case of particles settling out under gravity with partial absorption and diffuse reflection at the wall with inelastic collision for those particles that rebound. All this is a valuable precursor to our consideration of the way the pdf method deals with the most challenging case of transport of particles through a turbulent boundary where the transport through the boundary layer rate limits the particle deposition at the wall. It is a case where inhomogeneity of the flow and the nonlocal nature of the transport and the particle–surface interactions (through impact and absorption followed by resuspension) all play an equally important role.

2.5.5.1 General Boundary Conditions at the Wall

Referring to Figure 2.33, the general bc for a particle impacting at a wall at $\boldsymbol{x}$ with velocity $\boldsymbol{u}$ and rebounding with a range of possible velocities $\boldsymbol{v}$ is the flux condition

$$\boldsymbol{v}P(\boldsymbol{v},\boldsymbol{x},t) = \int_{\boldsymbol{u}\cdot\mathbf{n}\le 0} \boldsymbol{u}P(\boldsymbol{u},\boldsymbol{x},t)\Theta(\boldsymbol{v}\,|\,\boldsymbol{u})d\boldsymbol{u} \tag{2.256}$$

where

$\boldsymbol{n}$ is the direction normal to the wall at $\boldsymbol{x}$

$\Theta(\boldsymbol{v}|\boldsymbol{u})$ is the transition or scattering probability density that a particle will rebound with a velocity $\boldsymbol{v}$ after impacting the surface with velocity $\boldsymbol{u}$

$\boldsymbol{u}$ and $\boldsymbol{v}$ are related deterministically (specular reflection) or stochastically (diffuse scattering as in the case of a microscopically rough surface). Swailes and his coworkers (Swailes and Reeks, 1994, Swailes, 1997,

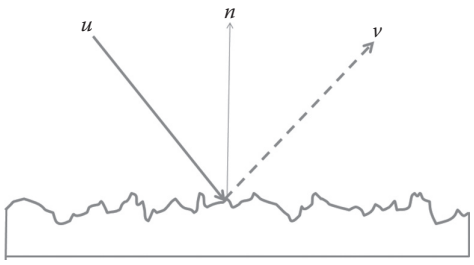

Figure 2.33

Particle impact and rebound velocities at a rough wall.

Reeks and Swailes, 1997, Devenish et al., 1999) have obtained solutions for the pdf equation for simple flows in these cases. Both cases involve duct flow in which the turbulence is regarded as homogeneous with uniform mean velocity in the streamwise direction. In these cases, therefore, the particle's response time is sufficiently large that it does not respond to the spatial variations in the mean flow and the turbulence especially near the wall. In these cases, it is the bc's themselves that determine the near-wall behavior where the continuum equations are inappropriate and the behavior can be well approximated by a simple steady-state solution of the pdf equation in 1D in $\boldsymbol{x}$ and in $\boldsymbol{v}$. The conditions for particle response times are consistent with the spatial gradients flux term in Equation 2.204 being set to zero as well as the body force due to inhomogeneity in the flow. In this case, the pdf equation can be normalized in a universal form under steady conditions as (Reeks and Swailes, 1997)

$$\left(v\frac{\partial}{\partial y}-\frac{\partial}{\partial v}v+g\frac{\partial}{\partial v}+\frac{\partial^2}{\partial v^2}\right)\langle W(y,x,t)\rangle=0 \tag{2.257}$$

where y is the normal distance from the wall ($y = 0$) and positive velocities are directed toward the wall, particles are acted upon by a gravitational force g directed toward the wall, and velocities and distances are normalized on the particle rms velocity at equilibrium (perfectly reflecting walls) and on the particle mean free path ϵ/v'.

In the simple flows considered by Swailes et al., the flow is divided into a far-wall region, which acts as a constant source of particles entering the near-wall region. The interface is set at some distance Υ from the wall in particle mean free paths where the spatial distribution of the particles is uniform. It follows from Equation 2.257 that this distribution will be Gaussian:

$$w(0,v)=(2\pi)^{-1/2}\exp\left(-\frac{1}{2}v^2\right)\quad \text{for } v>0. \tag{2.258}$$

2.5.5.1.1 Method of Solution The pdf equation is solved numerically using a spectral expansion in terms of Hermite polynomials, looking for solutions in the form

$$w(y,v)\approx\sum_{n=0}^{N}\phi_n(y)\psi_n(v) \tag{2.259}$$

where ψ_n are the orthonormal functions based on the Hermite polynomials H_n. They are

$$\psi_n(v)=\left(\frac{b}{2^n n!\sqrt{\pi}}\right)^{1/2}\exp\left(-\frac{1}{2}(bv)^2\right)H_n(bv) \tag{2.260}$$

The inclusion of the scaling factor b allows the placement of a set of collocation points v_j ($j = 0, 1, \ldots, N$) to be optimized. At these collocation points, the approximation in Equation 2.259 is exact. In this problem,

the collocation points are taken to be the zeros of the function ψ_{N+1} which provide discrete orthonormal properties for $\psi_n(v_s)$. Substituting the approximation in Equation 2.259 into 2.257 and making it exact at these collocation points give a system of first-order equations:

$$\frac{\mathrm{d}}{\mathrm{dy}}\mathbf{W} = A\mathbf{W} \tag{2.261}$$

where

W is the column vector whose elements are the values of the pdf at the collocation points

A is a matrix whose elements are functions of ψ_n^s.

The bc's given by Equations 2.256 and 2.258 are discretized at the points v_j. If we define N^* to be the integer such that $v_j < 0$ for $j < N^*$ and $v_j \geq 0$ for $j \geq N^*$, then the bc at the interface $y = \Upsilon$ can be written as

$$\sum_{n=0}^{N} \zeta_{jn} w_n = 1, \quad j \geq N^* \tag{2.262}$$

where $w_n = w(v_n, \Upsilon)$ and

$$\zeta_{jn} = \delta_{jn}(2\pi)^{1/2} \exp\left(\frac{1}{2}v_j^2\right) \quad j \geq N^* \tag{2.263}$$

The bc at the wall $y = 0$ is

$$\sum_{n=0}^{N} \zeta_{jn} w_n = 0, \quad j < N^* \tag{2.264}$$

where

$$\zeta_{jn} = \delta_{jn} v_n + h_n^{-1} \sum_{m=0}^{N} \psi_m^n I_m(v_j) \quad j \geq N^* \tag{2.265}$$

with

$$I_m(v_j) = \int_0^\infty \psi_m(u) u \Theta(v_j|u) du \tag{2.266}$$

The interface and wall bc's represent standard two-point bc's for the solutions of Equation 2.261 and can be solved by a standard numerical method. Figures 2.34 and 2.35 show some of the results obtained by Reeks and Swailes (1997), for particle deposition at a wall with or without gravity for specific examples of the wall scattering function $\Theta(v_j|u)$. In each case, results are compared with those obtained from a random walk simulation that simulates the system precisely. In this case, it was assumed that upon impact there was an energy loss that was conveniently described by defining a critical impact velocity v_c below which a particle adhered upon impact but above which a particle will rebound with a prescribed rebound velocity $\boldsymbol{v} = \Theta(\boldsymbol{u})$. Thus, $\Theta(\boldsymbol{v}|\boldsymbol{u})$ for specular reflection is

$$\Theta = \begin{cases} 0 & \text{for } 0 < v \leq v_c \\ \delta(v - \theta(u) & \text{for } v > v_c \end{cases} \tag{2.267}$$

Modeling the dependence of $v = \theta(u)$ from a constant energy loss upon impact as

$$v = -\sqrt{u^2 - v_c^2} \quad \text{for } u > v_c \tag{2.268}$$

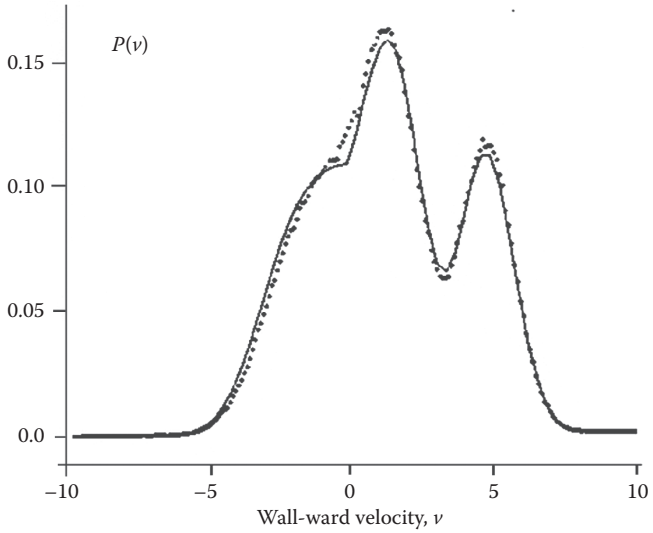

Figure 2.34

Velocity distribution $P(v)$ for particles settling under gravity in a homogeneous turbulent flow, impacting at a wall with partial absorption: $v_c = 5$, $v_g = 5$ (in normalized units). Impact velocities are for $v > 0$.

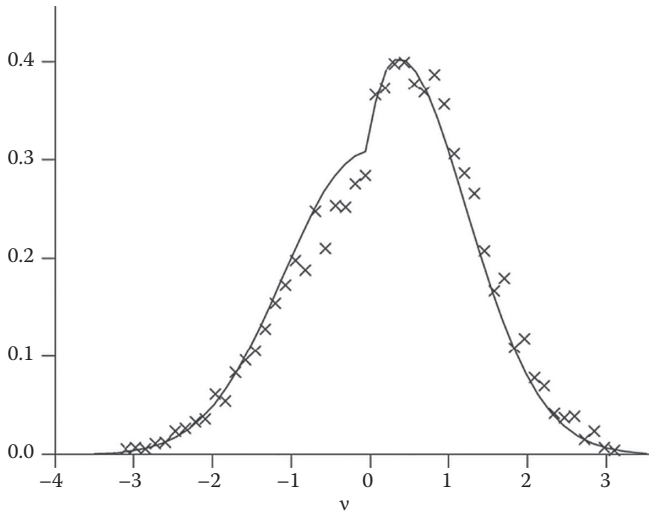

Figure 2.35

Wall distribution for specular reflection: $\gamma = 0°$, $v_c = 1$.

gives the simple form

$$\langle W(v,0)\rangle = \langle W(u,0)\rangle \quad \text{for } u > v_c \tag{2.269}$$

where v and u are related by Equation 2.268.

We note that $v_c = 0$ no absorption and no energy loss give the perfect reflection bc condition $\langle W(v,0)\rangle = \langle W(-v,0)\rangle$, while letting $v_c \to \infty$ gives the perfect absorption case $\langle W(v,0)\rangle = 0$, $v < 0$. Results were obtained for a range of values of the gravitational settling velocity v_g and critical impact velocities v_c. Figure 2.34 shows the results of solving the pdf Equation 2.257 with those obtained from the simulation for the velocity distribution at the wall for the specific case of a partially absorbing wall with $v_c = 5$ and $v_g = 5$ (in normalized units). Note there are two peaks: one centered at $v = v_g$ and the one with its center slightly displaced from the origin. The relative heights of these peaks depend upon the ratio of v_c/v_g: for $v_c/v_g = 0$ (zero absorption), the latter peak has a maximum value $v = 0$, with no contribution from the peak at $v = v_g$. In contrast, the reverse is the case when $v_c/v_g \to \infty$.

2.5.5.1.2 Diffuse Reflection with Deposition As an illustration, we suppose that particles arriving at the surface are still reflected with a deterministic speed, but now the velocity vector is directed at some random angle α to the surface. Since we are concerned only with particle transport in the direction normal to the wall, we may consider the rebound velocity to be $v = -r\cos\alpha$, where, as in Equation 2.268, the deterministic speed is $r = \sqrt{u^2 - v_c^2}$. If $u < v_c$, then the particle is considered to adhere.

A variety of distributions $\Theta(v|u)$ can be constructed depending on the prescribed distribution of α. For the purpose of illustration, Darbyshire and Swailes (1996) considered the simple case where the reflection angle α is uniformly distributed on (−γ, γ) in which case

$$\Theta(v \mid u) = \begin{cases} \gamma^{-1}(u^2 - a^2)^{-1/2} & \text{for } a \le u \le c \\ 0 & \text{otherwise} \end{cases} \tag{2.270}$$

where $a(v) = \sqrt{v_c^2 + v^2}$ and $c(v) = \sqrt{v_c^2 + v^2 \sec^2\gamma}$.

Predictions for the velocity distribution at the wall compared with those obtained from random walk simulations are shown in Figure 2.36 for γ = 75°. Compare this distribution with that for specular reflection with the same critical impact velocity shown in Figure 2.35, which illustrates the essential effect of diffuse reflection, namely, the reduction near the wall of the normal component of the particle rms velocity, the effect becoming more pronounced with increasing γ. These features are accompanied with an increase in particle–wall concentration as γ increases.

2.5.5.2 Transport and Deposition in Turbulent Boundary Layers

There has been intensive research over the last 20 years on the near-wall behavior of particles suspended in a turbulent flow (see, e.g., recent review by Li and Ahmadi, 1992), in particular how particles interact with near-wall structures and how are they transported and deposited at the wall. In this regard, DNS has been particularly useful in simulating the behavior of the fluid motion. Much of our understanding comes from particle tracking in these flows. Of particular note is the work of Soldati (2009) in illuminating the transport mechanisms and in developing models for the particle deposition that has been the major preoccupation from a practical point of view. The problems here have been in formulating an appropriate transport equation to account for the influence of the severe changes in the turbulence intensity in the near-wall region that in general makes the particle transport entirely nonlocal, that is, far from local equilibrium. In this regard, the pdf approach has been particularly successful. While the two-fluid equations are inappropriate near the wall, the solution of the pdf equation itself still provides a valid description. Furthermore, the bc's arising from the particle–wall interactions are only expressible in terms of bc's for a pdf equation since as

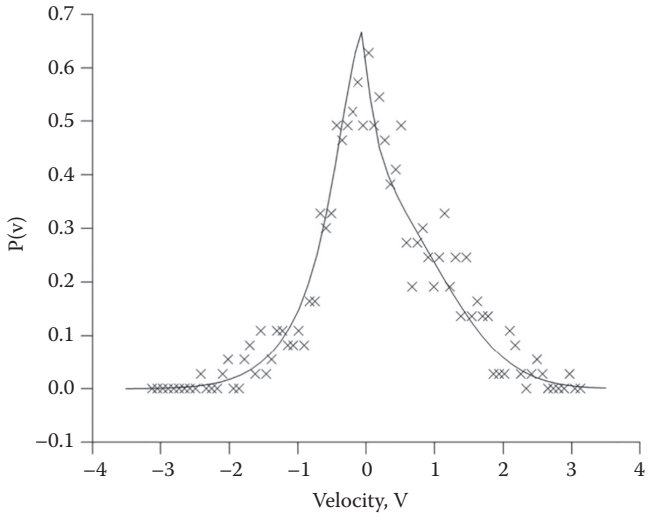

Figure 2.36

Wall distribution for diffuse reflection: γ = 75°, v_c = 1.

we have said they involve changes in the velocity distribution at the wall. Traditional fluid modeling is inappropriate because the bc's imposed are artificial. We note that advection–diffusion models for deposition are implicit in the particle momentum equation derived from the pdf equations where the inertial term is ignored (Reeks, 1993):

$$j = \langle \rho \rangle \boldsymbol{v}_d - \epsilon \cdot \frac{\partial \langle \rho \rangle}{\partial \boldsymbol{x}} \tag{2.271}$$

where

$$v_d = -\tau_p \frac{\partial}{\partial \boldsymbol{x}} \cdot \langle \boldsymbol{v}\boldsymbol{v} \rangle + \boldsymbol{\kappa} - \frac{\partial}{\partial \boldsymbol{x}} \cdot \boldsymbol{\lambda} \tag{2.272}$$

The drift velocity $\boldsymbol{v}_d$ is composed of essentially two terms that are of different origins. The first term arises from the gradients of the kinetic stress and reflects a balance between a drag force and the gradients of a stress, while the remaining terms are derived from body forces that arise directly from spatial inhomogeneous in the flow. The first term has often been referred to as turbophoresis (Reeks, 1983).

2.5.5.3 Particle Deposition in Turbulent Boundary Layers

Deposition of particles in turbulent pipe flow has a huge literature associated with it (see Li and Ahmadi, 1992)—there have been many attempts at predicting the deposition as a function of particle size or response time. The problem as we have seen is the rapid decay of turbulence near the wall and the way the particles respond to that decay and the lack of local equilibrium with the flow. The particles may start out in local equilibrium far away from the wall, but their inability to follow the steep changes in the fluid velocity means that at any point the particles have some memory of their previous history—their velocity has more to do with where they came from than what is happening to the fluid motion locally. The continuum equations break down. Not only that, we have to deal with the problem of bc's if we use continuum equations because perfect absorption at the wall means that the only bc is that there are no particles at the wall with velocities away from the wall. There is no means of fitting that behavior into a traditional no slip at the wall bc. pdf equations are ideally suited for this type of problem—first, they take account of the naturals bc's, and second, they take account of the influence of particle inertia and the steep turbulence gradients. They uniquely handle both effects together which traditional models are incapable of doing. It is useful to show some features of the near-wall behavior before considering what the deposition looks like. The results are taken from the recent analysis of van Dijk and Swailes (2012) based on the solution of the GLM pdf model using a discontinuous Galerkin method of solution. Figure 2.37a shows the concentration ratio as a function of distance $y+$ from the wall (denoted by x_2 in the Figure 2.37) for a range of values of the particle inertia or particle response time in wall units τ^+ equivalent to the Stokes number. You can see a significant peaking of the concentration near the wall as τ^+ reduces from very large values where the motion is basically ballistic (no response at all to the near-wall turbulence). Figure 2.37b shows the ratio of the rms of the particle–wall normal velocities v_2 to the local fluid rms of the fluid u_2 as a function of distance from the wall, indicating that this ratio $\gg 1$ as you approach the wall because of the particles' inertia and the much higher velocities they have attained further away from the wall where the gradients of the turbulence are much less.

Figure 2.37c for the particle pdf $p(v_2, x_2)$ shows that particles enter the domain at $x_2 = 100$ for $v_2 < 0$ and subsequently move toward the wall via, mainly, a diffusive mechanism; the pdf remains close to the local equilibrium state over a large part of the spatial domain. Closer to the wall, at about $x_2 = 20$, the fluid rms velocity decreases rapidly. The effect of this is that the particles are no longer driven by diffusion, but start moving in free flight. Most of the heavy particles ($\tau^+ = 300$, see Figure 2.37) have enough momentum to reach the wall, even those that have a relatively low speed. Only very slowly moving particles get trapped near the wall and slowly drift toward adhesion at $x_2 = X_0$. This results in a small buildup near the wall of particles with low velocity. For lighter particles ($\tau^+ = 10$, Figure 2.37c), only the fast particles reach the wall in free flight, while most will be trapped. Hence, they are only ones that can get to the very sharp peak in the pdf around zero particle velocity. This feature would not be picked up in the particle tracking because of the requirement of a very high resolution. This results in a strong buildup in a concentration that is also clearly visible in Figure 2.37a, where the particle concentration, ρ, in the boundary layer is shown. In fact, recent work suggests that there is threshold velocity of τ^+ below which particles are trapped in the region of almost stagnant fluid near the wall and never get deposited (see the recent analysis of Sikovsky, 2013).

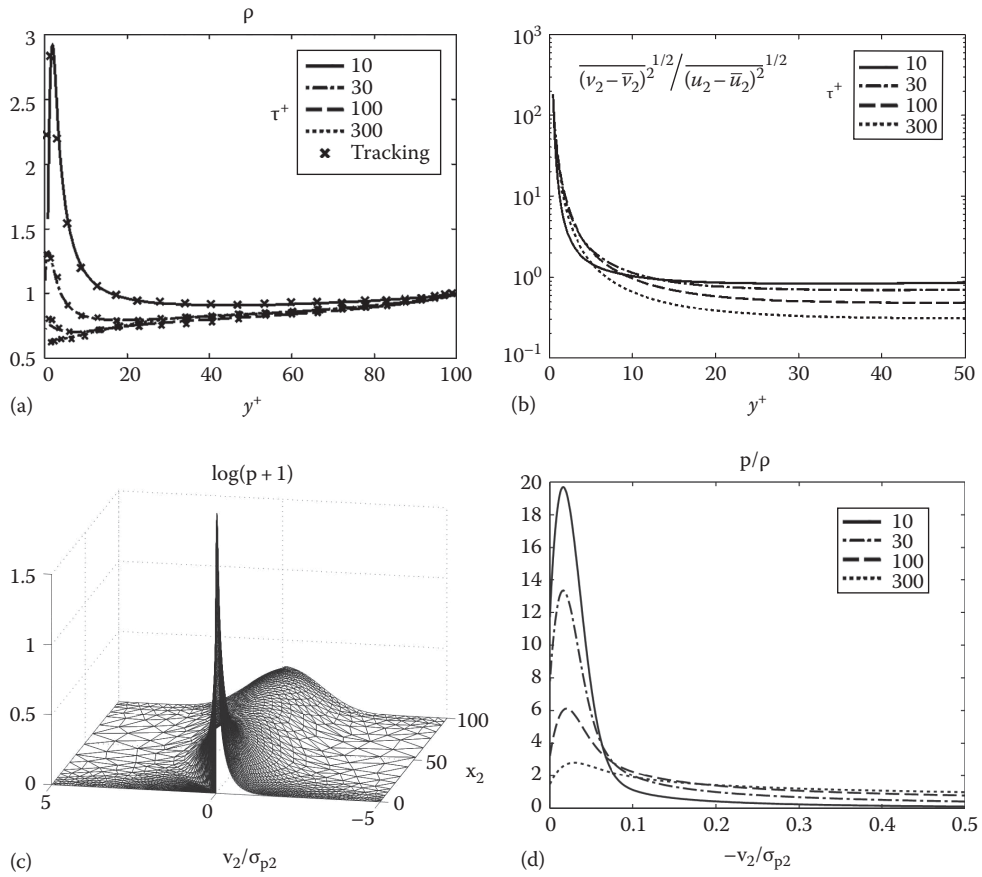

Figure 2.37

Particle near-wall behavior as a function of distance from wall y^+ and particle response time τ^+ (both in wall units) (van Dijk and Swailes, 2012). σ_{p2} is the local particle equilibrium rms velocity in the wall-normal direction. (a) Near-wall particle concentration ρ, (b) near-wall particle normal rms normal velocities, (c) near-wall pdf $\rho(v_2,x_2)$ for $\tau^+ = 10$, (d) particle velocity distribution for $\tau^+ = 10$ at "wall" (one particle radium from wall).

Similar features have been observed in particle pair collisions in homogeneous isotropic turbulence (Wang et al. 2000). The normalized particle velocity distribution, which is presented in Figure 2.37d, illustrates this process as well: the distribution for $\tau^+ = 300$ has a significant tail, while for $\tau^+ = 10$ the distribution is strongly localized near $v_2/\sigma_{p2} = 0$.

Finally, Figure 2.38 shows the predictions of the particle deposition velocity j^+ (in wall units) as a function of particle response time τ^+ obtained by Zaichik et al. (2010) compared to a range of experimental and DNS results. In particular, Zaichik's predictions were obtained by solving a closed set of moment equations derived from the pdf–kinetic equation. The closure is based on a quasi-normal assumption for the fourth-order moments of particle velocity and local equilibrium closure for third-order moments (neglecting their advection). The method of solution has thus much in common with the RANS approach in CFD involving Reynolds stress transport equations. Given the experimental error is very large, the pdf solutions predicts the huge changes in deposition velocity from 10^{-1} to 10^{-5} for a change in τ^+ from 10 to 10^{-1}, which reflects the role of particle inertia on the deposition.

2.5.5.4 Particle Resuspension

Pdf equations and their solutions play an important role in deriving a formula for the rate constant for the removal of particles from a surface by aerodynamic forces. The process is similar to the desorption of molecules from a surface, and the rate constant for removal is very similar to the Arrhenius formula for the molecular desorption rate. Because the near flow is turbulent, it is necessary to take account of the contribution of the fluctuating removal forces as well as the mean forces. This means that the process is stochastic rather than a force balance between the adhesive forces holding the particles onto the surface and the

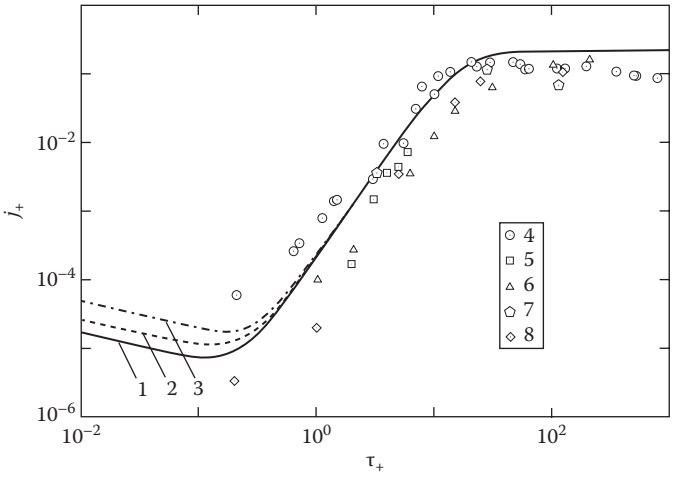

Figure 2.38

Particle deposition in turbulent pipe flow. (From Zaichik, L.I. et al., *Int. J. Heat Mass Transfer*, 53, 154, 2010.)

aerodynamic removal forces. More particularly, the removal process is described by a probability per unit time of a particle being removed from a surface or equivalently a rate constant. So, if the rate constant for removal is p, the fraction of particles $f_R(t)$ remaining on a surface at time t is given by

$$f_R(t) = \exp(-pt) \tag{2.273}$$

Figure 2.39a shows the aerodynamic removal forces acting on a spherical particle on a smooth surface in a turbulent boundary layer together with the van der Waals adhesive force holding the particle onto the surface. It shows the spherical particle to be deformed in the contact area between particle and surface (much exaggerated in Figure 2.39) indicating the presence of elastic restoring forces that balance the adhesive force when the particle is sitting on a surface in static equilibrium (in the absence of external forces). We can represent the dependence of the surface forces (adhesive and elastic forces) and a mean removal lift force upon

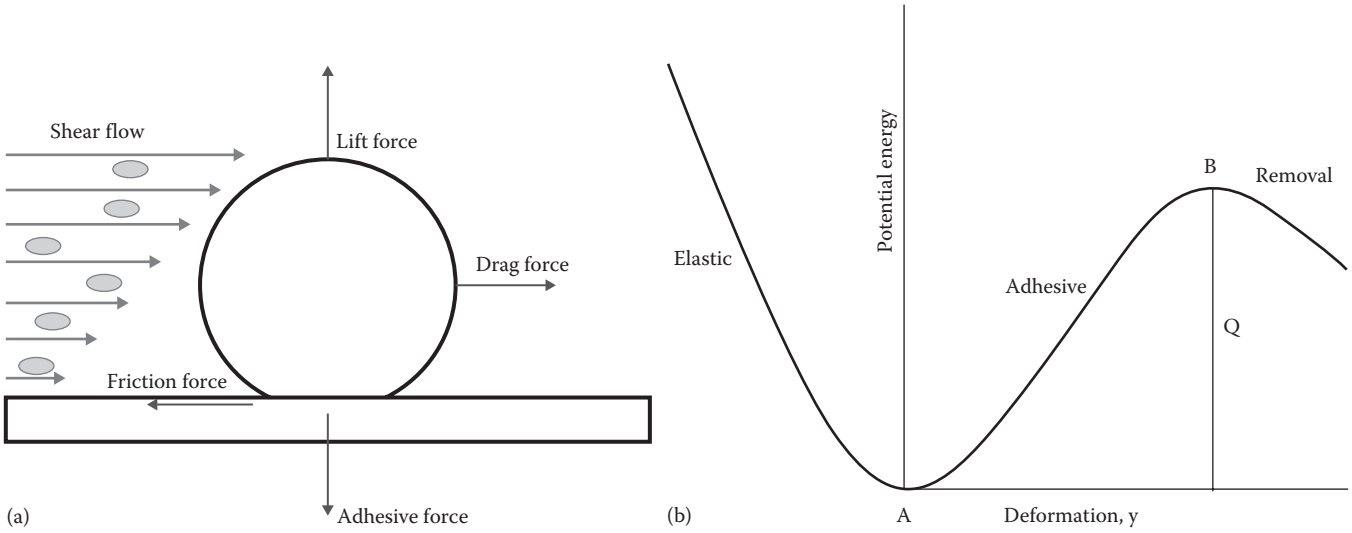

Figure 2.39

Removal of a particle from a surface by aerodynamic forces in a turbulent boundary layer. Note the deformation of the sphere in the region of contact with the surface that is exaggerated in (a). (a) Aerodynamic and surface intermolecular adhesive forces derived from a sphere in smooth contact with a surface, (b) surface adhesive potential well derived from the mean aerodynamic forces and adhesive forces in (a).

surface deformation by a *surface* potential well, a typical profile being shown in Figure 2.39b. This shows a position of stable equilibrium, A, where the adhesive force balances the repulsive elastic restoring force and a constant mean lift force and a position of instability, B, where the attractive adhesive force balances the mean lift force. Increasing the mean lift force reduces both the width of the potential well and the height of the potential barrier of B above A, Q, which a particle has to overcome before it can be detached from the surface. We suppose that the number of particles on the surface is sufficient to form an ensemble of all realizable states of a single particle in a constant potential well. The fluctuating removal force will cause the particle–surface deformation $y(t)$ to oscillate randomly about the point of minimum potential at A until a particle derives enough energy from the fluctuating forces (the turbulence) to escape over the potential barrier at B and detached from the surface. The objective therefore is to use the pdf equation to calculate the flux of particles out of the well at B, and this quantity divided by the number of particles in the well is the probability per unit time of a particle escaping from the well, that is, the resuspension rate constant.

In using the pdf equations to evaluate the rate constant, we recognize that the phase space dispersion coefficients μ and λ are functions of the particle–surface deformation y. In the case of a harmonic potential, the displacement $\Delta y(t)$ in Equation 2.274 determines the dispersion coefficients corresponding to the solution of a very stiff, lightly damped harmonic oscillator. Thus, for a particle of mass m, the deformation displacement $\Delta y(t)$ at time t, about the point of minimum potential, A, is obtained from

$$\ddot{\Delta} y(t) + \beta \dot{\Delta} y(t) + \omega^2 \Delta y(t) = m^{-1} f_L(t) \tag{2.274}$$

where $f_L(t)$ is the random fluctuating component of zero mean associated with the total aerodynamic lift force

$$F_L = \langle F_L \rangle + f_L(t) \tag{2.275}$$

where

$\langle F_L \rangle$ is the mean lift force that in this instance is assumed independent of time
ω is the natural frequency based on the harmonic approximation for small deformations about A
β is the fluid and mechanical damping term

Reeks et al. (1988) show that the rate constant p can be written as

$$p = \frac{\omega_0}{2\pi} \exp\left(\frac{-Q}{\langle PE \rangle} \right) \tag{2.276}$$

where

$\langle PE \rangle$ is the average potential energy of the particles in the potential well
ω_0 is a frequency for particle motion in the well

Both these quantities reflect a process of energy transfer from the turbulence to a particle in the potential well, the particle being resuspended when it has accumulated enough vibrational energy to detach itself from the surface. This is the basis of the kinetic model of RRH (Reeks et al., 1988) that allows for the possibility of resonant energy transfer when the forcing frequency of the lift force fluctuations is not too different from the natural frequency of vibration of the particle–surface deformation. Under such circumstances, a particle is removed much easier from a surface than applying the same lift force quasi-statically (which is the basis of the simple force balance approach). It is a more general model than the so-called force balance model because it admits the possibility of resonant energy transfer. When this transfer is zero, then the formula for the resuspension rate constant reduces to the form appropriate to a force balance. That is, the motion of the particle/surface deformation is approximated by a quasi-static balance between the instantaneous aerodynamic lift force and the adhesive force at each location/deformation in the adhesive surface potential well. This implies a functional relationship between the particle deformation and the removal force at each instant of time. Both resonant energy transfer and quasi-static removal are two extremes in the value of ω_0 and $\langle PE \rangle$ depending on the value n, forcing frequency $\left(\langle \dot{f}^2 \rangle / \langle f^2 \rangle \right)^{1/2}$, so for $n \ll \omega$, $\omega_0 \to n$, $n \to \omega$, and $\omega_0 \to \omega$ with corresponding values for $\langle PE \rangle$ at these limiting frequencies.

The situation of smooth contact of a sphere with a surface represented in Figure 2.39 is somewhat idealized. In reality, microscopic roughness significantly reduces the adhesion between particles and surface even in the case of particle contact with a polished surface. Contact with the surface is made by surface asperities so that the area of contact and hence adhesion are much reduced from that for perfectly smooth contact. In this case, experiments have shown that particles are removed from surfaces by rolling where the drag force plays a much more significant role than the lift force. Even so, the formula in Equation 2.276 still applies if the potential energy is based on the rocking and rolling of particles about surface asperities, and equivalent forces, involving the drag force, are used rather than lift forces normal to the surfaces as in Figure 2.39a. We refer to Reeks et al. (Reeks and Hall, 2001, Zhang et al., 2013a,b) for the way these models have been developed and applied to the resuspension of monolayer and multilayer coverages of particles on a rough surface.

2.5.6 Pdf Approach for Particle Pair Mixing and Dispersion

In this part, we examine and assess the way the pdf approach has been used to describe the motion of particle pairs in turbulent flows and, in particular, how it has been used to quantify interparticle collision rates and the influence they have on the continuum equations and constitutive relations for a particle suspension in a turbulent gas.

We also consider how the pdf approach can be used to quantify the demixing or segregation of particles at the small scales of turbulence through the calculation of the distribution of particle pairs as a function of their separation. The segregation influences the collision rates since it brings particle pairs closer together to begin with, and this in turn causes droplets to coalesce and solid particles to agglomerate. In the case of agglomeration, it is necessary to also consider whether particles stick or bounce upon collision or whether they detach from one another some time later. There is an obvious parallel here with similar processes of deposition and resuspension of particles to surfaces in a turbulent boundary layer.

The calculation of binary collision rates, which interests us here, and the issues that surround it necessitates the use of a two-particle pdf $P_2(\boldsymbol{v}_1, \boldsymbol{x}_1; \boldsymbol{v}_2, \boldsymbol{x}_2, t)$, where subscripts 1 and 2 refer to particles 1 and 2. The net collision rate of an individual particle with surrounding particles depends upon the relative velocities $\boldsymbol{v}_2 - \boldsymbol{v}_1$ between particle pairs and their concentration at their separation $\boldsymbol{x}_2 - \boldsymbol{x}_1$ upon collision. The influence of both on the collision rates is reflected in the value of the collision kernel Γ that we will define and formulate in terms of the two-particle pdf and discuss its dependence on the particle response to the small and large scales of the turbulence.

When considering a suspension of monodisperse particles, there are essentially two mechanisms that influence and control the collision between individual particles. The first is due to the random shearing of the flow and is associated with the small dissipating eddies of the turbulence. This gives rises to a velocity difference for colliding particles arising from the difference in carrier turbulent velocities encountered by particle pairs at the point of collision (the separation of the centers of two colliding spheres being known as the collision radius). This difference in particle velocities will also depend upon the particle response to the shearing itself measured by the particle's Stokes number St_K defined as the ratio of the particle response time τ_p to the typical shear rate $\sim \left(\epsilon/\nu\right)^{1/2}$. The influence of particle inertia defined in terms of St_K is similar to that of particle inertia defined in terms of τ_p^+ for particles deposited at a wall in a turbulent boundary layer where the velocity of depositing particles and local concentration have more to do with the history of their motion than their response to the local fluid motion. So, it is the same in this case with regard to the difference in fluid velocity experienced by a particle pair as a function of separation as the particles approach collision with some memory of the greater separation of velocities from encounters with small scales at earlier times and greater separation. Accompanying this is the process of segregation or clustering observed at the small scales, which leads to an increase in the particle concentration in the neighborhood of individual particles and enhances their collision rate with other particles. We will discuss this process and how the pdf approach can be used to capture and quantify both aspects of this mechanism in more detail later on.

The second mechanism is due to the lack of correlation of the particle motion with the local fluid motion and is entirely dependent upon the particle inertia, in which this time it is defined in terms of the Stokes number as the ratio of the particle response time to the large and inertial range of turbulent scales. For these particles, though they may partially or approximately follow the large scales, they are ballistic on the scale of the small-scale motion and the difference in velocities imposed by the shearing of the large scales is virtually zero. It is due to the influence of these particles with stop distances (spatial correlation) comparable to the integral length scale of the carrier flow that influences the mass, momentum, and energy equations of the dispersed phase, and it is necessary to add an extra term to the pdf equation to account for their collisions. This term is precisely analogous to the Boltzmann collision integral in the Maxwell–Boltzmann equation

but accounting for the correlative motion of particle and fluid. This feature highlights the invalidity of the molecular chaos assumption for particle collisions in turbulent flows except for very inert particles when particles and fluid motion are uncorrelated.

In the following sections, we discuss both these mechanisms in detail but we begin first with the formulation of the collision kernel in terms of the two-particle pdf.

2.5.6.1 Particle Collision Kernel

The particle collision kernel $\Gamma(\boldsymbol{x}_1)$ is the net collision rate $\overline{z}$ of an individual particle at position $\boldsymbol{x}_1$ with surrounding particles normalized by their average number concentration $\overline{n}$ of particles within a control volume where the number of particles remains constant in time (or more correctly the average concentration sufficiently far away from the individual particle at $\boldsymbol{x}_1$ that is constant)*. More precisely, the collision rate is the integrated influx $\boldsymbol{j}^+$ of surrounding particles colliding with an individual particle integrated over the total collision surface formed by the colliding particles. In terms of the particle pair distribution pdf $P_2(\boldsymbol{v}_1, \boldsymbol{x}_1; \boldsymbol{v}_2, \boldsymbol{x}_2, t)$ for arbitrary shaped particles and size, $\overline{z}$ is therefore given by

$$\overline{z} = \int\limits_{d\boldsymbol{S}\cdot(\boldsymbol{v}_2-\boldsymbol{v}_1)\leqslant 1} P_2(\boldsymbol{v}_1,\boldsymbol{x}_1;\boldsymbol{v}_2,\boldsymbol{x}_1+\boldsymbol{r}_c,t)(\boldsymbol{v}_2-\boldsymbol{v}_1)\cdot d\boldsymbol{S}(\boldsymbol{r}_c)d\boldsymbol{v}_1 \tag{2.277}$$

where

$\boldsymbol{r}_c$ defines the point of contact between an individual particle at $\boldsymbol{x}_1$ and a neighboring particle at $\boldsymbol{x}_1 + \boldsymbol{r}_c$,
$d\boldsymbol{S}(\boldsymbol{r}_c)$ is an elemental surface area whose normal is along the line of centers of the colliding particles at the point of contact.

So, $\boldsymbol{r}_c$ defines the location of the collision surface for all possible particle pair collisions. In the case of two small colliding spherical droplets of radii r_1 and r_2, the collision surface is a sphere of radius $r_c = r_1 + r_2$, and for collisions in isotropic homogeneous turbulence, the distribution of relative velocities w_r along the line of centers $\phi_r(w_r)$ is spherically symmetric (independent of ϕ, θ) and independent of $\boldsymbol{v}_1$ and $\boldsymbol{x}_1$. So, if we consider a collision with a single particle,

$$\overline{z} = 4\pi r_c^2 n(r_c)\frac{1}{2}\int |w_r|\,\phi(w_r)dw_r \tag{2.278}$$

where $n(r_c)$ is the number concentration of surrounding particles at r_c. The factor of 1/2 reflects the condition on the velocities for a collision in Equation 2.277 and to account for the fact that half the particles are moving toward a surface as they are moving away, considering that the surface is perfectly reflecting. So, we write explicitly

$$\Gamma = \frac{\overline{z}}{\overline{n}} = 2\pi r_c^2 g(r_c)\langle |w_r| \rangle \tag{2.279}$$

where $g(r_c) = n(r_c)/\overline{n}$ is known as the radial distribution function (Sundaram and Collins, 1997) and accounts for the enhancement of collision rates due to clustering or segregation. $\overline{n}$ may also be interpreted more precisely as the value of $n(r)$ at a sufficiently large distance $r \gg r_c$ from an individual particle that the concentration of surrounding particles is effectively constant and equivalent to the fully mixed concentration. $|w_r|$ is the net velocity toward any individual particle of the neighboring particles at the collision radius along their line of centers.

2.5.6.2 Influence of the Particle–Fluid Velocity Correlation on Particle Collisions

The way particle pairs close together interact with a coherent fluid structure increases the correlation of the velocity of each of the particles with the local fluid velocity and in turn the correlation between them. In so doing, it reduces the relative velocity between particle pairs and the rate of collision over the lifetime of the coherent stricture (see Zhou et al., 1998, for a simple 1D model). This can easily be seen in the expression

* Compare this definition with that of the deposition velocity of particles in a surface exposed to a turbulent flow.

for the mean square relative velocity $\langle v_{12}^2 \rangle$ between particle pairs in terms of the associated velocities of the individual particle pair velocities $\boldsymbol{v}_1$ and $\boldsymbol{v}_2$, namely,

$$\langle v_{12}^2 \rangle = \langle v_1^2 \rangle + \langle v_2^2 \rangle - 2\langle \boldsymbol{v}_1 \cdot \boldsymbol{v}_2 \rangle$$

for which $\boldsymbol{w}_r$ is the resolved component of $\boldsymbol{v}_{12}$ along the line of centers. Following Lavieville et al. (1995, 1997), Simonin et al. (2002) and Zaichik and Alipchenkov (2003), we can see the influence of the fluid–particle velocity correlation on the particle pair pdf, $P_2(\boldsymbol{v}_1, \boldsymbol{x}_1; \boldsymbol{v}_2, \boldsymbol{x}_2, t)$, if we introduce the joint two-point pdf of particle and fluid velocities $\boldsymbol{v}$, $\boldsymbol{u}$, respectively, namely, $P_2(\boldsymbol{v}_1, \boldsymbol{u}_1, \boldsymbol{x}_1; \boldsymbol{v}_2, \boldsymbol{u}_2, \boldsymbol{x}_2)$, given in terms of conditional probabilities, as

$$P_2(\boldsymbol{v}_1, \boldsymbol{u}_1, \boldsymbol{x}_1; \boldsymbol{v}_2, \boldsymbol{u}_2, \boldsymbol{x}_2) = P_1(\boldsymbol{v}_1, \boldsymbol{x}_1 | \boldsymbol{u}_1) P_1(\boldsymbol{v}_2, \boldsymbol{x}_2 | \boldsymbol{u}_2) P_2(\boldsymbol{u}_1, \boldsymbol{u}_2) \tag{2.280}$$

where

$P_1(\boldsymbol{v}_1, \boldsymbol{x}_1 | \boldsymbol{u}_1)$ means the conditional probability density for a particle velocity $\boldsymbol{v}_1$ measured at $\boldsymbol{x}_1$ conditional upon there being a fluid velocity $\boldsymbol{u}_1$ at the same position $\boldsymbol{x}_1$

$P_2(\boldsymbol{u}_1, \boldsymbol{u}_2)$ is the joint probability distribution of carrier flow velocities $\boldsymbol{u}_1$ and $\boldsymbol{u}_2$ encountered by particles 1 and 2 at $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$, respectively

We have

$$P_1(\boldsymbol{v}_1, \boldsymbol{x}_1 | \boldsymbol{u}_1) = \frac{P_1(\boldsymbol{v}_1, \boldsymbol{u}_1, \boldsymbol{x}_1)}{P_1(\boldsymbol{u}_1)}$$

and similarly for $P_1(\boldsymbol{v}_2, \boldsymbol{x}_2 | \boldsymbol{u}_2)$, where $P_1(\boldsymbol{u}_1)$ is the probability distribution of carrier flow velocities observed by particle 1 at $\boldsymbol{x}_1$.

From the two-point particle–fluid velocity distribution $P_2(\boldsymbol{v}_1, \boldsymbol{u}_1, \boldsymbol{x}_1; \boldsymbol{v}_2, \boldsymbol{u}_2, \boldsymbol{x}_2)$, we can calculate $P_2(\boldsymbol{v}_1, \boldsymbol{x}_1; \boldsymbol{v}_2, \boldsymbol{x}_2)$ from

$$P_2(\boldsymbol{v}_1, \boldsymbol{x}_1; \boldsymbol{v}_2, \boldsymbol{x}_2) = \int P_2(\boldsymbol{v}_1, \boldsymbol{u}_1, \boldsymbol{x}_1; \boldsymbol{v}_2, \boldsymbol{u}_2, \boldsymbol{x}_2) d\boldsymbol{u}_1 d\boldsymbol{u}_2 \tag{2.281}$$

using the relationship in Equation 2.280 and assumed formulae for the conditional probabilities. Lavieville et al. (1995), in the case of statistical stationary homogeneous isotropic turbulence, assumed a Gaussian for the conditional probabilities that involve the particle–fluid velocity correlation coefficient ξ at a fixed point in space and at equilibrium, that is, for an isotropic turbulent flow, namely,

$$\xi = \frac{\langle \boldsymbol{u} \cdot \boldsymbol{v} \rangle}{\langle v^2 \rangle^{1/2} \langle u^2 \rangle^{1/2}} \tag{2.282}$$

where, for example, $\langle v^2 \rangle = \langle \boldsymbol{v} \cdot \boldsymbol{v} \rangle$. The implicit assumption is that this correlation is the same as the Lagrangian correlation, which, because of homogeneity, is independent of position, that is,

$$\langle \boldsymbol{v}(\boldsymbol{x}, t) \cdot \boldsymbol{u}(\boldsymbol{x}, t) \rangle = \langle \boldsymbol{v}(\boldsymbol{x}, 0 | t) \cdot \boldsymbol{u}(\boldsymbol{x}, 0 | t) \rangle_{t \to \infty} = \beta^{-1} \mu_\infty$$

For the Stokes drag assuming an exponential autocorrelation for the flow velocity along a particle trajectory,

$$\xi = \left(\langle v^2 \rangle / \langle u^2 \rangle \right)^{1/2} = \frac{1}{(1 + St_L)^{1/2}} \tag{2.283}$$

where St_L is the particles Stokes number $1/\beta T_L$ in which T_L is the Lagrangian integral timescale of the fluid motion (in the case of Lavieville's model (Lavieville et al., 1995, 1997) T_L is associated with the

large-scale motion). The form for $P_2(\boldsymbol{u}_1, \boldsymbol{u}_2)$ in Equation 2.280 used in the evaluation of $P_2(\boldsymbol{v}_1, \boldsymbol{x}_1; \boldsymbol{v}_2, \boldsymbol{x}_2)$ in Equation 2.281 is based on a two-point particle-joint Gaussian distribution for the components of $\boldsymbol{u}_1$ and $\boldsymbol{u}_2$ involving the longitudinal and lateral velocity correlation $F(r)$ and $G(r)$, respectively, where r is the distance between the two points. This gives rise to a Gaussian distribution in the particle velocities $\boldsymbol{v}(\boldsymbol{x}_1)$, $\boldsymbol{v}(\boldsymbol{x}_2)$, which, when transformed to a distribution $P_1(\boldsymbol{w})$ for the relative velocities $\boldsymbol{w}$ between particle pairs, implies a similar Gaussian distribution for the fluid velocities but with values for the radial and normal component velocity correlation $F(r)$ and $G(r)$ scaled by ξ^2. Thus, the radial distribution $P^{(0)}(w_r)$ is given by

$$P_1(w_r) = \left(2\pi\left\langle w_r^2\right\rangle\right)^{-1/2} \exp\left(-w_r^2/2\left\langle w_r^2\right\rangle\right) \tag{2.284}$$

where, at the point of contact between colliding particles,

$$\left\langle w_r^2\right\rangle = 2\left\langle v^2\right\rangle(1-\xi^2 F(r_c)) \tag{2.285}$$

and, that with reference to the collision kernel Γ defined in Equation 2.279,

$$\left\langle\left|w_r\right|\right\rangle = \left(\frac{2}{\pi}\left\langle w_r^2\right\rangle\right)^{1/2} \tag{2.286}$$

So, the formula in Equation 2.285 accounts for both the effects of the induced correlation of particle motion and that of the local fluid for each member of the particle pair and the spatial correlation between particle pair velocities arising from the spatial correlation of fluid velocities themselves. Zaichik et al. (2008) have used these formulae to obtain expressions for Γ in both the large-scale, intermediate inertial subrange and small-scale viscous dissipating (Kolmogorov) range of scales considering both the influence of particle pair separation and fluid–particle correlation and its dependence on particle inertia. In particular, using the formula for $\left\langle w_r^2\right\rangle$ and $\langle|w_r|\rangle$ into Equation 2.279 for Γ and ignoring segregation, that is, we have

$$\Gamma = 4\pi^{1/2} r_c^2 \left\langle v^2\right\rangle^{1/2} (1-\xi^2 F(r_c))^{1/2} \tag{2.287}$$

While the results reproduce the conclusion made by Saffman and Turner (1956) for the collision kernel of inertialess passive scalar particles in the viscous small-scale dissipating range and that of Abrahamson (1992) for the large-scale large inertia $St_L \gg 1$, the approach implicitly assumes a local equilibrium between particles and fluid, which is inappropriate for collision at the small scale. The approach does not take account of the memory and history of the particle pair separation and the relative fluid velocities the particles encounter throughout the entire particle pair history before they collide. It assumes furthermore that particles are fully mixed and that any particles have a uniform concentration of the particles surrounding it. The process we may see is precisely analogous to the way particles are transported through a turbulent boundary layer, where there is a concentration buildup near the wall and nonlocal particle velocities at the wall. A number of deposition models in a turbulent boundary exploit this memory though the concept of free flight to the wall, which is missing from this local equilibrium approach. We will also see that using a solution of the pdf equation for relative particle motion, this feature is accounted for in a way similar to the way the solution of the pdf equation accounts for these features for particle transport in a turbulent boundary layer discussed in Section 2.5.5.3 and in particular the results of van Dijk and Swailes (2012).

2.5.6.3 Contribution of Interparticle Collisions to the Dispersed Phase Continuum Equations

In this section, we consider the transport of particles in a turbulent flow and the influence interparticle collisions have on the continuum equations of the dispersed particle phase. We will approach this in a similar way to the approach we used to obtain the continuum equation due to the turbulence acting alone. That is, we consider the way the collisions affects the pdf–kinetic equation for a single particle as an additional term that represents the rate of change $\partial P/\partial t$ due to particle collisions within and outside an elemental volume in particle phase space. Using the analogy of solid particle collisions with those of gas molecules, following the work of Lavieville et al. (1995), Simonin (1996), Zaichik and Simonin (2003, 2006), Lavieville (1997), we evaluate the Boltzmann collision integral for the collisions of inelastic solid spheres. As in kinetic theory,

we assume that the particle suspension is sufficiently dilute that only binary collisions are significant. We are specifically interested in cases where the particle's response time β^{-1} ~ the integral timescale T_L, $St_L \sim 1$. We note that experiment and numerical simulations have indicated that inert particle collisions have a measurable influence on coarse particle transport properties in gas–solid turbulent flows, even for small values of the dispersed phase volume fraction, $\alpha \sim 10^{-2}$. Neglecting hydrodynamic interaction between colliding particles, hard sphere kinetic theory can be used to account for interparticle inelastic collisions in a pdf approach to particle flows.

Thus, referring to Figure 2.40 for an inelastic collision between two identical spherical particles labeled 1 and 2,

$$\begin{aligned} \boldsymbol{v}_1^* &= \boldsymbol{v}_1 + \frac{1}{2}(1+e_c)(\boldsymbol{v}_{21}\cdot\hat{\boldsymbol{n}})\hat{\boldsymbol{n}} \\ \boldsymbol{v}_2^* &= \boldsymbol{v}_2 - \frac{1}{2}(1+e_c)(\boldsymbol{v}_{21}\cdot\hat{\boldsymbol{n}})\hat{\boldsymbol{n}} \end{aligned} \tag{2.288}$$

where $\boldsymbol{v}_1^*$ and $\boldsymbol{v}_2^*$ are the velocities of particles 1 and 2 after the collision related to the velocities $\boldsymbol{v}_1$ and $\boldsymbol{v}_2$ before the collision, involving the coefficient of restitution e_c, the unit vector $\hat{\boldsymbol{n}}$ directed from the center of the first colliding sphere to the center of the second at impact, and $\boldsymbol{v}_{12}$ is the relative velocity of particle 2 with respect to that of particle 1 at impact. Note that there is no interparticle friction.

While there are certain obvious similarities between molecular collisions and particle collisions in a turbulent flow, there are, as we have pointed out earlier, however fundamental differences, that is, in the kinetic theory of dilute gases, the statistics of binary collisions are derived by assuming that the velocities and positions of any two particles are independent of each other (the molecular chaos assumption), whereas in gas–solid flow, the probable positions and velocities of colliding particles will definitely be correlated through their interaction with the same surrounding turbulent flow. In this section, we describe the original approach due to Simonin (He and Simonin, 1993) that ignores this correlation and then the approach proposed by Lavieville et al. (1995) that attempts to take it into account. The detailed description of the modeling approach can be found in studies by He and Simonin (1993), Lavieville et al. (1995), and more recently Simonin et al. (2002).

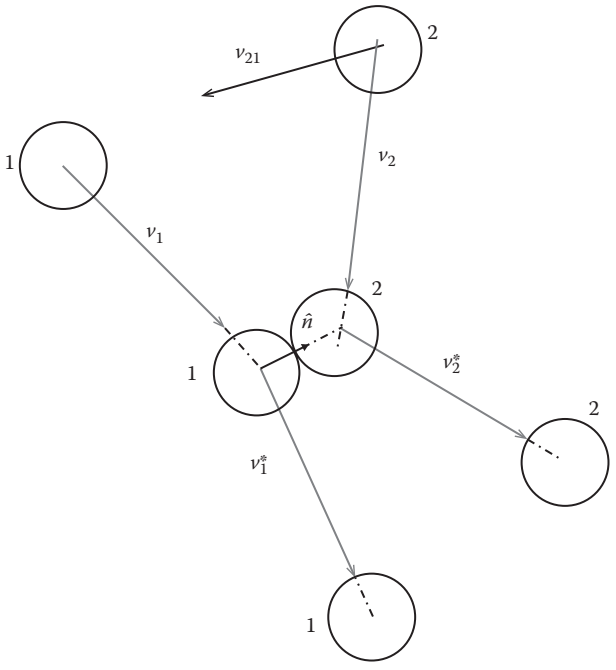

Figure 2.40

The collision of two spherical particles labeled 1 and 2 with velocities $\boldsymbol{v}_1$, $\boldsymbol{v}_2$ before impact and $\boldsymbol{v}_2^*$, $\boldsymbol{v}_2^*$ after impact, respectively.

2.5.6.3.1 Boltzmann Collision Integral for a Suspension of Particles in a Turbulent Flow If particle-to-particle interactions in which more than two particles take place are assumed to be negligible in number and effect, the collisional pdf rate of change may be written in terms of the particle–particle pair probability distribution function $P_2(\boldsymbol{v}_1, \boldsymbol{x}_1; \boldsymbol{v}_2, \boldsymbol{x}_2, t)$ for particle 1 with velocity $\boldsymbol{v}_1$ at position $\boldsymbol{x}_1$ and particle 2 with velocity $\boldsymbol{v}_2$ at position $\boldsymbol{x}_2$ for which special closure assumptions are needed. The net rate of change of the number of particles within an elemental volume of phase space $d\boldsymbol{v}_1 d\boldsymbol{x}_1$ at $\boldsymbol{v}_1$, $\boldsymbol{x}_1$ due to collisions with particles at $\boldsymbol{x}_1 + d_p\hat{\boldsymbol{n}}$ is made up of two contributions: The first contribution is the rate of loss directly due to collisions of particles within the phase space volume $d\boldsymbol{v}_1 d\boldsymbol{x}_1$ with particles at $\boldsymbol{x}_1 + d_p\hat{\boldsymbol{n}}$ over the collision surface for all particles with relative velocities directed toward the collision surface. Referring to Figure 2.40, we can write this explicitly as

$$\partial P^-(\boldsymbol{v}_1,\boldsymbol{x}_1,t)/\partial t = -d_p^2 \int \int_{\boldsymbol{v}_{21}\cdot\hat{\boldsymbol{n}}>0} \hat{\boldsymbol{n}}\cdot\boldsymbol{v}_{12} P_2(\boldsymbol{v}_1,\boldsymbol{x}_1;\boldsymbol{v}_2,\boldsymbol{x}_1+d_p\hat{\boldsymbol{n}},t)\, d\hat{\boldsymbol{n}}\, d\boldsymbol{v}_2 \tag{2.289}$$

The second contribution is a positive increase arising from the collision of particles within the phase space volume $d\boldsymbol{v}_1^+ d\boldsymbol{x}_1$ at $\boldsymbol{v}_1^+, \boldsymbol{x}_1$ with velocities $\boldsymbol{v}_2^+$ at $\boldsymbol{x}_1 + d_p\hat{\boldsymbol{n}}$ and ending up after collision in the elemental phase space volumes $d\boldsymbol{v}_1 d\boldsymbol{x}_1$ at $\boldsymbol{v}_1$, $\boldsymbol{x}_1$ and $d\boldsymbol{v}_2 d\boldsymbol{x}_1$ at $\boldsymbol{x}_1 + d_p\hat{\boldsymbol{n}}$. The total collision rate is then an integration of the collision *arrival* flux over the collision surface and over all $\boldsymbol{v}_2^+$ similar to that in the expression for the rate of loss in Equation 2.289, namely,

$$d\boldsymbol{v}_1^+ d\boldsymbol{x}_1 \partial P^+(\boldsymbol{v}_1^+,\boldsymbol{x}_1,t)/\partial t = d\boldsymbol{v}_1^+ d\boldsymbol{x}_1 d_p^2 \int \int_{\boldsymbol{v}_{21}\cdot\hat{\boldsymbol{n}}>0} \hat{\boldsymbol{n}}\cdot\boldsymbol{v}_{12}^+ P_2(\boldsymbol{v}_1^+,\boldsymbol{x}_1;\boldsymbol{v}_2^+,\boldsymbol{x}_1+\boldsymbol{d}_p\hat{\boldsymbol{n}},t)\, d\hat{\boldsymbol{n}}\, d\boldsymbol{v}_2^+ \tag{2.290}$$

For $\boldsymbol{v}_1^+, \boldsymbol{v}_2^+ \rightarrow \boldsymbol{v}_1\boldsymbol{v}_2$ after collision

$$\boldsymbol{v}_1^+ = \boldsymbol{v}_1 + \frac{1+e_c}{2e_c}\left(\boldsymbol{v}_{21}\cdot\hat{\boldsymbol{n}}\right) \quad \boldsymbol{v}_2^+ = \boldsymbol{v}_2 - \frac{1+e_c}{2e_c}\left(\boldsymbol{v}_{21}\cdot\hat{\boldsymbol{n}}\right) \tag{2.291}$$

which implies that

$$\left|\frac{\partial(\boldsymbol{v}_1^+,\boldsymbol{v}_2^+)}{\partial(\boldsymbol{v}_1,\boldsymbol{v}_2)}\right| = \frac{1}{e_c}; \quad \boldsymbol{v}_{12}^+ = \frac{1}{e_c}\boldsymbol{v}_{12}$$

Using these relations in Equation 2.290, we obtain

$$\begin{aligned}\left(\frac{\partial P(\boldsymbol{v}_1,\boldsymbol{x}_1,t)}{\partial t}\right)_{collisions} &= \partial P^+(\boldsymbol{v}_1^+,\boldsymbol{x}_1,t)/\partial t + \partial P^-(\boldsymbol{v}_1,\boldsymbol{x}_1,t)/\partial t \\ &= d_p^2 \int \int_{\boldsymbol{v}_{21}\cdot\hat{\boldsymbol{n}}>0} d\hat{\boldsymbol{n}}\, d\boldsymbol{v}_2 \cdot \boldsymbol{v}_{12}^+ \Delta P_2\left(\boldsymbol{v}_1,\boldsymbol{x}_1;\boldsymbol{v}_2,\boldsymbol{x}_1+d_p,t\right)\end{aligned} \tag{2.292}$$

where

$$\Delta P_2 = e_c^{-2} P_2(\boldsymbol{v}_1^+,\boldsymbol{x}_1;\boldsymbol{v}_2^+,\boldsymbol{x}_1+d_p\hat{\boldsymbol{n}},t) - P_2(\boldsymbol{v}_1,\boldsymbol{x}_1;\boldsymbol{v}_2,\boldsymbol{x}_1+d_p\hat{\boldsymbol{n}},t)$$

The mean collisional rate of change for some property ψ, for example, kinetic energy, is the integral over all possible binary collisions of the change in ψ in a particular collision multiplied by the probable frequency of such a collision, which can be written as

$$C(\psi) = d_p^2 \int\int \int \int_{\boldsymbol{v}_{21}\cdot\hat{\boldsymbol{n}}>0} (\psi_2^\star - \psi_2) P_2(\boldsymbol{v}_1,\boldsymbol{x};\boldsymbol{v}_2,\underline{x}+d_p\hat{k},t)\boldsymbol{v}_{21}\cdot\hat{\boldsymbol{n}}\, d\hat{\boldsymbol{n}}\, d\boldsymbol{v}_2 d\boldsymbol{v}_1 \tag{2.293}$$

where $\psi_2 = \psi_2(\boldsymbol{v}_1, \boldsymbol{v}_2)$ and $\psi_2^\star = \psi_2(\boldsymbol{v}_1^\star, \boldsymbol{v}_2^\star)$.

2.5.6.3.2 Collision Models Using the molecular chaos approach adopted in kinetic theory, the pair distribution function in the collision integral is simply written in terms of the single distribution function, assuming that colliding particle velocities are completely independent, namely,

$$P_2(\boldsymbol{v}_1,\boldsymbol{x}_1;\boldsymbol{v}_2,\boldsymbol{x}_1+d_p,t)=P_1(\boldsymbol{v}_1,\boldsymbol{x}_1,t)P_1(\boldsymbol{v}_2,\boldsymbol{x}_2+d_p,t)$$

$$\tau_p \gg \tau_e \text{ (eddy lifetime)} \tag{2.294}$$

This has been retained in the derivation of the collision integral used by Simonin (1991) and is referred to as the random collision model. This is also the assumption used implicitly by Oesterle and Petitjean (1993) and Sommerfeld (1995). However, the molecular chaos assumption is valid only when the particle response time is much larger than the eddy–particle interaction time, that is, when the particle motion is ballistic. However, as we have pointed out in Section 2.5.6.2 that when the particle response time is of the same order or smaller than this interaction time, the approaching particle velocities will be correlated through interaction with the same eddy and this needs to be taken account of.

2.5.6.3.2.1 Particle–Fluid-Correlated Collision Model We refer to Equation 2.280 and the particle pair probability density involving the particle position, velocity, and flow velocity encountered by the particle $P_2(\boldsymbol{v}_1, \boldsymbol{u}_1, \boldsymbol{x}_1; \boldsymbol{v}_2, \boldsymbol{u}_2, \boldsymbol{x}_2)$. For two colliding particles, the collision radius is so small compared to the length scale of the energy containing eddies that we may safely assume that both particles encounter the same fluid velocities $\boldsymbol{u}$, so we may write this probability density as

$$P_1(\boldsymbol{v}_1,\boldsymbol{x}_1\,|\,\boldsymbol{u},\boldsymbol{x}_1)P_1(\boldsymbol{v}_2,\boldsymbol{x}_1+d_p\,|\,\boldsymbol{u},\boldsymbol{x})P_1(\boldsymbol{u}_1,\boldsymbol{x}_1)$$

$$=P_1(\boldsymbol{v}_1,\boldsymbol{u},\boldsymbol{x}_1)P_1(\boldsymbol{v}_2,\boldsymbol{u},\boldsymbol{x}_1+d_p)/P_1(\boldsymbol{u},\boldsymbol{x}_1)$$

where we have assumed that since the colliding particles are separated by a distance comparable to the integral length scale and that $P_1(\boldsymbol{u}, \boldsymbol{x}_1) \cong P_1(\boldsymbol{u}, \boldsymbol{x}_{1+}d_p)$,

$$P_2(\boldsymbol{v}_1,\boldsymbol{x}_1;\boldsymbol{v}_2,\boldsymbol{x}_2+d_p)=\int d\boldsymbol{u}P_1(\boldsymbol{v}_1,\boldsymbol{u},\boldsymbol{x}_1)P_1(\boldsymbol{v}_2,\boldsymbol{u},\boldsymbol{x}_1+d_p)/P_1(\boldsymbol{u},\boldsymbol{x}_1) \tag{2.295}$$

2.5.6.3.2.2 Third-Order Moment Expansion (Grad's Theory) Following Grad's theory of rarefied gases (Grad, 1949), the distribution function in the collision term may be approximated by its third-order expansion in Hermite polynomials:

$$P(\boldsymbol{v},\boldsymbol{x},t)=\left[1+\frac{a_{ij}}{2T^2}v_i'v_j'+\frac{a_{ijk}}{6T^3}v_i'v_j'v_k'-\frac{a_{ijj}}{2T^2}v_i'\right]P^0(\underline{v},\underline{x},t) \tag{2.296}$$

where using q^2 to denote the mean particle turbulent kinetic energy per unit particle mass

$$T=\frac{2}{3}q^2;\quad a_{ij}=\overline{v_i'v_{,j}'}-\frac{2}{3}q^2\delta_{ij};\quad a_{ijk}=\overline{v_i'v_j'v_k'}$$

We recall that $\overline{(.....)}$ denotes a particle density-weighted average*.

$P^0(v, x, t)$ is the equilibrium pdf given by a Maxwell (Gaussian) distribution for the particle velocities, that is,

$$P^0(\boldsymbol{v},x,t)=\left(\frac{4\pi q^2}{3}\right)^{-3/2}\exp\left(-\frac{v'^2}{4q^2/3}\right) \tag{2.297}$$

* T is referred to as the granular temperature in granular flows.

Using the hard sphere collision model, Jenkins and Richman (1985) derived the following collisional terms in the transport equations for the particle mass (m), momentum (mv_i), and kinetic stresses $\left(\frac{1}{2}mv'^2\right)$ and kinetic stress flux $\left(mv'_iv'_jv'_k\right)$, respectively,

$$C(m)=0 \tag{2.298}$$

$$C(mv)=0 \tag{2.299}$$

$$C(mv'_iv'_j)=-\alpha_p\rho_p\frac{\sigma_c}{\tau_c}\left(\left\langle v'_iv'_j\right\rangle-\frac{1}{3}\left\{1-\frac{1}{3}(1-e_c^2)\right\}\left\langle v'^2\right\rangle\delta_{ij}\right) \tag{2.300}$$

$$C(mv'_iv'_jv'_k)=-\frac{5}{12}\alpha_p\rho_p\frac{\xi_c}{\tau_c}\left(9a_{ijk}-a_{ill}\delta_{jk}-a_{jll}\delta_{ik}-a_{mll}\delta_{ij}\right) \tag{2.301}$$

where

ρ_p is the particle material density
α_p is the local volume fraction of the dispersed particle phase
τ_c is the time between particle collisions, $\sigma_c=(1+e_c)(3-e_c)/5$, and $\xi_c=(1+e_c)(49-3e_c)/100$

The collisional term in the kinetic stress transport equation is written as a return to isotropy term analogous to the Rotta term in the Reynolds stress transport turbulence modeling approach. Elastic collisions ($e_c=1$) lead to a destruction of the off-diagonal correlations and redistribution of energy among the various normal stresses without modifying the total kinetic energy. The extension to inelastic collisions leads to a linear dissipation rate in the kinetic stress transport equations proportional to the collision frequency and a function of the coefficient of restitution e_c.

Extending the approach of Jenkins and Richman (1985), Lavieville et al. (1997), Simonin et al. (2002), and more recently Zaichik and Alipchenkov (1997), Zaichik et al. (2008), Grad's theoretical approach for particle–fluid-correlated collisions is used by performing a Hermite polynomial expansion on the fluid–particle-joint pdf. This eventually leads to the following generalized form for the collisional source term in the kinetic stress transport equation:

$$C(mv'_iv'_j)=-\rho_p\frac{\sigma_c}{\tau_c}\left(a_{p,ij}+\xi^4a_{f,ij}-\xi^2a_{pf,ij}\right) \tag{2.302}$$

where

$$a_{p,ij}=\overline{v'_iv'_j}-\frac{1}{3}\overline{\boldsymbol{v}'^2}\left\{1-\frac{1}{3}(1-e_c^2)\right\}\delta_{ij}\quad a_{f,ij}=\overline{u'_iu'_j}-\frac{1}{3}\overline{\boldsymbol{u}'^2}\delta_{ij}$$

$$a_{pf,ij}=\overline{u'_iv'_j}^{S}-\frac{1}{3}\xi^2\overline{\boldsymbol{u}'^2}\delta_{ij}$$

ξ is the particle fluid velocity correlation defined in Equation 2.282
τ_c is the interparticle collision time
$\overline{u'_iv'_j}^{S}$ is the symmetric part of $\overline{u'_iv'_j}$

We note that when $\xi=0$, the collision terms reduce to the forms given by Jenkins and Richman.

Following a similar approach, Zaichik et al. (2008) evaluated the collisional terms for the third-order moment C_{ijk} as

$$C_{ijk}=-\frac{3(1-\xi^2)}{\tau_{c2}}\overline{v'_iv'_jv'_k};\quad \tau_{c2}=\frac{180\tau_c}{(1+e_c)(49-33e_c)} \tag{2.303}$$

so that the influence on the C–E approximation for the third-order moment given in Equation 2.248 becomes

$$\overline{v_i' v_j' v_k'} = \frac{\left(1+(1-\xi^2)\tau_p/\tau_{c2}\right)^{-1}}{3}\left(\epsilon_{li}\frac{\partial}{\partial x_l}\overline{v_j' v_k'} - \epsilon_{lj}\frac{\partial}{\partial x_l}\overline{v_i' v_k'} - \epsilon_{lk}\frac{\partial}{\partial x_l}\overline{v_i' v_j'}\right) \tag{2.304}$$

2.5.6.3.2.3 Interparticle Collision Time Referring to the definition of collision rate in terms of the collision kernel and using the form of the collision kernel defined in Equation 2.287 with no segregation and $F(r_c) = 1$, we can write

$$\tau_c = \tau_c^k (1-\xi^2)^{-1/2} \tag{2.305}$$

where τ_c^k is the standard kinetic theory interparticle collision time based on the molecular chaos assumption and given explicitly by

$$\left(\tau_c^k\right)^{-1} = n\pi d_p^2 \sqrt{\frac{32}{12\pi}} \left\langle v^2 \right\rangle^{1/2}$$

where n is the particle number density.

The aforementioned equations show that the effective interparticle collision rate based on the correlated collision model is always smaller than the one given by standard kinetic theory and decreases with respect to the ratio of the eddy–particle interaction time to particle relaxation time as a result of the increase in correlation coefficient ξ_{12}. This behavior was observed by Lavieville et al. (1997) in LES/Lagrangian simulations in homogeneous isotropic turbulent flows showing that neighboring particles have correlated turbulent velocities. The following were also noted: the inclusion of interparticle collisions and the coupling with carrier flow turbulence, its effect on the continuum equations and the constitutive relations, and the influence of collisions on particles kinetic stresses and isotropy.

2.5.6.4 The Effect of Particle Collisions on Turbulent Stresses in a Homogeneous Shear Flow

As an important validation of the correlated collision model, we present the results of Moreau et al. (2003, 2004), who considered perfectly elastic collisions (in the absence of gravity) of spherical particles suspended in an evolving uniform shear flow whose turbulent characteristics were obtained by Lagrangian simulation of individual particle trajectories based on a Langevin equation for the carrier phase using data obtained from an LES. The initial flow conditions corresponded to isotropic turbulence and the particle volume fraction ~1.25×10^{-2}. Figure 2.41 shows the time evolution of normal turbulent stresses in the dispersed phase

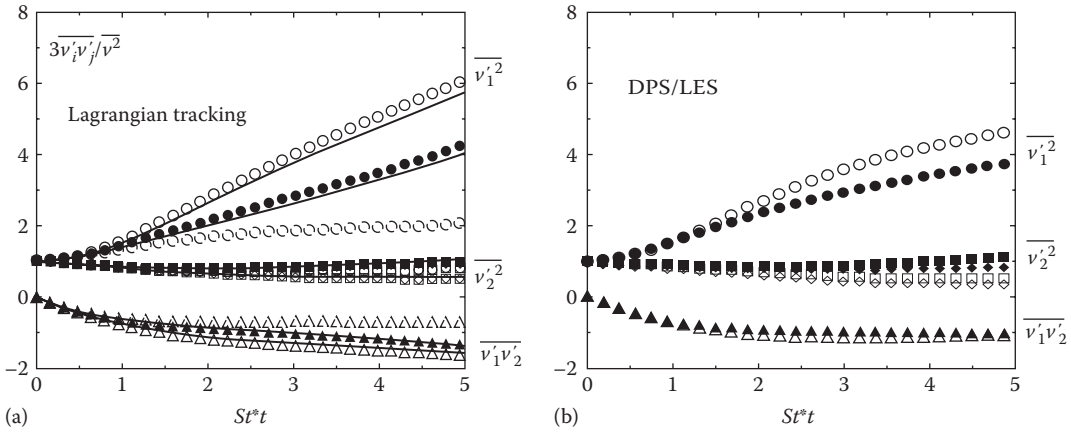

Figure 2.41

(a) Comparison of model predictions against Lagrangian tracking with correlated collisions (filled symbols), without collisions (open symbols), and decorrelated collisions (dashed symbols). (b) Results based on direct particle simulation (DPS) with an LES of the shear flow symbols as in (a).

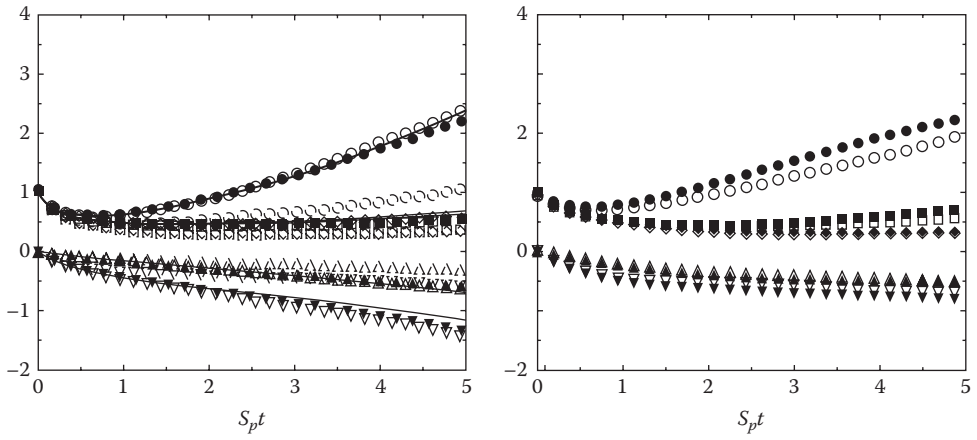

Figure 2.42

Time development of the fluid-particle velocity correlation. Comparison between Monte Carlo simulation results and model predictions based on the moment method GLM model without collisions (empty symbols), with decorrelated collisions (dashed symbols), and with correlated collisions (filled symbols). (a) DPS/LES results (on the right) without collision effect (empty symbols) and with collision effect (filled symbols). *Note:* streamwise components $\overline{u_1'v_1'}$: circles; transverse components: $\overline{u_2'v_2'}$: squares and $\overline{u_3'v_3'}$: diamonds; shear stress components: $\overline{u_2'v_1'}$: triangles up and $\overline{u_2'v_2'}$: triangles down). (Taken from Moreau, M. et al., Stochastic Lagrangian modelling and Monte Carlo simulation of collisions in gas-solid homogeneous shear turbulent flows, in *Fifth International Conference on Multiphase Flow* (*ICMF2004*), Paper no. 426, Yokohama, Japan, May 30–June 4, 2004.)

under the action of the rate of shear, the carrier and dispersed phases evolving from an isotropic the equilibrium state. The results obtained by solving the momentum and kinetic stress equations with and without the collision terms given in Equations 2.302 and 2.303 are given in Figure 2.41. The data obtained by DPS in the presence and in the absence of particle collisions are depicted by solid and open symbols, respectively. Turbulent kinetic stresses of the dispersed phase are normalized by the initial kinetic energy of particles and the correlations of velocity of the continuous and dispersed phases by the initial kinetic energy of these correlations.

Figure 2.41 reveals a strong anisotropy of particle velocity fluctuations in the absence of collisions. This anisotropy manifests in a significantly higher intensity of the longitudinal component as compared to the transverse components. Here, there are two mechanisms responsible for the generation of the longitudinal component of velocity of the dispersed phase: via the average velocity gradient and via the interaction of particles with the turbulent eddies of the continuum. On the other hand, fluctuations in the transverse direction are generated only via the interaction of particles with the turbulent fluid. Collisions tend to equalize the intensities of particle fluctuations in different directions, decreasing the intensity of the longitudinal component of velocity fluctuations and increasing the intensities of the transverse components; in other words, the net effect of collisions is the isotropization of the turbulent characteristics of the dispersed phase. As one can see from Figure 2.42, the theoretical model with collisions based on particle-fluid velocity correlations concurs with the numerical simulation data predicting an increase in $\overline{u_1'v_1'}$ due to collisions. The effect of collisions on $\overline{u_1'v_1'}$ manifests through the dependence of the duration of particle interactions with the turbulence on the time interval τ_c. A comparison of model predictions with the data obtained by Moreau et al. (2004) shows that this model reproduces all the essential features of the dependence of the character of dispersed phases velocity fluctuations as well as correlations of velocity between the two phases on particle collisions between particle collisions.

Figure 2.43 shows the model predictions for the collision times based on Equation 2.305 and the computation of the particle fluid velocity correlation £ from the moment equations. Also shown for comparison are the average particle relaxation time and the Stokes relaxation time together with the eddy particle interaction time.

2.5.6.5 Particle Segregation and Demixing

It is by now well known that turbulence, contrary to traditionally held views, can demix a suspension of particles (see, e.g., Fessler et al., 1994). The process of demixing often referred to as particle segregation,

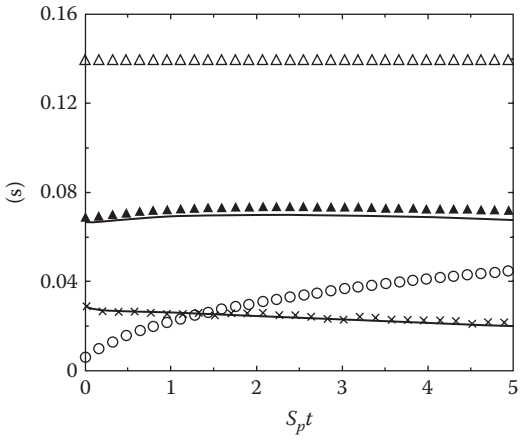

Figure 2.43

Time development of the particle relaxation time and the collision time in homogeneous turbulent shear flow with particle–particle collision influence. Symbols are the stochastic simulation results: mean particle relaxation time τ_{pf}^F (filled triangles), collision time (cross), eddy particle interaction time τ_{pf}^F (circle), Stokes relaxation time (empty triangles) and the lines are predictions from the moment method. (Taken from Moreau, M. et al., Monte Carlo simulation of colliding particles suspended in gas-solid homogeneous turbulent shear flows, in *Proceedings of FEDSM034TH ASME-JSME Joint Fluids Engineering Conference*, Honolulu, HI, Paper FEDSM2003-45736, July 6–10, 2003.)

clustering, or preferential concentration depends upon the ratio of the particle response time to the timescale of the turbulent structures in the flow (i.e., the Stokes number, *St*). Early experiments and simulations (e.g., Crowe et al., 1993) have shown that the demixing reaches a maximum when the particle response time is approximately equal to the timescale of the turbulent structures (i.e., $St \sim 1$) and in particular those associated with the highest strain rate in the flow, the suspended particles being observed to segregate into regions of high strain rate in between the regions of high vorticity. This feature is best illustrated graphically in Figure 2.44, which shows the segregation patterns arising from an initially fully mixed suspension of particles diffusing in a 2D random array of counterrotating vortices. The figure shows the segregation pattern at a given value of time $t = 20$ (in units of the integral timescale) from the initial fully mixed state for three values of the particle Stokes number $St = 0.05$, 0.5, and 5. It is clear that maximum segregation occurs for the case of $St = 1$. What this figure does not show however is the fact that the segregation evolves continuously in time, the patterns becoming more and more filamental as time progresses. Whatever their Stokes number that all particles will segregate, it is just that the greater the Stokes number, the longer the process it takes to achieve a given level of segregation. This is contrary to what many have thought that the segregation reaches an equilibrium state. Particles will continue to segregate until they touch. In fact, what happens is that the segregation forms a network of filamental *caustics* similar to the patterns of light obtained at the bottom of swimming pools as shown in Figure 2.44d, where within these filamental networks it is observed that the light beams cross one another. Similarly, in the case of particle segregation in a turbulent flow within the filamental caustics, particle trajectories are also observed to cross. The formation of caustics in particle demixing processes was first recognized by Wilkinson and Mehlig (2007), and this crossing of trajectories within a caustic is intimately related to the occurrence of random-uncorrelated motion (RUM) in flow fields that are spatially random but smoothly varying (Falkovich et al., 2002, Fevrier et al., 2005).

In recent years, the process of segregation of inertial particles has been studied from different viewpoints when the Stokes number is relatively small. On the one hand, Chen et al. (2006) demonstrated a strong correlation between the positions of small inertial particles and the locations of zero-acceleration points in the carrier flow. On the other hand, Balkovsky et al. (2001) carried out a theoretical analysis based on the assumption that the velocity of inertial particles can be directly related to the carrier flow velocity. By doing so, they were able to show that the segregation of particles continues indefinitely in the course of time, and they showed that the concentration of inertial particles in a turbulent flow is highly intermittent, so the particles are distributed uniformly over space. A similar approach was chosen by Chun et al. (2005) who demonstrated that the time-converged solution of the radial distribution function is of the form $g(r) \sim r^{-\chi}$, where χ is proportional to St_K^2 in which St_K is measured in terms of the particle response to the small dissipating scales of

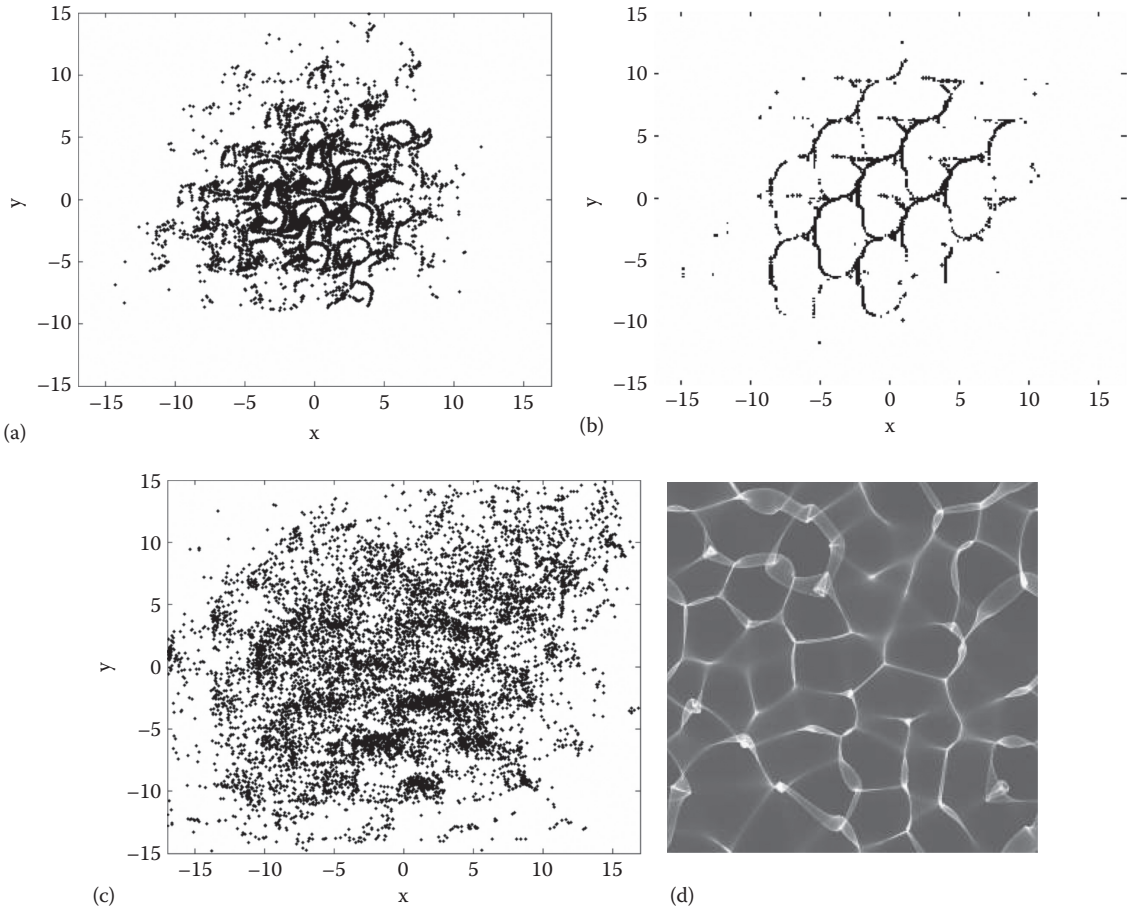

Figure 2.44

(a–c) Positions of 10^4 particles after time $t = 20$ in a nonisotropic random straining flow, for $St = 0.05$ (a), $St = 0.5$ (b), and $St = 5$ (c). (d) Caustic patterns observed at the bottom of a swimming pool.

the turbulence. In addition, they confirmed this by showing results from the DNS of statistically stationary homogeneous isotropic turbulence. Most importantly, the pdf–kinetic approach has been used by Zaichik (Zaichik and Alipchenkov, 2003, 2007) to obtain a similar result. We will discuss these features in more detail in Section 2.5.6.7 on segregation when we will consider the application of two-particle pdfs for calculating segregation using the pdf–kinetic equation for particle pair dispersion derived by Zaichik and his coworkers.

However, before doing so, we will first consider in more detail the mesoscopic and RUM components associated with the particle velocity field and how these components depend upon the particle Stokes number.

2.5.6.6 Formulation of RUM and Mesoscopic Eulerian Particle Velocity Fields

Segregation and RUM are related to the occurrence of interparticle collisions as follows from the seminal work of Sundaram and Collins (1997) and Zhou et al. (1998) in which they demonstrate the following: (1) segregation enhances the particle concentration of certain regions of the flow and (2) RUM, that is, the decorrelation of velocity between particles, causes two nearby particles to collide and possibly to agglomerate. Segregation is well known to manifest itself especially for particle with $St \sim 1$, whereas the effect of RUM is almost invisible for small particles and becomes increasingly important for larger St. Since the interplay between these two effects determines the collision rate in a turbulent flow, it is essential to quantify segregation and RUM as accurately as possible as a function of the Stokes number and some typical flow properties in order to correctly predict the rate of interparticle collisions.

Fevrier et al. (2005) observed that the velocity of suspended particles subject to Stokes drag in the DNS of homogeneous isotropic turbulence consisted of two components: a passive scalar component resulting from transport in a smoothly and continuously varying carrier flow velocity field that accounts for all

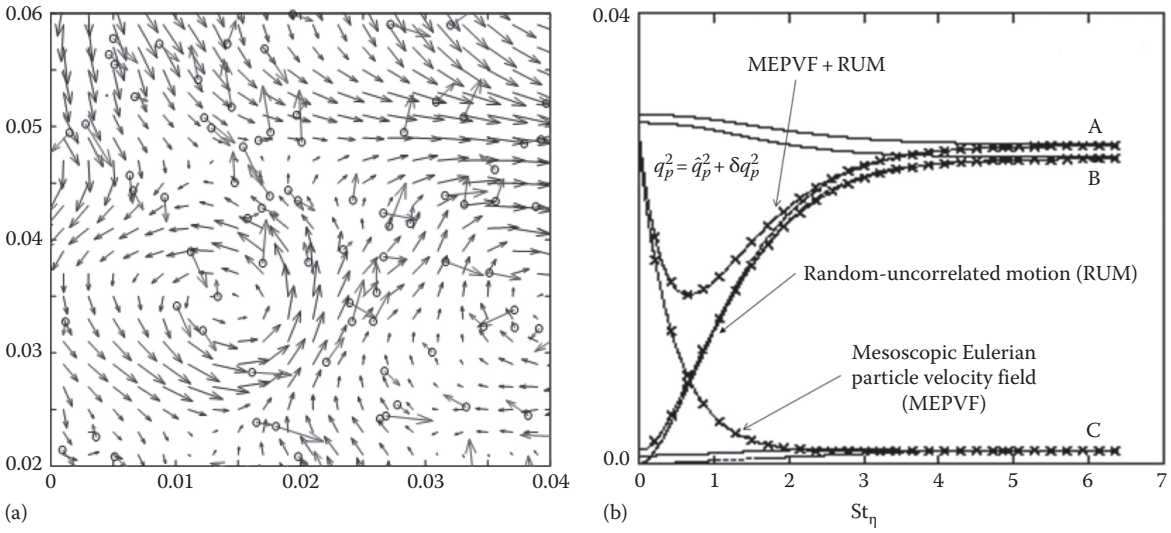

Figure 2.45

Random-uncorrelated motion (RUM): (a) Instantaneous fluid and particle velocity vectors from a single plane of a direct numerical simulation of forced isotropic turbulence with Lagrangian particle tracking. (b) RUM and mesoscopic Eulerian particle velocity field contribution to the particle kinetic energy as functions of Stokes number, St_K.

particle–particle and fluid–particle two-point spatial correlations, which they referred to as the mesoscopic Eulerian particle velocity field (MEPVF), and a spatially uncorrelated component, which we have referred to as RUM, the contribution of which to the particle kinetic energy increases as the particle inertia also increases. FSS attribute this feature to the ability of the particles with inertia to retain the memory of their interaction with very distant and statistically independent eddies in the flow field. This feature had also been observed by Falkovich et al. (2002), which they referred to as the "sling effect."

The presence of RUM in a particle-laden turbulent flow is illustrated in Figure 2.45a taken from FSS (Fevrier et al., 2005), which shows the instantaneous velocity vectors of particles and carrier flow suspended in an isotropic turbulent flow. You can see that a majority of the particle velocity vectors are correlated with a smooth vortex pattern associated with the underlying carrier flow field at that instant of time. But you will notice there are a number of particles whose vectors are randomly oriented and not part of this vortex pattern. It is the motion of these particles that constitutes RUM.

More precisely, Fevrier et al. (2005) quantified the contribution of MEPVF and RUM to the velocity $\boldsymbol{v}_p^m(t)$ of a single particle m by partitioning it into a mesoscopic component derived from the MEPVF $(\boldsymbol{x},t,\mathcal{H}_f)$ (where $\boldsymbol{x}$ is the position in the flow field) and a residual velocity component $\delta\boldsymbol{v}_p^m(t)$ by

$$\boldsymbol{v}_p^m(t) = (\boldsymbol{x}^m(t),t,\mathcal{H}_f) + \delta\boldsymbol{v}_p^m(t) \tag{2.306}$$

where $\mathcal{H}_f$ refers to a single realization of the continuously varying carrier flow velocity field. They pointed out that the MEPVF is defined in an Eulerian frame of reference and therefore may be considered as a velocity field shared by all particles of the dispersed system. In contrast, the total particle velocity $\boldsymbol{v}_p(t)$ and the residual component $\delta\boldsymbol{v}_p(t)$ are Lagrangian quantities defined along trajectories of individual particles $\boldsymbol{x}_p(t)$. The decomposition of the particle velocity given by Equation 6.29 is unique, decomposing the particle velocity into contributions that take into account the spatial structure of the particle velocity field in the first MEPVF term and the spatially uncorrelated motion in the second RUM term (FSS referred to this originally as the quasi-Brownian velocity distribution).

Figure 2.45b shows the contribution of the MEPVF and RUM to the turbulent particle kinetic energy k_p as a function of St_η, the particle Stokes number defined in terms of the Kolmogorov length scale η_K associated with the viscous dissipating length scales of the turbulence for the DNS isotropic homogeneous turbulent flow from which the particle and fluid velocity vectors, as shown in Figure 2.45a, have been extracted. Thus,

$$k_p = \tilde{k}_p + \delta k_p \tag{2.307}$$

where $\tilde{k}_p$ and δk_p are the MEPVF and RUM components of the particle turbulent kinetic energy k_p. Figure 2.45 shows the RUM part starting at zero for zero Stokes number St_η and reaching 100% for $St_\eta \gg 1$, when the particle motion is ballistic (with random velocities in any small volume of the particles). The reverse is the case for the mesoscopic part as a function of St_η.

FSS used the statistics of the particle velocity distribution to evaluate both the Lagrangian temporal correlation and the Eulerian two-point (spatial) correlation, which in this case involves contributions from the MEPVF and RUM. The Lagrangian velocity correlations are defined classically along particle trajectories as

$$R_L^p(\tau) = 1/3\left\langle v_{p,i}(t)v_{p,i}(t+\tau)\right\rangle \tag{2.308}$$

and obtained by averaging over all realizations of the flow for any given particle. This is shown in Figure 2.46a as a function of time t normalized on the fluid Lagrangian integral timescale T_L (along a particle trajectory) for a range of values of the particle Stokes numbers τ_p/T_L. It shows the well-known effect of particles becoming less correlated with their initial velocity with increasing time but becoming more persistent with increasing particle inertia.

The two-point velocity correlation of any two (separate) particles labeled m and n of the system is defined in terms of the two-particle pdf and expressed as

$$R_{ij}^{pp}(\boldsymbol{x},\boldsymbol{x}+\boldsymbol{r},t) = \left\langle v_{p,i}^{(m)}(t)v_{p,j}^{(n)}(t)\middle|\boldsymbol{x}=\boldsymbol{x}_p^{(m)}(t);\boldsymbol{x}+\boldsymbol{r}=\boldsymbol{x}_p^{(n)}(t)\right\rangle \tag{2.309}$$

The dependence on the separation r normalized on the longitudinal integral length scale L_F^f of the carrier flow turbulence is shown in Figure 2.46b for the same values of the particle inertia as in Figure 2.46a. An important result revealed in these spatial correlations is that in the limit $r/L_F^f \to 0$ this correlation does not $\to 1$, indicating that there is a portion of the particle velocity distribution that is not correlated in time or space, that is, the RUM component and analogous to the molecular distribution in kinetic theory of dilute gases. FSS note that if particle motion was completely analogous to molecular motion in a dilute system, the particle positions (in addition to the velocities) would be uncorrelated and the velocity distribution would be Gaussian. For a dilute particle-laden turbulent flow, this component satisfies the molecular chaos assumption.

In the seminal paper of FSS and in the subsequent work of Masi et al. (2010, 2011), a mesoscopic Eulerian formalism (MEF) involving contributions from the MEPVF and RUM has been developed and applied to

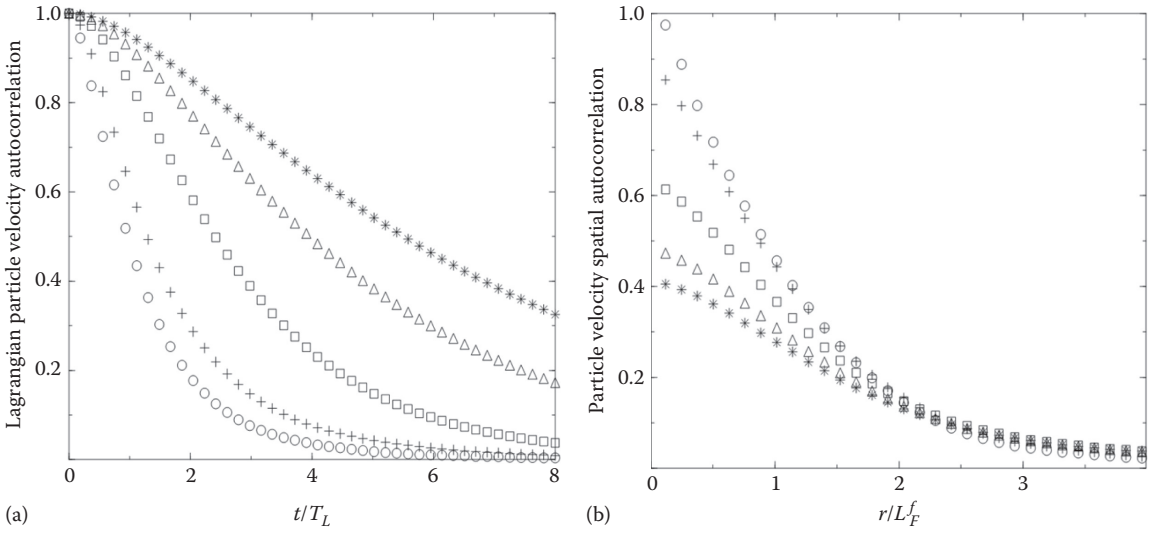

Figure 2.46

Influence of particle inertia on (a) Lagrangian particle velocity correlations and (b) the particle longitudinal spatial correlation function of particles suspended in isotropic turbulence. o, $\tau_p/T_L = 0.05$; +, $\tau_p/T_L = 0.3$; □, $\tau_p/T_L = 1.47$; Δ, $\tau_p/T_L = 3.4$; *, $\tau_p/T_L = 4.83$.

dispersed flows in more complex turbulent shear flows with heat transfer. In particular, the transport equations that describe the evolution of the MEPVF and RUM components have been derived and used to shed light on the properties of the particle velocity and temperature fields. In this regard, MEF has much in keeping with LES where the filtered equations for the large-scale and residual small-scale turbulent motion in LES are analogous to the MPVF and RUM components in MEF. So, for instance, the momentum equations for the MEPVF contain a contribution from the RUM component of the kinetic stress tensor. This tensor represents diffusion and pressure corresponding to the important physical characteristic that within any volume (with dimensions comparable to or smaller than the smallest length scales of the turbulence), separate particles will possess different velocities because of the separate fluid interaction histories. This is the case shown in Figure 2.46a.

2.5.6.7 Pdf Equation and solutions for particle pair dispersion

In this section, we show the way the pdf approach for two-particle dispersion quantifies segregation and RUM and provides a method for calculating particle collision kernel of colliding particles, reflecting the contribution of both processes to the collision rate. We recall the formula in Equation 2.287 that provides an analytic expression for the collision kernel, which, in principle, can be used over the entire range of the scales of turbulence from the large-scale to the small-scale Kolmogorov dissipating scales. We recall, however, recall that it assumes the particles are fully mixed (zero segregation) and that particle velocities are dependent on particle fluid velocity correlations based on a local equilibrium between particle and fluid at the same location. So while this approach is quite valid for the large scales of the turbulence where there is an absence of shear, in the small scales where the shearing of the flow is greatest, the memory of encounters with fluid elements at higher separation and hence higher relative velocities makes a significant contribution to the collision rate. It is of course encounters of this sort for particles transported in a turbulent boundary layer that gives rise to the buildup of particle concentration near the wall and higher wall impact velocities, the combination of both having a profound influence on particle–wall collision rates.

So, we consider a kinetic equation for the particle pairs $P(\boldsymbol{r}, \boldsymbol{w}, t)$, where $\boldsymbol{w}$ is the relative velocity between identical particle pairs a distance $\boldsymbol{r}$ apart for which the corresponding relative fluid velocity experienced by the particle pair is $\Delta\boldsymbol{u}(\boldsymbol{r}, t)$. The statistical properties of $\Delta\boldsymbol{u}(\boldsymbol{r}, t)$ are expressed in terms of its statistical moments that for the small scales of turbulence have spherical symmetry (independent of (θ, ϕ)) dependent only on the distance of separation r. These, therefore, are the structure functions of which the most relevant here are the second-order structure functions $\left\langle \Delta u_r^2(r) \right\rangle, \left\langle \Delta u_\theta^2(r) \right\rangle \sim \left(r/\eta_K\right)^2$ for $r/\eta_k \ll 1$. The equation of motion for $\boldsymbol{w}$ for identical particle pairs is exactly the same as that for the individual particles, so the pdf equation is identical to Equation 2.204 with $\boldsymbol{w}, \boldsymbol{r}, \Delta\boldsymbol{u}$ replacing $\boldsymbol{v}, \boldsymbol{x}, \boldsymbol{u}$. Thus,

$$\left(\frac{\partial}{\partial t} + \boldsymbol{w}\cdot\frac{\partial}{\partial \boldsymbol{r}} - \beta\frac{\partial}{\partial \boldsymbol{w}}\cdot\boldsymbol{w}\right)P(\boldsymbol{w},\boldsymbol{r},t) = -\beta\frac{\partial}{\partial \boldsymbol{w}}\cdot\overline{\Delta\boldsymbol{u}}P \tag{2.310}$$

Using the LHDI or Furutsu–Novikov-based closures, similar to Equations 2.204 and 2.210, we have

$$\beta\overline{\Delta\boldsymbol{u}}P(\boldsymbol{r},\boldsymbol{w},t) = -\left(\frac{\partial}{\partial \boldsymbol{r}}\boldsymbol{\lambda} + \frac{\partial}{\partial \boldsymbol{w}}\cdot\boldsymbol{\mu} - \boldsymbol{\kappa}\right)P(\boldsymbol{r},\boldsymbol{w},t) \tag{2.311}$$

with similar expressions for $\boldsymbol{\lambda}$, $\boldsymbol{\mu}$, and $\boldsymbol{\kappa}$ as those given in Equation 2.205 (Furutsu–Novikov closure) or Equation 2.210 (LHDI) (with velocities and displacements replaced by relative velocities and displacements and the fluctuating force $\boldsymbol{f}$ replaced by $\beta\Delta\boldsymbol{u}(\boldsymbol{r}, t)$, noting that for the small-scale turbulence $\langle\Delta\boldsymbol{u}(\boldsymbol{r}, t)\rangle = 0$. To consider the kinetic equation used by Zaichik and Alipchenkov (2003), we can write Equation 6.311 alternatively as

$$\beta\overline{\Delta\boldsymbol{u}}P(\boldsymbol{r},\boldsymbol{w},t) = \left(-\boldsymbol{\lambda}^T\cdot\frac{\partial}{\partial \boldsymbol{r}} - \boldsymbol{\mu}^T\cdot\frac{\partial}{\partial \boldsymbol{w}}\cdot + \boldsymbol{\kappa} - \nabla\cdot\boldsymbol{\lambda}\right)P(\boldsymbol{r},\boldsymbol{w},t)$$

Zaichik and Alipchenkov (2003, 2007, 2009) assume that

$$\boldsymbol{\kappa} - \nabla\cdot\boldsymbol{\lambda} = 0 \tag{2.312}$$

which is only true in homogeneous turbulence without body forces. It ignores therefore the extra drift that arises because of particle segregation in inhomogeneous flows. However, bearing this in mind, we will consider the results Zaichik obtained from the specific solutions of the moment equations obtained from Equation 2.310 using 2.311 with the drift term set equal to zero and using specific forms for $\left\langle \Delta u_r^2(r) \right\rangle, \left\langle \Delta u_\theta^2(r) \right\rangle$. The momentum equations are similar to those in the 1D case (appropriate for the boundary layer) except that now with spherical symmetry (θ, ϕ) independence, there is a contribution from centrifugal forces. Thus, at equilibrium and for an isotropic stationary flow, using Equation 2.312,

$$-(\boldsymbol{S}_2^p + \boldsymbol{\lambda}^T) \cdot \nabla \langle \rho \rangle - \langle \rho \rangle \nabla \cdot \boldsymbol{S}_2^p = 0 \tag{2.313}$$

where $\boldsymbol{S}_2^p(\boldsymbol{r})$ is shorthand for $\langle \boldsymbol{w}(\boldsymbol{r}, t)\boldsymbol{w}(\boldsymbol{r}, t) \rangle$. Again, if we multiply this equation by β^{-1}, this can be interpreted as an equation representing a balance between diffusion and what we have called turbophoresis.

Referring to Equation 2.247, we have the transport equation for $\boldsymbol{S}_2^p$ as

$$\boldsymbol{S}_2^p = \frac{1}{\beta} \boldsymbol{\mu}^S - \nabla \cdot \langle \rho \rangle \boldsymbol{S}_3^p \tag{2.314}$$

where $\boldsymbol{S}_3^p = \left\langle \boldsymbol{w}(\boldsymbol{r},t)\boldsymbol{w}(\boldsymbol{r},t)\boldsymbol{w}(\boldsymbol{r},t) \right\rangle$. We note, however, that in this case we have spherical symmetry (independent of orientation) and consider only variation along the particle pair separation r, in which the turbophoretic drift, termed in Equation 2.313, along the line of centers of the particle pairs contains an effective component arising from the centrifugal force. Thus, using the same notation as that of Zaichik and denoting $\overline{w_r^2(r)}$ by $S_{2,ll}^p(r)$ and $\overline{w_\theta^2(r)}$ by $S_{2,nn}^p(r)$, the longitudinal component of the turbophoretic velocity (along the line of centers $\overline{w}_r$) is given by

$$\overline{w}_r = \beta^{-1} \left(\frac{2(S_{2,nn}^p - S_{2,ll}^p)}{r} - \frac{dS_{ll}^p}{dr} \right)$$

which then gives the following equation upon combining this term with the radial component of the first term in Equation 2.313:

$$\frac{2(S_{2,nn}^p - S_{2,ll}^p)}{r} - \frac{dS_{ll}^p}{dr} - (\lambda_{ll} + S_{2,ll}^p) \frac{d \ln \langle \rho \rangle}{dr} = 0 \tag{2.315}$$

If we define $\langle \rho \rangle = 1$ for $r \to \infty$, then $\langle \rho \rangle$ becomes the radial distribution $g(r)$. A separate equation for $S_{2,ll}^p$ and $S_{2,nn}^p$ based on Equation 2.314 using the C–E approximation for $\boldsymbol{S}_3^p$ (see Equation 2.248), together with the longitudinal momentum balance Equation 2.315, gives a final set of closed equations for $g(r)$, $S_{ll}^p(r)$, S_{nn}^p (see Zaichik and Alipchenkov, 2003, 2009) that can be solved with appropriate boundary conditions using measured forms for the longitudinal and transverse structure functions for turbulence and integral timescales. These equations in principle, encompass both the large and small scales of the turbulence. The empirical forms used by Zaichik cover both the dissipating range and subinertial range with pair separation scaling as the Kolmogorov length scale η_K and the Kolmogorov timescales τ_K. β^{-1} then becomes the Stokes number $St_K = (\beta\tau_k)^{-1}$. Interestingly, Bragg and Collins (2014a,b) show that ignoring the influence of the divergence terms in Equation 6.314 with $\boldsymbol{S}_2^p = \frac{1}{\beta} \boldsymbol{\mu}^S$ gives a +ve value for $\overline{w_r}$ indicating that the inward –ve drift responsible for clustering arises entirely from the divergence term associated with the third-order moment in Equation 2.314. Furthermore, a *+ve* drift would suggest that the net outward–inward radial pressure gradient is outweighed by the centrifugal force.

Figure 2.47 illustrates the influence of particle inertia measured by the value of Stokes number St_K (associated with the small-scale turbulence) on the mean absolute relative velocity $\langle |w_r| \rangle$ over a wide range of Stokes numbers St_K, $\langle |w_r| \rangle$ being defined in terms of the particle longitudinal structure function using the formula

$$\left\langle |w_r| \right\rangle = \left(\frac{2}{\pi} \langle w_r'^2 \rangle \right)^{1/2} = \left(\frac{2}{\pi} S_{ll}^p \right)^{1/2}$$

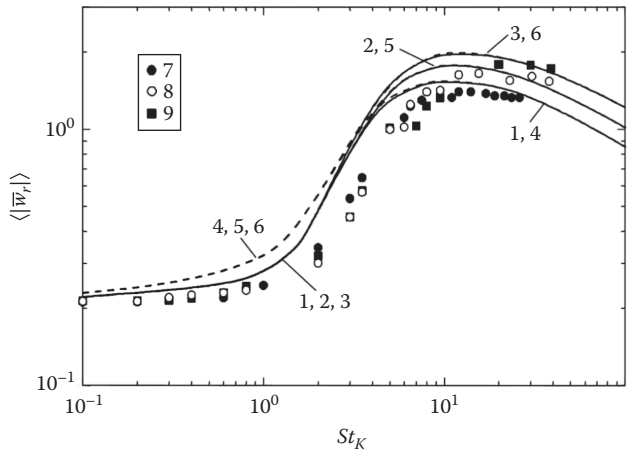

Figure 2.47

Influence of particle inertia St_K on the mean relative velocity magnitude $\langle|w_r|\rangle$ in units of $(\nu\varepsilon)^{1/4}$ for $r/\eta_K = 1$: 1–3, predictions with $r_C/\eta = 0$; 4–6, predictions with $r_C/\eta = 1$; 7–9, direct numerical simulation (Wang et al., 2000); 1, 4, 7, $Re_\lambda = 45$; 2, 5, 8, $Re_\lambda = 58$; 3, 6, 9, $Re_\lambda = 75$.

which assumes a Gaussian distribution for w_r. As is clear, both the predictions and the numerical simulations follow the same trend and indicate a pronounced maximum of $\langle|w_r|\rangle$ as a function of St_K. The initial rise in $\langle|w_r|\rangle$ is attributable to a decrease in the correlation of particle velocities with St_K manifested as RUM. The subsequent decay of $\langle|w_r|\rangle$ beyond the maximum results from a decrease in the particle fluctuating velocities, since the particles become more sluggish and less responsive to the fluid turbulence. Note the similarity to the deposition velocities k^+ as a function of τ^+ for particle deposition in turbulent pipe flow (see Figure 2.38). From Figure 2.47, it is also seen that the predictions with $rc/\eta_K = 1$ overestimate the DNS data at small Stokes numbers. The predictions that correspond to *ghost* particles lead to slightly smaller values of mean relative velocities at small St_K. However, a difference in the mean relative velocities of zero-size and finite-size particles takes place only for relatively small Stokes numbers and vanishes at large St_K.

Figure 2.48a shows the influence of Stokes number St_K on the radial distribution function (RDF) $g(r)$ for the separation $\overline{r} = r/\eta_K$ and Reynolds numbers Re_λ, corresponding to the DNS measurements of Wang et al. (2000). As expected, in the limiting cases of zero-inertia and high-inertia particles, the concentration field is statistically uniform, and so $g(r) = 1$. In accord with the computations, the predicted RDF passes through a peak as St_K increases. Thus, there exists a critical St_K that results in a maximum preferential concentration as simulations demonstrate (see Figure 2.44). Figure 2.48a shows a qualitative agreement between the predicted and simulated RDFs at particle contact, although the predicted effect

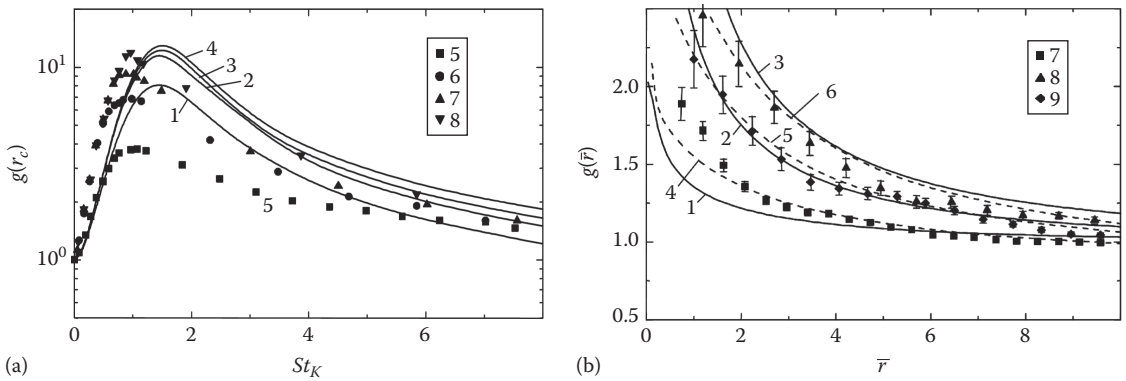

Figure 2.48

(a) RDF as a function of St_K for $r_c/\eta_K = 1$: 1–4, predictions; 5–8, direct numerical simulation (Wang et al., 2000); 1, 5, $Re_\lambda = 24$; 2, 6, $Re_\lambda = 45$; 3, 7, $Re_\lambda = 58$; 4, 8, $Re_\lambda = 75$. (b) RDF $g(r)$ as a function of particle pair separation $\overline{r} = r/\eta_K$: 1–3, predictions; 4–6, DNS (Salazar et al., 2008); 7–9, experiments (Salazar et al., 2008); 1, 4, 7, $St_K = 0.21$, $Re_\lambda = 108$; 2, 5, 8, $St_K = 0.4$, $Re_\lambda = 134$; 1, 4, 9, $St_K = 0.6$, $Re_\lambda = 147$.

of Re_λ is not as strong as it was in simulations and the maxima of $g(r)$ with St_K are slightly shifted toward particles with larger inertia.

2.5.6.8 Analytic Forms for S_2^p and RDF for Inertial Particles

Figure 2.48b shows good agreement of Zaichik and Alipchenkovs' (2009) (Z&A) predictions for the RDF of finite-size particles with low-inertia particles $St_K \lesssim 1$, with both the experimental measurements and DNS calculations of Salazar et al. (2008). In addition, Zaichik and Alipchenkov (2009) have obtained analytic expressions for the particle second-order structure functions $S^p_{2,ll}(r)$, $S^p_{2,nn}(r)$ and the RDF $g(r)$ as a function of St_K for low-inertia particles $St_K \lesssim 1$ with $r_c/\eta_K \ll 1$ as solutions of their closed set of equations for the momentum and kinetic stresses for the relative motion of particle pairs. In this case, the set of equations for ghost particles (overlapping spherical particle pairs) in the vicinity of the origin $\bar{r} = 0$ are solved without regard for bc's and the solutions are expressed in the form

$$S^p_{2,ll} = \alpha_l \bar{r}; \quad S^p_{2,nn} = \alpha_n \bar{r}; \quad g(\bar{r}) = C_g \bar{r}^{\chi} \tag{2.316}$$

in which the $S^p_{2,ll}$,S^p_{nn} coefficients α_l and α_n as well as the RDF exponent χ are functions St_K and Re_λ.

Figure 2.49* compares the exponent χ with DNS data for Re_λ = 47 and for Re_λ = 83, as well as with experimental and numerical data obtained in the range of Re_λ from 108 to 149. As is seen in Figure 2.49, the α_l coefficient and χ are well approximated if $St_K < 0.6$ and $Re_\lambda > 30$ by

$$\begin{aligned} \alpha_l &= \frac{1}{15} + 0.16St_K - 0.21St_K^2 + 0.18St_K^3 \\ \chi &= -6St^2 + 9.8St^3 - 6.2St^4 \\ C_g &= 1 + 12St_K^2 \end{aligned} \tag{2.317}$$

The predicted values of χ are in excellent agreement with DNS results (Chun et al., 2005), but they markedly overestimate those obtained by Salazar et al. (2008) and underestimate those given in Falkovich and Pumir (2007) for relatively large Stokes number.

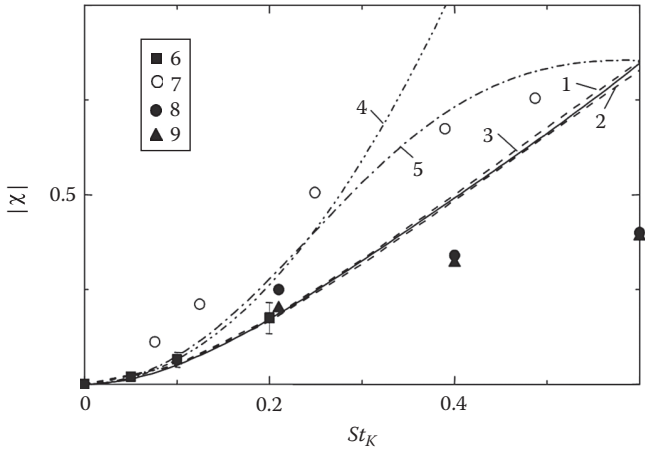

Figure 2.49

Effect of the Stokes number St_K on the power-law exponent of the RDF: 1 and 2, solutions to momentum and kinetic stresses (Equation 2.315) (for Re_λ = 30 and ∞); 3, 4, and 5, approximation equations (Zaichik and Aliphenkov, 2009; Chun et al., 2005) and (Derevyanko et al., 2008); 6, direct numerical simulation (DNS) (Chun et al., 2005); 7, DNS (Falkovich and Pumir, 2007); 8, experiment (Salazar et al., 2008); 9, DNS (Salazar et al., 2008).

* As Z&A point out, of great interest is the derivation of analytic solutions to the problem of preferential concentration of low-inertia particles at large Reynolds numbers as these exist in atmospheric conditions, because to date it is not possible to reach the atmospheric Reynolds number using DNS. Furthermore, the values of St_k and the particle size related to the Kolmogorov length scale for typical atmospheric aerosols and rain droplets are less than those realizable in both direct simulations and laboratory experiments.

Shown in Figure 2.49 is the theoretical dependence derived by Chun et al. (2005) for $St_K \ll 1$, namely,

$$\chi = -6.56St_K^2 \tag{2.318}$$

and the approximation obtained by Derevyanko et al. (2008) using the DNS data of Falkovich and Pumir (2004, 2007), namely,

$$\chi = -0.75St_K^2/(0.1 + St_K^3) \tag{2.319}$$

As can be observed, the dependences in Equations 2.316 and 2.317 correlate quite well with those given by Equations 2.316 at $St_K < 0.1$ are significantly greater when $St_K > 0.1$.

It is worth commenting on the agreement between the model predictions of Chun et al. (2005) in Equation 2.317 and that of Z&A's pdf results based on Equation 2.316, since the two approaches are seemingly very different and in the past have been the source of some controversy (Bragg and Collins, 2014a, Devenish et al., 2012). Only until recently has this agreement and lack of similarity in approach been properly explained [Bragg and Collins 2104a,b]. The probabilistic approach of Chun et al. (2005) is strictly limited to $St \ll 1$, which in essence treats the particles as passive scalars transported by their own velocity field $\boldsymbol{v}(\boldsymbol{r}, t)$ (in the case of two-particle dispersion, it is the relative particle velocity field between particles a distance r apart). The collision flux is modeled as the sum of two parts, namely, a *shear* diffusion flux $\boldsymbol{q}_D$, which depends on the mean concentration gradient of the satellite particles surrounding a target primary particle and a drift flux $\boldsymbol{q}_d$ that depends upon the local mean concentration of satellite particles and the compressibility of the relative particle velocity field. Explicitly for small Stokes numbers, where the concentration gradient is a small perturbation on the uniform concentration for passive tracers,

$$\boldsymbol{q}_i^D = -D_{ij}\frac{\partial\langle\rho\rangle}{\partial r_j}; \quad D_{ij}\int_{-\infty}^{t}\langle v_i(\boldsymbol{r},t)v_j(\boldsymbol{r},t|t')dt'$$

where

$v_j(\boldsymbol{r}, t|t')$ is the velocity of a particle at time t' that arrives at $\boldsymbol{r}$ at time t

D_{ij} is the dispersion coefficient for relative dispersion

and

$$\boldsymbol{q}^d = -\int_{-\infty}^{t}\langle \boldsymbol{v}(\boldsymbol{r},t)\nabla\cdot\boldsymbol{v}(\boldsymbol{r}^p(\boldsymbol{r},t|t'),t')dt'\langle\rho\rangle \tag{2.320}$$

which explicitly involves the divergence $\nabla\cdot\boldsymbol{v}(\boldsymbol{r}^p(\boldsymbol{r}, t)$ of the relative particle velocity field along a particle trajectory $\boldsymbol{r}^p(\boldsymbol{r}, t|t')$ that arrives at $\boldsymbol{r}$ at time t. We note that the form for the drift flux is the same as the form proposed by Maxey (1987) for the enhancement of drift due to gravity and the form derived by Reeks (2012) for particle dispersion in an inhomogeneous compressible flow field. In cases when $St_K \ll 1$, the particle pair equation of motion may be used to approximate $\boldsymbol{w}$ by

$$\boldsymbol{w} = \Delta\boldsymbol{u} - St_K\tau_K\boldsymbol{w}\cdot\nabla\boldsymbol{w} \tag{2.321}$$

Then substituting this in Equation 2.319, we obtain

$$\boldsymbol{w}_T = -\frac{1}{3}St_K\tau_K\boldsymbol{r}\left\langle S^2(\boldsymbol{x}^p(t),t) - R^2(\boldsymbol{x}^p(t),t)\right\rangle \tag{2.322}$$

where S^2 is shorthand for $\boldsymbol{S}$: $\boldsymbol{S}$,$\boldsymbol{S}(\boldsymbol{x}, t)$ being the local symmetric strain rate tensor and similar R^2 for $\boldsymbol{R}$: $\boldsymbol{R}$ $\boldsymbol{R}$ being the rotation tensor. From the force balance equation of Zaichik, we have:

$$\boldsymbol{w}_T = -St_\eta\tau_\eta\langle\rho\rangle\nabla\cdot\boldsymbol{S}_2^p$$

Bragg and Collins (2014a) have shown that using the energy equation for $\boldsymbol{S}_2^p$ and associated closure for $\boldsymbol{S}_3^p$ as Zaichik and Alipchenkov (2009) have done leads to the same expression as in Equation 2.321.

2.5.6.9 Collision Kernel Predictions

We recall the formula for the collision kernel given in Equation 2.279 that indicates the dependence upon two multiplicative factors, the RDF $g(r)$ (due to segregation/preferential concentration) and the collision speed $\langle|w_r|\rangle$, both of which are enhanced by the dependence on particle Stokes number St_K from their fluid tracer values, that is, $g(r)$ due to segregation and $\langle|w_r|\rangle$ due to inertial impaction at the collision surface, both peaking around $St_K \sim 1$. Assuming a Gaussian distribution of velocities w_r at the collision radius r_c and substituting the formulae given in Equations 2.315 for S_{ll}^p and $g(r_c)$, we obtain

$$\Gamma = \overline{r}\left(8\pi\alpha_l\right)^{1/2} C_g\left(\overline{r}_c\right)^{-\chi+3}\left(\frac{\eta_K^3}{\tau_K}\right) = \frac{r}{\eta_k} \tag{2.323}$$

Figure 2.50 shows the behavior of the collision rate predicted by the formula for Γ in Equation 2.322 as a function of the Stokes number $St_K < 0.6$ and collision radius r_c/η_K; in each case, $\Gamma(St_K)$ rises monotonically from the Stuart and Turner value at $St = 0$ for a passive scalar. The Z&A predictions compare favorably with the DNS results of Wang et al. (2001) for low-inertia particles. Figure 2.50 also shows the collision rate of Derevyanko et al. (2008), which accounts for segregation and singularities in the particle concentration (referred to as sling effects). In (60), the RDF exponent is specified by (43).

2.5.6.10 Particle Pair Dispersion RUM and Caustics

In this section, we examine in more detail the relationship between caustics and RUM and the way they have been quantified. In this regard, we refer specifically to the recent work of Bragg and Collins (2014b) who compared the pdf model of Zaichik and a more recent pdf model of Gustavsson and Mehlig (G&M) (Gustavsson and Mehlig, 2011) with DNS results in a Stokes number regime where the formation of caustics and the presence of RUM made a significant contribution to the particle pair structure function $S_{ll}^p(\overline{r})$. In Section 2.5.6.6, we described the observation first made by Fevrier et al. (2005) that the particle velocity field associated with a suspension of inertial particles in a turbulent flow could be split into two parts: a smoothly varying component (the mesoscopic particle velocity field, MEVPM) that was responsible for the finite spatial and temporal correlations of the particle motion and a totally RUM component. The extent to which these components contributed to the overall particle motion and in particular to the particles' kinetic energy that depended upon the particles Stokes number: for $St = 0$ the particle velocity was all derived from the MEPVF and for St

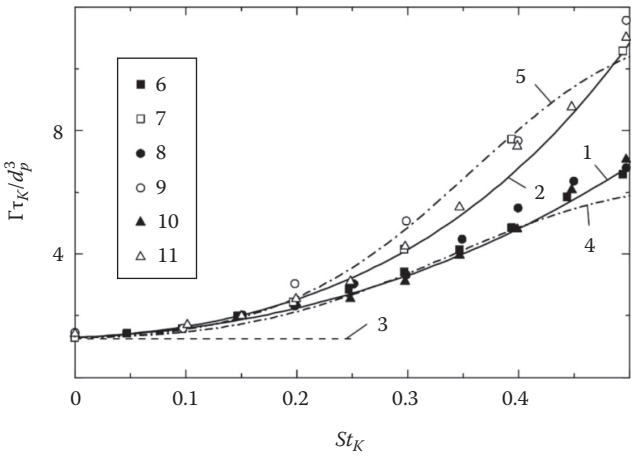

Figure 2.50

Effect of the Stokes number on the collision kernel Γ of low-inertia particles: 1 and 2, Equation 2.322; 3 (Saffman and Turner, 1956); 4 and 5 (Derevyanko et al., 2008); 1, 4, 6, 8, and 10, $r_c/\eta_k = 1$; 2, 5, 7, 9, and 11, $r_c/\eta_K = 0.5$; 6–11, direct numerical simulation (Zhou et al., 1998); 6, 7, $\mathrm{Re}_\lambda = 45$; 8 and 9, $\mathrm{Re}_\lambda = 59$; 10 and 11, $\mathrm{Re}_\lambda = 75$. Particle diameter $d_p = r_c$.

$\to \infty$ it was all RUM. It meant that the particle velocity at any one point in the field was not single valued, and particle trajectories could cross. Simonin et al. (2006) recognized that these features could be explained quite easily by a two-point statistical pdf approach. Thus, in the frame of reference of a moving particle, the RUM component represented the distribution of velocities that existed at point ignoring the fact that particles have a finite radius and could overlap (such particles being referred to as ghost particles). It is this RUM component that is responsible for particle collisions. Thus, according to this formalism, the total kinetic energy of the particulate phase is represented as the sum of the relevant contributions

$$k_p = \tilde{k}_p + \delta k_p$$

where $k_p = \tilde{k}_p + \delta k_p$ and δk_p are the mesoscopic-correlated and random-uncorrelated energy components. These two parts of the particle kinetic energy are expressed in terms of the second-order particle structure function S_{ll}^p as

$$\tilde{k}_p = \frac{S_{ii}^p(0) - S_{ii}^p(\infty)}{4} \quad k_p = \frac{S_{ii}^p(0) - S_{ii}^p(\infty)}{4} \tag{2.324}$$

Figure 2.51 shows the influence of St_K on the correlated (MEPVF) and uncorrelated (RUM) energy components as fractions of the total particle kinetic energy. As is clear, the model predictions obtained from the formulae in Equation 2.323 are in good agreement with the results of numerical simulations and follow the predicted asymptotic behavior with St_K. Compare these results with those shown earlier in Figure 2.45. We recall that RUM and the formation of caustics are intimately related. As an illustration we refer back specifically to the filamental network of caustics shown in Figure 2.44, where we remarked that within a caustic envelope particle trajectories cross one another. It happens because in any caustic there is a folding over of the particle phase space $\boldsymbol{v}, \boldsymbol{x}$ manifold so that particle trajectories double back on themselves, retracing their paths but in opposite directions similar to the motion of many particles distributed uniformly in a simple harmonic potential where at any one point there exists at least two velocities arising from particles traveling in opposite directions along the same trajectory. This feature is illustrated explicitly in Figure 2.52b showing a 2D caustic within which the particle velocities at any one point are multivalued. Outside of the caustic, the particle flow field is single valued corresponding to the smoothly varying mesoscopic velocity field (MEPVF) of FSS (Fevrier et al., 2005). The boundary between the single and multivalued flow fields defines the caustic envelope. The particle velocities within any one particular caustic are not random but are related to one another. It is only because the caustics themselves are randomly distributed in space and time that the particle motion associated with the caustics becomes random and uncorrelated at any one point fixed in space, that is, RUM. The RHS of Figure 2.52 shows the corresponding concentration of particles within the caustic where in the vicinity of the caustic envelope it is significantly enhanced.

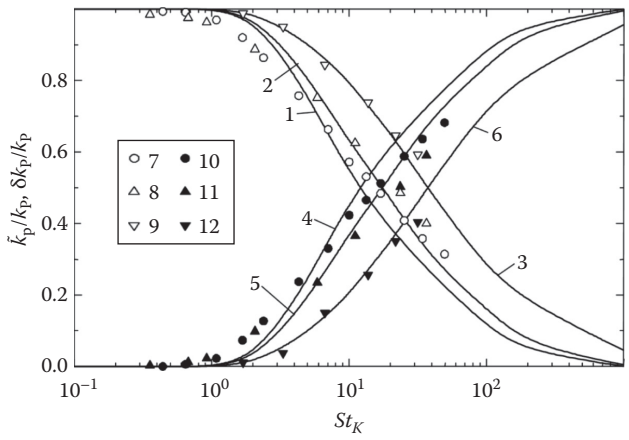

Figure 2.51

Effect of particle inertia on the mesoscopic Eulerian particle velocity field (1–3, 7–9) and random-uncorrelated (4–6, 10–12) components of the particle kinetic energy: 1–6, predictions; 7–12, direct numerical simulation (Fevrier et al., 2005); 1, 4, 7, and 10, $Re_\lambda = 52$; 2, 5, 8, and 11, $Re_\lambda = 67$; 3, 6, 9, and 12, $Re_\lambda = 134$.

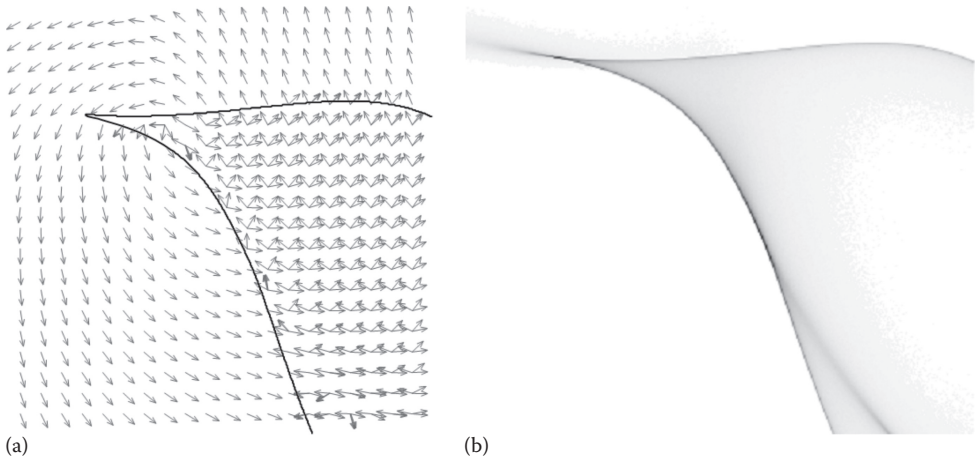

Figure 2.52

(a) Multivalued velocities of particles suspended in a 2D random flow with finite St_K. The orientation of the velocity is that of the arrow. All arrows have the same length (the magnitudes of the velocities are not shown). The blue line delineates the position of the caustics in the x–y-plane. The region of multivalued velocities ends in a cusp that is only approximately resolved. (b) Corresponding particle density in the *x*–*y*-plane, showing significantly enhanced particle number density in the vicinity of the caustic line. Black corresponds to high density and white to low density.

Indeed, the caustic envelope is a line of singularities in the particle concentration being the points at which the particle trajectories are at their extremities and turn back on themselves. The particle trajectories in these circumstances are nonlocal, with the particles possessing a memory of their history of the previous encounters with turbulent eddies. Bragg and Collins (2014b) refer to this as "scale breaking," the particle motion being more associated with the scaling of the inertial subrange and to dependence on Re_λ rather than the dissipating scales in the vicinity of the collision surface. It is this feature that greatly enhances the possibility of particles colliding with one another.

Further insights into the occurrence of caustics on the way they scale and depend on St_K can be inferred from the form of the particle structure function $S_{ll}^p(r)$ as a function of separation based on the predictions by Bragg and Collins (2014b) using Zaichik's pdf model shown in Figure 2.53 for three different Stokes

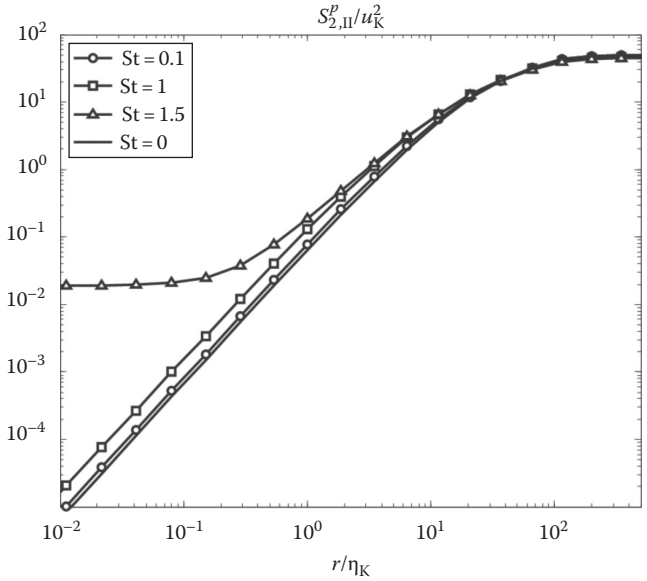

Figure 2.53

The predictions of Bragg and Collins (2014b) on Zaichik's probability density function model predictions of the particle velocity structure function.

numbers St_k. We note that for each value of St_K, $S^p_{2,ll} \geq S^f_{2,ll}$ (the fluid structure functions corresponding to $St_K = 0$) for $r/\eta_k \lesssim 10$, which must be entirely due to nonlocal effects of the particle pair relative motion arising from the contribution of the gradient of the third-order energy flux moment in Equation 2.314. In the case of $St_K = 1.5$, there are clearly two distinct regions for $S^p_{2,ll}$, a power-law region for $r/\eta_K > 0.3$ and a plateau region at smaller separations that follows, resulting in a nonzero intercept for $S^p_{2,ll}$ in the limit $r \to 0$. This is similar to the behavior of depositing particles in a turbulent boundary layer where we recall that particles may start out in local equilibrium far away from the wall but their inability to follow the steep changes in the fluid velocity means that at any point the particles have some memory of their previous history—their velocity has more to do with where they came from than what is happening to the fluid motion locally. The region over which $S^p_{2,ll}(r)$ is roughly constant and significantly different from its local is roughly constant is known as the free flight to the wall region in the particle–wall deposition models. At larger separations, $S^p_{2,ll} \leq S^f_{2,ll}$, implying that the particle's relative motion is growing increasingly local with increasing separation, the form of Δu becomes statistically independent of separation at the integral scales of the turbulence. Moreover, at large separations, the particles become independent of each other, causing the structure function to approach twice the kinetic energy of the particles, a decreasing function of the particle Stokes number due to the filtering effect of particle inertia (Fevrier and Simonin, 1998, Fevrier et al., 2005). Note that all of these trends qualitatively match those found in the DNS study of Salazar and Collins (2012).

Bragg and Collins (2014b) have compared their DNS results based on Zaichik's kinetic equation–based model predictions with that of the theory of G&M (Gustavsson and Mehlig, 2011), which focuses on the existence of caustics and the link they have between RUM and the smoothly varying mesoscopic component and the particle structure function. They use a pdf equation for the particle pair separation and relative velocity; however, Δu is approximated so that the pdf equation they derive is a classical Fokker–Planck equation ($\lambda = 0$, in the kinetic equation of Zaichik) and is therefore only strictly valid for $S_K \ggg 1$. From this, they construct approximate analytical expressions for the moments of the pdf in the dissipation range of the form

$$m_N = f_N \left(\frac{r}{\eta_K} \right)^{N+D_2-1} + g_N \left(\frac{r}{\eta_K} \right)^{d-1} \tag{2.325}$$

where

the subscript N refers to the order of the moment
D_2 is the phase space correlation dimension
d is the physical space dimension (i.e., $d = 3$ for a 3D flow)

The first term on the rhs of Equation 2.325 describes the smooth part of the relative velocity moment and the second term describes the caustic (RUM) contribution, that is, that associated with the nonlocal particle dynamics. The theory is unclosed since $f_N(St_K)$ and $g(St_K)$ are unknown functions (as in D2), although they state that their numerical results imply that $g_N(St_K)$ is of an activated form (i.e., modeled using an Arrhenius rate expression, in which the Stokes number plays the role of temperature in the classical expression). The influence of Re_λ in the G&M theory would be contained in its effect upon the unspecified variables f_N, g_N, and D_2. The particle second-order structure function is found from Equation 2.325 by $S^p_{2,ll} = m_2/m_0$ and for small r/η_K $m_0(r) \propto r^{d_2}$, where $d_2 = min,[D_2,d]$ is the configuration space correlation dimension, which then gives

$$S^p_{2,ll} = \frac{f_2}{f_0} \left(\frac{r}{\eta_K} \right)^2 + \frac{g_2}{f_2} \left(\frac{r}{\eta_K} \right)^{d-d_2} \tag{2.326}$$

In comparing the two theories for caustics and clustering, the case for $St = 1$ is revealing. The results in Bec et al. (2011) (for $d = 3$) show that $d_2(St_K = 1) \approx 2.3$, which implies that for $St = 1$ both contributions in (2.325) tend to zero as $r \to 0$. In other words, this does not allow for the simultaneous existence of small-scale clustering (i.e., $d < d$) and finite relative velocities at $r/nK = 0$. This is in contrast to Zaichik's model predictions and the DNS results (Salazar and Collins, 2012) (Figure 2.50).

In light of this, Zaichik's pdf kinetic equation can be considered to describe S2p $S^p_{2,ll}(r/\eta_K)$ in three regions, which depend upon St_K). The first two regions are qualitatively similar to those in the G&M model: a region of large separation where the effect of inertia is perturbative and locally dependent on $\Delta u(r/\eta_K)$ so that $S^p_{2,ll}/S^f_{2,ll}$ is independent of r and then at smaller separations a smooth transition to a nonsmooth region with $S^p_{2,ll}(r/\eta_K) \propto (r/\eta_K)^{-2}$. However, Zaichik's pdf model, unlike the G&M model, predicts that at sufficiently small r/η_K a third region exists in which the particle motions are entirely ballistic and $S^p_{2ll} \approx$ constant (this is the region that gives rise to the scale break). Bragg and Collins suggest that a possible explanation for this difference between the theories is that in the derivation of the G&M model equation, G&M make an a priori assumption that the clustering is always fractal, thus ruling out the possibility of a scale break at small r/η_K by definition. In fact, it is possible to show that Zaichik's model gives the same scaling predictions as that of the G&M model under the a priori assumption that $g(r) \propto r^{d_2-d}$ (Bragg and Collins, 2014b).

2.6 Euler–Lagrange Methods

Martin Sommerfeld and Santiago Lain

2.6.1 Introduction

Particle-laden confined two-phase flows are widely found in the processing industries; typical examples are pneumatic conveying, pneumatic mixing devices, fluidized beds, and particle separation equipment, such as gas cyclones. Pneumatic conveying is widely used in these areas for transporting fine powders within a production process over large distances and to convey pulverized coal in power plants. Depending on the application, different conveying regimes are used, such as dense- and dilute-phase conveying. Essential for the design of such systems is the pressure drop as a function of superficial gas velocity. This pressure drop is composed of the gas-phase pressure drop, which is quite well known already for different pipe elements, and the additional pressure drop due to particle transport. The single-phase pressure loss depends on the wall friction coefficient and hence on the flow Reynolds number and the wall roughness. For an entire pipe system, the contributions of the different elements (e.g., straight pipes, pipe bends, and/or constrictions) have to be added. For the additional pressure loss of the particles also, different contributions may be identified, namely, pressure loss caused by particle–wall friction (i.e., resulting from the momentum loss due to particle–wall collisions), pressure loss due to particle lifting in vertical conveying, and pressure loss due to particle acceleration upon injection or after a bend; hence, the particle contribution is strongly governed by the pipe geometry considered. In addition, the particle-phase pressure drop remarkably depends on pipe material and diameter, particle size, shape and material, wall roughness (since it is strongly correlated with the particle–wall collision frequency, see Sommerfeld, 2003), as well as particle-phase mass loading η, defined as the ratio between the particle mass flow rate and the gas mass flow rate. As a result of this complexity, universal correlations for the pressure drop as a function of conveying velocity are not available and normally experiments are required to develop such correlations as emphasized by Siegel (1991) resulting in an empirical design of pneumatic conveying systems. Quite often, phase diagrams are used to correlate the pressure drop with the superficial gas velocity and the particle mass loading as a parameter. Such experimental phase diagrams unfortunately depend on parameters such as pipe diameter, particle size, or size distribution, which implies that conveying of another type of particles requires conducting new measurements.

Another important design issue for dilute-phase pneumatic conveying systems is the temporal and spatial homogeneous delivery of gas particle mixtures, for example, to the burners of a coal-fired power plant. From the bunker to the burner, however, numerous pipe systems such as bends and branches have to be used, which yield a strong segregation of the mixture due to inertial effects. Consequently, in front of the burner, pipe inserts may be used to homogenize the mixture again, which of course is associated with additional pressure drop. Also, this issue has been experimentally assessed for many years.

Consequently, an experimental design and layout of pneumatic conveying systems is rather tedious and costly. Therefore, during the past two decades, numerical methods based on computational fluid dynamics (CFD) were developed for facilitating the understanding and design of pneumatic conveying systems. The continuous phase computations were mainly based on Reynolds-averaged conservation equations (mostly termed Reynolds-averaged Navier–Stokes [RANS] equations) in connection with an appropriate turbulence model (e.g., k–ε turbulence model or Reynolds stress models). For describing such a particle-laden confined flow, both the two-fluid approach, often termed as Euler–Euler method and the Euler–Lagrange method, were commonly used. For dense gas–solid flows, for example, in a vertical riser, the two-fluid approach was preferred (e.g., Dasgupta et al., 1998, Hidayat and Rasmuson, 2005) although not all details occurring on the particle scale can be described and modeled. The Euler–Lagrange approach, on the other hand, allows a very detailed description of the discrete particle behavior, including all relevant fluid dynamic forces acting on the particles, the rotation of particles mainly induced by wall collisions, interparticle collisions, and collisions of particles with rough walls. This, however, makes computations of large pneumatic conveying systems quite time consuming. The largest benefit in the application of the Euler–Lagrange method is that a particle size distribution, which is normally present in all applications, can be considered with marginal computational effort. The treatment of a particle size distribution in the two-fluid approach requires the solution of a number of conservation equation sets, one for each discretized particle size class. Therefore, this method also becomes computationally expensive.

As a result, dilute-phase pneumatic conveying was in the past mainly computed using the Euler–Lagrange approach with more or less sophisticated modeling. A big challenge for many years was the computation of powder rope formation in a bend and its disintegration in a downstream located vertical pipe (Bilirgen and Levy, 2001, Yilmaz and Levy, 2001, Kuan et al., 2007, Tian et al., 2008, Lain and Sommerfeld, 2012a,b, 2013, Sommerfeld and Lain, 2015).

2.6.2 Euler–Lagrange-Approach

The numerical scheme adopted to calculate the considered particle-laden two-phase flows was the fully coupled Euler–Lagrange approach as described in detail by Lain and Sommerfeld (2008). The fluid flow was calculated based on the Euler approach using a fixed grid by solving the Reynolds-averaged conservation equations (RANS) in connection with the standard k–ε turbulence model. All conservation equations were extended in order to account for the effects of the dispersed phase, that is, two-way coupling through momentum exchange and turbulence. The time-dependent 3D conservation equations for the fluid may be written in the general form (using tensorial notation) as

$$(\rho\phi)_{,t} + (\rho U_i \phi)_{,i} = (\Gamma_{ik}\phi_{,k})_{,i} + S_\phi + S_{\phi p} \tag{2.327}$$

where

ρ is the gas density

U_i are the Reynolds-averaged velocity components

Γ_{ik} is an effective transport tensor

The usual source terms within the continuous phase equations are summarized in S_ϕ, while $S_{\phi p}$ represents the additional source term due to phase interaction, that is, the influence of the particles on the fluid flow (see Lain and Sommerfeld, 2008). In the present study, the computations have been done for a stationary flow situation.

The simulation of the particle phase by the Lagrangian approach is based on tracking a large number of particles through the beforehand computed flow field. Particles are treated as point masses, and their shape is assumed to be spherical, which was also the case in the experiments considered for validation. In order to account for the correct particle mass flow rate, the considered computational particles represent a certain number of real particles with the same properties, which yields a computationally treatable number of parcels.

Tracking requires the solution of the equations of motion for each computational particle or parcels. The forces that were considered include particle inertia, drag, gravity/buoyancy, slip–shear lift force F_{ls}, and slip-rotational lift force F_{lr} (Sommerfeld et al., 2008). The Basset history term, the added mass, and the fluid inertia are negligible for the considered high ratio of particle to gas densities. The change in the angular velocity along the particle trajectory due to the viscous interaction with the fluid (i.e., the torque T_i) requires the solution of additional partial differential equations. Hence, the complete equations of motion for the particles are given by

$$\frac{dx_{pi}}{dt} = u_{pi} \tag{2.328}$$

$$m_p \frac{du_{pi}}{dt} = \frac{3}{4}\frac{\rho}{D_p} m_p c_D (u_i - u_{pi})\left|\vec{u} - \vec{u_p}\right| + m_p g_i \left(1 - \frac{\rho}{\rho_p}\right) + F_{lsi} + F_{lri} \tag{2.329}$$

$$I_p \frac{d\omega_{pi}}{dt} = T_i \tag{2.330}$$

where

x_{pi}, u_{pi}, and u_i are the components of the particle location vector and the instantaneous particle and fluid velocities, respectively
m_p is the particle mass
I_p is the moment of inertia
D_p is the particle diameter
g_i is the gravity vector
ρ and ρ_p are the fluid and particle material densities

The relevant different forces acting on the particles and the respective resistance coefficients allowing the extension of the equation of motion to higher particle Reynolds numbers have been used according to Sommerfeld et al. (2008) as well as Sommerfeld (2010). The drag coefficient is obtained using the following standard correlation:

$$c_D = \begin{cases} 24\,\mathrm{Re}_p^{-1}(1 + 0.15\,\mathrm{Re}_p^{0.687}) & \mathrm{Re}_p \le 1000 \\ 0.44 & \mathrm{Re}_p > 1000 \end{cases} \tag{2.331}$$

with $\mathrm{Re}_p = \rho D_p \left|\vec{u} - \vec{u_p}\right| / \mu$ as the particle Reynolds number.

The slip–shear force is based on the analytical result of Saffman (1965) and extended for higher particle Reynolds numbers according to Mei (1992):

$$\vec{F_{ls}} = 1.615 D_p \mu \mathrm{Re}_s^{1/2} c_{ls}\left[(\vec{u} - \vec{u_p}) \times \vec{\omega}\right] \tag{2.332}$$

where

$\vec{\omega} = \nabla \times \vec{u}$ is the fluid rotation
$\mathrm{Re}_s = \rho D_p^2 \left|\vec{\omega}\right| / \mu$ is the particle Reynolds number of the shear flow
$c_{ls} = F_{ls}/F_{ls,Saff}$ represents the ratio of the extended lift force to the Saffman (1965) force:

$$c_{ls} = \begin{cases} (1 - 0.331\sqrt{\beta})e^{-\mathrm{Re}_p/10} + 0.331\sqrt{\beta} & \mathrm{Re}_p \le 40 \\ 0.0524\sqrt{\beta\,\mathrm{Re}_p} & \mathrm{Re}_p > 40 \end{cases} \tag{2.333}$$

where β is a parameter given by $\beta = 0.5\ \mathrm{Re}_s/\mathrm{Re}_p$.

The applied slip-rotational lift force is based on the relation given by Rubinow and Keller (1961), which was extended to account for the relative motion between particle and fluid. Moreover, several authors allowed an extension of this lift force to higher particle Reynolds numbers. Hence, the following form of the slip-rotation lift force has been used:

$$\vec{F_{lr}} = \frac{\pi}{8} D_p^3 \rho \frac{\mathrm{Re}_p}{\mathrm{Re}_r} c_{lr}\left[\vec{\Omega} \times (\vec{u} - \vec{u_p})\right] \tag{2.334}$$

with $\vec{\Omega} = 0.5\nabla \times \vec{u} - \vec{\omega_p}$ and the Reynolds number of particle rotation is given by $\mathrm{Re}_R = \rho D_P^2 \left|\vec{\omega}\right| / \mu$. The lift coefficient according to Oesterlé and Bui Dinh (1998) is given for $\mathrm{Re}_p < 2000$ by

$$c_{lr} = 0.45 + \left(\frac{\mathrm{Re}_r}{\mathrm{Re}_p} - 0.45 \right) e^{-0.05684\, \mathrm{Re}_R^{0.4}\, \mathrm{Re}_p^{0.3}} \tag{2.335}$$

For the torque acting on a rotating particle, the expression of Rubinow and Keller (1961) was extended to account for the relative motion between fluid and particle and higher Reynolds numbers:

$$\vec{T} = \frac{\rho}{2} \left(\frac{D_p}{2} \right)^5 c_R \left|\vec{\Omega}\right| \vec{\Omega} \tag{2.336}$$

where the coefficient of rotation is obtained from Rubinow and Keller (1961) and direct numerical simulations of Dennis et al. (1980) in the following way:

$$c_R = \begin{cases} \dfrac{64\pi}{\mathrm{Re}_R} & \mathrm{Re}_R \le 32 \\ \dfrac{12.9}{\sqrt{\mathrm{Re}_R}} + \dfrac{128.4}{\mathrm{Re}_R} & 32 < \mathrm{Re}_R < 1000 \end{cases} \tag{2.337}$$

The equations to calculate the particle motion are solved by integration of the differential equations (Equations 2.326 through 2.328). For sufficiently small time steps and assuming that the forces remain constant during this time step, the new particle location, the linear and angular velocities are calculated. The time step for the particle tracking, Δt_L, was chosen to be 50% of the smallest of all local relevant time scales, such as the particle relaxation time, the integral timescale of turbulence, and the mean interparticle collision time. This choice guarantees the stability of the numerical integration scheme (Göz et al., 2004).

2.6.2.1 Modeling of Elementary Processes

In order to account for turbulence effects on particle motion, the instantaneous fluid velocity components along the particle trajectory are determined from the local mean fluid velocity interpolated from the neighboring grid points and a fluctuating component generated by a single-step isotropic Langevin model described by Sommerfeld et al. (1993). In this model, the fluctuation velocity is composed of a correlated part from the previous time step and a random component drawn from a Gaussian distribution function. The degree of correlation depends on the turbulent particle Stokes number St_T and is calculated using appropriate time and length scales of turbulence estimated from the k–ε turbulence model.

Especially in wall-bounded flows, as considered here, the modeling of particle–wall collisions needs special consideration (Sommerfeld, 1992). The applied wall collision model, accounting for wall roughness, is described and validated in Sommerfeld and Huber (1999). The wall roughness seen by a particle is simulated assuming that the instantaneous impact angle is composed of the particle trajectory angle plus a stochastic contribution due to wall roughness, drawn from a normal distribution with a standard deviation $\Delta\gamma$ that depends on the structure of wall roughness and particle size (Sommerfeld and Huber, 1999). Corresponding correlations for the restitution coefficient, the friction coefficient, and the roughness angle are presented by Lain et al. (2002), which are depending on the particle impact angle (Sommerfeld and Lain, 2009). Regardless of particle size, the standard deviation of the roughness angle was assumed to be $\Delta\gamma = 10°$ for all cases considered here, except for one case with low roughness demonstrating this important effect.

Interparticle collisions are modeled by the stochastic approach described in detail by Sommerfeld (2001). This model relies on the generation of a fictitious collision partner at each time step of tracking a real particle and accounts for a possible correlation of the translational velocities of colliding particles in turbulent flows. As model parameters for particle–particle collisions, the restitution coefficient has been taken to be constant with 0.9 and the static and dynamic friction coefficients were chosen to be 0.4. The convergence behavior for pneumatic conveying was demonstrated by Lain and Sommerfeld (2012a).

2.6.2.2 Two-Way Coupling Procedure

The source terms for the momentum equations resulting from the exchange between particles and fluid are obtained on the basis of the Particle-Source-In-Cell concept proposed by Crowe et al. (1977). Hence, the momentum exchange is calculated by averaging over all parcels traversing a given control volume during

one Lagrangian calculation. Instead of summing up all fluid dynamic forces acting on the particles, which is quite cumbersome, the momentum exchange is calculated from the velocity change of the parcels when traversing the control volume. In this procedure however, the external forces have to be subtracted, yielding the momentum source in the following form:

$$\overline{S_{U_I p}} = -\frac{1}{V_{cv}} \sum_k m_k N_k \sum_n \left\{ \left(\left[u_{pi} \right]_k^{n+1} - \left[u_{pi} \right]_k^n \right) - g_i \left(1 - \frac{\rho}{\rho_P} \right) \Delta t_L \right\} \tag{2.338}$$

where the sum over n indicates averaging along the particle trajectory (time averaging) and the sum over k is related to the number of computational particles passing the considered control volume with the volume V_{cv}. The mass of an individual particle is m_k and N_k is the number of real particles in one computational particle. Δt_L is the Lagrangian time step that is used in the solution of 2.326 through 2.328.

The source term in the conservation equation of the turbulent kinetic energy, k, is expressed in the Reynolds average procedure as

$$S_{kp} = \overline{u_i S_{U_i p}} - U_i \overline{S_{U_i p}} \tag{2.339}$$

while the source term in the ε-equation is modeled in the following standard way:

$$S_{\varepsilon p} = c_{\varepsilon 3} \frac{\varepsilon}{k} S_{kp} \tag{2.340}$$

with $C_{\varepsilon 3} = 1.8$ and the sum is implicit in the repeated subindex i.

A converged solution of the coupled two-phase flow system is obtained by successive solution of the Eulerian and Lagrangian part, respectively. Initially, the flow field is calculated without particle-phase source terms until a converged solution is achieved. Thereafter, a large number of parcels are tracked through the flow field (up to 10^6 computational particles) and the source terms are sampled for each control volume. In this first Lagrangian calculation interparticle collisions are not considered, since the required cell-based particle-phase properties are not yet available. Hence, for each control volume, the particle concentration, the local particle size distribution, and the size–velocity correlations for the mean velocities and the rms values are sampled. These properties are updated in each Lagrangian iteration in order to allow correct calculation of interparticle collisions. Additional particle-phase properties and profiles may be sampled for each transverse cell when the computational particles cross a predefined location. From the second Eulerian calculation, the source terms of the dispersed phase are introduced using an underrelaxation procedure in order to facilitate convergence (Kohnen et al., 1994). For the present calculations, typically about 25 to 35 coupling iterations with an underrelaxation factor between 0.5 and 0.1 were necessary in order to yield convergence of the Euler–Lagrange coupling.

2.6.2.3 Conveying Pipe Configuration

The considered configuration of the horizontal to vertical pipe with a 90° bend has an inlet horizontal pipe and an outlet vertical pipe, both 5 m in length. According to the configuration described in Huber and Sommerfeld (1994, 1998), the pipe diameters are D = 0.08 and 0.15 m and the elbow radius is 2.54 times the pipe diameter (i.e., R_{bend} = 0.203 and 0.381 m). The mean conveying velocity is different for each of the cases (Table 2.4). These conditions yield the nondimensional parameters summarized in Table 2.4, where the pipe Reynolds number and the Dean number of the bend flow are determined from

$$\mathrm{Re}_{pipe} = \frac{\rho D_{pipe} U_{av}}{\mu} \quad \mathrm{De}_{bend} = \frac{\mathrm{Re}_{pipe}}{\sqrt{R_{bend}/R_{pipe}}} \tag{2.341}$$

Table 2.4 Parameters and Nondimensional Properties of Pipe System (5 m Horizontal, Bend, and 5 m Vertical) for the Three Standard Experimental Conditions

Pipe Diameter	0.08 m	0.08 m	0.15 m
Bulk velocity	14 m/s	21 m/s	27 m/s
Mass loading	0.5	0.5	0.3
Re_{pipe}	74,667	112,000	270,000
De_{bend}	33,144	49,716	63,890

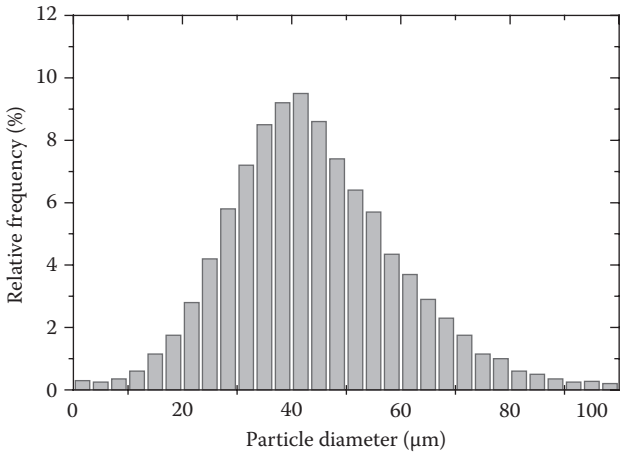

Figure 2.54

Size distribution of spherical glass beads (relative number frequency) used in the experiments of Huber and Sommerfeld (1998).

The considered fluid properties are $\rho = 1.2$ kg/m^3 and $\mu = 18.0\ 10^{-6}$ N s/m^2 (air at room temperature). The multiblock structured O-type grid is composed of 25 blocks with a total of 568,000 hexahedral control volumes to discretize the entire pipe system (i.e., 5 m horizontal pipe, a bend, and 5 m vertical pipe). This resolution was found to be sufficient for producing grid-independent results.

The particles considered in the numerical calculations for all standard cases summarized in Table 2.4 were spherical glass beads ($\rho_p = 2500$ kg/m^3) with the size distribution shown in Figure 2.54. These particles were also used in the experiments. The size distribution has a number mean diameter of 40 μm and is rather wide ranging from about 15 to 85 μm, which was discretized by 7 diameter classes of 10 μm width. It should be noted that the size of injected particles was sampled from a continuous cumulative distribution, yielding also a variation of particle size in a given size class.

The particle mass loading (mass flow rate of particles/mass flow rate of air) for the standard cases was selected according to the experiments (Huber and Sommerfeld, 1994, 1998); see Table 2.4. Besides that, mono-sized particle with 20, 40, 80, and 135 μm diameter and a binary mixture were considered (see Table 2.5), all being spherical glass beads with $\rho_p = 2500$ kg/m^3.

The boundary conditions used for the numerical calculations are as follows. At the inlet of the pipe, the fluid is injected with a uniform velocity profile (i.e., mean conveying velocity provided in Table 2.4) and a fluctuating velocity of around 3% of the bulk flow velocity for each component. At the pipe exit, an outlet condition (i.e., no gradients of the properties in streamwise direction) is applied, while at the pipe walls, no-slip conditions are adopted. The particle injection velocities are sampled from a normal distribution with fixed mean and rms velocities. The mean particle velocity is the bulk gas velocity in the streamwise direction (see Table 2.4), and the mean transverse components are assumed to be zero.

Table 2.5 Summary of Particle Response Characteristics for the Particle Size Distribution, Different Mono-Sized Particle, and a Binary Mixture

Diameter (μm)	Turbulent Stokes[a] (–)	Response Distance (mm)	Bend Stokes[b] (–)
❶ 15–85 (40)	0.169–5.412	0.03–30.49	0.078–2.515
❷ 20	0.300	0.093	0.139
❸ 40	1.199	1.5	0.557
❹ 80	4.794	23.9	2.228
❺ 135	13.653	194.0	6.344
❻ 30 + 60 (40)[c]	0.674 + 2.697	0.47 + 7.57	0.313 + 1.253

[a] Integral timescale of turbulence in the pipe core $T_L = 10.3$ ms.

[b] Calculated according to Equation 2.331 with $R_{bend} = 0.381$ m and $U_0 = 27$ m/s.

[c] Binary mixture with equal number of parcels and mass fractions of $w_{30} = 20\%$ (30 μm) and $w_{60} = 80\%$ (60 μm) and a number mean diameter of 40 μm (calculations were done for those with D = 150 mm and $U_0 = 27$ m/s).

The rms values are 3% of the bulk gas velocity for all three velocity components. These values were randomly drawn from normal distributions. Regarding the three components of the particle angular velocities, a mean of zero and a standard deviation of 10^3 1/s were assumed. For all the particle sizes considered, the two-phase flow was developed after a conveying distance of 5 m through the horizontal pipe. Hence, there is no effect of the specified inlet conditions on the pneumatic conveying through the bend and the connected vertical pipe.

All the numerical computations were done on a quad-core workstation, where the fluid flow was calculated on one processor and the Lagrangian tracking was done on two processors. With these resources, a four-way coupled converged result for the 5 m horizontal pipe, the pipe bend, and the 5 m vertical pipe was obtained after about two weeks with the in-house code FASTEST/Lag3D.

2.6.3 Results Horizontal to Vertical Pipe System

The particle motion in a horizontal straight pipe is determined by the balance between gravitational settling and turbulent dispersion. Hence, with increasing particle size (or response time), turbulence is not sufficiently strong to keep the particles in suspension and hence gravitational settling increases, yielding high particle concentration near the pipe bottom. On the contrary, small particles will be dominantly transported by turbulence whereby they will be more homogeneously distributed in the pipe cross section. The particle response to turbulence is characterized by the turbulent Stokes number given by $St_T = \tau_p/T_L$, where T_L is the integral timescale of turbulence. For the considered monosized particles, St_T ranges from 0.3 to 14, that is, from responsive to inertial particles (see Table 2.5). The particle response distance may be used for identifying the importance of particle–wall collisions. It is defined as $\lambda_p = \tau_p \cdot V_s$, where V_s is the terminal velocity of particles (Sommerfeld et al., 2008). In the case $\lambda_p \geq D$ (pipe diameter), the particles are not able to follow the gas flow after a wall rebound and hence will collide again with the opposite wall of the pipe (see, e.g., Sommerfeld, 2003). For the considered particle sizes, the 135 μm particles are dominantly affected by wall collisions (Table 2.5).

A particle-laden flow through a bend is characterized by strong segregation of the mixture due to inertial effects and secondary flow, whereby the particles accumulate at the outer wall of the elbow forming a relatively dense rope, that is, high-concentration region of particles. This rope will be again disintegrated in the connecting vertical pipe due to interparticle collisions, wall collisions, secondary flow, and turbulence. The redirection of the two-phase flow from horizontal to vertical also leads, as a result of particles inertia, to enhanced wall collisions with the outer bend wall followed by a rebound toward the core of the pipe. The particle response behavior regarding the mean motion through the bend is characterized by the bend Stokes number being the ratio of the particle response time (here the Stokesian response time is used) to the particle residence time along the centerline of the bend:

$$St_B = \frac{\tau_P}{\tau_{bend}} = \frac{\rho_P d_P^2}{18\mu} \frac{U_{av}}{C_{bend,90^o}} = \frac{\rho_P d_P^2}{18\mu} \frac{2U_{av}}{\pi R_{bend}} \tag{2.342}$$

Here,

$C_{bend,\,90^o}$ is the arc of the 90° bend radius measured along the centerline
R_{bend} is the bend radius (2.54 times pipe diameter)
U_{av} is the average conveying velocity

This definition of the bend particle Stokes number is more physical than using the bend timescale obtained as the ratio of pipe radius to the average gas conveying velocity as done in most deposition studies (see, e.g., Crane and Evans, 1977). The bend Stokes number for the different particle systems is also summarized in Table 2.5. Expectedly, an increase in this Stokes number is coupled with an increasing wall collision frequency, especially within the bend, and ultimately a growing pressure drop. The rebound characteristics of the particles are evidently affected by wall roughness and the involved shadow effect (Sommerfeld and Huber, 1999).

The high particle concentration region developing within a bend is of course altering the probability of interparticle collisions with the result that the distribution of the particles throughout the bend is strongly manipulated. In addition, the distribution of the particle phase within the bend will determine the local degree of two-way coupling. As the appearance of the particle concentration distribution within the bend (i.e., degree of segregation) is depending on the bend Stokes number, also the interparticle collision frequency is somehow coupled to this characteristic nondimensional number (i.e., particle inertia) and of course determined by the overall mass loading ratio. In case particles with a wide size distribution are conveyed the so-called impact efficiency also becomes of importance. This means that once a small and large

particle are on a collision trajectory, the small particle still might move around the larger collector particle with the relative velocity field and hence no collision occurs (Ho and Sommerfeld, 2002, Sommerfeld and Lain, 2009). In average, this phenomenon reduces the effective frequency of interparticle collisions as shown by Ho and Sommerfeld (2005) for particle separation in a gas cyclone. However, in the present computations with particle size distribution, impact efficiency is not considered.

In the following sections, the influence of the particle-phase properties and the elementary processes described earlier on the pneumatic conveying characteristics, the particle concentration distribution, and the resulting pressure drop will be discussed.

2.6.3.1 Validation of the Computations

The modeling approach summarized earlier has been thoroughly validated for different pneumatic conveying systems, that is, for a horizontal channel by Lain and Sommerfeld (2008, 2012a) and for a pipe system along the vertical pipe (Lain and Sommerfeld, 2010, 2011, 2013, Sommerfeld and Lain, 2012). In the following, the validation is based on results for the 80 mm pipe system, obtained at several cross sections in the vertical pipe by applying phase-Doppler anemometry (Huber and Sommerfeld, 1994). The average conveying velocity is 14 m/s and the particle mass loading is 0.5 (Table 2.4). Computational results are shown for both two- and four-way couplings in order to emphasize the importance of interparticle collisions.

A comparison between measured and calculated profiles for particle concentration and particle number mean diameter development downstream of the bend exit is shown in Figure 2.55 (please consider 4-way way results). The first two profiles exhibit a very good agreement, both in curve progression and in magnitude. Further downstream however, the predictions still show a higher concentration near the outer wall (right-hand side) than the measurements. Hence, in the experiments, the rope was faster dispersed in the vertical pipe that is most probably the result of the observed unsteady fluctuating motion of the rope downstream of the bend exit. The profiles of the calculated particle number mean diameter show a remarkable good agreement with the measurements, particularly since this property is the result of the size segregation within the bend and requires a good prediction of the size-dependent particle behavior and hence the local particle size distributions. Only the first profile shows some larger deviations, indicating a somewhat stronger rebound of the larger particles in the predictions.

The predicted particle mean velocities (vertical component) and the associated particle rms values are compared in Figure 2.56. The mean velocities in the first two cross sections are in reasonable good agreement; however, some larger deviations are found in the last profile, which is again associated with the differences in predicting the disintegration of the particle rope (Figure 2.55), being most likely due to the rope fluctuations observed in the experiments. The predicted particle-phase rms values of the vertical velocity component are in surprisingly good agreement with the measurements, as this property is affected by all relevant transport processes, especially the description of turbulence seen by the particles.

As to be expected, when neglecting interparticle collisions (two-way coupling), the rope behavior in the vertical pipe cannot be predicted properly (see Figures 2.55 and 2.56), and consequently, all the other particle-phase properties are also not correctly predicted. Here, the particles may be reflected unhindered from the bend outer wall toward the pipe core yielding the highest particle concentrations near the core of the pipe after some distance from the bend exit (Figure 2.55a, y = 0.6 and 1.1 m). Hence, interparticle collisions yield a more concentrated dust rope in a bend. As a consequence of the higher inertia of large particles, the particle number mean diameter left of the pipe axis is remarkably overpredicted when not considering interparticle collisions (Figure 2.55b). The particle velocity profiles (mean and rms) are naturally coupled with the particle concentration distribution and deviate in a two-way coupled calculation from those considering also interparticle collisions (Figure 2.56). Consequently, even at this relatively low overall particle mass loading, correct predictions cannot be expected when neglecting interparticle collisions.

2.6.3.2 Wall Roughness Effects

In order to decouple the problem, first calculations are considered where only the effect of wall roughness is analyzed by neglecting interparticle collisions, that is, conducting two-way coupled calculations, for the case with particle size distribution from 15 to 85 μm. For this case (D = 150 mm, U_{av} = 27 m/s, η = 0.3) *a short inlet pipe of 1 m* is used, which results in an almost homogeneous particle concentration distribution at the bend inlet (Lain and Sommerfeld, 2009, Sommerfeld and Lain, 2012). The degree of accumulation of particles at the bend outer wall depends strongly on wall roughness describing the rebound characteristics of the particles. Two degrees of roughness are considered, namely, Δγ = 1.5° and 10°, and

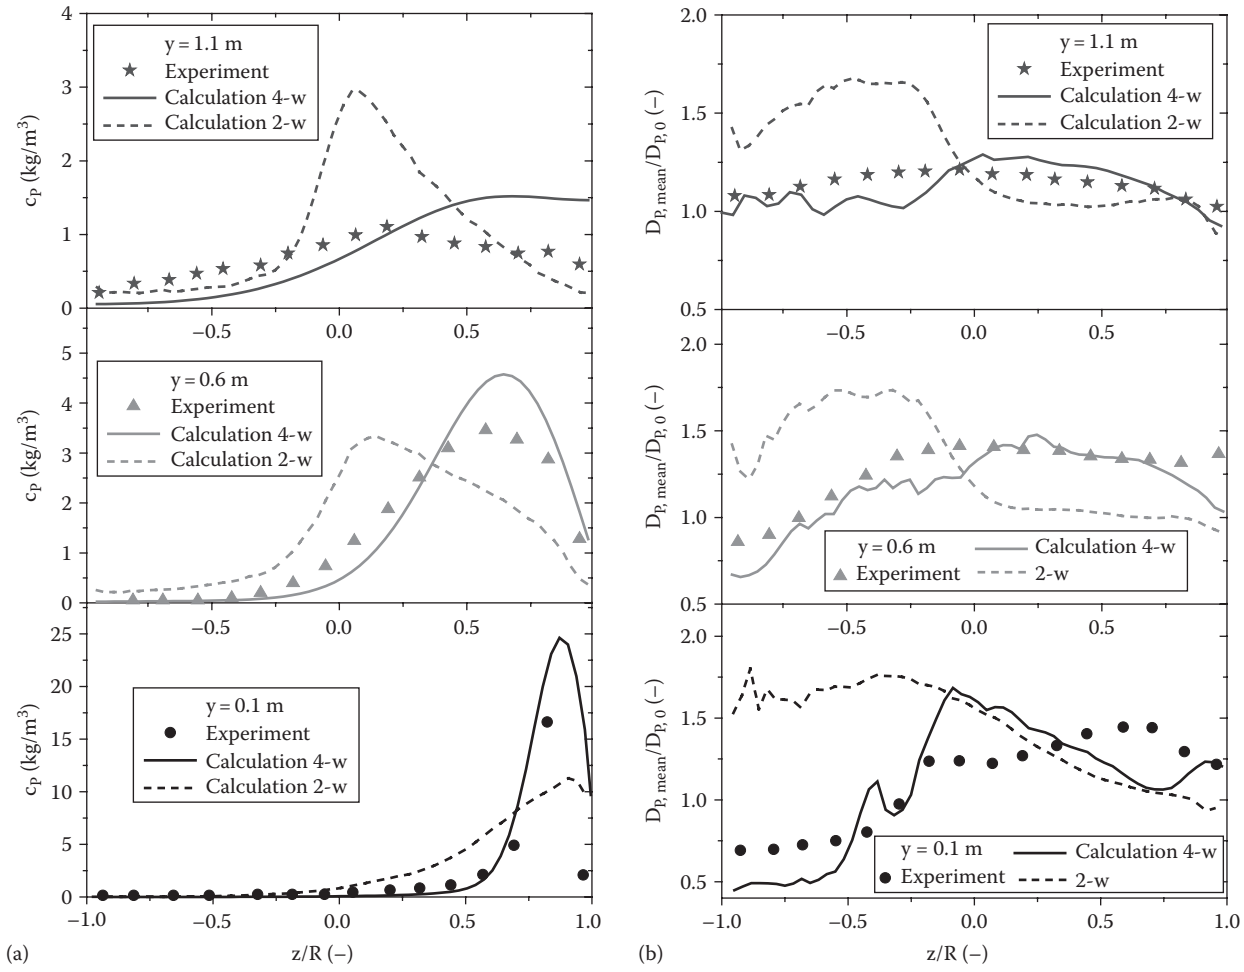

Figure 2.55

Profiles of particle concentration (a) and particle mean number diameter (b) downstream of the bend exit; comparison of calculations with experiments (D = 80 mm, R_{bend} = 0.203 m, U_0 = 14 m/s, η = 0.5, Δγ = 10°, four-way coupling, particle size distribution 15–85 μm, St_g = 0.076–2.445).

the resulting computational results are compared with respect to the particle concentration distribution along bend and vertical pipe (Figure 2.57a). When entering the bend, particles are first driven toward the bend outer wall mainly due to inertia and to a small extent by the secondary flow. For small roughness, Δγ = 1.5°, the particle rebound is not very strong (less pronounced shadow effect), and consequently, a quite dense rope is formed until to the bend exit. In the third cross section within the bend (θ = 60°), a small nose in the concentration distribution is visible caused by the focusing effect, that is, particles coming almost straight into the bend are reflected at a curved bend outer wall and bounced back toward the core of the pipe (Lain and Sommerfeld, 2009). Finally, at the end of the bend, particles are only present near the outer wall of the pipe bend leaving the bend inner region and the core almost without solids (Figure 2.57 upper block). Near the exit of the bend particles are again rebound from the outer (right-hand side) wall toward the core of the pipe (focusing), yielding a strip of high concentration (see magnified section between bend exit and 1 m downstream), which reaches the pipe core after about 1 m. Further downstream (i.e., at 2 and 3 m), a kind of mushroom-shaped concentration pattern is developed within the pipe cross section. This phenomenon is mainly the result of particle transport by secondary flow. This developing high-concentration region is barely dispersed until the exit of the vertical pipe.

The secondary flow structure developing in the bend and the vertical pipe is also shown in Figure 2.57 (upper block, right) for the low roughness case without interparticle collisions. As a result of the particle rebound from the outer bend wall, the particles are reflected back toward the pipe center. The associated momentum transferred to the fluid by this focusing (Lain and Sommerfeld, 2009) produces two new counter-rotating vortices, clearly visible at bend angles θ of 30° and 60°, which push the two secondary flow vortices

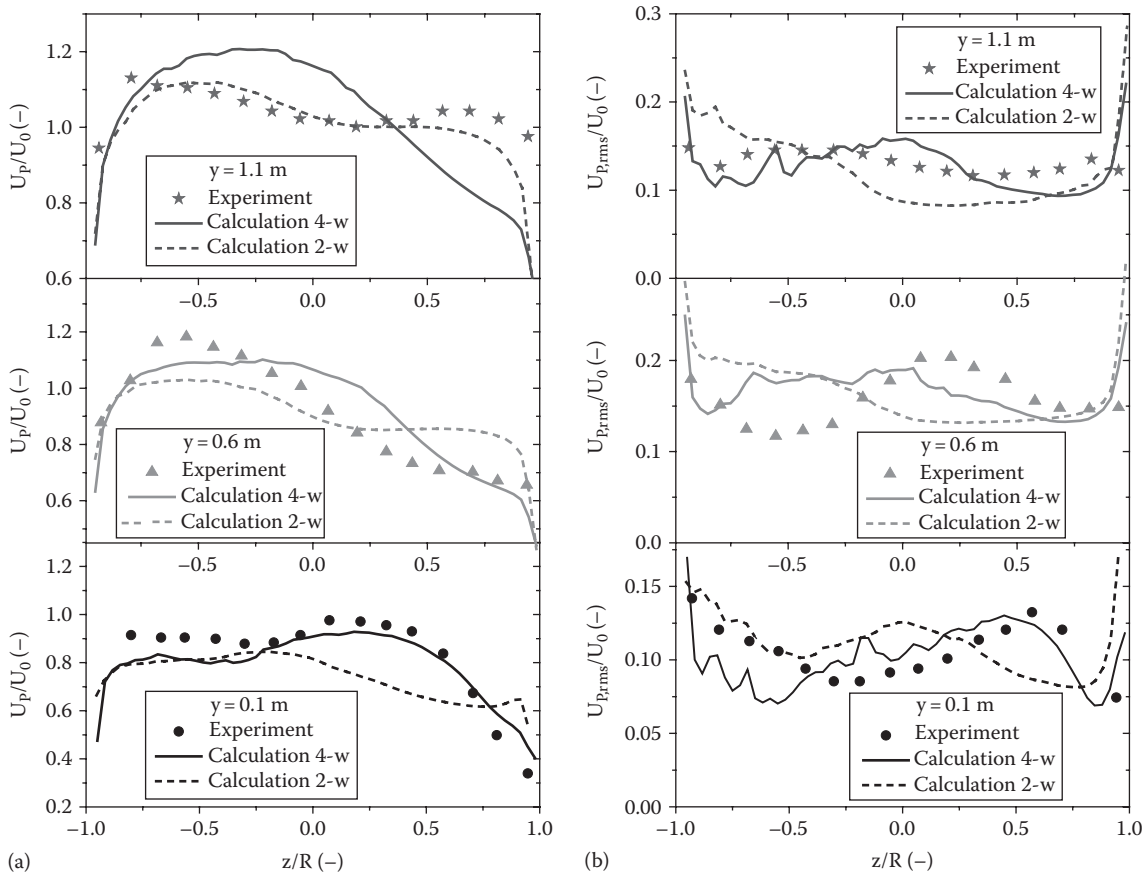

Figure 2.56

Profiles of vertical particle velocity (a) and the associated rms value (b) downstream of the bend exit; comparison of the calculations with experiments (D = 80 mm, R_{bend} = 0.203 m, U_0 = 14 m/s, η = 0.5, Δγ = 10°, four-way coupling, particle size distribution 15–85 μm, St_B = 0.076–2.445).

produced as a result of the bend flow toward the inner part of the pipe cross section. Until the exit of the bend the particle-induced vortices have disappeared again, but the typical single-phase secondary flow structure is completely destroyed. Particle rebound near the end of the bend again introduces momentum to the fluid so that the two-particle-induced counter-rotating vortices again appear a bit downstream the bend exit. Eventually, four vortex structures of roughly equal size develop in the pipe cross section that is preserved until the end of the vertical pipe. Through the associated particle transport, a stem-like and later on mushroom-shaped region of high particle concentration is developing in the vertical pipe (Figure 2.57 upper block, left). Until the end of the vertical pipe element, the regions of high particle concentration have barely disappeared.

In the case of higher roughness, that is, Δγ = 10°, particles rebound from the bend outer wall are farther reflected back into the core region of the bend flow (Figure 2.57 lower block). This behavior is due to the shadow effect of wall roughness (Sommerfeld, 2003, Lain and Sommerfeld, 2008) implying that the rebound angle may become larger than the impact angle if this is relatively shallow (i.e., resulting in an averaged transfer of wall parallel particle momentum toward the transverse components). Hence, although a more or less dense rope is formed at the outer wall near the bend exit, the particles are distributed over a larger portion of the cross section compared to the low roughness case (compare Figure 2.57 left, upper and lower part). Only near the inner wall there are almost no particles (i.e., this region corresponds to about one-third of the cross section). The hat-like shape of the region with high particle concentration developing in the bend is again resulting from the focusing effect, whereby the particles are reflected from the curved bend outer wall toward the pipe core. Therefore, eventually also momentum is transferred to the gas phase affecting the secondary flow. The T-shaped regions of high particle concentration at 1 and 2 m downstream the bend exit are again associated with the focusing effect pushing the particles toward the pipe core in combination with the developing secondary flow structure. Within the bend, already strong counterrotating vortices develop

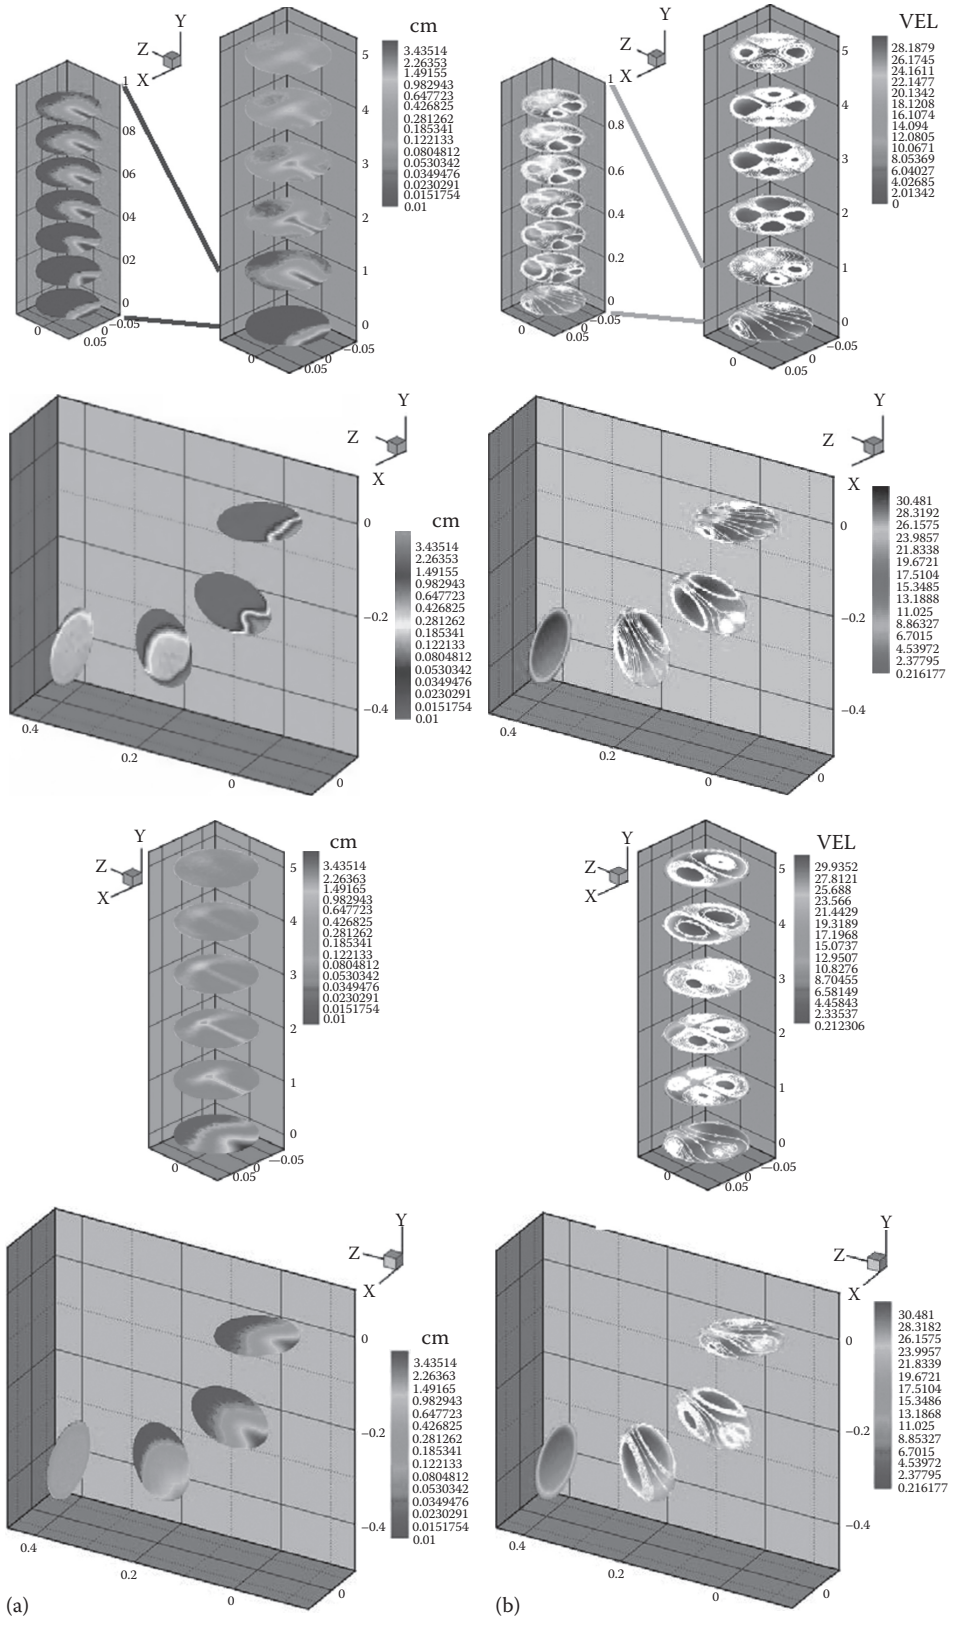

Figure 2.57

Development of cross-sectional distributions of particle concentration cm (kg/m³) (a) and absolute flow velocity *VEL* (m/s) (color) as well as streamlines of the cross-sectional flow (white lines) (b) for a particle-laden flow through the bend and vertical pipe; upper block, $\Delta\gamma = 1.5°$; lower block, $\Delta\gamma = 10°$ ($D = 150$ mm, $U_0 = 27$ m/s, $\eta = 0.3$, particle size distribution 15–85 μm, two-way coupling, 1 m horizontal inlet pipe).

due to the particle focusing, yielding in the initial part of the vertical pipe four circulation cells in the pipe cross section (Figure 2.57 lower block right). As the strength of the particle-induced circulation cells is quite high, the original circulation cells produced in the bend by the centrifuging effect are eventually completely entrapped (i.e., from about 3 m). Hence, at the end of the vertical pipe, two circulation cells are only present with a rotation opposite to that produced initially by the bend flow (i.e., bend angle of 30°).

2.6.3.3 *Influence of Interparticle Collisions*

For the following results, the standard case with a 5 m horizontal pipe, a bend, and a 5 m vertical pipe (pipe diameter 150 mm) is considered and the particles have a size distribution (Figure 2.54, Table 2.5, case ❶). This implies that the particle-laden flow entering the bend shows already a remarkable gravitational settling whereby the particle concentration at the inlet becomes nonsymmetric. The result obtained for solely two-way coupled calculations is shown in Figure 2.58a. Compared to the short inlet pipe with the same wall roughness (Figure 2.57 lower block left), the concentration distribution throughout the bend and in the connecting vertical pipe is remarkably modified. With a long inlet pipe, gravitational settling has altered the particle concentration distribution at the bend inlet cross section, that is, the maximum of particle concentration is shifted to the lower half of the pipe cross section (Figure 2.58a). This implies that most of the particles

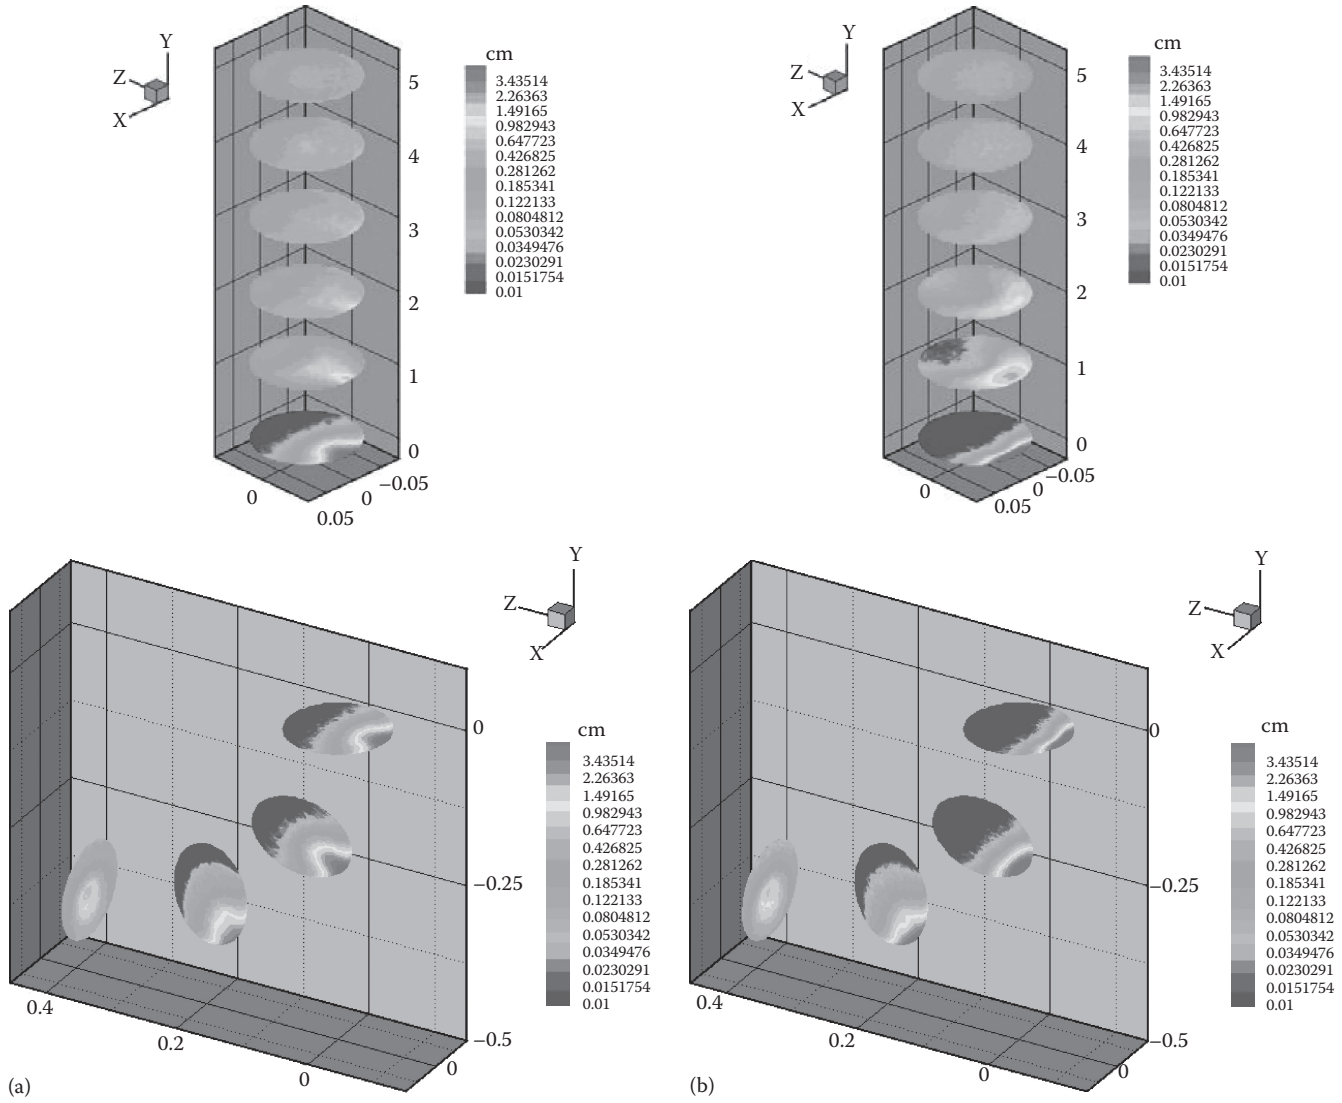

Figure 2.58

Cross-sectional distribution of particle concentration cm (kg/m^3) along bend and connecting vertical pipe demonstrating the effect of interparticle collisions: (a) two-way coupling and (b) four-way coupling (5 m horizontal pipe, bend, 5 m vertical pipe, D = 150 mm, bend radius 2.54 pipe diameters, U_{av} = 27 m/s, η = 0.3, $\Delta\gamma$ = 10°, particle size distribution 15–85 μm).

experience a more gradual redirection, whereby the rebound of particles from the bend outer wall is less strong. This has the consequence that the pipe cross section within the bend is somewhat less filled with the particles compared to a homogeneous distribution at the bend inlet (Figure 2.57 lower block left). The shape of the high-concentration region, however, still indicates the presence of the focusing effect, although it is not as pronounced than in the case with homogeneous inlet distribution. In this case, only weak counterrotating vortices are developed in the bend but do not persist for a long distance in the vertical pipe (not shown here). This is also the reason that the rope formed in the bend is dispersed much quicker in the vertical pipe.

When interparticle collisions are taken into account (i.e., four-way coupling), the particle rope developing in the bend is forced to be more concentrated and the particles are distributed in a smaller part of the cross section near the outer wall of the bend compared to the result with only two-way coupling (compare Figure 2.58a and b). This is caused by collisions of particles moving into the bend with those rebounding from the bend outer wall, which may be called "compression" effect and strongly depends on particle inertia and the overall mass loading. Hence, the rebound particles are "pushed" back toward the bend outer wall and will again collide with it (i.e., the resulting enhancement of wall collision rate will be discussed later). After rebound, they will again collide with other particles within the rope. Consequently, the particles are "trapped" in the rope due to interparticle collisions and the mean free path between particle collisions is rather small. Also, the redispersion of the particles in the vertical pipe section is hindered by interparticle collisions. Instead, a kind of detached closed rope develops near the bend outer wall (i.e., 1 m downstream the bend exit), which moves upward and is only dispersed 3 m downstream the bend exit (Figure 2.58). The trapping of the particles in the dust rope also reduces the focusing effect and the associated development of particle-induced counterrotating vortices (not shown here).

2.6.3.4 Influence of Particle Size

In order to demonstrate the effect of particle size on the conveying through the standard pipe configuration (5 m horizontal pipe, bend, and 5 m vertical pipe), monosized glass beads of 20, 40, 80, and 135 μm are considered. The particle behavior in the different pipe elements may be first analyzed by considering the different relevant transport mechanisms. In the horizontal pipe, particle motion is governed by gravitational settling and response to turbulence, that is, gravitational settling may be balanced by turbulence if the particles are small enough (i.e., their turbulent Stokes number is smaller than one). From the numerical calculations, the integral timescale of turbulence is estimated to be $T_L = 0.16\ k/\varepsilon = 10.3$ ms on the center line of the pipe. With the Stokesian response time of the particles (see Equation 2.332), turbulent Stokes numbers of 0.3, 1.2, 4.8, and 13.7 are found for the four particle sizes (Table 2.5). This shows that only the smallest particle size may be considerably affected by turbulence. The other elementary processes strongly affecting the particle behavior in the horizontal pipe are wall collisions, especially for rough walls and the involved shadow effect (Sommerfeld and Huber, 1999). Particle–wall collisions become of importance if their response distance (i.e., product of particle response time and terminal velocity) becomes larger than the dimension of the confinement (Sommerfeld et al., 2008), here the pipe diameter D:

$$D < \lambda_P = \tau_P V_S = \frac{\rho_P D_P^2}{18\mu} V_S \tag{2.343}$$

The particle response distances for the four particle diameters are as follows: 0.093, 1.5, 23.9, and 194.0 mm, respectively. This clearly demonstrates that the small particles are marginally influenced by wall collisions including roughness, as they, after rebound, quickly follow the flow again and forget about the wall collision event. Therefore, the resulting particle concentration distributions in the pipe cross section after the considered conveying distance of 5 m is the result of three competing effects: gravitational settling, turbulence, and wall collisions. Comparing the vertical profiles of the normalized particle concentration at the bend entrance (Figure 2.59) and later in this section the respective color-coded concentration fields in Figures 2.61 through 2.64, all obtained with four-way coupling, the following conclusions may be drawn:

1. The smallest particles (20 μm) are unaffected by wall collision phenomena, and gravitational settling is almost entirely balanced by turbulence, yielding virtually constant concentration in the pipe cross section, except for a small region near the upper wall.
2. For the 40 μm particle, gravitational settling becomes more dominant and cannot be balanced by turbulence, while wall collisions are still not very important (distinctive concentration maximum near the bottom at about y/D = 0.15, see Figure 2.59).

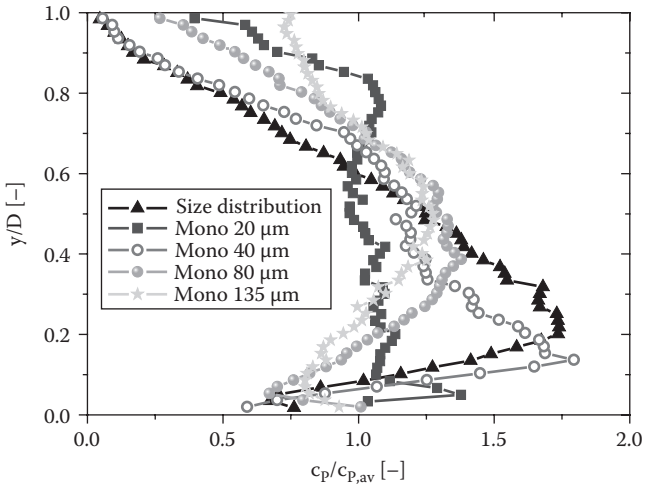

Figure 2.59

Vertical profiles of normalized particle concentration at the bend inlet after a conveying distance of 5 m, comparison for different particle sizes (size distribution according to Figure 2.54 and monosized cases according to Table 2.5); (D = 150 mm, U_{av} = 27 m/s, η = 0.3, $\Delta\gamma$ = 10°, four-way coupling).

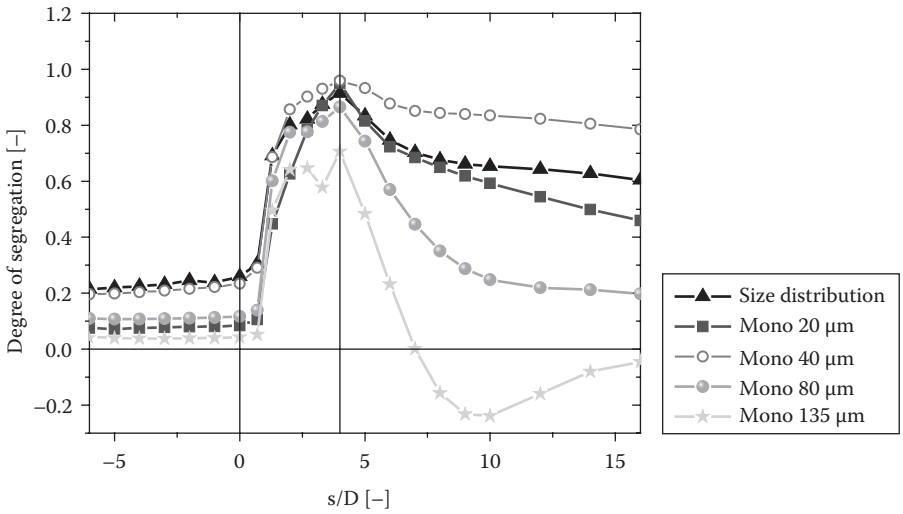

Figure 2.60

Nondimensional segregation parameter (Equation 2.333) along the pipe system for cases ❶ to ❺ in Table 2.5 (D = 150 mm, U_{av} = 27 m/s, η = 0.3, $\Delta\gamma$ = 10°, bend radius 2.54 pipe diameters, four-way coupling); vertical lines indicate bend inlet and outlet.

3. The larger particles (80 and 135 µm) are hardly affected by turbulence, and gravitational settling is more or less balanced by wall collision phenomena (i.e., the shadow effect). Consequently, the concentration maximum is found near the pipe core. Due to the large response distance of the 135 µm particles (i.e., λ_p = 194 mm), they are most likely bouncing from wall to wall (Sommerfeld, 2003).
4. With particle size distribution (Figure 2.54, dp, mean = 40 µm), the concentration profile is quite close to the result for the monosized 40 µm particles; however, due to the presence of smaller and larger particles in the size spectrum, they are slightly better dispersed (Figure 2.59).

The development of the particle concentration distribution along the pipe system may also be characterized in summary through a nondimensional segregation parameter that is a weighted average of the

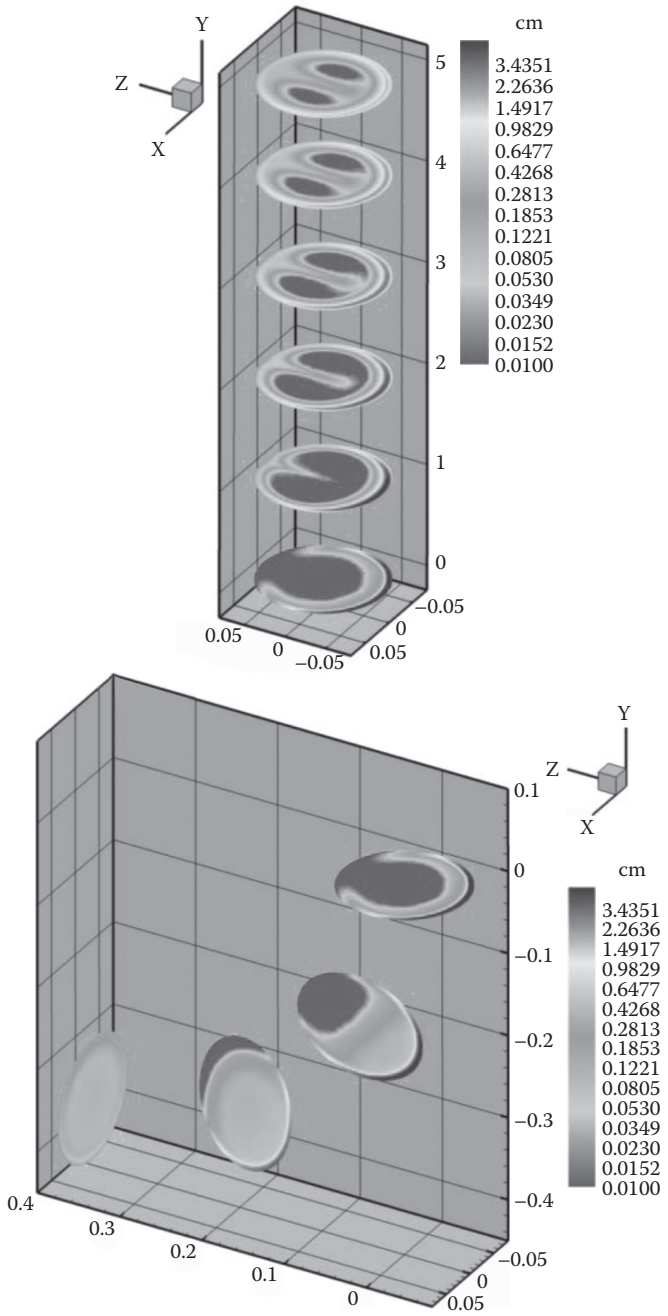

Figure 2.61

Cross-sectional distribution of particle concentration cm (kg/m^3) along bend and vertical pipe (5 m horizontal pipe, bend, 5 m vertical pipe, bend radius 2.54·D, D = 150 mm, U_0 = 27 m/s, η = 0.3, $\Delta\gamma$ = 10°, four-way coupling, monosized 20 μm).

local particle concentration with respect to the radial displacement of the control volume from the pipe center within each cross section:

$$R_{c,max} = \frac{1}{c_{av} R_o V_{cross}} \sum_{1}^{N_i} c_i r_i V_i \tag{2.344}$$

where

c_i is the particle concentration (kg/m^3) in the computational cell
r_i is the vector indicating the center of the cell
V_i is its volume

The product of these three quantities is summarized over all control volumes in one cross section and divided by the average concentration, c_{av}; the pipe radius R_o; and the total volume of the cross-sectional slice V_{cross}. In the present work, r_i is defined to be positive if the control volume is located below (horizontal pipe) or to the right (vertical pipe) of the center line. Hence, the segregation parameter varies in the range $-1 < R_{c,max} < 1$. Therefore, it is possible to identify the location of the maximum particle concentration within the pipe cross section. A value of $R_{c,max} = 0$ corresponds to a completely homogeneous particle distribution or an exactly symmetric distribution with respect to the center plane, which in the present case is not very likely to occur.

This segregation parameter is plotted versus the nondimensional distance along the pipe centerline s/D in Figure 2.60, where D is the pipe diameter. In the horizontal pipe (s/D < 0), gravitational settling can be clearly identified since $R_{c,max}$ is larger than zero. In the horizontal pipe, the strongest gravitational settling is found for the monosized particles with 40 μm and those with the size distribution (i.e., $R_{c,max} \approx 0.2$). The largest particles (135 μm) are clearly very well dispersed due to wall bouncing effects, and the smallest particles (20 μm) are dispersed by turbulence as described earlier.

Within the bend, the behavior of the particles is governed by their response to the mean flow deflection (characterized by the bend Stokes number), secondary flow structure developing throughout the bend, particle–wall collisions, and finally also interparticle collisions as already demonstrated in Figure 2.58. Although for the 20 μm particles the bend Stokes number is quite small, they are not able to completely follow the flow deflection since they are obviously strongly influenced by the secondary flow (Figure 2.61). Already at a bend angle of 30°, a thin layer of high particle concentration develops at the bend outer wall, and eventually, all particles are transported out of the pipe core region. They are carried along the lateral walls of the bend by the secondary flow toward the inner side of the bend, forming at the bend exit a horseshoe-shaped concentration field. Along the vertical pipe, these small particles are further transported by the secondary flow, fully mapping the secondary flow structure at the end of the vertical segment. Within the core of the two counterrotating vortices, almost no particles are present.

For larger particles (i.e., 40 μm), the development of the concentration pattern throughout bend and vertical pipe is completely different (Figure 2.62). Inertial segregation of the particles through the bend is rather strong, and a quite dense rope is formed at the bend exit, which is supported by the fact, that the bend Stokes number approaches unity; that is, ($St_B = 0.557$). The dip in the concentration distribution visible at a bend angle of 60° and at the bend outlet is a result of the particle transport by the secondary flow. More clearly, the transport of the 40 μm particles by the secondary flow becomes visible 1 m downstream of the bend exit where the particles start to be carried along the lateral side walls toward the inner side. At the end of the vertical pipe, the particle distribution in the cross section is still inhomogeneous leaving a core region with almost no particles. For the 40 μm particles, the degree of segregation is largest throughout the entire pipe system showing an almost complete segregation at the bend exit (Figure 2.60).

When the particle size is further increased (Figures 2.63 and 2.64), wall collision and inertial effects become more and more dominating over the developing particle concentration distribution in the pipe system. Consequently, the region with particles being present in the bend is increasing, which is the result of a farther rebound of the particles after a collision with the bend outer wall. The 80 μm particles fill about half the pipe cross section at the end of the bend and the 135 μm particles already more than about 90%. Consequently, the segregation parameter is lower for the 135 μm particles than for the 80 μm particles (Figure 2.60). For both particle sizes, the focusing effect is visible at the bend angle of 60°. In the case of the 80 μm particles, the dust rope is being disintegrated rather slowly. Particle transport happens mainly through secondary flow (Figure 2.63; 1 and 2 m downstream the bend exit). In contrary, the heavy particles (135 μm) are bounced back from the bend outer wall near the exit and move toward the inner side. Consequently, the high-concentration region appears left of the vertical center plane (Figure 2.64; 1 m downstream the bend exit). This results in negative values for the segregation parameter (Figure 2.60).

The evolution of particle concentration throughout the bend and the initial part of the vertical pipe (i.e., up to s/D = 17, corresponding to 1.8 m) may also be characterized by considering the maximum value within a cross section normalized with the average concentration (Figure 2.65). From the beginning toward the end of the bend, the concentration maximum increases rapidly for all particles sizes considered. In the case of the small 20 μm particles ($St_B = 0.139$) where inertial effects are weak, the maximum concentration ratio reaches only a value of about 30. Then increasing particle size and approaching a Stokes number of the order one, the maximum value rapidly increases to about 200 for the 40 μm particles ($St_B = 0.557$), which show the strongest segregation (see Figure 2.62). Beyond $St_B = 1$ (no results available for this case) particle inertia becomes more and more important (i.e., particles begin to bounce from wall to wall), whereby the maximum concentration ratio again drops down and reaches eventually a rather low value for the 135 μm

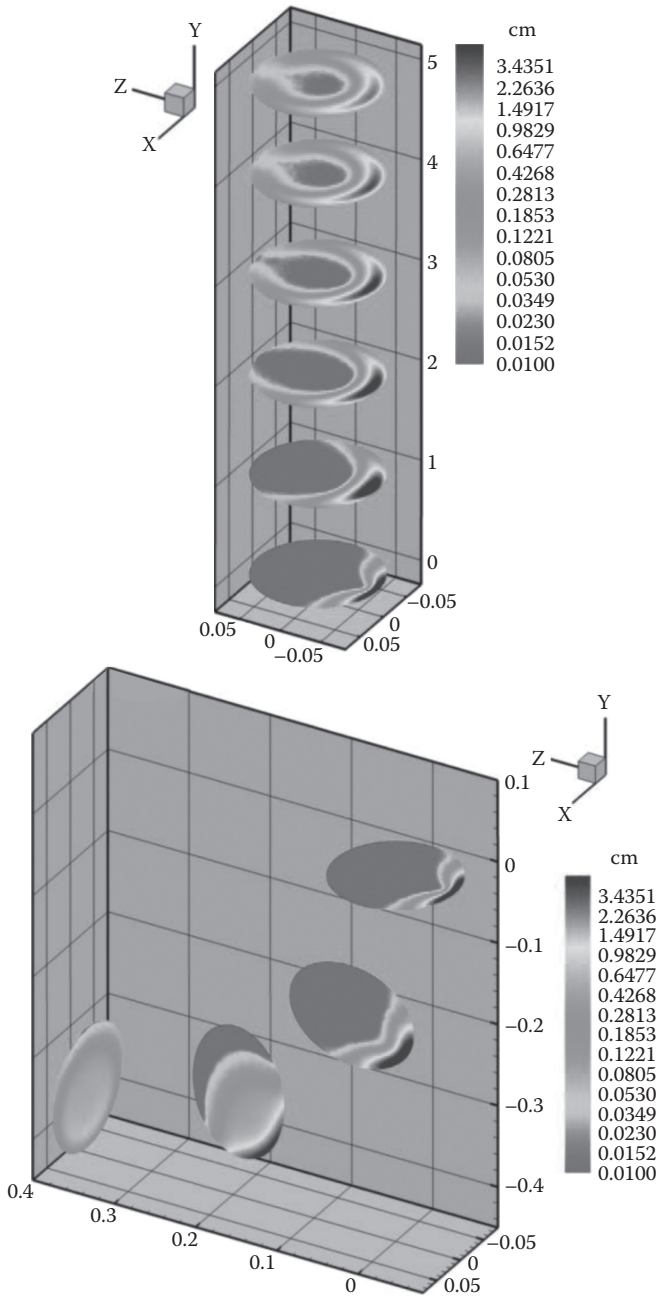

Figure 2.62

Cross-sectional distribution of particle concentration cm (kg/m³) along bend and vertical pipe (5 m horizontal pipe, bend, 5 m vertical pipe, bend radius 2.54·D, D = 150 mm, U_0 = 27 m/s, η = 0.3, Δγ = 10°, four-way coupling, monosized 40 μm).

particles (i.e., St_B = 6.344). From the end of the bend, the concentration ratio continuously decreases for all size cases indicating the dispersion of the dust rope. However, the 40 μm particles still show a high value, indicating a remaining strong segregation (see Figure 2.62).

2.6.3.5 *Influence of Mass Loading*

The influence of particle mass loading on the particle concentration distribution throughout the standard pipe system is analyzed for the case with particle size distribution (case ❶ in Table 2.5). The result for a mass loading of 0.3 with consideration of interparticle collisions is shown in Figure 2.58b. Here, a rather dense rope is formed within the bend filling a segment region of about 40% within the pipe cross section.

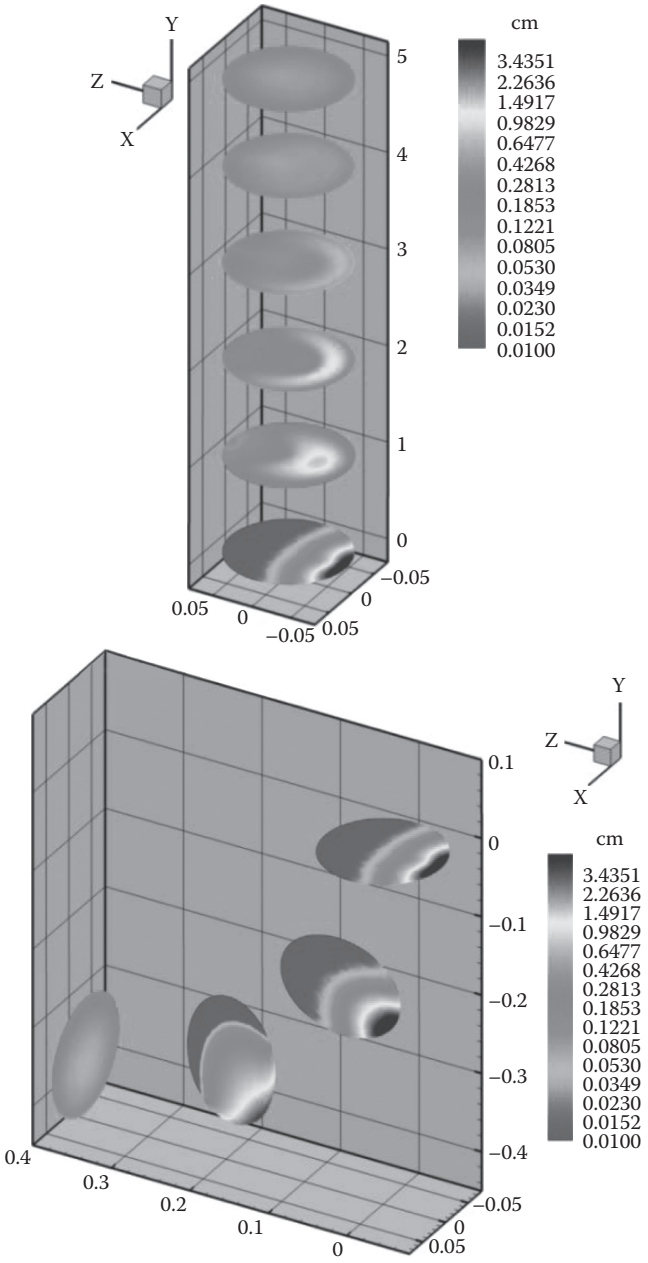

Figure 2.63

Cross-sectional distribution of particle concentration cm (kg/m³) along bend and vertical pipe (5 m horizontal pipe, bend, 5 m vertical pipe, bend radius 2.54·D, D = 150 mm, U_0 = 27 m/s, η = 0.3, Δγ = 10°, four-way coupling, monosized 80 μm).

In the vertical pipe, this dense particle region is rather quickly dispersed yielding an almost homogeneous particle distribution about 3 m downstream of the bend exit. In the case with a mass loading of 1.0, several phenomena may be observed. First, the gravitational settling of the particles in the horizontal pipe is more pronounced (Figure 2.66a). The particle rope formed within the bend is more concentrated for higher mass loading, and at the bend exit, the particles fill only about 30% of the cross section. Of course, the magnitude of particle concentration at the bend outer wall is much higher compared to the low loading case (see Figure 2.58). For the high mass loading, the concentrated rope formed within the bend is not disintegrating very well within the vertical pipe, even after 5 m conveying; however, the rope is expanding laterally along the side walls, being caused by the secondary flow in the pipe cross section. This transport of mainly the smaller particles by the secondary flow is clearly visible in the cross-sectional concentration field 2 m

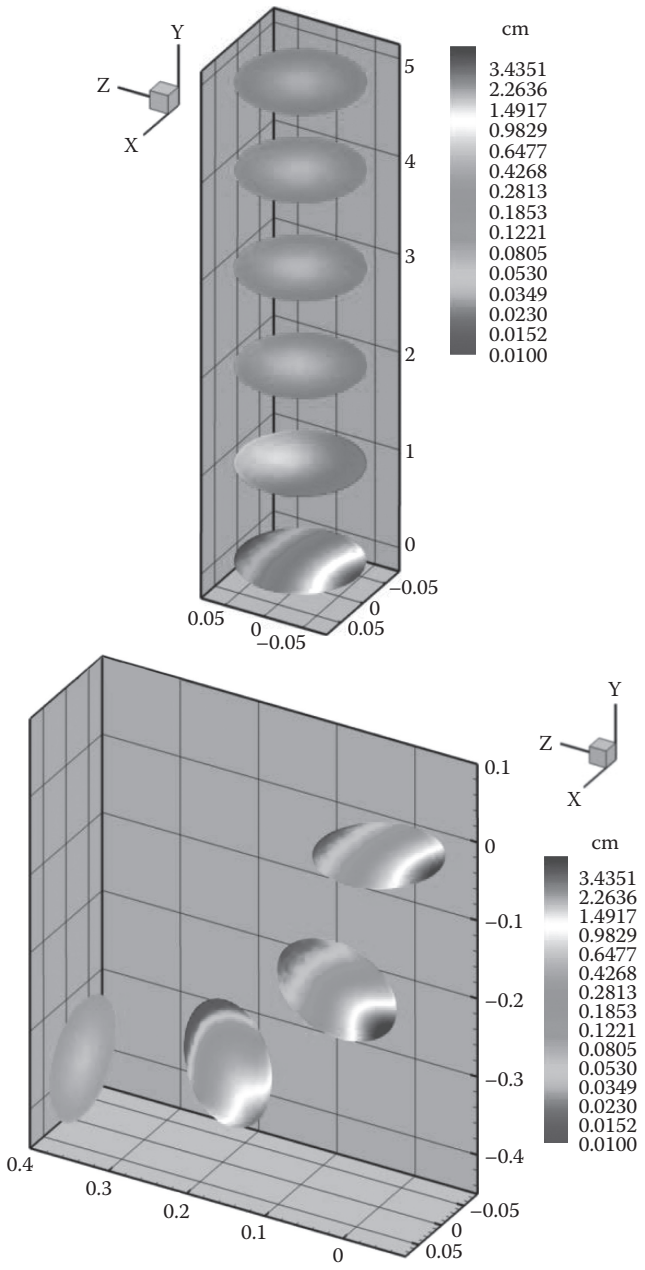

Figure 2.64

Cross-sectional distribution of particle concentration cm (kg/m³) along bend and vertical pipe (5 m horizontal pipe, bend, 5 m vertical pipe, bend radius 2.54·D, D = 150 mm, U_0 = 27 m/s, η = 0.3, Δγ = 10°, four-way coupling, monosized 135 μm).

downstream the bend exit (Figure 2.66a). Here, the particles are transported by the secondary flow from the inner side (left) to the outer side of the cross section, just in the middle between the counterrotating two main secondary vortices. As a result of the strong coupling between the phases and the focusing effect, the secondary flow is remarkably altered within the bend and in the first part of the vertical pipe (Figure 2.66b). Counterrotating particle-induced vortices are already visible at a bend angle of 60° and are preserved in the vertical pipe up to about 1 m downstream of the bend exit. Then they are again entrapped by the two main vortices and eventually disappear. The fact, that the particle rope is not disintegrated even after 5 m conveying in the vertical pipe, is mainly caused by the entrapment of the particles within the high-concentration region as a consequence of interparticle collision. Due to the high particle concentration, the mean free path between particle collisions is remarkably reduced so that the particles are not able to move out of the rope;

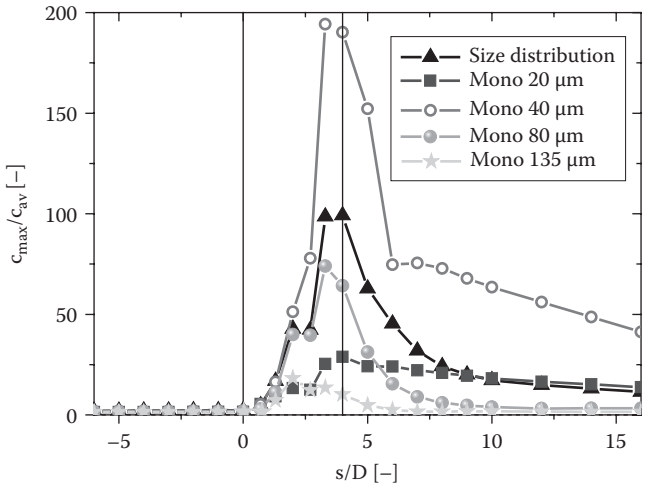

Figure 2.65

Maximum values of particle concentration (in kg/m³) within a cross section normalized with the average concentration along the bend with inlet and outlet sections in the straight pipes for cases ❶ to ❺ in Table 2.5 (D = 150 mm, U_{av} = 27 m/s, η = 0.3, Δγ = 10°, bend radius 2.54 pipe diameters, four-way coupling); vertical lines indicate bend inlet and outlet.

instead, they collide with particles within the rope and bounce back. The cross sections of the streamwise gas velocity being perpendicular to the planes (color coded) reveal that the air velocity within the particle rope is remarkably reduced resulting from two-way coupling (Figure 2.66b).

2.6.3.6 *Effect of Particles on Flow Structure*

In the following section, the secondary flow modification or secondary flow intensity (SFI) that is affected by two-way coupling and will also be influenced by interparticle collisions is analyzed in some more detail. First, the cross-sectional distributions of air velocity and secondary flow structure along bend and vertical pipe are considered for the 40 µm monosized particles comparing two- and four-way coupling (see Figure 2.67). As emphasized earlier, the particle rope formed within the bend is much wider when neglecting interparticle collisions (see Figure 2.58 for the case with size distribution). Accounting for interparticle collisions, the particle moving into the bend will collide with particles being rebound from the bend outer wall and hence the region of high particle concentration is "compressed"; that is, the particles are eventually "trapped" in the powder rope that is much more concentrated in this case. This is reflected in the distribution of the streamwise air velocity along the pipe system originating from two-way coupling. With two-way coupling, relatively wide regions near the bend and vertical pipe outer wall exhibit low gas velocities (Figure 2.67a), being about 75%–80% of the bulk gas velocity. These regions coincide with those of the dust rope where the particles have to be reaccelerated and lifted up against gravity, extracting the required momentum from the gas phase. With interparticle collisions, the dust rope is much more narrow (compare Figure 2.58), and hence, the regions with low gas velocity near the outer wall (right-hand side) are considerably smaller than without collisions (compare Figure 2.67a and b).

The white lines in Figure 2.67 show the cross-sectional air velocity streamlines. In the case of two-way coupling only, two counterrotating vortices develop in the region of high particle concentration between the second and third cross section of the bend and extend into the vertical pipe (Figure 2.67a). These vortices result from the rebound of particles from the bend outer wall toward the pipe core, whereby momentum is transferred to the fluid inducing these vortices. This phenomenon was called focusing effect in Lain and Sommerfeld (2013). The particle-induced vortices extend into the vertical pipe up to about 2 m from the bend exit. Further downstream, the particle-induced counterrotating vortices again decay, but the overall structure of the secondary flow is nevertheless strongly altered compared to the single-phase flow. With interparticle collisions (Figure 2.67b), the dust rope is much more narrow (i.e., particles are trapped within the rope due to collisions between them) and hence also the region with reduced gas velocity. Therefore, strong counterrotating vortices do not develop for this condition and can be only identified within the third cross section of the bend. In conclusion, the flow modification by the particles is much lower in four-way coupling than in two-way coupling.

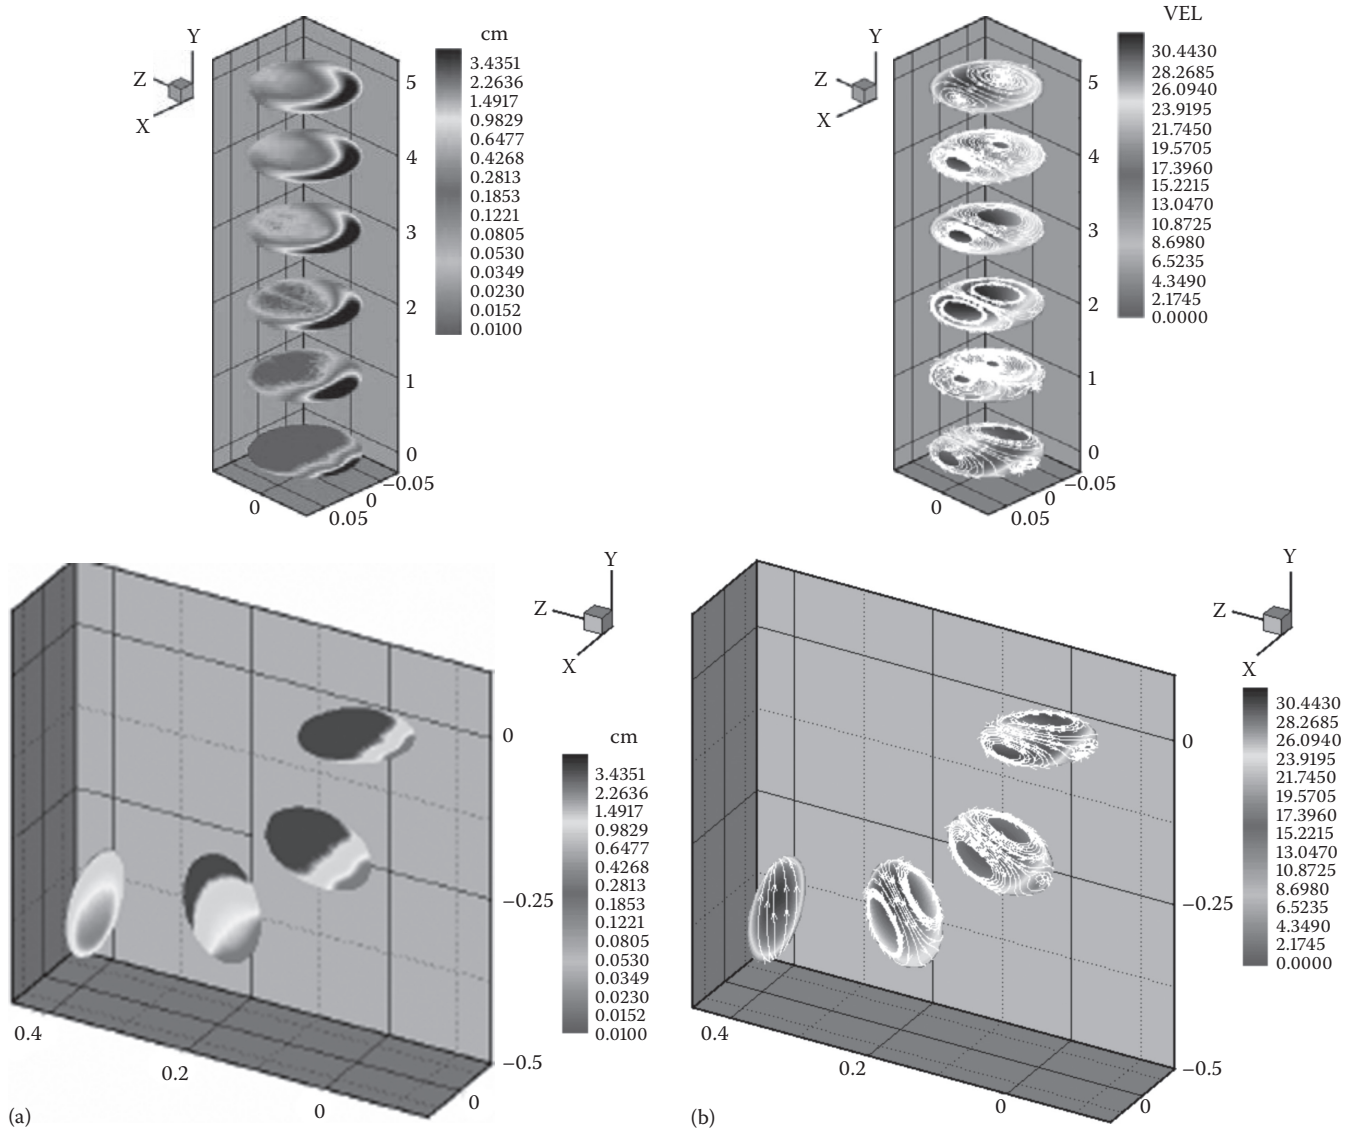

Figure 2.66

Cross-sectional distribution of particle concentration cm (kg/m³) (a) and streamwise air mean velocity *VEL* (m/s) (color) as well as secondary flow stream lines; white lines (b) both along bend and vertical pipe (5 m horizontal pipe, bend, 5 m vertical pipe, bend radius 2.54 · D, D = 150 mm, U_{av} = 27 m/s, η = 1.0, Δγ = 10°, particle size distribution 15–85 μm, four-way coupling).

Also, the other four-way coupled calculations for monosized particles did not show a distinctive development of counterrotating vortices induced through the particles by the focusing effect within bend or connecting vertical pipe. Of course, the secondary flow structure was nevertheless modified by the particles also in four-way coupling. In order to characterize the influence of the particle phase on the secondary flow, the SFI is used, which is obtained for one cross section from:

$$\mathrm{SFI} = \frac{1}{V_{cross}} \sum_{i=N} V_i \frac{U_{1,i}^2 + U_{2,i}^2}{U_{av}^2} \tag{2.345}$$

where

V_i is the volume of a computational cell

V_{cross} is the volume of the cross-sectional slice in the bend or the connecting vertical pipe

$U_{1,i}$ and $U_{2,i}$ are the gas velocity components in each cell lying in the cross-sectional planes

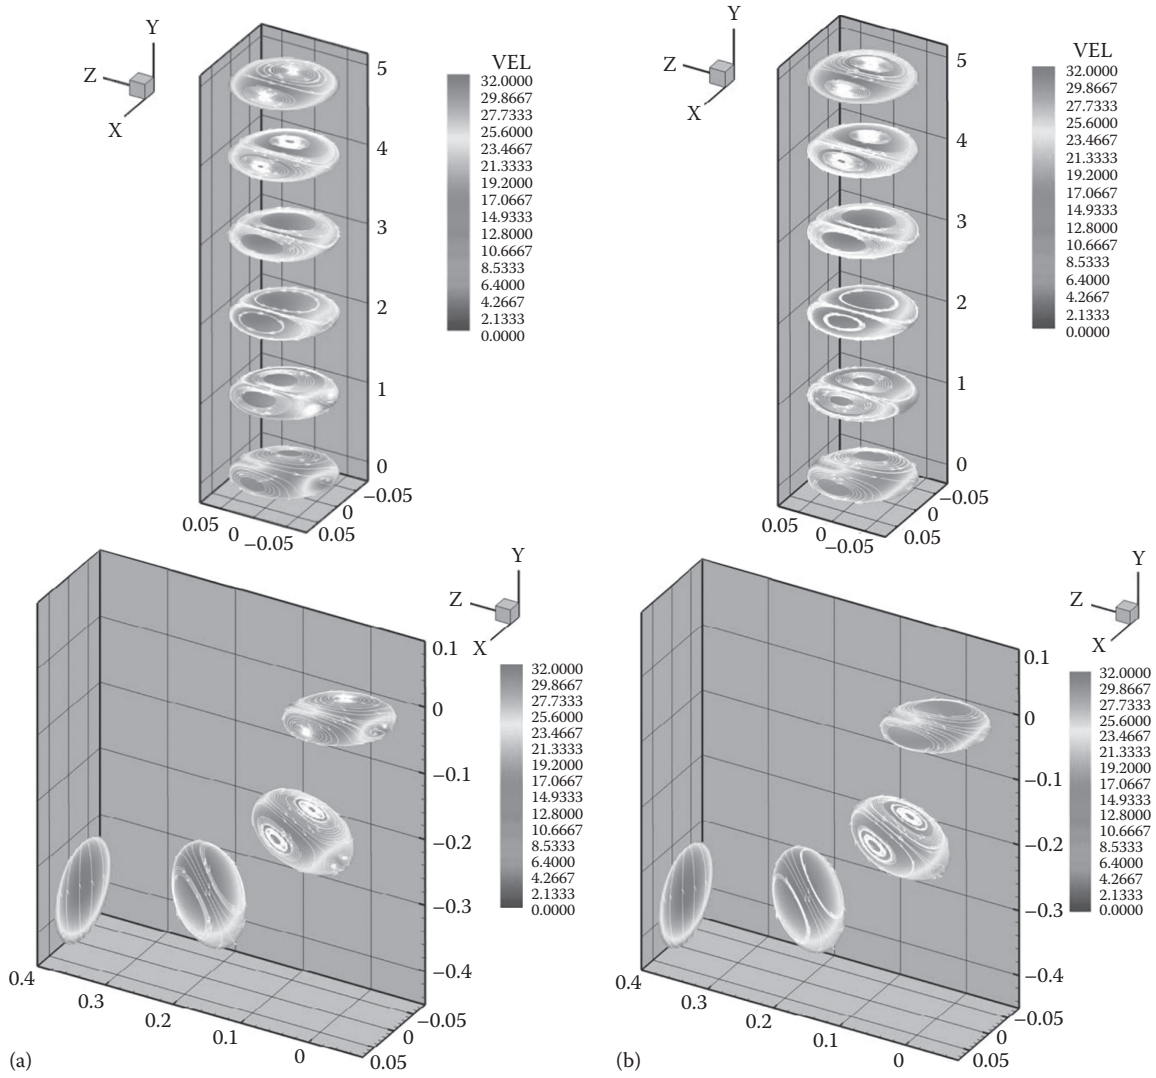

Figure 2.67

Cross-sectional distribution of streamwise air mean velocity *VEL* (m/s) (color) as well as secondary flow stream lines (white lines) both along bend and vertical pipe comparing (a) two-way coupling and (b) four-way coupling (5 m horizontal pipe, bend, 5 m vertical pipe, bend radius 2.54 · D, D = 150 mm, U_{av} = 27 m/s, η = 0.3, Δγ = 10°, particle size 40 μm).

As shown in Figure 2.68 for the development of SFI along the extended bend in the case of four-way coupling, the strongest reduction of the SFI within the first part of the bend (i.e., up to about 70° bend angle) is observed for the larger particles due to their relatively strong rebound and the involved more pronounced focusing effect (see Figures 2.63 and 2.64). Toward the end of the bend and along the vertical pipe, however, the smallest particles (i.e., 20 μm) yield the strongest decay of the SFI as they are closely interacting with the secondary flow and occupy a relatively large region of the pipe cross section; see Figure 2.61 (note there is however still slip between the phases). The lowest SFI modification is observed for the case with particle size distribution.

As shown earlier, also interparticle collisions have an influence on SFI (Figure 2.69), as the particle concentration distribution is modified (i.e., the extent of the dust rope in the bend is mostly reduced), mainly in the bend and the vertical pipe, which is summarized in Figure 2.69 for the overall values of SFI in the pipe bend and the vertical pipe separately in dependence of particle size. Naturally, the influence of particles on fluid flow yields a reduction of SFI compared to single-phase flow. With increasing particle size, the SFI for two-way coupling is continuously reduced in the bend with growing particle diameter. In the vertical pipe, SFI is almost independent of particle size and shows only a slight maximum for the 40 μm particles. When accounting for interparticle collisions, the SFI is mostly increasing again for the particle size cases considered;

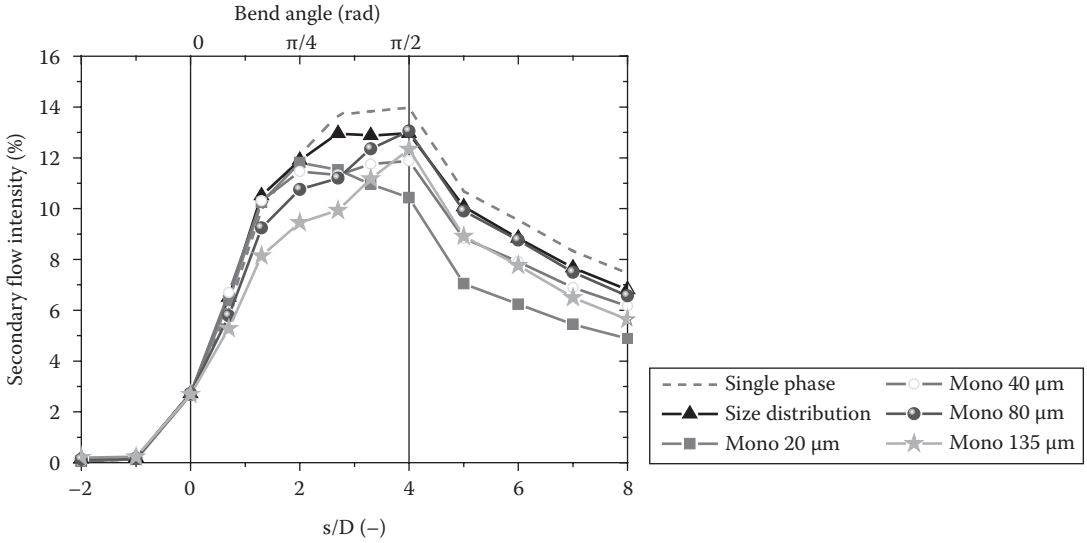

Figure 2.68

SFI (Equation 2.334) along the bend with inlet and outlet sections in the straight pipes for cases ❶ to ❺ in Table 2.5 (5 m horizontal pipe, bend, 5 m vertical pipe, bend radius 2.54 · D, D = 150 mm, U_{av} = 27 m/s, η = 0.3, Δγ = 10°, bend radius 2.54 · D, four-way coupling); vertical lines indicate the bend inlet and outlet.

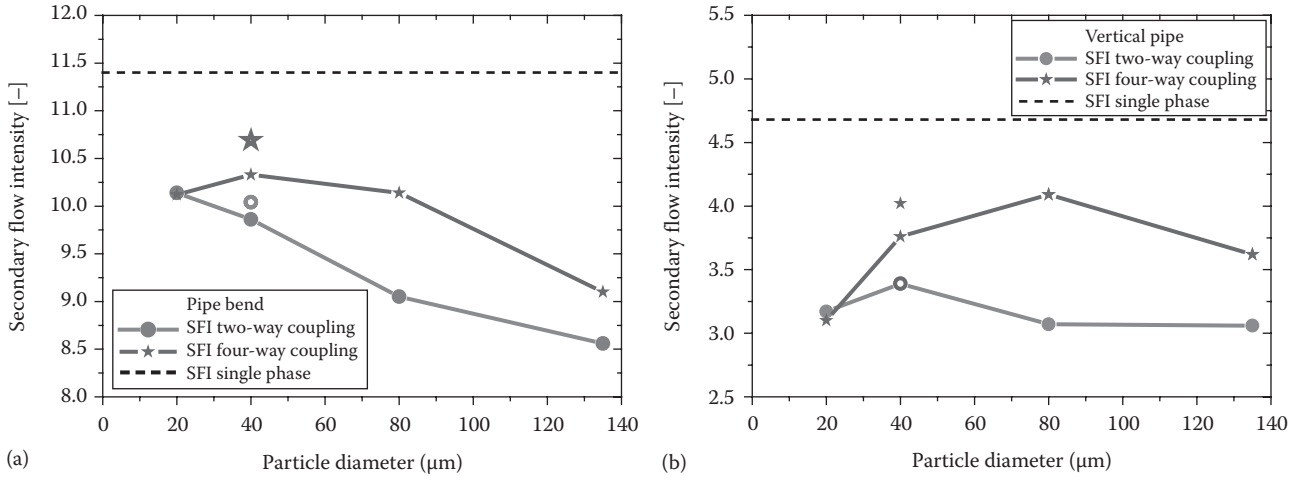

Figure 2.69

Averaged value of SFI along the bend (a) and the vertical pipe (b) for cases ❶ through ❺ in Table 2.5 in dependence of particle size; comparison of two- and four-way coupling; the open circle and star indicate the result for the size distribution (case ❶ in Table 2.5) with a number mean diameter of 40 µm (5 m horizontal pipe, bend, 5 m vertical pipe, bend radius 2.54 · D, D = 150 mm, U_{av} = 27 m/s, η = 0.3, Δγ = 10°).

however, this increase depends on particle inertia and hence the bend Stokes number. This implies that the flow modification by the particles is again reduced. There is almost no difference between two- and four-way coupling for the 20 µm particles with a small St_B = 0.139 (bend and vertical pipe). Then the difference increases, reaching a maximum for the 80 µm particles having a Stokes number of around unity (i.e., St_B = 2.228) for both bend and vertical pipe. For further growing particle size and bend Stokes number, the difference of SFI obtained for two- and four-way coupling is again reduced. For such large particles, the SFI within the bend has the lowest value (i.e., the strongest SFI modification by the particles) since the particles are dispersed over a wide region of the bend. Within the vertical pipe, the strongest flow alteration by the particles is found for the 20 µm particles. Also, the SFI for the case with particle size distribution is indicated in Figure 2.69 as open symbols. With two-way coupling, the SFI is almost identical with the value of the 40 µm monosized particles. However, with four-way coupling, the secondary flow modification by the particles is lower.

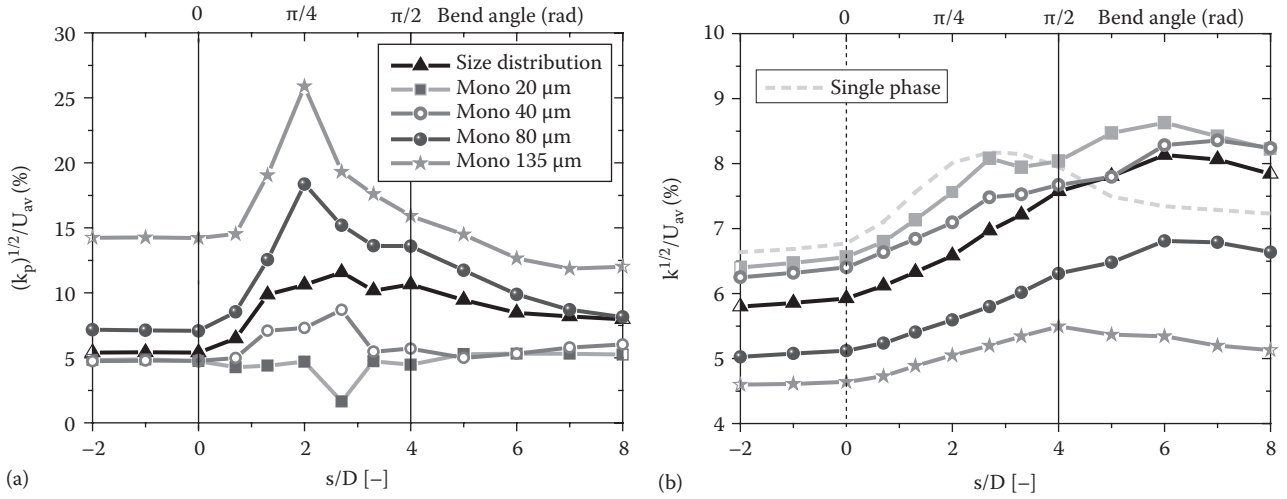

Figure 2.70

Fluctuating energy along the extended pipe bend configuration: (a) particle phase and (b) gas phase (5 m horizontal pipe, bend, 5 m vertical pipe, bend radius 2.54·D, D = 150 mm, U_{av} = 27 m/s, η = 0.3, Δγ = 10°, four-way coupling, different particle sizes).

In the following, cross-sectional averages of the normalized fluctuating velocities of both phases along an extended bend section (i.e., –2 < s/D < 8) are discussed, which are obtained as $k^{1/2}/U_{av}$ and $k_P^{1/2}/U_{av}$, respectively. Generally, the average fluctuating velocity of the particles increases with particle size in the entire considered pipe element (Figure 2.70a). This is associated with the growing particle inertia and the involved increasing importance of particle–wall collisions. Consequently, at the end of the horizontal pipe, the largest particles have the highest averaged fluctuating velocity. Note that these large particles may be expected to bounce from wall to wall (Sommerfeld, 2003). When the particles enter the bend, the wall collision frequency is increasing since the particles cannot follow the flow deflection completely. This of course is depending on the particle size and hence the bend Stokes number. As shown earlier, the wall rebound distance increases with particle size whereby particles with higher inertia are being further bounced back from the bend outer wall toward the pipe core (see Figures 2.61 through 2.64). Consequently, larger particles show a more random motion while smaller particles rather quickly follow the flow deflection. Thus, the particle mean fluctuating velocity drastically increases with particle size. Ultimately, the deflection of the particle stream in the first part of the bend yields growing particle fluctuating velocities, that is, up to about 45° bend angle for the largest particles and up to about 60° for the 40 µm particles. Further downstream, the deflection of the particle stream is largely completed and a more or less dense rope is formed at the bend outer wall. Therefore, the wall collision frequency is reduced, and additionally, the particles are trapped in the rope by interparticle collisions resulting in the damping of the fluctuating motion. Therefore, the particle velocity fluctuations are continuously reduced throughout the bend outlet section and the connecting vertical pipe approaching a new equilibrium value (Figure 2.70a). An exception is the development of the average fluctuating velocity for the smallest particles (20 µm) along the pipe segment. Due to the rapid response of these small particles to the flow deflection and the secondary flow structure, they begin quickly to slide along the bend outer wall and mainly remain in the low-flow-velocity region (see Figure 2.61). The particle velocity fluctuations for the case with size distribution are lying between those of the 80 and 40 µm monosized particles; however, rise beyond their values in the vertical pipe as a consequence of the different response of particles in a wide size spectrum, which was demonstrated by Sommerfeld (1990) for a vertical channel flow.

Cross-sectional averages of gas-phase fluctuation velocity along the bend with inlet and outlet sections are shown in Figure 2.70b. With increasing particle size, the gas-phase fluctuating velocity is remarkably reduced by the particles compared to the single-phase flow in the considered pipe segment. This continuously increasing turbulence dissipation with growing particle size is a consequence of indirect coupling through the momentum source terms (e.g., reduction of SFI and streamwise mean velocity within the dust rope) and direct coupling through the source terms in the k- and ε-equation. The single-phase turbulent kinetic energy increases continuously in the first part of the bend (i.e., up to about 70° bend angle) and then reduces again to approach a new equilibrium value in the vertical pipe, which is of course higher as in the horizontal pipe (Figure 2.70b). The increase of $k^{1/2}/U_{av}$ is associated with the deformation of the streamwise

mean velocity distribution and the development of the secondary flow that first increases up to the bend exit and then decreases in intensity along the vertical pipe section (Figure 2.68).

For most of the different particle size cases, the gas-phase fluctuating velocity continuously increases throughout the bend and also within the first part of the vertical pipe (i.e., up to about s/D = 6), except for the 135 µm particles (Figure 2.70b). As said earlier, this is a consequence of the modification of the streamwise mean gas velocity distribution and the secondary flow structure by the particles. Therefore, also the gas-phase fluctuating velocity becomes larger than the values for the single-phase flow at the beginning of the vertical pipe in the case of the small particles (i.e., 20 and 40 µm) and that with particle size distribution. This implies that turbulence is enhanced through the particles as an outcome of the strong particle segregation and the resulting introduction of additional shear to the gas flow at the edge of the high-concentration region. In more detail, within the narrow dust rope, the streamwise gas velocity is lowest as a result of momentum coupling. At the inner edge of the dust rope, the streamwise gas velocity increases toward the maximum value near the core (see also Figure 2.56), yielding high shear rates whereby turbulence is generated.

For larger particles (i.e., 80 and 135 µm), turbulence is distinctively lower throughout the entire pipe system compared to the single-phase flow and the small particle cases (Figure 2.70b). This is motivated by two effects. First, as a consequence of their inertia and wall rebound, the larger particles are distributed over a bigger region of the pipe cross section within bend and vertical pipe (compare Figures 2.61 through 2.64). Therefore, the particles also affect a larger region of the flow through two-way coupling and reduce turbulence. Second, the slip velocity between gas and particles increases with particle size, whereby the momentum source terms are also growing and consequently reduce turbulence more intensely. It should be mentioned that turbulence generation by the particles through their wakes is not occurring for the present cases (Gore and Crowe, 1989, Hetsroni, 1989, Crowe, 2000, Lain and Sommerfeld, 2003), as the particle Reynolds number is much lower than 200–400 even for the largest particles.

2.6.3.7 Analysis of Pressure Drop

For all the cases discussed earlier, the pressure drop in the entire pipe system, as well as that in the individual pipe elements, was determined from the calculations (Table 2.6). In pneumatic conveying, the pressure drop is composed of the single-phase pressure drop and the additional pressure drop due to the presence of the particles (Lain and Sommerfeld, 2013). This additional pressure drop, of course, depends on conveying velocity, mass loading, particle properties, and pipe geometry and material. In the following, the different effects responsible for the additional pressure drop are summarized and values are calculated with the correlations used for engineering design (Siegel, 1991), exemplarily for case ❶ in Table 2.6:

- Momentum loss due to particle–wall collisions (i.e., often termed particle–wall friction) is relevant for all pipe elements and depends on the wall collision frequency. With an assumed particle friction λ_{Part} according to Sommerfeld and Kussin (2003), one obtains for the different pipe elements with Equation 2.345 the following values:

$$\Delta p_{pwc} = \eta \lambda_{Part} \frac{L}{D} \frac{\rho}{2} U_{av}^2 \tag{2.346}$$

Table 2.6 Calculated Pressure Drop across the Different Pipe Elements for the Various Conditions Considered (D = 150 mm, U_{av} = 27 m/s, η = 0.3 [Except for the Case with η = 1.0], Δγ = 10° (Except for the Case with Δγ=1.5°), 5 m Horizontal Pipe, Bend, and 5 m Vertical Pipe, Bend Radius 2.54 Pipe Diameters, Four-Way Coupling)

Case	Δp Total (Pa)	Δp Hor. (Pa)	Δp Bend (Pa)	Δp Vertical (Pa)
Single phase	556	231	92	233
❶ η= 0.3	770	280	145	345
❶ η = 1.0	902	361	139	402
❶ Δγ=1.5°	757	265	130	362
❷20 µm	744	254	158	332
❸ 40 µm	740	265	126	349
❹ 80 µm	833	309	154	370
❺ 135 µm	1129	449	167	513
❻ 30 + 60 µm	748	276	142	330

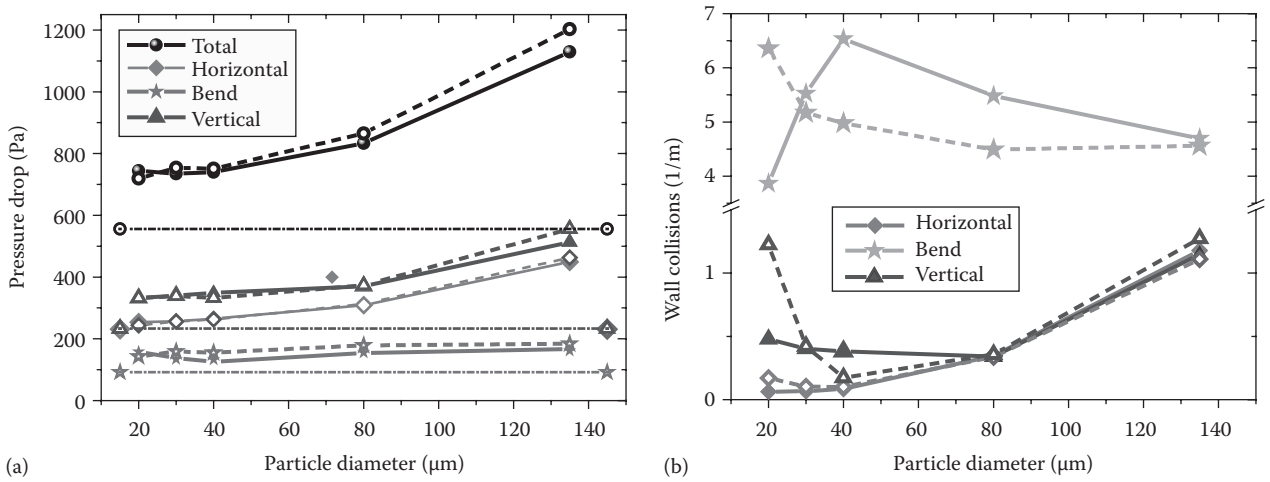

Figure 2.71

Dependence of pressure drop (a) and wall collision frequency (b) on particle size showing the influence of interparticle collisions (i.e., two- versus four-way coupling): closed lines and closed symbols, four-way coupling; dashed lines and open symbols, two-way coupling; and horizontal dash–dot lines with open symbols, single-phase flow pressure drop (5 m horizontal pipe, bend, 5 m vertical pipe, bend radius 2.54·D, D = 150 mm, U_{av} = 27 m/s, η = 0.3, Δγ = 10°).

Horizontal pipe (λ_{Part} = 0.01), 44 Pa
Pipe bend (λ_{Part} = 0.02), 10 Pa
Vertical pipe (λ_{Part} = 0.02), 88 Pa

(Due to the higher wall collision frequency in bend and vertical pipe here, a value of λ_{Part} = 0.02 was assumed; see Figure 2.71b.)

- Particle reacceleration after frequent wall collisions in the bend. Typically, the averaged particle velocity within the bend is reduced by about 20% of the average conveying velocity; this effect is relevant for the bend and partly also for the vertical pipe. According to Equation 2.346 and with $\Delta U_{p,acc}/U_{av}$ = 0.2, one obtains Δp_{pacc} = 52 Pa using the following equation:

$$\Delta p_{pacc} = 2\eta \frac{\Delta U_{p,acc}}{U_{av}} \frac{\rho}{2} U_{av}^2 \tag{2.347}$$

- Particle lifting in the 5 m long vertical pipe against gravity (since the particles are relatively small, it is assumed that $U_{av}/U_{p,av}$ = 1 and one obtains Δp_{plift} = 18 Pa):

$$\Delta p_{plift} = \eta \rho L g \frac{U_{av}}{U_{p,av}} \tag{2.348}$$

- Modification of the SFI in bend and vertical pipe has a minor effect due to the rather small modifications by the particles as shown in Figures 2.68 and 2.69.

In this estimate, the high number of particle–wall collisions occurring in the bend and vertical pipe (see Figure 2.71b) is considered by doubling the wall friction coefficient and the secondary flow modification is not accounted for. The total additional pressure drop for the particle phase is then obtained as 212 Pa (Δp_{hor} = 44 Pa, Δp_{bend} = 62 Pa, Δp_{vert} = 106 Pa). According to Table 2.6, the numerically calculated additional pressure associated with the particles in case of four-way coupling is 214 Pa, indicating that the estimate (Equations 2.344 to 2.346) is already very good, also for the individual pipe elements. It should, however, be kept in mind that the wall friction coefficient was estimated accounting for wall roughness and particle size (Sommerfeld and Kussin, 2003) and that it was assumed that the particle velocity in the bend is reduced by 20%. Moreover, it was presumed that the wall friction in bend and vertical pipe has twice the value assumed for the horizontal pipe, as the wall collision frequency is higher in these pipe segments (see Figure 2.71b) giving of course higher wall friction coefficients.

The calculated gas- and particle-phase pressure drop summarized in Table 2.6 for the different pipe elements allows for the following conclusions:

- Increasing wall roughness enhances wall collisions (through the shadow effect) and hence particle-phase pressure drop due to the required reacceleration of the particles by the fluid.
- Naturally, the pressure drop is increased with the mass loading of the particles since the absolute number of wall collisions increases.
- When increasing the size of monodispersed particles in the range considered here (i.e., from 20 to 135 μm), the particle response to turbulence goes from partly responsive to very inertial (see Table 2.5); thus, the overall wall collision frequency and the pressure drop increase (see Figure 2.71).
- The total pressure drop is the lowest in the bend followed by the horizontal pipe and then the vertical part (see Figure 2.71a). The high pressure drop in the vertical pipe results from particle–wall collisions induced by the bend flow and the required lifting of the particles.
- In the horizontal and vertical pipes, the pressure drop increases distinctively with particle size due to the increase in inertia and wall collision frequency.

The total pressure drop (i.e., gas and particle phase) for the different pipe elements in dependence of particle size is also summarized in Figure 2.71a comparing two- and four-way coupled calculations. The lowest pressure drop is found in the bend due to its size and the highest in the vertical pipe due to the additional effect of particle lifting. In all pipe elements, the pressure drop increases with the particle diameter due to growing particle inertia and wall collision rate, except for the bend region that does not show such strong variations of pressure drop. Interparticle collisions do not have a direct effect on the pressure drop, but only through the alteration of the wall collision rate and the modification of the flow structure (i.e., due to interparticle collisions the dust rope in the bend is compressed and it becomes more concentrated). For all pipe elements, the pressure drop is generally slightly reduced by considering interparticle collisions (Figure 2.71a). However, this trend is changing when going to the very small particles. The smallest impact of collisions between particles on the pressure drop is observed for the horizontal pipe.

In order to explain the main factors by which the pressure drop is modified through interparticle collisions, also the wall collision rate in dependence of particle size (i.e., wall collisions per meter pipe length) was extracted from the simulations for the different pipe elements (Figure 2.71b). For the horizontal and vertical pipe elements, the wall collision rate is increasing with particle size coupled with growing particle inertia; that is, particles increasingly bounce from wall to wall. The wall collision rate is only marginally altered through collisions between particles in the horizontal pipe similar to the pressure drop. The trends for the pipe bend and the vertical pipe are very similar. For the 20 μm particles (i.e., $St_B < 1$), the wall collision rate reduces through interparticle collisions; however, the pressure drop is slightly increased (see Figure 2.71a). In case of particles with $D_P \geq 40$ μm, the wall collision rate within the bend is remarkably higher accounting for interparticle collisions. This is evident, as the particles are trapped in the concentrated rope, bouncing with other particles and also more frequently with the wall. This implies that the decrease in pressure drop through interparticle collisions within the bend (Figure 2.71a) is dominantly the result of flow and pressure gradient modifications (i.e., streamwise velocity field and cross-sectional flow structure) as the dust rope is becoming more concentrated. The effect of growing pressure drop due to increasing wall collision rate is of lower importance in the bend (Figure 2.71b) since the particle reacceleration is the dominant contribution.

In the vertical pipe, the trends regarding the influence of interparticle collisions on the pressure drop closely follow those in the wall collision rate; decreasing wall collision rate also yields decreasing pressure drop (40 μm particles) and vice versa (135 μm particles). Consequently, the particle-phase pressure drop is mainly determined by wall collisions in addition to particle lifting.

As indicated earlier, particle–wall collisions are essentially responsible for the particle-phase additional pressure drop. Therefore, a further analysis of color maps for the wall collision rate (i.e., wall collisions/m^2) throughout the bend is performed for the different particle size cases. Since the small low inertia particles (i.e., 20 μm; $St_B = 0.139$) follow reasonably well the flow deflection through the bend, they also have the lowest wall collision rate as indicated in Figure 2.71b. The majority of wall collisions are observed to occur with the outer wall region of the bend and at large bend angles (i.e., bend angle > 45°), as shown in Figure 2.72a. In accordance with the particle concentration distribution (Figure 2.61), the wall collision rate is also high over a relative wide angular range. When particle size and hence inertia

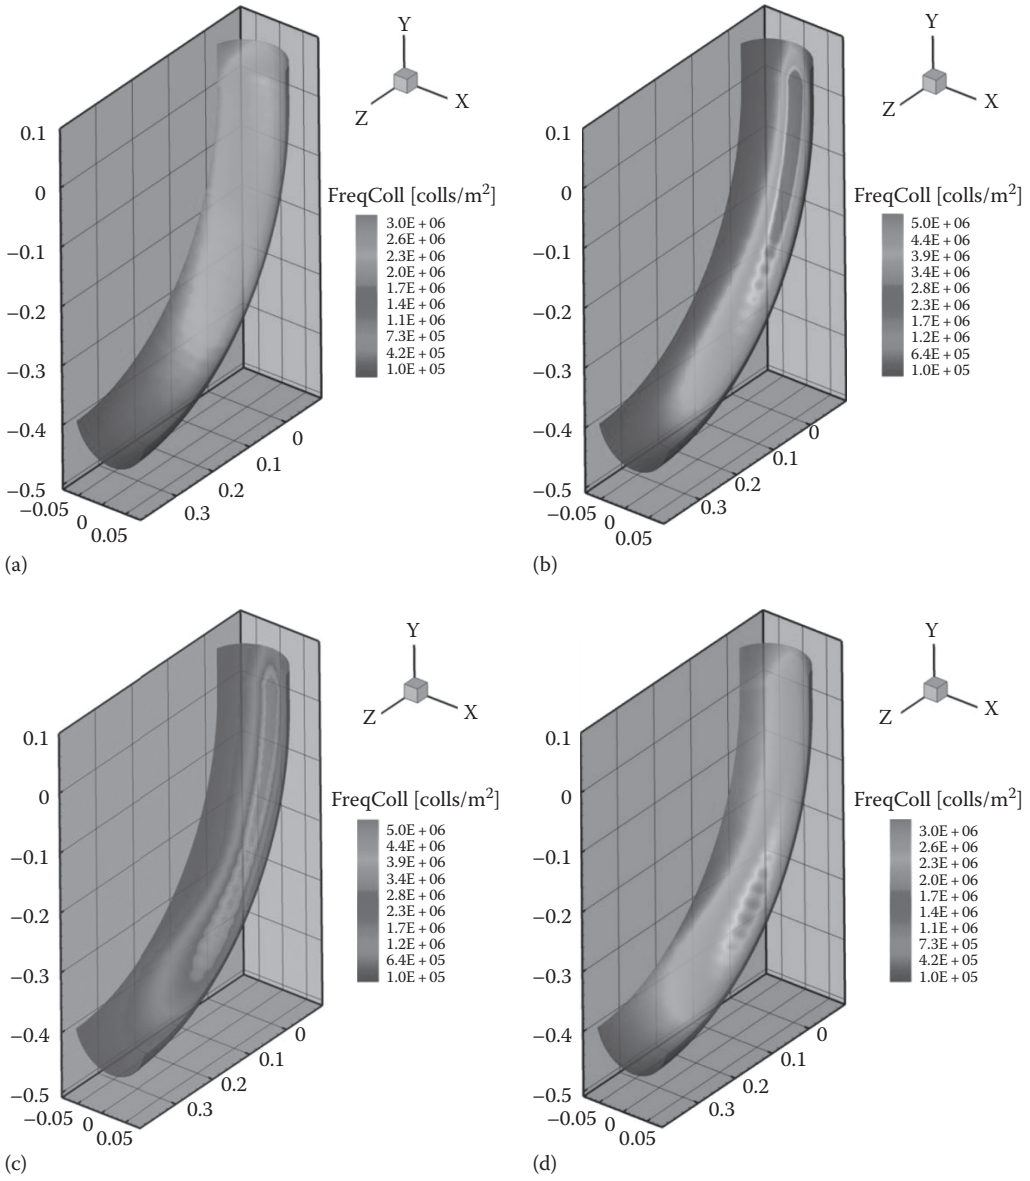

Figure 2.72

Maps of the particle–wall collision rate (collisions/m²) on the outer wall of the bend for different monosized particles: (a) D_P = 20 µm, (b) D_P = 40 µm, (c) D_P = 80 µm, and (d) D_P = 135 µm (5 m horizontal pipe, bend [radius 2.54 pipe diameters], 5 m vertical pipe, D = 150 mm, U_{av} = 27 m/s, η = 0.3, Δγ = 10°, four-way coupling inflow to the bend from the left; note that in graphs (a) and (d), a reduced color scale was used to improve clarity).

are increasing, the wall collision rate is growing (Figure 2.71b) and the pattern at the bend outer wall is shifted toward lower bend angles (i.e., higher wall collision rates are found for θ > 20°) and becomes more narrow (Figure 2.72b). Hence, very high wall collision rates are found in a narrow strip from θ > 40° up to the bend outlet. With a further increase in particle size, the strip of very high wall collision rates is shifted further to the bend entrance and becomes a bit more narrow (Figure 2.72c). These effects are associated with growing particle inertia whereby they are following less and less the flow defection through the bend and the gravitational settling in the horizontal pipe entering the bend that yields a shift of the high-concentration region toward the pipe bottom. The ripple structure in the wall collision pattern observed most pronounced for the 40 and 80 µm particles is a result of the particles' saltation motion along the bend outer wall. The map of wall collision rate is completely changed when considering the very inertial particles (i.e., D_P = 135 µm, St_B = 6.344), which are bouncing from wall to wall when moving through a pipe (Figure 2.72d). First of all, the total wall collision rate is lower due to the reduced number density at

the same mass loading. Second, the region of highest wall impact rates is further shifted toward the bend entrance where the pattern also shows a ripple structure due to saltation motion. Toward the end of the bend, a strip of higher wall collision rate is visible.

2.6.4 Erosion in Pipe Bend

The erosion of wall material in particle-laden confined flows is a severe problem in many areas of process engineering where the process is running for a long time period such as pneumatic conveying, particle separation, especially in cyclones, or fluidized beds. For predicting the erosion rate, mainly Lagrangian models for the particle phase are being used (see, e.g., Pereira et al., 2014). However, also a few studies were done using the two-fluid approach in connection with erosion modeling (see Weickert et al., 2011 and references therein).

As a result of the complexity of single particle erosion and the involved huge number of parameters, generally, erosion experiments are being done to provide input data for the models. Particle erosion is first affected by the involved materials, namely, the wall material and wall surface structure (e.g., wall roughness) and the material of the particles, their shape, and surface structure. This implies that the flow temperature, which influences material properties, also has to be considered. Second, the kinematic parameters of particle motion are of importance, namely, particle velocity (translational and rotation) and particle impact angle. It is generally accepted that the two physical mechanisms that are also coupled with the wall material are relevant for erosion:

- Cutting erosion wear mainly occurring at shallow particle impact angles where swarfs of metal are removed from the wall (Finnie, 1960). This type of erosion is mainly found for ductile material.
- Deformation erosion wear is primarily observed for close to normal particle impact and the material is removed as a result of plastic and elastic surface deformation, mostly after multiple particle impacts. Such kind of erosion is preferably occurring for brittle wall material.

Generally, both erosion phenomena occur at the same time and it is obvious to combine them into one model, as suggested already by Bitter (1963). Following these early research works, numerous erosion models were developed mainly due to the large number of influencing parameters as listed earlier. Consequently, many of the models are very specific to the case considered. For more details on erosion models, the reader is referred to Lyczkowski (2006) and Parsi et al. (2014) for detailed reviews.

This contribution is aimed at highlighting the influence of wall roughness and interparticle collisions (i.e., four-way coupling) as well as mass loading on predicted erosion rates. It should be emphasized that at present wall roughness is not considered directly in a modified erosion rate (which should be realistically also accounted for) but only in an altered wall collision frequency through the shadow effect (Sommerfeld and Lain, 2015) whereby naturally erosion rate is altered.

For describing the combined effect of cutting and deformation erosion, the recently proposed model of Oka et al. (2005) is used. It should be mentioned that the purpose of the Oka et al. (2005) paper was "to propose predictive equations for erosion damage caused by solid particle impact that can be applied to many types of metallic materials under various conditions involving impact angle, velocity, size and the properties of the particles." Therefore, the Oka model has been adopted in this work, which is briefly described as follows.

The predictive equation for erosion damage proposed by Oka et al. (2005) can be expressed as

$$E(\alpha) = g(\alpha) E_{90} \tag{2.349}$$

$E(\alpha)$ and E_{90} denote the volume of eroded material per mass of particles (mm^3/kg), where E_{90} is the erosion damage at normal impact angle

$g(\alpha)$ is the impact angle dependence expressed by two trigonometric functions that also depend on the material Vickers hardness number (Hv) in unit of GPa:

$$g(\alpha) = (\sin\alpha)^{n_1} \left[1 + Hv(1 - \sin\alpha)\right]^{n_2} \tag{2.350}$$

where n_1 and n_2 are the exponents determined by the eroded material hardness and other impact conditions such as particle material properties and shapes. These exponents show the effects of repeated plastic deformation and cutting action, and they are expressed by

$$n_1 = s_1(Hv)^{q_1}; \quad n_2 = s_2(Hv)^{q_2} \tag{2.351}$$

The first factor in Equation 2.349 is associated with repeated plastic deformation or the brittle characteristics and with the vertical component of particle impact energy. It is maximal at normal impact angle. The second term corresponds to the cutting action, which is more effective at shallower impact angles (Oka et al., 2005). The relative cutting action at an arbitrary angle to that at normal angle takes a maximum at 0°. The function $g(\alpha)$ is expressed as the product of the two factors in terms of mutual actions and is a continuous function of the particle–wall impact angle.

The reference erosion ratio E_{90} (erosion damage at normal impact angle) is related to the impact velocity, particle diameter, and eroded material hardness and can be expanded as follows:

$$E_{90} = K\left(aHv\right)^{k_1 b}\left(\frac{u_p}{u_{ref}}\right)^{k_2}\left(\frac{D_p}{D_{ref}}\right)^{k_3} \tag{2.352}$$

where

- u_p and D_p are the impact velocity (in m/s) and the particle diameter (in μm), respectively
- u_{ref} and D_{ref} are, respectively, the reference impact velocity and the particle diameter used in the experiments by Oka et al. (2005)
- The parameters a and b characterize the load relaxation ratio of the wall material
- K denotes a particle property factor, in arbitrary units, that involves particle shape (angularity) and particle hardness
- The exponents k_1 and k_3 are determined by the properties of the particle, although k_3 is found to be roughly constant by Oka et al. (2005)

The exponent k_2 can be determined by the Vickers hardness of eroded material and by particle properties and is given by

$$k_2 = r\left(Hv\right)^p \tag{2.353}$$

According to Oka et al. (2005), the term $K\left(aHv\right)^{k_1 b}$ is highly dependent on the type of the particle and eroded material Vickers hardness, which are not correlated with the impact conditions and other factors. Therefore, for the moment a and b were taken to be unity. The present work used the experimental data from Oka and Yoshida (2005) to obtain the relationship between eroded material Vickers hardness and E_{90} at the reference impact velocity for the materials investigated.

The main strength of the Oka model is that the coefficients for a particular combination of eroded material and eroding material (i.e., the particle) can be derived from more fundamental coefficients, which are specific to either the eroded material or the eroding material. The fundamental coefficients for the eroding material, in turn, are shown to be derivable from measurable properties of the eroding material such as its Vickers hardness.

The vast majority of CFD-based erosion modeling has been applied under conditions of very low particle mass loading. This approximation facilitates the measurements, on one side and on the other hand the computations are much faster because the coupling between the Euler and Lagrange modules is avoided (i.e., one-way coupling only). Moreover, the validation of CFD-based erosion models in complex geometries such as bends, tees, and valves has as target variable an erosion measure (i.e., erosion rate and penetration ratio) along the experimental specimen, but rarely the flow field has been validated.

Validation of the erosion model in this work has been performed by comparing the numerical results with the experiments on a vertical to horizontal bend flow considered by Mazumder et al. (2008) as sketched in Figure 2.73. Aluminum (6061-T6) elbow specimens (density $\rho_w = 2700$ kg/m^3, $Hv = 1.049$ GPa) were used in these studies. By applying CFD-based models, erosion predictions were performed for the same geometry. The continuum phase consists of air with a bulk velocity of 34.1 m/s ($\rho = 1.2$ kg/m^3 and $\mu = 18 \cdot 10^{-6}$ N · s/m^2). Almost monosized angular sand particles (density 2600 kg/m^3) having a mean number diameter of 182 μm

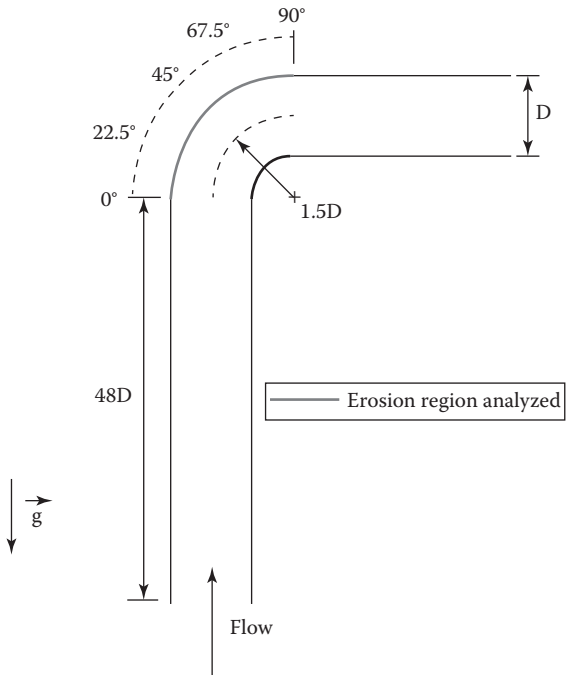

Figure 2.73

Sketch of the experimental pipe configuration of Mazumder et al. (2008), including vertical pipe, bend, and horizontal segment (pipe diameter D = 25.4 mm, bend radius R_{bend} = 1.5·D).

and a mass loading of 0.013 (kg particles/kg air) were injected vertically at about 1.22 m below the test piece. The bend Stokes number in this case is extremely large (St_B = 151) due to the small bend curvature and high conveying velocity. The test piece was a 90° elbow with a diameter of D = 25.4 mm and a curvature radius of R_{bend} = 38.1 mm, as shown in Figure 2.73, which gives a bend radius of 1.5 · D. Hence, the flow deflection is much stronger than in the previous considered cases (see chapter Conveying Pipe Configuration). In order to represent more realistic particle behavior at the specimen location, the whole domain was included in the calculation. After the elbow, a horizontal pipe with 10 pipe diameters was considered. This configuration attempts to reproduce the experimental conditions much better.

Since the geometry is simple, only hexahedra were used in the mesh construction, which generate less numerical diffusion than elements such as tetrahedra and pyramid. Gradual refinement is necessary in the near-wall region, where high-velocity gradients and the boundary layer exist. Hexahedra also allow the generation of higher quality meshes, with fewer distorted elements than one would obtain with tetrahedral, for example. The mesh resolution used in all simulations is approximately 1,000,000 elements, which yielded mesh-independent results. At the inlet 48 · D downstream of the bend, a fully developed pipe flow is imposed. Particles are introduced with the mean streamwise fluid velocity of 34.1 m/s, and a fluctuating velocity for all components of around 4.5% of the bulk flow velocity was specified. As the experiments were performed with very low mass loading of 0.013, interparticle collisions and flow modification by the solids are disregarded in these computations.

At first, the duct walls were considered perfectly smooth. In the simulations, the restitution model of Grant and Tabakoff (1975) was chosen because this model was originally obtained from experiments with sand particles hitting against an aluminum surface, the same materials that were used in the Mazumder et al. (2008) experiments. The normal restitution coefficient $e(\alpha)$ together with the standard deviation σ_e is given by (note the particle impact angle α is given in radians)

$$e(\alpha) = 0.993 - 1.76\alpha + 1.56\alpha^2 - 0.49\alpha^3$$
$$\sigma_e = 2.15\alpha - 5.02\alpha^2 + 4.05\alpha^3 - 1.085\alpha^4 \tag{2.354}$$

The employed friction coefficient, depending on the particle–wall angle of impact, is the same as in the Lain and Sommerfeld (2008, 2012) works. It is written as μ = max(0.15, 0.5–0.0175α), where α is again the particle

impact angle, but this time in degrees. In the present steady-state computations, 10^6 particles are tracked through the computational domain using the fluid forces and time step restrictions described earlier.

The Oka et al. (2005) model provides the erosion damage in mm³/kg (see Equation 2.348), which is converted in erosion ratio *ER* (kg eroded material/kg erodent agent) by

$$ER = 10^{-9}\rho_w E(\alpha) \tag{2.355}$$

where the constant 10^{-9} has the dimension (m^3/mm^3). Finally, the penetration ratio PR_S (m/kg) at each surface element of area A_S is obtained as (the index *S* marks the surface area)

$$PR_S = \frac{ER_S}{\rho_w A_S} = 10^{-9}\frac{E_S(\alpha)}{A_S} \tag{2.356}$$

where ER_s is the erosion ratio in the surface element. It is computed as the sum of erosion ratio caused by N_S particle–wall collisions in the surface area A_S (Parsi et al., 2014) divided by the total injected mass of erodent agent m_T:

$$ER_S = \frac{\sum_{i=1}^{N_f}(m_{pi}ER_i)}{m_{T,S}} \tag{2.357}$$

where m_{pi} represents the mass of particle i colliding with the wall.

The parameters of the model by Oka et al. (2005) for the SiO_2 angular particles colliding with an aluminum wall are listed in Table 2.7. The resulting function $g(\alpha)$ according to Equation 2.349 is shown in Figure 2.74 for the Mazumder et al. (2008) case. Due to the rather soft wall material this function rapidly increases, reaching a maximum around 25° wall impact angle and finally approaches for 90° a value of unity.

In Figure 2.75a, the penetration rate map on the outer wall of the bend geometry of Mazumder et al. (2008) is presented. Particle flow enters from the lower part, following the direction of the arrow. Hence,

Table 2.7 Parameters Used in the Oka Model for the SiO_2 Angular Particles and Aluminum Wall (Hv = 1.049 GPa)

K	k_1	k_2	k_3	u_{ref} (m/s)	D_{ref} (μm)	n_1	n_2
65	−0.12	$2.3Hv^{0.038}$	0.19	104	326	$0.71\ Hv^{0.14}$	$2.4\ Hv^{-0.94}$

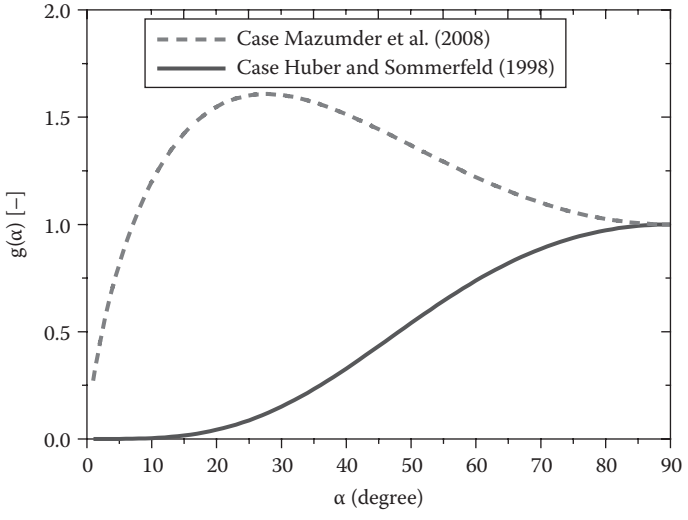

Figure 2.74

Dependence of the function g(α) on the particle–wall impact angle for different wall hardness and particles types: the case of Mazumder et al. (2008) and the case of Huber and Sommerfeld (1998).

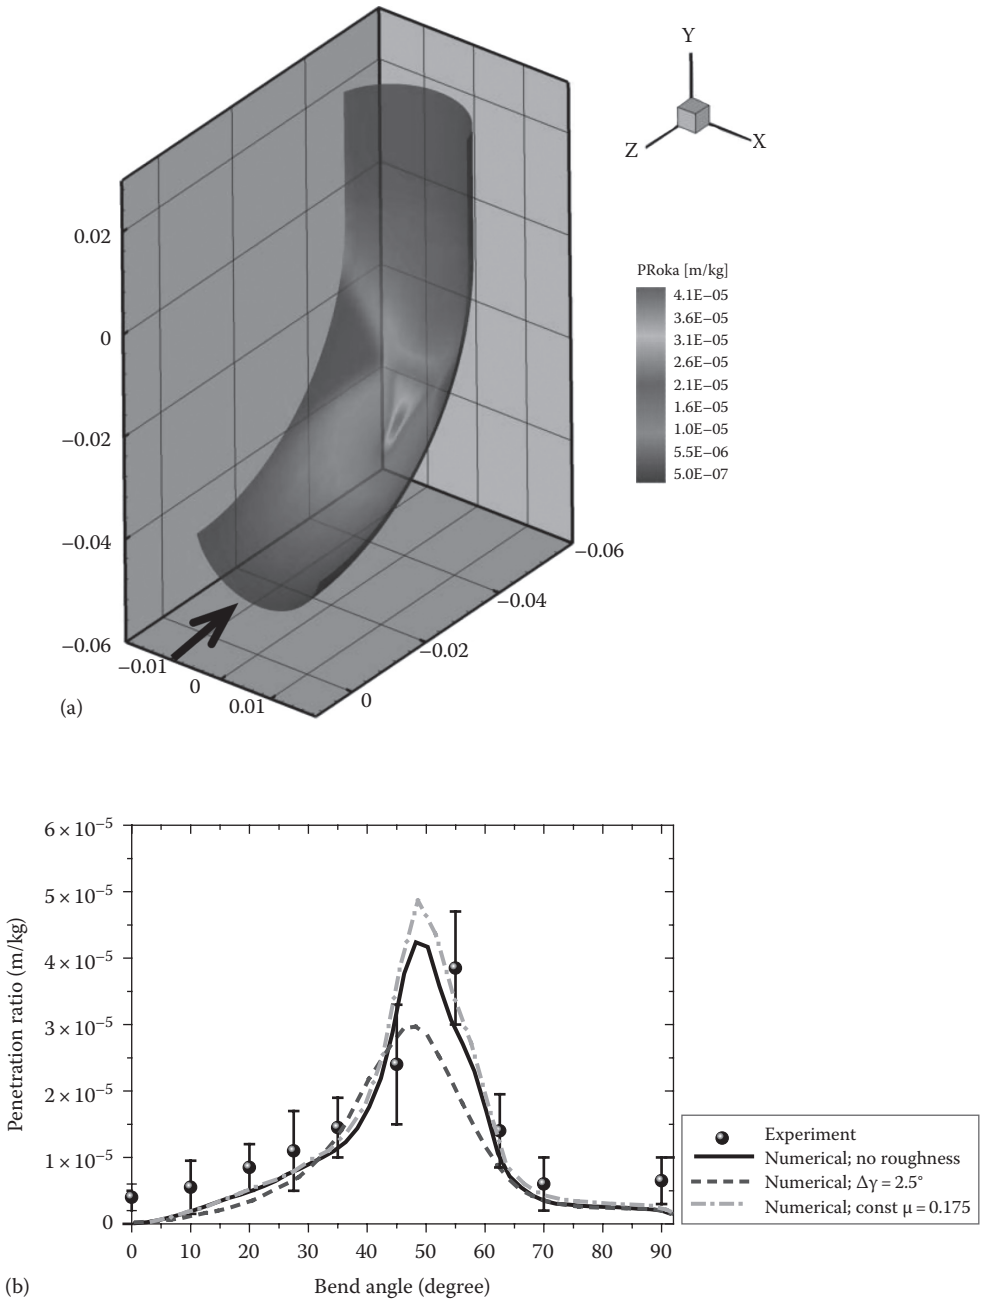

Figure 2.75

Numerical results obtained for the Mazumder et al. (2008) configuration: (a) Predicted erosion map on the bend outer wall. (b) Comparison of penetration ratio obtained for different assumptions in the numerical calculations with the experimental data (pipe diameter D = 25.4 mm, bend radius R_{bend} = 1.5·D).

gravity is acting against the inflow velocity in this illustration. The obtained erosion pattern is very similar to that obtained by other authors using CFD-based erosion models in bends (e.g., Chen et al., 2006, Parsi et al., 2014; Pereira et al., 2014). It consists of a narrow elongated spot of high penetration rate, due to the primary, high-velocity, particle–wall impacts, surrounded by a wider area of moderate erosion. Downstream of the spot of the highest PR, the particle erosion pattern shows a V-shaped structure. This area is mainly produced by secondary particle–wall collisions in the elbow (Pereira et al., 2014).

A quantitative comparison of the numerical results with the measured penetration ratio (including error bars) for a strip of roughly 5 mm width along the center of the bend outer wall is presented in Figure 2.75b. Here, the origin (θ = 0°) is set at the elbow inlet, and θ = 90° corresponds to the elbow outlet. It is obvious

that the simulation results without wall roughness (solid line) are lying within the lower part of the experimental uncertainty (vertical bars indicating the standard deviation of the measurement), and hence, a reasonable agreement with the experiments is obtained.

The presented computations are carried out considering a smooth wall. However, it is known that wall roughness plays a very important role in the particle motion along ducts (Lain and Sommerfeld, 2012a), Sommerfeld and Lain 2015). Therefore, an additional case with moderate roughness ($\Delta\gamma = 2.5°$ in notation of Lain and Sommerfeld, 2012a) was simulated to illustrate the effect of wall roughness in erosion computations. The obtained results are represented by the dashed line in Figure 2.75b. In short, wall roughness in a bend redisperses inertial particles remarkably and the dust rope becomes much wider (see Figure 2.57), which reduces the near-wall particle concentration and eventually results in a reduction of wall collision frequency; the maximum penetration rate is diminished, regarding the case without roughness, and also the location of the erosion peak is slightly displaced toward lower elbow angles.

Finally, the importance of the friction coefficient μ is emphasized by the dot–dashed line in Figure 2.75b. When assuming a constant value for the friction coefficient, that is, $\mu = 0.175$ in this particular case, the maximum of erosion rate increases slightly regarding the basic case (solid line), which has an average value around of 0.25. Although not shown, the results for penetration ratio decrease by a factor of two when friction coefficient is doubled to a value of 0.5, suggesting a nonnegligible sensitivity to this wall collision parameter. Such trends can be understood as follows: higher friction implies a decrease in particle velocity regarding the cases with lower friction; moreover, as the erosion ratio varies with particle impact velocity to a power larger than two, higher friction yields lower penetration ratio and vice versa.

It should be pointed out that in the publication of Mazumder et al. (2008) no information is provided regarding the two-phase flow field developing throughout the bend. Consequently, the gas- and particle-phase properties cannot be validated for this case.

Therefore, a further analysis of bend erosion is conducted for the configuration of a 5 m horizontal pipe, a bend, and a 5 m vertical pipe with a pipe diameter of D = 150 mm as considered earlier (case 3 in Table 2.4). For this case, the numerical calculations of the two-phase flow were thoroughly validated in previous studies (Lain and Sommerfeld, 2013, Sommerfeld and Lain 2015). In this configuration however, the bend radius is larger than in the Mazumder et al. (2008) configuration, namely, $R_{bend} = 2.54$ D and the conveying velocity is lower so that bend erosion is expected to be much smaller. The erosion calculations were conducted for the case with particle size distribution (case ❶ in Table 2.5) and for the monosized particles with 40 and 135 μm (cases ❷ and ❺ in Table 2.5), all with a mass loading of $\eta = 0.3$. The main objective for considering these test cases, although so far no erosion studies were conducted, is related to analyzing the effect of interparticle collisions on bend erosion. For making this effect stronger, a higher mass loading of $\eta = 0.6$ was also simulated for the case with size distribution. The numerical realization of this test case is summarized in detail in the earlier chapter "Conveying Pipe Configuration."

For this test case, the dependence of the normal restitution coefficient on impact angle was modeled for spherical particles as follows: $e(\alpha) = \max(0.7, 1.0–0.0136\ \alpha)$ according to Lain and Sommerfeld (2012). Regarding erosion modeling for this case, the Vickers hardness of the stainless steel wall has been taken as $Hv = 1.96$ GPa (Nguyen et al., 2014) with a density $\rho_w = 7929$ kg/m^3. The parameters of the Oka et al. (2005) model for spherical glass beads and stainless steel wall are listed in Table 2.8. The resulting function $g(\alpha)$ according to Equation 2.349 is also shown in Figure 2.74, yielding lower values than the Mazumder et al. (2008) case due to the higher wall hardness and the consideration of spherical particles. Moreover, here the function continuously increases from zero to one at the wall impact of 90°.

Another difference of this test case compared to the Mazumder et al. (2008) configuration is the direction of gravity being perpendicular to the horizontal pipe, whereby gravitational settling produces a nonsymmetric particle concentration distribution at the bend inlet. This will of course yield a modified erosion pattern at the bend outer wall. Moreover, in the Huber and Sommerfeld (1998) case, particle sizes and conveying velocity are smaller, yielding of course also lower erosion rates.

Interparticle collisions cause a "compression" of the powder rope formed in the bend as discussed earlier and illustrated in Figure 2.58. This phenomenon yields for the considered configuration (Huber and

Table 2.8 Parameters Used in the Model by Oka et al. (2005) for the Glass Beads and Stainless Steel Wall (Hv = 1.96 GPa)

K	k_1	k_2	k_3	u_{ref} (m/s)	D_{ref} (μm)	n_1	n_2
27	−0.16	2.1	0.19	100	200	$2.8\ Hv^{0.41}$	$2.6\ Hv^{-1.46}$

Sommerfeld, 1998) and the particle size distribution an enhancement of particle–wall collision frequency as obvious from Figure 2.71b. For illustrating the effect of interparticle collisions, the penetration ratio obtained with the Oka et al. (2005) model is shown in Figure 2.76 using color contours. Note that for these simulations a wall roughness parameter of $\Delta\gamma = 10°$ has been considered. Without particle–particle collisions, the area of maximum erosion has an elongated tear-like shape whose peak is located at a bend angle of around 35° from the inlet. It is interesting to note that the V-shaped region appearing in Figure 2.75a for the narrow bend is not present. Beyond $\theta = 50°$ the erosion is rather weak. When interparticle collisions are considered, the peak value of penetration ratio decreases by about 50%, the location of maximum erosion is displaced toward smaller bend angles (i.e., $\theta \sim 30°$), and at higher bend angles only a strip of moderate erosion is observed. The extent of the maximum erosion region in the streamwise direction is slightly reduced and broadened sideways. This observation for the erosion pattern is strongly linked with the compression of the dust rope by interparticle collisions and a slight lateral widening (see Figure 2.58). The reduction of penetration rate in the four-way coupling case is not explained readily, since the particle–wall collision rate is slightly increased due to interparticle collisions, that is, from 5.0 to 5.3 1/m, which will in the first instance enhance penetration rate. Therefore, a decrease in erosion can only result from reduced particle impact velocities or modified impact angles, which are both included in the erosion model, and hence, their influence will be further discussed in the following by looking at the profiles of the PR along a small strip (i.e., 5 mm width) of the bend outer wall.

The effect of interparticle collisions on erosion may be more clearly studied by considering monosized particles. Therefore, the PR along the bend outer wall is compared in Figure 2.77a for the case with size distribution (case ❶ in Table 2.5) and 40 μm monosized particles (case ❷ in Table 2.5). As already obvious from Figure 2.76 (color contours of PR), the penetration ratio is remarkably reduced due to interparticle collisions for particles with size distribution (mean number diameter 40 μm), which is quantitatively seen in Figure 2.77a. This reduction of PR is also found in the case of monosized particles although the wall collision rate clearly increases (see Figure 2.71b). Moreover, the PR for the size distribution is larger than for

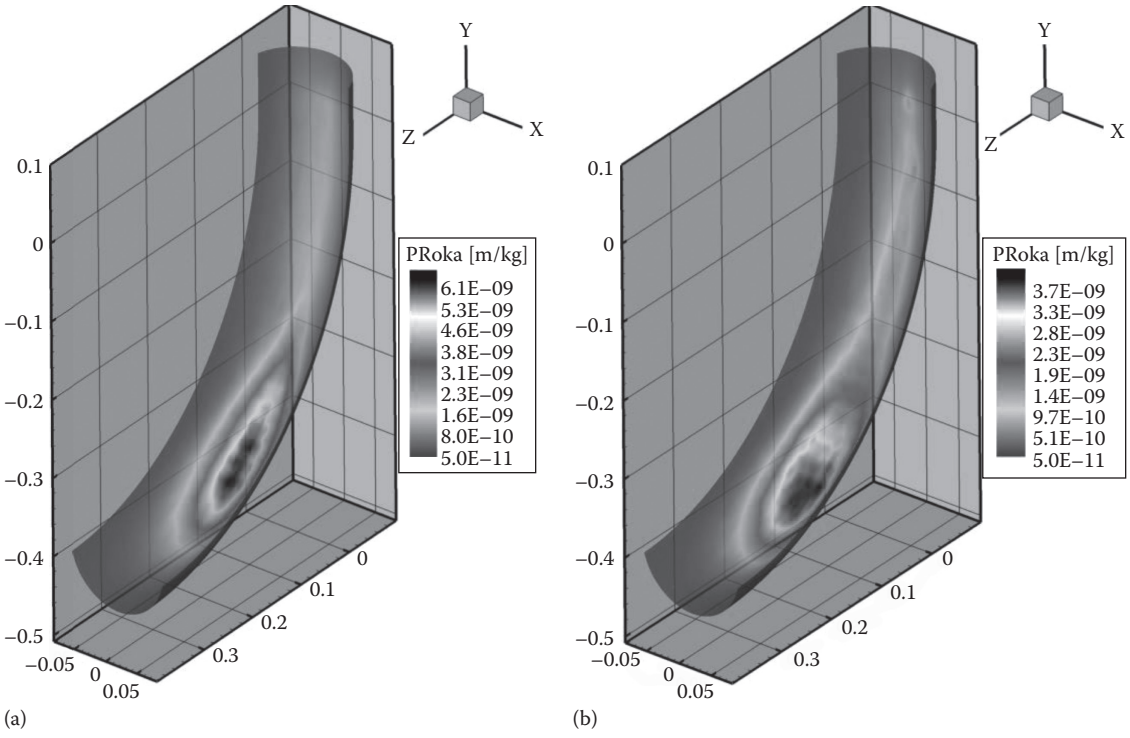

Figure 2.76

Penetration ratio in (m/kg) on the bend outer wall: (a) two-way coupling, (b) four-way coupling (5 m horizontal pipe, bend, 5 m vertical pipe, D = 150 mm, bend radius 2.54 pipe diameters, U_{av} = 27 m/s, μ = 0.3, $\Delta\gamma$ = 10°, particle size distribution 15–85 μm).

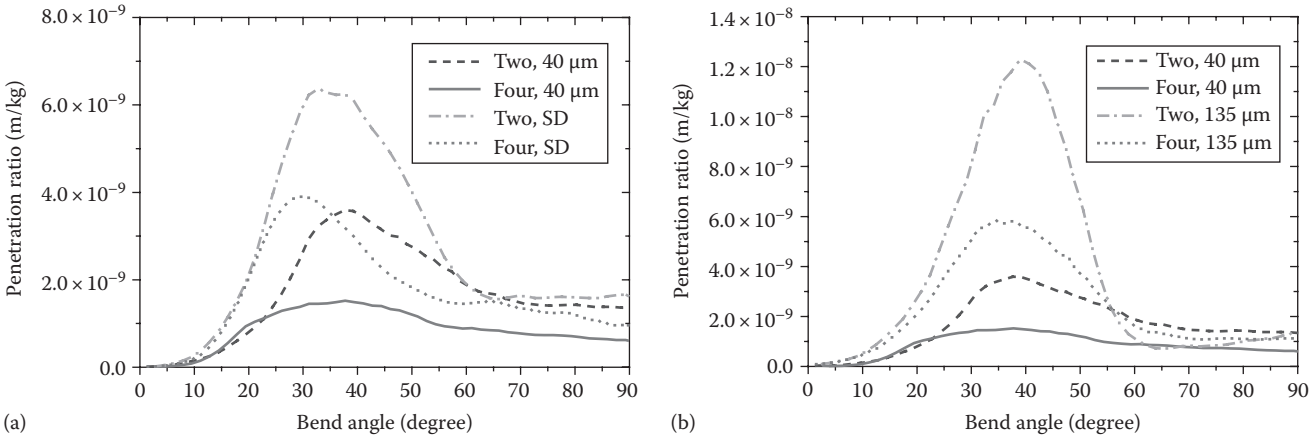

Figure 2.77

Penetration ratio in m/kg for a small strip along in the bend outer wall for spherical glass beads comparing two- and four-way coupling for different particle size distributions: (a) Monosized of 40 µm particles and SD with number mean diameter 40 µm. (b) Monosized 40 and 135 µm particles (5 m horizontal pipe, bend, and 5 m vertical pipe, D = 150 mm, bend radius 2.54·D, U_{av} = 27 m/s, η = 0.3, $\Delta\gamma$ = 10°).

the comparable monosized particles in two- and four-way coupling, respectively. This results from bigger particles being included in the SD, which of course yield higher erosion (i.e., larger impact energy). For the same reason, erosion also begins at smaller bend angles, as these large particles have higher inertia and do not easily follow the flow deflection. This is made clearer comparing the PR for 40 and 135 µm monosized particles (Figure 2.77b). As a consequence of that, the erosion pattern for the larger particles is narrower in the streamwise direction.

The reduction of the PR due to interparticle collisions is mainly caused by the associated decrease in particle–wall impact velocity, since the particles are trapped in the powder rope and experience numerous interparticle collisions and wall collisions reducing the average particle velocity in the near-wall region (see Figure 2.56) as shown in Figure 2.78a for the wall impact velocity of two monosized particles. The impact velocity initially rapidly increase with the bend angle and then continuously decrease toward the bend exit due to continuous loss of particle momentum. Expectedly, the wall impact velocity is larger for the more inertial particles, that is, 135 µm. It should be noted that the PR increases with an exponent larger than the square of the wall impact velocity (see Equation 2.351). The decrease in wall impact velocity begins after the first wall collisions with the bend and is therefore this location is coupled with particle inertia.

The particle–wall impact angle determines the way and the amount of erosion by a single particle and is included in the erosion model of Oka et al. (2005) in the nonlinear term g(α) given by Equation 2.349 and shown in Figure 2.74. Also, the averaged impact angle first continuously increases with growing bend angle and then decreases toward the bend exit again; except for the inertial particles, where the average wall impact angle again increases for two-way coupling from $\theta \approx 65°$ onward since the particles can freely rebound at the bend outer wall (Figure 2.78b). For larger and more inertial particles, the average wall impact angle is higher than for smaller particles throughout the bend. The averaged particle–wall impact angle is remarkably reduced due to interparticle collisions beginning from a bend angle larger than about 25°. The resulting function g(α) given in Equation 2.349 runs very similar than the average wall impact angle (Figure 2.78c); yielding a reduction in erosion due to interparticle collisions.

In conclusion, although the particle–wall collision frequency is increased due to interparticle collisions for monosized particles lager than about 30 µm (see Figure 2.71) the erosion damage is however reduced, mainly due to the distinct reduction of particle–wall impact velocity and average wall impact angle.

Finally, the effect of particle mass loading on bend erosion is analyzed. Due to the increasing particle number density for higher mass loading, one would naturally expect an increase in erosion and PR. The penetration ratio pattern in the bend for a higher particle mass loading of η = 0.6 is shown in Figure 2.79a for the condition when interparticle collisions are considered. In comparison with Figure 2.76b for the case with η = 0.3, it can be readily seen that the maximum penetration ratio decreases and that this region is also displaced toward lower values of the bend angle. The pattern of the highest PR has a V-like shape

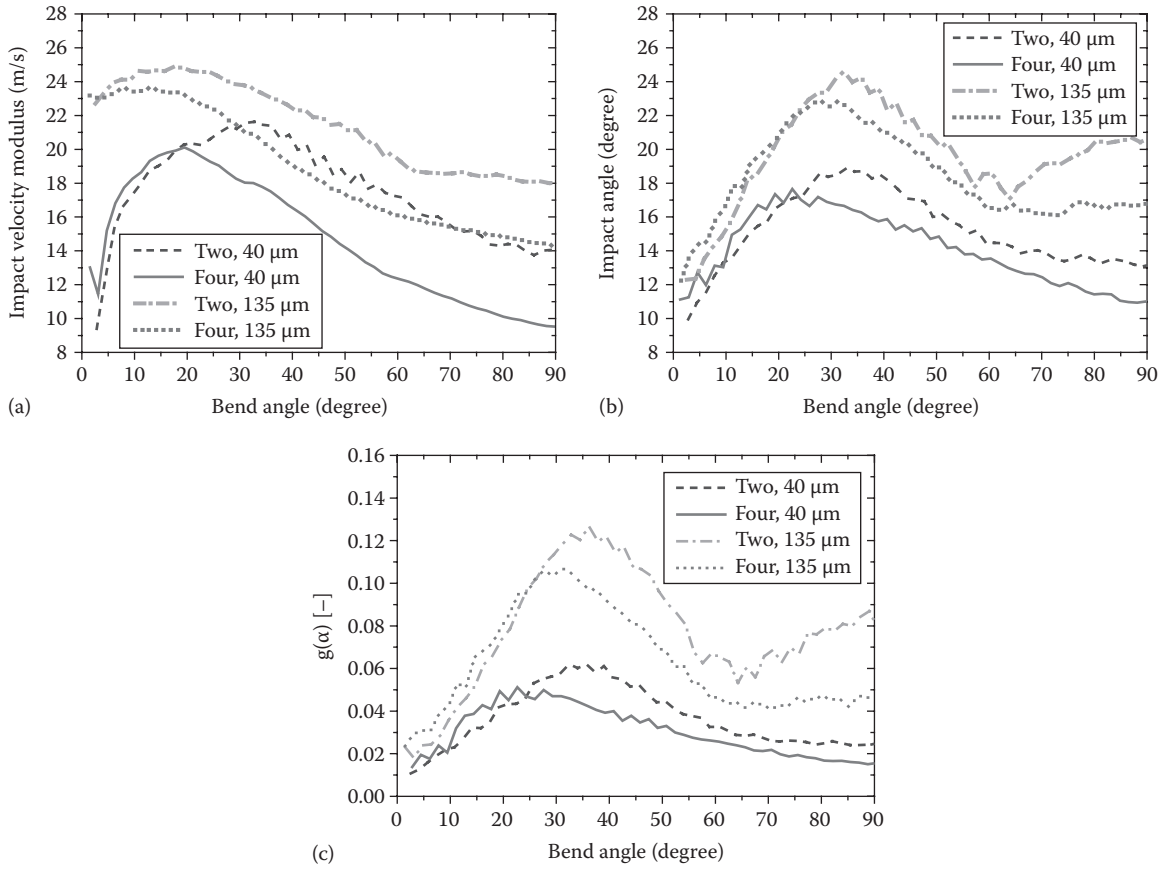

Figure 2.78

Averaged modulus of particle–wall impact velocity (a), averaged wall impact angle (b), and function g(α) given by Equation 2.349 (c) for a 5 mm strip along the bend outer wall for different monosized particles (40 and 135 µm) (5 m horizontal pipe, bend, and 5 m vertical pipe, D = 150 mm, bend radius 2.54·D, U_{av} = 27 m/s, η = 0.3, Δγ = 10°).

and is surrounded by a tear-like shaped region of lower PR values. Toward the end of the bend, a narrow strip of higher PR with two maxima is observed, indicating a multiple impact of particle clouds. Just at the elbow exit, a small spot of rather high PR is identified.

The penetration ratio for a strip along the bend outer wall again allows for a quantitative comparison (Figure 2.79b). The reduction of the erosion damage due to interparticle collisions has been thoroughly explained earlier. Now, the question is why an increased mass loading reduces PR for major parts of the bend outer wall considering both two- and four-way couplings. When interparticle collisions are neglected, a slight decrease in PR with increasing mass loading is observed only between $20° < \theta < 45°$ and above $\theta = 55°$. In the four-way coupling case, however, PR is remarkably reduced with increasing loading between $20° < \theta < 55°$. Beyond this bend angle, however, erosion increases with mass loading reflecting the PR pattern shown in Figure 2.79b, resulting from multiple particle–wall collisions. By comparing Figures 2.58b and 2.67a, it is obvious that the dust rope at higher mass loading appears to become more concentrated occupying as smaller region of the bend cross section. This means that at higher loading, particles moving into the bend will collide more probably with particles in the concentrated dust rope and not with the bend outer wall. This phenomenon may be called "shielding" effect, which however is only relevant for the initial part of the bend (Bikbaev et al., 1979). The extent of this region is correlated with particle inertia.

The main reason for the reduction of erosion with increasing mass loading (at least for the considered values) is related to the trapping of the particles in the rather dense dust rope moving along the bend outer wall, which increases first the wall collision frequency and thereby also reduces particle velocity due to wall collision momentum loss. Moreover, the particles are held in the low-velocity region of the gas flow induced by two-way coupling. This naturally involves a reduced average particle–wall collision velocity as summarized in Figure 2.79c. A remarkable reduction of the impact velocity with growing mass loading is found from

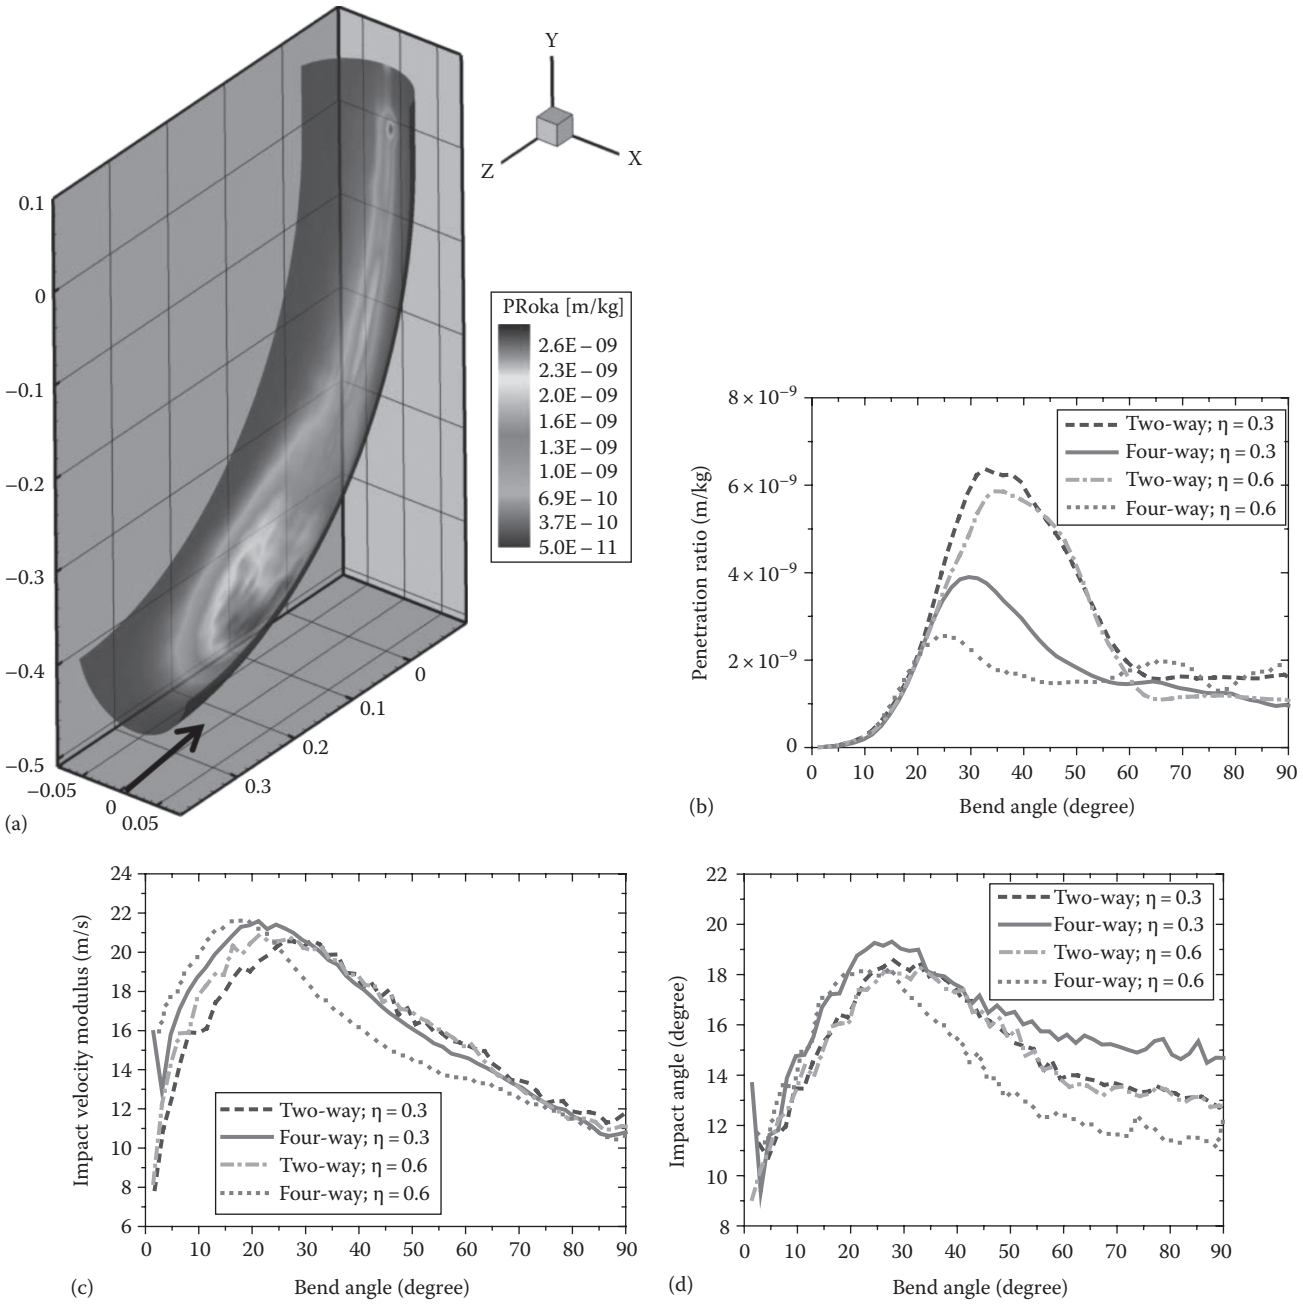

Figure 2.79

Effect of particle mass loading on bend erosion: (a) Color map of penetration ratio in (m/kg) within the bend outer wall for glass beads using four-way coupling (η = 0.6; compared with Figure 2.75b for η = 0.3). (b) Penetration ratio along the bend outer wall for a 5 mm strip. (c) Average particle–wall impact velocity along the bend outer wall for a 5 mm strip. (d) Average wall impact angle along the bend outer wall for a 5 mm strip; comparison of two- and four-way coupled simulations and two mass loadings of η = 0.3 and 0.6 (5 m horizontal pipe, bend, and 5 m vertical pipe, D = 150 mm, bend radius 2.54·D, U_{av} = 27 m/s, Δγ = 10°, particle size distribution 15–85 μm).

bend angles larger than 20° when comparing the four-way coupled calculations. These arguments are also supported by the fact that the two-way coupled calculations show almost no difference for the considered mass loadings. As a result of the compression of the dust rope and the resulting particle trapping, also the average impact angle is reduced when considering four-way coupling (Figure 2.79d). In the dilute conveying regime reduced erosion may be observed with increasing mass loading for a horizontal to vertical bend due to interparticle collisions damping particle motion within the compressed rope.

2.7 Two-Fluid Model in MFIX

Madhava Syamlal, Jordan Musser, and Jean-François Dietiker

2.7.1 Introduction to MFIX

Multiphase Flow with Interphase eXchanges (MFIX) is a multiphase computational fluid dynamics (CFD) code written in Fortran for describing the hydrodynamics, heat transfer, and chemical reactions in dense or dilute gas–solid flows. The MFIX team's objective is to create a tool to aid in the understanding, design, optimization, and scale-up of multiphase systems such as gasifiers, carbon capture devices, and chemical looping reactors. The development of MFIX started at the U.S. Department of Energy's (DOE) National Energy Technology Laboratory (NETL) in 1991 as a continuation of a multiparticle (Syamlal, 1985) version of the Eulerian–Eulerian code of Gidaspow and Ettehadieh (1983). Initially developed as a two-fluid model (TFM) for fossil energy applications at NETL, MFIX is now capable of discrete element model (DEM), hybrid TFM-DEM, and particle in cell (PIC) simulations. It is distributed as open-source software and used for solving various multiphase flow problems by numerous institutions around the world. This chapter is on MFIX-TFM and describes the theory, numerical techniques, and example applications.

The first MFIX-TFM version was completed in 1993. The two-fluid modeling technique uses averaging to construct mathematical models describing gases and solids as interpenetrating continua. Public distribution of the code was made through the Energy Science and Technology Software Center starting in 1995. Afterward, the code underwent several revisions whereby high-resolution discretization methods were added, the source code was migrated from Fortran 77 to Fortran 90, and it was parallelized to run on shared memory (e.g., OpenMP) and distributed memory (e.g., MPI) systems (Syamlal et al., 2008). More recent advancements include the development of a $k-\epsilon$ turbulence model (Benyahia et al., 2005), Cartesian cut cells for complex geometries (Dietiker et al., 2013), a stiff chemistry solver, variable solid density (Xue et al., 2011), and a number of kinetic theories for granular flows (Garzo and Dufty, 1999, Iddir and Arastoopour, 2005, Garzo et al., 2007a,b, 2012).

A Lagrangian solid model was implemented in 2004 whereby the position and trajectory of each solid particle are tracked through resolving all particle collisions via a soft-sphere spring-dashpot model (Boyalakuntla, 2003, Garg et al., 2012a). The DEM, MFIX-DEM, is capable of pure granular simulations in addition to being executed alongside the Eulerian gas-phase model for coupled gas–solid simulations. This gas–solid modeling technique uses fewer and less complex closures than the TFM and is therefore considered to contain more certainty overall. However, the computational intensity of tracking particles limits its application to small-scale devices. Recent efforts have included comprehensive verification and validation studies (Garg et al., 2012b, Li et al., 2012a), dynamic solids inventory capabilities, and the inclusion of species and energy conservation equations (Musser, 2011). Moderate-sized investigations containing tens of millions of particles have also been made possible because of recent distributed (Gopalakrishnan and Tafti, 2013) and shared memory (Liu et al., 2014) parallelization efforts.

A second Lagrangian solid model, MFIX-PIC, was implemented in 2013 (Garg and Dietiker, 2013). The multiphase PIC technique uses parcels, also referred to as notional particles, for the solids where a parcel may represent a fraction of one particle or thousands of individual particles. This approach is more computationally efficient than other Lagrangian solid models because collisions are not resolved, but rather approximated using frictional stress models and averaged field quantities. Uncertainty in PIC models arises from the closure needed for the solids, interaction terms as well as the need for accurate interpolation between the Eulerian and Lagrangian frames of reference. However, this approach offers the potential to shorten the time to solution making it ideal for initial design investigations.

The MFIX development activities have been preserved through a concurrent versioning system (CVS) since 1999 to track source code changes. The CVS database has recently been transferred to a Git repository, which accommodates a more flexible development environment between the core MFIX development team and external collaborators. The new repository allows greater transparency with respect to code development

activities because users are permitted to access the archival history of MFIX. This supports efforts to extend the reach of MFIX by encouraging greater community involvement in development and maintenance activities.

The integrity of the source code was originally maintained through nightly regression tests where a subset of tutorial and test cases were executed and the results compared to a fixed solution set (Syamlal et al., 2008). This approach was replaced by a continuous integration (CI) server (www.jenkins-ci.org) to expand the testing capabilities by running all tests and tutorials anytime modifications are committed to the source code repository. Nightly snapshots from the CI server are uploaded to the MFIX website and archived in the code repository.

As of 2014, the MFIX community contains over 3200 registered members and reaches professionals in academia (68%), industry (18%), national laboratories (4%), and other institutions (10%) across the globe. The number of MFIX citations per year has increased in the open literature with 100, 110, 138, and 120 citations in 2010–2013, respectively (https://mfix.netl.doe.gov/citatons.php). MFIX theory and some of the recent developments and applications have been documented in a recently edited book (Pannala et al., 2011). The state-of-the-art technical significance and uniqueness of MFIX has been recognized with several awards including an R&D 100 award in 2007 and a Federal Laboratories Consortium Mid-Atlantic Region Technology Transfer award in 2006.

As the code capabilities are improved, emphasis is being placed on uncertainty quantification, acceleration of time to solution, and realistic geometry representation. This will allow predictive simulations to become an integral part of device scale-up engineering processes and accelerate the introduction of new technologies to market. Current and future code development will continue to appeal to academia for fundamental multiphase flow modeling research and to increase the number and quality of industrial applications.

MFIX is now an active player in the development of computational tools that will enable the deployment of new technologies for clean and efficient utilization of fossil energy. As part of the carbon capture simulation initiative, MFIX is being exercised in a validation, calibration, and scale-up prediction study of sorbent-based CO_2 capture units, and an uncertainty quantification framework tailored to multiphase flow simulations is being developed (Lai et al., 2014a,b).

The open-source nature of the code distribution is essential in the development of new constitutive laws or new models. Large amount of data required to postulate new models can be generated by the original MFIX source code. New models are postulated and coded within the MFIX framework for further testing and refinement. Once finalized, the new models are made available to the MFIX community. This cycle can be repeated to improve or expand the current implementations. This type of model development motivated the open-source distribution strategy of MFIX. Members of the multiphase community can download the code, implement new models, and contribute to the tool's improvement and versatility. The recent migration of the MFIX repository to GitLab will facilitate collaborations among users and shorten the time to make a new model available to the MFIX community.

With the development of high-performance computing, MFIX continues to evolve and follow the trend of hardware development to accelerate computations. Current efforts include porting key sections of the code to GPU and many-core chips. This highlights another benefit of the open-source distribution of MFIX, as there is no limit to the amount of cores the code can be run on.

It is an exciting time to be involved in multiphase flow simulations. The level of maturity of various models and speed of execution are now such that simulations are becoming a vital complement to experiments in the scale-up and optimization of various energy systems such as the next-generation gasification and carbon capture units. Multiphase flow simulations will play a major role in finding solutions to global energy and environmental problems, and MFIX is at the forefront of this momentous challenge.

The following section outlines the conservation equations in MFIX-TFM with details concerning their theoretical development. Subsequent sections describe the numerical technique used to discretize and solve the governing equations as well as some advanced approaches used to extend modeling capabilities. Finally, details concerning MFIX-TFM access and usage are presented along with a few interesting MFIX-TFM applications found in the literature.

2.7.2 Two-Fluid Model Equations

MFIX-TFM (TFM or gas–solid continuum model or Euler–Euler model) describes the motion of a mixture of gas and solids as two or more interpenetrating continuum phases, one gas phase and one or more solid phases. Although referred to as "gas" in this chapter, the continuous phase could also be a liquid. The collective motion of particles is described by the motion of a continuum, referred to herein as a solid phase. The particles may be differentiated by their size, density, or composition and assigned to separate solid phases (Figure 2.80).

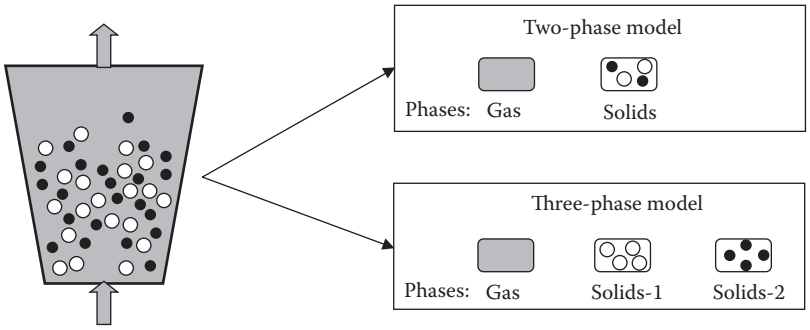

Figure 2.80

A fluidized bed containing two types of particles (black and white) could be described by a two-phase or a three-phase model depending upon the objectives of the modeling study.

By representing the particles as a solid phase, the motion of individual particles or the gas flow around each particle is not calculated. This approach considerably reduces the computational cost. To compensate for the model's reduced resolution, constitutive equations need to be included in the continuum model (e.g., gas–solid drag, solid stress).

The conservation equations governing the multiphase continua are either postulated (mixture theory) or derived by averaging the particle-scale equations. In the mixture theory approach, the multiphase flow equations are postulated, and restrictions on the constitutive relations are derived from general principles of continuum mechanics (Atkin and Craine, 1976, Bowen, 1976, Bedford and Drumheller, 1983). In the averaging approach, the equations are derived by space, time, or ensemble averaging of the local, instantaneous balances for each of the phases (Anderson and Jackson, 1967, Drew, 1983, Ishii and Mishima, 1984, Joseph et al., 1990, Zhang and Prosperetti, 1994a,b, Jackson, 1997, 2000, Prosperetti, 2007). Both approaches yield a set of balance equations for mass, momentum, and energy that need to be closed by specifying constitutive equations. Because of the limited space, only a subset of the equations used in the MFIX code is presented here. For complete details of the equations, see Syamlal et al. (1993), Syamlal and Pannala (2011), Benyahia et al. (2012), and other references mentioned in the following sections.

2.7.2.1 Conservation of Mass

The conservation of mass (or continuity equation) for the gas phase is

$$\frac{\partial}{\partial t}\left(\varepsilon_g \rho_g\right) + \frac{\partial}{\partial x_j}\left(\varepsilon_g \rho_g U_{gj}\right) = \sum_{n=1}^{N_g} R_{gn} \tag{2.358}$$

The first term on the left-hand side accounts for the rate of mass accumulation per unit volume, and the second term is the net rate of convective mass flux. The term on the right accounts for interphase mass transfer because of chemical reactions or physical processes, such as evaporation.

There are M solid-phase continuity equations, one for each solid phase. Subscript m going from 1 to M represents different solid phases.

$$\frac{\partial}{\partial t}\left(\varepsilon_m \rho_m\right) + \frac{\partial}{\partial x_j}\left(\varepsilon_m \rho_m U_{mj}\right) = \sum_{n=1}^{N_m} R_{mn} \tag{2.359}$$

2.7.2.1.1 Equation of State The gas phase is either incompressible or obeys the ideal gas law

$$\rho_g = \frac{P_g M_w}{R T_g} \tag{2.360}$$

The solid-phase densities can be a constant or they can change because of chemical reactions (see Section 2.7.4.2).

2.7.2.2 Conservation of Momentum

The gas-phase momentum balance is

$$\frac{\partial}{\partial t}\left(\varepsilon_g \rho_g U_{gi}\right) + \frac{\partial}{\partial x_j}\left(\varepsilon_g \rho_g U_{gj} U_{gi}\right) = -\varepsilon_g \frac{\partial P_g}{\partial x_i} + \frac{\partial \tau_{gij}}{\partial x_j} + \sum_{m=1}^{M}\left[\mathcal{R}_{mg} U_{mi} - \mathcal{R}_{gm} U_{gi} - I_{gmi}\right] + f_{gi} + \varepsilon_g \rho_g g_i \tag{2.361}$$

where the $\mathcal{R}$ terms represent momentum transfer caused by the mass transfer from the gas phase to the mth solid phase and I_{gmi} is the momentum transfer between the gas phase and the mth solid phase due to interphase forces such as drag force.

The mth solid-phase momentum balance is

$$\frac{\partial}{\partial t}\left(\varepsilon_m \rho_m U_{mi}\right) + \frac{\partial}{\partial x_j}\left(\varepsilon_m \rho_m U_{mj} U_{mi}\right) = -\varepsilon_m \frac{\partial P_g}{\partial x_i} - \varepsilon_m \frac{\partial P_c}{\partial x_i} + \frac{\partial \tau_{mij}}{\partial x_j} + \sum_{l=0}^{M}\left[\mathcal{R}_{lm} U_{li} - \mathcal{R}_{ml} U_{mi} - I_{mli}\right] + \varepsilon_m \rho_m g_i \tag{2.362}$$

where the $\mathcal{R}$ terms represent momentum transfer caused by the mass transfer from the mth phase to the lth phase, and I_{mli} is the momentum transfer between the mth and lth phases ($l = 0$ being the gas phase) due to interphase forces such as drag force. There could be other forces caused by mass transfer that cannot be accounted for in a TFM—caused, for example, by jets of volatile gases issuing from heated coal particles (Syamlal and Pannala, 2011).

In the equations given earlier, $\mathcal{R}_{ml}$ is the rate of mass transfer from the mth phase to the lth phase and $\mathcal{R}_{lm}$ is the rate of mass transfer from the lth phase to the mth phase (m or l set to g or 0 being the gas phase). By definition, both $\mathcal{R}_{ml}$ and $\mathcal{R}_{lm}$ are greater than or equal to zero. They could be equal in magnitude, but usually they are not. For example, in the case of carbon particles burning in air ($C + O_2 \rightarrow CO_2$), $\mathcal{R}_{gm}$ is the mass flux of O_2 from the gas phase to the particle surface and $\mathcal{R}_{mg}$ is the mass flux of CO_2 from the particle surface to the gas phase. Furthermore, the net rate of mass transfer to the mth phase is equal to the total rate of generation of the species mass in that phase:

$$\sum_{l=0}^{M}\left(\mathcal{R}_{lm} - \mathcal{R}_{ml}\right) = \sum_{n=1}^{N_m} R_{mn} \tag{2.363}$$

By default, MFIX accounts for the buoyancy through a shared gas pressure formulation (i.e., $\varepsilon_m(\partial P_g/\partial x_i)$), which Bouillard et al. (1989) call Model A. Although widely used in open-source and commercial computer codes, Model A in the inviscid limit leads to ill-posed initial value problems. This problem could be overcome by explicitly including a buoyancy force term in the momentum equations, which is called Model B option in MFIX, using the terminology of Bouillard et al. (1989). However, Model B accounts for the buoyancy resulting only from the gravitational force and cannot account for a general buoyant force. Syamlal (2011) showed that Model A with a newly proposed buoyant force term (resulting from the relative velocity between gas and solid phases) leads to well-posed initial value problems. The magnitude of the new buoyant force term is likely to be small and, hence, Model A is a good approximation of the well-posed model.

2.7.2.3 Gas–Solid Momentum Transfer

The mechanisms and formulation of momentum transfer have been reviewed in detail by Johnson et al. (1990) and Massoudi (2003). From the studies of the motion of a single particle in a fluid (e.g., Maxey and Riley, 1983), several different mechanisms for momentum transfer have been identified: drag force caused by velocity differences between the phases; buoyancy caused by the fluid pressure gradient; virtual mass effect caused by relative acceleration between phases; Saffman lift force caused by fluid-velocity gradients; Magnus force caused by particle spin; Basset force, originating from the history of the particle's motion through the fluid; Faxen force, a correction applied to the virtual mass effect; and forces caused by temperature and density gradients.

Drag force is the most significant interphase momentum transfer mechanism. Several well-known formulas accurately represent the drag force on a single sphere as a function of the Reynolds number (e.g., Khan et al., 1987). In a multiparticle system, the nearness of other particles makes the drag force on each particle significantly

greater than that given by the single-particle drag formula. Thus, the formula for multiparticle drag force must include the gas volume fraction as an additional parameter to account for the effect of neighboring particles.

To ensure that the aforementioned requirements are satisfied, a multiparticle drag coefficient is defined as follows:

$$I_{gmi} = \frac{3}{4}\frac{C_{Dm}\varepsilon_g\varepsilon_m\rho_g}{d_{pm}}\left|U_g - U_m\right|\left(U_{gi} - U_{mi}\right) \tag{2.364}$$

where C_{Dm} is a function of the Reynolds number and gas volume fraction ε_g.

The drag coefficients are usually obtained from correlations developed from two types of experimental data. One type, valid for high values of the solids volume fraction, is the packed-bed pressure drop correlation, such as the Ergun equation (Ergun, 1952). Because the Ergun equation does not have the correct dependence on the Reynolds number in the limit of $\varepsilon_g \to 1$ (single-particle limit), it is often supplemented with a drag correlation, such as the Wen and Yu equation, applicable in that limit (Gidaspow, 1986). The combined form is sometimes called the Gidaspow drag model (Gidaspow, 1994):

$$C_{Dm} = \begin{cases} \dfrac{200\left(1-\varepsilon_g\right)}{\varepsilon_g^2\,\mathrm{Re}_m} + \dfrac{7}{3\varepsilon_g} & \varepsilon_g \le 0.8 \\ \dfrac{24}{\varepsilon_g\,\mathrm{Re}_m}\left(1+0.15\left(\varepsilon_g\,\mathrm{Re}_m\right)^{0.687}\right)\varepsilon_g^{-2.65} & \varepsilon_g > 0.8, \left(\varepsilon_g\,\mathrm{Re}_m\right) < 1000 \\ 0.44\varepsilon_g^{-2.65} & \varepsilon_g > 0.8, \left(\varepsilon_g\,\mathrm{Re}_m\right) \ge 1000 \end{cases} \tag{2.365}$$

The other type of experimental data is the terminal velocity measured in fluidized or settling beds, given as correlations for the ratio of the terminal velocity of a multiparticle system to that of a single particle. Richardson and Zaki (1954) correlation, for example, is a well-known formula of this type. Syamlal and O'Brien (1987) showed that a formula for the multiparticle drag coefficient can be derived from such terminal velocity correlations as follows:

$$C_{Dm} = \frac{C_{Ds}\left(\dfrac{\mathrm{Re}_m}{V_{rm}}\right)}{V_{rm}^2} \tag{2.366}$$

where

$C_{Ds}(\mathrm{Re}_m/V_{rm})$ is a single-particle drag formula expressed as a function of Re_m/V_{rm} (rather than as a function ofc Re_m)

V_{rm} is the ratio of the terminal velocity of a multiparticle system to that of a single particle given by a Richardson–Zaki-type correlation

An explicit formula for drag can be derived from such a correlation reported by Garside and Aldibouni (1977):

$$V_{rm} = 0.5\left[A - 0.06\,\mathrm{Re}_m + \sqrt{\left(0.06\,\mathrm{Re}_m\right)^2 + 0.12\,\mathrm{Re}_m\left(2B - A\right) + A^2}\right] \tag{2.367}$$

where

$$A = \varepsilon_g^{4.14} \tag{2.368}$$

$$B = \begin{cases} 0.8\varepsilon_g^{1.28} & \varepsilon_g \le 0.85 \\ \varepsilon_g^{2.65} & \varepsilon_g > 0.85 \end{cases} \tag{2.369}$$

and the Reynolds number of the mth solid phase is given by

$$\mathrm{Re}_m = \frac{d_{pm}\left|U_g - U_m\right|\rho_g}{\mu_g} \tag{2.370}$$

Numerous formulas are available for C_{Ds} (e.g., Khan et al., 1987), including the following simple formula proposed by Dalla Valle (1948):

$$C_{Ds} = \left(0.63 + \frac{4.8}{\sqrt{\mathrm{Re}}}\right)^2 \tag{2.371}$$

The parameter Re in Equation 2.370 must be replaced with Re/V_{rm} when this formula is used in Equation 2.365.

The drag coefficients have an irreducible uncertainty, which could be reduced by calibrating them with the minimum fluidization velocity (Syamlal and O'Brien, 2003, Syamlal and Pannala, 2011).

Drag coefficients can also be derived from accurate numerical experiments, some of which are included in MFIX-TFM. For example, Hill et al. (2001a,b) derived a set of drag correlations from their Lattice–Boltzmann simulations. Benyahia et al. (2006) combined those drag correlations with known limiting forms of the drag formula to derive a formula applicable to the full range of void fractions and Reynolds numbers encountered in fluidized beds. MFIX-TFM also includes drag coefficients for polydispersed systems proposed by Beetstra et al. (2007a,b), Yin and Sundaresan (2009a,b), and Holloway et al. (2010). Several other closure equations for the drag force on particles and drops are included in Chapter 1.

2.7.2.4 Solid–Solid Momentum Transfer

As in the case of gas–solid drag, the drag between solid phases arises due to velocity differences. Formulas for the drag have been derived or suggested by several researchers: Soo (1967), Nakamura and Capes (1976), Syamlal (1985, 1987), and Srinivasan and Doss (1985).

In MFIX-TFM, the solid–solid momentum transfer, I_{mli}, is represented as

$$I_{mli} = F_{ml}\left(U_{mi} - U_{li}\right) \tag{2.372}$$

Syamlal (1987) used a simplified version of kinetic theory to derive an expression for the drag coefficient F_{ml}

$$F_{ml} = 3\left(1+e_{ml}\right)\left(\frac{\pi}{2} + C_{fml}\frac{\pi^2}{8}\right)\frac{\left(d_{pm}+d_{pl}\right)^2}{2\pi\left(\rho_m d_{pm}^3 + \rho_l d_{pl}^3\right)}\rho_m\rho_l g_{0ml}\left|U_m - U_l\right| + S_{coef}P_c \tag{2.373}$$

where the last term accounting for a "hindrance effect" caused by particles in enduring contact was later added by Gera et al. (2004) and S_{coef} is an adjustable parameter. The radial distribution function at contact for a mixture of hard spheres is given by Lebowitz (1964):

$$g_{0ml} = \frac{1}{\varepsilon_g} + \frac{3\left(\sum_{\ell=1}^{M}\frac{\varepsilon_\ell}{d_{p\ell}}\right)d_{pl}d_{pm}}{\varepsilon_g^2\left(d_{pl}+d_{pm}\right)} \tag{2.374}$$

MFIX also has polydisperse kinetic theory models with their own inherent solid–solid drag due to relative velocity (e.g., Iddir and Arastoopour, 2005). If one of those theories is invoked, the formula given earlier will be changed to the appropriate one.

2.7.2.5 Gas-Phase Stress Tensor

The total gas-phase stress is given by the formula $-P_g\delta_{ij} + \tau_{gij}$. But the addition of the buoyant force term gives rise to the term $-\varepsilon_g(\partial P_g/\partial x_i)$ in the Model A version of gas-phase momentum equation (see Section 2.7.2.2.)

MFIX-TFM uses modified k–ϵ theories to model gas-phase turbulence:

$$\varepsilon_g\rho_g\left[\frac{\partial k_g}{\partial t} + U_{gj}\frac{\partial k_g}{\partial x_j}\right] = \frac{\partial}{\partial x_j}\left(\varepsilon_g\frac{\mu_g^t}{\sigma_k}\frac{\partial k_g}{\partial x_j}\right) + \varepsilon_g\tau_{gij}\frac{\partial U_{gi}}{\partial x_j} + \Pi_{k_g} - \varepsilon_g\rho_g\epsilon_g \tag{2.375}$$

$$\varepsilon_g \rho_g \left[\frac{\partial \epsilon_g}{\partial t} + U_{gj} \frac{\partial \epsilon_g}{\partial x_j} \right] = \frac{\partial}{\partial x_j} \left(\varepsilon_g \frac{\mu_g^t}{\sigma_\epsilon} \frac{\partial \epsilon_g}{\partial x_j} \right) + \varepsilon_g \frac{\epsilon_g}{k_g} \left(C_{1\epsilon} \tau_{gij} \frac{\partial U_{gi}}{\partial x_j} - \rho_g C_{2\epsilon} \epsilon_g \right) + \Pi_{\epsilon_g} \tag{2.376}$$

The stress tensor τ_{gij} is given by

$$\tau_{gij} = 2(\mu_g + \mu_g^t) D_{gij} - \frac{2}{3} \delta_{ij} \left(\rho_g k_g + (\mu_g + \mu_g^t) D_{gkk} \right) \tag{2.377}$$

where D_{gij} is the strain rate tensor for the gas phase

$$D_{gij} = \frac{1}{2} \left(\frac{\partial U_{gi}}{\partial x_j} + \frac{\partial U_{gj}}{\partial x_i} \right) \tag{2.378}$$

The eddy viscosity μ_g^t is

$$\mu_g^t = \rho_g C_{1\mu} \frac{k_g^2}{\epsilon_g} \tag{2.379}$$

See Benyahia et al. (2005) for the definition of the other functions and constants in the modified $k - \epsilon$ equations: σ_k, σ_ϵ, Π_{k_g}, Π_{ϵ_g}, $C_{1\epsilon}$, $C_{2\epsilon}$, and $C_{1\mu}$.

For dense gas–solid flows without any high-velocity gas jets, the turbulence model could be turned off as the collisional stresses dominate when $\varepsilon_g < 0.99$ (Benyahia et al., 2005). By default, MFIX-TFM does not solve the turbulence equations, and only the molecular viscosity terms remain in Equation 2.376.

2.7.2.6 Solid-Phase Stress Tensor

The development of constitutive equations for particle–particle interactions over the entire range of dilute to dense granular flows must consider the fundamentally different modes for particle–particle force transmission in different flow regimes. A general formulation for solid stresses can be written as

$$\tau_{mij} = \begin{cases} \left(1 - \phi(\varepsilon_g)\right) \tau_{mpij} + \phi(\varepsilon_g) \tau_{mvij} & \varepsilon_g < \varepsilon^* \\ \tau_{mvij} & \varepsilon_g \geq \varepsilon^* \end{cases} \tag{2.380}$$

where the quasi-static and plastic stresses are represented by τ_{mpij} and the viscous stresses are represented by τ_{mvij}. The function $\phi(\varepsilon_g)$ is a blending function that has a smooth but rapid variation across the transition point, the void fraction at close packing ε^* (Pannala et al., 2009, Syamlal and Pannala, 2011). For uniformly sized particles ε^* is a specified constant. For a mixture of particles of different sizes, ε^* can be calculated from the Fedors and Landel (1979) or the Yu and Standish (1987) correlations available in MFIX-TFM.

2.7.2.6.1 Plastic Regime Syamlal et al. (1993) developed constitutive equations for the plastic regime using the frictional theory of Schaeffer (1987):

$$\tau_{mpij} = 2\mu_{mp} D_{mij} \tag{2.381}$$

The shear viscosity is adapted from Schaeffer (1987):

$$\mu_{mp} = \begin{cases} \min \left\{ \dfrac{P_c \sin(\phi)}{\sqrt{4 I_{m2D}}} \dfrac{\varepsilon_m}{\sum_{l=1}^{M} \varepsilon_l}, \mu_s^{\max} \right\} & \varepsilon_g < \varepsilon^* \\ 0 & \varepsilon_g \geq \varepsilon^* \end{cases} \tag{2.382}$$

where

ϕ is the angle of internal friction

$\mu_s^{\max}$ is a specified maximum granular viscosity

The solid pressure in the close-packed regions is related to the void fraction (Jenike, 1987):

$$P_c = \begin{cases} 10^{24}\left(\varepsilon^* - \varepsilon_g\right)^{10} & \varepsilon_g < \varepsilon^* \\ 0 & \varepsilon_g \geq \varepsilon^* \end{cases} \tag{2.383}$$

The second invariant of the rate of strain tensor is

$$I_{m2D} = \frac{1}{6}\left[\left(D_{m11} - D_{m22}\right)^2 + \left(D_{m22} - D_{m33}\right)^2 + \left(D_{m33} - D_{m11}\right)^2\right] + D_{m12}^2 + D_{m23}^2 + D_{m31}^2 \tag{2.384}$$

Another option available in MFX-TFM is the Srivastava and Sundaresan (2003) stress model. Benyahia (2008a) has compared the earlier two plastic regime stress models. Also see Oger and Savage (2013) who modified the Srivastava and Sundaresan model in MFIX-TFM to model the development of higher concentration flows in airslides, which are used to transport granular materials over long distances.

2.7.2.6.2 Viscous Regime The closure relationships for the solid-phase stresses for $\varepsilon_g \geq \varepsilon^*$ are derived from the kinetic theory of granular gases. The kinetic theory equations typically are derived for a monodisperse granular media without considering the gas phase (e.g., Jenkins and Savage, 1983, Lun et al., 1984, Campbell, 1990, Gidaspow, 1994). These equations are combined with two-fluid equations to develop closure relations for the solid-phase stresses (Johnson and Jackson, 1987, Sinclair and Jackson, 1989, Syamlal et al., 1993, Gidaspow, 1994, Peirano and Leckner, 1998, Jackson, 2000, Agrawal et al., 2001). Two things happen when the equations are combined: (1) The solid stress τ_{mv} in TFM is taken as the granular stress in the kinetic theory of granular gases; (2) a granular energy equation is added to the TFM. An example of the kinetic theory stresses implemented in MFIX-TFM is summarized later. Explanations for the equations can be found in Syamlal et al. (1993) and Agrawal et al. (2001). Although a subscript *m* is used, the following equations are valid only for a single solid phase.

The collisional stress tensor from the kinetic theory can be represented by the following equations:

$$\tau_{mvij} = \left(-P_m + \eta\mu_b \frac{\partial U_{mi}}{\partial x_i}\right)\delta_{ij} + 2\mu_m S_{mij} \tag{2.385}$$

where the deviator of the strain rate tensor is

$$S_{mij} = \frac{1}{2}\left(\frac{\partial U_{mi}}{\partial x_j} + \frac{\partial U_{mj}}{\partial x_i}\right) - \frac{1}{3}\frac{\partial U_{mk}}{\partial x_k}\delta_{ij} \tag{2.386}$$

and the normal solid pressure is

$$P_m = \varepsilon_m \rho_m \Theta_m \left[1 + 4\eta \sum_{l=1}^{M} \varepsilon_l g_{0ml}\right] \tag{2.387}$$

The solids, viscosity is

$$\mu_m = \left(\frac{2+\alpha}{3}\right)\left[\frac{\mu_m^*}{g_{0mm}\eta(2-\eta)}\left(1 + \frac{8}{5}\eta\sum_{l=1}^{M}\varepsilon_l g_{0ml}\right)\left(1 + \frac{8}{5}\eta(3\eta-2)\sum_{l=1}^{M}\varepsilon_l g_{0ml}\right) + \frac{3}{5}\eta\mu_b\right] \tag{2.388}$$

where

$$\mu_m^* = \frac{\rho_m \varepsilon_m g_{0mm} \Theta_m \mu}{\rho_m \sum_{l=1}^{M} \varepsilon_l g_{0ml} \Theta_m + \left(\frac{2\beta\mu}{\rho_m \varepsilon_m}\right)} \tag{2.389}$$

$$\mu = \frac{5}{96}\rho_m d_{pm}\sqrt{\pi\Theta_m} \tag{2.390}$$

$$\mu_b = \frac{256}{5\pi}\mu\varepsilon_m \sum_{l=1}^{M}\varepsilon_l g_{0ml} \tag{2.391}$$

$$\eta = \frac{1+e_{mm}}{2} \tag{2.392}$$

Here, Θ_m is the granular temperature or pseudo-thermal energy. The granular temperature is a measure of the kinetic energy of the fluctuating motion of particles, just as thermal temperature is a measure of the kinetic energy of the fluctuating motion of molecules. The granular temperature is calculated from the following granular energy balance equation:

$$\frac{3}{2}\varepsilon_m\rho_m\left[\frac{\partial\Theta_m}{\partial t}+U_{mj}\frac{\partial\Theta_m}{\partial x_j}\right]=\frac{\partial}{\partial x_j}\left(\kappa_m\frac{\partial\Theta_m}{\partial x_j}\right)+\tau_{mvij}\frac{\partial U_{mi}}{\partial x_j}+\Pi_m-\varepsilon_m\rho_m J_m \tag{2.393}$$

The first term on the right-hand side stands for the granular temperature diffusion or conduction, the second term represents the production, the third term includes viscous dissipation and the effect of gas-particle slip, and the final term stands for the collisional dissipation. The granular conductivity, associated with the conduction of granular temperature, is

$$\kappa_m=\left(\frac{\kappa_m^*}{g_{0mm}}\right)\left[\left(1+\frac{12}{5}\eta\sum_{l=1}^{M}\varepsilon_l g_{0ml}\right)\left(1+\frac{12}{5}\eta^2(4\eta-3)\sum_{l=1}^{M}\varepsilon_l g_{0ml}\right)+\frac{64}{25\pi}(41-33\eta)\eta^2\left(\sum_{l=1}^{M}\varepsilon_l g_{0ml}\right)^2\right] \tag{2.394}$$

where

$$\kappa_m^* = \frac{\rho_m\varepsilon_m g_{0,mm}\Theta_m\kappa_m^{**}}{\rho_m\sum_{l=1}^{M}\varepsilon_l g_{0ml}\Theta_m+\left(\frac{6\beta\kappa_m^{**}}{5\rho_m\varepsilon_m}\right)} \tag{2.395}$$

$$\kappa_m^{**} = \frac{75\rho_m d_{pm}\sqrt{\pi\Theta_m}}{48\eta(41-33\eta)} \tag{2.396}$$

The collisional dissipation term and the exchange terms are

$$J_m = \frac{48}{\sqrt{\pi}d_{pm}}\eta(1-\eta)\sum_{l=1}^{M}\varepsilon_l g_{0ml}\Theta_m^{3/2} \tag{2.397}$$

$$\Pi_m = -3\beta\Theta_m + \frac{81\varepsilon_m\mu_g^2\left|U_g-U_m\right|^2}{g_{0mm}d_{pm}^3\rho_m\sqrt{\pi\Theta_m}} \tag{2.398}$$

If the transport of the granular energy is not important (e.g., in bubbling beds the granular energy produced could be mostly dissipated locally), one can construct the algebraic form by equating the rate of production to the rate of dissipation and derive the following algebraic equation:

$$\Theta_m=\left\{\frac{-K_{1m}\varepsilon_m D_{mii}+\sqrt{K_{1m}^2(D_{mii})^2\varepsilon_m^2+4K_{4m}\varepsilon_m\left[K_{2m}(D_{mii})^2+2K_{3m}(D_{mij}D_{mij})\right]}}{2\varepsilon_m K_{4m}}\right\}^2 \tag{2.399}$$

$$K_{1m} = 2\left(1+e_{mm}\right)\rho_m g_{0mm} \tag{2.400}$$

$$K_{2m} = \frac{4d_{pm}\rho_m\left(1+e_{mm}\right)\varepsilon_m g_{0,mm}}{3\sqrt{\pi}} - \frac{2}{3}K_{3m} \tag{2.401}$$

$$K_{3m} = \frac{d_{pm}\rho_m}{2}\left\{\frac{\sqrt{\pi}}{3\left(3-e_{mm}\right)}\left[0.5\left(3e_{mm}+1\right)+0.4\left(1+e_{mm}\right)\left(3e_{mm}-1\right)\varepsilon_m g_{0,mm}\right]+\frac{8\varepsilon_m g_{0,mm}\left(1+e_{mm}\right)}{5\sqrt{\pi}}\right\} \tag{2.402}$$

$$K_{4m} = \frac{12\left(1-e_{mm}^2\right)\rho_m g_{0,mm}}{d_{pm}\sqrt{\pi}} \tag{2.403}$$

The algebraic form may reduce the computational cost of simulations (Van Wachem et al., 2001).

There are several other kinetic theory options available in MFIX-TFM. One option is the Garzó and Dufty (1999) theory, derived from the Enskog kinetic equation, which assumes molecular chaos (i.e., that the velocities of colliding particles are uncorrelated) and is applicable to flows up to moderate concentrations. With the help of that theory, for example, Mitrano et al. (2014) demonstrated that kinetic-theory-based continuum models are surprisingly accurate even at large Knudsen numbers. Benyahia et al. (2007) evaluated MFIX-TFM implementation of the theories of Simonin (1996) and Balzer et al. (1996) and Cao and Ahmadi (1995), which include kinetic theory stresses as well as gas-phase turbulence models that account for the exchange of turbulence energy between the gas and solid phases. Several kinetic theories for describing polydispersed systems have been implemented in MFIX (Garzo et al., 2007a,b, 2012). See Hrenya (2011) for a critical comparison of kinetic theories for polydispersed systems. Benyahia (2008b) compared four different kinetic theories for polydispersed systems and found the most accurate one to be Iddir and Arastoopour (2005) theory, which was implemented in MFIX-TFM by Galvin (2007).

2.7.2.7 Conservation of Species Mass

The gas and solid phases may contain an arbitrary number of chemical species, N_m. The mass conservation equation for the gas-phase species n is

$$\frac{\partial}{\partial t}\left(\varepsilon_g\rho_g X_{gn}\right)+\frac{\partial}{\partial x_j}\left(\varepsilon_g\rho_g U_{gj}X_{gn}\right)=\frac{\partial}{\partial x_j}\left(\mathcal{D}_{gn}\frac{\partial X_{gn}}{\partial x_j}\right)+R_{gn} \tag{2.404}$$

The species conservation equation for solid phase, m, species n, is

$$\frac{\partial}{\partial t}\left(\varepsilon_m\rho_m X_{mn}\right)+\frac{\partial}{\partial x_j}\left(\varepsilon_m\rho_m U_{mj}X_{mn}\right)=R_{mn} \tag{2.405}$$

2.7.2.8 Conservation of Internal Energy

The internal energy balances are implemented in MFIX-TFM in terms of the temperatures. The equation for the gas phase is

$$\varepsilon_g\rho_g C_{pg}\left[\frac{\partial T_g}{\partial t}+U_{gj}\frac{\partial T_g}{\partial x_j}\right]=-\frac{\partial q_{gj}}{\partial x_j}+\sum_{m=1}^{M}\gamma_{gm}\left(T_m-T_g\right)+\gamma_{Rg}\left(T_{Rg}^4-T_g^4\right)-H_g \tag{2.406}$$

where the second term on the right-hand side is the gas–solid interphase heat transfer and the third term is a simplified model for the heat transfer due to radiation. The equation for the mth solid phase is

$$\varepsilon_m\rho_m C_{pm}\left[\frac{\partial T_m}{\partial t}+U_{mj}\frac{\partial T_m}{\partial x_j}\right]=-\frac{\partial q_{mj}}{\partial x_j}-\gamma_{gm}\left(T_m-T_g\right)+\gamma_{Rm}\left(T_{Rm}^4-T_{\boldsymbol{m}}^4\right)-H_m \tag{2.407}$$

where the second term on the right-hand side is the gas–solid interphase heat transfer and the third term is a simplified model for the heat transfer due to radiation. Three simplifying assumptions have been made in the formulation of internal energy Equations 2.404 and 2.405: (1) The irreversible rate of increase in internal energy due to viscous dissipation and interphase momentum transfer has been neglected. Such terms are negligible except in the case of very large relative velocities. (2) The direct heat transfer between different solid phases has been neglected. (3) Interfacial work terms have been neglected.

The total rate of enthalpy change due to chemical reactions and phase changes is given by Syamlal and Pannala (2011) and Musser et al. (2015):

$$H_g = \sum_n^{N_g} h_{gn}\left(T_g\right)\frac{\partial}{\partial x_j}\left(\mathcal{D}_{gn}\frac{\partial X_{gn}}{\partial x_j}\right) + \sum_p^{P}\left(\sum_{m=0}^{M}\left(-\xi_{gmp} + \sum_{n=1}^{N_g} h_{gn}\left(T_g\right)R_{gmnp}\right)\right) \tag{2.408}$$

and

$$H_m = \sum_n^{N_m} h_{mn}\left(T_m\right)\frac{\partial}{\partial x_j}\left(\mathcal{D}_{mn}\frac{\partial X_{mn}}{\partial x_j}\right) + \sum_p^{P}\left(\xi_{gmp} + \sum_{n=1}^{N_m} h_{mn}\left(T_m\right)\left(R_{mgnp} + R_{mmnp}\right)\right) \tag{2.409}$$

The enthalpy change due to species diffusion, although shown in Equations 2.406 and 2.407, is small and has been neglected in MFIX. R_{gmnp} is the rate of formation (or destruction) of the nth gas-phase species attributed to the pth reaction between the gas phase and the mth phase. The case of $m = 0$ represents homogeneous gas-phase reactions. R_{mgnp} is the rate of formation (or destruction) of the mth solid phase's nth species resulting from the pth reaction between the mth phase and the gas phase. R_{mmnp} is the rate of formation in homogeneous mth solid-phase reactions, and any direct solid–solid reactions are not considered. ξ_{gmp} is the enthalpy transfer attributed to mass transfer between the mth solid phase and the gas phase for the pth reaction.

Musser et al. (2015) proposed the following constitutive equation for ξ_{gmp} to account for enthalpy transfer caused by mass transfer:

$$\xi_{gmp} = \sum_{n=1}^{N_g} h_{gn}\left(T_{gm}\right)R_{gmnp} \tag{2.410}$$

The temperature at which the specific enthalpy is evaluated, T_{gm}, is identified explicitly and given by

$$T_{gm} = \begin{cases} T_g & \text{for } R_{gmnp} \le 0 \text{ (i.e., consumption of } n\text{th gas species)} \\ T_m & \text{for } R_{gmnp} > 0 \text{ (i.e., formation of } n\text{th gas species)} \end{cases} \tag{2.411}$$

2.7.2.9 Gas–Solid Heat Transfer

The heat transfer between the gas phase and solid phase m is assumed to be a function of the temperature difference and given by $\gamma_{gm}(T_m - T_g)$, where γ_{gm} is the coefficient of heat transfer between the gas phase and the mth solid phase. γ_{gm} is a corrected heat transfer coefficient, the correction necessitated by the interphase mass transfer (Bird et al., 2006):

$$\gamma_{gm} = \frac{C_{pg}\mathcal{R}_{gm}}{\left[\exp\left(\dfrac{C_{pg}\mathcal{R}_{gm}}{\gamma^0_{gm}}\right) - 1\right]} \tag{2.412}$$

Note that in the limit

$$\lim_{\mathcal{R}_{gm}\to 0}\gamma_{gm} = \gamma^0_{gm}$$

where the intrinsic heat transfer coefficient γ^0_{gm} is calculated from

$$\gamma^0_{gm} = \frac{6\lambda_g \varepsilon_m \mathrm{Nu}_m}{d^2_{pm}} \tag{2.413}$$

where Nu_m is the Nusselt number for the particles constituting the mth solid phase.

The Nusselt number is typically determined from one of the many correlations reported in the literature for calculating the heat transfer between particles and fluid in packed or fluidized beds (e.g., Zabrodsky, 1966, Gelperin et al., 1971, Gunn, 1978). Syamlal and Gidaspow (1985) and Kuipers et al. (1992) used such correlations in their TFMs. MFIX-TFM uses the Gunn (1978) correlation, applicable for a porosity range of 0.35–1.0 and a Reynolds numbers up to 10^5:

$$\mathrm{Nu}_m = \left(7 - 10\varepsilon_g + 5\varepsilon_g^2\right)\left(1 + 0.7\,\mathrm{Re}_m^{0.2}\,\mathrm{Pr}^{1/3}\right) + \left(1.33 - 2.4\varepsilon_g + 1.2\varepsilon_g^2\right)\mathrm{Re}_m^{0.7}\,\mathrm{Pr}^{1/3} \tag{2.414}$$

where the Prandtl number is defined as

$$\mathrm{Pr} = \frac{C_{pg}\mu_g}{\lambda_g} \tag{2.415}$$

2.7.2.10 Conductive Heat Flux in Gas Phase

The conductive heat flux within the gas phase, q_{gj}, is given by Fourier's law

$$q_{gj} = -\lambda_g \frac{\partial T_g}{\partial x_j} \tag{2.416}$$

2.7.2.11 Conductive Heat Flux in Solid Phase

In a simulation of the heat transfer from a fluidized bed to a wall, Syamlal and Gidaspow (1985) found that solid-phase conductive heat flux must be considered in order to accurately calculate bed-to-wall heat transfer coefficients. The conductive heat flux in the solid phase, q_{mj}, is assumed to have a form similar to that in the gas phase:

$$q_{mj} = -\lambda_m \frac{\partial T_m}{\partial x_j} \tag{2.417}$$

MFIX-TFM uses a particle phase conductivity model taken from Syamlal and Gidaspow (1985), who adapted a model proposed by Zehner and Schlunder (Bauer and Schlunder, 1978).

2.7.2.12 Initial and Boundary Conditions

The initial values of all the field variables (ε_g, ε_m, P_g, U_{gi}, U_{mi}, Θ_m, T_g, T_m, X_{gn}, X_{mn}) must be specified for the entire computational domain. Although the initial conditions serve as a starting point for the simulations, the stationary state that is reached after the initial transients subside is the solution that is of interest in most engineering applications. Therefore, the initial conditions chosen are such that the stationary state solution is reached faster. In fluidized beds, for example, the solids, velocity is usually initialized to zero, and the gas velocity is initialized to some uniform unidirectional value.

On the other hand, the accuracy of the stationary state solution critically depends upon the boundary conditions. The different types of boundary conditions available in MFIX-TFM are described as follows:

Inflow boundary: An inflow boundary condition should be specified at a location where uniform flow is expected. All the field variables must be specified at the boundary. Two types of inflow boundary conditions are possible, specified pressure or specified mass flux; the specified mass flux condition is more commonly used inflow boundary condition.

Outflow boundary: Specified constant pressure with zero-gradient velocity at the exit is the most common condition for the gas outflow boundary. For this condition to be valid, the outflow must be spatially uniform with no flow reversal across the boundary. If there is flow reversal at a specified boundary (caused, e.g., by a jet crossing the outflow boundary), the domain must be extended so that the flow is uniform at the outflow boundary.

Cyclic boundary: A cyclic boundary condition may be specified for a pair of boundaries in the x-, y-, or z-direction. The field variable values at one end of the domain in the cyclic direction become the same as those at the other end. There is also the option of fixing the pressure drop so that the gas pressure changes by a specified constant value across the cyclic boundary. Another option is to fix the domain-averaged mass flux of gas instead of the pressure drop.

Walls: Boundary conditions for all the variables must be specified at the walls. Since, in most devices, walls play an important role in the overall performance of the reactor, much attention must be paid to selecting wall boundary conditions. Typically, at the wall, the gas-phase normal component of velocity is set to zero (no-penetration condition) and either the gradient of the tangential component is set to zero (free-slip condition) or the tangential component itself is set to zero (no-slip condition). Benyahia et al. (2005) compared a standard wall function with a wall function modified to include the effect of particles and found only a small effect on the radial profile of gas turbulent kinetic energy.

The boundary conditions for the solids velocities could have a profound effect on the simulation results (e.g., Benyahia et al., 2005). The boundary conditions developed by Johnson and Jackson (1987) are widely used to determine the solutions for solids velocity and granular temperature. These boundary conditions rely on two parameters: the specularity coefficient and the particle–wall coefficient of restitution. Jenkins (1992) has proposed a different form of the boundary condition for frictional particles, which requires parameters related to the frictional properties of the particles and the nature of the wall surfaces. These boundary conditions were further extended for both small and large sliding cases (Jenkins and Louge, 1997). Benyahia et al. (2005) evaluated these boundary conditions by simulating dilute, turbulent gas/solids flows in a pipe and concluded that the experimental data for solids velocity, gas turbulent kinetic energy, and solids turbulent kinetic energy fell between the small-friction/all-sliding and large-friction/no-sliding limits of Jenkins and Louge (1997) boundary condition. The experimental data fell much closer to the small-friction limit. The small-friction limit could be mimicked with a small specularity coefficient in the Johnson and Jackson (1987) boundary condition. The significant effect of the specularity coefficient (and particle–wall restitution coefficient) on the predicted solids, velocity and bubble properties in a bubbling fluidized bed is discussed by Li et al. (2010a). The specularity coefficient is, however, experimentally not measureable, and Li and Benyahia (2012) developed a model for calculating the specularity coefficient as a function of the measurable quantities particle–wall restitution coefficient, the frictional coefficient, and the normalized slip velocity at the wall. Li and Benyahia (2013) evaluated their model by simulating bubbling and circulating fluidized beds. These different boundary condition models for solids velocity and granular temperature are available in MFIX-TFM. Other boundary conditions for MFIX and similar Eulerian models, which are based on DNS simulations, have been studied by Davies et al. (2012) and Feng et al. (2014).

The thermal boundary condition is implemented in MFIX-TFM as

$$\frac{\partial T_m}{\partial n} + h_{wm}(T_m - T_{wm}) = c_m \tag{2.418}$$

where n is the normal pointing from the fluid into the wall. In the limit when the wall heat transfer coefficient $h_{wm} \to 0$, the heat flux at the boundary is a specified value, and in the limit of $h_{wm} \to \infty$, the temperature at the boundary is a specified value.

Similarly, the boundary conditions for the species mass fractions are implemented as

$$\frac{\partial X_{mn}}{\partial n} + h_{wmn}(X_{mn} - X_{wmn}) = c_{mn} \tag{2.419}$$

where n is the normal pointing from the fluid into the wall. In the limit when the wall mass transfer coefficient $h_{wmn} \to 0$, the mass flux at the boundary is a specified value, and in the limit of $h_{wmn} \to \infty$, the species mass fraction at the boundary is a specified value.

2.7.3 Numerical Method

MFIX utilizes the finite volume method to discretize the governing equations over a staggered grid where scalar values are located at the center of a control volume and velocity components are situated along the control volume faces. This approach is desirable because it invokes the physical basis of the conservation equation derivations while ensuring global conservation of mass, momentum, and energy, even on coarse grids (Patankar, 1980). Details on the control volume method are available elsewhere (Patankar, 1980, Versteeg and Malalasekera, 1995, Syamlal, 1998).

MFIX-TFM uses an extension of the SIMPLE algorithm (Patankar, 1980) for solving the discretized conservation equations. As the original algorithm was derived for single-phase flows, Spalding (1980) identified three issues that result from extending it to multiple phases: (1) there are more field variables and therefore more equations to solve, (2) no unique fluid pressure correction equation exists because there are multiple continuity equations, and (3) interphase exchange terms strongly couple momentum equations, which can lead to instability if not adequately addressed.

Two additional concerns arise in granular multiphase flows that determine the success of a numerical scheme (Syamlal, 1998). The first potential problem is managing solids in close-packed regions because it is difficult to constrain the solids, volume fraction to be at or below maximum packing in a numerical algorithm. Overpacking is resisted by the numerical algorithm by using an equation of state for the solid pressure that increases exponentially as the solids, volume fraction approaches the close-packed limit. In monodisperse simulations, MFIX utilizes solids, volume fraction correction equation to account for solid pressure and stabilize computations in close-packed regions.

The second issue encountered with multiphase systems is how to calculate field variables across phase discontinuities where the volume fraction goes to zero. A harmonic mean is used to calculate face values of scalar field variables to ensure that arbitrary values are not used. The linearization of the convection terms in the momentum equations complicates this task because the normal velocity may become very large across a phase discontinuity. The resulting error in momentum conservation is negligible because the product of a near-zero volume fraction and normal velocity remains small. However, the large normal velocities may destabilize calculations (or force the use of very small time steps) and therefore are avoided in MFIX by approximating the normal velocity when the phase volume fraction drops below a threshold value.

MFIX employs automated time step adjustment to account for the inherently transient nature of multiphase flows where the limiting timescales change throughout a simulation. Small upward or downward modifications to the step size are applied to ensure that simulations progress with the highest possible execution speed. This minimizes simulation failure by reducing the time step if divergence is detected or the maximum number of iterations per time step is exceeded. Conversely, the step size is increased when the number of iterations becomes small to reduce the time to solution.

The individual procedures executed during a time step can be summarized as follows:

1. At the start of each iteration, the physical (e.g., specific heat) and exchange coefficients (e.g., convective heat transfer coefficients) are calculated.
2. The gas and solid momentum equations are solved using the pressure fields and volume fractions from the previous time step. The calculated velocities are referred to as the intermediate or starred velocities, $u_m^\star$, $v_m^\star$, and $w_m^\star$. At this time, the coefficients for the fluid pressure correction equation are calculated, but the pressure correction equation is not solved.
3. The solid-phase continuity equations are solved:
   a. Monodisperse simulations solve a solid volume fraction correction equation. The correction is used to update the solid volume fraction and solid velocity components.
   b. Polydisperse simulations solve a solid continuity equation for each phase. No corrections are made to the solid velocities.
4. The gas-phase volume fraction is calculated from the solid volume fractions.
5. The solid pressure is calculated from a state equation, $P_m = P_m(\varepsilon_m)$.
6. The face-centered densities are calculated.
7. The fluid pressure correction equation is solved. The corrections are used to update the gas pressure field and gas velocity components.
8. The material densities and the face-centered mass fluxes are calculated.
9. The scalar equations (e.g., species, energy) are solved.
10. The normalized residuals are calculated and checked for convergence. The time step is advanced if the convergence criteria are satisfied; otherwise, iterations are continued (Step 1).

As noted earlier, details on the control volume method (Patankar, 1980, Versteeg and Malalasekera, 1995, Syamlal, 1998) and SIMPLE algorithm (Patankar, 1980, Spalding 1980) are available elsewhere. Information specific to the numerical methods and implementations of MFIX-TFM, such as the multiphase partial elimination algorithm and solids, volume fraction correction equation, are also available (Syamlal, 1998). The following section presents more advanced methods that have been incorporated to increase modeling capabilities.

2.7.4 Advanced Numerical Methods

This section provides an overview of several advanced numerical techniques used in modeling reacting gas–solid flows as implemented in MFIX-TFM. The stiff chemistry and variable solid density sections discuss how chemical reactions are managed and used to modify the gas and solid phases. The point source and filter model sections discuss coarse grid modeling options to reduce the time to solution. Finally, the Cartesian grid cut-cell technique presents how complex geometries are integrated into staggered grid codes.

2.7.4.1 Stiff Chemistry Solver

As indicated in previous sections, multiphase CFD models solve governing equations for each phase that are tightly coupled through interphase transfer terms. Chemical reactions further couple the continuity, species, and energy equations with the formation and destruction of chemical species, interphase mass transfer, and heats of reaction. Unlike the interphase transfer terms found in the momentum and energy equations, coupling by reactions cannot be separated through "partial elimination" techniques. Therefore, numerical stability of chemically reacting flows is typically achieved through small time steps making the simulations prohibitively time consuming. The objective of a stiff chemistry solver, also referred to as a fractional step method, is to reduce the time to solution. This is accomplished by maintaining stability using time step sizes limited by the hydrodynamic timescales rather than chemical reaction timescales, which may be several orders of magnitude smaller.

The key aspect of a stiff chemistry solver is that transport (convection–diffusion) and chemical reaction effects are treated independently such that different solution methodologies can be used for each problem type. For example, discretized transport equations for nonreacting, cold flow systems result in large, sparse matrices whereby interphase transfer terms binding the phases are decoupled through partial elimination algorithms. The linear systems are solved in succession using iterative techniques that aim to exploit the matrix structure. In contrast, chemical reactions couple mass, species composition, and temperature through highly nonlinear source terms. Locality is such that chemical reactions in a computational cell are independent of reactions occurring in adjacent cells. Therefore, a low-dimensional, nonlinear system of coupled mass, species, and energy equations is solved to account for reactions.

The general approach of a stiff chemistry solver is depicted in Equation 2.419. First, the transport equations are solved without chemical reaction source terms. These intermediate solutions are denoted by a star, $\phi^*(t + \Delta t)$ and provide the initial conditions for the set of differential equations based on the chemical reaction source terms. The set of differential equations is directly integrated for each computational cell, completing the time step:

$$\phi(t) \xrightarrow{transport} \phi^*(t+\Delta t) \xrightarrow{reaction} \phi(t+\Delta t) \tag{2.420}$$

The set of differential equations sent to the stiff solver is dynamically constructed for each computational cell; every time step is constructed to minimize the computational impact of the solver. The form of the chemical reaction conservation equations is given in the following equations:

$$\frac{d}{dt}(\varepsilon_m \rho_m) = \sum_n^{N_g} R_{mn} \tag{2.421}$$

$$\frac{d}{dt} X_{mn} = \frac{1}{\varepsilon_m \rho_m}\left[R_{mn} - X_{mn} \sum_n^{N_g} R_{mn} \right] \tag{2.422}$$

$$\frac{d}{dt} T_m = \frac{-H_m}{\varepsilon_m \rho_m C_{Pm}} \tag{2.423}$$

Following the solution of the transport equations, the stiff solver evaluates the reaction rates for a computational cell, skipping cells where all reaction rates fall below a minimum threshold. If a cell does not contain any reactive solids, the cell is restricted to homogeneous gas-phase reactions to minimize computational overhead. The energy equations for all phases are an important exception and are always included in the set of

differential equations. This allows for an otherwise inert solid phase to act as a solid catalyst, thereby receiving the heat of reaction. Once the set of differential equations is determined, the active variables are mapped into the low-dimensional space and passed to the solver, ODEPACK (Hindmarsh, 1983). After the direct integration is preformed, the results are mapped back to the full dimensional space.

2.7.4.2 Variable Solid Density

A variable solid density model is used to capture the effect of solid particles maintaining a constant size while losing mass due to a chemical reaction or phase change. This is similar to the progressive conversion model of Levenspiel (1972) but adapted for a TFM. The traditional TFM accounts for solids mass sources and sinks by adjusting the solids, volume fraction. If the solids, diameter and density are constant, this leads to the implicit assumption that any loss (or gain) of solids, mass is the result of a decrease or increase in the particle number density.

The variable solid density model, as implemented in MFIX-TFM, requires that each solid phase be defined with a baseline species mass fraction composition, X^B_{mn}, along with the material densities of each species, ρ^B_{mn}. Here, the subscripts m and n indicate the phase and species, respectively. The superscript B indicates that this is a baseline quantity. The baseline apparent solid density for the solid phase is then calculated as

$$\frac{1}{\rho^B_m} = \sum_n^{N_m} \frac{X^B_{mn}}{\rho^B_{mn}} \tag{2.424}$$

where N_m is the total number of species comprising solid phase m.

The term baseline is used to assert that these values are specific to the phase definition and do not restrict the initial conditions or instantaneous composition of the solid phase. For example, consider a solid phase defined to represent coal particles and taken to be composed of the four pseudo-species char, ash, volatiles, and moisture. The baseline composition of the coal would likely reflect the proximate analysis (e.g., 40% char, 15% ash, 35% volatiles, and 10% moisture), whereas the initial conditions for the solid phase might be defined as either a normalized char/ash mixture (73% char and 27% ash) or all ash (100% ash).

The definition of the baseline solid density is only valid with respect to the baseline mass fractions of solids species. The equation employs the assumption that the volume of a particle is equivalent to the mass of a particle divided by the material density; however, as mass is lost or gained, this assumption no longer holds. This is easily demonstrated again by considering a coal particle. If all of the char, volatiles, and moisture are consumed such that only ash remains, then Equation 2.423 indicates that the solid density approaches the material density of ash as the mass fraction of ash goes to one. This is incorrect as the solid density should approach the mass of ash divided by the volume of solids. Xue et al. (2011) noted this phenomenon and suggested that the apparent solid density is related to the baseline density by a porosity, ε_p, such that

$$\rho_m = \rho^B_m \left(1 - \varepsilon_p\right) \tag{2.425}$$

This approach is not desirable in a generalized multiphase CFD code because it requires users to provide an additional closure to account for the evolution of porosity.

The variable solid density model in MFIX-TFM is generalized by having users identify one solid-phase species as inert. This is a reasonable approach given that the solids diameter is considered invariant to mass loss, and therefore, an inert material is needed to provide a rigid matrix to support reactants and/or products. Continuing with the example of a coal particle, the ash species can be marked as inert because it is not consumed or formed by any chemical reactions. The fact that an inert species is neither formed nor destroyed as a result of phase change or chemical reactions can then be exploited to construct a variable density model.

First, observe that an instantaneous solid density can be defined as the sum of the individual species masses, m_{mn}, divided by the volume that the phase occupies, V_m:

$$\rho_m = \sum_n \frac{m_{mn}}{V_m} \tag{2.426}$$

Using the assumption that the inert species mass is constant gives

$$m_m = \frac{m_m^0 X_{mI}^B}{X_{mI}} \tag{2.427}$$

where
the superscript "0" indicates the initial value
the subscript "I" is the index of the inert species

The definition of the initial solids mass, $m_m^0 = \rho_m^0 V_m$, is then used to condense the instantaneous solid density calculation:

$$\rho_m = \sum_n \left(\frac{m_m^0 X_{mI}^B}{X_{mI}} \right) \frac{m_{mn}}{V_m} \rho_m^B V_m = \rho_m^B \frac{X_{mI}^B}{X_{mI}} \tag{2.428}$$

The simplified form of the instantaneous solid density is compact making it ideal for implementation in CFD programs. Additionally, this approach does not require any new information, such as new field variables or additional species data, to calculate the solid density. Finally, the calculation is reasonably safe to perform without risk of floating-point arithmetic errors because the mass fraction of the inert material remains sufficiently large, in most practical cases.

2.7.4.3 Point Sources

As the name implies, point sources provide a way to specify mass sources to the discretized governing equations at either a specific location (point) or a region defined by a plane or volume. They are typically used in place of flow boundary conditions to model features such as injector tubes. Point sources are especially useful when substantial mesh refinement would otherwise be required to model the geometry of these small-scale mass sources as illustrated in Figure 2.81.

In MFIX, point sources are defined by specifying the mass flow rate, species composition, and temperature of incoming material and predominately operate on the scalar field. Unlike a traditional flow boundary condition, which defines the velocity at the face of a computational cell, point sources do not need to contribute directly to the momentum equations. If desired, point sources can be made directional by specifying magnitude and orientation whereby the momentum source is applied to the cell face in the point source's flow direction.

2.7.4.4 Filtered Models

Gas–solid flows in fluidized beds, circulating fluidized beds, and risers typically exhibit fluctuations and instabilities over a wide range of length and timescales. For example, inhomogeneous structures, or clusters,

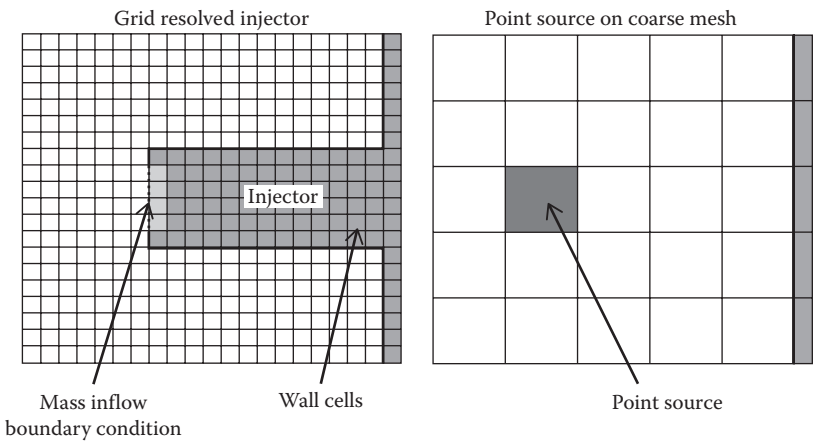

Figure 2.81

Illustrative example of an injector that is modeled either by resolving the grid or by a point source.

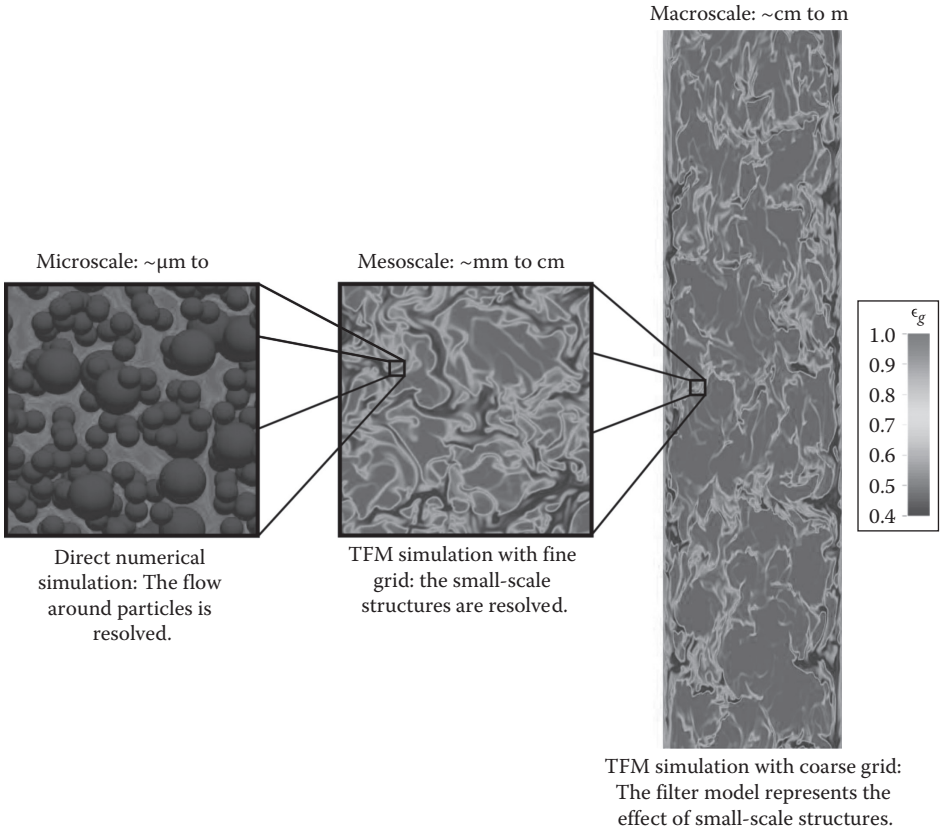

Figure 2.82

Gas–solid flow simulations at various scales. (Adapted from Milioli, C. et al., Constitutive model for the fluid-particle drag coefficient in filtered two-fluid models for gas-particle flows, in *AIChE Annual Meeting*, AIChE, Pittsburgh, PA, 2012.)

can develop within very small scales, on the order of 10 particle sizes (Agrawal et al., 2001), which can affect the flow dynamics. As noted earlier, TFM is based on locally averaged quantities wherein details of the flow at the individual particle level are unresolved, unlike direct numerical simulations (Figure 2.82). This approach requires closures (constitutive relations) to close the system of equations. These closures are typically based on data and/or analysis of homogeneous systems that do not natively take into account the formation of clusters at scales smaller than the computational cell size. When the computational mesh is sufficiently fine to resolve small scales (smaller than the cluster size), no additional modeling effort is required to capture their effects, but the burden is placed on the computational resources to achieve such fine resolution. For example, at the mesoscale level, high-resolution TFM simulations can capture small-scale structures, provided the computational cells are of the order of a few particle diameters. While high-resolution TFM simulations of large-scale devices, like those found in the industry, are theoretically possible, they are practically beyond current computational capabilities. Consequently, coarse mesh simulations are preferred. Coarse grids, however, are insufficient to resolve small-scale structures (i.e., at the subgrid scale level). As a result, the constitutive equations must be modified to account for the effects of the unresolved structures. For example, in the presence of clusters, the drag force needs to be reduced and compared to a homogeneous particle distribution to represent the lower resistance encountered by the air flowing around clusters. Similarly, mass and energy transfer will be reduced due to the tendency of the gas to bypass dense particle regions. The drag law can be corrected through an apparent cluster size (O'Brien and Syamlal, 1993, Heynderickx et al., 2004) or by using an energy minimization multiscale approach (Li and Kwauk, 2003, Yang et al., 2004). The implementation of these correction terms in the constitutive relations is referred to as *filtered models*. Although this is a fairly new development and a rapidly evolving field in the multiphase community, a similar technique is routinely applied to model single-phase turbulent flows and is known as large eddy simulation (Smagorinsky, 1963, Pope, 2000, Sagaut, 2006). The following sections describe two filtered models currently implemented in MFIX for monodisperse systems. For monodisperse systems, the Igci and

Milioli filtered models are currently available in MFIX (Release 2014-1). Details about the formulations can be found in Igci et al. (2008, 2012), Igci and Sundaresan (2011), and Milioli et al. (2012, 2013). A discussion of filtered models for bidispersed system can be found in Holloway and Sunderasan (2014).

2.7.4.5 Cartesian Grid Cut-Cell Technique

MFIX uses a 3D structured Cartesian or cylindrical coordinate system, with staggered grid representation of the velocity components. The advantages of the structured grid are the simple discretization of the governing equations, fairly straightforward programming of the numerical method, and fast mesh generation. However, structured grids have the disadvantage of not being able to accurately represent curved or sloping boundaries, which limits its range of applications. In a structured grid system, a boundary that is not aligned with the grid is typically approximated by a series of steps, referred to as staircase representation. Accuracy can be improved by refining the grid, but this requires additional computational resources, which often proves prohibitive.

For improved flexibility, the Cartesian grid cut-cell technique was implemented to represent complex geometries. This technique has the advantage of keeping the traditional Cartesian grid formulation to discretize the computational domain away from the boundaries, while computational cells near the boundaries are truncated so that they conform to the boundary surface. Therefore, additional treatment is only required for the boundary cells. A description of the Cartesian grid cut-cell method for staggered grid system is given in Kirkpatrick et al. (2003), and the original MFIX implementation can be found in Dietiker et al. (2009). In the latter, improvement over the usual staircase representation of curved or sloped boundary was highlighted through several simple benchmark tests. For a 2D single-phase flow in a skewed channel, the error on the velocity can be reduced by an order of magnitude. Figure 2.83 shows an example of velocity profile across a channel with a coarse grid. The solution with cut cell is smooth and compares well with the exact solution, whereas the solution with staircase boundary exhibits large discrepancies, even far away from the walls.

In the Cartesian grid cut-cell method, once the geometry is defined, the computational cells are truncated to conform to the shape of the boundaries. Current geometry input methods include quadric surfaces for relatively simple shapes (cylinders, cones, etc.), 2D polygons, user-defined functions, or direct input from a CAD file (STL format). Velocity nodes are moved to the center of cut-cell faces, and computation of fluxes through cut-cell faces is modified to account for the new nodes location.

Figure 2.84 shows the computational grid near a curved boundary, where arrows indicate the location of velocity nodes. The wall is represented by a thick solid line. Three types of cells are shown: standard (uncut) cells, cut cells that require special treatment due to the presence of the wall, and blocked cells that are excluded from computations. Figure 2.85 shows an x-momentum cut cell (cell bordering a boundary surface), where u_P refers to the x-velocity in that cell and u_E refers to the x-velocity in the east-neighbor cell. The interpolated velocity, u_e, at a boundary cell surface based on velocity nodes u_P and u_E is not necessarily

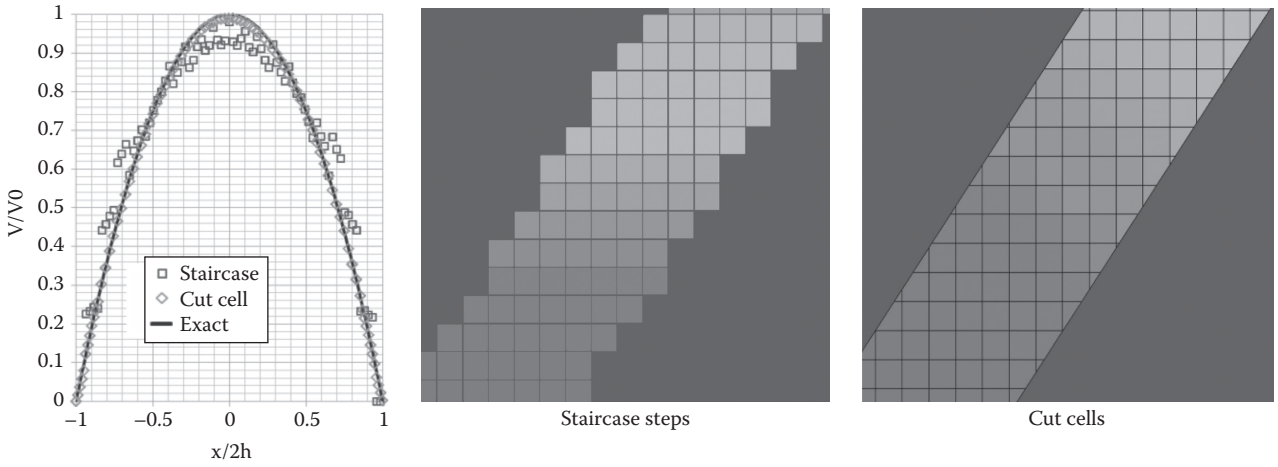

Figure 2.83

Illustration of the benefits of Cartesian grid cut cell. The velocity profile across a skewed channel shows large error with a staircase representation on the boundaries. When cut cells are used, the wall boundary is smooth and the velocity profile matches the exact parabolic solution.

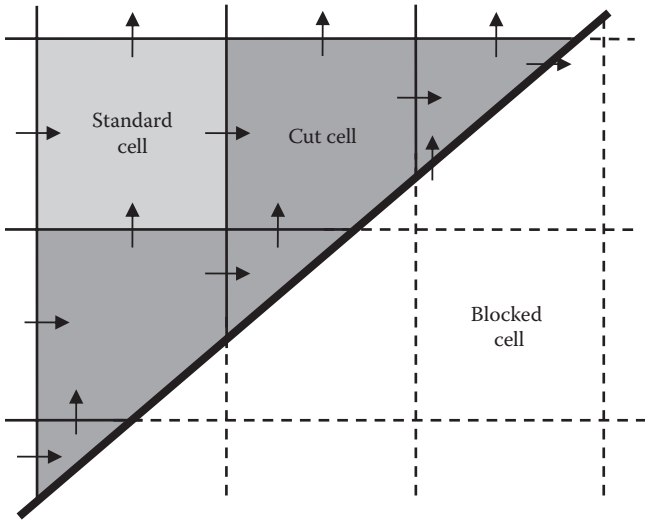

Figure 2.84

Different types of scalar cells and location of velocity nodes with the Cartesian grid cut-cell technique.

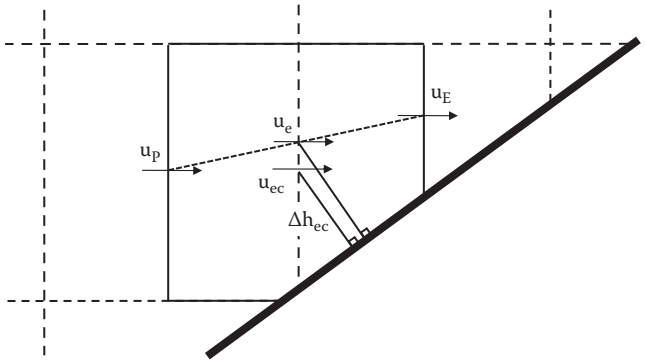

Figure 2.85

Interpolation correction for u_{ec} at the east face of an x-velocity cut cell.

located at the center of the cell face. To calculate the velocity at the cell face center, u_{ec}, a correction is applied. For a no-slip boundary condition, u_{ec} is computed by assuming zero velocity at the wall using the ratio of normal distances to the wall from $u_{ec} = \Delta h_{ec} u_e / \Delta h_e = \alpha_e u_e$. For a free-slip boundary condition, the coefficient α_e is set to one. For partial slip (Johnson–Jackson), the value of α_e is between 0 and 1 and depends on the specularity coefficient. Since the line between u_P and u_E is not aligned with the *x*-axis, nonorthogonality correction terms are included in the computation of velocity gradients.

A wide variety of cut cells are typically generated, and cut cells vary in shape and size. The generation of small pressure cells can lead to stability issues. Due to the staggered grid formulation, velocity cells require pairs of pressure nodes (East/West, North/South, and Top/Bottom) to compute pressure gradients. However, when some pressure cells are removed (blocked cells), the corresponding velocity cells will only have one pressure node and the pressure gradient cannot be computed in that direction. When this situation occurs, the velocity cell is flagged as a "wall cell," and the momentum equation is not solved for this cell. The treatment of single-pressure velocity cells effectively limits their size to half the size of a standard cell in any direction. This criterion automatically avoids problems linked to small velocity cells.

The treatment of cut cells involves additional interpolation and correction terms, which increases the computational cost of the flow solver. However, the geometric parameters are computed during preprocessing and have negligible impact on the overall code efficiency. Cut-cell simulation results are stored in vtk files (Avila, 2010) for visualization. For meshes that contain a large number of unused computational cells (i.e., blocked cells), it is beneficial to reindex the cells in the program memory, such that the flow solver only

Figure 2.86

Example of a simulation using the Cartesian grid cut-cell technique.

loops over fluid and boundary cells. Reindexing is performed after the preprocessing and has been shown to greatly improve the performance of the code. Figure 2.86 shows an example of a chemical looping reactor simulation with a fairly complex geometry. The rendered image shows the void fraction in the unit, where the light gray corresponds to a packed solid phase and the dark gray corresponds to a dilute region. The geometry was created in a CAD software and imported into MFIX at run time. The geometry was defined using an STL file and consists of about 175,000 triangular facets. The total number of cells is about 2.7 million, but due to the large number of blocked cells, only 0.3 million cells are actually active computational cells. In this case, the reindexing method provided a speedup factor of 4.5, which greatly reduces the time to solution. An example of an ongoing industrial application of MFIX-TFM at NETL is shown in Figure 2.87. The entire geometry is defined by quadric surfaces, and the mesh consists of 4 million cells after reindexing.

2.7.5 Accessing and Using MFIX

MFIX is an open-source multiphase flow solver developed and maintained at the NETL. Over the years, many additional researchers from national laboratories or universities have contributed to the code. MFIX can be downloaded for free from the MFIX website (https://mfix.netl.doe.gov/), and a one-time (free) registration is required prior to downloading the source code. Typically, one or two new releases occur per year, and bug fixes are provided on a regular basis.

MFIX is primarily designed to run on Linux operating system; therefore, users should be familiar with basic Linux operating system commands and procedures before attempting to install and use MFIX. A Windows operating system executable file is also available for download, which can run basic models. Advanced models requiring user-defined functions (such as chemical reaction rate specifications) are not available from the Windows executable file. Users that do not have access to a Linux machine can install the Linux emulator Cygwin (https://cygwin.com/) on their machine to have the capability to customize the code. Other options to run MFIX on Windows include MINGW (http://mingw.org/). The code may also be compiled with a Windows Fortran compiler, but the MFIX development team does not support this format.

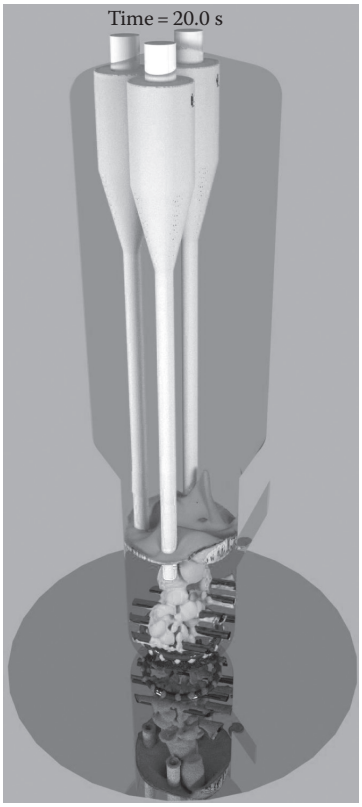

Figure 2.87

Example of an ongoing industrial application of MFIX-TFM at the National Energy Technology Laboratory. The Integrated Waste Treatment Facility Unit, developed to process sodium-bearing waste (acidic radioactive waste resulting primarily from radioactive decontamination of equipment and other components) stored at the Idaho Nuclear Technology and Engineering Treatment Center, will convert the waste into a granular product that can be further processed for disposal with the help of a fluidized bed conversion process similar to coal gasification/combustion. An MFIX-TFM model is providing insights into how the bed operates in the current design and is helping to optimize the bed operation. This figure shows void fraction isosurfaces in the unit, illustrating the bubble pattern in the bed, above the sparge ring and rail distributors.

MFIX is distributed as a single tarball that contains the source code, documentation, and a suite of tutorials. A Fortran 90 compiler is required to compile the code. Typical compilers include GNU (gfortran), Portland Group (pgf90), and Intel (ifort) compilers. For parallel execution in distributed memory parallel (DMP) mode, an MPI library must also be available (mpich or openmpi). Once the tarball is extracted, the code can be installed by invoking a build script. Typically, the compilation is performed in a directory called the run directory, where the input file and user-defined files are located. Invoking the makefile goes through a series of options to select the mode of execution (serial, DMP, SMP, or hybrid mode), the level of optimization (ranging from none for debugging purposes to aggressive for production runs), and the Fortran compiler. Advanced users can customize the compilation flags to use a compiler that is not listed in the makefile or take advantage of their hardware architecture by adding specific compilation flags that will optimize the code. After successful compilation, an executable file called mfix.exe is created.

As with any CFD tool, becoming fully accustomed with the operation of the software requires time, and a careful study of the various tutorials that are distributed along with the source code is recommended. For basic simulations, the entire setup is contained within a single input file, called mfix.dat. This is a text file with a list of keywords/values that can be edited to modify the simulation parameters. A complete description of the keywords is given in the user guide (also called the Readme file). Only keyword values that differ from the default value or do not have a default value need to be specified. Keywords can be entered in any order, but they are usually grouped into logical sections. Typically, new users will study a few tutorials and then select one that is similar to the simulations they want to perform. The input file from the tutorial serves as a starting point, which minimizes the effort required to define the simulation parameters.

Knowledge of Fortran programming language is not required to use MFIX. However, simulations involving chemical reactions require editing a user-defined subroutine to define the chemical reaction rates. Careful study of the tutorials is always recommended to gain experience before attempting to build and run a simulation, especially, a chemically reacting simulation. To implement new models or modify a feature of the code, good knowledge of Fortran is necessary, and time must be invested to understand the code structure and variable names. Both Doxygen (http://www.stack.nl/~dimitri/doxygen/) and STI (https://scitools.com) documentations are available for developers and interested users. These documentations provide in-depth analysis of the code. They allow users to navigate through the code and see how variables, subroutines, and functions are used. Call graphs allow users to get more quickly accustomed with the code structure and reveal where to implement their own models or improve existing ones. Finally, a mailing list system has been set up to provide a mechanism for communication among MFIX users and developers. Users can post technical questions, and members of the development team or other users provide the answers.

MFIX development activities are tracked through a Git repository. Therefore, MFIX users that actively collaborate with the MFIX development team can view the source code changes as they are being made by developers or other users through the Git interface. In addition to downloading the latest release, MFIX users can also retrieve a previous version of the code. Therefore, simulations may be conducted with an older version allowing users to exactly reproduce simulations reported in the literature or compare different versions of the code.

Results can be postprocessed after the simulation is complete, or while the simulation is running, as long as intermediate data are saved regularly. A simple postprocessing tool, called post_mfix, is distributed with MFIX, which allows the flow field to be probed at specified locations. This tool can also be used to extract time or spatial averages. Similar to the flow solver mfix.exe, post_mfix must be compiled prior to its first use. The data can also be visualized by other open-source tools, such as ParaView (www.paraview.org/) and VisIt (wci.llnl.gov/simulation/computer-codes/visit/).

2.7.6 MFIX Applications

The scale and complexity of simulations leveraging the MFIX suite continue to grow as the modeling capabilities are expanded and refined. Although primarily intended to aid in the design and troubleshooting of reacting, multiphase systems, especially with respect to fossil energy technologies such as gasifiers, MFIX has been used in a variety of applications. This section reviews a sample of the interesting MFIX research activities and applications reported in the literature.

2.7.6.1 Kinetic Theory of Gas–Solid Flows

As an open-source project, MFIX is regularly used to test new gas–solid flow theories and modeling techniques. One area of active research is the kinetic theory of gas–solid flows for which MFIX contains several theories (Garzo and Dufty, 1999, Iddir and Arastoopour, 2005, Garzo et al., 2007a,b, Garzo et al., 2012). These types of gas–solid flow theories are derived as pure mathematical models employing different assumptions such as the number of phases, granular or gas solids, and base state of the Enskog expansion (see Garzo et al., 2007b, Hrenya 2011). Verification of the theories is typically restricted to cases that yield analytical solutions for highly idealized conditions (e.g., a homogeneously cooling system). After being implemented into MFIX, these highly sophisticated theories can be evaluated with respect to more complex flow dynamics, compared against existing models, used in validation studies, or used to analyze fundamental flow dynamics (e.g., Mitrano et al., 2014).

2.7.6.2 Subgrid Cylinder Array Model

In industrial-size fluidized beds, heat exchange is often provided by arrays of immersed tubes, such as in a solid sorbent–based CO_2 capture reactor. The tube diameter is much smaller than the vessel size, and it is computationally expensive to model each individual tube. Similar to the filtered drag models discussed in Section 2.7.4.5, Sarkar et al. (2013) developed a subgrid drag model to represent the presence of a horizontal cylinder array in a fluidized bed. A series of highly resolved simulations were conducted to gather the necessary data to construct the closure models. For each simulation, a pressure drop was imposed vertically on a periodic domain with an immersed array of cylinders. The pressure drop controls the average gas and solids velocity in the domain. Figure 2.88 shows an example of a computational domain. The cylinders were represented by the Cartesian grid cut-cell technique described in Section 2.7.4.4. The simulations were conducted with various values of the tube diameters, spacing between tubes, averaged solids, volume fraction in the domain, and pressure drop. Figure 2.89 illustrates the flow structures for various solids, volume fractions.

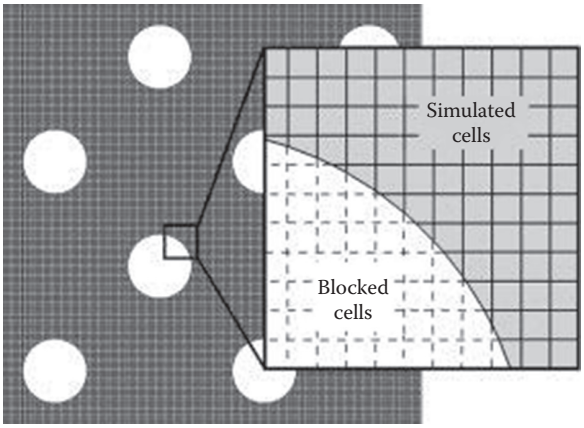

Figure 2.88

Illustration of the computational domain for high-resolution simulations. (From Sarkar, A. et al., *Chem. Eng. Sci.*, 104, 399, December 2013.)

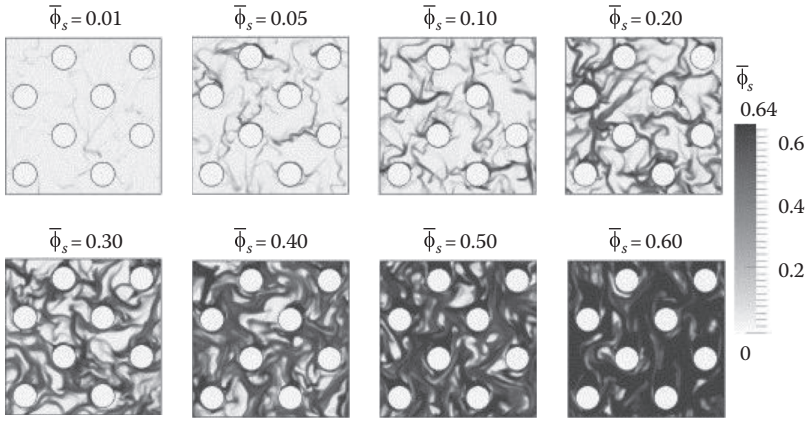

Figure 2.89

Snapshots of the solids, volume fraction distribution for averaged volume fractions ranging from 0.01 to 0.6. (From Sarkar, A. et al., *Chem. Eng. Sci.*, 104, 399, December 2013.)

For small volume fractions, the formation and dissociation of clusters are visible, whereas at larger volume fractions, bubbles develop and break around the tubes.

For coarse grid simulations that cannot resolve the flow around individual cylinders, an additional stationary solid phase is introduced, and a closure is required to model the drag force exerted on the gas–solid suspension by the cylinder array. The filtered drag force was obtained by curve fitting the data obtained from hundreds of simulations and was expressed as a function of averaged volume fractions, velocities, and geometric parameters (cylinder diameter and spacing). The formulation clearly shows a kinetic component and a buoyancy component. Another series of simulations where the pressure drop was imposed horizontally, that is, perpendicular to gravity, showed that the horizontal drag coefficient is smaller than the vertical drag coefficient. The presence of cylinders also modifies the structure of the gas–solid suspension for solids, volume fractions larger than 0.30. For dense suspensions, the cylinders promote the formation of bubbles, and the Igci drag coefficient must be further reduced. Details about the proposed subgrid drag models can be found in Sarkar et al. (2013), and verification of the subgrid models is described in Sarkar et al. (2014).

2.7.6.3 High-Fidelity Gasifier Simulations

First of their kind, high-fidelity gasifier simulations were carried out with MFIX-TFM to demonstrate the use of multiphase CFD as a tool for studying system scalability, performance optimization, and troubleshooting analysis (Gel et al., 2010). As part of this effort, two commercial-scale configurations were simulated with nearly 10 million computational cells each. The nonproprietary, commercial-scale, reactor was 50 m tall with a

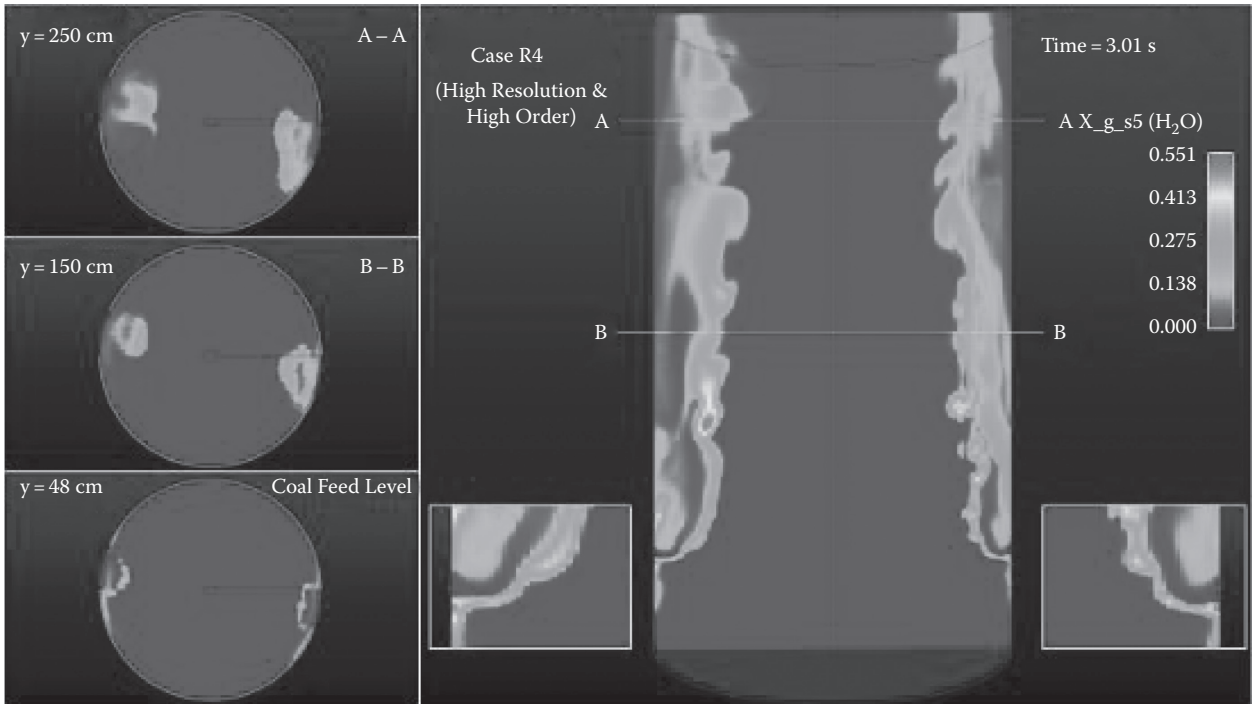

Figure 2.90

Instantaneous gas-phase steam mass fraction predicted in a simulation used for studying jet penetration in a gasifier. (From Li, T. et al., *Ind. Eng. Chem. Res.*, 49, 10767, 2010b.)

1.6 m in diameter, which was represented with a grid at 1 mm resolution in regions of interest. A reduced scale system utilizing 2.4 million computational cells and a high-order discretization scheme was used to investigate coal jet penetration (Li et al., 2010b). Time-averaged data from the full-scale simulations were used to impose the flow boundary conditions for the reduced case. A snapshot of the gas-phase steam mass fraction is shown with a volume rendering in Figure 2.90 for three vertical locations (left) and the centerline (right).

MFIX simulation results of the pilot-scale gasifier at the Power Systems Development Facility in Wilsonville, Alabama, provided insight into the systems operation (Syamlal et al., 2011). Simulations showed that oxygen penetrated into the upper region of the mixing zone, whereas the design called for oxygen to be consumed in the lower mixing zone region. This prediction was later confirmed by measuring the oxygen concentration in the gasifier. Additionally, simulations showed higher concentrations of carbon monoxide in the disengager, which again was later confirmed.

Modifications to the pilot-scale gasifier were simulated in 2 weeks at a cost of around $10 thousand, while the physical changes took 14 weeks and cost approximately $6 million. The simulation predicted a substantial increase in the carbon monoxide concentration in the syngas. Measurements taken on the modified geometry later confirmed these results. Furthermore, it was possible to determine from the simulation results that the increase in the carbon monoxide concentration was caused by the larger concentration of solids along the walls of the modified reactor. Finally, the validated model was employed in the design of a commercial-scale gasifier with a scale-up factor of 50. Simulation results provided guidance in design selection as they indicated that various configurations may lead to hotspots that could impact the gasifier's performance and operability.

2.7.6.4 Wood Gasification

Wood gasification is a promising renewable energy technology that needs to be better understood and optimized. Although experiments are still required to study the complex nature of gasification in fluidized bed reactors, numerical simulation tools provide useful data for quantities that cannot be easily measured in experiments. To gain confidence in those predictions, validation studies are often performed at increasing levels of complexity. For example, Gerber et al. (2010) used the MFIX-TFM to model wood gasification in a bubbling fluidized bed reactor and compared their results with experiment. In this case, they implemented a comprehensive model for wood pyrolysis, char gasification, and homogeneous gas-phase reaction. Three

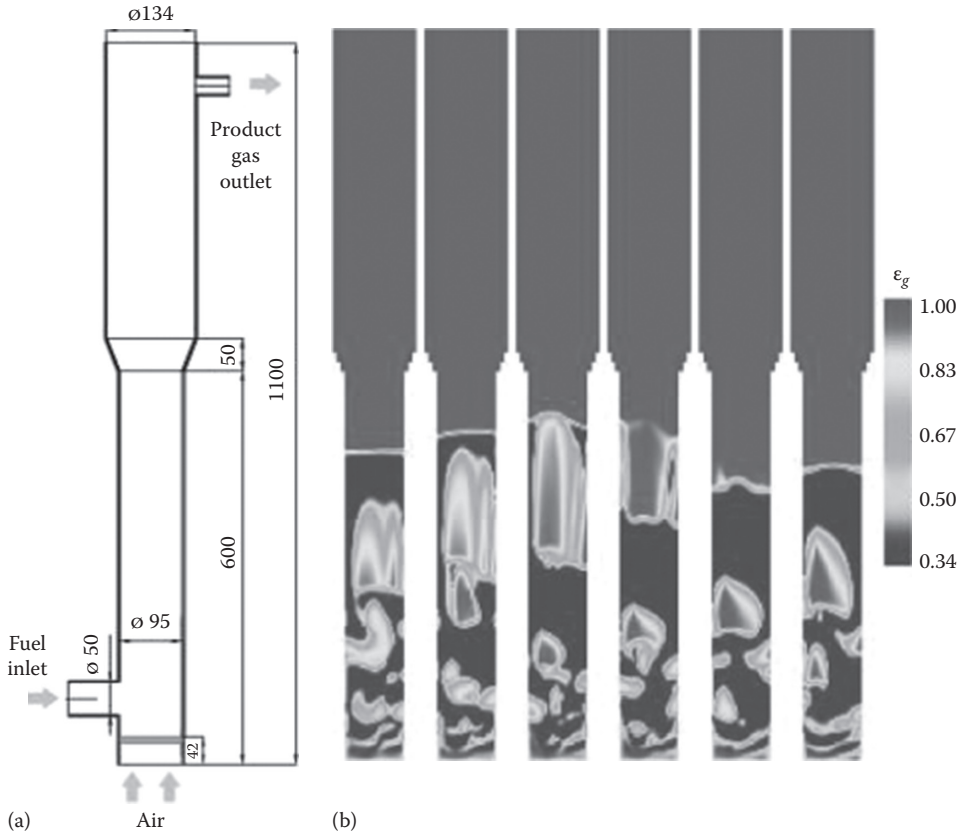

Figure 2.91

(a) Schematic of the wood gasification reactor. (b) Snapshots of the gas-phase volume fraction. (From Gerber, S. et al., *Fuel*, 89, 2903, October 2010.)

solid phases were used, one phase for wood, and two phases of different particle sizes for char. The gas phase consisted of eight species (N_2, O_2, H_2, CH_4, CO, CO_2, H_2O, and tar). A primary pyrolysis model, converting wood into wood gas (CO, CO_2, CH_4, H_2, H_2O), char, and tar was taken from Grønli (1996). For the secondary pyrolysis model, two descriptions (Boroson and Howard, 1989, Rath and Staudiger, 2001) were investigated. Figure 2.91a shows a schematic of the reactor. Wood is fed into the reactor at a rate of 2 kg/h. Preheated air fluidized the bed from the bottom. The products of gasification were analyzed at the outlet, located near the top of the reactor. Figure 2.91b illustrates the gas-phase volume fraction and shows the bubbling pattern in the bed. The steady-state concentrations of some components of the product gas are compared with the experimental data in Table 2.9. The predicted values are all within the experimental range.

2.7.6.5 Spouted-Bed Nuclear Fuel Coater

Pannala et al. (2006, 2007) used MFIX-TFM to model the hydrodynamics of a spouted-bed nuclear fuel coater. The project objective was to model a coating device used for making the tristructural isotropic (TRISO) fuel particle, which is at the heart of the advanced gas reactor concept of U.S. DOE Nuclear Energy (DOE-NE)

Table 2.9 Steady-State Values of Gas Species Concentrations at the Outlet

		Experiments	
Gas Species	MFIX Results	Min	Max
CO	0.139	0.13	0.21
CO_2	0.158	0.13	0.17
H_2	0.076	0.07	0.11
CH_4	0.036	0.02	0.06

(Kinsey, 2014). The TRISO particles consist of a UO_2 kernel coated with buffer carbon (to accommodate fission gases), pyrolytic carbon (to prevent chlorine and other species from attacking SiC), silicon carbide (pressure capsule), and pyrolytic carbon (protect SiC from cracking during fuel assembly). The particles are fabricated in a high-temperature (1300°C–1500°C) spouted-bed reactor operated in a batch mode, cycling them through deposition and annealing zones that affect complex chemical changes in the particles. The particles can be fabricated with very low rates of defect to contain fission products with a high degree of safety. The scaled-up design must maintain optimal temperatures, gas compositions, and residence times in each zone in order to attain the right microstructure of the coating layers at a nanometer scale. Pannala et al. (2006) addressed this scale-up challenge by building an MFIX model and then validating it with lab-scale data. The resulting model was used to conduct simulations and identify important characteristics for evaluating the designs of a production-scale coater.

Pannala et al. (2007) describe 2D and 3D MFIX-TFM simulations of spouted beds and compare the simulation results with experimental data. A key finding of their study was that MFIX-TFM captured the experimentally observed features of the solids, circulation and spout formation. Specifically, MFIX-TFM simulations showed that solids are transported up through the spout and deposited across the bed surfaces. Meanwhile, solids move downward along the walls and accumulate at the spout inlet until sufficient gas pressure builds to push the solid packet up through the bed. This predicted pattern of solids accumulation and discharge at the inlet lead to pulsations in the gas pressure, which were also observed in experiments.

Over 20 discriminating characteristics (DCs) of importance to the coating process (e.g., particle residence time in the coating zone) were determined from the modeling study. Using DCs was necessary because all the nondimensional parameters of the full-scale coater could not be matched in the lab-scale coater. Pannala et al. (2006) evaluated four different designs with the help of the DCs. Cardioid chalice with the multiport design appeared to have the best gas–solid mixing and heat transfer rates (see Figure 2.92). The full-scale coater was built by B&W at Lynchburg, Virginia. After some initial fine tuning, the coater was used to coat nuclear fuel particles for DOE-NE's advanced gas-cooled reactor program. This is an example of reducing the design cycle time from what could be two decades to around 2 years with the help of a validated CFD model (personal communication with S. Pannala, 2009).

2.7.6.6 Pyroclastic Flows from Volcanic Eruptions

A less traditional MFIX application is in the geological and earth sciences field (Dufek and Bergantz, 2006, Dartevelle and Valentine, 2007, Ruprecht et al., 2008, Dartevelle, 2011, Molina et al., 2012). Particularly interesting simulations of the Kos Plateau Tuff volcanic eruption were conducted by Dufek and Bergantz (2007) to investigate the role of bed load and suspended solids as well as the role of topography and overwater/overland effects on the transportation of pyroclastic flows. Specialty boundary conditions were developed to account for flow overwater (leaky) and flow overland (saltation). The simulations were carried out using

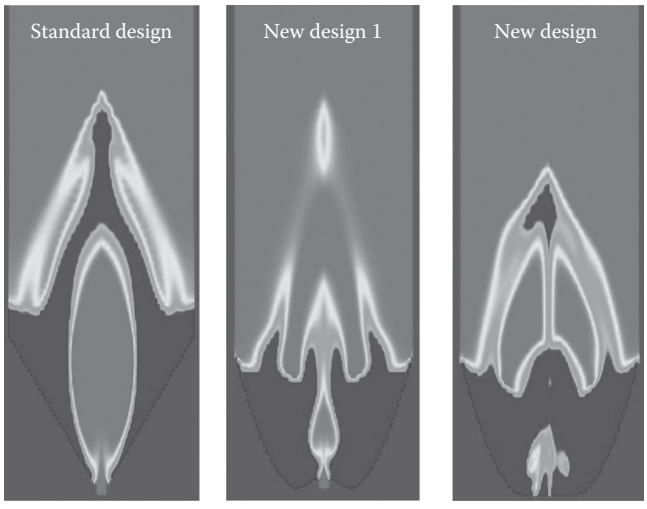

Figure 2.92

Evaluating the design of fluidized bed chemical vapor deposition coater for making nuclear fuel particles. (From Pannala, S., Personal communication, 2009.)

cylindrical coordinates with a vertical resolution of 10 m near the boundary expanding to 100 m in the far field. The horizontal resolution ranged from 20 to 100 m as needed to capture the topography of the model region. Dufek and Bergantz (2006) used simulation results to estimate the ring vent eruptive flux and thereby approximate the eruption duration needed to generate the observed depositional distribution of volcanic solids. Furthermore, simulation results suggested that there was likely a body of water south of Kos at the start of the eruption that could aid in estimating the neotectonic subsidence in the area.

Acknowledgments

This technical effort was performed in support of the NETL's ongoing research in multiphase flows in part under the RDS contract DE-AC26–04NT41817. The authors acknowledge the contributions of the developers of MFIX, the software described in this chapter. The authors thank the following colleagues for reviewing the chapter and pointing out corrections and suggestions for improvement: S. Benyahia (NETL), J. Carney (NETL), T. Li (NETL), and S. Pannala (Oak Ridge National Lab).

Nomenclature

C_{Dm}	Multiparticle drag coefficient
C_{Ds}	Single-particle drag coefficient
C_{fml}	Coefficient of friction between particles constituting the lth and mth solid phases
C_{pm}	Specific heat of the mth phase; J/kg·K
d_{pm}	Diameter of the particles constituting the mth solid phase; m
D_{mij}	Rate of strain tensor for mth phase; s^{-1}
$\mathcal{D}_{mn}$	Diffusion coefficient of nth species in the mth phase; kg/m·s
e_{ml}	Coefficient of restitution for the collisions between particles constituting the lth and mth solid phases
f_{gi}	Fluid flow resistance due to porous media; N/m^3
g_i	Acceleration due to gravity; m/s^2
g_{0ml}	Radial distribution function at contact for a mixture of hard spheres
h_{mn}	Specific enthalpy of the nth species in the mth phase; J/kg
H_m	Total rate of enthalpy change in the mth phase due to chemical reactions and phase changes; $J/m^3 \cdot s$
i,j,k	Subscripts for identifying vector and tensor components; if there are multiple subscripts, these indices appear at the end of the list of subscripts and summation convention is implied only for these indices
I_{mli}	Momentum transfer between the mth and the lth phases due to interphase forces such as drag force; N/m^3
k_g	Gas-phase turbulent kinetic energy; m^2/s^2
m,l	Subscripts for identifying phases: $m = 0$ or g is gas phase; $m = 1$ to M are solid phases
M	Total number of solid phases
M_w	Average molecular weight of gas
n	Subscript for the nth chemical species
N_m	Total number of chemical species in phase m
Nu_m	Nusselt number
p	Subscript for identifying a chemical reaction out of the P chemical reactions in total
p,v	Subscripts for identifying plastic regime (p) and viscous regime (v) stresses in the solid phase
P_g	Gas-phase pressure; Pa
P_c	Solid-phase pressure in close-packed regions; Pa
P_m	Viscous regime pressure in the mth solid phase; Pa
Pr	Prandtl number
q_{mj}	Conductive heat flux in the mth phase; $J/m^2 \cdot s$
R	Universal gas constant; $Pa \cdot m^3/kmol \cdot K$
Re_m	Particle Reynolds number of the mth solid phase
$\mathcal{R}_{lm}$	Rate of transfer of mass from lth phase to mth phase; $kg/m^3 \cdot s$
R_{mn}	Rate of formation (or destruction) of the nth chemical species in the mth phase; $kg/m^3 \cdot s$
R_{mlnp}	Rate of formation (or destruction) of the nth species in mth phase attributed to the pth reaction between the mth and lth phases; $kg/m^3 \cdot s$

S_{mij} Deviator of rate of strain tensor for mth hase; s^{-1}
t Time; s
T_m Thermodynamic temperature of the mth phase; K
T_{Rm} Background temperature in a radiation model; K
u_e Interpolated velocity; m/s
u_{ec} Velocity at the cell face center; m/s
u_E x-velocity in east-neighbor x-momentum cell; m/s
u_P x-velocity in x-momentum cell; m/s
U_{mj} jth component of the mth phase velocity; m/s
v_t Particle terminal velocity; m/s
V_{rm} Ratio of the terminal velocity of a multiparticle system to that of a single particle of the mth solid phase
x_j jth coordinate direction; m
X_{mn} Mass fraction of the nth chemical species in the mth phase

Greek Letters

α_e Ratio of wall distances $\Delta h_{ec}/\Delta h_e$
δ_{ij} Identity tensor
Δh_e Wall distance to the location of interpolated velocity; m
Δh_{ec} Wall distance to cell center; m
γ_{gm} Gas–solid heat transfer coefficient; $J/m^3 \cdot K \cdot s$
γ_{Rm} Radiative heat transfer coefficient for the mth phase; $J/m^3 \cdot K^4 \cdot s$
ε^* Void fraction (or gas volume fraction) of close-packed solids
ε_m Volume fraction of the mth phase
ϵ_g Turbulent energy dissipation rate in the gas phase; m^2/s^3
η Function of the restitution coefficient
Θ_m Granular temperature of the mth solid phase; m^2/s^2
κ_m Granular temperature conductivity of the mth solid phase; $kg/m \cdot s$
λ_g Thermal conductivity of the mth phase; $J/m \cdot K \cdot s$
μ_g Molecular viscosity of the gas phase; $kg/m \cdot s$
μ_g^t Turbulent viscosity of the gas phase; $kg/m \cdot s$
μ_m Granular viscosity of the mth solid phase in plastic or viscous regimes; $kg/m \cdot s$
ρ_m Microscopic (material) density of the mth phase; kg/m^3
ξ_{gmp} Enthalpy transfer attributed to mass transfer between the gas and the mth solid phases for the pth reaction; $J/m^3 \cdot s$
τ_{mij} Stress tensor of the mth phase; Pa
ϕ Angle of internal friction

2.8 Uncertainty Quantification

Madhava Syamlal, Jordan Musser, and Jean-François Dietiker

In the current applications of multiphase CFD, some examples of which are discussed in other chapters of this book, predictive calculations are considered deterministic, which seems to be justified by the fact that multiphase CFD is based on a set of deterministic equations. However, various sources of uncertainty can affect predictive simulations, making their results uncertain; quantifying those uncertainties is essential for establishing the degree of confidence in the predictions. If the degree of confidence is known, technology developers will be able to use predictive simulations for making better design decisions, enabling them to take larger steps while scaling up a technology. Thereby, the time and cost of bringing new technologies to

market will be reduced. Quantifying the confidence in multiphase CFD predictions is currently a major research focus at NETL, and some of the methods and recent results are reviewed in this section.

2.8.1 Verification and Validation

A series of steps are required for establishing the degree of confidence in predictive simulations. The first two steps are *verification* and *validation* (V&V): verification is "the process of determining that a model implementation accurately represents the developer's conceptual description of the model and the solution to the model" and validation is "the process of determining the degree to which a model is an accurate representation of the real world from the perspective of the intended uses of the model" (Oberkampf and Trucano, 2002). Typically, CFD code developers ensure that their code solves the model equations correctly by comparing the solution given by their code with benchmark numerical solutions (generated by other highly accurate codes), analytical solutions for simplified problems, or asymptotic solutions (the verification step). Another useful technique is *the method of manufactured solutions*. In that method an analytical solution is picked and the source terms required to generate that solution are determined and added to the governing equations. By numerically solving the modified equations, the discretization error can be determined exactly and the order of reduction of the discretization error can be evaluated. Then by comparing the observed order of accuracy with the formal order of accuracy, coding errors and algorithm inconsistencies can be identified. Choudhary et al. (2014) describe such an approach for verifying MFIX-TFM.

The user of a CFD code ensures that the equations solved by the code accurately describe the real world by comparing the simulation results with data from experiments closely related to their application (the validation step). Usually comparisons with experiments at multiple levels of complexity are necessary for complete model validation because no single lab-scale experiment is sufficient to capture all the complexities of a real-world multiphase reactor and sufficiently detailed data are often not available from the more complex pilot-scale experiments. Such a validation hierarchy is developed and used, for example, by the Carbon Capture Simulation Initiative (CCSI), which is developing multiscale and multiphysics computational tools for enabling the rapid scale-up of carbon capture technologies (Miller et al., 2014). CCSI's validation hierarchy for a solid sorbent-based carbon capture system comprises CFD simulations of experiments ranging from simple fluidized beds to complex CO_2 reactors as shown in Figure 2.93 (Ryan et al., 2012).

2.8.2 Validation Uncertainty Quantification

Traditionally, a *good* agreement between the simulation results and experimental data justifies the use of the model for predictive simulations. This approach has some inherent difficulties, however. The goodness of agreement is a subjective judgment, which could be unreliable and overly optimistic (e.g., Grace and Taghipour, 2004). More importantly, the judgment is solely based on the validation comparison error (E), which by itself may not provide a good estimate of the error in a predicted quantity. E is the mean of an uncertainty distribution, which results from the various sources of uncertainty that unavoidably are introduced in CFD simulations (see Figure 2.94). Unless the *spread* of the uncertainty distribution is known, it is not possible to know whether the error in a predicted quantity will be of the order of E because the error in the predicted quantity will be a realization of the uncertainty distribution and for a wide distribution the probability that the realization falls far away from the mean is high. A solution to this problem is offered by ASME V&V Standard (2009), which requires that the validation uncertainty u_{val}—a measure of the spread of the uncertainty distribution—also be determined to quantify "the degree of accuracy inferred from the comparison of solution and data" (ASME V&V Standard 2009, Coleman and Steele, 2009):

$$u_{val} = \sqrt{u_{num}^2 + u_{input}^2 + u_D^2} \tag{2.429}$$

where three known sources of uncertainties are considered: the numerical solution (u_{num}), the model inputs (u_{input}), and the experimental data (u_D).

If $|E| \gg u_{val}$, the errors other than the model form error (resulting from modeling assumptions and approximations) are very small, and the model form error is approximately equal to E. Then the analyst may decide either that the model form error is acceptably small for the predictive simulations or that the model needs to be improved or calibrated to reduce u_{val}. If $|E| \leq u_{val}$, the other errors are comparable or greater than the model form error, and the analyst cannot judge the acceptability of the model for predictive simulations.

In the earlier discussion we made, the tacit assumption that the model validity established at the validation domain holds good at the prediction domain. That is not necessarily true as the validation and prediction

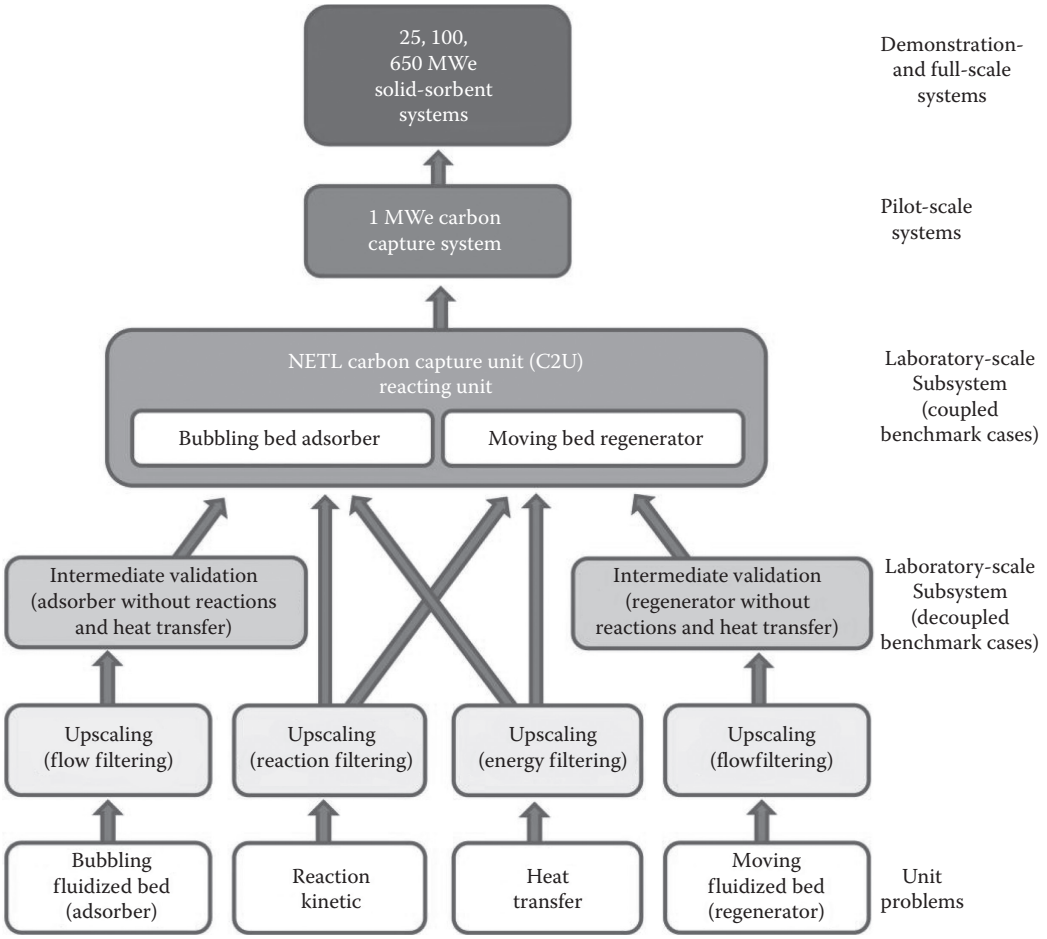

Figure 2.93

A CFD validation hierarchy, illustrating the various unit problems and the levels of validation that lead up to a quantitative confidence on predictions for full-scale devices. (Adapted from Ryan, E.M. et al., CCSI validation and uncertainty quantification hierarchy for CFDmodels, CCSI Technical Report Series, 2012, http://www.acceleratecarboncapture.org/drupal/sites/default/files/elfinder/CCSI_Directory/Deliverables/Sept_30_2012/CCSI_V-UQ%20Hierarchy_FINAL.pdf.)

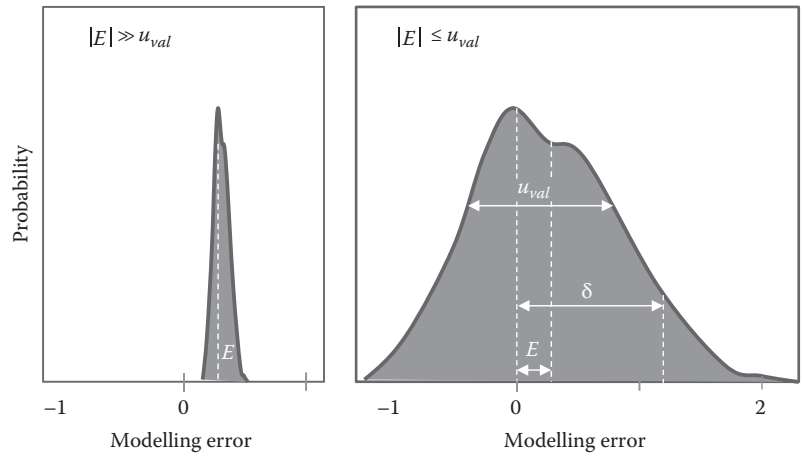

Figure 2.94

The probability distribution of modeling errors. Even when the validation comparison error (E) is small, the error in a predictive simulation (δ) could be large if the error distribution is not narrow ($|E| \leq u_{val}$).

domains can have many different relations: one contained in another, partially overlapping or not overlapping. The prediction domain in a scale-up simulation, for example, is likely not to overlap the validation domain. The first step in quantifying the uncertainty in predictive simulations is the estimation of the model form error from the validation domain as required by ASME V&V Standard (2009). In addition, the model form error must be extrapolated to the prediction domain and other uncertainties in the predictive simulation must be quantified. Such a method was proposed by Roy and Oberkampf (2011), which is discussed in the next section.

2.8.3 Predictive Uncertainty Quantification

Gel et al. (2013a) applies the method of Roy and Oberkampf (2011) to perform a validation assessment of an MFIX-TFM model of a circulating fluidized bed. They use experimental data of Shadle et al. (2011) to validate the model. Their results are discussed later to illustrate the Roy and Oberkampf (2011) method for uncertainty quantification in predictive simulations.

In an uncertainty quantification analysis, first, it is necessary to identify the quantity of interest (QoI), which is an important design parameter that the engineer needs for scaling up a device. Gel et al. (2013a) use the pressure drop (ΔP) across the circulating fluidized bed as their QoI.

Next, all the sources of input uncertainty must be identified and characterized. The input uncertainty could be *aleatory* or *epistemic*, which Roy and Oberkampf (2011) define as follows: "Aleatory uncertainty (also called irreducible uncertainty, stochastic uncertainty, or variability) is uncertainty due to inherent variation or randomness and can occur among members of a population or due to spatial or temporal variations. Aleatory uncertainty is generally characterized by either a probability density function (PDF) or a cumulative distribution function (CDF)." For example, the *inlet gas velocity*, which is an input in the circulating fluidized bed model, is an aleatory uncertainty. The inlet gas velocity can be measured, but its values vary from run to run, making the uncertainty irreducible.

"Epistemic uncertainty (also called reducible uncertainty or ignorance uncertainty) is uncertainty that arises due to a lack of knowledge on the part of the analyst, or team of analysts, conducting the modeling and simulation. Epistemic uncertainty is traditionally represented as either an interval with no associated PDF or a PDF that represents degree of belief of the analyst (as opposed to frequency of occurrence of an event in aleatory uncertainty)." For example, the *particle restitution coefficient* for the glass beads used in the circulating fluidized bed experiment is an epistemic uncertainty. It has a fixed but unknown value because the value is not reported by Shadle et al. (2011). From the physics of particle collisions we can deduce that the restitution coefficient must fall in the interval [0, 1]. The interval can be further narrowed down to [0.8, 0.9] based on the values reported in the literature. Had Shadle et al. (2011) measured the restitution coefficient precisely, the uncertainty would have been reduced or even eliminated.

A list of all the uncertain model input parameters is created by surveying the open literature and polling subject-matter experts. The experts are asked to provide a nominal (or baseline) value and a range for the upper and lower bounds for each of the input parameters. Typically, this list turns out to be long, and considering the entire list is not desirable for two reasons. One, conducting simulations by varying all the input parameters could be prohibitively expensive. Two, the results of the validation study would be less precise (contain higher variability) because the amount of validation data available is often limited. If the subject-matter experts are confident that some input parameters are not important, it is better to eliminate them from the analysis. Therefore, the list is shortened to include only the important input parameters.

The important input parameters could also be determined with the help of a (more expensive) sensitivity analysis. For example, Gel et al. (2013b) use the Sobol' sensitivity indices method to apportion the output uncertainty to the input uncertainty in certain MFIX-TFM simulations. They show that the particle–particle restitution coefficient contributed the most to the variability observed in the QoI *mean bed height*. Therefore, particle–particle restitution coefficient will be the highest ranked input parameter for an uncertainty analysis with the mean bed height as the QoI. A less expensive alternative is to use scatterplots to understand the relationships between the uncertainty in inputs and the uncertainty in the predictions as discussed by Helton et al. (2006).

For the QoI *pressure drop across the circulating fluidized bed*, Gel et al. (2013a) select the gas velocity (U_g) and the solid circulation rate (G_s) as the important input parameters, both of which are aleatory uncertainties. For demonstrating the methodology, Gel et al. (2013a) characterize U_g as a truncated normal distribution with a mean of 7.2 m/s and standard deviation of 0.04 m/s, and G_s as a truncated normal distribution with a mean of 14.0 kg/s and standard deviation of 0.34 kg/s.

The next step is the propagation of the uncertainty in input parameters. This involves running the MFIX-TFM circulating fluidized bed model for multiple realizations of gas velocity and solids circulation rate

sampled from their distributions. This is an impossible task because of the huge number of MFIX-TFM simulations that would be required, each simulation taking 2–4 weeks of computational time. Therefore, the propagation of the input uncertainty is carried out with the help of a *surrogate model*. Gel et al. (2013a) develop a surrogate model by expressing the ΔP predicted by 13 simulations as a polynomial in U_g and G_s. Of the 13, seven are preexisting simulations; six additional simulations are identified through a central composite design sampling method. The optimum form of the surrogate model is determined with the help of an *adjusted* R^2 method. Then the input uncertainty is propagated by drawing 100,000 samples from the distributions of U_g and G_s and conducting a Monte Carlo simulation.

The use of a surrogate model in place of the simulator causes an additional uncertainty, which Gel et al. (2013a) assume to be the maximum difference between MFIX-TFM results and the surrogate model predictions. However, a better estimate of this uncertainty could be obtained by conducting new MFIX-TFM simulations and determining the maximum difference between those simulation results and surrogate model predictions (i.e., cross validated error).

The next step is to determine the *model form uncertainty*, which comes exclusively from the inadequacies of the model. However, model form uncertainty can only be estimated, and the estimates tend to incorporate uncertainties in the validation data and input parameters. Roy and Oberkampf (2011) define model form uncertainty as the minimum area between the CDFs of experimental data and the simulation results. This yields the model form uncertainty at the validation domain.

The model form uncertainty at the prediction domain can be determined through an extrapolation method (Roy and Oberkampf 2011). The total uncertainty in the predictions can be then calculated by combining the model form uncertainty and the uncertainties arising from input, surrogate model, discretization, and time averaging at the prediction domain. See Roy and Oberkampf (2011) for an example of uncertainty quantification for predictive simulations.

Gel et al. (2013a) demonstrate the output of the method by simply combining the uncertainties at the validation domain. The output of the method is the cumulative probability for the QoI ΔP (Figure 2.95). The plot is called a p-box (probability box), which consists of the two S-shaped curves that merge while approaching the cumulative probability values of 0 and 1. The regions within the p-box, identified with different colors in Figure 2.95, are shown only for explaining the contributions from the various sources of uncertainty. The blue curve at the center arises from the (aleatoric) uncertainty in the input parameters U_g and G_s. The other uncertainties (surrogate, model form, discretization, and time averaging) are added to this curve as epistemic uncertainties because we know only their interval values, not their distributions. The addition of these epistemic uncertainties transforms the blue curve into the p-box, which represents all the possible families of CDFs that fit within its bounds. The greatest uncertainty arises from the spatiotemporal discretization

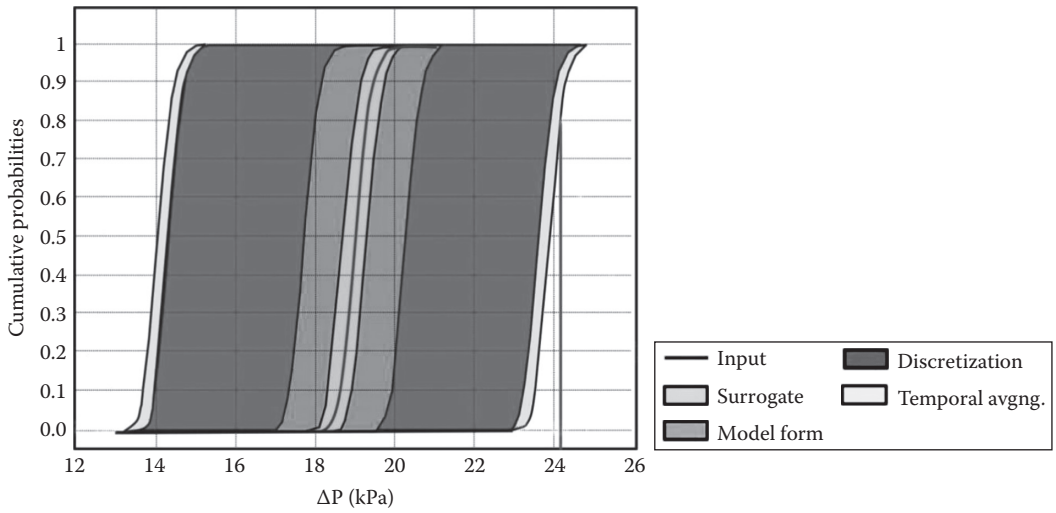

Figure 2.95

The p-box summarizes all the uncertainties considered in a predictive simulation. The box is colored to show the contributions from various sources of uncertainty in a multiphase application. (Adapted from Gel, A. et al., *Ind. Eng. Chem. Res.*, 52(33), 11424, 2013a.)

(17.9%), which Gel et al. (2013a) calculate by applying a mixed-order analysis method proposed by Roy (2003), and the next highest uncertainty is the model form uncertainty (5.2%).

It is instructive to compare the p-box resulting from the uncertainty quantification study with the traditional approach of validation and prediction. In the traditional approach, the calculated ΔP (~19 kPa) would be compared with the experimental value of 20 kPa, to establish the validity of the model. Then it will be assumed that the error in the predictive simulation will be similar to that observed in the validation simulation (~5%). Figure 2.95, which includes all sources of uncertainties, tells an entirely different story. It does not give a unique value for the predicted ΔP or a unique error bar. Rather it gives the upper and lower limits of probabilities for observing different values of ΔP. For example, for $\Delta P = 20$ kPa, the probability range is [0, 1]; that is, no meaningful information can be gained for this value from the p-box. For $\Delta P = 14$ kPa, the probability range is [0, 0.5]; that is, the probability is at most 50% that the ΔP would be less than 14 kPa. For $\Delta P = 24.2$ kPa, the probability range is [0.8, 1.0]; that is, the probability is at least 80% that the ΔP would not exceed 24.2 kPa.

What is the value in making such a nondeterministic prediction of ΔP? Suppose a design specification requires $\Delta P \leq 24.2$ kPa. Then Figure 2.95 predicts that there is [80%–100%] certainty that the specification will be met when the device is built as designed and operated; conservatively, there is 80% certainty. In contrast, the traditional approach would have placed 100% certainty that the design specification will be met. However, that degree of certainty is just an illusion, in light of all the uncertainties involved in making the prediction, especially the epistemic uncertainties arising from the numerical discretization and the model form. Now, an 80% certainty might be sufficient for certain applications, in which case the design engineer would accept the proposed design. For more critical applications, however, the design engineer may need a greater degree of certainty (say 95%) in the predicted quantities. In that case, the engineer can either revise the design or try to reduce the uncertainty in the predictive simulation. The design engineer could choose a higher pressure drop (e.g., 25 kPa) because there is greater certainty (95%) that ΔP would not exceed that value. In that case, the design will need to be revised, for example, by increasing the pressure vessel wall thickness to withstand the higher pressure expected from the predictions. Or the design engineer may try to reduce the uncertainty in the predictions by measuring the important model parameters with greater accuracy or increasing the grid resolution or using higher-fidelity constitutive equations or using a combination of these approaches. The improved predictive simulations could very well increase the certainty in meeting the specification $\Delta P \leq 24.2$ kPa, and the design engineer need not revise the design; however, there is no guarantee that the certainty will increase.

More importantly, Figure 2.95 also tells the design engineer where to put his or her resources in order to reduce the uncertainty. Finer grids and additional experiments for model calibration would be the likely candidates for reducing the uncertainty in the predictions.

2.8.4 Bayesian Calibration

In the approach described earlier, all the uncertainties identified during the validation are attributed to model form uncertainty, and the (epistemic) uncertainties in the model parameters are kept fixed or disregarded. The aforementioned approach cannot handle situations where many parameters are used to describe different physical phenomena in a complex multiphysics problem and a hierarchy of cases is needed to validate the model (e.g., Figure 2.93). The approach does not provide a way to *learn* from each addition of new information and improve the model progressively (or reduce model parameter uncertainty) as the model is hierarchically validated. This limitation can be overcome through the application of Bayes' theorem (Efron, 2013). When new information K (experimental data) becomes available, it can be used to improve our knowledge of the unknown U (model parameters) by applying Bayes' theorem:

$$P(U|K) = P(U)\frac{P(K|U)}{P(K)} \tag{2.430}$$

where

$P(U)$ is the prior distribution of U (our existing knowledge about U)

$P(K|U)$ is the probability of K given U (Little, 2013)

Kennedy and O'Hagan (2001) use this basic idea to propose a method for improving the traditional model calibration by (1) allowing for all sources of uncertainties in predictions and (2) correcting for inadequacies

in the calibrated model by introducing a *discrepancy function*. Higdon et al. (2004) further extend this approach and represent the problem as follows:

$$\boldsymbol{y}(x_i) = \boldsymbol{\eta}(x_i, \theta) + \boldsymbol{\delta}(x_i) + \boldsymbol{e}(x_i) \tag{2.431}$$

where

x_i is the input variables
$\boldsymbol{y}$ is the experimental observations
θ is the model parameters
$\boldsymbol{\delta}$ is the discrepancy between the simulator $\boldsymbol{\eta}$ and reality
$\boldsymbol{e}$ is the experimental observation error

In this approach, θ and $\boldsymbol{\delta}$ are the unknowns (U), although prior knowledge about them may exist. θ are unknown scalars, whose estimate in the Bayesian paradigm is a random variable and the prior information about θ is represented by PDFs (prior distribution). $\boldsymbol{\delta}$ are functions and the prior information is represented by a stochastic process, usually assumed to be a Gaussian process (Kennedy and O'Hagan, 2001). With the new information $\boldsymbol{y}$, the knowledge about θ and $\boldsymbol{\delta}$ is updated to generate their posterior distributions.

The simulator is treated as a *black box*, and computationally expensive simulators are replaced by an *emulator*. An emulator is not just an approximation of the simulator, but rather a statistical approximation. If the simulator (e.g., MFIX) is represented as a function that calculates an output $\mathcal{F}(x)$ for an input x, then a surrogate model (e.g., Section 7.3) is an approximation $f(x)$ that gives a unique value, say $f_0 = f(x_0)$, for each value of the input $x = x_0$. In contrast, an emulator will provide an entire probability distribution for $\mathcal{F}(x = x_0)$ at each value of x, which will be a normal distribution if the emulator is constructed as a Gaussian process (O'Hagan, 2006). At the design points where MFIX simulations were actually run, the variance of the distribution will be equal to zero; the further x_0 is away from those design points, the variance will increase.

As already discussed, four sources of uncertainty must be considered for determining the confidence bands for predicted quantities: (1) model parameters and constitutive models (e.g., friction coefficient, drag model); (2) model form (accounting for the known and unknown approximations in the mathematical model); (3) input parameters (e.g., the solids flux in a circulating fluidized bed); and (4) numerical approximations (e.g., grid resolution, time averaging).

The uncertainties from sources (1) and (2) must be determined during validation simulations. Source (1) includes model parameters that may need to be calibrated because of insufficient measurements (e.g., particle–wall friction coefficient) or the inability to measure certain parameters (e.g., specularity coefficient). From the previously known plausible values of the model parameters (prior distributions) and new experimental observations (e.g., bubble frequencies measured in a fluidized bed), the Bayesian calibration enables the analyst to generate better estimates of the model parameters (posterior distributions). In addition to calibrating scalar parameters, the best categorical parameters also could be identified through Bayesian calibration (e.g., which drag formula explains the new experimental observations the best), as demonstrated perhaps for the first time by Storlie et al. (2014). Source (2) that accounts for the inadequacies in the model is captured by the discrepancy function.

The uncertainties from sources (3) input quantities and (4) numerical approximations are determined during predictive simulations. The analyst may conduct multiple predictive simulations for values sampled from input distributions specified by the design engineer (e.g., solids flux) to quantify the uncertainty in the predicted QoIs (e.g., pressure drop) arising from the input uncertainty. Likewise, the analyst may run longer simulations to reduce and estimate the uncertainty arising from time averaging; the analyst may run simulations with finer grid resolution to reduce and estimate the uncertainty arising from spatial discretization.

This method is demonstrated by Lane et al. (2014) with the help of an MFIX-TFM model developed by Li et al. (2011). The physical system is a bubbling fluidized bed that contains 25 heat transfer tubes. The QoI are chosen as the bubble frequency and bubble-phase fraction around a tube at the center of the tube bank, for which Kim et al. (2003) have reported experimental data. These experimental data are the new information $\boldsymbol{y}$. The bubble frequency and bubble-phase fraction predicted by the MFIX-TFM model or an emulator are $\boldsymbol{\eta}$; the gas velocity and angular location on the tube are the input parameters x_i. The MFIX-TFM model parameters selected are θ (particle–particle and particle–wall restitution coefficients, particle–particle and particle–wall friction angles, packed-bed void fraction, and drag models). There are two discrepancy functions $\boldsymbol{\delta}$, one for the bubble frequency and another for the bubble-phase fraction, each of which is a function of the gas velocity and the angular location. The measurement errors in the bubble frequency and bubble-phase fraction are $\boldsymbol{e}$.

The physical ranges and the most likely values of θ are determined from a literature review and expert advice, and their prior distributions are constructed. Coefficients of restitution and packed-bed void fraction are assigned symmetric distributions: shifted and scaled β-distributions centered at their respective modes. Friction angles are assigned asymmetric distributions: shifted and scaled β-distributions that matched their respective modes. The drag models are treated as three categorical variables weighted equally with a discrete uniform distribution: Gidaspow, Syamlal-O'Brien, and Wen-Yu.

To reduce the computational cost, an emulator is developed. The emulator and discrepancy functions are modeled with Bayesian Smoothing Spline Analysis of Variance (BSS-ANOVA) models (Reich et al., 2009). The BSS-ANOVA model is a form of Gaussian process that increases the ease of handling categorical inputs and correlated outputs. Forty thousand Markov chain Monte Carlo iterations are used to calculate the posterior distributions of the emulator, discrepancy functions, and model parameters. The analysis shows that the posterior distributions of the parameters are similar to the prior distributions in all but two cases. For the parameter particle–particle friction angle, the posterior distribution changes from a wide distribution to a narrow distribution centered at 25° (Figure 2.96); for the categorical variable *drag model*, Wen-Yu is identified as the drag model that best explains the new information. The calibrated model parameters and discrepancy function and the emulator are used to make predictions for a held-out data set (i.e., the data set that was not used for model calibration). For example, Figure 2.96 shows that the experimental data fall well within the 95% confidence bands of the predicted bubble frequency.

2.8.5 Hierarchical Validation and Prediction

Lai et al. (2014a) use the method described in the previous section for the hierarchical validation of an MFIX-TFM model of a CO_2 adsorber. Unit problems with increasing levels of physical complexities are used

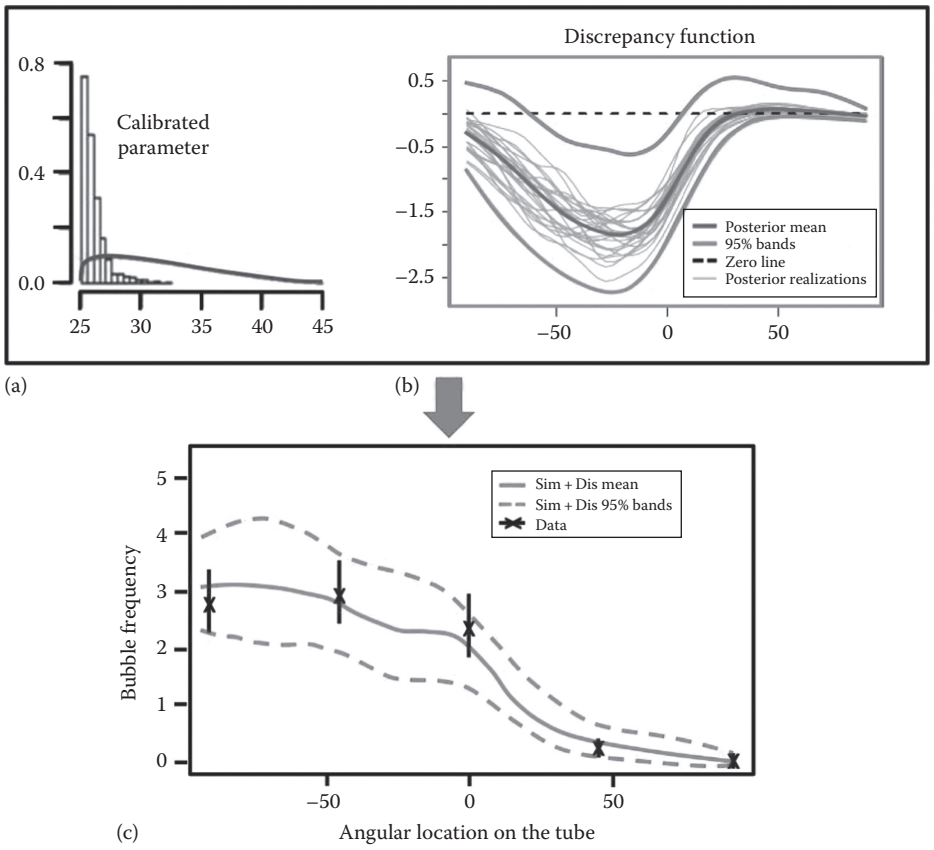

Figure 2.96

Bayesian calibration of a bubbling fluidized bed and the prediction of a held-out data set. (a) The continuous line is the prior distribution and the stacked bar graph is the posterior distribution determined from Bayesian calibration. (b) The mean (dark gray), several realizations (light gray), and the 90% bands (medium gray) of the discrepancy function. (c) Mean (continuous line) and 95% confidence bands (broken lines) given by predictive simulations compared with experimental data. (Adapted from Lane, W.A. et al., *Powder Technol.*, 253, 733, 2014.)

as the building blocks for progressive model parameter calibration (see the hierarchy in Figure 2.93). First, the model is calibrated with data from cold flow experiments where only the hydrodynamics is considered and the pressure drop is the only QoI. Next, heat transfer is considered by simulating a hot, nonreacting bed, where bed temperature (temporal and spatial) is also included as a QoI. Finally, chemical reactions are introduced to simulate the multiphase hydrodynamics coupled with heat transfer and chemical reactions in the adsorber, where CO_2 adsorption capacity and the breakthrough curve are included as QoIs. The posterior distributions from each level of the hierarchy become prior distributions for the simulations for the next higher level in the hierarchy, and the BSS-ANOVA calibration is used to process the simulation data with the corresponding experimental measurements and to determine the new posterior distributions.

The chemical kinetics model developed by Lee et al. (2011) is used to model CO_2 adsorption kinetics. Lee et al. (2011) determined prior distributions of the parameters in the chemical kinetics model with the help of data from thermogravimetric analysis experiments. Fifteen model parameters are calibrated: the sorbent particle size, sorbent capacity, sorbent decay rate, and 12 equilibrium and chemical kinetics parameters for the 3 chemical reactions involved in CO_2 adsorption. The data from NETL's carbon capture unit (C2U) are the new information used for model parameter calibration. Seventy-one experimental data sets for CO_2 breakthrough curves are available from the C2U experiments. Nine of the experimental data sets are not used for the calibration (held out) so that out-of-sample validation predictions could be made for those experimental settings without the benefit of their data influencing the calibration results. These calculations show that "the emulator prediction bands are within observation error in all cases" (Lai et al., 2014a); a typical plot is shown in Figure 2.97.

The posterior distributions of model parameters from the earlier validation study are used by Lai et al. (2014b) to predict the behavior of a conceptual, pilot-scale (1 MW) CO_2 adsorber. They use five flue-gas flow rates and 351 parameter settings sampled from the 15 posterior distributions, to conduct a total of 1755 MFIX-TFM simulations. From the results of the over 1200 successful simulations, they calculate the uncertainty distributions for the QoIs CO_2 *adsorption rate* and *bed height*. At a flue-gas flow rate of 0.72 kg/s, they predict that the conceptual adsorber will capture more than 95% of the CO_2. However, the lower, 95%-confidence bound suggests that the value could be as low as 83% capture. They predict that a flow rate below 0.65 kg/s guarantees that the lower, 95%-confidence bound exceeds the DOE target of 90% capture.

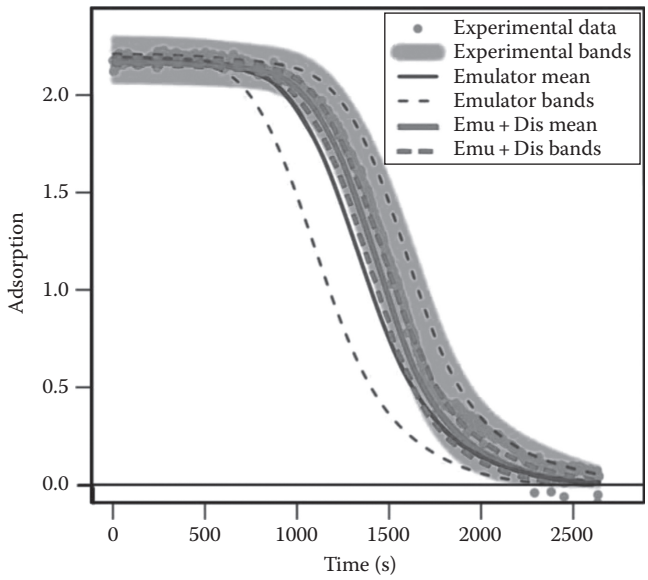

Figure 2.97

The predicted CO_2 breakthrough curves for a held-out data set. The predicted breakthrough curve (continuous red line) and 95% confidence bands (broken red line) are well within observation error (green region). The blue lines are the predictions before the discrepancy function correction is applied. (Adapted from Lai, K. et al., Hierarchical calibration and validation of high-fidelity CFD models with C2U experiments, CCSI Milestone Report, 2014a.)

2.8.6 Comments about the Calibration Process

As mentioned before, treating the computer code as a *black box* is customary in the Bayesian calibration process. Although this process has the great advantage of avoiding custom code development for uncertainty quantification, the process could disregard direct relationships between the input parameters and the output results dictated by the underlying physics. Calibrating the particle diameter with experimental data on pressure drop, for example, is physically reasonable because a direct relationship between the two can be deduced from the multiphase CFD equations. Calibrating the particle diameter with experimental data on the conversion of a gas-phase species, however, need not be physically reasonable. Whereas carbon monoxide (CO) generation from carbon combustion would be affected by the diameter of the carbon particle, CO generation from the (gas phase) water gas shift reaction would not be. The physical connection between CO conversion and particle diameter is then ambiguous, and a deficiency in the reaction kinetics model could corrupt the diameter calibration. Although the reader is cautioned about this possibility, the calibration process need not be so easily fooled: The model form discrepancy should allow for the reaction model deficiency, and the calibration process should (in principle) give the prior distribution for particle size back as the posterior.

The calibration process also must anticipate the design specifications. If, for example, the particle size distribution is one of the design specifications, a calibrated particle diameter would not be useful for conducting predictive simulations. In that case, the predictive simulation needs a method for determining the mean particle diameter from a given particle size distribution (e.g., Sauter mean diameter vs. volume–width diameter). If there is no compelling physical reason for selecting one averaging method over another, the different averaging methods could be included as categorical variables, and a suitable method could be identified through the calibration process.

The discrepancy function accounts for every uncertainty in the CFD model that caused the validation simulation results to differ from the experimental observations and that could not be corrected by calibrating the model parameters. However, the discrepancy function cannot very well compensate for the missing physics or numerical approximations. Suppose a particle-scale, reaction rate model ignores the effects of mass transfer. That deficiency could appear in the discrepancy function developed through the calibration process. The discrepancy function will not be able to account for the missing physics in predictive simulations, however. That is, the discrepancy function may not predict an increased reaction rate in response to an increased relative velocity, although the underlying physics implies an increased reaction rate, caused by an increased mass transfer rate, which, in turn, is caused by an increased relative velocity. Bhat et al. (2016) have proposed a way to correct for the missing physics by putting the discrepancy function directly into the reaction rate and equilibrium expressions. Furthermore, any unquantified uncertainty caused by a poor grid resolution in the validation simulations could appear in the discrepancy function, which may distort the uncertainty arising from the grid resolution used in the predictive simulations.

Acknowledgments

This technical effort was performed in support of the National Energy Technology Laboratory's ongoing research in multiphase flows in part under the RDS contract DE-AC26-04NT41817. The authors would like to thank the following colleagues for reviewing the manuscript and pointing out corrections and suggestions for improvement: C. Roy (Virginia Tech), C. Storlie (Los Alamos National Lab), and X. Sun (Pacific Northwest National Lab).

Gas–Liquid Flow in Ducts

Afshin J. Ghajar and Swanand M. Bhagwat

3.1 Introduction
3.2 Flow Patterns, Flow Maps, and Transition Theories
3.3 Void Fraction
3.4 Pressure Drop
3.5 Modeling of Stratified Flow
3.6 Modeling of Annular Flow
3.7 Nonboiling Two-Phase Heat Transfer

3.1 Introduction

The phenomenon of gas–liquid two-phase flow embraces several applications pertinent to oil and gas industry, process engineering, heat exchangers (evaporators and condensers), cooling of nuclear reactors, etc. Gas–liquid two-phase flows are classified as one-component and two-component two-phase flow. One-component two-phase flow consists of the two phases of a single chemical species such as steam water and refrigerant vapor–liquid flow used in nuclear and refrigeration applications, whereas two-component two-phase flow consists of the two phases of two chemically different species such as air–water and air–oil. The two-component two-phase flow is often referred to as nonboiling two-phase flow and is usually encountered in industrial applications such as artificial lift systems and simultaneous transportation of oil and natural gas from remote extraction locations to the processing units. Chemical operations requiring flow of two chemical species together for enhanced mass transfer, as in the case of ozone treatment of water, also rely on the two-component two-phase flow phenomenon. For the purpose of flow assurance and designing, sizing, and optimization of industrial processes and equipments handling two-phase flow, the determination of the void fraction, total two-phase pressure drop, and heat transfer is crucial. In particular, for nonboiling two-phase flow applications, the total two-phase pressure drop based on flow patterns, void fraction, and pipe geometry influences the design of a two-phase flow system. Knowledge of nonboiling heat transfer in two-component two-phase flows is equally important to estimate and prevent advent of wax deposition in subsea pipeline carrying hydrocarbons. The two-phase flow literature reports a plethora of correlations for the determination of flow patterns, void fraction, two-phase pressure drop, and nonboiling heat transfer correlations; however, the validity of a majority of these correlations is restricted over a narrow range of two-phase flow conditions. Consequently, it is quite a challenging task for the end user to select an appropriate correlation/model for the type of two-phase flow under consideration. Selection of a correct correlation also requires some fundamental understanding of the two-phase flow physics and the underlying principles/assumptions/limitations associated with these correlations. Thus, it is of significant interest for a design engineer to have knowledge of the flow patterns and their transitions and their influence on two-phase flow variables. To address some of these issues and facilitate selection of appropriate two-phase flow models, this chapter presents a succinct review of the flow patterns, void fraction, pressure drop, and nonboiling heat transfer phenomenon and recommend some of the well-scrutinized modeling techniques. Additionally, this chapter provides three illustrative

Table 3.1 Basic Definitions of Interest to Two-Phase Flow

Parameter	Definition	Description
x	$\frac{\dot{m}_G}{\dot{m}_G+\dot{m}_L}$	Two-phase flow quality
α_G	$\frac{A_G}{A}$ or $1-\frac{A_L}{A}$, $\frac{V_G}{V}$ or $1-\frac{V_L}{V}$	Void fraction
λ	$\frac{U_{SG}}{U_{SG}+U_{SL}}$ or $\left[1+\frac{1-x}{x}\left(\frac{\rho_G}{\rho_L}\right)\right]^{-1}$	Gas volumetric flow fraction
U_{SG}	$\frac{Gx}{\rho_G}$ or $\frac{\dot{m}_G}{A\rho_G}$	Superficial gas velocity (m/s)
U_{SL}	$\frac{G(1-x)}{\rho_L}$ or $\frac{\dot{m}_L}{A\rho_L}$	Superficial liquid velocity (m/s)
U_G	$\frac{U_{SG}}{\alpha_G}$ or $\frac{\dot{m}_G}{A_G\rho_G}$	Actual gas velocity (m/s)
U_L	$\frac{U_{SL}}{1-\alpha_G}$ or $\frac{\dot{m}_L}{A_L\rho_L}$	Actual liquid velocity (m/s)
U_M	$U_{SL}+U_{SG}$ or $U_L(1-\alpha_G)+U_G\alpha_G$	Two-phase mixture velocity (m/s)
S	$\frac{U_G}{U_L}$ or $\left(\frac{x}{1-x}\right)\left(\frac{1-\alpha_G}{\alpha_G}\right)\left(\frac{\rho_L}{\rho_G}\right)$	Slip ratio
Re_{SL}	$\frac{\rho_L U_{SL} D}{\mu_L}$ or $\frac{G(1-x)D}{\mu_L}$	Superficial liquid Reynolds number
Re_{SG}	$\frac{\rho_G U_{SG} D}{\mu_G}$ or $\frac{GxD}{\mu_G}$	Superficial gas Reynolds number

example problems focused on some iterative methods for the determination of void fraction and pressure drop and the use of Reynolds analogy–based and empirical heat transfer correlations for the calculation of nonboiling two-phase heat transfer.

3.1.1 Basic Concepts and Definitions

The gas–liquid two-phase flow is realistically a 3D flow with flow conditions and fluid properties varying with respect to the pipe cross section, length, and time. A valid assumption of 1D two-phase flow to a great extent simplifies several two-phase flow variables and modeling techniques. At the outset, this section introduces some of the primary variables used throughout this chapter and adopted by different two-phase flow models. The parameters listed in Table 3.1 are defined in context to single-phase flow of gas and liquid phase and their simple relationships that represent some two-phase flow variables. The two-phase flow quality (x) is defined using the mass flow rate of the gas ($\dot{m}_G$) and liquid ($\dot{m}_L$) phase and is similar to the thermodynamic quality based on enthalpy balance only when thermodynamic equilibrium exists between the two phases. Based on the measurement technique such as cross-sectional or volumetric method, void fraction (α_G) is defined as the ratio of pipe cross section/volume of pipe occupied by the gas to the total cross section/volume of the pipe. The gas volumetric flow fraction (λ) is essentially the homogeneous void fraction under the assumption of no slippage between the two phases. The phase superficial velocity (U_{SG} or U_{SL}) is defined assuming the phase mass flow rate/mass flux (G) through the entire pipe cross section (A). Actual phase velocity (U_G or U_L) is based on the phase mass flow rate through the pipe cross-sectional area (A_G or A_L) occupied by that phase. The two-phase mixture velocity is simply the summation of the superficial velocity of each phase. The slip ratio (S) is the ratio of actual gas-phase velocity to actual liquid-phase velocity. Finally, the phase superficial Reynolds number (Re_{SL} or Re_{SG}) is based on the phase superficial velocity, phase density (ρ_L or ρ_G), and phase dynamic viscosity (μ_L or μ_G).

3.2 Flow Patterns, Flow Maps, and Transition Theories

The physical structure of two-phase flow known as "flow pattern" is most fundamental among all two-phase flow variables and also forms the basis of two-phase flow modeling methods. Unlike single-phase flow theory, two-phase flow cannot be distinguished as laminar, transitional, or turbulent but rather is classified on the basis

of several user-defined flow patterns. In this section, a brief information about the flow patterns occurring in different pipe orientations, their mapping technique using physically measurable quantities, and mathematical models to estimate their existence is laid out.

3.2.1 Flow Patterns

The flow patterns observed in gas–liquid two-phase flow are quite intriguing in nature and depend on the alignment of one phase with respect to the other across the pipe cross section. The morphological variations in the structure of flow patterns are essentially due to the significantly different physical properties of the two phases such as viscosity and density, compressible nature of the gas phase, and the interaction between gravity, inertia, and buoyant forces. Correct understanding of the physical structure of flow patterns and their transition is instrumental in the general understanding of the mechanism of mass, momentum, and energy transfer in two-phase flow. This preliminary section of this chapter is aimed at describing the physical structure of some key flow patterns illustrated in Figure 3.1 and their physical variations as a function of varying two-phase flow conditions:

Bubbly flow: Bubbly flow often called as dispersed bubbly flow is characterized by the flow of small gas bubbles dispersed in continuous liquid medium. The size (much smaller than the pipe diameter), shape (typically spherical or oblong), and distribution (uniform, center peaked, or wall peaked) of bubble density depend upon the pipe geometry and inclination, fluid properties, and phase flow rates. For nonvertical pipe orientations, bubbly flow appears in the form of small bubbles oriented in the vicinity of pipe upper wall. With increase in liquid-phase flow rates, bubbles tend to get dispersed evenly across the pipe cross section to appear in the form of dispersed bubbly flow. In addition to the dispersed form, bubbly flow may also appear in the form of elongated or agglomerated bubbles during the transition from bubbly to slug or dispersed bubbly to slug/intermittent flows. This physical form of bubbly flow is often identified as bubbly–slug flow.

Slug flow: Slug flow is characterized by the alternate flow of gas and liquid slugs. The size (elongated and comparable to pipe diameter), shape (usually bullet shaped with hemispherical nose and a blunt tail), and frequency of slugs depend upon the pipe geometry, pipe orientation, and fluid properties. For horizontal and nonvertical upward pipe inclinations, gas slug is in the vicinity of the pipe upper wall while it is symmetrically distributed around the pipe axis in vertical flow orientation. The translational velocity of the gas slug along the pipe axis is a function of pipe orientation such that the upward pipe inclinations aid the slug motion, while the downward pipe inclinations oppose the slug motion. The length of the gas slugs reduces, while their frequency increases with increase in the liquid flow rate. The opposite is true for a fixed liquid flow rate and decreasing gas flow rates.

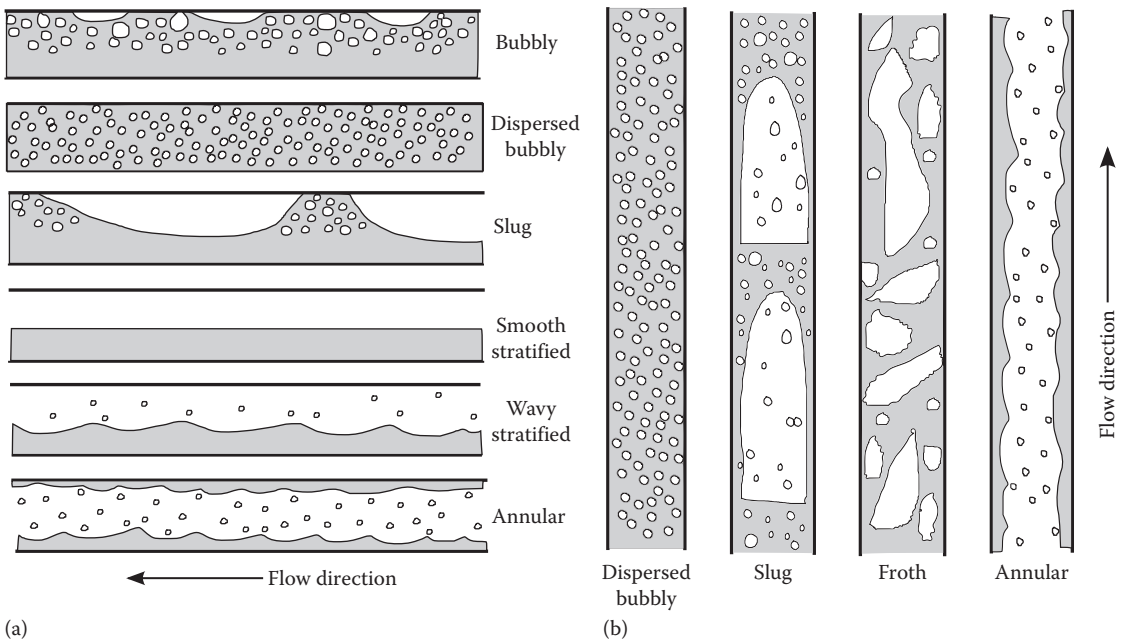

Figure 3.1

Flow patterns in (a) horizontal and (b) vertical upward gas–liquid two-phase flows.

Intermittent flow: The intermittent two-phase flow that typically exists at moderate gas and liquid flow rates is a representation of two-phase flow having chaotic, pulsating, and indefinite phase alignment characteristics. Different subcategories of key flow patterns such as slug wavy, annular wavy, churn, and froth flow exhibit disorderliness, intermittency, and indefinite flow structure, and hence, it is appropriate to club these all different subflow patterns together to call as intermittent flow. This approach of calling certain flow patterns as intermittent flow has been adopted by many researchers to reduce the ambiguity in identifying the transition boundaries between key flow patterns.

Stratified flow: Stratified flow exists in the form of gas and liquid layers flowing parallel to each other such that the pipe bottom wall is in contact with liquid phase, while the upper wall is in contact with the gas phase. Stratified flow in general can be classified as smooth stratified and wavy stratified flow. Smooth stratified flow appears at low liquid and low gas flow rates and is characterized by the complete separation of the two phases sharing a smooth and stable interface, whereas at high gas flow rates, the wavy stratified flow exists and it is characterized by the wavy, dynamic, and rough gas–liquid interface. At relatively high gas and liquid flow rates, the interfacial instability generates disturbance waves at the interface that grow and tend to touch the pipe wall giving an appearance of rolling wave. This type of stratified flow is recognized as rolling wave flow; however, the general flow structure still resembles the stratified flow pattern. A specific case of stratified flow identified as "falling film flow" is observed in vertical downward two-phase flow. The falling film flow is characterized by the downward flow of thin liquid film in contact with the pipe wall. Due to the physical resemblance of this flow pattern with the annular flow, some researchers have classified this flow pattern as a subregion of annular flow. However, there is a significant difference in these two-flow patterns in terms of the intensity of gas core turbulence, interfacial shear, thickness of liquid film, and the amount of liquid entrainment.

Annular flow: Annular flow appears in the form of a turbulent gas core surrounded by the thin/thick (depending upon liquid flow rates) and wavy liquid film. The liquid film distribution in annular flow is affected by the pipe orientation such that for horizontal flow, the asymmetric liquid film is thick at pipe bottom while it is evenly distributed around the circumference in case of vertical two-phase flow. Depending upon the gas and liquid flow rates, the gas–liquid interface may be stable or perturbed by small amplitude waves causing the liquid droplets to detach from liquid film and enter into the turbulent gas core known as the liquid entrainment phenomenon. The amplitude and frequency of interfacial disturbance waves and the amount of liquid entrainment depend on the phase flow rates, fluid properties, pipe geometry, and pipe inclination. A special form of annular flow also known as annular mist flow exists when most of the liquid phase initially flowing in the form of film is entrained into the central gas core by the shearing action of the fast-moving gas core. This type of flow pattern is mostly encountered in applications involving high system pressure and high heat flux conditions.

3.2.2 Flow Maps

The flow pattern maps or flow maps serve as a tool to estimate the span and sequence of appearance of different flow patterns with change in gas and liquid flow rates for a given set of flow conditions. The flow patterns and their transitions are defined qualitatively based on visual observations, and hence, the accurate mapping of the transition between different flow patterns is highly subjective and totally depends upon the observer's perception. Moreover, the transition between different flow patterns is gradual and sensitive to several parameters such as pipe diameter, pipe orientation, and fluid properties making it extremely difficult to have a universal flow pattern map that can correctly predict the existence of different flow patterns covering a wide range of two-phase flow conditions.

Despite the lack of the universal flow pattern map, it is important to consider some of the existing most referred flow pattern maps to get an idea about the sequence, extent, and transitions between different flow patterns. These flow pattern maps may serve as a guideline in understanding the appearance of flow patterns as a function of gas and liquid flow rates. To begin with, let us consider the flow pattern maps of Mandhane et al. (1974) and Taitel and Dukler (1976) for horizontal two-phase flow. The flow map of Mandhane et al. (1974) shown in Figure 3.2 is developed based on the two-phase flow parameters listed as follows:

$12.7 \leq D \leq 165.1$ mm	$0.0003 \leq \mu_L \leq 0.09$ Pa s
$705 \leq \rho_L \leq 1009$ kg/m^3	$10^{-5} \leq \mu_G \leq 2.2 \times 10^{-5}$ Pa s
$0.8 \leq \rho_G \leq 51$ kg/m^3	$0.024 \leq \sigma \leq 0.1$ N/m

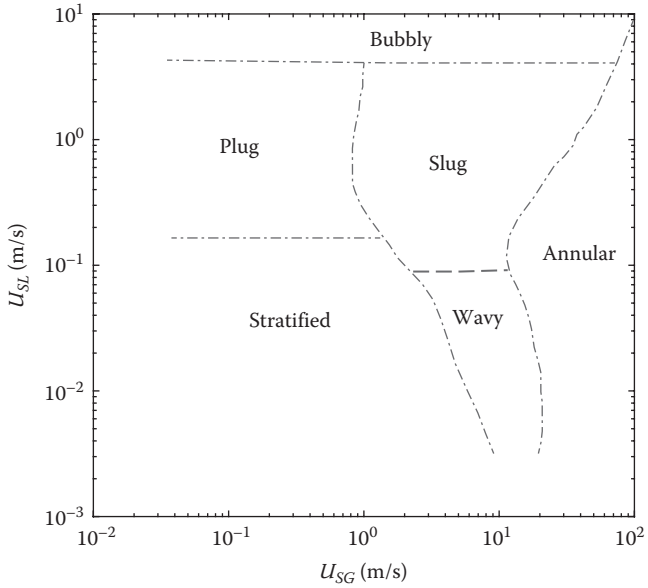

Figure 3.2

Flow pattern map for horizontal flow. (Adapted from Mandhane, J.M. et al., *Int. J. Multiphase Flow*, 1, 537, 1974.)

It is evident that the flow map of Mandhane et al. (1974) considers the existence of bubbly/dispersed bubbly flow to be insensitive to the change in liquid flow rate. Moreover, their flow pattern map shows a common transition boundary between slug and annular flow patterns. Based on the experience, it can be said that the slug flow in the vicinity of annular flow may not exhibit true slug flow characteristics and may appear in the form of agitated two-phase flow without any particular flow structure. Although the flow pattern map of Mandhane et al. (1974) is based on data consisting of a wide range of liquid-phase densities, their flow pattern map is claimed to be more accurate for air–water two-phase flow and is limited to horizontal pipe orientation.

The flow map of Taitel and Dukler (1976) shown in Figure 3.3 is based on mechanistic modeling of two-phase flow patterns and is presented in nondimensional form using the parameter X and parameters F and T of Lockhart and Martinelli (1949) shown in Equations 3.1 through 3.3. The parameter X of Lockhart and

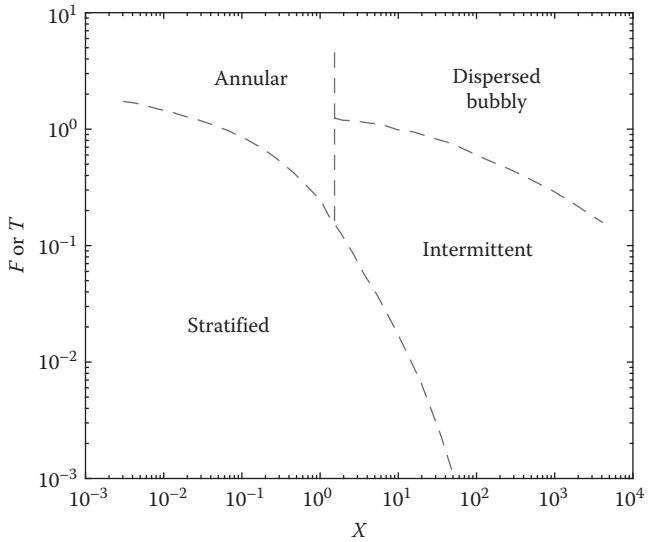

Figure 3.3

Flow pattern map for horizontal flow. (Adapted from Taitel, Y. and Dukler, A.E., *AIChE J.*, 22, 47, 1976.)

Martinelli (1949) is the square root of the ratio of the frictional pressure drop assuming single-phase flow of liquid ($(dp/dz)_L$) and gas ($(dp/dz)_G$) through the pipe, while parameter F is a modified Froude number based on superficial gas velocity (U_{SG}) and accounts for the effect of pipe orientation (θ) and phase densities (ρ_L and ρ_G). For the calculation of single-phase pressure drop, please refer to Section 3.4.7.1. The parameters $F-X$ are used to determine annular, stratified, and intermittent flows, while $T-X$ are used to determine the existence of dispersed bubbly flow. Unlike the flow map of Mandhane et al. (1974), Taitel and Dukler (1976) classify plug/slug/wavy flow patterns as intermittent flow. The flow pattern transition boundaries shown in Figure 3.3 are valid for horizontal two-phase flow. For other pipe orientations, these transition lines could be generated using the transition theories proposed by Taitel and Dukler (1976):

$$X = \sqrt{\frac{(dp/dz)_L}{(dp/dz)_G}} \tag{3.1}$$

$$F = \sqrt{\frac{\rho_G}{\rho_L - \rho_G}} \frac{U_{SG}}{\sqrt{gD}\cos\theta} \tag{3.2}$$

$$T = \sqrt{\frac{(dp/dz)_L}{(\rho_L - \rho_G)g\cos\theta}} \tag{3.3}$$

In case of vertical upward two-phase flow, the flow pattern map of Hewitt and Roberts (1969) developed for air–water two-phase flow and pipe diameters within the range of $10 \leq D \leq 30$ mm provides guidelines on the existence of different flow patterns and transition between them. The flow map of Hewitt and Roberts (1969) shown in Figure 3.4 is plotted using momentum flux of each phase. This flow map is also verified against the high-pressure steam–water data and is found to give satisfactory prediction of the flow patterns. With reference to the horizontal and vertical flow maps, the flow map (in terms of transition boundary between different flow patterns) is systematically affected by the change in upward pipe inclinations. Flow pattern maps for upward pipe inclinations shown in Figure 3.5 are based on the experimental observations and data collected at the Two-Phase Flow Lab, Oklahoma State University (OSU). It is evident from this

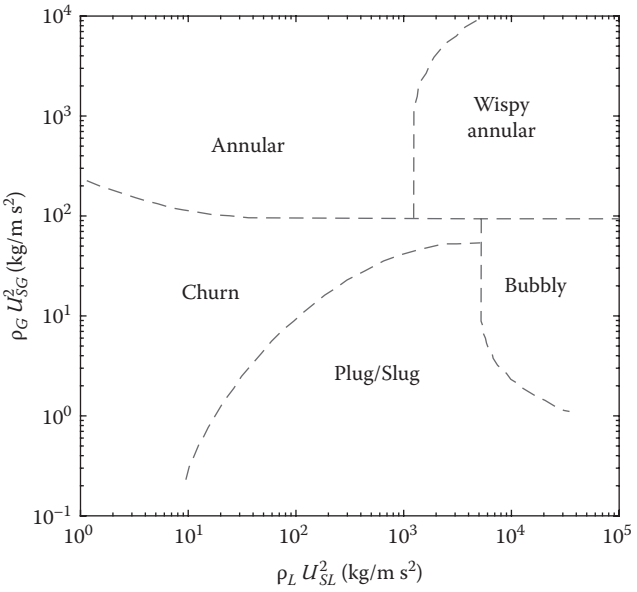

Figure 3.4

Flow pattern map for vertical upward flow. (Adapted from Hewitt, G.F. and Roberts, D.N., Studies of two phase flow patterns by simultaneous x-ray and flash photography, Technical Report AERE-M 2159, Atomic Energy Research Establishment, 1969.)

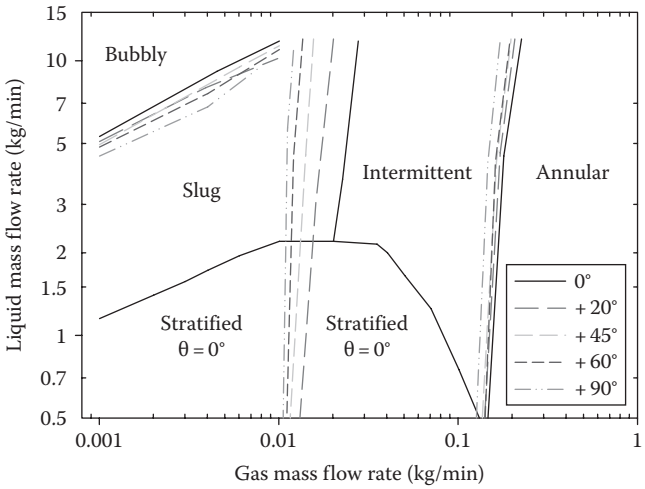

Figure 3.5

figure that increase in the pipe orientation from horizontal toward vertical upward direction causes early transition from bubbly to slug flow and shifts the slug/intermittent flow transition line toward lower gas flow rates. The transition boundary between intermittent and annular flow regimes is virtually unaffected by the change in pipe orientation. Note that stratified flow exists in horizontal pipe orientations. For all upward pipe inclinations, this region of stratified flow is replaced by slug and intermittent flow patterns. In comparison to flow map for upward pipe inclinations, the flow pattern map for gas–liquid two-phase flow in downward pipe inclinations is of particular interest due to buoyancy-dominated two-phase flow regions in these orientations. Figure 3.6 shows representative flow pattern maps for different downward pipe inclinations based on flow visualization done at the Two-Phase Flow Lab, OSU. It is found that the effect of change in downward pipe orientation is significant on the transition between stratified–slug and stratified–intermittent flow patterns. The transition from stratified to slug flow regime shifts toward higher liquid flow rates with increase in downward pipe inclinations approximately up to $\theta = -45°$ from horizontal and then again decreases toward lower liquid flow rates thereafter.

It is quite interesting that unlike other pipe inclinations, in steeper downward orientations, two-phase flow pattern that exists inside a pipe for a fixed gas and liquid flow rates may exhibit a transient behavior. This small region where flow patterns tend to change with time is indicated in Figure 3.6. It is also seen that this transient nature of two-phase flow aggravates with increase in downward pipe inclination and propagates toward slightly higher gas flow rates. The transient behavior of flow patterns exists for steeper orientations and is always found to be in the vicinity of bubbly, slug, and stratified flow patterns. The visual observation of this transient nature of flow patterns can also be confirmed by analyzing the two-phase pressure drop signal in time domain as shown in Figure 3.7. A plausible explanation for the transient behavior of flow patterns can be given by considering the two-phase flow physics in downward pipe inclinations. A pressure drop signal in this unsteady region recorded over a period of time shows significant fluctuations. A visual observation of the flow pattern in the transparent test section during the pressure drop data acquisition can confirm the transient nature of two-phase flow that exhibits combined behavior of bubbly, slug, and stratified flows. It is seen that these flow patterns repeat one after another continuously without establishing one fixed flow pattern. For the case of stratified flow with very little gas flow rate, the liquid phase accelerates downstream under the influence of gravity, while the gas phase is believed to either stay virtually stationary or move upstream under the influence of buoyancy. As the liquid phase travels downstream, it further accelerates and creates unstable gas–liquid interface. These instabilities tend to grow at the gas–liquid interface and splash liquid on the pipe upper wall and further try to bridge the entire pipe cross section to trap a gas pocket in the form of slug flow. Slug flow pattern favors dominant buoyancy forces, and consequently, a pseudostationary elongated gas pocket (gas slug) is observed in the pipe. Meanwhile, the liquid phase coming from upstream direction gets accumulated on the top of pseudostationary slug that further slips past the elongated gas bubble and eventually forces the gas bubble to move in the downstream

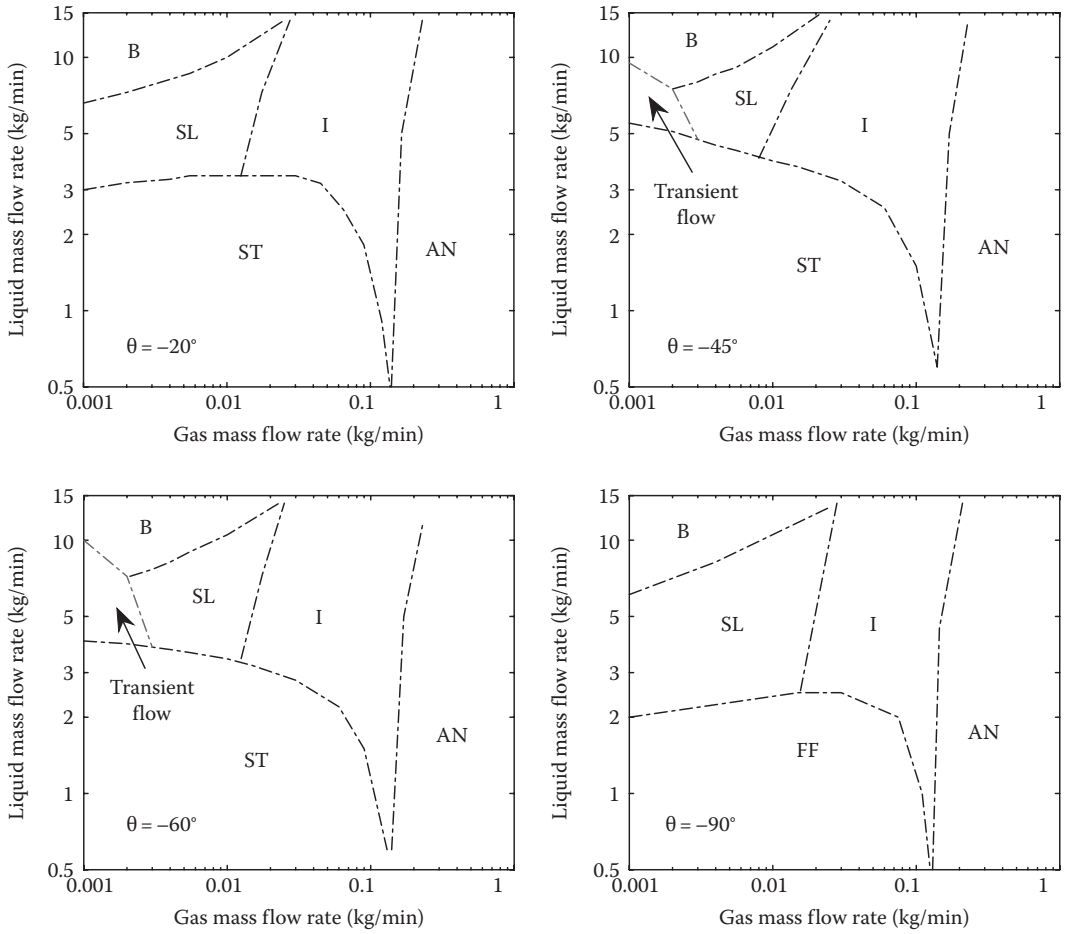

Figure 3.6

direction. During this process, the liquid phase churns the elongated gas bubbles causing it to disintegrate and move further in the form of small bubbles. After the gas pocket is pushed downstream, the incoming two-phase flow is again in the form of stratified flow pattern, and this process repeats continuously showing stratified, bubbly, and slug flow patterns periodically.

Considering the several forms of flow pattern maps reported earlier, it appears that it is difficult to have an exact agreement between the shape and trends of transition lines between specific flow patterns represented in different flow maps. This is partly because of the different coordinate systems adopted to generate flow maps and variations in the definitions of flow patterns adopted by different researchers. However, in a broad sense these flow pattern maps show agreement between the qualitative range (low, moderate, high) of gas and liquid flow rates that represent certain flow patterns. For instance, the bubbly flow appears at low gas and high liquid flow rates, intermittent and slug flow appears at moderate gas and liquid flow rates, and annular flow exists for low liquid and high gas flow rates. Another important issue that must be brought to the reader's attention is the "gradual" transition between different flow patterns. For the purpose of clarity, the transition boundaries between flow patterns are shown as thin lines; however, in reality, the transition region may be spread over a range of gas and liquid flow rates. In general, keeping in mind the uncertainty, sensitivity, and qualitative identification of flow patterns, following facts and limitations about the flow pattern maps must be perceived:

1. It is difficult to have a universal flow pattern map that can accurately predict the transition of one flow pattern to another for a wide range of two-phase flow conditions.
2. Unlike represented in most flow pattern maps, the transition from one flow pattern to another is always gradual and cannot be presented in the form of a thin continuous line.
3. Correct identification of a flow pattern in the vicinity of the transition line depends on the judgment of an individual.

3.2.3 Flow Pattern Transitions

The two-phase flow literature reports both mechanistic and empirical models to predict transition between different flow patterns. However, these transition models are developed based on the visual observations, limited data bank, and several simplifying assumptions that render uncertainty in their practical applications specifically if the two-phase flow under consideration is on the verge of transition. The following section provides some of the existing flow pattern transition models available in the two-phase flow literature. Considering the vague definition of intermittent flow pattern, the transition models listed here are only for well-defined flow regimes such as bubbly, slug, stratified, and annular flows.

3.2.3.1 Transition between Bubbly and Slug Flows

The transition from bubbly to slug flow occurs when bubbles no longer move independently and tend to coalesce to form a larger bubble usually known as the Taylor bubble. The transition from bubbly to slug flow can be achieved with the decrease in liquid flow rate at a constant gas flow rate or with increase in gas flow rate at a constant liquid flow rate. In general, the two-phase flow literature shows that this transition from bubbly to slug flow occurs for void fraction in the range of 0.25–0.3. The transition from bubbly to slug flow will occur if Equation 3.4 suggested by Taitel et al. (1980) is satisfied. This relationship is obtained by assuming that the maximum void fraction during transition from bubbly to slug flow is approximately 0.25 and that the bubble velocity is equal to the slip velocity ($U_b \cong U_G - U_L$). The bubble velocity at different pipe inclinations represented by Equation 3.5 is the modified form of Haramathy (1960) equation for bubble rise velocity suggested by Taitel et al. (1980) and Barnea (1987):

$$U_{SL} \le 3U_{SG} - 1.32\left(\frac{\sigma g(\rho_L - \rho_G)}{\rho_L^2}\right)^{0.25} \sin\theta \Bigg\} (+60^\circ \le \theta \le +90^\circ) \tag{3.4}$$

$$U_b = 1.53\left[\frac{g\sigma(\rho_L - \rho_G)}{\rho_L^2}\right]^{0.25} \sqrt{1-\alpha_G}\,\sin\theta \tag{3.5}$$

Note that Equation 3.4 is recommended for use for near vertical pipe orientations ($+60^\circ \le \theta \le +90^\circ$) since as per Taitel et al. (1980) and Barnea (1987) it is difficult for bubbly flow to exist in horizontal and near

horizontal pipe orientations. Moreover, Taitel et al. (1980) also reported that the bubbly flow would exist if the pipe diameter of two-phase flow under consideration follows

$$D > 19\left(\frac{(\rho_L - \rho_G)\sigma}{\rho_L^2 g}\right)^{0.5} \tag{3.6}$$

Following a similar concept, Mishima and Ishii (1984) presented a model to predict transition between bubbly and slug flows (valid for vertical upward flow) of the form shown in Equation 3.7. The transition from bubbly to slug flow would occur if Equation 3.7 is satisfied. The parameter C_o is expressed as $C_o = 1.2 - 0.2\sqrt{\rho_G/\rho_L}$ such that for near atmospheric operating conditions $C_o \approx 1.2$. The bubble velocity equation (Equation 3.8) used by Mishima and Ishii (1984) is similar to Equation 3.5, however with different multiplying factors and exponents:

$$U_{SL} \le \left(\frac{3.33}{C_o} - 1\right)U_{SG} - \frac{0.76}{C_o}\left(\frac{\sigma g \Delta\rho}{\rho_L^2}\right)^{0.25}\Bigg\}(\theta = +90°) \tag{3.7}$$

$$U_b = 1.41\left[\frac{g\sigma(\rho_L - \rho_G)}{\rho_L^2}\right]^{0.25}(1-\alpha_G)^{1.75} \tag{3.8}$$

For vertical upward flow, a comparison between Equations 3.4 and 3.7 shows that transition from bubbly to slug flow will occur at relatively lower U_{SL} using the criteria of Mishima and Ishii (1984). This discrepancy is essentially due to their assumption of $\alpha_G \approx 0.3$ during the transition and a slightly different form of bubble velocity (U_b) used by Mishima and Ishii (1984). As mentioned earlier, bubbly flow pattern can be further classified as bubbly–slug and dispersed bubbly flow. Thus, the bubbly flow predicted by Equations 3.4 and 3.7 may contain both bubbly–slug and dispersed bubbly two-phase flow. Unlike bubbly (elongated bubbly/slug bubbly) flow, the dispersed form of bubbly flow is known to exist in the entire range of pipe orientations, and its existence could be determined using the transition model of Barnea (1986). The model of Barnea (1986, 1987) requires calculation of three different diameters, namely, maximum bubble diameter ($d_{\max}$), critical bubble diameter above which bubble is deformed (d_{def}), and critical bubble diameter below which migration of bubbles is prevented (d_{migr}). These different bubble diameters could be determined from Equations 3.9 through 3.11, respectively. Thus, according to Barnea (1986), dispersed bubbly flow would exist if both $d_{\max} < d_{def}$ and $d_{\max} < d_{migr}$ conditions are satisfied. For these conditions typically at high liquid flow rates, dispersed bubbly flow exists since the turbulent fluctuations are capable to break down bubbles to spherical shape and also suppress the bubble coalesce that leads to slug formation.

$$d_{\max} = \left[0.725 + 4.15\left(\frac{U_{SG}}{U_M}\right)^{0.5}\right]\left(\frac{\sigma}{\rho_L}\right)^{0.6}\left(\frac{2f_M U_M^3}{D}\right)^{-0.4} \tag{3.9}$$

$$d_{def} = 2\left[\frac{0.4\sigma}{(\rho_L - \rho_G)g}\right]^{0.5} \tag{3.10}$$

$$d_{migr} = 0.375\left(\frac{f_M U_M^2 \rho_L}{g\cos\theta(\rho_L - \rho_G)}\right) \tag{3.11}$$

In Equation 3.9, f_M is friction factor based on two-phase mixture velocity U_M and can be calculated using any single-phase friction factor correlation. Considering the packing density and packing configuration of bubbles, Barnea (1986) showed that this transition model for dispersed bubbly flow is valid for void fraction in the range of $0 < \alpha_G \le 0.52$. For dispersed bubbly flow, the slippage at gas–liquid interface is quite small and it can be assumed that $\alpha_G \approx \lambda$. Thus, the transition from dispersed bubbly to slug or intermittent flow would occur at $\lambda = U_{SG}/U_M > 0.52$.

3.2.3.2 Transition between Stratified and Nonstratified Flows

The stratified flow pattern exists only in horizontal and downward pipe inclinations, and hence, the transition model for estimating the existence of stratified flow is required to be used for this limited range of pipe orientations. The most referred transition model in the two-phase flow literature to separate out stratified flow from nonstratified flow is that of Taitel and Dukler (1976). Their transition model is based on the momentum balance between the two phases, assumes a smooth and flat gas–liquid interface such that $f_i/f_G \approx 1$, and gives the transition line equation that requires the use of a graphical solution. As per the model of Taitel and Dukler (1976), stratified flow will exist if Equation 3.12 is satisfied where F is defined by Equation 3.2:

$$F^2\left[\frac{1}{(1-\tilde{h}_L)^2}\frac{\tilde{U}_G\sqrt{1-(2\tilde{h}_L-1)^2}}{\tilde{A}_G}\right]<1 \tag{3.12}$$

The nondimensional parameters $\tilde{A}_G$ and $\tilde{U}_G=(\pi/4)/\tilde{A}_G$ are the function of nondimensional liquid height ($\tilde{h}_L=h_L/D$). The nondimensional pipe cross-sectional area occupied by the gas phase is calculated using Equation 3.13. As shown in Figure 3.8, the nondimensional liquid height $\tilde{h}_L$ is obtained through the graphical solution of $\tilde{h}_L$ versus X for different values of Y. The parameters X and Y are obtained from the following equations, respectively:

$$\tilde{A}_G=0.25\left[\cos^{-1}(2\tilde{h}_L-1)-(2\tilde{h}_L-1)\sqrt{1-(2\tilde{h}_L-1)^2}\right] \tag{3.13}$$

$$Y=\frac{(\rho_L-\rho_G)g\sin\theta}{(dp/dz)_G} \tag{3.14}$$

The application of Taitel and Dukler (1976) transition model to predict stratified flow is rather tedious due to the use of a graphical solution to determine nondimensional liquid height $\tilde{h}_L$ and consequently other parameters such as $\tilde{U}_G$ and $\tilde{A}_G$. The use of a graphical solution to determine h_L/D could be circumvented by adopting an iterative solution technique. For more details, refer to Taitel and Dukler (1976).

Taitel and Dukler (1976) further attempted to classify stratified flow as smooth stratified and wavy stratified flows. They suggested that the transition between smooth and wavy stratified flow is associated with the phenomenon of wave generation at the gas–liquid interface and that the smooth stratified flow exists

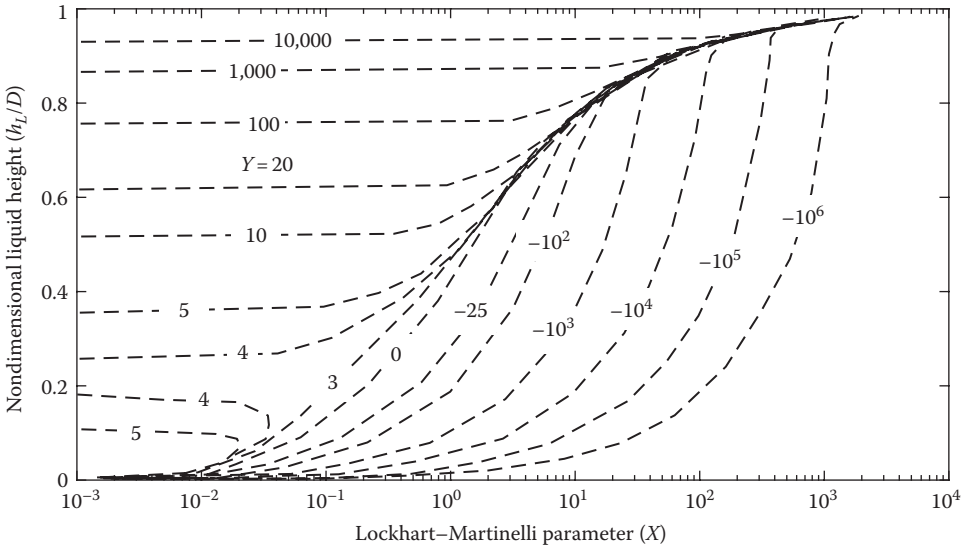

Figure 3.8

Graphical solution to determine the liquid-level height in stratified flow. (Adapted from Taitel, Y. and Dukler, A.E., *AIChE J.*, 22, 47, 1976.)

for superficial gas velocities (U_{SG}) that satisfy Equation 3.15. In practice, smooth stratified flow exists for a very narrow range of two-phase flow conditions and is of less practical significance compared to other flow patterns.

$$U_{SG,t} \geq \left(\frac{4\nu_L g \Delta\rho \cos\theta}{0.01\rho_L U_L} \right)^{0.5} \tag{3.15}$$

A simplifying approximation to the Taitel and Dukler (1976) model has been presented by Cheng et al. (1988). They approximated the trend of Equation 3.12 and presented a criterion given by Equation 3.16 to identify the existence of stratified flow pattern in horizontal pipes in terms of the parameter of Lockhart and Martinelli (1949) applicable for turbulent–turbulent gas–liquid two-phase flow where *Fr* is the modified Froude number given by Equation 3.17:

$$Fr_{SG} \leq \left(\frac{1}{0.65 + 1.11 X_{tt}^{0.6}} \right)^2 \tag{3.16}$$

$$Fr_{SG} = \frac{Gx}{\sqrt{gD\rho_G(\rho_L - \rho_G)}} = \frac{U_{SG}}{\sqrt{gD}} \sqrt{\frac{\rho_G}{\rho_L - \rho_G}} \tag{3.17}$$

Combining these equations gives the criteria for the existence of stratified flow in terms of two-phase mixture mass flux. Equation 3.18 represents the maximum value of two-phase mixture mass flux (for a given quality and fluid properties), below which stratified flow will always exist and is recommended for use only in case of horizontal two-phase flow:

$$G_{\max} = \frac{\sqrt{gD\rho_G(\rho_L - \rho_G)}}{x} \left(\frac{1}{0.65 + 1.11 X_{tt}^{0.6}} \right)^2 \Bigg\} (\theta = 0°) \tag{3.18}$$

Using the concept of growth of disturbance waves on the gas–liquid interface of stratified flow, Mishima and Ishii (1980) presented a criterion to determine the limit of stratified flow in horizontal two-phase flow. Note that the use of this correlation also requires the determination of liquid height that could be obtained using graphical solution given by Figure 3.8.

$$U_G - U_L = 0.487 \sqrt{\frac{g(D_h - h_L)(\rho_L - \rho_G)}{\rho_G}} \Bigg\} (\theta = 0°) \tag{3.19}$$

The recent work of Bhagwat and Ghajar (2015a) expressed by Equation 3.20 provides an empirical correlation to predict the existence of stratified flow in horizontal and downward pipe inclinations. Similar to the approach of Cheng et al. (1988), the correlation of Bhagwat and Ghajar (2015a) attempts to approximate the trends of Taitel and Dukler (1976) in terms of nondimensional parameters of Fr_{SG} and X and is developed based on the experimental data in horizontal and downward pipe inclinations. The Froude number in Equation 3.20 is similar to that given by Cheng et al. (1988) in Equation 3.17. The variables C_1, C_2, C_3, and C_4 required to solve Equation 3.20 are expressed by Equations 3.21 through 3.24. The nondimensional pipe diameter (D^+) is the normalized pipe diameter defined by $D^+ = D/0.0254$:

$$Fr_{SG} \leq (0.6 + C_2) \exp(-C_1 C_2 X^{C_3}) X^{-C_4} \Bigg\} \begin{array}{l} 12 < D < 150 \text{ mm} \\ 750 \leq \rho_L \leq 1420 \text{ kg/m}^3 \\ 1.2 \leq \rho_G \leq 35 \text{ kg/m}^3 \\ 0° \geq \theta > -90° \\ 0.0002 \leq \mu_L \leq 0.08 \text{ Pa s} \end{array} \tag{3.20}$$

$$C_1 = 1.3\ln(D^+) + 2.5 \tag{3.21}$$

$$C_2 = \frac{C_4^{0.65}}{\left[1 + 2\sin(2|\theta|) \times (1 + 10\tanh(1/|\theta|))\right]} \tag{3.22}$$

$$C_3 = \begin{cases} 0.65(D^+)^{-0.15}((\rho_L - \rho_G)/1000) & : \rho_L < 1000\ \text{kg/m}^3 \\ 0.65(D^+)^{-0.15} & : \rho_L \geq 1000\ \text{kg/m}^3 \end{cases} \tag{3.23}$$

$$C_4 = 0.2\sqrt{1/D^+} \tag{3.24}$$

Variables C_1 and C_2 account for the combined effect of pipe diameter and pipe orientation on the shift in transition line. The shift in transition line by including these variables is in accordance with the observations of Nguyen (1975), Barnea et al. (1982), Crawford et al. (1985), and Ghajar and Bhagwat (2014a) that the increase in downward pipe inclination shifts the transition between stratified and nonstratified flow patterns toward higher values of liquid flow rates or alternatively toward higher values of X. Variable C_3 ensures that the transition line between stratified and nonstratified flows is shifted toward higher values of X with a decrease in liquid-phase density. The variables C_1, C_2, C_3, and C_4 are adjusted such that C_1, C_2, and C_3 control the slope of transition line in the buoyancy-driven region (large values of X), while C_4 controls the slope of transition line in inertia-driven region (small values of X).

A graphical comparison between Taitel and Dukler (1976), Cheng et al. (1988), and Bhagwat and Ghajar (2015a) for horizontal two-phase flow is shown in Figure 3.9. Note that Bhagwat and Ghajar (2015a) model given by Equation 3.20 is of empirical form and merely attempts to mimic the trends of Taitel and Dukler (1976) model using $Fr_{SG} - X$ coordinates. Nevertheless, considering the practical difficulty of using a graphical/iterative solution involved in Taitel and Dukler (1976) model, Equation 3.20 may be regarded as a quick method for hand calculations and to get an estimate of the existence of stratified flow in horizontal and downward pipe inclinations.

3.2.3.3 Transition between Annular and Nonannular Flows

Typically, annular flow shares the transition boundary with intermittent (churn/annular wavy) flow patterns. Moreover, in case of horizontal and downward pipe inclinations, the annular flow also shares a transition

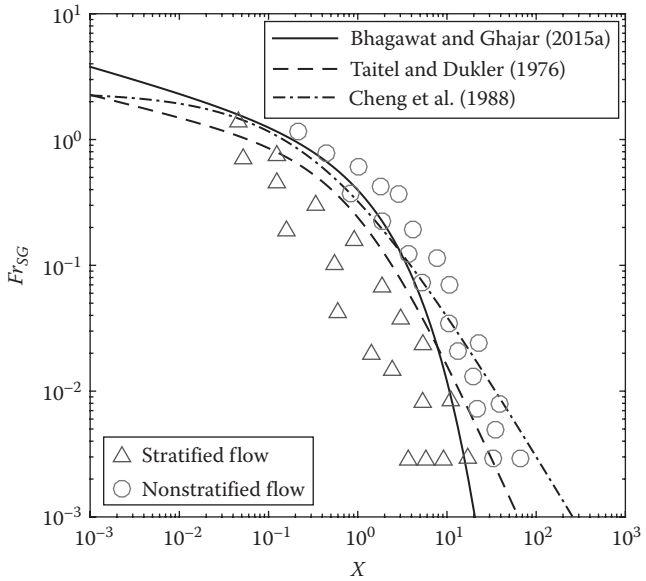

Figure 3.9

Trends of different stratified flow transition models for horizontal flow.

boundary with stratified flow pattern. In annular flow regime, the inertial forces greatly exceed the effect of gravitational forces, and hence, it is usually assumed that the change in pipe orientation will have little effect on the transition between annular and other flow regimes. However, pipe diameter and fluid properties do affect the transition to annular flow regime, and hence, it is desired to have a transition equation for annular flow regime as a function of both pipe diameter and fluid properties. One such transition criterion proposed by Weisman and Kang (1981) is expressed by Equation 3.25 and can be used for all pipe orientations. This criterion, however, at high liquid flow rates is found to incorrectly classify some region of the intermittent flow pattern as annular flow:

$$U_{SL} \geq U_{SG}\left[1.9\left(\frac{gD}{U_{SG}^2}\right)^{0.18}\left(\frac{g\Delta\rho\sigma}{U_{SG}\rho_G^2}\right)^{0.2}\right]^8 \tag{3.25}$$

Another simple yet practical approach to predict the transition to annular flow regime is based on nondimensional gas velocity (Froude number) corresponding to the point of pressure gradient minimum (concept discussed in Section 3.4.6). The two-phase flow literature for vertical upward flow reports that the pressure gradient minimum corresponds to the transition between churn/intermittent and annular flow regimes and the corresponding nondimensional gas velocity satisfies Equation 3.26. Based on the flow visualization and pressure drop measurements carried out at the Two-Phase Flow Lab, OSU, it is found that the criteria given by Equation 3.26 for transition to annular flow regime are a good approximation for the entire range of pipe orientations. The right-hand side of Equation 3.26 gives a range between which the nondimensional gas velocity can vary and for simplicity a value of 1.0 can be used. It also implies that the transition to annular flow regime would be independent of liquid velocity. Based on experience, it is recommended that in conjunction with Equation 3.26, additional simple criteria of $\alpha_G > 0.75$ can be used to confirm the existence of annular flow regime:

$$\frac{U_{SG}}{\sqrt{gD}}\sqrt{\frac{\rho_G}{(\rho_L-\rho_G)}} \geq 0.9-1.1 \tag{3.26}$$

Taitel et al. (1980) present a criterion for transition from dispersed bubbly to annular flow regimes. Their transition criteria based on force balance between the drag on liquid droplet and its weight lead to

$$\frac{U_{SG}\sqrt{\rho_G}}{(g\Delta\rho\sigma)^{0.25}} \geq 3.1 \tag{3.27}$$

A quick comparison between Equations 3.26 and 3.27 shows that the superficial gas velocity (U_{SG}) predicted by Equation 3.27 will always be higher than that predicted by Equation 3.26. This is possibly because Equation 3.26 gives transition to annular flow regime from churn/intermittent flow regimes at lower liquid flow rates, while Equation 3.27 predicts transition from dispersed bubbly flow at high liquid flow rates and hence would need higher gas flow rates for transition to annular flow regime. In addition to the transition theories, here we present in Table 3.2 a thumb rule based on the range of void fraction and qualitative range of gas and liquid flow rates associated with different flow patterns. It must be mentioned that this qualitative and quantitative range of two-phase flow variables is an approximate range based on experience and may give slight deviations compared to the real two-phase flow scenario.

Table 3.2 Thumb Rule for Qualitative Classification of Flow Patterns

	Mass/Volumetric Flow Rate		
Void Fraction (α_G)	Gas Phase	Liquid Phase	Flow Regime
Low ($\alpha_G \leq 0.25$)	Low	Moderate/High	Bubbly
Low to moderate ($0 \leq \alpha_G \leq 0.5$)	Low	High	Dispersed bubbly
Moderate ($0.25 < \alpha_G \leq 0.75$)	Low	Low/Moderate	Slug
Moderate ($0.25 < \alpha_G \leq 0.75$)	Moderate	Low/Moderate	Intermittent
Moderate to high ($0.3 < \alpha_G \leq 0.9$)	Low/Moderate	Low	Stratified
High ($0.75 < \alpha_G < 1$)	High	Low	Annular

3.3 Void Fraction

Void fraction (α_G) also referred to as liquid holdup ($\alpha_L = 1 - \alpha_G$) is defined based on its measurement technique such as local void fraction (using single-point probes), segmental void fraction (using gamma ray absorption method), cross-sectional void fraction (using capacitance probe), and volumetric void fraction (using quick closing valves). It must be noted that irrespective of the measurement technique $\alpha_G + \alpha_L = 1$. Among these different methods, typically the cross-sectional ($\alpha_G = A_G/A$) and volumetric ($\alpha_G = V_G/V$) types of void fraction measurement are most preferred and of practical importance. Under the adiabatic two-phase flow condition over a short pipe length, it can be assumed that the two-phase flow structure remains unaltered throughout the pipe length and cross-sectional void fraction can be equated to volumetric void fraction. The void fraction as a stand-alone physical parameter is typically of no use unless embedded in other constitutive equations to calculate parameters such as actual phase velocity, two-phase mixture density, and hence hydrostatic two-phase pressure drop and heat transfer, liquid height in stratified flow, and liquid film thickness in annular flow regime. Acknowledging the importance of void fraction in practical applications, this section first presents parametric analysis of the void fraction and then provides a quick review of the modeling techniques for the determination of the void fraction.

3.3.1 Effect of Pipe Orientation

The effect of pipe orientation on the void fraction is essentially due to the change in flow patterns and influence of buoyancy force acting on the gas phase. As shown in Figure 3.10, the effect of pipe orientation on void fraction is significant (up to 100%) for low gas and liquid flow rates. These flow rates correspond to slug/intermittent flow in upward pipe inclinations and stratified flow in downward pipe inclinations. At these flow rates, buoyancy acting on the gas phase aids the two-phase flow motion in upward pipe inclinations while resists its flow in downward pipe inclinations increasing its residence time in the pipe and hence the void fraction. For a fixed flow pattern (slug/intermittent) in upward inclined flow, it is seen that the void fraction initially decreases up to $+30° < \theta < +45°$ and then increases again with increase in the pipe orientation. This trend of change in void fraction with change in pipe orientation is due to the similar trend of the translational velocity of the gas slug (as a function of pipe orientation) that decides the residence time of the gas phase in the pipe and hence the void fraction. The effect of pipe orientation on void fraction is found to vanish for the inertia-driven region of intermittent (wavy annular) and annular two-phase flow. Moreover, the void fraction in stratified flow is apparently insensitive to the change in pipe orientation. At moderate

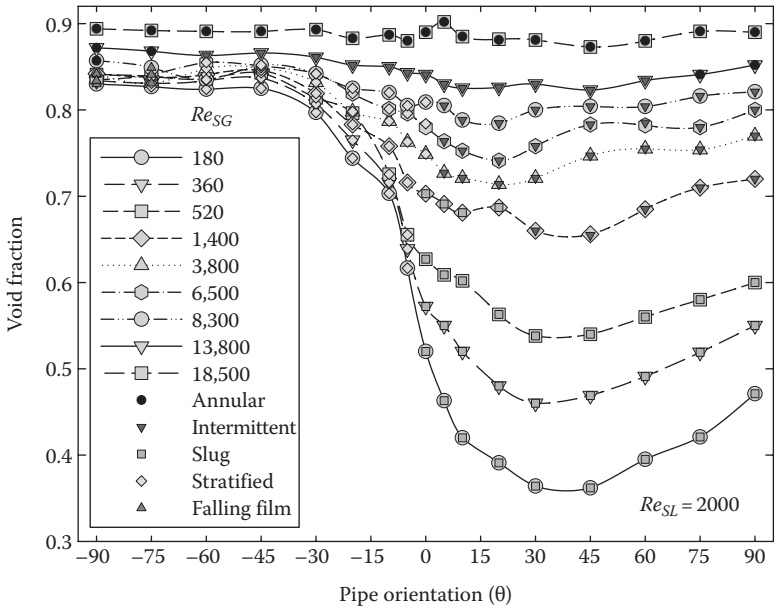

Figure 3.10

Effect of pipe orientation on void fraction at low liquid flow rates. (Data from the Two-Phase Flow Lab, OSU, Stillwater, OK.)

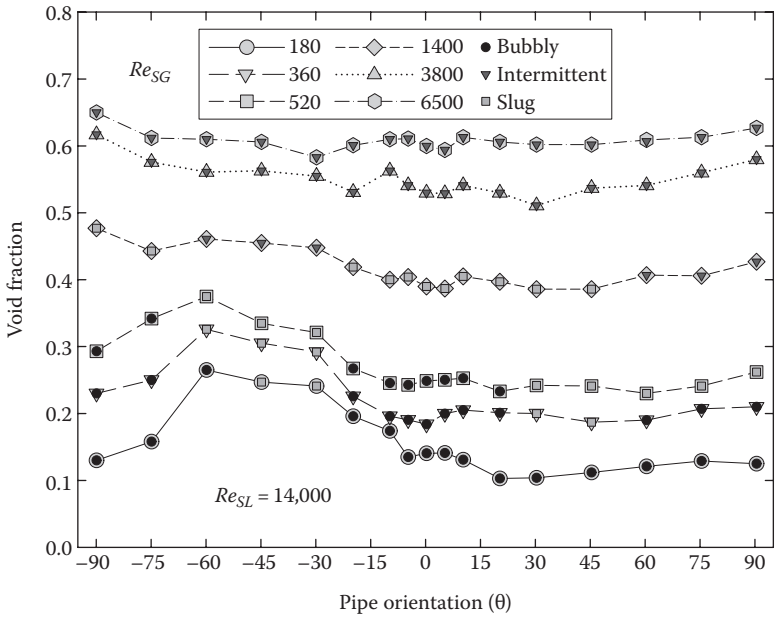

Figure 3.11

Effect of pipe orientation on void fraction at high liquid flow rates. (Data from the Two-Phase Flow Lab, OSU, Stillwater, OK.)

gas and liquid flow rates, void fraction in pipe orientations steeper than −45° drops downs due to the change in flow pattern from stratified to slug/intermittent at similar phase flow rates. As shown in Figure 3.11, at high liquid flow rates, the effect of pipe orientation on void fraction gradually fades away; however, a similar type of flip in void fraction trend as mentioned earlier occurs after −60° of pipe orientations. This change in trend of void fraction is again due to dissimilar flow patterns that may exist for similar phase flow rates but different pipe orientations. It is also clear from these trends that the void fraction in downward pipe inclinations is always greater than that in upward pipe inclinations essentially due to the resistance offered by the buoyancy force to the gas phase.

Considering the overall effect of the pipe orientation on the void fraction, three different relationships between α_G and λ can be deduced such that for buoyancy-driven flows $\alpha_G > \lambda$ and for inertia-driven flows $\alpha_G < \lambda$ hold true. The third relationship would be $\alpha_G = \lambda$ when the change in buoyancy to inertia-driven flow takes place. The relationship $\alpha_G > \lambda$ implies that for buoyancy-driven two-phase flow in downward pipe inclinations, the gas phase travels at a lower velocity than the liquid phase and hence results into higher void fraction values. Note that for all upward pipe inclinations, gas phase moves faster than the liquid phase giving a positive slippage at the gas–liquid interface and hence $\alpha_G < \lambda$ holds true. These three different cases of $\alpha_G - \lambda$ relationship that may exist in downward pipe inclinations are illustrated in Figure 3.12. In general, the flow patterns/pipe orientations that may correspond to these different cases of $\alpha_G - \lambda$ are summarized in Table 3.3.

3.3.2 Effect of Phase Flow Rates and Fluid Properties

The effect of phase flow rate on void fraction is indirectly through the change in flow pattern with change in phase flow rates. Figure 3.13 shows the effect of change in gas and liquid flow rate on void fraction. The void fraction data are plotted against a nondimensional phase velocity ratio (U_{SG}/U_{SL}) to reduce the scatter of the data. Broadly, the void fraction as a function of phase flow rates can be divided into three regions shown in Figure 3.13. In region I occupied by bubbly and slug flow patterns, for a fixed liquid flow rate, void fraction increases rapidly with a small increase in the gas flow rate, whereas in region III occupied by intermittent, stratified, and annular flow patterns, void fraction remains virtually independent of change in gas- and liquid-phase flow rates. Region II is a mixed bag of slug, intermittent, and stratified flow patterns, and its slope merges smoothly with that in regions I and III. Compared to other flow patterns, the void fraction corresponding to stratified flow shows a different behavior in region II. Void fraction in stratified flow regime remains relatively insensitive to the change in phase flow rates for

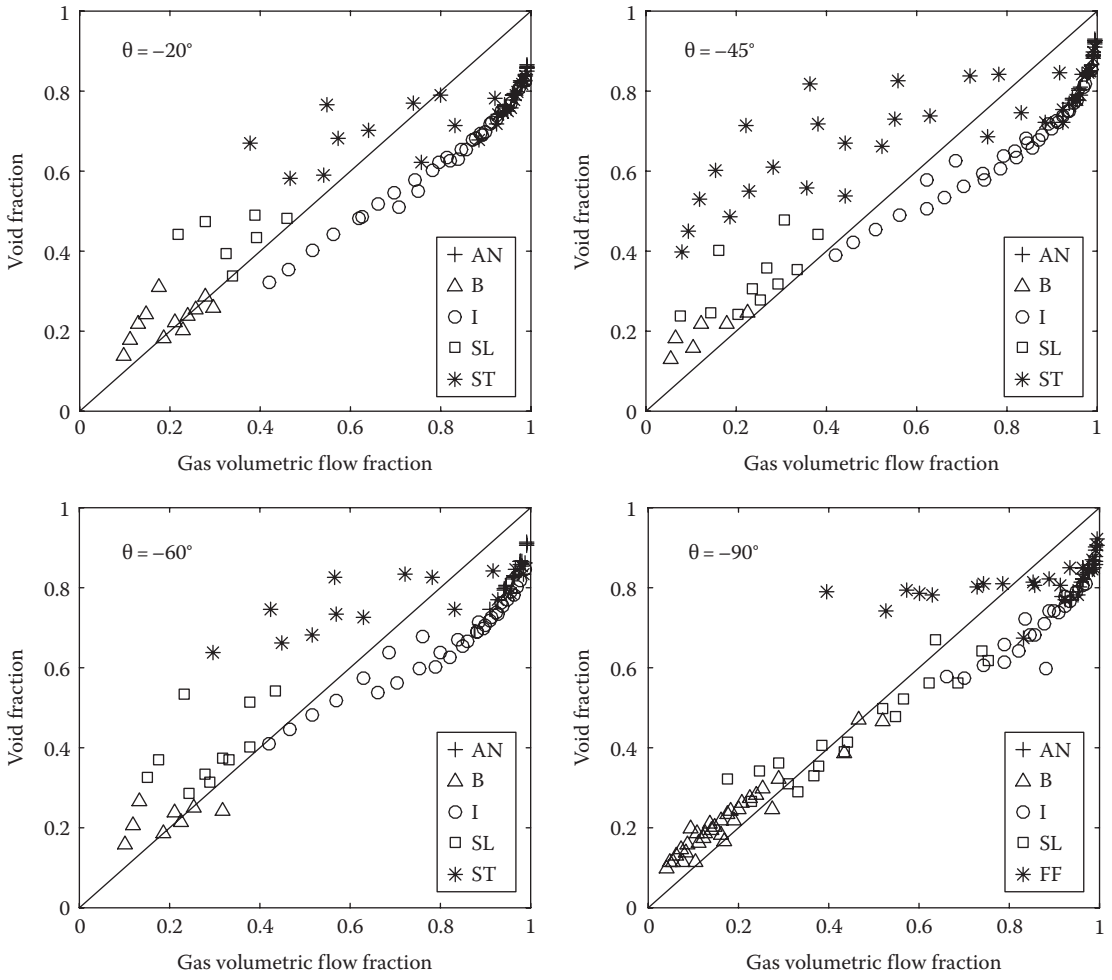

Figure 3.12

Void fraction and gas volumetric flow fraction relationship in downward pipe inclinations. (AN, annular; B, bubbly; FF, falling film; I, intermittent; SL, slug; ST, stratified.)

Table 3.3 Summary of Two-Phase Flow Situations Corresponding to $\alpha_G - \lambda$ Relationships

Condition	Flow Patterns/Pipe Orientation
$\alpha_G < \lambda$ ($U_G > U_L$, $S > 1$)	All flow patterns in upward pipe inclination
$\alpha_G = \lambda$ ($U_G \approx U_L$, $S \approx 1$)	Homogeneous flow (dispersed bubbly, annular mist)
$\alpha_G > \lambda$ ($U_G < U_L$, $S < 1$)	Stratified, slug flow $Fr_{SG} < 0.1$ and $\theta < 0°$

both regions II and III. Similar conclusions could be drawn by plotting the void fraction against two-phase flow quality, a well-adopted presentation style in high system pressure two-phase flows.

The variation of void fraction with change in two-phase flow quality is depicted in Figure 3.14 for (a) constant system pressure and varying slip ratios and (b) constant slip ratio and varying system pressure. For fixed two-phase flow conditions such as system pressure and quality, an increase in slip ratio reduces the void fraction. For these fixed conditions, the maximum void fraction is essentially the homogeneous void fraction obtained for no-slip condition ($S = 1$). In case of fixed slip ratio, an increase in system pressure decreases the specific volume occupied by the gas phase (due to increase in gas-phase density) and hence reduces the void fraction. Intuitively, it can be said that for a limiting case of critical system pressure or ($\rho_G \approx \rho_L$), void fraction varies linearly with change in two-phase flow quality ($\alpha_G = x$). Considering the definition of gas volumetric flow fraction (see Table 3.1), the relationship $\alpha_G = \lambda$ is also true for $\rho_G \approx \rho_L$. In addition to the gas-phase density, void fraction is also known to be affected by the

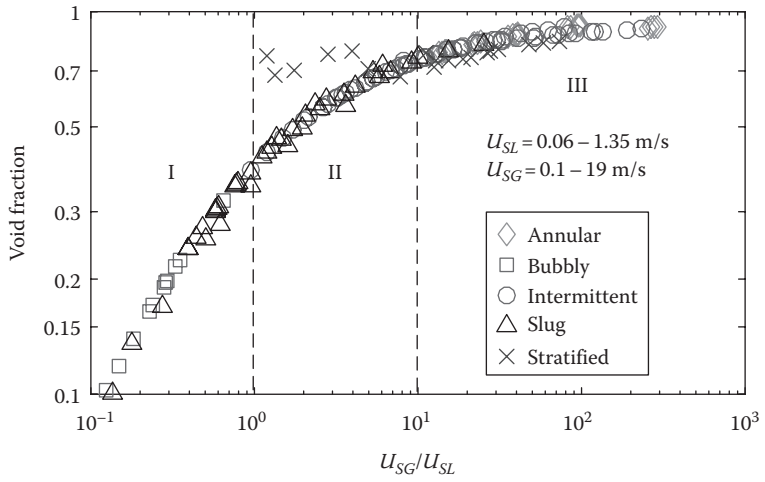

Figure 3.13

Variation of void fraction with change in gas and liquid flow rates.

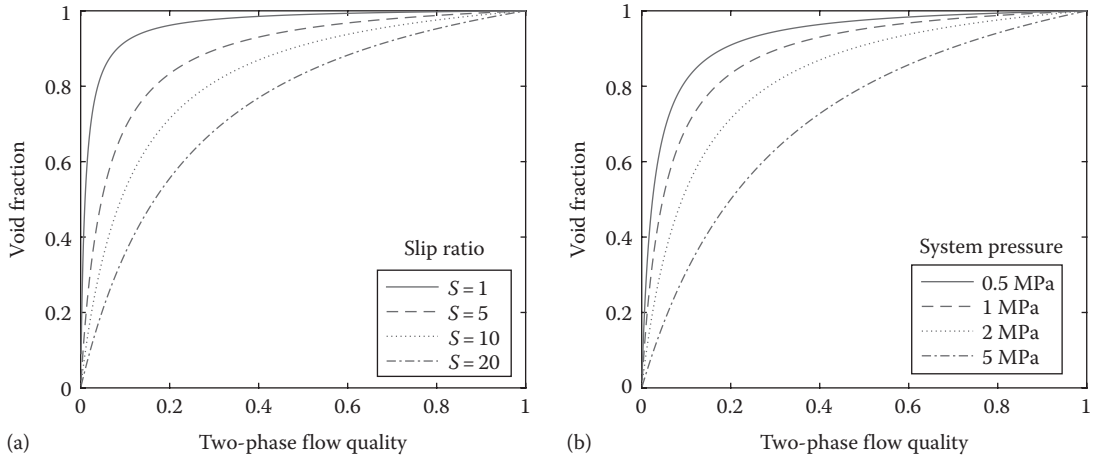

Figure 3.14

Variation of void fraction with change in two-phase flow quality. (a) System pressure = 1 MPa. (b) Slip ratio = 2.

change in liquid dynamic viscosity. Experiments of Oshinowo (1971), Mukherjee (1979), and Gokcal (2008) reveal that the void fraction is inversely proportional to the liquid dynamic viscosity. These studies report that the increase in liquid viscosity increases the viscous drag on liquid phase and reduces its velocity causing it to accumulate in the pipe and hence results in decrease in void fraction due to increase in liquid holdup.

3.3.3 Effect of Pipe Diameter

The effect of pipe diameter on void fraction is reflected in the form of pipe wall–induced drag exerted on the gas phase. In comparison to large pipes, small-diameter pipes offer more resistance to the motion of gas phase increasing its residence time and hence the local and averaged void fraction in pipes. Experimental data of Bowers and Hrnjak (2010) in Figure 3.15 show about 20%–80% increase in measured void fraction for a decrease in pipe diameter from 15 to 7 mm. The void fraction as a function of pipe diameter also depends upon phase flow rates (flow patterns/mass flux/quality) such that the effect of change in pipe diameter on void fraction is most prominent for bubbly/slug/intermittent flows, while it is fairly insensitive to the annular flow regime. Kaji and Azzopardi (2010) have reported negligible effect of change in pipe diameter (5–50 mm) on the void fraction in annular flow regime for similar gas and liquid superficial velocities. This relationship between void fraction and pipe diameter may not be applicable to microscale two-phase flow.

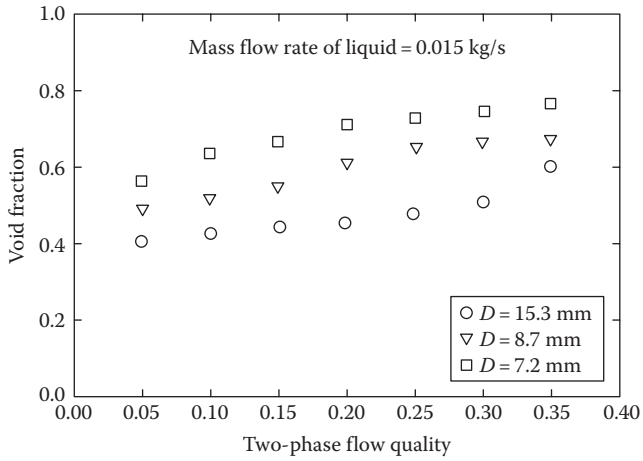

Figure 3.15

Effect of pipe diameter on void fraction. (Adapted from Bowers, C.D. and Hrnjak, P.S., Determination of void fraction in separated two phase flows using optical techniques, *International Refrigeration and Air-Conditioning Conference*, Purdue University, West Lafayette, IN, 2010, pp. 2293–2302.)

The parametric analysis of void fraction reveals that the void fraction must be modeled to consider the effect of flow patterns, pipe orientation, pipe diameters, and fluid properties. What follows is a brief review of some of the void fraction modeling methods available in the two-phase flow literature and recommendation of well-scrutinized void fraction correlations applicable for a wide range of two-phase flow conditions.

3.3.4 Modeling of Void Fraction

The two-phase flow literature reports a plethora of void fraction models/correlations; however, most of these models are confined to certain flow patterns, pipe orientation, and fluid properties. Based on the general physical form of these correlations, they can be broadly classified as those based on separated flow models (SFMs), drift flux model (DFM), $k - \lambda$ models, and empirical models. A comprehensive review of these different types of models is presented by Woldesemayat and Ghajar (2007), Godbole et al. (2011), and Ghajar and Bhagwat (2014b). Among all these models, correlations based on SFM and DFM are more versatile and flexible and are also preferred in several industrial applications. The following is a brief summary of the physical structure of SFM- and DFM-based void fraction correlations.

3.3.4.1 Separated Flow Model

The SFM considers the two phases to flow separately in the form of two streams: each phase is constant but with different velocities sharing a definite interface. The flow patterns such as stratified and annular flow behave as a separated flow and can be effectively modeled using these types of correlations. The SFM-based correlations are mostly preferred in refrigeration industry due to the stratified and annular flow pattern–dominated two-phase flow in evaporators and condensers. The general form of SFM-based void fraction correlations is presented in Equation 3.28. Some of the well-known SFM model-based void fraction correlations are listed in Table 3.4. The multiplying factor "S" is essentially the slip ratio, that is, the ratio of actual gas velocity (U_G) to actual liquid velocity (U_L) (see Table 3.1). The slip ratio (S) for homogeneous flow that assumes no slippage at

Table 3.4 Parameters Used in SFM by Different Correlations

Correlation	S	q	r	s
Homogeneous	1	1	1	0
Lockhart and Martinelli (1949)	0.28	0.64	0.36	0.07
Zivi (1964)	1	1	0.67	0
Chen (1986)	0.18	0.6	0.33	0.07
Smith (1969)	Equation 3.30	1	1	0
Xu and Fang (2014)	Equation 3.31	1	1	0

the gas–liquid interface is equal to unity ($S = U_G/U_L = 1$). Thus, for such a case, the void fraction expressed by Equation 3.28 is essentially equal to the gas volumetric flow fraction (λ) as shown in Equation 3.29:

$$\alpha_G = \left[1 + S\left(\frac{1-x}{x}\right)^q \left(\frac{\rho_G}{\rho_L}\right)^r \left(\frac{\mu_L}{\mu_G}\right)^s\right]^{-1} \tag{3.28}$$

$$\alpha_G = \left[1 + \left(\frac{1-x}{x}\right)\left(\frac{\rho_G}{\rho_L}\right)\right]^{-1} = \frac{U_{SG}}{U_{SG} + U_{SL}} = \lambda \tag{3.29}$$

$$S = 0.4 + 0.6\sqrt{\frac{\rho_L/\rho_G + 0.4(1/x - 1)}{1 + 0.4(1/x - 1)}} \quad \left.\begin{array}{l} 6 < D < 38 \text{ mm} \\ 0.1 \le p_{sys} \le 14.5 \text{ MPa} \\ 50 \le G \le 2050 \text{ kg/m}^2\text{ s} \end{array}\right\} \tag{3.30}$$

Equation 3.30 gives the expression for slip ratio used by Smith (1969). The constant of 0.4 used in Smith (1969) correlation is applicable only for circular pipes and may not guarantee accurate results for other pipe geometries. The correlation of Smith (1969) is valid for all flow patterns and the entire range of two-phase flow quality; however, it is observed that this correlation does not predict void fraction accurately in stratified flow regime. A recent work of Xu and Fang (2014) also provides an expression shown in Equation 3.31 to determine slip ratio to be used in SFM. Their model for slip ratio is mostly based on two-phase flow of refrigerants in small-size pipe ($D < 10$ mm) and is a function of mass flux, gas volumetric flow fraction, pipe diameter, and the liquid-phase density:

$$S = 1 + 2\lambda^{3.5}\left(\frac{G^2}{gD\rho_L^2}\right)^{-0.2} \quad \left.\begin{array}{l} 0.5 \le D \le 10 \text{ mm} \\ 40 \le G \le 1000 \text{ kg/m}^2\text{ s} \\ 6 \le \rho_L/\rho_G \le 250 \end{array}\right\} \tag{3.31}$$

Recently, Cioncolini and Thome (2012a) have developed a void fraction model for annular flow regime consisting of data for both circular and noncircular channels and applicable for both adiabatic and evaporating two-phase flows:

$$\alpha_G = \frac{hx^n}{1 + (h-1)x^n} \quad \left.\begin{array}{l} \text{(annular flow)} \\ 1 < D < 45.5 \text{ mm} \\ 0.1 < p_{sys} < 20 \text{ MPa} \\ 20 \le G \le 3400 \text{ kg/m}^2\text{ s} \end{array}\right\} \tag{3.32}$$

$$h = -2.129 + 3.129\left(\frac{\rho_G}{\rho_L}\right)^{-0.2186} \tag{3.33}$$

$$n = 0.3487 + 0.6513\left(\frac{\rho_G}{\rho_L}\right)^{0.515} \tag{3.34}$$

Figure 3.16 shows the discrepancy between predictions of void fraction by different SFMs typically for $\alpha_G < 0.7$. This difference between the outcomes of different correlations is probably because these correlations

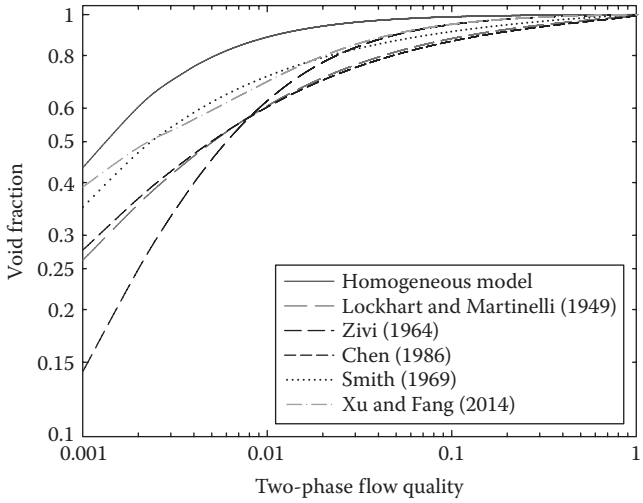

Figure 3.16

Void fraction prediction of separated flow models.

are based on the assumptions and flow physics of annular (separated) flow and are supposed to be used for higher values of void fraction. It is also evident that the homogeneous void fraction (under no-slip assumption) is the highest and sets the theoretical limit of the maximum possible void fraction in two-phase flow systems. This statement is true for all two-phase flow situations with the exception of buoyancy-driven region in downward pipe inclinations identified by $Fr_{SG} < 0.1$. Note that since these correlations based on SFM are essentially developed or valid for annular flow regime and since annular flow is relatively insensitive to the change in pipe orientation, these models can be used independent of pipe orientations provided annular flow pattern exists.

3.3.4.2 Drift Flux Model

The DFM assumes one phase dispersed in other continuous phase and requires the determination of distribution parameter (C_o) and drift velocity (U_{GM}) as variables to calculate the void fraction. The DFM is best applicable for 1D flows and is usually not recommended for flow patterns involving significant interfacial slippage such as stratified and annular flow patterns. The flow patterns such as bubbly flow, slug flow, and mist flow are the preferred flow patterns to be modeled using the concept of drift flux. However, with appropriate formulations that consider the two-phase flow physics, the application of DFM can also be extended to other flow patterns such as annular flow. The general form of DFM to calculate void fraction is presented by

$$\langle \alpha_G \rangle = \frac{\langle U_{SG} \rangle}{C_o \langle U_M \rangle + \langle \langle U_{GM} \rangle \rangle} \tag{3.35}$$

where $U_M = U_{SL} + U_{SG}$.

The terms involving $\langle\rangle$ represent cross-sectional averaged properties, while those involving $\langle\langle\rangle\rangle$ indicate cross-sectional and void fraction weighted averaged properties. The distribution parameter C_o is a representation to account for the distribution of the gas phase across the pipe cross section (concentration profile). It also serves as a correction factor to the homogeneous flow theory (which assumes no local slip between the two phases) to acknowledge the fact that the concentration profile and the two-phase flow velocity profile can vary independently of each other across the pipe cross section. Whereas the physical interpretation of drift velocity (U_{GM}) is the cross-sectional void fraction weighted average of the local relative velocity of the gas phase with respect to the two-phase mixture velocity at the pipe volume center. The local relative motion between the gas- and the two-phase mixtures is considerable and uniform across the pipe cross section when there is a strong coupling between the two phases as in case of the flow of dispersed bubbles in continuous liquid medium, that is, dispersed bubbly flow. As the two-phase flow transits to annular flow regime, the local relative velocity of the gas phase with

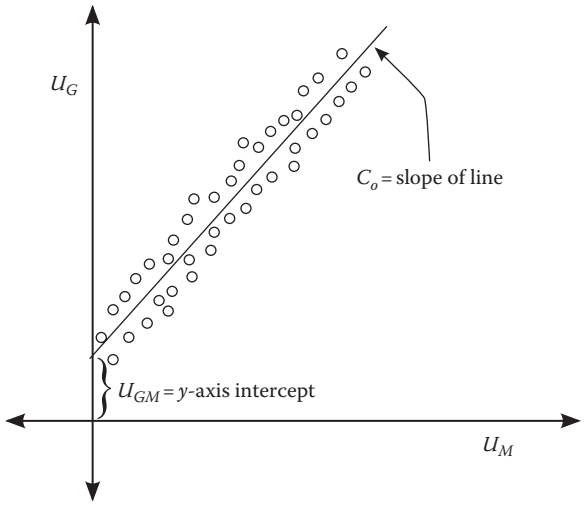

Figure 3.17

Graphical representation of drift flux model.

respect to the two-phase mixture at the pipe volume center becomes negligible and so does the drift velocity. Although the 1D DFM is used in the context of cross-sectional averaged void fraction, there are several DFM-based correlations available in the literature that can be practically implemented for void fraction calculations based on volumetric void fraction experimental data instead of the cross-sectional void fraction. The parity between the cross-sectional and volumetric void fraction holds true in case of nonboiling two-phase flow (two-component two-phase flow) where the cross-sectional distribution of the gas phase with respect to the liquid phase remains virtually unaltered over a short length of pipe. Henceforth, without making any distinction between the cross-sectional and volumetric void fractions, the void fraction is simply expressed as $\langle \alpha_G \rangle = \alpha_G$. Similar justification is applicable for all the cross-sectional averaged quantities involved in Equation 3.35. The physical form of Equation 3.35 resembles the equation of a straight line ($y = mx + c$) shown in Figure 3.17 such that the distribution parameter C_o is analogous to the slope "m" and the drift velocity is analogous to the y-intercept "c." Thus, the distribution parameter and the drift velocity could be obtained by plotting the data with $U_G = U_{SG}/\alpha_G$ and U_M coordinates and then by finding the slope and intercept of the best-fitting line. However, this method is highly impractical since the slope and intercept of line would depend on the scatter of data and cannot be used in case of real-time applications where void fraction information is not known beforehand. Obviously, another approach to determine C_o and U_{GM} is to use empirical correlations (as a function of two-phase flow variables) available in the two-phase flow literature. The following text presents some of the well-scrutinized and validated flow pattern–specific and flow pattern–independent correlations to determine C_o and U_{GM}.

The distribution parameter and drift velocity equations given by Hibiki and Ishii (2003) for vertical upward bubbly flow are given in Equation 3.36. To use these equations, the existence of bubbly flow could be determined by first using flow pattern transition equation given by Equation 3.7.

$$\left.\begin{aligned} C_o &= \left(1.2 - 0.2\sqrt{\frac{\rho_G}{\rho_L}}\right)\left(1 - \exp(-18\alpha_G)\right) \\ U_{GM} &= \sqrt{2}\left(\frac{\sigma g(\rho_L - \rho_G)}{\rho_L^2}\right)^{0.25}(1-\alpha_G)^{1.75} \end{aligned}\right\} \quad \begin{matrix}\text{(bubbly flow)} \\ \theta = +90^\circ\end{matrix} \tag{3.36}$$

Another most referred void fraction model for bubbly flow is that of Gomez et al. (2000) given by Equation 3.37. This model is essentially developed for upward pipe inclinations, and it may not reproduce correct results if used for horizontal two-phase flow since Equation 3.37 would give $U_{GM} = 0$. Moreover, Gomez et al. (2000) have recommended the use of a constant to represent distribution parameter that does not account for the effect of fluid properties, flow properties, and pipe orientation on the

distribution parameter. Although the void fraction model of Gomez et al. (2000) is developed for bubbly flow, our experience shows that this correlation also works well for the slug flow regime. Note that to use Equation 3.37, the existence of bubbly flow can be confirmed by using bubbly–slug flow transition model given by Equation 3.4:

$$\left.\begin{aligned} C_o &= 1.15 \\ U_{GM} &= 1.53\left(\frac{g\sigma(\rho_L-\rho_G)}{\rho_L^2}\right)^{0.25}\sqrt{1-\alpha_G}\sin\theta \end{aligned}\right\} \quad \begin{aligned} &\text{(bubbly, slug flow)} \\ &0° < \theta \le +90° \end{aligned} \tag{3.37}$$

For slug flow regime, Hibiki and Ishii (2003) proposed expressions for distribution parameter and drift velocity given by Equation 3.38. The drift velocity used in their equations is essentially the modified form of proportionality (between pipe diameter and slug translational velocity) proposed by Nicklin et al. (1962). These correlations given by Equations 3.36 and 3.38 are valid for small-diameter pipes ($10 < D_h < 50$ mm). For large-diameter pipes, Kataoka and Ishii (1987) have proposed sets of equations given by Equation 3.39 to account for the effect of pipe diameter and fluid properties on the drift velocity. The nondimensional hydraulic pipe diameter (D_h^+), nondimensional drift velocity (U_{GM}^+), and viscosity number (N_μ) are defined by Equations 3.40 through 3.42, respectively. Their equation is developed based on data of air–water and steam–water vertical upward two-phase flow consisting of data with $20 < D_h < 240$ mm and $0.1 \le p_{sys} \le 18$ MPa. The distribution parameter of Kataoka and Ishii (1987) correlation is the same as that of Equation 3.38. In case of two-phase flow through rectangular ducts, the constants "1.2" and "0.2" in Equation 3.38 are replaced by "1.35" and "0.35," respectively:

$$\left.\begin{aligned} C_o &= \left(1.2-0.2\sqrt{\frac{\rho_G}{\rho_L}}\right) \\ U_{GM} &= 0.35\sqrt{\frac{gD(\rho_L-\rho_G)}{\rho_L}} \end{aligned}\right\} \quad \begin{aligned} &\text{(slug flow)} \\ &\theta = +90° \end{aligned} \tag{3.38}$$

$$U_{GM}^+ = \begin{cases} 0.00019(D_h^+)^{0.809}\left(\dfrac{\rho_G}{\rho_L}\right)^{-0.157} N_\mu^{-0.562} & : N_\mu \le 2.25\times10^{-3}, D_h^+ > 30 \\ 0.030\left(\dfrac{\rho_G}{\rho_L}\right)^{-0.157} N_\mu^{-0.562} & : N_\mu \le 2.25\times10^{-3}, D_h^+ \le 30 \\ 0.92\left(\dfrac{\rho_G}{\rho_L}\right)^{-0.157} & : N_\mu > 2.25\times10^{-3} \end{cases} \tag{3.39}$$

$$D_h^+ = \frac{D_h}{\sqrt{\sigma/(g\Delta\rho)}} \tag{3.40}$$

$$U_{GM}^+ = \frac{U_{GM}}{((\sigma g\Delta\rho)/\rho_L^2)^{0.25}} \tag{3.41}$$

$$N_\mu = \frac{\mu_L}{(\rho_L\sigma\sqrt{\sigma/(g\Delta\rho)})^{0.5}} \tag{3.42}$$

The DFM-based void fraction correlation of Rouhani and Axelsson (1970) given by Equations 3.43 and 3.44 is one of the most preferred correlations used in refrigeration industry to estimate void fraction in

evaporators and condensers. The term $(1 - x)$ ensures decrease in distribution parameter with increase in two-phase flow quality or alternatively shift of flow pattern from bubbly/slug to annular flow.

$$C_o = \begin{cases} 1 + 0.2(1-x)\left(\dfrac{gD\rho_L^2}{G^2}\right)^{0.25} & : \theta = +90°, 0.1 \le p_{sys} \le 14\,\text{MPa} \\ 1 + 0.12(1-x) & : \theta = 0°, 0.1 \le p_{sys} \le 14\,\text{MPa} \end{cases} \tag{3.43}$$

$$U_{GM} = 1.18\left[\frac{g\sigma(\rho_L - \rho_G)}{\rho_L^2}\right]^{0.25} \tag{3.44}$$

To get rid of the flow pattern dependency, Woldesemayat and Ghajar (2007) proposed equations for distribution parameter and drift velocity as a function of fluid properties, pipe diameter, and pipe orientation shown in Equations 3.45 and 3.46. Woldesemayat and Ghajar (2007) correlation is a modification of Dix (1971) correlation for two-phase flow over rod bundles and is independent of flow patterns. The correlation of Woldesemayat and Ghajar (2007) is verified against data for horizontal and the entire range of upward pipe inclinations and pipe diameters in the range of 12–80 mm. In case of unknown flow pattern in horizontal and upward pipe inclinations, Woldesemayat and Ghajar (2007) correlation can be used with a reasonable accuracy (except for stratified flow). Note that the multiplying factor of 2.9 has units of $\text{m}^{-0.25}$.

$$C_o = \lambda\left(1 + \left[\frac{U_{SL}}{U_{SG}}\right]^{(\rho_G/\rho_L)^{0.1}}\right) \tag{3.45}$$

$$U_{GM} = 2.9\left[\frac{gD\sigma(1+\cos\theta)(\rho_L - \rho_G)}{\rho_L^2}\right]^{0.25}(1.22 + 1.22\sin\theta)^{p_{atm}/p_{sys}} \tag{3.46}$$

A recent modeling work of Bhagwat and Ghajar (2014) considers the effect of flow patterns (in the form of phase flow rates), pipe orientation, pipe diameter, and fluid properties on the distribution parameter and drift velocity as shown in Equations 3.47 and 3.50, respectively. The void fraction correlation of Bhagwat and Ghajar (2014) is based on the most comprehensive data bank and is the most robust correlation applicable for a wide range of two-phase flow conditions listed in Table 3.5. The variable $C_{o,1}$ in Equation 3.48 is modeled as a variable such that it may vary between 0.2 and 0 to ensure the variation of distribution parameter for bubbly flow $C_o \approx 1.2$ to annular flow where $C_o \to 1.0$. Note that the two-phase friction factor (f_M) is based on two-phase mixture Reynolds number (Re_M) given by Equation 3.49 and could be calculated using appropriate single-phase friction factor equation for laminar and turbulent flows.

$$C_o = \frac{2 - (\rho_G/\rho_L)^2}{1 + (Re_M/1000)^2} + \frac{\left[\sqrt{(1 + (\rho_G/\rho_L)^2\cos\theta)/(1+\cos\theta)}^{(1-\alpha_G)}\right]^{2/5} + C_{o,1}}{1 + (1000/Re_M)^2} \tag{3.47}$$

Table 3.5 Application Range of Two-Phase Flow Parameters for Bhagwat and Ghajar (2014) Void Fraction Correlation

Parameter	Range
Pipe diameter (mm)	0.5–305
Pipe orientation (θ)	$-90° \le \theta \le +90°$
Density ratio (ρ_L/ρ_G)	6–875
Liquid dynamic viscosity (Pa s)	0.0005–0.6
Mixture mass flux (kg/m^2 s)	10–8450
Two-phase quality (x)	0–1
Two-phase Reynolds number (Re_M)	$10 - 5 \times 10^6$
Pipe geometry	Circular, rectangular, annular
Flow patterns	All (except stratified flow with $Fr_{SG} \le 0.1$ in $\theta < 0°$)

$$C_{o,1} = \left(c_1 - c_1\sqrt{\rho_G/\rho_L}\right)\left[(2.6-\lambda)^{0.15} - \sqrt{f_M}\right](1-x)^{1.5} \tag{3.48}$$

The constant c_1 is 0.2 for circular pipes and 0.4 for rectangular and annular ducts.

$$Re_M = \frac{(U_{SL}+U_{SG})\rho_L D_h}{\mu_L} \tag{3.49}$$

The expression for drift velocity used by Bhagwat and Ghajar (2014) is essentially based on the translational velocity of the gas slug in different pipe inclinations suggested by Bendiksen (1984). However, instead of using the constant of 0.54 as originally proposed by Bendiksen (1984), a proportionality constant of 0.45 is used since it gave a better accuracy in overall prediction of the void fraction. The correction factors c_2 and c_3 used in Equation 3.50 account for the effect of increase in liquid viscosity and pipe diameter on the reduction in drift velocity. These correction factors are expressed by Equations 3.51 and 3.52. More details and justification about the effect of these parameters on drift velocity and hence the use of these correction factors could be obtained from Gokcal et al. (2009), Kataoka and Ishii (1987), and Bhagwat and Ghajar (2014). The pipe diameter beyond which the correction to drift velocity in the form of c_3 is deemed necessary is identified using Laplace number (nondimensional pipe diameter) defined by Equation 3.53:

$$U_{GM} = (0.35\sin\theta + 0.45\cos\theta)\sqrt{\frac{gD_h(\rho_L-\rho_G)}{\rho_L}}(1-\alpha_G)^{0.5}c_2c_3 \tag{3.50}$$

$$c_2 = \begin{cases} \left(\dfrac{0.434}{\log_{10}(\mu_L/0.001)}\right)^{0.15} & : (\mu_L/0.001) > 10 \\ 1 & : (\mu_L/0.001) \le 10 \end{cases} \tag{3.51}$$

$$c_3 = \begin{cases} (La/0.025)^{0.9} & : La < 0.025 \\ 1 & : La \ge 0.025 \end{cases} \tag{3.52}$$

$$La = \sqrt{\frac{\sigma}{g(\rho_L-\rho_G)}}\frac{1}{D_h} \tag{3.53}$$

Note that the correlation of Bhagwat and Ghajar (2014) is not validated against data for microchannels with pipe diameters less than 0.5 mm. For gas–liquid two-phase flow in small-size pipes less than 0.5 mm, the correlation of Xiong and Chung (2006) could be used. Their correlation is based on the experimental data for pipe diameters in the range of 0.1–0.6 mm and consists of bubbly, slug, annular flow, and entire range of gas volumetric flow fraction (λ). The correlation of Xiong and Chung (2006) accounts for the nonlinear relationship between void fraction and gas volumetric flow fraction as a function of hydraulic pipe diameter (D_h) measured in mm:

$$\left.\alpha_G = \frac{a_1\lambda^{0.5}}{1-(1-a_1)\lambda^{0.5}}\right\} \quad \begin{array}{l} 0.1 \le D_h \le 0.6\,\text{mm} \\ 4 \le Re_{SL} \le 1670, 4 \le Re_{SG} \le 1725 \end{array} \tag{3.54}$$

$$a_1 = \frac{0.266}{1+13.8\exp(-6.88D_h)} \tag{3.55}$$

It must be noted that DFM-based void fraction correlations are not suitable to model stratified type of flow. Compared to DFMs, SFMs listed in Table 3.4 work better for stratified flow. However, these models too cannot provide accurate prediction of the void fraction with desired accuracy. In particular for stratified flows, flow pattern–specific models are required, which will be discussed later in Section 3.5.

3.4 Pressure Drop

Similar to single-phase flow, pressure drop in gas–liquid two-phase flow comprises hydrostatic, accelerational, and frictional components as shown in Equation 3.56. However, unlike the single-phase flow, these components of two-phase pressure drop in gas–liquid flows may depend upon several parameters such as void fraction, pipe orientation, flow patterns, and liquid entertainment fraction. The hydrostatic or gravitational component of two-phase pressure drop due to the pipe inclination depends on the two-phase mixture density, which in turn is a function of flow patterns and void fraction. Accelerational pressure drop is due to the change in momentum of the two-phase mixture and can be neglected for adiabatic two-phase flows within a short pipe length. However, for two-phase flow undergoing phase change process or even for adiabatic two-phase flow in long and inclined pipes, depending upon the flow pattern, the accelerational pressure drop can contribute up to 20% of the total two-phase pressure drop. Finally, the frictional component of two-phase pressure drop is a result of the interfacial friction between the two phases and wall friction with both or either phase and depends upon the flow pattern structure, pipe diameter, and fluid properties:

$$-\left(\frac{dp}{dz}\right)_{TP} = -\left(\frac{dp}{dz}\right)_{h} - \left(\frac{dp}{dz}\right)_{f} - \left(\frac{dp}{dz}\right)_{a} \tag{3.56}$$

Before discussing different two-phase pressure drop modeling methods, it is interest to know about the effect of different two-phase flow variables on the two-phase pressure drop. Following text describes the effect of pipe orientation on the total two-phase pressure drop and the effects of phase flow rates and pipe surface roughness on the frictional component of two-phase pressure drop. Following this discussion, different modeling approaches to determine hydrostatic, accelerational, and frictional components of two-phase pressure drop are presented.

3.4.1 Effect of Pipe Orientation

The effect of pipe orientation on two-phase pressure drop is primarily due to the effect of pipe orientation on the hydrostatic component of the two-phase pressure drop. The two-phase literature reports that very few studies focused on the measurement of two-phase pressure drop over the entire range of pipe orientations. Some of these studies include the works of Beggs (1972), Mukherjee (1979), Spedding et al. (1982), and Lips and Meyer (2012). The experimental measurements carried out at the Two-Phase Flow Lab, OSU and that reported in the literature are presented in Figures 3.18 and 3.19.

A comparison between Figures 3.18 and 3.19 shows that the variation of two-phase pressure drop as a function of pipe orientation is similar for both nonboiling and condensing two-phase flows. It is evident that at low gas and liquid flow rates, two-phase pressure drop is relatively insensitive to the change in downward pipe inclination. This is due to the fact that at these flow rates, stratified flow exists and its physical structure and associated void fraction is relatively insensitive to the change in pipe orientation. In upward pipe inclinations, two-phase pressure drop increases rapidly with increase in the pipe orientation, and it is fascinating to see that two-phase pressure drop at lower gas flow rates is greater than that at higher gas flow rates. This is because of the reversal of liquid film that induces decreasing trend of pressure gradient with increase in gas flow rates. Please refer to Section 3.4.6 for more details on this phenomenon. At higher liquid flow rates, negative values of the total two-phase pressure drop in downward pipe inclinations represent partial pressure recovery due to gain in hydrostatic component of two-phase pressure drop.

3.4.2 Effect of Phase Flow Rates

The effect of change in phase flow rates on the two-phase pressure drop is essentially due to the change in physical structure of the flow patterns and is of different nature for the hydrostatic and frictional components of two-phase pressure drop. Since the hydrostatic component of two-phase pressure drop depends only on the void fraction, for a fixed liquid flow rate, increase in gas flow rate decreases the contribution of hydrostatic pressure drop (due to decrease in mixture density), whereas it increases the frictional pressure drop component. The relation between change in phase flow rates and the frictional pressure drop could be construed in a better way by presenting their relationship in different coordinate systems. As shown in Figure 3.20, for low liquid and low gas flow rates, the two-phase frictional pressure drop remains virtually constant and increases drastically only for moderate to high gas flow rates (intermittent and annular flow regimes). For intermittent type of flow, sharp increase in the frictional pressure drop is essentially due to the turbulent and chaotic nature of the two-phase mixture. For annular flow, the pressure gradient increases

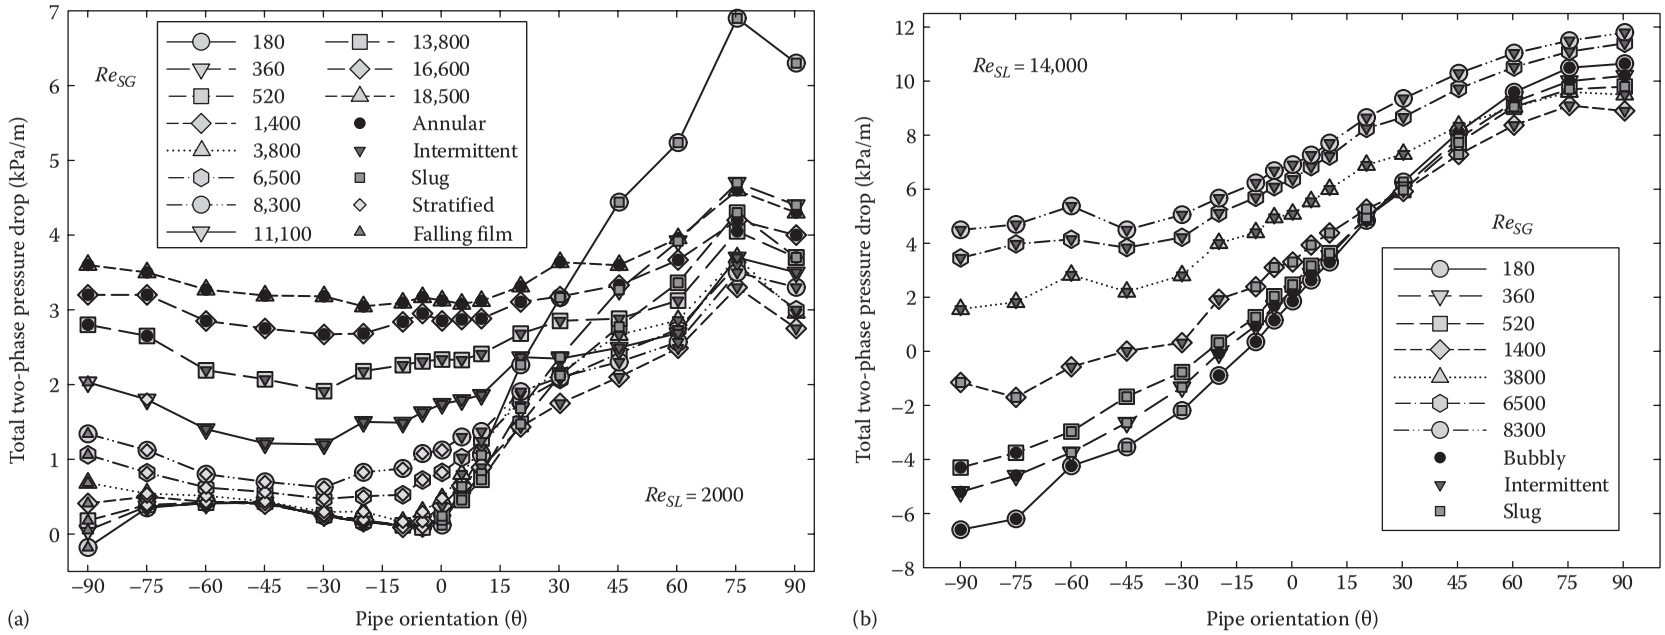

Figure 3.18

Effect of pipe orientation on total two-phase pressure drop. (a) Re_{SL} = 2,000 and Re_{SG} = 180-18,500. (b) Re_{SL} = 14,000 and Re_{SG} = 180-8,300. (Data measured at the Two-Phase Flow Lab, OSU, Stillwater, OK.)

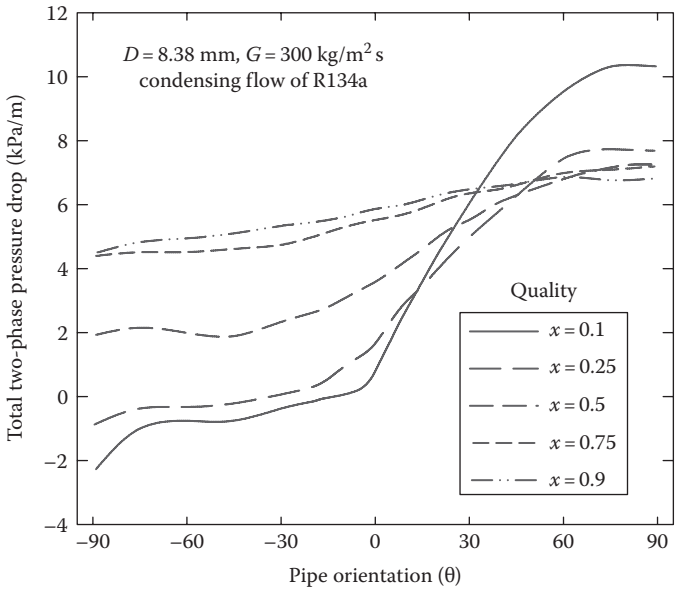

Figure 3.19

Effect of pipe orientation on two-phase pressure drop. (Data of Lips, S. and Meyer, J.P., *Int. J. Heat Mass Transfer*, 55, 405, 2012.)

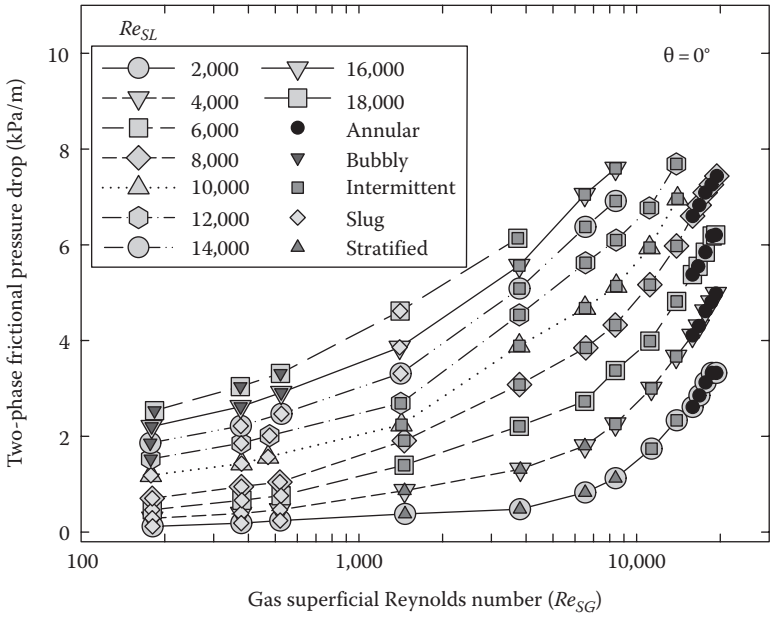

Figure 3.20

Two-phase frictional pressure drop for varying gas and liquid flow rates. (Data measured at the Two-Phase Flow Lab, OSU, Stillwater, OK.)

sharply with increase in the gas and liquid flow rates. At a fixed gas flow rate, increase in the liquid flow rate increases the liquid film thickness and thus reduces the cross-sectional area available for the gas phase. This increases the actual gas velocity and exerts higher shear on the gas–liquid interface to increase the two-phase frictional pressure drop. Additionally, the gas–liquid interface offers a rough surface to the gas flow, and the interface gets roughened progressively with the increase in the liquid film thickness or alternatively the liquid flow rate that augments the frictional pressure drop.

Variation of two-phase pressure drop with change in two-phase flow rates could also be presented in an another perspective using two-phase flow quality. This type of presentation shown in Figure 3.21 is usually

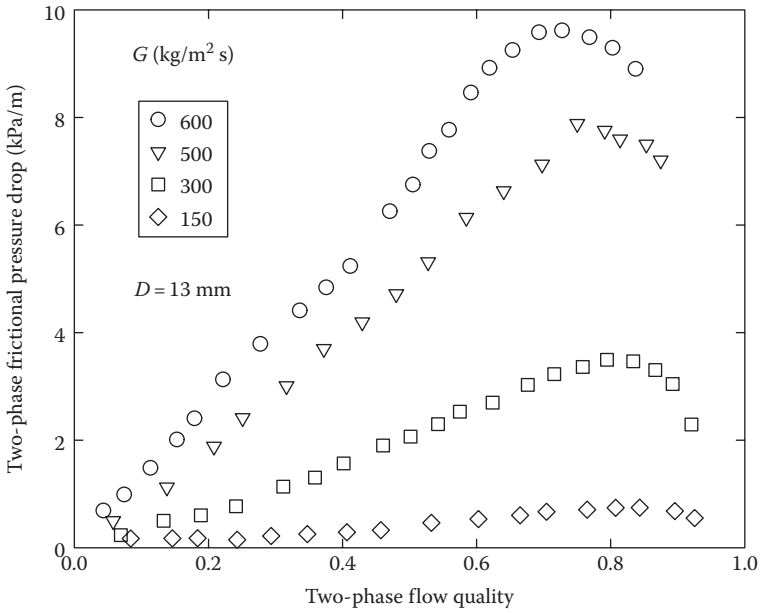

Figure 3.21

Two-phase pressure drop as a function of phase flow rates. (Data of Quiben, J.M. and Thome, J.R., *Int. J. Heat Fluid Flow*, 28, 1049, 2007.)

adopted for high-pressure systems (often encountered in refrigeration and nuclear applications) that tend to occupy the entire range of two-phase flow quality ($0 < x < 1$). It is evident that the two-phase pressure drop increases systematically with increase in the mass flux and quality. An inflection point that flips the trend of increase in two-phase pressure drop with increase in quality is quite noticeable. This change in the trend of two-phase pressure drop could be explained based on the change in structure of the two-phase flow pattern at the inflection point. By the time the two-phase flow system reaches the point of maximum pressure drop (inflection point), the flow pattern attains annular flow structure; however, beyond that point due to severe entrainment process, the liquid phase in contact with the pipe wall is gradually moved to the central gas core reducing the liquid film thickness and consequently reducing the effective viscosity in the near-wall region. This ultimately results into a reduced frictional pressure drop. This type of trend is not evident in Figure 3.20 since the data presented there do not contain two-phase flow with significant entrainment. It is also evident from Figure 3.21 that the quality at the point of maximum pressure drop shifts toward lower qualities with increase in the two-phase mixture mass flux. Additionally, Ducoulombier et al. (2011) reported that the quality associated with maximum frictional pressure drop also depends upon the fluid properties. The combined effect of mass flux and fluid thermophysical properties on the quality at maximum pressure drop is reported in Figure 3.22. It is clear that the two-phase flow quality corresponding to the point of maximum pressure drop may vary approximately between 0.65 and 0.95.

3.4.3 Effect of Pipe Diameter

Similar to the single-phase pressure drop, the effect of decrease in pipe diameter is to increase the two-phase frictional pressure drop. However, this effect of pipe diameter is usually in conjunction with two-phase flow patterns. The two-phase frictional pressure drop in the annular flow regime depends on the pipe diameter to a great extent, whereas it is relatively less sensitive to the pipe diameter in the bubbly flow regime. It is evident from Figure 3.23a that for a fixed mass flux of R134a, the two-phase frictional pressure drop for different pipe diameters deviates significantly for higher values of two-phase flow quality (annular flow pattern), whereas for low values of two-phase flow quality (bubbly flow), the effect of pipe diameter on two-phase frictional pressure drop gradually diminishes. Similar conclusions could be drawn for air–water two-phase flow system from the work of Kaji and Azzopardi (2010) who studied the effect of pipe diameters in the range of 10–50 mm on two-phase pressure drop in the annular flow regime. As shown in Figure 3.23b, for a fixed liquid flow rate, the effect of change in pipe diameter is most significant at higher gas flow rates (i.e., higher two-phase flow qualities). The two-phase frictional pressure

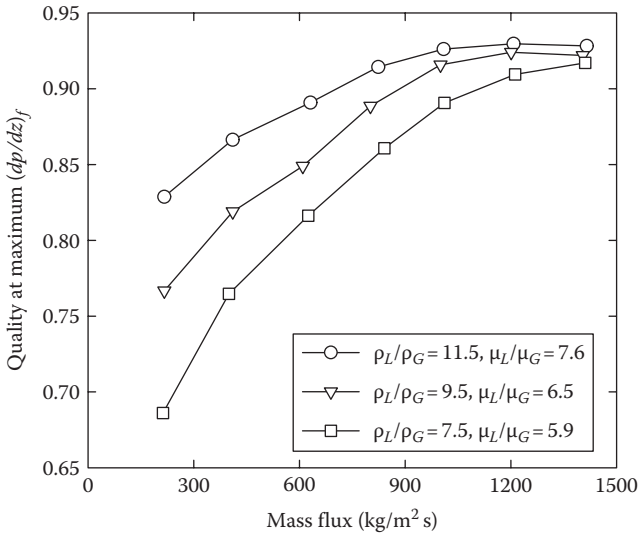

Figure 3.22

Influence of mass flux and fluid properties on quality corresponding to maximum pressure drop. (Adapted from Ducoulombier, M. et al., *Exp. Therm. Fluid Sci.*, 35, 581, 2011.)

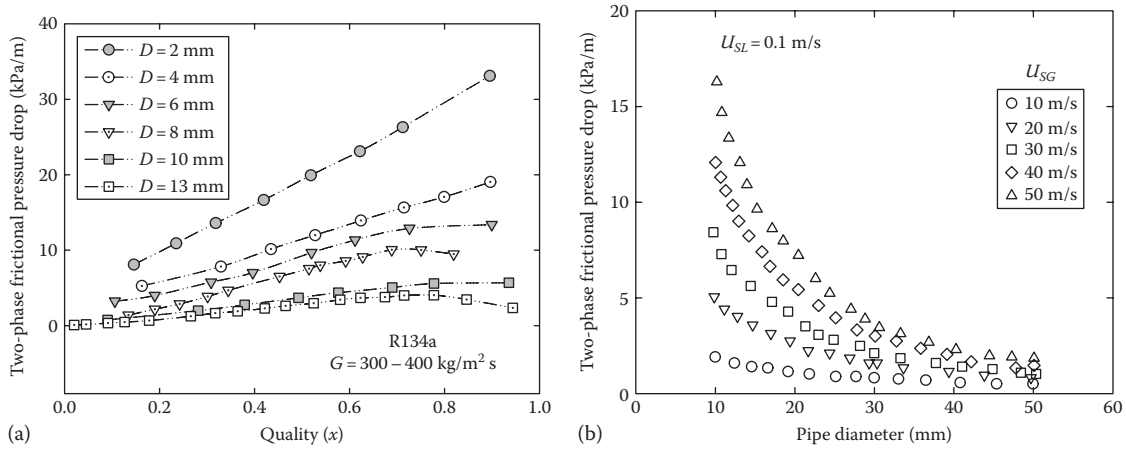

Figure 3.23

Effect of pipe diameter on two-phase frictional pressure drop. (a) Two-phase flow of R134a refrigerant. (b) Two-phase flow of air-water. (Adapted from Kaji, M. and Azzopardi, B.J., *Int. J. Multiphase Flow*, 36, 303, 2010.)

drop is due to the friction at the pipe wall as well as the gas–liquid interface and the gas–liquid interfacial area increases with increase in the pipe diameter, and hence, the nondimensional two-phase pressure drop (Φ^2) may be greater than that for the relatively smaller-diameter pipes. Thus, it is evident that any two-phase frictional pressure drop correlation must definitely account for the pipe diameter effect in the annular flow regime.

3.4.4 Effect of Fluid Properties

The important fluid properties that show a noticeable effect on two-phase frictional pressure drop are the gas-phase density and liquid-phase dynamic viscosity. The increase in gas-phase density decreases the slippage at the gas–liquid interface and hence decreases the frictional component of two-phase pressure drop, whereas the increase in liquid dynamic viscosity increases the shear in the liquid phase in contact with the pipe wall and also the shear at the gas–liquid interface resulting in increase in frictional pressure drop. Intuitively, it can be said that the effect of fluid properties on two-phase frictional pressure drop is more prominent for shear-driven flows than for buoyancy-driven two-phase flow. For more details on the effect

of fluid properties on frictional pressure drop, readers are advised to refer to Oshinowo (1971), Fukano and Furukawa (1998), Abduvayat et al. (2003), Hlaing et al. (2007), and Gokcal (2008).

3.4.5 Effect of Surface Roughness

The effect of pipe surface roughness on two-phase pressure drop is crucial in applications involving two-phase flow through steel or microfinned tubes. The internally ribbed or microfinned tubes are used in air-conditioning and refrigeration applications to improve the tube side heat transfer, however, at the expense of enhanced pressure drop. Most of the two-phase flow research reported in the literature is carried out in a transparent (smooth pipe), while the effect of pipe surface roughness on the frictional two-phase pressure drop is a relatively less investigated issue. The work of Wongs-ngam et al. (2004) and Shannak (2008) reported a considerable effect (20%–60%) of wall roughness on pressure drop especially for the two-phase flow at high mass flux and quality. Figure 3.24 shows that the effect of pipe wall roughness on two-phase pressure drop is considerable at high gas velocities and increases with increase in liquid velocity. Obviously, similar to single-phase flow, the effect of wall roughness on two-phase pressure drop increases with decrease in the pipe diameter. Experiments performed at the Two-Phase Flow Lab, OSU, confirm these observations. Moreover, their work also shows that the effect of pipe roughness on two-phase pressure drop is independent of the pipe orientation. The effect of pipe surface roughness on two-phase frictional pressure drop is maximum for the annular flow (at high gas flow rates) since, in addition to the effect of pipe wall roughness acting on the liquid phase, the structure of this flow pattern also offers a continuous and rough gas–liquid interface responsible for enhanced pressure drop.

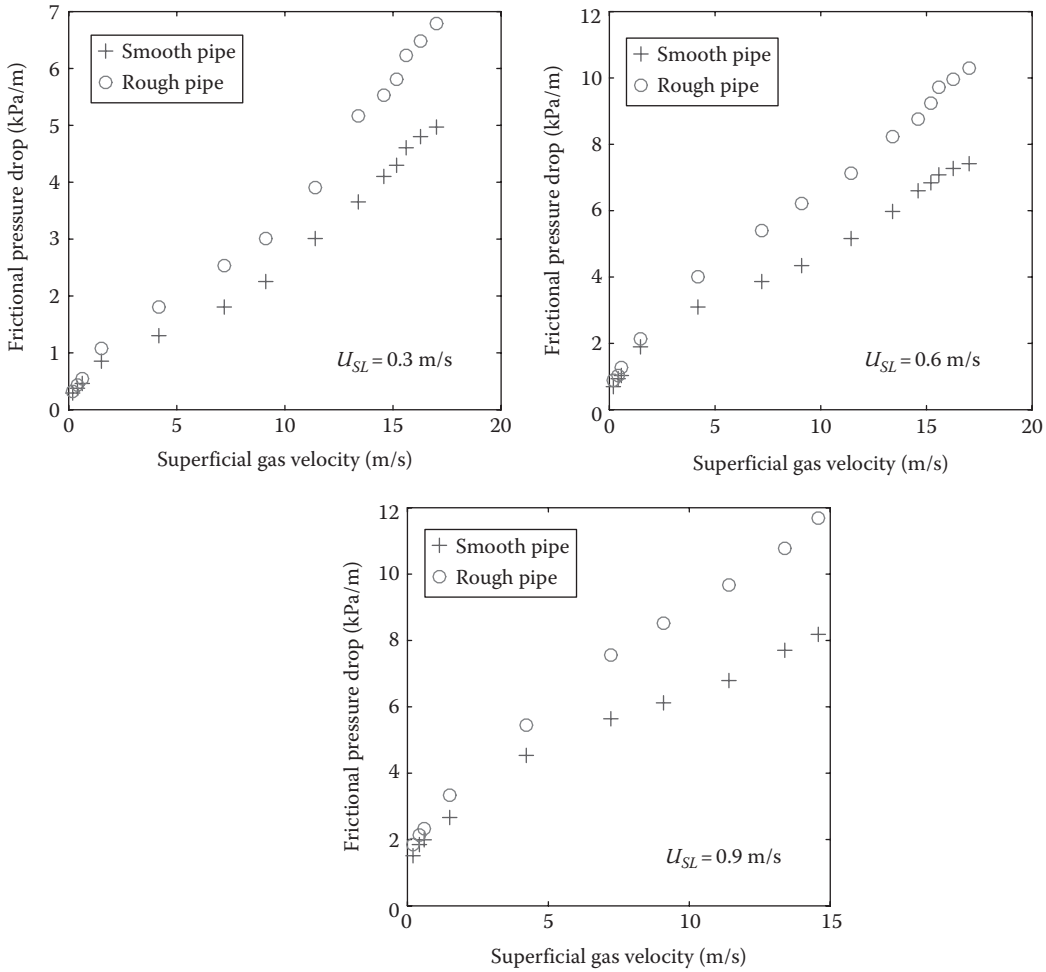

Figure 3.24

Effect of pipe surface roughness on two-phase frictional pressure drop. (Data from the Two-Phase Flow Lab, OSU, Stillwater, OK.) (D = 12.5 mm, ε = 20 μm for rough pipe).

3.4.6 Pressure Gradient Minimum and Flow Reversal in Upward Inclined Flow

In cocurrent gas–liquid upward inclined two-phase flow, at low liquid and moderate gas flow rates, although the net two-phase flow is observed in the upward direction, reversal of liquid film in contact with the pipe wall is observed under the influence of gravity forces. This phenomenon is a consequence of the interaction between the interfacial shear stress (exerted by gas phase on liquid film) and the gravitational forces acting on the liquid film. The liquid film in contact with the pipe wall may undergo a partial reversal (fluctuating wall shear stress) or complete reversal (negative wall shear stress) depending upon the gas and liquid flow rates and exhibit a decreasing trend of two-phase pressure gradient. Assuming churn/annular–annular flow regime with constant phase density, uniform circumferential film thickness, and negligible acceleration of the liquid film, the shear stress distribution in the liquid film in upward inclined flow can be given by Equation 3.57 where d is any given location on the pipe diameter (see Hewitt and Hall-Taylor (1970) and Collier and Thome (1996)):

$$\tau = \tau_i\left(\frac{D-2\delta}{d}\right)+\frac{1}{4}\left(\rho_L g\sin\theta+\frac{dp}{dz}\right)\left(\frac{(D-2\delta)^2-d^2}{d}\right) \tag{3.57}$$

Using the boundary condition of zero wall shear stress at $d = D$ for the case of stationary liquid film in contact with pipe wall, Equation 3.57 can be expressed as

$$\tau_w = \tau_i\left(\frac{D-2\delta}{D}\right)+\frac{1}{4}\left(\rho_L g\sin\theta+\frac{dp}{dz}\right)\left(\frac{(D-2\delta)^2-D^2}{D}\right)=0 \tag{3.58}$$

Assuming negligible acceleration in the gas core and negligible entrainment of liquid drops to the gas core, the interfacial shear stress exerted by the gas phase on the liquid film can be expressed as

$$\tau_i = \frac{D-2\delta}{4}\left(\frac{dp}{dz}+\rho_G g\sin\theta\right) \tag{3.59}$$

After combining Equations 3.58 and 3.59 and considering that $\delta \ll D$, the following relationship given by Equation 3.60 is obtained. Following our assumption of negligible liquid entrainment and uniform film thickness distribution, the void fraction can simply be expressed as that given by Equation 3.61. Using this definition of void fraction, it is evident that the right-hand side of Equation 3.60 is indeed the hydrostatic component of two-phase pressure drop:

$$\left(\frac{dp}{dz}\right)_{\tau_w=0}=\left[\rho_G\left(\frac{(D-2\delta)^2}{D^2}\right)+\rho_L\left(1-\frac{(D-2\delta)^2}{D^2}\right)\right]g\sin\theta \tag{3.60}$$

$$\alpha_G = \frac{A_G}{A}=\frac{(D-2\delta)^2}{D^2}=1-\frac{4\delta}{D}\Bigg\}(\delta \ll D) \tag{3.61}$$

The physical implication of Equation 3.60 is that as long as there is a balance between interfacial shear stress and hydrostatic pressure drop, the liquid film in contact with the pipe wall will either remain stationary or oscillate giving a net zero wall shear stress. Thus, when the interfacial shear stress is large enough to supersede the gravity forces (in the form of hydrostatic pressure drop), the net flow of two-phase mixture will be in upward direction without any reversal of liquid film.

Experimentally, this condition could be determined by analyzing the pressure drop signal as a function of gas and liquid flow rates. At a fixed liquid flow rate and with an increase in the gas flow rate, a point is reached where the gas phase does not have enough potential to carry liquid phase along with it in the downstream direction. At this point, the liquid phase in contact with the pipe wall appears to oscillate or move in the downward direction. The point corresponding to the inception of decreasing pressure gradient trend (in spite of increase in gas flow rate) is regarded as the flow reversal point, while the condition at which the pressure

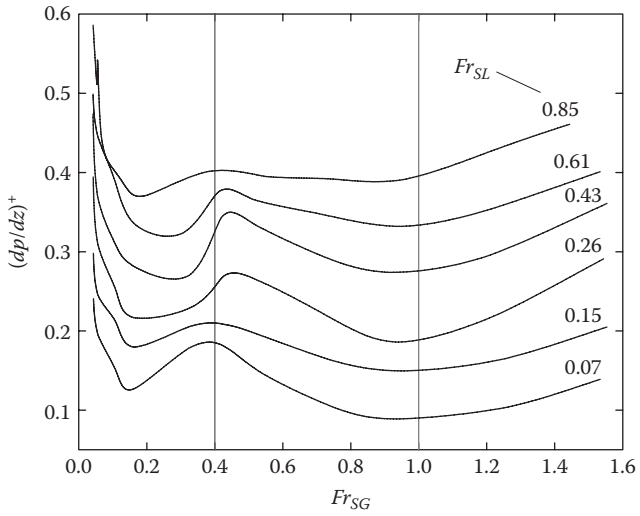

Figure 3.25

Nondimensional pressure drop for varying nondimensional gas and liquid flow rates. (Data measured at the Two-Phase Flow Lab, OSU, Stillwater, OK.)

gradient commence to increase again with increase in gas flow rate is identified as pressure gradient minimum point. The two-phase literature provides several instances of decreasing pressure gradient trends in context to churn–annular transition in vertical upward two-phase flow. As a matter of fact, the decreasing trend of pressure gradient minimum also exists at lower gas flow rates during slug–churn transition in upward inclined pipes. Nevertheless, the flow physics governing these two separate regions of pressure gradient minimum is significantly different. A typical example of decreasing trends of pressure gradient minimum in vertical upward pipe inclination is illustrated in Figure 3.25. The measured two-phase pressure drop and corresponding gas and liquid flow rates are made nondimensional as shown in Equations 3.62 through 3.64, respectively:

$$\left(\frac{dp}{dz}\right)_t^+ = \frac{(dp/dz)_t}{(\rho_L - \rho_G)g} \tag{3.62}$$

$$Fr_{SG} = \frac{U_{SG}}{\sqrt{gD}}\sqrt{\frac{\rho_G}{(\rho_L - \rho_G)}} \tag{3.63}$$

$$Fr_{SL} = \frac{U_{SL}}{\sqrt{gD}}\sqrt{\frac{\rho_L}{(\rho_L - \rho_G)}} \tag{3.64}$$

It is seen that for a fixed liquid flow rate, when the gas flow rate is increased, the two-phase pressure gradient exhibits first a minimum at $Fr_{SG} \approx 0.2 - 0.3$ and a maximum at $Fr_{SG} \approx 0.4$. The first instance of decreasing pressure drop is due to falling film surrounding the gas slug. As the gas slug rises in downstream direction it sheds liquid phase surrounding it to maintain the continuity. The sudden increase in pressure drop between $Fr_{SG} \approx 0.2 - 0.4$ is due to the high level of turbulence caused by disintegration of gas slug during slug to churn/intermittent flow transition. Further this point of maximum pressure gradient at $Fr_{SG} \approx 0.4$, churn/intermittent flow is known to commence and again a decreasing trend of pressure gradient followed by a pressure gradient minimum is observed at $Fr_{SG} \approx 0.9 - 1$. Beyond this point, the annular flow is known to exist. Note that this value of the nondimensional gas flow rate is essentially the criteria given by Equation 3.26.

The second trend of decreasing pressure drop could be explained using Figure 3.26. During churn–annular flow transition, large interfacial disturbance waves are generated that travel in downstream direction (Figure 3.26-sketch b). During the swiping action of disturbance wave, the liquid film travels in downstream direction under the influence of interfacial drag. However, once the disturbance wave passes by a certain pipe cross section, there is no driving potential for the liquid film and it tends to fall back under the influence

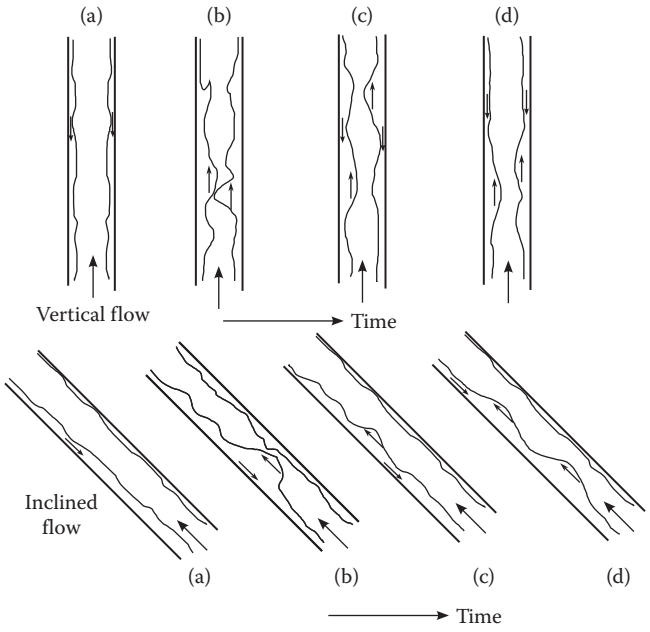

Figure 3.26

Schematics of mechanism governing pressure gradient minimum phenomenon.

of gravity (Figure 3.26 sketch c and d). The direction of travel of liquid film for different cases is depicted by small arrows inside the film. During and just after the encounter of liquid film with the disturbance wave, the portion of liquid film near interface may travel in upward direction, while that away from interface (or near pipe wall) may travel in downward direction leading to severe fluctuations in shear stress and velocity distributions in liquid film. The falling liquid film is again lifted up by upcoming disturbance wave, and the process continues until the frequency of disturbance waves is high enough to prevent the reversal of liquid film. More details about this phenomenon and its dependency on disturbance waves could be found in Hewitt et al. (1965, 1985), Hewitt and Lacey (1965), and Owen (1986).

When it is desirable to operate a two-phase flow system in the region *not affected* by the reversal of liquid film, it is crucial to identify the gas and liquid flow rates that belong to the region *affected* by flow reversal. Compared to first trend of decreasing pressure gradient, its second instance is more important since this region is marked by severe turbulence and instability of the liquid film. The two-phase flow literature reports that the point of second pressure gradient minimum occurs at $Fr_{SG} \approx 1$. However, this criterion does not provide any idea on the range of liquid flow rates for which this trend would exist. Experiments carried out at the Two-Phase Flow Lab, OSU, reveal that the liquid flow rates at which this trend of second pressure gradient minimum would exist depend upon the pipe orientation such that the relationship between nondimensional liquid flow rates and pipe orientation corresponding to second pressure gradient minimum is given by Equation 3.65. Note that this relationship need not be used for pipe orientations less than +10° from horizontal since the effect of pipe orientation on pressure gradient is negligibly small. For a fixed pipe orientation, Equation 3.65 gives a threshold value of nondimensional liquid flow rate (Fr_{SL}) above which decreasing pressure gradient trends or alternatively reversal of liquid film will no longer exist. Independent of pipe orientation and liquid flow rates, the nondimensional gas flow rates (Fr_{SG}) corresponding to this point are in the range of 0.9–1:

$$Fr_{SL} = 0.6575(\sin\theta)^{1.1175}\Big\} + 10° \le \theta \le +90° \tag{3.65}$$

3.4.7 Two-Phase Pressure Drop Modeling

The two-phase flow literature provides different methods for the calculation of two-phase pressure drop that can be broadly classified as methods based on (1) homogeneous flow model, (2) SFM, (3) phenomenological models, and (4) empirical models. The following text provides a brief description of these models and presents some of the top-performing pressure drop correlations.

3.4.7.1 Homogeneous Flow Model

As mentioned earlier, the correlations based on homogeneous flow model assume the two phases to remain well mixed and move with identical velocities (no slippage at the gas–liquid interface). The homogeneous flow model thus considers the two-phase mixture as a pseudo single-phase mixture having two-phase physical properties. Under the consideration of homogeneous flow model, the hydrostatic two-phase pressure drop is calculated using homogeneous two-phase mixture density (ρ_M) as shown in Equation 3.66. The two-phase mixture density can be expressed either in terms of two-phase flow quality (x) or the gas volumetric flow fraction (λ_G). See Table 3.1 for interchangeability between λ and x:

$$-\left(\frac{dp}{dz}\right)_h = \rho_M g \sin\theta \tag{3.66}$$

$$\rho_M = \left(\frac{x}{\rho_G} + \frac{1-x}{\rho_L}\right)^{-1} = \lambda_G \rho_G + (1-\lambda_G)\rho_L \tag{3.67}$$

The pressure drop due to acceleration of the two-phase mixture is calculated from Equation 3.68. For the case of two-component two-phase flow (nonboiling, noncondensing), the two-phase flow quality remains constant for a relatively short length of pipe and the magnitude of pressure drop due to change in specific volume of two-phase mixture is negligible and hence is ignored:

$$-\left(\frac{dp}{dz}\right)_a = G^2 \frac{dv_M}{dz} = G^2\left(v_{LG}\frac{dx}{dz} + x\frac{dv_G}{dp}\frac{dp}{dz}\right) \tag{3.68}$$

Finally, the frictional component of two-phase pressure drop is expressed in terms of the two-phase friction factor. The two-phase friction factor (f_M) is calculated based on two-phase Reynolds number (Re_M), which in turn is the function of two-phase mixture dynamic viscosity (μ_M). The two-phase flow literature provides several models to calculate two-phase dynamic viscosity as a function of two-phase flow quality. Some of these models are listed in Table 3.6:

$$-\left(\frac{dp}{dz}\right)_f = \frac{2 f_M G^2}{D\rho_M} \tag{3.69}$$

$$Re_M = \frac{GD}{\mu_M} \tag{3.70}$$

Table 3.6 Two-Phase Dynamic Viscosity Models

Source	Correlation
McAdams et al. (1942)	$\mu_M = \left(\frac{x}{\mu_G} + \frac{1-x}{\mu_L}\right)^{-1}$
Ciccihitti et al. (1960)	$\mu_M = x\mu_G + (1-x)\mu_L$
Dukler et al. (1964)	$\mu_M = \lambda_G\mu_G + (1-\lambda_G)\mu_L$
Beattie and Whalley (1982)[a]	$\mu_M = \mu_L(1-\lambda_G)(1+2.5\lambda_G) + \lambda_G\mu_G$
Awad and Muzychka (2008) Model 1[b]	$\mu_M = \mu_L\left[\frac{2\mu_L + \mu_G - 2(\mu_L - \mu_G)x}{2\mu_L + \mu_G + 2(\mu_L - \mu_G)x}\right]$
Awad and Muzychka (2008) Model 2[b]	$\mu_M = \mu_G\left[\frac{2\mu_G + \mu_L - 2(\mu_G - \mu_L)(1-x)}{2\mu_G + \mu_L + 2(\mu_G - \mu_L)(1-x)}\right]$
Awad and Muzychka (2008) Model 3[b]	Arithmetic mean of Model 1 and Model 2
Awad and Muzychka (2008) Model 4[b]	$\mu_M = 0.25[(3x-1)\mu_G + [3(1-x)-1]\mu_L] + \sqrt{[(3x-1)\mu_G + [3(1-x)-1]\mu_L]^2 + 8\mu_L\mu_G}$

[a] Use the correlation of Colebrook (1939) to calculate two-phase friction factor.

[b] Use the correlation of Churchill (1977) to calculate two-phase friction factor.

The two-phase friction factor (f_M) is calculated using single-phase fanning friction factor correlations such as Blasius (1913) and Churchill (1977) shown in Equations 3.71 and 3.72, respectively. The Reynolds number (Re_j) is expressed for jth phase that can be gas-, liquid-, or two-phase mixture:

$$f_j = \begin{cases} 16/Re_j & : Re_j \le 2300 \\ 0.079/Re_j^{0.25} & : Re_j > 2300 \end{cases} \tag{3.71}$$

$$f_j = 2\left[\left(\frac{8}{Re_j}\right)^{12} + \frac{1}{(a+b)^{3/2}}\right]^{1/12} \tag{3.72}$$

In Equation 3.72, parameters a and b are expressed as follows:

$$a = \left[2.457 \ln\left(\frac{1}{(7/Re_j)^{0.9} + (0.27\varepsilon/D)}\right)\right]^{16} \quad \text{and} \quad b = \left(\frac{37530}{Re_j}\right)^{16}$$

Thus, the total two-phase pressure drop assuming negligible contribution of the accelerational component is calculated from Equation 3.73. Note that the frictional component of two-phase pressure drop can also be expressed in terms of wall shear stress calculated as $\tau_w = (f_M G^2)/2\rho_M$:

$$-\left(\frac{dp}{dz}\right)_t = \frac{2f_M G^2}{D\rho_M} + (\lambda_G \rho_G + (1-\lambda_G)\rho_L) g \sin\theta \tag{3.73}$$

$$= \tau_w \frac{P}{A} + \rho_M g \sin\theta \tag{3.74}$$

It is interesting to see that the two-phase frictional pressure drop calculation method based on homogeneous flow model can also be expressed in terms of two-phase frictional multiplier (Φ^2) (see Equations 3.85 through 3.88). Consider the two-phase frictional pressure drop equation of homogeneous flow model and divide it with the pressure drop equation for single-phase gas or liquid phase. The resultant equation would be the two-phase frictional multiplier. Assuming turbulent flow of each phase and using the Blasius (1913) correlation for friction factor, this two-phase frictional multiplier using homogeneous flow model approach can be casted as

$$\Phi_{LO}^2 = \frac{(dp/dz)_f}{(dp/dz)_{LO}} = \frac{2f_M G^2/(D\rho_M)}{2f_{LO} G^2/(D\rho_L)} = \frac{\rho_L}{\rho_M}\left(\frac{\mu_L}{\mu_M}\right)^{-0.25} \tag{3.75}$$

Using the definition of homogeneous two-phase mixture density given by Equation 3.67 and two-phase mixture viscosity definition of McAdams et al. (1942) (Table 3.6), Equation 3.75 would become Equation 3.76. Similarly, using the definitions for single-phase pressure drop due to flow of liquid and gas (see Equations 3.86 through 3.88), two-phase frictional multipliers Φ_L^2, Φ_{GO}^2, and Φ_G^2 using homogeneous flow models can be expressed as Equations 3.77 through 3.79, respectively:

$$\Phi_{LO}^2 = \left[(1-x) + x\frac{\mu_L}{\mu_G}\right]^{-0.25}\left[1 + x\left(\frac{\rho_L}{\rho_G} - 1\right)\right] \tag{3.76}$$

$$\Phi_L^2 = (1-x)^{-1.75}\Phi_{LO}^2 \tag{3.77}$$

$$\Phi_{GO}^2 = \left[x + (1-x)\frac{\mu_G}{\mu_L}\right]^{-0.25}\left[x + (1-x)\frac{\rho_G}{\rho_L}\right] \tag{3.78}$$

$$\Phi_G^2 = x^{-1.75}\Phi_{GO}^2 \tag{3.79}$$

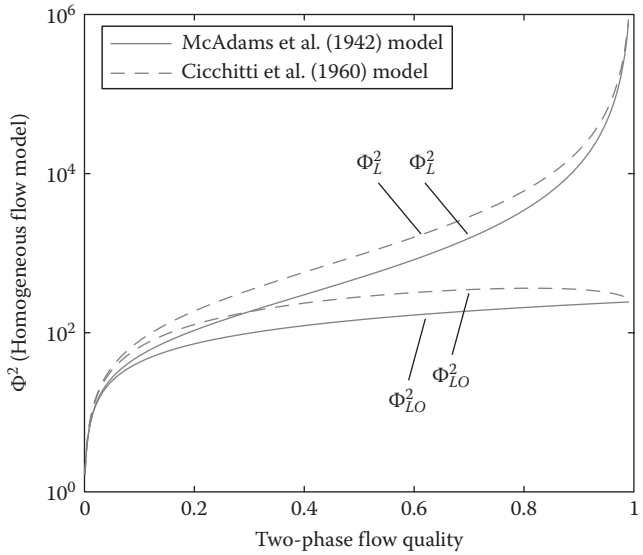

Figure 3.27

Two-phase frictional multiplier based on homogeneous flow model.

It must be mentioned here that the physical form of homogeneous flow model-based two-phase frictional multiplier derived in the aforementioned equations depends on the selection of friction factor and two-phase dynamic viscosity model. For instance, the use of the two-phase dynamic viscosity model of Ciccihitti et al. (1960) would render a different form of two-phase frictional multiplier. The comparison between Φ_{LO}^2 and Φ_L^2 using the dynamic viscosity models of McAdams et al. (1942) and Ciccihitti et al. (1960) is presented in Figure 3.27. Based on the trends of Φ_{LO}^2 and Φ_L^2 using homogeneous flow model, some discrepancies between these theoretical trends and reality can be highlighted. The trend of Φ_{LO}^2 shows a rapid increase with increase in two-phase flow quality up to $x \approx 0.1$ and thereafter increases slowly with increase in quality. Comparatively, Φ_L^2 increases rapidly for both lower and higher values of two-phase flow quality. In reality, Φ_{LO}^2 or Φ_L^2 may not exhibit a continuous increasing trend but rather show an inflection point close to higher values of $x \approx 0.7 - 0.9$ (see Figure 3.21). It must be noted that the two-phase pressure drop calculation based on homogeneous flow model is appropriate for bubbly and annular mist region that to a good extent exhibits homogeneous flow characteristics. The use of these models for intermittent, stratified, and annular flow regimes may result into significant deviations from the actual two-phase flow conditions.

3.4.7.2 Separated Flow Model

As mentioned earlier, SFM assumes two phases to flow separately and share a definite and continuous interface between them, and unlike homogeneous flow model, it considers the slippage at the gas–liquid interface. Thus, using two-phase SFM, the two-phase mixture density and hence the two-phase hydrostatic pressure drop calculation are based on the void fraction as given by Equation 3.80 where the two-phase mixture density is $\rho_M = \alpha_G\rho_G + (1 - \alpha_G)\rho_L$:

$$-\left(\frac{dp}{dz}\right)_h = \rho_M g \sin\theta = (\alpha_G\rho_G + (1-\alpha_G)\rho_L)g\sin\theta \tag{3.80}$$

It is of interest to check the agreement between the calculated values of two-phase mixture density considering the interfacial slippage (SFM approach) and assuming no slip at the gas–liquid interface (HFM approach). It is clear from Figure 3.28 that the agreement between the two methods is valid only for $\lambda < 0.2$ and $\lambda \to 1$. These two conditions approximately correspond to the bubbly and annular mist types of the flow where to some extent two-phase flow may exhibit homogeneous flow characteristics.

The accelerational component of two-phase pressure drop is expressed by Equation 3.81. This expression is valid for all but annular flow pattern with considerable liquid entrainment. In particular, for annular flow,

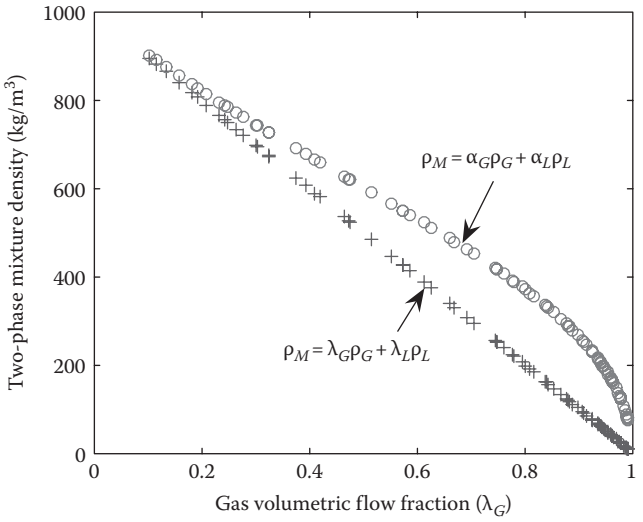

Figure 3.28

Two-phase mixture density calculation using a homogeneous and separated flow model.

when the entrainment of liquid droplets into the central gas core is significant, the error associated with the assumption of negligible accelerational pressure drop can be severe. In case of annular flow with liquid entrainment, the process of entrainment also contributes to the two-phase pressure drop and hence cannot be ignored. For such a specific case (annular flow with liquid entrainment), Equation 3.81 can be expressed in the form of Equation 3.82:

$$-\left(\frac{dp}{dz}\right)_a = G^2 \frac{d}{dz}\left[\frac{x^2}{\alpha_G \rho_G} + \frac{(1-x)^2}{(1-\alpha_G)\rho_L}\right] \tag{3.81}$$

$$-\left(\frac{dp}{dz}\right)_a = G^2 \frac{d}{dz}\left[\frac{x^2}{\alpha_G \rho_G} + \frac{(1-E)^2(1-x)^2}{\beta \rho_L} + \frac{E^2(1-x)^2}{(1-\alpha_G-\beta)\rho_L}\right] \tag{3.82}$$

The volume fraction occupied by the liquid film (β) defined by Equation 3.83 does not consider the fraction of liquid droplets entrained in the gas core and hence may not be confused with liquid holdup (α_L). However, it is evident that under the condition of $E \approx 0$, the volume fraction of liquid film is equal to the liquid holdup, that is, $\beta = \alpha_L$. Equation 3.83 is based on a valid assumption that entrained liquid droplets travel at a velocity same as that of the gas:

$$\beta = 1 - \alpha_G - \frac{\alpha_G E(1-x)}{x(\rho_L/\rho_G)} \tag{3.83}$$

It must be reiterated that this is required only in case of annular flow with considerable liquid entrainment. For the case of annular flow at low system pressures ($E \approx 0$) and at flow patterns other than annular flow ($E = 0$), it is simplified back to Equation 3.81 such that the accelerational pressure drop at a given location can be determined based on void fraction and mass flux of each phase. For the case of adiabatic two-phase flow over a short pipe length, two-phase flow quality and void fraction can be assumed to remain constant and hence $(dp/dz)_a \approx 0$.

Finally, the frictional component of two-phase pressure drop is calculated as

$$\left(\frac{dp}{dz}\right)_f = \Phi_j^2 \left(\frac{dp}{dz}\right)_j \tag{3.84}$$

The two-phase frictional multiplier Φ^2 can be expressed in several different forms depending upon the assumption of flow of either single phase through the pipe. Broadly, four different cases of two-phase

frictional multiplier can be defined as shown in Equations 3.85 through 3.88. In these equations, single-phase pressure drop is the single-phase frictional drop unless otherwise specified and $(dp/dz)_f$ would always represent the frictional component of the two-phase pressure drop:

$$\left(\frac{dp}{dz}\right)_f = \Phi_{LO}^2 \left(\frac{dp}{dz}\right)_{LO} \quad \text{where} \left(\frac{dp}{dz}\right)_{LO} = \frac{2f_L G^2}{D\rho_L} \tag{3.85}$$

$$\left(\frac{dp}{dz}\right)_f = \Phi_{L}^2 \left(\frac{dp}{dz}\right)_{L} \quad \text{where} \left(\frac{dp}{dz}\right)_{L} = \frac{2f_L G^2(1-x)^2}{D\rho_L} \tag{3.86}$$

$$\left(\frac{dp}{dz}\right)_f = \Phi_{GO}^2 \left(\frac{dp}{dz}\right)_{GO} \quad \text{where} \left(\frac{dp}{dz}\right)_{GO} = \frac{2f_G G^2}{D\rho_G} \tag{3.87}$$

$$\left(\frac{dp}{dz}\right)_f = \Phi_{G}^2 \left(\frac{dp}{dz}\right)_{G} \quad \text{where} \left(\frac{dp}{dz}\right)_{G} = \frac{2f_G G^2 x^2}{D\rho_G} \tag{3.88}$$

The two-phase literature provides several frictional pressure drop correlations based on these different two-phase frictional multipliers. One of the first such correlations is proposed by Lockhart and Martinelli (1949). Their correlation expresses two-phase frictional multipliers Φ_L^2 and Φ_G^2 as a function of X parameter and is expressed by Equation 3.89. The parameter (X) of Lockhart and Martinelli (1949) is given by Equation 3.90 where the single-phase friction factors (f_L and f_G) are found using appropriate single-phase friction factors such as Equations 3.71 and 3.72. In these equations, $Re_j = Re_{SG}$ and $Re_j = Re_{SL}$ for gas and liquid phase, respectively:

$$\Phi_L^2 = 1 + C/X + 1/X^2 \quad \text{or} \quad \Phi_G^2 = 1 + CX + X^2 \tag{3.89}$$

$$X = \left[\frac{(dp/dz)_{f,L}}{(dp/dz)_{f,G}}\right]^{0.5} = \frac{1-x}{x}\left[\frac{f_L}{f_G}\frac{\rho_G}{\rho_L}\right]^{0.5} = \frac{U_{SL}}{U_{SG}}\left[\frac{f_L}{f_G}\frac{\rho_L}{\rho_G}\right]^{0.5} \tag{3.90}$$

The value of C used in Equation 3.89 given by Chisholm (1967) is given in Table 3.7, and it depends on the laminar or turbulent nature of the gas and liquid phase, respectively. The graphical form of Equation 3.89 for laminar and turbulent regimes of single-phase flow of gas and liquid phase is illustrated in Figure 3.29. Apart from the correlation of Lockhart and Martinelli (1949), there are several other correlations for two-phase frictional multiplier that could be used to determine the frictional component of the two-phase pressure drop. Some of these correlations valid for a wide range of two-phase flow conditions are listed as follows.

Chisholm (1973) proposed a method to calculate two-phase frictional pressure drop in adiabatic and evaporating flow conditions based on the concept of SFM and applicable for vapor qualities $0 \le x \le 1$. The two-phase friction multiplier is expressed as shown in Equation 3.91, where Y is defined by Equation 3.92:

$$\Phi_{LO}^2 = 1 + (Y^2 - 1)\left(B_s x^{0.875}(1-x)^{0.875} + x^{1.75}\right) \tag{3.91}$$

$$Y = \sqrt{\frac{(dp/dz)_{GO}}{(dp/dz)_{LO}}} \tag{3.92}$$

Table 3.7 Values of Constant C to Be Used in the Correlation of Lockhart and Martinelli (1949) for Different Single-Phase Flow Regimes

Liquid Phase	Gas Phase	C
Turbulent (t)	Turbulent (t)	20
Laminar (l)	Turbulent (t)	12
Turbulent (t)	Laminar (l)	10
Laminar (l)	Laminar (l)	5

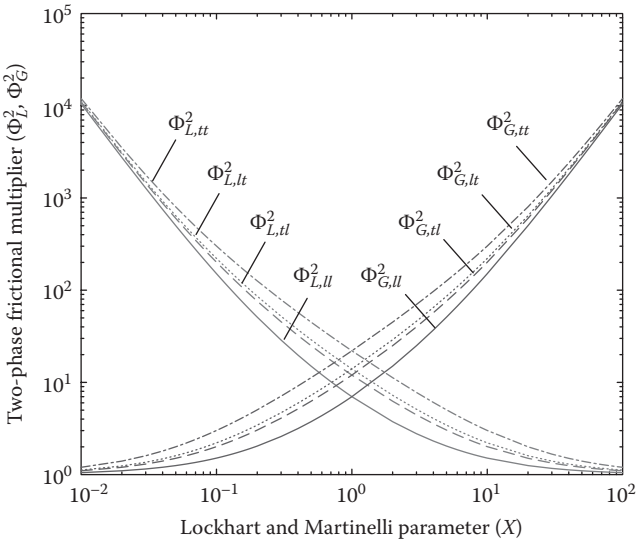

Figure 3.29

Graphical representation of different forms of two-phase frictional multiplier given by Lockhart and Martinelli (1949).

The frictional pressure gradients for single-phase liquid and gas phase are calculated using Equations 3.85 and 3.87, respectively. His correlation is essentially a transformation of graphical solution of Barcozy (1966) to predict the two-phase frictional pressure drop. The correlation is claimed to be applicable for a pressure range of 0.6–4 MPa. Chisholm (1973) proposed a set of different conditional equations to predict parameter B_s for different values of Y and mixture mass flux (G) as shown in Table 3.8.

Muller-Steinhagen and Heck (1986) developed a correlation to extrapolate between single-phase liquid and single-phase gas flow. This correlation can be used for both adiabatic and evaporating two-phase flow conditions (provided the two-phase flow quality distribution across the pipe length is known). The physical form of the correlation is as shown in Equation 3.93. The parameter Y is the same as that defined by Chisholm (1973) in Equation 3.92. The correlation is verified against 9300 measurements including data of air–oil, air–water, and steam–water fluid combinations and pipe diameters ranging from 4 to 39 mm I.D. The application of Equation 3.93 is restricted to $Re_{LO} > 100$ and $Y^2 > 1$. Note that for the determination of single-phase friction factor f_j, their correlation separates single-phase laminar and turbulent regions using a threshold value of $Re_j = 1187$ where "j" can be gas or liquid phase:

$$\Phi_{LO}^2 = Y^2 x^3 + (1-x)^{0.33}(1+2x(Y^2-1)) \tag{3.93}$$

Recently, Xu and Fang (2012) have proposed a two-phase frictional pressure drop correlation for evaporating two-phase flow of refrigerants in horizontal pipe. Their correlation is based on 2622 data points

Table 3.8 Values of Parameter B_s Used in the Correlation of Chisholm (1973)

Y	G (kg/m²s)	Equation for B_s
$0 < Y < 9.5$	$G \geq 1900$	$B_s = 55/\sqrt{G}$
	$500 < G < 1900$	$B_s = 2400/G$
	$500 > G$	$B_s = 4.8$
$9.5 < Y < 28$	$G \leq 600$	$B_s = 520/(Y\sqrt{G})$
	$G \geq 600$	$B_s = 21/Y$
$Y > 28$		$B_s = 15{,}000/(Y^2\sqrt{G})$

of 14 refrigerants (R11, R12, R22, R134a, R32, R407C, R507, R507A, R410A, CO_2, R404A, R32/R125, R123, and ammonia) for $1 < D_h < 19$ mm (circular and rectangular pipe geometries) and $25 < G < 1150$ kg/m^2 s. They found that the pipe hydraulic diameter and gas–liquid interface surface tension affect the two-phase frictional pressure drop significantly than any other two-phase flow parameter, and hence, their correlation accounts for these two variables through the inclusion of nondimensional Laplace number. The physical form of their correlation is as expressed in

$$\Phi_{LO}^2 = \left[Y^2 x^3 + (1-x)^{0.33} \left(1 + 2x(Y^2 - 1)\right) \right] \left(1 + 1.54(1-x)^{0.5} La\right) \tag{3.94}$$

In this equation, Y is calculated from Equation 3.92, while La is the Laplace number defined by Equation 3.53. Their correlation is claimed to predict the two-phase frictional pressure drop data with a mean absolute relative deviation of 25.2%. It should be noted that Xu and Fang (2012) recommend the use of the correlation of Fang et al. (2011) to calculate single-phase Darcy friction factor (4× fanning friction factor), and hence, the single-phase liquid pressure drop required in Equation 3.85 must be changed to $(dp/dz)_f = f_L G^2/(2D\rho_L)$. The correlation of Fang et al. (2011) for single-phase Darcy friction factor is reported in

$$f_{LO} = 0.25 \left[\log\left(\frac{150.39}{Re_{LO}^{0.98865}} - \frac{152.66}{Re_{LO}} \right) \right]^{-2} \tag{3.95}$$

For mini-/microchannels having pipe diameters in the range of 0.1–6 mm, Zhang et al. (2010) proposed a two-phase frictional pressure drop correlation (for adiabatic two-phase flow) based on the experimental data of two-phase flow of refrigerants, air–water and air–ethanol. Their correlation for two-phase frictional multiplier is the same as that of Lockhart and Martinelli (1949) (see Equation 3.89), however with the parameter C as a variable given by

$$C = \begin{cases} 21[1 - \exp(-0.674/La)] \text{ (two-component two-phase flow)} \\ 21[1 - \exp(-0.142/La)] \text{ (one-component two-phase flow)} \end{cases} \tag{3.96}$$

3.4.7.3 Two-Phase Friction Factor Models

In addition to homogeneous and SFMs, the two-phase literature also reports two-phase friction factor models of empirical nature. Although these models provide two-phase friction factor, they are different from two-phase friction factors used in homogeneous flow models. Some of the recent correlations developed for determining two-phase friction factors are that of Shannak (2008) and Cioncolini et al. (2009). The two-phase Darcy friction factor correlation (4× fanning friction factor) of Shannak (2008) is developed based on data for both boiling and nonboiling two-phase flow and accounts for the pipe wall surface roughness. His correlation requires the determination of modified two-phase flow Reynolds number (Re_M) given by Equation 3.97. Based on this two-phase mixture Reynolds number, the two-phase friction factor (f_M) is defined using the correlation of Chen (1979) given by Equation 3.98. The two-phase frictional pressure drop is calculated using the modified form of Equation 3.69 expressed as $(dp/dz)_f = f_M G^2/(2D\rho_M)$ where ρ_M is the homogeneous mixture density defined by Equation 3.67. Equation 3.98 is verified against 16,000 data consisting of the entire range of two-phase flow quality, pipe diameters in the range of 3–150 mm, system pressure in the range of 0.1–17 MPa, and two-phase mixture mass flux in the range of 15–8200 kg/m^2 s:

$$Re_M = \frac{GD\left(x^2 + (1-x)^2 \rho_G/\rho_L\right)}{\mu_G x + \mu_L (1-x)\rho_G/\rho_L} \tag{3.97}$$

$$\frac{1}{\sqrt{f_M}} = -2\log\left[\frac{\varepsilon}{3.7065D} \frac{5.0452}{Re_M} \log\left(\frac{1}{2.2857} \left(\frac{\varepsilon}{D} \right)^{1.1098} + \frac{5.8506}{Re_M^{0.8981}} \right) \right] \tag{3.98}$$

Since Shannak (2008) correlation is based on two-phase mixture Reynolds number and uses Equation 3.67 to find two-phase mixture density, Equation 3.66 based on homogeneous flow model should be used to determine the hydrostatic component of the two-phase pressure drop.

Another two-phase friction factor correlation developed exclusively for the annular flow is given by Cioncolini et al. (2009). The two-phase friction factor (f_M) given by Equation 3.99 is modeled as a function of core Weber number (We_c) and liquid film Reynolds number (Re_{LF}) given by Equations 3.100 and 3.101, respectively. The core mass flux (G_c), core density (ρ_c), and core diameter (D_c) are defined using Equations 3.102 through 3.104, respectively. Appropriate void fraction (see Section 3.3.4) and liquid entrainment fraction E (see Section 3.6.1) correlation developed for the annular flow must be used in the calculation of parameters G_c, ρ_c, and D_c. Note that the expression recommended by Cioncolini et al. (2009) for two-phase frictional pressure drop in the form of Equation 3.105 is based on gas core mass flux (G_c) and core density (ρ_c). Unlike Shannak (2008) correlation, Cioncolini et al. (2009) recommend the use of Equations 3.80 and 3.82 based on SFM to determine the total two-phase pressure drop:

$$f_M = \begin{cases} 0.172 We_c^{-0.372} & : D > 3\,\text{mm} \\ 0.0196 We_c^{-0.372} Re_{LF}^{0.318} & : D \le 3\,\text{mm} \end{cases} \tag{3.99}$$

$$We_c = \frac{G_c^2 D_c}{\rho_c \sigma} \tag{3.100}$$

$$Re_{LF} = \frac{(1-E)(1-x)GD}{\mu_L} \tag{3.101}$$

$$G_c = \frac{4\dot{m}[x + E(1-x)]}{\pi D_c^2} \tag{3.102}$$

$$\rho_c = \frac{x + E(1-x)}{(x/\rho_G) + (E(1-x)/\rho_L)} \tag{3.103}$$

$$D_c = D\alpha_G^2 \sqrt{1 + E\left(\frac{1-x}{x}\right)\frac{\rho_G}{\rho_L}} \tag{3.104}$$

$$-\left(\frac{dp}{dz}\right)_f = \frac{2 f_M G_c^2}{\rho_c D} \tag{3.105}$$

The two-phase pressure drop models listed in this section are some of the relatively good performing correlations validated over a fairly comprehensive range of two-phase flow conditions. The accuracy of these correlations could be up to ±50% compared to actual operating conditions. Considering the difficulty in modeling two-phase pressure drop as a function of several two-phase flow variables, this range of accuracy has received acceptance in the two-phase flow community. All the correlations presented in this section are found to work well for all but stratified flow pattern. In the following section, we will present stratified flow pattern–specific mechanistic and semimechanistic models to estimate void fraction and two-phase pressure drop.

3.5 Modeling of Stratified Flow

As mentioned earlier, stratified flow pattern in horizontal and downward pipe inclinations has a peculiar flow structure, and it is practically difficult to accurately model it with existing flow pattern–independent two-phase flow models. Apparently, the stratified flow pattern needs to be modeled using mechanistic

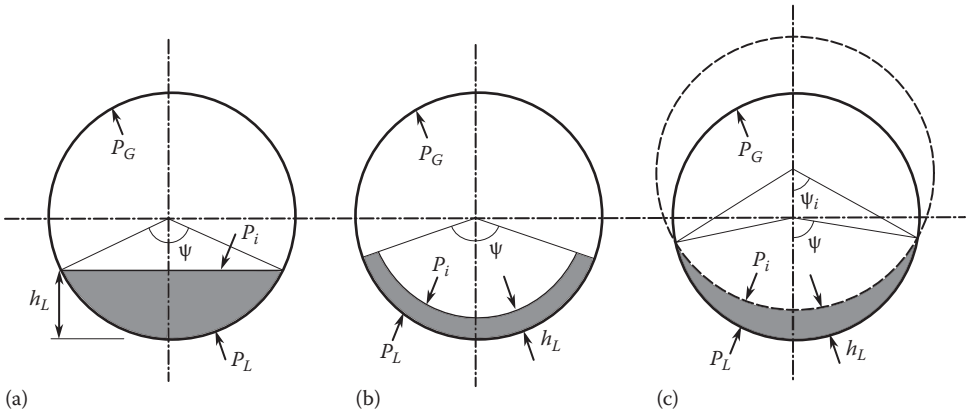

Figure 3.30

Geometry considerations in different types of stratified flow models. (a) Flat surface model. (From Taitel, Y. and Dukler, A.E., *AIChE J.*, 22, 47, 1976.) (b) Apparent rough surface model. (From Hart, J. et al., *Int. J. Multiphase Flow*, 15, 947, 1989.) (c) Double circle model. (From Chen, X.T. et al., *J. Energy Resour. Technol.*, 119, 209, 1997.)

flow model approach introduced by Taitel and Dukler (1976) and its derivatives. In addition to Taitel and Dukler (1976) model, the two-phase literature also reports semimechanistic models such as apparent rough surface (*ARS*) model and "double circle model" to calculate void fraction and two-phase pressure drop in stratified two-phase flow. It must be mentioned that the ARS and double circle models are developed only for stratified flow in horizontal pipe orientation and needs to be scrutinized against stratified flow data in downward pipe inclinations. This section describes step-by-step procedure involved in solving the stratified flow model using these three different methods. The schematics of the type (shape) of gas–liquid interface associated with each of these methods are illustrated in Figure 3.30.

3.5.1 Taitel and Dukler (1976) Model

The Taitel and Dukler (1976) model also known as "flat surface model" is developed for stratified flow at equilibrium, and as its name suggests, it assumes a flat interface between the gas and the liquid phase. It also assumes that the gas–liquid interface is smooth and that the interfacial friction factor is equal to the gas-phase friction factor. Their model considers the stratified flow of the pattern shown in Figure 3.31. The momentum balance equations for each phase (gas and liquid) could be written as shown in Equations 3.106 and 3.107. These equations also show the simplified forms of these momentum balance equations under the assumption of negligible acceleration of each phase and constant liquid level (height) along the pipe length. Considering that the pressure drop in the gas phase is equal to the pressure drop in the liquid phase, the momentum balance equations written for individual phases can be combined together to form Equation 3.108. The individual phase and interfacial shear stress required in Equation 3.108 are calculated using Equation 3.109 where the single-phase friction factor for individual phase ($j = G, L$) is calculated from Equation 3.110:

$$-A_G\left(\frac{dp}{dz}\right) = \tau_{wG}P_G + \tau_i P_i + A_G\rho_G g\left(\sin\theta - \cos\theta\frac{d}{dz}(1-h_L)\right) - A\frac{d}{dz}(GxU_G)$$
$$= \tau_{wG}P_G + \tau_i P_i + A_G\rho_G g\sin\theta \tag{3.106}$$

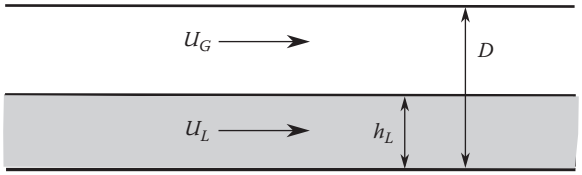

Figure 3.31

Schematic of horizontal stratified flow at equilibrium.

$$-A_L\left(\frac{dp}{dz}\right)=\tau_{wL}P_L-\tau_iP_i+A_L\rho_Lg\left(\sin\theta-\cos\theta\frac{dh_L}{dz}\right)-A\frac{d}{dz}(G(1-x)U_L)$$
$$=\tau_{wL}P_L-\tau_iP_i+A_L\rho_Lg\sin\theta \tag{3.107}$$

$$\tau_{wL}\frac{P_L}{A_L}-\tau_{wG}\frac{P_G}{A_G}-\tau_iP_i\left(\frac{1}{A_L}+\frac{1}{A_G}\right)+(\rho_L-\rho_G)g\sin\theta=0 \tag{3.108}$$

The interfacial friction factor (f_i) is assumed to be equal to the gas-phase friction factor (f_G). The gas- and liquid-phase Reynolds number are based on the actual phase velocity and the hydraulic pipe diameters (based on the area occupied by each phase) expressed as $Re_G = (\rho_G D_G U_G)/\mu_G$ and $Re_L = (\rho_L D_L U_L)/\mu_L$, respectively. The hydraulic diameters are calculated from Equation 3.111 where the area occupied by gas (A_G) and liquid (A_L) phase is defined by Equation 3.112. Considering the flat gas–liquid interface geometry of the Taitel and Dukler (1976) model, the wetted perimeter of pipe occupied by the gas (P_G) and liquid (P_L) phase and the interface (P_i) is expressed by Equation 3.113:

$$\tau_{wG}=\frac{f_G\rho_GU_G^2}{2},\quad \tau_{wL}=\frac{f_L\rho_LU_L^2}{2},\quad \tau_i=\frac{f_i\rho_G(U_G-U_L)^2}{2} \tag{3.109}$$

$$f_j=\begin{cases}16/Re_j & :(Re_j\le 2300)\\ 0.046Re_j^{-0.2} & :(Re_j>2300)\end{cases} \tag{3.110}$$

$$D_G=\frac{4A_G}{P_G+P_i},\quad D_L=\frac{4A_L}{P_L} \tag{3.111}$$

$$A_G=\alpha_G\frac{\pi D^2}{4},\quad A_L=(1-\alpha_G)\frac{\pi D^2}{4} \tag{3.112}$$

$$P_L=\frac{\Psi D}{2},\quad P_G=\pi D-P_L,\quad P_i=\sin\left(\frac{\Psi}{2}\right)D \tag{3.113}$$

$$\alpha_G=1-\frac{\Psi-\sin\Psi}{2\pi} \tag{3.114}$$

$$\Psi=2\arccos\left(1-\frac{2h_L}{D}\right) \tag{3.115}$$

The void fraction, liquid height, and the angle subtended by the flat interface with the pipe centerline are correlated with each other in the form of Equations 3.114 and 3.115. The liquid height (h_L) required in calculation of Ψ can be obtained using graphical solution presented in Figure 3.8. Alternatively, Equations 3.106 through 3.114 are to be solved iteratively until Equation 3.108 is satisfied. The void fraction value that satisfies Equation 3.108 is then used to calculate actual phase velocities, hydraulic diameters, Reynolds number, friction factors, and subsequently the shear stress values. Finally, Equation 3.106 or 3.107 is solved to obtain the frictional pressure gradient.

3.5.2 Apparent Rough Surface Model

The concept of ARS model was first introduced by Hamersma and Hart (1987) and Hart et al. (1989) for wavy stratified two-phase flow in horizontal pipes and is in the form of gas pressure drop equation using

two-phase friction factor. This two-phase friction factor (f_{TP}) is based on the gas (f_G) and interfacial (f_i) friction factors weighted by the fraction of pipe circumference (ϕ) wetted by the liquid phase. The following step-by-step approach needs to be followed to determine the values of α_G, f_G, f_i, ϕ, and f_{TP} and finally the two-phase frictional pressure drop using the ARS model:

1. First, calculate the void fraction using

$$\frac{1-\alpha_G}{\alpha_G} = \frac{U_{SL}}{U_{SG}}\left[1+\left(108 Re_{SL}^{-0.726}\frac{\rho_L}{\rho_G}\right)^{0.5}\right] \tag{3.116}$$

2. Calculate fraction of the pipe circumference (ϕ) wetted by the liquid phase using Equation 3.117. It must be noted that ϕ is the fraction of circumference and not the angle formed by the pipe centerline with the gas–liquid interface (Ψ). The relation between ϕ and Ψ can be expressed as, $\phi = \Psi/2\pi$:

$$\phi = 0.52(1-\alpha_G)^{0.374} + 0.26\left(\frac{\rho_L U_L^2}{(\rho_L-\rho_G)gD}\right)^{0.58} \tag{3.117}$$

3. Calculate interfacial friction factor (f_i) using Equation 3.118, where ε is the interfacial roughness:

$$f_i = \left.\frac{0.0625}{\left[\log\left(\frac{15}{Re_G}+\frac{\varepsilon}{3.715D}\right)\right]^2}\right\} \quad \text{where } \varepsilon = \frac{2.3D(1-\alpha_G)}{4\phi} \tag{3.118}$$

4. From Equation 3.119, calculate the gas-phase friction factor (f_G) based on gas-phase Reynolds number as a function of actual gas velocity ($Re_G = (\rho_G U_G D)/\mu_G$):

$$f_G = \left.\frac{0.07725}{(\log(Re_G/7))^2}\right\} \quad 2100 < Re_G < 10^8 \tag{3.119}$$

5. The two-phase friction factor is then calculated using

$$f_{TP} = f_G(1-\phi) + f_i\phi \tag{3.120}$$

6. Finally, the two-phase pressure drop based on two-phase friction factor is calculated from Equation 3.121. Note that Equation 3.121 uses actual gas-phase velocity (U_G) and not the superficial gas velocity (U_{SG}):

$$-\left(\frac{dp}{dz}\right)_f = \frac{2f_{TP}\rho_G U_G^2}{D} \tag{3.121}$$

3.5.3 Double Circle Model

Double circle model is a mechanistic model proposed by Chen et al. (1997), which considers the concave shape of the gas–liquid interface by using the geometrical intersection of a hypothetical circle with the pipe centerline (see Figure 3.30). Compared to the ARS model, the shape of gas–liquid interface used by double circle model is more realistic and the overall model is based on the mechanistic model of Taitel and Dukler (1976). To begin with, the use of Chen et al. (1997) model requires the determination of Ψ and Ψ_i in radians.

Note that the subtended angle (Ψ) used by Chen et al. (1997) is half of that used by Taitel and Dukler (1976) and ARS models. The following step-by-step procedure is required to solve for void fraction and frictional pressure drop using double circle model:

1. Calculate the angle subtended by the liquid phase with the pipe centerline using the relationship $\Psi = \pi\phi$ where the fraction of pipe circumference wetted by the liquid phase is obtained by Equation 3.117 (same as the ARS model).
2. Once the angle Ψ is known, the angle Ψ_i is calculated from Equation 3.122 using iterative technique. The value of void fraction required in this equation is a guess value obtained by solving for the Taitel and Dukler (1976) flat surface model:

$$\Psi_i = \left(\frac{\sin\Psi_i}{\sin\Psi}\right)^2 \left(\Psi + \frac{\sin^2\Psi}{\tan\Psi_i} - \frac{\sin 2\Psi}{2} - \pi(1-\alpha_G)\right) \tag{3.122}$$

3. Next, the diameter of offset circle (D_i) is determined from

$$D_i = D\frac{\sin\Psi}{\sin\Psi_i} \tag{3.123}$$

4. The perimeter of pipe occupied by the gas and liquid phase and the gas–liquid interface is determined from Equation 3.124. The calculation of the hydraulic diameters (D_G and D_L) and the area occupied by each phase (A_G and A_L) is the same as that given by Equations 3.111 and 3.112:

$$P_G = (\pi - \Psi)D, \quad P_L = \Psi D, \quad P_i = \Psi_i D_i \tag{3.124}$$

5. Interfacial friction factor is calculated using Equation 3.125 where the superficial gas velocity during smooth to wavy stratified flow transition is defined by Equation 3.126. Friction factors for gas (f_G) and liquid (f_L) phase are obtained using the procedure similar to Taitel and Dukler (1976) model, that is, Equation 3.110.

$$\frac{f_i}{f_G} = 1 + 3.75\left(\frac{1-\alpha_G}{\phi}\right)^{0.2}\left(\frac{U_{SG}}{U_{SG,t}} - 1\right)^{0.08} \tag{3.125}$$

$$U_{SG,t} = \sqrt{\frac{4\nu_L(\rho_L - \rho_G)g}{0.06\rho_G U_L}} \tag{3.126}$$

6. Solve for Equation 3.108 by updating the values of void fraction until convergence is obtained.
7. Use converged value of void fraction obtained from step 6 to calculate for two-phase pressure drop using Equation 3.106 or 3.107.

Note that for a quick convergence, the initial guess of void fraction required to calculate actual phase velocities, hydraulic diameters, and Ψ_i is calculated from the Taitel and Dukler (1976) model. It must be mentioned that the double circle method is more complex than the Taitel and Dukler (1976) and ARS models since it involves two iterative solutions for α_G and Ψ_i. The following example problem provides an overview of the procedure required to solve for void fraction and pressure drop in two-phase stratified flow.

Example Problem 3.1

Consider the horizontal two-phase flow of air and water in a 78 mm I.D. smooth polycarbonate pipe. The gas- and liquid-phase superficial velocities are 20 and 0.04 m/s, respectively. Assuming the stratified flow pattern to exist, determine the void fraction and two-phase frictional pressure drop using

(a) Taitel and Dukler (1976) (flat surface), (b) ARS, and (c) double circle models. The physical properties of gas and liquid phase can be taken as follows:

Property	Air	Water
Density	1.2 kg/m^3	998 kg/m^3
Dynamic viscosity	18.5×10^{-6} Pa s	0.001 Pa s

Solution

(a) Calculation of void fraction and pressure drop using Taitel and Dukler (1976) method: First, calculate the Reynolds number based on superficial velocity of gas and liquid phase. The single-phase friction factors for smooth pipe are found using appropriate friction factor correlation such as that of Blasius (1913) (see Equation 3.71):

$$Re_{SG} = \frac{\rho_G U_{SG} D}{\mu_G} = \frac{1.2 \times 20 \times 0.078}{18.5 \times 10^{-6}} = 1.012 \times 10^5 \Rightarrow f_G = 0.00448$$

$$Re_{SL} = \frac{\rho_L U_{SL} D}{\mu_L} = \frac{998 \times 0.04 \times 0.078}{0.001} = 3113.7 \Rightarrow f_L = 0.0107$$

Now calculate single-phase pressure drop (based on superficial phase velocity) for each phase and hence X parameter from Equation 3.90. The single-phase pressure drop calculation for each phase using Equations 3.88 and 3.86 is shown as follows:

$$-\left(\frac{dp}{dz}\right)_G = \frac{2 f_G \rho_G U_{SG}^2}{D} = \frac{2 \times 0.00448 \times 1.2 \times 20^2}{0.078} = 55.14 \text{ Pa/m}$$

$$-\left(\frac{dp}{dz}\right)_L = \frac{2 f_L \rho_L U_{SL}^2}{D} = \frac{2 \times 0.0107 \times 998 \times 0.04^2}{0.078} = 0.438 \text{ Pa/m}$$

$$\therefore X = \sqrt{\frac{(dp/dz)_L}{(dp/dz)_G}} = \sqrt{\frac{0.438}{55.14}} = 0.09$$

For horizontal two-phase flow, Equation 3.14 gives $Y = 0$, and using the graphical solution in Figure 3.8, the nondimensional liquid height is $h_L/D \approx 0.1$. Using this ratio of equilibrium liquid height and pipe diameter, the angle subtended by the liquid phase with pipe centerline and hence the void fraction in stratified flow is calculated using Equations 3.115 and 3.114:

$$\Psi = 2\arccos(1 - 0.2) = 73.74°(1.287^r) \Rightarrow \alpha_G = 1 - \frac{\Psi - \sin\Psi}{2\pi} = 0.948$$

This value of void fraction of 0.948 is an initial estimate of the void fraction obtained using the graphical solution. This void fraction may be further updated to satisfy Equation 3.108. Once the void fraction is determined, the actual phase velocities (see Table 3.1 for U_G and U_L), hydraulic diameters (Equation 3.111), the cross-sectional area occupied by each phase (Equation 3.112), and the wetted perimeter of each phase (Equation 3.113) are calculated as follows:

$$U_G = \frac{U_{SG}}{\alpha_G} = \frac{20}{0.948} = 21.1 \text{ m/s}, \quad U_L = \frac{U_{SL}}{1 - \alpha_G} = \frac{0.04}{1 - 0.948} = 0.77 \text{ m/s}$$

$$A_G = \alpha_G \frac{\pi D^2}{4} = 0.00453 \text{ m}^2, \quad A_L = (1 - \alpha_G)\frac{\pi D^2}{4} = 0.000248 \text{ m}^2$$

$$P_L = 0.0502 \text{ m}, \quad P_G = 0.195 \text{ m}, \quad P_i = 0.0468 \text{ m}, \quad D_G = 0.0749 \text{ m}, \quad D_L = 0.0197 \text{ m}$$

The Reynolds numbers based on actual gas and liquid-phase velocities are found to be

$$Re_G = \frac{1.2 \times (20/0.948) \times 0.0749}{18.5 \times 10^{-6}} = 1.025 \times 10^5$$

$$Re_L = \frac{998 \times (0.04/(1-0.948)) \times 0.0197}{0.001} = 15139$$

The single-phase friction factors for each phase are found using Equation 3.110:

$$f_G = 0.046(1.025 \times 10^5)^{-0.2} = 0.00457$$

$$f_L = 0.046 \times (15139)^{-0.2} = 0.00671$$

Now, the wall and interfacial shear stresses using $f_i = f_G$ are calculated using Equation 3.109:

$$\tau_{wG} = \frac{0.00457 \times 1.2 \times 21.1^2}{2} = 1.232 \text{ N/m}^2$$

$$\tau_{wL} = \frac{0.00671 \times 998 \times 0.77^2}{2} = 1.985 \text{ N/m}^2$$

$$\tau_i = \frac{0.00457 \times 1.2 \times (21.1 - 0.77)^2}{2} = 1.133 \text{ N/m}^2$$

Now solve Equation 3.108 using the known values of shear stress, wetted perimeter, and cross-sectional area occupied by each phase. For these values, Equation 3.108 is not satisfied (residual = –121.1), and hence, the value of h_L/D is updated to find a new value of void fraction and the remaining steps are repeated. Iterate through these calculations until the residual of Equation 3.108 is approximately zero. After a few iterations, it is found that Equation 3.108 is satisfied (residual = 0.008) for $h_L/D \approx 0.1117$ and $\alpha_G = 0.938$ ($\Psi = 78.1° = 1.363^r$). Finally, after the convergence of Equation 3.108, two-phase frictional pressure drop is obtained by solving either Equation 3.106 or Equation 3.107. It should be noted that the use of Equation 3.106 or 3.107 requires calculation of updated values of shear stresses (τ_{wL}, τ_{wG}, τ_i) based on updated friction factors (f_G, f_L, f_i), the cross-sectional area occupied by each phase (A_G, A_L), and wetted perimeters of each phase and the gas–liquid interface (P_G, P_L, P_i). Two-phase pressure drop calculation using Equation 3.107 is shown as follows:

$$-\left(\frac{dp}{dz}\right)_f = \tau_{wL}\frac{P_L}{A_L} - \tau_i\frac{P_i}{A_L} = 1.445\frac{0.0531}{0.000296} - 1.17\frac{0.0491}{0.000296} = 66.1 \text{ Pa/m}$$

(b) *ARS model*: Calculate void fraction using Equation 3.116 where $Re_{SL} = \rho_L U_{SL} D/\mu_L = 3113.7$:

$$\frac{1-\alpha_G}{\alpha_G} = \frac{0.04}{20}\left[1 + \left(108 \times 3113.7^{-0.726} \times \frac{998}{1.2}\right)^{0.5}\right] \Rightarrow \alpha_G = 0.966$$

Now, calculate the actual gas and liquid-phase velocities (see Table 3.1), U_G = 20.7 m/s and U_L = 1.176 m/s. The fractional wetted perimeter is calculated from Equation 3.117:

$$\phi = 0.52(1-0.966)^{0.374} + 0.26\left(\frac{998 \times 1.176^2}{(998-1.2) \times 9.81 \times 0.078}\right)^{0.58} = 0.523$$

Calculate gas Reynolds number based on the actual gas velocity:

$$Re_G = \frac{\rho_G U_G D}{\mu_G} = \frac{1.2 \times 20.7 \times 0.078}{18.5 \times 10^{-6}} = 1.046 \times 10^5$$

Using Equation 3.119, the friction factor for single-phase gas flow (f_G) is calculated as follows:

$$f_G = \frac{0.07725}{(\log(Re_G/7))^2} = \frac{0.07725}{(\log(1.046 \times 10^5)/7)^2} = 0.0044$$

The interfacial friction factor is calculated using Equation 3.118 where the interfacial roughness is $\varepsilon = 2.3D(1-\alpha_G)/4\phi = 0.00291$:

$$f_i = \frac{0.0625}{\left[\log\left(\frac{15}{Re_G} + \frac{\varepsilon}{3.715D}\right)\right]^2} = \frac{0.0625}{\left[\log\left(\frac{15}{1.046 \times 10^5} + \frac{0.00291}{3.715 \times 0.078}\right)\right]^2} = 0.0156$$

Now, from Equation 3.120, the two-phase friction factor is calculated as

$$f_{TP} = (1-\phi) f_G + \phi f_i = (1-0.523) \times 0.0044 + 0.523 \times 0.0156 = 0.01025$$

The two-phase frictional pressure drop is calculated using Equation 3.121:

$$-\left(\frac{dp}{dz}\right)_f = \frac{2 f_{TP} \rho_G U_G^2}{D} = \frac{2 \times 0.01025 \times 1.2 \times 20.7^2}{0.078} = 135.1 \text{ Pa/m}$$

(c) *Double circle model*: Initially, the angle subtended by the liquid layer with the pipe centerline is calculated using the relationship $\Psi = \pi\phi = 1.153^r$ where $\phi = 0.367$ is calculated at a void fraction of $\alpha_G = 0.938$ (converged solution of Taitel and Dukler (1976) model) using Equation 3.117. Next, the angle Ψ_i is calculated using Equation 3.122. It should be noted that the angles (Ψ and Ψ_i) used in Equation 3.122 are expressed in radians:

$$\Psi_i = \left(\frac{\sin \Psi_i}{\sin(1.153)}\right)^2 \left(1.153 + \frac{\sin^2(1.153)}{\tan \Psi_i} - \frac{\sin(2 \times 1.153)}{2} - \pi(1-0.938)\right)$$

The solution to this equation, $\Psi_i = 0.931^r$, is obtained iteratively. Now, the diameter D_i of eccentric circle is found using Equation 3.123:

$$D_i = D \frac{\sin \Psi}{\sin \Psi_i} = 0.078 \times \frac{\sin(1.153)}{\sin(0.931)} = 0.088 \text{ m}$$

The wetted perimeter of gas and liquid phase based on Ψ and that of gas–liquid interface based on Ψ_i is calculated from Equation 3.124. The calculation of hydraulic diameters is similar to that of Taitel and Dukler (1976) given by Equation 3.111:

$$P_L = 0.0899 \text{ m}, \quad P_G = 0.155 \text{ m}, \quad P_i = 0.0827 \text{ m}, \quad D_G = 0.0753 \text{ m}, \quad D_L = 0.0132 \text{ m}$$

The Reynolds number of each phase is based on actual phase velocity and hydraulic pipe diameter, and the single-phase friction factors for each phase using Equation 3.110 are calculated as follows:

$$Re_G = \frac{\rho_G U_G D_G}{\mu_G} = \frac{1.2 \times 21.3 \times 0.0753}{18.5 \times 10^{-6}} = 104{,}036$$

$$Re_L = \frac{\rho_L U_L D_L}{\mu_L} = \frac{998 \times 0.645 \times 0.0132}{0.001} = 8497$$

$$f_G = 0.046(Re_G)^{-0.2} = 0.046(104{,}036)^{-0.2} = 0.00456$$

$$f_L = 0.046(Re_L)^{-0.2} = 0.046 \times (8497)^{-0.2} = 0.00753$$

To find f_i from Equation 3.125, first, determine the superficial gas velocity corresponding to the smooth to wavy stratified flow transition ($U_{SG,t}$) from Equation 3.126:

$$U_{SG,t} = \sqrt{\frac{4 \times (0.001/998)(998 - 1.2) \times 9.81}{0.06 \times 1.2 \times 0.465}} = 0.918$$

$$f_i = 0.00456\left[1 + 3.75\left(\frac{1 - 0.938}{0.367}\right)^{0.2}\left(\frac{20}{0.918} - 1\right)^{0.08}\right] = 0.0198$$

Now, the wall and interfacial shear stresses are calculated using Equation 3.109:

$$\tau_{wG} = \frac{0.00456 \times 1.2 \times 21.3^2}{2} = 1.244 \text{ N/m}^2$$

$$\tau_{wL} = \frac{0.00753 \times 998 \times 0.645^2}{2} = 1.563 \text{ N/m}^2$$

$$\tau_i = \frac{0.0198 \times 1.2 \times (21.3 - 0.645)^2}{2} = 5.087 \text{ N/m}^2$$

Equation 3.108 is not satisfied (residual = 1083), and hence, the void fraction value is updated and all other subsequent steps are repeated. At convergence (residual = 0.002), $\alpha_G = 0.961$, $\Psi = 1.48^r$, and $\Psi_i = 1.407^r$. For the converged value of void fraction, recalculate the gas, liquid, and interfacial shear stress from Equation 3.109 and then calculate two-phase pressure drop using Equation 3.106 or 3.107. Note that these equations require updated values of shear stresses based on the converged values of void fraction. Pressure drop from Equation 3.107 is calculated as follows:

$$-\left(\frac{dp}{dz}\right)_f = \tau_{wL}\frac{P_L}{A_L} - \tau_i\frac{P_i}{A_L} = 4.277\frac{0.1156}{0.0001834} - 4.234\frac{0.1109}{0.0001834} = 135.6 \text{ Pa/m}$$

Discussion: For similar flow conditions, Badie et al. (2000) measured $\alpha_G = 0.956$ and $(dp/dz)_f = 115$ Pa/m. Note that the void fraction and frictional pressure drop obtained by solving for ARS model and double circle model are comparable to the measurements of Badie et al. (2000). The prediction of void fraction using Taitel and Dukler (1976) model is within ±2% of the measured void fraction by Badie et al. (2000). However, the frictional pressure drop calculated using Taitel and Dukler (1976) is significantly less than the experimental value. This is possibly because of the use of $f_i/f_G = 1$ in their model. The use of suitable and more realistic model for f_i/f_G in Taitel and Dukler

(1976) may yield better results. For example, the use of $f_i/f_G = 10$ recommended by Crowley et al. (1992) would give a better prediction of frictional pressure drop as 126.5 Pa/m. Conclusively, the success of these three methods in the prediction of void fraction and pressure drop in stratified two-phase flow is subject to the validity and accuracy of the closure relationships used in these models. Different forms of models for the calculation of f_i/f_G could be obtained from Ottens et al. (2001).

3.6 Modeling of Annular Flow

The annular flow structure exhibits separated flow characteristics and hence could be appropriately modeled using SFM approach. The two-phase flow literature reports several annular flow pattern–specific models to determine two-phase flow parameters such as void fraction, pressure drop, and heat transfer. Section 3.3.4 gives some of the existing correlations in the two-phase flow literature that can satisfactorily predict void fraction in annular flow. This section specifically focuses on some salient features of annular flow such as liquid entrainment fraction, film thickness, film flow rates, interfacial friction, and their interrelationships.

3.6.1 Entrainment

A peculiar phenomenon known as entrainment is observed in the annular flow due to the relative motion between the gas and the liquid phase. The entrainment process is characterized by the flow of tiny liquid droplets into the central fast-moving gas core. The liquid entrainment is a consequence of the significant shear at the gas–liquid interface that causes tearing of the liquid waves crests in the form of ligaments and depends on the phase flow rates, pipe diameter, and orientation and the surface tension at the gas–liquid interface. The liquid entrainment fraction (E) is defined as the ratio of mass flow rate/flux of liquid drops entering into the gas core to the total mass flow rate/flux of the liquid phase. Correct knowledge of the rate of liquid entrainment or alternatively the fraction of liquid entrainment is crucial in analyzing heat and mass transfer processes in annular flows. In case of boiling two-phase flows, accurate estimation of the liquid entrainment fraction is necessary in the determination of critical heat flux and dryout conditions. Ishii and Grolmes (1975) studied the different possible mechanisms responsible for liquid entrainment process. They found that liquid entrainment can happen due to any or all of the wave undercut, wave rolling, wave coalescence, and ripple shearing mechanisms. Additionally, the phenomenon of "bubble burst" due to rupture of liquid-phase crests and "droplet impingement" due to rolling waves may also contribute to the entrainment process.

The different entrainment mechanisms suggested by Ishii and Grolmes (1975) are illustrated in Figure 3.32. As shown in Figure 3.33, critical values of gas and liquid flow rates are associated with the entrainment process and below which no liquid entrainment is expected to occur. Based on the experimental data, two-phase flow literature offers several correlations to determine the nondimensional critical gas

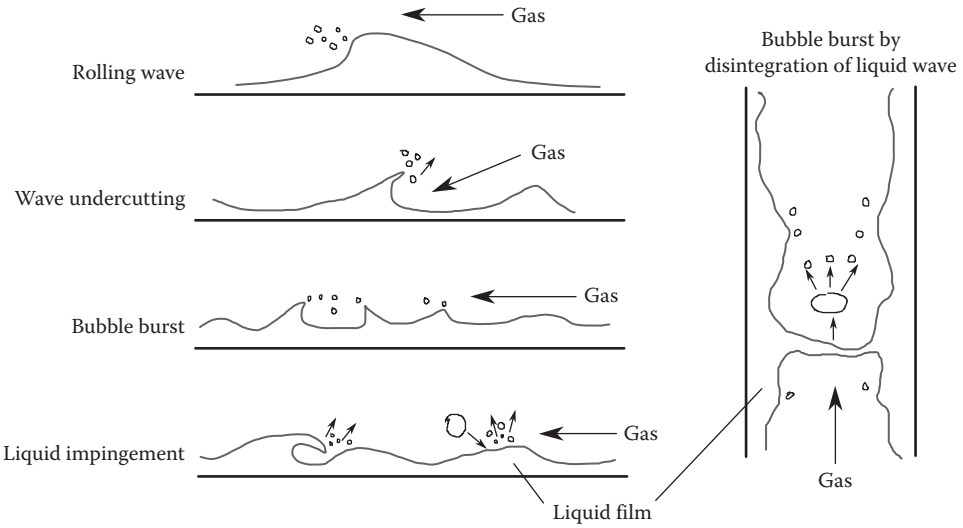

Figure 3.32

Entrainment mechanisms suggested by Ishii and Grolmes (1975).

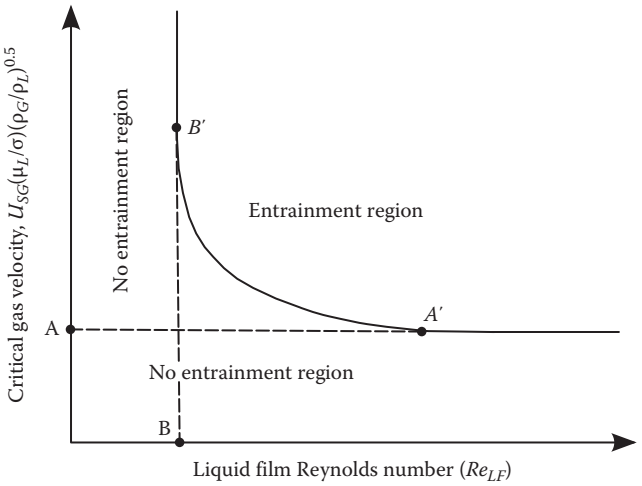

Figure 3.33

Inception criteria for entrainment. (Adapted from Ishii, M. and Grolmes, M.A., *AIChE J.*, 21, 308, 1975.)

velocity and the liquid film Reynolds (Re_{LF}) number below which the entrainment phenomenon is negligible or alternatively above which the amount of liquid entrainment is significant. Note that the Reynolds number based on liquid flowing in the form of film is defined by Ishii and Grolmes (1975) as $Re_{LF} = (4\delta U_L \rho_L)/\mu_L$ and using the concept of equivalent diameter it follows that $Re_{SL} = (\rho_L U_{SL} D)/\mu_L$. Refer to Section 3.6.2, Equation 3.138, for this identity between two forms of Reynolds number ($Re_{LF} = Re_{SL}$).

One such criterion in terms of liquid film Reynolds number proposed by Ishii and Grolmes (1975) is represented by Equation 3.127. Equation 3.127 sets the absolute limit for the inception of entrainment process and represents point *B* in Figure 3.33 below which entrainment cannot take place. Ishii and Grolmes (1975) found that at point *A*′, $Re_{LF} = 1635$ and beyond which the entrainment affected region is insensitive to the increase in liquid flow rates. The critical gas velocity for Re_{LF} greater than that by Equation 3.127 is obtained from Equation 3.128. The critical gas velocity to the left-hand side of this equation is essentially a nondimensional superficial gas velocity normalized using liquid-phase dynamic viscosity and the surface tension. Note that for Re_{LF} greater than $Re_{LF,C}$ but less than 160, critical gas velocity is independent of liquid viscosity number given by Equation 3.129:

$$Re_{LF,C} = 154.7\left(\frac{\rho_L}{\rho_G}\right)^{0.75}\left(\frac{\mu_G}{\mu_L}\right)^{1.5} \tag{3.127}$$

$$\frac{U_{SG}\mu_L}{\sigma}\sqrt{\frac{\rho_G}{\rho_L}} \geq \begin{cases} 1.5Re_{LF}^{-0.5} & : Re_{LF,C} < Re_{LF} < 160 \\ 11.78N_{\mu}^{0.8}Re_{LF}^{-0.33} & : N_{\mu} \leq 0.066, 160 \leq Re_{LF} \leq 1635 \\ 1.35Re_{LF}^{-0.33} & : N_{\mu} > 0.066, 160 \leq Re_{LF} \leq 1635 \\ N_{\mu}^{0.8} & : N_{\mu} \leq 0.066, Re_{LF} > 1635 \\ 0.1146 & : N_{\mu} > 0.066, Re_{LF} > 1635 \end{cases} \tag{3.128}$$

$$N_{\mu} = \frac{\mu_L}{(\rho_L \sigma \sqrt{\sigma/(g\Delta\rho)})^{0.5}} \tag{3.129}$$

Note that Equations 3.127 and 3.128 predict the onset of entrainment and not the magnitude of entrainment fraction. To predict the liquid entrainment fraction, Ishii and Mishima (1989) proposed a correlation applicable to air–water equilibrium annular flow. As shown in Equation 3.130, their correlation is a function of modified Weber number given by Equation 3.131. Although the correlation of Ishii and Mishima (1989) consists of nondimensional numbers as a function of fluid physical

properties, their correlation is primarily based on air–water data and its validity for other fluid combinations must be scrutinized before use:

$$E = \tanh\left(7.25\times10^{-7} We^{1.25} Re_{SL}^{0.25}\right) \left\{ \begin{array}{l} 0.1 \le p_{sys} \le 0.4\,\text{MPa} \\ 9.5 \le D \le 32\,\text{mm} \\ 370 \le Re_{SL} \le 6400 \end{array} \right. \tag{3.130}$$

$$We = \frac{\rho_G U_{SG}^2 D}{\sigma}\left(\frac{\rho_L - \rho_G}{\rho_G}\right)^{0.33} \tag{3.131}$$

Cioncolini and Thome (2012b) proposed a method to predict liquid entrainment fraction in gas–liquid annular flows. In comparison to Ishii and Mishima (1989), their correlation is based on a more comprehensive data set and is claimed to be valid for $5 \le D \le 95$ mm, $0.1 \le p_{sys} \le 20$ MPa, and for both adiabatic and evaporating flows in vertical upward flow. Recently, Bhagwat and Ghajar (2015b) have introduced a correction factor ($\xi + 120\cos^2\theta$) to the Cioncolini and Thome (2012b) correlation to improve its accuracy at high system pressures and horizontal and inclined pipe orientations. This correction factor embedded into the original correlation of Cioncolini and Thome (2012b) is expressed by Equation 3.132 where ξ is calculated from Equation 3.133. The need of a correction factor for the effect of high system pressure on liquid entrainment fraction is explained in the work by Bhagwat and Ghajar (2015b). Note that the use of Equation 3.133 requires system pressure (p_{sys}) with units of MPa. The gas core Weber number and the gas core density are calculated using Equations 3.134 and 3.135, respectively:

$$E = \left(1 + \left(\xi + 120\cos^2\theta\right) We_c^{-0.8395}\right)^{-2.209} \left\{ \begin{array}{l} 0.1 \le p_{sys} \le 20\,\text{MPa} \\ 5 \le D \le 95\,\text{mm} \\ 10 \le We_c \le 10^5 \end{array} \right. \tag{3.132}$$

$$\xi = \begin{cases} 280 & : 0.1 \le p_{sys} < 10\,\text{MPa} \\ 4637.8 \times p_{sys}^{-1.6} & : p_{sys} \ge 10\,\text{MPa} \end{cases} \tag{3.133}$$

$$We_c = \frac{\rho_c U_{SG}^2 D}{\sigma} \tag{3.134}$$

$$\rho_c = \frac{x + E(1-x)}{(x/\rho_G) + (E(1-x)/\rho_L)} \tag{3.135}$$

Equation 3.132 needs to be solved using iterative technique since the core density required in the calculation of the core Weber number depends upon the liquid entrainment fraction. Cioncolini and Thome (2012b) suggested a two-step predictor and corrector method such that the predictor method predicts the liquid entrainment fraction for an initial guess of core density approximately equal to the gas-phase density (i.e., $\rho_c \approx \rho_G$). In the corrector step, the E value from predictor step is used to calculate new value of gas core density and hence the liquid entrainment fraction. The variation of liquid entrainment fraction as a function of system pressure using the proposed modification by Bhagwat and Ghajar (2015b) to the original Cioncolini and Thome (2012b) correlation is illustrated in Figure 3.34. It is evident that at low ($We_c \le 10$) and high ($We_c \ge 10^5$) gas core Weber numbers, the effect of system pressure on liquid entrainment fraction is small. Figure 3.34 is plotted for vertical two-phase flow and can be used as a graphical solution to determine liquid entrainment fraction.

3.6.2 Triangular Relationship in Annular Flow

Triangular relationship in the annular flow in essence is a relationship between three principle dependent system parameters, that is, pressure gradient, liquid film thickness (δ), and the liquid film flow rate ($\dot{m}_{LF}$), such that if any of these two variables are known, the third unknown variable may be calculated. Although the triangular relationship forms a basis for different correlations developed for annular flow, these dependent

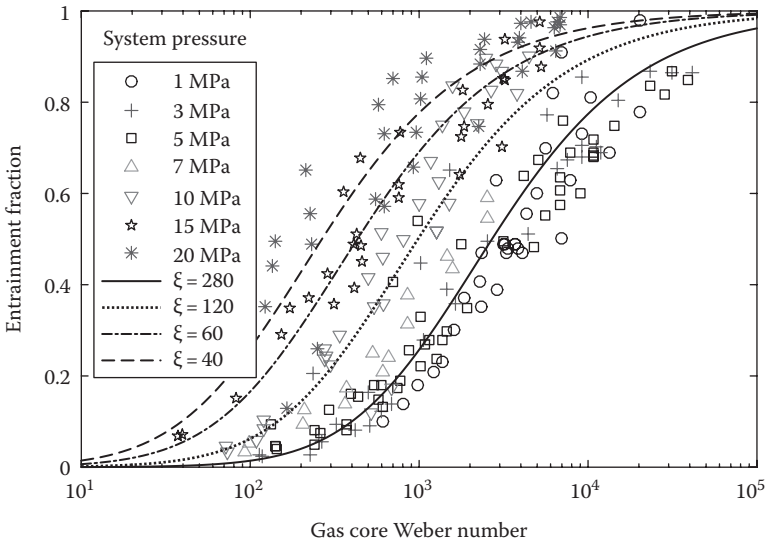

Figure 3.34

Variation of liquid entrainment fraction as a function of system pressure (trends predicted by Equation 3.132).

variables that form a triangular relationship cannot be practically calculated from the independent system parameters such as phase flow rates, fluid properties, and pipe geometry and thus further require closed-form solutions. The closed-form solutions required to form triangular relationship for the annular flow are usually in the form of equations for liquid entrainment fraction (E) and two-phase frictional multiplier (Φ^2) involving two-phase (f_{TP}) or interfacial (f_i) friction factors. This section briefly introduces the concept of triangular relationship and illustrates a step-by-step approach to calculate the system parameters in the annular flow. For more details, refer to works of Hewitt and Hall-Taylor (1970) and Collier and Thome (1996).

In order to solve for the triangular relationship, Hewitt and Hall-Taylor (1970) recommend the use of the following simplifying assumptions:

1. Film thickness is very small with respect to pipe diameter, that is, $\delta \ll D$.
2. Shear stress in liquid film is constant and equal to the wall shear stress.
3. Hydrostatic and accelerational effects on the gas core and liquid film are negligible (compared to frictional pressure drop).

Assuming axis symmetric flow, uniform film thickness, and negligible contribution of hydrostatic and accelerational pressure drops (in comparison to frictional pressure drop), the momentum balance on the liquid film in the annular flow leads to Equation 3.136 for two-phase frictional pressure drop. This two-phase frictional pressure drop is expressed in terms of actual velocity of the liquid flowing in the form of film (in contact with pipe wall) and that the liquid entrainment is negligible. Using the definition of Φ_L^2, Equation 3.86 could also be expressed as Equation 3.137:

$$-\left(\frac{dp}{dz}\right)_f = \frac{4\tau_{wL}}{D} = \frac{2f_{TP}\rho_L U_L^2}{D} \tag{3.136}$$

$$\Phi_L^2 = \frac{(dp/dz)_f}{(dp/dz)_L} = \frac{1}{(1-\alpha_G)^2}\left(\frac{f_{TP}}{f_L}\right) \tag{3.137}$$

Hewitt and Hall-Taylor (1970) have reported that using the concept of equivalent diameter and definition of void fraction under no entrainment, the Reynolds number of liquid flowing in the form of film is identical to the Reynolds number of liquid phase flowing alone through the pipe. This implies that based on identical Reynolds number defined by Equation 3.138, the friction factors of liquid flowing in the form of film and that alone through the pipe must be identical, that is, $f_{TP} = f_L$. Using this relationship,

Equation 3.137 reduces to Equation 3.139. This relationship however does not acknowledge the existence of liquid entrainment fraction that in certain practical cases may not be ignored. To account for the liquid entrainment fraction, Turner and Wallis (1965) have proposed the use of a similar relationship in which the single-phase pressure drop for the total liquid flow is replaced by the single-phase pressure drop for that part of the liquid flow that is in the form of film. The two-phase frictional multiplier suggested by Turner and Wallis (1965) is expressed by Equation 3.140 where the single-phase pressure drop of the liquid film flow is obtained from Equation 3.141:

$$\frac{\rho_L U_L 4\delta}{\mu_L} = \frac{\rho_L U_{SL} D}{\mu_L} \tag{3.138}$$

$$\Phi_L^2 = \frac{1}{(1-\alpha_G)^2} \tag{3.139}$$

$$\Phi_{LF}^2 = \frac{(dp/dz)_f}{(dp/dz)_{LF}} = \frac{1}{(1-\alpha_G)_{LF}^2} \tag{3.140}$$

$$-\left(\frac{dp}{dz}\right)_{LF} = \frac{2f_{LF}\rho_L(U_{SL}(1-E))^2}{D} = \frac{2f_{LF}(G(1-x)(1-E))^2}{D\rho_L} \tag{3.141}$$

Equation 3.140 can be considered as an empirical correlation for the determination of void fraction in the presence of liquid entrainment process; however, its implementation also requires the knowledge of two-phase frictional pressure drop. For a known or measured value of void fraction and liquid entrainment fraction, Equation 3.140 may not predict the correct magnitude of two-phase frictional pressure drop due to lack of information on the interfacial roughness and hence the interfacial shear stress. To address this issue, one more closure relationship is required that links the interfacial friction/roughness to the liquid flow rate or any other previously calculated variables such as void fraction or liquid entrainment fraction. This relationship could be obtained by considering yet another form of two-phase frictional multiplier in the form of Φ_G^2. Using similar assumptions that are used to obtain Equation 3.136, a momentum balance for gas core is used to obtain Equation 3.142. Using Equation 3.142, the two-phase frictional multiplier (Φ_G^2) assuming only gas phase flowing through pipe can be written as Equation 3.143 where the interfacial and gas shear stress are expressed by Equations 3.144 and 3.145, respectively. Thus, Φ_G^2 could be expressed as a function of void fraction, interfacial friction factor, core density, actual gas velocity, and liquid film velocity as expressed by Equation 3.146:

$$-\left(\frac{dp}{dz}\right)_f = \frac{4\tau_i}{(D-2\delta)} \tag{3.142}$$

$$\Phi_G^2 = \frac{(dp/dz)_f}{(dp/dz)_G} = \frac{4\tau_i/(D-2\delta)}{4\tau_G/D} \tag{3.143}$$

$$\tau_i = f_i\left(\frac{\rho_c(U_G - U_{LF})^2}{2}\right) \tag{3.144}$$

$$\tau_G = f_G\left(\frac{\rho_G U_{SG}^2}{2}\right) \tag{3.145}$$

$$\Phi_G^2 = \frac{1}{\sqrt{\alpha_G}}\frac{f_i}{f_G}\frac{\rho_c}{\rho_G}\frac{(U_G - U_{LF})^2}{U_{SG}^2} = \frac{1}{\sqrt{\alpha_G}}\frac{f_i}{f_G}\frac{\rho_c}{\rho_G}\left[\frac{1}{\alpha_G} - \frac{U_L(1-E)}{U_{SG}}\right]^2 \tag{3.146}$$

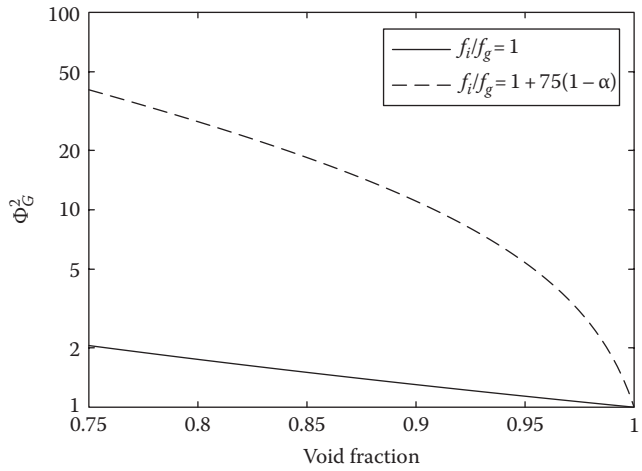

Figure 3.35

Effect of f_i/f_G on two-phase frictional multiplier (Φ_G^2).

Note that for low liquid flow rates, the velocity of liquid flowing in the form of film may be small compared to the fast-moving gas core such that $U_{LF} \ll U_G$. Also for low liquid flow rates, the liquid entrainment fraction may be negligible leading to $\rho_c/\rho_G \approx 1$. Thus, for such a simplified two-phase flow situation, Equation 3.146 reduces to Equation 3.147. Furthermore, for a more simplified assumption of smooth gas–liquid interface, ($f_i \approx f_G$) and Φ_G^2 can be expressed as Equation 3.148:

$$\Phi_G^2 = \frac{1}{\alpha_G^{5/2}} \frac{f_i}{f_G} \tag{3.147}$$

$$\Phi_G^2 = \frac{1}{\alpha_G^{5/2}} \tag{3.148}$$

It must be mentioned that the assumption of smooth gas–liquid interface (f_i/f_G) is an unrealistic assumption for the annular flow and the calculation of two-phase frictional multiplier, and, the two-phase frictional pressure drop may deviate significantly from actual conditions. It is evident from Figure 3.35 that by accounting for the interfacial roughness, the predicted values of Φ_G^2 could be significantly greater than that for the ideal conditions. Going back to Equation 3.146, the ratio f_i/f_G could be replaced with the empirical correlation in the form of Equation 3.149 proposed by Wallis (1962). Note that the two-phase flow literature reports several empirical relationships to model the ratio of f_i/f_G. Some of these correlations are listed in Table 3.9:

$$\frac{f_i}{f_G} = 1 + 300\frac{\delta}{D} = 1 + 75(1-\alpha_G) \tag{3.149}$$

The mass flow rate of liquid phase in the form of film, the actual velocity of the liquid film, and the Reynolds number of the liquid film are defined by Equations 3.150 through 3.152, respectively:

$$\dot{m}_{LF} = \dot{m}_L(1-E) \tag{3.150}$$

$$U_{LF} = U_L(1-E) \tag{3.151}$$

$$Re_{LF} = Re_{SL}(1-E) \tag{3.152}$$

The density of the gas core (ρ_c) is obtained using Equation 3.135 based on liquid entrainment fraction. Note that only for negligible liquid entrainment fraction $\rho_c \approx \rho_G$. Figure 3.36 shows the algorithm to use in

Table 3.9 List of Correlations for Interfacial Friction Factors

Source	Correlation
Moeck (1970)	$f_i = 0.005\left(1+1458\left(\frac{\delta}{D}\right)^{1.42}\right)$
Laurinat et al. (1984)	$f_i = f_G\left(2+2.5\times10^{-5}\frac{Re_{LF}}{D}\right)\alpha_G^{5/2}$
Wallis (1962)	$f_i = 0.005(1 + 75(1 - \alpha_G))$

Fore et al. (2000)	$f_i = 0.005\left(1+300\left[\left(1+\frac{17{,}500}{Re_G}\right)\frac{\delta}{D}-0.0015\right]\right)$

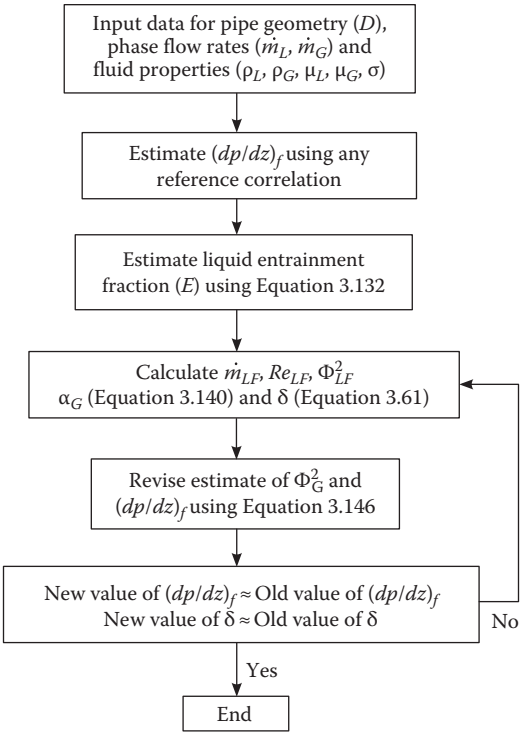

Figure 3.36

Algorithm to solve triangular relationship in annular flow.

triangular relationship for the determination of frictional pressure drop, liquid film thickness, and flow rate of liquid in the form of film.

Example Problem 3.2

Consider the vertical upward two-phase flow of air–water mixture in a 45 mm I.D. smooth pipe. At near atmospheric system pressure, the two-phase mixture flows with a quality (x) and mass flux (G) of 0.25 and 210 kg/m^2, respectively. The physical properties of air and water are as follows: $\rho_G = 1.5$ kg/m^3, $\rho_L = 998$ kg/m^3, $\mu_G = 18.5 \times 10^{-6}$ Pa s, $\mu_L = 0.001$ Pa s, and $\sigma = 0.072$ N/m. Using triangular relationship for annular flow, determine the film thickness (δ), film flow rate ($\dot{m}_{LF}$), and pressure drop $(dp/dz)_f$. Assume that adiabatic annular flow at equilibrium exists in the pipe.

Solution

The solution to this problem follows the calculation algorithm illustrated in Figure 3.36.

(1) *Make initial estimate of two-phase pressure drop*: Calculate gas- and liquid-phase Reynolds numbers (see Table 3.1) and single-phase friction factors from Equation 3.71:

$$Re_{SG} = \frac{GxD}{\mu_G} = \frac{210 \times 0.25 \times 0.045}{18.5 \times 10^{-6}} = 127703 \Rightarrow f_G = 0.00418$$

$$Re_{SL} = \frac{G(1-x)D}{\mu_L} = \frac{210 \times (1-0.25) \times 0.045}{0.001} = 7088 \Rightarrow f_L = 0.0086$$

Calculate the frictional pressure drop for gas and liquid phase assuming each phase flowing alone through the pipe:

$$-\left(\frac{dp}{dz}\right)_G = \frac{2 f_G (Gx)^2}{D\rho_G} = \frac{2 \times 0.00418 (210 \times 0.25)^2}{0.045 \times 1.5} = 341.3 \,(\text{Pa/m})$$

$$-\left(\frac{dp}{dz}\right)_L = \frac{2 f_L (G(1-x))^2}{D\rho_G} = \frac{2 \times 0.0086 (210 \times 0.75)^2}{0.045 \times 998} = 9.5 \,(\text{Pa/m})$$

The parameter (X) of Lockhart and Martinelli (1949) and the two-phase frictional multiplier $\left(\Phi_G^2\right)$ are now obtained from Equations 3.90 and 3.89, respectively. For turbulent–turbulent region of gas and liquid flow $C = 20$ from Table 3.7:

$$X = \sqrt{\frac{(dp/dz)_L}{(dp/dz)_G}} = \sqrt{\frac{9.5}{341.3}} = 0.167$$

$$\Phi_G^2 = 1 + CX + X^2 = 1 + 20 \times 0.167 + 0.167^2 = 4.37$$

Now, the two-phase frictional pressure drop is calculated as

$$\left(\frac{dp}{dz}\right)_f = \Phi_G^2 \times \left(\frac{dp}{dz}\right)_G = 4.37 \times 341.3 = 1491.5 \,(\text{Pa/m})$$

(2) *Estimate liquid entrainment fraction* (E): Liquid entrainment fraction can be estimated using Equation 3.132. First estimate the gas core Weber number using gas-phase density and predict the initial estimate of liquid entrainment fraction. The superficial gas velocity required in the determination of We_c is calculated as $U_{SG} = Gx/\rho_G = 210 \times 0.25/1.5 = 35$ m/s. Then find the gas core density using the initial estimate of E and recalculate Weber number and liquid entrainment fraction in corrector step. For near atmospheric system pressure $\xi = 280$ from Equation 3.133.

$$We_c = \frac{\rho_G U_{SG}^2 D}{\sigma} = \frac{1.5 \times 35^2 \times 0.045}{0.072} = 1148.4$$

$$E = (1 + 280 \times We_c^{-0.8395})^{-2.209} = 0.288$$

$$\rho_c = \frac{x + E(1-x)}{(x/\rho_G) + (E(1-x)/\rho_L)} = \frac{0.25 + 0.288 \times 0.75}{(0.25/1.5) + (0.288 \times 0.75/998)} = 2.8 \,(\text{kg/m}^3)$$

$$We_c = \frac{\rho_c U_{SG}^2 D}{\sigma} = \frac{2.8 \times 35^2 \times 0.045}{0.072} = 2143.7$$

$$E = (1 + 280 \times We_c^{-0.8395})^{-2.209} = 0.44$$

The updated value of core density (ρ_c) based on entrainment in corrector step is $\rho_c = 3.47$ kg/m^3. Based on the predicted entrainment value ($E = 0.44$) and using Equation 3.150, the liquid film flow rate can be calculated as follows. The liquid mass flow rate required in this equation is $\dot{m}_L = G(1-x)\times A = 210(1-0.25)\times \pi/4 \times 0.045^2 = 0.25$ kg/s:

$$\dot{m}_{LF} = (1-E)\dot{m}_L = (1-0.44)\times 0.25\,(\text{kg/s}) = 0.14\,(\text{kg/s})$$

(3) *Estimate liquid film thickness* (δ): To determine the liquid film thickness, first calculate the two-phase frictional multiplier $\left(\Phi_{LF}^2\right)$ based on the liquid film flow rate given by Equation 3.140. To determine Φ_{LF}^2, first calculate the friction factor (f_{LF}) for liquid film flow. The Reynolds number of liquid film is calculated from Equation 3.152 such that $Re_{LF} = Re_{SL} \times (1 - E) = 3969$, and hence, the corresponding friction factor from Equation 3.71 is $f_{LF} = 0.00995$:

$$\left(\frac{dp}{dz}\right)_{LF} = \frac{2f_{LF}(G(1-x)(1-E))^2}{D\rho_L} = \frac{2\times 0.00995\times(210\times 0.75\times 0.56)^2}{0.045\times 998} = 3.45\,(\text{Pa/m})$$

$$\Phi_{LF}^2 = \frac{(dp/dz)_f}{(dp/dz)_{LF}} = \frac{1491.5}{3.45} = 432.3$$

$$\Phi_{LF}^2 = \frac{1}{(1-\alpha_G)^2} = 432.3 \Rightarrow (1-\alpha_G) = \frac{4\delta}{D} = 0.0481$$

$$\therefore \alpha_G = 0.952 \quad \text{and} \quad \delta = 0.541\,\text{mm}$$

(4) *Update the value of two-phase pressure drop*: Use Equation 3.146 along with Equation 3.149 to calculate the new value of two-phase frictional multiplier $\left(\Phi_G^2\right)$ and compare it with the initial calculated value of $\Phi_G^2 = 4.37$. Here, we first find $U_{SL} = G(1 - x)/\rho_L = 210 \times 0.75/998 = 0.158$ m/s and $U_L = U_{SL}/(1 - \alpha_G) = 0.158/0.0481 = 3.28$ m/s:

$$\Phi_G^2 = \frac{1}{\sqrt{\alpha_G}}\frac{f_i}{f_G}\frac{\rho_c}{\rho_G}\left[\frac{1}{\alpha_G} - \frac{U_L(1-E)}{U_{SG}}\right]^2$$

$$\Phi_G^2 = \frac{1}{\sqrt{0.952}}(1+75\times 0.0481)\times\frac{3.47}{1.5}\left(\frac{1}{0.952} - \frac{3.28\times(1-0.44)}{35}\right)^2 = 10.88$$

Now, the updated value of two-phase frictional pressure drop is calculated as

$$\left(\frac{dp}{dz}\right)_f = \Phi_G^2 \times \left(\frac{dp}{dz}\right)_G = 10.88\times 341.3 = 3713.3\,(\text{Pa/m})$$

(5) *Repeat steps (3) and (4) to get consistent values of* δ *and* $(dp/dz)_f$: Since the new value of Φ_G^2 and frictional pressure drop is greater than the initial estimate, recalculate Φ_{LF}^2 value to obtain new estimates of δ and Φ_G^2. After 12 iterations consistent values of liquid film thickness, two-phase frictional multiplier $\left(\Phi_G^2\right)$ and hence the two-phase frictional pressure drop are obtained. The final values of parameters in triangular relationship are

Liquid film thickness (δ) = 0.398 mm.
Liquid film flow rate $\left(\dot{m}_{LF}\right) = 0.14$ kg/s.
Two-phase pressure drop $(dp/dz)_f = 2745$ Pa/m.
In addition, based on the iterated value of Φ_{LF}^2, $\alpha_G = 0.965$.

Discussion: For similar experimental conditions, Nguyen (1975) measured $\alpha_G = 0.951$ and $(dp/dz)_f = 2440$ Pa/m. Note that the converged values of void fraction and pressure drop obtained by solving triangular relationship are comparable with measured data of Nguyen (1975).

Moreover, the film thickness ($\delta = 0.398$ mm) obtained using triangular relationship is comparable to the predicted ($\delta = 0.431$ mm) film thickness by empirical correlation of Henstock and Hanratty (1976). It must be mentioned that the final converged values obtained using triangular relationship depend upon the closure relationships for liquid entrainment fraction (E), interfacial friction factor (f_i), and hence the two-phase frictional multiplier $\left(\Phi_G^2\right)$. There is no unanimity over the use of a particular set of closure equations, and hence, the use of different set of equations may yield slightly different solutions of triangular relationship.

3.7 Nonboiling Two-Phase Heat Transfer

Knowledge about nonboiling two-phase heat transfer is important in several applications in oil and gas and chemical engineering industry. In particular, during the production of two-phase hydrocarbon fluids from oil reservoirs and its transportation to the surface processing facilities, the temperature of hydrocarbons drops drastically and is favorable for hydrates formation and wax deposition. Wax deposition can result in problems including reduction of inner tube diameter causing blockage, increase in surface roughness of tube leading to restricted flow line pressure, and decrease in production and can lead to various mechanical problems. In such situations, the correct knowledge of heat transfer coefficients in two-phase flow is of utmost importance for the purpose of flow assurance in oil and gas industry. The following text provides a brief information on the phenomenon of two-phase flow models for nonboiling two-phase heat transfer. Detailed information on the effect of fluid properties and pipe orientation on two-phase heat transfer coefficient can be obtained from Tang (2011), Ghajar and Tang (2010), and Bhagwat et al. (2012).

3.7.1 Two-Phase Heat Transfer Model

In the two-phase flow literature, majority of the documented nonboiling two-phase heat transfer modeling methods are limited to specific pipe orientations, fluid combinations, and most importantly flow patterns. The subsea and surface pipe lines carrying a mixture of oil and gas together are usually laid in undulated form having near horizontal inclinations, and the existence of a specific flow pattern is uncertain. For such a scenario, the use of flow pattern and pipe orientation-specific two-phase heat transfer correlations may predict significant deviations from the actual conditions. To address this issue, Ghajar and coworkers in a series of papers have extensively studied the phenomenon of nonboiling two-phase heat transfer in pipes at different orientations. Ghajar and Tang (2009) proposed a robust correlation for two-phase heat transfer coefficient (h_{TP}) as presented by Equation 3.153. Their correlation is based on 986 experimental data points for different pipe orientations and fluid combinations:

$$h_{TP} = h_L F_p \left[1 + 0.55 \left(\frac{x}{1-x} \right)^{0.1} \left(\frac{1-F_p}{F_p} \right)^{0.4} \left(\frac{Pr_G}{Pr_L} \right)^{0.25} \left(\frac{\mu_L}{\mu_G} \right)^{0.25} I^{0.25} \right] \tag{3.153}$$

$$F_p = (1-\alpha_G) + \alpha_G F_s^2 \tag{3.154}$$

$$F_s = \frac{2}{\pi} \arctan\left(\sqrt{\frac{\rho_G (U_G - U_L)^2}{gD(\rho_L - \rho_G)}} \right) \tag{3.155}$$

$$I = 1 + Eo\,|\sin\theta| \tag{3.156}$$

The flow pattern factor (F_p) given by Equation 3.154 makes the Ghajar and Tang (2009) correlation independent of the flow patterns and depends on shape factor F_s and void fraction (α_G). The shape factor (F_s) given by Equation 3.155 considers the effect of the shape of gas–liquid interface on two-phase heat transfer, while the void fraction needs to be calculated using the correlations of Woldesemayat and Ghajar (2007) (use Equations 3.45 and 3.46). The variable I given by Equation 3.156 is defined in terms of Eötvös number, and it accounts for the effect of pipe orientation on h_{TP}:

$$Eo = \frac{(\rho_L - \rho_G) g D^2}{\sigma} \tag{3.157}$$

The single-phase heat transfer coefficient required in Equation 3.153 is based on in situ Reynolds number. All thermophysical properties required are calculated at bulk mean temperature except for the μ_w that is calculated at the pipe wall temperature. Note that the in situ liquid phase the Reynolds number used in Equation 3.158 for h_L is defined in terms of the square root of liquid holdup as shown in Equation 3.159:

$$h_L = 0.027 Re_L^{0.8} Pr_L^{0.33} \left(\frac{k_L}{D}\right)\left(\frac{\mu_L}{\mu_w}\right)^{0.14} \tag{3.158}$$

$$Re_L = \frac{4\dot{m}_L}{\pi D \mu_L \sqrt{1-\alpha_G}} = \frac{G(1-x)D}{\mu_L \sqrt{1-\alpha_G}} \tag{3.159}$$

3.7.2 Reynolds Analogy and Two-Phase Heat Transfer

The concept of Reynolds analogy that relates the skin friction factor or the frictional pressure drop with heat transfer in single-phase flow can also be extended to the case of two-phase flow. Using the concept of Reynolds analogy, Tang and Ghajar (2011) have developed a correlation that correlates the two-phase to single-phase heat transfer coefficient ratio to the two-phase frictional multiplier (ratio of two-phase to single-phase pressure drop). The physical form of this correlation is given by Equation 3.160. The two-phase mixture density (ρ_M) is calculated using void fraction, $\rho_M = \rho_L(1 - \alpha_G) + \rho_G\alpha_G$, F_p is calculated from Equation 3.154, h_L is calculated from Equation 3.158 using the Reynolds number (Re_{SL}) based on superficial liquid velocity (see Table 3.1). Note that Φ_L is the square root of the two-phase frictional multiplier calculated using Equation 3.86. In case if the two-phase frictional pressure drop is not known/measured, then suitable correlation valid for given two-phase flow conditions may be used to determine Φ_L. The void fraction required in the calculation of two-phase mixture density (ρ_M) is calculated using Woldesemayat and Ghajar (2007) correlation (Equations 3.45 and 3.46). Tang (2011) suggested that the exponents of F_p and Φ_L could vary between 0.1 and 0.5 depending upon the pipe orientation and fluid properties; however, the general structure of Reynolds analogy–based correlation remains unaltered. In Equation 3.160, the exponent (0.3) of F_p and Φ_L is based on the overall performance of their model for various pipe inclinations and fluid combinations:

$$h_{TP} = h_L F_p^{0.3} \left(\frac{\dot{m}_L}{\dot{m}}\right)\left(\frac{\rho_L}{\rho_M}\right)^{0.5} \Phi_L^{0.3} \tag{3.160}$$

Both the correlations of Ghajar and Tang (2009) (general heat transfer correlation) and Tang and Ghajar (2011) (Reynolds analogy–based heat transfer correlation) are applicable over the following range of parameters: $750 \le Re_{SL} \le 1.27 \times 10^5$, $14 \le Re_{SG} \le 21 \times 10^5$, $0.01 \le Pr_G/Pr_L \le 0.15$, $910 \le \rho_L \le 1210$ kg/m^3, $0.0036 \le \mu_G/\mu_L \le 0.026$, and $0° \le \theta \le +90°$. Within the range of these two-phase flow variables, both correlations are known to predict more than 80% and 90% of data points within ±20% and ±30% error bands, respectively. The physical structure of these correlations is modular and robust, and hence, the application of these correlations can be potentially extended to a wider range of two-phase flow conditions by modifying the empirical multiplying factors and exponents.

Example Problem 3.3

Consider the vertical upward two-phase flow of air and silicone oil in a 12 mm I.D. stainless steel pipe having a surface roughness of 20 μm. The mass flow rates of gas and liquid phase are 0.0015 kg/s and 0.9 kg/s, respectively. The fluid thermophysical properties may be taken as follows: $\rho_G = 1.2$ kg/m^3, $\rho_L = 920$ kg/m^3, $\mu_G = 18.4 \times 10^{-6}$ Pa s, $\mu_L = 0.005$ Pa s, $\mu_w = 0.004$ Pa s, $\sigma = 0.02$ N/m, $k_L = 0.12$ W/mK, $Pr_G = 0.71$, and $Pr_L = 64$. For a measured void fraction of $\alpha_G = 0.5$, determine the two-phase heat transfer coefficient for the flow of air and silicon oil using (1) heat transfer correlation of Ghajar and Tang (2009) given by Equation 3.153 and (2) Reynolds analogy given by Equation 3.160.

Solution

(1) Calculation of h_{TP} using Ghajar and Tang (2009) correlation:
The superficial gas (U_{SG}) and liquid (U_{SL}) velocities and the two-phase flow quality (x) are first calculated as follows:

$$U_{SG} = \frac{4\dot{m}_G}{\pi D^2 \rho_G} = \frac{4 \times 0.0015}{\pi \times 0.012^2 \times 1.2} = 11.05 \text{ m/s}$$

$$U_{SL} = \frac{4\dot{m}_L}{\pi D^2 \rho_L} = \frac{4 \times 0.9}{\pi \times 0.012^2 \times 920} = 8.65 \text{ m/s}$$

$$x = \frac{\dot{m}_G}{\dot{m}_G + \dot{m}_L} = \frac{0.0015}{0.0015 + 0.9} = 0.00166$$

From the given information of void fraction, the actual velocity of each phase is calculated as follows. In case if the void fraction is not known, Woldesemayat and Ghajar (2007) correlation (Equations 3.45 and 3.46) can be used for void fraction calculation. For the given flow conditions, Woldesemayat and Ghajar (2007) correlation gives $\alpha_G = 0.52$ that is within ±5% of the given void fraction value of 0.5:

$$U_G = \frac{U_{SG}}{\alpha_G} = \frac{11.05}{0.5} = 22.1 \text{ m/s}$$

$$U_L = \frac{U_{SL}}{1 - \alpha_G} = \frac{8.65}{1 - 0.5} = 17.3 \text{ m/s}$$

Now, the shape factor is calculated from Equation 3.155:

$$F_s = \left[\frac{2}{\pi} \arctan\left(\sqrt{\frac{\rho_G (U_G - U_L)^2}{gD(\rho_L - \rho_G)}} \right) \right]$$

$$= \left[\frac{2}{\pi} \arctan\left(\sqrt{\frac{1.2 \times (22.1 - 17.3)^2}{9.81 \times 0.012 \times (920 - 1.2)}} \right) \right] = 0.298$$

The flow pattern factor is obtained from Equation 3.154:

$$F_p = (1 - \alpha_G) + \alpha_G F_S^2 = (1 - 0.5) + 0.5 \times 0.298^2 = 0.544$$

The inclination factor for the vertical flow is calculated by Equation 3.156:

$$I = 1 + \frac{(\rho_L - \rho_G) g D^2}{\sigma} |\sin\theta| = 1 + \frac{(920 - 1.2) \times 9.81 \times 0.012^2}{0.02} = 65.9$$

Next, the in situ Reynolds number based on void fraction is calculated from Equation 3.159:

$$Re_L = \frac{4\dot{m}_L}{\pi D \mu_L \sqrt{1 - \alpha_G}} = \frac{4 \times 0.9}{\pi \times 0.012 \times 0.005 \times \sqrt{1 - 0.5}} = 27{,}009.5$$

The single-phase heat transfer coefficient is then calculated using Equation 3.158:

$$h_L = 0.027 Re_L^{0.8} Pr_L^{0.33} \left(\frac{\mu_L}{\mu_w}\right)^{0.14} \left(\frac{k_L}{D}\right)$$

$$= 0.027 \times 27{,}009.5^{0.8} \times 64^{0.33} \times \left(\frac{0.005}{0.004}\right)^{0.14} \left(\frac{0.12}{0.012}\right)$$

$$= 3{,}856 \text{ W/m}^2 \text{ K}$$

Using the two-phase heat transfer correlation of Ghajar and Tang (2009) given by Equation 3.153, h_{TP} is calculated as

$$h_{TP} = h_L F_p \left[1 + 0.55 \left(\frac{x}{1-x}\right)^{0.1} \left(\frac{1-F_p}{F_p}\right)^{0.4} \left(\frac{Pr_G}{Pr_L}\right)^{0.25} \left(\frac{\mu_L}{\mu_G}\right)^{0.25} I^{0.25}\right]$$

$$= 3856 \times 0.544 \left[1 + 0.55 \left(\frac{0.00166}{1-0.00166}\right)^{0.1} \left(\frac{1-0.544}{0.544}\right)^{0.4} \left(\frac{0.71}{64}\right)^{0.25} \left(\frac{0.005}{18.4 \times 10^{-6}}\right)^{0.25} 65.9^{0.25}\right]$$

$$= 4224 \text{ W/m}^2 \text{ K}$$

(2) Calculation of h_{TP} using the concept of Reynolds analogy: To use the concept of Reynolds analogy, we first need to find the two-phase frictional pressure drop and hence the two-phase frictional multiplier $\left(\Phi_L^2\right)$. The following steps calculate the two-phase pressure drop using the method of Lockhart and Martinelli (1949).

The Reynolds number of each phase and associated friction factors are calculated as shown as follows. Since the two-phase flow is through steel pipe having a roughness of 20 μm, we need to use appropriate correlation such as Colebrook (1939) or Churchill (1977) to account for the effect of pipe wall surface roughness on friction factor. Here, we use Colebrook (1939) friction factor correlation:

$$Re_{SG} = \frac{\rho_G U_{SG} D}{\mu_G} = \frac{1.2 \times 11.05 \times 0.012}{18.4 \times 10^{-6}} = 8{,}648 \Rightarrow f_G = 0.0081$$

$$Re_{SL} = \frac{\rho_L U_{SL} D}{\mu_L} = \frac{920 \times 8.65 \times 0.012}{0.005} = 19{,}099 \Rightarrow f_L = 0.0063$$

Now the single-phase pressure drop due to flow of gas and liquid phase is calculated by

$$-\left(\frac{dp}{dz}\right)_G = \frac{2 f_G \rho_G U_{SG}^2}{D} = \frac{2 \times 0.0081 \times 1.2 \times 11.05^2}{0.012} = 197.8 \text{ Pa/m}$$

$$-\left(\frac{dp}{dz}\right)_L = \frac{2 f_L \rho_L U_{SL}^2}{D} = \frac{2 \times 0.0063 \times 920 \times 8.65^2}{0.012} = 72{,}278.5 \text{ Pa/m}$$

The parameter X of Lockhart and Martinelli (1949) is calculated using the single-phase pressure drop as shown here:

$$X = \sqrt{\frac{(dp/dz)_L}{(dp/dz)_G}} = \sqrt{\frac{72{,}278.5}{197.8}} = 19.11$$

Since the single-phase flow of both phases is in turbulent region, we use $C = 20$ from Table 3.7 and the two-phase frictional multiplier using the method of Lockhart and Martinelli (1949) is calculated from Equation 3.89 as shown here:

$$\Phi_L^2 = 1 + \frac{20}{X} + \frac{1}{X^2} = 1 + \frac{20}{19.11} + \frac{1}{19.11^2} = 2.05 \Rightarrow \Phi_L = 1.43$$

Two-phase mixture density based on void fraction is calculated as follows:

$$\rho_M = \alpha_G \rho_G + (1 - \alpha_G)\rho_L = 0.5 \times 1.2 + (1 - 0.5) \times 920 = 460.6 \text{ kg/m}^3$$

Now using Equation 3.160, the two-phase heat transfer coefficient can be found. The value of h_L based on Re_{SL} is calculated from Equation 3.158. The value of $F_p = 0.544$ is found earlier in this problem:

$$h_L = 0.027 Re_{SL}^{0.8} Pr_L^{0.33} \left(\frac{\mu_L}{\mu_w}\right)^{0.14} \left(\frac{k_L}{D}\right)$$

$$= 0.027 \times 19{,}099^{0.8} \times 64^{0.33} \times \left(\frac{0.005}{0.004}\right)^{0.14} \left(\frac{0.12}{0.012}\right) = 2{,}922.6 \text{ W/m}^2 \text{ K}$$

Finally, the two-phase heat transfer coefficient using Reynolds analogy is found using Equation 3.160:

$$h_{TP} = h_L F_p^{0.3} \left(\frac{\dot{m}_L}{\dot{m}}\right) \left(\frac{\rho_L}{\rho_M}\right)^{0.5} \Phi_L^{0.3}$$

$$= 2922.6 \times 0.544^{0.3} \left(\frac{0.9}{0.9015}\right) \left(\frac{920}{460.6}\right)^{0.5} 1.43^{0.3}$$

$$= 3824 \text{ W/m}^2 \text{ K}$$

Discussion: Rezkallah and Sims (1987) made two-phase heat transfer measurements for similar experimental conditions and found that $h_{TP} \approx 3900$ W/m^2 K. The value of h_{TP} predicted by Ghajar and Tang (2009) and that by Reynolds analogy of Tang and Ghajar (2011) is within ±10% and ±2% deviation from their measured values, respectively. The general heat transfer correlation and Reynolds analogy–based heat transfer correlation are sensitive to the void fraction (through F_P and ρ_M). Note that in case if the two-phase frictional pressure drop is not known, the accuracy of the Reynolds analogy concept depends on the choice of two-phase frictional multiplier correlation appropriate to the two-phase flow under consideration.

Nomenclature

Symbols	Description
a_1	Variable in the correlation of Xiong and Chung (2006)
A	Cross-sectional area (m^2)
B_s	Variable in Chisholm (1973)
c_1	Variable in the correlation of Bhagwat and Ghajar (2014)
c_2	Variable in the correlation of Bhagwat and Ghajar (2014)
c_3	Variable in the correlation of Bhagwat and Ghajar (2014)
C	Constant in the parameter of Lockhart and Martinelli (1949)
C_o	Distribution parameter
$C_{o,1}$	Variable used by Bhagwat and Ghajar (2014)
C_1	Variable in the correlation of Bhagwat and Ghajar (2015a)

C_2	Variable in the correlation of Bhagwat and Ghajar (2015a)
C_3	Variable in the correlation of Bhagwat and Ghajar (2015a)
C_4	Variable in the correlation of Bhagwat and Ghajar (2015a)
d	Local distance along the pipe diameter
d_{def}	Bubble diameter above which bubble is deformed
$d_{\max}$	Maximum bubble diameter
d_{migr}	Bubble diameter below which migration of bubbles is prevented
dp/dz	Pressure gradient (Pa/m)
$(dp/dz)^+$	Nondimensional pressure gradient
D	Pipe diameter (m)
D_h	Hydraulic diameter (m)
D^+	Nondimensional pipe diameter used by Bhagwat and Ghajar (2015a)
D_h^+	Nondimensional hydraulic diameter by Kataoka and Ishii (1987)
E	Liquid entrainment fraction
Eo	Eötvös number
f	Fanning friction factor
F, Fr	Froude number
F_p	Flow pattern factor
F_s	Shape factor
g	Acceleration due to gravity (m/s^2)
G	Mass flux (kg/m^2 s)
h	Variable in Cioncolini and Thome (2012a) correlation
h_L	Liquid level in stratified flow (m), single-phase heat transfer coefficient (W/m^2 K)
h_{TP}	Two-phase heat transfer coefficient (W/m^2 K)
I	Inclination factor
k	Thermal conductivity (W/mK)
La	Laplace number
$\dot{m}$	Mass flow rate (kg/s)
n	Variable in the correlation of Cioncolini and Thome (2012a)
N_μ	Viscosity number
p	Pressure (Pa)
P	Perimeter (m)
Pr	Prandtl number
q	Exponent in SFM Equation 3.28
r	Exponent in SFM Equation 3.28
Re	Reynolds number
s	Exponent in SFM Equation 3.28
S	Slip ratio
T	Taitel and Dukler (1976) parameter
U	Phase velocity (m/s)
U_b	Bubble velocity (m/s)
U_{GM}	Drift velocity (m/s)
U_{GM}^+	Nondimensional drift velocity by Kataoka and Ishii (1987)
$U_{SG,t}$	Superficial gas velocity at smooth to wavy stratified flow transition (m/s)
v	Specific volume (m^3/kg)
V	Volume (m^3)
We	Weber number
x	Two-phase flow quality
X	The parameter of Lockhart and Martinelli (1949)
Y	The parameter of Taitel and Dukler (1976), the parameter of Chisholm (1973)

Greek Symbols

α	Void fraction
β	Volume fraction of liquid film
δ	Liquid film thickness in annular flow (m)
Δρ	Density difference (kg/m^3)

ε	Roughness (m)
μ	Dynamic viscosity (Pa s)
ν	Kinematic viscosity (m^2/s)
σ	Surface tension (N/m)
ρ	Density (kg/m^3)
λ	Gas volumetric flow fraction
τ	Shear stress (N/m^2)
θ	Pipe orientation (°)
ϕ	Fraction of pipe circumference occupied by liquid phase
Φ^2	Two-phase frictional multiplier
Ψ	Angle subtended by liquid phase with pipe centerline (radian)
ξ	Correction factor in Equation 3.132

Subscripts

a	Accelerational
atm	Atmospheric
c	Gas core
C	Critical
f	Frictional
G	Gas
GO	Gas only
h	Hydrostatic
i	Interface
j	Phase
L	Liquid
LF	Liquid film
LO	Liquid only
max	Maximum
M	Mixture
S	Superficial
sys	System
t	Total
tt	Turbulent–turbulent
TP	Two phase
w	Wall

Superscripts

~	Nondimensional quantities in the model by Taitel and Dukler (1976)
+	Nondimensional quantities in the model by Kataoka and Ishii (1987)

Fluid–Solid Flow in Ducts

4.1 Pneumatic Conveying
4.2 Slurry Flows

4.1 Pneumatic Conveying

Shrikant Dhodapkar and Karl Jacob

4.1.1 Background

One of the earliest pieces of documentation, dating back to 1847, of conveying solids for industrial application was an exhaust system for dust removal from grindstones in a Peugeot plant (Molerus, 1996). Later in 1878, applications of pneumatic conveying of agricultural products (grains and wood chips) emerged. While the basic concept matured quickly, advances in the design of air movers, feeders, and dust collectors resulted in a widespread application of this technology. The research in gas-particle dynamics has helped to create a systematic approach for designing pneumatic conveying systems. Presently, pneumatic conveying is the primary means of moving solid products and intermediates between process stages and the transfer of materials to and from silos. Most of the bulk solid unloading operations rely on some kind of pneumatic transfer.

A pneumatic conveying system consists of a gas mover (fan, centrifugal blower, rotary lobe blower, etc.), a product feeder (rotary feeder, screw feeder, blow tank, etc.), conveying line, and a gas–solid separator (cyclone, baghouse, etc.). With a suitable choice of components, the bulk material can be reliably conveyed over considerable distance. The conveying line can be routed to provide maximum flexibility in layout and operation. The material can be picked up from multiple sources and delivered to many destinations easily. Due to the enclosed nature of transfer in pipe, no dust is emitted to the environment. Pneumatic conveying systems are also easy to automate. However, there are some drawbacks to this technology:

1. High specific power consumption
2. Potential particle breakage or degradation
3. High wear rate on components
4. Relatively short distances (typically less than 3000 ft)

It is not uncommon to come across pneumatic conveying systems that do not meet performance expectations. High particle degradation, capacity limitations, and unstable flow are some of the common problems faced by plant personnel. In most cases, these systems have been designed using generalized correlations and procedures

that do not reflect the conveying characteristics of the material at hand. This results in a nonoptimal system design. Lack of clear design guidelines and calculation procedures makes it difficult to optimize these operations.

More accurate design calculations can be made by empirically correlating test data on conveying characteristics. These data can be obtained on a pilot-scale test loop or from a properly instrumented conveying system in the plant. Generally, it is easier to vary conveying conditions and measure the air and solid flow rates along with pressure drops in various sections in a test loop than to adapt conveying systems in the plant. The test data can be condensed into material-specific correlations for solids' friction factor, saltation velocity correlation, and pressure drop correlation for bends and acceleration region. This information can then be used to design new systems and optimize existing systems.

Pneumatic conveying of materials implies the conveying of material in pipelines using gas as a motive fluid. When the fluid is a liquid, it is known as hydraulic conveying. Gas-particle dynamics is the foundation of pneumatic conveying technology and, hence, discussed briefly here.

4.1.1.1 Flow Patterns in Gas–Solid Systems

Consider cocurrent flow of gas and solid particles in a horizontal pipe, where the gas velocity is high enough to keep the particles homogeneously suspended as shown in flow pattern 1 in Figure 4.1. This flow pattern represents ideal dilute phase flow. If the gas velocity were increased from this point, the flow pattern would visually appear to be the same. However, if it were decreased, at some velocity the solids would no longer be homogeneously suspended as shown in flow pattern 2. A moving strand is often observed at the bottom of the pipe. As the gas flow is further reduced, more of the solids fall out of suspension, resulting in a layer of solids on the bottom of the pipe. Further reduction in gas flow results in the formation of dunes (flow patterns 4 and 5) and eventually slugs of solids that completely fill the pipe cross section (flow pattern 7). For most materials, the flow of solids will stop before reaching flow patterns 9 and 10; however, for some materials that aerate easily and have good air retention characteristics, the material can be moved in the form of a fluidized plug. Dilute phase flow is characterized by predominately flow patterns 1 and 2, with some occurrence of flow pattern 3 at or near the point where solids are injected into the conveying line. Dense phase conveying includes all other flow patterns, although stable conveying will most likely not be achieved for any given material in all flow patterns shown.

The range of flow patterns observed during pneumatic conveying of bulk materials depends on the material characteristics (particle size, size distribution, shape, hardness, and density). Broadly speaking, fine powders and coarse materials show characteristically different flow patterns. Fine powders, such as PVC powder,

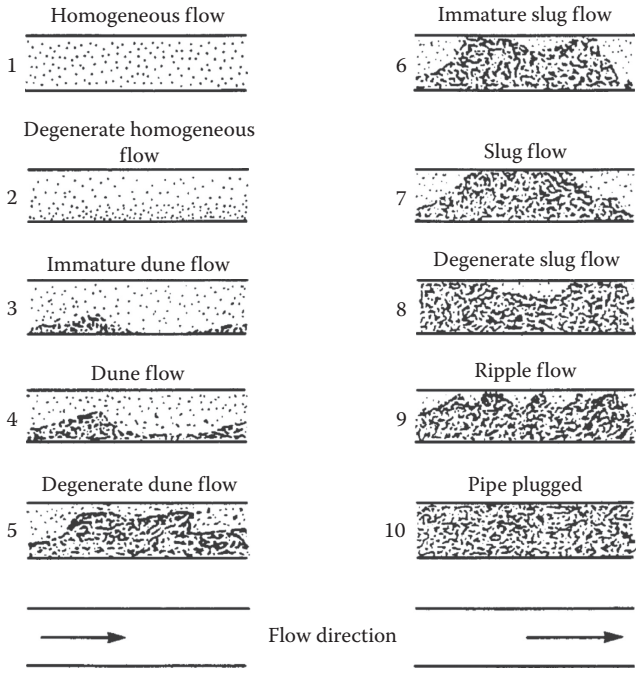

Figure 4.1

Flow patterns in horizontal pneumatic conveying lines. (From Wen, C.Y., US Department of Interior, Bureau of Mines, PA, IC 8314, 1959. With permission.)

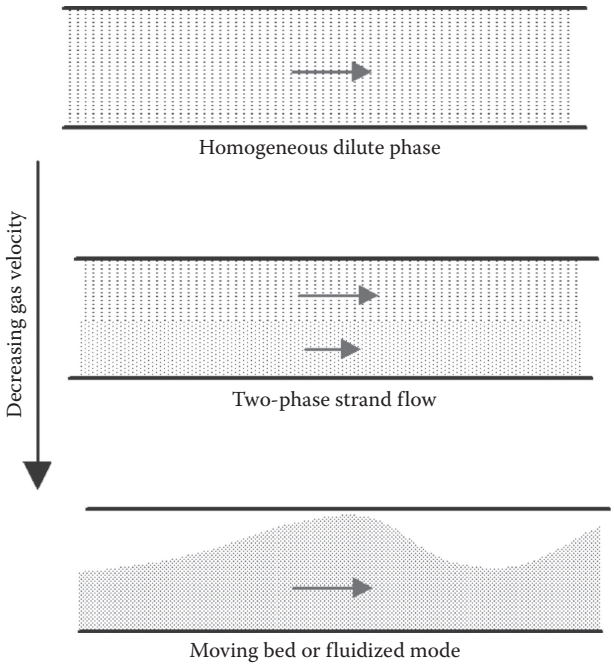

Figure 4.2

Flow patterns for fine powders.

high-density polyethylene powder, fly ash, cement, fine coal, and carbon fines, can be transported in fluidized- or moving-bed mode at low gas velocities. The flow can be turbulent and sometimes appears like a fast-moving bed, waves, or dunes (see Figure 4.2). At higher solids' loadings, the entire cross section of the pipe is filled with a dense mixture of gas and solids. The transition from dilute phase to dense phase is smooth and predictable. Some coarse materials with significant fraction of fines (less than 75 μm) will also exhibit similar behavior. On the other hand, coarse particles, such as plastic pellets, grains, and coffee beans, form slugs naturally when conveyed at low velocity in nonsuspension mode. These slugs show periodic and self-regulating behavior. The transition from dilute to dense flow is marked by an unstable region that corresponds to dune flow (Figure 4.3).

4.1.1.2 Classification of Bulk Solids

Classification or characterization is an essential step in the selection of a suitable conveying mode (dilute or dense) and to optimize the operation of an existing conveying system. Various approaches have been proposed in the literature to predict the expected behavior of a bulk material in a pneumatic conveying system. Unfortunately, due to the complexity of interactions, none of them is definitive but they do provide a good basis for evaluation. It is the authors' experience that a combination of approaches coupled with practical experience must be used. Product classification approaches by Geldart (1973), Dixon (1981), Mainwaring and Reed (1987), Jones and Mills (1990), and Pan (1999) are discussed briefly here. This should provide initial guidance to a process engineer. It is recommended that conveying trials be conducted on new materials to understand the conveying characteristics.

The following properties affect the conveying characteristics of bulk solids:

1. Particle size and size distribution
2. Particle shape
3. Bulk density (loose and tapped)
4. Particle density
5. Permeability
6. Deaeration rate or air retention characteristics
7. Surface characteristics: sticky, wet, cohesive, and electrostatic charging
8. Temperature sensitivity (hardness, modulus, and surface tackiness)

4.1.1.2.1 Geldart or Dixon Classification In his classic paper, Geldart (1973) demarcated regions of different fluidization behaviors based on a 2D plot (Figure 4.4). The *x*-axis is surface volume mean particle size

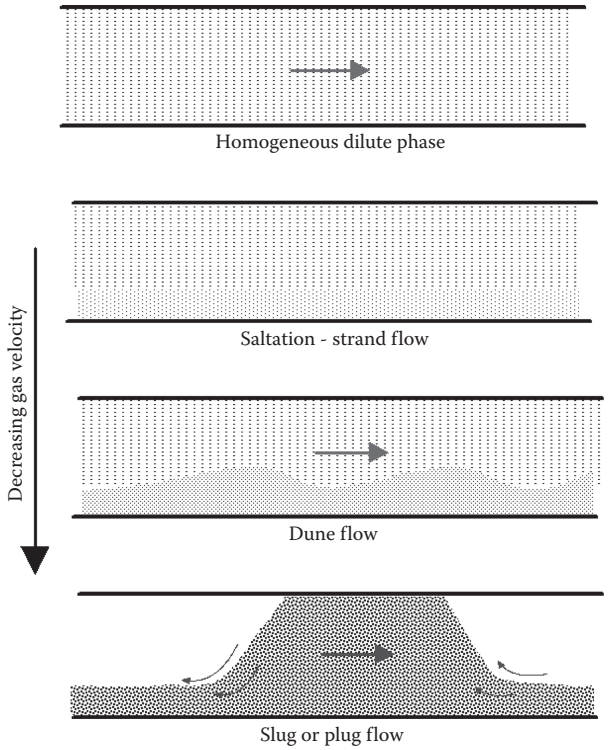

Figure 4.3

Flow patterns for coarse granular materials.

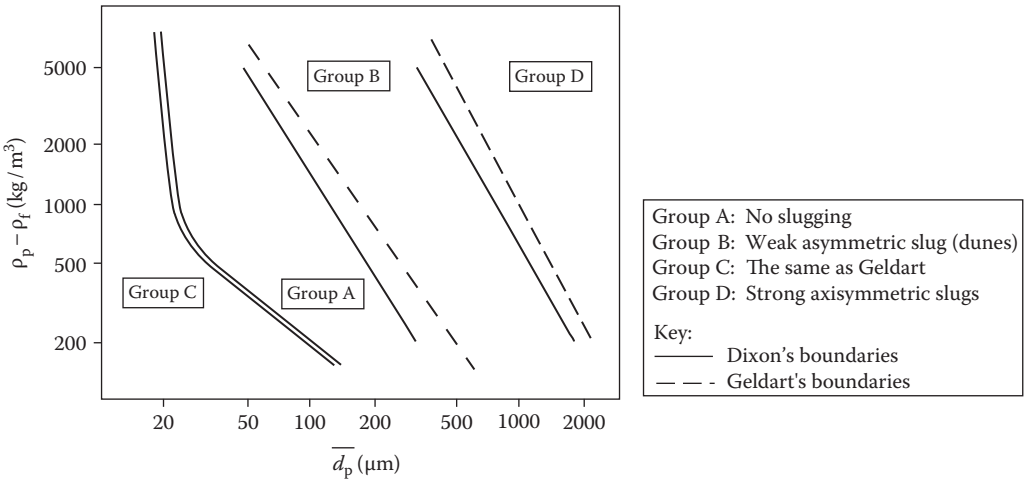

Figure 4.4

Comparison of Geldart and Dixon classification. (From Mason, A., PhD thesis, Thomes Polytechnic, London, U.K., 1991. With permission.)

and the *y*-axis is density difference between the particle and the fluid. This diagram has stood the test of timeand is still used to classify the fluidization behavior of bulk solids. Subsequent work by Dixon (1981) on the classification of slugging behavior in vertical pipes produced a similar diagram. Fluidization, permeability, and deaeration characteristics are closely related to pneumatic conveyability (see Table 4.1).

Wypych (1989) has shown that the use of surface-volume mean diameter overemphasizes the influence of finer fraction on fluidization behavior. He recommended the use of volume median diameter instead. The boundaries in Geldart classification are ambiguous when the particle size distribution is wide or the particle shape is

Table 4.1 Characteristics of Geldart (1973) or Dixon (1981) Classification

Geldart or Dixon Classification	Fluidization Characteristics	Dense Phase Conveying Characteristics
A	Fine powders, good air retention, small bubble size, considerable bed expansion	Can be conveyed in fluidized mode, easy to convey, do not form slugs naturally
B	Coarse granules, poor air retention, low bed expansion, large bubbles, asymmetric slugging	Difficult to convey in "conventional" dense phase, unsteady and unpredictable plug formation, large-pipe vibrations
C	Cohesive, difficult to fluidize, tends to channel, once aerated might retain air for extended periods, adhesion to walls	Very difficult to convey in conventional dense phase, forms impermeable plugs that break up. Special techniques required to convey
D	Highly permeable, negligible bed expansion, high minimum fluidization velocity, large bubbles or slugs can form, axisymmetric slugs	Natural slugging ability and high permeability helps in dense phase conveying. Operationally easiest to convey in dense phase

nonspherical. Wypych (1989) also pointed out that the ratio of particle size to pipe diameter plays a role in the determination of natural slugging behavior. It is recommended that full-scale tests be conducted to ascertain the actual behavior.

4.1.1.2.2 Mainwaring and Reed Classification (1987) Permeability and deaeration have proven to be the two most important properties of bulk material in establishing the conveying behavior. While Geldart (1973) or Dixon (1981) classification is based on a similar concept, this classification relies on the direct measurement of permeability factor and deaeration factor. These measurements are used to determine whether the material can be conveyed in plug-type dense phase conveying, moving-bed-type dense phase conveying, or only in dilute phase mode.

4.1.1.2.2.1 Permeability Factor Permeability is a measure of resistance of gas flow through a packed bed of given bulk material under conditions below minimum fluidization. It can be measured by measuring the pressure gradient across a packed bed at various gas velocities (Figure 4.5a). The permeability factor, p_f, is the ratio A/B. The higher the permeability factor, the lesser the resistance it offers to the gas flow:

$$p_f = \frac{U_g}{(\Delta P/L)_c}$$

The pressure drop curve reaches an asymptotic value at high gas velocities when the drag force on the particles equals the weight of the bed. This critical pressure gradient $(\Delta P/L)_c$ is a property of the bulk material.

The permeability data for various bulk solids were plotted against the critical pressure gradient by Mainwaring and Reed (1987) as shown in Figure 4.5b. A line of constant minimum fluidization can be plotted on the same graph. It has been found from practical experience that a line representing minimum fluidization velocity of 0.05 m/s (50 mm/s) classifies materials that can be conveyed in plug- or slug-type dense phase conveying and those that can be conveyed in moving-bed-type dense phase or dilute phase only. All materials with high permeability (data above the line) can be conveyed in plug or slug conveying mode, whereas materials with low permeability can be conveyed either in moving-bed-type dense phase flow or in dilute phase only. The basic assumption here is that no special air injection or vibration flow aids are being used.

4.1.1.2.2.2 Deaeration Factor Air retention or deaeration characteristics are measured by bringing the bed to a state of minimum fluidization and rapidly turning off the air supply. The bulk density increases and the level falls as the bed deaerates. It would be ideal to monitor the bed height as a function of time. However, most fine powders tend to coat the wall of the column, thereby making the observations difficult. It is reasonable to measure the pressure decay characteristics instead. Research has shown that the pressure gradient in the bed is inversely proportional to the time, as shown in Figure 4.6a:

$$\frac{\Delta P}{L} t = A_f$$

The product of pressure gradient and time is defined as the deaeration constant, A_f. The shape of deaeration curve is sensitive to many parameters. This test needs to be standardized or it must be used for comparative purposes only.

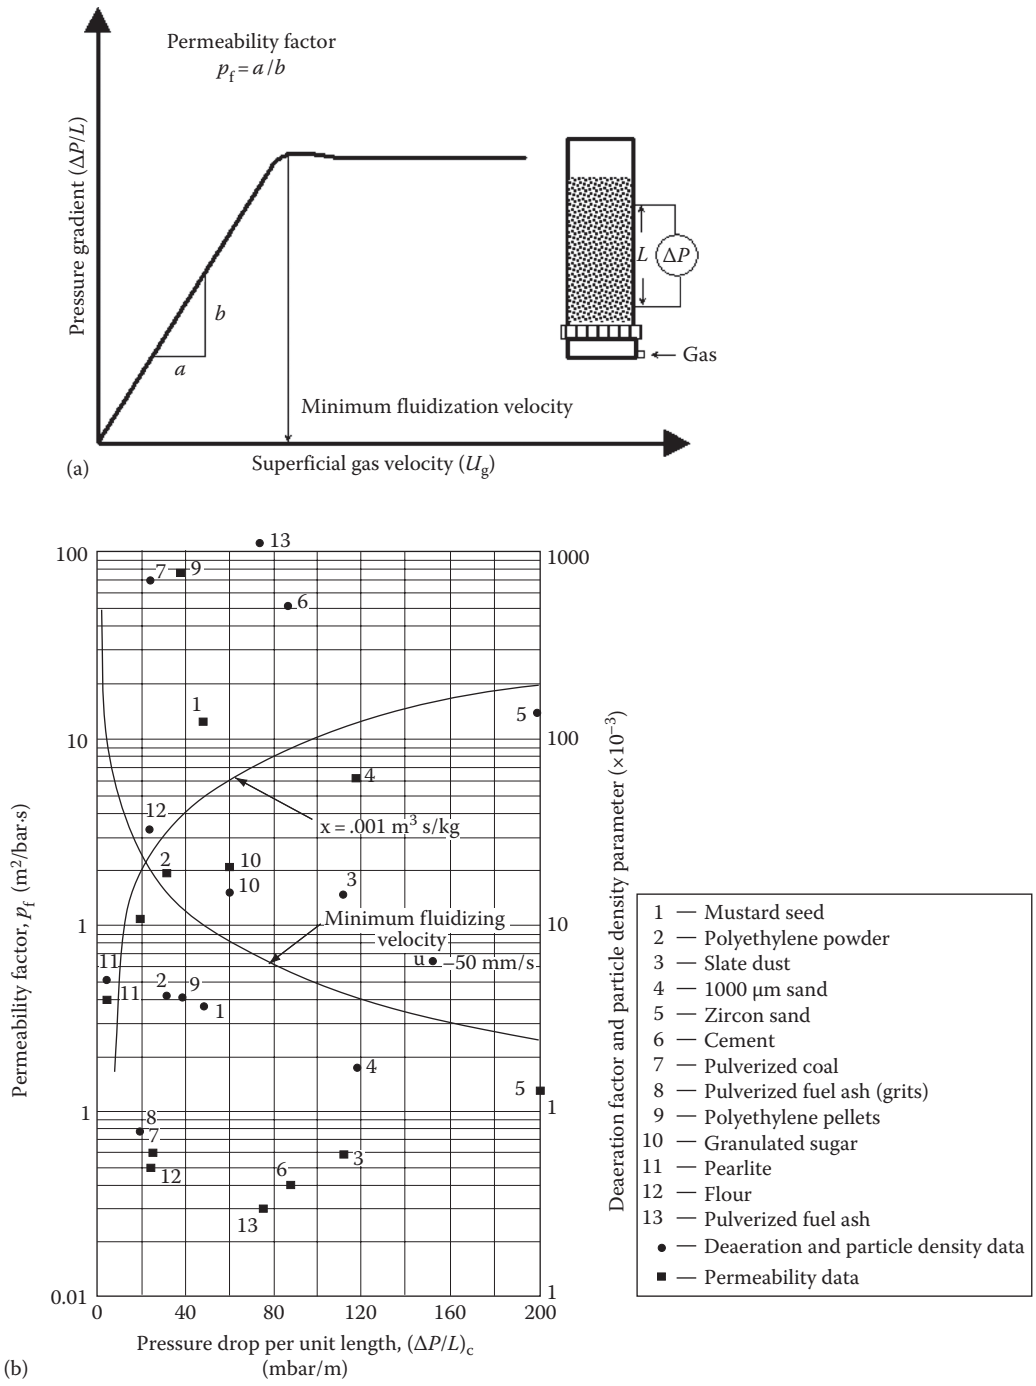

Figure 4.5

(a) Measurement of permeability using a fluidized-bed setup; (b) classification based on permeability. (From Mainwaring, N.J. and Reed, A.R., *Bulk Solids Handling*, 7, 415, 1987. With permission.)

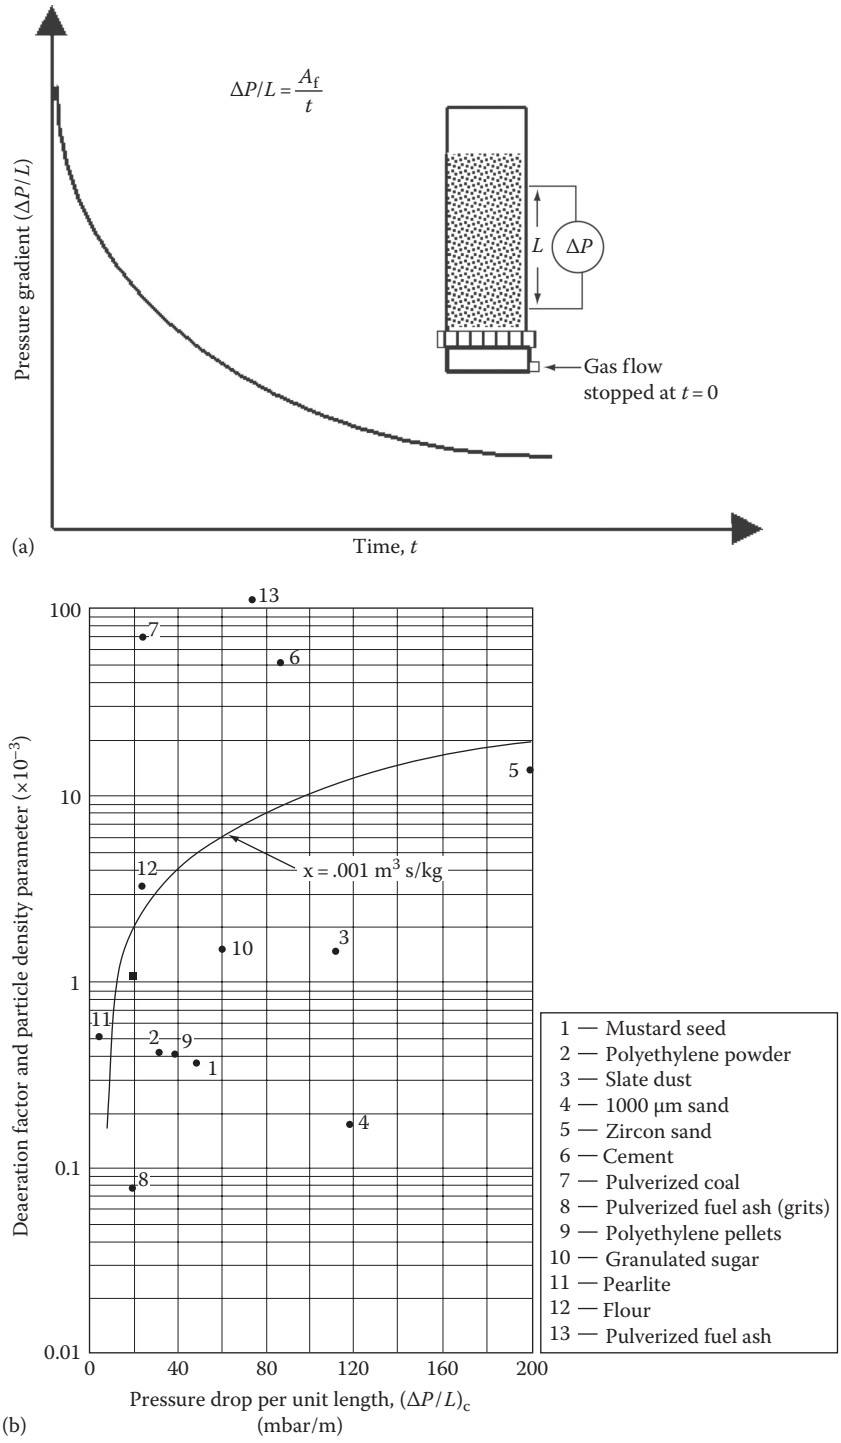

Figure 4.6

(a) Interpretation of deaeration data and proposed test setup; (b) classification based on deaeration factor.

To account for the effect of particle density, it was further proposed that a new factor X (m^3 s/kg) be defined as follows:

$$X = \frac{\left(A_f/\rho\right)}{\left(\Delta P/L\right)}$$

Low values of X imply low air retention and vice versa. As shown in Figure 4.6b, it has been proposed that a curve representing $X = 0.001$ m^3 s/kg classifies materials that can be conveyed in slug- or plug-type dense phase conveying (below the curve) and those suitable for only moving bed or dilute phase (above the curve).

4.1.1.2.3 Jones and Mills (1990) Jones and Mills (1990) have rightly pointed out the limitations of Geldart and Dixon diagram in their failure to account for particle size distribution and shape. Similar to Mainwaring and Reed, they used permeability and deaeration as the two primary factors to determine flow modes. However, the deaeration characteristics were generated in the presence of vibration to assist deaeration of powders, which can take an inordinate amount of time. The proposed product classification is shown in Figure 4.7.

As evident from Jones and Mills classification:

1. Materials with low permeability and high air retention (small deaeration constant) can be conveyed in moving bed or fluidized mode.
2. Materials with high permeability and low air retention can be conveyed in the plug type of dense phase flow.
3. The rest of the materials can be conveyed only in dilute phase mode.

The boundaries between dilute phase (Group 2) and dense phase (Groups 1 and 3), however, are tentative.

4.1.1.2.4 Pan (1999) Pan (1999) proposed a simplified flow mode diagram based on loose, poured bulk density and median particle size. This diagram (Figure 4.8) is based on a database of over 50 materials. The materials are grouped into three categories:

1. Materials in group PC 1 can be transported in dilute phase and dense phase fluidized- or moving-bed mode. Examples are fly ash, pulverized coal, cement, flour, PVC powder, fuel ash, and others.
2. Materials in group PC 2 can be transported in dilute phase and slug- or plug-type dense phase mode. The transition from dilute phase to dense phase is marked by an unstable zone. Examples are plastic pellets, wheat, mustard seeds, granulated sugar, semolina, and others.
3. Materials in group PC 3 can be transported only in dilute phase. Examples are silica sand, alumina, zircon sand, fuel ash grit, and others.

Pan classification. (From Pan, R., *Powder Technol.*, 104, 157, 1999. With permission.)

4.1.1.2.5 Limitation of Classification Diagrams Many materials classified as difficult to convey in dense phase can be conveyed by applying special techniques, such as air injection, air bypass, air knife, and pulse piston method. No generalized classification has been developed to predict the effectiveness of these techniques. It is recommended that pilot-scale tests be conducted to determine the feasibility of dense phase conveying for such materials.

4.1.1.3 Phase Diagram

While observing flow patterns is an easy way to differentiate between dilute and dense phase conveying, most conveying systems do not provide this opportunity. Consequently, process measurements such as differential pressure (DP) are used in conjunction with the gas and solids' flow rates to provide a picture of what occurs within the conveying line. An elegant way to represent the performance characteristics of pneumatic conveying systems is to plot the pressure gradient versus gas velocity for different solids' flow rates. This is often known as the "Zenz plot" (see Figure 4.9). The pressure gradient is measured across a test section of known length, pipe diameter, and orientation. Each curve represents system characteristics at constant solids' flow rate. It should be noted that Zenz used logarithmic scales for the two axes. In a log–log plot, the pressure curve due to single-phase gas flow becomes a straight line; however, the curves for gas–solid flow remain nonlinear. It is now common practice to plot the data with linear axes. The saltation transition can be visualized better by using a linear plot.

In the absence of solids, the well-known Darcy's or Fanning's friction factors can be used to quantify the pressure drop in pipes for single-phase flow. The pressure gradient in the conveying line decreases with the gas flow rate and eventually becomes zero under stationary conditions.

4.1.1.3.1 Dilute Phase Conveying Dilute phase pneumatic conveying refers to the transport of solid particles in gas such that all particles are fully entrained in the gas phase. It is possible to achieve dilute phase conveying or fully suspended mode for all materials. The difference in velocity between gas molecules and solid particles, also known as slip velocity, provides necessary drag force to propel them forward. The addition of particles in the gas stream complicates the dynamics. Due to gas–particle interaction, additional energy lost by the gas manifests itself as additional pressure drop. The energy imparted to the particles is used to move them and to overcome the frictional and impact losses at the pipe wall. Unlike the curve for single-phase airflow, a distinct minimum can be observed for two-phase gas–solid flow.

In horizontal orientation, the suspension becomes progressively nonhomogeneous as the gas velocity is reduced (Figure 4.9). The particles start to fall out of the suspension, as the drag and lift forces are no

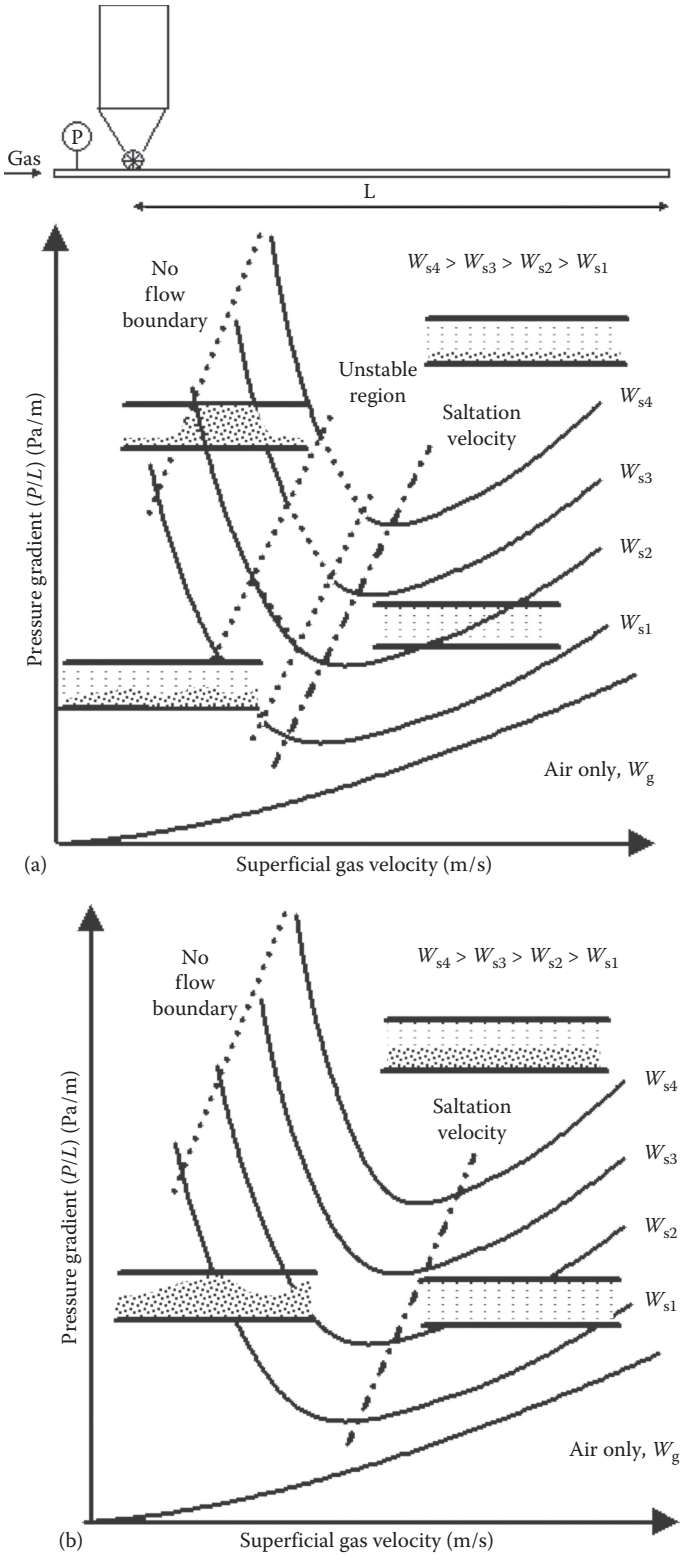

Figure 4.9

Zenz plot with superimposed flow patterns for coarse materials (a) and fine materials (b).

longer able to keep them suspended. The condition when the particles begin to fall out of suspension is called *saltation*. The superficial gas velocity corresponding to this condition is called the saltation velocity. For coarse particles, saltation velocity and the minima in the pressure drop curve are the same, whereas the pressure minima occur at a velocity greater than saltation velocity for fine powders. Since the operating condition at saltation corresponds to minimum pressure drop, it also results in the lowest power consumption. Generally, a safety factor of 10%–20% is added to saltation velocity to account for nonidealities in system configuration.

4.1.1.3.2 Dense Phase Conveying Conveying in nonsuspension flow (slugs, plugs, moving bed, or fluidized bed) is called dense phase conveying. As the gas velocity is reduced below the minimum requirement to maintain the particles in suspension, there are two possibilities:

1. Smooth transition from dilute phase to moving beds or dunes to fluidized mode
2. Transition to dune or degenerate dune flow that eventually transforms into smooth slug flow

The following important observations can be made from this diagram.

1. The pressure gradient curve does not decrease monotonically with gas velocity when conveying solids. This is unlike single-phase gas flow.
2. There is a minimum in the pressure characteristic (at constant solids' conveying rate). This point also corresponds to the lowest power consumption. In dense phase, the pressure gradient increases as the gas velocity is further decreased.
3. At a given pressure gradient and dilute phase flow condition, the conveying rate (capacity) decreases with increase in gas velocity (gas flow rate), as shown by A → B line in Figure 4.10. This can be explained by the fact that more energy is expended in solids' frictional and impact losses at the higher velocity. This observation is extremely important and useful when we are optimizing conveying systems.

In vertical orientation, as the gas velocity reduces at the same solids' mass flow rate, solids' concentration in the pipe increases and the wall frictional loss decreases. Initially, the decrease in wall frictional loss is significantly higher than the increase in gravitational component; therefore, the overall pressure gradient decreases with reduction in gas velocity. However, at sufficiently low gas velocity, the gravitational component due to solids' holdup becomes predominant and the overall pressure gradient starts to increase (Figure 4.11). The flow conditions at and below this gas velocity are classified as dense phase flow.

The mechanism of choking is not clearly understood: Also, not all systems exhibit this behavior. Whether the system will exhibit slugging or nonslugging behavior with internal recirculation of solids depends on the properties of the material and the pipe size. In general, fine particles in large pipes tend toward nonslugging dense phase flow, while choking with slugging is observed with coarse particles in small-diameter pipes. If the transition from dilute or lean phase to dense phase is sharp, then choking corresponds to the pressure minimum. However, if the transition from dilute to dense phase is "fuzzy," then actual choking can occur at a velocity lower than that corresponding to the pressure minimum.

Comparison of saltation velocity and choking velocity data for different materials suggests that

1. For fine particles, saltation velocity is about 3–5 times larger than the choking velocity.
2. For coarse particles, the saltation and choking velocity are almost identical.

Most of the conveying systems are configured such that the material is fed into a horizontal section of the pipe. Therefore, the saltation velocity (with appropriate safety factor) should be used for design calculations; this will result in a conservative design. From a design point of view, it is desirable to choose an operating point that would result in minimum pressure drop, power consumption, erosion, and particle degradation, and yet provide reliable and stable operation. The region immediately to the right (toward higher gas velocity) of the minimum is considered to be the optimal region.

4.1.1.3.3 Saltation Velocity As discussed earlier, the saltation velocity of coarse particles (such as pellets) can be estimated by locating the minimum in the pressure gradient curve in Zenz plot. A nondimensional representation of the saltation velocity data was proposed by Barth (1958) and then successfully extended by Rizk (1976). A straight-line relationship is obtained by plotting solids loading versus Froude number

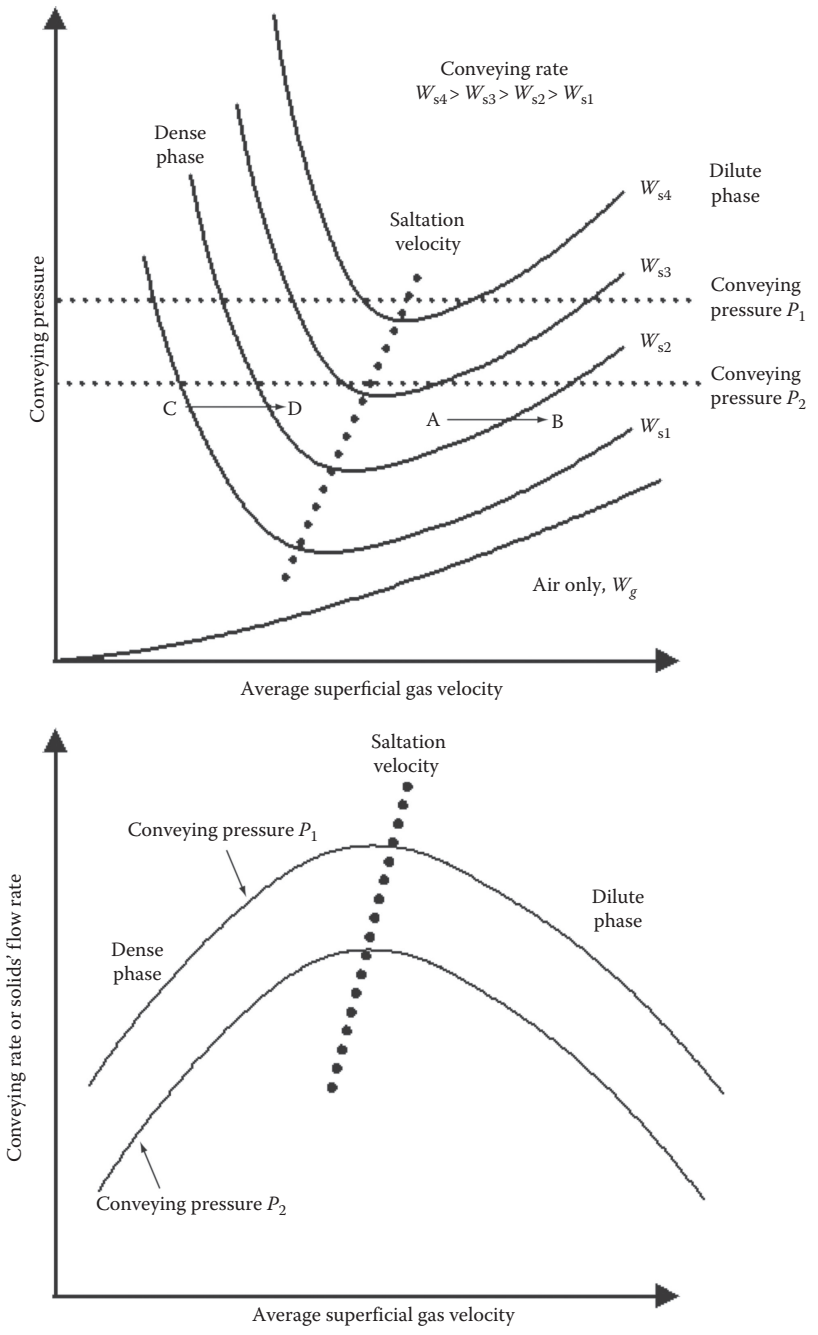

Figure 4.10

Influence of gas velocity on conveying capacity.

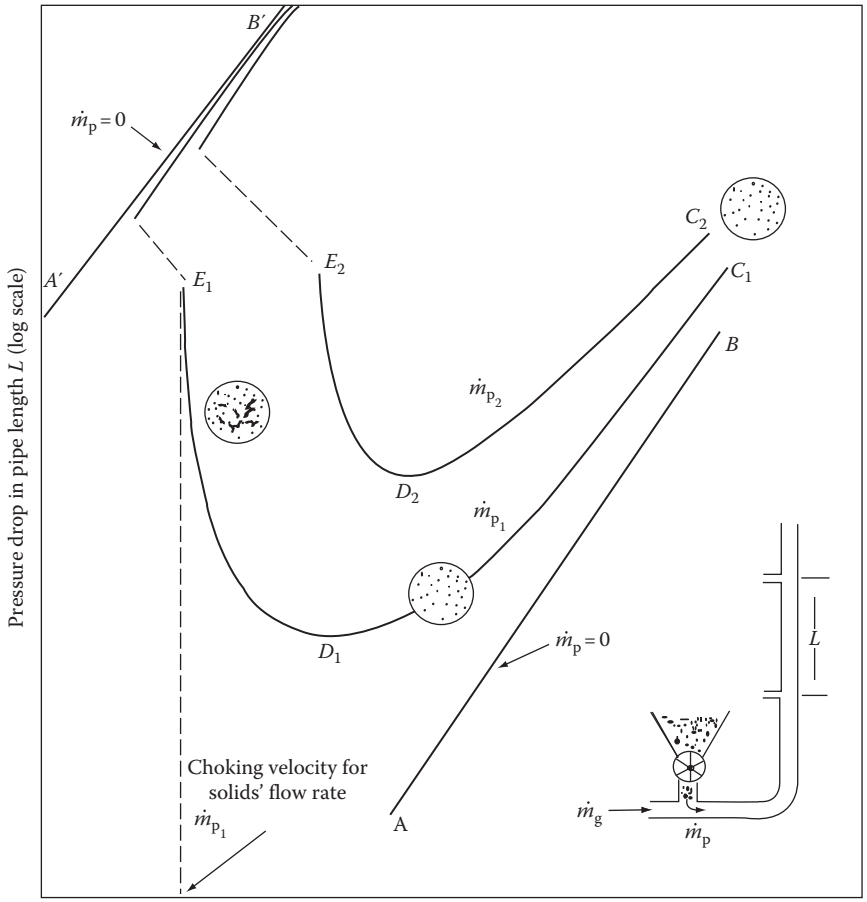

Figure 4.11

Conveying characteristics for vertical pneumatic conveying. (From Zenz, F.A. and Othmer, D.F., *Fluidization and Fluid Particle Systems*, Reinhold, New York. With permission.)

corresponding to each of the pressure minimums (same as saltation) on a log–log scale. This straight line represents a relationship of the form

$$\mu_{\text{saltation}} = \alpha Fr_{\text{saltation}}^{\beta}$$

α and β can be estimated from regression where α and β are dimensionless coefficients.

Barth (1958) suggested that the power-law index β is 4.0. Rizk (1976) proposed the following expressions to estimate the indices:

$$\alpha = \frac{1}{10^{\left(1.4d_p + 1.96\right)}}$$

$$\beta = \left(1.1d_p + 2.5\right)$$

with d_p in millimeters. It should be noted that Rizk's correlation does not include the effect of particle density.

Saltation velocity can be explicitly derived from the earlier expression as follows.

$$U_{gs} = \left[\frac{W_s\left(gD\right)^{\beta}}{A\rho_g\alpha}\right]^{1/(2\beta+1)}$$

Based on an extensive experimental database, Matsumoto et al. (1977) proposed the following correlations. He observed that coarse and fine materials behave differently. The saltation velocity of fine powders decreases with particle size until a critical particle diameter, $d_p^\star$, is reached, and then the saltation velocity increases with particle size.

Critical particle diameter, $d_p^\star$ is defined as

$$\frac{d_p^\star}{D} = 1.39\left(\frac{\rho_p}{\rho_f}\right)^{-0.74}$$

For $d_p \geq d_p^\star$:

$$\mu_s = 0.373\left(\frac{\rho_p}{\rho_f}\right)^{1.06}\left(\frac{Fr_p}{10}\right)^{-3.7}\left(\frac{Fr_{ss}}{10}\right)^{3.61}$$

where

$$Fr_p = \frac{U_t}{\sqrt{gd_p}}$$

$$Fr_{ss} = \frac{U_{gs}}{\sqrt{gD}}$$

$$\mu_s = \frac{W_s}{W_g} \quad \text{(solids loading at saltation condition)}$$

For $d_p < d_p^\star$

$$\mu_s = 55\left(\frac{d_p}{D}\right)^{1.43}\left(\frac{Fr_{ss}}{10}\right)^{4.0}$$

Guidelines for correlation selection

- For coarse particles (d_p > 500 μm) and particle specific gravity less than 3, use the Rizk correlation.
- For coarse particles (d_p > 500 μm) and particle specific gravity greater than 3, use Matsumoto correlation.
- For fine particles (d_p < 500 μm), use Matsumoto correlation.

Example 4.1: Calculate the Saltation Velocity Using the Following Data

- Particle density ρ_p = 950 kg/m^3 = 59.3 lbm/ft^3
- Gas density (ρ_g) = 1.2 kg/m^3 = 0.075 lbm/ft^3
- Average particle diameter (d_p) = 0.003 m = 3 mm
- Inner diameter of the pipe D = 0.161 m = 6.357 in.
- Conveying rate for solids (W_s) = 3.0 kg/s = 23,760 lbm/h

(A) Calculation of Rizk saltation velocity:

$$\mu_s = \frac{1}{10^\delta} Fr_s^x$$

$$\delta = 1.44d_p + 1.96 = 6.28$$

$$\chi = 1.1d_p + 2.5 = 5.8$$

$$Fr_s = \frac{U_{gs}}{\sqrt{gD}}$$

$$\mu_s = \frac{\text{solids' flow rate}}{\text{gas flow rate}} = \frac{W_s}{W_g} = \frac{W_s}{A\rho_f U_{gs}}$$

$$\frac{W_s}{A\rho_f U_{gs}} = \frac{1}{10^{\delta}}\left(\frac{U_{gs}}{\sqrt{gD}}\right)^{x}$$

$$U_{gs} = \left[\frac{W_s 10^{\delta}}{A\rho_f}\left(\sqrt{gD}\right)^{x}\right]^{1/(x+1)}$$

$$U_{gs} = \left[\frac{3\times 10^{6.28}}{0.02\times 1.2}\left(\sqrt{9.81\times 0.161}\right)^{5.8}\right]^{1/6.8}$$

$$U_{gs} = \left(8.938\times 10^{8}\right)^{1/6.8}$$

$$U_{gs} = 20.72 \text{ m/s} = 4077 \text{ ft/min}$$

(B) Calculation of Matsumoto saltation velocity of calculation:

$$\frac{d_p^*}{D} = 1.39\left(\frac{\rho_p}{\rho_f}\right)^{-0.74} = 1.39\left(\frac{950}{1.2}\right)^{-0.74} = 0.00995$$

$$d_p^* = 0.0016 \text{ m}$$

Since $d_p^* < d_p$

$$\frac{W_s}{W_g} = 0.373\left(\frac{\rho_p}{\rho_f}\right)^{1.06}\left(\frac{Fr_p}{10}\right)^{-3.7}\left(\frac{Fr_s}{10}\right)^{3.61}$$

$$Fr_p = \frac{U_t}{\sqrt{gd_p}} = \frac{7.93}{\sqrt{9.81\times 0.003}} = 46.22$$

$$Fr_s = \frac{U_{gs}}{\sqrt{gD}}$$

Rearranging,

$$U_{gs} = \left[\left(\frac{\rho_p}{\rho_f}\right)^{-1.06}\left(\frac{Fr_p}{10}\right)^{3.7}\frac{W_s\times 10^{3.61}\left(\sqrt{gD}\right)^{3.61}}{(0.373)(A\rho_f)}\right]^{1/4.61}$$

$$U_{gs} = \left[(791.66)^{-1.06}(4.622)^{3.7}(3115189.4)\right]^{1/4.61}$$

$$U_{gs} = 18.87 \text{ m/s} = 3713 \text{ ft/min}$$

4.1.1.3.4 Choking Velocity (Yousifi and Gau, 1974) There are numerous correlations available in the literature on choking velocity (Chong and Leung, 1986). The following correlation has been found to be reliable (especially for Geldart A and B class of materials).

$$\frac{U_c}{\sqrt{gd_p}} = 32Re_p^{-0.06}\mu^{0.28}$$

where

$$Re_p = \frac{\rho_f U_t d_p}{\mu_f}$$

$$\mu = \frac{W_s}{W_g}$$

Example 4.2: Calculate the Choking Velocity Using the Following Data

- Particle density $\rho_p = 950$ kg/m^3 = 59.3 lbm/ft^3
- Gas density $\rho_g = 1.2$ kg/m^3 = 0.075 lbm/ft^3
- Average particle diameter $d_p = 0.003$ m = 3 mm
- Inner diameter of the pipe (D) = 0.161 m = 6.357 in.
- Conveying rate for solids $W_s = 3$ kg/s = 23,760 lbm/h
- Gas viscosity $\mu_g = 1.8 \times 10^{25}$ kg/(ms) = 0.018 cP

$$Re_p = \frac{\rho_f U_t d_p}{\mu_f} = \frac{1.2 \times 7.93 \times 0.003}{1.8 \times 10^{-5}} = 1586$$

$$U_c = \left[\sqrt{g d_p} \times 32 Re_p^{-0.06} \left(\frac{W_s}{A \rho_f} \right)^{0.28} \right]^{1/1.28}$$

$$U_c = \left[\sqrt{(9.81 \times 0.003)} \cdot 32 (1586)^{-0.06} \left(\frac{3}{0.02 \times 1.2} \right)^{0.28} \right]^{1/1.28}$$

$$U_c = 7.69 \text{ m/s} = 1514 \text{ ft/min}$$

Note that saltation velocity > choking velocity.

4.1.2 Classification of Pneumatic Conveying Systems

Pneumatic conveying systems can be configured and operated in a number of different ways for a given application. The common classifications and their basis are summarized in Table 4.2. The most fundamental classification from a design and operation perspective is based on flow pattern, that is, dilute phase versus dense phase systems.

Dilute phase conveying: The particles are in a fully suspended state along the entire system. All segments of the system operate at velocities greater than the saltation velocity. Dilute phase conveying systems are typically designed to operate at less than 1 bar gauge with maximum solids' loading less (kg of solids/kg of gas) than 10.

Dense phase conveying: When the material is conveyed in nonsuspension mode (slugs, strand, moving bed, and fluidized mode) for the entire conveying length, the system is classified as a dense phase conveying system. It should be noted that the flow pattern can change from the feed point to the end of the line due to the continual expansion of gas. It is not uncommon to have a well-defined slug flow at the feed point and fully suspended flow at the end of a long transfer system. Therefore, a definition based solely on solids' loading is misleading.

4.1.2.1 Classification of Dilute Phase Conveying Systems

4.1.2.1.1 Pressure Type Any pneumatic conveying system can be operated either at a positive pressure or under vacuum depending on the configuration of its components. Positive pressure or push systems (Figure 4.12) have the air mover positioned upstream of the solids' feed point and the cyclone or dust

Table 4.2 Classification of Pneumatic Conveying Systems

Basis	Type of System
Flow pattern	Dilute phase, strand flow or medium dense phase, dense phase
Loop configuration	Open loop, closed loop
Pressure (type)	Pressure (push), vacuum (pull), combined (pull–push)
Pressure (magnitude)	Low pressure (−0.1 bar to +0.1 bar), medium pressure (−0.5 bar to 1 bar), High pressure (>1 bar)
Feeder type	Air into solids, solids into air
Air mover type	Fan, rotary lobe blower, compressor, other
Solids' loading	Very low (<1), low (0–5), medium (5–15), high (>15), very high (>100)

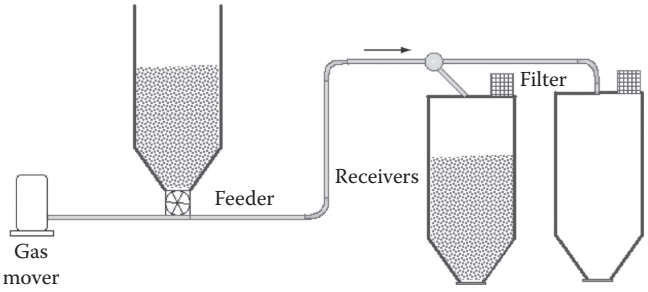

Figure 4.12

Typical positive pressure or push system.

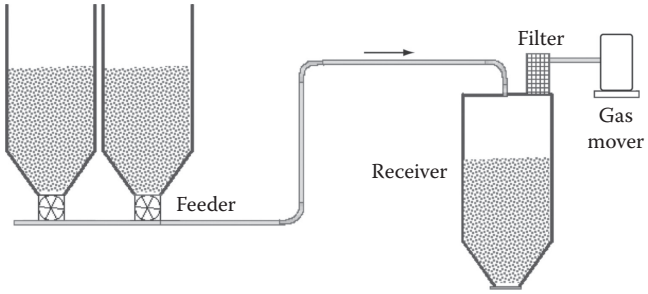

Figure 4.13

Typical vacuum or pull system.

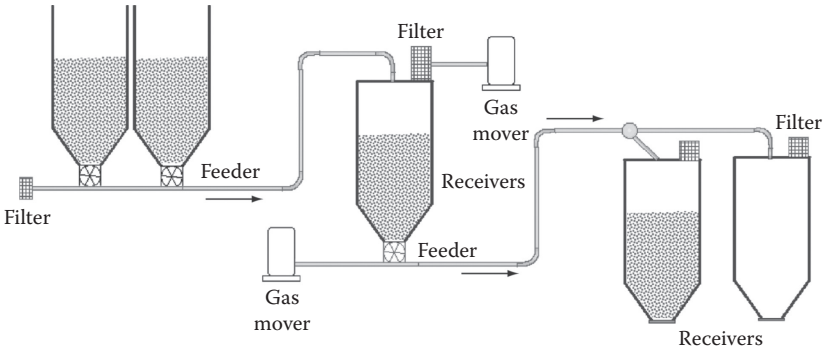

Figure 4.14

Typical combined or pull–push system.

collector operated near atmospheric pressure. The air mover is situated closer to the feed point to provide higher than ambient air pressure, which results in positive pressure in the entire line.

The air mover for a vacuum system or pull system is located downstream of the dust collector and the pressure at the feed point is near the atmospheric pressure (Figure 4.13). A combined system (pull–push) uses a single blower to vacuum convey material from one or more sources to a dust collector and then pressure convey the material using the same gas to one or more destinations (Figure 4.14). A summary of characteristics based on this classification is given in Table 4.3.

4.1.2.1.2 Loop Configuration Most pneumatic conveying systems operate as open-loop systems. An open-loop system is one where the conveying gas is vented (or treated and vented) after a single pass through the conveying line. A closed-loop system recycles the gas to the feed point (Figure 4.15).

Table 4.3 Comparison of Pressure, Vacuum, and Combined Conveying Systems

Process Requirement	Vacuum or Pull System	Pressure or Push System	Combined Vacuum Pressure or Pull–Push System
Multiple source, single destination	Preferred	Expensive to implement	Use when single destination is far
Single source, multiple destinations	Expensive to implement	Preferred	Used if high-pressure feeder cannot be used, for example, railcar unloading system
Handle toxic material (containment)	Preferred	No	No
Explosive material	No	Only with inert gas	No
Long-distance conveying (>500 ft)	Limited capacity	Feasible	Feasible but not necessary
Control	Sluggish	Good	Sluggish

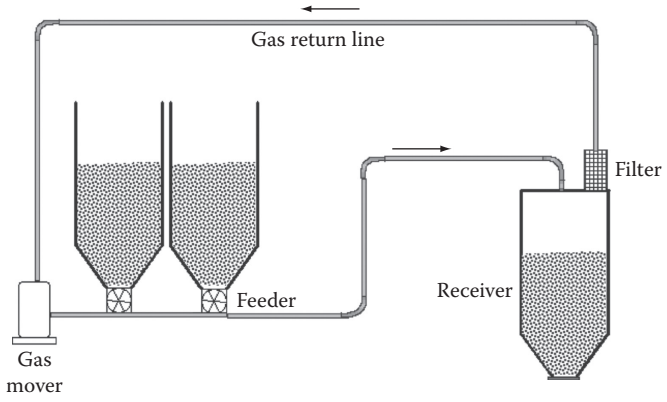

Figure 4.15

Typical closed-loop system.

4.1.2.1.3 Feeder Type or Air–Solids' Mixing Device Conveying gas and solids need to be mixed together to create a gas–solid suspension. This can be accomplished in two ways:

1. Air into material: Using pressure vessel (e.g., blow tank)
2. Material into air: Using mechanical feeders (e.g., screw feeder, rotary feeder, and venturi eductor)

Air-into-material systems are generally batch-type systems that can be operated at very high pressures. It is possible to achieve low velocity, high solids' loading, and long-distance conveying with these systems. Material-into-air systems are continuous systems limited only by pressure rating, leakage rate, wear rate, and feed characteristics of the material.

4.1.2.1.4 Air Mover Type Air movers provide the motive force or energy for conveying. Energy efficiency, system stability, and conveying capacity limitation is largely dictated by the choice of air mover (Table 4.4). Some applications, such as when the material passes through the air mover, require specific types of air movers (e.g., fans).

4.1.2.2 Classification of Dense Phase Conveying Systems

As mentioned earlier, a dense phase pneumatic conveying system operates in a flow regime to the left of saltation velocity (Figure 4.9). The material moves in a nonsuspended mode within the pipe. Unlike dilute phase conveying, where fluid–particle interactions and particle–wall interactions determine the flow behavior, in dense phase conveying the interparticle forces and contact mechanics dominate the flow behavior.

Simple examples of dense phase conveying are conveying of cement and plastic pellets. Once aerated, cement retains air for a long time and remains essentially fluidized. It can be transported through a conveying line at very high solids' loading with nonspecialized hardware over large distances. Similarly, plastic pellets have a natural tendency to slug when fed into a pipe with motive air. This system is self-adjusting and easy to operate.

Table 4.4 Classification Based on Air Movers

Air Mover Type	Typical System Characteristics
Fan or centrifugal blower	Short or lightly loaded systems, low pressure drop, cannot tolerate surging solids' feed, low noise, can tolerate material pass through
Rotary lobe blower	Most common for dilute phase systems, pressure drop up to 1 bar, blower characteristics ideal for varying feed rates
Screw compressors	Common for dense phase system, pressure drop up to 6 bar, blow tanks or high-pressure airlock as feeders

However, there is a broad range of materials that do not possess the high aeration of cement or natural slugging ability of plastic pellets. To convey these materials in smooth dense phase mode, various innovations have been implemented in the industry. The objective of these innovations has been to extend the range of applicability of dense phase system and to make them less sensitive to product characteristics.

Dhodapkar (1990) proposed a broad classification for various dense phase conveying concepts (see Figure 4.16).

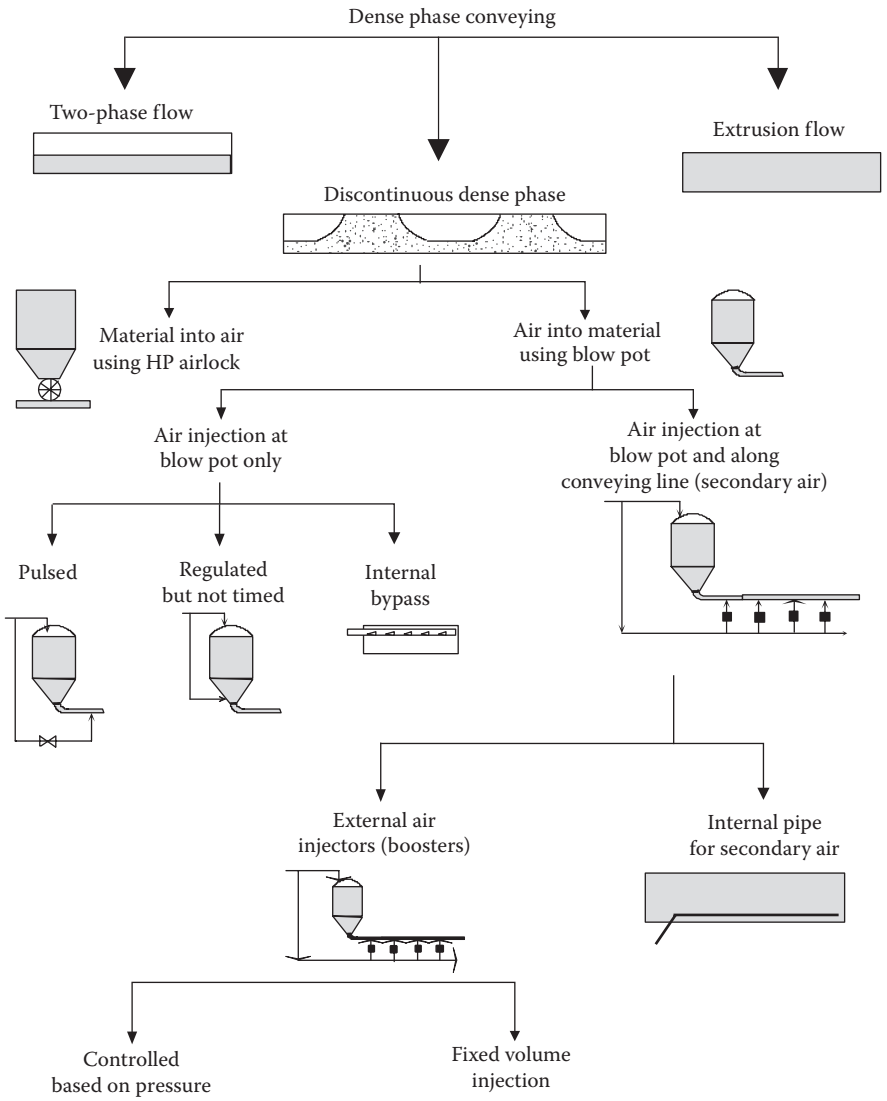

Figure 4.16

Classification of dense phase conveying system.

Two-phase flow: Refers to systems operating just below saltation. The material moves in a strand type flow. The hardware requirements are similar to dilute phase conveying systems, but these systems can operate at much higher pressures (between 1 and 6 bar).

Extrusion flow: A typical example would be dense phase conveying of cement, fine coal, or fly ash. The material is highly aerated, and the gas is homogeneously dispersed with the solids.

Discontinuous dense phase: Refers to plug or slug type of conveying. The conveying gas and material are nonuniformly dispersed to create a variety of flow patterns from slugs and dunes to waves.

Discontinuous dense phase conveying can be achieved either by feeding material into air stream, commonly using a rotary airlock or feeder, or by injecting air into material such as in a blow-tank system.

Material into air: Refers to systems using a high-pressure rotary airlock as a feeder. The construction of these feeders is very similar to conventional rotary airlock with the exception of tight clearances, robust shaft design, and design modifications to minimize gas leakage. It is possible to design continuous dense phase system with high-pressure feeders. The limitations due to abrasive wear and particle degradation can be addressed on a case-by-case basis.

Air into material: Conventional blow tank type of systems fall into this category. The blow tank acts as a high-pressure feeder. These systems typically run in batch mode unless two tanks are operated in tandem. The discharge characteristic of a blow tank is affected by downstream pressure and the nature of air distribution around the blow tank. The main advantage of a blow tank is the lack of moving parts in constant contact with the material. Loss of conveying air due to wearing of valve seat can be a maintenance problem.

Air distribution at the blow tank and along the conveying line can be used as a tool to create and maintain smooth dense phase conveying mode.

4.1.2.2.1 Air Injection Only at Blow Pot or Tank Various methods are possible:

- *Pulsed*. Air injection is used at regular intervals (pulsed) to create air gaps between slugs and plugs and limit their length. The ability to change the length of air gaps between plugs is helpful to run the conveying system at low solids' rate without causing unstable flow. There are several commercial adaptations of this concept.
- *Regulated, not timed*. The conveying air is split between the top and the bottom of the blow tank in a regulated fashion. The top air controls the discharge rate, while the secondary air at the bottom is used to control the solids/air ratio.
- *Internal bypass*. This concept provides a bypass for the conveying air so that it can reach the location of a plug easily. It is assumed that conveying consists of making and breaking of impermeable plugs. No external air is added. The internal bypass line may not be continuous along the conveying length.

4.1.2.2.2 Air Injection at Blow Pot or Tank and Along Conveying Line External air injection can be accomplished by providing either discrete injection points or a perforated tube along the conveying line for continuous air injection.

- *Discrete air injection*. It is commonly known as *Booster Systems*. The air injectors or boosters are installed on the conveying line. Each location has a check valve, which prevents the solids from backing into the air supply header. The majority of systems presently in operation today are based on the concept of fixed volume air injection. Each injector or booster station has a flow control valve that can be set to feed a constant volume of air into the system. The pressure profile or flow conditions in the conveying line generally does not affect the air flow, since these flow control valves act as a critical flow orifice. Some systems are designed with pressure sensors to inject air at locations with high-pressure gradient, which will correspond to a long or stalled plug. The air injection helps to break the plug and maintain smooth conveying conditions.
- *Continuous air injection*. This is accomplished by a pipe in a pipe arrangement. The internal pipe has holes at regular intervals for air injection. Very few of these are commercially available. The clogging of internal pipe is the biggest reason.

4.1.3 Components of Conveying System

A short discussion of the three major components of a conveying system, namely, feeder, air mover, and gas–solid separator, is given here.

4.1.3.1 Feeders

A feeder in a pneumatic conveying system serves the purpose of an airlock between the conveying line and the feed hopper and regulates the feed rate of solids into the line. In vacuum systems, where the feed point is at ambient pressure, the airlock function is not required. Table 4.5 summarizes the operating range and material suitability of various common feeders.

The design of feeder–hopper interface is critical to assure reliable flow out of the hopper. The mass flow pattern in a hopper can be disrupted by a feeder that extracts the material preferentially from one corner of the outlet, which in turn affects the flow into the feeder. Also, the feed shoe or feed box that connects the feeder to the conveying line must be properly designed to provide good mixing and entrainment of solids in gas.

Among these feeders, rotary airlock or feeders and blow tanks are the workhorses of the industry and deserve more attention.

Table 4.5 Summary of Feeders for Pneumatic Conveying Applications

Feeder	Suitable for System Types	Operating Pressure	Suitable Materials	Unsuitable Materials	Conveying Mode	Comments
Suction nozzle	Vacuum	Up to 0.5 bar vacuum	All free flowing	Caking, large chunks, sticky, cohesive	Continuous dilute phase	Feed rate control is difficult
Rotary feeder	Vacuum and pressure	0.5 bar vacuum −3.5 bar pressure (6 bar maximum)	Wide range of materials	Abrasive, caking, sticky, very cohesive	Continuous dilute and dense phases	Most common feeder. Wide variety of design features
Eductor	Pressure	0.25 bar	Free flowing	Abrasive, friable, highly cohesive	Continuous dilute phase	Special design for abrasive materials, high-pressure motive gas may be required
Blow tank–bottom discharge	Pressure	0–10 bar	Wide range of materials, abrasive materials	Very cohesive, sticky or compressible materials	Batch dilute and dense phases	Poorly flowing materials will require air injection in the cone, difficult to control conveying rate
Blow tank–fluidization type, top discharge	Pressure	0–10 bar	Fine fluidizable materials (Geldart class A/C, A)	Geldart class B, B/D, D or material with large chunks	Batch dilute and dense phases	
Double flapper valve	Pressure	0–0.5 bar	Abrasive and free-flowing material	Cohesive	Continuous dilute phase	Pulsing feed. Difficult to obtain; good and consistent seal
Screw feeder	Pressure and vacuum	0.5 bar vacuum to 1 bar pressure	Wide range of materials	Sticky, compressible	Continuous dilute phase	Improper design will result in feed rate control. Rate sensitive to material properties
Fuller–Kinyon Pump	Pressure	2 bar	Fine powders	Coarse materials	Continuous dilute and dense phase	Typically used in cement industry
Slide gate	Vacuum	Up to full vacuum	Coarse materials, preferably free flowing	Cohesive, sticky materials	Continuous dilute phase	Simple, discharge rate depends on material properties
Other specialized feeders: diaphragm pump	Pressure	0–0.5 bar	Materials with high air retention or low deaeration, preferably low bulk density	Sticky, cohesive, low air retention	Continuous dilute and dense phases	

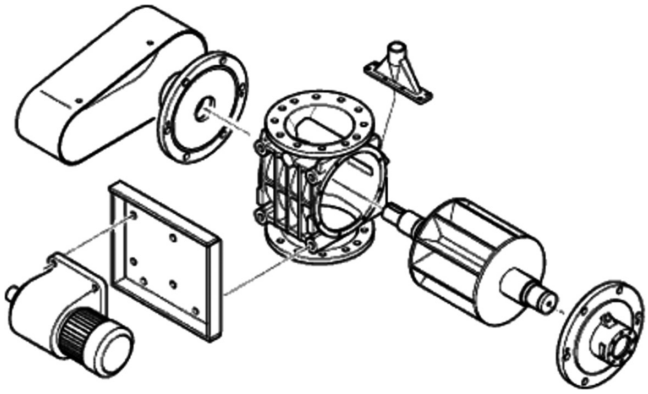

Figure 4.17

Exploded view of a rotary airlock/feeder. (Courtesy of Coperion Waeschle.)

4.1.3.1.1 Rotary Airlock or Feeder This feeder comprises vanes welded on a shaft where the space (pockets) between the vanes fills and empties as the shaft turns (Figure 4.17). The high- and low-pressure sides are isolated by tight clearances between the vanes and the housing. A range of designs are available, and careful selection of features and operating range must be made, based on bulk properties. The critical issues are

- Volumetric capacity of the rotor and its relationship with r/min
- Gas leakage rate at various pressures and r/min
- Particle degradation and wear
- Venting arrangement of gas
- Design of inlet and outlet
- Seal and bearing design

4.1.3.1.2 Blow Tank Blow tanks or blow pots are commonly used as feeders for high-pressure applications. There are two common configurations of blow tanks: bottom discharge and top discharge. The top discharge blow tanks are used for fine powders, whereas bottom discharge blow tanks can be used for powders and coarse materials. The conveying air can be injected at various locations at the blow tank and along the conveying line (as shown in Figure 4.18). Blow tanks operate in batch mode. A complete cycle consists of filling, valve setting, pressurization, conveying, and depressurization (Figure 4.18). The average conveying rate is lower than instantaneous conveying rate due to time lost in nonconveying steps.

The advantages of the blow tank as a feeder are as follows:

1. No moving parts in contact with solids
2. Can operate or feed against high pressures (>3 bar)
3. Good for abrasive materials
4. Low maintenance

However, the disadvantages are as follows:

1. Do not provide good control on discharge rate or solids loading
2. Unsuitable for very cohesive or sticky materials
3. Batch operation, but can be made continuous using two blow tanks

4.1.3.2 Air Movers

Air movers provide the motive energy for pneumatic transfer. Fans, centrifugal blowers, rotary lobe (roots type) blowers, screw compressors, sliding vane compressors, and reciprocating compressors cover the majority of the applications. The suitability of an air mover must be judged based on the operating conditions and requirements of the application.

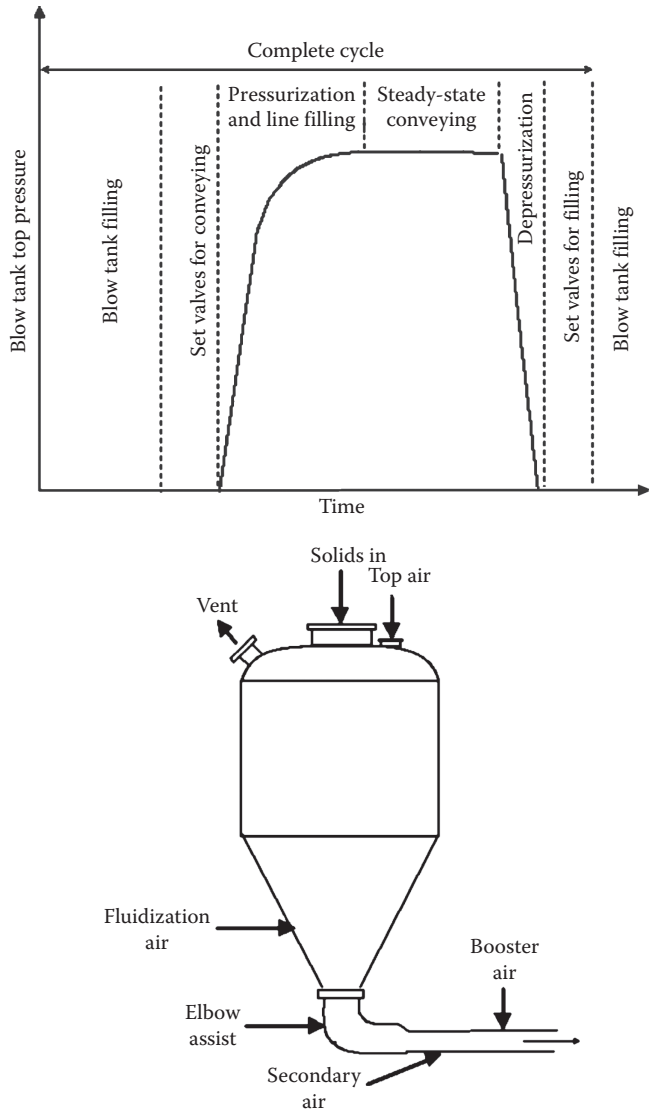

Figure 4.18

Typical bottom discharge blow tank configuration and conveying cycle.

4.1.3.2.1 Fans Fans convert kinetic energy of the gas generated by the rotating impeller into pressure and the volume as a result of displacement of the blades. Depending on the direction of flow through the impeller, fan designs can be broadly classified into four categories, namely, axial flow, radial flow (centrifugal fans), mixed flow (axial and radial), and cross-flow. In pneumatic conveying applications, radial flow or centrifugal fans are primarily used.

There are three primary impeller designs available for centrifugal fans: radial, backward curving, and forward curving. The forward-curved design provides maximum pressure head for a given rotor size and speed, while the backward curved design provides the least. On the other hand, backward-curved impeller design is more energy efficient with lower operating costs. Radial flow fans offer the best compromise. Radial flow design can also tolerate particulate material in the gas stream and tend to be more robust.

Fans are generally driven directly with a motor that limits the speed of rotation. To change the gas flow rate, inlet or outlet throttling valves can be used. Proper balancing of the fans is necessary to minimize the maintenance of the bearings.

The performance of all fans is governed by fan laws that state the following:

1. Air volume varies directly with fan speed.
2. Static pressure varies with square of the speed.

3. Brake horsepower and air horsepower varies with the cube of the speed.
4. For geometrically similar fans, air volume varies with the cube of size.
5. For geometrically similar fans, static pressures vary with the square of the size.
6. For geometrically similar fans, break horsepower varies with the fifth power of size.

These laws can be used to scale up or predict the performance of a machine at different operating conditions. In order to convert the performance curve of a fan from one speed to another, select a number of points on the curve and convert the corresponding data for air volume, static pressure, brake horsepower, and noise using the following equations:

$$\frac{Q_2}{Q_1} = \left(\frac{D_2}{D_1}\right)^3 \frac{\text{rpm}_2}{\text{rpm}_1}$$

$$\frac{P_2}{P_1} = \left(\frac{D_2}{D_1}\right)^2 \left(\frac{\text{rpm}_2}{\text{rpm}_1}\right)^2$$

and

$$\frac{\text{HP}_2}{\text{HP}_1} = \left(\frac{D_2}{D_1}\right)^5 \left(\frac{\text{rpm}_2}{\text{rpm}_1}\right)^3$$

where
Q is the air flow rate
P is the static pressure
D is the impeller diameter of fan
HP is the break horsepower

For detail treatment of fan design, operation, and performance, see Fan Engineering (2003).

4.1.3.2.1.1 Controlling Air Flow Rate The most efficient means of reducing air flow rate from a fan is to change the fan speed. While the efficiency remains unchanged, the noise level and power consumption are significantly reduced. Since the fan curves are shifted, there is no risk of operation in the unstable region. The cost of a variable speed motor can be high if the adjustment needs to be made very often.

Another approach is to install adjustable inlet and outlet vanes. Vane control systems are cheaper to implement but do not provide the same level of power savings as speed control. Inlet vane control is used for large fans since it is cheaper, but the power savings are better than that in the outlet vane control.

4.1.3.2.2 Rotary Lobe Blowers Rotary lobe blowers (roots-type blowers) are ideally suited for pneumatic conveying applications operating at less than 1 bar gauge pressure or 0.5 bar vacuum and require oil-free gas. While most rotary lobe blowers are rated for 1 bar and less, special lobe designs can deliver 1.24 bar differential pressure. These can be considered before opting for a screw compressor as the choice for the air mover. The air mover operates on positive displacement principle where the gas at the inlet is trapped between two counterrotating lobes. As the two lobes rotate, the gas is expelled at the discharge end (see Figure 4.19). There is no gas compression within the lobes, and all the compression occurs as the gas is expelled against the higher

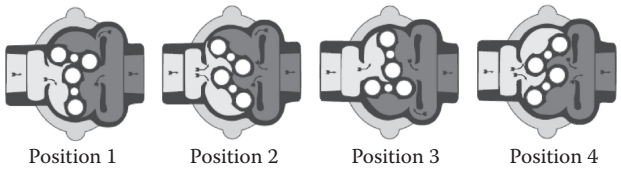

Figure 4.19
Roots blower operating principle. (Courtesy of Roots Dresser Industries.)

pressure at the outlet. Therefore, the horsepower consumption is proportional to discharge pressure and the inlet air volume remains relatively constant with back pressure. The slight decrease in air delivery volume is due to slippage of gas owing to clearances between the lobes. These blowers can be very noisy during the operation, and hence, inlet or outlet silencers are highly recommended. The pulsating nature of the gas flow can be reduced by using a trilobe design. The pulsations also result in the loss of thermodynamic efficiency.

In specifying blower performance, one may use actual cubic feet per minute (ACFM) and inlet cubic feet per minute (ICFM) alternately. These refer to the flow rate at the inlet of blower based on actual conditions of temperature, pressure, and RH% (relative humidity) at the blower inlet. It is essential to distinguish ACFM/ICFM from standard cubic feet per minute (SCFM). SCFM refers to the gas flow rate at a standard reference pressure, temperature, and RH%. According to ASME and CAGI standards, the standard reference is 14.7 psia, 68°F, and 36% relative humidity. Most blower curves are based on ICFM and not SCFM.

4.1.3.2.3 Screw Compressors Screw compressors are required when conveying pressure exceeds 1 bar. The screw compressor is a positive displacement volume reduction machine. In simplest configuration, it consists of a male rotor (driver) and a female rotor (driven). The gas is trapped in the void space between the counterrotating rotors at the inlet. As the screws turn, the volume is reduced and the compression is achieved. Unlike reciprocating compressors, there are no discharge valves in screw compressors. The end of compression automatically occurs at the discharge port. Since the energy is already spent on compressing the gas through the compressor, any changes in system characteristics (reduced load) will not affect the power consumption. The performance of a screw compressor must be controlled independently either through throttling of the inlet valve or the variable speed drive on the rotor.

A comparison of the characteristics of fan, rotary lobe blower, and screw compressor is shown in Figure 4.20 and Table 4.6.

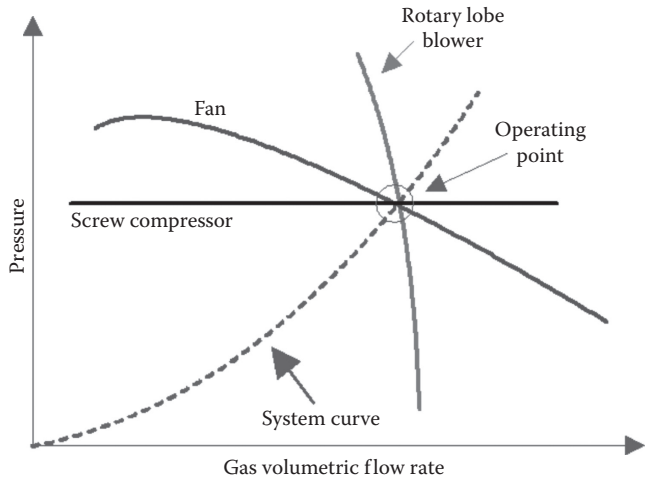

Figure 4.20

Comparison of air mover characteristics and relationship with system characteristics.

Table 4.6 Comparison of Air Movers (Typical Performance Limits)

Type	Maximum Delivery Pressure or Vacuum (bar)	Maximum Flow Rate (m^3/min)
Fans	±0.2	1000
Single-stage centrifugal blowers	−0.5 to +0.5	1000
Rotary lobe blowers	−0.5 to +1	1200
Screw compressors	0–10	1000
Reciprocating compressor	No limit	200
Sliding-vane compressor	1–5	100

4.1.3.3 Gas–Solid Separation Devices

The three common gas–solid separation devices are

1. Inertial separator
2. Cyclone separator
3. Dust collector or baghouse

Selection and specification of suitable gas–solid separation device will depend on process requirements and material properties, namely,

1. Desired efficiency of separation based on particle size distribution of incoming solids
2. Acceptable pressure drop range
3. Operating pressure and temperature
4. Cleanout and contamination requirement
5. Dust explosion potential
6. Acceptable turn down in gas flow rate
7. Compatibility with material (corrosiveness, abrasion, etc.)

A simplified guideline is presented in Table 4.7.

4.1.4 Calculating Pressure Drop in Dilute Phase Systems

The total pressure drop across a conveying system can be assumed to be the sum of pressure drops across various components. The total pressure drop in turn must be overcome by the air mover to satisfy the pressure balance:

$$\Delta P_{\text{air-mover}} = \Delta P_{\text{blower-piping}} + \Delta P_{\text{feed-section}} + \Delta P_{\text{accleration(gas+solids)}} + \Delta P_{\text{straight-sections}} + \Delta P_{\text{bends}} + \Delta P_{\text{filter-receiver}}$$

The equations of pressure drop for the various components are presented as follows.

4.1.4.1 Blower Piping and Feed Section Pressure Drop

The pressure drop in the piping carrying gas from the blower to feed section of the conveying system can be calculated by using the standard calculations for single-phase gas flow in pipes. Additional pressure drop due to inlet or outlet filters and inlet or outlet silencers must be added.

4.1.4.2 Acceleration (Gas–Solids) Pressure Drop

When solids are fed into a gas stream, additional energy is expended to accelerate the solids to their steady-state velocity. This loss occurs at the feed (pickup) point. Similar loss occurs when accelerating the gas phase; however, it is relatively smaller.

For the solid phase,

$$\Delta P_{\text{ACC-solids}} = \frac{U_{\text{p}} W_{\text{s}}}{A}$$

Table 4.7 Comparison of Major Gas–Solid Separation Devices

Type of Gas–Solid	Suitable for	Unsuitable for	Comments Separation Device
Inertial separator	Separating large nonhazardous particles with minimal fines	Fine powders or hazardous materials	Simple, low-pressure drop, no maintenance
Cyclone separator	Most nonfriable and nonabrasive materials	Very hazardous materials where 99.5% collection efficiency must be guaranteed	Typical pressure drop of 10″ WC (25 mbar), proper design and installation is critical, scalability with gas flow rate is limited
Dust collector or baghouse	Efficient solution for most materials	Very few materials	Gives high degree of separation, collection efficiency independent of gas flow rate and particle size, bag replacement is major maintenance issue

For the gas phase,

$$\Delta P_{\text{ACC-gas}} = \frac{\rho_g U_g^2}{2}$$

By adding the components given earlier,

$$\Delta P_{\text{ACC}} = \Delta P_{\text{ACC-solids}} + \Delta P_{\text{ACC-gas}}$$

$$\Delta P_{\text{ACC}} = \frac{U_p W_s}{A} + \frac{\rho_g U_g^2}{2}$$

$$\Delta P_{\text{ACC}} = \frac{\rho_g U_g^2}{2}\left(1 + 2\frac{W_s}{A\rho_g U_g}\left(\frac{U_p}{U_g}\right)\right)$$

$$\Delta P_{\text{ACC}} = \frac{\rho_g U_g^2}{2}\left(1 + 2\mu\left(\frac{U_p}{U_g}\right)\right)$$

The velocity ratio, U_p/U_g, for the horizontal flow can be calculated by the (1953) Hinkle correlation:

$$\frac{U_p}{U_g} = 1 - 0.044 d_p^{0.3} \rho_p^{0.5}$$

or modified Hinkle correlation (IGT correlation):

$$\frac{U_p}{U_g} = 1 - 0.68 d_p^{0.92} D^{-0.54} \rho_p^{0.5} \rho_g^{-0.2}$$

where d_p and D in m and ρ_p and ρ_g in kg/m^3.

For vertical flow, one may simply use slip condition based on single-particle terminal velocity.

$$U_p = U_g - U_t$$

4.1.4.3 Steady-State Pressure Drop in Straight Sections

The overall pressure drop for fully accelerated and steady-state dilute phase conveying in straight pipe can be considered as the sum of static and frictional components:

$$\Delta P_{\text{total}} = \Delta P_{\text{static}} + \Delta P_{\text{frictional}},$$

$$\Delta P_{\text{static}} = \rho_p (1 - \varepsilon) \Delta Z g + \varepsilon \rho_g \Delta Z g$$

where the first term on the right-hand side is the contribution due to solids and the second term is due to gas. ΔZ is the change in elevation or height of the vertical section. The static component is zero for horizontal orientation.

The voidage, ε, can be calculated as

$$\varepsilon = 1 - \frac{W_s}{A\rho_p U_p}, \quad U_p = U_g - U_t$$

where the pressure drop term due to gas–solid friction is customarily split into gas and solids' contributions.

$$\Delta P_{\text{frictional}} = \Delta P_{\text{air}} + \Delta P_{\text{solids}}$$

The first term represents the contribution due to gas friction and the second term due to solids' friction. The pressure drop due to air is calculated by well-established single-phase calculation methods:

$$\Delta P_{\text{air}} = \lambda_{\text{f}} \frac{\rho_{\text{g}} U_{\text{g}}^2 L}{2D}$$

where the friction factor for gas alone can be estimated by the explicit correlation of Swamee and Jain (1976):

$$\lambda_{\text{f}} = \frac{1.325}{\left[\ln\left(k_{\text{s}}/3.7D + 5.74/Re^{0.9}\right)\right]^2}$$

For common pipes, the pipe roughness, k_{s}/D, is typically 0.001.

The expression for pressure drop due to solids is formulated similar to single-phase gas flow with added solids' loading factor:

$$\Delta P_{\text{solids}} = \left(\mu\lambda_{\text{z}}\right)\frac{\rho_{\text{g}} U_{\text{g}}^2 L}{2D}$$

4.1.4.3.1 Estimation of Friction Factor λ_z Several approaches have been proposed in the literature to calculate the solids' friction factor based on material properties and system parameters. Unfortunately, none of them are comprehensive and fundamental enough to cover all factors. Weber (1982, 1991), after analyzing a large set of data, proposed the following expression:

$$\lambda_{\text{z}} = K\mu^a Fr^b Fr_{\text{s}}^c \left(\frac{D}{d_{\text{p}}}\right)^d$$

where

$$\mu = \text{solids loading} = \frac{W_{\text{s}}}{W_{\text{g}}}$$

$$Fr = \frac{U_{\text{g}}^2}{gD}, \quad Fr_{\text{s}} = \frac{U_{\text{t}}^2}{gd_{\text{p}}}$$

In pneumatic conveying literature, two forms of Froude number can be found:

$$Fr_1 = \frac{U_{\text{g}}^2}{gD}, \quad Fr_2 = \frac{U_{\text{g}}}{\sqrt{gD}}$$

The reader is cautioned to verify the definition of Froude number before applying any correlation.

In the absence of any experimental data on a material, the parameters listed in Table 4.8 can be chosen for preliminary calculations. It should be noted that the earlier correlation does not account for the effect of elastic properties of particles and wall, surface characteristics, particle size distribution, and particle shape. The exponent of Froude number is always negative; however, the coefficient of solids loading in the correlation need not be negative.

Table 4.8 Summary of Exponents for Friction Factor Correlation

Investigator/Material	*K*	*a*	*b*	*c*	*d*
Stegmaier, fine powder ($d_{\text{p}} < 0.5$ mm)	2.1	−0.3	−1	0.25	0.1
Weber (Siegel data), coarse material ($d_{\text{p}} > 0.5$ mm)	0.082	−0.3	−0.86	0.25	0.1

Source: Weber, M., *Bulk Solids Handling*, 2(2), 231, 1982. With permission.

In the authors' experience using a constant value of friction factor will usually suffice for preliminary calculations. This value can be backcalculated if operating data from an installed system are available.

From experimental data: If conveying data can be generated on a pilot-scale test rig, a more accurate estimation of material-specific friction factor can be made. It is advisable to install a DP transmitter across a straight horizontal section that is away from the bends at each end. A static gage at the test section is necessary to calculate the local gas velocity:

$$\Delta P_{\text{total}} = \Delta P_{\text{frictional}} = \Delta P_{\text{air}} + \Delta P_{\text{solids}}$$
$$\Delta P_{\text{solids}} = \Delta P_{\text{total}} - \Delta P_{\text{air}}$$

where ΔP_{air} can be estimated by regressing pressure drop data for single-phase air flow in the test section. Solids' friction factor can be calculated from experimental data at each of the test condition by using the following equation:

$$\lambda_z = \frac{\Delta P_{\text{solids}} 2D}{\rho_g U_g^2 \mu \Delta L}$$

These data can be correlated with the generalized format or a simplified expression if the test data are not available for a range of pipe sizes:

$$\lambda_z = K\mu^a Fr^b$$

4.1.4.4 Pressure Drop in Vertical Section

The pressure drop in the vertical section can be calculated as follows:

$$\Delta P_{\text{total}} = \Delta P_{\text{frictional}} + \Delta P_{\text{static}}$$
$$\Delta P_{\text{static}} = \rho_p (1-\varepsilon)\Delta Z g + \varepsilon \rho_g \Delta Z g$$
$$\Delta P_{\text{frictional}} = \Delta P_{\text{total}} - \Delta P_{\text{static}}, \quad \Delta P_{\text{frictional}} = \Delta P_{\text{solids}} + \Delta P_{\text{air}}$$
$$\Delta P_{\text{solids}} = \Delta P_{\text{frictional}} - \Delta P_{\text{air}}, \quad \lambda_z = \frac{\Delta P_{\text{solids}} 2D}{\rho_g U_g^2 \mu L}$$

4.1.4.5 Pressure Drop in Bends

In contrast to straight sections, frictional losses have relatively minor contribution to the pressure drop across a bend. The majority of the pressure drop is due to reacceleration of solids that were slowed down during transit through the bend. Since the particles may continue to reaccelerate even after they exit the bend, the pressure drop due to a bend cannot be measured simply by pressure difference between inlet and outlet of the bend. Also, the pressure drop across a bend depends on its geometry and orientation. No generalized correlation that takes all the factors into account is available in the literature: Bradley (1990), Chambers et al. (1986), Marcus et al. (1990), Morikawa et al. (1978), Park et al. (1980), and Schuchard (1970). The following correlations are sufficiently accurate for practical design:

4.1.4.5.1 Chambers–Marcus Correlation (1986) The Chamber–Marcus correlation is given as follows:

$$\Delta P_B = B(1+\mu)\frac{\rho_g U_g^2}{2}$$

This expression is very similar to the expression proposed by EEuA (1963). The bend loss coefficient B depends on the ratio of bend radius to pipe diameter. In the absence of experimental data, Chambers and Marcus (1986) recommend the use of the values given in Table 4.9.

Table 4.9 Bend Constant B or Various Bends

R_B/D	B
2	1.5
4	0.75
≥6	0.50

Note: R_B is the radius of the bend curve. Bends are often specified by the R_B/D ratio. $R_B/D > 10$ is considered as a long radius bend.

4.1.4.5.2 Correlation (1987) of Westman et al. The correlation of Westman et al. is given as follows

$$\frac{\Delta P_{\text{Bend}}}{0.5\rho_g U_g^2} = \zeta_{\text{Total}} = \zeta_{\text{air}} + \zeta_{\text{solids}}$$

$$\zeta_{\text{air}} = 0.167\left[1 + 17.062\left(\frac{D_B}{D}\right)^{-1.219}\right] Re^{-0.17}\left(\frac{D_B}{D}\right)^{0.84}$$

$$\zeta_{\text{solids}} = \frac{5.4\mu^{1.293}}{Fr^{0.84}\left(D_B/D\right)^{0.39}}$$

4.1.4.6 Pressure Drop in Gas–Solid Separator or Filter Receiver

The pressure drop across gas–solid separators depends on the gas flow rate and solids' loading (see the vendor of the unit for pressure drop estimation). Typically, these units are designed for 5–10 in. WC in the normal operating range.

4.1.4.7 Calculation of Overall Pressure Drop in Dilute Phase Conveying System

The overall pressure drop in a dilute phase conveying system (pressure or vacuum) can be determined by systematically calculating the pressure gradient across various elements (straight horizontal, straight vertical, or bends). It is logical to begin the calculation from a point in the system where the pressure conditions are well defined and then work toward the other end. For pressure systems, the exit conditions are known, whereas feed conditions are known for vacuum systems. The following example outlines the approach for pressure system that can be modified slightly for vacuum system calculations:

Example 4.3: Given

1. Material properties: particle size and particle density
2. Conveying rate
3. Conveying line layout (see Design Tips)
4. Pipe diameter D
5. Pickup or saltation velocity U_{pickup}

find

1. Overall pressure loss
2. Total gas flow rate (SCFM) required

It is assumed that the temperature of the conveying gas is constant along the conveying line. Appropriate corrections to the gas volume must be made if a temperature gradient exists.

Step 1: Draw an isometric layout of the conveying system. Mark all the bends, elbows, and diverter valves.

As mentioned earlier, the gas velocity and gas density continually changes from feed point to destination. The use of an average value leads to inaccurate estimation of the pressure drop. It is recommended

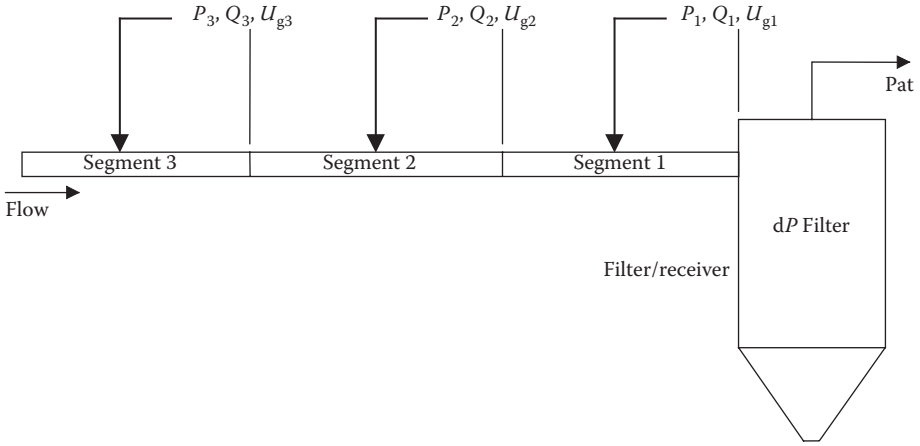

Figure 4.21

Segmentation and flow condition representation.

that the conveying line has to be broken down into smaller segments of 50 ft (15 m) or less. The calculations are performed on an incremental basis by using local values of gas velocity and gas density.

It is assumed that the flow conditions (pressure, velocity, gas density, temperature, etc.) in a segment are represented by the conditions calculated at the exit of the segment (see Figure 4.21). The last segment is the nth segment.

Step 2:

(1) Depending on the total length of the system and material type, select solids to air loading ratio μ from Table 4.10.

(2) Assume the pressure at pickup point (Ppickup, psia). Calculate the saltation velocity. As a first approximation, use saltation velocity as pickup velocity:

$$\mu = \frac{W_s}{W_g} = \frac{W_s}{AU_{\text{gsaltation}}\rho_f}$$

$$D = \sqrt{\frac{4W_s}{\pi U_{\text{gsaltation}}\rho_f}}$$

where ρ_f is the gas density at P_{pickup}.

(3) Calculate the conveying gas flow rate at standard conditions

$$Q_0(\text{scfm}) = U_{\text{gsaltation}}\left(\pi/4 * D^2\right)\left(P_{\text{pickup}}\right)/P_{\text{atm}}$$

Step 3: Estimate the flow conditions at the first segment:

$$P_1 = P_{\text{atm}} = \text{d}P_{\text{filter}}$$
$$Q_1 = Q_0(\text{SCFM})P_{\text{atm}}/P_1$$
$$U_{g1} = Q_1/A$$
$$\rho_{f1} = \left(\rho_{f\text{-atm}}/P_{\text{atm}}\right)P_1$$

Temperature correction for density must be made where temperature gradient exists.

Table 4.10 Selection of Approximate Solids' Loading

System Length (ft)	Coarse Material d_p > 0.5 mm	Fine Material d_p < 0.5 mm
0–500	5	6
500–1000	4	4
1000–1500	2.5	3

Step 4: Estimate the pressure drop across the segment.
If the segment is a straight section,

$$\Delta P_{\text{segment}} = \Delta P_{\text{static}} + \Delta P_{\text{frictional}}$$

$$\Delta P_{\text{static}} = \rho_p (1-\varepsilon)\Delta L \frac{g}{g_c} + \varepsilon \rho_g \Delta L \frac{g}{g_c}$$

where

$$\varepsilon = 1 - \frac{W_s}{A\rho_p U_p}$$

Use IGT correlation to calculate U_p:

$$\frac{U_p}{U_g} = 1 - 0.68 d_p^{0.92} D^{-0.54} \rho_p^{0.5} \rho_g^{-0.2}$$

where
d_p, D are in meters
ρ_p, ρ_g are in kg/m^3

ΔP_{static}, which is the pressure drop due to static head of gas–solid mixture, is zero for horizontal orientation:

$$\Delta P_{\text{frictional}} = \left(\lambda_f + \mu\lambda_z\right)\frac{\rho_g U_g^2 \Delta L}{2Dg_c} = \lambda_f \frac{\rho_g U_g^2 \Delta L}{2Dg_c} + \left(\mu\lambda_z\right)\frac{\rho_g U_g^2 \Delta L}{2Dg_c}$$

Swamee and Jain (1976) correlation for gas friction factor, λ_f, is recommended:

$$\lambda_f = \frac{1.325}{\left[\ln\left(k_s/3.7D + 5.74/Re^{0.9}\right)\right]^2}$$

Use generalized form of solids' friction factor correlation, λ_z:

$$\lambda_z = K\mu^a Fr^b Fr_s^c \left(\frac{D}{d_p}\right)^d$$

$$\mu = \text{solids loading} = \frac{W_s}{W_g}$$

$$Fr = \frac{U_g^2}{gD}$$

$$Fr_s = \frac{U_t^2}{gd_p}$$

In the absence of material-specific data, use Stegmaier's coefficients for fine powders and Weber's coefficient for coarse materials (Table 4.11) as suggested by Chambers and Marcus (1986). The values of K can be adjusted to fit the available plant data and then used for predictive calculations.

Table 4.11 Coefficients for Solids' Friction Factor Correlation

Investigator/Material	K	a	b	c	d
Stegmaier fine powder ($d_p < 0.5$ mm)	2.1	−0.3	−1	0.25	0.1
Weber (Siegel data) coarse material ($d_p > 0.5$ mm)	0.082	−0.3	−0.86	0.25	0.1

If the segment is a bend or an elbow, use Chambers–Marcus bend pressure drop correlation:

$$\Delta P_{\text{segment}} = \Delta P_{\text{B}} = \left(1+\mu\right)\frac{\rho_{\text{g}} U_{\text{g}}^2}{2g_{\text{c}}}$$

where the bend constant B can be experimentally determined or read from Table 4.9 when no data are available.

The flow conditions in the next (upstream) segment (Figure 4.21) can then be established as follows:

$$P_2 = P_1 + \Delta P_{\text{segment}}$$
$$Q_2 = Q_0\left(\text{SCFM}\right)P_{\text{atm}}/P_2$$
$$U_{\text{g}2} = Q_2/A_2$$
$$\rho_{\text{f}2} = \left(\rho_{\text{f-std}}/P_{\text{atm}}\right)P_2$$

Step 5: Repeat Step 4 until the pressure and velocity profile in the entire system is obtained. The last segment corresponds to the feed section.

For remaining segments,

$$P_{i+1} = P_i + \Delta P_{\text{segment}}$$
$$Q_{i+1} = Q_0\frac{P_{\text{atm}}}{P_{i+1}}$$

assuming isothermal conditions.

Step 6: Estimate the pressure at the inlet of the last nth segment (see Figure 4.22). Add acceleration zone pressure drop:

$$P_{\text{pickup}} = \left(P_n + \Delta P_{\text{last segment}}\right) + \Delta P_{\text{ACC}}$$

where

P_{pickup} and P_n are in psia

$\Delta P_{\text{last segment}}$ and ΔP_{ACC} are in psi

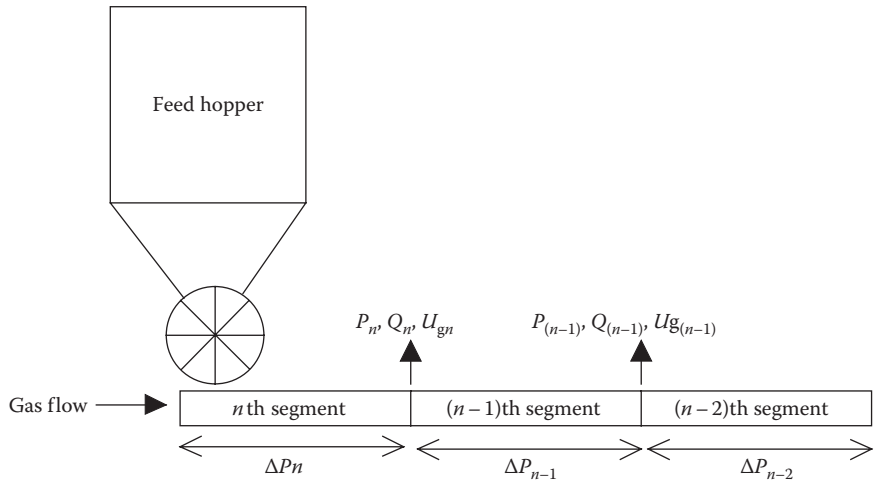

Figure 4.22

Flow conditions at feed point.

$$\Delta P_{ACC} = \frac{\rho_g U_g^2}{2g_c}\left(1 + 2\mu\left(\frac{U_p}{U_g}\right)\right)$$

and ρ_g and U_g are calculated for conditions at the feed point.

Use IGT correlation to calculate U_p/U_g:

$$\frac{U_p}{U_g} = 1 - 0.68 d_p^{0.92} D^{-0.54} \rho_p^{0.5} \rho_g^{-0.2}$$

Step 7: Compare P_{pickup} with the value used in Step 2. Update the estimation of P_{pickup}. Repeat Steps 2 to 6 until convergence is reached.

Step 8: Add the miscellaneous pressure drops due to blower piping and filters or silencer to estimate the blower outlet pressure:

$$\Delta P_{misc} = dP_1 + dP_2 + dP_3$$

(see Figure 4.23 for more details)

$$P_{blower\ outlet} = \Delta P_{misc} + P_{pickup}$$

Step 9: Add the leakage loss through the rotary airlock or feeder to estimate the blower gas delivery rate:

$$Q_{blower\ outlet} = \left(Q_0 + Q_{leakage}\right) P_{atm} / P_{blower\ outlet}$$

$Q_{leakage}$ (scfm) must be estimated from vendor charts and corrected for pressure at the feed point.

Blower inlet cfm can be calculated by using the Gas law:

$$Q_{blower\ inlet} = Q_{blower\ outlet} P_{blower\ outlet} / P_{blower\ inlet}$$

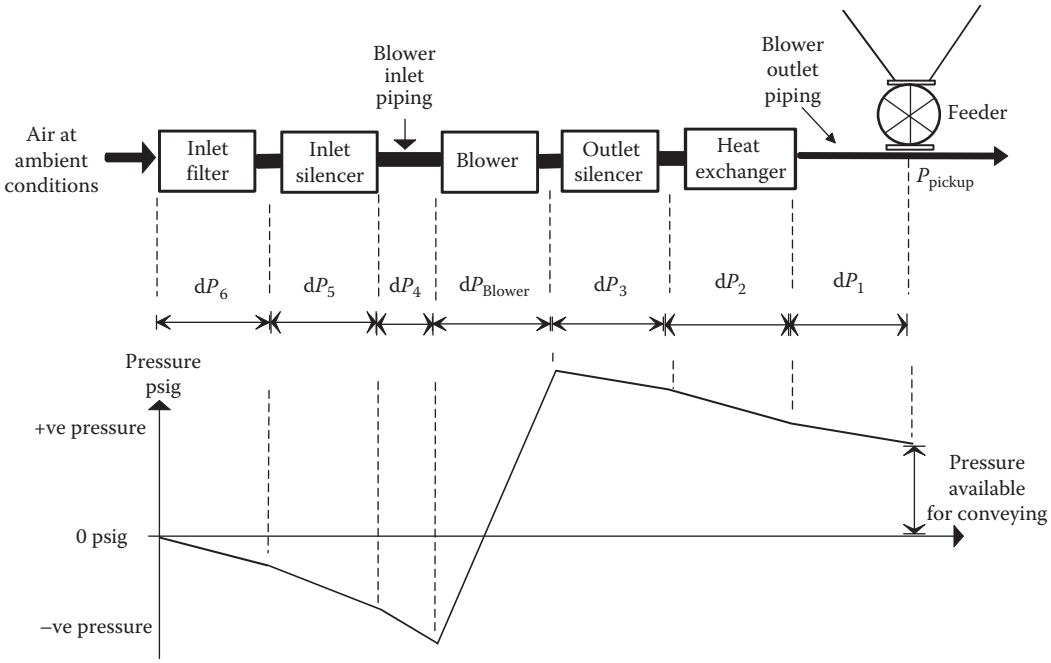

Figure 4.23

Pressure profile at the blower.

where

$$P_{\text{blower inlet}} = P_{\text{atm}} - \left(dP_6 + dP_5 + dP_4\right)$$

From Figure 4.7,

$$P_{\text{blower inlet}} = P_{\text{atm}} - \left(dP_6 + dP_5 + dP_4\right)$$

$P_{\text{blower outlet}}$ and $Q_{\text{blower inlet}}$ define the operating point for the blower.

Example 4.4: Calculate the Pressure Drop Given

Material: Coarse granular material

- Conveying rate W_s = 30,060 lb/h = 8.35 lb/s
- Solids' loading μ = 2.5 lb. solids/lb. gas
- Particle density = 59 lb/ft^3
- Particle size d_p = 4 mm = 0.013 ft
- Pipe diameter D = 10 in. = 0.833 ft
- Pipe roughness k_s/D = 0.0002
- Gas density at standard conditions (14.7 psia, 68°F) = 0.075 lb/ft^3
- Gas viscosity μ_g = 0.018 cP = 1.2 × 10^{-5} lb/(ft s)
- Single particle terminal velocity U_t = 1840 ft/min

Assume

- Pressure drop across cyclone = 0.1 psi
- Gas temperature = 68°F is constant across the system

Conveying line layout is shown in Figure 4.24.

Divide the system into segments starting from the filter or receiver end as shown in Figure 4.21. Start the analysis from segment 1.

Segment 1: System pressure at exit = (14.7 + 0.1) psia = 14.8 psia

$$\rho_g = \left(\frac{14.8}{14.7}\right)0.075 = 0.0755 \text{ lbm/ft}^3$$

$$U_g = \left(\frac{2680}{0.545}\right)\left(\frac{14.7}{14.8}\right) = 4884 \text{ ft/min}$$

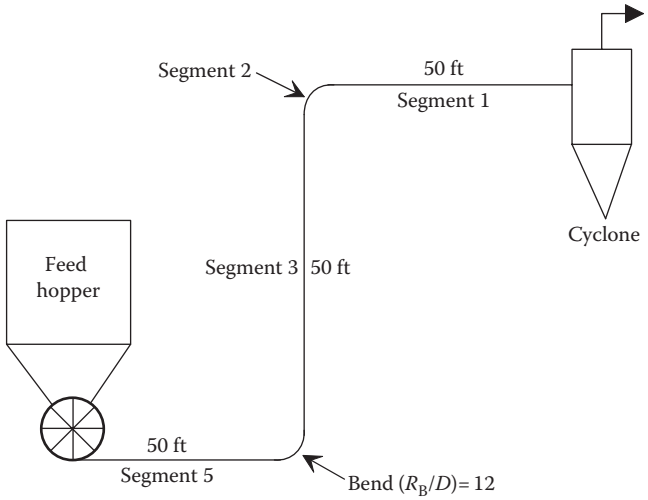

Figure 4.24

Conveying line layout for test problem.

$$Re = \frac{DU_g\rho_g}{\mu_g} = \frac{\left(\frac{10}{12}\right)\left(\frac{4884}{60}\right)(0.0755)}{1.2\times10^{-5}} = 4.268\times10^5$$

$$\lambda_f = \frac{1.325}{\left[\ln\left(k_s/3.7D + 5.74/Re^{0.9}\right)\right]^2} = \frac{1.325}{\left[\ln(0.000054 + 0.000049)\right]^2} = 0.0157$$

$$\Delta P_{air} = \lambda_f \frac{\rho_g U_g^2 L}{2Dg_c} = \frac{0.0157(0.0755)(4884/60)^2 50}{2(10/12)32.2} = 7.31\ \text{lb/ft}^2 = 0.050\ \text{psi}$$

$$\Delta P_{solids} = \mu\lambda_z \frac{\rho_g U_g^2 L}{2Dg_c}$$

For coarse particles,

$$\lambda_z = 0.082\mu^{-0.3} Fr^{-0.86} Fr_s^{0.25}\left(\frac{D}{d_p}\right)^{0.1}$$

$$\mu = 2.5$$

$$Fr = \frac{(4884/60)^2}{32.2(10/12)} = 246.9$$

$$Fr_s = \frac{(1840/60)^2}{(32.2)(0.0131)} = 2229$$

$$\frac{D}{d_p} = 63.6$$

$$\lambda_z = 0.082(2.5)^{-0.3}(246.9)^{-0.86}(2229)^{0.25}(63.6)^{0.1} = 0.00568$$

$$\Delta P_{solids} = 2.5(0.00568)\frac{(0.0755)(4884/60)^2 50}{2(10/12)32.2} = 6.62\ \text{lbf/ft}^2 = 0.046\ \text{psi}$$

$$\Delta P_T = \Delta P_{air} + \Delta P_{solids} = 0.050 + 0.046 = 0.096\ \text{psi}$$

Pressure at the outlet of segment 2 = 14.8 + 0.096 = 14.896 psia.

Segment 2: Segment 2 is a bend:

$$\Delta P_{segment} = \Delta P_B = B(1+\mu)\frac{\rho_g U_g^2}{2g_c}$$

Use $B = 0.5$:

$$\rho_g = \frac{14.896}{14.7}0.075 = 0.076\ \text{lbm/ft}^3$$

$$U_g = \frac{2680}{0.545}\frac{14.7}{14.896} = 4852\ \text{ft/min}$$

$$\mu = 2.5$$

$$\Delta P_{segment} = \Delta P_B = 0.5(1+2.5)\frac{0.076(4852/60)^2}{2.32.2} = 13.5\ \text{lbf/ft}^2 = 0.093\ \text{psi}$$

Therefore, pressure at the outlet of segment 3 = 14.896 + 0.093 = 14.989 psia.

Segment 3: Segment 3 is vertical:

$$\Delta P_{\text{segment}} = \Delta P_{\text{static}} + \Delta P_{\text{frictional}}$$
$$\Delta P_{\text{frictional}} = \Delta P_{\text{air}} + \Delta P_{\text{solids}} = 0.050\,\text{psi} + 0.046\,\text{psi} = 0.096\,\text{psi}$$
$$\Delta P_{\text{static}} = \rho_{\text{p}}(1-\varepsilon)\Delta L\frac{g}{g_{\text{c}}} + \varepsilon\rho_{\text{g}}\Delta L\frac{g}{g_{\text{c}}}$$

where

$$\varepsilon = 1 - \frac{W_{\text{s}}}{A\rho_{\text{p}}U_{\text{p}}}$$

$$\varepsilon = 1 - \frac{8.35}{0.545(59)(0.74)(4822/60)} = 0.995$$

$$\Delta P_{\text{static}} = 59(1-0.995)50\frac{32.2}{32.2} + 0.995(0.0765)50\frac{32.2}{32.2} = 18.55\ \text{lbf/ft}^2 = 0.129\ \text{psi}$$

$$\Delta P_{v} = 0.096 + 0.129 = 0.225\ \text{psi}$$

Pressure at the outlet of segment 4 = 14.989 + 0.225 = 15.214 psia.

Segment 4: Segment 4 is a bend. Calculating similar to segment 2,

$$\Delta P_{\text{B}} = 0.092\ \text{psi}$$

Pressure at the outlet of segment 5 = (15.214 + 0.092) psia = 15.306 psia.

Segment 5: Segment 5 is a straight horizontal section:

$$\Delta P_{\text{frictional}} = \Delta P_{\text{air}} + \Delta P_{\text{solids}} = 0.049\ \text{psi} + 0.047\ \text{psi} = 0.096\ \text{psi}$$

Pressure at segment 5 inlet = (15.306 + 0.096) psia = 15.402 psia.

Add acceleration d*P*:

$$\Delta P_{\text{ACC}} = \frac{\rho_{\text{g}}U_{\text{g}}^2}{2g_{\text{c}}}\left(1 + 2\mu\left(\frac{U_{\text{p}}}{U_{\text{g}}}\right)\right)$$

$$\Delta P_{\text{ACC}} = \frac{(0.078)(4893/60)^2}{2(32.2)}(1 + 2(2.5)(0.74))$$

$$= 34.83\ \text{lb/ft}^2 = 0.242\ \text{psi}$$

Pressure at feed point = (15.402 + 0.242) psia = 15.644 psia.

Assume $\Delta P_{\text{blower piping}}$ = 0.1 psi. Pressure at blower outlet = 15.744 psia = 1.044 psig. Then the overall ΔP = 1.044 psi = 28.9 in WC.

4.1.5 Designing Conveying Systems

The design of a dilute phase conveying system can be subdivided into eight steps, namely:

1. Acquire material properties
2. Establish conveying requirements and performance criterion
3. Selection of system type or conveying mode
4. Identify suitable line layout
5. Select initial pipe diameter based on expected loading
6. Calculate the overall pressure drop and gas flow rate requirement
7. Recheck selection of pipe diameter, consider stepping
8. Select dust collection system, feeder, and air mover

Table 4.12 Material Properties for Conveying System Selection and Specification

Material Property	Required for the Determination of
Particle size distribution and average particle size	Conveying characteristics, feeder selection, filter design
Particle density	Conveying mode, conveying characteristics
Bulk density	Feeder capacity, storage silo capacity, conveying mode
Permeability	Conveying mode, dense phase design
Aeration and deaeration characteristics	Conveying mode, dense phase design
Moisture content, cohesion, and flowability	Storage silo design, feeder selection, dust collector design
Friability	Conveying mode, feeder selection, dust collector selection
Abrasiveness	Feeder selection, dust collector selection, material of construction
Toxicity	Conveying mode, dust collector filter design
Dust explosion potential	Selection of conveying gas, dust collector design, and grounding requirements
Hygroscopic nature	Conditioning of conveying gas, conveying mode
Sensitivity to temperature	Cooling requirement for conveying gas, selection of conveying mode
Corrosiveness	Material of construction
Stickiness or tackiness	Mode of conveying, coating of parts

4.1.5.1 Acquire Material Properties

Characterization of bulk material is the first step in designing conveying system. It is important to acquire a representative sample for analysis and be aware of the variability in properties along with their effect on system performance. Table 4.12 summarizes the relevance of particle properties to selection and specification of a conveying system.

4.1.5.2 Establish Conveying Requirements and Performance Criterion

Many failures in design of dilute phase conveying systems can be traced back to omissions by the designer regarding conveying requirements and performance criteria. Here are some guidelines to avoid costly mistakes.

- Identify the entire range of products (product wheel): It may be impossible to identify a single product as a representative product. For example, the product with least friction factor may be most friable. If one needs to minimize product attrition and maintain conveying rate for all the products, more products need to be tested.
- Establish the correct conveying capacity: If the operation is in batch mode, instantaneous conveying rate will be higher than average conveying rate. Occasionally, even higher rates may be required to catch up after process upsets.
- Identify sources and destinations: All sources and destinations must be identified upfront. Proper thought should be given to future expansions in conveying distance and capacity.
- Identify special requirements for temperature, humidity, inert, containment, toxicity, cross-contamination, and ease of cleanout.
- Establish limits on acceptable product degradation: Pneumatic conveying systems, especially dilute phase systems, result in breakage or degradation of the product. It is important to identify acceptable limits, method of measurement, and sensitivity to operating conditions.
- Wear life of components: When dealing with abrasive materials, it is important to outline expectations on the performance and wear life of components, especially feeder and pipeline.
- Identify the need to have a spare air mover online if the conveying system is a critical link in the process.
- Conveying system can be used for a dual purpose, for example, as a dryer or a cooler. The operational range can be severely limited by combining the two operations and it is important to establish that upfront.

4.1.5.3 Selection of Conveying System Type and Conveying Mode

A fundamental design decision when configuring a new pneumatic conveying system is whether to convey a dilute phase or dense phase mode. Dilute phase conveying can be generally characterized by high velocities, low pressure drops, and low ratios of solids to gas. Conversely, dense phase conveying systems have lower velocities, higher pressure drops, and higher solid to gas ratios (Table 4.13). Due to gas expansion or secondary gas injection along the conveying line, some systems will convey in the dense phase mode near the feed point but will transition into dilute phase near the end of the conveying line.

Table 4.13 Comparison of Dilute Phase and Dense Phase Conveying Modes

Characteristic	Dilute Phase Conveying	Dense Phase Conveying
Degradation or particle attrition	Can be high	Usually low
Change in product properties (particle size distribution, etc.)	Conveying characteristics will change but system can continue to perform at reduced capacity	Conveying characteristics are significantly affected. May result in plugging
Turndown of conveying rate	Easy	Limited turndown
Wear	Can be high for abrasive materials	Slow motion conveying results in minimum wear
Line vibration	None	Significant, special design considerations required
Inert gas conveying	Accomplished by closed-loop system	Low amounts can be once through

The advantages for selecting dilute phase conveying are as follows:

1. Many more materials can be conveyed successfully in dilute phase mode than in dense phase.
2. Dilute phase conveying systems are generally less susceptible to plugging due to changes in material properties or operational upsets such as temporary loss of conveying gas.
3. Dilute phase conveying systems are easier to design. The window of stable operation for dense phase conveying is much smaller than that of dilute phase conveying.
4. Dilute phase systems require less specialized feeders and air movers.

The greatest advantages of dense phase conveying stem from the fact that the conveying velocities are lower. This can impact the amount of particle attrition and the amount of erosion of pipe bends and other system components that can occur. Both these phenomena tend to vary with velocity raised to the third power, although literature values for this exponent range from 2 to 6. For a specific application particle attrition may or may not be a consideration. The definition of particle attrition includes both the breakage or chipping of brittle particles to produce fine fragments and the smearing of polymeric materials along the pipe walls to create fines, floss, and snake skins. Some reasons why particle attrition could be problematic are

1. Attrition can create a real or perceived quality issue.
2. It may adversely affect downstream gravity flow characteristics, such as the minimum hopper outlet size.
3. It may increase specific surface area, which may influence product properties or downstream processing.

Dense phase conveying can be a viable option if

1. Low particle degradation is a requirement.
2. Material is highly abrasive and metal contamination is an issue.
3. Low gas usage (especially inert gases) is desirable.
4. The material does not change significantly from batch to batch.
5. Pressure conveying does not pose problems (toxicity or hygiene).
6. Conveying operation is not from multiple sources to single destination type.
7. The particle size distribution is not very wide.
8. The material tends to coat and plug the conveying line at high velocity.

4.1.5.3.1 Selection of System Type: Open Loop versus Closed Loop Unless there is a compelling reason to do otherwise, a conveying system should be operated in an open-loop manner (Figures 4.12 through 4.14). The advantages for operating this way are

1. *Lower capital cost*. This is due to not needing a gas return line to the feed point, a smaller blower or compressor, less instrumentation, and less extensive conveying gas conditioning.
2. *Simpler operations*. The mass of gas in the conveying system changes during start-up and shutdown. This process is self-regulating in an open-loop system, whereas it needs to be actively managed

for a closed-loop process. Also, unless there is an adequate purge on the closed-loop system or a sophisticated gas conditioning system, moisture or other undesirable condensable materials may accumulate in the recycled gas stream to concentrations where condensation can occur. This can result in restrictions in and possible plugging of the conveying line or blinding of filter media in the dust collector. Also, heat due to compression needs to be removed from the closed-loop system.

Despite the advantages of an open-loop system, there are circumstances where closed-loop systems are preferable and will reduce the overall cost of installing and operating the system. The selection of a closed-loop system (Figure 4.15) should be considered when:

1. The conveying gas is expensive or the supply is limited.
2. Treatment of the gas prior to venting requires more than just gas–solid filtration. If there are either toxic or simply noxious nature of vapors present in the conveying gas stream after the solids have been separated, the gas stream may need to be sent through a carbon bed or incinerated prior to venting to the atmosphere.
3. The solids need to be conveyed in a carefully controlled environment such as very low moisture or oxygen concentrations. The use of a closed-loop system in this case will reduce the size of the gas conditioning equipment required.

4.1.5.3.2 Selection of Pressure Mode: Vacuum, Pressure, or Combined In most situations, it is mechanistically feasible to convey in both pressure and vacuum mode. Therefore, the selection of conveying mode is dictated by process issues. For instance, a pressure system should be used where ambient air leakage into the conveying system cannot be tolerated. This could be due to a quality or product degradation concern by exposure to oxygen or moisture. Another case where a pressure system should be used is if an oxygen lean environment is used as a line of defense for the prevention of a dust or vapor explosion. On the other hand, a pressure system should not be used if material spill cannot be tolerated due to safety or industrial hygiene concerns. A vacuum system should be strongly considered if there are significant consequences in the event of a leak of material from the conveying system, such as cases where the solids are extremely toxic to humans, animals, or plants. While all equipment connections can be made "dust tight," all shaft seals for rotary and diverter valves can be purged, and all high wear areas such as elbows can be monitored for erosion. Experience has shown that considerable preventative maintenance effort is required to keep a pressure conveying system dust tight in all places and at all times.

The final criteria for determining the conveying pressure mode, if not fully dictated by any of the considerations earlier, are based on the number of sources and destination and, to a lesser extent, the source or destination layout:

1. *Single source to single destination (Figure 4.12)*: Either pressure or vacuum system will work for this case. Use a pressure system for long-distance (greater than 300 ft) and high-throughput requirements.
2. *Single source to multiple destinations (Figure 4.12)*: Use a positive pressure (or push) system with diverter valves to direct material to multiple destinations. A vacuum system would require an air mover at each destination and would be expensive to install.
3. *Multiple sources to a single destination (Figure 4.13)*: Use a vacuum (or pull) system. Unless the sources are close together, a blower would be needed for each source if the pressure conveying mode were used. However, if a single conveying line can be routed past the pickup points for each source without significantly altering the number of bends or the overall length of the conveying line, the pressure conveying mode may be a reasonable option as well as vacuum conveying.
4. *Multiple sources to multiple destinations (Figure 4.14)*: Use a combined vacuum–pressure or pull–push system. This recommendation logically follows from the previous two items.

4.1.5.4 Identify Suitable Line Layout

Conveying line layout should never be an afterthought during plant layout. Conveying pipe cannot be routed like other utilities (steam, air, and water) without paying significant penalty on performance. Some effective line layout practices are outlined as follows:

- Layout conveying routes when the plant process equipment is being laid out. This will provide flexibility for the optimization of conveying route.
- Consider creative ways to minimize conveying distance.

- For dilute phase systems, provide sufficient horizontal run after the feed point and before any change in direction (bend) occurs. It is recommended to provide at least 50D of horizontal run. There is no such requirement for dense phase systems.
- For dilute phase systems, avoid inclined lines near the feed point.
- Minimize change in directions (bends, elbows, or 45° bends).
- Avoid placing bends within 50D of one another.
- Minimize the use of flexible hoses.
- For dense phase systems, proper consideration must be given to design line support to handle pipeline vibrations. Current state of knowledge is insufficient to predict the line forces accurately.
- Do not use process equipment or silos to support dense phase lines.
- Components, such as diverter valves, need maintenance. They should be made accessible.

4.1.5.5 Select Initial Pipe Diameter Based on Expected Loading and Velocity at Feed Point

The initial pipe diameter can be calculated by assuming solids loading based on previous experience or general guidelines:

$$\mu = \frac{W_s}{W_g} = \frac{W_s}{A\rho_g U_g}$$

$$A = \frac{W_s}{\mu\rho_g U_g} = \frac{\pi}{4}D^2$$

$$D = \sqrt{\frac{4W_s}{\pi\mu\rho_g U_g}}$$

where

U_g is the gas velocity at feed point
ρ_g the gas density at feed point
μ the assumed solids' loading

4.1.5.6 Calculate Overall Pressure Drop and Gas Flow Rate Requirement

See Section 4.1.4 for details on pressure drop calculations.

4.1.5.7 Recheck Selection of Pipe Diameter

With refined values of conveying pressure at the feed point, the line diameter calculation should be rechecked. The conveying pressure estimation should also be compared with the typical limits of air movers. If the pressure drop is higher than expected, choose a large pipe size. Redo the calculations until convergence is achieved.

4.1.5.8 Select Dust Collection System, Feeder, and Air Mover

4.1.5.8.1 Gas–Solid Separator Selection Factors affecting the selection of gas–solid separation device are

1. Desired efficiency of separation based on particle size distribution of incoming solids
2. Acceptable pressure drop range
3. Operating pressure and temperature
4. Cleanout and contamination requirement
5. Dust explosion potential
6. Acceptable turndown in gas flow rate
7. Compatibility with material (corrosiveness, abrasion, etc.)

4.1.5.8.2 Feeder Selection Factors affecting the selection of feeder are

1. Operating pressure/pressure differential
2. Type of conveying system
3. Material characteristics: bulk density, size, abrasiveness, tackiness, fluidization, and so on

(see Table 4.5 For more details.)

4.1.5.8.3 Air Mover Selection Factors affecting the selection of air mover are

1. Range of pressure or vacuum during operation
2. Volumetric flow rate
3. Stability of solid feed rate and nature of operation
4. Control requirements: turndown and adjustability
5. Special requirements (e.g., material flow through)

4.1.6 Stepping Pneumatic Conveying Lines

The superficial velocity increases as the pressure decreases from feed point to discharge point. From mass balance on the conveying gas, we obtain

$$\left(A\rho_g U_g\right)_{\text{feed_zone}} = \left(A\rho_g U_g\right)_{\text{discharge_zone}}$$

By applying gas laws,

$$\frac{U_{g1}}{U_{g2}} = \frac{P_2}{P_1}$$

where P is the absolute pressure. The superficial gas velocity in a conveying system increases from feed point to destination in all conveying systems. Since higher superficial velocity is related to higher wear and product attrition, it is beneficial to reduce the gas velocity by increasing the line diameter at some point in the system. The same effect is achieved by leaking some gas out of the system.

There are two approaches to stepping (increasing) the line size:

1. To keep the Froude number constant between the feed point and the step location. In other words, maintain a Froude number greater than the minimum required (Fr_{min}) at the stepped location.
2. To keep the superficial velocity at the feed point and at the step location higher than saltation velocity.

Currently, there is no consensus on the best approach for designing stepped lines.

4.1.7 Modeling and Designing Dense Phase Conveying

The mechanisms for dense phase conveying are not as well understood and quantified as dilute phase flow. Significant progress in the modeling of noncohesive granular materials has been made in the last 20 years (Konrad and Harrison, 1980, Legel and Schwedes, 1984, Konard, 1986, Mi and Wypych, 1994). The design equations by Mi and Wypych (1994) are discussed in this section. For fluidized-mode conveying, it is recommended that scale-up approach be used.

4.1.7.1 Modeling of Plug/Slug Flow

Noncohesive coarse granular material (e.g., plastic pellets) exhibits a natural slugging ability. When conveyed in nonsuspension mode, they form slugs or plugs that move in a wave-like fashion. Each slug is constantly picking up material from the stationary layer in the front and dropping off material from the tail end. The material moves a short distance with the passing of each slug.

A force balance on the plug results in the following equation (Figure 4.25):

$$\frac{\Delta P}{l_s} = \frac{4\mu_w \lambda}{D}\sigma_f + 2\rho_b g\mu_w$$

where λ is the stress transmission coefficient or the ratio of radial stress to axial stress. A theoretical estimation of the stress transmission coefficient can be made by assuming active conditions for failure; however, experimental data indicate that the values are between active and passive estimates:

$$\lambda = \frac{1-\sin\phi_s\cos\left(\omega-\phi_w\right)}{1+\sin\phi_s\cos\left(\omega-\phi_w\right)}$$

$$\sin\omega = \frac{\sin\phi_w}{\sin\phi_s}$$

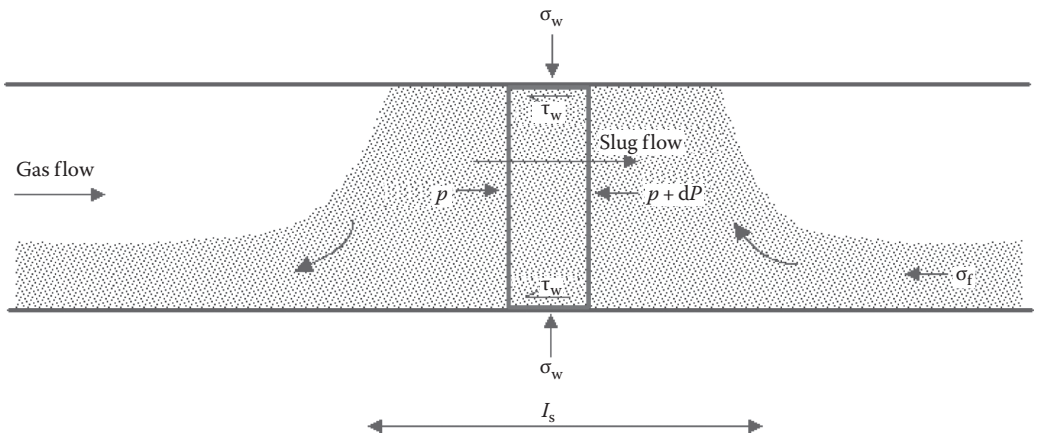

Figure 4.25

Force balance on slug or plug in dense phase conveying.

σ_f represents the frontal stress experienced by the slug due to the stationary layer and uptake of material from the stationary layer. The momentum balance gives the following expression:

$$\sigma_f = \alpha \rho_b U_s^2$$

The existence of stationary layer plays a critical role in the formation, stability, and movement of the slug. The average height of a stationary layer in the line depends on the superficial gas velocity at that location. It decreases with an increase in superficial gas velocity.

The cross-sectional area ratio of stationary bed to pipe, α, is calculated by the following expression:

$$\alpha = \frac{1}{\left(1 + U_s / 0.542\sqrt{gD}\right)}$$

In reality, there are multiple slugs in a transfer system that is separated by air pockets. As the pressure drops and gas expands, the superficial gas velocity increases along the conveying length. Consequently, the slug velocity will also increase. For analysis, if we assume that each slug goes through the same velocity profile, then we can characterize the bulk movement of material through the system by an average slug velocity. Further, if the pressure drop across the air pockets is assumed to be negligible, all the slugs in the system of length L_t can be assumed to be of an equivalent length l_s.

$$l_s = \frac{m_s L_t}{A\left(1-\alpha\right)\rho_b U_s}$$

The overall system pressure drop can be calculated by an appropriate substitution.

$$\Delta P_{system} = \left(1 + 1.084\lambda\sqrt{Fr} + \frac{0.542}{\sqrt{Fr}}\right)\frac{2g\mu_w m_s L_t}{AU_s}$$

where

$$Fr = \frac{U_s^2}{gD}$$

4.1.7.2 Slug or Plug Velocity Estimation

As evident from the previous section, a reliable estimate of slug velocity is critical for design calculations. The slug velocity for impermeable bulk solids is equal to the superficial gas velocity (Figure 4.26). For permeable

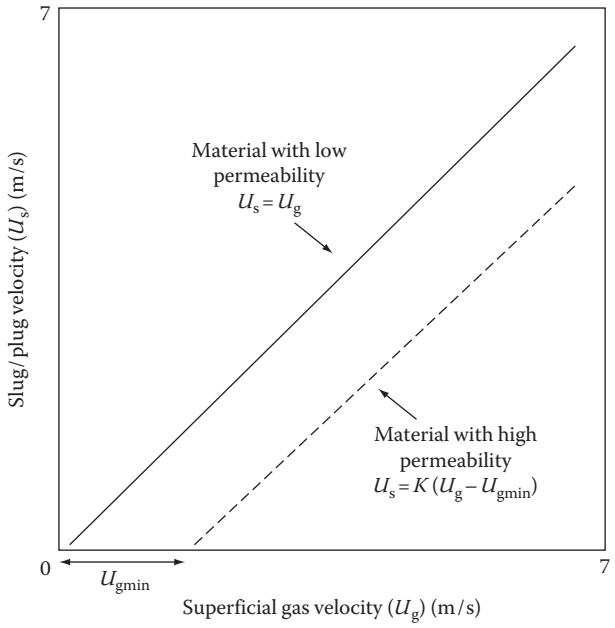

Figure 4.26

Relationship between slug velocity and superficial gas velocity.

Table 4.14 Examples of K and U_{gmin} Values

Test Material	K	U_{gmin} (m/s)
Plastic pellets		
White	0.873	1.02
Black	1.059	1.566
Wheat	1.013	2.19
Barley	1.359	2.77

Source: Mi, B., and Wypych, P.W., *Powder Handling and Processing*, 5(3), 233, 1993. With permission.

materials (e.g., plastic pellets, grains, etc.), a slip between gas and solids has been observed. A minimum gas velocity can also be identified below when the slug velocity is zero, when implies a plugged condition.

Mi and Wypych (1993) have experimentally shown that (see Table 4.14)

$$U_s = K\left(U_g - U_{gmin}\right)$$

The minimum conveying velocity for plugged condition can also be calculated theoretically:

$$U_{gmin} = \frac{\rho_p g \tan\phi_w \varepsilon^3 d_p^2}{180(1-\varepsilon)\eta}$$

The slope of the slug-slip characteristic is empirically calculated as follows:

$$K = C\frac{\varepsilon d}{D}\left(\frac{\tan\phi_w}{\tan\phi_s}\right)^{1/3}$$

where C is a dimensionless constant. Use a value of 100 as an initial estimate.

4.1.7.3 Pressure Drop Calculation in Slug-Type Dense Phase System

According to Mi and Wypych (1994), the following steps are involved:

1. Calculate stress transmission coefficient
2. Assume initial value of total pressure drop. Calculate mean air density and superficial velocity
3. Estimate mean slug velocity and Froude number
4. Calculate pressure drop using the proposed analytical equation
5. Compare the estimate with assumption in step 2. Recalculate until convergence is obtained.

4.1.7.4 Control of Pneumatic Conveying Systems

Production plants are often multiproduct plants where products must be transported from various sources to multiple destinations. The differences in conveying characteristics (friction factor, wear, and attrition) and process constraints (e.g. conveying velocity, temperature, humidity, cleanliness) between various products can pose significant challenges during design phase and subsequent operability of the conveying system. One key process variable, namely, conveying gas velocity, can be adjusted and controlled during operation to broaden the operating window and achieve optimal conveying conditions in a given system (Wilms and Dhodapkar, 2014). Both dilute and dense phase systems can benefit from such an air control system. As shown earlier in Figure 4.10, the system response to change in gas flow rate for dilute and dense phase system is very different.

4.1.7.4.1 Dilute Phase Conveying Dilute phase conveying systems will operate in stable and reliable mode as long as the conveying gas velocities in the pipe at all locations are maintained above saltation velocity, and solids' loading below saturation limit and acceptable design practices regarding line configuration have been followed. The saltation velocity depends on material and gas properties, line diameter, and conveying rates, whereas local gas velocity depends on gas mass flow rate, and pressure, temperature and flow area at a given location.

For a non-stepped system, where the line diameter is constant, the gas velocity is the lowest at the pickup location. Therefore, an air control system that maintains gas velocity at the pickup above saltation for all transfer situations will deliver optimal performance. Three common approaches to hardware configuration for achieving pickup velocity control are shown in Figure 4.27, namely,

a. Gas bleed
b. Control valve or variable orifice Laval nozzle
c. Blower speed control

The gas bleed approach is the simplest to implement; however, system stability and energy efficiency may be compromised. Whether the gas bleeds in or out depends on the type of conveying system (pressure vs. vacuum). Certain conveying systems, for instance vacuum systems or with fan as an air mover, have a sluggish response to changes in air flow rate. They may be difficult to control with the gas bleed approach. Laval (sonic) nozzle offers a stable way to maintain constant pickup velocity in pressure system. The Laval nozzle operates at sonic conditions, so pressure fluctuations in the downstream conveying system do not affect the air mass flow rate. The mass flow rate of air can be varied by changing the upstream pressure or cross section of the throat. They are commonly used in large-scale pneumatic conveying systems. Blower speed control is the most energy efficient approach limited only by the motor and blower specifications.

4.1.7.4.2 Dense Phase Conveying The dense phase region of the classic Zenz plot (Figure 4.9) can be re-plotted with a different set of axes. The overall system pressure drop (instead of pressure gradient) is the *Y*-axis and the conveying gas flow rate at exit conditions (instead of superficial gas velocity) is the *X*-axis. The modified diagram (Figure 4.28), which is unique to a given system configuration and material properties, now serves as a basis for air control system design. The dense phase region is bounded by the plugging zone on the left size (low gas velocity), the unstable zone (high gas velocity) on the right-hand size, and air mover pressure capability as the upper limit. The operating window (Figure 4.28) can be demarcated after allowing for appropriate safety margins. The primary objective of an air control system for dense phase is to maintain the operating point within the stable operating window regardless of the system conveying pressure and conveying rate changes. The system pressure drop can change due to changes in material properties, conveying distance and conveying rate. The air control management strategy requires the knowledge of phase diagram, which is typically obtained through pilot- or full-scale testing. The overall strategy to develop air control

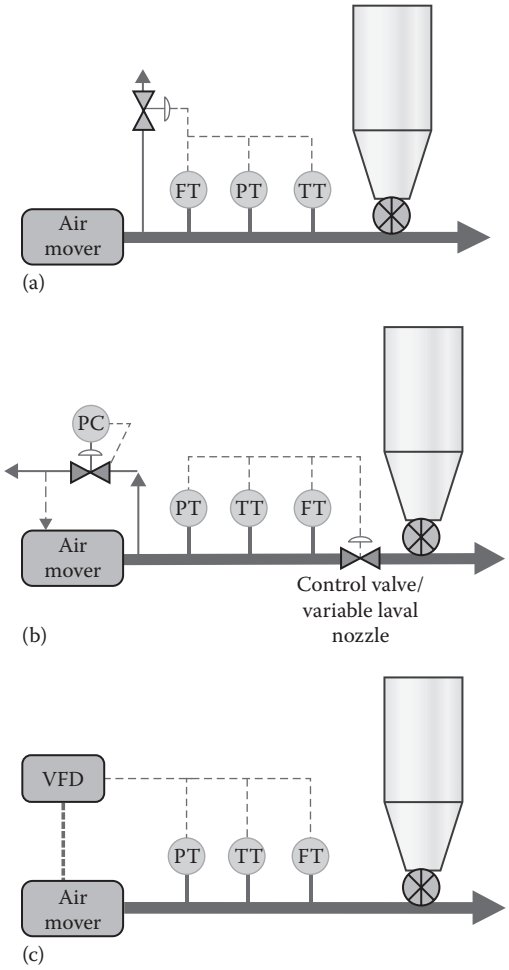

Figure 4.27

General concepts for controlling pickup velocity in pneumatic conveying systems. (a) Gas bleed, (b) control valve or Laval (sonic) nozzle, (c) air-mover speed control. (FT, flow transmitter; PT, pressure transmitter; PC, pressure-control valve; TT, temperature transmitter; VFD, variable-frequency drive.) (From Wilms, H. and Dhodapkar, S., *Chem. Eng.*, 59, October 2014.)

system is shown in Figure 4.29. These systems, which are often implemented in a PLC, can additionally monitor pressure trends and fluctuations and react accordingly. Table 4.15 summarizes typical inputs and corresponding control actions taken by control system. Interesting examples of application of neural networks and self-learning algorithms can be found in the literature. It should be noted that various vendors have developed complex proprietary systems based on their expertise, and the discussion given earlier is meant to be an instructive introduction to the topic.

4.1.8 Practical Design Considerations

4.1.8.1 Common Design Errors

Given the simplicity of the task of moving product from one point to another in a plant, it would appear that the design of pneumatic conveying systems would be relatively straightforward. However, design errors that compromise the system performance are routinely committed. While it would be impossible to list all of the design errors for pneumatic conveying systems, the following section highlights some common ones.

4.1.8.1.1 Selection of Conveying Velocity The optimum conveying for dilute phase system is saltation velocity with an additional 10% factor added for safety. Additional safety factor must be added if the first elbow is within 5 m (15 ft) from feed point. Since saltation velocity depends on the conveying rate, the highest instantaneous rate must be used.

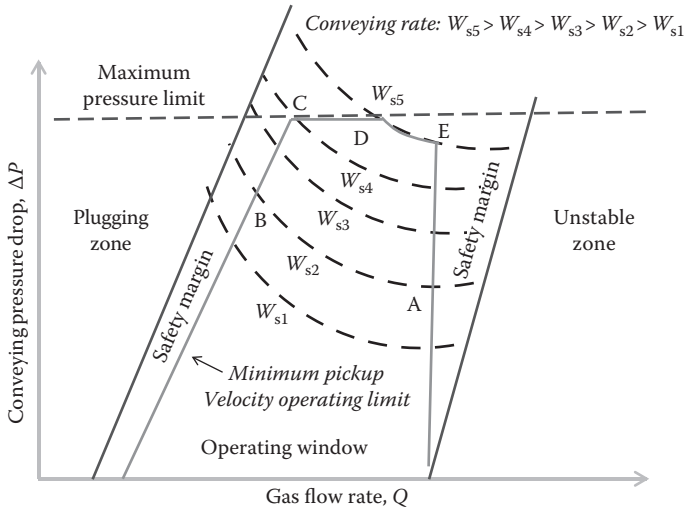

Figure 4.28

Operating window for dense phase conveying. (From Wilms, H. and Dhodapkar, S., *Chem. Eng.*, 59, October 2014.)

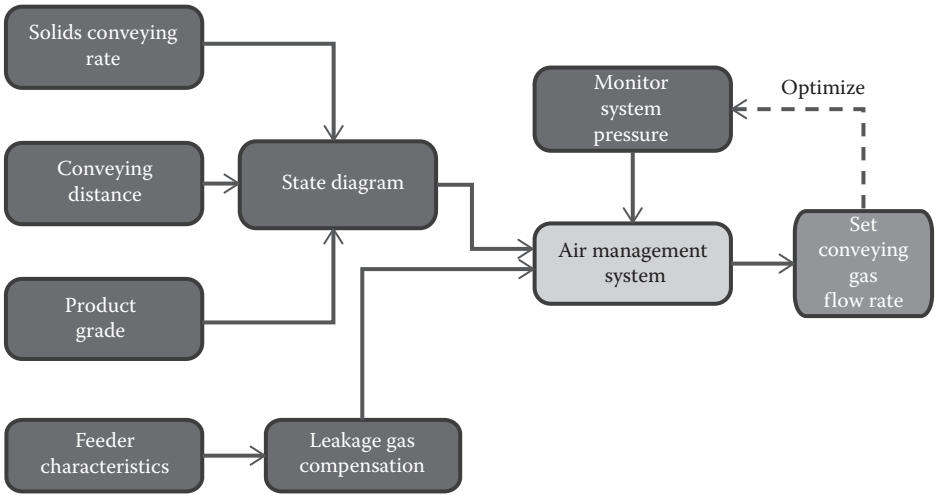

Figure 4.29

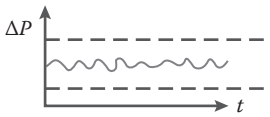

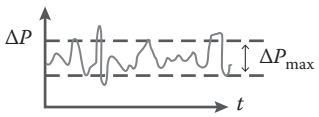

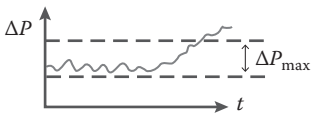

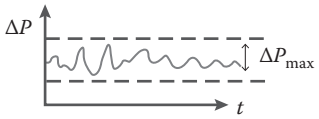

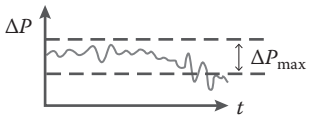

Typical air management control strategy. (From Wilms, H. and Dhodapkar, S., *Chem. Eng.*, 59, October 2014.)

Systems are routinely designed where the design conveying velocity is excessive. In dilute phase conveying systems, this will result in high product degradation or attrition and system wear. Also, the conveying capacity is substantially reduced. The effect of conveying velocity on conveying capacity has been explained in Figure 4.10.

Dense phase conveying systems must be operated within two limits of gas velocity, the lower bound corresponds to fixed bed or nonmoving plugs and the upper bound corresponds to the unstable conveying regime (see Figure 4.9). Excessive gas velocity will result in the system operating in the unstable region and cause severe line vibrations and pressure fluctuations.

4.1.8.1.2 Conveying Line Layout and Use of Elbows and Bends The layout of conveying systems is usually done after the process equipment is laid out and structural steel is designed. A pipe designer adept at configuring process piping will try to route a conveying line in a similar way, with little regard to the negative influence of bends or elbows. In stark contrast to incompressible single-phase fluid flow where the fluid

Table 4.15 Control and Diagnostics Strategy for Dense Phase System Based on Pressure Fluctuations Measurement

Pressure Measurement	Control Strategy
	Pressure fluctuations within acceptable limits, no trend no big spikes • Stable operating conditions • No adjustment of conveying gas flow needed
	Pressure fluctuations exceed permissible range or total pressure exceeds limits, strong fluctuations, no trend: • Close to instable operating conditions • Reduce conveying gas flow rate to leave instable zone
	Pressure fluctuations within acceptable limits, but trend toward higher total pressure (increased flow rate, humidity): • Approaching plugging limit • Incrase conveying gas flowrate
	Pressure fluctuations decrease to acceptable limits, stable operating conditions: • No more adjustments needed • Maintain current conveying gas flowrate
	Pressure fluctuations increase and exceed acceptable limits with trend toward lower total pressure (reduced flow rate, low solids-to-air ratio): • Approaching instable zone • Reduce conveying gas flowrate to return to stable operating window

Note: Dashed lines represent acceptable operating limits.

does not slow through a bend, the particles will slow considerably as they proceed through a bend. This problem is further magnified if bends are placed one after another without sufficient distance to permit the solids to reaccelerate. A good conveying layout will minimize the number of bends or elbows and avoid inclined lines.

4.1.8.1.3 Failure to Account for System Gas Leakage It is important to account for gas leakage in and out of the system when estimating conveying velocity and air mover size. For positive pressure systems, the air leakage from the rotary feeder can be significant and can result in plugging at the feed point. If the material is a fine powder, the air leakage will impede material feed and cause reduced capacity. Also, the air leakage can be a significant fraction of the total air flow for dense phase system, and therefore, it must be correctly estimated.

4.1.8.1.4 Multiple Source and Multiple Destination Systems For systems where there are either multiple destinations (when the product is moved from the production process to storage silos) or multiple sources (when the material is moved from the storage silos to a packaging operation), care must be taken to ensure that the conveying capacity is estimated based on the longest pipe run. In many cases, systems are designed for the midpoint of a bank of silos; consequently, these silos that are located further than the midpoint will not deliver the required flow rate. Another extremely important consideration is the potential leakage of conveying gas through multiple rotary, diverter, or flapper valves in multiple source and destination systems. In the vacuum case, gas leakage into the conveying system along its length means that there may be insufficient gas at the pickup point.

4.1.8.1.5 Insufficient Attention to Component Selection Improper selection of air mover, feeder, and dust collector can result in a problematic system. For instance, fans are commonly selected as air movers for low-pressure applications. As discussed earlier, fans typically have a strong relationship between pressure head and volume of gas delivered. If fans are used for systems where the solids' flow is not regulated, it could lead to a plugged condition on account of the fan's inability to deliver the required volume of air for the increased pressure drop. Similarly, if a rotary feeder is chosen for feeding abrasive solids then excessive gas leakage can result in frequent plugging.

4.1.8.1.6 Understand the Limitations of Dual-Purpose Systems There is a tendency when conveying wet material (from a centrifuge or filter to a dryer, e.g.) to use the conveying system to both move the material within the plant and dry at the same time. This will work *only* when the solids' loading is low (0.05–0.25 kg solids/kg of gas).

4.1.8.1.7 Insufficient Support for Dense Phase Conveying Lines Lines forces in dense phase system are orders of magnitude higher than dilute phase systems. It is essential to design the supports and structure to bear these high dynamic loads. A safety factor of 3–5 is often recommended for specifying the structural supports.

4.1.8.2 Performance Measurement in Conveying

Unlike to many pieces of process equipment in plants in which the material is significantly changed either physically or chemically (e.g., composition, particle size, etc.), the conveying system is relatively simple—it is required to move bulk solids from point A to point B. In that sense, the measurement of performance can be distilled into two points: (1) how quickly is the material moved from one point in the plant to another (system throughput) and (2) does the material undergo any attrition (and lose important attributes) during the conveying process. It could be argued that power consumption would be a third important metric. With most conveying systems, it is far more important for the system to deliver the product at the desired rate with little or no attrition as opposed to save a few kW-h of power. This is particularly the case for higher value-added products being manufactured today.

System throughput is important because it is undesirable that the conveying system be the plant bottleneck. In many cases, both dilute and dense phase systems are routinely designed to operate near the maximum pressure that the air mover can deliver in order to maximize system throughput. The speed of the feeding device (quite often a rotary valve with electronic variable speed control) is tied to the air mover discharge or suction pressure to maximize solids' flow through the conveying system.

Another key metric is attrition or degradation. In many cases, product specifications or customer requirements demand that a product be "fines free." As indicated earlier, the creation of fines is a strong function of gas velocity in a conveying system. These fines can have a substantial impact on flowability, dustiness, dissolution rate, to name a few.

Another example is the conveying of polyethylene (PE). Many grades of PE will form angel hair or streamers during conveying. These streamers (they vary in size from short, low centimeter, long threads to large ribbons of several meters long) are formed on the inside of the conveying pipe during the conveying process and subsequently are released from the pipe surface. Often, streamers will aggregate in a silo to form a low-density ball, which in many cases will clog downstream equipment such an extruder. In this case, the product itself shows little or no degradation as a result of the streamer formation process, but it is the streamers that will compromise system performance due to process blockages.

An ancillary metric to attrition is that of wear. Wear can be an important performance metric, especially in cases where extremely abrasive products are handled, such as sand, glass batch, and mineral ores, for example. It is important that the wear situation be addressed such that it is not either a maintenance (and consequently cost) problem or a source of metal contamination in the process.

4.1.8.3 Troubleshooting Basics

Conveying systems will not always perform as designed or the performance may degrade gradually or suddenly. Consequently, there is a need to troubleshoot conveying systems. This should be done in a logical manner with emphasis on finding the root cause of the problem (Dhodapkar and Jacob, 2002), that is, to clearly identify the nature of the problem. For conveying systems, problems fall into three broad categories:

1. Lack of system throughput—the inability for the conveying system to deliver the required throughput. This could mean that the system is operating at less than the desired rate or the instantaneous rate is fine but cycle times are slow (similar to dense phase blow-pot systems) or plugging may be occurring.
2. Material degradation on attrition—on account of the velocities in conveying systems, products may attrite or break as a result of the conveying process.
3. System degradation—with high velocities or particularly abrasive products, both pipe and system components can experience high wear resulting in an inoperable system. Even systems where the product is thought to be relatively benign can experience wear after significant service. For example, aluminum elbows can wear through in conveying service.

Once the nature of the problem is identified, the next logical step in the troubleshooting process is the data gathering phase. A key philosophy in this process is to take the "systems approach" when examining the problem. This means that rather than focusing on the conveying system alone, it is important to look at the process steps both before and after the system as they may be contributing to the problem. For example, if a dryer precedes the conveying system, moisture fluctuations in the product out of the dryer could have a substantial effect on the ability of product to be conveyed.

Initially, it is important to examine the process flow sheet, the original design specifications for the system, if available, and the pneumatic conveying control system as implemented. Equally important is a physical examination of the entire conveying system to check if the system was built as designed and if there have been modifications to the system since start-up. At this point, it is useful to note any abnormalities such as misaligned pipe, worn valves (such as squeaky rotary valves and diverter valves not returning to a fully closed or open position), and so on.

Key process data must be gathered for effective troubleshooting. Key items would be pressure drop across the conveying system, pressure drop across the dust collection device, pipe size, gas velocity (either measured directly or calculated from blower speed, preferably both), system conveying rate. If data are available from a process control system, it can be very useful in troubleshooting a conveying problem, particularly those that are erratic in nature. During the troubleshooting process, it is not uncommon for conflicts in data to occur. For example, a blower curve and a set of measurements made with a Pitot tube or anemometer may not give the same value for gas flow through the system. In these situations, one must experimentally resolve this conflict in data. In this particular case, one can look at the pressure drop across a specific section of pipe in the system for only conveying gas or measure the pressure drop across a cyclone and infer the gas flow rate from that number.

Depending on the nature of the problem, a number of different fixes are possible. The key is to provide the most robust solution at the most economical cost. In many instances, the speed of the blower can be reduced (see prior discussions on the Zenz curve) to increase the capacity. In other cases, where the blower may be operating at or near maximum pressure, it may be logical to step the pipe (see stepping), in order to increase the throughput.

The key to optimization is an understanding of the operating limits (window) of a system and to ensure that the system operating conditions stay within these limits. A detailed discussion on this can be found in Agarwal and Dhodapkar (2004).

4.1.8.4 Start-up of Conveying Systems

Many of the procedures used for the starting up conveying systems are common to that of all process equipment. It makes sense that the plant is built as designed and also ensures that all instrumentation is operating correctly. The following is a list of start-up issues specific to both dense and dilute phase conveying systems:

1. Check that rotary valve rotation is correct in order to minimize the reentrainment of solids into the emptied pockets.
2. Check the valve sequencing is appropriate for blow-tank operation.
3. Check the piping for both alignment (application of self-aligning flange systems is very useful) and the intrusion of welds into the conveying flow.
4. Check that an appropriately designed pipe cushioning system is in place so as to tolerate the dynamic stresses associated with large plugs moving through the conveying system for dense phase systems (especially those > 150 mm pipe diameter).
5. Check that the blower rotation must be correct.
6. Check the clearances on the rotary valves such that the valves not only rotate freely but also are sufficiently close so as to minimize leakage.
7. Check that the relief valves and rupture disks are in place so as to minimize the damage associated with an accidental over or underpressurization. This is particularly important for systems where a dust collector or baghouse is used and the bags have the possibility of being coated over with bulk solid on account of moisture and so on.

4.1.8.5 Wear

Wear issues are pervasive in pneumatic conveying applications. Many studies have been undertaken to quantify the effect of various parameters to predict the wear life of components. While we now understand

the influence of various factors and their relative importance, it is not possible to generalize the conclusions. The solution to one wear problem cannot necessarily be applied to another problem. Further details can be found in Section 12.4.3.

4.2 Slurry Flows

Shenggen Hu

4.2.1 Introduction

Slurry is a suspension of solid particles in a carrier liquid. The transport of slurries through circular pipelines is widespread in the minerals, coal, chemical, food, water, and other industries. Unlike the flow of single-phase liquid, the flow velocity of slurries must be higher than a certain value to maintain solid particles in suspension. The flow of single-phase liquid is homogeneous at all velocities, while slurry flows may behave heterogeneously or exhibit some combination of both. The slurry may also behave rheologically as a Newtonian fluid or may exhibit a variety of non-Newtonian rheological properties.

The large number and range of variables encountered in slurry flows in pipelines cause the flow behavior of these slurry systems to vary over a wide range, and therefore, different approaches have been used to describe their behavior in various flow regimes. The variables influencing the behavior of slurry flows include the orientation of the pipeline, the characteristic dimension of the conduit, flow velocity, particle size, particle size distribution, particle density, particle shape, solids' concentration, and the properties of the fluid–particle interface, which are determined by the compositions of the fluid and the solids. Due to this long list and wide variation ranges of variables, the literature abounds with numerous studies of special cases that cover a limited range of conditions. Consequently, it is impractical to provide a thorough or even an adequate survey of the subject of slurry pipeline flows in a single section of this handbook.

The intent of this section is to summarize what appears to be the most widely accepted and the most comprehensive studies and results in the context of slurry flow, which may apply to various flow regimes. In particular, we will examine the classification of slurry flow regime, the frictional pressure loss estimation for both homogeneous and heterogeneous slurry flows, the prediction of the critical velocity for horizontal pipe flow, design and operation aspects, and measurement techniques.

4.2.2 Basic Concepts of Slurry Flows

4.2.2.1 Basic Definitions

4.2.2.1.1 Slurry Flow Velocity

The mean slurry flow velocity U_m is defined by

$$U_m = \frac{\dot{V}_s + \dot{V}_l}{A} \tag{4.1}$$

where $\dot{V}_s$ and $\dot{V}_l$ are volumetric flow rate of solids and liquid, respectively.

4.2.2.1.2 Solids' Concentration The solids' concentration can be expressed as volume fraction α_s or mass fraction. The volumetric fraction of solids is given by

$$\alpha_s = \frac{\dot{V}_s}{\dot{V}_s + \dot{V}_l} \tag{4.2}$$

and the mass fraction of solids' C_s is defined as

$$C_s = \frac{\rho_s \dot{V}_s}{\rho_s \dot{V}_s + \rho_l \dot{V}_l} \tag{4.3}$$

It can be shown that

$$C_s = \frac{\alpha_s \rho_s}{(\alpha_s \rho_s + (1-\alpha_s)\rho_l)} \tag{4.4}$$

4.2.2.1.3 Slurry Density The density of slurry mixture ρ_m is given by

$$\rho_m = \alpha_s \rho_s + (1-\alpha_s)\rho_l \tag{4.5}$$

4.2.2.1.4 Apparent Viscosity The steady-state rheological behavior of most slurry mixtures can be expressed by the following general form:

$$\tau = \eta \dot{\gamma} \tag{4.6}$$

where
- τ is the shear stress
- $\dot{\gamma}$ is the shear rate
- η is the apparent viscosity

The plot of shear stress τ versus the shear rate $\dot{\gamma}$ is called *rheogram*, which is schematically illustrated in Figure 4.30. If η is a constant and equal to the slope of the straight line from the origin, the slurry rheological behavior is Newtonian. Slurry mixtures that do not behave in this fashion are termed non-Newtonian slurry mixtures, in which η is not a constant and may be expressed as a function of either $\dot{\gamma}$ or τ. In regions in which η decreases with the increasing rate of shear $\dot{\gamma}$ the behavior is termed *pseudo-plastic* or *shear thinning*; in regions in which η increases with the increasing rate of shear $\dot{\gamma}$ the behavior is termed *dilatant* or *shear thickening*. The curve intercepts at zero rate of shear are called *yield stresses*.

4.2.2.2 Slurry Flow Regimes

The slurry flow regime (also referred to as flow pattern) varies with the properties of the solid particles relative to those of the liquid. The flow regime affects the dependence of the pressure drop on the flow rate as well as the magnitude of the pressure drop and it also influences the pipe erosion and other performance characteristics. Because of the complexity of slurry flows and the gradual transitions between flow regimes, only an imperfect classification of the regimes is possible.

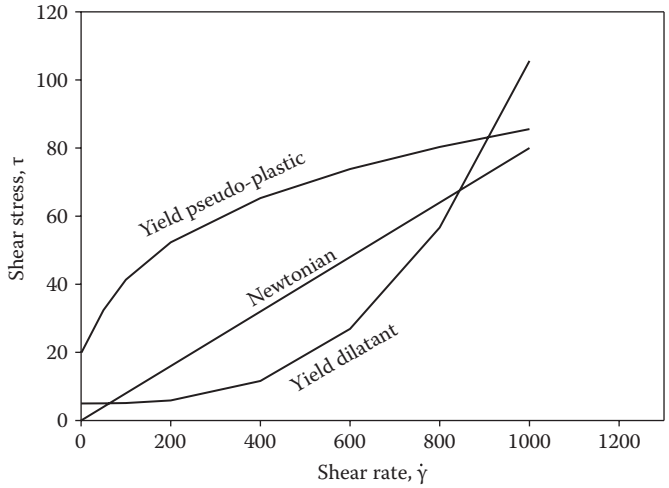

Figure 4.30

Illustrative rheograms.

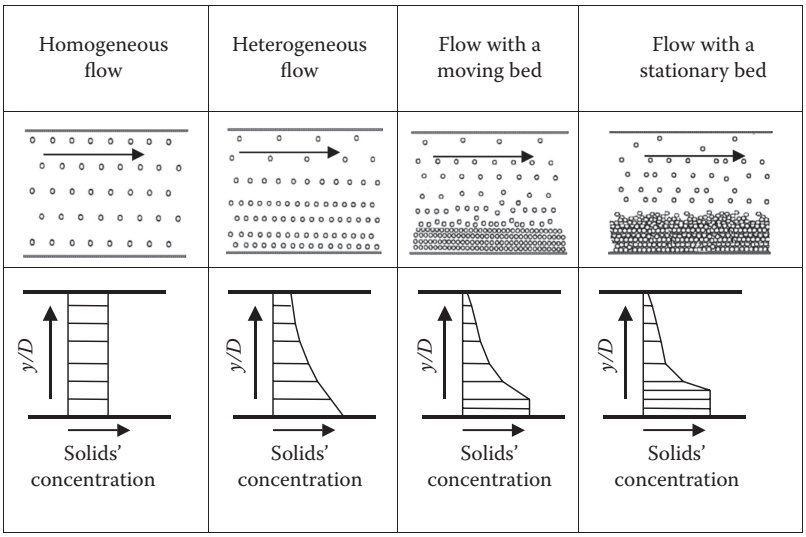

Figure 4.31

Illustration of particle distributions and solids' concentration profiles in a pipe for different slurry flow regimes.

Since Durand and Condolios (1952) proposed the initial classification of slurry flow regimes based on average particle size, a number of refined classifications have been developed over the years (Newitt et al., 1955, Thomas, 1964, Wicks, 1971, Ercolani et al., 1979, Brown, 1991). One of the most common classifications is to broadly categorize slurry flows in pipelines into four regimes: homogeneous, heterogeneous, heterogeneous with a moving bed, and heterogeneous with a stationary bed. The schematic views of particle spatial distributions and solids' concentration profiles in a pipe for different slurry flow regimes are shown in Figure 4.31.

Homogeneous slurry flow is characterized by a uniform distribution of solid particles throughout the carrier liquid and across the pipeline cross section. Typically, this type of slurry has a high solids' concentration of fine solid particles (<40 μm) of low particle density and exhibits viscous behavior. An example of homogeneous flow is the minerals ore slurry after comminution and thickening, in which the particles are very fine and the solids' concentration is high (>40% by weight). Although no slurry is ever truly homogeneous because it consists of distinct phases, there are situations in which the slurry can be described satisfactorily by single-phase models. Therefore, the principle of continuum mechanics may be applied to the analysis of homogeneous slurry flow, and the rheological properties of the slurry are most often non-Newtonian.

In heterogeneous slurry flow, solid particles that are sufficiently large (>40 μm) and sufficiently dense and/or in a sufficiently dilute state will settle to various degrees so that the particles are no longer uniformly distributed in the flow filed, that is, the slurry is heterogeneous, but the majority of the particles are still fully suspended. The different phases retain their properties and the analysis of this flow behavior needs to consider separately the forces on the particles, resulting from interaction with the surrounding suspending medium. Heterogeneous slurries are encountered in many industrial processes, such as minerals' processing. Solids' concentration in these slurries is relatively low, typically less than 35% by weight. Heterogeneous slurry flows are much more complicated than the homogeneous slurry flow, and consequently, most of the experimental studies in the literature have been concerned with these flows. Both critical deposit velocities and pressure losses are of interest.

The terms *nonsettling* and *settling* have often been used synonymously with *homogeneous* and *heterogeneous*.

When a large fraction of particles in a slurry are fine but there remain a sufficient fraction of coarse particles, intermediate regimes may occur, in which the fine particles are homogeneously distributed and the coarse particles are heterogeneously distributed or may deposit as the flow speed is reduced below a minimum value. Intermediate regime flows include tailings from mineral processing plants and a wide range of industrial slurries. Although many of slurry flow cases are clearly homogeneous or heterogeneous, many more are a combination of both. This is because the particle size is the single most important parameter that governs the flow regime. Most of the practical slurry systems contain solid particles having a rather broad

particle size distribution. Such systems are often considered to be in a mixed homogeneous–heterogeneous mode, and their flow behavior must be analyzed accordingly.

Under certain conditions, the flow regime of heterogeneous with moving bed can be observed. In this flow regime, the larger and/or denser particles will accumulate at the bottom of the conduit and form a bed. The particles in the bed will move or slide along the bottom of the conduit because the shear forces due to the moving fluid are sufficiently large. The concentration of this bed corresponds to maximal packing, or nearly so, and the upper part of the pipe cross section is occupied by a heterogeneous mixture.

In the regime of heterogeneous flow with a stationary bed, the slurry flow velocity is too low to enable the motion of all immersed particles, a stationary deposit bed is formed at the bottom of the pipe. On top of this deposit bed particles are transported as a separate moving layer. Although stationary bed type flows can be encountered in practical situations, they should be avoided whenever possible since they tend to result in a highly unsteady type of flow behavior at best and plugging at worst.

The prediction of the flow regime that would exist in the pipe for any given set of operational conditions is very important. One would like to avoid the formation of a stationary deposit, which causes partial blockage of the pipe, thus reducing its efficiency. A moving bed probably enhances pipe wear. Moreover, the pressure drop behavior is different from one flow regime to another. A variety of criteria have been proposed for determining whether a given slurry flow is considered homogeneous or heterogeneous or flows with deposited solids' bed. However, criteria based on a single parameter, such as particle size (Durand and Condolios, 1952), are incomplete, since slurry flow behavior also depend on other parameters. The more reliable approach for the determination of the flow regime is using suitable empirical correlations (Turian and Yuan, 1977, Turian et al., 1987) or mechanistic models, such as two-layer (Wilson, 1970, 1976, Gillies et al., 1991) or three-layer models (Doron and Barnea, 1993). Some of these correlations and models will be examined in Section 4.2.4.

A typical flow regime plot for slurry flow in a pipe is shown in Figure 4.32. This figure was generated using Turian and Yuan's correlations (Turian and Yuan, 1977) for the conditions as given in the figure. According to Figure 4.32, a slurry containing particles of 300 μm would be in the homogeneous regime, if the slurry velocity is higher than 2.3 m/s. A plot such as this is useful to determine the flow regime that applies under a given set of conditions and how much the slurry velocity must change before the flow enters another regime.

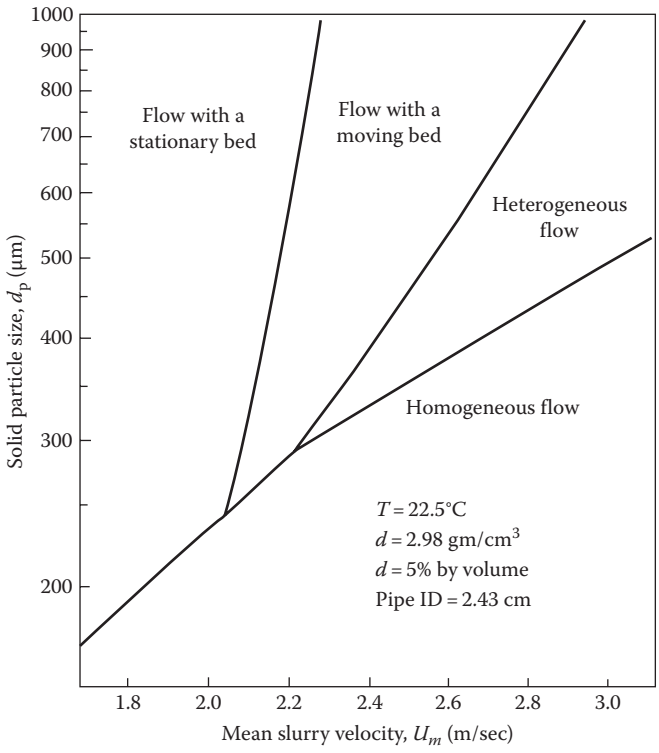

Figure 4.32

Flow regime diagram for slurry flow in 25 mm pipe under the conditions given in the figure. (Adapted from Turian, R.M. and Yuan, T.F., *AIChE J.*, 23, 232–243, 1977. With permission.)

4.2.3 Homogeneous Flow of Nonsettling Slurries

4.2.3.1 Rheological Models

In homogeneous slurry flows, slurries show no segregation or a small but finite tendency to settle when allowed to stand. In this respect, the slurries resemble a single-phase fluid, for which the science of rheology and continuum mechanics are well established. The major technical tasks for assessing homogeneous slurry flows are

1. To determine an appropriate rheological model from a test program and evaluate the specific coefficients for the slurry at the temperature and solids' concentration of interest.
2. To predict the pressure loss for laminar and turbulent flow and the transition point between them.

Rheological property is one of the major factors influencing the homogeneous flow behavior and pressure loss. At the present time, it is not possible to predict slurry rheological properties or the viscosity–concentration–shear rate relationship for most of industrial slurries, except for Newtonian slurries. Experimental characterization of the rheological property is possible and essential, and measurement techniques will be examined in Section 4.2.6.1.

The rheological data may be utilized directly for predicting the flow behavior under certain conditions. However, it is more convenient and more useful if the data can be represented by an appropriate model. It is also desirable to have a model that is as simple mathematically as possible and yet adequately describes the slurry rheological property. A number of models have been proposed for representing the viscosity function of homogeneous slurries. Although there is some degree of logical deduction behind some of the models, they are largely empirical models. The more complex models are capable of representing more complex behavior, although they are also more difficult to evaluate and to apply and often are not necessarily more useful in a practical sense.

4.2.3.1.1 Newtonian Slurries In homogeneous slurry flows, the nonsettling slurries may behave as a Newtonian fluid under certain conditions, such as sufficiently low solids' concentration, low particle densities, and/or high fluid viscosities. Rheological properties of Newtonian slurries are a function of both liquid and solids' characteristics but independent of the magnitude of the shear stress or the shear rate. The viscosity of the Newtonian slurry is often presented as the relative viscosity μ_r, the viscosity of the mixture μ_m normalized with that of the carrier fluid μ_l:

$$\mu_r = \frac{\mu_m}{\mu_l}. \tag{4.7}$$

The relative viscosity μ_r may vary with the volume fraction of solids, particle size and size distribution, particle shape, particle surface properties, fluid electrolyte concentration, and ionic charge and temperature. Some models that relate the relative viscosity μ_r to the volumetric fraction of solids α_s are shown in Table 4.16.

The Einstein's model is only applicable to slurries with the volumetric fraction of solids α_s smaller than 1%. The other models in the table can be used for slurries with a high volumetric fraction of solids. Although a number of other models have also been proposed, one of those shown in Table 4.16 will probably suffice for fitting experimental data. Since solids' concentration is not the only relevant parameter, there is no best model for the relationship between μ_r and α_s. The relative viscosity is also affected by solids' particle size distribution (Probstein and Sengun, 1987) and particle shape (Happel and Brenner, 1965).

Table 4.16 Some Common Relative Viscosity Models for Newtonian Slurries

Model Equation	Model Parameters	Reference
$\mu_r = 1 + 2.5\alpha_s$		Einstein (1906)
$\mu_r = \exp(B\alpha_s)/(1 - \alpha_s/\alpha_{max})$	B and α_{max}	Krieger (1972)
$\mu_r = 1 - \alpha_s/\alpha_{max}$	α_{max}	Krieger (1972)
$\mu_r = \exp[(B - n/\alpha_{max})\,\alpha_s]/(1 - \alpha_s/\alpha_{max})^n$	B, n, and α_{max}	Vocadlo (1976)
$\mu_r = 1 + 2.5\alpha_s + 10.05\alpha_s^2 + 0.00273\exp(16.6\alpha_s)$		Thomas (1965)

4.2.3.1.2 Non-Newtonian Slurries As the solids' concentration increases, the rheological properties of nonsettling slurries will deviate from Newtonian behavior. When this deviation occurs, the apparent viscosity η, as defined in Equation 4.6, is no longer a constant, but is instead dependent upon the magnitude of the shear stress τ or the shear rate $\dot{\gamma}$. Such nonsettling slurries are called non-Newtonian. For the majority of non-Newtonian slurries, η is a decreasing function of shear stress τ or shear rate $\dot{\gamma}$ (pseudo-plastic or shear thinning). However, for some slurries of very fine particles (e.g., starch), η may increase with increasing τ or $\dot{\gamma}$ (dilatant or shear thickening). Certain slurries, such as flocculated slurries encountered in minerals processing plants, may develop an internal structure leading to the time-dependent non-Newtonian behavior (i.e., the thixotropic slurry). Since the dilatant type of behavior is relatively rare and the time-dependent non-Newtonian slurry flows are difficult to model, the examination of rheological models for non-Newtonian slurries in this sections will be limited to the time-independent pseudo-plastic behavior.

Many models have been proposed for representing the viscosity function of non-Newtonian slurries. The model equation that best represents a given slurry depends not only upon the nature of the behavior of that slurry but also upon the quality and range of viscosity data available for that slurry. Hence, a relatively simple equation might be adequate to represent viscosity data over only a limited range of shear rate. However, if a wide range of shear rate is covered, a complex equation might be needed to represent the entire range of data.

Typical models that have been found useful for representing rheological properties of non-Newtonian slurries are shown in Table 4.17. Each model is written in three equivalent equations except the Sisko model. Limitations associated with each model are also indicated in the table.

Both the Bingham plastic and the Casson models contain two parameters: a yield stress (τ_b or τ_c) and a limiting viscosity (η_b or η_c). Both models approach Newtonian behavior with a viscosity of η_b or η_c as shear stress τ or shear rate $\dot{\gamma}$ increases. Although these two models are simple, they exhibit proper limiting behavior at both extremes of shear rate and are consequently useful for representing the viscous properties of slurries that exhibit an apparent yield stress resulting from the interparticle contact resistance in a rest state. The Casson model is a theoretical two-parameter model. Recent work in the prediction of laminar and turbulent pipeline flow of non-Newtonian, nonsettling slurries seems to focus largely on the use of the Casson model rather than the Bingharn plastic and the Herschel–Bulkley models for describing shear-thinning slurry behavior. The Casson model has an advantage over the Bingham plastic model because it can predict the curvature of the rheogram curve at low shear rates. The Casson model has been used to describe the non-Newtonian flow behavior of a wide variety of materials, including printing inks, blood, chocolate, and oil-based drilling mud.

Table 4.17 Typical Rheological Models for Non-Newtonian Slurries

Model Name	Model Equation	Limitations
Bingham plastic (Bird et al., 1960)	$\tau = \tau_b + \eta_b\dot{\gamma}$ for $\tau > \tau_b$ $\dot{\gamma} = 0$ for $\tau < \tau_b$ $\eta = \eta_b + \tau_b/\dot{\gamma}$ or $\eta = \tau\eta_b/(\tau - \tau_b)$	τ_b and η_b depend on solids' concentration α_s and particle size distribution (PSD)
Casson (1959)	$\tau^{1/2} = \tau_c^{1/2} + (\eta_c\dot{\gamma})^{1/2}$ $\eta = [\eta_c^{1/2} + (\tau_c/\dot{\gamma})^{1/2}]$ or $\eta = \tau\eta_c/\left(\tau^{1/2} - \tau_c^{1/2}\right)^2$	τ_c and η_c depend on α_s and PSD
Power-Law (Bird et al., 1960)	$\tau = K_p\dot{\gamma}^n$ $\eta = K_p\dot{\gamma}^{n-1}$ or $\eta = \tau(K_h/\tau)^{1/n}$	Predict $n \to \infty$ for $n < 1$ and $\dot{\gamma} \to 0$; predict $n \to 0$ for $n < 1$ and $\dot{\gamma} \to \infty$; K_p and n depend on solids' concentration and PSD
Herschel–Bulkley (1926)	$\tau = \tau_h + K_h\dot{\gamma}^p$ $\eta = K_p\dot{\gamma}^{p-1} + \tau_h/\dot{\gamma}$ or $\eta = \tau[K_h/\left(\tau - \tau_h\right)]^{1/p}$	Predict $n \to 0$ for $p < 1$ and $\dot{\gamma} \to \infty$; τ_h, K_h, and p depend on α_s and PSD
Sisko (1958)	$\tau = \eta_s\dot{\gamma} + K_s\dot{\gamma}^m$ $\eta = \eta_s + K_s\dot{\gamma}^{m-1}$	η_s, K_s, and m depend on α_s and PSD

The power-law model can represent Newtonian (for $n = 1$), shear thinning (for $n < 1$), or shear thickening (for $n > 1$) behavior. Although most non-Newtonian slurries can exhibit a "power-law" region over a certain range of shear rate, the model will fail at very high and/or low shear rates. For example, the model will predict $\eta \to \infty$ for $n < 1$ and $\dot{\gamma} \to 0$, and $\eta \to 0$ for $n < 1$ and $\dot{\gamma} \to \propto$, both of which are unrealistic for slurries with no yield stress.

The Herschel–Bulkley model (also referred to as the *yield power-law* or *generalized Bingham* model) is basically the power-law model with an added yield stress parameter. Although this model is more flexible than the Bingham model for modeling rheogram data due to the additional model parameter, it suffers the same limitation as the power-law model with regard to unrealistic limiting behavior at high shear rates (or stresses). The estimation of Herschel–Bulkley model parameters from curve fitting often contains a significant degree of uncertainty (Turian et al., 1997), as it is found that different sets of values of the model parameters in the model can provide equivalent fit of the experimental data. This is a fundamental weakness of the Herschel–Bulkley model.

The Sisko model has been found to be a good model for describing the shear stress–shear rate dependence for many non-Newtonian slurries over the range of shear most appropriate to flow in pipes (Turian et al., 1992, 1998a). Unlike other three-parameter empirical models, one of the model parameters, η_s, can be determined independently, as it is given by the high-shear asymptote of the viscosity–shear rate plot. Consequently, the parameter value of η_s is instrument-geometry indifferent and depends upon suspension microstructure. The remaining two model parameters, K_s and m, are then determined through the best curve fitting to the data over the whole range of shear. The rheogram curves for most concentrated non-Newtonian slurries usually possess a power-law region covering the lower and the intermediate shear rate ranges, followed by an asymptotic approach to a high-shear Newtonian limit. The Sisko model not only describes such behavior well but also does so over the entire range of shear rates attainable even in the highest shear rheometer and with a unique set of unambiguously determined model parameter values.

The model parameters in the equations listed in Table 4.17 can be estimated through linear or nonlinear regression. However, extrapolation outside the experimental shear rate range should be done only with caution. Heywood and Cheng (1984) have used two different methods for the curve fitting. One involves nonlinear least-squares regression on weighted data while, in the other method, the data are not weighted. They have shown that while both methods will give best estimates of the three parameters that will then allow prediction of τ to within ±2% over the original viscometric shear rate range, extrapolation well outside this shear rate range leads to very different τ predictions using the two methods.

Bingham plastic, Casson, and Herschel–Bulkley models include a yield-stress parameter, τ_b, τ_c, and τ_h, respectively. However, Turian et al. (1998a) indicated that curve-fitting shear stress/shear rate data to determine these yield-stress parameters will not, and generally does not, insure that a yield stress, as an intrinsic, instrument-geometry indifferent slurry property has been determined or, for that slurry, exists. The yield-stress values obtained from curve fitting should not necessarily be considered as an absolute property of the slurry but rather a constant that arises out of the correlation of shear stress/shear rate data. The true yield stress of a slurry, if it exists, may have a value quite different from the value derived from the curve fitting of experimental data for which the lower limit of the viscometric shear rate range is of the order of tens or even hundreds of reciprocal seconds. A knowledge of the true yield stress facilitates the calculation of the start-up pressure gradient for stagnant fluid in a pipe according to Section 4.2.5.3. A detailed discussion of determination of yield stresses for slurries has been given by Turian el al. (1992).

It should be noted that all model parameters for the models listed in Table 4.17 are influenced by solids' concentration, particle size distribution, and the properties of the interface between solids and liquid. Bird et al. (1982) have summarized various equations from the literature that relate the parameters of the Bingham and Casson models to various properties of slurries, including solids' concentration. In general, the dependence of parameters in Bingham and power-law models on solids' concentration can be modeled using the following equation:

$$\tau_b\,(\text{or}\,\eta_b, K_p, n) = E\exp(F\alpha_s), \tag{4.8}$$

where E and F are constants derived from tests measuring particle size distribution, shape, and the nature of their surface. A number of other empirical models for correlating the parameters in non-Newtonian rheological models with various factors have been reported in the literature (Thomas, 1961, Bird et al., 1982, Turian et al., 1997).

4.2.3.2 Pressure Loss through Straight Circular Pipe

4.2.3.2.1 Friction Factor in Pipe Flows For steady slurry flows in a piping system with straight conduit of uniform cross section, the total pressure change, Δp, in general comprises

$$\Delta p = p_f + p_{ft} + \rho_m g \Delta z \tag{4.9}$$

where

p_f is the frictional pressure loss in the pipe
p_{ft} is the frictional pressure loss arising from flow through fittings
The last term, $\rho_m g \Delta z$, is the pressure loss or gain resulting from elevation changes and is negative for a reduction in static head and positive for an increase in static head
Δz is the net change in pipeline elevation, assuming that the pipeline is full of slurry

The frictional pressure loss over a straight pipe with a length L and an internal diameter D is given by

$$p_f = f\left(4L/D\right)\left(\rho_m U_m^2/2\right) \tag{4.10}$$

where f is the friction factor of pipe flow. This equation shows that the evaluation of f is the major task in the determination of the frictional pressure loss. The friction factor can also be defined in terms of the shear stress at the pipe wall, τ_w:

$$f = \frac{\tau_w}{(\rho_m U_m^2/2)} \tag{4.11}$$

4.2.3.2.2 Laminar Flows For laminar flow, the pipeline pressure loss can be calculated from first principles for any given rheological data or model fitted to the data. The accuracy of pressure drop prediction is limited only by the accuracy of the data and the closeness with which the slurry flow properties fit any chosen model. The rheological models as presented in Section 4.2.3.1 can be used either to obtain analytical expressions for volumetric flow rate as a function of wall shear stress and other relevant variables in the laminar flow regime or for the friction factor as a function of model-specific modified Reynolds number.

The volume flow rate through a pipe with a local slurry velocity $v(r)$ at the radial position r in the pipe is given by

$$\dot{V}_m = \int_0^{D/2} 2\pi v(r) \mathrm{d}r \tag{4.12}$$

The shear stress at a radial position, r, can be related to the frictional pressure loss over the pipe of length, L, by equating the resultant force, $\pi r^2 p_f$, from the pressure drop over a cylinder of radius, r, with the force derived from the shear stress, $2\pi r\tau$

$$\tau = \frac{r}{2}\frac{p_f}{L}. \tag{4.13}$$

After integration by parts and using Equation 4.13, Equation 4.12 becomes

$$\dot{V}_m = \frac{\pi}{8}\left(D/\tau_w\right)^3 \int_0^{\tau_w} \tau^2 \dot{\gamma} \mathrm{d}\tau, \tag{4.14}$$

where the shear stress at the pipe wall, τ_w, is given by

$$\tau_w = \frac{D p_f}{4L}. \tag{4.15}$$

4.2.3.2.2.1 Newtonian Slurries For steady, fully developed, laminar flow of Newtonian slurries in a circular pipe, the apparent viscosity η ($\eta = \mu_m$) is independent of the shear rate or shear stress. Substitution of the Newtonian model (i.e., $\tau = \mu_m\dot{\gamma}$) into Equation 4.14 leads to the well-known Hagen–Poiseuille equation

$$\dot{V}_m = \frac{\pi D^4 p_f}{128\mu_m L} = \frac{\pi D^3 \tau_w}{32\mu_m} \tag{4.16}$$

By using Equation 4.16 to eliminate τ_w in Equation 4.11 and rearranging to solve for f gives

$$f = \frac{16\mu_m}{DU_m\rho_m}. \tag{4.17}$$

This equation can be rewritten in dimensionless form:

$$f = \frac{16}{Re}, \tag{4.18}$$

where $Re = DU_m\rho_m/\mu_m$ is the pipe flow Reynolds number. The upper limit of Newtonian laminar flow regime is defined by the Reynolds number with a value of 2100.

4.2.3.2.2.2 Non-Newtonian Slurries For non-Newtonian slurries, analytical expressions for the volumetric flow rate and the friction factor can be obtained by substituting a non-Newtonian rheology model into Equation 4.14 and then evaluating the integral of the equation. For rheology models with a yield stress (e.g., Bingham plastic), the lower limit of the integral in Equation 4.14 must be replaced by the yield stress. In the evaluation of Equation 4.14, using either data or a model, the range of shear stress from zero (or a yield stress) to $\tau_w = Dp_f/4L$ is involved. Experimental data may not cover this entire range, especially at the lower limit. Consequently, some extrapolation is inevitable. In this situation, the reliability of the results depends upon the degree to which the database covers the range of conditions (i.e., shear stress) of interest.

4.2.3.2.2.2.1 Power-Law Model For the power-law model, $\tau = K_p\dot{\gamma}^n$, the integration of Equation 4.14 gives

$$\dot{V}_m = \frac{\pi D^3}{32}\left(\frac{4n}{3n+1}\right)\left(\frac{\tau_w}{K_p}\right)^{1/n} \tag{4.19}$$

which is the power-law equivalent of the Hagen–Poiseuille equation and reduces to Equation 4.16 for $n = 1$ and $K_p = \mu_m$. Using Equation 4.19 to eliminate τ_w in Equation 4.11 and rearranging to solve for f gives

$$f = \frac{16}{Re_p} \tag{4.20}$$

where Re_p is the equivalent Reynolds number for power-law non-Newtonian slurries and is given by

$$Re_p = \frac{\rho_m U_m D}{K_p}\left(\frac{4n}{3n+1}\right)^n\left(\frac{D}{8U_m}\right)^{n-1}. \tag{4.21}$$

It should be noted that the definition of Re_p does not have any physical meaning, and it is so defined that Equation 4.20 and Equation 4.18 are of identical form.

4.2.3.2.2.2.2 Bingham Plastics Model Due to the yield stress in the Bingham Plastic model (i.e., $\tau = \tau_b + \eta_b\dot{\gamma}$), a region extending from the center of the pipe to $r = R\tau_b/\tau_w = r_0$ will move as a "plug." Therefore,

the total volume flow rate will be the sum of flow rate in the "plug" and that in the deformed region surrounding the plug and is given by

$$\dot{V}_{\mathrm{m}} = \dot{V}_{\mathrm{plug}} + \int_{r_0}^{D/2} 2\pi v(r)\mathrm{d}r \tag{4.22}$$

After integration by parts and substituting the Bingham Plastic model equation, the evaluation of Equation 4.22 yields the Buckingham (1921) equation:

$$\dot{V}_{\mathrm{m}} = \frac{\pi D^3 \tau_{\mathrm{w}}}{32\eta_{\mathrm{b}}}\left[1 - \frac{4}{3}\frac{\tau_{\mathrm{b}}}{\tau_{\mathrm{w}}} + \frac{1}{3}\left(\frac{\tau_{\mathrm{b}}}{\tau_{\mathrm{w}}}\right)^4\right] \tag{4.23}$$

Substituting $\tau_{\mathrm{w}} = f\rho_{\mathrm{m}} U_m/2$ into Equation 4.23 and solving for f give the equivalent dimensionless expression

$$f = \frac{16}{Re_{\mathrm{b}}}\left[1 + \frac{1}{6}\frac{He_{\mathrm{b}}}{Re_{\mathrm{b}}} - \frac{1}{3}\frac{He_{\mathrm{b}}^4}{f^3 Re_{\mathrm{b}}^7}\right] \tag{4.24}$$

where

$$Re_{\mathrm{b}} = DU_{\mathrm{m}}\rho_{\mathrm{m}}/\eta_{\mathrm{b}} \quad \text{and} \quad He_{\mathrm{b}} = D^2\rho_{\mathrm{m}}\tau_{\mathrm{b}}/\eta_{\mathrm{b}}^2 \tag{4.25}$$

in which He_{b} is the Hedstrom number defined for Bingham Plastics model. Since Equation 4.24 is implicit in terms of f, an iterative technique is necessary to obtain f. If the last term in the bracket is small relative to the other terms, a brief iteration using the first two terms as the starting value will converge very rapidly.

4.2.3.2.2.2.3 Herschel–Bulkley or Generalized Bingham Model A procedure analogous to that given earlier can be followed using the Herschel–Bulkley model (i.e., $\tau = \tau_{\mathrm{h}} + K_{\mathrm{h}}\dot{\gamma}^p$) with Equation 4.22 to determine the flow rate and friction factor. The analytical expressions for volume flow rate and the friction factor are

$$\dot{V}_{\mathrm{m}} = \frac{\pi D^3 p}{8(3p+1)}\left(\frac{\tau_{\mathrm{w}} - \tau_{\mathrm{h}}}{K_{\mathrm{h}}}\right)^{1/p}\left[\chi^3 + \frac{2(3p+1)}{2p+1}\frac{\tau_{\mathrm{h}}}{\tau_{\mathrm{w}}}\chi^2 + \frac{(3p+1)}{2p+1}\left(\frac{\tau_{\mathrm{h}}}{\tau_{\mathrm{w}}}\right)^2\chi^2\right] \tag{4.26}$$

where $\chi = (1 - \tau_{\mathrm{h}}/\tau_{\mathrm{w}})$, and

$$f = \frac{2He_{\mathrm{h}}}{Re_{\mathrm{h}}^2} + \frac{16}{Re_{\mathrm{h}}}\left[\chi^3 + \frac{2(3p+1)}{2p+1}\frac{\tau_{\mathrm{h}}}{\tau_{\mathrm{w}}}\chi^2 + \frac{(3p+1)}{2p+1}\left(\frac{\tau_{\mathrm{h}}}{\tau_{\mathrm{w}}}\right)^2\chi^2\right]^{-p} \tag{4.27}$$

where

$$Re_{\mathrm{h}} = \frac{\rho_{\mathrm{m}} U_{\mathrm{m}} D}{K_{\mathrm{h}}}\left(\frac{4p}{3p+1}\right)^p\left(\frac{D}{8U_{\mathrm{m}}}\right)^{p-1} \tag{4.28}$$

and

$$He_{\mathrm{h}} = \left(\frac{\tau_{\mathrm{h}}}{\rho_{\mathrm{m}}}\right)\left(\frac{Re_{\mathrm{h}}}{U_{\mathrm{m}}}\right)^2 \tag{4.29}$$

Due to $\tau_{\mathrm{w}} = f\rho_{\mathrm{m}} U_{\mathrm{m}}/2$, Equation 4.27 requires an iterative procedure to solve for f. Unlike the Bingham model, no simplifying assumption can be made easily to derive an expression from Equation 4.27, which is then explicit in f.

4.2.3.2.2.2.4 Casson Model For Casson model (i.e., $\tau^{1/2} = \tau_c^{1/2} + (\eta_c \dot{\gamma})^{1/2}$), the analytical expressions are

$$\dot{V}_m = \frac{\pi D^3 \tau_w}{32\eta_c}\left[1 + \frac{4}{3}\frac{\tau_c}{\tau_w} - \frac{16}{7}\left(\frac{\tau_c}{\tau_w}\right)^{1/2} - \frac{1}{21}\left(\frac{\tau_c}{\tau_w}\right)^4\right] \tag{4.30}$$

and

$$f = \frac{16}{Re_c}\left[1 - \frac{1}{6}\frac{He_c}{Re_c} + \frac{1}{7}\left(2fHe_c\right)^{1/2} + \frac{1}{21}\frac{He_c^4}{f^3 Re_c^7}\right] \tag{4.31}$$

where

$$Re_c = DU_m\rho_m/\eta_c \quad \text{and} \quad He_c = D^2\rho_m\tau_c/\eta_c^2 \tag{4.32}$$

4.2.3.2.2.2.5 Numerical Integration Method Substituting Equation 4.15 into Equation 4.14 and solving for P_f give

$$P_f = \left(\frac{8\pi L^3}{\dot{V}_m}\int_0^{\tau_w} \tau^2\dot{\gamma}\,d\tau\right)^{1/3} \tag{4.33}$$

This relationship suggests a simplified but rigorous approach to the estimation of the frictional pressure loss for the laminar flow of a slurry having any rheological property. If a rheogram curve (also called flow curve) data for a slurry have been obtained using a smaller (or larger) pipe diameter and there are no *wall-slip* effects, the integral in the equation given earlier can be readily evaluated by plotting $\tau^2\dot{\gamma}$ against τ and calculating the area under the curve. The method is useful for complex rheogram curves that simplified rheological models have a difficulty to represent. It should also be noted that the relationship is valid for any pipe diameter as long as the flow remains in the laminar regime. Thus, this master curve may be used to predict the frictional pressure loss for flows in any other pipe size.

4.2.3.2.3 Turbulent Flows

4.2.3.2.3.1 Newtonian Slurries Unlike in laminar flow, in the turbulent flow of a Newtonian slurry the relative pipe wall roughness can be important and correlations for the friction factor, *f,* can be classified according to whether the pipe wall is essentially smooth or is sufficiently rough to affect frictional losses. These correlations are obtained with or without theoretical guidance. Many different versions of correlations have been developed (e.g., von Karman, 1931, Colebrook, 1939, Moody, 1947, Olujic, 1981). For the turbulent flow of a Newtonian fluid in smooth tubes, the classical mixing length theory of Prandtl was applied by von Karman (1931) to derive the well-known expression

$$\frac{1}{\sqrt{f}} = 4.0\log\left(Re\sqrt{f}\right) - 0.4 \tag{4.34}$$

When the pipe wall is not smooth, an estimate for the relative roughness of the wall, *e*/*D*, is required, as it is an additional variable in equations for the prediction of friction factor (Colebrook, 1939). For rough pipe surfaces, Equation 4.34 was modified by Colebrook (1939) to include the effect of relative roughness, *e*/*D*:

$$\frac{1}{\sqrt{f}} = -4.0\log\left[\frac{e/D}{3.7} + \frac{1.255}{Re\sqrt{f}}\right] \tag{4.35}$$

This equation is the basis for the well-known Moody diagram for pipe friction factors and applies for $Re > 2100$.

However, the equation by Churchill (1977) is probably the most useful for turbulent flows, as it is explicit in f and valid for either smooth or rough pipe surface in both the laminar and turbulent flow regimes:

$$f = 2\left[\left(\frac{8}{Re}\right)^{12} + (A+B)^{-1.5}\right]^{1/12} \tag{4.36}$$

where

$$A = \left[2.457\ln(1/C)\right]^{16}, \quad B = \left(\frac{37530}{Re}\right)^{16}, \quad \text{and} \quad C = \left(\frac{7}{Re}\right)^{0.9} + 0.27\frac{e}{D} \tag{4.37}$$

4.2.3.2.3.2 Non-Newtonian Slurries Turbulence is a natural form of fluid motion that is characterized by random eddy motions both parallel and transverse to the direction of the main flow. Both direction and magnitude of solids and liquid velocities fluctuate on a continuous random basis. The turbulent flow of non-Newtonian slurries is more complex than that for Newtonian slurries, as the turbulent behavior of non-Newtonian slurries appears unrelated to their laminar behavior and yet has been found similar to Newtonian turbulent flow behavior, in spite of the obvious difference in rheology. Many theoretical models have therefore been developed to predict the turbulent flow behavior of non-Newtonian slurries.

Many empirical, semianalytical, and analytical models for turbulent non-Newtonian flow have been developed. Most equations are based on the power-law model or Bingham plastic, for example, those developed by Dodge and Metzner (1959), Tomita (1959), and Szilas et al. (1981), while others have been derived specifically for use with the Herschel–Bulkley flow model, that is, Torrance (1963) and Hanks (1978). Govier and Aziz (1972) give a review of these models.

Dodge and Metzner (1959) developed a semitheoretical equation for the smooth wall fully developed turbulent friction factor for, time independent, purely viscous non-Newtonian fluids. This was based upon Prandtl's mixing length theory with different values for the empirical constants being obtained from experimental data. Tomita (1959) used a similar method to develop equations specifically for Bingham plastic and power-law fluids, respectively. Torrance (1963) extended this work for yield-pseudo-plastics to account for pipe roughness. Wilson and Thomas (1985) developed the work further by including terms for the viscous sublayer due to shear thinning.

Most of the models or methods for turbulent non-Newtonian flow are based on a specific rheological model, while a few of them are generalized models, such as the Wilson and Thomas model (1985). We will proceed in our discussion from a generalized model to those based on a specific rheological model.

4.2.3.2.3.3 The Wilson and Thomas Model Non-Newtonian rheological properties can increase the turbulent micro-eddy size, leading to an increase in the thickness of the viscous sublayer. If other quantities are unaffected the thickened sublayer will, in turn, produce a higher mean velocity for the same wall shear stress, giving a lower friction factor. Based on this consideration, Wilson and Thomas (1985) and Thomas and Wilson (1987) developed a predictive model for non-Newtonian turbulent flow. The model uses the ratio of the integrals under the non-Newtonian and Newtonian rheograms, denoted by α, to estimate the size increase of the micro-eddies, and it was found that the thickness of the sublayer should also be multiplied by a factor equal to α. As shown by Wilson and Thomas (1985), the value of the mean velocity U_m, which results from this thickened viscous sublayer, is given by

$$\frac{U_m}{u^*} = \frac{U_N}{u^*} + 11.6(\alpha - 1) - 2.5\ln\alpha - \Omega \tag{4.38}$$

where

U_m is the mean slurry velocity

u^* is the friction velocity ($u^* = (\tau_w/\rho_m)^{0.5}$)

U_N represents the mean velocity for equivalent Newtonian flow, that is, flow with the same wall shear stress τ_w for Newtonian fluid with the same viscosity corresponding to the non-Newtonian value at $\tau = \tau_w$

The term Ω represents the reduction in mean velocity due to flattening of the central core of the velocity profile when the fluid possesses a yield stress, τ_y

$$\Omega = -2.5\ \ln(1-\xi) - 2.5\,\xi(1+0.5\xi), \quad \xi = \tau_y/\tau_w \tag{4.39}$$

The work by Wilson and Thomas (1985) has some theoretical justification and has been shown to give fairly good agreement with experimental data. It is generally accepted that the model of Wilson and Thomas is the most successful of the Prandtl type of models. For the power-law and some other models, expressions for the area ratio α have been worked out (Thomas and Wilson, 1987).

For a yield power-law fluid (i.e., Herschel–Bulkley fluid, $\tau = \tau_h + K_h\dot{\gamma}^p$, and $\tau_y = \tau_h$,), the area ratio α is

$$\alpha = \frac{2(1+\xi p)}{(1+p)} \tag{4.40}$$

For a power-law fluid ($\tau = K_p\dot{\gamma}^n$ and $\tau_y = 0$), the expression for α is

$$\alpha = \frac{1}{(1+n)} \tag{4.41}$$

For a Bingham fluid ($\tau = \tau_b + \eta_b\dot{\gamma}$ and $\tau_y = \tau_b$), the area ratio α is given by

$$\alpha = 1+\xi \tag{4.42}$$

For a Casson fluid ($\tau^{1/2} = \tau_c^{1/2} + (\eta_c\dot{\gamma})^{1/2}$ and $\tau_y = \tau_c^{1/2}$), the area ratio α is

$$\alpha = 1 + 2\chi^{0.5}/3 + \chi/3 \tag{4.43}$$

Theoretically, the Wilson and Thomas model, that is, Equation 4.38 is applicable to a slurry having any rheological property. If rheogram curve data for a slurry have been obtained, the ratio of the integrals under the non-Newtonian and Newtonian rheograms can be readily evaluated using a numerical technique.

The mean velocity of the equivalent Newtonian flow, U_N, is evaluated using a friction factor determined by using the model-specific Reynolds number: $Re_M = DV_N\rho_m/\eta$. The effective viscosity η is evaluated from the slurry rheogram $(\tau, \dot{\gamma})$ or a rheological model at τ_w. The effective viscosity evaluated at τ_w using typical rheological models is shown in Table 4.18.

The Wilson and Thomas model is not explicit in the friction factor *f*. Equation 4.38 requires the following iterative procedure to solve for *f* for a given slurry mean velocity U_m:

1. Assuming a value of wall shear stress, τ_w
2. Calculating the effective viscosity at τ_w using a suitable rheological model such as those shown in Table 4.18
3. Evaluating the friction velocity using $u^* = (\tau_w/\rho_m)^{0.5}$
4. Assuming a value of the mean velocity of the equivalent Newtonian flow U_N
5. Evaluating the friction factor *f* at the model-specific Reynolds number: $Re_M = DU_N\rho_m/\eta$. The friction factor *f* is calculated using Equation 4.34 for smooth pipe wall or Equation 4.36 for rough pipe wall.

Table 4.18 Effective Viscosity of Typical Rheological Models at τ_w

Model Name	Model Equation
Bingham plastic	$\eta = \tau_w\eta_b/(\tau_w - \tau_b) = \eta_b/(1-\chi), \quad \chi = \tau_b/\tau_w$
Casson	$\eta = \tau_w\eta_c/\left(\tau_w^{1/2} - \tau_c^{1/2}\right)^2 = \eta_c/\left(1-\chi^{1/2}\right)^2, \ \chi = \tau_c/\tau_w$
Power law	$\eta = \tau_w(K_h/\tau_w)^{1/n}$
Herschel–Bulkley	$\eta = \tau_w[K_h/(\tau_w - \tau_h)]^{1/p}$

6. Evaluating U_N using $U_N = (2\tau_w/\rho_m f)^{0.5}$
7. Returning to Step 4 if the difference between the U_N from Step 6 and the one assumed at Step 4 is higher than a specified tolerance
8. Evaluating the U_m using the Wilson and Thomas model
9. Returning to Step 1 if the difference between the U_m from Step 8 and the given value is higher than a specified tolerance

The effect of the pipe wall roughness on the turbulent flow of non-Newtonian slurries can be accommodated in the Wilson and Thomas model by using the appropriate roughness in the determination of U_N, as indicated in the earlier procedure. However, this can only be approximate, since the interaction between the pipe roughness and the laminar sublayer will be different when the thickened laminar sublayer is present.

4.2.3.2.3.4 Models for Power-Law Slurries The equations for the friction factor f, based on the power-law ($\tau = K_p\dot{\gamma}^n$) Reynolds number Re_p defined in Equation 4.21, are given by

1. *Dodge and Metzner (1959).* Dodge and Metzner developed a model of turbulent flow of a power-law fluid in a smooth pipe based on the laminar flow model of Metzner and Reed (1955). The model was developed following the form of the von Karman–Nikuradse equation for Newtonian turbulent flow, and the final relationship is of the same format as Newtonian smooth wall turbulent flow and reverts to the Newtonian form under Newtonian conditions ($K_p = \mu$ and $n = 1$). The model is

$$\frac{1}{\sqrt{f}} = \frac{4.0}{n^{0.75}}\log\left(Re_p f^{1-n/2}\right) - \frac{0.4}{n^{1.2}} \tag{4.44}$$

2. *Tomita (1959).* For power-law fluids, Tomita extended his laminar flow model to turbulent flows in smooth pipes by applying Prandtl's mixing length concept and developed an implicit equation

$$1/\sqrt{f_{T0}} = 4.0\log\left(Re_{T0}\sqrt{f_{T0}}\right) - 0.4 \tag{4.45}$$

where

$$f_{T0} = \left(\frac{1+2n}{1+3n}\right)\frac{4}{3}f \tag{4.46}$$

and

$$Re_{T0} = Re_p 8^{1-n}\left(\frac{1+3n}{4n}\right)^n \frac{6\left[(1+3n)/n\right]^{1-n}}{2n\left[(1+2n)/n\right]} \tag{4.47}$$

3. *Szilas* et al *(1981).* Szilas et al. developed the following equation for power-law oil flow in rough pipes at high Reynolds number

$$\frac{1}{\sqrt{f}} = \frac{4.0}{n}\log\left(Re_p(4f)^{1-n/2}\right) + 1.51^{1/n}\left(4.24 + \frac{1.414}{n}\right) - \frac{8.03}{n} - 2.114 \tag{4.48}$$

4. *Irvine (1988).* Irvine developed a generalized Blasius equation for power-law fluids in smooth pipes

$$f = \frac{F'(n)}{Re_p^{1/(3n+1)}} \tag{4.49}$$

where

$$F'(n) = \frac{2}{8^{n-1}}\left[\frac{8n^n}{7^{7n}(1+3n)^n}\right]^{1/(3n+1)} \tag{4.50}$$

4.2.3.2.3.5 Models for Herschel–Bulkley or Generalized Bingham Slurries The turbulent flow of Herschel–Bulkley or generalized Bingham fluids in circular pipes has been studied by a number of people, including

1. *Torrance (1963).* Torrance developed a theoretical equation for Herschel–Bulkley or generalized Bingham fluids ($\tau = \tau_h + K_h\dot{\gamma}^p$) to include a wall shear stress. For fully turbulent flows in smooth pipes, the Torrance equation is

$$\frac{1}{\sqrt{f}} = \frac{1.966}{n}\ln\left(\left(1-\xi\right)Re_n f^{1-n/2}\right) + \frac{0.682}{n}\left(5n-8\right) + \frac{2.678}{n} - 2.949 \tag{4.51}$$

where $\xi = \tau_h/\tau_w$, and $Re_n = 8^{1-p}D^pU_m^{2-p}\rho_m/K_h$.
For flows in rough pipes with a relative roughness, e/D, the Torrance equation is

$$\frac{1}{\sqrt{f}} = 1.767\log\left(\frac{Re_n}{e}\right) + 6 - \frac{2.65}{n} \tag{4.52}$$

2. *Slatter et al. (1996).* Slatter et al. proposed a new model for describing the turbulent pipe flow of Herschel–Bulkley or generalized Bingham fluids. By analogy with the Newtonian approach, they defined the roughness Reynolds number, Re_r, in terms of friction velocity, Herschel–Bulkley model parameters, and the representative particle diameter d_{85}:

$$Re_r = \frac{8\rho_m\left(u^\star\right)^2}{\tau_h + K_h\left[8u^\star/d_{85}\right]^p} \tag{4.53}$$

If $Re_r < 3.32$ then smooth wall turbulent flow exists and the mean velocity is given by

$$\frac{U_m}{u^\star} = 2.5\ln\left(\frac{D}{2d_{85}}\right) + 2.5\ln\left(Re_r\right) + 1.75 \tag{4.54}$$

If $Re_r > 3.32$ then fully developed rough wall turbulent flow exists and the mean velocity is given by

$$\frac{U_m}{u^\star} = 2.5\ln\left(\frac{D}{2d_{85}}\right) + 4.75 \tag{4.55}$$

and the friction factor is a constant.

Prediction of f for turbulent flow in rough pipes can be also based on the relations for smooth wall pipe. Govier and Aziz (1972) suggested that if the pipe is rough, the pressure loss calculated by the methods for smooth pipes should be multiplied by the ratio of the friction factor for rough pipe to the friction factor for smooth pipe, as determined from the Moody chart for Newtonian materials at the appropriate Reynolds number consistent with the fluid model being used, that is, Re_b, for the Bingham plastic model or Re_p for the power-law models. For pipe flows where friction factors are independent of Reynolds number but are dependent upon relative roughness, e/D, the Torrance equation, that is, Equation 4.52 should be used.

4.2.3.2.3.6 Models for Bingham Plastic Slurries The equations for the friction factor f based on the Bingham plastic ($\tau = \tau_b + \eta_b\dot{\gamma}$) Reynolds number Re_b defined in Equation 4.25 are those given by

1. *Thomas (1963)*: For slurries whose rheograms may be adequately described by Bingham plastic model, Thomas has developed a Blasius-type equation

$$f = B_T Re_b^{-\beta} \tag{4.56}$$

where the parameters B_T and β are related to fluid properties using data in smooth pipes:

$$\left.\begin{aligned} B_T &= 0.079\left[\left(\eta_f/\eta_b\right)^{0.48} + \left(\rho_m \tau_b K_{T1}^2/\eta_f^2\right)^2\right] \\ \beta &= 0.25\left[\left(\eta_f/\eta_b\right)^{0.15} + \left(\rho_m \tau_b K_{T2}^2/\eta_f^2\right)^2\right] \end{aligned}\right\} \tag{4.57}$$

in which K_{T1} = 1.94 μm, K_{T2} = 1.73 μm, and η_f is the Newtonian viscosity of the suspending medium.

2. *Darby and Melson (1981)*: Darby and Melson employed the approach taken by Churchill (1977) to combine the Buckingham equation for f_L for laminar flow (Equation 4.24) with an empirical correlation for f_T for turbulent flow regime to arrive at a single friction factor expression valid for all flow regimes:

$$f = \left(f_L^m + f_T^m\right)^{1/m} \tag{4.58}$$

where the exponent m depends on Bingham Reynolds number according to

$$m = 1.7 + 40{,}000/Re_b \tag{4.59}$$

and the empirical correlation for f_T for turbulent flow regime is

$$\left.\begin{aligned} f_T &= 10^{\beta} Re_b^{-0.193} \\ \beta &= -1.378\left[1 + 0.146\exp\left(-0.29\times10^{-5} Re_b\right)\right] \end{aligned}\right\} \tag{4.60}$$

Equation 4.60 does not apply when the Hedstrom number, defined by Equation 4.25, is less than 1000, but this is not a practical constraint for most slurries with a measurable yield stress.

4.2.3.2.4 Laminar–Turbulent Transition It is important to identify the transition between laminar and turbulent flow for the following reasons:

- The fluid behavior and relevant equations for pressure loss prediction change fundamentally at this point. Once this transition point is defined for a slurry with a particular flow property, it is then possible to decide whether expressions for laminar flow are relevant or whether turbulent flow equations need to be used.
- Overall optimization of slurry pipeline system often suggests that it is most economical to operate the pipeline system in the transition region between the laminar and turbulent regimes.
- It is necessary in some cases to operate into the turbulent flow regime in order to maintain coarse size fraction of the solids in suspension.

For Newtonian slurries, the lower critical Reynolds number for the initial breakdown of laminar flow, Re_1, is 2100 and the upper value of Re_2 for the commencement of fully turbulent flow is approximately 3000. The flow region between these two critical Reynolds numbers is typically referred to as the transitional flow regime. However, for non-Newtonian slurries, the individual values of Re_1 and Re_2 are much more difficult to predict. Various methods have been developed for Re_1 prediction based on different flow models. Cheng (1970) has also developed an approach for predicting both Re_1 and Re_2 valid for both power-law slurries and generalized Bingham slurries. The most economical design often suggests that flow should be in the transitional regime and some pipelines operate just above Re_2. However, Re_2 is difficult to define precisely due to the fact that the fluctuations in pressure gradient prevalent in the transitional regime diminish progressively rather than abruptly as the flow velocity is increased, when the fully turbulent flow regime is reached.

4.2.3.2.4.1 Intersection Method A practical and simple approach toward dealing with the transitional region between laminar and turbulent flow is to assume that the transition, as the flow velocity is progressively increased, occurs completely at a single operating point. In this case, only one critical Reynolds number needs to be predicted and this can be achieved by taking the intersection of the (f, Re) or (f, U_m) relationships for laminar and turbulent flow for the non-Newtonian fluid model under consideration. The degree of success of this method is entirely dependent on the accuracy of the turbulent model used. It should be noted that this approach cannot explain the flow behavior as does the Newtonian Reynolds number approach. This approach also does not work with Newtonian behavior, where the critical point is clearly not the intersection of the laminar and turbulent theoretical lines.

4.2.3.2.4.2 Stability Function Method Ryan and Johnson (1959) defined a stability parameter in terms of the velocity distribution, $v(r)$, in the pipe as follows:

$$Z = -\frac{D}{2\tau_w}\rho_m v(r)\frac{dv}{dr} \tag{4.61}$$

which is the ratio of energy input to energy dissipation within a fluid element. It is clear that Z has the form of a Reynolds number with no reference to a fluid model. It vanishes at both the pipe wall and the centerline, attaining a maximum at some intermediate position. For a Newtonian fluid, the laminar flow solution indicates that Z attains a maximum at the reduced radial position $r/R = 1/\sqrt{3}$, with

$$Z_{max} = 0.3849Re \tag{4.62}$$

Taking the transition Reynolds number for laminar flow as $Re_c = 2100$ gives $Z_{max} = 808$. Since Z is not restricted to any fluid model, Ryan and Johnson (1959) proposed that the laminar–turbulent transition occurs at the same value of the ratio (i.e., $Z_{max} = 808$) for non-Newtonian fluids as it does for Newtonian fluids. For Newtonian fluids, the stability parameter pertaining to this ratio can be expressed in terms of transition Reynolds number. However, since the definition of Reynolds number for non-Newtonian fluids is model dependent, so are the laminar–turbulent transition criteria. Using Equations 4.61 and 4.62 together with the velocity distribution $v(r)$ appropriate to the rheological model, laminar–turbulent transition criteria can be derived.

When applied to the power-law model ($\tau = K_p\dot{\gamma}^n$), Ryan and Johnson (1959) obtained an expression for the lower critical Reynolds number Re_c:

$$Re_c = \frac{6464n(n+2)^{(n+2)/(n+1)}}{(1+3n)^2}, \tag{4.63}$$

or, alternatively, the lower critical friction factor f_c is given by

$$f_c = \frac{(1+3n)^2}{404n}\frac{1}{(n+2)^{(n+2)/(n+1)}}. \tag{4.64}$$

Such results have also been obtained for Bingham plastic slurries by Hanks (1981) and for the Casson and Herschel–Bulkley slurries by Hanks and Ricks (1974).

4.2.3.2.4.3 Metzner–Reed Method Metzner and Reed (1955) developed a generalized Reynolds number for the correlation of non-Newtonian pipe flow data. They define two rheological parameters K' and n':

$$\tau_w = K'\left(\frac{8U_m}{D}\right)^{n'} \tag{4.65}$$

which represents the tangent to the logarithmic plot of $\tau_0 vs 8U_m/D$. The Reynolds number is then defined as

$$Re_{MR} = \frac{8\rho_m U_m^2}{K'(8U_m/D)^{n'}} \tag{4.66}$$

The transition criterion is $Re_{MR} = 2100$.

4.2.3.3 Pressure Losses from Pipe Fittings

Pressure losses arising from flow through pipe fittings are required before the total system head loss estimation can be made. Pipeline fittings may be classified as branching (tees), reducing/expanding (bushes and sudden changes in flow area), or deflecting (elbows and bends).

The literature on Newtonian flow through pipe fittings is extensive and embodies experimental and theoretical studies as well as extensive tabulations of resistance coefficients and empirical correlations. For the turbulent flow of Newtonian nonsettling slurries, much information exists with pressure loss often expressed in terms of the number of equivalent pipe diameters of straight pipe giving the same pressure loss (Perry and Chilton, 1985).

Friction losses for fittings are expressed in terms of the so-called resistance coefficients K_f defined by

$$K_f = \frac{p_f}{(\rho U_m^2/2)} \tag{4.67}$$

Alternatively, the friction loss can be expressed in terms of the equivalent length of straight pipe of the same diameter and having the same friction loss as the fitting. The equivalent length is expressed in numbers of pipe diameters:

$$\frac{L_e}{D} = \frac{K_f}{4f} \tag{4.68}$$

Edwards et al. (1985) reviewed the flow of non-Newtonian slurries in laminar regimes, and they proposed that the model-specific Reynolds numbers (such as Re_b or Re_h) be used to correlate with the resistance coefficients K_f of Newtonian flows in laminar regimes.

For non-Newtonian flows in transition and turbulent regimes, Govier and Aziz (1972) proposed that the method of equivalent length be used, that is, that the equivalent length of pipe fittings for Newtonian liquids be added to computations of total length for pressure loss of the non-Newtonian slurry. Both Cheng (1970) and Turian etal. (1983) have concluded that the pressure losses of non-Newtonian flows through pipe fittings do not depend significantly on the non-Newtonian character of the slurry.

Turian et al. (1998b) carried out an experimental investigation on the friction losses of non-Newtonian slurry flows through pipe fittings and concluded that the resistance coefficients for all tested fittings approached constant asymptotic values that are the same as for the corresponding coefficients for flow of water. This means one can establish the turbulent-flow friction-loss characteristic for any pipe fitting using data with water. Then, one only need to use the density of the suspension to calculate the applicable friction loss.

4.2.4 Heterogeneous Flow of Settling Slurries

4.2.4.1 Transitional Velocities of Horizontal Pipe Flows

Although most of industrial slurries consist of small-size particles (usually up to a few tens of microns), slurries containing coarse and/or high density particles are also widely encountered in various industries. These types of slurries cannot be treated as pseudo-fluids with effective rheological properties, since the solid particles are not uniformly mixed in the horizontal plane and tend to settle at the bottom of the pipe due to the effect of gravity. Hence, they are considered as settling slurries.

Due to the settling tendency of the solids' particles, several flow regimes or patterns may be encountered in a horizontal pipe flow of settling slurries. As illustrated in Figure 4.31, slurry flows of settling slurries can be classified into flow regimes as follows: (1) heterogeneous flow—at high slurry mixture velocities, all the solids' particles are fully suspended by the carrier liquid as a result of high turbulence; (2) flow with a moving bed—at lower slurry mixture velocities, the fluid turbulence is not sufficient to balance the gravity, hence the particles accumulate at the bottom of the pipe, forming a packed bed of moving particles; (3) flow with a stationary bed—when the slurry mixture velocity is too low to move all the immersed particles, and some of them form a stationary deposit bed at the bottom of the pipe.

The flow regimes affect the dependence of the pressure drop on the flow velocity as well as the magnitude of the pressure drop and they also influence pipe erosion and other performance characteristics. Figure 4.33 shows a schematic diagram of pressure gradient dependence on mean slurry mixture velocity for various flow regimes. The straight line in this figure represents the behavior of a carrier fluid, such as water, in a

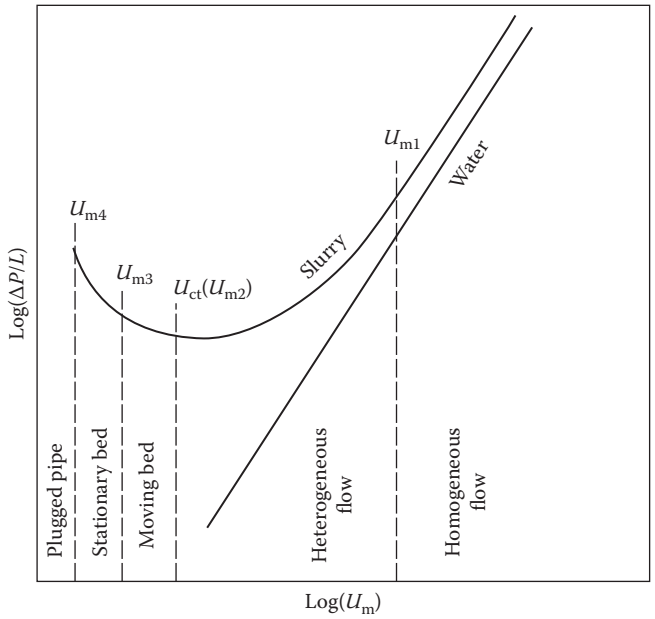

Figure 4.33

Schematic diagram of pressure gradient dependence on mean slurry velocity for various flow regimes.

given pipe size. The pressure gradient for the slurry is always higher than that of the carrier fluid at the same velocity, and the difference increases as the degree of heterogeneity increases. As the velocity decreases, the pressure gradient for slurry will decrease till reaching a minimum after which the pressure gradient will increase with a decrease in the velocity. This was first noticed by Blatch (1906).

There are four transitional velocities (Figure 4.33) between the flow regimes that are usually determined by visual observations. The transitional velocities are defined as

1. U_{m1}: velocity at or above which all solids move as a homogeneous suspension.
2. U_{m2} or U_{ct}: velocity at or above which all particles move as a heterogeneous suspension and below which the solids start to settle and form a moving bed.
3. U_{m3}: velocity at or above which the mixture flows as a heterogeneous mixture with the coarser particles forming a moving bed.
4. U_{m4}: velocity at or above which the bed in the lower half of the pipe is stationary. In the upper half of the pipe, some solids may move by saltation or suspension.

Transitional velocities U_{m3} and U_{m4} are obviously not used for the operation of slurry pipelines, and therefore, the prediction of U_{m3} and U_{m4} will not be discussed here. The transitional velocity U_{m2} or U_{ct} marks the transition to a generally undesirable condition, since deposited particles will greatly enhance erosion problems and a bed of solids promotes unstable operation. Approaches for the prediction of U_{ct} will be presented in the next section.

The determination of the transitional velocity U_{m1} from homogeneous to heterogeneous flow is required in some applications. Newitt et al. (1955) expressed the transitional velocity U_{m1} in terms of particle terminal velocity U_t as

$$U_{m1} = 38.7(gDU_t)^{1/3} \tag{4.69}$$

4.2.4.2 Critical Velocity of Horizontal Pipe Flows

The transition velocity demarcating flows in which the solid particles form a bed at the bottom of the pipe is very difficult to determine experimentally, because the flow becomes unstable near the transition velocity. The definition of transition velocities naturally depends on the definitions of the flow regimes. Therefore, various reports assign different names to the same transition velocity or the same name to different transition

velocities between the flow regimes, leading to quite confusing terminology for the transition velocities. Most of the confusion is associated with the transition from the flows with a stationary bed, since it was claimed by some investigators that it is associated with the velocity at minimal pressure gradient. However, Wasp et al. (1970) claimed that the minimum in the pressure loss versus velocity curve has nothing to do with the transition velocities.

The term *limit deposit velocity* has been employed by a number of investigators, for example, Wilson (1970) for marking the separation between the deposit and nondeposit regimes. This transition velocity is also called the *critical deposit velocity* (Kazanskij, 1979). The *deposition velocity* was used for the same purpose by Parzonka et al. (1981) and Shook and Roco (1991). The term *critical deposit velocity* was defined as the velocity below which there are deposited particles (Oroskar and Turian, 1980, Turian et al., 1987).

In the present contribution, the mean flow velocity required to prevent the accumulation of a layer of stationary or sliding particles on the bottom of a round horizontal pipe is termed as the *critical velocity*, U_{ct}. The prediction of this velocity for any given set of operational conditions is very important, since it is rarely desirable to operate with a partially blocked pipeline. Head losses would be increased by the reduced cross-sectional area and a bed layer would increase pipe wear. In fact, once a deposit forms, fluctuating flow conditions may eventually lead to blockage.

A large number of investigations have been devoted to the prediction of the critical velocity, but most of the more useful results are based primarily on empirical correlations. The approaches used for obtaining empirical correlations or theoretical expressions include the minimum in the pressure loss versus velocity relationship (e.g., Bain and Bonnington, 1970), fluctuating solids' velocity (e.g., Ercolani et al., 1979), balancing the energy required to suspend the particles with that derived from dissipation of an appropriate fraction of turbulent eddies (Oroskar and Turian, 1980), the equilibrium of forces on the first particle layer to form (Hanks and Sloan, 1981), the velocity distribution of solids near the bottom of the pipe (Roco and Shook, 1985), and chord-average solids' concentration close to the bottom of the pipe as a function of bulk velocity (Gillies et al., 2000).

It is important that values of U_{ct} are not excessively conservative (high). Excessively conservative estimates of U_{ct} will result in the high pipeline velocities, high power consumption, and high rates of wear on pipes and pumps. It is always prudent to make the actual pumping velocity some 10% higher than the calculated U_{ct} to cater for uncertainties and possible changes of future pumping conditions. In order to determine the critical velocity U_{ct} accurately, it is necessary to conduct tests with the slurry on a pipeline test rig. As a practical alternative, where this is not possible, the U_{ct} may be estimated by one of the following methods.

4.2.4.2.1 Durand's Correlation The pioneering investigations on critical velocity U_{ct} in horizontal pipelines were carried out by Durand and Condolios (1952) and Durand (1953) using water slurries of sand and gravel with narrow particle size distributions. They developed the following correlation:

$$U_{ct} = F_L\sqrt{2gD(\rho_s/\rho_l - 1)} \tag{4.70}$$

The Durand factor F_L, also known as a modified Froude number, is dependent upon solids' volume fraction α_s and particle diameter d_p. In the correlation, the Durand factor F_L was presented in the graphical form as shown in Figure 4.34.

Subsequent investigations indicated that values of F_L from Figure 4.34 provide conservative (high) values for U_{ct} in respect of

- Slurries containing mixtures of particles of different sizes
- Slurries with a sizing containing significant proportions of particles finer than 100 μm

Although predictions of critical velocities from Durand's original method have been considered conservative, the correlation and nomogram are still in wide use today due to more built-in safety against pipe blockages.

Wilson and Judge (1976) and Judge (1977) developed a sliding bed model for slurries having medium-size particles. The theoretical prediction of the Durand factor F_L can be expressed as a function of particle size d_p, pipe diameter D, and the particle drag coefficient C_D:

$$F_L = 2 + 0.3\log_{10}\left(\frac{d_p}{DC_d}\right) \tag{4.71}$$

This equation was considered to be valid in the range $10^{-5} < d_p/DC_D < 10^{-3}$.

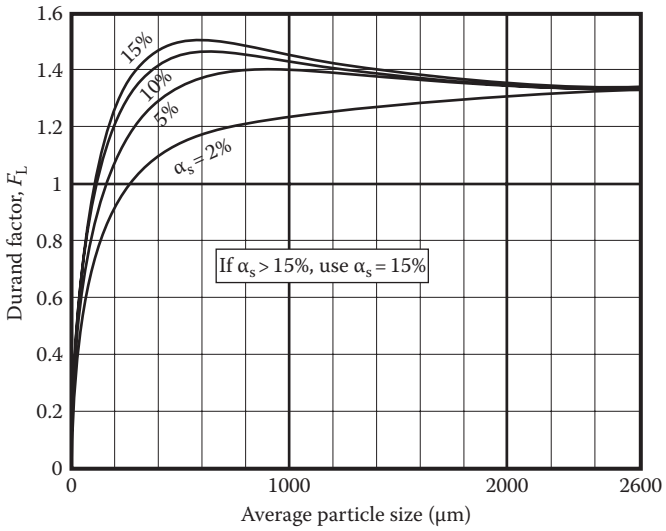

Figure 4.34

Nomogram for estimating the Durand factor F_L as a function of solids' volume fraction α_s and particle diameter d_p. (After Durand, R., Basic relationships of the transportation of solids in pipes—Experimental research, *Proceedings of Fifth Congress of International Association Hydraulic Research*, Minneapolis, MN, 1953.)

Example 4.5

A water slurry of coal (ρ_s = 1600 kg/m^3, d_{50} = 200 μm) is to be pumped in a horizontal pipe with an inner diameter of 0.3 m at the solids' volume fraction of 18%. Using the nomogram and Equation 4.71 to determine the critical velocity U_{ct} if the particle drag coefficient C_D is assumed to be 0.46.

Solution

Nomogram:

From Figure 4.34, for d_{50} = 300 μm and solids' volume fraction α_s = 18%, F_L is 1.25

$$U_{ct} = 1.25 \times \sqrt{2 \times 9.8 \times 0.3 \times (1600/1000 - 1)} = 2.35\,(\text{m/s})$$

Wilson and Judge:

From Equation 4.71, the Durand factor F_L is given by

$$F_L = 2 + 0.3 \log_{10}\left(\frac{0.2}{300 \times 0.46}\right) = 1.15$$

$$U_{ct} = 1.2 \times \sqrt{2 \times 9.8 \times 0.3 \times (1600/1000 - 1)} = 2.16\,(\text{m/s})$$

4.2.4.2.2 Wilson's Nomogram Of the numerous approaches proposed for predicting the critical velocity, Wilson's nomogram (Wilson, 1979) is one of the most notable because the approach incorporates theoretical model of sliding bed and is applicable for a wide range of particle size, pipe diameter, and fluid properties. The critical velocity increases with the delivered solids' concentration till reaching a maximum (denoted U_{cm}) and then decreases with the solids' concentration. The effects of pipe diameter, particle diameter, and relative density on the U_{cm} have been expressed concisely by means of a nomographic chart as shown in Figure 4.35 (Wilson, 1979). This nomogram provides a useful simple method for estimating the conditions where stationary deposition becomes likely.

The left-hand panel in the nomographic chart deals with sand-weight materials (relative density $S = \rho_s/\rho_l$ = 2.65). The pipe diameter appears on the left vertical axis, with U_{cm} on the central vertical axis.

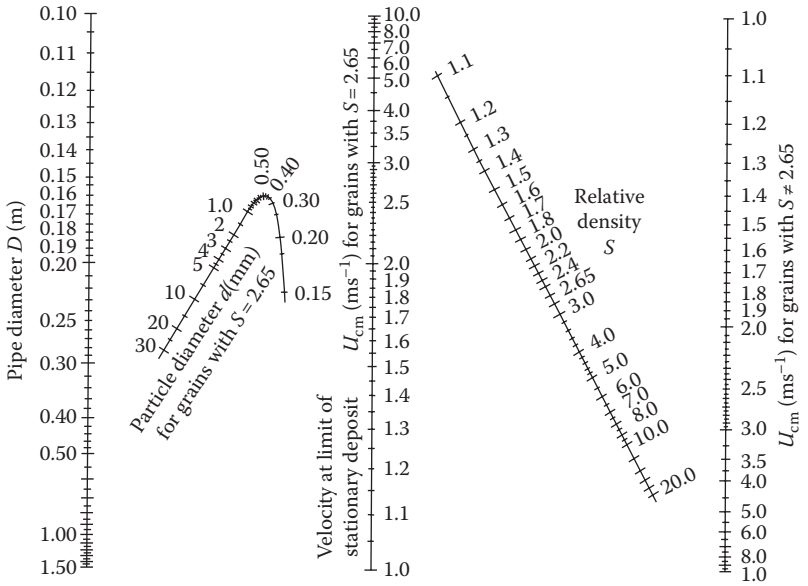

Figure 4.35

Nomogram for estimating the critical velocities. (After Wilson, K.C., Deposition limit nomograms for particles of various densities in pipeline flow, in *Proceedings Hydrotransport 6 Conference*, BHRA, Cranfield, U.K., 1979, pp. 1–12. With permission.)

The particle diameter is plotted on the curved scale. To estimate the critical velocity for particles with a relative density $S = 2.65$ in a given pipe diameter D, a line is drawn from the pipe diameter D-axis through the appropriate particle diameter on the curved scale. The critical velocity U_{cm} is then obtained by projecting to the central vertical scale. For an example, if a slurry flow in a pipe diameter of 0.4 m contains particles with a relative density $S = 2.65$, a particle size d_p of 0.7 mm gives a U_{cm} of about 4.5 m/s. For particles of other relative density values (i.e., $S \neq 2.65$), a point on the central vertical axis ($S = 2.65$) is first determined from a pipe diameter and a particle density, and then this point is joined by a straight line to an appropriate particle relative density on the inclined axis. The extrapolated line intersects with the right-hand vertical axis, giving a value of U_{cm}.

The nomogram summarized the effects of particle size and pipe diameter. According to the nomogram, a maximum critical velocity occurs near a particle diameter of 0.5 mm. However, it has been observed that (Carleton et al., 1978) the decrease in the critical velocity with the particle diameter does not always occur above about 0.5 mm particle diameter. This means that an additional safety allowance is desirable when the nomogram is used for particle sizes larger than 0.5 mm. The nomogram was generated for viscosities near one centipoise and the effect of viscosity is not included in the nomogram so that caution is required when dealing with slurries containing a significant portion of fines.

For applications with limited control of particle size, the conservative estimation of the U_{cm} may be based on the particle size that gives the largest value of U_{cm} for the pipe under consideration. In this case, it should be noted that the values of U_{cm} obtained from the nomogram tend to be conservatively high, especially for large pipe diameters, and hence can be considered to be directly suitable for use as operating velocities.

Example 4.6

Using Wilson's nomogram to determine the critical velocity U_{ct} for the same case as Example 4.5.

Solution

Draw a line from $D = 0.3$ m at D-axis through the $d_p = 0.2$ mm at the curved particle size scale. The critical velocity $U_{cm} = 2.75$ m/s was then obtained by projecting to the central vertical scale for particle density of 2.65 and then this point (i.e., $U_{cm} = 2.75$ m/s) is joined by a straight line to a $\rho_s = 1.6$ kg/m^3 on the inclined axis. The extrapolated line intersects with the right-hand vertical axis, giving a U_{cm} value of 1.55 m/s.

4.2.4.2.3 Turian's Correlations Turian's empirically fitted correlations (Turian et al., 1987) were developed based on a total collection of 864 experimental critical velocity data with pipe diameters up to 0.5 m and particle sizes up to 19 mm, representing a broad variety of solids and pertaining to wide ranges of the important variables involved. The correlations take the following form:

$$\frac{U_{ct}}{\left[2gD(S-1)\right]^{0.5}} = \chi_1 \alpha_s^{\chi_2}(1-\alpha_s)^{\chi_3}\left\{\frac{D\rho_l\left[gD(S-1)\right]^{0.5}}{\mu_l}\right\}^{\chi_4}\left(\frac{d_p}{D}\right)^{\chi_5} \tag{4.72}$$

Five different forms of this equation were developed, and the corresponding values of the adjustable constants in each case are given in Table 4.19. It should be noted that the correlations given earlier do not take in account the effect of the width of particle size distribution.

According to the *SD* and *RMS* values in Table 4.19, the correlations corresponding to all five forms are virtually equally effective in predicting the critical velocity. The parameter values also indicate that the dependence of the U_{ct} on the particle diameter is quite weak and the U_c dependence on pipe diameter is nearly $D^{0.5}$.

4.2.4.2.4 Gillies–Shook Correlation Gillies and Shook (1991) developed a correlation based on data obtained with pipes up to 0.5 m in diameter and aqueous slurries with viscosities between 0.5 and 5 centipoises. The correlation uses an equivalent fluid density defined as

$$\rho_f = \frac{\rho_s\alpha_f + \rho_l(1-\alpha_r)}{1-\alpha_r+\alpha_f} \tag{4.73}$$

where

α_r is the mean in situ total solids' concentration

α_f is defined as $\alpha_r \times$ (volume of less than 74 μm solids/total volume of solids)

The correlation for calculating the critical velocity is given by

$$\frac{U_{ct}}{\left[gD(\rho_s-\rho_f)/\rho_f\right]^{0.5}} = \exp(0.51-0.0073C_D-12.5K_2) \tag{4.74}$$

where C_D is the drag coefficient of the median diameter (d_{50}) of larger than 74 μm fraction, calculating from the density ρ_f and viscosity μ_f. The viscosity μ_f can be measured or estimated from a correlation in Table 4.16 if data are not available. K_2 is calculated by

$$K_2 = \left[\frac{(\mu_l/\rho_l)^{2/3}}{g^{1/3}d_{50}} - 0.14\right]^2 \tag{4.75}$$

4.2.4.2.5 Correlations of Wani et al. Most of the published correlations developed for the critical velocity did not sufficiently account for the breadth of particle size distribution. Wani et al. (1982) believed that the particle

Table 4.19 Parameter Values of Equation 4.72 for Five Different Cases

Case	χ_1	χ_2	χ_3	χ_4	χ_5	*SD*[a]	*RMS*[a]
1	1.7951	0.1087	0.2501	0.00179	0.06623	20.53	0.3416
2	1.08471	0.1126	0.03421	−0.03093	0	21.54	0.3447
3	1.8176	0.1086	0.2525	0	0.06486	20.57	0.3412
4	1.3213	0.1182	0.3293	0	0	21.04	0.3552
5	1.1228	0.07367	0	0	0	21.35	0.3559

[a] SD is the overall absolute average percent deviation and RMS is the root mean square deviation.

size distribution and its width are best represented by the weighted mean diameter d_w and the standard deviation σ of the particle size distribution, and they developed correlations for the critical velocity by including the variables of d_w and σ. Two of the correlations that have been reported to give better predictions are as follows:

$$U_{ct} = \left[2.3\times10^{-4} g d_w (S-1) Re_p^{0.27} \left(\frac{100\sigma}{d_w} \right)^{0.973} \alpha_s^{0.307} \varepsilon_f^{1.67} \right]^{0.5} \tag{4.76}$$

for Re_p in Stokes range (i.e., $Re_p \leq 1$) and

$$U_{ct} = \left[7.7\times10^{-6} g d_w (S-1) Re_p^{0.0014} \left(\frac{100\sigma}{d_w} \right)^{-1.25} \alpha_s^{0.272} \varepsilon_f^{4.77} \right]^{0.5} \tag{4.77}$$

for Re_p in intermediate range (i.e., $1 \leq Re_p \leq 1000$). The particle Reynolds number is given by $Re_p = d_w U_t \rho_l / \mu_l$, where U_t is the free settling velocity of the particle with a diameter of d_w. ε_f is the Hazen–Williams pipe roughness factor.

It has been reported by Wani et al. (1982) that the correlations given earlier give better predictions for slurry mixtures with multisized particles.

4.2.4.3 Pressure Loss of Horizontal Pipe Flows

In addition to the prediction of critical velocity, other important technical problems in the pipe flow of heterogeneous slurries are the determination of the pressure loss—throughput relationship and the prediction of the prevailing flow regimes. The literature contains many correlations and a few mechanistic models for prediction of pressure drop and a number of schemes for delineating slurry flow regimes. Empirical correlations for the determination of the pressure loss include those by Durand and Condolios (1952), Newitt et al (1955), Zandi and Govatos (1967), Turian and Yuen (1977), and Wasp et al. (1977). Mechanistic models are mainly represented by the two-layer model (Wilson, 1970, Gillies et al., 1991) and the three-layer model (Doron and Barnea, 1993).

Most of the correlations make use of the dimensionless excess pressure loss ϕ, which is defined as

$$\phi = \frac{i_m - i_l}{\alpha_s i_l} \quad \text{or} \quad i_m = i_l(1+\varphi\alpha_s), \tag{4.78}$$

where

i_m is slurry frictional pressure loss in terms of meters of fluid per meter of pipe
i_l is the frictional pressure loss for an equivalent volume of carrier fluid
α_s is the volumetric solids' concentration in a homogeneous slurry

For a truly homogeneous slurry flow, ϕ approaches $(S - 1)$ if the friction factor for a slurry is the same as that for a liquid flowing at the same velocity in the same pipe.

4.2.4.3.1 Zandi–Govatos Correlation for Fully Suspended Heterogeneous Flow Based on the first empirical correlation proposed by Durand and Condolios (1952) and more test data, Zandi and Govatos (1967) derived the following correlation:

$$\varphi = K\psi^{-m} \quad \text{and} \quad \psi = \frac{U_m^2 C_D^{0.5}}{gD(S-1)} \tag{4.79}$$

where $m = 0.354$ and $K = 6.3$ for $\psi > 10$ and $m = 1.93$ and $K = 280$ for $\psi < 10$. The drag coefficient C_D is that for settling of the particle at its terminal velocity U_t in the quiescent unbounded liquid. For the equivalent spherical particle of diameter d_p, C_D can be given by the following correlation (Karamanev, 1996)

$$C_D = 432(1+0.047 Ar_c^{2/3})/Ar_c + 0.517/(1+154 Ar_c^{-1/3}) \tag{4.80}$$

where

$$Ar_c = (\rho_s - \rho_l)\rho_l g d_p^3/\mu_l^2 .$$

For particles with a broad size distribution, the weighted mean drag coefficient C_{DM} for the particle mixture is better than using the median particle size (Shook, 1986). The C_{DM} is computed as

$$\frac{1}{C_{DM}} = \sum\left(\frac{\alpha_i}{C_{Di}}\right) \tag{4.81}$$

where

α_i is the volume fraction of ith size fraction with mean diameter d_i and $\sum\alpha_i = 1$
C_{Di} is the drag coefficient of ith size fraction

Although this correlation does not account sufficiently for the effect of solids' concentration, the particle size, and the nonuniform distribution of solids in the flow field, it is still useful for predicting the behavior of slurry flows compatible with these assumptions, that is, narrow particle size distribution and highly turbulent flows. From the analysis of a large number of data points, Zandi and Govatos (1967) concluded that the correlation would apply only if

$$N_I = \frac{U_m^2 C_D^{0.5}}{\alpha_s g D(S-1)} < 40 \tag{4.82}$$

Equation 4.79 does not approach the $(S - 1)$ limit as the flow is near-pseudo-homogeneous, that is, $\psi \to \infty$. Charles (1970) proposed a modified version of the correlation to rectify the deficiency:

$$\varphi = (S-1) + 120\psi^{-1.5} \tag{4.83}$$

For slurries with coarse particles or for slurries in which friction is dominated by the coarse fraction of the mixture, Zandi–Govatos correlation or its modified versions are not recommended.

Example 4.7

A slurry of sand (ρ_s = 2700 kg/m^3, d_{50} = 200 μm) in water (μ_L = 0.00112 Pa · s, ρ_L = 1000 kg/m^3) is to be pumped in a horizontal pipe of D = 0.3 m at 3.5 m/s. The solids' volume fraction is 0.18. The pipe-specific roughness is 1.5 μm. Using Equation 4.79 to determine the slurry frictional pressure loss.

Solution

$$Ar_c = (2700-1000)\times 1000 \times 9.81 \times 0.0002^3/0.00112^2 = 106.4$$

$$C_D = 432(1 + 0.047 \times 106.4^{2/3})/106.4 + 0.517/(1 + 154 \times 106.4^{-1/3}) = 8.36$$

$$\psi = 3.5^2 \times 8.36^{0.5}/(9.81 \times 0.3 \times (2.7-1)) = 7.07 < 10$$

$$\phi = 280 \times 7.07^{-1.93} = 6.4$$

Using Churchill equation (Equation 4.36), the fluid frictional pressure loss in the same pipe at the same flow velocity was found to be 0.02 m water/m pipe

$$i_m = i_l\left(1 + \phi\alpha_s\right) = 0.02 \times \left(1 + 6.4 \times 0.18\right) = 0.043\left(\text{m water/m pipe}\right)$$

4.2.4.3.2 Newitt Correlation In a frequently cited paper, Newitt et al. (1955) developed correlations for a wide range of velocities, solids' loading, and particle size in a 1 in. pipe, which covered homogeneous, fully suspended heterogeneous, and flow with a moving bed. The correlations consist of a set of criteria for defining the flow regime and a regime-specific set of equations.

For homogeneous flow, that is, $U_m > (1800gDU_t)^{1/3}$, they assumed that the friction factor for the slurry is the same as that for carrier fluid so that the difference in density is the only factor causing the difference in pressure loss, leading to

$$\phi = 0.6(S-1) \tag{4.84}$$

where the 0.6 is an empirical constant.

For fully suspended heterogeneous flow, that is, $17U_t < U_m < (1800gDU_t)^{1/3}$, it was assumed that there is no relative velocity between the particles and the fluid and that the extra energy required to transport the particles is proportional to the energy expended when the particles fall at their terminal velocity U_t. The resulting equation can be written as

$$\phi = 1100\frac{gDU_t}{U_m^3}(S-1) \tag{4.85}$$

For flow with a moving bed, that is, $U_m < 17U_t$, they assumed that the work done to overcome sliding friction between the bed and the pipe wall leads to the extra pressure loss due to the solids. The resulting expression is as follows:

$$\phi = 66\frac{gD}{U_m^2}(S-1) \tag{4.86}$$

The transition velocities, $U_H = (1800gDV_s)^{1/3}$ and $U_B = 17V_s$, can be used for delineating the three flow regimes. The boundary between homogeneous and fully suspended heterogeneous flow is obtained by equating Equations 4.84 and 4.85, and the boundary between fully suspended heterogeneous flow and flow with a moving bed is obtained by equating Equations 4.85 and 4.86.

The Newitt correlation applies only to monodispersed systems. For solids with broad size distribution, Newitt suggested a weighted mean particle diameter as

$$d_{pm} = \sum_{i=1}^{n} C_{si}d_{pi} \quad \text{and} \quad \sum_{i=1}^{n} C_{si} = 1 \tag{4.87}$$

where C_{si} is the mass fraction of solids with the particle diameter d_{pi}.

4.2.4.3.3 Model of Wasp et al. Many practical slurries contain both coarse and fine particles. The fines move as a homogeneous mixture while the coarse particles move as a heterogeneous mixture. For the analysis of this kind of compound or heterogeneous–homogeneous mixtures, Wasp et al. (1977) proposed a method based on the assumption that the total pressure loss can be split into two parts: pressure loss due to the vehicle (homogeneously distributed particles) and excess pressure drop due to the bed formation (heterogeneously distributed particles). The method is an iterative procedure, which can be summarized as follows:

1. Dividing the particles into 4–6 size fractions
2. Assuming the slurry mixture to be completely homogeneous and calculating the pressure gradient using the formula:

$$i_{vehicle} = \frac{2fU_m^2}{gD} \tag{4.88}$$

where

$i_{vehicle}$ is the pressure gradient due to homogeneously distributed particles (vehicle)
f is the friction factor evaluated by Wood's equation:

$$f = a + bRe_m^{-c} \tag{4.89}$$

where

$a = 0.026(e/D)^{0.225} + 0.133(e/D)$
$b = 22(e/D)^{0.44}$
$c = 1.62((e/D)^{0.134}$
e/D is the relative pipe roughness
Re_m is the Reynolds number for the slurry and calculated by $Re_m = \rho_m U_m D/\mu_m$

The slurry viscosity μ_m can be calculated using appropriate correlations such as those listed in Table 4.16. For higher flow velocities, the modified Wood's equation (Mukhtar, 1991) should be used for the calculation of the friction factor:

$$f = a + bRe_m^{-c}\left(1 - 0.33C_{wf}\right) \tag{4.90}$$

where C_{wf} is the efflux solids' concentration by weight.

3. For each size fraction, the percentage of solids in the vehicle is calculated as

$$\log\frac{\alpha_j}{\alpha_A} = -1.8\frac{V_s}{\beta\kappa u^*} \tag{4.91}$$

where

α_j/α_A is the ratio of volumetric concentration of jth particle size fraction at $0.08D$ from top to that at pipe axis
κ (=0.4) is vonKarman coefficient
u^* is the friction velocity calculated from the pressure loss obtained in Step 2
V_s is the settling velocity of jth particle size fraction calculated using standard drag relationships
$\beta(\approx 1)$ is the dimensionless particle diffusivity

4. The total percentage of solids in the vehicle is calculated after computing the vehicle portion for each particle size fraction and then calculating the vehicle pressure loss for slurry with this concentration using Equation 4.88.
5. Calculating the pressure loss due to the coarse particles in moving bed in each particle size fraction using Durand type of relationship given as

$$i_{jbed} = 82 i_w C_{vjbed}\left[\frac{gD(S-1)}{U_m^2 C_D^{0.5}}\right]^{1.5} \tag{4.92}$$

where

i_w is the pressure gradient due to the flow of carrier liquid
C_{vjbed} is the volumetric concentration of bed portion of jth size particles
S is the specific gravity of solids

The total pressure drop due to bed is the sum of pressure drop due to each particle size fraction in the bed:

$$i_{bed} = \sum_{j=1}^{n} j_{jbed} \tag{4.93}$$

6. Calculating the total pressure loss, which is the sum of pressure loss due to the vehicle and the total pressure loss due to the moving bed. If the difference in pressure drops in the two successive iterations is greater than 5%, repeat steps 2 to 6.

The critical factors in this model are the determination of the particle size split between the homogeneous vehicle and the heterogeneous phase, and a knowledge of the equivalent homogeneous vehicle properties (i.e., density and viscosity) as a function of particle size fraction and concentration. Experimental data would be required to evaluate these effects. Although Wasp assumed the homogeneous vehicle to behave as a Newtonian fluid, Hanks (1980) has extended this approach to account for non-Newtonian properties of the vehicle.

4.2.4.3.4 Turian–Yuan Correlation Turian and Yuan (1977) developed an extended pressure loss correlation scheme that takes into account the fact that various flow regimes are observed to prevail in slurry transport depending upon flow conditions. Their correlation is given by the following relationship:

$$f - f_L = K\alpha_s^{m1} f_L^{m2} C_D^{m3} \left[\frac{U_m^2}{Dg(S-1)} \right]^{m4} [0,1] \tag{4.94}$$

where K, $m1$, $m2$, $m3$, and $m4$ are regime-specific coefficients given in Table 4.20. In this equation, f and f_L are the friction factors for the slurry and water, respectively, at the same mean velocity. Both f and f_L are defined in terms of the carrier liquid density ρ_l. Thus,

$$f = \frac{1}{2} \frac{D}{\rho_l U_m^2} \left(-\frac{\Delta p_f}{L} \right) \tag{4.95}$$

Turian and Yuan (1977) proposed a regime delineation scheme based on their pressure loss correlation, given by Equations 4.94 and 4.95. In the scheme, maps of the various flow regimes may be drawn using the regime transition number R_{ij}, which pertains to transition between regimes i and j. The flow regime code is defined in Table 4.20. The expression for the regime transition numbers is given by the following equation:

$$R_{ij} = \frac{U_m^2}{K_t \alpha_s^{n1} f_w^{n2} C_D^{n3} gD(S-1)} \tag{4.96}$$

The coefficients in this equation are given in Table 4.21.

The transition point between flow regimes i and j is given by $R_{ij} = 1$. For a given set of conditions, the corresponding flow regime can be determined by evaluating the signs (i.e., "+" or "–") of $(R_{ij} - 1)$ and then

inspect Table 4.22 to find the regime code. An example of flow regime diagram determined by this delineation procedure is shown in Figure 4.32.

4.2.4.3.5 Two-layer Model It has long been appreciated that the only satisfactory methods for predicting pressure loss for heterogeneous slurry flows in horizontal pipelines are those that take account of the flow mechanisms. In the early 1970s, Wilson (1970) developed a mechanistic model approach by introducing the concept of a two-layer model in which particles were in suspended flow in the upper layer and in which, for at least a proportion of the particles in the lower layer, solids' interaction forces at the pipe wall counterbalanced part of their buoyant weight. After undergoing progressive developments (Shook et al., 1986, Wilson, 1988, Gillies et al., 1991), this two-layer model has been set out in Shook and Roco's book (1991) in a form which is easier to follow.

In the two-layer model, heterogeneous slurry flows in a horizontal or sloping pipe are considered to consist of two layers separated by a hypothetical horizontal interface, as shown schematically in Figure 4.36. The assumptions made in this model are summarized as follows:

- The slurry flowing in a horizontal pipe comprises two hypothetical layers: an upper layer of particles less than 74 μm and a lower layer containing all particle sizes in the slurry.
- Each layer has its own uniform velocity (U_{m1}, U_{m2}) and uniform volumetric solids' concentration (α_{s1}, α_{s2}), and there is no slip between the solids and the liquid within either layer.

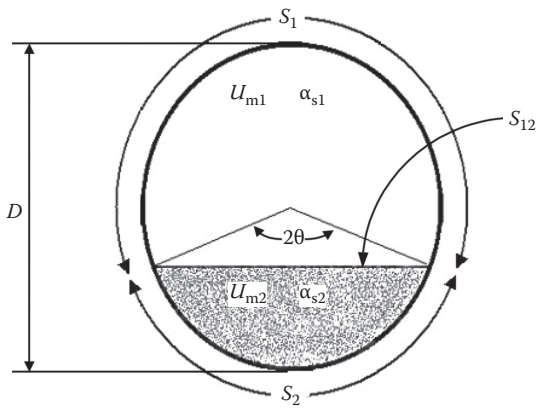

Figure 4.36

Basic concept of the two-layer model.

- The slurry mixture in the upper layer, of volumetric solids' concentration α_{s1}, behaves essentially as a liquid as far as the wall shear stress is concerned, and the wall shear stress in the upper layer is kinematic, that is, velocity dependent.
- The total solids' concentration in the lower layer α_{s2} is that of packed bed and is taken as 0.6. The solids are considered as constituting a suspended load of concentration α_{s1} and solids of concentration $\alpha_{s2} - \alpha_{s1}$ whose buoyant weight is supported at the walls as a result of interparticle contacts. This concentration, averaged over the total cross section of the pipe, is defined as the "contact load" α_c. The "contact load"α_c is given by $\alpha_c = (\alpha_{s2} - \alpha_{s1})A_2/A$.
- The particles in contact with the pipe wall in the lower layer experience a Coulombic friction force.

By referring to Figure 4.36, the total cross-sectional area of flow for the upper layer of fines and the lower layer of coarser particles is $A = A_1 + A_2$, and A_1 and A_2 are given by

$$A_1 = 0.25D^2(\pi - \theta - \sin\theta\cos\theta) \quad \text{and} \quad A_2 = 0.25D^2(\theta - \sin\theta\cos\theta) \tag{4.97}$$

The upper and lower perimeters (S_1 and S_2) and the width of interface (S_{12}) in terms of the half angle θ subtended at the center of the pipe are given by $S_1 = D(\pi - \theta)$, $S_2 = D\theta$ and $S_{12} = D \sin\theta$.

The model employs both mass and force balances. The mass balances in terms of mean delivered concentration α_s are as follows:

For the mixture:

$$U_m A = U_{m1}A_1 + U_{m2}A_2 \tag{4.98}$$

For solids:

$$\alpha_s U_m A = \alpha_{s1}U_{m1}A_1 + \alpha_{s2}U_{m2}A_2 = \alpha_{s1}U_m A + (\alpha_{s2} - \alpha_{s1})U_{m2}A_2 \tag{4.99}$$

For liquid:

$$(1 - \alpha_s)U_m A = (1 - \alpha_{s1})U_{m1}A_1 + (1 - \alpha_{s2})U_{m2}A_2 \tag{4.100}$$

For narrow particle size distribution and $Ar < 3 \times 10^5$ (Ar is the Archimedean number defined by $4gd_p^3(S-1)\rho_l^2/3\mu_l^2$, the "contact load" α_c is calculated using an empirical correlation

$$\frac{\alpha_c}{\alpha_r} = \exp\left[-0.124Ar^{-0.061}\left(\frac{U_m^2}{gd_p}\right)^{0.028}\left(\frac{d_p}{D}\right)^{-0.431}(S-1)^{-0.272}\right] \tag{4.101}$$

where $\alpha_r(=\alpha_{s1} + \alpha_c)$ is the mean in situ concentration.

The two-layer model employs momentum equations for each layer. They are written in terms of the boundary and interfacial stresses. The upper layer is considered to contribute only kinetic friction so that the momentum equation for horizontal flow is

$$i_m = \frac{(\tau_1 S_1 + \tau_{12}S_{12})}{(A_1\rho_1 g)} \tag{4.102}$$

where

i_m is the pressure gradient
τ_1 is the wall stress of upper layer
τ_{12} is the interfacial stress at hypothetical interface
S_1 is the partial perimeter of upper layer
S_{12} is the width of interface

The momentum equation for the lower layer is

$$i_m = \frac{(\tau_2 S_2 - \tau_{12} S_{12} + F_z)}{(A_2 \rho_1 g)} \tag{4.103}$$

where

τ_2 is the kinetic stress at the partial perimeter of lower layer S_2

F_z is the total force per unit length exerted normally to the surface of the pipe by the contact load solids

If the interfacial stress terms are eliminated between Equations 4.102 and 4.103 we have the force balance for the pipe as a whole:

$$i_m = \frac{(\tau_1 S_1 + \tau_2 S_2 + F_z)}{(A \rho_1 g)} \tag{4.104}$$

The boundary stress τ_1 is evaluated using the velocity and density of the upper layer:

$$\tau_1 = \frac{1}{2} f_1 U_{m1}^2 \rho_1 \tag{4.105}$$

where the friction factor f_1 is based on the Reynolds number of the liquid flowing at the mean slurry velocity U_m in the pipe, that is, $DU_m\rho_l/\mu_l$ and on the relative roughness of the pipe e/D. f_1 is calculated using the Churchill equation (Equation 4.36).

At the boundary S_2 of the lower layer, the boundary stress τ_2 is given by

$$\tau_2 = \frac{1}{2} f_1 U_{m2}^2 \rho_2 \tag{4.106}$$

where ρ_2 is the density of (liquid + suspended solids) in the lower layer.

The interface S_{12} is visualized as a boundary with a roughness depending on the diameter of particles. The interfacial stress τ_{12} is calculated from friction factor f_{12} and the difference in velocity between the layers:

$$\tau_{12} = \frac{1}{2} f_{12} (U_{m1} - U_{m2})^2 \rho_1 \tag{4.107}$$

where the interface fraction factor f_{12} is calculated using the following equation suggested by Wilson (1988):

$$f_{12} = \frac{(1 + 2Y)}{\left[4 \log(D/d_p) + 3.36\right]^2} \tag{4.108}$$

where $Y = 4 + 1.42\log(d_p/D)$ for d_p/D greater than 0.0015 and $Y = 0$ otherwise.

The term F_z in Equation 4.103 reflects the balance of forces in the vertical direction in the lower layer for the fluid, the suspended solids, and the contact load particles. The F_z can be calculated using the following equation given by Shook and Roco (1991):

$$F_z = 0.5 f_c D^2 g (\rho_s - \rho_l)(\sin\theta - \theta\cos\theta)\left[\frac{(\alpha_{s2} - \alpha_{s1})(1 - \alpha_{s2})}{1 + \alpha_{s1} - \alpha_{s2})}\right] \tag{4.109}$$

where f_c is the coefficient of Coulombic friction between the particle and the pipe wall. This coefficient depends upon the nature of the two surfaces (the particles and the substrate) and can be experimentally determined using a direct shear cell. The value of f_c is generally between 0.42 and 0.5.

The two-layer model was developed from experimental results of fairly narrow particle size distribution. For industrial slurries with broad particle size distributions, the effects of the fine particles (<74 μm) on

the viscosity and density of the carrier liquid should be taken into account (Shook and Roco, 1991). An appropriate model from Table 4.16 can be used for calculating the viscosity of slurries with fine particles. However, the slurry in the upper layer needs to be represented as a non-Newtonian fluid if the slurry contains sufficient fine particles. Shook and Roco (1991) also indicated that the two-layer model is not suitable for slurry flows with very low contact load concentration. For cases with low contact load concentrations, a homogeneous slurry flow model or correlation should be used.

It must be stressed that the existence of two distinct layers within the pipeline is a concept used simply for modeling purposes and is not of a physical reality, any more than a boundary layer formed during the flow of a fluid over a surface has a distinct identity.

Some models similar to the two-layer model have been proposed since Wilson (1970) reported the original two-layer model. Khan and Richardson (1996) proposed a simplified model that has the major features of the original two-layer model of Wilson (1970). Doron et al. (1987) developed a model with either a stationary or a moving bed at the bottom of the pipe and a heterogeneous suspension in the upper portion.

4.2.4.4 Combined Homogeneous–Heterogeneous Flows in Horizontal Pipes

In many practical systems, the solids are not all of uniform size. The combined heterogeneous–homogeneous slurry system is, therefore, the most important and most common in slurry transportation. It involves coarse and fine particles. The fines move as a homogeneous mixture while the remainder move as a heterogeneous mixture.

Condolios and Chapus (1963) suggested that the particle drag coefficient in correlations, such as Equation 4.79, is replaced by a weighted mean value (Equation 4.81) determined by the relative concentration of each particle size fraction. Newitt et al. (1955) proposed the use of a weighted average particle diameter (Equation 4.87), but Hill et al. (1986) proposed that the particles should be divided. The finer particles would move as a heterogeneous flow, while the coarser particles would move as a bed by saltation. The frictional pressure loss for each size fraction is calculated by correlations, such as Newitt Correlation (Equations 4.84 through 4.86). This approach worked well when applied to pumping water–coal mixtures (Hill et al., 1986, Wasp et al., 1977).

Wasp et al. (1977) employed the concept of a "two-phase vehicle" for the analysis of combined homogeneous–heterogeneous system. The approach is to consider that portion of the suspension existing at the top of the conduit, with its corresponding concentration and size distribution, to comprise the homogeneous vehicle uniformly distributed over the entire conduit, with the remainder of the suspension comprising the heterogeneous phase. The total friction loss is considered to be the sum of that due to the homogeneous vehicle alone, plus that due to the heterogeneous phase carried by the vehicle. Wasp et al. assumed that the vehicle could be described as a Newtonian fluid, although Hanks (1980) has extended this approach to account for non-Newtonian properties of the vehicle, assuming the vehicle behaves as a Bingham plastic. The method proposed by Wasp et al. (1977) has been summarized in Equations 4.88 through 4.93.

4.2.4.5 Vertical Pipe Flows of Slurries

It was suggested that the minimum velocity for vertical pipe flows of slurries should be twice the settling velocity of the largest particles in the flowing mixture (Govier and Aziz, 1972). This suggestion used the settling velocity to estimate the maximum possible slip and included an allowance for the effect of the variation of solids' concentration over the cross section. If the operating velocity falls below the minimum value required to fluidize the solids' high axial stresses are generated that result in a plugged line.

Although it is possible to operate at such low velocities for slurries with narrow particle size distributions, Sellgren's (1982) criterion (a factor of 6 or 7 instead of 2) seems to be a useful practical guide. If the pipeline is to have any horizontal sections, to avoid deposition in these, the velocity will be much greater than a limiting value chosen to accommodate the vertical pipe.

In a steady vertical slurry flow operated at a velocity higher than the minimum velocity, it would not be possible to develop dunes, a bed, or saltation, although redistribution of the particles can occur within the slugs as the coarse, or more dense, material settles through fine, or less dense particles. There is no concentration gradient, and the flow may be treated as pseudo-homogeneous for frictional pressure loss calculations, as discussed in Section 4.2.3.2. At low concentrations of solids (in the region of 2%–5% by volume), the frictional pressure loss at high flow rates is frequently reported to be almost indistinguishable from that of the flow of clear liquid. At higher concentrations, Einstein and Graf (1966) reported that the frictional pressure drop can be approximated by a mixture-density correction to the clear fluid frictional loss.

4.2.4.6 Inclined Slurry Pipe Flows

Inclined slurry pipe flows are important but are not the subject of extensive studies because fairly long inclined pipes are necessary to allow the disturbance produced by a bend to decay before representative measurements are made. One important issue in designing a pipeline is determining the critical slope of the pipe to avoid areas of blockage once the flow is shutdown. Due to lacking predictive approaches, the critical slope has to be experimentally determined. To avoid blockage of the pipeline due to solids' sliding back in the inclined pipeline during shutdown, it is necessary to adopt the design restriction of 10%–16% slope or 5.7°–9° inclined angle when there is no knowledge of the critical slope.

The two-layer model presented in Section 4.2.4.3 has been applied to inclined slurry pipe flows (Shook and Roco, 1991).

4.2.5 Design and Operational Aspects

4.2.5.1 Design Procedure

There are four types of practical slurry pipeline design problems: (1) determination of the net driving force required to move the given slurry through the given pipe at the given flow rate; (2) determination of the flow rate that would result for a slurry with known properties being transported through a given pipe with a specified driving force; (3) determination of the pipe diameter required to transport a slurry with known properties at a specified flow rate with a given driving force; and (4) determination of economic optimum pipe diameter at specified flow rate and slurry properties but being free to select both the driving force (e.g., the pumping power) and the pipe diameter. Only the fourth design problem will be discussed here since it is probably the most frequently used and most practical.

As the flowchart in Figure 4.37 shows, the design of a slurry transport system begins with an identification of the slurry to be conveyed, and relevant information to be collected in this step is solids' density, particle size distribution, solids' concentration, flow rate, and carrier liquid. The next important step is to determine whether the slurry can be considered as settling or nonsettling with regard to pipeline transportation. Typically, nonsettling slurry has a high solids' concentration of fine solid particles (<40 μm) of low particle density and exhibits viscous behavior. Slurries stabilized with additives and those behaving as non-Newtonian fluids are nonsettling. The remaining steps in the design procedure depend on the settling tendency of slurries because the analysis approach for settling slurries is different from those for nonsettling slurries.

4.2.5.1.1 Settling Slurries In the specification of design requirements for settling slurries, a route selection has to be carried out to determine the length of pipe sections of different orientation, the number of pipe fittings of different types, and slopes of inclined pipe sections. The major difference of route selection between no-settling and settling is the requirement that slopes be kept between 10% and 16% for settling slurries. The initial pipe diameter can be selected using Figure 4.35 based on the flow rate and top particle size. Selection of the final pipe diameter will result from an economic balance weighing such factors as initial pipe cost, pipe wear as a function of slurry velocity, solids' abrasivity, slurry corrosiveness, and projected operating costs largely in terms of system horsepower requirements.

After specifying the design requirements, the designer must choose an operating velocity. Pipelines for slurries that settle under conditions of no flow are usually operated without a deposit. The formation of a moving or stationary deposit bed is associated with unstable operating regime. Under these conditions, a small decrease in flow rate can result in increased holdup of solids that may cause a blockage if sufficient pumping capacity is not available to overcome the increase in pressure head. Prediction of the minimum carrying velocity that will sustain transport is an essential starting point from which an operating velocity can be assigned. The critical velocity discussed in Section 4.2.4.2 is the minimum carrying velocity for horizontal pipe slurry flows. This velocity can be determined by predictive models presented in Section 4.2.4.2 or through small-scale experimental tests. The practical operating velocity should be higher than the minimum carrying velocity of pipe sections with different orientations, and the offset must include an allowance for the effect of the variations of solids' concentration and particle size distribution.

The next step is to evaluate the corresponding frictional pressure loss for pipe sections of different orientations as a function of pipe diameter and operating velocity. Estimation of the pressure loss is an essential precursor to pump sizing. For heterogeneous flows of settling slurries, the estimation of the frictional pressure loss of horizontal pipe flow scan follow the predictive models described in Section 4.2.4.3. For the vertical pipe flow of settling slurries, approaches presented in Section 4.2.3.2 can be used for estimating the frictional pressure loss as vertical slurry flows can be treated as homogeneous.

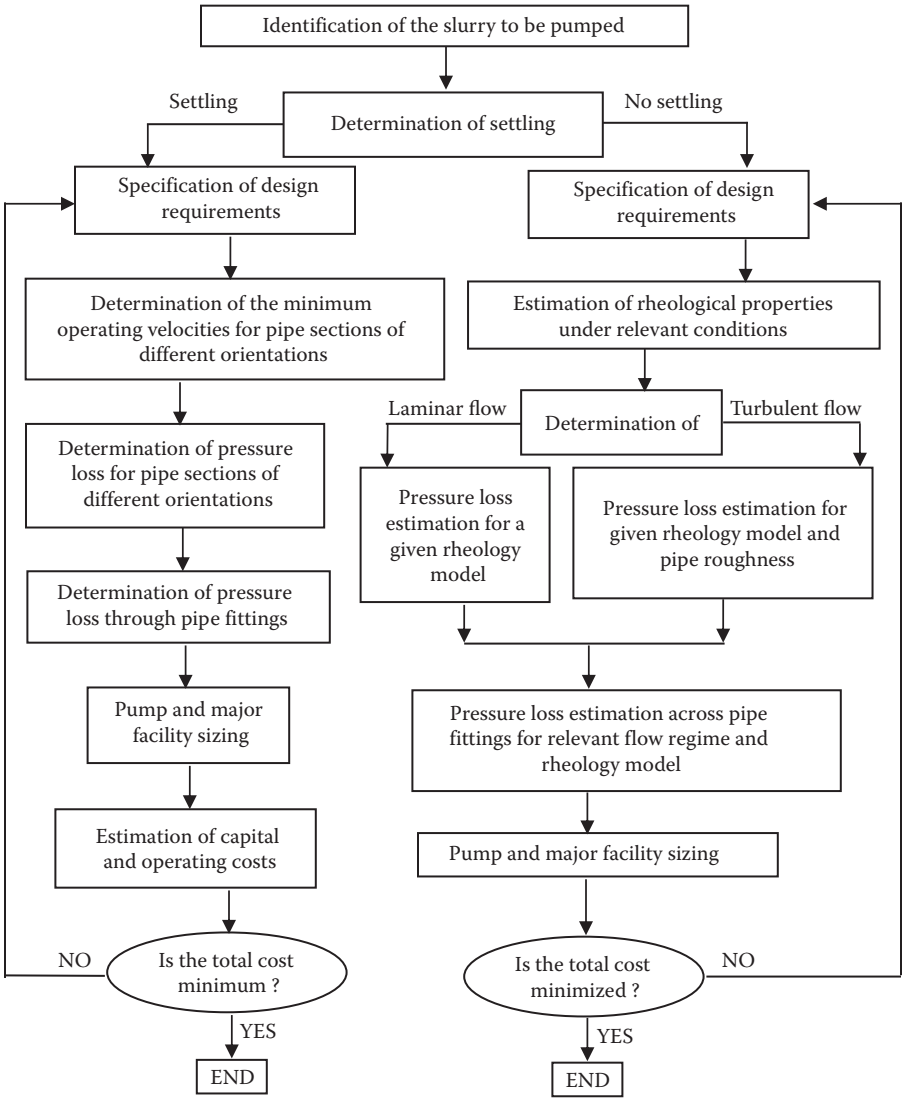

Figure 4.37

Flowchart for slurry pipeline design procedure.

Pressure losses arising from flow through pipe fittings are required before total system head loss estimation can be made. Both the resistance coefficient and the equivalent length methods discussed in Section 4.2.3.3. are suitable for estimating pressure loss from pipe fittings. The total pressure change is the sum of hydrostatic (or potentially recoverable) pressure, frictional (irrecoverable) pressure loss of straight pipe sections, and pressure loss from pipe fittings.

Pumping requirement and other major facilities sizing can then be determined from the design parameters (e.g., pipe diameter, operating flow velocity, total pressure loss, and slurry characteristics). Once proper pump and facility sizing are completed, an economic analysis of the pipeline can be carried out to estimate the capital and operating costs.

To find the design parameters that minimize the total costs of the pipeline system, the design procedure can be repeated for a few times. The optimum values of the design parameters depend on how these parameters affect the capital and running costs for the whole pipeline system and on the effects of likely changes in the operating conditions under normal operation.

4.2.5.1.2 Nonsettling Slurries In the route selection for nonsettling slurries, there is no restriction on the slopes of inclined pipe sections. For nonsettling slurries, the flow can be laminar or turbulent, as the slurry mixture will not segregate under any circumstance, and therefore, the selection of operating flow velocity and hence the pipe diameter are mainly based on the minimum total cost.

Nonsettling slurries may behave as a Newtonian or different types of non-Newtonian fluid. One of the major tasks in the pipeline design for nonsettling slurry flows is to determine an appropriate rheological model from experimental tests, including viscometric and small-scale pipe flow tests. Relevant measurement techniques for characterizing slurry properties can be found in Section 4.2.6.1.

After the determination of slurry rheological property, the next step is to determine whether the flow regime is considered as laminar or turbulent flow with regard to pipeline transportation. The identification of the transition between laminar and turbulent flow is of paramount importance because the fluid behavior and flow equations change fundamentally at this point. As described in Section 4.2.3.2.4, an estimate of the laminar–turbulent transition condition can be obtained. Although most practical operating velocities are in turbulent flow regime, laminar flow can be found in practical slurry pipelines due to high viscosity or other considerations.

Using suitable approaches as discussed in Section 4.2.3.2, the pressure loss under given flow regime, rheology model, and pipe roughness can be evaluated and then pumping requirement and other facilities selected.

The procedures outlined in this section are suitable for both preliminary and detailed design. They also provide a sensible starting point for the design of full-scale tests that are necessary if accurate design data are required. The designer of a slurry pipeline will generally start with a conceptual or preliminary design to generate sufficient data for a budget estimate of capital investment and operating costs. The difficulty in many cases is that a designer will be required to provide a preliminary design before any tests can be performed. In this case, the designer has very few options. He can try to find operating data of systems using similar materials to arrive at approximate figures for operating flow velocity, pressure drop, and pipe diameter. For a detailed design, it is important to perform laboratory tests to establish the actual slurry characteristics to be used for the pipeline under consideration.

4.2.5.2 Limitations of Predictive Models

Many different empirical correlations based on dimensional analysis have been proposed for predicting the critical velocity and pressure loss in the heterogeneous pipe flows of settling slurries, each reportedly providing an improved description of existing and/or new data. While many successful pipelines have been designed using empirical correlations, prediction outside the range of variables for which they were developed would be unsatisfactory because correlations do not consider physical processes that occur within the slurry. It is wise to check the original data. Empirical correlations could be considered as effective tools when correct correlation coefficients are obtained by experimental testing of the slurry system to be pumped.

Considerable success has been achieved in predicting the behavior of settling slurries using mechanistic approaches, such as two-layer and three-layer models. However, these models contain model parameters that require careful calibration that reduces their generality and utility for preliminary design. Therefore, the use of a model validated with similar slurry flows is recommended.

There are a number of assumptions and approximations involved in the development of predictive models for settling slurries, which provide limits to the degree of accuracy of the predictions. One assumption is that the superficial velocity in each layer is uniform in the two-layer or three-layer model. It should be evident that this assumption is adequate for model development but would contribute to the limitation. The error contained in data for the development of empirical correlation is another contribution to the limited accuracy of predictions.

Although predictive models proposed for the turbulent friction factor for non-Newtonian fluids or homogeneous slurries cover a wide range of possible combinations of properties, flow rates, pipe sizes, and so on, there are insufficient data in the literature to provide experimental confirmation of the predictions over a large portion of the range represented by these models. Therefore, caution has to be taken in applying these models to predict turbulent pipe flow behavior, especially for Bingham plastic slurries with high values of the Hedstrom numbers or power-law slurries with low values of the flow index, where the nature of turbulence is much different from that in Newtonian fluids.

The accuracy of the predictions depends not only on the quality of predictive model but also on the validity of a particular rheological model. Predictions of the turbulent friction factor for non-Newtonian fluids from models are generally very sensitive to appropriate determination of parameters of rheological models. However, parameter estimates for various rheological models contain a certain degree of uncertainty due to extrapolation outside the experimental shear rate range. This is because experimental shear rate ranges employed in viscometric measurement are rarely wide enough to cover most of the relevant shear rate range unless adequate resources are available for such work. Thus, it may be worthwhile sometimes to assess different methods of flow model parameter estimation to determine which method gives the least uncertainty in the predictions of shear stress outside the shear rate range used in viscometric tests. The proper selection of a suitable rheological model can

reduce the uncertainty in the model parameter estimation. The Sisko model has been found to be a model for which a unique set of unambiguously determined model parameter values can be obtained (Turian et al., 1992, 1997, 1998).

In lieu of the limitations of predictive models for slurry flows, the design of large-scale slurry pipeline system still demands pipeline trials to insure success, however, and is generally justified because of the costs involved. Data for industrial slurries are highly specific to the slurry mixture for which it has been measured and depends on a large number of variables including relative density of the phases, solids' concentration and particle shape, and size distribution. In addition, the chemical environment of the particles and surface charge can be particularly important to flocculation in fine-particle systems and fluid–particle and particle–wall friction in settling slurry systems.

There is no substitute for good quality experimental data. Testing in flow loops generally requires substantial quantities of slurry and experiments are often costly to execute. Small-scale testing can provide important operating velocities and frictional data. Experimental data are used to validate a predictive model or improve the parameters in the model. The validated model can then be used to scale up the small-scale pipe-flow test data.

4.2.5.3 Transient Pipe Flow Behavior

For non-Newtonian slurries with a yield stress, the start-up pressure developed by the pumping system must be more than adequate to initiate a wall shear stress along the pipeline that exceeds the yield stress. The start-up pressure, p_{st}, for pumping a Bingham plastic expressed in terms of yield stress, τ_0 is given by

$$p_{st} = \frac{4\tau_0 L}{D}. \tag{4.110}$$

It is particularly important to determine if yield stress progressively increases with time as the structure in a slurry builds up at rest. The proposed pumping system must be able to cope with the highest yield stress levels that the slurry could develop. Calculations need to be made to establish the maximum permissible shutdown period beyond which the pumping system would be unable to restart the pipeline flow.

When a velocity change occurs in a flowing slurry, some of the kinetic energy is converted into pressure energy giving an effect called *hydraulic surge*. This can be caused by valve closure or open, pump start-up or shutdown. The hydraulic surge could create pressures significantly above or below those occurring during steady conditions, leading to the risk of mechanical failure. It is prudent for the designer to include hydraulic surge considerations from the earliest stage of the design to remove the risk of failure by modifying either the design or operating conditions.

The pressure rise, Δp, caused by the velocity change, ΔU, is given by

$$\Delta p = -\rho_m \alpha_0 \Delta U, \tag{4.111}$$

where

α_0 is the pressure wave speed
ρ_m is the density of the slurry

If the fluid velocity increases then there is a pressure decrease. The pressure wave speed, α_0, in a slurry is given by (Thorley and Hwang, 1979)

$$\alpha_0 = \sqrt{\frac{1/\rho_m}{\left(\frac{1-\alpha_s}{K_L} + \frac{\alpha_s}{K_s} + \frac{D}{Ee}\right)}}, \tag{4.112}$$

where

E is Young's modulus for the pipe wall
e is the pipe wall thickness
K_L is the bulk modulus of the liquid phase
K_s is the bulk modulus of solid particles

The K_L for water is 2.06 Gpa and K_s for sand 16.0 Gpa (Bechteler and Vogel, 1981).

4.2.6 Measurement Techniques

4.2.6.1 Slurry Viscosity

The experimental determination of slurry viscosity is often required for the analysis of slurry flows. However, many existing standard viscometers for single-phase liquid, such as cone and plate, parallel plate, bob and cup, and capillary tube are not suitable for measuring the viscosity of settling slurries, as they cannot prevent the particles from settling during the measurement. Therefore, there are a number of viscometers that are potentially useful for measuring the viscosity of nonsettling slurries (Dealy, 1984, Heywood, 2000), but only few of the instruments are applicable to settling slurries (Albert et al., 1966, Ferrini et al., 1979, Akroyd and Nguyen, 2003). Basic types of viscometers suitable for measuring slurry viscosity are listed in Table 4.23. Important features of viscometers suitable for slurries include

- Fast response to changes in slurry properties.
- Knowing the shear rate at which viscosity is being measured.
- Being able to operate at different shear rates.
- Maintaining slurry in homogeneous but not promoting turbulence.

Coaxial cylinders are probably the most versatile and hence commonly used viscometers in both laboratory and online applications. The measured quantities are the angular velocity (ω) of the inner cylinder with a radius R_1 and the torque per unit height (T). The expression linking the parameters in a rheological model to the measured quantities is given by

$$\omega = \int_{\tau_2}^{\tau_1} \left(\frac{\dot{\gamma}}{2\tau} \right) d\tau, \tag{4.113}$$

where τ_1 and τ_2 are equal to $T/2\pi R_1^2$ and $T/2\pi R_2^2$, respectively, and R_2 is the radius of outer cylinder. The relationship between $\dot{\gamma}$ and τ for various rheological models can be found in Table 4.17. For a power-law slurry, the integration of Equation 4.113 gives

$$\omega = (n/2)\left(T/2\pi K_p\right)^{1/n}\left(1/R_1^{2/n} - 1/R_2^{2/n}\right). \tag{4.114}$$

By fitting the data (ω, T) to this equation, parameters (n, K_p) can be determined.

The data analysis procedure for other viscometers can be found in the references indicated in Table 4.23. Flow conditions in viscometers must be laminar as it is one of the assumptions that must be met for the calculation of viscosity. The criteria of laminar flow in coaxial cylinders are

$$R_\omega \le 45(R_m/\delta)^{0.5}, \tag{4.115}$$

where

$R_\omega = R_m \omega \delta \rho_m \mu_m$
$R_m = 0.5(R_1 + R_2)$
$\delta = (R_2 - R_1)$

4.2.6.2 Solids' Concentration

Solids' concentration is one of the major process variables in slurry flows. A number of methods have been developed for the online measurement of solids' concentration in the past. Generally, these methods seek to find a specific property that is significantly different for the solids and liquid phases. The value of this property for the mixture will then depend on the solids' concentration m and by measuring this property, one would be able to find the solids' concentration. Examples of the specific property are electrical properties (e.g., conductivity), density, absorption of light, or absorption of radioactive radiation. Measurement techniques suitable for measuring solids' concentration of slurries are listed in Table 4.24.

Table 4.23 Viscometers for Measuring Slurry Viscosity

Viscometer	Operating Principle	Advantages	Limitations
Coaxial cylinder (Shook and Roco, 1991)	Inner cylinder is rotated inside an outer cylinder at a known speed, and the resulting torque on the inner cylinder is measured	Shear rate can be varied, simple procedure for data analysis	Must be mounted vertically, not suitable for settling slurries
Helical flow in coaxial cylinder (Akroyd and Nguyen, 2003)	Rotating inner or outer cylinder with axial slurry flow in the upward or downward direction	Can handle settling slurries, shear rate can be varied	Must be mounted vertically, complex procedure for data analysis
Tube (Shook and Roco, 1991)	Pressure loss required to create the flow is measured across a suitable length of pipe at different flow rate and pipe diameter	Inexpensive, simple procedure for data analysis, shear rate can be varied by changing the diameter	Not suitable for settling slurries
Vibrating sphere (Ferry, 1977)	Immersed sphere oscillates with a controlled amplitude. The viscosity is computed from the force needed to maintain the predetermined amplitude of oscillation	Fast response time, simple installation	Requiring independent density measurement, undefined shear rate
Falling cylinder (Dealy, 1984)	A piston falling in a sample contained in a tube with a closed end. The time of fall is proportional	A wide operating range to viscosity	Not suitable for settling

Table 4.24 Measurement Techniques for Solids' Concentration of Slurries

Measurement	Operating Principle	Advantages	Limitations Technique
Nucleonic gages (Fanger et al., 1978, Brown, 1988)	Gamma rays are attenuated as they pass through matter. The attenuation is an exponential function of the path length and the density	Applicable to a wide range of slurries and large diameter pipes, high precision, and robustness	Sensitive to slurry chemical composition, radioactive nature of the sources
Conductivity (Nasr-El-in et al., 1987)	The conductivity of slurry is a function of volumetric concentration of solids	Inexpensive, simple procedure for data analysis	Sensitive to the change of carrier liquid conductivity
Electrical impedance spectrum (Hu and Firth, 2002, 2003)	The electrical impedance spectrum (EIS) of slurry is a function of volumetric concentration of solids	Applicable to slurry streams where the conductivity of the liquid phase changes with time	A large number of cases required for calibration
DP cell (Clift and Clift, 1981, Shook and Roco, 1991)	The DP over a fixed height of slurry is proportional to the slurry density through a vertical pipe with a constant dynamic head	Simple construction and operation	Not suitable to low solids' concentrations with large particle sizes and wear of the diaphragm face; requires periodic maintenance
Pipe weighing (Kachel, 1986)	Weighing an isolating section of pipe	Direct measurement	Limited pipe diameter and operating pressure
Ultrasonic reflection (Greenwood and Bamberger, 2002)	The amount of ultrasonic beam reflection at the wedge–slurry interface depends on the slurry density	Compact design	The wedge material has to have a low acoustic impedance and subject to wear

Nucleonic gauges are commonly used instrumentation for measuring solids' concentration of industrial slurries due to their high precision and robustness. The basic principle is that if a narrow collimated beam of gamma photons is passed through a slurry, the attenuation of the beam will strictly obey the relationship

$$\frac{I}{I_0} = \exp(-B_\mu \rho_m L), \tag{4.116}$$

where

I is the beam intensity after distance L
I_0 is the initial beam intensity
B_μ is the mass attenuation coefficient of the material
ρ_m is the density of the slurry over distance L

In practice, the predictable logarithmic nature of the gauge response to density means that online calibration can be readily achieved by sampling a minimum of two different densities. Major factors to be considered in their application include the following:

1. Pipes have to be full and free of air as even a small amount of air bubbles will seriously affect the estimation of solids' concentration for low-density solids such as coal.
2. Solids need to be uniformly distributed across the pipe section; hence, it is recommended that installations only be carried out on vertical pipes with upward flows.

Precise and safe measurement of electrical conductivity requires relatively simple instrumentation. Thus, methods based on conductivity have been widely used in practice for measuring solids' concentration. The electrical conductivity of a slurry depends upon the conductivity of the carrier fluid and the volume fraction of solids. For nonconductive solids, the relationship between slurry conductivity and the volume fraction is given by (Maxwell, 1881)

$$\frac{\sigma_m}{\sigma_l} = \frac{2(1-\alpha_s)}{2+\alpha_s}, \tag{4.117}$$

where σ_m and σ_l are conductivities for slurry and the carrier fluid, respectively. MacTaggart et al. (1993) have given a review on other correlations for the relationship between slurry conductivity and the volume fraction.

However, electrical conductivity–based methods are very sensitive to the variations in the electrical conductivity of the aqueous phase of slurry mixtures. When the conductivity of the liquid phase changes with time, the conductivities of both the slurry mixture and the liquid phase are required in order to calculate the solids' content. But the online measurement of the conductivity of the liquid phase in a slurry mixture is generally difficult due to the requirement of separating solids from the liquid phase. Hu and Firth (2002, 2003) developed a new technique for measuring solids' concentrations in slurries. In this technique, the electrical impedance spectrum of slurry mixtures is measured at different excitation signal amplitudes and over a wide frequency range. Changes in the frequency response reflect changes in the slurry composition and the electrical conductivity of the liquid phase. The volumetric fraction of the solids' phase can be determined by analyzing the spectra using an artificial neural network. The technique has been successfully tested for various slurries under different conductivities of liquid phase and temperatures. In contrast with previous techniques based on conductivity, this new technique can be used for the online measurement of solids' concentration in slurry streams even when the conductivity of the liquid phase changes with time.

Another simple technique for measuring solids' concentration is based on the DP over a fixed height of vertical slurry flow in a full and air-free pipe. The DP is then given by

$$\Delta p = \rho_m g h + H_d, \tag{4.118}$$

where

h is the vertical height between the two pressure sensor tappings
H_d is the dynamic head, which is the pressure drop along the pipe due to frictional hydraulic loss

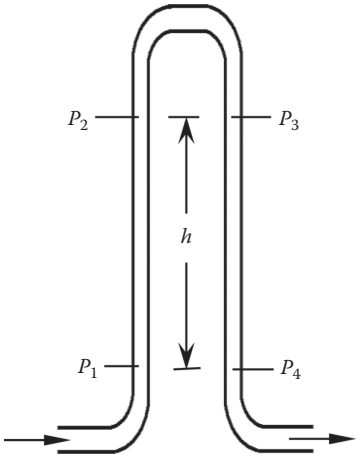

Figure 4.38

U-bend used for solids' concentration measurement.

Hence, by regulation of the flow of slurry through the pipe (such as feeding from a constant head and restricting the outlet through an orifice plate), the dynamic head should be relatively constant. By suitable calibration procedures, the pressure drop can then be related directly to the average density of the slurry.

If a vertical U-bend as shown schematically in Figure 4.38 is used, the pressure drops for the upward and downward flowing sections can be combined on the assumption that the frictional effects are the same in the two limbs of the U bend. The analysis given by Clift and Clift (1981) shows that the averaged slurry density can be obtained from

$$\rho_m = \frac{(p_1 - p_2) + (p_4 - p_3)}{2gh}. \tag{4.119}$$

4.2.6.3 Flow Rate

The measurement of flow rate is another common requirement in processes involving slurry flows. Numerous flowmeter types based on a variety of measurement principles are available. Each type has its own advantages and limitations. Typical flowmeter types for slurry flows are listed in Table 4.25. Except the Coriolis flowmeter, these flowmeters are restricted to fully filled vertical pipe flows where the slurry flow is homogeneous.

Magnetic flowmeters can be used to measure the flow rate or superficial velocity of slurries with conductive carrier liquids. Although their initial purchase price is relatively high, especially for large-diameter pipes, they are highly accurate (typically ±1.0% of full scale) and can be used with confidence without calibration with a wide range of slurries.

There are two types of ultrasonic flowmeters: Doppler and transit-time flowmeters that have been extensively used in slurry flows. Ultrasonic flowmeters have gone through many technological advances, especially in electronic circuitry and with the power of computers crunch numbers faster. Both Doppler and transit time flowmeters may use clamp-on sensors with their associated assemblies and detect flow rate from the outside of the pipe without stopping the process or cutting through the pipe. The clamp-on types of applications have considerably eased the job of the flow survey. Now users are able to ensure that old or new pump is working to its capacity, gather data for flow balancing, check if permanently installed meters are measuring incorrectly or are in need of maintenance, or simply clamp on a flowmeter where there is no flowmeter or where other flowmeter installations are impractical. Doppler ultrasonic flowmeters require the presence of reflectors, such as solids, in the flowstream so that the signal can bounce off them. Hence, they are particularly suitable for slurry flows. Transit time flowmeters send an ultrasonic signal from one side of a pipe to the other. A signal is then sent in the reverse direction. When an ultrasonic signal travels with the flow, it travels faster than when it travels against the flow. The flowmeter measures both transit times. The difference between the two transit times (across the pipe and back again) is proportional to the flow rate. Transit time flowmeters are mainly used for slurries with low solids' concentration.

Table 4.25 Flowmeters for Slurry Flows

Flowmeter	Operating Principle	Advantages	Limitations
Magnetic flowmeter (Heywood and Melita, 1988)	Creates a magnetic field within a pipe, typically using electrical coils. As electrically conductive fluid moves through the pipe, it generates a voltage. Flow rate is proportional to the amount of voltage, which is detected by electrodes	Independent of fluid rheology, density, temperature, and pressure; high accuracy and no pressure drop	Sensitive to magnetic noise from other equipment, not suitable for slurries containing ferrous particles, high initial cost, electrodes subject to coating
Ultrasonic Doppler (Sanderson and Hemp, 1981)	Calculates flow rate based on the shift in frequency observed when ultrasonic waves bounce off particles in the flow stream	Can meter dirty flows, no pressure drop, clamp-on convenience	Sensitive to the velocity profile and air bubble, sensitive to gaps between metal pipe wall and lined materials
Ultrasonic transit time (Sanderson and Hemp, 1981)	The velocity of the acoustic signal is increased when the direction of propagation is with the flow and decreased when it is against. The time difference between the two signals is used to calculate a velocity of the flow	Multiple-path model offers higher accuracy, no pressure loss, clamp-on convenience	Sensitive to variations in concentration and air bubbles, affected by flow profile, some models have high initial cost, attenuation of ultrasound by high solids' concentration.
Cross-correlation (various) (Bech and Plaskowski, 1987)	Flow rate measurement based on measuring the transit time of some kinds of disturbance such as electrical resistance between two points	Simple construction and operation	Not suitable to low solids' concentrations with fine particles
DP (Shook and Roco, 1991)	A flow restriction element (e.g., orifice plate, venturi) in the pipeline causes a pressure loss that is proportional to the density of the medium and the square of the volumetric flow rate	Low initial price, ease of installation, well understood	Creating nonrecoverable pressure loss, flow restriction element subject to wear, requires periodic maintenance, wear of the diaphragm face
Coriolis (Young, 1985)	Slurry is passed through a vibrating tube; this causes the tube to twist. Mass flow is proportional to the amount of twisting by the tube	High accuracy, low maintenance, insensitive to flow profile, pipeline pressure and temperature	High initial costs, units for larger sized pipes are restricted in pressure capability, and bent tubes subject to fouling

Cross-correlation flowmeters are based on measuring the transition time of some kinds of disturbances, such as electrical resistance between two points in a flow system (Beck et al., 1970, 1974). Schematic representation of the cross-correlation flowmeters technique is shown in Figure 4.39. In slurry flows, suspended particles in carrier fluids can lead to fluctuations in the conductivity of slurry flows due to the conductivity difference between solids and water. Two conductance sensors located at X and Y, arranged at an axial distance L in the pipe, detect conductance fluctuations as caused by the random changes of slurry phase composition. $X(t)$ and $Y(t)$ are electrical conductance signals measured at upstream (X) and downstream (Y) sensor locations. The patterns are similar in both signals but time shifted according to the traveling time of disturbances of slurry composition between the two sensor locations. With the assumption of the pipe slurry flow having the constant(bulk) velocity U_m and the fluctuation patterns being "frozen" during the flowing from location X to Y, the signal $X(t)$ detected by the first (upstream) sensor should be equal to the signal $Y(t)$ perceived by the second (downstream) sensor but delayed by the transit time τ^*:

$$X(t) = Y(t + \tau^*). \tag{4.120}$$

However, turbulent pipe flow causes the fluctuation patterns to be convected with velocities dependent on the radial position and Reynolds number and to be dispersed due to turbulent diffusion. As a consequence of these unavoidable processes, the traveling time from location X to Y of individual fluctuation event is a distribution with the transit time τ^* as the norm.

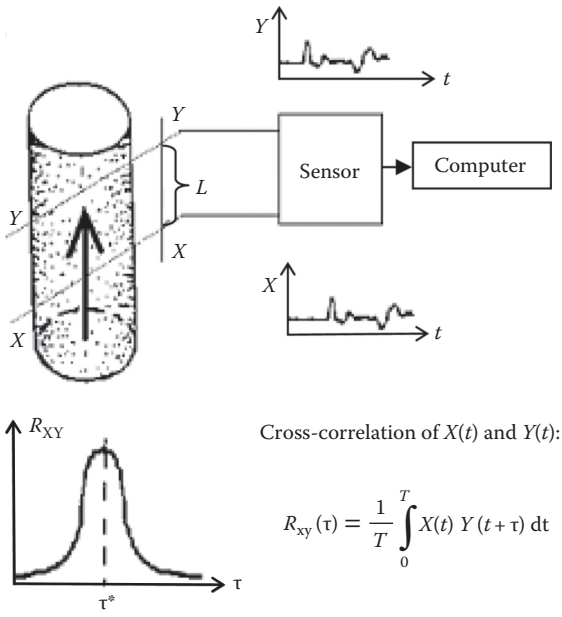

Figure 4.39

Schematic representation of cross-correlation flowmeter.

The distribution of the traveling (or delay) time can be determined from the cross-correlation function of the two signals according to stochastic process theory (Ross, 1996). The cross-correlation function, $R_{xy}(\tau)$ is given by

$$R_{xy}(\tau) = \frac{1}{T}\int_0^T X(t)Y(t+\tau)\mathrm{d}t, \tag{4.121}$$

where

T is the total sampling time

τ is the delay time of similar signal perturbations

The transition time, τ^* is taken here as the delay time τ for which the cross-correlation function has the maximum: $\tau^\star = \tau\,|_{R_{xy}(\tau)=\mathrm{MAX}(R_{xy}(\tau))}$. The mean velocity is therefore given by $U_m = L/\tau^\star$.

DP flowmeter is a less expensive, older technology that measures the flow rate based on the principle of conservation of energy between the liquid static and the velocity head. A flow constriction element (e.g., orifice plate, venturi, nozzle, and pitot) in the pipeline causes a pressure loss that is proportional to the density of the medium and the square of the volumetric flow rate. Two of the advantages of this technology are its consistency and common usage. However, its disadvantage is the permanent pressure loss due to the pipe constriction, potential for fouling, and wear of the constriction element. This type of flowmeter requires regular maintenance to prevent fouling at the constriction point.

Coriolis flowmeters are made up of one or more vibrating tubes. Slurry flows passing through a vibrating tube would cause the tube to twist. The amount of twisting motion is directly proportional to mass flow. Position detectors can sense the positions of the vibrating tubes. Temperature is constantly measured because the oscillatory properties of the tube vary with temperature. This makes it possible to make any necessary adjustments in the measurement.

While these meters are highly accurate, they are limited in terms of the pipe sizes they can efficiently be used on. While they can be used in pipes up to 6 in. in diameter, the flowmeters become expensive. The higher cost of Coriolis flowmeters is offset by normally low maintenance costs.

The selection process of flow measurement device for slurry flows should be based on application (volumetric or mass, pipe size, process temperature and pressure, fluid condition, fluid density and viscosity,

flow profile, range, and Reynolds number constraints), performance (accuracy, reliability, range, and repeatability), cost (purchase price, installation cost, cost of ownership, and maintenance cost), and supplier (flowmeter type, service requirements, training, and responsiveness) criteria in order to select a flowmeter. Reliability and accuracy are the two highest rated performance criteria by flowmeter users. Coriolis meters have the highest accuracy, followed by ultrasonic and magnetic meters. While Coriolis flowmeters typically have a higher purchase price, many users are now distinguishing between initial cost and cost of ownership. A flowmeter that offers reduced maintenance costs may be a better value than one with a lower purchase price that requires significant maintenance.

4.2.6.4 Pressure

Pressure needs to be measured in the majority of slurry handling applications. High-quality pressure transducers are readily available from specializing manufacturers, and the selection of the type of transducer and signal transmitter are not usually of prime importance in slurry flows. However, slurry applications frequently require that the sensing element contained in the transducer is isolated from the slurry in order to reduce wear and corrosion and to prevent fouling with solids. Isolation is usually achieved using an elastomeric sleeves or diaphragm seals.

4.2.6.5 Particle Size

A large number of techniques are available for off-line determination of particle size (Allen, 1981). For samples containing particles above about 1 mm, the choice of techniques is limited to screen analysis. Although wet mechanical screening can be used to analyze samples down to around 5 μm, more sophisticated automated techniques are available that can analyze to smaller particle size. Particle size analyzers based on laser diffraction (e.g., Malvern laser particle size analyzer) are widely used for the laboratory determination. These laboratory systems operate on highly dilute solutions (<5 g solids/L).

Present commercial online slurry particle size analyzers have been based on distance measurement (Miettunen et al., 1993), laser scattering (Sparks and Dobbs, 1993), laser diffraction, and ultrasound. The laser scattering technique is based on a scanning laser microscope technique in which the sample is scanned at constant speed by a high-intensity laser beam and the reflected light is measured. This analyzer has the advantage that dilution of the stream is not necessary. The online version of the Malvern laser particle size analyzer has been available. However, this analyzer has the disadvantages of high cost, sample bylines, high dilution, and sensitivity to window fouling. Particle size analyzers based on ultrasonic techniques (Reibel and Loffler, 1989, McClements, 1991, Pendse and Sharma, 1993, Dukhin and Goetz, 1996) have advantages of operating on undiluted and optically opaque slurries, rapid, precise, robust, compact, and relatively inexpensive.

Compressible Multiphase Flow

John D. Schwarzkopf, S. Balachandar, and William T. Buttler

5.1 Introduction
5.2 Compressible Multicomponent and Multiphase Continua
5.3 Compressible Dispersed Phase Flows
5.4 Shocked Continua Interfaces

5.1 Introduction

Compressible multiphase flows are found in several applications related to combustion, explosion, or high-speed systems. Examples are solid and liquid propellants such as those used in rocket engines, fragments from explosive devices, energy transformation such as inertial confinement fusion, and supernovae explosions, to name a few. Although the breadth and depth of this topic could produce a book by itself, the purpose of this chapter is to highlight important concepts and aspects of compressible multiphase flows.

In this chapter, we will discuss current modeling practices for multicomponent and multiphase compressible flows. The chapter is divided into three main sections: (1) compressible multicomponent and multiphase continua, (2) compressible dispersed phase flows, and (3) formation of particles from shocked surfaces. The latter section addresses the transition from continua to dispersed flows.

Multiphase compressible flows typically contain a mixing region of one or more materials; therefore, we have included a brief introduction to averaging techniques used to determine mixture properties or statistical quantities. The compressible multicomponent and multiphase continua section will begin with a brief discussion on Lagrangian techniques but will mainly focus on Eulerian techniques. The basic conservation equations for compressible multicomponent single-phase fluid mixtures are introduced, and closure models for turbulence quantities are discussed. Next, the conservation equations for multiphase multicomponent flows, commonly referred to as the two-fluid mechanical and thermal nonequilibrium model, are introduced. The continua section ends with discussions on shock interaction with material interfaces, shock jump conditions, and equations of state. The next section covers compressible dispersed phase flows. Within this section, we discuss dilute and dense particle-laden flows, Reynolds and Mach number effects, particle–shock interaction, and dispersed and carrier phase motion. The chapter is closed with a discussion on particle formation from shocked continua.

We begin this chapter by defining multicomponent, multiphase mixtures, which cover a wide spectrum of flow conditions and applications. A *component* is a chemical species such as oxygen, water, or aluminum. A *phase* refers to the solid, liquid, or vapor state of the component. The Atwood number

Table 5.1 Compressible Single and Multicomponent, Multiphase Flows

	Single Component	Multicomponent
Single phase	Shocked helium gas	Shocked air
Multiphase	Cavitation	Liquid fuel combustion

characterizes the density difference between materials (usually along an interface) and for a binary mixture it is defined as

$$At = \frac{\rho_1 - \rho_2}{\rho_1 + \rho_2}, \tag{5.1}$$

where $-1 < At < 1$ and $At = 0$ for single-phase materials. Examples of compressible single-phase and multicomponent, multiphase flows are provided in Table 5.1.

5.1.1 Averaging Techniques

Much of the current modeling practices involve averaging, which is required if the geometry is large and the mixing scales are small. In order to resolve these large differences in scales, an enormous amount of computational resources would be required. However, many engineering problems involve complex geometries and various levels of scales that should be accounted for using a modest amount of computational resources. This requirement drives the need for averaging.

Near an interface of different phase materials, averages are needed to estimate the property in a mixed region. Mixture averages usually take into account the volume fractions of the materials in the averaging process of the property.

In addition to mixture properties, turbulence may be present and depending on the model may require average properties. Turbulence can be modeled by decomposing an instantaneous property into an average and a fluctuation or deviation. In essence, there are three approaches to averaging turbulence: time, volume, and ensemble averaging. We will limit our discussion to temporal or spatial averaging and its relation to the Favre average.

5.1.1.1 Temporal Averaging

Time average is the result of averaging the flow properties over time at a point in the flow field. A point in this context is the smallest volume that would contain enough atoms to describe a continuum property (such as fluid density). However, the time average cannot distinguish between the different phases that may occupy that continuum point at different times, and therefore, its usefulness is limited to similar phase materials. The time average of some property B of the flow is defined as

$$\overline{\overline{B}} = \frac{1}{T}\int_0^T B dt, \tag{5.2}$$

where T is the total time over which B varies. Time averaging has been used extensively in single-phase flows to treat turbulent fluctuations and develop time-averaged conservation equations with additional terms, such as Reynolds stress, to account for the effects of mixing and turbulence. Obviously, the averaging time, T, must be large compared to the local fluctuation time, t', in order to define a true average value; that is, an average value that is independent of the averaging time. Also, the averaging time must be smaller than a characteristic time associated with the flow system, T', such that $t' \ll T \ll T'$. In some transient flow systems, this condition may not be realizable.

As mentioned earlier, this averaging approach is valid for multicomponent, similar phase fluids where a continuum mixture density can be used, such as air. However, for multiphase fluids, such as rain drops in air, a spatial averaging approach is used to distinguish between the phases.

5.1.1.2 Spatial Averaging

Volume averaging is carried out by averaging properties at an instant in time over a volume. For example, the *volume-averaged* property B would be defined as

$$\overline{B} = \frac{1}{V}\int_{V_A} B dV, \tag{5.3}$$

where

V is the averaging volume
V_A is the volume of fluid A

The bulk average, defined by Equation 5.3, is related to the *phase average*, by the volume fraction,

$$\overline{B} = \alpha_A \langle B \rangle, \quad \text{where } \langle B \rangle \equiv \frac{1}{V_A}\int_{V_A} B dV \tag{5.4}$$

and α_A is the volume fraction of fluid A. If B is the density of the fluid A, then $\langle \rho_A \rangle$ is the average material density of the fluid. If the density is constant, then $\langle \rho_A \rangle = \rho_A$. The constraints on the averaging volume are $\ell^3 \ll V \ll L^3$, where ℓ^3 is the local volume and L^3 is the characteristic volume associated with the flow system. This constraint is essential to approximate the spatial derivatives of $\overline{B}$ in the flow field.

A volume deviation is described as the instantaneous value at a continuum point within the volume average (of the phase of interest) that deviates from the average, such as

$$B = \langle B \rangle + B'. \tag{5.5}$$

Additional details on volume averaging can be found in Crowe et al. (2012).

5.1.1.3 Favre Averaging

Favre averaging is a method of simplifying the equations of fluid motion when variations in density are present, such as found in compressible flows. The Favre average is based on a mass-weighted ensemble average and for property B is defined as

$$\tilde{B} = \frac{\overline{\overline{\rho B}}}{\overline{\overline{\rho}}} \quad \text{or} \quad \frac{\langle \rho B \rangle}{\langle \rho \rangle}, \tag{5.6}$$

which can be formulated from a temporal or spatial decomposition. The instantaneous property B can be defined in terms of a Favre average and a deviation such as (Besnard et al., 1992)

$$B = \tilde{B} + B'' = \frac{\langle \rho B \rangle}{\langle \rho \rangle} + B' - \frac{\langle \rho' B' \rangle}{\langle \rho \rangle} = \langle B \rangle + B', \tag{5.7}$$

which is also equal to the volume average and its deviation.* Although Equation 5.7 is written in terms of a volume average, there is no loss of generality when applying the time average. The Favre deviation is then defined as (Besnard et al., 1992)

$$B'' = B' - \frac{\overline{\overline{\rho' B'}}}{\overline{\overline{\rho}}}, \quad \text{or} \quad B' - \frac{\langle \rho' B' \rangle}{\langle \rho \rangle}. \tag{5.8}$$

* This can be proved by decomposing the instantaneous properties within the Favre average into a volume average and a deviation, such as $\frac{\langle \rho B \rangle}{\langle \rho \rangle} = \frac{\langle \rho \rangle \langle B \rangle}{\langle \rho \rangle} + \frac{\langle \rho' \rangle \langle B \rangle}{\langle \rho \rangle} + \frac{\langle \rho \rangle \langle B' \rangle}{\langle \rho \rangle} + \frac{\langle \rho' B' \rangle}{\langle \rho \rangle}$, where the average of the deviations is zero, for example, $\langle \rho' \rangle = \langle B' \rangle = 0$.

If the property is velocity, then the average of the fluctuations within the Favre deviation (i.e., $\langle B'' \rangle$) can be interpreted as a mass-weighted turbulent velocity, defined as

$$a_i = \frac{\langle \rho' u_i' \rangle}{\langle \rho \rangle}, \tag{5.9}$$

and when multiplied by the average density becomes the turbulence mass flux. The Favre decomposition for velocity is then

$$\tilde{u}_i = \langle u_i \rangle + a_i \quad \text{and} \quad u_i'' = u_i' - a_i \tag{5.10}$$

where
$\langle u_i'' \rangle = -a_i$
$\langle \rho u_i'' \rangle = 0$

5.1.1.4 Mixture Properties

Average properties within a mixture, such as near the interface of different density fluids, are necessary to determine the transition of a property from one fluid to another. Average properties are needed when modeling multiphase flows in Eulerian frames of reference. In a mixed cell, the mixture density is defined as

$$\rho_m = \sum_{k=1}^{K} \alpha_k \rho_k, \tag{5.11}$$

where
α is the volume fraction
k is the material number
K is the total number of materials

This formulation has also been used for various properties such as specific heat and the ratio thereof. The harmonic average can also be used for properties such as specific heat, thermal conductivity, and sound speed. The harmonic average for the ratio of specific heats for a mixture is given as

$$\frac{1}{\gamma_m} = \sum_{k=1}^{K} \frac{\alpha_k}{\gamma_k}, \tag{5.12}$$

but any property could be substituted to obtain the mixture value. Other formulations involving mass concentration have also been used to formulate mixture averages. The mixture speed of sound proposed by Wood (1941) is of the form

$$\frac{1}{\rho c_m^2} = \sum_{k=1}^{K} \frac{\alpha_k}{\rho_k c_k^2}, \tag{5.13}$$

which can produce an average sound speed that is lower than the sound speed in either fluid. The Wood sound speed was derived for a homogeneous mixture of bubbles in a liquid. The effect of the bubbles on compressibility can significantly decrease the overall sound speed of the mixture.

For sound speed, the three averages provided in Equations 5.11 through 5.13 are shown in Figure 5.1 for a mixture of air and helium (multicomponent, single phase) and air and mercury (multicomponent, multiphase). The harmonic and Wood averages are close for moderate Atwood, $|At| \leq 0.75$, but drastically different for very high Atwood, $|At| \geq 0.9998$. Saurel et al. (2007a) also show that the mixture sound speed of water and air is very low over a large range of (air) volume fraction using the Wood model.

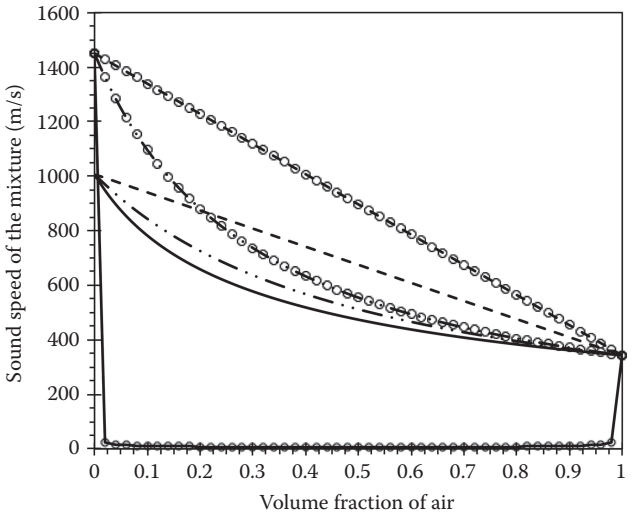

Figure 5.1

Mixture sound speed as a function of volume fraction of air. Dashed lines (Equation 5.11), dashed-double-dot lines (Equation 5.12), and solid lines (Equation 5.13) are shown for air–helium (lines only) and air–liquid mercury (circles). The Wood sound speed underpredicts the sound speed of either fluid. The sound speed of air, helium, and mercury is 343, 1007, and 1450 m/s, respectively, with their corresponding densities 1.21, 0.166, and 13, 600 kg/m^3.

5.2 Compressible Multicomponent and Multiphase Continua

There have been many recent developments in the area of modeling multiphase compressible flows. Two approaches are typically used: Lagrangian and Eulerian, both of which have pros and cons. This section will introduce the Lagrangian approach but mainly focus on the Eulerian approach.

5.2.1 Lagrangian Approach

The Lagrangian approach tracks the change in momentum and energy associated with a fixed mass throughout space and time. This approach minimizes numerical errors associated with advection in an Eulerian reference frame and is typically favored when computational resources are limited and multiphysics processes are numerous. Another benefit of using Lagrangian techniques to model multiphase compressible flows is that the interface of two materials is preserved throughout the dynamic process. Although this assumption is valid for materials containing strength (e.g., solid and gas/liquid interfaces), when the interface loses strength or when the shock is strong enough to overcome strength, instabilities can arise due to perturbations on the surface, which can lead to mixing and/or turbulence. In addition, if molecular diffusion occurs across a material interface or a material changes phase at the interface, a Lagrangian model may overpreserve the interface and constitutive models are needed to accommodate mixing or molecular diffusion at an interface.

Lagrangian codes have proven to capture shock fronts and jumps in material density, pressure, velocity, etc., reasonably well. Additional information on modeling compressible flows in a Lagrangian reference frame can be found in Noh (1987), Sambasivan et al. (2013), Lew et al. (2001), Francois et al. (2013), and for Arbitrary Lagrangian–Eulerian (ALE) methods, Yanilkin et al. (2013), and Waltz et al. (2014) and references therein.

5.2.2 Eulerian Approach

The Eulerian approach tracks mass, momentum, and energy through space and time relative to a fixed grid. With the increase in computational power over the last few decades, this approach has been used extensively to model shocked multicomponent and multiphase flows; however, more computational power is needed to capture viscous/turbulence effects across shocks in industrial applications.

Compressible multiphase and multicomponent flows can be modeled using an Eulerian approach. In the conservation equations, that is, the Euler equations, the viscous terms are neglected in comparison to the pressure terms. The development of the mass, momentum, and energy equations depends on the assumptions

associated with the problem. Because of this, multiphase/multicomponent flows are typically formulated in n-equation models. The basic equations for the instantaneous mass, momentum, and energy are

$$\text{Mass} \quad \frac{\partial}{\partial t}(\rho) + \frac{\partial}{\partial x_j}(\rho u_j) = 0, \tag{5.14}$$

$$\text{Species mass fraction} \quad \frac{\partial}{\partial t}(\rho c^k) + \frac{\partial}{\partial x_j}(\rho c^k u_j) = -\frac{\partial J_j^k}{\partial x_j}, \tag{5.15}$$

$$\text{Momentum} \quad \frac{\partial}{\partial t}(\rho u_i) + \frac{\partial}{\partial x_j}(\rho u_i u_j) = -\frac{\partial p}{\partial x_i} - \frac{\partial \tau_{ij}}{\partial x_j}, \tag{5.16}$$

$$\text{Energy} \quad \frac{\partial}{\partial t}(\rho E) + \frac{\partial}{\partial x_j}(\rho E u_j) = -\frac{\partial q_j^c}{\partial x_j} - \frac{\partial q_j^d}{\partial x_j} - \frac{\partial}{\partial x_j}(p u_j) + \frac{\partial}{\partial x_j}(u_i \tau_{ij}), \tag{5.17}$$

where

- ρ is the material density
- u_i is the velocity
- c^k is the mass fraction of species k,*
- J_j^k is the diffusive flux of mass fraction
- p is the pressure
- τ_{ij} is the viscous stress tensor
- E is the total energy ($e + u^2/2$)
- q^c is the molecular heat conduction
- q^d is the interdiffusion enthalpy flux (Cook, 2009)

In these equations, the potential energy and body forces have been neglected.

Starting with the basic equations, an averaging process can be used to interconnect fluid A and B at a material interface or describe properties across a shock in a mixture. This type of model typically assumes mechanical and thermal equilibrium in the mixture region or across the shock. For instance, if fluid A and B are gases, it is reasonable to assume that the pressure and temperature will rapidly equilibrate relative to the timescales of the shock. However, this assumption may not be valid for a gas next to a solid or liquid interface. Another type of model treats the two fluids as separate materials where the pressure, temperature, and velocity of each species are computed within a mixture region or across the shock. This type of model is typically referred to as a two-fluid model and does not assume mechanical or thermal equilibrium but requires relaxation models. Both types of models will be discussed.

5.2.2.1 Mechanical and Thermal Equilibrium

Starting with the instantaneous equations shown earlier, the instantaneous variables are decomposed into a volume average and a volume deviation to form the Favre average.† The assumption is made that the two fluids in a mixed cell are in mechanical and thermal equilibrium, which is only valid if the mechanical and thermal response times between materials are much smaller than the characteristic timescales of the flow, for example, multicomponent, single-phase flows. The resultant equations for two fluids are

$$\text{Mass} \quad \frac{\partial}{\partial t}\left(\alpha_1 \langle \rho_1 \rangle\right) + \frac{\partial}{\partial x_j}\left(\alpha_1 \langle \rho_1 \rangle \tilde{u}_j\right) = 0, \tag{5.18}$$

* We distinguish the concentration c^k from the sound speed c by the superscript k.

† There is no loss of generality in applying the temporal average instead.

$$\frac{\partial}{\partial t}\left(\alpha_2\langle\rho_2\rangle\right)+\frac{\partial}{\partial x_j}\left(\alpha_2\langle\rho_2\rangle\tilde{u}_j\right)=0, \tag{5.19}$$

$$\text{Species mass fraction}\quad \frac{\partial}{\partial t}\left(\overline{\rho}\tilde{c}^k\right)+\frac{\partial}{\partial x_j}\left(\overline{\rho}\tilde{c}^k\tilde{u}_j\right)=-\frac{\partial}{\partial x_j}\left\langle c''^k\rho u_j''\right\rangle, \tag{5.20}$$

$$\text{Momentum}\quad \frac{\partial}{\partial t}\left(\overline{\rho}\tilde{u}_i\right)+\frac{\partial}{\partial x_j}\left(\overline{\rho}\tilde{u}_i\tilde{u}_j\right)=-\frac{\partial\langle p\rangle}{\partial x_i}-\frac{\partial}{\partial x_j}\left(\overline{\rho}\tilde{R}_{ij}\right), \tag{5.21}$$

$$\text{Energy}\quad \frac{\partial}{\partial t}\left(\overline{\rho}\tilde{E}\right)+\frac{\partial}{\partial x_j}\left(\overline{\rho}\tilde{E}\tilde{u}_j\right)=-\frac{\partial}{\partial x_j}\left(\langle p\rangle\langle u_j\rangle\right)-\frac{\partial}{\partial x_j}\left(\overline{\rho}\tilde{u}_i\tilde{R}_{ij}\right)-\frac{\partial}{\partial x_j}\left\langle p'u_j'\right\rangle-\frac{\partial}{\partial x_j}\left\langle\rho E''u_j''\right\rangle, \tag{5.22}$$

where

k is the species number

$\tilde{R}_{ij}=\left\langle\rho u_i''u_j''\right\rangle/\overline{\rho}$ is the Reynolds stress

$\overline{\rho}$ is the mixture density (or ρ_m defined in Equation 5.11)

The Favre fluctuation terms are related to turbulence transport; the molecular transport and conduction terms were neglected. If we neglect the volume deviation terms, the resultant set of equations are commonly referred to as the four-equation model, where the volume fractions are related due to the saturation constraint

$$\alpha_1+\alpha_2=1. \tag{5.23}$$

Four-equation models are commonly used to model compressible flow, and the results have been compared to a large number of data and exact solutions for shocked flows. When considering the volume fraction, researchers have proposed a transport equation for the volume fraction of the form

$$\frac{\partial\alpha_1}{\partial t}+\tilde{u}_j\frac{\partial\alpha_1}{\partial x_j}=\begin{cases}0 & \text{(Allaire et al. 2002),}\\ \dfrac{\rho_2c_2^2-\rho_1c_1^2}{\dfrac{\rho_2c_2^2}{\alpha_2}+\dfrac{\rho_1c_1^2}{\alpha_1}}\dfrac{\partial\tilde{u}_j}{\partial x_j} & \text{(Saurel et al. 2007a),}\end{cases} \tag{5.24}$$

where c is the sound speed. This model is typically referred to as a five-equation model, where a closure is necessary to relate the volume fraction to pressure and/or internal energy. Allaire et al. (2002) evaluated isobaric and isothermal closure models and concluded that an isobaric model can handle interfaces between fluids without introducing spurious pressure oscillations.

The averages of the fluctuating terms shown in Equations 5.20 through 5.22 are related to turbulence and mixing. Closure models for the Favre fluctuation terms in Equations 5.20 through 5.22 were proposed by Besnard et al. (1987, 1992) and compared to DNS and experimental data for Rayleigh–Taylor (RT) (Rayleigh, 1883, Taylor, 1950), Richtmyer–Meshkov (RM) (Richtmyer, 1960, Meshkov, 1969), and shear-driven instabilities using a single set of coefficients (Schwarzkopf et al., 2011). Other researchers either varied the coefficients from one type of instability to another (Banerjee et al., 2010) or compared a single set of coefficients to a single instability (Grégoire et al., 2005). Closure models for the turbulence parameters are discussed as follows.

5.2.2.1.1 Turbulence Instabilities evolve from a strong acceleration that passes over a change in density with perturbations, such as the surface finish of an interface. Three basic instabilities that evolve into turbulence in compressible flows are as follows: (1) RT, (2) RM, and (3) Kelvin–Helmholtz

(von Helmholtz, 1868, Kelvin, 1871). RT instabilities develop from an acceleration of heavy fluid into a light fluid, such as water or SF_6 into air, with a seeded perturbation at the interface. RM instabilities develop from a shocked interface containing different density fluids on either side and a perturbation seed at the interface. When a strong shock passes across an interface having initial perturbations, the perturbations evolve into instabilities and eventually transition to turbulence. An example is shown in Figure 5.2 where Balasubramanian et al. (2013) set up a heavy gas (SF_6) curtain that is initially created by a series of jets. A Mach 1.2 shock impacts the heavy gas curtain creating RM instabilities that eventually transition to turbulence. Multiple shocks passing through an interface with different density materials

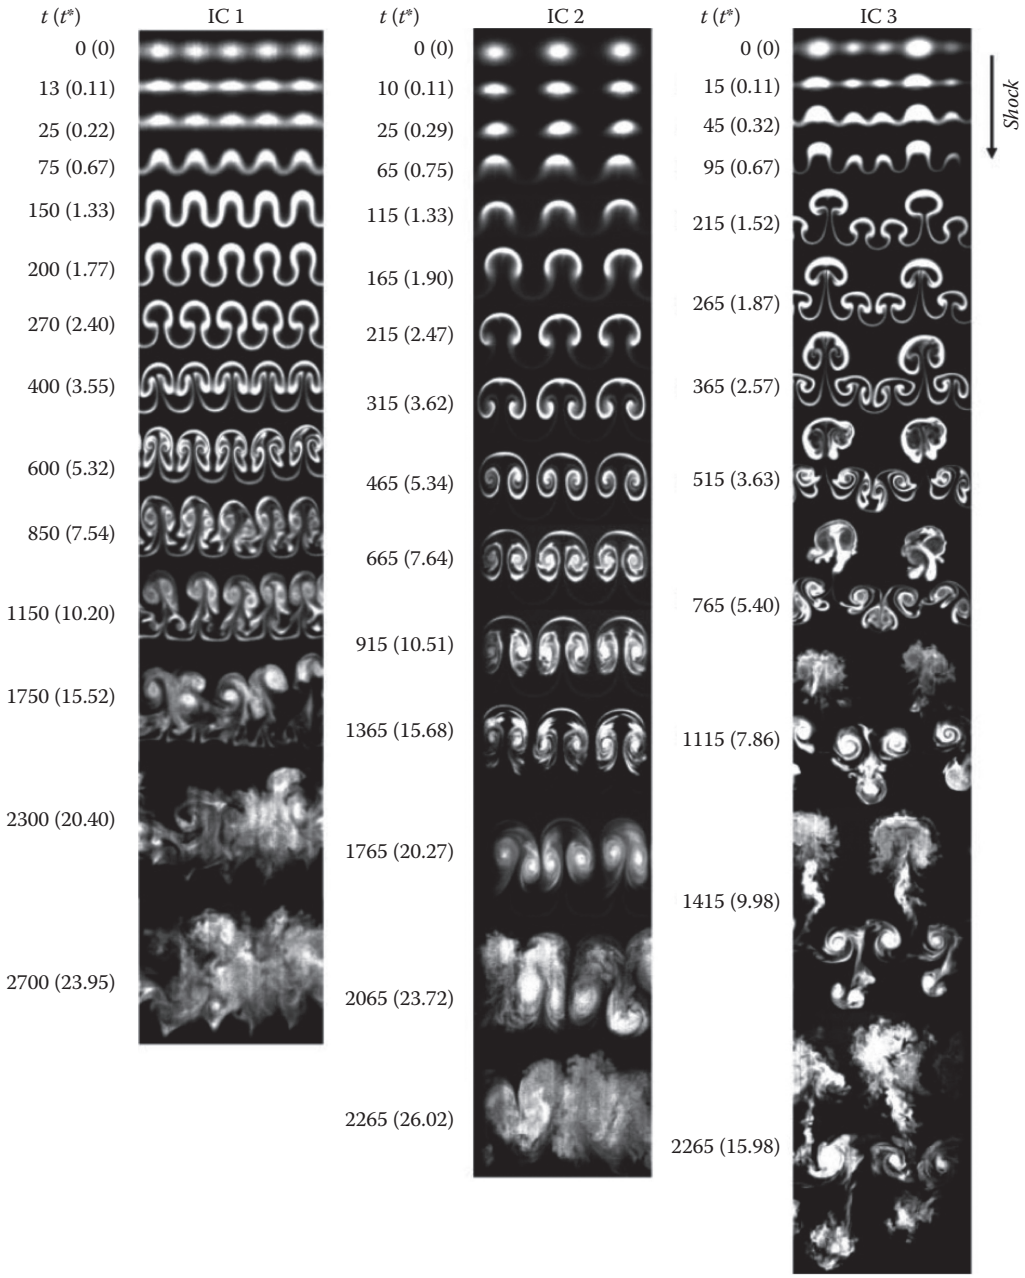

Figure 5.2

Evolution of density fields of a shocked (SF_6 [white] and air [black]) interface (curtain) for three different initial conditions: single mode and short wavelength (IC 1), single mode and long wavelength (IC 2), and multimode (IC 3). Time (t) is in microseconds, and t^* is the normalized time based on the initial linear growth. All modes show transition to turbulence without reshock. (Reprinted from Balasubramanian, B. et al., *J. Turb.*, 14, 170, 2013. With kind permission from Taylor & Francis.)

can also generate turbulence. These reshocked instabilities transition to turbulence much quicker than single shocked interfaces (Balasubramanian et al., 2012).

There are several approaches to modeling turbulence in multicomponent or multiphase compressible flows, some of which are (1) direct numerical simulation (DNS), (2) large eddy simulation (LES), and (3) Reynolds-averaged Navier–Stokes (RANS). Direct numerical and LES are 3D simulations that require large computational resources for complex geometry and multiphysics problems. The main difference between these simulation techniques is that DNS captures the turbulence energy transfer down to the Kolmogorov scale, that is, the scale at which energy is converted to heat through viscosity, whereas LES captures the large-scale effects and models the small-scale effects, which is set by a filter that is related to the grid size. The RANS approach captures the ensemble effects of turbulence without simulating the details related to the energy cascade process. These models are convenient when the 3D problem is complex and/or computational resources are limited.

The average of the Favre fluctuation terms in the species concentration equation is typically modeled as a turbulent diffusion process, such as

$$-\frac{\partial}{\partial x_j}\left\langle c''^k \rho u_j'' \right\rangle \approx C_c \frac{\partial}{\partial x_j}\left(\bar{\rho}\frac{S}{\sqrt{K}}\tilde{R}_{jn}\frac{\partial \tilde{c}^k}{\partial x_n}\right). \tag{5.25}$$

Similarly, the averages of the Favre fluctuation term in the energy equation are combined into a diffusion term

$$-\frac{\partial}{\partial x_j}\left\langle P'u_j'\right\rangle - \frac{\partial}{\partial x_j}\left\langle \rho E''u_j''\right\rangle \approx \frac{\partial}{\partial x_j}\left(\bar{\rho}\frac{S}{\sqrt{K}}\tilde{R}_{jn}\left[C_e\frac{C_v}{\mathrm{Pr_t}}\frac{\partial \tilde{T}}{\partial x_n} + C_k\frac{\partial K}{\partial x_n} + C_c\bar{h}^k\frac{\partial \tilde{c}^k}{\partial x_n}\right]\right), \tag{5.26}$$

where $\bar{h}^k$ is the enthalpy $\left(\tilde{e}^k + \frac{p^k}{\rho^k}\right)$ of species k due to species turbulence diffusion (Cook, 2009) and the sum over k is implied; $Pr_t = C_v\nu_t/k_{eff}$ is the turbulent Prandtl number; $\nu_t = C_\mu S\sqrt{K}$ is the turbulent (kinematic) viscosity;* k_{eff} is the effective thermal conductivity; C_v is the specific heat; and C_e, C_k, and C_c are calibration coefficients. The Reynolds stress is a by-product of the averaging process that results in a velocity covariance that describes the mean momentum flux caused by the fluctuating velocity components (Pope, 2000). RANS models for closing the turbulence quantities are given by Besnard et al. (1992), Grégoire et al. (2005), and Schwarzkopf et al. (2011). A transport equation for the Reynolds stress is given as

$$\begin{aligned}\frac{\partial \bar{\rho}\tilde{R}_{ij}}{\partial t} + \frac{\partial \bar{\rho}\tilde{u}_k\tilde{R}_{ij}}{\partial x_k} &= a_i\frac{\partial\langle p\rangle}{\partial x_j} + a_j\frac{\partial\langle p\rangle}{\partial x_i} - \bar{\rho}\tilde{R}_{ik}\frac{\partial \tilde{u}_j}{\partial x_k} - \bar{\rho}\tilde{R}_{jk}\frac{\partial \tilde{u}_i}{\partial x_k}\\ &+ C_r\frac{\partial}{\partial x_k}\left(\bar{\rho}\frac{S}{\sqrt{K}}\tilde{R}_{kn}\frac{\partial \tilde{R}_{ij}}{\partial x_n}\right) - C_{r3}\bar{\rho}\frac{\sqrt{K}}{S}\left(\tilde{R}_{ij} - \frac{1}{3}\delta_{ij}\tilde{R}_{kk}\right)\\ &- C_{r1}\left(a_i\frac{\partial\langle p\rangle}{\partial x_j} + a_j\frac{\partial\langle p\rangle}{\partial x_i} - \frac{2}{3}\delta_{ij}a_k\frac{\partial\langle p\rangle}{\partial x_k}\right)\\ &+ C_{r2}\bar{\rho}\left(\tilde{R}_{ik}\frac{\partial \tilde{u}_j}{\partial x_k} + \tilde{R}_{jk}\frac{\partial \tilde{u}_i}{\partial x_k} - \frac{2}{3}\delta_{ij}\tilde{R}_{mk}\frac{\partial \tilde{u}_m}{\partial x_k}\right)\\ &- \frac{2}{3}\delta_{ij}\bar{\rho}\frac{K^{3/2}}{S} - Y_{Rij},\end{aligned} \tag{5.27}$$

where

$S = K^{3/2}/\varepsilon$ is the turbulent length scale
$K = \tilde{R}_{ii}/2$ is the turbulence kinetic energy
ε is the turbulence dissipation
$a_i = \overline{\rho' u_i'}/\bar{\rho}$ is the mass-weighted turbulent velocity

* For this model, $C_\mu = 0.28$, but other values, such as 0.09, have been used with a different set of coefficients (Grégoire et al., 2005).

The pressure strain terms were modeled using the *IP* model of Naot et al. (1970) and the return to isotropy model given by Rotta (1951). Banerjee et al. (2009) studied several different pressure strain models (including modern models and the *IP* model) and compared them to experimental results of contraction and expansion flows. Overall, considering the simplicity and robustness of the *IP* model, Banerjee et al. (2009) showed it also compared reasonably well with the experimental data. The turbulent mass flux $\left(\overline{\rho}a_i\right)$ is a result of Favre averaging and the dominant form of advection in an RT instability. The model for the turbulence mass flux $\left(\overline{\rho}a_i\right)$ is

$$\frac{\partial\overline{\rho}a_i}{\partial t}+\frac{\partial\overline{\rho}\tilde{u}_j a_i}{\partial x_j}=b\frac{\partial\langle p\rangle}{\partial x_i}-\tilde{R}_{ij}\frac{\partial\overline{\rho}}{\partial x_j}+\overline{\rho}\frac{\partial a_i a_j}{\partial x_j}-\overline{\rho}a_j\frac{\partial\overline{u}_i}{\partial x_j}+\overline{\rho}C_a\frac{\partial}{\partial x_k}\left(\frac{S}{\sqrt{K}}\tilde{R}_{kn}\frac{\partial a_i}{\partial x_n}\right)-C_{a1}\overline{\rho}\frac{\sqrt{K}}{S}a_i-Y_{ai}, \tag{5.28}$$

where $b=-\overline{\rho'\upsilon'}$ is the density-specific volume covariance, which is a nonnegative measure of how well two fluids mix. For single-component and single-phase fluid and binary fluids, where the two fluids are perfectly mixed (i.e., an azeotropic fluid), $b = 0$. For the immiscible case, $b = \alpha_1\alpha_2(\rho_1 - \rho_2)^2/\rho_1\rho_2$ (Banerjee et al., 2010), and as $At \to |1|$, $b \to \infty$. A model for the density-specific volume covariance is

$$\frac{\partial\overline{\rho}b}{\partial t}+\frac{\partial\overline{\rho}\tilde{u}_j b}{\partial x_j}=-2(b+1)a_j\frac{\partial\overline{\rho}}{\partial x_j}+2\overline{\rho}a_j\frac{\partial b}{\partial x_j}+\overline{\rho}^2C_b\frac{\partial}{\partial x_i}\left(\frac{S}{\overline{\rho}\sqrt{K}}\tilde{R}_{ij}\frac{\partial b}{\partial x_j}\right)-C_{b1}\overline{\rho}\frac{\sqrt{K}}{S}b. \tag{5.29}$$

The final turbulence equation to close is the turbulent length scale. The turbulent length scale is defined as an integral length scale and is derived from combining the turbulence energy and dissipation transport equations.* The turbulent length scale model serves to transfer turbulence energy from this scale to heat. A model for the turbulence length scale is

$$\begin{aligned}\frac{\partial\overline{\rho}S}{\partial t}+\frac{\partial\overline{\rho}\tilde{u}_j S}{\partial x_j}=&-\frac{S}{K}\left(\frac{3}{2}-C_{s1}\right)\overline{\rho}\tilde{R}_{ij}\frac{\partial\tilde{u}_i}{\partial x_j}+\frac{S}{K}\left(\frac{3}{2}-C_{s3}\right)a_j\frac{\partial\langle p\rangle}{\partial x_j}-C_{s4}\overline{\rho}S\frac{\partial\overline{u}_j}{\partial x_j}\\&+C_s\frac{\partial}{\partial x_i}\left(\overline{\rho}\frac{S}{\sqrt{K}}\tilde{R}_{ij}\frac{\partial S}{\partial x_j}\right)-\left(\frac{3}{2}-C_{s2}\right)\overline{\rho}\sqrt{K}-Y_s.\end{aligned} \tag{5.30}$$

The *Y* terms at the end of Equations 5.27 through 5.30 are intended to suppress the turbulence in the presence of material strength. For multiphase problems that contain strength, Denissen and Plohr (2015) developed equations for the suppression parameters shown in the turbulence equations. The model development follows after Youngs (1997), with the idea that the material yield strength acts to suppress turbulence. These models can be applied to two-fluid mixed cells where one material in that cell contains a solid with strength. For such a mixture, the yield strength is given as

$$Y_{mix}=\alpha_1\langle Y_1\rangle+\alpha_2\langle Y_2\rangle. \tag{5.31}$$

The turbulence suppression terms due to material strength are given for binary fluid mixture as

$$Y_{Rij}=4\frac{\overline{\rho}}{|\Delta\rho|}\frac{Y_{mix}}{S}\frac{a_i a_j}{|a|}, \tag{5.32}$$

$$Y_{ai}=C_{a1}\frac{Y_{mix}}{S\sqrt{K}}a_i+2\frac{\overline{\rho}b}{|\Delta\rho|}\frac{Y_{mix}}{S|a|}a_i, \tag{5.33}$$

* Originally developed by Harlow and Steinkamp (unpublished); published details can be found in Schwarzkopf et al. (2011).

Table 5.2 Coefficients for Equations 5.25 through 5.30

C_a	C_{a1}	C_b	C_{b1}	C_c	C_r	C_e	C_k	C_{r1}	C_{r2}	C_{r3}	C_s	C_{s1}	C_{s2}	C_{s3}	C_{s4}
0.3	3.2	0.3	2.0	0.56	0.42	1.0	1.0	0.3	0.6	1.8	4.2	1.2	1.92	1.2	−1.2

$$Y_s = 2\frac{\bar{\rho}}{|\Delta\rho|}\frac{Y_{mix}}{K}|a|, \tag{5.34}$$

where $|a|$ is the magnitude of a_i.* Additional terms were included in Denissen and Plohr's model, but the coefficients were set to zero and therefore omitted in the equations mentioned earlier. For multicomponent, single-phase gas or liquid compressible flows, $Y_{mix} = 0$.

The coefficients for the turbulence model mentioned earlier, Equations 5.25 through 5.30, were tuned using variable density turbulence gas mixing, $|At| \leq 0.5$. A single set of coefficients (given in Table 5.2) were found from turbulence generated by RT and single-phase shear-driven instabilities using DNS and experiments.

Poggi et al. (1998) conducted shock tube experiments and was one of the first few to measure turbulence quantities in a turbulent compressible mixing layer produced by reshocked RM instabilities containing air and SF_6 gases, $|At| = 0.67$. The two gases were initially separated by a thin membrane that also served to seed perturbations. Schwarzkopf et al. (2011) used the previous equations and the coefficients found from RT and shear-driven turbulence (given in Table 5.2) to model Poggi's experiment. The turbulence equations were implemented in a compressible Eulerian hydrocode RAGE (Gittings et al., 2008), which uses a Godunov scheme to solve the mass, momentum, and energy equations, while the turbulence equations were solved using traditional finite volume methods. The experiment of Poggi et al. (1998) was simulated in 1D. The Reynolds stress $\left(\tilde{R}_{ij}\right)$ was initialized as isotropic along the diagonal components ($2K/3$, where K was estimated to be ~1% of the mean kinetic energy) and zero for the off-diagonals, and the length scale (S) initialized to the wavelength of the perturbations (~1 mm). The turbulence mass flux (a_i) was initialized to zero, and the specific volume covariance (b) was initialized as the two-fluid immiscible value, for example, $b = \alpha_1\alpha_2(\rho_1 - \rho_2)^2/(\rho_1\rho_2)$. Overall, considering that the majority of the coefficients were not tuned for this type of compressible flow, reasonable agreement was found for the velocity profile, Reynolds stress components,† and mix widths, shown in Figure 5.3.

This model was also applied to shock impacting an inverse chevron interface with multicomponent fluids. The shape of the chevron and turbulent quantities was compared before and after reshock to ILES simulations and experimental data (Haines et al., 2013). Overall, reasonable agreement was also found.

5.2.2.2 Mechanical and Thermal Nonequilibrium

Next, we consider a system of equations for two-fluid compressible flow where the mechanical and thermal equilibrium assumption is relaxed. Kapila et al. (2001) extended the work of Baer and Nunziato (1986) and developed a seven-equation model with additional terms that are dependent on interfacial effects, and they recognized that the pressure, velocity, and temperature fields can be different for the two fluids. This model was specifically developed around a solid–gas mixture of interacting continua for a porous explosive and includes mass, momentum, and energy transfer effects between the two species. Saurel et al. (2007a) applied a different form of this model to two-phase mixtures. The effects include nonequilibrium interactions between the phases due to interfacial drag, heat transfer, chemical reaction, and compaction. Each of these processes has characteristic length and timescales that can be used to determine if a two-fluid model is necessary, that is, if the velocity of each species rapidly relaxes to a mixture velocity, carrying around two equations for the velocity of each species in a computation is unnecessary.

* A realizability condition such as $0 \leq \bar{\rho}a_i a_j \leq bR_{ij} \leq 1$ should be considered in Equation 5.32. Caution is required to ensure that Equations 5.32 through 5.34 do not become production terms in Equations 5.27 through 5.30.

† The Reynolds-averaged Reynolds stress was compared, and it is related to the Favre average by $\overline{u_i'u_j'} = \tilde{R}_{ij} + a_i a_j - \frac{\overline{\rho' u_i' u_j'}}{\bar{\rho}}$, where the last term is typically negligible compared to the first two terms on the right-hand side.

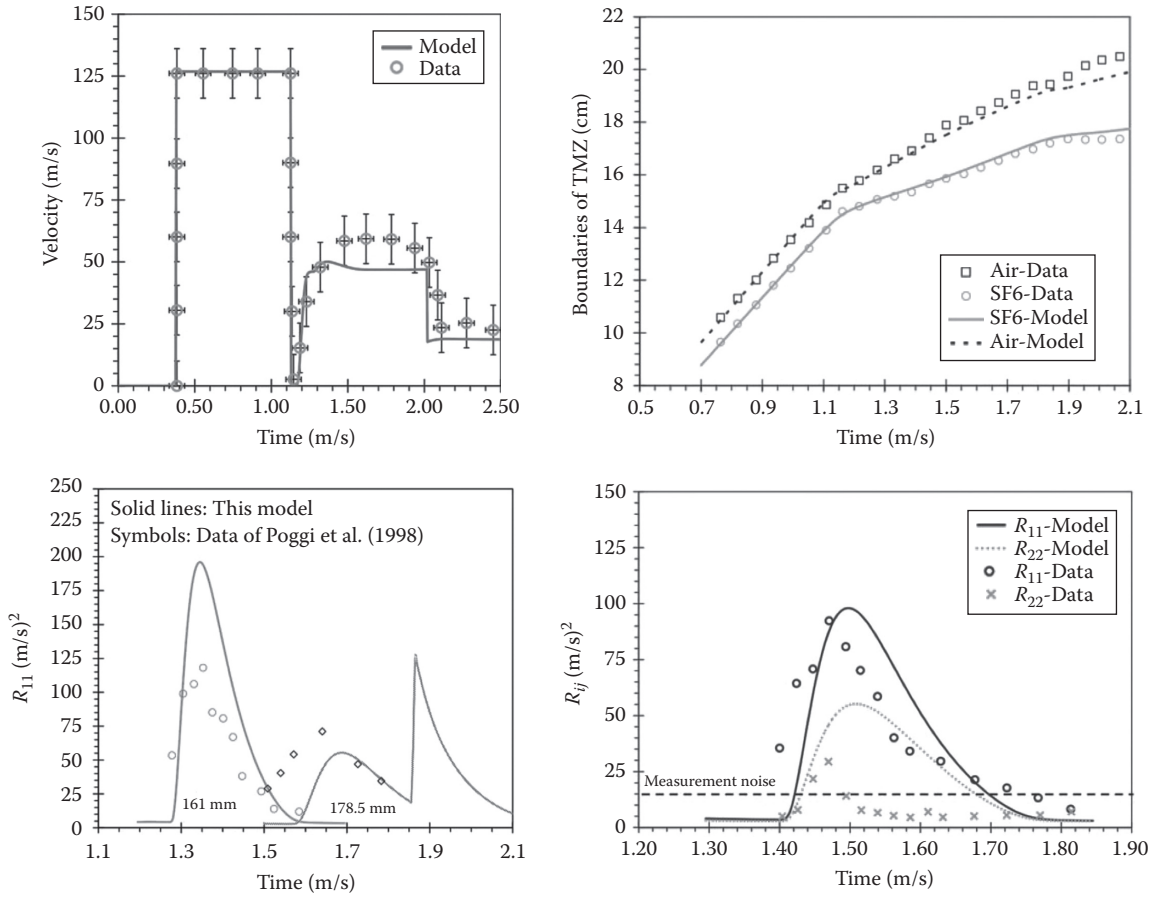

Figure 5.3

Comparison of the velocity, turbulence mixing zone thickness, and Reynolds stresses. Symbols (measurements from shock tube experimental data, Poggi et al. (1998)) and lines (model described by Equations 5.20 through 5.22 and 5.25 through 5.30) show reasonable agreement for 161 mm, 169 mm (shown in the bottom right), and 178.5 mm downstream from the initial interface position. (Reprinted from Schwarzkopf, J.D. et al., *J. Turb.*, 12, 1, 2011. With kind permission from Taylor & Francis.)

The conservation equations are given for

$$\text{Mass} \quad \frac{\partial}{\partial t}\left(\alpha\rho\right)_1 + \frac{\partial}{\partial x_j}\left(\alpha\rho u_j\right)_1 = -\dot{M}, \tag{5.35}$$

$$\frac{\partial}{\partial t}\left(\alpha\rho\right)_2 + \frac{\partial}{\partial x_j}\left(\alpha\rho u_j\right)_2 = \dot{M}, \tag{5.36}$$

$$\text{Momentum} \quad \frac{\partial}{\partial t}\left(\alpha\rho u_i\right)_1 + \frac{\partial}{\partial x_j}\left(\alpha\rho u_i u_j + \delta_{ij}\alpha p\right)_1 = p_I \frac{\partial \alpha_1}{\partial x_i} + \Phi\left(u_{2i} - u_{1i}\right) - \dot{M}u_{1i}, \tag{5.37}$$

$$\frac{\partial}{\partial t}\left(\alpha\rho u_i\right)_2 + \frac{\partial}{\partial x_j}\left(\alpha\rho u_i u_j + \delta_{ij}\alpha p\right)_2 = p_I \frac{\partial \alpha_2}{\partial x_i} - \Phi\left(u_{2i} - u_{1i}\right) + \dot{M}u_{1i}, \tag{5.38}$$

$$\text{Energy} \quad \frac{\partial}{\partial t}\left(\alpha\rho E\right)_1 + \frac{\partial}{\partial x_j}\left(\alpha u_j\left[\rho E + p\right]\right)_1 = p_I U_i \frac{\partial \alpha_1}{\partial x_i} + \Phi U_i^I\left(u_{2i} - u_{1i}\right) - \dot{M}H_1 - \Psi\left(p_1 - p_2\right) + hA_{eff}\left(T_2 - T_1\right), \tag{5.39}$$

$$\frac{\partial}{\partial t}\left(\alpha\rho E\right)_2+\frac{\partial}{\partial x_j}\left(\alpha u_j\left[\rho E+p\right]\right)_2=p_I U_i\frac{\partial\alpha_2}{\partial x_i}-\Phi U_i^I\left(u_{2i}-u_{1i}\right)+\dot{M}H_1+\Psi\left(p_1-p_2\right)-hA_{eff}\left(T_2-T_1\right), \quad (5.40)$$

where

α is the volume fraction (the saturation Equation 5.23 applies)
ρ is the material density
u is the velocity
p is the pressure
E is the total energy ($e + u^2/2$)
$\dot{M}$ is the mass transfer due to burning or phase change (assuming $1 \rightarrow 2$)
Φ and Ψ are coefficients
p_I and U_i are the interfacial pressure and velocity, respectively
U_i^I is the impedance-averaged velocity
H is the enthalpy of the phase transferring mass
h is the heat transfer coefficient
A_{eff} is the effective area over which heat is being transferred from one phase to the other and the subscripts 1 and 2 relate to continua

Saurel et al. (2007a) set $\dot{M}=0$ and neglected the heat transfer coefficient by assuming that the heat transfer was much slower than the mechanical relaxation. The terms containing volume fraction gradients are referred to as the *nozzling* terms, which account for rapid changes in volume or cross-sectional area of the flow due to compression or expansion of one phase relative to the other.

If porous (or solid) materials (assuming subscript 1) are considered, then a compaction equation is necessary to determine the proper density of the material during chemical reactions or after shock release. This process is modeled as (described in Kapila et al. (2001))

$$\frac{\partial\rho_1}{\partial t}+\frac{\partial\rho_1 u_{1j}}{\partial x_j}=-\frac{\rho_1\alpha_2}{\mu_{cp}}\left(p_1-p_2\right), \quad (5.41)$$

where μ_{cp} is the compaction viscosity. Alternatively, the compaction equation can be written in terms of the volume fraction

$$\frac{\partial\alpha_1}{\partial t}+\begin{Bmatrix}u_{1j}\\U_{1j}\end{Bmatrix}\cdot\frac{\partial\alpha_1}{\partial x_j}=\begin{cases}\dfrac{\alpha_1\alpha_2}{\mu_{cp}}\left(p_1-p_2\right)-\dfrac{\dot{M}}{\rho_1} & \text{(Kapila et al. 2001),}\\ \mu_Z\left(p_1-p_2\right) & \text{(Saurel et al. 2007a).}\end{cases} \quad (5.42)$$

In the conservation equations, the parameter, Φ, has units of mass/(length$^3\cdot$time) and represents drag in Kapila's model and is defined as a velocity relaxation coefficient in Saurel's model

$$\Phi=\begin{cases}\mu/L^2-\dot{M}/2 & \text{(Kapila et al. 2001),}\\ \mu_Z\zeta_1\zeta_2 & \text{(Saurel et al. 2007a),}\end{cases} \quad (5.43)$$

where

μ is the dynamic viscosity of the flowing material
L is a characteristic length scale associated with the drag effects
$\zeta = \rho c$ represents the acoustic impedance

The parameter μ_Z is the pressure relaxation coefficient

$$\mu_Z=\frac{A_I}{2\left(\zeta_1+\zeta_2\right)}, \quad (5.44)$$

where A_I is the specific interfacial area (i.e., A_I = (area/vol)). The parameter Ψ is (1) the compaction coefficient in Kapila's model and (2) the pressure relaxation at the two-phase interface in Saurel's model

$$\Psi = \begin{cases} p_2\alpha_1\alpha_2/\mu_{cp} & \text{(Kapila et al. 2001)}, \\ \mu_Z \dfrac{\zeta_2 p_1 + \zeta_1 p_2}{\zeta_2 + \zeta_1} & \text{(Saurel et al. 2007a)}. \end{cases} \tag{5.45}$$

Saurel et al. (2007a) applied the work of Abgrall and Saurel (2003) to close the interface variables U_i and p_I, which are given in terms of the acoustic impedance

$$p_I = \frac{\zeta_2 p_1 + \zeta_1 p_2}{\zeta_2 + \zeta_1} + \text{sgn}\left(\frac{\partial \alpha_1}{\partial x_i}\right)\frac{\zeta_2\zeta_1}{\zeta_2 + \zeta_1}\left(u_{2i} - u_{1i}\right), \tag{5.46}$$

$$U_i = U_i^I + \text{sgn}\left(\frac{\partial \alpha_1}{\partial x_i}\right)\frac{p_2 - p_1}{\zeta_2 + \zeta_1}, \quad \text{where } U_i^I = \frac{\zeta_2 u_{2i} + \zeta_1 u_{1i}}{\zeta_2 + \zeta_1}, \tag{5.47}$$

and Kapila et al. (2001) set the interfacial variables as $p_I = p_2$ and $U_i = U_i^I = u_{1i}$.

The timescale for velocity equilibration between the two materials is estimated as $\tau_{vel} \sim \alpha\rho L^2/\mu$, where L is a characteristic length scale related to the drag and, for porous materials, L^2 is the permeability (Kapila et al., 2001). The timescale for pressure equilibration between two materials is $\tau_{press} \sim \mu/p$, and the timescale for thermal equilibrium is $\tau_{therm} \sim \rho C_v L^2/k$, where k is the thermal conductivity. Kapila et al. (2001) provide estimates for these timescales associated with an explosive material.

According to Saurel et al. (2007a), this nonequilibrium two-fluid model, that is, Equations 5.35 through 5.40, can describe shock propagation in mixtures when solved by an appropriate numerical algorithm.* The model was applied to a test case consisting of periclase and epoxy, $|At| = 0.5$. Overall, excellent agreement is found between the numerical model and the experiments for the shock velocity, material velocity, pressure, and density, shown in Figure 5.4.

In addition to the models mentioned earlier, there are several other two-fluid models in the literature, some of which are tailored to a specific flow type. However, all contain models that capture the general features of interfacial physics such as mass, momentum, and heat transfer and chemical reactions. Llor (2005) describes closure models for the turbulence in two-fluid models and also describes Young's two-fluid turbulence model (Youngs, 1995). Saurel et al. (2007b) and Petitpas et al. (2007) discuss a relaxation method for pressure computation using complex equation of state (EOS) that is capable of problems with interfaces having large density differences and strong shocks. Other approaches to modeling two-fluid nonequilibrium flows can be found in Gallouet et al. (2004), García-Cascales and Paillére (2006), Niu et al. (2008), and Yeom and Chang (2013). These references also provide methods for developing a set of discretized equations and numerical schemes.

5.2.3 Shock Interaction with Material Interfaces

A normal shock (planar wave) impacting an interface with different density materials sends transmitting and reflecting shocks though the materials. If a shock is traveling through a low density material and encounters a high density material, a reflected shock travels back through the lower density material and a transmitted shock propagates through the higher density material, shown in Figure 5.5a. However, if a shock is traveling through a high density material and encounters a drop in density, a rarefaction wave reflects (scatters back) through the high density material and a shock is transmitted through the lower density materials, shown in Figure 5.5b. Harlow and Amsden (1971) note several important observations after a shock has passed across a material discontinuity: (1) if no material passes across the material discontinuity, then the velocity across the interface must be constant, and (2) the pressure across the material discontinuity must be continuous or infinite acceleration would exist. Harlow and Amsden (1971) provide shock relations for the variable density shock tube scenarios shown in Figure 5.5.

Shocks passing over surfaces with perturbations, caused by a manufacturing finish, can lead to the formation of particles, referred to as ejecta. If the shock is strong enough, this process is initiated by the RM instability, which forms sheets, and these sheets transition to ligaments and then break apart to form droplets or particles. Further discussion on the shock interaction with perturbed surfaces is given in Section 5.4.

* The reader is referred to Saurel et al. (2007a) for additional details.

Shock impacting a material interface with (a) step-up in density and (b) step-down in density, as depicted by Harlow and Amsden (1971).

5.2.4 Equation of State and Jump Relations

For mechanical and thermal equilibrium and nonequilibrium assumptions, an EOS is needed to relate the average pressure and internal energy. Typical models are the ideal gas, stiff gas, and Mie–Grüneisen (Mie, 1903, Grüneisen, 1912), described as

$$\text{Ideal gas} \quad \langle p\rangle = \left(\langle\gamma\rangle - 1\right)\overline{\rho}\tilde{e}, \tag{5.48}$$

$$\text{Stiff gas} \quad \langle p\rangle = \left(\langle\gamma\rangle - 1\right)\overline{\rho}\tilde{e} + \langle\gamma\rangle\langle p_\infty\rangle, \tag{5.49}$$

$$\text{Mie Grüneisen} \quad \langle p\rangle = \langle\Gamma\rangle\overline{\rho}\left(\tilde{e} - \tilde{e}_H(\rho)\right) + \langle p_H(\rho)\rangle, \tag{5.50}$$

where

$\tilde{e} = \tilde{e}\left(\langle p,\rangle\overline{\rho}\right)$ is the average specific internal energy
$\langle p\rangle$ is the average pressure of the mixture
$\overline{\rho}$ is the mixture density given by Equation 5.11
$\langle\gamma\rangle$ is the ratio of specific heats for the mixture given by Equation 5.12
$\langle\Gamma\rangle = \langle V(dp/de)_V\rangle$ is the average Grüneisen parameter for the mixture

The averages apply only to mixture regions; in regions of pure fluid, the averages are equal to the instantaneous values, for example, $\langle p\rangle = p$. The subscript H in the Mie–Grüneisen equation refers to a reference curve such as a Hugoniot for a specific material. The parameters $\langle\gamma\rangle$ and $\langle p_\infty\rangle$ in the stiff gas equation are fit to a specific material or mixture. For the ideal and stiff gas relations, the temperature is related to the internal energy by the specific heat

$$\tilde{e} = C_v\tilde{T}, \tag{5.51}$$

and for the Mie–Grüneisen

$$\tilde{e} - \tilde{e}_H(\rho) = C_v\left(\tilde{T} - \tilde{T}_H(\rho)\right). \tag{5.52}$$

The Hugoniot curve is approximated by the linear relation

$$u_s = c_+ + su_-, \tag{5.53}$$

where

u_s is the shock speed
c_+ is the speed of sound of the material ahead of the shock
u_- is the postshock velocity of the material behind the shock
the coefficient s is determined by shock compression data for a specific material

In a single material, the averages in the earlier relations are taken as the properties of the material.

Petel and Jetté (2010) note that there are three major categories for determining shock propagation in mixtures: (1) unsteady flow models that attempt to resolve the interactions of mixture components, (2) steady models of mixtures in mechanical equilibrium, and (3) mechanical and thermal equilibrium models. However, the models all assume some sort of mixture properties based on averaging, and therefore, the differences between such models, when comparing to experimental data, are small.

Saurel et al. (2007a) give the general Rankine–Hugoniot jump conditions for a system of conservation laws of the form

$$\frac{\partial B}{\partial t} + \frac{\partial F(B)}{\partial x} = 0, \quad \text{as} \tag{5.54}$$

$$F(B_-) - v_sB_- = F(B_+) - v_sB_+. \tag{5.55}$$

For mechanical and thermal equilibrium conditions, neglecting the turbulence terms, the jump conditions for Equations 5.18 through 5.22 are

$$\alpha_+^k \langle \rho \rangle_+^k \left(\tilde{u}_+ - v_s \right) = \alpha_-^k \langle \rho \rangle_-^k \left(\tilde{u}_- - v_s \right), \quad \text{or} \tag{5.56}$$

$$\bar{\rho}_+ \tilde{c}_+^k \left(\tilde{u}_+ - v_s \right) = \bar{\rho}_- \tilde{c}_-^k \left(\tilde{u}_- - v_s \right), \quad \text{and} \tag{5.57}$$

$$\bar{\rho}_+ \tilde{u}_+ \left(\tilde{u}_+ - v_s \right) + \langle p \rangle_+ = \bar{\rho}_- \tilde{u}_- \left(\tilde{u}_- - v_s \right) + \langle p \rangle_-, \tag{5.58}$$

$$\bar{\rho}_+ \left(\tilde{u}_+ - v_s \right) \tilde{E}_+ + \langle p \rangle_+ \langle u \rangle_+ = \bar{\rho}_- \left(\tilde{u}_- - v_s \right) \tilde{E}_- + \langle p \rangle_- \langle u \rangle_-, \tag{5.59}$$

where subscripts + and − refer to the preshock and postshock conditions, respectively.

However, for mechanical and thermal nonequilibrium models, there arises a complexity in capturing the interaction or relaxation terms. Saurel et al. (2007a) applied the mechanical equilibrium condition to Equations 5.35 through 5.40. This condition eliminates the relaxation parameters, greatly simplifying the equations. Jump conditions were derived with the assumption that the two fluids have different internal energies and are given as

$$\frac{\alpha_+^k \rho_+^k}{\bar{\rho}_+} = \frac{\alpha_-^k \rho_-^k}{\bar{\rho}_-}, \tag{5.60}$$

$$\bar{\rho}_+ \left(\tilde{u}_+ - v_s \right) = \bar{\rho}_- \left(\tilde{u}_- - v_s \right) = m, \tag{5.61}$$

$$p_+ - p_- + m^2 \left(\upsilon_+ - \upsilon_- \right) = 0, \tag{5.62}$$

$$e_+^k - e_-^k + \frac{1}{2} \left(p_+ + p_- \right) \left(\upsilon_+^k - \upsilon_-^k \right) = 0, \tag{5.63}$$

where

v_s is the shock velocity

υ^k is the specific volume of species k

They then applied these jump conditions to a variety of experiments with various Atwood numbers comparing shock velocity, pressure, material velocity, and volume fraction and specific volume where available. Overall, the comparisons are very good for numerous material mixtures. A moderate $At = 0.45$ water and calcite comparison is shown in Figure 5.6.

The earlier discussion on multiphase, multicomponent flows has been central to the assumption that the phases are continuous. Next, we relax this assumption and consider methods to model a discontinuous phase within a continuous phase.

5.3 Compressible Dispersed Phase Flows

Dispersed phase flows contain particles or droplets that are dispersed throughout a continuous phase, such as rain drops in air. This type of flow is typically modeled using an Eulerian frame for the continuous phase and Lagrangian tracking for the particle motion. The boundaries and gradients between the particle (dispersed) and the carrier (continuous) phases require attention. A direct numerical, or fully resolved, simulation for particle-laden flows would simulate the flow near the particle surface, which includes resolving the viscous sublayer and the wake region. For problems involving millions of particles, this is computationally prohibitive. The next best method is to average the carrier phase equations and track the effects of multiple particles.

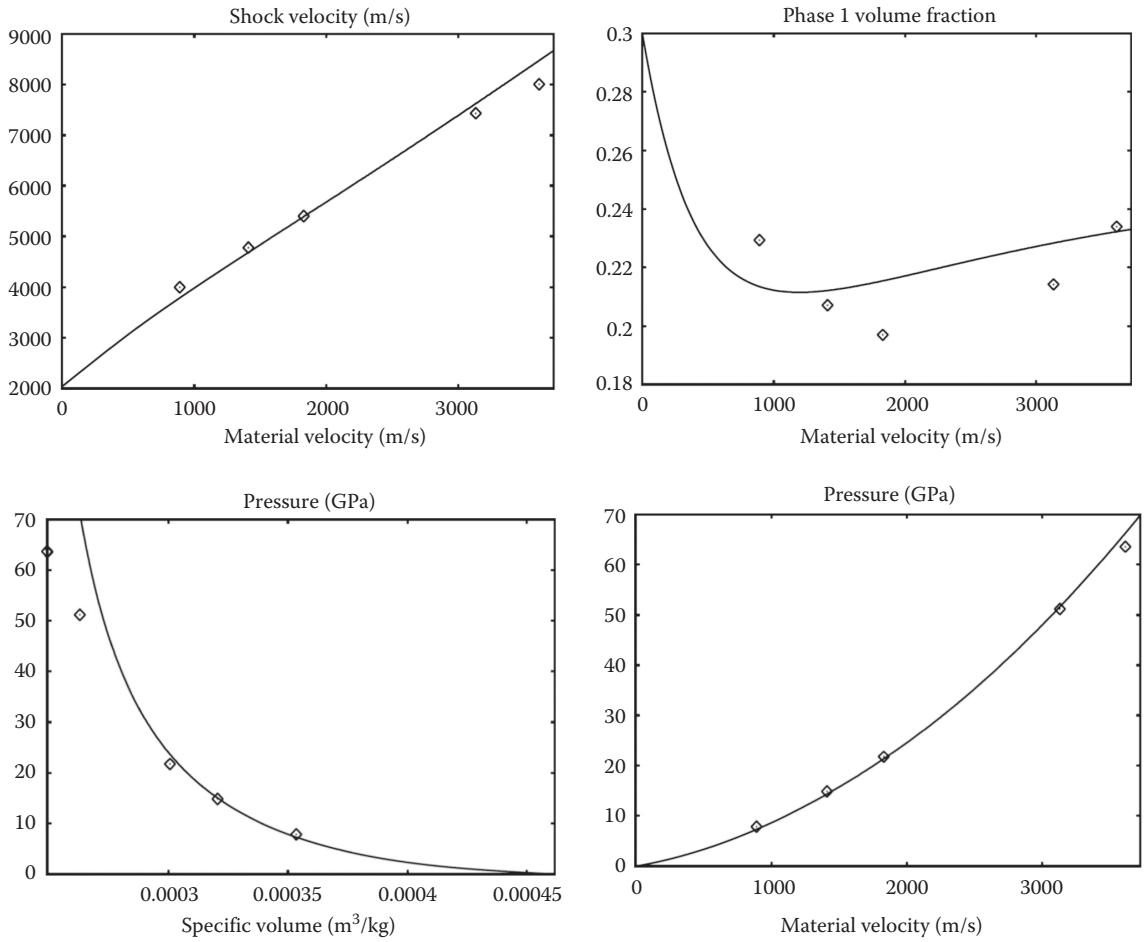

Figure 5.6

Comparison of jump relations with experimental data for a mixture of water and calcite. (With kind permission from Springer Science + Business Media: *Shock Waves*, Shock jump relations for multiphase mixtures with stiff mechanical relaxation, 16, 209, 2007, Saurel, R., Le Métayer, O., Massoni, J., and Gavrilyuk, S.)

The method of volume averaging, introduced by Slattery (1972) and further developed by Crowe et al. (2012) (briefly discussed in Section 5.1.1.2), accounts for the interactions between the dispersed and carrier phases. Models are then applied to determine the hydrodynamic drag force, heat transfer, etc., between the phases. These models are valid for dilute flows, which assume that the particles do not interact and are a sufficient distance apart. Models for tracking multiple particles, such as the particle-source-in-cell method Crowe et al. (2012) or the multiphase particle-in-cell model (Andrews and O'Rourke, 1996), are used to determine the forces acting on several particles that are nominally the same size, velocity, etc.

There are many examples of droplet/particle flows in energy conversion and propulsion systems ranging from coal-fired or oil-fired furnaces to drying systems. Examples of compressible particle-laden flows include fuel injection in a combustion chamber, rocket propulsion, volcanic eruption, explosive debris, supernova explosion, aerodynamic ablation, and shocked liquid or solid surfaces. Previous importance has been placed on explosion in confined areas, such as powder mills, mine shafts, and chemical plants; however, recent importance includes pulsed detonation engines, attenuation or augmentation of detonation waves (Chang and Kailasanath, 2003), and effects of explosive debris.

In this section, we describe some of the physics and present models associated with compressible particle-laden flow, but first we introduce the reader (i.e., new to this field) to some of the nomenclature.

5.3.1 Background and Nomenclature

The dispersed phase is described as particles, droplets, or bubbles that are surrounded and carried by a continuous phase (liquid or gas). An example would be aluminum particles (dispersed phase) transported in air (carrier phase). The terminology used is described as follows.

5.3.1.1 Dilute and Dense Flows

Dilute flows are described as flows with sufficient enough spacing between the particles such that the particle motion is governed by the hydrodynamic forces (i.e., particle contact is absent or minimal). Dense flows are described as collision- or contact-dominated flows, such as granular flows. It is difficult to delineate dense and dilute flows. Typically, if the dispersed phase volume fraction is less than 0.001, the flow is thought to be dilute. Crowe et al. (2012) suggest that dilute flow exists if

$$\frac{\tau_V}{\tau_C} < 1, \tag{5.64}$$

where

τ_V is the particle response time

τ_C is the average time between particle–particle collisions, defined as

$$\tau_C = \frac{1}{f_C} = \frac{1}{4\sqrt{\pi} n D^2 v'}, \tag{5.65}$$

where

n is the particle number density

D is the diameter

v' is the fluctuation velocity (Abrahamson, 1975)

The dilute regime can be further simplified as very dilute when the volume fraction is so low that each particle can be considered dynamically relatively independent of all other particles. When the flow is dilute, but not very dilute, gas-mediated particle–particle interaction must be accounted in terms of volume fraction effect on drag and heat transfer correlations. This indirect influence of the neighboring particles can be substantial in the dilute regime even though direct particle–particle interaction through collisions may be rare and unimportant.

5.3.1.2 Phase Coupling

Depending on the nature of the multiphase flow, phase coupling could be important when considering modeling choices for multiphase flows. Phase coupling describes the interactions between the dispersed and carrier phase flows. One-way coupling accounts for the effects of the carrier phase on the dispersed phase but not vice versa; it assumes that the particle number and size have a negligible effect on the fluid. This typically is the case under very dilute condition. An example of one-way coupling is heat transfer from the carrier phase to a single particle. One-way coupling is sometimes assumed in the derivation of shock jump relations. Two-way coupling considers mass, momentum, and energy transfer between the particle and the carrier phase. Two-way coupling is important in the dilute (but not very dilute) regime. Back coupling is another term (often used in place of two-way coupling) to indicate when the particle influences the carrier phase. When the particle volume fraction increases above the dilute limit then particle–particle interaction becomes important and the flow is in the four-way coupled regime (Elghobashi, 1994, Balachandar and Eaton, 2010).

5.3.2 Compressible Dilute Particle Flows

In this section, we present two-way coupled models for capturing the effect of the dispersed phase on the carrier phase and vice versa and comment on the importance of terms in shocked flows. We begin with a short discussion on particle momentum and thermal response time and how it relates to shock transit times. We then discuss the importance of Mach and Reynolds numbers on the hydrodynamic drag and present recent models developed for compressible flows. We then introduce the carrier phase equations in Eulerian form and the equations for particle motion in Lagrangian form.

5.3.2.1 Response Times

Response times are important characterization parameters in particle-laden flows. The derivations of the response times can be found in Crowe et al. (2012).

The momentum response time is the time required for the velocity of a particle to reach a percentage of the carrier phase velocity due to particle drag and is given as

$$\tau_p = \frac{\rho_d D^2}{18\mu_c}, \tag{5.66}$$

where

ρ_d is the particle density
D is the diameter (assuming spheres)
μ_c is the dynamic viscosity of the carrier phase fluid

The momentum response time of a particle gives an indication of how likely the particle is to accelerate due to a force imposed on it, such as a shock. As a shock passes over nanosized particles with low density, the particles will likely follow closely behind the shock and may produce preferential concentration (Maxey, 1987, Maxey et al., 1997). However, if the particles are large with sufficient mass, their response in motion due to the passage of a shock may be negligible. Likewise, the thermal response time is the time required for a particle to reach a percentage of the carrier phase temperature given as

$$\tau_T = \frac{\rho_d C_d D^2}{12 k_c}, \tag{5.67}$$

where

C_d is the specific heat of the dispersed phase material
k_c is the thermal conductivity of the carrier phase material

The Stokes number is defined as

$$St_V = \frac{\tau_V}{\tau_F}, \tag{5.68}$$

where

τ_F is a characteristic timescale of the carrier phase flow
τ_V is the particle response time and it can be taken to be either τ_p or τ_T

Another important parameter in shocked particle-laden flows is the ratio of the time it takes for a shock to traverse a particle to the response of the particle motion, such as

$$\frac{\tau_s}{\tau_p} = \frac{18\mu_c}{U_s \rho_d}. \tag{5.69}$$

In shocked flows if $\tau_s/\tau_p \geq 1$, the unsteady effects, such as added mass or history terms, are very important, whereas if $\tau_s/\tau_p \ll 1$, the unsteady effects can be neglected. To illustrate this, data were taken from experiments of particles in shocked air, and the ratio of the timescales was plotted as a function of the shock Mach number for various values of particle mass per unit area ($\rho_d D$), shown in Figure 5.7. From the data (for particles in air), if $\tau_s/\tau_p < 10^{-3}$, the acceleration effects can be neglected. For shocked air, particles with large $\rho_d D$ do not respond to the acceleration effects caused by the shock nearly as much as particles with small $\rho_d D$ values. If $\rho_d D > 0.01$ kg/m^2, in air, one can assume that the unsteady terms can be neglected. The previous statements are valid for dilute conditions, such as shock propagation over nearly isolated particles, where the effect of the particles on the gas (back coupling) and gas-mediated particle–particle interaction effects are negligible. When particle volume fraction and the back-coupling effects on the gas flow are substantial, the timescale of the postshock flow can be much longer than the timescale of shock propagation over an individual particle, and correspondingly, the unsteady effects can become important (Ling et al., 2012, 2013).

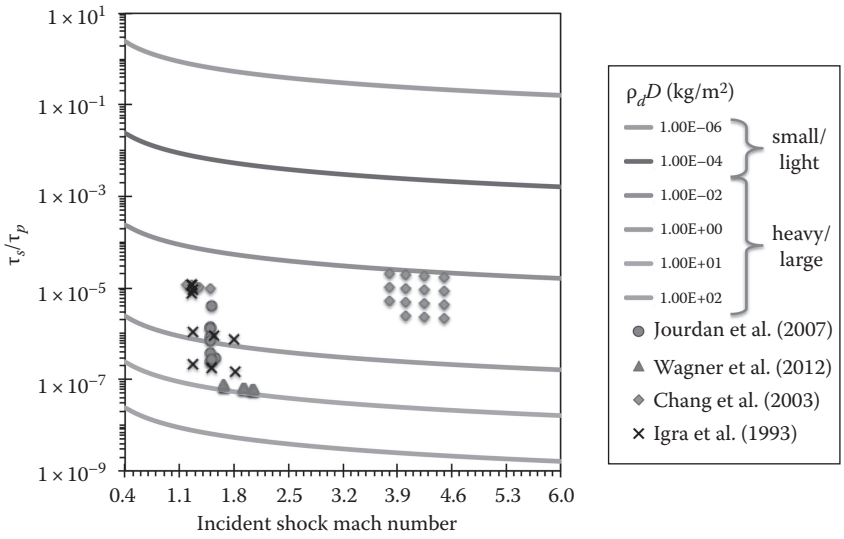

Figure 5.7

Ratio of shock transit time over a particle to the particle response time for various incident shock Mach numbers and $\rho_d D$ values in air.

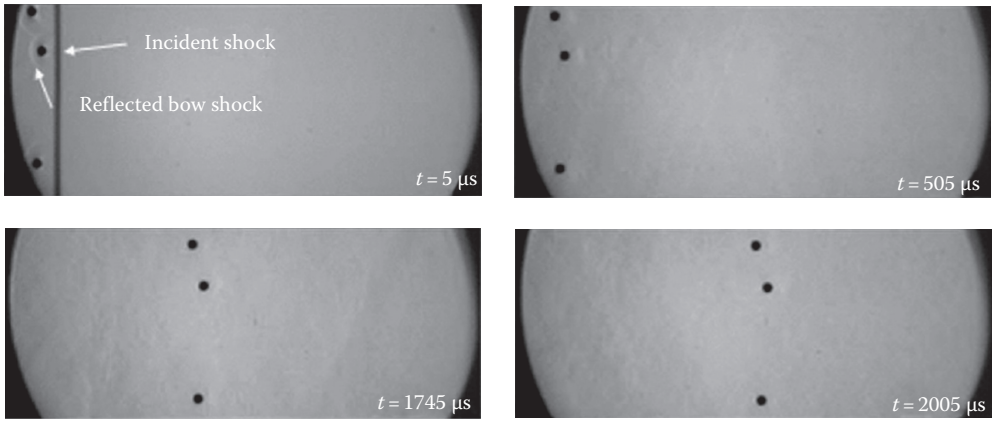

Figure 5.8

Schlieren images, provided by Wagner et al. (2012), showing the lag in particle motion after the passage of a 1.68 Mach shock over stainless steel 1 mm particles. (Reprinted with permission from Wagner, J.L., Beresh, S.J., Kearney, S.P., Pruett, B.O.M., and Wright, E.K., Shock tube investigation of quasi-steady drag in shock-particle interactions, *Phys. Fluids*, 24, 123301. Copyright 2012, American Institute of Physics.)

A Schlieren image of particles with $\rho D \sim 7.6$ kg/m^2 was provided by Wagner et al. (2012), shown in Figure 5.8. At 5 μs, the incident shock has passed over the particles and by 500 μs the shock is out of the image. After the passage of the shock, the pressure and velocity of the gas, outside of the particle wake and reflected shock region, have equilibrated. The particle response time is 23 s and the acceleration of the particle is nearly constant (~10^4 m/s^2) for the first 2 ms, and the gas velocity is constant at 312 m/s. Beyond 5 μs, the particle motion is primarily due to drag effects.

Another indication that the unsteady effects may be negligible is the ratio of the carrier phase density to the particle density. If $\rho_c/\rho_d \ll 0.001$, then the unsteady contribution to the particle motion can be neglected. For the experiment shown in Figure 5.8, $\rho_c/\rho_d \sim 1.5 \cdot 10^{-4}$.

5.3.2.2 Mach and Reynolds Number Effects

Particle Mach and Reynolds number effects are important in compressible particle-laden flows. The particle Reynolds number is defined as

$$Re_p = \frac{\rho_c D|u-v|}{\mu_c}, \tag{5.70}$$

where $|u - v|$ is the relative velocity, which is the magnitude of the velocity difference between the carrier phase velocity (u) and the dispersed phase velocity (v). The particle Mach number is also defined in terms of the relative velocity as

$$M_p = \frac{|u-v|}{c_c}, \tag{5.71}$$

where c_c is the sound speed of the carrier phase. Another important parameter is the particle Knudsen number, which characterizes a rarefied flow and defined as*

$$Kn_p = \frac{\lambda_m}{D}, \tag{5.72}$$

where λ_m is the mean free path of the carrier phase molecules in the vicinity of the particle, defined as

$$\lambda_m = \frac{M_{mol}}{\sigma_c \rho_c A_v}, \tag{5.73}$$

where

σ_c is the collision cross section
M_{mol} is the molar mass
A_v is Avogadro's number

There are several regions described for rarefied flows:

$$\begin{aligned} &Kn_p < 0.01 \quad \text{continuum flow} \\ &0.01 \le Kn_p < 0.1 \quad \text{slip flow} \\ &0.1 \le Kn_p < 10 \quad \text{transition flow} \\ &Kn_p > 10 \quad \text{free molecular flow} \end{aligned}$$

These parameters have an important effect on particle drag in compressible or rarefied flows. The critical M_p is defined as the limit that below the drag coefficient is indistinguishable from incompressible flows. The critical Re_p distinguishes rarefied flow from compressible flow and the critical Kn_p separates continuum from rarefied flow. The established values or ranges are

$$\begin{aligned} &M_{p_c} = 0.6 \quad \text{critical Mach number} \\ &Re_{p_c} = 40 - 45 \quad \text{critical Reynolds number} \\ &Kn_{p_c} = 0.01 \quad \text{critical Knudsen number} \end{aligned}$$

* It can also be shown that $Kn_p \propto M_p/Re_p$ (Loth, 2008, Crowe et al., 2012).

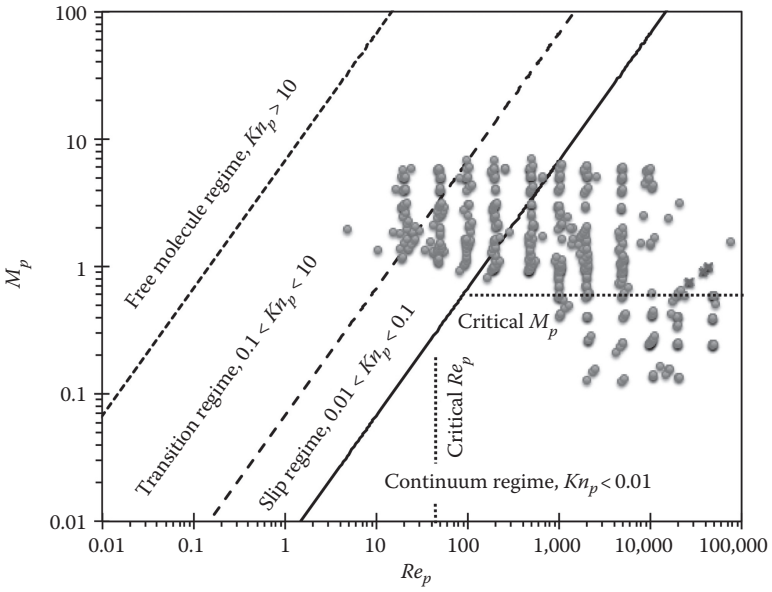

Figure 5.9

Continuum, compressible, transition, and free molecular flow regimes for M_p and Re_p for air (the mean free path was taken at standard pressure and temperature). (Data abstracted from Bailey, A.B. and Hiatt, J., Free-flight measurements of sphere drag at subsonic, transonic, supersonic, and hypersonic speeds for continuum, transition, and near-free-molecular flow conditions, Office of Aerospace Research, Tech. Rep., AEDC-TR-70-291, 1971 (dots); Wagner, J.L. et al., *Phys. Fluids*, 24, 123301, 2012 (x).)

The continuum regime to the free molecular flow regime for air is plotted in M_p and Re_p space and shown in Figure 5.9. The critical M_p and Re_p are identified in this plot along with data from Bailey and Hiatt (1971) and Wagner et al. (2012) spanning the incompressible, compressible, slip, and transition regimes.

5.3.2.3 Drag Coefficient

When a particle travels through a carrier phase (e.g., a gas), the particle experiences a drag force that is caused by the pressure gradient and the viscous shear effects due to the velocity difference between the particle and the surrounding gas. In a Stokes regime, the drag force acting on the particle can be computed analytically; however, outside of the Stokes regime, a Re_p correction to the Stokes drag is required to obtain the measured drag force. In compressible flows, additional corrections for M_p and Kn_p are applied to obtain the measured drag force.

The dependence of the quasi-steady drag coefficient (C_D) on M_p and Re_p is shown in Figure 5.10. The quasi-steady drag is sufficient to compute the total drag force on a particle when unsteady effects are unimportant. These data from Bailey and Hiatt (1971) show that $C_D \to 1$ for large M_p and Re_p and $1 < C_D < 2$ near Re_{pc}. For $Re_p > 1000$, the drag coefficient does not vary much for $1.75 < M_p < 7$. At low Re_p and high M_p, the data by Macrossan (2004) show that $2 < C_D < 3$ and appear to extend into the free molecular regime where the drag coefficient is independent of Re_p (for $M_p > 0.5$) and decreases monotonically toward the transition regime (Crowe, 1967).

In the compressible regime, the quasi-steady drag coefficient is significantly affected by flow compressibility when M_p exceeds a critical value ($M_{p,cr}$). When this happens, the flow, as it accelerates around the particle, becomes locally supersonic resulting in the formation of a shock. With increasing M_p, this shock moves upstream and collapses to a bow shock for $M_p > 1.0$, as shown in Figure 5.8. The presence of a shock increases the quasi-steady drag force, and this effect is distinct from the unsteady effects. Wagner et al. (2012) were careful to reduce the unsteady effects in their shock tube experiment and deduced that the increase in the drag coefficient was due to compressibility effects, for example, increased relative velocity difference and not acceleration/unsteady effects. In order to understand this effect of compressibility, it is convenient to conceptually separate the inviscid and viscous contributions to the drag force on the particle. When $M_p < M_{p,cr}$, the steady inviscid uniform flow around a particle will remain potential (i.e., irrotational) and make zero contribution to the drag force. In this regime, the effect of M_p on the viscous drag is not strong. At postcritical M_p, the appearance of a shock within

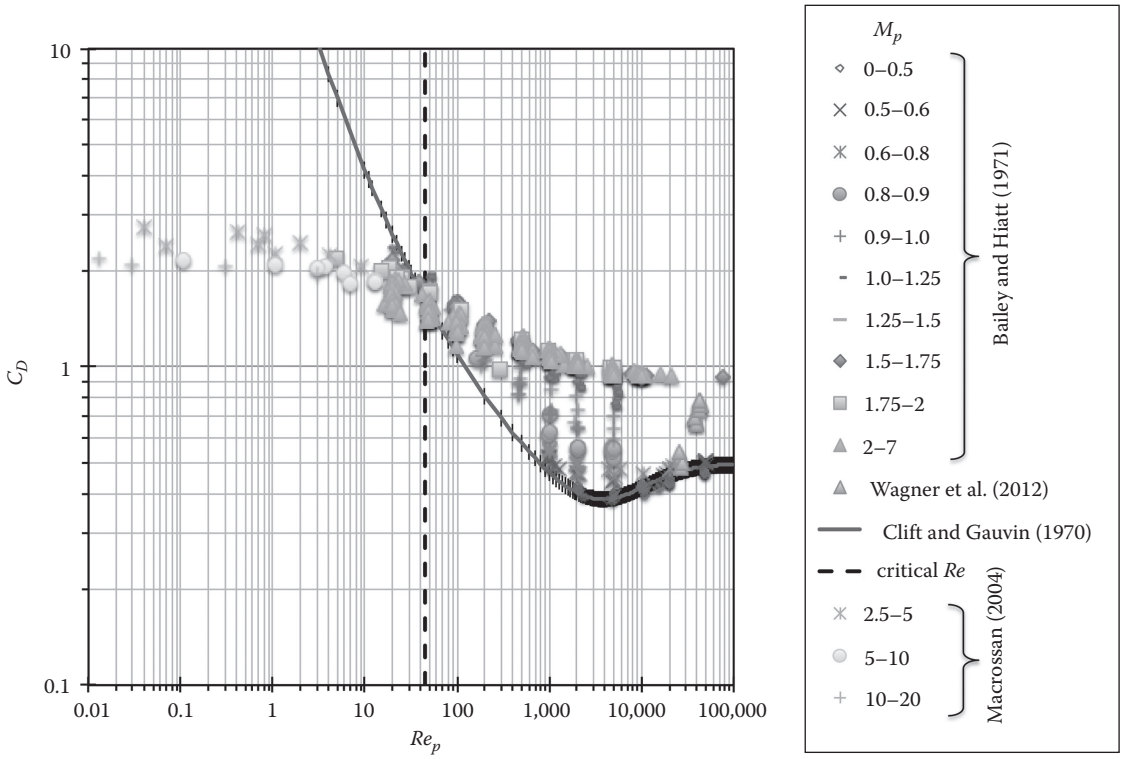

Figure 5.10

Measured drag coefficients for compressible and transitional flow over a wide range of particle Mach and Reynolds numbers. The solid line and the bars represent the uncertainty in the correlation developed by Clift and Gauvin (1970) for the incompressible drag coefficient.

the flow breaks the fore-aft symmetry of even the steady uniform inviscid flow. This results in a nonzero inviscid contribution to the quasi-steady force. Thus, for $M_p > M_{p,cr}$, there is a strong compressibility effect on the quasi-steady drag force.

There are several empirical correlations for the Mach and Knudsen effect on the drag coefficient. Commonly used correlations were developed by Crowe (1967) and Henderson (1976). More recently, Loth (2008) developed a correlation for the compressible and rarefied regimes with transition criteria. Later, Parmar et al. (2010) developed a detailed correlation for the compressible flow region that is valid up to $M_p = 1.75$, $Re_p = 2 \cdot 10^5$, and $Kn_p \leq 0.01$. For the incompressible and compressible regimes, the correlation for the drag coefficient proposed by Parmar et al. (2010) is

$$C_D(M_p) = \begin{cases} C_{D,std} + \left(C_{D,M_{cr}} - C_{D,std}\right)\dfrac{M_p}{M_{cr}} & \text{if } M_p \leq M_{cr}, \\ C_{D,M_{cr}} + \left(C_{D,M=1} - C_{D,M_{cr}}\right)\xi_{sub} & \text{if } M_{p,cr} < M_p \leq 1.0, \\ C_{D,M=1} + \left(C_{D,M=1.75} - C_{D,M=1}\right)\xi_{sup} & \text{if } 1.0 < M_p \leq 1.75. \end{cases} \tag{5.74}$$

The standard equation for the drag coefficient is modeled after Clift and Gauvin (1970) and is of the form

$$C_{D,\chi} = \frac{24}{Re_p}\left(1 + A_1 Re_p^{n1}\right) + A_2\left(1 + \frac{A_3}{Re_p^{n2}}\right)^{-1}, \tag{5.75}$$

where the coefficients A_1 through A_3 and powers $n1$ and $n2$ are given in Table 5.3.

Table 5.3 Coefficients and Exponents for Equation 5.75

χ	A_1	A_2	A_3	$n1$	$n2$
std	0.15	0.42	42,500	0.687	1.16
M_{cr}	0.15	0.513	483	0.684	0.669
$M = 1$	0.118	0.69	3,550	0.813	0.793
$M = 1.75$	0.107	0.646	861	0.867	0.634

Table 5.4 Coefficients a_0–a_5 and C_1–C_3 for $N = sub$ or sup in Equations 5.76 and 5.77

	3	4.362	−16.91	19.84	−6.296	0	—			
sup	1	−2.963	4.392	−1.169	−0.027	−0.233	0.011			
	2	−6.617	12.11	6.501	1.182	−0.174	0.010	6.48	8.93	12.21
	3	−5.866	11.57	−6.665	1.312	−0.35	0.012			

The additional factor, ξ, is given by

$$\xi_N = \sum_{i=1}^{3} f_i\left(M_p\right) \prod_{\substack{j=1 \\ j\neq i}}^{3} \frac{\log\left(Re_p\right) - C_j}{C_i - C_j}, \quad \text{where} \tag{5.76}$$

$$f_i\left(M_p\right) = a_0 + a_1 M_p + a_2 M_p^2 + a_3 M_p^3 + a_4 \exp(1 - M_p)/a_5 . \tag{5.77}$$

The coefficients for Equations 5.76 and 5.77 are given in Table 5.4.

The correlation for the drag coefficient given by Parmar et al. (2010) was developed using the data of Bailey and Starr (1976). They applied the correlation to the data of Goin and Lawrence (1968), May and Witt (1953), and Jourdan et al. (2007) for the drag measurement of spheres in a fluid and found excellent agreement.

Wagner et al. (2012) conducted shock tube experiments of particles in a shocked gas to understand if the unsteady terms contributed to the increase in drag coefficient. The drag coefficient of 1 mm stainless steel spheres was measured for three M_p (0.99, 0.91, and 0.75) and shown in Figure 5.11. They also compared recently developed correlations by Parmar et al. (2010) and Loth (2008) to their measured values of C_D and found that Loth's correlation overpredicted the data for high Re_p in the range of $0.75 \leq M_p \leq 0.99$, as shown in Figure 5.11. The correlation of Parmar et al. (2010) provides an excellent match to the data.

The drag coefficient for rarefied flows is given by Loth (2008) as

$$C_D\left(Kn\right) = \frac{\dfrac{24}{Re_p}\left(1 + 0.15\mathrm{Re}_p^{0.687}\right) f_{Kn} + M_p^4 C_{D,fm}}{1 + M_p^4}, \quad \text{for } Re_p \leq 45, \tag{5.78}$$

where the free molecular contribution to the drag coefficient is given as

$$C_{D,fm} = \frac{\Phi(s) + \dfrac{2}{3s}\sqrt{\pi \dfrac{T_p}{T_\infty}}}{1 + \left(\dfrac{\Phi(s)}{1.63} - 1\right)\sqrt{\dfrac{\mathrm{Re}_p}{45}}}, \quad \text{and} \tag{5.79}$$

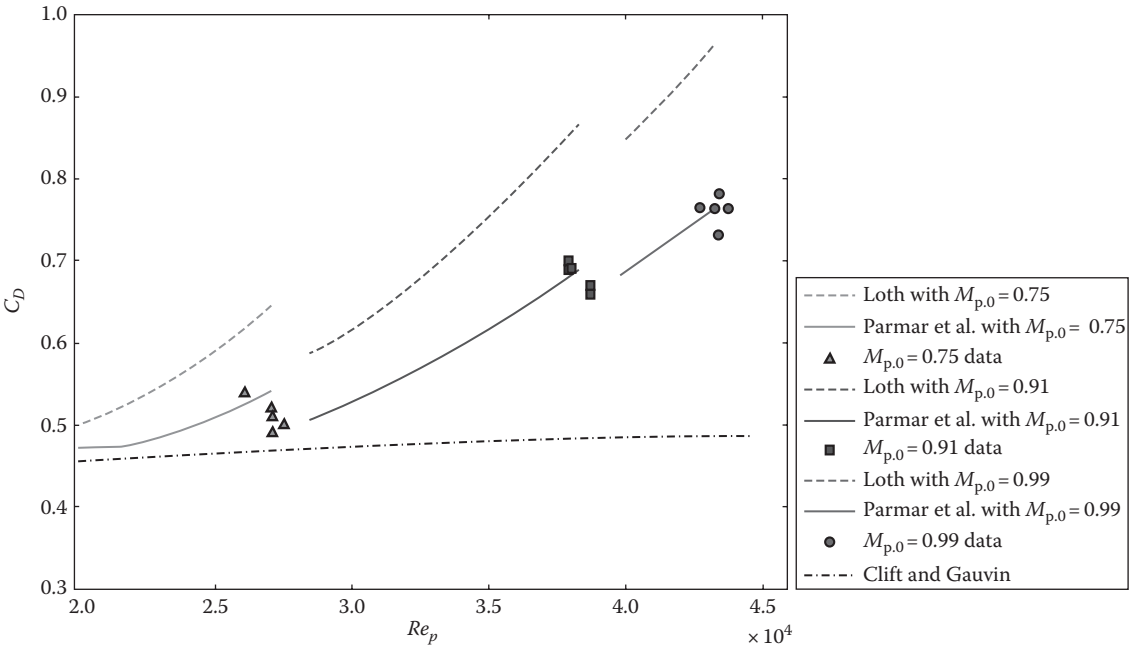

Figure 5.11

A comparison of the compressible drag coefficient correlation by Loth (2008) and Parmar et al. (2010) to the data measured by Wagner et al. (2012). The correlation by Parmar et al. (2010) shows excellent agreement with the measured compressible C_D. (Reprinted with permission from Wagner, J.L., Beresh, S.J., Kearney, S.P., Pruett, B.O.M., and Wright, E.K., Shock tube investigation of quasi-steady drag in shock-particle interactions, *Phys. Fluids*, 24, 123301. Copyright 2012, American Institute of Physics.)

$$\Phi(s) = \frac{\left(1+2s^2\right)\exp\left(-s^2\right)}{s^3\sqrt{\pi}} + \frac{\left(4s^4+4s^2-1\right)\mathrm{erf}\left(s\right)}{2s^4}, \tag{5.80}$$

where $s = M_p\sqrt{\gamma/2}$ is the molecular speed ratio and the parameter f_{Kn} in Equation 5.78 is given as

$$f_{Kn} = \left(1 + Kn_p\left[2.514 + 0.8\exp\left(\frac{-0.55}{Kn_p}\right)\right]\right). \tag{5.81}$$

where Kn_p is given in Equation 5.72.

Comparisons of this drag correlation with those of Crowe (1967), Henderson (1976), and Hermsen (1979) are shown in Loth (2008). Overall, this correlation has been shown to fit the selected data better than prior attempts (Loth, 2008).

The earlier results are all for an isolated particle. When local particle volume fraction exceeds a few percent, then the effect of gas-mediated particle–particle interactions increases C_D. This in turn will influence both the particle motion and the back-coupling effect on the gas (Ling et al., 2013).

5.3.2.4 Nonspherical Effects

Although many experiments use spherical particles for simplicity, in reality, particles are typically irregular. Reviews of the effect of irregular particles on incompressible drag are provided by Clift et al. (1978) and Michaelides (2006) with more recent developments by Tran-Chong et al. (2004) and Hölzer and Sommerfeld (2008). For compressible drag, Boiko and Poplabskii (2005) studied an irregular particle (cube, ~5 mm) and compared it to a sphere of similar size in shocked flows for $M = 0.5 - 1.5$ and $Re_p \sim 10^5$ and concluded that values of the drag were similar, both much higher than the standard drag; however, differentiation between unsteady effects and compressible drag was not discussed. The particles were

made of light wood with a density of 120 kg/m^3 and Schlieren images show slight differences in particle position based on the orientation of the cube normal to the flow. The acceleration of the cube with the flow incident on an edge or apex was lower than when the flow incident on the face.

5.3.2.5 Carrier Phase Equations of Motion

The carrier phase is described as the continuous fluid that transports the dispersed phase. In dilute flows, the volume fraction of the carrier phase α_c is on the order of unity; however, in dense particle-laden flows it can be much less. As Crowe et al. (2012) point out, the carrier phase equations cannot be derived by simply adding representative effects of the dispersed phase (i.e., drag) to the carrier phase equations. The Navier–Stokes equations are valid at a continuum point in the flow; however, the particle drag force is not valid at a continuum point but represents the average force due to the boundary and wake effects of the dispersed on the carrier phase. This region, where the particle affects the surrounding fluid, can span up to a few particle radii away from the particle surface. For this reason, we present the volume average of the carrier equations. The equations describing the mass, momentum, and energy of the carrier phase for a dilute flow are

$$\text{Mass} \quad \frac{\partial}{\partial t}\left(\alpha_c \langle \rho_c \rangle\right) + \frac{\partial}{\partial x_j}\left(\alpha_c \langle \rho_c \rangle \tilde{u}_j\right) = 0, \tag{5.82}$$

$$\text{Momentum} \quad \frac{\partial}{\partial t}\left(\alpha_c \langle \rho_c \rangle \tilde{u}_i\right) + \frac{\partial}{\partial x_j}\left(\alpha_c \langle \rho_c \rangle \tilde{u}_i \tilde{u}_j\right) = -\alpha_c \frac{\partial \langle p \rangle}{\partial x_i} - \frac{\partial}{\partial x_j}\left(\alpha_c \langle \rho_c \rangle \tilde{R}_{ij}\right) - \frac{1}{V}\sum_k F_{k,i}, \tag{5.83}$$

$$\begin{aligned}\text{Energy} \quad & \frac{\partial}{\partial t}\left(\alpha_c \langle \rho_c \rangle \tilde{E}\right) + \frac{\partial}{\partial x_j}\left(\alpha_c \langle \rho_c \rangle \tilde{E}\tilde{u}_j\right) = -\frac{\partial}{\partial x_j}\left(\alpha_c \langle p \rangle \langle u_j \rangle\right) - \frac{\partial}{\partial x_j}\left(\alpha_c \langle \rho_c \rangle \tilde{u}_i \tilde{R}_{ij}\right) - \frac{\partial}{\partial x_j}\left(\alpha_c \langle p' u_j' \rangle\right) \\ & -\frac{1}{2}\frac{\partial}{\partial x_j}\left(\alpha_c \langle \rho u_i'' u_i'' u_j'' \rangle\right) - \frac{\partial}{\partial x_j}\left(\alpha_c \langle \rho e'' u_j'' \rangle\right) + \frac{\partial}{\partial x_j}\left(\alpha_d \langle p \rangle \hat{v}_j\right) + \langle p \rangle \frac{\dot{V}_d}{V} - \frac{1}{V}\sum_k v_{k,j} F_{k,j} - \frac{1}{V}\sum_k \dot{Q}_k,\end{aligned} \tag{5.84}$$

where

$\hat{v}_j$ is the average particle (or parcel) velocity
$v_{k,j}$ is the local particle velocity
$F_{k,i}$ is the force on the particle
$\dot{Q}_k$ is the heat transfer due to the local particle k

In these equations, for simplicity, the effects of mass transfer between particles and the fluid were omitted, and the heat transfer from a severed particle (i.e., the boundary of a numerical cell slicing the particle) and molecular (i.e., conduction and viscous) terms have been neglected.* The force acting on the carrier phase due to the presence of particles is the volume-averaged force, described in Crowe et al. (2012), and includes the effects of quasi-steady drag, lift, rotation, pressure-gradient, added mass, and viscous-unsteady forces (discussed further in Section 5.3.2.6). The average force due to quasi-steady drag is

$$F_{k,i} = 3\pi\mu_c D_k f_k\left(\tilde{u}_i - v_{k,i}\right), \tag{5.85}$$

where

$f = C_D Re_p/24$ is the drag factor
subscript k is the particle number

Ling et al. (2012) and Sun et al. (2005) showed that the pressure-gradient, added mass, and viscous-unsteady forces are of the same order of magnitude and significant while a shock passes over a particle; however, after the shock passes, these forces decay to negligible values on the acoustic timescale, which is typically much shorter than the response time of the particle. Ling et al. (2012), however, point out that the unsteady forces are important for contact dominated, or dense particle flows with high particle

* Further discussion and information on these subjects can be found in Crowe et al. (2012).

volume fractions, for a significant time after the shock passes. The heat transfer $\dot{Q}_k$ can include several effects, such as quasi-steady, undisturbed-unsteady, and diffusive-unsteady contributions (discussed further in Section 5.3.2.8), and can also include radiation and rarefied, compressible and turbulence effects on convection. A simple model for the convective heat transfer between the particle and the carrier phase is given as

$$\dot{Q}_k = Nu\pi Dk_c\left(T_s - \langle T_c \rangle\right) \tag{5.86}$$

where
- Nu is the Nusselt number
- D is the particle diameter
- k_c is the thermal conductivity of the carrier phase
- T_s is the surface temperature of the particle
- $\langle T_c \rangle$ is the average temperature of the surrounding (carrier phase) fluid (formulas for Nu can be found in Crowe et al. (2012), Fox et al. (1978), and Feng and Michaelides (1996))

A simple diffusion model for the covariance terms in the energy Equation 5.84 is

$$-\frac{\partial}{\partial x_j}\left[\alpha_c\langle p'u_j'\rangle + \frac{1}{2}\frac{\partial}{\partial x_j}\alpha_c\langle \rho u_i''u_i''u_j''\rangle + \frac{\partial}{\partial x_j}\alpha_c\langle \rho e''u_j''\rangle\right] \approx \frac{\partial}{\partial x_i}\left(\alpha_c\langle \rho_c\rangle\tilde{R}_{ij}\frac{\varepsilon}{K}\left[C_k\frac{\partial K}{\partial x_j} + C_e k_{eff}\frac{\partial \tilde{T}}{\partial x_j}\right]\right), \tag{5.87}$$

where the pressure–velocity covariance has been neglected and the fluctuation of internal energy is modeled as an effective heat flux.

If the carrier phase is an ideal gas, the average pressure is modeled by the ideal gas EOS

$$\langle p\rangle = \left(\langle \gamma_c\rangle - 1\right)\langle \rho_c\rangle\tilde{e}_c, \tag{5.88}$$

where the internal energy is modeled by the caloric EOS

$$\tilde{e}_c = C_c\tilde{T}_c. \tag{5.89}$$

The carrier phase volume fraction is determined from

$$\alpha_c = 1 - \alpha_d, \tag{5.90}$$

where the particle volume fraction is determined by tallying the number of particles in a computational cell

$$\alpha_d = \frac{1}{V}\sum_k V_k^d, \tag{5.91}$$

where V_k^d is the volume of the dispersed phase particle k.

5.3.2.5.1 Carrier Phase Turbulence Carrier phase turbulence can be augmented or attenuated due to the presence of particles (Schwarzkopf et al., 2009a,b, Balachandar and Eaton, 2010, Crowe et al., 2012). In order to capture the modulation of turbulence due to particles in compressible flow, Horwitz and Schwarzkopf (2015) extended the work of Besnard et al. (1992) and Crowe et al. (2012) to include the effects of particle on the carrier phase compressible turbulence equations. To simplify the equations, dilute flow was assumed and mass transfer was neglected. The viscous stress was assumed to be negligible compared to the pressure gradient. It should be noted that under dilute assumptions $\alpha_d \approx 0$, and several terms were omitted from the

following equations and caution is encouraged when applying these equations to dense flows. The Reynolds stress for the carrier phase fluid is given as

$$\begin{aligned}\frac{\partial \alpha_c \langle \rho_c \rangle \tilde{R}_{ij}}{\partial t} + \frac{\partial \alpha_c \langle \rho_c \rangle \tilde{u}_k \tilde{R}_{ij}}{\partial x_k} &= a_i \frac{\partial \langle p \rangle}{\partial x_j} + a_j \frac{\partial \langle p \rangle}{\partial x_i} - \alpha_c \langle \rho_c \rangle \left(\tilde{R}_{ik} \frac{\partial \tilde{u}_j}{\partial x_k} + \tilde{R}_{jk} \frac{\partial \tilde{u}_i}{\partial x_k} \right) \\ &\quad - C_{r1} \left(a_i \frac{\partial \langle p \rangle}{\partial x_j} + a_j \frac{\partial \langle p \rangle}{\partial x_i} - \frac{2}{3} \delta_{ij} a_k \frac{\partial \langle p \rangle}{\partial x_k} \right) \\ &\quad + C_{r2} \alpha_c \langle \rho_c \rangle \left(\tilde{R}_{ik} \frac{\partial \tilde{u}_j}{\partial x_k} + \tilde{R}_{jk} \frac{\partial \tilde{u}_i}{\partial x_k} - \frac{2}{3} \delta_{ij} \tilde{R}_{mk} \frac{\partial \tilde{u}_m}{\partial x_k} \right) \\ &\quad + C_r \frac{\partial}{\partial x_k} \left(\alpha_c \langle \rho_c \rangle \frac{K}{\varepsilon} \tilde{R}_{kn} \frac{\partial \tilde{R}_{ij}}{\partial x_n} \right) \\ &\quad - C_{r3} \alpha_c \langle \rho_c \rangle \frac{\varepsilon}{K} \left(\tilde{R}_{ij} - \frac{1}{3} \delta_{ij} \tilde{R}_{kk} \right) - \frac{2}{3} \delta_{ij} \alpha_c \langle \rho_c \rangle \varepsilon \\ &\quad + \frac{1}{V} \sum_k 3\pi \mu_c D_k f_k \left(\tilde{u}_i - v_{k,i} \right) \left(u_{k,j} - v_{k,j} \right) \\ &\quad + \frac{1}{V} \sum_k 3\pi \mu_c D_k f_k \left(\tilde{u}_j - v_{k,j} \right) \left(u_{k,i} - v_{k,i} \right), \end{aligned} \tag{5.92}$$

where

$\tilde{R}_{ij} = \langle \rho u_i'' u_j'' \rangle / \langle \rho_c \rangle$ is the Reynolds stress

$a_i = \langle \rho' u_i' \rangle / \langle \rho_c \rangle$ is the mass-weighted turbulent velocity*

The local force acting on the kth particle in the jth direction is $F_{k,j} = 3\pi\mu_c D_k f_k (u_{k,j} - v_{k,j})$, and the particle center-of-mass velocity is $v_{k,j}$. As the flow transitions to single phase, that is, $\alpha_c \to 1$, $F_k \to 0$, and $\langle \rho_c \rangle \to \bar{\rho} = \rho_m$,† the single-phase multicomponent Reynolds stress, Equation 5.27, can be recovered when substituting $\varepsilon = K^{3/2}/S$. The modulation of turbulence is governed by $\frac{1}{V} \sum_k 3\pi\mu_c D_k f_k \left(\tilde{u}_i - v_{k,i} \right) \left(u_{k,j} - v_{k,j} \right)$ and ε. It turns out that for compressible flows, the modulation terms are only slightly different from the incompressible case given in Crowe et al. (2012). The compressible effects come from M_p in the compressible drag coefficient, Equation 5.74, and the mean Favre velocity, $\tilde{u}_i$. In addition, the unsteady and added mass terms were neglected in order to simplify the equation.

In the previous equation, an additional term arises, that is, the mass-weighted turbulence velocity. A model for the carrier phase turbulence mass flux ($\langle \rho_c \rangle a_i$) is

$$\begin{aligned}\frac{\partial \alpha_c \langle \rho_c \rangle a_i}{\partial t} + \frac{\partial \alpha_c \langle \rho_c \rangle \tilde{u}_k a_i}{\partial x_k} &= b \frac{\partial \langle p \rangle}{\partial x_i} - \tilde{R}_{ij} \frac{\partial \alpha_c \langle \rho_c \rangle}{\partial x_j} + \alpha_c \langle \rho_c \rangle \frac{\partial a_i a_j}{\partial x_j} \\ &\quad - \alpha_c \langle \rho_c \rangle a_j \frac{\partial \bar{u}_i}{\partial x_j} + \alpha_c \langle \rho_c \rangle C_a \frac{\partial}{\partial x_k} \left(\frac{K}{\varepsilon} \tilde{R}_{kn} \frac{\partial a_i}{\partial x_n} \right) \\ &\quad - C_{a1} \alpha_c \langle \rho_c \rangle \frac{\varepsilon}{K} a_i + b \frac{1}{V} \sum_k 3\pi \mu_c D_k f_k \left(u_{k,i} - v_{k,i} \right), \end{aligned} \tag{5.93}$$

where $b = -\langle \rho' v' \rangle$ is the density-specific volume covariance (similar to the definition in Section 5.2.2.1). Since $b \geq 0$ (Besnard et al., 1992), the presence of particles can alter the turbulence mass flux based on the sign of $F_{k,i}$. The effects of particles act as a stirring mechanism on the turbulence mass flux. Under the present assumptions, the particle contributions to a_i require that a nonzero b exists in the carrier phase, which can only occur in a multicomponent carrier phase flow or across a shock front. Again, the previous

* These definitions differ slightly when compared to the definitions for mixing continua, given in Section 5.2.2.1.

† For this condition, the transition in density is necessary when going from a single-phase, single-component carrier fluid density to a single-phase multicomponent fluid.

Table 5.5 Coefficient Values for Equation 5.95

C_ε	$C_{\varepsilon 1}$	$C_{\varepsilon 2}$	$C_{\varepsilon 3}$	$C_{\varepsilon 4}$
4.2	1.2	1.92	1.2	−1.2

equation reduces to Equation 5.28 under the conditions mentioned earlier. A model for the density-specific volume covariance is

$$\frac{\partial \alpha_c \langle \rho_c \rangle b}{\partial t} + \frac{\partial \alpha_c \langle \rho_c \rangle \tilde{u}_k b}{\partial x_k} = -2(b+1) a_j \frac{\partial \alpha_c \langle \rho_c \rangle}{\partial x_j} + 2\alpha_c \langle \rho_c \rangle a_j \frac{\partial b}{\partial x_j} + \alpha_c \langle \rho_c \rangle^2 C_b \frac{\partial}{\partial x_i}\left(\frac{K}{\alpha_c \langle \rho_c \rangle \varepsilon} \tilde{R}_{ij} \frac{\partial b}{\partial x_j} \right) - C_{b1} \alpha_c \langle \rho_c \rangle \frac{\varepsilon}{K} b, \tag{5.94}$$

which is similar to Equation 5.29. Although neglected, the effects of particles on b are mainly due to mass transfer from the dispersed to the carrier phase, which could occur due to evaporation, condensation, or mass transfer from chemical reactions. Therefore, this special case shows that b within the carrier phase fluid can only be generated across a shock and by multicomponent carrier phase mixing. A model for the turbulence dissipation, ε, is found by assuming the turbulence dissipation scales with the turbulence energy

$$\frac{\partial \alpha_c \langle \rho \rangle \varepsilon}{\partial t} + \frac{\partial \alpha_c \langle \rho \rangle \tilde{u}_k \varepsilon}{\partial x_k} = -C_{\varepsilon 1} \alpha_c \langle \rho \rangle \frac{\varepsilon}{K} \tilde{R}_{ij} \frac{\partial \tilde{u}_i}{\partial x_j} + C_{\varepsilon 3} \frac{\varepsilon}{K} a_j \frac{\partial \langle p \rangle}{\partial x_j} - C_{\varepsilon 4} \bar{\rho} \varepsilon \frac{\partial \bar{u}_j}{\partial x_j} + C_\varepsilon \frac{\partial}{\partial x_i}\left(\alpha_c \langle \rho \rangle \frac{K}{\varepsilon} \tilde{R}_{ij} \frac{\partial \varepsilon}{\partial x_j} \right) - C_{\varepsilon 2} \alpha_c \langle \rho \rangle \frac{\varepsilon^2}{K} + C_{\varepsilon 5} \frac{\upsilon_c^2}{V} \sum_k f_k \frac{\left| \tilde{u}_i - v_{k,i} \right|^2}{D_k}. \tag{5.95}$$

The last term was derived by Schwarzkopf et al. (2009a) and accounts for the augmentation and attenuation of carrier phase turbulence dissipation due to the dispersed phase. The coefficient $C_{\varepsilon 5}$ is given as a function of the particle Reynolds number*

$$C_{\varepsilon 5} = 0.025 C_{\varepsilon 2} Re_p^{1.524}, \tag{5.96}$$

and there is no understanding of M_p on $C_{\varepsilon 5}$. However, similar to $\tilde{R}_{ij}$, compressibility effects are accounted for in the drag factor (recall $f = C_D Re_p/24$) and in $\tilde{u}_i$. Although not studied, suggested coefficients for Equations 5.92 through 5.94 are given in Table 5.2, and suggested starting coefficients for Equations 5.95 and 5.96 are given in Table 5.5.

5.3.2.6 Dispersed Phase Equations of Motion

Here, we consider a Lagrangian representation of the dispersed phase. For simplicity, we assume the particles to be rigid, nonreacting (no mass exchange with the surround gas), constant heat capacity, and uniform temperature distribution. The governing equations for the dispersed phase (for the kth particles) are given by

$$\frac{d\mathbf{x}_{d,k}}{dt} = \mathbf{u}_{d,k}, \tag{5.97}$$

$$m_{d,k} \frac{d\mathbf{u}_{d,k}}{dt} = \mathbf{F}_{dc,k} + \mathbf{F}_{dd,k}, \tag{5.98}$$

$$m_{d,k} C_{d,k} \frac{dT_{d,k}}{dt} = Q_{dc,k}. \tag{5.99}$$

The position, velocity, temperature, mass, and heat capacity of the kth particle are denoted by $\mathbf{x}_{d,k}$, $\mathbf{u}_{d,k}$ (which is $v_{i,k}$ in the carrier phase equations mentioned earlier), $T_{d,k}$, $m_{d,k}$, and $C_{d,k}$. It should be noted that often the

* The coefficient and exponent for $C_{\varepsilon 5}$ are slightly different from those published in Schwarzkopf et al. (2009b).

number of particles in a real system can far exceed the number of particles used in a simulation. Hence, the term *particle* used in modeling denotes a computational particle, which can account for a collection of physical particles that are located around the location $\mathbf{x}_{d,k}$.

The hydrodynamic force and heat transfer exerted on the kth particle by the surrounding gas is given by $\mathbf{F}_{dc,k}$ and $Q_{dc,k}$. The force and heat transfer appear on the right-hand side of the gas momentum and energy (Equations 5.83 and 8.84, respectively) as the back-coupling effect of the particles on the gas flow. In these equations, $\sum_k$ represents sum over all the particles within a cell. Note that the back-coupling effect of particle force and heat transfer must be appropriately scaled by the local ratio of real to computational particles.

Under dense conditions, the kth particle also experiences a net force due to collisions with its neighbors, which is represented by $\mathbf{F}_{dd,k}$. There can also be associated heat transfer due to such interparticle collisions, whose effects however can be expected to be small, and thus is neglected here.

Following the works of Parmar et al. (2011, 2012) and Ling et al. (2011a, b, 2012), the hydrodynamic force is expressed as the sum of following individual contributions:

$$\mathbf{F}_{dc,k} = \mathbf{F}_{qs,k} + \mathbf{F}_{pg,k} + \mathbf{F}_{iu,k} + \mathbf{F}_{vu,k}, \tag{5.100}$$

where $\mathbf{F}_{qs,k}$, $\mathbf{F}_{pg,k}$, $\mathbf{F}_{am,k}$, and $\mathbf{F}_{vu,k}$ are the quasi-steady, pressure-gradient, inviscid-unsteady, and viscous-unsteady forces, respectively.

5.3.2.6.1 Quasi-Steady Force The expression for quasi-steady force on an isolated particle (limit of zero volume fraction) in a compressible flow with complete Re_p and M_p dependence is presented in Section 5.3.2.3. The corresponding drag coefficient for finite particle volume fraction can be expressed as

$$C_D\left(\mathrm{Re}_p, M_p, \alpha_d\right) = C_{D,0}\left(\mathrm{Re}_p, M_p\right)\xi\left(\alpha_d\right), \tag{5.101}$$

where

$C_{D,0}(Re_p, M_p)$ is the drag coefficient in the limit of zero volume fraction

$\xi(\alpha_d)$ is the particle volume-fraction correction function given by (Sangani et al., 1991)

$$\xi(\alpha_d) = \frac{1+2\alpha_d}{(1-\alpha_d)^3}, \tag{5.102}$$

where α_d is the particle volume fraction given in Equation 5.91. The expression for $\xi(\alpha_d)$ was analytically derived for dilute periodic arrays of spheres in the incompressible regime. However, it has been shown to be a good approximation for random arrays of spheres for $\alpha_d < 0.3$. Here, it is presented in the context of compressible flows and thus requires caution.

5.3.2.6.2 Pressure-Gradient Force The pressure-gradient force arises from the undisturbed flow. Even if the particle was not there (as a result the flow is undisturbed), the volume of fluid at the particle location will experience a force if there is nonzero local stress gradient. This force can be expressed as

$$\mathbf{F}_{pg,k} = V_d(\nabla \cdot \sigma_c)_k, \tag{5.103}$$

where V_d is the volume of the particle. Here, σ_c represents the stress tensor of undisturbed continuous phase (gas). In the case of an inviscid ambient flow, the divergence of the stress tensor becomes the pressure gradient (and hence the term *pressure-gradient force*)

$$\mathbf{F}_{pg,k} = -V_d(\nabla p_c)_k. \tag{5.104}$$

5.3.2.6.3 Inviscid-Unsteady Force In compressible flows, the expression for the added mass force is more complicated than in the incompressible counterpart. The added mass force involves a history integral since the acoustic disturbances resulting from the relative acceleration between the particle and the surrounding gas propagate at a finite speed. In an incompressible flow, these acoustic disturbances travel at sonic speed,

and as a result, the added mass force is directly proportional to the relative acceleration at that instant. This direct proportionality is lost in a compressible flow, and as a result, this force cannot be viewed as an added mass and must be termed inviscid-unsteady force. Due to finite speed of sound, the inviscid-unsteady force at any instance depends on the past history of relative acceleration. As shown in Parmar et al. (2008), the resulting convolution integral can be written as

$$\mathbf{F}_{iu,k} = V_d \int_{-\infty}^{t} K_{iu}(t-\chi)\left[\left(\frac{d}{dt}(\rho_c \mathbf{u}_c)\right)_k - \frac{d}{dt}(\rho_c \mathbf{u}_{d,k})\right]\frac{c_c}{R}d\chi, \tag{5.105}$$

where the density-weighted relative acceleration (the term within the square brackets) is evaluated at χ (an arbitrary time within the impulsive acceleration region) and the inviscid kernel K_{iu} is evaluated at $t-\chi$. Here, $R = D/2$ is the radius of the particle and c_c is the sound speed of the carrier (or continuous) phase. Due to compressibility, the density of the ambient flow cannot be taken as a constant, and thus, flow and particle accelerations must be generalized to their momentum forms. Here, D/Dt is the total derivative following the fluid at the particle location, while d/dt is the rate of change following the particle.

In an incompressible flow, the inviscid-unsteady kernel K_{iu} reduces to a delta function, and thus, the added mass force depends only on instantaneous relative acceleration. In a compressible flow, in the zero Mach number limit, the inviscid kernel takes the following explicit form

$$K_{iu}(t-\chi) = \exp\left[\frac{c_c(t-\chi)}{R}\right]\cos\left[\frac{c_c(t-\chi)}{R}\right], \tag{5.106}$$

where the subscript *iu* stands for inviscid-unsteady force. The inviscid kernel depends only on Mach number. Finite Mach number extensions to the zero Mach number analytic kernel mentioned earlier have been obtained through DNSs (Parmar et al., 2008).

The kernel K_{iu} decays on an acoustic timescale. For example, $K_{iu}(\tau)$ is virtually zero for $\tau > 10R/c_c$, indicating that acceleration history is almost forgotten for times longer than 10 acoustic time units. Such rapid decay allows significant simplification in situations where the acceleration history of the ambient flow and the particle is slow compared to the acoustic timescale. Under nonshock conditions, where the particle is not subjected to rapid flow variation, the relative acceleration in Equation 5.105 can be taken out of the integral and an effective added mass coefficient can be defined as

$$C_M = \int_{-\infty}^{t} K_{iu}(t-\chi)\frac{c_c}{R}d\chi, \tag{5.107}$$

and correspondingly, the inviscid-unsteady force can be expressed as

$$\mathbf{F}_{iu,k} = V_d C_M\left[\left(\frac{d}{dt}(\rho_c \mathbf{u}_c)\right)_k - \frac{d}{dt}(\rho_c \mathbf{u}_{d,k})\right]. \tag{5.108}$$

In the case of shock–particle interaction, this approximation is inappropriate since relative acceleration varies on the acoustic timescale (shock–particle interaction will be discussed in Section 5.3.2.7).

In compressible particle-laden flows of finite particle volume fraction, K_{iu} and C_M will be functions of M_p and α_d. A model for C_M is suggested in Ling et al. (2013) as

$$C_M(M_p, \alpha_d) = 0.5\eta_1(M_p)\eta_2(\alpha_d), \tag{5.109}$$

where 0.5 is the incompressible added mass coefficient for a sphere. Here, η_1 and η_2 are correction functions that take into account the effects of compressibility and particle volume fraction given by

$$\eta_1(M_p) = 1 + 1.8(M_p)^2 + 7.6(M_p)^4, \tag{5.110}$$

$$\eta_2(\alpha_d) = \frac{1+2\alpha_d}{1-\alpha_d}. \tag{5.111}$$

When M_p and α_d approach zero, η_1 and η_2 both reduce to unity and we recover $C_M = 0.5$. When $M_p = 0$ but α_d is finite, Equation 5.109 is identical to the expression of added mass force for a distribution of spheres in incompressible flows given by Sangani et al. (1991). When $\alpha_d = 0$ and $M_p > 0$, Equation 5.109 reduces to the numerical correlation of effective finite Mach number added mass coefficient for a sphere by Parmar et al. (2008). For $M_p > M_{p,cr}$ the increase in quasi-steady force due to the bow shock will be more important than contribution from the added mass force.

5.3.2.6.4 Viscous-Unsteady Force The viscous-unsteady force, also called the Basset history force, can be expressed as

$$\mathbf{F}_{vu,k} = 3\pi\nu_c D \int_{-\infty}^{t} K_{vu}(t-\chi)\left[\left(\frac{d(\rho_c \mathbf{u}_c)}{dt}\right)_k - \frac{d(\rho_c \mathbf{u}_{d,k})}{dt}\right] d\chi, \tag{5.112}$$

where K_{vu} is the viscous-unsteady force kernel, which is a function of Re_p, M_p, and α_d. In the limit of zero Reynolds number incompressible dilute flow, K_{vu} is known as the Basset history kernel. Finite Reynolds number incompressible extension of K_{vu} has been presented by Mei and Adrian (1992) and Kim et al. (1998). The effects of M_p and α_d on viscous-unsteady force are still not fully understood and thus often ignored.

5.3.2.7 Shock–Particle Interaction

Typical shock front thicknesses in gases are on the order of hundred nanometers or less. Thus, even micron size particles will appear to be of finite size compared to the shock wave front. Here, we are concerned with evaluating the time-dependent force on a particle as the shock wave propagates over it. It is important to recognize that not only is the timescale associated with shock propagation rapid but also the length scale over which the flow properties, such as gas velocity, pressure, and temperature, change from preshock to postshock conditions is very thin. For example, consider the expressions for quasi-steady, pressure-gradient, inviscid-unsteady and viscous-unsteady forces given in Equations 5.101, 5.103, 5.105, and 5.112. In these equations, flow quantities such as $\mathbf{u}_c$, ρ_c, and σ_c are the continuous phase velocity, density, and stress tensor as seen by the particle. In the point-particle approach, these are properties of the undisturbed flow that would exist at the particle location in the absence of the particle. Typically, these undisturbed flow quantities are evaluated at the center of the particle. This would be sufficient if the ambient flow variation across the particle is small. In the context of shock–particle interaction, as the shock propagates over the particle, part of the particle sees the preshock flow, while the rest of the particle is subjected to postshock flow. Thus, there is ambiguity in the application of Equations 5.101, 5.103, 5.105, and 5.112 for the calculation of the time-dependent force on a particle during the passage of the shock.

There is a remarkable theorem by Faxén (1923) that generalized the Stokes drag on a spherical particle from a steady uniform flow to an arbitrary spatially varying flow. The key result of Faxén's theorem is to replace in the Stokes drag formula the ambient flow velocity at the particle center with the undisturbed ambient flow velocity averaged over the surface of the sphere. If the ambient flow velocity varies substantially over the size of the particle, then the Faxén's correction to Stokes drag is substantial. The extension of Faxén theorem to unsteady flows has a long history culminating in the works of Maxey and Riley (1983) and Gatignol (1983). The resulting Maxey–Riley–Gatignol (MRG) equation is an exact expression for force on a spherical particle subjected to unsteady spatially varying ambient flow. The MRG equation is rigorous in the limit of zero Reynolds number and assumes the length scale of ambient flow variation to be large compared to particle size.

In the context of shock–particle interaction, clearly, the ambient flow varies on the scale of the particle. Thus, an extension of the Faxén's theorem to the compressible flow regime, in other words a compressible MRG equation, is required in order to accurately model the force on a particle. Parmar et al. (2012) obtained such a compressible extension of the MRG equation for the force on a particle in arbitrary motion in a compressible ambient flow that is varying both in time and in space. This theoretical derivation, as in the MRG equation, is in the limit of zero Reynolds and Mach numbers and for length scales of ambient flow variation much longer than the particle size. For the application of this theory to the case of shock–particle

interaction, the limitation on length scale of ambient flow variation is not appropriate. Recently, this limitation was relaxed, and the force on a particle during the passage of a shock was expressed again as the sum of quasi-steady, pressure-gradient, inviscid-unsteady, and viscous-unsteady forces. As will be seen, each of these forces will depend on either volume or surface averages of the undisturbed ambient flow over the particle, which are well defined even when the ambient flow varies sharply over the scale of the particle. The unsteady forces must again be separated into surface and volume contributions as

$$\mathbf{F}_{iu,k} = \mathbf{F}_{iu,1,k} + \mathbf{F}_{iu,2,k}, \tag{5.113}$$

$$\mathbf{F}_{vu,k} = \mathbf{F}_{vu,1,k} + \mathbf{F}_{vu,2,k} + \mathbf{F}_{vu,3,k}. \tag{5.114}$$

Each of these components can now be expressed as in terms of volume and surface averages of the surrounding gas as

$$\mathbf{F}_{qs,k} = 6\pi\mu R(\overline{\mathbf{u}_c}^S - \mathbf{u}_{d,k}), \tag{5.115}$$

$$\mathbf{F}_{pg,k} = \frac{4}{3}\pi R^3 \overline{\rho_c \frac{D\mathbf{u}_c}{Dt}}^V, \tag{5.116}$$

$$\mathbf{F}_{iu,1,k} = \frac{4}{3}\pi R^3 \int_{\xi=-\infty}^{t} K_{iu}(\tau)\left[\frac{D\overline{(\rho_c \mathbf{u}_c)}^V}{Dt} - \frac{D\overline{(\rho_c \mathbf{u}_{d,k})}^V}{Dt}\right]\frac{c_c}{R}d\xi, \tag{5.117}$$

$$\mathbf{F}_{iu,2,k} = \frac{4}{3}\pi R^3 \int_{\xi=-\infty}^{t} K_{iu}(\tau)\left[\frac{D\overline{(\mathbf{r}\nabla\cdot(\rho_c \mathbf{u}_c))}^V}{Dt} - \frac{D\overline{(\mathbf{r}\nabla\cdot(\rho_c \mathbf{u}_{d,k}))}^V}{Dt}\right]\frac{c_c}{R}d\xi, \tag{5.118}$$

$$\mathbf{F}_{vu,1,k} = 6R^2\sqrt{\pi\nu}\int_{\xi=-\infty}^{t} K_{vu}^V(t-\xi)\left[\frac{D\overline{(\rho_c \mathbf{u}_c)}^V}{Dt} - \frac{D\overline{(\rho_c \mathbf{u}_{d,k})}^V}{Dt}\right]_{t=\xi} d\xi, \tag{5.119}$$

$$\mathbf{F}_{vu,2,k} = 6R^2\sqrt{\pi\nu}\int_{\xi=-\infty}^{t} K_{vu}^V(t-\xi)\left[\frac{D\overline{(\mathbf{r}\nabla\cdot(\rho_c \mathbf{u}_c))}^V}{Dt} - \frac{D\overline{(\mathbf{r}\nabla\cdot(\rho_c \mathbf{u}_{d,k}))}^V}{Dt}\right]_{t=\xi} d\xi, \tag{5.120}$$

$$\mathbf{F}_{vu,3,k} = 6R^2\sqrt{\pi\nu}\int_{\xi=-\infty}^{t} K_{vu}^S(t-\xi)\left[\frac{D\overline{(\rho_c \mathbf{u}_c)}^S}{Dt} - \frac{D\overline{(\rho_c \mathbf{u}_{d,k})}^S}{Dt}\right]_{t=\xi} d\xi. \tag{5.121}$$

In these equations, $\overline{(\,)}^S$ (and $\overline{(\,)}^V$ represent averages over the surface and volume of the spherical particle, respectively. As a consequence of splitting the viscous-unsteady force into surface and volume averages, the viscous-unsteady kernels also split accordingly as

$$K_{vu}^V = C^V(\tau)K_{vu}, \tag{5.122}$$

$$K_{vu}^S = C^S(\tau)K_{vu}, \tag{5.123}$$

where K_{vu} is the incompressible Basset history kernel (Basset, 1888). The effects of compressibility and flow inhomogeneity are built into the correction functions (see Parmar et al., 2012). The previous equation is the generalized version of Faxén's theorem in the time domain.

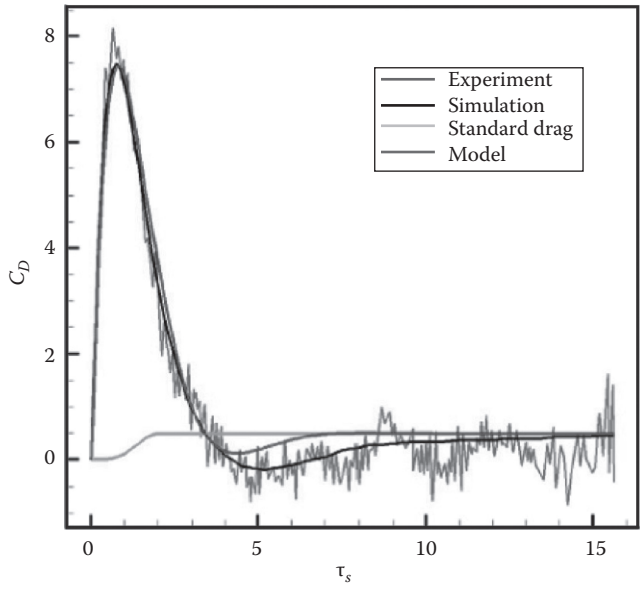

Figure 5.12

Comparison of the experimental measurement of force on an 8 mm spherical particle subjected to shock (in air) of Mach number 1.22 (Sun et al., 2005) against simulation and point-particle model prediction. Shown in the figure are comparisons of time history of the drag coefficient obtained by the experiment, (direct numerical) simulation, standard drag (quasi-steady model), and (improved point-particle) model.

Although the earlier expressions have been rigorously obtained for the limit Re_p, $M_p \to 0$, we now apply the formulation to a particle subjected to a shock wave of Mach number 1.22 propagating over it. This case was experimentally and computationally considered by Sun et al. (2005) for a fixed shock Mach number for a range of particle sizes. Note that the Mach number of the postshock flow is only about 0.3. The experimental results are compared against the model prediction mentioned earlier and shown in Figure 5.12. Also presented is the result from fully resolved DNS. In comparison, the model involves the solution of the force contributions given in Equations 5.115 through 5.121. The model was able to predict the magnitude and time of occurrence ($\tau_s \sim 1$) of the peak force quite well. The deviation in the drag coefficient for $\tau_s > 2.75$ can be attributed to the fact that the model uses zero Reynolds number kernels. Detailed analysis of the different contributions to the total force shows that the viscous-unsteady (Basset) forces, given in Equations 5.119, 5.120, and 5.121, are not significant in predicting the peak force. Therefore, one may obtain a good estimate of the drag force by neglecting the viscous-unsteady forces and computing only the quasi-steady and inviscid-unsteady contributions given in Equations 5.115 through 5.118.

5.3.2.7.1 Particle Deformation Here, we are interested in the problem of a strong shock interacting with a particle, where the shock strength is of sufficient magnitude that the deformation of the particle cannot be ignored. For example, in the context of condensed phase detonation with embedded metal particles, the problem of detonation–particle interaction becomes important. Here, the density of the products of detonation is substantial, and the postshock pressure can be significantly larger than the yield strength of the particle. But experiments of shock interaction with a deforming particle (SIDP) in the context of metal particles subjected to an intense shock in a condensed matter ambience are rare in the literature, due to the complex nature of such experiments. Modeling and simulation are an attractive alternative that can provide time-resolved details of such interaction of a particle with a strong shock wave.

It is of interest to extend the earlier described theoretical model and present an SIDP model that includes the leading order effects of particle deformation and compression heating. To motivate such a model, it is appropriate to first consider the DNS of a deforming particle subjected to a strong shock in condensed matter. The material properties are characterized by appropriate equations of state, for example, Mie–Grüneisen EOS. The DNS results show the interaction details, such as shock reflection, refraction, and evolutions of average properties of particles. Based on the knowledge obtained from the DNS study, one can improve the model by including the effects of particle deformation and compression heating. Note that SIDP occurs in other interesting applications as well. For example, shock interaction with a droplet or a bubble can lead

to significant deformation of the droplet or the bubble. In fact, a sufficiently strong shock can lead to violent breakup and fragmentation of the droplet or bubble, for example, see Niederhaus et al. (2008), Quirk and Karni (1996), and Ranjan et al. (2011). Current modeling and simulation efforts are generally limited to modest deformation, and only limited investigations have addressed more complex scenarios such as breakup and fragmentation (Theofanous and Li, 2008, Theofanous, 2011, Theofanous et al., 2012).

As an example, Figure 5.13 shows the DNS results of Ling et al. (2013) where an aluminum particle is subjected to an intense shock in nitromethane (shock speed is 4800 m/s, the postshock pressure and velocity are 10.7 GPa and 2270 m/s). Details of particle deformation and fully resolved pressure and thermal fields computed at the microscale are shown in frames a–d. The time evolution of particle velocity and average temperature obtained from the DNS are shown in Figure 5.13e and f. A highly resolved axisymmetric grid was used in this simulation; however, it is impossible to resolve the flow around a particle when millions of particles must be considered, so a point-particle approach is often employed at the mesoscale, where all the microscale details must be accurately encapsulated into mass, momentum, and energy coupling models.

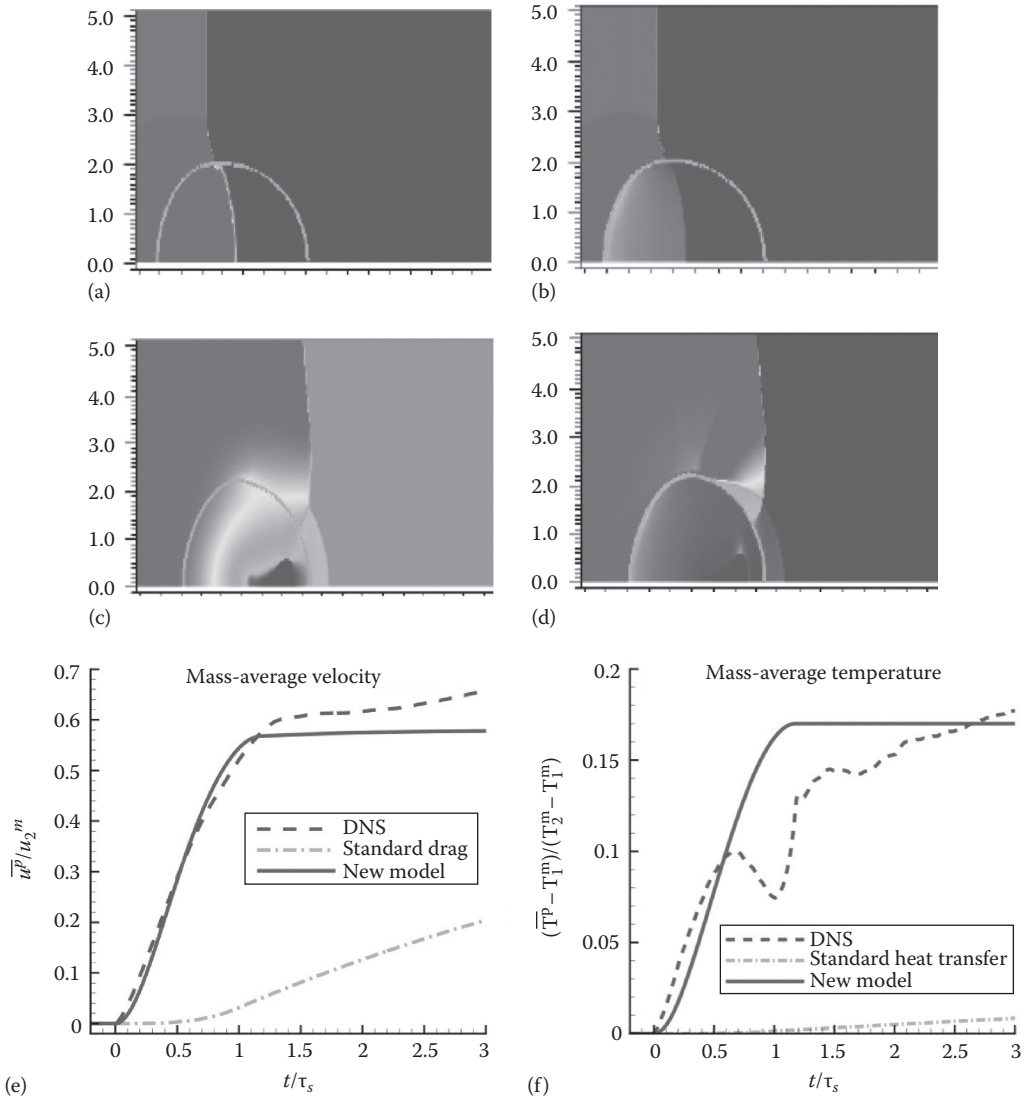

Figure 5.13

ALE3D simulations of intense shock propagation over an aluminum particle embedded in nitromethane (Ling et al., 2013). Frames (a) and (c) are pressures and (b) and (d) are temperature contours at 0.3 and 0.8 ns, respectively. Frames (e) and (f) compare the time evolution of nondimensional particle velocity and volume-averaged temperature against standard and improved physics-based models. (The vertical axis in (a) through (d) shows particle size in μm.)

Also shown in Figure 5.13e and f are the particle velocity and temperature predicted by conventional quasi-steady drag and heat transfer point-particle models. It is quite clear that such standard models result in large errors, since they have not been developed and tested for the intense unsteady pressure and temperature conditions representative of detonation–particle interaction. As a consequence, it can be expected that mesoscale simulations performed with the standard models can result in serious error. In contrast, physics-based coupling models employed in Ling et al. (2013) that include inviscid-unsteady effects can be seen to perform reasonably.

The results of the DNS can be generalized to a broader class of shock–particle interaction conditions. Representative scenarios of flow fields arising from SIDP are shown in Figure 5.14. The two key parameters that characterize the nature of particle deformation and the shock diffraction pattern are the impedance ratio (ζ_d/ζ_c) and the shock speed ratio (U_{st}/U_{si}) (here, ζ_d and ζ_c are the shock impedance in the particle and in the surrounding medium and U_{si} and U_{st} are the incidence and transmission shock propagation speeds in the surrounding medium and in the particle). The former ratio determines the reflected wave to be an expansion fan or a shock wave, while the latter ratio determines the shape of the transmitted shock (see Figure 5.14). In summary, there are four different scenarios: (1) a reflected expansion fan and a convex transmitted shock ($\zeta_d/\zeta_c < 1$ and $U_{st}/U_{si} > 1$), (2) a reflected shock and a concave transmitted shock ($\zeta_d/\zeta_c > 1$ and $U_{st}/U_{si} < 1$), (3) a reflected expansion fan and a concave transmitted shock ($\zeta_d/\zeta_c < 1$ and $U_{st}/U_{si} < 1$), and (4) a reflected shock and a convex transmitted shock ($\zeta_d/\zeta_c > 1$ and $U_{st}/U_{si} > 1$).

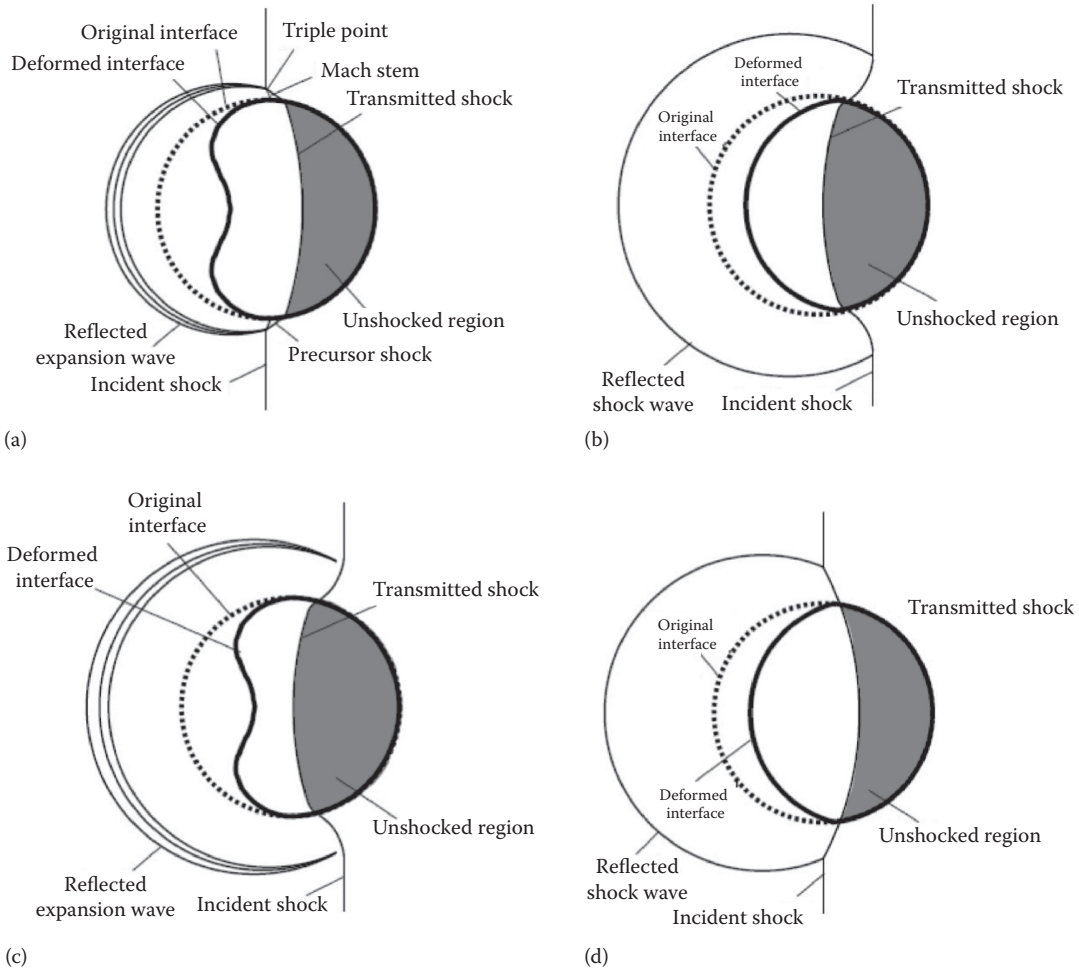

Figure 5.14

Representative scenarios of flow field arising from shock interaction with a deformable particle for different shock impedance and shock speed ratios. (a) $\zeta_d/\zeta_c < 1$, $U_{st}/U_{si} > 1$, (b) $\zeta_d/\zeta_c > 1$, $U_{st}/U_{si} < 1$, (c) $\zeta_d/\zeta_c < 1$, $U_{st}/U_{si} < 1$, and (d) $\zeta_d/\zeta_c > 1$, $U_{st}/U_{si} > 1$.

5.3.2.8 Heat Transfer due to Gas–Particle Interaction

Similar to Equation 5.100, the overall heat transferred to the kth particle $Q_{dc,k}$ is expressed as

$$Q_{dc,k} = Q_{qs,k} + Q_{uu,k} + Q_{du,k}, \tag{5.124}$$

where $Q_{qs,k}$, $Q_{uu,k}$, and $Q_{du,k}$ represent quasi-steady, undisturbed-unsteady, and diffusive-unsteady contributions, which are the thermal analogs of $\mathbf{F}_{qs,k}$, $\mathbf{F}_{pg,k}$, and $\mathbf{F}_{vu,k}$, respectively. Note that there is no thermal analog to the added mass force because the latter is inviscid in nature and arises from the no-penetration boundary condition.

The undisturbed-unsteady contribution accounts for heat conduction and work done by the surface stresses on the volume of gas replaced by the particle (Ling et al., 2011a). For incompressible viscous flows and rigid particles, the expression of $Q_{uu,k}$ is given by Balachandar and Ha (2001). In the present context, gas flow is considered as inviscid, and therefore, $Q_{uu,k}$ reduces to be equivalent to the compression work done by the gas pressure on a particle. When a particle interacts with an intensive shock wave, particles can experience serious compression and deformation and the compression work done by the surrounding gas can contribute significantly in heating the particle (Ruggirello et al., 2010, Ling et al., 2011a,b).

Similar to the analysis for the quasi-steady and viscous-unsteady forces, it can be expected that compressibility and finite particle volume fraction will also influence the quasi-steady and diffusive-unsteady contributions to heat transfer. For lack of detailed information, we can use the expressions of $Q_{qs,k}$ and $Q_{du,k}$ for a single particle given by Fox et al. (1978) and Feng and Michaelides (1996). In the correlation of Fox et al. (1978), the Nusselt number depends on M_p, and therefore, compressibility effect on quasi-steady heat transfer has been taken into account. In the governing equations, heat transfer to particles will influence the gas-phase energy Equation 5.84, which is coupled with the gas momentum Equation 5.83. As a result, the simplification on particle heat transfer model may influence the gas and particle motion. However, the errors caused by the simplified heat transfer model are expected to be of secondary importance.

Another important energy transfer effect in compressible flows is radiation heat transfer. The radiative heat transfer is the net heat transfer due to absorption and emission of radiant energy. If the particle is considered a gray body, then the absorptivity and emissivity are equal and a simple model, which assumes that a particle is within a black body enclosure, is given as (Crowe et al., 2012)

$$\dot{Q}_{rad} = \epsilon \sigma \pi D^2 \left(T_{ec}^4 - T_d^4 \right), \tag{5.125}$$

where

ϵ is the emissivity
σ is the Stefan–Boltzmann constant (5.67×10^{-8} W m^{-2} K^{-4})
D is the particle diameter
T_{ec} is the temperature of the enclosure
T_d is the temperature of the particle

This equation is for a single particle, and it becomes more complex as the volume fraction increases to dense limits primarily due to the modeling of the scattering effects in these regimes. Compressibility and rarefaction effects can play a role by altering the mean free path of the photons in the carrier phase. In addition, particle concentration due to turbulence can also shadow particles within a cloud. There are limited studies on the effect of radiation heat transfer within a cloud of finite size particles; some additional information on this topic can be found in Crowe et al. (2012), Kessel-Deynet and Burkert (2000), Fiveland (1988), Siegel (1981), and Chu and Churchill (1955). There are however many studies on the topic of radiation in aerosols.

5.3.3 Compressible Dense Particle Flows

Dense particle-laden flows (typically between the not-so-dilute and granular limits) are found in applications involving fluidized beds. In these flows, the volume fractions are high 1%–40%, and the effects of neighbor particles and contact forces between particles become important. Shocks in dense particle-laden flows are complex, having multiple reflections, transmissions, and interactions. Because of this, particle wakes and boundary layers are affected and simple models (derived from Stokes flow) to

describe the forces are questioned. Wagner et al. (2012) conducted a set of experiments to address questions related to shocked dense particle flows. Their experiment consisted of a gravity-driven curtain of ~100 μm glass spheres with a volume fraction of ~20%, inside of a shock tube. Three tests were conducted with incident shock Mach numbers in the range of 1.66–2.02, and since the timescales for the falling particles within the curtain were much larger than the timescale of the shock, the particles look stationary relative to the shock. Schlieren images were used to measure the expansion of the curtain (and identify shock locations), and pressure measurements were used to measure the effects of the particles on the downstream shock. Overall, they found that the thickness of the particle curtain expanded ~×10 for Mach 1.62 and nearly × 20 for Mach 2.02. They also concluded that the effect of the particle curtain lowered the momentum and energy fluxes in the gas by 30%–40% far downstream of the curtain relative to experiments without the curtain.

Ling et al. (2012) modeled the experiment of Wagner et al. (2012). In addition to the quasi-steady, pressure-gradient, added mass, and viscous-unsteady forces (further described in Section 5.3.2.6) in dilute particle-laden flows, dense particle-laden flows require an additional force(s) to account for the interparticle interaction, which includes particle–particle contact and the effect of neighbor particles on wake structures. An empirical force ($\mathbf{F}_{dd,k}$, shown in Equation 5.98) to account for these effects was proposed by Harris and Crighton (1994) and used by Andrews and O'Rourke (1996) and is commonly referred to as the gradient of the *solid stress*

$$\mathbf{F}_{dd,k} = -\frac{1}{\alpha_d \rho_d} \nabla \tau, \tag{5.126}$$

where τ is not a stress but a scalar given by (Snider, 2007)*

$$\tau = \frac{P_s \alpha_d^n}{\max\left[\left(\alpha_{d,cp} - \alpha_d\right), \epsilon\left(1 - \alpha_d\right)\right]}, \tag{5.127}$$

where

P_s is an empirical constant with units of pressure

$\alpha_{d,cp}$ is the close-packed particle volume fraction (~68% for spheres in a body-centered cubic configuration (Crowe et al., 2012))

ϵ is a small number ~10^{-7}

($n \sim 3$) the exponent that is an empirical constant (Snider et al., 1998)

This model shows a heavy dependence on the volume fraction and since it is empirical, it may need to be tuned for each set of experiments. When simulating the particle curtain experiments, Ling et al. (2012) found that the results were not all that sensitive to P_s, so long as it had the correct magnitude. They also identified that unsteady forces, volume fraction, compressibility, and interparticle collision were all needed to correctly capture the expansion of the shocked dense particle curtain. The effect of the unsteady forces is very large while the shock transitions over a particle and decays on the acoustic timescale after the passage of the shock to negligible values. Correction functions were applied to the quasi-steady, added mass, and viscous-unsteady forces to account for the effect of volume fraction. In addition, Mach number effects on quasi-steady and added mass forces were accounted for by correction functions. With these corrections, Ling et al. (2012) provided a simulation that agreed rather well with the measured pressure profiles and the time-dependent expansion of the particle curtain. Further discussion on these forces is given in Section 5.3.2.6.

5.3.4 Jump Relations for Dusty Gas Flows

The jump relations for dusty gas flows can be determined by assuming that the shock is steady and planar and that viscous effects are neglected. However, when particles are present within the shock width, complications arise in determining jump conditions. These complexities are due to shock–particle interactions, quasi-steady drag, added mass, unsteady viscous forces, mass transfer, void fractions, contact forces, and turbulence, and differences in properties such as pressure, temperature, internal energy,

* Snider (2007) proposed a modified form of solid stress introduced by Harris and Crighton (1994) to avoid the singularity as $\alpha_d \to \alpha_{d,cp}$.

density, sound speed, and specific heats that can occur in particle-laden flows. For most systems, the momentum and thermal response times are much longer than the shock transit time, and these are important in determining the relaxation behind the shock. Therefore, the assumption of thermal and mechanical equilibrium fails for particle-laden compressible flows containing metal particles in a gas. However, like two-fluid models, simplifications can be made to obtain a set of conservative equations for mass, momentum, and energy. Such simplifications typically require the response times of the particle to be similar to those of the gas. This results in a dusty gas formulation.

Anand (2014) derived such a set of equations for dusty gas conditions. The jump conditions were formulated based on the assumption of mixture properties for the pressure, velocity, mass, sound speed, gamma, and internal energy. In a frame of reference that is moving with the shock wave front, the jump conditions are

$$\text{Mass} \quad \bar{\rho}_{-}\left(v_s-\bar{u}_{-}\right)=\bar{\rho}_{+}v_s, \tag{5.128}$$

$$\text{Momentum} \quad \bar{P}_{-}+\bar{\rho}_{-}\left(v_s-\bar{u}_{-}\right)^2=\bar{P}_{+}+\bar{\rho}_{+}v_s^2, \tag{5.129}$$

$$\text{Energy} \quad \bar{e}_{-}+\frac{\bar{P}_{-}}{\bar{\rho}_{-}}+\frac{\left(v_s-\bar{u}_{-}\right)^2}{2}=\bar{e}_{+}+\frac{\bar{P}_{+}}{\bar{\rho}_{+}}+\frac{v_s^2}{2}, \tag{5.130}$$

where

subscripts + and − refer to the preshock and postshock conditions, respectively
v_s is the velocity of the shock wave front
$\bar{\rho}$, $\bar{u}$, $\bar{P}$, and $\bar{e}$ are the density, velocity, pressure, and internal energy of the mixture, respectively

The EOS for the mixture pressure and temperature is given as

$$\bar{P}=\left(\frac{1-\phi}{1-\alpha_d}\right)\bar{\rho}\Re\bar{T}, \tag{5.131}$$

$$\bar{e}=\left(\phi C_d+\left[1-\phi\right]C_v\right)\bar{T}, \tag{5.132}$$

where

$\phi=\dfrac{\alpha_d\rho_d}{\alpha_c\rho_c}$ is the mass concentration of the dispersed phase
$\Re$ is the gas constant
C_d is the specific heat of the dispersed phase
C_v is the specific heat of the carrier phase

The mixture properties behind the shock relative to those ahead of the shock are formulated in terms of the shock Mach number as

$$\frac{\bar{\rho}_{-}}{\bar{\rho}_{+}}=\frac{\left(\gamma_m+1\right)M_s^2}{M_s^2\left(\gamma_m-1-2\alpha_{d+}\right)+2\left(1-\alpha_{d+}\right)}, \tag{5.133}$$

$$\frac{\bar{P}_{-}}{\bar{P}_{+}}=\frac{2\gamma_m M_s^2-\gamma_m+1}{\gamma_m+1}, \tag{5.134}$$

$$\frac{\bar{T}_{-}}{\bar{T}_{+}}=\frac{\left(\left[2M_s^2-1\right]\gamma_m-1\right)\left(2\left[\left(1-\alpha_{d+}\right)\right]+M_s^2\left[\gamma_m-1+2\alpha_{d+}\right]\right)^2}{M_s^2\left(\gamma_m+1\right)^2\left(M_s^2\left[\gamma_m-1\right]+2\right)}, \tag{5.135}$$

$$\frac{\bar{u}_-}{c_+} = \frac{2\left(1-\alpha_{d+}\right)\left(M_s^2-1\right)}{\left(\gamma_m+1\right)M_s}, \tag{5.136}$$

where

M_s is the Mach number of the incident shock

c_+ is the sound speed of the material ahead of the shock

γ_m is the ratio of the specific heats, defined as

$$\gamma_m = \frac{\gamma_g + \dfrac{\phi}{1-\phi}\gamma_p}{1+\dfrac{\phi}{1-\phi}\gamma_p}, \tag{5.137}$$

where

γ_g is the ratio of specific heats for the gas

γ_p is the ratio of specific heats for the particles (or dispersed phase)

Equations 5.133 through 5.136 reduce to the single-phase shock relations when $\alpha_d \to 0$ and $\gamma_m \to \gamma$.

5.4 Shocked Continua Interfaces

In this section, we discuss the mechanisms that drive the formation of particles from a shocked continua surface, commonly referred to as "ejecta." The term *ejecta* refers to the mass excavated from the rough, back side of a shocked metal sample into the vacuum or atmosphere beyond it. To clarify, metal samples or targets that might be driven with high-pressure shock waves are usually finished with a lathe or milling machine—the metals can of course be cast and then machined, or simply cast. In this context, the tools used to shape the metal leave periodic tooling marks or scratches on the surface that we refer to as (surface) perturbations. These perturbations are usually defined by a periodic wavelength λ and initial amplitude h_0, both of which can be characterized through optical profilometry across the surface. The dominant wavelength scale on the surface is determined as the highest energy mode in a *Fourier* transform of a characteristic set of *xy*-pairs from the profilometry, and the amplitude of the perturbations is related to the average deviation of the amplitude across the surface, R_a:

$$R_a = \int_{x_1}^{x_2} y(x)dx \Big/ \int_{x_1}^{x_2} dx. \tag{5.138}$$

These amplitude variations have finer scale fluctuations $\ll h_0$ along λ, but the dominant amplitude scale R_a is typically half the average perturbation amplitude ($R_a \approx h_0/2$), or about 1/4 the average of the maximum-to-minimum deviation of the perturbation amplitudes, of the dominant λ. The λ typically are set (machined) onto longer scale, slower surface—variations referred to as the *waviness* of the surface, which is typically caused by vibrations in the machining equipment.

If the metal targets/samples are placed in contact with a high explosive (HE) that is otherwise confined, and if the HE is initiated to detonation, then the detonation wave interacting with the metal will form a shock wave that drives through the target's *front side* to its *back side*. When the shock wave reaches the metal–vacuum or metal–gas interface it first releases to zero pressure at the perturbation minima and then reflects back into the metal as a rarefaction wave. A brief time later the shock wave releases to zero pressure at the perturbation maxima, also reflecting back into the metal as a rarefaction wave. Under these conditions, the stresses produced by the shock wave interacting with the perturbations cause the perturbation minima to compress, invert, and then grow in tension as RM instabilities (I), a.k.a. spikes. Because the RMI grow quickly relative to the initial perturbation maxima, the initial maxima invert and form bubbles that grow unstably into the metal causing metal to flow into the spikes to support the spike growth, as illustrated in Figure 5.15. In the RMI picture, bubbles and spikes refer to the peak penetration depth on opposite sides of the free surface, which is nominally defined as the plane through which the

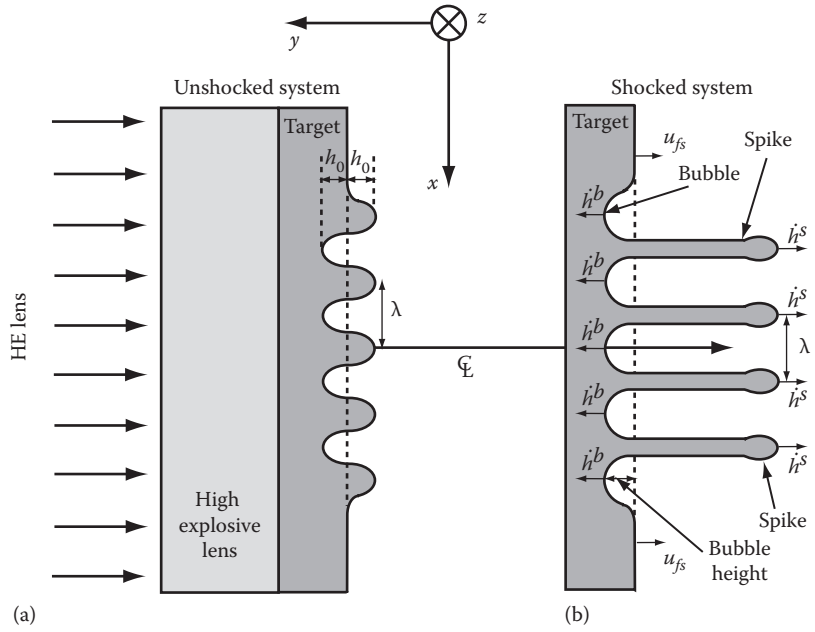

Figure 5.15

The preshocked (a) and postshocked (b) geometries. The preshock geometry includes sinusoidal surface perturbations. Initiation of the high explosive drives a planar shock wave through the target. When the shock wave reaches the metal–vacuum or metal–gas interface, it releases pressure and the free-surface jumps from its initial state to a shock-released state with velocity u_{fs}. During the shock wave loading, leading to release, the perturbations invert and the spikes form (ejecta) and grow beyond the free surface, and the bubbles grow into the free surface and feed mass into the spikes. CL, center line. (A version of this figure appears in Buttler et al. (2012b).)

inflections of the initial 2D surface perturbations center on. Of particular note is that in this geometry ejecta form as a special limiting case of an RMI where the Atwood number $At = -1$, where $\rho_1 \approx 0$ relative to the full density of metals ρ_2.

The formation of the ejecta is referred to as the *source* term. The mass from this source can be ejected into a medium such as a gas, where $0 < \rho_{gas} \Rightarrow \rho_1 \ll \rho_2 \therefore At \approx -1$. During the ejection process, the sheets/ligaments will break up due to Reynold's (hydrodynamic) drag and other potential mechanisms to form particles.

There have been numerous studies of ejecta over the years, most of which have centered on the formation of the source term: mass–velocity distributions $\rho^*(t;z)$ and total ejected areal–mass $\rho_A(t;z)$, where $\rho^*(t;z)$ is a reduced mass density,* and $\rho_A(t;z)$ is the time integral of $\rho^*(t;z)$ from the fastest ejecta down to the free surface—z is a parameter.

Early work in this area was pioneered by Asay (1976, 1977, 1978). In his work, Asay developed a simple prescription for the amount of mass ejected from shocked materials that linked to whether or not the material was shocked, and to the volume of the surface defects, V_{df}, caused by the fabrication of the samples, that is, the surface roughness R_a. In his prescription, Asay postulated that if a material was solid after shock and shock release it would eject about × 1 the target mass that would occupy the perturbations' defect volume V_{df}, $M_{ej} \approx \rho_{metal} V_{df} = \rho_m V_{df}$, and if the shocked metal was liquid it would eject $M_{ej} \approx 10\rho_m V_{df}$. His work was done with flyer plates (guns), and he studied Al, Au, Cu, Pb, and W. To study ejecta, he developed an ejecta diagnostic now known as an Asay foil (Asay, 1976). The Asay foil measurements gave $\rho^*(t;z)$ and $\rho_A(t;z)$ as ejecta mass accumulates with time onto the Asay foil at height z.

Subsequent to Asay's work, mass measurements on Ta, Sn, and CuPb alloys were made by Andriot et al. (1982) and Cheret et al. (1985), concluding that the 2D surface roughness R_a is the source of the ejected mass. Similar to Asay's work, they measured $\rho^*(t;z)$ and $\rho_A(t;z)$ with the Asay foil technique, and they shocked their system with flyer plates. Their gun systems were able to shock some of the materials to a liquid phase on shock release—the Sn and the CuPb alloys. They did observed a sharp increase in $\rho_A(t;z) \Leftrightarrow (M_{ej})$ from

* The density of an individual Sn fragment is the full density of solid or liquid Sn. In this context, $\rho^*(t)$ is the average density of the ejecta cloud arriving at the probes, an average that includes full density particles, as well as vacuum.

liquid metals as predicted by Asay. Shortly afterward, McMillan (1986) measured ejecta particle sizes with a Mie scattering diagnostic (Mie, 1908, Bohren and Huffman, 2004). His work centered on gun experiments on Pb targets with peak shock stresses that liquefied the Pb. McMillan reported ejecta sizes from 1 to 10 μm. Monfared et al. (2015) have reported recent dynamic Mie scattering studies as well.

The body of these early works—mid-1970s to early 1990s—focused on characterizing $\rho^*(t;z)$ and $\rho_A(t;z)$ and the sizes of the ejecta fragments or particles and their size–velocity distribution. Work on improving diagnostic techniques and the precision of mass measurement, and the temporal resolution of the mass–velocity distributions continues. For example, more precise ejecta size measurements on various metals utilizing dynamic holographic techniques have been done (Sorenson et al., 2002a, b), finding size distributions from 1 to 10 μm that nominally follow an r^{-5} percolation model size distribution, which is quite close to a log-normal distribution that is an effective description.

Along these lines, much work on characterizing the mass–velocity distributions on Sn has been done by Vogan et al. (2005), Zellner et al. (2007, 2008b, 2009a,b), Monfared et al. (2014), along with recent work on Pb by Ogorodnikov et al. (2009), Chen et al. (2012a,b), Georgievskaya and Raevsky (2012), and Mikhailov et al. (2014). The goal of the Sn work centered on the development of a physics-based source term model. Other researches have pursued ejecta models as well, for example, Georgievskaya and Raevsky (2012) presented an RMI-based ejecta model, Liu and Grieves (2014) reported on ejecta formation and transport from random and periodic perturbations with DNS, and others have relied extensively on molecular dynamics simulations to inform the understanding of ejecta phenomena as an RMI (Cherne et al., 2012, Durand and Soulard, 2012, 2013, Ren et al., 2014, He et al., 2015). In the Sn experiments, ejecta production was studied with gun and HE techniques, shock-loading techniques that drive the samples with a supported- or triangular-shock wave loading profile.

In one type of ejecta experiment, the perturbation parameters (wavenumber ($k = 2\pi/\lambda$) amplitude products kh_0), and the shock wave breakout pressure P_{SB}, were varied to explore ejecta production from a fixed finish versus P_{SB}. In other Sn experiments, P_{SB} was fixed and kh_0 was varied. Most of the HE Sn results, where P_{SB} was fixed and kh_0 was varied, are reported in Monfared et al. (2014). Zellner et al. (2009a) reported similar Sn experimental results from gun experiments where R_a and λ were fixed (λ, h_0) = (50, 1.6) μm. Some of the HE ejecta data, where P_{SB} was varied and R_a was fixed (λ, h_0) = (50, 1.6) μm, with (λ, h_0) = (25, 0.8) μm, are reported in Zellner et al. (2007). However, we will report later, for the first time, the full collection of the fixed finish HE- and gun-driven experimental ejecta data, where P_{SB} was varied and $R_a \approx 0.8$ μm, with (λ, h_0) = (50, 1.6) μm. The body of the Sn ejecta data was used to develop (Buttler et al., 2012a, b) and implement (Fung et al., 2013) an RMI physics-based ejecta model, which will be discussed later. Any ejecta model must explain the Sn ejecta data set.

5.4.1 Ejecta Experimental Details

To survey the phase space of ejecta variables, we mainly utilized two venues: guns and HE drives. The HE experiments gave unsupported (triangular) or Taylor wave shock waves, and the gun shots supported or square wave shock waves. A supported shock wave is characterized by a steep rise in pressure that is sustained as the shock front traverses the material. Upon reaching the free surface, the shock stress undergoes a steep release to vacuum or low pressure, causing a rarefaction wave to scatter back into the material, releasing the internal pressure. A Taylor shock wave has a similar steep rise in pressure; however, the rise is followed immediately by the propagation of a rarefaction wave from release at the HE backside. Because the HE rarefaction wave propagates into the HE shocked material, that is, into compressed mass at high pressure, it travels at a velocity greater than the shock wave front velocity into the unshocked material with relatively lower pressure. Eventually, the rarefaction wave overtakes the shock wave front and begins to attenuate the peak shock pressure as the shock wave moves through the material. Figure 5.16 schematically presents the different geometries of the two venues. Figure 5.16a shows the Taylor wave geometry and Figure 5.16b the gun geometry. The choice of venue, gun, or HE shock physics was directly tied to the particular ejecta question under investigation.

Figure 5.17 shows the basic HE physics and diagnostics package used to acquire the HE (PBX 9501) Sn ejecta data for all P_{SB}. The Sn sample and standard diagnostics, which included lithium niobate (LN) piezoelectric pins to measure ejecta masses (Figure 5.18), and either an optical heterodyne velocimeter (OHV) (Cummins et al., 1963a,b, Yeh and Cummins, 1964, Forman et al., 1965, Buttler et al., 2004, Strand et al., 2006) or velocity interferometer system for any reflector (VISAR) (Barker and Hollenbach, 1972) probes, that completed the physics package that was usually at 1- to 5-torr pressure for the experiments. The package was always placed inside a test chamber, or "boom box," as shown in Figure 5.16a. The boom box included two replaceable Poly(methyl methacrylate), also known as Plexiglas, Acrylite, Lucite, and Perspex (PMMA) windows—often damaged by debris from the explosion—positioned perpendicular to the target face, allowing for the

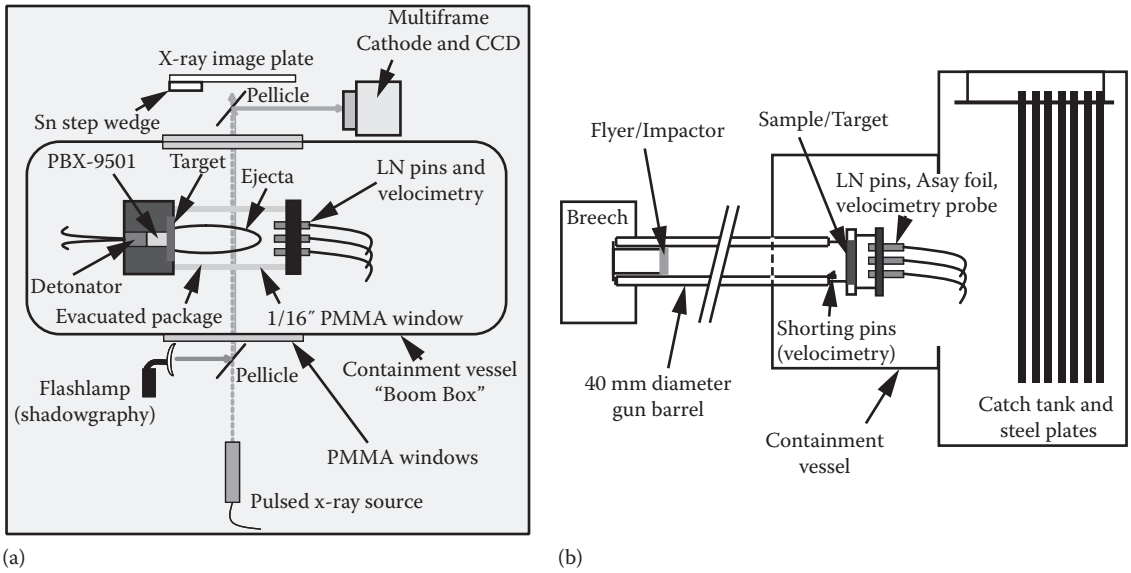

Figure 5.16

These figures illustrate the basic experimental geometries for the high explosive- and gun-driven ejecta experiments, labeled (a) and (b), respectively. Versions of (a) appear in Vogan et al. (2005), Zellner et al. (2007, 2008a,b,c), and Monfared et al. (2014), and a version of (b) appears in Zellner et al. (2009a).

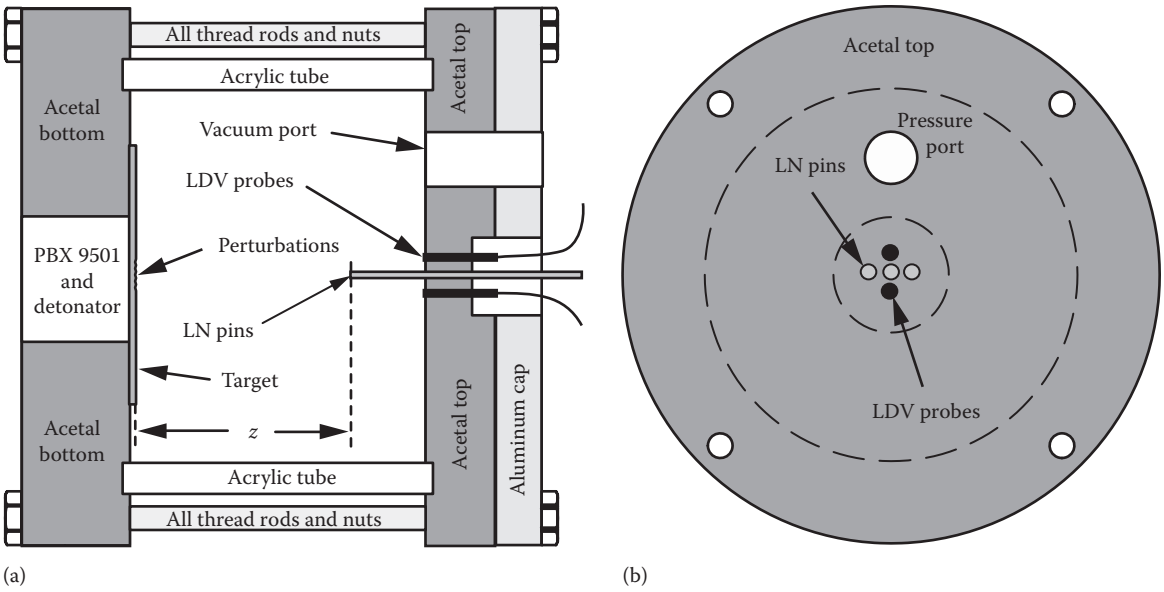

Figure 5.17

(a) A typical ejecta physics package and the all-thread rods out of rotation; otherwise, both schematics are drawn to scale. (b) A common diagnostic arrangement for a typical ejecta experiment, including the frequent locations and orientations of the lithium niobate pins (gray) and the laser Doppler velocimetry probes (black). (A version of this figure appears in Monfared et al. (2014).)

use of both multiframe optical shadowgraphy (usually 9 frames) to observe the ejecta and target evolution, and x-radiography (x-ray) to acquire ejecta density versus distance beyond the shocked target surface at one time, t_{xray}. The LN probes for the HE experiments were distributed above the surface, usually at height 20 μm $\leq z \leq$ 30 μm, and velocimetry probes were adjacent to the LN probes and/or above the target center. The number of LN probes per package was typically determined by the height of the cylindrical Sn sample and by the height and diameter of the HE, variables that were modified as needed to vary P_{SB}. All diagnostics and the HE

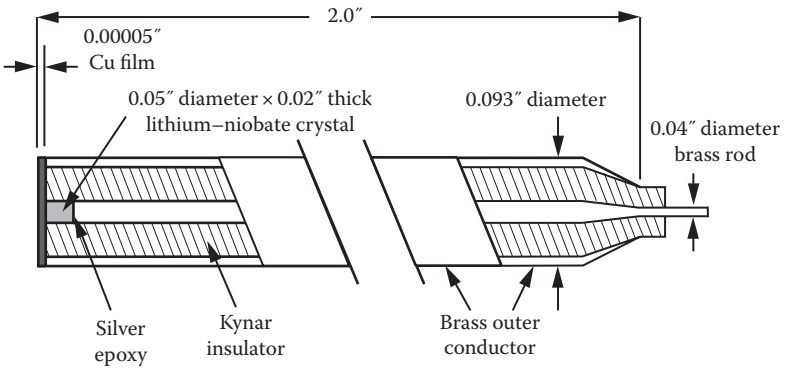

Figure 5.18

The Dynasen piezoelectric probes. (This figure appears in Monfared et al. (2014).)

detonation were initiated from a centrally located high-voltage source (capacitive discharge unit, or CDU), and the diagnostics were *commonly timed* to the CDU voltage pulse for correlated analysis.

The velocimetry provided P_{SB} just prior to shock release; the x-ray diagnostic provided accuracy validation for the piezoelectric measurements; the optical shadowgraphy gave ejecta speeds for comparison with x-ray and LN probe observations, as well as an approximate time of shock wave breakout in the event that the velocimetry diagnostics failed.

The supported shock wave experiments were fielded using the same Sn and machining processes that were used in the HE experiments. The basic gun geometry is depicted in Figure 5.16b. In the gun experiments, the shock wave forms in the target as the gun-fired *sabot*, or flyer, impacts an otherwise stationary Sn target—the sabot moves left to right in this representation. For the gun experiments, the sabots were tipped with either Cu or Ti_{64} cylindrical discs that collided with the stationary target (Ti_{64} is a titanium alloy with 6% vanadium and 4% aluminum).

5.4.2 Ejecta Experimental Results and Analysis Techniques

5.4.2.1 Laser Doppler (Optical Heterodyne) Velocimetry

Figure 5.19 shows two laser Doppler velocimetry (LDV) measurements from a 2012 HE-driven Sn experiment. The two LDV probes were positioned about 50 mm above the target at a radius of 4 mm off the target center. The HE drive was PBX 9501, as described, and the target was 3 mm thick. The perturbations had $(\lambda, h_0) = (50.3, 8.4)$ μm, which gave $kh_0 = 1.05$; this kh_0 product produces ejecta that travel about twice the velocity of the free surface, u_{fs}.

The observed free-surface (release) velocity on both probes was $u_{fs} \approx 1.725$ mm/μs at this radius, about 0.1 mm/μs lower than it would be if the probe was centered above the target. From these data, we also get the shock wave breakout time t_{SB}, which we common time with the LN pins, x-ray data, and the visible imaging to CDU. The release velocity, u_{fs}, is also used to analyze the LN pin data. Essentially, what is needed is the time the shock wave breaks out at (reaches) the free surface, and the time at which the free surface arrives at the LN pins as the ejecta are thought to form quickly and then expand self-similarly beyond the free surface as the shocked system (ejecta and target) approaches the stationary LN pins. Of course, u_{fs} can be integrated to get $z(t)$ as desired.

5.4.2.2 Lithium Niobate Piezoelectric Diagnostic

The LN probes are purchased directly from Dynasen* and are generally used in unmodified form. The probes are compact and have their active piezoelectric material mounted to the ends of copper wires to make "pins." Figure 5.18 presents an engineering diagram of the basic LN probe.

The manufacturer specified sensitivity of the LN piezoelectric crystal is $S = 24.8$ pC/N, and the LN sensitivity is accurately determined by x-ray diffraction from the lattice structure. The LN pin quasi-static failure stress is 6–8 kbar, but we have observed accurate mass measurements up to about 12 kbar. Mears et al. (2010) questioned the accuracy of the value of S used, reporting $S \approx 36$ pC/N, but $S = 24.8$ pC/N is consistent with the x-ray validation data.

* The LN pins are purchased directly from Dynasen, Inc., Goleta, Ca. (www.dynasen.com).

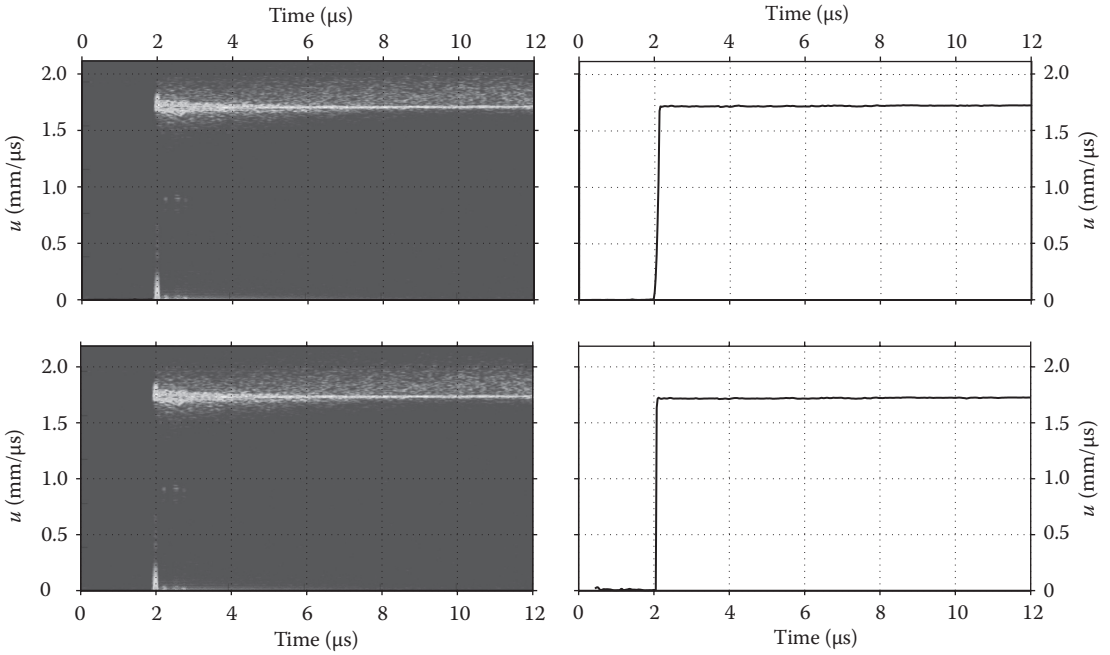

Figure 5.19

Two laser Doppler velocimetry (LDV) measurements, two probes, acquired from a 3 mm thick Sn target. The images on the left follow naturally after *Fourier,* transforming the LDV data from the frequency to time domain, and the plots to the right were extracted from the images. (These LDV data were acquired in June 2012 at STL.)

Extracted quantitative results from the LN pins are based on several assumptions, with the primary assumption being that a probe's response to ejecta is described as

$$\begin{aligned}\frac{d}{dt}(mu) &= u\frac{dm}{dt} + m\frac{du}{dt}\\ &\approx m\frac{\partial u}{\partial z}\frac{\partial z}{\partial t}\\ &= A\rho^{\star}(t;z)u^2(t;z) = AP(t;z),\end{aligned} \tag{5.139}$$

where A is the active area of the piezoelectric probe and the temporally varying quantities are $P(t;z)$, the pressure—linear stress—on the probe; $u(t;z)$, the velocity of a particle or fragment; m, the fragment mass; and $\rho^{\star}(t;z)$, the average density of the fragments sticking to the probes, as caused by the ejecta accreting onto the probe at LN pin height z. It is further assumed that there is no source term for the mass, that is, $dm/dt \equiv 0$.

Equation 5.140 relates the acceleration of the piezoelectric material to the ejecta velocity gradient by the time rate of change of the position z, under the assumptions that (1) the particles inelastically come to rest within an infinitely thin layer on the piezoelectric material ($\delta z \times A \approx V$, the volume), (2) the change in velocity as the particle comes to rest in distance δz is $\delta u \equiv u$, and (3) $\partial z/\partial t \approx u$ is the velocity of the particle. When these conditions are met, the force on the probe is $F(t;z) \approx AP(t;z)$ and the probes respond to the time derivative of the pressure—otherwise, the probes would be an infinite charge source. When the piezoelectric material is abruptly squeezed, it generates charge during the impulse. When it is held at a fixed pressure, that is, the time derivative of the force is zero, it generates no charge. When the pressure is released, the charge flows in the opposite sense.

During usage, the LN probes are connected to a digitizer via coaxial cable terminated into $R = 50\ \Omega$ to measure the $V(t)$, giving a time history of current:

$$\frac{dF}{dt} = \frac{V(t;z)}{RS}. \tag{5.140}$$

The time derivative of the pressure is $dP/dt = A^{-1}dF/dt$. The ejecta cloud pressure is recovered by integrating $A^{-1}dF/dt$:

$$P(t;z) \equiv \rho^{\star}(t;z)u^2(t) = \int dt \frac{V(t;z)}{ARS}. \tag{5.141}$$

Based on our assumption that $P(t;z) \equiv \rho^{\star}(t;z)u^2(t;z)$, the dynamic volume density can be calculated by dividing $P(t;z)$ by $u^2(t;z)$. Because these experiments were executed in vacuum, the arrival of the ejecta is simply characterized as a time-of-flight measurement, that is, $u(t;z) = z/t$ (Buttler et al., 2007, Zellner and Buttler, 2008).

The final quantity we often seek from the data is the cumulative areal mass of material ejected from the shocked surface, which is found after first calculating the dynamic areal density, dm/dA:

$$\rho_A(t;z) = \frac{dm}{dA} = \int dt\, \rho^{\star}(t;z)u(t;z). \tag{5.142}$$

The cumulative areal mass is the value of $\rho_A(t;z)$ at the time of the free surface arrival at the LN probe, $t_{fs} = z/u_{fs}$.

These three quantities ($P(t;z)$, $\rho^{\star}(t;z)$ and $\rho_A(t;z)$) are the main data we seek in our ejecta model development. All three quantities can be expressed versus the velocity ($u(t;z) = z/t(u;z)$), or they can be expressed as a snapshot at time t where the mass is distributed versus z as described in Buttler et al. (2007) and clarified in Zellner and Buttler (2008).

In a presentation of $P(z;t)$, $\rho^{\star}(z;t)$, and $\rho_A(z;t)$, z is the variable and t the parameter, typically chosen as the time at which the free surface arrives at the pin. However, to compare the LN pin data with x-ray data taken at time t', the data can be transformed from the time at which the surface reaches the probe at time t to the earlier time t', again as shown in Buttler et al. (2007) and Zellner and Buttler (2008). In fact, this transformation is used to validate the performance of the LN pin precision and accuracy in Zellner et al. (2008b) and Monfared et al. (2014).

Figure 5.20 shows typical LN pin quantities acquired on Sn ejecta experiments in 2012. We plot $V(t;z)$, $P(u;z)$, $\rho^{\star}(u;t)$, and $\rho_A(u;z)$, where the pin height was $z = 20.4$ mm. In these experiments, our target was cold-rolled Sn of purity 0.9995, which gave Sn grain size diameters on the order of $d \approx \mathcal{O}(100\,\mu\text{m})$. The wavelength and amplitudes were $(\lambda, h_0) = (50\,\mu\text{m}, 8.4\,\mu\text{m})$, which gave $kh_0 = 1.05$. There were three LN pins on the experiment ($z = 20.4$ mm), one above the target center and two at a radius of 4 mm off center. Two Doppler OHV probes were adjacent to the LN pins, also at a radius of 3 mm, to give $u_{fs} = 1.72$ mm/μs. Previous experiments have shown that on center this would be $u_{fs} \approx 1.82$ mm/μs. These velocities imply $P_{SB} \approx 26$ GPa.

In Figure 5.20, $\rho_A(u;z)$, the center pin, integrates up to about 15 mg/cm^2. The other two pins integrated to 10.8- and 11.6-mg/cm^2 so that $\rho_A(u = u_{fs}) = 12.5 \pm 2.2$ mg/cm^2. This variability is higher than normal, but the result is consistent with other data from similar targets presented in Monfared et al. (2014).

5.4.2.3 Accuracy: LN Pin and X-Ray Comparisons

The accuracy of LN pin ejecta mass measurements was validated on numerous STL experiments through a comparison of LN probe with x-ray measurements. The cross-validation is typically achieved by comparing the $\rho^{\star}$ from the LN pin measurement with the $\rho^{\star}$ from the radiography measurement.

Considering x-radiography physics, if an x-ray beam with intensity I_0 passes through material with transverse areal density $\rho_A^{T\star}$ and mass attenuation coefficient κ, then the ratio of the transmitted to incident intensities is

$$\frac{I}{I_0} = e^{-\kappa\rho_A^T}, \tag{5.143}$$

where ρ_A^T is the product of the attenuating material thickness τ with its density $\rho^{\star}$, that is, $\rho_A^T = \rho^{*}\tau$. The determination of ρ_A^T requires a static and a dynamic radiograph of the physics package, which determines I_0 and I,

* The ejecta areal density transverse to the LN pin ρ_A is ρ_A^T, but $\rho_A^T \neq \rho_A^L$. However, the $\rho^{\star}(z;t_{xray})$ calculated from the x-ray and LN pins are quantitatively comparable.

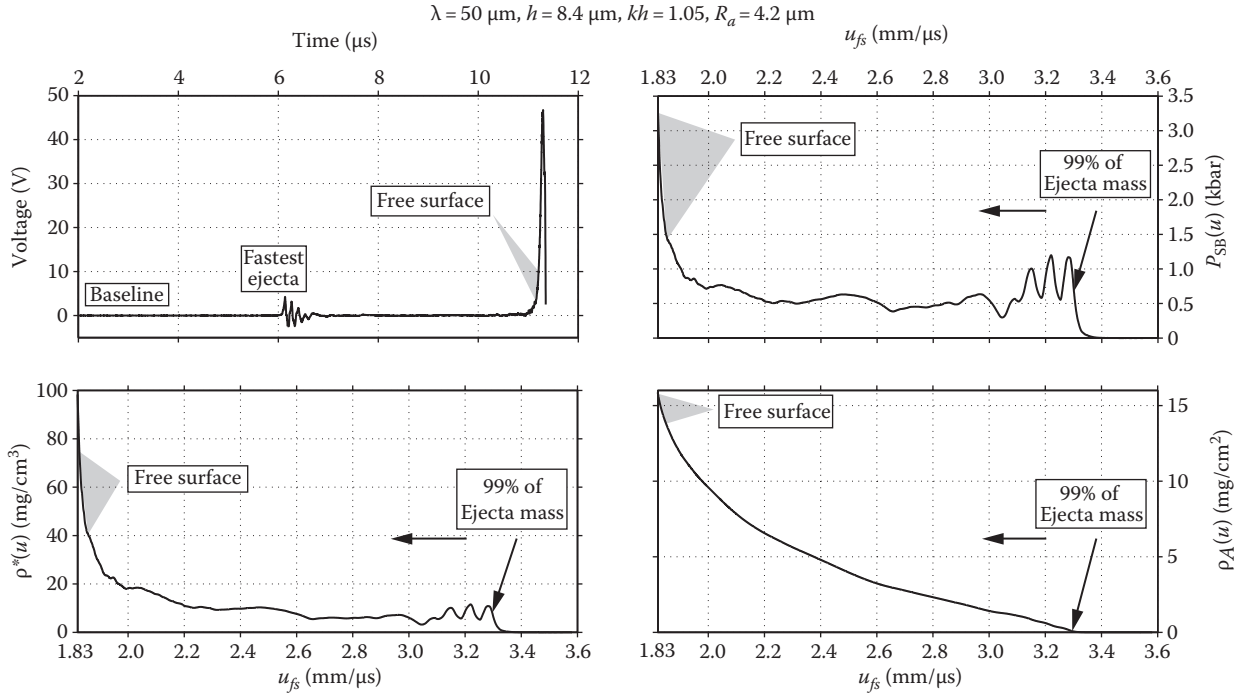

Figure 5.20

The lithium niobate (LN) pin voltage $V(t;z)$ (upper left), $P(u;z)$ (upper right), $\rho^*(u;z)$ (lower left), and $\rho_A(u;z)$ (lower right). The LN pin height is $z = 20.4$ mm, the free-surface velocity on center is $u_{fs} \approx 1.825$ mm/μs, and the finish parameters are quoted above the figures.

respectively. Prior to the dynamic radiograph, however, a Sn step wedge that includes small strips of solid density Sn foils of varying thicknesses (τ_{Sn} = 0.03, 0.05, 0.08, 0.10, 0.13, 0.15, 0.20, 0.46, 0.97, and 1.83 mm) is included in the image area. The static and dynamic images are digitized, and the dynamic image is then divided by the static image to determine I/I_0. Two examples of the x-ray ratios are seen in Figure 5.21, where the x-ray image on the top left is from a 2007 Sn experiment, and the x-ray image on the bottom left is from a 2013 Sn experiment (the x-ray data in Figure 5.21b are discussed extensively in Monfared et al. [2014]).

After the ratio image is computed, the average I/I_0 is fit to the foil (step-wedge) region to compare with the foil's known areal density, $\rho_A^T = \rho^*\tau \equiv \rho_{Sn}\tau_{Sn}$, and the resulting ratio is related as

$$\frac{I}{I_0} = Ae^{-B\rho_A^T}, \tag{5.144}$$

which gives constants A and B. Equation 5.144 is then inverted, and the results are applied to the ratio image pixels to determine ρ_A^T.

Consider the two x-radiographs seen in Figure 5.21; their character is quite different because their HE target geometries were different. In the 2007 experiment, the target was 2 mm thick with a perturbation finish of $(\lambda, h_0) \approx (50, 1.6)$ μm across the entire surface, while the target in the 2013 experiment in the Figure 5.21b x-ray image was 3 mm thick with a perturbation finish of $(\lambda, h_0) = (50, 8.4)$ μm. The latter target, however, had the perturbations embedded in a 4 mm wide strip just below a mirror like finish, a finish that is known to suppress ejecta (see Zellner et al., 2008a). The other differences were the HE. The PBX 9501 on the 2007 Sn experiment was 12.7 mm tall and the HE diameter was d = 12.7 mm, but the HE on the 2013 Sn experiment was 8.9 mm tall with d = 25.4 mm. These geometries gave u_{fs} = 1.9 mm/μs ($P_{SB} \lessapprox 27.7$ GPa) on the 2007 experiment and u_{fs} = 1.74 mm/μs ($P_{SB} \lessapprox 24.6$ GPa) on the 2013 experiment. The dimensionless target parameters were $kh_0 = 0.2$ (2007) and $kh_0 = 1.05$ (2013).

As noted in the discussion, the areal density ρ_A^T extracts simply by the application of Equations 5.143 and 5.144, which requires the ejecta path length τ. The quantity τ is approximated by subtracting twice the Sn height from the diameter of the HE, that is, $\tau_{2007} \approx 12.7 - 4 = 8.7$ mm and $\tau_{2013} \approx 25.4 - 6 = 19.4$ (this analysis follows from simple shock physics release wave rules). An inspection of the 2007 radiograph shows

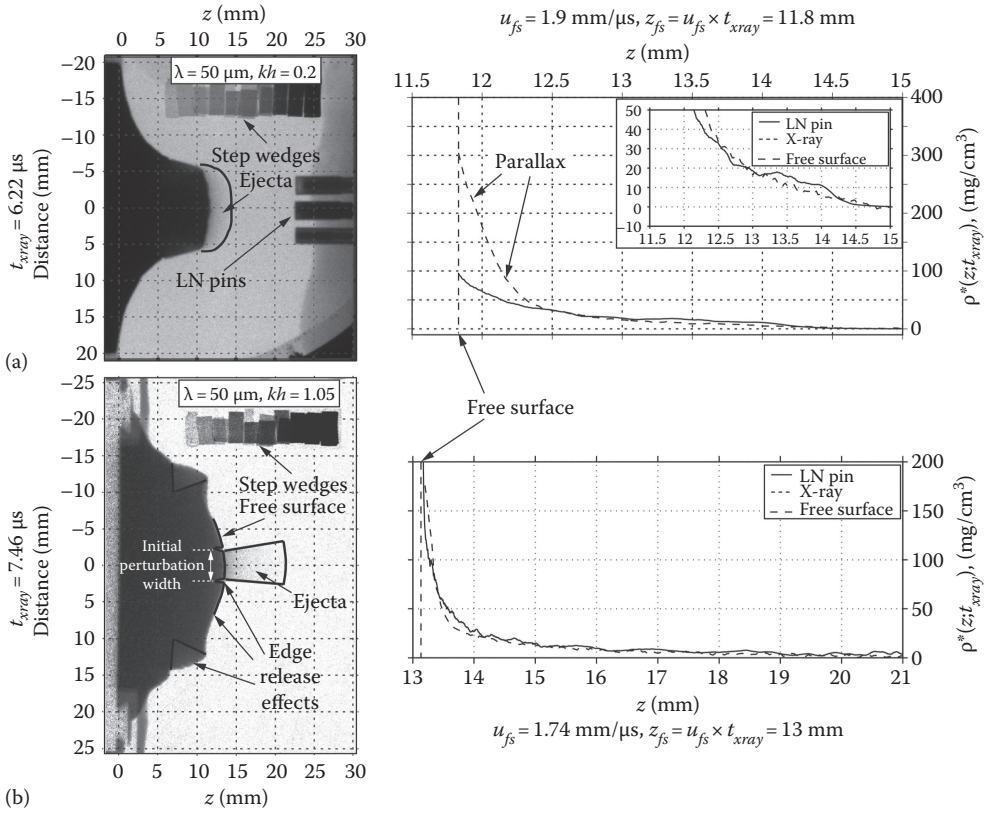

Figure 5.21

Shocked Sn target radiographs (to the left) showing an ejecta cloud (black outline), compared with their lithium niobate (LN) pin and x-ray $\rho_A^*(z;t)$ (to the right). The LN pin data (right) were transformed to the free-surface height (see Zellner et al. (2009a)) at the x-ray time (t_{xray}). The Sn step wedges aid density calibrations. Radiograph (a), t_{xray} = 6.22 μs after breakout. Radiograph (b), t_{xray} = 7.46 μs. (The data in (b) were acquired in 2013 and appear in Monfared et al. (2014).)

that this approximation is supported in the width of the ejecta cloud (vertical dimension), which is $\lessapprox$10 mm wide. Given the target geometry of the 2013 experiment, however, we cannot see the ejecta cloud width. Nevertheless, the curvature of the target in the lower image turns upward when the distance from the center is $\lessapprox$10 mm, or a width of about 20 mm—again consistent with the approximation of 19.4 mm. With this ejecta cloud dimension, $\rho^*(z;t_{xray}) = \rho_A^T(z;t_{xray})/\tau$, with uncertainties of ±10%.

5.4.2.4 Optical Shadowgraphy

Figure 5.22 shows nine *shadowgrams* captured with multiframe optical shadowgraphy. A typical optical shadowgraphy system includes a bright, intense flash lamp that is pulsed orthogonally (transverse) to the dynamic system of interest. Lenses relay the light through the dynamic region onto a photocathode that couples the image onto a fiber-coupled CCD camera. Depending on the number of frames desired, the photocathode directs the images to an appropriate section of the CCD for digitization after the experiment is over. A common CCD includes 4000 by 4000 pixels.

In the Figure 5.22 images, a total of nine "frames" were captured, which means each image is stored in an area of about 1300 by 1300 pixels. A typical pixel size might be 50 μm, and the image might be 30 mm by 30 mm, which relates the optical transfer function of the system, yielding an image resolution of about 3.5 to 4 line pairs per millimeter, about 125 μm.

Important system parameters include the exposure duration and interframe time. For our experiments, we normally used an exposure time of about 150 ns, but shorter times are possible. The minimum interframe time is 300 ns, and we usually chose the interframe times to be 300 ns for the first three frames in an attempt to bracket the time of the shock wave breakout at the surface in the time window of the first three frames. With these first three frames, in the event the velocimetry diagnostic failed, which was frequent with the VISAR diagnostic, then the time of shock wave breakout estimated from the framing camera can be used

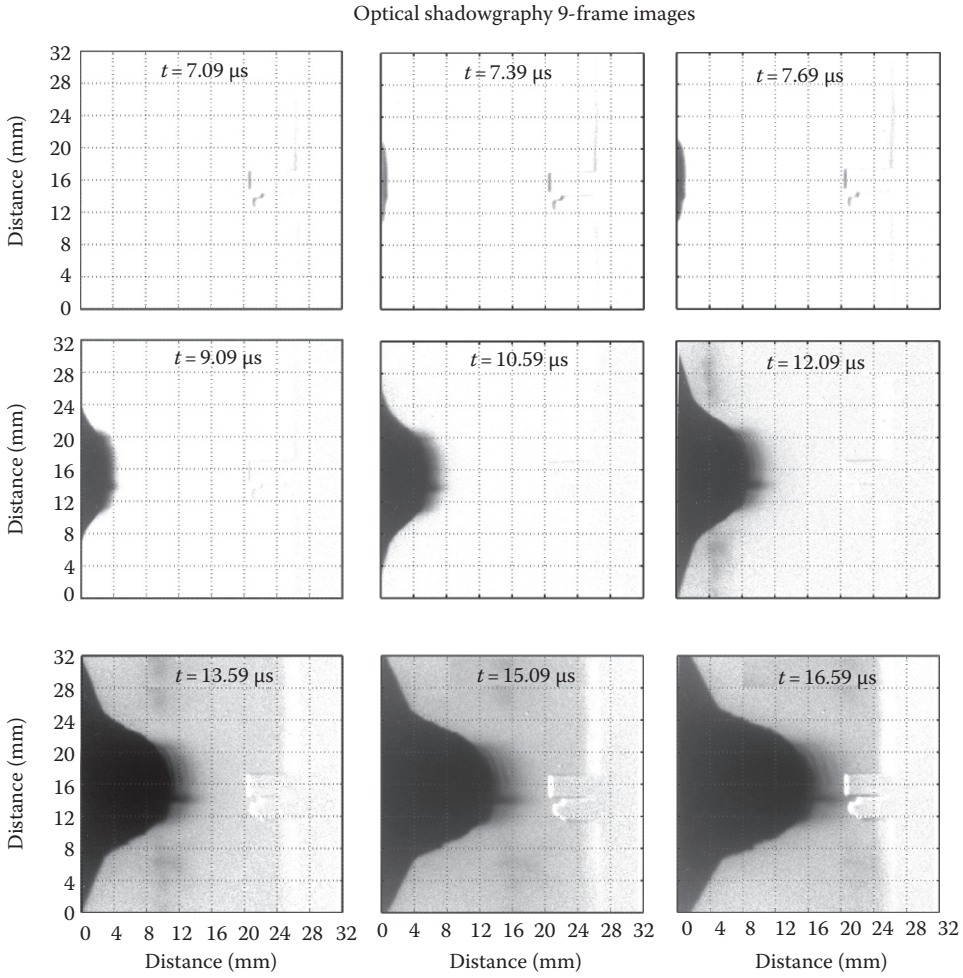

Figure 5.22

Typical optical shadowgraphy data. The first three frames were timed to capture shock breakout and allow an estimate of P_{SB} from the asymptotic pin velocity (the time of shock breakout to pin-failure time—this was vital when VISAR was the velocimetry diagnostic). The ejecta cloud is often optically thick and only reveals the leading ejecta cloud leading edge. Here, however, three ejected layers are seen within the shadowgrams.

with the time of flight of the Sn target to the LN pins to estimate u_{fs} (and P_{SB}).* The final six frames were nominally separated about 2 μs to observe the qualitative hydrodynamics.

Optical shadowgraphy data are useful for validating the qualitative hydrodynamic behavior of the shocked target and ejecta system and the quality of experimental data and results. Quantitative information that can be extracted includes an estimate the shock wave breakout time at the surface, but we also get the speed of the ejecta. In addition, if the ejecta cloud is not optically thick, the structure within the ejecta cloud the x-ray is insensitive to can be observed. The types of structural information that can be observed in the shadowgrams are seen in Figure 5.23a, which is the eighth frame from Figure 5.22. In this image, it is seen that the ejecta are confined between 11 mm and 21 mm in the vertical dimension—about 10 mm as determined in the x-ray image and estimated with the simple shock physics rules. In addition, high- and low-intensity ejecta "waves" are seen in the image—three if one looks closely. There is also an apparent spike traveling faster than the other ejecta around 14 mm in the vertical dimension. Because these are 2D shadows of potentially 3D features we cannot tell where the imaged structures originate, unless the symmetries are observed by the LN pins. As confirmation, consider the x-ray and LN pin $\rho^*(u_{ej}/u_{fs})$ data plotted in Figure 5.23b. The average densities seen by the LN pins and the x-ray agree, but the LN pins see three distinct ejecta waves the low-resolution x-ray data do not resolve. Again, the data confirm the value of the precision and accuracy of the LN pin data.

* Direct LDV (OHV) techniques are the common shock physics velocimetry diagnostic now and that diagnostic is robust.

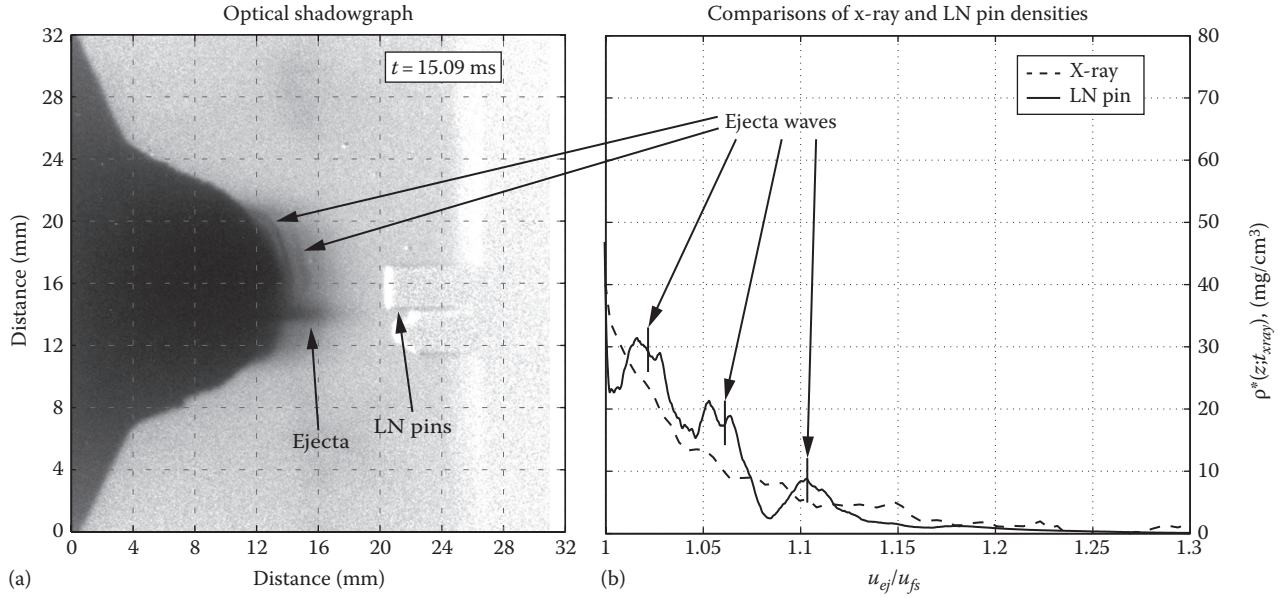

Figure 5.23

Optical shadowgraph (a): the eighth frame from Figure 5.22 (t = 15.09 μs). This image shows ejecta layers not seen in the x-ray $\rho^*_A(u_{ej}/u_{fs};t_{xray})$ in (b). However, $\rho^*_A(u_{ej}/u_{fs})$ from the lithium niobate (LN) pin data shows three ejecta layers, illustrating the better resolution and precision of the LN pin data relative to the x-ray data. This is because the x-ray resolution is only 2–3 line pairs/mm. Also seen in (a) is an asymmetry to the cloud. Because this is a 2D *shadow*, it cannot be determined from where this "jet" originated from the surface. ((a) appears as Figure 5 and the LN data of (b) as Figure 7 in Zellner et al. (2007).)

5.4.3 Richtmyer–Meshkov Instability Model of Ejecta

Studies of the Sn ejecta data set (mentioned earlier) lead to the development of an RM-physics-based ejecta source model (Buttler et al., 2012a,b) and a similar model by Dimonte et al. (2013). The basis of the 2D ejecta-sheet model is conceptually described by the geometry seen in Figure 5.15. There are important solid RMI results in Buttler et al. (2012b), but the key liquid metal RMI results are that the bubble tip velocity versus time is

$$\dot{h}^b(t) = \frac{\dot{h}^b_0}{1+\frac{3}{2}\dot{h}^b_0 kt} \approx \frac{2}{3kt} \equiv \dot{h}^b_t \to 0 \quad \text{as } t \to \infty \tag{5.145}$$

and the spike tip velocity is

$$\dot{h}^s_\infty = \sqrt{3}\,\dot{h}^s_0, \tag{5.146}$$

where superscripts b and s refer to the *bubble* and *spike* and $\dot{h}^{b,s}_0 \equiv \dot{h}^b_0 = -\dot{h}^s_0 = kh_0u_{fs}$ refers to the initial RM impulse for shock wave–driven incompressible linear instability growth, as shown by Richtmyer (1960).* Considering the physics implications of Equation 5.145, it is seen that the bubble velocity decays inversely with time to zero relative to u_{fs}, which is nominally twice the particle velocity u_p that appears naturally in shock physics conservation equations. We also see that for shorter wavelengths ($k \gg 1$) the bubble velocity asymptotes more quickly than for longer wavelengths, which possess more inertia. The spike, on the other hand, obtains a limited ballistic velocity independent of time, and as noted in Mikaelian (2010), this is the *maximum* velocity attainable by 2D spikes, that is, it is more accurate to say

$$\dot{h}^s_\infty \le \sqrt{3}\,\dot{h}^s_0. \tag{5.147}$$

* Equations 5.145 and 5.146 are expressed as Equations 5.16 and 5.17 in Buttler et al. (2012b).

There is an important linear correction to the Richtmyer impulse $\left|\dot{h}_0^{b,s}\right| = kh_0 u_{fs}$ when $At = -1$, namely, because the perturbations must invert through $y(x) = 0$ as they unstably grow they experience a compression different than the case where $At \approx 1$. In the work of Richtmyer, $At \approx 1$, he showed that to account for compressibility, one should use the postshock amplitude $h_0 = (1 - u_{fs}/u_{sh})$ and not the preshock amplitude h_0, where u_{sh} is the shock wave speed in the metal caused by the loading stress P_{SB}. For the opposite case where $At = -1$, however, Meyer and Blewett (1972) found that using the average of the preshock and postshock amplitudes gave better agreement. Therefore, we use

$$F_l = 1 - \frac{u_{fs}}{2u_{sh}} \tag{5.148}$$

as the linear (l) compression factor, which applies to both the bubbles and spikes.

The solutions in Equations 5.145 and 5.146, together with the Richtmyer impulse and the linear correction in Equation 5.148, apply when $kh_0 \ll 1$.* When $kh_0 \gtrsim 1$, nonlinear (subscript nl) corrections to the bubble and spike growth rates become important. The nonlinear corrections to the spikes are informed by simulations found in Velikovich and Dimonte (1996), and Buttler et al. (2012b) did a similar fit to data bound in Dimonte and Ramaprabhu (2010) for the nonlinear bubble correction:

$$F_{nl}^s = \frac{1}{1 + \left(\frac{kh_0}{2}\right)^2} \quad \text{and} \quad F_{nl}^b = \frac{1}{1 + \frac{kh_0}{6}}. \tag{5.149}$$

The product of these nonlinear and linear factors with the Richtmyer impulse and the bubble and spike velocities can be used to bound to the 99% level, ρ^* and ρ_A, where ρ_A is best estimated with an integration of Equation 5.145 to find

$$\begin{aligned} \rho_A(t) &= \frac{\rho_m V_d}{L\lambda} \\ &= \frac{\rho_m}{L\lambda} \int\int\int dt dx dz \cdot \dot{h}^b(t) y(x,t) \\ &= \frac{\rho_m}{L\lambda} \int\int\int dt dx dz \cdot y(x,t) \frac{\dot{h}_0^b}{1 + \frac{3}{2}\dot{h}_0^b kt}, \end{aligned} \tag{5.150}$$

where

$L\lambda$ is the surface area

$y(x, t)$ is the bubble shape function of the unstable RM growth into the surface

The shape function $y(x, t)$ is of great interest in RM unstable ejecta physics. For example, in the event that the surface is shocked again sometime later, and we have developed explosively driven two-shockwave tools to evaluate such mass ejection events (Buttler et al., 2014a,b), then we want to be able to predict the mass ejection source at the second event. In such an event, we postulate the shape and effective height of the bubble at the time of the second shock wave event will lead to an RMI mass ejection as well, meaning our RM models will predict the mass ejection caused by the second shock. The prediction of the second shock mass ejecta requires the effective height of the bubble at the time t' of the second event to know or estimate kh_0', which determines the RM impulse and total mass ejected. It is difficult to measure this height diagnostically in a once shocked metal, but techniques to bound h' are discussed in Buttler et al. (2014b).

So long as there is an infinite well of mass to support spike growth, the Buttler et al. (2012b) RMI model describes a mass ejection that increases with increasing P_{SB}, but that asymptotes with increasing time once the unstable RMI growth has begun. Experimentally, however, we have observed that this is true only for supported shock waves, such as from a flyer plate or gun type of experiment (Zellner et al., 2009a). For explosively

* In Buttler et al. (2012b), the RMI Sn validation data reported in Table I are in excellent agreement when $kh \leq 0.5$, which is typical for finished metals.

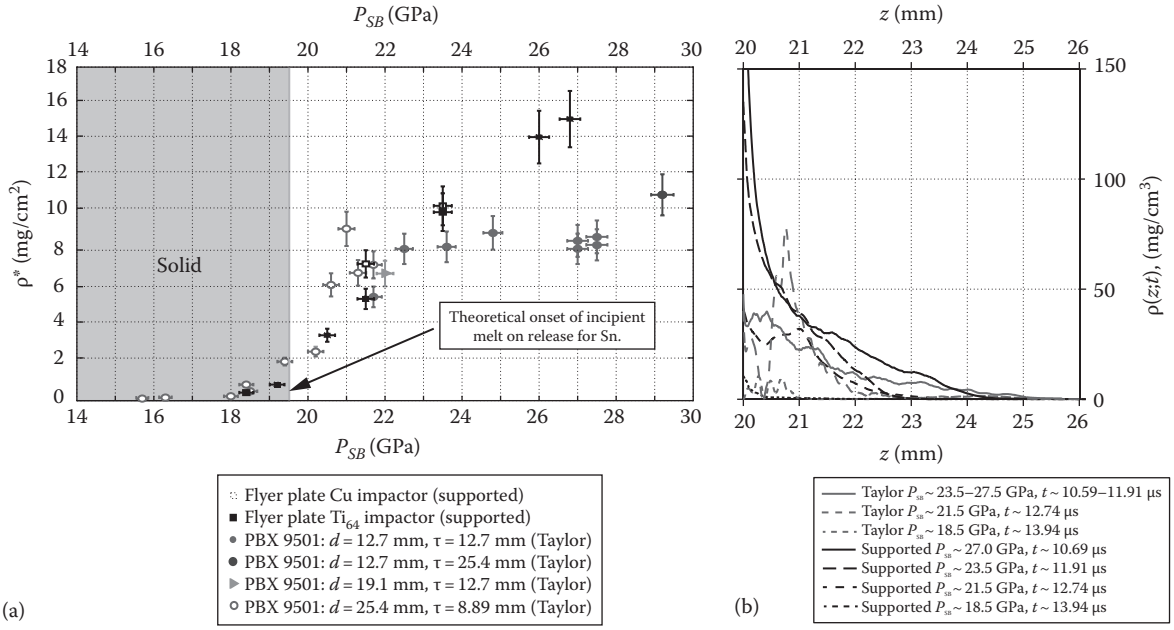

Figure 5.24

Plots in (a) and (b) are ejecta data from gun and HE experiments on Sn targets finished to $R_a \approx 0.8$ μm, $(\lambda, h_0) \approx (50, 1.6)$ μm. The (a) data are $\rho_A(P_{SB})$ and (b) $\rho^*(P_{SB}, z;t)$. In (a) the gray area ($P_{SB} \lesssim 19.5$ GPa) indicates the range of shock pressures below which Sn releases to a solid phase, according to the Sn EOS by Mabire and Hereil (2000) and Greeff et al. (2005); the EOS also says that Sn releases to a mixed solid–liquid phase when $19.5 < P_{SB} < 33$ GPa, and Sn is 100% liquid on release when $P_{SB} > 33$ GPa. The legends in (a) and (b) describe the experimental conditions: HE or flyer plate. P_{SB} was varied on the HE experiments by selecting the HE thickness τ and diameters d or by changing the flyer plate velocity. In (b) t is the time after shock breakout that the flyer reached the lithium niobate pins.

driven experiments, we have observed that the mass feeding into the spikes becomes asymptotic quickly and $\rho_A(P_{SB})$ plateaus (saturates), as seen in Figure 5.24a when $P_{SB} \gtrapprox 22.5$ GPa. This is not to say that the bubble velocity does not asymptote *quickly* in both HE and gun-driven ejecta systems, but in HE systems the asymptotic bubble velocity plateaus so that both ρ_A and ρ^* saturate when $22.5 \lessapprox P_{SB} \lessapprox 28$ GPa. In contrast, on the gun experiments it is seen that ρ_A increases linearly with P_{SB}, and ρ^* presents with higher ejecta densities further beyond the surface with increasing P_{SB}, as seen in Figure 5.24b. This divergence in $\rho_A(z;t)$ and the mass–velocity saturation in $\rho^*(z;t)$ for the HE-driven experiments is surprising. It is simplistic to say that this *plateau* in ρ_A and the different ρ^* distributions is linked to the Taylor wave shape of the shock waves caused by HE drives, as the shocked material will release into tension versus the release to zero pressure of a supported shock—all agree that this is the relevant phenomenon. However, the phenomenon is not well understood as a shutdown caused by spallation or cavitation of the shocked metal as the timescales for those processes appear to be too long. Because of the observed saturation in ρ_A and ρ^* for the HE experiments, our ejecta experiments were focused on HE-driven ejecta phenomena. This realization simplifies the calculation of $\rho_A(t)$ if we can define a $y(x, t)$ to define the mass production versus time. A lower limiting possibility on the total mass ejected assumes that $y(x, t)$ ends as it began, that is, $y(x,t) \mapsto y(x) = h_\infty^b \cos(kx) \mapsto h_0 \cos(kx)$. The opposite limit is that $y(x, t) = 1$. It is more likely that $y(x, t)$ is quadratic, or even some more complex shape, but the lower limit gives

$$\rho_A(t) = \rho(L\lambda)^{-1} \int\int\int dt dx dz \cos(kx) \frac{\dot{h}_0^b}{1 + \frac{3}{2}\dot{h}_0^b kt},$$

$$= \rho \frac{1}{\pi} \int dt \frac{\dot{h}_0^b}{1 + \frac{3}{2}\dot{h}_0^b kt},$$

$$= \frac{1}{\pi} \frac{\lambda\rho}{3\pi} \ln(1 + t/\tau), \tag{5.151}$$

where $\tau = \lambda/(3\pi F_1 F_{nl}^b \dot{h}_0^b) = \lambda^2/(6h\pi^2 u_{fs})$. Our Sn HE experiments indicate that $t/\tau \approx \mathcal{O}(10)$ when $\lambda \approx \mathcal{O}(100\,\mu\text{m})$ and $kh < 1$, which gives a critical time t_c such that $\dot{h}^b(t) = 0$ when $t \geq t_c$. This gives the mass–velocity distributions, which expand self-similarly with the constraint that $\dot{h}^b \mapsto u_{fs}$ when $t/\tau \approx 10$. In the upper limit where $y(x, t) = 1$, we find

$$\rho_A(t) = \rho(L\lambda)^{-1} \int\int\int dt dx dz \cos(kx) \frac{\dot{h}_0^b}{1 + \frac{3}{2}\dot{h}_0^b kt}$$

$$= \rho \int dt \frac{\dot{h}_0^b}{1 + \frac{3}{2}\dot{h}_0^b kt}$$

$$= \frac{\lambda\rho}{3\pi} \ln(1 + t/\tau). \tag{5.152}$$

These results imply an upper and lower bound on the mass ejection, and the mass velocity distribution will be limited less than the spike velocity.

As seen in Figure 5.15, our assumptions in the RMI model development are that the perturbations are described as a sinusoidal perturbation, when in fact a triangular perturbation is the more common surface perturbation geometry caused by machine tooling (see Vogan et al., 2005, Zellner et al., 2008b, Monfared et al., 2014). We assume, and experiments have borne out, that the two are simply related through the ratios of their defect volumes V_{fd}, but work in this area is ongoing, and other shape effect models have been proposed (Mikaelian, 2005, Li et al., 2014).

Combustion with Particles and Drops

Farzad Mashayek and Farhad A. Jaberi

6.1 Introduction
6.2 Overview of Single-Phase (Gaseous) Combustion
6.3 Isolated Drop
6.4 Group of Drops
6.5 Two-Phase Turbulent Combustion

6.1 Introduction

Two-phase flows involving a carrier gas laden with a dispersed phase composed of a large number of solid particles or liquid drops occur in many natural and technological applications. One of the most important applications involves the endothermic chemical reaction of the dispersed phase, as a fuel, with the carrier gas, as an oxidizer. For example, the engines that propel missiles, jets, and many other devices must rely heavily on combustion in a two-phase environment. Within the combustion chamber, the liquid fuel, which is first atomized into small drops, undergoes evaporation and reaction with the oxidizer gas. To enhance the rate of mixing and reaction, these systems are designed to operate in the presence of turbulence. Furthermore, chemical reaction triggers the formation of high-gradient regions in the flow and thus serves as a source for generation and amplification of instabilities that lead to turbulence. As a result, turbulence cannot be ignored in the majority of the situations involving chemically reacting flows. The presence of turbulence significantly adds to the complexity of such flows and to the challenges encountered in their physical understanding, theoretical description, and practical prediction. These challenges are primarily a consequence of the numerous degrees of freedom associated with a turbulent flow, which itself has remained as one of the main unsolved problems in science and engineering. The addition of fuel drops, with the associated phenomena of evaporation and chemical reaction, further introduces new sets of variables, often accompanied by large variations in scales.

The topic of combustion, let alone in the presence of a second phase, is too broad to be covered completely in one chapter. Further, if the solid phase is carbonaceous, both heterogeneous and homogeneous oxidations occur. A thorough description of heterogeneous or homogeneous combustion requires basic knowledge in thermodynamics, fluid mechanics, heat transfer, chemical reaction, two-phase transport, etc. In this section, we deal with drop evaporation and combustion only and refer to the review articles by Annamalai and Ryan (1993), Annamalai et al. (1994), and references therein for detailed discussion of solid particle combustion. We also restrict our discussion to subcritical conditions and refer to the review by Bellan (2000) for supercritical fluid behavior and modeling. As argued earlier, the presence of turbulence cannot be overlooked in a majority of practical situations. Turbulence effects will be discussed in more details in this second edition, but the reader is also referred to several other chapters, in this handbook, which are entirely devoted to interactions of the dispersed phase with turbulence. Regardless of the role of turbulence, the dispersed phase processes could become "interactive" when the distance between the drops is comparable

to a few times the drop radius. In this situation, evaporation and combustion of one drop may significantly be affected by the presence of other drops.

The next section provides a brief overview of single-phase or gaseous combustion. This overview assists the reader with no or little previous knowledge of combustion to follow the main discussions on two-phase combustion. The discussion of drop evaporation and combustion is presented first for an isolated drop. Although in an actual spray, isolated drop burning is somewhat unlikely, the study of isolated drops serves as an important first step toward understanding the physical phenomena and the underlying mechanisms for evaporation and combustion. It should be emphasized that the theoretical study of isolated drops involves several simplifying assumptions, the validity of which may be arguable in real sprays, in particular near the injector where the spray is dense. For example, the isolated drop combustion model results predict increasing temperature as size is reduced, which is contrary to the industrial experience. Therefore, the interactions among the drops must be considered. This is the subject of the second part of this discussion where a group of drops are considered. From a modeling and theoretical point of view, it is noted that the models for group combustion often use the isolated drop results as their starting point, hence another reason for discussing isolated drops. Finally, new to this second edition of the handbook, we provide a general discussion of practical spray modeling, followed by an overview of one of the most advanced modeling approaches currently available for spray combustion simulation.

6.2 Overview of Single-Phase (Gaseous) Combustion

Liquid-fuel combustion systems lead to a chemical reaction between the fuel vapor and the oxidizer gas, thus forming a single-phase, or homogeneous (typically gaseous), combustion process. Therefore, as a necessary prelude to two-phase combustion, in this section we provide a brief overview of the gaseous combustion. Gaseous combustion can be described through continuum transport equations for mass fractions of various species that participate in the chemical reaction. For a system of n chemically reacting species, the mass balance for the mass fraction Y_i of species i yields

$$\rho\frac{\partial Y_i}{\partial t}+\rho\boldsymbol{u}\cdot\nabla Y_i=-\nabla\cdot\boldsymbol{j}_i+\omega_i,\quad i=1,2,\ldots,n \tag{6.1}$$

where $\boldsymbol{j}_i$ and ω_i denote the diffusive flux and the chemical source term, respectively. The molecular transport processes that cause the diffusive flux can be quite complicated (Williams, 1985). For turbulent flows, which occur in many practical applications, this term can be simplified by considering a binary flux approximation, $\boldsymbol{j}_i=-\rho D_i\nabla Y_i$, where D_i is the binary diffusion coefficient, or mass diffusivity, of species i with respect to an abundant species. While this approximation provides a convenient form for describing the governing transport equations in turbulent flows, it should not be used in laminar flame calculations (Peters, 2000).

For a total number of r reactions

$$\sum_{i=1}^{n}\nu'_{ik}X_i\Leftrightarrow\sum_{i=1}^{n}\nu''_{ik}X_i,\quad k=1,2,\ldots,r \tag{6.2}$$

that may be considered in the calculation, the chemical source term ω_i in Equation 6.1 is described as

$$\omega_i=W_i\sum_{k=1}^{r}(\nu''_{ik}-\nu'_{ik})w_k \tag{6.3}$$

where $\sum_{i=1}^{n}\omega_i=0$ and for inert, nonreacting species $\omega_i=0$. In Equation 6.2, ν'_{ik} and ν''_{ik} are the stoichiometric coefficients on the reactants and products sides, respectively, for the ith species in the kth reaction, and X_i represents the chemical formula for species i. In Equation 6.3, W_i is the molecular weight of species i and w_k is the rate of reaction k in a mechanism containing r chemical reactions,

$$w_k=k_{fk}\prod_{i=1}^{n}\left(\frac{\rho Y_i}{W_i}\right)^{\nu'_{ik}}-k_{bk}\prod_{i=1}^{n}\left(\frac{\rho Y_i}{W_i}\right)^{\nu''_{ik}} \tag{6.4}$$

Here, k_{fk} and k_{bk} are the rate coefficients of the forward and backward reactions, respectively, and are in general temperature dependent. They may also depend on pressure in some cases.

To simplify the analysis, a "global" reaction mechanism may be considered. For overall reaction of the fuel F and oxygen O_2, yielding the products P, the global reaction mechanism can be described as

$$\nu_F F + \nu_{O_2} O_2 \rightarrow \nu_P P \tag{6.5}$$

For this single-step reaction, the reaction rate is written as

$$w = A\left(\frac{\rho Y_F}{W_F}\right)^{n_f}\left(\frac{\rho Y_{O_2}}{W_{O_2}}\right)^{n_{O_2}} \exp\left(-\frac{E}{RT}\right) \tag{6.6}$$

where

A is the preexponential factor
E is the activation energy

The exponential expression $A\exp(-E/RT)$ is known as the Arrhenius form and is widely used to describe the temperature dependency of the reaction rate. The exponents n_f and n_{O_2} relate to *reaction order*. According to Equation 6.6, the reaction is of order $n_f + n_{O_2}$ overall. For global reactions, n_f and n_{O_2} are not necessarily integers and are found by curve-fitting experimental data. In general, a particular global expression in the form of Equation 6.6 holds only over a limited range of temperatures and pressures and may depend on the details of the apparatus used to define the rate parameters (Turns, 1996).

In addition to species transport equations (6.1), the overall continuity, momentum, and energy equations of the mixture are needed to fully describe the gaseous combustion system. The continuity and momentum equations are similar to those in nonreacting flows; the energy equation is modified to account for combustion effects. The latter can be derived from the first law of thermodynamics as (Peters, 2000)

$$\rho\frac{\partial h}{\partial t} + \rho \boldsymbol{u}\cdot\nabla h = \frac{\partial p}{\partial t} + \boldsymbol{u}\cdot\nabla p - \nabla\cdot \boldsymbol{j}_q + q_R \tag{6.7}$$

where the frictional heating has been neglected as it has a small contribution for low-speed flows. The last term, q_R, is due to radiation and must be retained in furnace combustion. Here, the enthalpy h of the mixture is defined in terms of the enthalpies h_i of species i,

$$h = \sum_{i=1}^{n} Y_i h_i \tag{6.8}$$

Assuming ideal gas, h_i only depends on temperature T:

$$h_i = h_{ref,i} + \int_{ref}^{T} c_{pg,i}(T)dT \tag{6.9}$$

where

$c_{pg,i}$ is the constant pressure specific heat of species i
T is the temperature in Kelvin

The reference enthalpy $h_{ref,i}$ includes the chemical bond energy and is generally taken to be zero for H_2, O_2, N_2, and solid carbon. The reference enthalpy of combustion products such as CO_2 and H_2O is negative and is tabulated (Burcat, 1984). The specific heat of the mixture is also defined in terms of specific heats of various species:

$$c_{pg} = \sum_{i=1}^{n} Y_i c_{pg,i} \tag{6.10}$$

The heat flux $\boldsymbol{j}_q$ in Equation 6.7 includes the effect of enthalpy transport by the diffusive fluxes $\boldsymbol{j}_j$:

$$\boldsymbol{j}_q = -k\nabla T + \sum_{i=1}^{n} h_i \boldsymbol{j}_i \tag{6.11}$$

To close, the system of continuity, momentum, energy, and species conservation equations is augmented by the equation of state for ideal gas.

6.3 Isolated Drop

Evaporation and combustion of a single drop are among the fundamental processes in liquid-fuel combustion and have been studied extensively since the pioneering works of Spalding (1953) and Godsave (1953). The analysis for a general case involving all important processes such as internal circulation, drop deformation (Haywood et al., 1994a,b, Mashayek, 2001), turbulence (Sornek et al., 2000, Wu et al., 2001), and gravity (Gogos et al., 2003) effects is quite complicated. Under special circumstances, simplifying assumptions can be made to derive an analytical solution. This solution is very useful in providing insights into the physics of drop evaporation and combustion and has produced reasonable predictions in real applications. In this section, we briefly review the derivation of the analytical solution and its underlying physical assumptions.

6.3.1 Evaporation

Consider an isolated drop evaporating in a quiescent and infinitely large medium and assume that the evaporation is quasi-steady, that is, at any instant in time the process can be described as if it were in the steady state. The drop temperature is uniform, typically at the saturation temperature $T_s < T_b$, where T_b is the boiling point of the fuel at the given pressure. Without loss of generality, in the following we assume that the drop is at its boiling temperature. The drop preheat period does not significantly contribute to the overall combustion process and can be neglected. Also, in order to find an analytical solution, all thermophysical properties are assumed constant (Turns, 1996).

With these assumptions, the gas-phase mass conservation for a spherically symmetric drop at quasi-steady state reads

$$\dot{m} = \rho v 4\pi r^2 = \text{constant} \tag{6.12}$$

A relationship for the temperature variation in the gas can be found by considering the gas-phase energy conservation, which states a balance between the conduction and convection heat transfer:

$$4\pi k_g \frac{d}{dr}\left(r^2 \frac{dT}{dr} \right) = \dot{m} c_{pg} \frac{dT}{dr} \tag{6.13}$$

where

T is the gas temperature

subscript g refers to the gas properties

For a unitary Lewis number ($Le = k_g/\rho c_{pg} D$), by defining $\xi = c_{pg}/4\pi k_g = 1/4\pi\rho D$, the following problem can be stated for the gas-phase temperature:

$$\frac{d}{dr}\left(r^2 \frac{dT}{dr} \right) = \xi \dot{m} \frac{dT}{dr} \tag{6.14}$$

with boundary conditions $T(r = a) = T_b$ and $T(r \to \infty) = T_\infty$, where a is the drop radius. The solution of this equation for constant $\dot{m}$ yields

$$T(r) = \frac{(T_\infty - T_b)\exp(-\xi\dot{m}/r) - T_\infty \exp(-\xi\dot{m}/a) + T_b}{1 - \exp(-\xi\dot{m}/a)} \tag{6.15}$$

which indicates a steep temperature gradient near the surface of the drop. This temperature gradient determines the heat conducted into the drop that will be consumed entirely for evaporation since the drop is at its boiling point. Therefore, writing the energy balance at the drop–gas interface gives

$$4\pi k_g a^2 \left.\frac{dT}{dr}\right|_a = \dot{m} h_{fg} \tag{6.16}$$

Differentiating Equation 6.15 and substituting into Equation 6.16 gives the mass flow rate of the vapor

$$\dot{m} = \frac{4\pi k_g a}{c_{pg}} \ln(1 + B_e) \tag{6.17}$$

where

$$B_e = \frac{c_{pg}(T_\infty - T_b)}{h_{fg}} \tag{6.18}$$

is the transfer number, also known as the Spalding number. With the relation for mass in terms of drop diameter and density, a more common form of Equation 6.17 is the so-called d^2-law written as

$$d^2(t) = d_0^2 - Kt, \quad K = \frac{8k_g}{\rho_l c_{pg}} \ln(1 + B_e) \tag{6.19}$$

where

d is the drop diameter with an initial value of d_0

subscript l refers to liquid properties

To account for the temperature dependency of thermophysical properties, following the approach of Law and Williams (1972) for burning drops, c_{pg} and k_g are evaluated at the temperature $\overline{T} = (T_b + T_\infty)/2$:

$$c_{pg} = c_{pF}(\overline{T}), \quad k_g = 0.4k_F(\overline{T}) + 0.6k_\infty(\overline{T}) \tag{6.20}$$

where F refers to fuel vapor. Other approximations are suggested in Hubbard et al. (1975).

Adopting a similar set of assumptions as in the previous analysis, Mashayek (2001) investigated the effect of a deformation in the surface of a drop on its rate of evaporation by conducting finite element simulations of the gas surrounding the drop. The drop was assumed to be at its boiling temperature, and the gas properties were considered constant for a quasi-steady analysis. The surface of the drop was deformed using spherical harmonics:

$$h(\phi) = R_n[1 + \epsilon_n P_n(\cos\phi)] \tag{6.21}$$

where

$P_n(\cos\phi)$ is the Legendre polynomial of degree n

ϵ_n is the amplitude of disturbance (with respect to the spherical shape)

R_n is a correction factor introduced to keep the volume of the drop the same as the amplitude is changed

All lengths were normalized with the radius of the unperturbed (spherical) drop. Figure 6.1 shows the computational domain and the coordinate system used. The angle ϕ is measured from the axis of symmetry toward the equator of the drop.

Figure 6.2 shows the deviation parameter ψ as a function of ϕ for $n = 2$ at various amplitudes. Here, ψ indicates the difference between the evaporation rates of the deformed drop and the spherical drop as normalized by the evaporation rate of the spherical drop. The results indicate that the evaporation rate is larger near the axis of symmetry and lower near the equator, and the deviation from the evaporation rate of a spherical drop increases with the increase in the amplitude. Based on the results of the simulations, the following model was presented for calculating the evaporation rate of a deformed drop:

$$\chi = \left[F_n \left(\mathcal{K} - \frac{2}{\mathcal{R}_s} \right) + \frac{2}{\mathcal{R}_s} \right] \beta \tag{6.22}$$

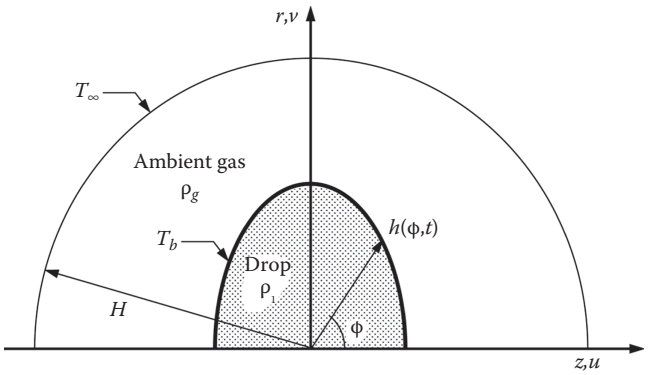

Figure 6.1

Coordinate system and solution domain used in computations of a deformed drop. (From Mashayek, F., *Int. J. Heat Mass Transfer,* 44, 1517, 2001.)

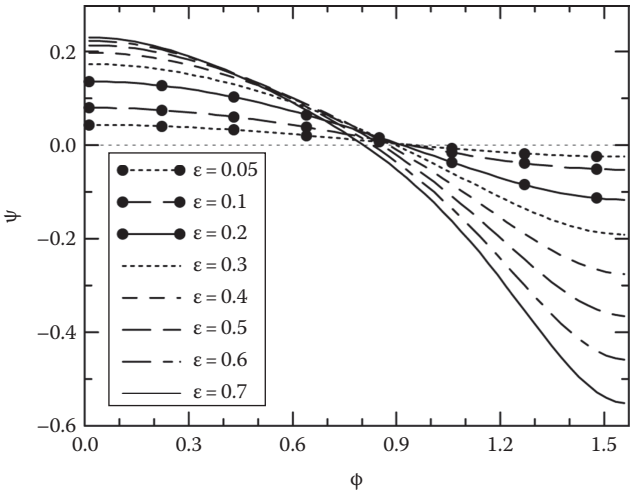

Figure 6.2

Variations of the normalized mass flux with angle ϕ at various amplitudes for a drop deformed with second spherical mode $n = 2$. (From Mashayek, F., *Int. J. Heat Mass Transfer,* 44, 1517, 2001.)

where $\mathcal{K}$ and $\mathcal{R}_s$ are the surface curvature and the nondimensional radius of the equivalent spherical drop, respectively. Also,

$$\chi = \left[\frac{\rho_l \sigma}{r_0}\right]^{(-1/2)} \dot{m} \tag{6.23}$$

is the dimensionless mass flux, and

$$\beta = \frac{1}{2}(\rho_l r_0 \sigma)^{(-1/2)} \left(\frac{k_g}{C_{pg}}\right) \ln(1 + B_e) \tag{6.24}$$

where r_0 and σ are the initial radius of the unperturbed drop and the surface tension coefficient, respectively. The function F_n depends on the mode of the surface disturbance and is defined as

$$F_n = \frac{3n+2}{2[n(n+1)+2]} \tag{6.25}$$

Equation 6.22 is valid for surface amplitudes up to 10% of the initial drop radius and has been tested for $0.1 \leq B_e \leq 2$ and for surface deformation up to $n = 8$. It is noted that Equation 6.22 reduces to Equation 6.17 for a spherical drop for which the surface curvature $\mathcal{K} = 2/\rho$.

6.3.2 Combustion

The analysis of a burning drop is understandably more complicated, but an analytical solution can be found for a simplified case. The diffusion flame requires that fuel and oxidizer react in stoichiometric proportions at the spherical flame that forms around the drop at a radius r_f. The reaction is assumed to be infinitely fast, and the flame is represented by an infinitesimally thin sheet. A single-component fuel is considered with zero solubility for gases, and there is phase equilibrium at the drop surface.

The analysis is also based on a Lewis number equal to 1 ($Le = 1$), where Le represents the relative importance of the thermal conductive transfer and transport by mass diffusion. For $Le > 1$, the mass diffusion transports thermal energy in the direction of increasing concentration. The role of the nonunitary Lewis number has been examined quantitatively in Chiu (2000) using a canonical theory of drop.

Figure 6.3 illustrates the two main regions formed inside and outside the flame. In the first region, between the drop surface and the flame, the fuel vapor concentration decreases monotonically with the radius, whereas the products, concentration shows the opposite variation. Since the products do not dissolve in the liquid, they do not move and remain stagnant in this region. At the flame, the products, concentration reaches the maximum (one) and the fuel concentration is zero. In the region outside the flame, the products, concentration decreases monotonically with increasing radius. The oxidizer concentration decreases from its free stream value of $Y_{Ox,\infty}$ at distances far away from the flame to zero at the flame.

Based on the physical model illustrated in Figure 6.3, the analysis is conducted to determine five parameters: fuel mass flow rate $\dot{m}_F$, fuel mass fraction at the drop surface $Y_{F,s}$, drop surface temperature T_s, flame temperature T_f, and flame radius r_f. The final results can be summarized as follows (Turns, 1996):

$$T_f = \frac{q_{i-l} + h_{fg}}{c_{pg}(Y_{Ox,\infty} + \nu)}[\nu B_c - Y_{Ox,\infty}] + T_s \tag{6.26}$$

$$r_f = a\frac{\ln[1 + B_c]}{\ln[(\nu + Y_{Ox,\infty})/\nu]} \tag{6.27}$$

$$Y_{F,s} = \frac{B_c - Y_{Ox,\infty}/\nu}{1 + B_c} \tag{6.28}$$

$$\dot{m}_F = \frac{4\pi k_g a}{c_{pg}} \ln(1 + B_c) \tag{6.29}$$

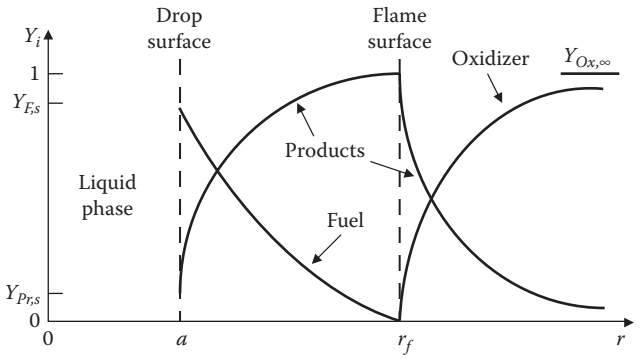

Figure 6.3

Species profiles in spherical drop burning without convection effects.

where

$$B_c = \frac{Y_{Ox,\infty}\Delta h_c/\nu + c_{pg}(T_\infty - T_s)}{q_{i-l} + h_{fg}} \tag{6.30}$$

with Δh_c denoting the lower heating value. One may rewrite Equation 6.29 as

$$\dot{m}_F = \frac{2Sh\pi k_g a}{c_{pg}} \ln(1 + B_c) \tag{6.31}$$

using the Sherwood number $Sh = h_m d/\rho D$ with h_m denoting the mass transfer coefficient. In this form, convective effects can also be included by empirically modifying Sh. For a spherical drop in quiescent atmosphere $Sh = 2$. Empirical correlations are found in the literature for cases with convective effects. It is also noted that Equation 6.29 can be expressed in the form of the d^2-law in Equation 6.19 with B_c replacing B_e.

In Equations 6.26 and 6.30, q_{i-l} is the rate of heat conducted into the interior of the drop per unit mass flow rate of vapor. The expression for q_{i-l} depends on the model used for drop heat up. If the drop rapidly heats up, then one can assume negligible thermal inertia and $q_{i-l} = 0$. The other easily tractable model is the so-called onion skin model for which $q_{i-l} = c_{pl}(T_s - T_0)$, where T_0 is the drop initial temperature.

Equations 6.26 through 6.30 can be evaluated for assumed T_s. For a saturated drop surface, one may alternately use the Clausius–Clapeyron relation to derive an expression for T_s in terms of the gas pressure P:

$$T_s = \frac{-B_c}{\ln\left[\dfrac{-Y_{F,s}PW_{Pr}}{A(Y_{F,s}W_F - Y_{F,s}W_{Pr} - W_F)}\right]} \tag{6.32}$$

where subscript Pr refers to products. This can be used in conjunction with an iterative approach to determine T_s along with the other unknowns. The effects of temperature dependency of the properties can be approximated by following the suggestions in Law and Williams (1972):

$$c_{pg} = c_{pF}(\bar{T}), \quad k_g = 0.4k_F(\bar{T}) + 0.6k_{Ox}(\bar{T}), \quad \rho_l = \rho_l(T_s) \tag{6.33}$$

where $\bar{T} = (T_s + T_f)/2$.

The assumption of quasi-steadiness is convenient for arriving at a closed analytical solution. However, this assumption could break down as a consequence of unsteady diffusion, drop heating, fuel vapor accumulation, compositional change of multicomponent drops, natural and forced convection, and finite-rate chemical kinetics (Chiu, 2000). The effect of this assumption was investigated by Law et al. (1980) for both evaporating and burning drops. The quasi-steadiness assumption implies that the total mass of vapor between the flame and the drop surface remains constant. However, when a drop is suddenly placed in an environment for which the vapor mass fraction is less than the saturation vapor mass fraction, the drop starts to evaporate and the mass of the vapor gradually increases. During these initial times, there is not much fuel vapor available for burning. For a lower flow rate of fuel into the flame, a lower supply of O_2 is required, thus the flame stands closer to the drop surface. As more fuel vapor is produced compared to fuel consumption, fuel vapor accumulates, the flame is pushed away from surface, and the burning rate gradually increases due to larger flame surface area for consumption. At larger times, the drop radius is small, vapor production is low, and hence consumption exceeds supply and as such flame is pushed back toward the surface. This behavior was captured by the analysis in Law et al. (1980) as demonstrated in Figure 6.4 for three different values of $Y_{Ox,\infty}/\nu$. It is observed that for small $Y_{Ox,\infty}/\nu$ the flame may not reach a steady location and instead continue to expand outward. The results in Law et al. (1980) also provided the rate of variation of d^2/d_0^2 and indicated that the d^2-law is adequate in predicting the evaporation rate and the instantaneous drop size. This suggests that despite the variations in flame surface location, the quasi-steady analysis may provide reasonable predictions for the drop burning rate, which is of primary concern in theoretical description of combustion systems.

In the presence of a convective flow, the flame surface could significantly deviate from a spherical shape. Chiu and Huang (1996) formalized the concept of the multistate for a drop, which refers to the existence of more than a single state under a given relative Reynolds number (see below) and ambient temperature. Three

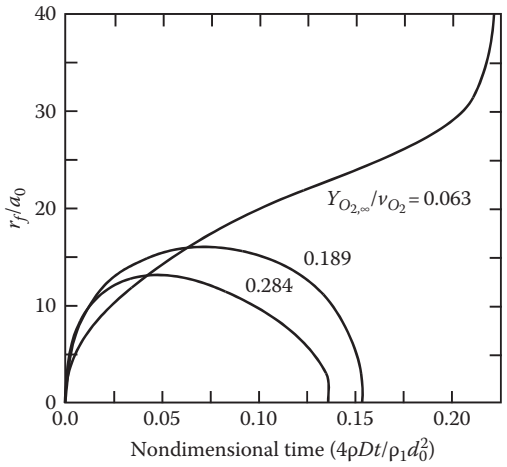

Figure 6.4

Temporal variations of the normalized flame radius for a heptane drop burning in the standard atmosphere. (From Law, C.K. et al., *Combust. Flame*, 38, 173, 1980.)

distinctive flame shapes were recognized, namely, *envelope* flame, *wake* flame, and *boundary layer* flame. The last flame is stabilized in the boundary layer of the liquid sphere. According to Chiu and Huang (1996), there are five distinct regions of Reynolds number bands in which the following multistates are possible: (1) one-state envelope flame, (2) two-state envelope flame vaporization, (3) three-state envelope flame-wake flame vaporization, (4) two-state wake flame vaporization, and (5) one-state vaporization. This multistate behavior also depends on the temperature that affects the transfer number and the Damköhler number *Da*. The Damköhler number is a measure of the relative importance of the flow timescale and combustion timescale. For an infinitely fast reaction $Da \to \infty$.

The effects of convection can be considered in the calculations by introducing a Nusselt number, *Nu*, into Equation 6.29 as

$$\dot{m}_F = \frac{2\pi k_g a Nu}{c_{pg}} \ln(1 + B_c) \tag{6.34}$$

The following empirical relations have been suggested for *Nu* as a function of relative Reynolds number, $Re_r = v_r d\rho_g/\mu_g$, where v_r represents the relative velocity between the drop and the surrounding gas:

1. Ranz and Marshall (1952)

$$Nu = 2 + 0.572 Re_r^{1/2} Pr^{1/3} \quad 1 < Re_r < 2000 \tag{6.35}$$

2. Clift et al. (1978)

$$\begin{aligned} Nu &= 1 + (1 + Re_r)^{1/3} \quad Re_r < 1 \\ Nu &= 1 + (1 + Re_r)^{1/3} Re_r^{0.077} \quad Re_r \geq 1 \end{aligned} \tag{6.36}$$

3. Faeth (1977)

$$Nu = 2 + \frac{0.555 Re_r^{1/2} Pr^{1/3}}{[1 + 1.23/(Re_r Pr^{4/3})]^{1/2}} \tag{6.37}$$

where *Pr* is the Prandtl number. It is noted that for all of these relations *Nu* = 2 in the absence of convection and Equation 6.34 reduces to Equation 6.29. Several other expressions for the heat and mass transfer of particles and drops have been obtained from numerical computations and are included in Sections 1.4.4.1 and 1.4.4.2 of this handbook.

6.4 Group of Drops

The analysis of a single drop is instructive for a basic understanding of evaporation and combustion processes; however, in real applications of liquid-fuel sprays large numbers of drops are present. In these situations, the interactions between neighboring drops become important for high drop number density (Umemura, 1994). These interactions are discussed in this section.

6.4.1 Interactive Evaporation

As the distance between two evaporating drops decreases, the drops compete for heat. Furthermore, the vapor concentration increases while temperature decreases. This combination results in a saturation condition in the spacing between the drops. A criterion for interactive evaporation of two drops is given in Annamalai and Ryan (1992) by considering the temperature profiles, Equation 6.15, around each drop. Based on this criterion, interaction between two drops becomes significant at a distance where the difference between the drop wet-bulb temperature (taken as the drop surface temperature boundary condition) and the local temperature is 90% of the difference between the drop wet-bulb temperature and the ambient temperature. This situation occurs at $r = 10a$; therefore, two evaporating drops begin to interact when the interdrop spacing l is such that $l < 20a$.

Theoretical studies often consider a group of drops confined in a spherical region with radius R_c. The analysis is conducted by considering different timescales, including the individual drop heating time and the time for the penetration of heat from outside to the core of the group of drops (Annamalai and Ryan, 1992). Another important phenomenon is the Stefan flow, which is due to the blowing of vapor from the drops and may drag the drops outwardly in dense sprays (Umemura, 1994). Nevertheless, most studies have neglected the effect of the Stefan flow and, as a result, predict higher evaporation rates. This is also true for an isolated drop, that is, a higher evaporation rate is predicted for an isolated drop when Stefan effects are neglected. However, the ratio of the evaporation rates, termed as the "correction factor" η, remains the same with or without Stefan effects. The correction factor is defined as the ratio of the vapor mass flow rate $\dot{m}_s$ of a single drop in the group to the vapor mass flow rate $\dot{m}_{iso}$ of an isolated drop

$$\eta = \frac{\dot{m}_s}{\dot{m}_{iso}} \tag{6.38}$$

The group evaporation usually results in $\eta < 1$.

In situations like spray combustion, the group of drops is suddenly exposed to a hot ambient gas. In these situations, the drops at the center of the group evaporate rather quickly and create a saturation condition in the spacing between the drops. This case can be analyzed as a confined volume problem with adiabatic condition with respect to the outside gas. A detailed discussion of various studies on group evaporation drop is presented in Annamalai and Ryan (1992); here, we provide a brief summary of the final results from some of these studies.

Zung (1967) presented a "cellular model" in which the inner drops evaporated in an adiabatic impermeable cell. For the drops in the outer cell, it was assumed that only half of the drop (shaded area in Figure 6.5) participated in evaporation and the other half did not evaporate. When the outside layer evaporated then the next layer was considered. Zung's analysis did not consider the energy balance equation and predicted that, for a fixed cloud radius, the cloud evaporation time reduces proportional to the drop radius regardless of the heat transfer from the ambient gas. Improved results were later presented by Tishkoff (1979) by considering a "bubble model" as shown in the inset of Figure 6.5. The spherical shell with radius b, considered around the drop with radius a, was permeable and elastic. Mass, energy, and species conservation equations were solved, and unsteady drop heating was allowed with a quasi-steady analysis for the gas phase. Saturation was reached for small b/a whereas for large b/a the drop fully evaporated. The transition from partial to full evaporation was dependent on temperature and pressure of the gas. The ratio b/a increased with the decrease in the initial gas temperature and/or pressure. Similar studies were also conducted by Bellan and Cuffel (1983) and Bellan and Harstad (1987a, 1988) who also included turbulence effects.

The previous studies were conducted by concentrating on the details of flow around individual drops within a cell, bubble, etc. A different class of studies has been reported in the literature that provides solutions for the global behavior of a cloud of drops by considering continuum transport equations for the entire cloud. These macroscopic equations are derived by averaging over a volume containing the drops of interest and are similar to equations for the gas but with source terms due to drop evaporation (and combustion in case of a reacting system). For example, for quasi-steady evaporation of a cloud of monosized drops,

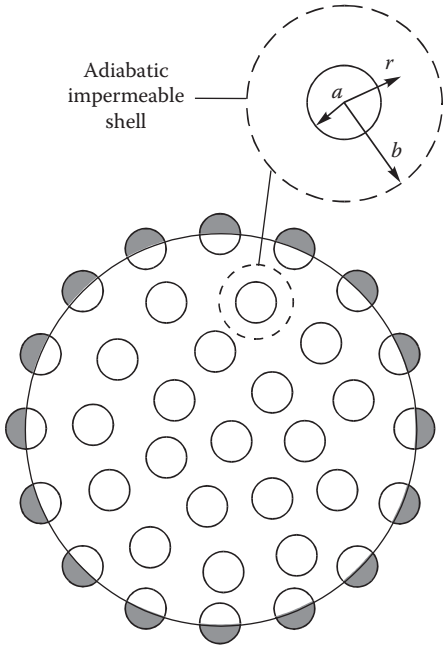

Figure 6.5

Illustration of cell model for group combustion. (From Annamalai, K. and Ryan, W., *Prog. Energy Combust. Sci.*, 18, 221, 1992.)

when the Stefan flow is neglected, the continuum equation for the average vapor mass fraction, $Y(r)$, in a spherical coordinate is described as (Annamalai and Ryan, 1992)

$$\frac{1}{r^2}\frac{d}{dr}\left(\rho D r^2 \frac{dY}{dr}\right) = -\dot{m}''' \quad \text{for } r < R_c$$

$$= 0 \quad \text{for } r > R_c \tag{6.39}$$

The volumetric source term $\dot{m}'''$ is due to evaporation of drops and is obtained by averaging over all the drops present in the volume of interest. The appropriate boundary conditions for this problem are

$$Y(r) = Y_\infty, \quad r \to \infty \tag{6.40}$$

$$\frac{dY}{dr} = 0, \quad r = 0 \tag{6.41}$$

The solution of Equation 6.39 with boundary conditions (6.40) and (6.41) for a monosized and uniform cloud yields the average correction factor as

$$\eta = \frac{3}{G}\left[1 - \frac{\tanh\left\{G^{(1/2)}\right\}}{G^{(1/2)}}\right] \tag{6.42}$$

Here, G is the group evaporation number:

$$G = 2Sh\pi naR_c^2 \tag{6.43}$$

where n is the number density of the drops. It should be noted that the definition of G depends on the geometry and spray distribution parameters in the cloud. Various forms used by researchers were summarized in Table 3 of Annamalai and Ryan (1992).

Annamalai (1985) considered Stefan flow in the quasi-steady analysis of a cloud of drops and showed that

$$\dot{m}_c = \dot{m}_{c,SE}\left[1 - \frac{\tanh\left\{G^{(1/2)}\right\}}{G^{(1/2)}}\right] \tag{6.44}$$

where $\dot{m}_c$ is the cloud evaporation rate for a monosized and uniform (n = constant) cloud and

$$\begin{aligned}\dot{m}_{c,SE} &= 4\pi\rho D\ln(1+B_e)nR_c, \quad \text{Stefan flow included}\\ &= 4\pi\rho DB_e nR_c, \quad \text{Stefan flow neglected}\end{aligned} \tag{6.45}$$

The average evaporation rate per drop is

$$\dot{m}_{s,c} = \frac{\dot{m}_c}{\frac{4}{3}n\pi R_c^3} \tag{6.46}$$

which yields

$$\eta = \frac{\dot{m}_{s,c}}{\dot{m}_{iso}} = \frac{3}{G}\left[1 - \frac{\tanh\left\{G^{(1/2)}\right\}}{G^{(1/2)}}\right] \tag{6.47}$$

for a monosized and uniform cloud. It is interesting to note that Equation 6.47 with Stefan flow included is the same as Equation 6.42, which was obtained by neglecting Stefan flow.

The G number can be used as an indicator for the denseness of a spray. Evaluation of Equation 6.47 shows $\eta \simeq 0.9$ and 0.1 for $G = 0.1$ and 100, respectively. Therefore, for practical purposes, clouds having $G < 0.1$ may be considered dilute enough such that drops can be treated as isolated. Clouds with $G > 100$ should be considered as dense. For very small G values, approaching zero, every drop in the cloud is surrounded by the gas at T_∞ whereas for very large values of G, approaching infinity, every drop in the interior of the cloud is at the same temperature. In the latter case, the vapor mass fraction in the spacing between the drops corresponds to the saturated condition and only drops near the outer region of the cloud evaporate. In this case, the cloud is said to evaporate in the *sheath* evaporation mode. It should also be noted that, in a real spray situation, drops move around with the flow and drop–drop collisions are likely for dense clouds. In this situation, the analysis here may not be applicable.

The effects of size distribution were also considered in Annamalai (1985) by assuming a monotonic distribution for the number density n and drop radius a in the form

$$\frac{na}{(na)_{R_c}} = \left[\frac{r}{R_c}\right]^{-q} \tag{6.48}$$

where $(na)_{R_c}$ is the reference quantity at $r = R_c$. For $q = 0$, Equation 6.48 yields the uniform distribution considered earlier. The correction factor for this case is given as

$$\eta = \left[1 + \frac{G_1}{3-q} + \frac{G_1^{(1/2)}}{3-q}\frac{l_{(5-2q)/(2-q)}[2G_1^{(1/2)}/(2-q)]}{l_{(3-q)/(2-q)}[2G_1^{(1/2)}/(2-q)]}\right]^{-1} \tag{6.49}$$

with G_1 defined as

$$G_1 = (1-q)^{(1/3)}G \tag{6.50}$$

for fixed size and varying number densities and

$$G_1 = (1 - q/3)G \tag{6.51}$$

for fixed number density and varying sizes. In Equation 6.49, $l_{(5-2q)/(2-q)}$ represents the modified Bessel function of order $(5 - 2q)/(2 - q)$.

6.4.2 Interactive Combustion

The analysis in previous sections for an isolated drop assumes that a spherical flame is formed at a radius r_f around the drop. This assumption may be valid as long as there is no other drop in the vicinity of the first drop. When the distance l between two drops is decreased, there is an opportunity for two flames to interact. This interaction is intensified by the fact that the two drops must also compete for oxygen in order to continue their combustion. This intuitive conclusion can also be drawn from Equation 6.27, for the flame radius, in which $Y_{Ox,\infty}$ appears in the denominator. With the decrease of $Y_{Ox,\infty}$, the denominator becomes smaller and the flame radius increases. As the distance between the two drops is further decreased, their flames merge and a common flame is formed around the two drops. According to Williams (1985), a simple criterion for the interaction of two burning drops can be stated as $l < 2r_f$.

Similar interactions occur for a system consisting of a large number of drops, forming a group of drops. In this case, several different "modes" of group combustion can be identified. A large body of literature is devoted to group combustion studies; however, it appears that the studies by Chiu and coworkers (Suzuki and Chiu, 1971, Chiu and Liu, 1977, Chiu et al., 1982) have been more widely recognized. In order to characterize various combustion modes, Suzuki and Chiu (1971) and Chiu et al. (1982) used the group combustion number:

$$G = 3\left[1 + 0.276 Re_r^{(1/2)} Sc^{(1/3)}\right] LeN^{(2/3)}(d/l) \tag{6.52}$$

where

Sc is the Schmidt number

N is the total number of drops in the group

This nondimensional number represents the ratio of the heat transfer in the gas phase and the heat transfer between two phases accounting for the convective effect.

The G number has been used to differentiate between weak and strong drop interactions. According to Chiu et al. (1982), four modes of group combustion are identified as shown in Figure 6.6. For low values of G, the drops are widely separated and individual drop combustion is dominant (Figure 6.6a). As G is

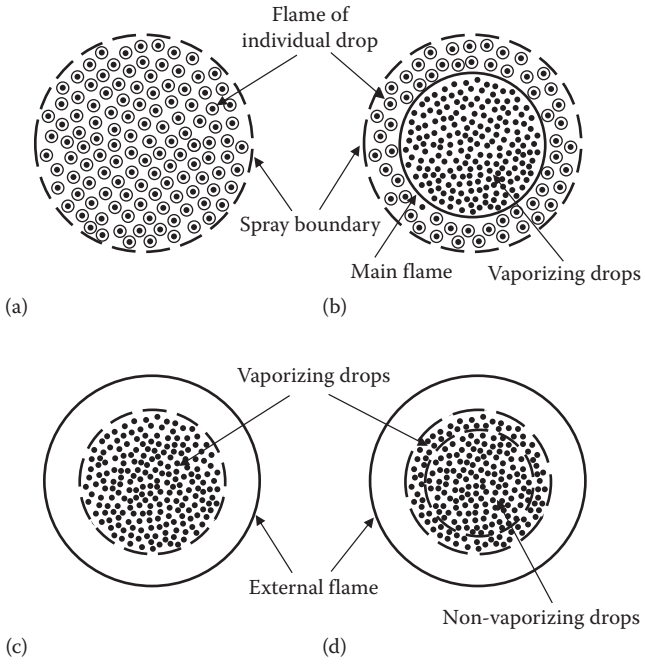

Figure 6.6

Four group combustion modes of a drop cloud. (a) Single drop combustion at low G, (b) internal group combustion, (c) external group combustion with a *standoff* flame, and (d) external group combustion with *sheath vaporization* at high G. (According to Chiu, H.H. et al., Internal group combustion of liquid droplets, in *Proceedings of 19th Symposium* (*International*) *on Combustion*, The Combustion Institute, Pittsburgh, PA, 1982, pp. 971–980.)

increased, the spacing between the drops decreases and the flames from various drops combine. For moderate increases in G, the main flame is located somewhere within the cloud of drops (Figure 6.6b). Between this main flame and the external boundary of the cloud, single drop burning is observed. Further increase in G pushes the flame outside the cloud boundary and forms a *standoff* flame (Figure 6.6c). In this case, all the drops are vaporizing as combustion takes place at the flame. Finally, for very large values of G, while the standoff flame forms outside the cloud, the drops in the core of the flame are saturated and do not evaporate. In this sheath evaporation case, evaporation occurs only for the drops located near the edge of the cloud (Figure 6.6d). As these boundary drops fully evaporate the evaporation front shrinks toward the center of the cloud and the drops in the core begin to evaporate.

The earlier group combustion modes can be applied to spray combustion as shown in Figure 6.7 (Chiu and Croke, 1981). Due to cold temperatures and high drop number density in the spray near the nozzle, the ignition of the spray takes place at a distance from the nozzle exit. Once the spray is ignited, an external flame forms while the core of the spray consists of evaporating drops. Further downstream, the spacing between the drops increases and the flame penetrates into the spray, thus forming multiple group combustion. At the end, combustion continues by consuming the unburnt gaseous fuel.

Annamalai and Ryan (1992) presented a modified form of the spray classification of Chiu and coworkers by considering six modes of combustion as seen in Figure 6.8. This figure maps these various modes on a plot of the total number of drops in the cloud versus the ratio of the drop spacing to drop diameter, l/a, for various values of G in Equation 6.43. Region (I) corresponds to isolated drop combustion for $G < 0.01$, whereas region (II) involves isolated to incipient group combustion for $0.01 < G < 0.1$. The incipient combustion is when the flame radii of the center drops in the cloud just touch each other. Regions (III) through (V) for $0.1 < G < 1$, $1 < G < 10$, and $10 < G < 100$ are termed as partial group combustion, group combustion, and intermediate group combustion, respectively. In partial group combustion, while there is a group flame for the inner drops, the outer drops burn with individual flames but still allow O_2 to penetrate into the flame located within the cloud. Finally, for $G > 100$ combustion is in the sheath mode where the temperature at the cloud surface is at the wet-bulb temperature of the drops and the cloud behaves as an equivalent single drop of radius R_c. Any convective effects will move the lines in Figure 6.8 downward and downward movement will be greater at smaller interdrop spacing.

The model of Chiu and coworkers and their G parameter have been extensively assessed by experimentalists in spray combustion (Chen and Gomez, 1997, Wark et al., 2000). Wark et al. (2000) examined the variation of G in their experiment of an acoustically forced jet. The forcing resulted in the formation of organized structures consisting of core and wings as seen in Figure 6.9. Phase Doppler interferometry was used to obtain drop statistics for the calculation of the group combustion number. It was not possible to experimentally generate the exact conditions to evaluate G using Equation 6.52. Therefore, several assumptions were made, including the neglect of the convective effects and $Le = 1$. The expression of G used by Wark et al. (2000), after applying the simplified assumptions, was

$$G = 2\pi nd(R_c)^2 \tag{6.53}$$

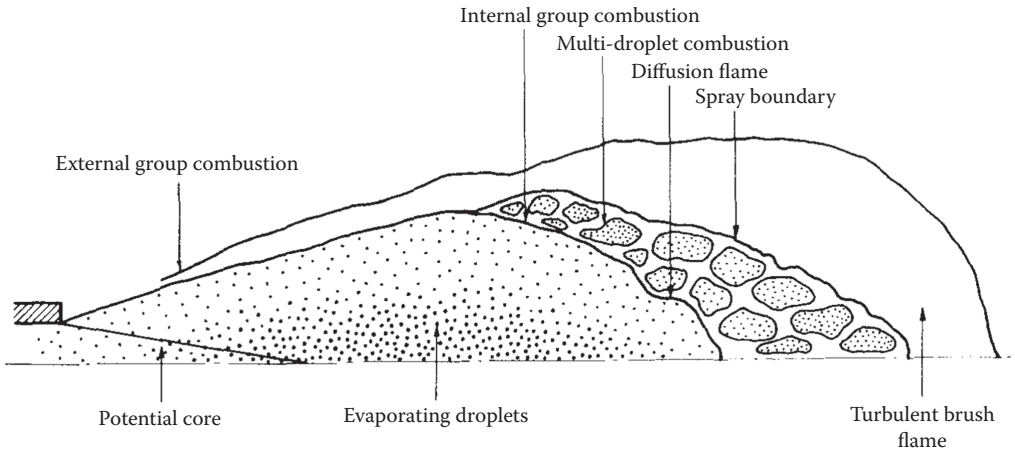

Figure 6.7

Schematic of liquid-fuel spray group combustion. (From Chiu, H.H. and Croke, E.J., Group combustion of liquid fuel sprays, Technical Report 81-2, University of Illinois at Chicago, Energy Technology Lab, Chicago, IL, 1981.)

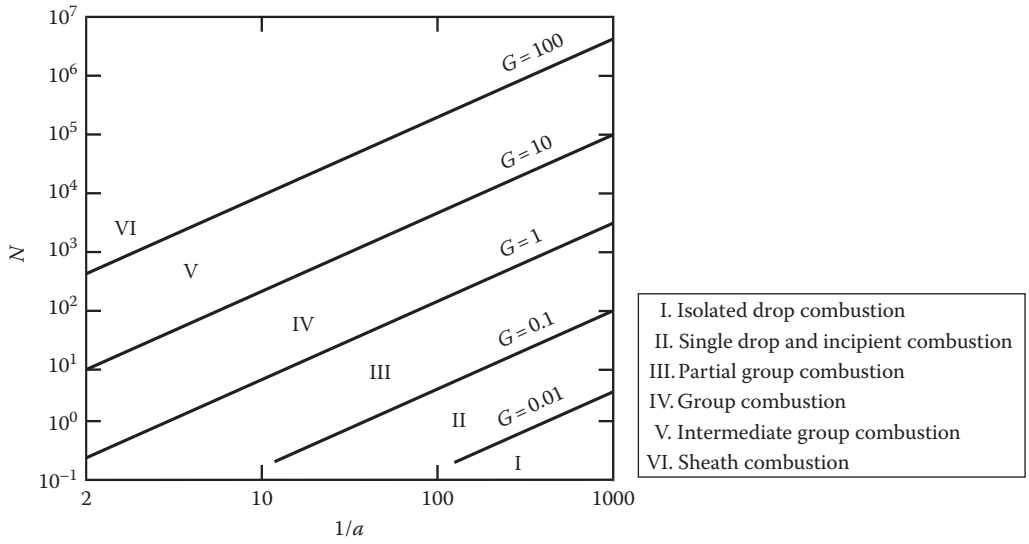

Figure 6.8

Group combustion number as a function of nondimensional spacing *l*/*a* and the total number of drops. (From Annamalai, K. and Ryan, W., *Prog. Energy Combust. Sci.*, 18, 221, 1992.)

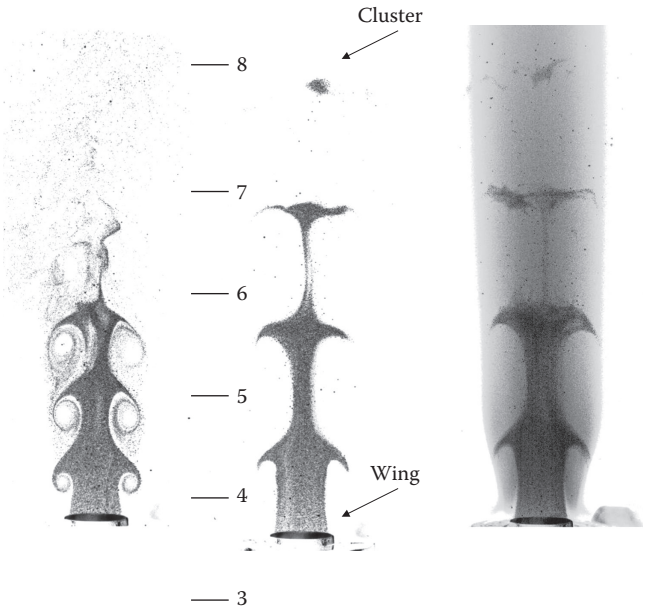

Figure 6.9

Phase-locked images of the drop-laden jet considered in the study of Wark et al. (2000).

which is the same as Equation 6.43 when $Sh = 2$ is used in the absence of convective effects. The drop number density n was obtained directly from the measurements. The mean drop diameter from the measurements was used as a representative diameter for use in Equation 6.53, although the drop size distribution was not uniform. The assessment of G was very sensitive to the choice of R_c as witnessed from Equation 6.53. An appropriate value was chosen for R_c depending on whether the core or the wing region was considered. In the core region, the radius of the drop-laden portion of the jet was considered as a reasonable choice.

Wark et al. (2000) calculated the axial variation of G as shown in Figure 6.10. The results suggested that close to the nozzle the jet was burning in external sheath mode and then changed to internal group burning after $z/D \simeq 2$ where D and z represent the jet diameter and the axial distance, respectively. After the third structure, the value of G dropped significantly, corresponding to individual drop burning.

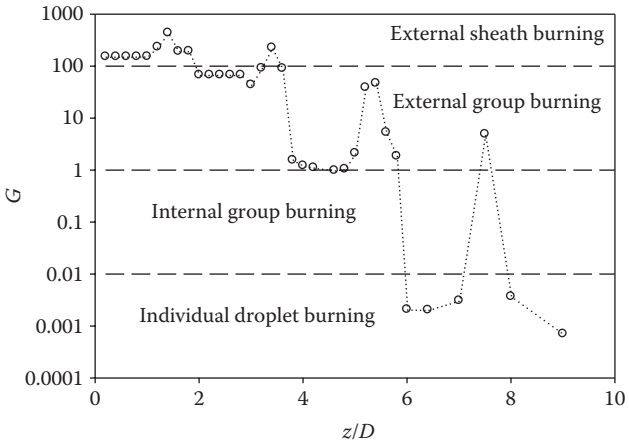

Figure 6.10

Phase-locked (0°) axial development of the group combustion behavior of drops. (From Wark, C. et al., *Combust. Flame*, 120, 539, 2000.)

From the comparison of Figures 6.9 and 6.10, it was not unreasonable to expect external sheath burning early in the flame. However, Wark et al. (2000) questioned whether individual drop burning was taking place between the third and fourth structures, as was predicted by the calculation of *G*. This was in agreement with previous experiments (e.g., McCreath and Chigier, 1973), which did not show any signs of single drop burning in the spray.

Annamalai (1985) provided similar relations to those in Equations 6.44, 6.47, and 6.49 for quasi-steady combustion of a cloud of drops. These relations were provided for both monosized uniform cloud and a cloud with the product of size and number density of the drops given as Equation 6.48. These results gave correction factors that can be used for the calculation of the cloud burning rate in terms of the burning rate of an isolated drop.

6.5 Two-Phase Turbulent Combustion

The theoretical approaches discussed in previous sections are very useful for developing a fundamental understanding of the physical processes involved in two-phase combustion in laminar flows. However, as was also emphasized in the introduction, the practical situations encountered in spray combustion and other multiphase reacting systems often involve turbulence whose effect cannot be fully described by these theories; see Li (1997) for a review of spray combustion in laminar stagnation flows. A thorough description of spray combustion requires modeling of turbulence interactions with drops and its effect on chemical reaction. More specifically, modeling is required for interactive processes involving turbulence and combustion, along with drop dispersion, heat transfer, and evaporation.

The significance of turbulence in multiphase systems and the modeling of turbulence effects on drop dispersion are extensively discussed in Sections 1.4.3.3 and 1.4.4.4 and in Chapter 12 of this handbook. The level of modeling for turbulence varies depending on the nature of the problem and the computational resources available. To this end, the three major simulation strategies, namely, direct numerical simulation (DNS), large eddy simulation (LES), and Reynolds-averaged Navier–Stokes (RANS) simulation, have been widely employed in the computational analysis of multiphase turbulent flows. In addition to these three methods, there are some methods that are labeled as *hybrid* such as hybrid LES/RANS. DNS requires significant computational resources, and its application has been limited to basic research problems involving simple geometries and moderate Reynolds numbers (Mashayek, 2000, Reveillon and Vervisch, 2000). Such simulations make use of high-order computational methods on powerful computer platforms to deal with specific physical issues. They have also been very useful in assessing the performances of many of the closures in RANS and LES. RANS has been the method of choice for practical applications and perhaps this trend will continue for the near future. LES makes use of many of the desirable features of both DNS and RANS and has experienced significant growth in two-phase flow simulations within the past decade or so. However, the predictive capability of LES depends on the success of its subgrid-scale (SGS) closures (Lesieur and Métais, 1996, Meneveau and Katz, 2000) and the numerical solution method.

The numerical methods employed for two-phase turbulent flow simulations are generally based on three different approaches (Brennen, 2005, Crowe, 2006): (1) Eulerian–Eulerian approach (Elperin et al., 1996, Scardovelli and Zaleski, 1999, Shyy and Narayanan, 1999, Lakehal, 2002, Pandya and Mashayek, 2002a,b, Herrmann, 2003, Mashayek and Pandya, 2003, Sethian and Smereka, 2003, Cuenot et al., 2006), (2) Eulerian–Lagrangian approach (Faeth, 1987, Shirolkar et al., 1996, Crowe et al., 1998, Sirignano, 1999, Bellan, 2000, Loth, 2000, Apte et al., 2003, Mahesh et al., 2006, Menon and Patel, 2006, Patel et al., 2007), and (3) Lagrangian–Lagrangian approach (Chen and Doolen, 1998, Mashayek and Pandya, 2003, Salman and Soteriou, 2004). In the first approach, the continuum transport equations for both phases are solved. These equations are somewhat similar for both phases and are often obtained by some form of volume averaging, which is conceptually different from the ensemble averaging in RANS or space averaging in LES. In the second approach, the carrier fluid equations are solved in its instantaneous form in DNS or in its averaged form in RANS and LES over an Eulerian grid system. However, the dispersed phase (particles, drops, etc.) is described by a set of modeled Lagrangian equations that determine the position, velocity, temperature, and other properties of the dispersed phase (Drew, 1983, Zhang and Prosperetti, 1994, Jackson, 1997, Crowe et al., 1998, Sirignano, 1999, Loth, 2000, Pandya and Mashayek, 2003). In the third approach, both phases are described by Lagrangian models.

Most of the practical models for spray have been based on the Eulerian–Lagrangian approach, which is the focus of our attention in this chapter. The Eulerian–Eulerian and Eulerian–Lagrangian models have been employed for RANS, LES, and DNS of a wide range of two-phase or two-fluid turbulent flows including free surface flows or dispersed turbulent flows (Faeth, 1987, Shirolkar et al., 1996, Crowe et al., 1998, Scardovelli and Zaleski, 1999, Shyy and Narayanan, 1999, Sirignano, 1999, Bellan, 2000, Loth, 2000, Menon, 2000, Lakehal, 2002, Mashayek and Pandya, 2003, Sethian and Smereka, 2003, Cressman et al., 2004, Moin, 2004, Madnia et al., 2006). In comparison, there are a limited number of models based on Lagrangian–Lagrangian approach. An example is the two-phase random vortex model of Salman and Soteriou (2004). Neither these types of models are not discussed here nor we discuss RANS models developed based on Eulerian–Eulerian and Eulerian–Lagrangian methods. Detailed descriptions of the numerical methods in multiphase flow are given in Chapter 1.

6.5.1 Modeling in Various Spray Regimes

Multiphase flow systems are often classified by the flow regimes: dilute, moderately dense, and very dense. All of these regimes are present in sprays (Faeth, 1987). In the dilute spray regime, the volume fraction of drops (or particles) to carrier fluid is very small and the drop–drop interactions are rare, making the continuum assumption and Eulerian–Eulerian formulation essentially invalid. In this regime, the drops are often treated as point masses that are affected by the carrier gas through mass, momentum, and energy interactions. The coupling could be two way, allowing the particles to also modify the carrier fluid.

The traditional approach to the spray simulation has been to compute the gas phase by a grid-based Eulerian method and the spray by the particle-based Lagrangian method. For this, the drops are treated as point sources within a given computational cell. The effects of each drop are distributed over the nodes of the cell, with some weights inversely proportional to the distance of the drop from various nodes. This approach is known as particle source in cell (PSIC) method (Crowe et al., 1977). The approximations involved in this approach have prompted some researchers to seek more accurate methods (see, e.g., Maxey et al., 1997); however, due to its simplicity of implementation, PSIC has remained as a method of choice for the simulation of turbulent sprays. In theory, it is possible to simulate the flow domain outside the drop in the boundary layer and wake region. However, these simulations, referred to as "resolved-volume simulations" (Loth, 2000), are very expensive and are usually limited to one or handful number of particles in simple flows and do not seem to be applicable to realistic spray simulations.

In the PSIC and hybrid Eulerian–Lagrangian approach, submodels are required to account for various physical processes taking place at small time and length scales in both Eulerian and Lagrangian fields. Even with an accurate modeling of the gas flow, the accuracy of simulations is still dependent on the models used for the drop transport, liquid evaporation, micromixing, chemical kinetics, and turbulence–combustion interactions (Jiang et al., 2010, Jenny et al., 2012). For the drop transport, a modified nonlinear version of the Lagrangian–Stokes equation is often used (Crowe et al., 1998, Sirignano, 1999, Loth, 2000). The "exact" gas velocity is available in DNS for calculating the drop velocity and for moving the drops. In the most early LES studies of dilute two-phase turbulent flows (Yeh and Lei, 1991), particles were tracked by using only the filtered Eulerian velocity field, and the effects of two-way coupling and SGS velocity on the particles were not taken into account. However, these effects are often considered in later studies (Armenio et al., 1999,

Boivin et al., 2000, Almeida and Jaberi, 2008). Also, with the point mass approximation, the mass and heat transfer between phases are obtained from a set of semiempirical relations. Crowe et al. (1998), Loth (2000), and Sirignano (2010) provide a comprehensive review of the available momentum, heat, and mass transfer models for small particles and droplets, while discussing the effects of turbulence, compressibility, particle spin, particle deformation, virtual mass, Basset history, stress gradient, and wall on the particle forces in details. Chapter 1 of this handbook also provides a comprehensive review of these effects on single drops and particles.

In the dense regime of any particulate turbulent flow, the particle–particle collisions are significant, the particle number density is large, and the volume displaced by the particles often has noticeable influence on the carrier fluid. Normally, a significant portion of the physical activities associated with the fluid–particle and particle–particle interactions takes place at small or SGS. This imposes serious challenges on the LES of dense two-phase turbulent flows. Similarly, in liquid sprays, the primary and secondary breakup regions of the spray are complicated by the presence of complex SGS liquid–gas interfaces that require interface capturing methods. Various grid-based and particle-based Eulerian–Eulerian computational models have been used for the interface simulations (Ashgriz and Poo, 1991, Sethian and Smereka, 2003, Li et al., 2008). Common grid-based methods are volume of fluid (Ashgriz and Poo, 1991) and level set (Sethian and Smereka, 2003) front-capturing methods. Alternatively, in the particle-based front-tracking method (Li et al., 2008), marker particles are used to track the interface. All of these methods have had varying degrees of success in handling interfacial problems in nonturbulent flows but they have also been used for turbulent flows in a limited sense (Shen and Yue, 2001, Herrmann, 2003, Li et al., 2008).

Despite their advantages, Eulerian–Eulerian interface tracking models are not often viable for multiphase turbulent flows that involve preferential concentration of the particles and the simultaneous presence of both dense and dilute regimes, thus they have to be combined with Eulerian–Lagrangian and PSIC models (Som and Aggarwal, 2010). Also, the interface tracking models are not always appropriate for the secondary breakup region of spray, where the volume fraction occupied by liquid is still high and there are considerable collisions between drops and ligaments, which can lead to coalescence, shattering, and bouncing or glancing. For the LES of moderately dense two-phase particulate flows, efficient droplet–droplet or particle–particle collision models can be incorporated in the Lagrangian particle simulations. For example, Apte et al. (2003) developed a mathematical/computational model to incorporate particle collisions and finite particle volume effects in an incompressible suspending fluid. The model has been shown to produce accurate results in relatively simple flows and has been incorporated in an unstructured LES code for simulations of spray in complex flow configurations (Apte et al., 2003).

6.5.2 Modeling of Reacting Flows

The numerical simulation of reacting turbulent sprays is very challenging not only due to multiscale and multitime nature of liquid–gas interactions but also because of the complexity of finite rate evaporation, mixing, and multistep reactions (Aggarwal, 1998, Venugopal and Abraham, 2007, Mastorakos, 2009). In most of spray combustion computational models, the flow is seeded or injected by a large number of drops, which can be followed individually in the Lagrangian frame, using the equations described in Section 1.4 of this handbook. In DNS, no modeling is performed for the gas flow turbulence and all flow time and length scales are resolved exactly by considering small time step and grid sizes. However, for situations involving a large number of drops, it is not possible to resolve the details of the flow in and around each drop. Therefore, physical models are introduced for describing heat, mass, and momentum transfer between the two phases, as elaborated in this section and also reviewed in previous chapters of this handbook.

The other important issue in theoretical description of spray combustion is the interaction between turbulence and chemical reaction. Turbulence modeling for combustion has been the subject of an overwhelming number of studies within the past four decades and cannot be reviewed here in detail. A number of different methods have emerged from these studies with varying levels of success (Pope, 1985, Givi, 1989, Peters, 2000). Nevertheless, the issue of turbulence modeling for combustion still appears far from being fully resolved and is even more complicated by the fact that the chemistry of combustion for most fuels is not yet well understood. Among the more popular models for turbulent combustion simulations are the laminar flamelet models (Williams, 1975, Bray and Peters, 1994), the probability density function (PDF)-based models (Pope, 1985, Givi, 2003), the eddy breakup models (Spalding, 1971), and the eddy dissipation models (Magnussen and Hjertager, 1977), which provide varying levels of accuracy and complexity. Transported PDF methods have proven to be particularly effective in accounting for turbulence–chemistry

interactions (Haworth and Pope, 2011). Filtered mass density function (FMDF) is a single-point SGS PDF model for the LES of turbulent reacting flows (Jaberi et al., 1999). In this approach, the joint statistics of turbulent variables are obtained by solving the transport equation for the FMDF. The main advantage of FMDF is that the single-point statistics like reaction terms appear in a closed form in its formulation. This allows simulations of various types of reactions (slow, fast, premixed, nonpremixed, etc.) with different chemical kinetic models (James and Jaberi, 2000, Sheikhi et al., 2005, Givi, 2006, Raman and Pitsch, 2006, Afshari et al., 2008, Haworth, 2010, Yaldizli et al., 2010). Recently, Li et al. (2014) have developed a two-phase FMDF model for the simulation of two-phase reacting flows. They validated the model by comparison with DNS data in a spatially developing droplet-laden reactive mixing layer.

Depending on the type of spray and flame, the reaction timescales can be very different or comparable to those of the turbulence and the spray. This has led to the development and usage of reaction mechanisms at various levels of details and comprehensiveness (Lu and Law, 2009). For some of the hydrocarbon fuels such as n-heptane (Battin-Leclerc, 2008), *complex* (skeletal or reduced) kinetics models are available beyond simple global mechanisms (Seiser et al., 2000, Liu et al., 2004, Yoo et al., 2011). Complex reaction models are normally needed for high-speed spray combustion simulations. However, the computational cost of performing the chemistry calculations with complex kinetics is often prohibitive and efficient implementation of chemistry is necessary. Several different methods have been proposed for efficient implementation of chemical reaction in computational models such as LES/FMDF. Among them are the storage/retrieval algorithms (Pope and Ren, 2009), including the structured lookup tabulation (Chen et al., 1989), the repro-modeling (Turanyi, 1994), the artificial neural networks (Christo et al., 1996, Blasco et al., 1998), the in situ adaptive tabulation (ISAT) (Pope 1997, Lu and Pope, 2009), the piecewise reusable implementation of solution mapping (Bell et al., 2000), and the high-dimensional model representations (Rabitz and Alis, 1999). ISAT is a storage and retrieval methodology that has been widely adopted especially with PDF methods. The ISAT algorithm has been applied to nonpremixed piloted jet flames (Cao and Pope, 2005) with a speedup factor of 100–1000.

The DNS of high-speed reacting sprays with complex chemistry models is not currently feasible; the latest published DNS work in this area is limited to relatively simple dilute two-phase homogeneous turbulent reacting flows (Borghesi et al., 2013). LES models (Shukla and Mamun, 2002), on the other hand, are applicable to turbulent spray combustion. LES has been widely applied to single-phase reacting flows (Pitsch, 2006, Haworth, 2010, Haworth and Pope, 2011). However, its use for turbulent spray combustion simulations has been somewhat limited (Irannejad and Jaberi, 2014b) mainly because of difficulties in modeling of SGS interactions among droplets, turbulence, and combustion and the computational cost associated with complex chemical kinetic mechanisms (Jenny et al., 2012). The two-phase reacting LES model in Patel et al. (2007) and Sankaran and Menon (2002) is based on the Eulerian–Lagrangian approach. In this model, the carrier gas equations are solved for a fixed 3D grid system. However, the mixing and reaction are implemented in 1D domain using the linear eddy model. The spray is based on a Lagrangian droplet model that includes empirical evaporation and secondary breakup submodel. The reaction is modeled with a global multistep mechanism. The two-phase reacting LES model in Mahesh et al. (2006) is based on a similar hybrid Eulerian–Lagrangian approach. The zero Mach number Navier–Stokes equations are solved on an unstructured grid in the Eulerian part and the spray is modeled with Lagrangian method and some empirical droplet evaporation and breakup submodels. The LES models in Apte et al. (2003), Mahesh et al. (2006), Menon and Patel (2006), and Sankaran and Menon (2002) are applied to realistic (complex) gas turbine combustors. The two-phase reacting LES model of Cuenot et al. (2006) is fundamentally different from the previous models as it solves the Eulerian equations for both phases.

The two-phase reacting LES/FMDF model (Irannejad and Jaberi, 2014b, Li et al., 2014) is different from the models mentioned earlier; it is based on an Eulerian–Lagrangian–Lagrangian methodology. The two-phase FMDF model is recently employed (Irannejad and Jaberi, 2014b) together with complex chemical kinetic mechanisms for simulations of experimentally studied high-speed evaporating and reacting sprays in a closed combustion chamber (Siebers, 1998, Siebers and Higgins, 2001, Siebers et al., 2002, Pickett et al., 2010, Bhattacharjee and Haworth, 2013, Pei et al., 2013). Details of the two-phase FMDF model are given in the following subsection.

6.5.3 LES/FMDF Model

As illustrated in Figure 6.11, the computational method used in two-phase LES/FMDF model has one Eulerian and two Lagrangian solvers. The gas-phase field is computed by a hybrid methodology. The compressible LES equations for velocity and pressure are solved by grid-based Eulerian flow solvers like high-order compact

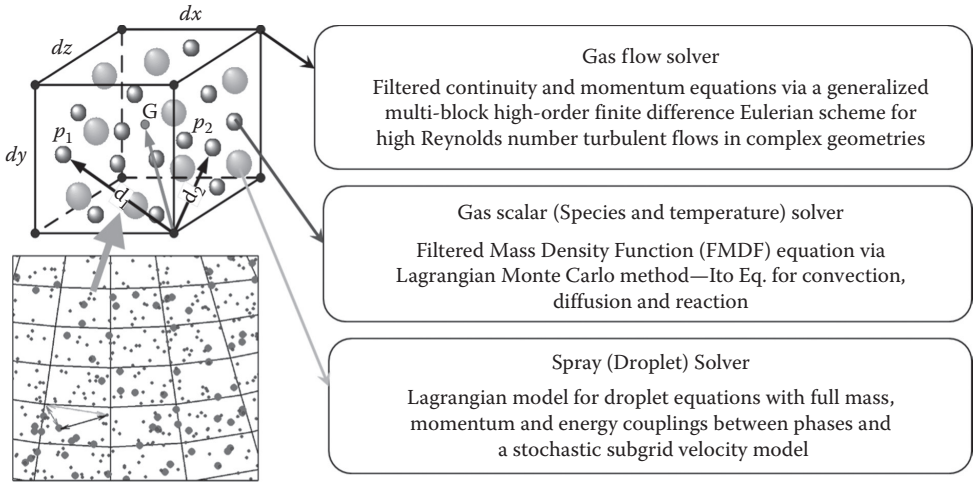

Figure 6.11

A block diagram showing different components of the two-phase LES/FMDF and its Eulerian–Lagrangian–Lagrangian flow solver. Figures on the left show the Eulerian grid together with droplets and Monte Carlo particles. Large particles are droplets, while smaller particles represent Monte Carlo particles.

finite-difference schemes (Afshari et al., 2008, Banaeizadeh et al., 2011, Irannejad and Jaberi, 2014b). The scalar field (i.e., the species mass fractions and enthalpy) is obtained from FMDF by solving the FMDF equation with an efficient Lagrangian stochastic Monte Carlo (MC) method (Jaberi et al., 1999, Li et al., 2014). The spray is simulated with a nonequilibrium Lagrangian particle method together with a stochastic droplet breakup model that allows full two-way mass, momentum, and energy coupling between phases (Irannejad and Jaberi, 2014a). The chemistry is based on finite-rate skeletal kinetics. Consequently, the two-phase LES/FMDF model is composed of three different mathematical components: (1) the filtered gas dynamics equations, (2) the FMDF equations, and (3) the Lagrangian spray/droplet equations.

The gas dynamics field is obtained from the following compressible Favre-filtered continuity, momentum, and energy equations (Irannejad and Jaberi, 2014b):

$$\frac{\partial\langle\rho\rangle_l}{\partial t}+\frac{\partial\langle\rho\rangle_l\langle u_i\rangle_L}{\partial x_i}=\langle\dot{S}^{sp}_{Mass}\rangle_l \tag{6.54}$$

$$\frac{\partial\langle\rho\rangle_l\langle u_i\rangle_L}{\partial t}+\frac{\partial\langle\rho\rangle_l\langle u_i\rangle_L\langle u_j\rangle_L}{\partial x_j}=-\frac{\partial\langle p\rangle_l}{\partial x_i}+\frac{\partial\langle\tau_{ij}\rangle_l}{\partial x_j}-\frac{\partial(\tau^{sgs}_{ij})}{\partial x_j}+\langle\dot{S}^{sp}_{mi}\rangle_l \tag{6.55}$$

$$\frac{\partial\langle\rho\rangle_l\langle E\rangle_L}{\partial t}+\frac{\partial(\langle\rho\rangle_l\langle E\rangle_L+\langle p\rangle_l)\langle u_i\rangle_L}{\partial x_i}=-\frac{\partial(\langle q_i\rangle_l+H^{sgs}_i)}{\partial x_i}+\langle\dot{Q}\rangle_l+\langle\dot{S}^{sp}_E\rangle_l+\frac{\partial[(\langle\tau_{ij}\rangle_l-\tau^{sgs}_{ij})\langle u_j\rangle_L]}{\partial x_i} \tag{6.56}$$

In Equations 6.54 through 6.56, $\langle\cdot\rangle_l$ and $\langle\cdot\rangle_L$ represent the filtering and Favre-filtering operations, respectively. The primary variables are the filtered density $\langle\rho\rangle_l$, the filtered pressure $\langle p\rangle_l$, the Favre-filtered velocity $\langle u_i\rangle_L$, and the Favre-filtered total energy $\langle E\rangle_L=\langle e\rangle_L+\frac{1}{2}\langle u_i\rangle_L\langle u_i\rangle_L$. The filtered viscous stress tensor, $\langle\tau_{ij}\rangle_l$, is assumed to be a linear function of the Favre-filtered strain rate for the simulated Newtonian fluid, and the filtered heat flux vector, $\langle q_i\rangle_l$, is evaluated based on Fourier's law.

The terms involving variable S represent the combustion and droplet/spray source or sink terms (Irannejad and Jaberi, 2014b). The specific internal energy of the mixture is defined as

$$\langle e\rangle_L=\sum_{\alpha=1}^{N_s}\langle\phi_\alpha\rangle_L h_\alpha(\langle T\rangle_L)-\langle R\rangle_L\langle T\rangle_L, \tag{6.57}$$

where h_α is the species sensible enthalpy. The filtered form of ideal gas equation of state is used to close the system of equations. The unclosed SGS terms, which appear in the filtered equations, can be closed by gradient type or other closures (Moin et al., 1991, Ghosal et al., 1995, Irannejad and Jaberi, 2014b).

The scalar FMDF is a joint PDF of the scalars (species mass fractions and energy) at the subgrid level, which was originally developed by Jaberi et al. (1999) for single-phase reacting flows and has proven to be very reliable and accurate for these flows (Jaberi, 1999, James and Jaberi, 2000, Sheikhi et al., 2005, Givi, 2006, Madnia et al., 2006, Afshari et al., 2008, Yaldizli et al., 2010, Ansari et al., 2011, Banaeizadeh et al., 2011, Li et al., 2014). The FMDF is defined as

$$F_L(\boldsymbol{\Psi};\mathbf{x},t)=\int_{-\infty}^{+\infty}\rho(\mathbf{x}',t)\xi\big(\boldsymbol{\Psi},\boldsymbol{\Phi}(\mathbf{x}',t)\big)G(\mathbf{x}'-\mathbf{x})d\mathbf{x}' \tag{6.58}$$

where

t and $\mathbf{x}$ represent time and space vector, respectively

G denotes the filter function

$\boldsymbol{\Phi}$ and $\boldsymbol{\Psi}$ are the scalar vector and scalar vector in the sample space, respectively

ξ is the fine grained density (Colucci et al., 1998), defined based on a series of delta functions

The scalar vector includes species mass fractions ($\alpha = 1, \ldots, N_s$) and specific sensible enthalpy ($\alpha = N_s + 1$).

The FMDF transport equation is obtained by inserting the instantaneous unfiltered scalar equation into the time derivative of the fine grained density and filtering that. For a compressible two-phase reacting system with negligible liquid volume fraction, the FMDF equation can be written in the following form:

$$\begin{aligned}\frac{\partial F_L}{\partial t}+\frac{\partial}{\partial x_i}\Big[\langle u_i(\mathbf{x},t)\rangle_L F_L\Big]&=-\frac{\partial}{\partial x_i}\Big[\big(\langle u_i(\mathbf{x},t)\,|\,\boldsymbol{\Psi}\rangle_l-\langle u_i\rangle_L\big)F_L\Big]\\&+\frac{\partial}{\partial\psi_\alpha}\left[\left\langle\frac{1}{\rho(\boldsymbol{\Phi})}\frac{\partial J_i^\alpha}{\partial x_i}\middle|\boldsymbol{\Psi}\right\rangle_l F_L\right]-\frac{\partial}{\partial\psi_\alpha}(\dot{S}_\alpha(\boldsymbol{\Psi})F_L)-\frac{\partial}{\partial\psi_\alpha}\Big[\langle\dot{S}_\alpha^{comp}\,|\,\boldsymbol{\Psi}\rangle_l F_L\Big]\\&-\frac{\partial}{\partial\psi_\alpha}\left[\frac{\langle\dot{S}_\alpha^{sp}\,|\,\boldsymbol{\Psi}\rangle F_L}{\rho(\boldsymbol{\Psi})}\right]+\frac{\partial}{\partial\psi_\alpha}\left[\frac{\langle\dot{S}_{Mass}^{sp}\,|\,\boldsymbol{\Psi}\rangle\psi_\alpha F_L}{\rho(\boldsymbol{\Psi})}\right]+\frac{\langle\dot{S}_{Mass}^{sp}\,|\,\boldsymbol{\Psi}\rangle F_L}{\rho(\boldsymbol{\Psi})}\end{aligned} \tag{6.59}$$

It is noted here that in the aforementioned FMDF equation, the reaction term (the third term on the right-hand side) is closed but in conventional LES methods it is not closed and requires additional modeling. The first term on the right-hand side of Equation 6.59 represents the SGS convection, which can be modeled with a gradient-type closure as

$$\big(\langle u_i(\mathbf{x},t)\,|\,\boldsymbol{\Psi}\rangle_l-\langle u_i\rangle_L\big)F_L=-\Gamma_t\frac{\partial(F_L/\langle\rho\rangle_l)}{\partial x_i} \tag{6.60}$$

where $\Gamma_t = \mu_t/Pr_t$ or $\Gamma_t = \mu_t/Sc_t$ is the turbulent diffusivity.

The term due to molecular diffusion is decomposed into two parts, the molecular transport and the SGS dissipation. The SGS dissipation can be modeled with the linear mean-square estimation (Dopazo and O'Brien, 1976, O'Brien, 1980) or the interaction by exchange with the mean model (Borghi, 1988)

$$\frac{\partial}{\partial\psi_\alpha}\left[\left\langle\frac{1}{\rho(\boldsymbol{\Phi})}\frac{\partial J_i^\alpha}{\partial x_i}\,|\,\boldsymbol{\Psi}\right\rangle_l F_L\right]=\frac{\partial}{\partial x_i}\left[\Gamma\frac{\partial}{\partial x_i}\left(\frac{F_L}{\langle\rho\rangle_l}\right)\right]+\frac{\partial}{\partial\psi_\alpha}[\Omega_m(\psi_\alpha-\langle\phi_\alpha\rangle_L)F_L] \tag{6.61}$$

where the molecular diffusivity is $\Gamma = \mu/Pr$ or $\Gamma = \mu/Sc$ and the SGS mixing frequency is $\Omega_m=\frac{1}{2}c_\phi(\Gamma+\Gamma_t)/(\overline{\Delta}^2\langle\rho\rangle_l)$.

The source term due to pressure in the scalar FMDF is obtained by taking into account the total derivative of filtered pressure for the mixture enthalpy as (Banaeizadeh et al., 2011)

$$\langle\dot{S}_\alpha^{comp}\,|\,\boldsymbol{\Psi}\rangle_l=\frac{1}{\langle\rho\rangle_l}\left(\frac{\partial\langle p\rangle_l}{\partial t}+\langle u_i\rangle_L\frac{\partial\langle p\rangle_l}{\partial x_i}\right),\quad \alpha=N_s+1 \tag{6.62}$$

For spray combustion, the viscous dissipation term in enthalpy equation is small and neglected. The last three conditionally averaged terms on the RHS of Equation 6.59 represent the spray/droplet effects on FMDF. They involve particle source/sink terms affecting the gas composition and density. For simplicity, the conditionally averaged quantities in spray terms can be replaced by unconditional filtered values of particle source or sink terms (Irannejad and Jaberi, 2014). This approximation is not expected to have a very significant effect on the filtered scalar variables.

The modeled FMDF transport equation is solved to obtain the scalar FMDF and consequently all single-point statistical information concerning reactive species and temperature at various times and locations, including the first moments or filtered variables. The most convenient means of solving the FMDF transport equation is via the Lagrangian MC procedure (Pope, 1985). With the Lagrangian procedure, the FMDF is represented by an ensemble of computational "stochastic elements" or "MC particles." These notional particles evolve through a "stochastic process," described by a set of stochastic differential equations (Gardiner, 1990, Kloeden and Platen, 1995). The stochastic process is described by a Fokker–Planck equation. A comparison between the Fokker–Planck equation and the FMDF equation under consideration identifies the parameters of the stochastic equations (Jaberi et al., 1999). A unique feature of this stochastic procedure is that the large-scale, SGS, and molecular mixing, the chemical reaction and the two-phase effects can be separately incorporated and evaluated, offering a systematic way to compute and interpret these processes in the LES/FMDF calculations. The simplest means of simulating the spatial transport in this equation is via the Euler–Maruyama approximation (Gardiner, 1990). The spray terms in the FMDF equation are weighted averaged from FD grid points to the MC particle locations.

To manage the number of MC particles and to reduce the computational cost, a procedure involving the use of nonuniform weights is considered. The variable weighting for particles allows the particle number density to stay above a certain minimum value regardless of density variations. For the spray simulation, particle weights are modified due to added mass to the carrier gas from the evaporating droplets. The effects of spray heat and mass transfer on the MC particles are implemented by a series of source terms in the particle equations (Irannejad and Jaberi, 2014). Details of SGS mass transfer between droplets and MC particles do not seem to have a very significant effect on the global spray and flame behavior simulated by LES/FMDF (Irannejad and Jaberi, 2014b). However, in some circumstances, when, for example, the individual droplet combustion becomes important, it would be necessary to use a more detailed description of the mass transfer between the liquid and the gas. This issue has been discussed in detail in the context of RANS/PDF spray simulations in Jenny et al. (2012).

The chemical kinetics model plays a crucial role in the LES of reacting spray and is important to the flame ignition, liftoff, and extinction. In a recent study, Irannejad and Jaberi (2014b) used the skeletal mechanism of Liu et al. (2004) for spray combustion simulations using parallel ISAT method (Irannejad and Jaberi, 2014b). This mechanism has 44 species and 185 reactions, counting forward and backward reactions individually. ISAT uses the ordinary differential equation solver DDASAC (Caracotsios and Stewart, 1985) to integrate reaction equations and stores the relevant information in a binary tree, with each termination node (or leaf) representing a record of the tabulation point for a specific composition, the reaction mapping in time step, and the mapping gradient matrix. Using this matrix, for a given query composition close to a tabulated composition point, a linear approximation to the mapping is obtained under a controlled tolerance.

As indicated earlier, the spray can be modeled with a Lagrangian model using drops (Irannejad and Jaberi, 2014a). In this model, the drop motion is simulated using Basset–Boussinesq–Oseen equation (Crowe et al., 1998, Loth, 2000, Sirignano, 2010). Under the assumptions of high liquid-to-gas density ratios, the Lagrangian equations describing the drop motion become

$$\frac{d\mathbf{x}_p}{dt} = \mathbf{u}_p \tag{6.63}$$

$$\frac{d\mathbf{u}_p}{dt} = \frac{\mathbf{u}_{rel}}{\tau_p} \tag{6.64}$$

In Equation 6.64, the relative velocity, $\mathbf{u}_{rel} = \mathbf{u}_g - \mathbf{u}_p$, is calculated based on the gas velocity at the drop location, $\mathbf{u}_g = \langle \mathbf{u} \rangle_L + \mathbf{u}^*$, which is reconstructed using the filtered velocity and the stochastic subgrid velocity $\mathbf{u}^*$

(Pozorski and Apte, 2009). The stochastic subgrid velocity is calculated from the SGS velocity $u_{sgs} = \sqrt{2k_{sgs}/3}$ and characteristic timescale $\tau_L^\star$:

$$du_i^\star = -\frac{u_i^\star}{\tau_L^\star}dt + \sqrt{\frac{2u_{sgs}^2}{\tau_L^\star}}dW_i \tag{6.65}$$

where dW_i is an increment of the Wiener process (Gardiner, 1990). The SGS velocity reconstruction is intended to cover a wide range of drop Stokes numbers (Pozorski and Apte, 2009). Furthermore, the drop relative velocity is reduced by wake interactions of nearby drops in the spray (Irannejad and Jaberi, 2013). This modified relative velocity is then used for drop motion, heat, and mass transfer calculations. The drop response time is defined as

$$\tau_p = \tau_{st}/f_d(Re_{sl})\,, \tag{6.66}$$

in which $\tau_{st} = d_p^2\rho_l/18\mu_g$ is the drop Stokes timescale and $f_d(Re_{sl})$, the drag factor, is the finite Reynolds number ($Re_{sl} = \rho_g d_p u_{rel}/\mu_g$, d_p is the drop diameter) correction to the Stokes drag. The drag factor f_d includes the effects of evaporation through a blowing Reynolds number, Re_{bw} for low Reynolds numbers ($Re_{sl} < 100$) (Bellan and Harstad, 1987b). The drag factor is modified for a distorted drop, using the simple assumption that the drag coefficient of a distorted drop lies between the lower limit of a rigid sphere and the upper limit of a disk where the distortion is computed using Taylor analogy breakup model (Liu et al., 1993).

For high injection pressure evaporating and reacting sprays operating in realistic combustion systems, the initial development of liquid jet is often modeled by a set of round liquid blobs injected from the nozzle with similar mass flow rate (Moin and Apte, 2006, Gorokhovski and Herrmann, 2008, Jiang et al., 2010). These large drops then go through a series of breakup processes mimicking the primary and secondary breakup. This is based on the reasonable assumption that the atomization and fragmentation of liquid jet, blobs, or drops are indistinguishable processes within the dense liquid core region near the injector nozzle exit. Spray atomization is then modeled by a stochastic model in which the characteristic radius of drops is assumed to be a time-dependent stochastic variable with a given initial distribution (Kolmogorov, 1941, Gorokhovski and Saveliev, 2003). The breakup of parent drops into daughter drops is viewed as the temporal and spatial evolution of the distribution function according to the following Fokker–Planck differential equation (Gorokhovski and Saveliev, 2003):

$$\frac{\partial\mathfrak{I}(\chi,t^\star)}{\partial t} = -\frac{\langle\varsigma\rangle}{\tau_{bu}}\frac{\partial\mathfrak{I}(\chi,t^\star)}{\partial\chi} + \frac{1}{2}\frac{\langle\varsigma^2\rangle}{\tau_{bu}}\frac{\partial^2\mathfrak{I}(\chi,t^\star)}{\partial\chi^2} \tag{6.67}$$

where $\langle\varsigma\rangle$ and $\langle\varsigma^2\rangle$ are the first two moments of the breakup intensity spectrum, which is assumed to be Gaussian. The breakup time, τ_{bu} is based on the Lagrangian relative velocity fluctuations for the drop (Irannejad and Jaberi, 2014a).

The following spherically symmetric heat and mass transfer equations inside each individual drop are solved for the liquid density, energy, and species mass fractions (Torres et al., 2003, Srivastava et al., 2013, Irannejad and Jaberi, 2014a):

$$\frac{\partial\rho_l}{\partial t} + \frac{1}{r^2}\frac{\partial}{\partial r}(r^2\rho_l v_l) = 0 \tag{6.68}$$

$$\frac{\partial(\rho_l\phi_{l\alpha})}{\partial t} + \frac{1}{r^2}\frac{\partial}{\partial r}(r^2\rho_l v_l\phi_{l\alpha}) = \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\rho_l D_l\frac{\partial\phi_{l\alpha}}{\partial r}\right) \tag{6.69}$$

$$\frac{\partial(\rho_l T_l)}{\partial t} + \frac{1}{r^2}\frac{\partial}{\partial r}(r^2\rho_l v_l T_l) = \frac{1}{c_p r^2}\frac{\partial}{\partial r}\left(r^2\lambda_l\frac{\partial T_l}{\partial r}\right) \tag{6.70}$$

The mass and energy conservation equations provide the necessary drop interface parameters such as radial velocity v_{ls}, and species mass fraction and temperature gradients at the drop surface. Moreover, global drop mass and energy changes such as the total change in the drop internal energy are also obtained by integrating these equations. The internal drop circulation, caused by the relative motion of gas and liquid, and its effect on the drop variables are accounted for by changing the effective mass and thermal liquid diffusivities (Abramzon and Sirignano, 1989). For a multicomponent drop, the mass flux of species α at the drop interface is defined based on the species mass fraction on the liquid side of the drop surface, $\phi_{ls\alpha}$; the drop radius, r_s; the species diffusivity in the gas, $D_{g\alpha}$; the species Sherwood number, Sh_α; and the Spalding mass transfer number, $B_{M\alpha}$ as

$$\dot{m}_\alpha = \phi_{ls\alpha} 2\pi r_s \rho_{gs} D_{g\alpha} Sh_\alpha \ln(1 + B_{M\alpha}) \tag{6.71}$$

The Spalding mass transfer number relates the liquid and gas interface mass fractions ($\phi_{ls\alpha}$ and $\phi_{gs\alpha}$) to the free stream (with respect to drop) mass fraction $\phi_{\infty\alpha}$ as

$$B_{M\alpha} = \frac{\phi_{gs\alpha} - \phi_{\infty\alpha}}{\phi_{ls\alpha} - \phi_{gs\alpha}} \tag{6.72}$$

The Ranz–Marshall correlations for Nusselt and Sherwood numbers may be modified to account for the surface blowing effect (Abramzon and Sirignano, 1989), as explained further in Sections 1.4.3.4 and 1.4.4.5 in this handbook. The surface regression rate can be found by summing the mass flux over all species and by solving the species mass conservation and energy equations at drop interface (Irannejad and Jaberi, 2014a). The effects of drops on the carrier gas are included via a series of source/sink terms in the gas continuity, momentum, energy, and scalar equations and also in the subgrid kinetic energy equations. These source terms are evaluated by volumetric averaging and interpolation of the Lagrangian variables from all drops in each cell (Irannejad and Jaberi, 2014a).

Using isolevel contours of stoichiometric equivalence ratio and background temperature contours, Figure 6.12 illustrates various regions in a reacting n-heptane fuel spray injected in a closed chamber filled with high temperature and pressure air (Irannejad and Jaberi, 2014b). The results in this figure are obtained by the two-phase LES/FMDF model with complex chemical kinetics and ISAT as described in Irannejad and Jaberi (2014b). Figure 6.12 shows that as the spray breaks and drops are formed, dispersed, heated, and evaporated, the combined effects of drop drag and evaporated fuel mass generate a high-speed main gas jet that becomes highly turbulent further downstream. The entrainment and mixing in the turbulent jet are strongly affected by the combustion. The separation of the high temperature and highly turbulent flame from the liquid spray and drops is clearly visible in the simulated reacting spray. The ambient gas temperature is high enough for the drops to evaporate and provide the fuel for the flame without needing the main flame's heat. Yet, the spray is very fast and generates significant gas flow and turbulence that push the flame away from the spray. Consequently, as Figure 6.12 shows, there is a relatively cool evaporated fuel that

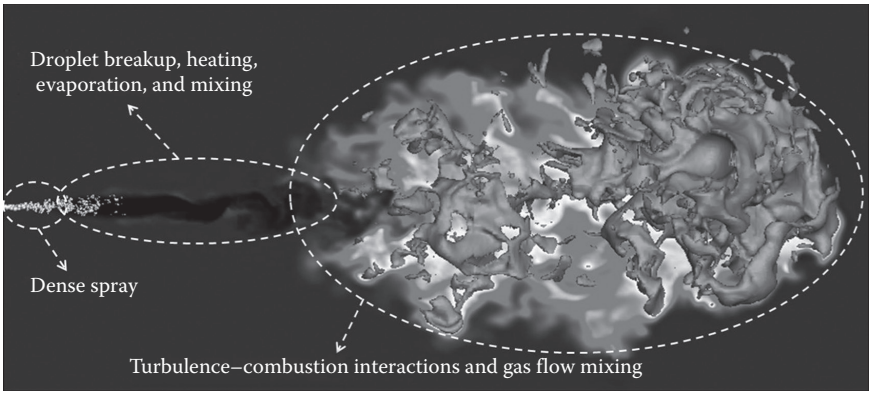

Figure 6.12

Various parts of the reactive high-speed turbulent spray simulated by LES/FMDF model. Isolevels of stoichiometric equivalence ratio are shown on background temperature contours.

separates the main spray from the main flame. The low-temperature, vapor fuel–rich gas jet breaks into smaller turbulent structures with much more effective mixing by the spray-generated gas flow turbulence before disappearing into the complicated flame plume.

The simulation of turbulence, once dominated by RANS models, is now also being conducted using LES models. By offering advantages in highly transient flows, LES is growing as a viable replacement for RANS. Nevertheless, with the current computational resources, RANS still remains as the primary method of choice for very practical multiphase reacting systems.

7.10 Definition of Wave Shape and Wave Characteristic

7.1 Introduction

The majority of analytical and empirical models used for the prediction of hydrodynamics and heat transfer behavior in two-phase gas–liquid flows are based on research data that were collected under terrestrial conditions. Under such conditions, where gravity plays a very important role in *shaping* the flow, empirical correlations used for the prediction of flow regimes, pressure drop, slip velocities, heat transfer rates, etc., may not be adequately suitable for microgravity (or near zero-gravity conditions).

Mainly due to the demand for active heat transport systems in modern communications and earth observation satellites and space stations, two-phase gas–liquid flow loops for space applications emerged in the early 1980s as an active research area in academic institutions as well as space centers in the United States and abroad. When gravity is reduced, buoyancy forces are severely reduced, and secondary forces such as those attributed to surface tension, which are usually very small at terrestrial conditions, play more significant role in establishing the flow conditions. The hydrodynamic characteristics of the flow, as well as the heat transfer mechanism, become different under such conditions in that effects of buoyancy forces on the momentum and heat transfer diminish, while those due to body forces (e.g., surface tension) become more dominant.

Theories and correlations that were derived at terrestrial conditions must be tested and possibly modified (or rejected) before they are used with confidence for conditions of reduced gravity.

For example, at reduced gravity, the slip velocity between the two phases is minimized and in some cases is very small or totally diminished (bubble and slug flows). This allows for better measurements and predictions of actual phase velocity and interfacial areas (since the interface is much more stable in μ-g bubble and slug flows). A better understanding of the actual contribution of each force acting on the flow can then be gained from the analysis of two-phase flow measurements at μ-g.

7.2 Applications of Two-Phase Flows at Microgravity Conditions

One of the major applications of two-phase flows at microgravity conditions is the design and maintenance of active thermal management systems for future space stations and high-power communications satellites. Past thermal management requirements for satellites and orbiting spacecraft have been characterized by low

power (<25 kW) and short lifetime (<3 years). These modest requirements can usually be satisfied by passive devices, such as heat pipes, or by pumped single-phase fluid cooling systems. The performance of passive and single-phase devices is mostly independent of gravity.

In addition, two-phase flow phenomena occur in many life-support systems in space stations and space labs. For example, the environmental conditions inside a space station (e.g., level of O_2 and humidity) have to be maintained at comfortable levels for personnel and living species inside orbiting stations. Water used for personal hygiene or other purposes, in many instances, has to be collected and processed for reuse. Two-phase flows are also prevalent in material processing in space, cryogenic transfer and storage, and several other enabling technologies (mining, water processing, etc.).

Studies of two-phase flows under microgravity conditions are also of great interest to better understand the behavior of terrestrial flows away from the masking effects of earth gravity (9.81 m/s^2). Since earth gravitational force plays an overwhelming role in *shaping* the flow characteristics, microgravity conditions provide an ideal environment to study the influence of other less dominant forces such as those due to surface tension, lift force, and turbulence.

7.3 Flow Patterns

The liquid–gas distribution pattern inside a conduit varies considerably depending on, among other factors, the mass flow rates of both phases, the conduit size, the phase properties, and the gravity vector with respect to the flow direction. Groups with similar phase distribution characteristics are classified into flow patterns (or flow regimes). Extensive efforts have been made to study the flow patterns and their transitions under normal and microgravity conditions. Since the identification of a particular phase distribution is somewhat subjective, the literature contains a host of flow pattern definitions and descriptions. More sophisticated studies aimed at minimizing this subjectivity via statistical analysis of void fraction data were successfully made in the last two decades (e.g., Lowe and Rezkallah, 1999). In those studies, void fraction measurements were taken using helical wound electrodes with electronics operating on a charge/discharge principle. The measurement then represented a true average value of the void fraction at each set point. More details could be found in Gabriel (2007).

Basically, four flow patterns are observed to exist under microgravity conditions. These are as follows: bubbly flow, slug flow, transitional flow, and annular flow. Bubbly flow consists of gas bubbles that are less than or equal to the tube diameter, distributed in a liquid continuum. Figure 7.1a shows a group of spherical medium-sized bubbles with some small dispersed bubbles. The bubbles tend to flow at or near the tube center where the liquid velocity is at maximum.

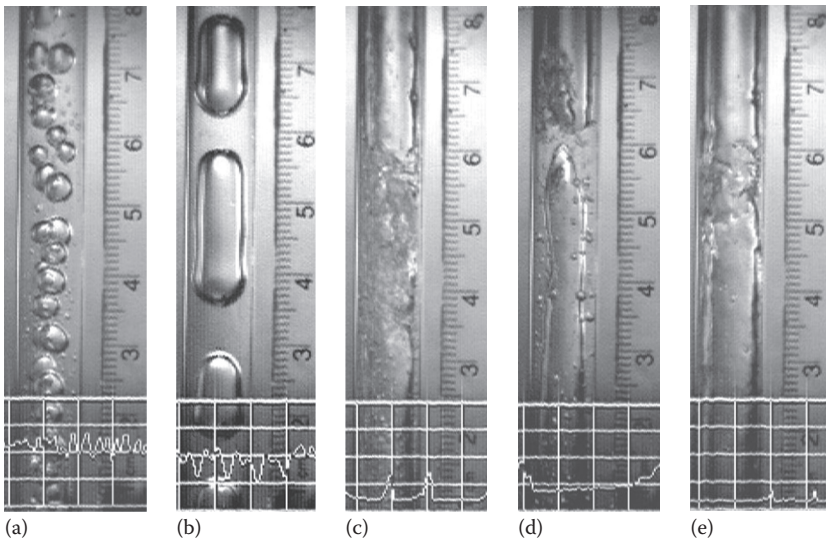

Figure 7.1

Four flow regimes: (a) bubbly flow, (b) slug flow, (c) transitional flow I, (d) transitional flow II, and (e) annular flow.

Slug flow consists of gas bubbles that are longer than the tube diameter but have diameters close to the tube diameter. Figure 7.1b shows a series of rounded, smooth, uniform bubbles of approximately two to three tube diameters.

Transitional or *frothy slug–annular flow* occurs when the liquid flows in the form of a film at the tube wall and the gas phase flows in the center of the tube. Frothy slugs pass frequently and, though it is difficult to discern the details, they likely consist of densely packed fine gas bubbles in a liquid continuum at relatively low gas flow rates or small liquid droplets at relatively high gas flow rates. Figure 7.1c shows transitional flow for a liquid flow rate of 0.16 m/s and a gas flow rate of 5.96 m/s. The figure shows a smooth film interrupted by a frothy slug region. Figure 7.1d shows transitional flow for a liquid flow rate of 0.11 m/s and a gas flow rate of 1.59 m/s. The figure shows a liquid slug that separates two large bubbles. Small bubbles are dispersed in the thick liquid film.

Annular flow occurs when the liquid phase flows at the tube wall and the gas phase flows uninterruptedly at the center of the tube. Figure 7.1e shows the passage of a wave at the center of the image. This flow regime is of special importance as the thermal resistance to heat transfer across the tube wall is minimum under such conditions. It is, therefore, a regime that is usually used by designers to operate at despite the risk of what is known as "dryout" condition where the liquid film is totally wiped out and the transfer of heat is maximized to the point of potential meltdown. We will be addressing this flow regime in some more details in Section 7.10 of this chapter.

7.4 Flow Pattern Transitions

In a two-phase flow system, there are several forces acting on the mixture, each of which has some impact on the overall flow configuration and its characteristics (Figure 7.2). Such forces include those due to inertia, buoyancy, surface tension, and turbulent eddies. The flow pattern is determined by a delicate balance of these forces. The influence of buoyancy force due to gravity can be evaluated using the Froude number:

$$Fr = \frac{V_m^2}{gD} = \frac{\text{inertial force}}{\text{buoyancy force}} \tag{7.1}$$

where

V_m is the sum of the gas and liquid superficial velocities; $V_m = V_{SG} + V_{SL}$

g is the apparent gravity

D is the tube diameter

The influence of surface tension is determined by the Weber number:

$$We = \frac{\rho V^2 D}{\sigma} = \frac{\text{inertial force}}{\text{surface tension}} \tag{7.2}$$

which represents the balance between inertial force and surface tension. This dimensionless group must be an important correlating parameter at microgravity conditions.

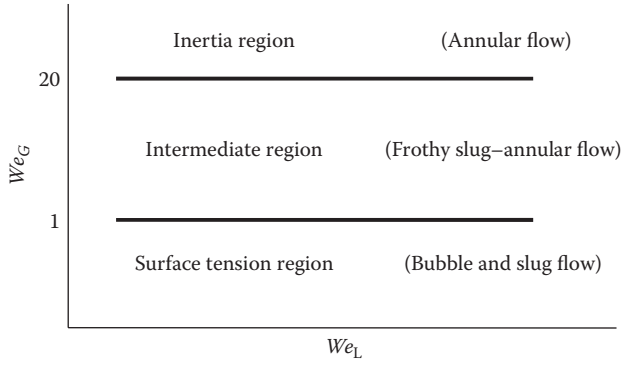

Figure 7.2

Two-phase flow regions at microgravity conditions.

At low gas velocity, and hence for a low We_G, surface tension is dominant. The flow is usually bubbly flow, and the bubble shape is determined by surface tension. Owing to the minimum slip in microgravity bubbly flow, the bubble velocity at microgravity can be reasonably represented by the expression

$$V_G = 1.2\left(V_{SG} + V_{SL}\right) \tag{7.3}$$

When the gas velocity is increased, the inertial force becomes large enough to overcome surface tension. The gas phase breaks through the liquid slug and forms tiny packed gas bubbles. This transition region is called frothy slug–annular due to the continuous appearance of frothy mixtures in the liquid slugs. Based on experimental data, the transition from slug flow to frothy slug–annular flow appears to take place at

$$We_G = \frac{\rho_G V_G^2 D}{\sigma} \approx 1 \tag{7.4}$$

As the gas flow rate further increases, the density of the liquid droplets in the frothy core decreases, and the frothy slugs become thinner until eventually annular flow is reached. In this region, the flow pattern is mainly dominated by forces due to inertia. From the experimental data (Lowe and Rezkallah, 1999), it was found that annular flow occurs at

$$We_G \approx 20 \tag{7.5}$$

7.5 Flow Pattern Map

In general, two-phase gas–liquid flow under microgravity conditions can be divided into three main flow regions.* These are surface tension controlled, intermediate, and inertial force controlled. The first region is where the forces due to surface tension are significantly higher than those due to inertia ($We_G < 1$), which includes bubble and slug flows. The second region is where the two forces are comparable ($1 < We_G < 20$), which is occupied by transitional flows (frothy slug–annular flow). The third region is where the forces due to inertia are dominant ($We_G > 20$). This region is occupied by annular flow. A dimensionless flow pattern map based on these criteria and a very comprehensive dataset was developed (Rite and Rezkallah, 1993) and is shown in Figure 7.3.

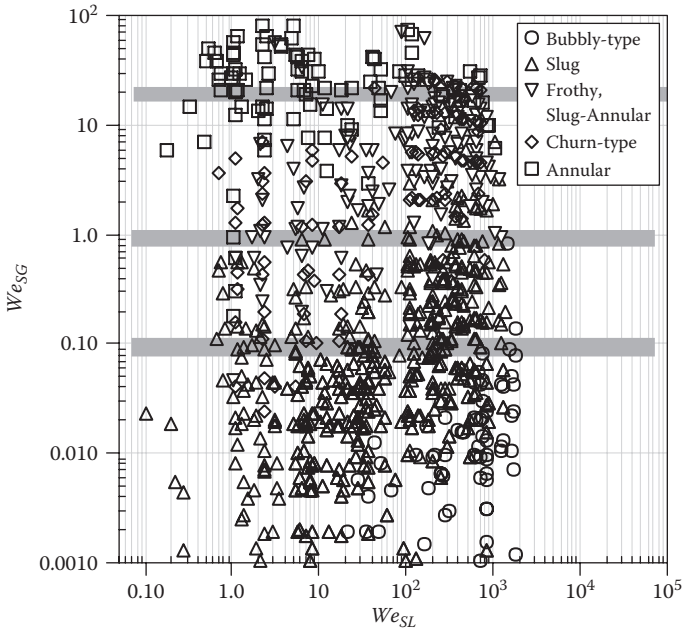

Figure 7.3

Dimensionless flow patterns map and experimental data for microgravity two phase adiabatic flow.

7.6 Gas–Liquid Pressure Drop

7.6.1 Momentum Equations

The determination of pressure losses in two-phase flow systems is essential to the design of a thermal management system. The pressure loss, dp/dz, in a two-phase flow system includes pressure losses due to friction, f; gravitational force, g; and momentum change, m. The total pressure loss is estimated from

$$\left(\frac{dp}{dz}\right)_{tot} = \left(\frac{dp}{dz}\right)_f + \left(\frac{dp}{dz}\right)_g + \left(\frac{dp}{dz}\right)_m \tag{7.6}$$

The calculations of the last two terms, gravitational and momentum, require the knowledge of the void fraction. The gravitational component can be rewritten as

$$\left(\frac{dp}{dz}\right)_g = \left[\alpha\rho_G + (1-\alpha)\rho_L\right]g \tag{7.7}$$

And for the momentum component, the equation becomes

$$\left(\frac{dp}{dz}\right)_m = G^2\frac{d}{dz}\left[\frac{x^2}{\alpha\rho_G} + \frac{(1-x)^2}{(1-\alpha)\rho_L}\right] \tag{7.8}$$

where G is the total mass flux of both phases. When gravity is changed, the methods to calculate these two terms remain the same, only the numerical value of the void fraction might be different. In this section, only the estimation of the frictional pressure drop component will be discussed in details.

7.6.2 Empirical Methods*

Many empirical or semiempirical correlations are available for the prediction of the frictional pressure drop (e.g., Lockhart and Martinelli, 1949, Dukler et al., 1964a,b, Chisolm, 1967, Friedel, 1979). More details are available in Gabriel (2007). Such correlations were mostly based on experimental data collected at different orientations on ground in different tube diameters and with a wide range of liquid and gas properties. Some of these models are discussed hereafter.

7.6.3 Homogeneous Model

The basic assumption of this model is that the two phases are well mixed and that the velocities of the two phases are equal. These assumptions are closer to what is actually experienced in bubbly and slug flows (short slugs) at microgravity than at 1-g. The mixture density is given in terms of the gas quality, x:

$$\frac{1}{\rho_{mi}} = \frac{x}{\rho_G} + \frac{1-x}{\rho_L} \tag{7.9}$$

The calculation of the mixture viscosity could be done using one of several methods. One of them is to use the liquid viscosity (let $\mu_{mi} = \mu_L$) in the calculation of the Reynolds number. Another is to use a mixture viscosity instead of the liquid viscosity. Several correlations were recommended for μ_{mi}, among which is the correlation suggested by Dukler et al. (1964b):

$$\mu_{mi} = \mu_G\frac{x\rho_{mi}}{\rho_G} + \mu_L\frac{(1-x)\rho_{mi}}{\rho_L} \tag{7.10}$$

The friction factor C_f can be calculated from the *Blasius* equation, in which the Reynolds number is given by

$$\mathrm{Re}_{mi} = \frac{\rho_{mi}V_{mi}D}{\mu_{mi}} \tag{7.11}$$

* With kind permission of Springer Science + Business Media.

The pressure drop can then be obtained from

$$\left(\frac{dp}{dz}\right)_f = \frac{2}{D} C_f \rho_{mi} V_{mi}^2 \tag{7.12}$$

where V_m is the mixture velocity: $V_m = V_{SL} + V_{SG}$.

7.6.4 Lockhart–Martinelli Correlation

Another widely used method for the estimation of two-phase flow pressure drop is the Lockhart–Martinelli correlation. While the original correlation is given in a graphical form (Lockhart and Martinelli, 1949), it could be written using the following expression (Zhao and Rezkallah, 1993a):

$$\left(\frac{dp}{dz}\right)_{TP} = \left(\frac{dp}{dz}\right)_L + C\left(\frac{dp}{dz}\right)_L^{1/2}\left(\frac{dp}{dz}\right)_G^{1/2} + \left(\frac{dp}{dz}\right)_G \tag{7.13}$$

This implies that the two-phase pressure drop equals to the sum of the pressure drop for the liquid phase flowing alone, plus the pressure drop for the gas phase flowing alone, plus a two-phase flow effect. The coefficient "C" represents the importance of the two-phase flow effects. It can be argued that these effects at microgravity conditions are generally high without discriminating between the fluid flow rates. When the velocities of both phases are high, the differences between microgravity and normal gravity conditions are almost negligible. On the other hand, when the flow rates are low, the microgravity pressure drop is higher than that at normal gravity conditions. A constant $C = 20$ fits the experimental data over a wide range of flow rates. In general, the Lockhart–Martinelli correlation underpredicts the pressure drop in microgravity flows.

7.6.5 Dimensional Analysis Model

The μ-g two-phase pressure drop was correlated (deJong and Rezkallah, 2000) in terms of the Euler number. The correlation was based on a dimensional analysis approach and is given by

$$Eu_{SL} = \left[\frac{\left(\partial P/\partial z_f\right)D}{\rho_L V_{SL}^2}\right] = C_L Re_{SL}^{-0.33}\left(\frac{x}{1-x}\right)^{0.80}\left(\frac{\rho_G}{\rho_L}\right)^{0.5}\left(\frac{\mu_G}{\mu_L}\right)^{-0.1} \tag{7.14}$$

The quality ratio term, $(x/1-x)$, has a direct relationship with the superficial liquid Euler number. Modifying Eu_{SL} through dividing it by $(x/1-x)^{0.8}$ enables us to plot the relationship between Eu_{SL} and Re_{SL}; this is shown in Figure 7.4. As Re_{SL} increases, the effect is to reduce the Euler number. The relationship is of a power law type.

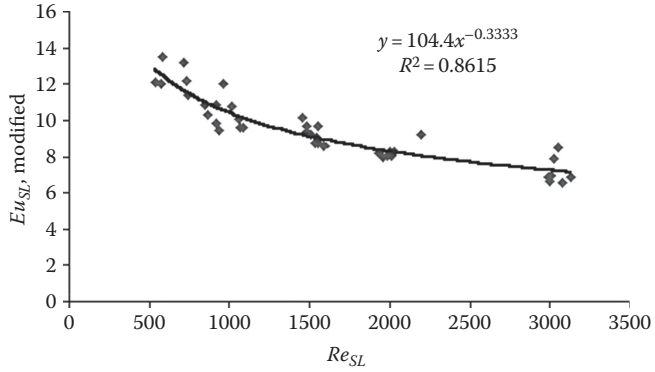

Figure 7.4

Euler number–based correlation. (From deJong, P. and Rezkallah, K.S., A dimensional analysis of microgravity annular flow: Pressure drop and film characteristics, in *Proceedings of Spacebound Conference*, Ottawa, Ontario, Canada, 2000.)

7.7 Void Fraction

Measurement techniques of void fraction in two-phase gas–liquid flow continue to evolve owing to the transient nature of the flow that gives rise to difficulties in relying on traditional instrumentation for accurate measurements. Among the most favorable methods available for measuring void fraction in gas–liquid flow are the nonintrusive techniques. Due to the transient nature of two-phase flows, most analysis techniques involve an ensemble average that is obtained from various data at the same flow conditions or by a time average from a single recording. Some of the common techniques for obtaining void fraction measurements include the following: gamma ray attenuation, conductance probe, quick closing valves, and capacitance methods. The selection of any of these methods depends on its application and whether a volumetric average or a local void fraction measurement is desired.

The volume average void fraction, α, in a two-phase mixture is defined as

$$\alpha = \frac{\text{Volume of gas in mixture}}{\text{Total volume of gas and liquid}} \tag{7.15}$$

In addition to obtaining a void fraction measurement, the statistical analysis of the signal can also be used to determine the flow regimes associated with the flow and their transitions.

Since two-phase flow measurements are strongly flow regime dependent, comparisons between 1-g data and μ-g data were made for each flow regime individually. The main findings from those comparisons are summarized later. For more comprehensive coverage of this topic and actual flow regime photos, see Gabriel (2007)

For a pseudo-void fraction approximately below 0.1, the results in the bubbly flow regime showed a tendency for the μ-g data to be approximately 8%–25% higher than those taken at 1-g. Above $V_{sg}/V_{sl} = 0.1$, the difference is reduced until the trend is reversed with the 1-g data slightly higher than the μ-g counterpart (approximately 7%–16% higher). The higher void fraction at μ-g for $\alpha < 0.2$ can be attributed to the significant reduction in slip between the phases, combined with an increased influence of surface tension under reduced gravity. These changes lead to the bubbles being able to sustain their shape even at high gas content, while the rate of collision and coalescence of the bubbles is significantly reduced.

The slug flow results showed that the void fraction was consistently higher for the μ-g data, with a difference that ranges from 3% to 35%, with an overall average of approximately 10%. This trend seems to be consistent up to a void fraction of approximately 0.70 beyond which the percentage difference in void fraction decreases. This occurs near the transition to slug–annular flow at μ-g and churn flow at 1-g. In the latter, flow reversal due to the pull of gravity is observed and could greatly skew the void fraction readings in that region.

The results for transitional flows (slug–annular flow at μ-g and churn flow at 1-g) showed that the void fractions are comparable in this highly transitional region for both the μ-g and 1-g cases. As mentioned earlier, the slug–annular flow is in a transition where inertia forces become more dominant when compared to surface tension forces. The liquid slug at these conditions contains a highly aerated frothy mixture, which could cause large fluctuations in the void fraction measurements.

Finally, the results for annular flow showed that the μ-g and 1-g data are very similar. This is expected since, under both 1-g and μ-g conditions, the flow is highly turbulent and inertia forces are dominant in both cases. The difference between the 1-g and μ-g void fraction values is within 5% and could be assumed insignificant.

7.8 Heat Transfer in Microgravity

Heat transfer measurements were made during a series of parabolic flights on board NASA's KC-135 zero-gravity aircraft spanning over a number of years and totalling approximately 40 hours. A flight typically consisted of four sets of 10 parabolic maneuvers during which equipment and personnel inside the aircraft experience 20–22 s of near weightlessness followed by a short period of 1.8-g pull-up maneuver. The short duration of the microgravity period during each maneuver gives rise to the question whether the time response of the heated test section and the flow is such that steady-state thermal conditions could have been possibly achieved.

It was determined from extensive analysis (Gabriel, 2007) that *quasi-steady* heat transfer condition existed and that the measured coefficients for two-phase convective flow accurately represented the local heat transfer rates during such periods.

There are two sources of transients during any flight test: one is due to the variation of the gravity field and the other is due to the changing gas and liquid flow rates and the heater power. Changes in these parameters will affect the five basic measured quantities that are of interest in such study: the flow rates of the liquid and gas phases, the heat flux at the surface of the heated test section, the temperatures along the surface, and the bulk fluid temperature.

Since the heat transfer coefficient is based on the difference between the surface temperature and the fluid temperature, the *quasi-steady-state* condition will be determined based on the time when this difference approaches a constant value. Although the absolute values of both of these quantities tended to slowly increase throughout the duration of tests, it was found that the difference between them did in fact reach an approximately constant value. Hence, this difference will be used to define *quasi-steady-state* condition in thermal terms.

To minimize the impact of the set point transient, changes to the set points were always made at the completion of a flight parabola. This allowed a settling time of approximately 60 s before the next data collection window was opened. Therefore, the time constant that the test section must have in order to reach *quasi-steady-state* conditions after a change in set point is on the order of a minute. The transient response of the heated test section to changes in the set point was determined in the laboratory to see if this was indeed feasible. It was found that after 10 s, the difference between the surface and fluid temperatures was within approximately 90% of its *quasi-steady-state* value.

7.8.1 Influence of Flow Patterns

The influence of flow patterns and their transitions on the heat transfer rates in two-phase flows has been recognized for many years. Shortly after the behavior of two-phase flows was first explored in depth for terrestrial applications (such as in the nuclear, petroleum, and process industries), it was discovered that the geometry of the flow was important in determining the local heat transfer values and trends.

Likewise, for microgravity research, the need to account for the influence of the gravitational level as well as the flow regime on the two-phase heat transfer has been well established from early work during the Space lab era in the 1970s. From the results of Rite and Rezkallah (1993), it was shown that, at low liquid velocities and void fractions, 1-g heat transfer data were greater than μ-g data. As the liquid velocity increased, similar trends were observed, but only at very low void fractions in the bubble flow regime. As the void fraction increased, the 1-g and μ-g data points approached one another until the two sets were nearly identical (μ-g was marginally greater than 1-g by 10%–15%). This confirmed that the difference between 1-g and μ-g behavior is flow regime dependent.

It is important to note that the trends in 1-g versus μ-g heat transfer rates that were observed during flights could not be simply correlated with the traditional two-phase heat transfer dimensionless groups of Reynolds number, Prandtl number, and superficial velocity ratio. Other effects due to gravity and surface tension must be included in the analysis, although in some cases their effects may be of secondary importance. The question that needs to be addressed is: What is the mechanism responsible for this effect?

It appears that under 1-g conditions the gas is influencing the local heat transfer by disturbing the liquid flow at the wall of the tube. This agrees with the findings of Vijay et al. (1971), who hypothesized that the effect of buoyancy forces on the gas bubbles caused the gas to have a greater velocity than the surrounding liquid. This *slip* between the phases led to a breakdown in the laminar sublayer near the tube wall, thus leading to a movement away from laminar flow–type behavior. However, under μ-g conditions this would not happen. The reduction of gravity greatly lessens the buoyancy forces and therefore the turbulence-generating ability of the gas bubbles. The bubble dynamics at μ-g do not seem to interfere with the maintenance of the laminar sublayer.

7.8.2 Empirical Correlations*

In order to develop useful empirical correlations to model observed phenomena, the identification of dimensionless groups that describe the phenomena is required. For low-gravity two-phase flow heat transfer, in addition to the most commonly used groups (e.g., Reynolds and Prandtl numbers), the effect of gravitational and surface tension forces on the arrangement of the gas and liquid phases must also be considered in the dimensional analysis.

The flow regime transitions proposed by Zhao and Rezkallah (1993b) were incorporated into the analysis in order to account for the influence of the change in the flow regime due to reduced gravity on the two-phase heat transfer. In their analysis, it was reported that the flow regime transitions were very much dependent on the force balance between inertia forces and surface tension forces. This balance was well

* With kind permission of Springer Science + Business Media.

represented as a function of the gas Weber number such that the annular flow was shown to be present for $We_{SG} > 20$ (inertia-dominated region), slug–annular flow for $1 < We_{SG} < 20$, and slug and bubbly flows for $We_{SG} < 1$ (surface tension–dominated region). In this last range of Weber numbers, another transition has been added at $We_{SG} = 0.1$ to identify the region where true bubbly flow can only exist. The associated heat transfer coefficients for such homogeneously dispersed flows would be different from that of typical Taylor-type slug flows.

From a dimensional analysis, it was determined that for $Re_{SL} < 2300$, the following dimensionless groups are pertinent: Graetz number (Gz_{SL}) based on the liquid superficial velocity and properties, the ratio of the superficial velocities or the pseudo-void fraction α', and a property group known as the liquid Morton number (Mo_L). The Graetz number is defined as

$$Gz_{SL} = Re_{SL} \times Pr_L \times \frac{D}{L} \tag{7.16}$$

where

Pr_L is the Prandtl number of the liquid phase

L is the length of the heated test section

The Morton number is defined by

$$Mo_L = \rho_L \times \frac{\sigma^3}{g} \times \mu L^4 \tag{7.17}$$

where

g is the gravitational acceleration

μ_L is the liquid dynamic viscosity

As seen in the aforementioned equation, Morton number is strictly dependent on fluid properties and gravity. This incorporates the effect of gravitational forces and surface tension forces in the analysis of the heat transfer data.

With liquid superficial Reynolds numbers above 2300, the nondimensional numbers that are important include Re_{SL}, α', the liquid Froude number (Fr_{SL}), and the Morton number (Mo_L).

Froude number, based on the liquid superficial velocity, is defined as

$$Fr_{SL} = \frac{V_{SL}}{\sqrt{gD}} \tag{7.18}$$

For $We_{SG} < 0.1$, the correlation developed for this case is given as

$$\psi^2 = 1 + 0.8 Gz_{SL}^{-0.114} \times \alpha'^{-0.084} \times Mo_L^{0.058} \tag{7.19}$$

where ψ^2 is the normalized two-phase flow heat transfer coefficient with respect to the single-phase liquid heat transfer coefficient; ($\psi = h_{TP}/h_L$).

For the next range of gas Weber numbers, $0.1 < We_{SG} < 1$, the empirical correlation has the following form:

$$\psi^2 = 1 + 2.1 Gz_{SL}^{-0.074} \times \alpha'^{-0.023} \times Mo_L^{0.010} \tag{7.20}$$

For the next range of data, $1 < We_{SG} < 20$, for which the flow regime is predominantly slug, the recommended correlation is given as

$$\psi^2 = 1 + 0.7 Gz_{SL}^{0.106} \times \alpha'^{0.251} \times Mo_L^{-0.010} \tag{7.21}$$

Finally, for $We_{SG} > 20$ (annular flow regime), the correlation is given by

$$\psi^2 = 1 + 37.2 Gz_{SL}^{-0.291} \times \alpha'^{0.194} \times Mo_L^{-0.059} \tag{7.22}$$

Extensive analysis and comparisons with other correlations and actual measured heat transfer data can be found in Gabriel (2007).

7.9 Interfacial Waves in Microgravity Annular Two-Phase Flows

The hydrodynamic and heat transport characteristics of annular two-phase flows are closely connected to the existence of interfacial waves at the gas–liquid interface. Annular flow is of particular interest because of its frequent occurrence in heat transfer systems. Usually, part of the liquid phase flows as droplets entrained in the gas core. In a normal gravity environment, two-phase flow is common in nuclear reactor, power plants, transport of cryogenics, and many petrochemical processing plants. The annular flow is usually the preferred regime of operation for most heat transfer devices due to the high heat transfer rates.

However, if the surface temperature or heat flux is large enough, the film thickness of liquid phase will become thinner and eventually disappear followed by serious deterioration of the heat transfer process. This phenomenon is known as "dryout" in the nuclear industry and could cause catastrophic accidents. Therefore, knowledge of the film thickness characteristic in annular flow is of considerable importance in advancing safety control measures in nuclear industry.

It could be argued that the study on the wave structure is the foundation for further investigations of annular two-phase flows. Most investigators readily admit that the existence of such waves complicates the measurements due to the interfacial shear stress that in turn influences the pressure drop and the liquid film. There are at least two reasons to account for why the interface structure can influence the pressure drop:

1. The existence of the surface waves contributes to increased *surface roughness* at the interface which in turn increases the pressure drop. In fact, not only the increased wave amplitude influences the pressure drop, but also the wave separation affects it. If the waves space sparsely, they should exert different influences compared to when they are densely spaced.
2. The presence of waves enhances the liquid atomization into the gas core and directly changes the mass and momentum transfer between the gas stream and the liquid film. Consequently, the pressure drop is influenced as well.

Microgravity provides an ideal environment to study interfacial waves (small-scale phenomena) without the dominating effects of gravity.

7.10 Definition of Wave Shape and Wave Characteristic

As shown in Figure 7.5, wave spacing equals to the total length of the film thickness time trace divided by the number of peaks that appear in the entire time trace. Starting with as many identified local wave peaks, the local wave shapes were found by extending forward and backward for the length of half-wave spacing. Then a wave band was determined by locating all of the local wave shapes in the film thickness time trace and superimposing them onto one another. The line of average value in the wave band, called the "central trend line", represents the entire local waves in the 4-s window of film thickness time trace.

Referring again to Figure 7.5, the following terms are of significance in terms of the classification and description of the interfacial wave phenomena. The *wave peak height*, H, is defined as the average of observed peaks in the film thickness time trace. The *wave base height*, h, is defined as the average value of the film thickness between the starting and ending points of adjacent waves. The *starting point*, A, in Figure 7.5 represents the first value of the film thickness time trace that exceeded the average film thickness between the starting and ending points by 5% or more. Conversely, the *ending point*, C, is the first value in the film thickness time trace that is 5% greater than the following wave base height.

Generally, the average film thickness between the starting and ending points of the adjacent waves is defined as the wave base height. The ending point also represents the last point in the time trace that is above the wave base height. The *wave roughness height*, (*H-h*), is defined as the difference between the wave

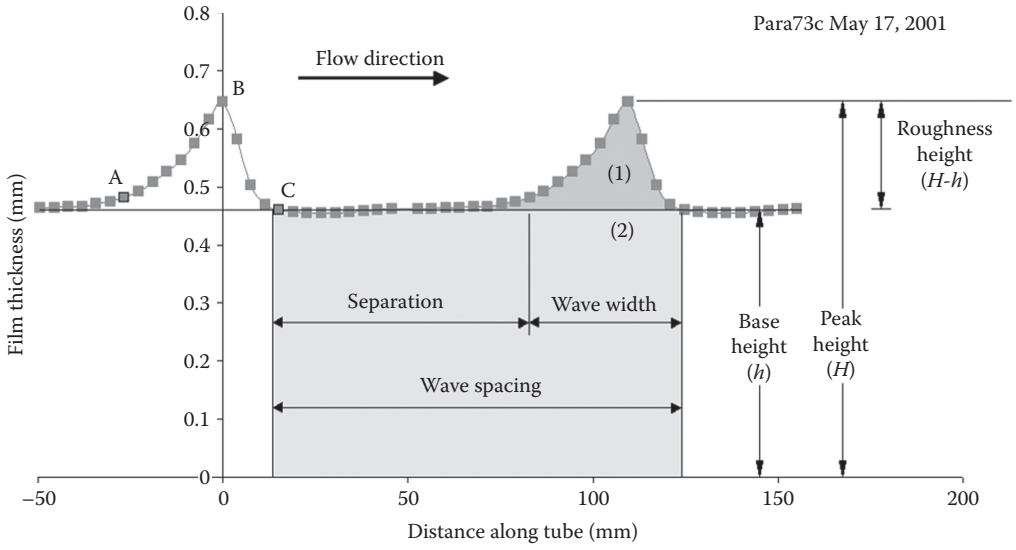

Figure 7.5

A sample wave shape: (1) wavy area and (2) base area.

peak height and the wave base height. The wave structure is separated into two areas, as shown in Figure 7.5. The area below the wave base height is called the "base area," while the region above the wave base height is known as the "wavy area."

The *wave separation* is defined as the distance between the starting point of one wave and the ending point of the previous one. The *wave width* is the distance between the starting point and the ending point of a single wave. It is important to remember that these properties have been determined for a single wave and represent all of the waves in the 4 s window of data acquisition.

In general, an increase in the gas mass flux results in an increase in the interfacial velocity at the liquid–gas interface. More momentum is transferred from the highly energetic gas core to the liquid film, resulting in an increase in the film velocity in the base area. The increase in the interfacial velocity results in an increase in the interfacial shear stress and a subsequent increase in the friction factor; hence, it causes an increase in the pressure drop. The use of an interfacial friction factor to predict the frictional pressure drop has been studied and results could be found in deJong and Rezkallah (2000).

An investigation into the effects of increasing the gas mass flux on the wave characteristics in annular, liquid–gas flows was also carried at 1-g (Wang et al., 2005). A wave shape was obtained for each set point using the recorded film thickness time traces. Two film thickness probes were used in conjunction with the cross-correlation technique to obtain the velocity of the wavy area and the base area. The results from that study can be summarized as follows:

1. At a constant liquid mass flux, the wave spacing increases with decreasing the gas mass flux indicating that the frequency of the disturbance waves in a film thickness decreases. The frequency of the disturbance waves has a direct relationship with the gas mass flux.
2. The wave base height and the average film thickness slightly decrease with an increase in the gas mass flux at a constant liquid mass flux.
3. At a constant liquid mass flux, the wave peak height decreases as the gas mass flux increases.
4. The wave roughness height decreases, and the wave frequency increases with increasing the gas mass flux at a constant liquid mass flux.
5. The wavy area occupies less than 15% of the total liquid volume at a liquid mass flux of 110 kg/m^2 s. The ratio decreases with an increase in the gas mass flux.
6. The liquid velocity in the base area is much less than that in the wavy area (at constant gas and liquid mass fluxes). The ratio is approximately 1:14.
7. The wavy region of the unit wave transports the majority of the liquid mass assuming the wavy region travels at a velocity equal to the velocity of the wave above the base and that the droplet entrainment fraction is so small and could be neglected.

Nomenclature

C_f	friction coefficient
C_L	constant in equation (7.14); $C_L = 1982$
D	tube diameter, m
dp/dz	pressure gradient, Pa/m
Eu	Euler number
Fr	Froude number, $V/(gD)^{1/2}$
G	total mass flux, kg/m^2 s
g	gravitational acceleration, m/s^2
P	pressure, Pa
R	radius, m
Re	Reynolds number, $\rho VD/\mu$
V	velocity, m/s
V_m	sum of gas and liquid superficial velocities, m/s
We	Weber number, $\rho V^2 D/\sigma$
x	gas mass quality

Greek Symbols

α	void fraction
μ	dynamic viscosity, Ns/m^2
ρ	density, kg/m^3
σ	surface tension, N/m

Subscripts

f	friction
G	single-phase gas
L	single-phase liquid
m	momentum change
mi	mixture
SG	superficial gas
SL	superficial liquid
tot	total
TP	two-phase

Boiling

Satish G. Kandlikar

8.1 Pool Boiling
8.2 Flow Boiling

8.1 Pool Boiling

The change of phase from liquid to vapor across a liquid–vapor interface is called evaporation. Boiling refers to the heat transfer–induced evaporation associated with vapor bubbles nucleating over a heat transfer surface. The nature of the specific liquid–vapor system gives rise to two types of boiling:

1. "Pool boiling" refers to the boiling process in which the liquid is essentially quiescent and vapor bubbles rise as a result of buoyancy forces induced by gravity or other body forces.
2. "Flow boiling" refers to the boiling process in which the liquid and the resulting vapor phase are subjected to a flow field.

In the literature, additional terminology is employed to identify specific configurations; *thin-film evaporation* or *falling-film evaporation* refers to evaporation across the liquid–vapor interface of a thin liquid film that is formed on a heater surface. The term *convective flow boiling* refers to the change of phase from liquid to vapor during internal flow, while *external flow boiling* refers to the change of phase from liquid to vapor during external flow such as flow over tube banks.

Pool boiling is also of interest from the perspective of understanding the boiling phenomenon. Some of its applications include kettle reboilers, batch-type vaporizers, liquid immersed electronic component cooling, and quenching of metals in metallurgical processes. Flow boiling is employed in many applications, such as steam generators and refrigeration evaporators, and is being considered for high-flux cooling of electronic components.

8.1.1 Introduction to Pool Boiling

Although a number of investigators have observed different regions of pool boiling heat transfer, Nukiyama (1934) conducted a systematic study on pool boiling over electrically heated nichrome and platinum wires and presented a boiling curve. Figure 8.1 shows a boiling curve for water at atmospheric pressure. It incorporates a number of additional features that have been identified by later investigators. The heat flux q'' at the heater surface is plotted against the wall superheat ($\Delta T_{Sat} = T_{Heater} - T_{Sat}$). The nature

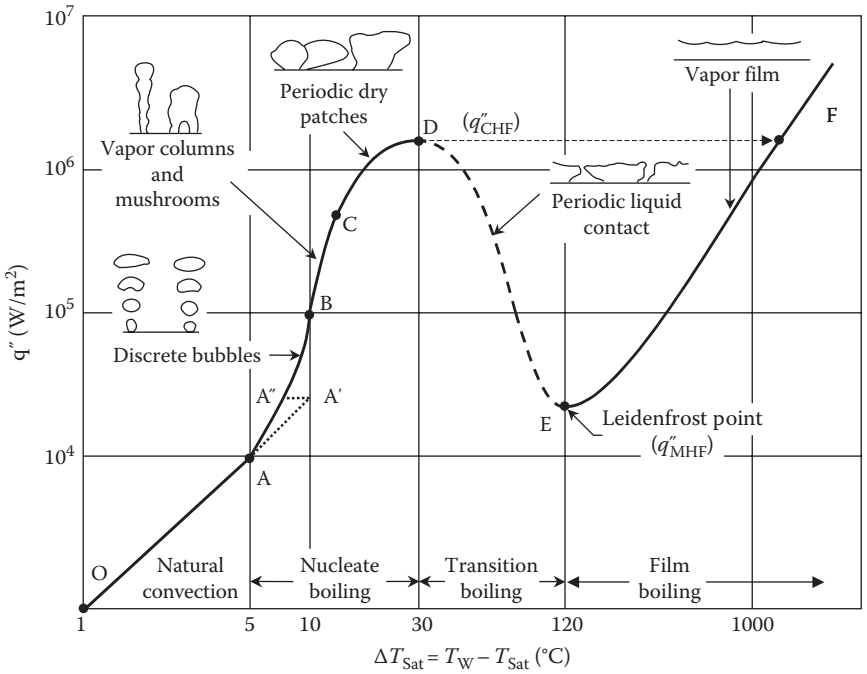

Figure 8.1

Boiling curve showing different regions in pool boiling.

of bubbles or a vapor film surrounding the heater in different regions is also depicted in Figure 8.1. The pool of water is held at its saturation temperature of T_{Sat} corresponding to the system pressure (hence the term *saturated pool boiling*).

In the region O–A in Figure 8.1 with a small ΔT_{Sat}, heat is transferred by *natural convection*. At location A′ corresponding to a certain value of $\Delta T_{Sat} = \Delta T_{Sat,ONB}$, bubble nucleation is initiated on the cavities present on the heater surface. This condition is called *onset of nucleate boiling* (ONB). With the inception of nucleation, the heater surface temperature drops to A″ for a given imposed heat flux. This hysteresis effect shown by the dotted lines AA′A″ disappears during repeated boiling cycles with increasing and decreasing values of heat flux. The slope of the curve beyond the ONB point increases at higher ΔT_{Sat} values as the bubbles grow and depart more rapidly in the partial nucleate boiling region (region A″–B). As heat flux is increased, more nucleation sites become active and *fully developed nucleate boiling* ensues (regions B–C). At higher heat fluxes, the heater surface becomes overcrowded with bubbles at various stages of growth. In addition, the intense evaporation under the bubble leads to periodic dry patches on the heater surface that are rewetted by the surrounding liquid, resulting in a reduction in the slope of the boiling curve (the heat transfer coefficient begins to decrease). As the wall superheat increases further, liquid is unable to rewet the heater surface, causing a sudden formation of a dry patch that eventually covers a large region of the heater surface. A thin film of vapor eventually separates the liquid from the heater surface and leads to a large temperature excursion of the heater surface (drastic reduction in the heat transfer coefficient). The heat flux corresponding to this condition at location D, q''_{CHF}, which represents the maximum heat flux sustained under the nucleate boiling condition, is called the *critical heat flux* (CHF). This is an unstable condition and the heater temperature jumps to point F. The ensuing mode of heat transfer in which the heater is blanketed with a thin vapor film is called film boiling. Through experimental investigation, Nukiyama (1934) observed that the high temperature following the CHF point leads to physical burnout of the nichrome wires, while platinum wires were able to withstand the higher temperatures.

The dotted region D–E in Figure 8.1 following the CHF represents the *transition boiling* region. This region is not accessible with an electrical heater that imposes a constant heat flux boundary condition. It can only be traced under stable conditions by employing a constant temperature boundary condition on the heated wall. In the transition region, the heat transfer is associated with formation followed by rewetting of the dry patches in rapid successions. As the heater surface temperature is increased, eventually the rewetting cannot be sustained at the Leidenfrost condition represented by E, and the heater is surrounded by

a stable vapor film. The heat flux at E is called the *minimum heat flux* (MHF), q''_{MHF}. The region E–F is the film boiling region in which heat is transferred by combined radiative and convective modes across the thin vapor film.

In studying boiling phenomena, the nucleation characteristics and bubble behavior are of great importance as they directly affect the heat transfer. Some of the early investigators, including Moissis and Berenson (1963), Gaertner (1965), and Johnston et al. (1966), employed high-speed photography to reveal the bubble behavior. Gaertner obtained still and video images at 3000 frames/s identifying various boiling regions, such as the discrete bubble region, first transition region (vapor columns are observed), and second transition region (stems of the vapor column become unstable with the formation of local dry patches). Cole (1960) obtained high-speed images and measured bubble frequency, bubble diameter, and contact angles close to CHF condition. The actual CHF mechanism is still a subject of active research, as the Helmholtz instability in the second transition region is used as the basis of some of the CHF models (Zuber, 1959, Haramura and Katto, 1983), while the role of evaporation momentum force and capillary flows is being considered in the recent models (Kandlikar, 2001a, Chu et al., 2013).

8.1.2 Onset of Nucleate Boiling

Bankoff (1958) showed that the presence of nucleating cavities on a heater surface leads to nucleation at lower superheats (heterogeneous nucleation) compared to the homogeneous nucleation in which vapor embryos are formed in a highly superheated liquid. Cavities trap vapor and gases and act as nucleation sites for bubbles on a heater surface. A certain amount of wall superheat is needed to activate the cavities depending on various factors: (1) cavity size and shape; (2) fluid properties, including surface tension and contact angles; and (3) temperature profile in the liquid immediately surrounding the heater surface.

Consider a vapor bubble of radius R_b in a pool of liquid at a temperature T and pressure p_L as shown in Figure 8.2. The pressure inside the bubble is p_G. Taking a diametric section reveals the forces due to pressure difference and surface tension along the circumference. At equilibrium, equating these two forces yields

$$p_G - p_L = \frac{2\sigma}{R_b} \tag{8.1}$$

The liquid and vapor states corresponding to the condition given earlier are shown as L and G, respectively, in Figure 8.2. The liquid state L lies in a metastable condition corresponding to p_L and T. The metastable equilibrium liquid line in the saturation dome represents the equilibrium over a curved interface. The lowest pressure point on this curve corresponds to the homogeneous nucleation condition.

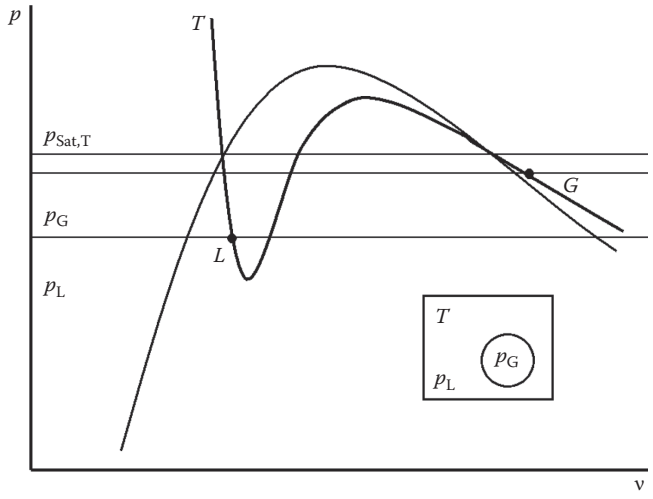

Figure 8.2

Metastable liquid and vapor conditions for a bubble growing in a pool of liquid.

The vapor state G is in the superheated region corresponding to p_G and T. The saturation pressure $p_{Sat,T}$ over a planar interface corresponding to T can be expressed in terms of pressures p_L and p_G by equating the molar Gibbs free energies for the two phases (Fujita, 1999):

$$p_{Sat,T} - p_G = \left(\frac{v_L}{v_{G,Sat,T} - v_L} \right) \frac{2\sigma}{R_b} \tag{8.2}$$

$$p_{Sat,T} - p_L = \left(\frac{v_{G,Sat}}{v_{G,Sat,T} - v_L} \right) \frac{2\sigma}{R_b} \tag{8.3}$$

For low reduced pressures, ($P_r \ll 1$), v_L, $v_{G,Sat}$, and Equations 8.2 and 8.3 are simplified as follows:

$$p_G = p_{Sat,T} \tag{8.4}$$

$$p_L = p_{Sat,T} - \frac{2\sigma}{R_b} \tag{8.5}$$

Figure 8.3 shows the growth of a bubble inside and over a cavity. The residual vapor or gas in the cavity activates the cavity. As the wall temperature rises, the liquid–vapor interface moves out toward the mouth of the cavity, assumed to be circular for the purpose of this analysis. Eventually, the bubble becomes anchored on the cavity's mouth as the contact angle adjusts from the inner cavity surface to the heater surface. The minimum radius of the bubble occurs when the bubble assumes a hemispherical shape with a radius R_b equal to the cavity's mouth radius R_C.

Hsu and Graham (1961) and Hsu (1962) postulated that a vapor bubble will grow, thus initiating nucleate boiling, if the temperature in the liquid at the top of the hemispherical bubble cap exceeds the saturation temperature corresponding to the pressure p_G inside the bubble. Under this condition, Equation 8.1 becomes

$$p_G - p_L = \frac{2\sigma}{R_C} \tag{8.6}$$

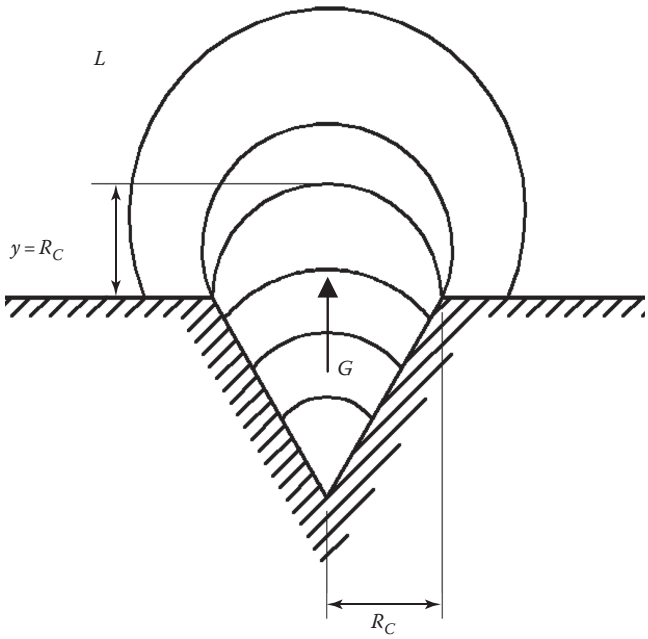

Figure 8.3

Growth of a vapor bubble nucleating from a cavity.

Applying the Clausius–Clapeyron equation, $dp/dT = h_{fg}/(v_{fg}T_{Sat})$, and assuming $v_{fg} \approx v_G$, Equation 8.6 becomes

$$T - T_{L,Sat} = \frac{2\sigma T_{Sat} v_G}{h_{fg} R_C} \tag{8.7}$$

where

T is the temperature of the liquid surrounding the bubble

$T_{L,Sat}$ (=T_{Sat}) is the saturation temperature (in K) corresponding to the liquid pressure p_L

Since there is a temperature gradient in the liquid normal to the heated wall, the minimum liquid temperature adjacent to the bubble interface occurs at $y = R_C$, where y is the distance normal to the heater surface. Using this temperature T in Equation 8.7 as T_G, the equilibrium temperature of the vapor in the hemispherical bubble on the bubble mouth, Equation 8.7, becomes

$$T_G - T_{L,Sat} = \frac{2\sigma T_{Sat} v_G}{h_{fg} R_C} \tag{8.8}$$

The liquid temperature profile in the vicinity of the heater surface can be approximated by applying the heat conduction equation in the liquid:

$$\frac{dT}{dy} = \frac{T_w - T_L}{y} = \frac{q''}{k_L} \tag{8.9}$$

The liquid temperature T_L at $y = R_C$ can be found from Equation 8.9.

Graphically, Figure 8.4 shows the plots of Equations 8.8 and 8.9. The intersection points of these two plots yield the range of the cavity radii, R_{min} and R_{max}, for which $T_L > T_G$ at $y = R_C$. Introducing $\Delta T_{Sat} = T_w - T_{Sat}$ at system pressure p_L, the following range is obtained by solving Equations 8.8 and 8.9:

$$R_{C,\max}, R_{C,\max} = \frac{1}{2}\left\{\frac{\Delta T_{Sat}}{q''} \pm \sqrt{\left(\frac{\Delta T_{Sat}}{q''}\right)^2 - \frac{8\sigma T_{Sat} v_G k_L}{h_{fg} q''}}\right\} \tag{8.10}$$

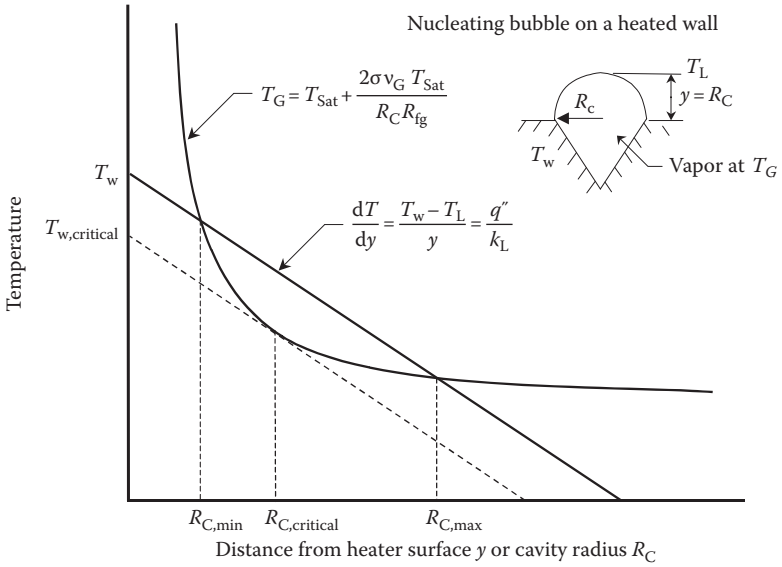

Figure 8.4

Nucleation criterion for the activation of a cavity in pool boiling.

Bubble nucleation further depends on the availability of cavities in the range between $R_{C,min}$ and $R_{C,max}$ over the heater surface. On the other hand, if cavities of all sizes are present, the minimum required heat flux to initiate nucleation and the critical cavity radius, defined as the radius of the first cavity to nucleate under a given heat flux q'', are obtained by drawing a line with a slope given by Equation 8.9 that is tangent to the curve for T_G, resulting in $T_w = T_{w,crit}$ as shown in Figure 8.4. Equating the slope dT_G/dR to the slope given by Equation 8.9, the critical radius R_{crit} at ONB is obtained. Alternatively, the term under the radical can be set to zero to obtain the critical radius:

$$R_{C,crit} = \frac{1}{2}\frac{\Delta T_{Sat}}{q''} \tag{8.11}$$

The wall superheat at the ONB is then obtained by setting the term under the radical in Equation 8.10 to zero:

$$\Delta T_{Sat,crit} = \left[\frac{8\sigma T_{Sat} v_G q''}{h_{fg} k_L}\right]^{1/2} \tag{8.12}$$

The nucleation criterion has been further investigated by researchers to include (1) the effect of cavity shape (Lorentz et al., 1974); (2) the effect of contact angle, resulting in bubbles that are of different shapes when compared with the hemispherical shape at the critical condition (Hsu and Graham, 1961); (3) subcooling; and (4) transient conduction effects due to liquid renewal (Marcus and Dropkin, 1965) and effect of dissolved gases (Murphy and Bergles, 1972). Equations 8.10 through 8.12 provide reasonable estimates of ONB conditions and are used extensively in practical applications.

Cavitation is similar to nucleation in boiling, except that the bubbles are generated as a result of lowering the pressure rather than increasing the temperature. The presence of dissolved gases leads to early nucleation before the local saturation conditions corresponding to a pure liquid are reached. As the liquid temperature increases, the solubility of dissolved gases generally decreases and they begin to come out of the liquid at the nucleation sites on the heater surface. Murphy and Bergles (1972) used the partial pressure of vapor in a gas–vapor mixture inside a vapor bubble for developing the nucleation criterion under these conditions.

8.1.3 Bubble Dynamics in Nucleate Pool Boiling

A bubble on a heater surface goes through an ebullition cycle consisting of the following four stages during nucleate boiling: (1) Bubble nucleation—when the temperatures of the wall and liquid in the vicinity of a cavity reach conditions conducive to nucleation, a bubble forms on the cavity mouth. (2) Growth period—relaxation of liquid superheat around the liquid–vapor interface due to evaporation causes the bubble to grow. (3) Bubble departure—as the bubble grows, eventually the forces tending to push the bubble away from the heater surface become greater than the retaining forces, and the bubble leaves the heater surface. (4) Waiting period—as the cooler liquid from the bulk rushes to take the place of the departed bubble, the temperature of the wall and the liquid adjacent to the cavity begin to rise until the nucleation criterion is met. A bubble is formed again, and the ebullition cycle continues.

8.1.3.1 Bubble Nucleation

Bubble nucleation is closely related to the size and shape of the cavity holding gases or vapors. For a given wall superheat, a range of nucleation cavities are activated. As the wall superheat increases, the active cavity size range increases as the liquid temperature distribution line moves higher in Figure 8.2. The presence of a vapor embryo in the cavity is essential for the activation of a cavity. Reentrant cavities are able to trap the gases or vapor left behind from a previously departed bubble that act as embryos. Bubble nucleation also depends on the availability of cavities, their shape and size ranges, local temperature profile in the liquid near the wall (dependent on the wall superheat and liquid subcooling), presence of dissolved gases, hysteresis effects, liquid properties, and contact angle.

8.1.3.2 Growth Period

The bubble continues to grow due to evaporation occurring at expanding the liquid–vapor interface on the bubble and also from the thin film left behind on the heater surface. The growth period is divided into

inertia-controlled and thermally controlled regions. Inertia-controlled growth occurs in the early stages of bubble growth. Rayleigh (1917) analyzed the growth process and derived the following equation for the bubble growth rate:

$$R(t)=\left\{\frac{2}{3}\left[\frac{T_L-T_{Sat}(P_L)}{T_{Sat}(p_L)}\right]\frac{h_{fg}\rho_g}{\rho_L}\right\}^{1/2} t \tag{8.13}$$

The growth rate is linear in the early stages as seen from Equation 8.13. Superheated liquid provides the thermal energy for rapid evaporation at the interface in this region, but the bubble growth is limited by the inertia of the surrounding liquid.

Subsequent to the initial rapid growth, evaporation is limited by conduction heat transfer from the surrounding liquid to the interface. Thus, bubble growth is thermally controlled. Plesset and Zwik (1954) derived the following equation for bubble growth in this region:

$$R(t)=\frac{2\Delta T_{Sat}k_L}{h_{fg}p_G}\left(\frac{3t}{\pi\alpha_L}\right)^{1/2} \tag{8.14}$$

where α_L is the thermal diffusivity of the liquid.

These equations for bubble growth are derived for the case of uniformly heated liquid over a spherical bubble. Mikic et al. (1970) derived the following equation by incorporating the shape of a bubble growing in the vicinity of a heated surface. The entire growth cycle, including the inertia-controlled and thermally controlled regions, is covered:

$$R^+=\frac{2}{3}\left[\left(t^++1\right)^{3/2}-\left(t^+\right)^{3/2}-1\right] \tag{8.15}$$

where

$$R^+=\frac{R(t)A}{B^2}\quad t^+=\frac{tA^2}{B^2}$$

$$A=\left\{\frac{2\left[T_L-T_{Sat}(p_L)\right]h_{fg}\rho_G}{p_LT_{Sat}(p_L)}\right\}^{1/2}\quad B=\left(\frac{12\alpha_L}{\pi}\right)^{1/2}\left\{\frac{2\left[T_L-T_{Sat}(p_L)\right]c_{p,L}\rho_L}{\rho_Gh_{fg}}\right\}$$

In the limit, this reduces to Equation 8.13 in the inertia-controlled region for small values of t and to Equation 8.14 in the thermally controlled region for large values of t.

8.1.3.3 Bubble Departure Diameter

As the bubble grows, it experiences the following forces: (1) Surface tension force—this holds down the bubble on the heater surface through the contact angle. (2) Inertia force—as the bubble grows, the acceleration and deceleration of the interface introduce inertia forces that push the bubble onto the heater surface during the earlier part of the growth period, while the bubble is pulled away during the later part. (3) Buoyancy force—depending on the orientation and geometry, the buoyancy force helps or opposes the bubble removal. Additionally, there are viscous forces as well as forces due to Marangoni convection in the liquid around the bubble. As a result of all these forces, a bubble departs from the heater surface after attaining a certain size. The bubble shape also undergoes considerable changes. The departure bubble diameter D_b is of great interest in boiling studies and has been extensively studied. Before applying any correlation, it should be realized that D_b depends on a number of additional variables, such as nucleation site interactions and convection currents that are statistical in nature. A wide variation in experimental values of D_b, up to 50%, from the prediction is not uncommon.

The following correlations by Jensen and Memmel (1986) were developed from a data bank of 504 data points for 15 fluids, including water, boiling on mostly horizontal plates and wires over a wide range of pressures. The correlations were compared with 12 other correlations and were found to perform consistently better than the other correlations available in the literature.

For the case when wall superheat is available,

$$\left[g\left(\rho_L-\rho_G\right)D_b^2/\sigma\right]^{1/2}=0.19\left(1.8+10^5K_1\right)^{2/3} \tag{8.16}$$

where

$$K_1=\left(\frac{Ja}{Pr_L}\right)^2\left\{\left[\frac{q\left(\rho_L-\rho_G\right)}{\mu_L^2}\right]\left[\frac{\sigma}{g\left(\rho_L-\rho_G\right)}\right]^{3/2}\right\}^{-1} \tag{8.17}$$

and Ja ($=\rho_L c_{p,L}\Delta T_{Sat}/(\rho_G h_{fg})$) is the Jakob number, Pr ($=\mu_L c_{p,L}/k_L$) is the Prandtl number, and the wall superheat is given by $\Delta T_{Sat} = T_w - T_{Sat}$.

For cases where wall superheat is not available,

$$D_b=2.97\times10^4\left(\frac{p}{p_{cr}}\right)^{-1.09}\left(\frac{KT_{cr}}{p_{cr}M}\right)^{1/3} \tag{8.18}$$

where

K ($=1.38\times10^{-23}$ J/K) is the Boltzmann constant

M is the molecular weight

subscript "*cr*" refers to the critical point for the fluid

The average deviations for Equations 8.16 and 8.18 were 44% and 52%, respectively, when compared with 30 data sources covering 15 different fluids at pressures from about 4.7 to 13,500 kPa.

8.1.3.4 Bubble Frequency

The frequency of bubbles being released from cavities depends on a number of factors, including wall superheat, fluid thermal properties, contact angle, cavity size, and interaction with neighboring bubbles. An empirical correlation by Malenkov (1971) takes into account the interaction between the bubble departure diameter and the bubble departure frequency and is recommended:

$$fD_b=\frac{V_b}{\pi}\left(1-\frac{1}{1+V_b\rho_G h_{fg}/q''}\right) \tag{8.19}$$

where

$$V_b=\left[\frac{D_b g\left(\rho_L-\rho_G\right)}{2\left(\rho_L+\rho_G\right)}+\frac{2\sigma}{D_b\left(\rho_L+\rho_G\right)}\right]^{1/2} \tag{8.20}$$

and D_b is the departure bubble diameter.

8.1.4 Heat Transfer Mechanisms during Nucleate Pool Boiling

Heat transfer in nucleate pool boiling is a result of a number of interacting mechanisms:

1. *Transient conduction*: As the bubble departs, the bulk liquid rushes over the heater surface surrounding the nucleating cavity. The liquid undergoes a transient heat conduction process. The wall thermal properties also play a role during the transient heat conduction process. The superheated

liquid moves away into the bulk during bubble growth and departure. The superheated liquid also contributes to the evaporation at the bubble interface. Mikic and Rohsenow (1969) proposed a model based on transient conduction in which they assumed a liquid layer from a circular region of diameter twice the departure diameter being replaced with the bulk liquid. This liquid experiences transient conduction from the heater surface. Demiray and Kim (2004) modified this model further by accounting for the gradual coverage of the liquid film. Subsequently, Moghaddam and Kiger (2009b) further modified to account for the transient heat transfer after complete rewetting. It is well accepted that the transient conduction plays an important role in heat transfer around a nucleating bubble during the ebullition cycle.

2. *Enhanced convection*: The bubble ebullition cycle introduces convective currents around a nucleating bubble that contribute to the heat transfer during nucleate pool boiling. The microconvection-induced heat transfer is significantly above the natural convection heat transfer. Since it covers a larger area around a bubble, its contribution is higher than from other modes.
3. *Microlayer evaporation*: A thin layer of liquid, called a microlayer, is left below an expanding bubble during the bubble growth period. Evaporation of this liquid film is believed to contribute to heat transfer especially at higher heat fluxes (Judd and Hwang, 1976).
4. *Contact line region heat transfer*: The contact line region separates the bulk liquid from the microlayer, which continues to evaporate until it assumes a thin adsorbed layer and eventual dryout. In this layer, the local curvature introduces a reduction in the saturation temperature of the interface and causes lowering of the heater surface temperature. This is an area of current research interest. The localized heat transfer in the contact line region makes the role of transient substrate conduction an important consideration in the overall heat transfer during nucleate boiling (Kandlikar, 2015).

The periodic nature of liquid flow in the bubble ebullition cycle, development of the superheated liquid layer, release of the liquid sensible energy in the form of evaporation at the bubble interface, and evaporation from the microlayer have all been extensively studied in the literature, for example, Kim (2009) and Moghaddam and Kiger (2009a). These studies provide valuable insight into heat transfer mechanisms and help in identifying pathways for further enhancing the boiling performance.

8.1.5 Models and Correlations for Nucleate Pool Boiling

It has been recognized that the heat transfer during nucleate pool boiling is closely related to the bubble activity over a heater surface. In addition to knowing the contributions from different mechanisms described in the previous section, a detailed knowledge of the nucleation cavity size and distribution on the heater surface is needed for accurately predicting the boiling heat transfer performance of a heated surface. In principle, the heat transfer rate can be predicted by knowing the bubble frequency, active nucleating cavity site density (per unit heater surface area), and heat transferred during each bubble ebullition cycle. Dhir (1999, 2001) numerically solved the conservation equations of mass, momentum, and energy for the two phases while continuously tracking liquid–vapor interfaces at or near a heated surface. These solutions provide detailed information on the underlying physics of the hydrodynamic and thermal processes occurring at the interface. It is now possible to simulate boiling phenomena under a variety of conditions, including nucleate boiling, film boiling, and under microgravity conditions.

The numerical approach often requires detailed information about the nucleation cavity size distribution and density, which is generally not available in practical equipment design. For such cases, semiempirical correlations are available that can predict the heat transfer coefficients generally within ±30% to 50%.

Rohsenow (1952) developed a semiempirical model by using the liquid Reynolds number in the vicinity of a bubble. The influence region was considered to be twice the diameter of the departure bubble diameter. Rohsenow introduced an empirical constant C_{sf} to account for the fluid–surface effect on nucleate boiling and proposed the following correlation:

$$\frac{c_{p,L}\Delta T_{Sat}}{h_{fg}} = C_{sf}\left\{\frac{q''}{\mu_L h_{fg}}\sqrt{\frac{\sigma}{g(\rho_L-\rho_G)}}\right\}^{0.33} Pr_L^n \tag{8.21}$$

The values of C_{sf} and n for different heater materials and surface finishes are given in Table 8.1. These values are derived from Rohsenow (1952) and Vachnon et al. (1968).

Table 8.1 Values of C_{sf} and n in the Rohsenow Correlation (Equation 8.21)

Fluid–Surface Combination	C_{sf}	n
Water–copper		
Scored	0.0068	1.0
Polished	0.0130	1.0
Lapped	0.0147	1.0
Water–brass	0.006	1.0
Water–stainless steel		
Chemically etched	0.0130	1.0
Mechanically polished	0.0130	1.0
Ground and polished	0.0060	1.0
Teflon pitted	0.0058	1.0
Water–platinum	0.013	1.0
Water–nickel	0.006	1.0
Benzene–chromium	0.101	1.7
Carbon tetrachloride–polished copper	0.007	1.7
Ethanol–chromium	0.0027	1.7
Isopropanol–copper	0.0025	1.7
n-Butanol–copper	0.003	1.7
n-Pentane–chromium	0.015	1.7
n-Pentane–copper		
Polished	0.0154	1.7
Emery-rubbed copper	0.0074	1.7
Lapped	0.0049	1.7

In case the constant C_{sf} is not available for a given fluid–surface combination, a value of 0.013 is recommended as an initial guess. Liaw and Dhir (1989) established a clear dependence of the constant C_{sf} and the contact angle during pool boiling of water on copper surfaces. By varying the surface finish, they obtained different contact angles and showed that the contact angle and C_{sf} decreased as the surface was made smoother. This trend is also seen in Table 8.1 for different surface treatments.

Among other empirical correlations, the Stephan and Abdelsalam (1980) correlation is recommended. It is based on 5000 data points derived from 72 published sources. Stephan and Abdelsalam conducted a dimensional analysis and arrived at eight nondimensional groups to represent the nucleate pool boiling phenomenon. By carefully carrying out a regression analysis of the data, the following correlations were developed. The ranges of reduced pressures p/p_{cr} and contact angles θ are listed for different fluids.

Water (mean absolute error = 11.3%):

$$Nu = 2.64\times10^{6} X_1^{0.673} X_4^{-1.58} X_3^{1.26} X_8^{5.22} \quad \text{for } 10^{-4} \le p/p_{cr} \le 0.886, \quad \theta = 45° \tag{8.22}$$

Hydrocarbons (mean absolute error = 12.2%):

$$Nu = 0.0546\left(X_5^{0.5} X_1\right)^{0.67} X_8^{4.33} X_8^{0.248} \quad \text{for } 5.7\times10^{-3} \le p/p_{cr} \le 0.9, \quad \theta = 35° \tag{8.23}$$

Cryogenic liquids (mean absolute error = 14.3%):

$$Nu = 4.82 X_1^{0.624} X_7^{0.117} X_5^{0.257} X_3^{0.374} X_4^{-0.329} \quad \text{for } 4.0\times10^{-3} \le p/p_{cr} \le 0.97, \quad \theta = 1° \tag{8.24}$$

Refrigerants (mean absolute error = 10.6%):

$$Nu = 207 X_1^{0.745} X_5^{0.581} X_6^{0.533} \quad \text{for } 3.0\times10^{-3} \le p/p_{cr} \le 0.78, \quad \theta = 35° \tag{8.25}$$

All fluids (general correlation for all of the aforementioned fluids; mean absolute error = 22.3%):

$$Nu = 0.23X_1^{0.674}X_5^{0.297}X_4^{0.371}X_8^{-1.73}X_4^{0.35} \quad \text{for } 10^{-4} \le p/p_{cr} \le 0.97 \tag{8.26}$$

The definitions of Nusselt number, d, and nondimensional groups X_1 through X_8 are given as follows:

$$Nu = \frac{q''d}{\Delta T_{sat}k_L}, \quad d = 0.145\theta\left[\frac{2\sigma}{g(\rho_L - \rho_G)}\right]^{1/2}$$

$$X_1 = \frac{q''d}{k_L T_{Sat}}, \quad X_5 = \frac{\rho_G}{\rho_L}$$

$$X_2 = \frac{\alpha_L^2\rho_L}{\sigma d}, \quad X_6 = \frac{\mu_L}{\rho_L\alpha_L}$$

$$X_3 = \frac{c_{pL}T_{Sat}d^2}{\alpha_L^2}, \quad X_7 = \frac{(\rho c_P k)_S}{(\rho c_P k)_L}$$

$$X_4 = \frac{h_{fg}d^2}{\alpha_L^2}, \quad X_8 = \frac{\rho_L - \rho_G}{\rho_L}$$

where

$\alpha(=k/(\rho c_p))$ is the thermal diffusivity
d is the equilibrium break-off bubble diameter as defined earlier
θ is the contact angle in degrees (not in rad)
the subscripts S and L refer to the solid surface and liquid, respectively

8.1.6 Effect of Subcooling

Judd et al. (1991) studied the effect of subcooling on pool boiling heat transfer with water on a copper surface. Their results indicate that first, at low subcooling, the wall superheat increases due to changes in the number of active nucleation sites and bubble departure frequency. The subcooling effect is more pronounced at higher heat fluxes. For water with a heat flux of 1.26 MW/m^2, the wall superheat varied from 24 K at the saturation condition to about 32 K at a subcooling of 60 K. For higher values of subcooling, the wall temperature begins to decrease as the natural convection heat transfer is able to accommodate higher heat fluxes.

Subcooling introduces an evaporation condensation mechanism across different regions of a bubble interface. The interface closer to the heater surface continues to evaporate, while vapor condenses at the interface near the cooler bulk liquid. This additional mechanism increases the heat transfer rate over the corresponding saturated boiling condition.

At very high subcooling, a new type of boiling involving microbubble emission was discovered by Inada et al. (1986). The bubbles collapse during the growth and give out multiple microbubbles resulting in high heat flux dissipation (Suzuki et al., 2005).

8.1.7 Effect of Orientation

Orientation affects the bubble removal process at low heat fluxes. A horizontal surface provides the most efficient heat transfer geometry. As the orientation angle changes to a vertical surface and then a downward facing surface, heat transfer deteriorates systematically (Nishikawa et al., 1983). El-Genk (1996) presents an extensive overview of the effect of orientation on the entire pool boiling curve as shown in Figure 8.5. It is important to note that at high heat fluxes all curves tend to merge, but the boiling curve is affected in almost every region.

8.1.8 Nucleate Boiling with Mixtures

Nucleate boiling of mixtures of two liquids with different boiling points results in the preferential evaporation of the more volatile component at the evaporating liquid–vapor interface. The more volatile component is depleted at the interface, and the heat transfer is degraded as the more volatile component diffuses through

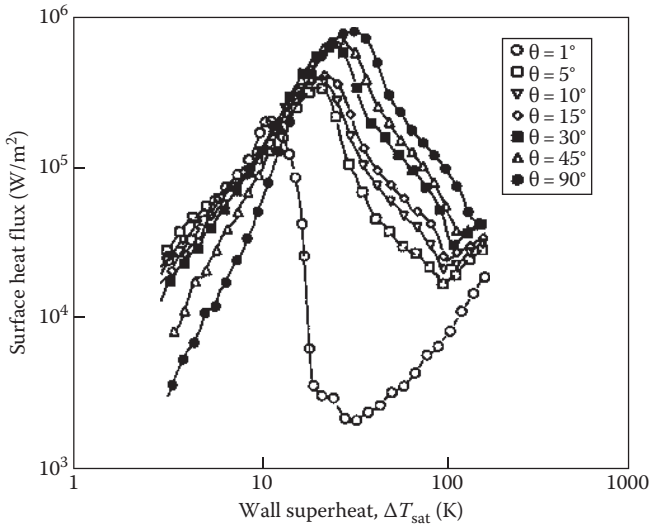

Figure 8.5

Effect of orientation on the pool boiling curve. (Reproduced from El-Genk, M., A review of pool boiling from inclined and downward-facing flat surfaces, in *Second European Thermal-Sciences and 14th UIT National Heat Transfer Conference,* Celta, G.P., Di Marco, P., and Mariani, A., Eds., Edizioni ETS, Pisa, Italy, 1996. With permission.)

the bulk of the liquid toward the interface. The interface temperature therefore rises and heat transfer is degraded. A number of researchers have studied the phenomena and presented detailed models. Kandlikar (1998b) presented a methodology to predict the interface concentration, which can be used in predicting the interface temperature. An extensive survey of the earlier work can be found in Kandlikar (1999). In general, the heat transfer coefficient for the mixture is below the linear-averaged heat transfer coefficient obtained from the respective pure component values.

The interface concentration of a nucleating bubble introduces a mass transport limit. Kandlikar (1998b) analyzed the coupled heat and mass transfer phenomena and presented a methodology to predict the interface concentration, which can be used in predicting the interface temperature. The interface liquid and vapor phase concentrations of more volatile component $x_{1,s}$ and $y_{1,s}$ are related through the equilibrium condition. Further, considering the transient mass transfer through the concentration boundary layer of thickness δ_m,

$$x_{1,s} = x_1 - \frac{2.13}{\pi}\mathrm{Ja}_0\left(\frac{\alpha}{D_{12}}\right)^{1/2}\frac{\rho_G}{\rho_L}\left(y_{1,s} - x_1\right) \tag{8.27}$$

where

x_1 is the bulk liquid–phase concentration
α is the thermal diffusivity
D_{12} is the mass diffusivity of the more volatile component 1 in the mixture
Ja_0 is the modified Jakob number given by

$$\mathrm{Ja}_0 = \frac{(T_W - T_{L,sat})}{\left(\frac{\rho_G}{\rho_L}\right)\left[\frac{h_{fg}}{c_{p,L}} + \left(\frac{\alpha}{D_{12}}\right)^{1/2}\frac{\Delta T_s}{g}\right]} \tag{8.28}$$

where

T_W is the wall temperature
$T_{L,sat}$ is the saturation temperature at the bulk liquid concentration
h_{fg} is the latent heat of vaporization
ΔT_s is the difference between the saturation temperatures corresponding to the interface and the bulk liquid–phase concentrations

An iterative scheme is needed to calculate the interface concentration. The corresponding increase in the interface saturation temperature acts as an additional resistance to heat transfer during pool boiling in a binary system. Kandlikar (1998b) used this concentration and analytically derived an expression for the heat transfer coefficient in a binary system. Readers are referred to this publication for further details.

Fujita et al. (1996) developed an empirical correlation from their own experimental data on methanol/water, ethanol/water, methanol/ethanol, ethanol/*n*-butanol, methanol/benzene, benzene/*n*-heptane, and water/ethylene glycol systems. It incorporates several key features of previous investigators and

$$h_m = \frac{\left(\tilde{x}_1/h_1 + \tilde{x}_2/h_2\right)^{-1}}{1+\left\{1-\exp\left[-2.8\dfrac{\tilde{x}_1\Delta T_1 + \tilde{x}_2\Delta T_2}{T_{Sat,2}\big|_p - T_{Sat,1}\big|_p}\right]\right\}\left\{\dfrac{T_{dp}-T_{bp}}{\tilde{x}_1\Delta T_1 + \tilde{x}_2\Delta T_2}\right\}} \tag{8.29}$$

where

h_1 and h_2 and ΔT_1 and ΔT_2 are the heat transfer coefficients and the wall superheat values with the two pure components

$T_{Sat,1}|_p$ and $T_{Sat,2}|_p$ refer to the saturation temperatures of the pure components at the total system pressure p

Component 1 is the more volatile component with a lower boiling point

T_{dp} and T_{bp} are the dew point and bubble point temperatures, respectively

8.1.9 Critical Heat Flux in Pool Boiling

CHF is defined as the highest heat flux that can be sustained under the nucleate boiling mode. As the heat flux is increased, the bubble activity increases dramatically over a heater surface. Both the number of nucleation sites and bubble frequency increase. The intense vapor–liquid interaction at the heater surface has prevented researchers from gaining clear visual access to the events occurring just prior to CHF.

Early researchers, for example, Kutateladze (1948) and Zuber (1959), formulated their models based on the hydrodynamic instability theory. They assumed the presence of either a stable liquid–vapor interface or stable vapor columns, which are then analyzed for stability conditions based on Helmholtz or Taylor's instability criteria. The hydrodynamic model does not represent the events leading to the CHF, and further, it does not address the interaction between the liquid–vapor interface and the solid-heated surface during frequent rewetting occurring just prior to CHF. The following equation was proposed by Zuber:

$$\frac{q''_{CHF}}{h_{fg}\rho_G^{1/2}\left[\sigma g\left(\rho_L - \rho_G\right)\right]^{1/4}} = K \tag{8.30}$$

where K is a constant equal to 0.13. Another model, developed by Haramura and Katto (1983), considers the depletion of a liquid macrolayer that exists under vapor mushrooms. Estimation of the initial macrolayer thickness and the role of the rewetting phenomenon and contact angles are not adequately addressed by this model.

Kandlikar (2001a) proposed a model based on the rapid evaporation of the liquid–vapor interface near the base of the liquid–vapor contact line at the heater surface. The rapid evaporation occurring in this region introduces a force due to momentum change that causes the interface to retreat, leaving a thin film of vapor underneath. Figure 8.6 depicts the cutback phenomenon, and Figure 8.7 shows a high-speed photographic sequence showing the vapor cutback under a liquid droplet placed on a flat heater surface (Kandlikar and Steinke, 2002).

Figure 8.8 shows the forces acting on a vapor bubble close to CHF condition. Kandlikar (2001a) considered the balance of forces due to evaporation momentum surface tension forces acting on one half of the bubble as shown in Figure 8.8. The balance between the evaporation momentum force F_M and the retaining forces due to surface tension force $F_{s,1}$ and $F_{s,2}$, and the hydrostatic force F_g was used by Kandlikar (2001a) in deriving an expression for CHF. The receding contact angle was introduced in the force balance for retaining surface tension force at the wall. The final expression for CHF is given by

$$q''_{CHF} = h_{fg}\rho_G^{1/2}\left(\frac{1+\cos\theta_r}{16}\right)\left[\frac{2}{\pi} + \frac{\pi}{4}\left(1+\cos\theta_r\right)\cos\phi\right]^{1/2}\left[\sigma g\left(\rho_L - \rho_G\right)\right]^{1/4} \tag{8.31}$$

where

θ_r is the receding contact angle

ϕ is the angle of orientation of the heater surface with respect to the horizontal

This expression accounts for the contact angle and orientation. Equation 8.31 reduces to the expression given by Kutateladze (1948) with $K = 0.13$ for a horizontal surface with a receding contact angle of 57.5°. Table 8.2 shows the variation of K with contact angle for a horizontal surface as predicted from Equation 8.31.

8.1.10 Enhanced Surfaces

Pool boiling enhancement can be classified into the following types:

- Artificial nucleation cavities
- Fins
- Porous structures
- Microstructures
- Wettability control—nanostructures
- Hybrid microporous structures
- Hybrid micro-/nanostructures
- Other techniques (acoustic, electric field, etc.)

Enhancement in nucleate boiling heat transfer is mainly accomplished by providing more active nucleation sites on the heater surface. A reentrant shape that traps gases or vapors in the cavities is found to be most effective. Figure 8.9 shows a schematic of a reentrant cavity. The reentrant cavities are manufactured by a variety of processes, including rolling of perforated fins protruding from the base, structured surfaces, porous surfaces created through sintering or other techniques, such as machined tunnels with openings of predetermined shapes and sizes. A number of enhanced geometries are commercially available. They are

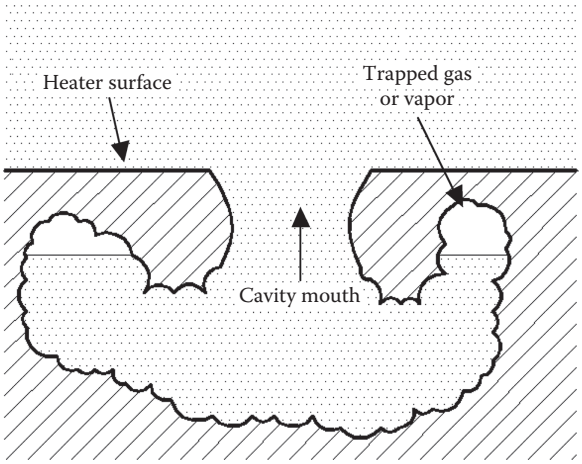

Figure 8.9

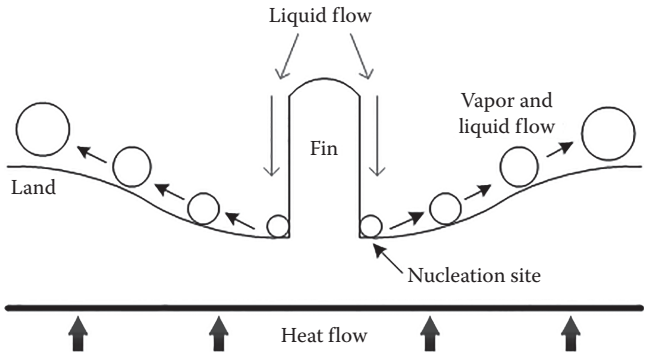

Figure 8.10

Schematic of a microstructure designed by Kandlikar (2013).

routinely employed in cryogenic, air separation, refrigeration, and chemical industries. A good survey of enhancement mechanisms is given by Bergles (1997).

Fins provide additional surface area for heat transfer. They are effective especially when the heat transfer coefficients are relatively low. For pool boiling of water, the high heat transfer coefficient makes short fins, smaller than 0.5 mm attractive. While for refrigerants, since their HTC is relatively low, fins of 1–5 mm are routinely employed.

A new class of enhanced boiling surfaces is being developed to meet the high heat flux dissipation needs in electronics cooling application. Microstructures are specifically designed to provide separate liquid–vapor pathways in an effort to enhance the CHF. Figure 8.10 shows a schematic of a microstructure designed by Kandlikar (2013). It utilizes the evaporation momentum force occurring at the evaporating interface to propel a bubble in a desired direction to create separate liquid–vapor pathways. The departing bubble sweeps over the contoured surfaces, thereby enhancing the HTC as well.

Wettability affects the nucleation as well as heat transfer characteristics. A hydrophobic surface enhances nucleation characteristics, while a hydrophilic surface improves the HTC. Recently, a number of patterned surfaces have been developed with hydrophobic and hydrophilic surface combinations to improve both CHF and HTC (Betz et al., 2010, Yao et al., 2011). Figure 8.11 shows one such patterned surface developed by Betz et al. (2010). Ahn et al. (2010) developed a nano- and microstructure for enhancing boiling on zircaloy-4 surfaces.

Nanostructures are also used to modify the wettability of a surface. Additionally, their ability to retain and wick liquid improves the CHF. Combining the microstructures with nanostructures to create hierarchical surfaces provides the next level of enhancement. Chu et al. (2013), O'Hanley et al. (2013), and Rahman et al. (2012) developed surfaces with microscale posts coated with nanostructures. Cooke and Kandlikar (2013) developed open microchannel surfaces with channels serving as liquid conduits for the nucleating bubble. Yao et al. (2012) coated open microchannels with nanowires on silicon substrates. Patil and Kandlikar (2014) coated fin tops of open microchannels with sintered coatings, while Jaikumar

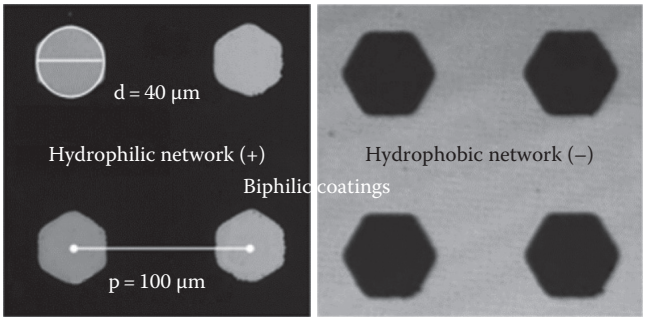

Figure 8.11

Patterned surface developed by Betz et al. (2010).

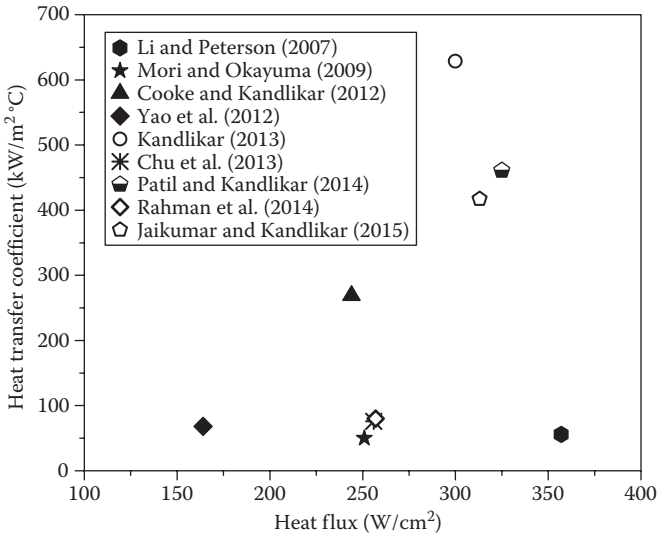

Figure 8.12

Plot of CHF versus HTC for some of the high-performance surfaces in pool boiling.

and Kandlikar (2015) coated all surfaces of open microchannels with a sintered coating. Li and Peterson (2007) developed sintered porous mesh to understand the effect of coating thickness. Mori and Okayuma (2009) used honeycomb plates as porous templates to understand the effect of wicking.

Chu et al. (2013) modified the Kandlikar CHF model (2001a) to incorporate the roughness effect introduced by the hierarchical structures. Their equation for predicting CHF is given as follows:

$$q_c'' = K \times h_{fg} \rho_g^{1/2} \left[\sigma_{lv} g \left(\rho_L - \rho_G \right) \right]^{1/4} \tag{8.32}$$

where

$$K = \left(\frac{1+\cos\beta}{16} \right) \left[\frac{2(1+\alpha)}{\pi(1+\cos\beta)} + \frac{\pi}{4}(1+\cos\beta)\cos\phi \right]^{1/2} \tag{8.33}$$

$$\alpha = r\cos\theta_{rec} \tag{8.34}$$

and r is the modified roughness factor. It is obtained as the ratio of actual surface area divided by the projected area.

Figure 8.12 shows a plot of CHF versus HTC for some of the high-performance surfaces in pool boiling. It is seen that the CHF is enhanced by several folds, and extremely high values of HTC are obtained as compared to the values obtainable with plain polished surfaces.

Other techniques include the application of an electric field and vibrations. The electric field causes enlargement of the bubble base area, thereby exposing more of the thin film underneath a bubble. Mechanical vibrations provide pressure fluctuations that are especially effective under subcooled boiling conditions. These techniques provide marginal improvements, while the techniques employing microstructures and nanostructures are seen as breakthrough technologies in the field of boiling.

8.1.11 Film Boiling and Transition Boiling

The post-CHF region consists of transition boiling (D–E in Figure 8.1), MHF condition in film boiling (point E), and fully developed film boiling (E–F). Heat transfer in the transition region depends on the rewetting characteristics of the heater surface. Some empirical form of averaging techniques is employed between the CHF and MHF locations. The early work by Bromley (1950) provides an excellent insight into the film boiling phenomenon.

The MHF q''_{MHF} is predicted by a correlation developed by Zuber (1959):

$$q''_{MHF} = C\rho_g h_{fg}\left[\frac{g\sigma(\rho_L-\rho_g)}{(\rho_L+\rho_g)^2}\right]^{1/4} \tag{8.35}$$

The value of constant C was determined to be 0.09 by Berenson (1961) based on his data for MHF for a flat plate.

The film boiling heat transfer coefficient h_F consists of the convective and radiative components:

$$h_F = h_{F,C} + h_{F,r} \tag{8.36}$$

The radiative component is approximated by using appropriate radiation correlations between the heater surface and the surrounding vapor film. The emissivity of the liquid surface is generally taken as 1, and an empirical shape factor value of 0.75 is used.

The following correlation by Hsu and Westwater (1960) is recommended for $h_{F,c}$ for a vertical flat plate of length L:

$$h_{F,C} = 0.943\left[\frac{g\sigma(\rho_L-\rho_G)\rho_G k_G^3 h'_{fg}}{L\mu_G(T_w-T_{Sat})}\right]^{1/4} \tag{8.37}$$

where $h'_{fg} = h_{fg}\left[1+0.34c_{p,G}(T_w-T_{sat})\right]$ is the latent heat corrected for the vapor superheating.

For a horizontal flat plate, the correlation by Berenson (1961) is used extensively:

$$h_{F,C} = 0.425\left\{\left[\frac{k_G^3 g\rho_g(\rho_L-\rho_g)h'_{fg}}{\mu_G(T_w-T_{Sat})}\right]\left[\frac{g(\rho_L-\rho_g)}{\sigma}\right]^{1/2}\right\}^{1/4} \tag{8.38}$$

where the corrected latent heat term takes the form $h'_{fg} = h_{fg}\left[1+0.5c_{p,G}(T_w-T_{sat})\right]$.

Transition boiling region occurs as the heater surface temperature is reduced from film boiling condition, and it comes in occasional contact with the liquid. This region is identified by the dotted line DE in Figure 8.1 and is accessible only when the heater surface temperature is independently controlled.

Ramilison and Lienhard (1987) considered the heat transfer in this region as the sum of the heat transfer due to film boiling and during liquid contact. Approaching from the film boiling region, the actual liquid contact with the heater surface is initiated at a heat flux somewhat higher, by 10%–15%, over the MHF given by Equation 8.32. This temperature is identified as T_{dfb} and has been correlated as a function of advancing contact angle by Ramilison and Lienhard (1987). Carey (2007) proposed the following correlation to represent this plot:

$$\frac{T_{dfb}-T_{sat}}{T_{hn}-T_{sat}} = 0.97\exp(-0.000600\theta_a^{1.8}) \tag{8.39}$$

where

θ_a is the advancing contact angle in degrees

T_{hn} is the homogeneous nucleation temperature of the liquid given by the following equation:

$$T_{hn} = \left[0.932+0.077\left(\frac{T_{sat}}{T_c}\right)^9\right]T_c \tag{8.40}$$

where T_c is the critical temperature of the liquid.

The heat flux during the transition boiling is then given by the following equation by Ramilison and Lienhard (1987):

$$Bi^{\star} = 3.74 \times 10^{-6} \left(Ja^{\star} \right)^2 K \tag{8.41}$$

where

$$Bi^{\star} = \frac{\left(q'' - q''_{fb} \right) \sqrt{\alpha_h \tau}}{k_h \left[T_w - T_{sat} \left(P_L \right) \right] K} \tag{8.42}$$

$$Ja^{\star} = \frac{\left(\rho c_p \right) \left(T_{dfb} - T_w \right)}{\rho_v h_{lv}} \tag{8.43}$$

$$\tau = \left[\frac{\sigma}{g^3 \left(\rho_L - \rho_v \right)} \right]^{1/4} \tag{8.44}$$

$$K = \frac{k_L / \alpha_L^{1/2}}{k_L / \alpha_L^{1/2} + k_h / \alpha_h^{1/2}} \tag{8.45}$$

The film boiling heat flux q''_{fb} in Equation 8.42 is the heat flux during film boiling given by the following Klimenko's (1981) correlation for turbulent vapor film:

$$\frac{q''_{fb} \lambda_D}{k_v \left(T_w - T_{sat} \right)} = 0.0086 \sqrt{3} \left[\frac{g \lambda_D}{(3)^{3/2} \nu_v^{2/3}} \left(\frac{\rho_L - \rho_v}{\rho_v} \right) \right]^{1/2} Pr_v^{1/3} \tag{8.46}$$

The most dangerous wavelength λ_D is given by

$$\lambda_D = 2\pi \left[\frac{3\sigma}{\left(\rho_L - \rho_v \right) g} \right]^{1/2} \tag{8.47}$$

Equation 8.46 neglects the radiation effect, which is quite reasonable as the wall temperature is not as high as in the film boiling region.

8.2 Flow Boiling

8.2.1 Introduction to Flow Boiling

The process of flow boiling of a liquid heated in a confined passage is commonly encountered in many applications, such as steam generators in power plants, evaporators in refrigeration and air conditioning equipment, distillation and other processes in chemical and petrochemical industries, and high heat flux removal systems.

Figure 8.13 shows the flow boiling process in a uniformly heated circular tube. Subcooled liquid enters the tube and is heated by single-phase convection. The heat transfer coefficient in the single phase is almost constant except for a small variation due to property changes with increasing liquid temperature along the tube length. Although the wall temperature reaches the saturation temperature, nucleation does not occur immediately because a certain amount of wall superheat is needed to nucleate cavities existing on the wall. The first bubbles appear on the wall at a location identified as the ONB. It may also be associated with a reduction in wall temperature due to improved heat transfer from two-phase flow. The wall temperature begins to level off, as more nucleation sites are activated beyond ONB. Further downstream, as more sites are activated, the contribution to heat transfer from the nucleate boiling continues to rise, while the

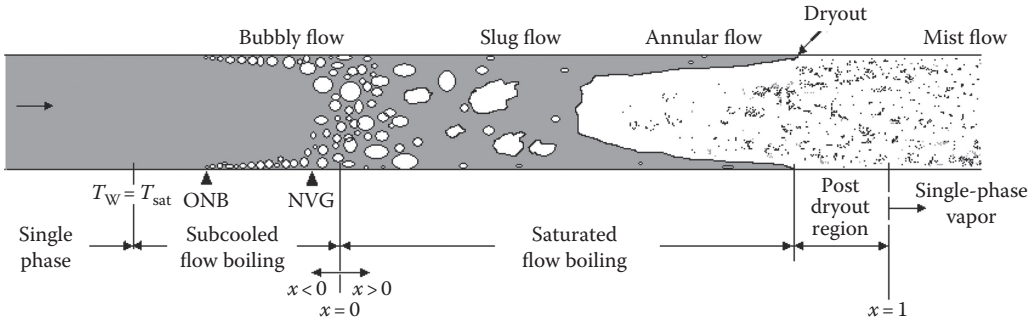

Figure 8.13

Flow boiling in a circular tube.

single-phase convective contribution diminishes. This region is called the "partial boiling region." The convective contribution continues to diminish, and eventually, *fully developed boiling* (FDB) is established. The wall temperature varies depending on the variation of the heat transfer coefficient with quality.

The bubbles generated at the wall immediately following ONB encounter condensation at the bubble surface exposed to the subcooled liquid flow, and their growth is impeded. As a result, a thin layer of stationary bubbles is formed on the wall. As the bulk liquid temperature increases in the flow direction, the layer becomes populated with more bubbles, whose size also increases with decreasing subcooling. At some location, identified as the point of *net vapor generation* (NVG; also called OSV), the bubbles eventually detach from the wall and flow toward the liquid core. Some bubbles condense along the way. The heat transfer following NVG is in the two-phase region.

The vapor present in the subcooled flow following NVG is at the saturation temperature. This gives rise to a thermodynamic nonequilibrium condition with the liquid temperature falling below the equilibrium subcooled liquid temperature dictated by the local enthalpy. As heat addition continues downstream, the saturation condition ($x = 0$) under thermodynamic equilibrium is reached. The flow beyond the location where thermodynamic quality reaches zero falls under the saturated flow boiling region.

The state of the subcooled liquid can be defined in terms of an equilibrium *quality* based on the liquid enthalpy relative to the saturation state:

$$x = \left(h_L - h_{L,Sat}/h_{fg}\right) = -c_p \Delta T_{sub}/h_{fg} \tag{8.48}$$

where ΔT_{Sub} ($=T_{Sat} - T_L$) is the liquid subcooling. This results in a negative quality in the subcooled region. In the single-phase region of the subcooled flow before any boiling is initiated, the heat flux is expressed in terms of the single-phase liquid heat transfer coefficient and the wall-to-liquid temperature difference:

$$q'' = h_L\left(T_W - T_L\right) = h_L\left(\Delta T_{Sat} + \Delta T_{Sub}\right) \tag{8.49}$$

The single-phase heat transfer coefficient h_L is given by the appropriate single-phase heat transfer coefficient in the laminar or turbulent region.

The heat transfer to a liquid flowing inside a tube is by the single-phase mode as long as the liquid and wall are both below the saturation temperature of the liquid at the local pressure. As the wall temperature exceeds the local saturation temperature, boiling can occur depending on the tube surface characteristics and the operating conditions. The bulk liquid may still be in the subcooled region. Boiling under these conditions is called subcooled flow boiling. Saturated flow boiling covers the region when the wall temperature exceeds the local saturation temperature of the liquid, and the equilibrium thermodynamic quality (mass fraction of vapor) is between 0 and 1.

8.2.2 Onset of Nucleate Boiling

The condition for the ONB under flow conditions is obtained as an extension to the pool boiling analysis presented in Section 8.1.2. The liquid temperature profile near the heater surface is obtained from the single-phase heat transfer coefficient prior to nucleation. In the absence of hysteresis effects, the nucleation criterion

suggested by Hsu and Graham (1961) has been confirmed by many later investigators. Bergles and Rohsenow (1964) described the nucleation criterion graphically in terms of the tangency condition and presented an empirical correlation for the ONB condition. Hsu (1962) and Sato and Matsumura (1964) presented equations for $\Delta T_{Sat,ONB}$ and q''_{ONB} considering a hemispherical bubble over a nucleation cavity. This corresponds to a contact angle of 90°:

$$\Delta T_{Sat,ONB} = \frac{4\sigma T_{Sat} v_{1g} h_L}{k_L h_{fg}} \left[1 + \sqrt{1 + \frac{k_L h_{fg} \Delta T_{Sub}}{2\sigma T_{Sat} v_{fg} h_L}} \right] \tag{8.50}$$

and

$$q''_{ONB} = \left[k_L h_{fg} / \left(8\sigma v_{fg} T_{Sat} \right) \right] \left[\Delta T_{Sat,ONB} \right]^2 \tag{8.51}$$

The range of active cavity radii was also presented by Hsu (1962) and Sato and Matsumura (1964). A nondimensionalized form of these equations was presented by Kandlikar and Spiesman (1997) using the following parameters:

$$R_c^* = \frac{R_c}{\delta_t} \tag{8.52}$$

$$\Delta T_{Sat}^* = \frac{\Delta T_{sat} h_{fg} \delta_t}{8\sigma T_{Sat} v_{fg}} \tag{8.53}$$

$$\Delta T_{Sub}^* = \frac{\Delta T_{sub} h_{fg} \delta_t}{8\sigma T_{Sat} v_{fg}} \tag{8.54}$$

where the single-phase thermal boundary layer thickness in the liquid is given by $\delta = k_L/h_L$.

The range of the active cavity radii in nondimensional form is then given by the following equation:

$$R_{\max}^*, R_{\min}^* = \frac{1}{2} \left[\frac{\Delta T_{Sat}^*}{\Delta T_{Sat}^* + \Delta T_{Sub}^*} \pm \sqrt{\left(\frac{\Delta T_{Sat}^*}{\Delta T_{Sat}^* + \Delta T_{Sub}^*} \right)^2 - \frac{1}{\left(\Delta T_{Sat}^* + \Delta T_{Sub}^* \right)}} \right] \tag{8.55}$$

The properties in Equations 8.50 through 8.55 are evaluated at the saturation temperature and h_L is calculated from an appropriate single-phase correlation incorporating a wall temperature correction if necessary.

The nucleation criterion has been further studied, and the effect of contact angle has been incorporated by Davis and Anderson (1966). The effect of flow also modifies the temperature around the bubble surface and affects the onset of nucleation. Kandlikar et al. (1997) considered the stagnation effect of the flow upstream of the bubble and modified the nucleation criterion to include both thermal field and contact angle effects. A detailed presentation of these effects is given by Kandlikar (2014).

8.2.3 Flow Patterns

The distribution of liquid and vapor phases in a flow channel plays an important role in the pressure drop and heat transfer during flow boiling. Figure 8.13 shows the flow patterns observed in a horizontal tube. The major flow patterns are as follows: (1) Bubbly flow—discrete bubbles—exists in the flow field with a continuous liquid phase, generally observed at low vapor qualities. (2) Slug or plug flow—as vapor quality increases, bubbles start to coalesce and fill the entire tube with liquid and vapor flowing alternately in the channel. (3) Annular flow—at higher vapor qualities, the vapor forms a continuous core with liquid flowing around the periphery as a smooth or wavy film. (4) Mist flow—it consists of liquid droplets flowing in a continuous vapor phase; this flow pattern occurs beyond the *dryout* location (see Figure 8.13). There are additional flow patterns, such as a stratified flow pattern, that occur at low flow rates. The transitional flow patterns, such

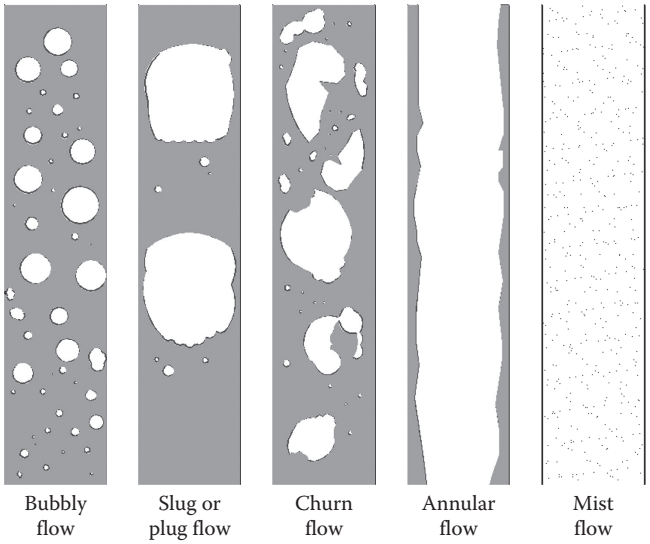

Figure 8.14

Flow patterns during flow boiling in a vertical tube.

as bubbly–slug and annular–mist, also appear as the flow patterns change with increasing quality along the evaporator length. All flow patterns, except for the mist flow and single-phase vapor, can be classified under wetted wall condition, which is desirable from a heat transfer perspective. Heat transfer and pressure drop are closely related to the existing flow patterns.

The flow patterns described in Figure 8.13 refer to flow boiling in a horizontal tube. Figure 8.14 shows the flow patterns in a vertical tube. The major differences are the existence of a churn flow pattern, in which the liquid and vapor flow as an agitated mixture, the distortion of the vapor plugs due to buoyancy forces, and the absence of a stratified flow. Vertical upflow and downflow have some differences, mainly at low flow velocities.

Numerous attempts have been made in the literature to identify flow patterns existing under a given set of operating conditions—liquid- and vapor-phase properties, tube diameter, and mass flux. Flow pattern maps developed for adiabatic flows are generally used for flow boiling, although such an approach introduces significant errors at higher heat fluxes.

The influence of boiling on flow patterns becomes important at higher heat fluxes as the rapidly evaporating liquid–vapor interface of a growing bubble or a vapor plug introduces additional forces. In the studies conducted on the conventional channels (>3 mm hydraulic diameter), the effect of heat flux has been ignored, and researchers have used the adiabatic flow pattern maps for flow boiling as well. As the heat flux increases, the rapid expansion at a nucleating bubble causes major changes in the flow patterns, particularly for small hydraulic diameter channels ($D_h < 3$ mm). This aspect has been extensively discussed by Kandlikar (2004) for flow boiling in microchannels.

8.2.4 Subcooled Flow Boiling Heat Transfer

Kandlikar (1998a) proposed that the nucleate boiling term in the nucleate boiling region of the saturated flow boiling correlation by Kandlikar (1990) (see Equation 8.56) should be able to represent the FDB in a subcooled flow since the convective contribution is negligible. One of the features of this correlation, as reported by Kandlikar (1991a), is its ability to predict the trends in h versus x in the low-quality region, explaining the reasons for increasing or decreasing h for different cases. The heat transfer coefficient h^* in the *FDB* region is thus given by the following equation derived from the nucleate boiling–dominant region of the Kandlikar correlation:

$$h^* = 1058.0 Bo^{0.7} F_{Fl} h_{LO} \tag{8.56}$$

Note that h^* is based on the wall superheat with $q'' = h^* \Delta T_{Sat}$. The boiling number is defined as $Bo = q''/(Gh_{fg})$, with G (kg/m^2 s) being the total mass flux, F_{Fl} the fluid–surface parameter that accounts for the different

nucleation characteristics of different surface–fluid combinations, and h_{LO} the single-phase heat transfer coefficient for all flow in the liquid phase at the saturation temperature obtained from appropriate equations: for the laminar flow, Nu is constant for fully developed laminar flow, or for the turbulent flow (Gnielinski, 1976, Petukhov and Popov, 1963 correlations along with the following property correction factor recommended by Petukhov, 1970)

$$Nu_{LO} = Nu_{LO,cp}\left(\frac{\mu_B}{\mu_w}\right)^{0.11} \tag{8.57}$$

where $Nu_{LO,cp}$ is the Nusselt number with constant properties obtained from the following equations and the subscripts B and w refer to the properties at bulk and wall temperatures, respectively:

Petukhov and Popov (1963), for $0.5 \le Pr \le 2000$ and $10^4 \le Re_{LO} \le 5 \times 10^6$, obtained

$$Nu_{LO,cp} = \frac{Re_{LO}Pr_L(f/2)}{1.07 + 12.7\left(Pr_L^{2/3} - 1\right)(f/2)^{0.5}} \tag{8.58}$$

and Gnielinski (1976), for $0.5 \le Pr \le 2000$ and $2300 \le Re_{LO} \le 10^4$, obtained

$$Nu_{LO,cp} = \frac{\left(Re_{LO} - 1000\right)(f/2)Pr_L}{\left[1 + 12.7\left(Pr_L^{2/3} - 1\right)(f/2)^{0.5}\right]} \tag{8.59}$$

where f is the friction factor given by the following equation:

$$f = \left[1.58\ln\left(Re_{LO}\right) - 3.28\right]^{-2} \tag{8.60}$$

The location of where the FDB begins, corresponding to $q''_{FDB,i}$, is obtained by first locating the heat flux q''_{int} at the intersection of the extended single-phase line and the FDB curve given by

$$1058F_{F1}\left(Gh_{fg}\right)^{-0.7} q''_{int} - q''^{0.3}_{int} - 1058h_{LO}F_{F1}\left(Gh_{fg}\right)^{-0.7}\Delta T_{sub} = 0 \tag{8.61}$$

A model proposed by Bowring (1962) is then used to obtain the location where FDB begins:

$$q''_{FBD,i} = 1.4q''_{int} \tag{8.62}$$

A comparison of the predicted heat flux in the FDB region using Equation 8.56 with experimental data of Bergles and Rohsenow (1964) is shown in Figure 8.15. The other three prediction methods by Shah (1977), Thom et al. (1965), and Mikic and Rohsenow (1969) are also shown in Figure 8.15. It is seen that the present model is able to predict the trend as well as actual values in the FDB region accurately.

The heat transfer in the partial boiling region, from $x = 0$ to the beginning of the FDR, is obtained by interpolation between the two end locations. Further details of the interpolation method are described by Kandlikar (1998a, 1999).

The *partial boiling* region is identified as the region between the ONB and the onset of FDB. The heat transfer in this region is calculated by a procedure outlined by Kandlikar (1998a) as follows.

The heat flux q''_{FDB} at FDB is obtained from Equation 8.62, and q''_{ONB} at ONB is obtained from Equation 8.51. For the heat flux q''_{PB} in the partial boiling region, the following equation is employed:

$$q''_{PB} = a + b\left(T_w - T_{Sat}\right)^m \tag{8.63}$$

The constants a and b are obtained from the known heat fluxes at FDB and ONB as follows:

$$b = \frac{q''_{FBD} - q''_{ONB}}{\left(\Delta T_{Sat,FDB}\right)^m - \left(\Delta T_{Sat,ONB}\right)^m} \tag{8.64}$$

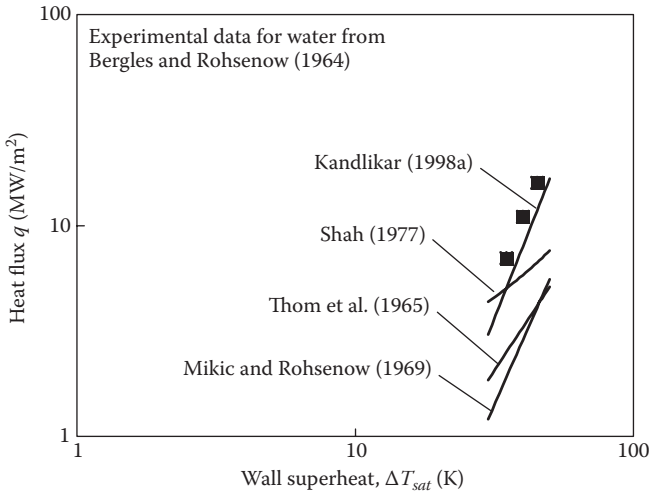

Figure 8.15

Comparison of the predictions from Equation 8.42 in the fully developed boiling with experimental data of Bergles and Rohsenow (1964). (Reproduced from Kandlikar, S.G., *J. Heat Transfer,* 120, 395, 1998a. With permission from ASME.)

and

$$a = q''_{ONB} - b\left(\Delta T_{Sat,ONB}\right)^m \tag{8.65}$$

The exponent m is allowed to vary linearly with heat flux as follows:

$$m = n + pq''_{PB} \tag{8.66}$$

where the constants n and p are obtained by matching the slopes of $m = 1$ at ONB to $m = 1/0.3$ at FDB:

$$p = \frac{\left(1/0.3 - 1\right)}{\left(q''_{FBD} - q''_{ONB}\right)} \tag{8.67}$$

and

$$n = 1 - pq''_{ONB} \tag{8.68}$$

This procedure assures smooth transitions from the single-phase region to the partial boiling region and then to the FDB region. The gradual increase in the exponent m also reflects the fact that more nucleation sites are activated as the wall superheat increases.

A comparison of the present model with the experimental data of McAdams et al. (1949) is shown in Figure 8.16. Equations 8.61 through 8.68 are used in the predictive model. It is seen from this figure that the agreement is quite good in the partial boiling region.

8.2.5 Saturated Flow Boiling Heat Transfer

As liquid flows inside a heated tube surface, nucleate boiling initiates the process of vapor generation during flow boiling. As the bubbles grow and depart, the vapor quality in the flow increases and two-phase flow ensues. The higher specific volume of the vapor causes the flow velocity to increase. The heat transfer in this mode is thus a combination of the nucleation phenomena and enhanced convection, each being influenced by the other mode. The presence of nucleate boiling and convective boiling modes in flow boiling has long been recognized. The heat transfer in saturated flow boiling is thus a combination of the convective heat transfer from the wall to liquid and subsequent film evaporation at the liquid–vapor interface and nucleate boiling at the wall.

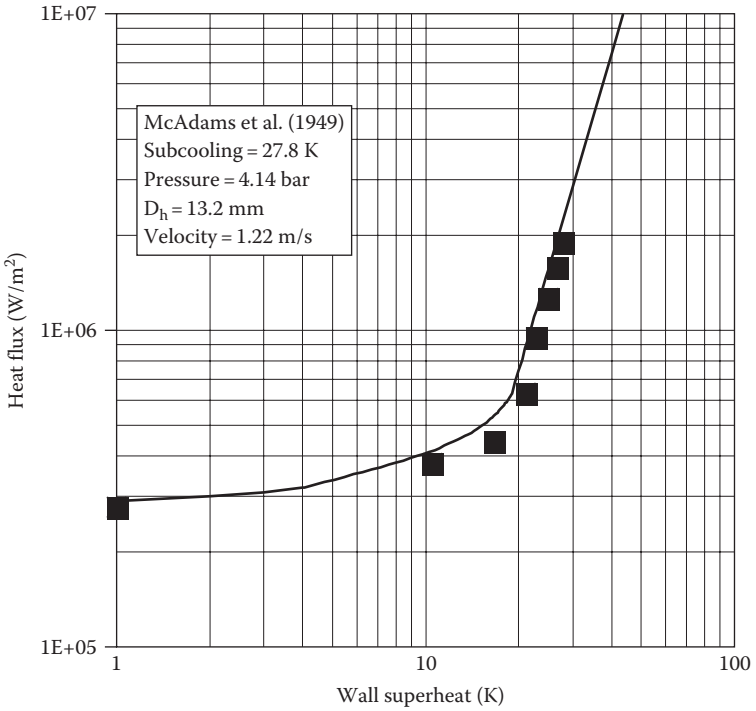

Figure 8.16

Comparison of predictions from Equations 3.47 to 3.54 in the partial boiling region with experimental data of McAdams et al. (1949). (Reproduced from Kandlikar, S.G., *J. Heat Transfer,* 120, 395, 1998a. With permission from ASME.)

There are a large number of correlations available in the literature on the flow boiling of saturated liquids. The Chen (1966) correlation was developed using an additive model with convective enhancement and nucleate boiling suppression due to two-phase flow. It works reasonably well with low-pressure water data but yields significantly higher errors with high-pressure water data and refrigerants. Shah (1982) proposed a correlation in a chart form that worked well with many fluids. Gungor and Winterton (1987) combined the Chen model and the Shah model. Other recent correlations, such as those used by Liu and Winterton (1991) and Steiner and Taborek (1992), employ an asymptotic model in which $h_{\mathrm{TP}}^n = h_{\mathrm{conv}}^n + h_{\mathrm{nucl}}^n$ with $n = 2$ and 3, respectively. The h_{conv} and h_{nucl} are obtained from a combination of earlier models published in the literature. These models work well in some cases; however, because of their highly empirical nature, they do not correctly represent the trends of h_{TP} vs. x. Also, because of their exponentially averaged form, it becomes difficult to identify the role of different mechanisms in studying the parametric effects.

The correlation by Kandlikar (1990, 1991b) is developed from a large data bank consisting of over 10,000 data points and different fluids, including water, refrigerants, and cryogens. It is also able to accurately predict the parametric trends. In particular, it has been shown to predict the variation in h_{TP} well, yielding an increasing trend in h_{TP} with increasing x for fluids with low boiling number, $(=q''/(Gh_{fg}))$, and high liquid-to-vapor density ratio $(=\rho_L/\rho_G)$, representative of the convective boiling–dominant (CBD) region, for example, with water at low pressure and low *Bo*. In contrast, a decreasing trend is predicted for high *Bo* and low density ratio, representative of the nucleate boiling–dominant (NBD) region, for example, with some refrigerants with low density ratios and with high heat fluxes. The flow boiling correlation has been successfully extended to subcooled flow boiling (Kandlikar, 1998a), binary mixtures (Kandlikar, 1998c), and flow boiling in microchannels and minichannels (Kandlikar and Balasubramanian, 2004). In addition, it accounts for nucleation characteristics of a given surface through a fluid–surface parameter F_{Fl}. The Kandlikar (1990, 1991b) correlation is given by

$$h_{TP} = \text{larger of} \begin{cases} h_{TP}\big|_{NBD} \\ h_{TP}\big|_{CBD} \end{cases} \tag{8.69}$$

where h_{TP} in the respective regions are given by the following equations:

$$h_{TP,NBD} = 0.6683 Co^{-0.2} (1-x)^{0.8} f_2(Fr_{LO}) h_{LO} + 1058.0 Bo^{0.7} (1-x)^{0.8} F_{Fl} h_{LO} \tag{8.70}$$

and

$$h_{TP,NBD} = 1.136 Co^{-0.9} (1-x)^{0.8} f_2(Fr_{LO}) h_{LO} + 667.2 Bo^{0.7} (1-x)^{0.8} F_{Fl} h_{LO} \tag{8.71}$$

where

$Co = (\rho_G/\rho_L)^{0.5} [(1-x)/x]^{0.8}$ is the convection number

$Bo = q''/(Gh_{fg})$ is the boiling number

$Fr_{LO}(=G^2/(\rho_L g D))$ is the Froude number with all flow as liquid

The Froude number multiplier $f_2(Fr_{LO})$ is 1 for vertical tubes and for horizontal tubes with $Fr_{LO} \geq 0.04$.

For $Fr_{LO} < 0.04$, $f_2(Fr_{LO})$ is given by the following equation:

$$f_2(Fr_{LO}) = (25 Fr_{LO})^{0.3} \tag{8.72}$$

The single-phase all-liquid heat transfer coefficient h_{LO} is obtained from the Gnielinski (1976) correlation in the range $0.5 \leq Pr_L \leq 2000$ and $2300 < Re_{LO} \leq 10^4$:

$$h_{LO} = \frac{(Re_{LO} - 1000) Pr_L (f/2)(k_L/D)}{\left[1 + 12.7 (Pr^{2/3} - 1)(f/2)^{0.5}\right]} \tag{8.73}$$

The Petukhov and Popov (1963) correlation is employed for $0.5 \leq Pr_L \leq 2000$ and $10^4 < Re_{LO} \leq 5 \times 10^6$:

$$h_{LO} = \frac{Re_{LO} Pr_L (f/2)(k_L/D)}{1.07 + 12.7 (Pr^{2/3} - 1)(f/2)^{0.5}} \tag{8.74}$$

The friction factor f is given by the following equation:

$$f = [1.58 \ln(Re_{LO}) - 3.28]^{-2} \tag{8.75}$$

F_{Fl} is a fluid–surface parameter that depends on the fluid and the heater surface characteristics. Table 8.3 lists the F_{Fl} values for several fluids in copper tubes. These values should be considered as representative for commercial tubing. For stainless steel tubes, F_{Fl} should be taken as 1.0 with all fluids.

Introduction of F_{Fl} in the nucleate boiling term is an important aspect of the Kandlikar correlation. It has been recognized that the nucleation characteristics and associated heat transfer depend on contact angle, surface tension, and available cavity sizes and their distribution on the heater surface. Gaertner (1965) noted that

> …analytical treatments of nucleate boiling that do not consider the nature of the surface cannot accurately predict heat transfer relationships…

The flow boiling model is thus able to account for the different nucleation characteristics of different fluid–surface combinations through the incorporation of F_{Fl}. However, this constant needs to be obtained from the experimental data. Table 8.3 provides the values of F_{Fl} obtained from Kandlikar (1990, 1991b, 1999) and Melin (1996) for different fluids.

Figure 8.17 shows a comparison of the Kandlikar (1990) correlation with the experimental data of Schrock and Grossman (1962). The correlation is able to correctly predict the increasing trend in h_{TP} with x for the low-pressure data (large values of ρ_L/ρ_G) and a decreasing trend for the high-pressure data (low values of ρ_L/ρ_G).

Table 8.3 F_{FI} Values in the Kandlikar Correlation

Fluid	F_{FI}
Water	1.00
R-11	1.30
R-12	1.50
R-13B1	1.31
R-22	2.20
R-32[a]	1.88
R-113	1.30
R-114	1.24
R-125[a]	2.27
R-134a	1.63
R-142b[a]	1.74
R-143a[a]	2.39
R-152a	1.10
R-32/R-132	3.30
60%–40% (by wt)	
Butane[a]	1.50
Kerosene	0.488
Propane[a]	2.15

Note: For stainless steel tubes, use $F_{FI} = 1.0$ for all fluids.

[a] Values obtained by Melin (1996).

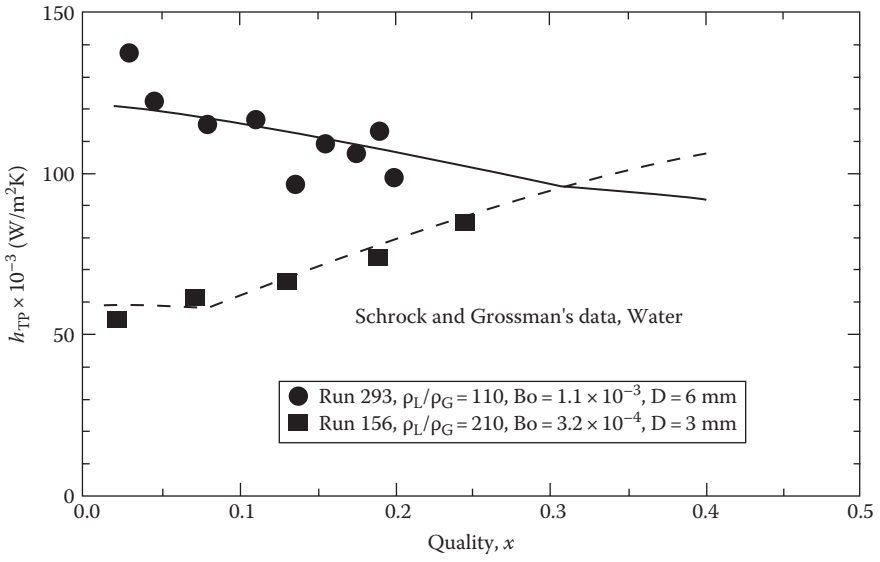

Figure 8.17

Comparison of Schrock and Grossman's (1962) experimental data with the Kandlikar (1990) correlation. (Reprinted from Kandlikar, S.G., Flow boiling in circular tubes, Sections 15.1–15.3, in *Handbook of Phase Change, Boiling and Condensation*, Kandlikar, S.G., Dhir, V.K., and Celata, G.P., Eds., Taylor & Francis, Philadelphia, PA, 1999. With permission from Taylor & Francis.)

The Kandlikar (1990) correlation is recommended in the wetted wall region below a quality of about 0.8. At higher qualities, local dryout may occur with a significant reduction in the heat transfer coefficient.

The Kandlikar (1990, 1991b) correlation was extended to microchannels (10 μm < $D_h \leq$ 200 μm) and minichannels (200 μm < $D_h \leq$ 3 mm) by Kandlikar and Balasubramanian (2004). The final form is given in Kandlikar (2014). As the all-liquid flow Reynolds number enters the laminar region, the use of Nu_{LO} = constant (dependent on geometry and wall boundary conditions) is recommended for calculating h_{LO} instead of the single-phase turbulent flow correlations. Furthermore, for microchannels, it is found that

h_{TP} falls entirely in the NBD region and is given by Equation 8.70 without the Froude number correction (use $f_2(Fr_{LO}) = 1$). The flow boiling heat transfer mechanisms in these geometries are discussed in detail by Kandlikar and Balasubramanian (2004).

8.2.6 Flow Boiling Map

The main parameters governing the flow boiling heat transfer can be represented in terms of the following four nondimensional groups:

1. Nondimensionalized heat transfer coefficient, h_{TP}/h_{LO}
2. Modified boiling number, $Bo^* = Bo(F_{Fl})^{1/0.7} = q''(F_{Fl})^{1/0.7}/(Gh_{fg})$
3. Density ratio, ρ_L/ρ_G
4. Vapor quality, x

The parametric trends of h_{TP} with various operating parameters were represented by Kandlikar (1991a) in terms of a flow boiling map, as shown in Figure 8.18. Density ratio is seen as an important factor governing the role of the convective contribution, which gives rise to an increasing trend in an h_{TP}/h_{LO} versus x plot in the CBD region. The magnitude of Bo^* governs the nucleate boiling contribution, which essentially displays a decreasing trend in an h_{TP}/h_{LO} versus x plot in the NBD region. These parametric trends have been confirmed for a number of fluids, including water and refrigerants.

8.2.7 Flow Boiling of Binary Mixtures
