The flow boiling of mixtures is encountered in many practical applications, including chemical, petrochemical, process, and refrigeration industries. The difference in boiling points of the pure components in a mixture causes preferential vaporization of the more volatile component across liquid–vapor interfaces at the nucleating bubbles, near an annular film or around a vapor slug. Depletion of the more volatile component raises the local saturation temperature at the liquid–vapor interface. This also results in the diffusion of the more volatile component in the liquid phase toward the interface. The net result is the lowering of the heat transfer coefficient for the mixture below the average value obtained from the linear mass- or mole-fraction-averaged interpolation between the pure component values.

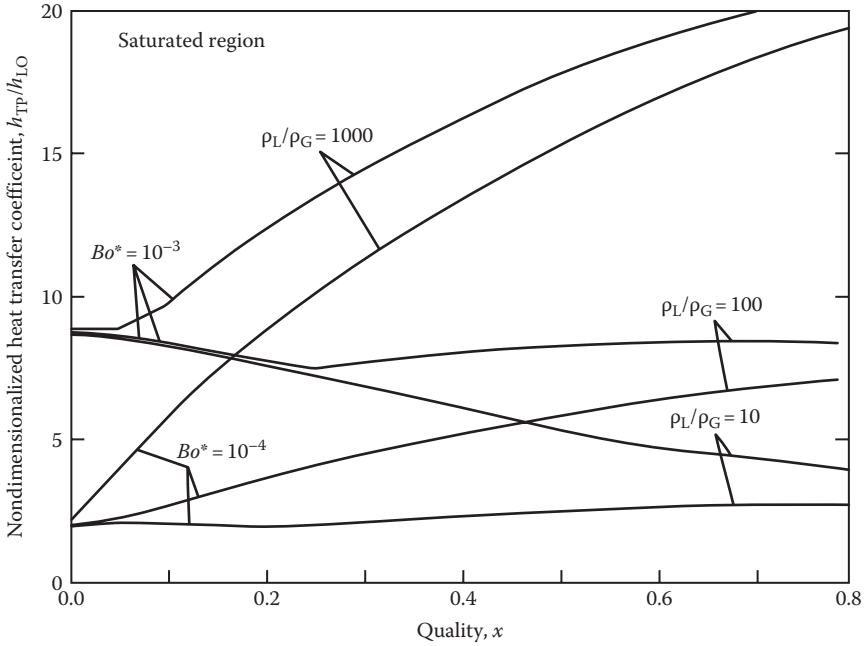

Figure 8.18

Flow boiling map for subcooled and saturated flow boiling. (Reproduced from Kandlikar, S.G., *Trans. ASME, J. Heat Transfer,* 113, 190, 1991a. With permission from ASME.)

A number of researchers have provided useful correlations to predict the heat transfer coefficients in a binary (two components in both liquid and vapor phases) system. Among the more successful ones are Calus et al. (1973), Bennett and Chen (1980), Jung (1988), and Kandlikar (1998c). One of the main difficulties encountered in modeling binary flow boiling is the uncertainty in predicting the interfacial concentration at the nucleating bubble interface. Kandlikar (1998b) used a control volume approach to obtain the interfacial concentration in pool boiling and later extended it to flow boiling.

In the Kandlikar (1998c) model, a volatility parameter V_1 is defined as:

$$V_1 = \left(\frac{c_{p,L}}{h_{fg}}\right)\left(\frac{\alpha}{D_{12}}\right)^{0.5}\left|\frac{dT}{dx_1}\left(y_1 - x_1\right)\right| \tag{8.76}$$

where

α is the thermal diffusivity of the liquid

D_{12} is the mass diffusivity of component 1 in a mixture of components 1 and 2

x_1 and y_1 are the liquid and vapor mass fractions of the more volatile component 1

Three regions in binary flow boiling are identified based on the value of V_1

Region I: Near-azeotropic region, $V_1 < 0.03$:

$$h_{TP} = \text{larger of}\begin{cases} h_{TP}\big|_{NBD} \\ h_{TP}\big|_{CBD} \end{cases} \tag{8.77}$$

Use pure component correlations, Equations 8.70 and 8.71, with mixture properties.

Region II: Moderate diffusion-induced suppression region, $0.03 < V_1 < 0.2$, and $Bo > 1E\text{-}4$:

$$h_{TP} = h_{TP}\big|_{CBD} \tag{8.78}$$

The heat transfer is entirely in the CBD region. Use the pure component correlation in the NBD region, Equation 8.70, with mixture properties.

Region III: Severe diffusion-induced suppression region: (a) for $0.03 < V_1 < 0.2$ and $Bo < 1E\text{-}4$ and (b) $V_1 > 0.2$:

$$h_{TP,CBD} = 1.136Co^{-0.9}\left(1-x\right)^{0.8} f_2\left(Fr_{LO}\right)h_{LO} + 667.2Bo^{0.7}\left(1-x\right)^{0.8} F_{Fl}h_{LO}F_D \tag{8.79}$$

A diffusion-induced suppression factor F_D is introduced in the nucleate boiling term to reflect the reduction in heat transfer coefficient due to the mass diffusion resistance present at the interface. F_D is given by the following equation:

$$F_D = 0.678\left[1 + \left(\frac{c_{p,L}}{h_{fg}}\right)\left(\frac{\alpha}{D_{12}}\right)^{0.5}\left|\frac{dT}{dx_1}\left(y_1 - x_1\right)\right|\right]^{-1} \tag{8.80}$$

The equilibrium phase mass concentrations are calculated at the total system pressure, and dT/dx_1 corresponds to the slope of the bubble point curve at a liquid-phase concentration of x_1. The diffusivity D_{12} is calculated from the following equation:

$$D_{12} = \left(D_{12}^0\right)^{\tilde{x}_2}\left(D_{21}^0\right)^{\tilde{x}_1} \tag{8.81}$$

where

$\tilde{x}_1$ and $\tilde{x}_2$ are the respective molar concentrations of components 1 and 2

D_{12}^0 and D_{21}^0 are the individual component diffusivities at very low concentrations given by the following Wilke–Chang correlation

$$D_{12}^{0} = 1.1782 \times 10^{-16} \frac{(\phi M_2)^{1/2} T}{\mu_{L,2} V_{m,l}} \tag{8.82}$$

where

ϕ is the association factor for the solvent (2.26 for water, 1.9 for methanol, 1.5 for ethanol, 1.9 for ethylene glycol, and 1.0 for unassociated solvents, including benzene, methane, and refrigerants)
M is the molecular weight
μ_L is the liquid viscosity
V_m is the molar volume in m^3/kg mol
T is the temperature in K

Table 8.4 shows the mean deviations between the predicted values using the Kandlikar (1998c) correlation described earlier and the experimental data of Jung et al. (1988), Hihara et al. (1989), Takamatsu et al. (1993), Celata et al. (1993), and Murata and Hashizume (1993). The ranges of parameters are also included in Table 8.4. It is seen that the agreement is quite good in all three regions. Figure 8.19 shows a comparison of a data set obtained by Murata and Hashizume (1993) for R-134a/R-123 mixture in the severe suppressed region, that is, Region III.

Heat transfer coefficients in multicomponent systems are even more difficult to predict. There is no reliable general methodology available to make any recommendation for mixtures of three or more components. It is suggested that the most volatile component be taken as component 1 and the rest of the mixture treated as component 2, and the binary flow boiling correlation scheme applied as a first approximation.

Table 8.4 Comparison of the Binary Flow Boiling Correlation of Kandlikar (1998c) with Experimental Data from the Literature

Data Source	Binary System	*Bo* (×10⁻⁵)	*Co*	V_1	Mean Average Dev. (%)
Jung et al. (1988)	R-12/R-152a	6.1–6.3	0.52–1.8	0.025–0.044	8.3
	R-12/R-152a	8.8–71	0.01–1.45	0.013–0.022	10.4
	R-22/R-114	7.1–77	0.04–1.39	0.1–0.72	13.0
	R-500	7.5–77	0.01–1.83	0.0006–0.002	11.4
Hihara et al. (1989)	R-12/R-22	47–61	0.01–1.91	0.015–0.064	13.3
	R-22/R-114	37–60	0.023–1.64	0.07–0.67	9.0
Takamatsu et al. (1993)	R-22/R-114	19–76	0.018–3.2	0.28–0.54	9.2
Celata et al. (1993)	R-12/R-114	9.4–88	0.52–1.83	0.06–0.15	8.9
Murata and Hashizume (1993)	R-134a/R-123	20–185	0.004–0.05	0.28–0.34	12.1

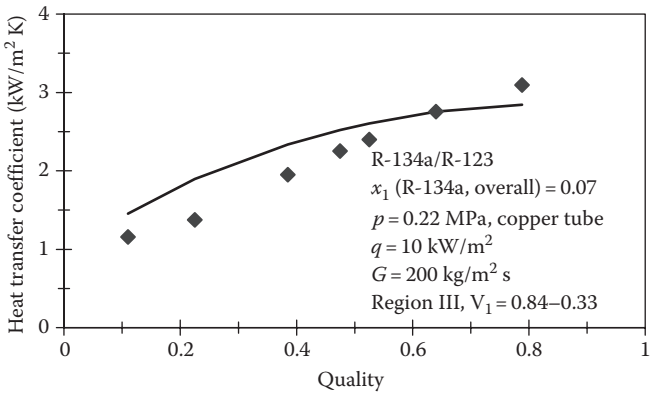

Figure 8.19

8.2.8 Critical Heat Flux in Flow Boiling

The heat transfer coefficient in flow boiling is dramatically reduced as the liquid ceases to be in contact with the walls of the flow channel. CHF condition represents the upper limit of operation of a boiling system in heat flux–controlled systems. It results in a considerable heat transfer degradation in temperature-controlled systems (Kandlikar, 2001b). *Dryout* condition represents the upper limit of the convective boiling heat transfer. It follows the gradual depletion of liquid due to evaporation and entrainment of the liquid film in the vapor. Knowledge of the conditions leading to CHF and prediction of CHF for a given geometry under a given set of operating conditions are extremely important in the safe operation of flow boiling equipment, such as nuclear reactors, boilers, refrigeration and cryogenic evaporators, and cooling of high heat flux components and devices.

Mitigating the risks associated with a catastrophic failure following the CHF condition have attracted significant research efforts worldwide for over 60 years. Earlier, Lang (1888) recognized the existence of severe heat transfer degradation through his experiments with high-pressure water. Drew and Mueller (1937) provide an excellent summary of historical developments in this area. Extensive experimental and numerical studies have been conducted since the 1960s on the CHF with water in nuclear reactors under safe operating as well as under accident conditions. A better CHF predictive ability allows the operation of a nuclear reactor with lower safety margins, thereby increasing the output capacity of the nuclear power plant. Understanding the mechanisms leading to CHF permit the development of techniques or operating procedures to increase the CHF for a given system configuration.

CHF in subcooled and saturated flow boiling has been studied with water and some other fluids under different conditions: (1) uniform heat flux along a channel length; (2) uniform heat flux along a tube, with a short length of higher heat flux; and (3) circumferentially uniform, but axially nonuniform heat flux.

A brief overview of CHF under subcooled and saturated flow boiling conditions in uniformly heated circular tubes is presented in this section. For more extensive coverage, the reader is referred to the detailed treatise on this topic; see, for example, Tong (1965), Boyd (1983a,b), Tong (1988), Collier and Thome (1994), Hewitt (1998), Celata and Mariani (1999), Kandlikar et al. (1999), and Tong and Tang (1997).

8.2.8.1 CHF in Subcooled Flow Boiling

The CHF in subcooled flow boiling is reached in one of the following three ways (Tong and Hewitt, 1972):

1. A dry patch forms on the heater surface after a bubble has departed. The local temperature in some cases rises to a point where the water fails to rewet the surface, leading to the CHF condition.
2. A thin layer of bubbles is formed on the wall at moderate heat and mass fluxes. The neighboring bubbles then cluster together to form a vapor layer underneath the bulk liquid and restrict liquid access to the heater wall.
3. A slug flow is observed under certain conditions at low mass fluxes. The liquid film surrounding the vapor bubble evaporates and dries out. If the vapor bubble is sufficiently long, the heater wall becomes heated during the passage of the bubble and leads to the CHF condition.

Celata and Mariani (1999) summarize the previous models in the following five categories: (1) boundary layer ejection model, (2) critical enthalpy in the bubble layer model, (3) liquid flow blockage model, (4) vapor removal limit and near-wall bubble crowding model, and (5) liquid sublayer dryout model. A brief description of each of the mechanisms is given as follows (Kandlikar, 2001b).

8.2.8.1.1 Boundary Layer Ejection Model. This model was originally proposed by Kutateladze and Leont'ev (1966). The boiling mechanism is compared with the injection of a gas stream into the liquid flow through a permeable plate. The ejection of bubbles into the mainstream is postulated to be the cause of the boundary layer separation at the heater surface. However, the photographic study conducted by Mattson et al. (1973) does not show any abrupt changes or high-velocity vapor ejection in the macroscopic structure of the flow near the CHF location.

8.2.8.1.2 Critical Enthalpy in the Bubble Layer Model. This model was proposed by Tong et al. (1966). They assumed that a layer of small bubbles flowing adjacent to the heater surface traps the liquid between the bubble layer and the heated surface. This bubble layer separates the trapped superheated liquid layer from the mainstream. They postulated that CHF condition is reached when this superheated liquid layer attains a

certain limiting enthalpy. This model does not provide a clear explanation of the physical events leading to CHF other than stating the existence of a critical liquid enthalpy in the superheated liquid layer.

8.2.8.1.3 Liquid Flow Blockage Model Bergel'son (1980) proposed this model based on the assumption that the flow of liquid toward the heated surface is blocked by the outflow of vapor from the heater surface. This behavior may be feasible under very low mass flux conditions, where the liquid and vapor flow structure is similar to that in the case of pool boiling. However, the vapor flow away from the wall is not seen to be a limiting factor in subcooled flow boiling. Owing to inadequate evidence supporting this mechanism, this model is not being pursued by other researchers.

8.2.8.1.4 Vapor Removal Limit and Near-Wall Bubble Crowding Model This model is based on the limit of turbulent interchange between the bubbly layer and the bulk of the liquid and the crowding of bubbles preventing liquid access to the heated wall (Hebel et al., 1981).

Weisman and Pei (1983) consider the existence of a bubbly layer adjacent to the wall at subcooled or low-quality conditions. It is postulated that the CHF condition occurs when the volume fraction of vapor in the bubbly layer just exceeds the critical volume fraction at which an array of ellipsoidal bubbles can be maintained without significant contact between the bubbles. Weisman and Pei used the homogeneous flow model in the bubbly layer. The resulting model has three adjustable empirical constants that are evaluated from the experimental data. This model includes the two-phase flow considerations that are readily extendable to the saturated flow conditions as well.

8.2.8.1.5 Liquid Sublayer Dryout Model Katto and Yokoya (1968) proposed a preliminary model describing the macrolayer dryout as the mechanism leading to CHF in pool boiling. Later, Haramura and Katto (1983) completed the development of the model by introducing the mechanism for macrolayer formation. This model is extended to flow boiling by considering a liquid film trapped between a bubble and the heater wall. Numerous vapor stems emerge on the heater surface through the liquid film. Under flow conditions, both the liquid sublayer and the vapor film move in the flow direction. Liquid is fed into the film from the upstream end, whereas the film thickness decreases along the flow direction due to evaporation. The CHF condition is reached when the heat supplied by the heater surface provides the necessary latent heat required to completely evaporate the liquid entering the film. Katto (1990a,b) provided a detailed description of the model based on the macrolayer evaporation. His model uses several empirical constants in determining the thickness, liquid film flow rate, and temperature of the liquid entering into the sublayer.

Lee and Mudawar (1988) considered the effect of velocity in the subcooled flow in terms of stretching the large bubble in the Haramura and Katto (1983) model to a vapor blanket of length equal to the critical Helmholtz wavelength. The sublayer mass velocity, its thickness, and the vapor blanket length were calculated with buoyancy and drag forces acting on the vapor blanket. The modeling resulted in a correlation scheme with three empirical constants that were determined from a large set of experimental data.

Celata et al. (1994) eliminated the empirical constants in the Katto (1990a,b) and Lee and Mudawar (1988) models by using the homogeneous flow model and introducing appropriate correlations from available literature to calculate the sublayer thickness, flow rate, enthalpies, and vapor blanket length. However, the basic features of the model are similar to that proposed by Lee and Mudawar (1988).

The recent models discussed in the preceding section present a significant improvement over the earlier models by considering CHF as a local phenomenon. However, further improvements are needed to account for the effect of contact angle on CHF. A major question that remains unanswered in the earlier models is the description of the mechanism that prevents rewetting of the dry patches. The pool boiling model of Kandlikar (2001a) considers the evaporation momentum force experienced by an evaporating interface, and it is postulated that this force is responsible for pushing the liquid front away. Recently, Kandlikar (2004) developed two nondimensional groups that compare the evaporation momentum, surface tension, and inertia forces. The use of these new nondimensional groups in CHF prediction in flow boiling has shown promising results.

8.2.8.2 CHF in Low-Quality Saturated Flow Boiling

CHF at low qualities in saturated flow boiling is similar to CHF in subcooled flow boiling. Bubble crowding and liquid film dryout under a growing bubble or a slug are the two main mechanisms leading to CHF in low-quality subcooled flow boiling. Therefore, the mechanisms and correlations are the same under these conditions.

8.2.8.3 Correlations for CHF in Subcooled Flow Boiling and Low-Quality Saturated Flow Boiling

Numerous correlations specific to certain geometries and operating conditions are available in the literature and are recommended for use if they match the corresponding conditions. An extensive review of CHF correlations for different geometries and operating conditions is given by Tong and Tang (1997).

For general usage, Gunther's (1951) correlation should be used to provide a good approximation:

$$q''_{CHF} = 7198u^{0.5}\Delta T_{Sub.exit} \tag{8.83}$$

(The recommended ranges are p = 0.1 – 1.1 MPa, u = 1.5–12.1 m/s, $q''_{\mathrm{CHF}} = 0.4 - 11.4\ \mathrm{MW/m^2}$, and $\Delta T_{\mathrm{Sub,exit}}$ = 11–39 K.)

Note that this correlation is valid only for water and cannot be extrapolated beyond the quoted ranges of parameters (it does not approach the pool boiling CHF as $u \to 0$).

The correlation of Tong et al. (1968) for CHF with water in uniformly heated tubes is widely accepted:

$$\frac{q''_{CHF}}{Gh_{fg}} = \frac{C}{\mathrm{Re}^{0.6}} \tag{8.84}$$

(recommended ranges are p = 5.5–13.6 MPa; u = 0.68–5.9 m/s; void fraction at CHF, 0.35; D = 3–10 mm; L/D = 5–100; void fraction is evaluated using Thom et al. (1965) model; and $T_{\mathrm{Sub,exit}}$ = 11–39 K) where G is the mass flux, Re the Reynolds number, and

$$C = 1.76 - 7.433x_{exit} + 12.222x_{exit}^2 \tag{8.85}$$

All properties are evaluated at saturation condition. Celata et al. (1994) extended the range of the proposed correlation to lower pressures by replacing C with C' given by the following correlation:

$$C' = \left(1.76 - 7.433x_{exit} + 12.222x_{exit}^2\right)\Psi \tag{8.86}$$

(recommended ranges are p = 5.5 MPa, u = 2.2–40 m/s, $T_{\mathrm{Sub,exit}}$ = 15–190 K, and D = 0.33–15 mm) with Ψ (in MPa) given by the following equation:

$$\Psi = \begin{cases} 1 & \text{for } x_{exit} < -0.1 \\ 0.825 + 0.986x_{exit} & \text{for } 0 > x_{exit} \geq 0.1 \end{cases} \tag{8.87}$$

In evaluating CHF from the previous equations, the heat balance method requiring an iterative procedure is recommended (Celata and Mariani, 1999).

For small-diameter tubes, the experimental data by Vandervort et al. (1994) show the effect of diameter. They performed experiments in tubes having inside diameter ranging from 0.3 to 2.7 mm, mass flux from 5,000 to 40,000 kg/m^2 s, exit subcoolings from 40°C to 135°C, and exit pressures from 0.2 to 2.2 MPa.

8.2.8.4 CHF in Annular Flow due to Liquid Film Dryout in Saturated Flow Boiling

As quality increases, the flow pattern changes to annular flow with its characteristic liquid film around the circumference and a central vapor core. The liquid film dryout depends on the rates of its evaporation, liquid entrainment in the vapor, and deposition of liquid back from the vapor core into the film. The rates of evaporation as well as entrainment to some extent depend on the imposed heat flux. The location of the dryout and the corresponding value of CHF at this location are of interest. It is desirable to extend the dryout location to higher qualities as the heat transfer rate is dramatically reduced following the *dryout*.

Simple correlations are not available to predict the *dryout* location. Elaborate methods are available in the literature to predict the entrainment and deposition rates (e.g., Collier and Thome, 1994). Another method that is widely followed consists of extensive tabulation of CHF data for a standardized circular tube of 8 mm diameter as a function of pressure, mass flux, and quality at CHF. This approach was originally developed by Doroshchuk et al. (1975). The recent updated tables are published by Groeneveld et al. (1996).

Using these tables, the CHF value for various tube diameters under the same pressure, mass flux, and quality conditions is obtained by the following equation:

$$q''_{CHF} = q''_{CHF,8\text{ mm}}\left(\frac{D}{0.008}\right)^{k} \tag{8.88}$$

Groeneveld et al. (1996) recommend a value of $k = -1/2$ based on 22,946 data points for water covering the ranges of pressure from 0.1 to 20 MPa, mass flux up to 8,000 kg/m^2 s, and quality of −0.5 to 1.0 at discrete values covering tube diameters from 3 to 25 mm. Other researchers proposed a value of $k = -1/3$ (Groeneveld et al., 1986, Smith, 1986).

The heat transfer mechanisms were investigated by Kandlikar (2004), who proposed the following two nondimensional numbers. K_1 represents the ratio of evaporation momentum force to inertia force, whereas K_2 represents the ratio of evaporation momentum and surface tension forces:

$$K_1 = \left(\frac{q''}{h_{fg}}\right)^2 \frac{\rho_L}{\rho_G} \tag{8.89}$$

and

$$K_2 = \left(\frac{q''}{h_{fg}}\right)^2 \frac{D}{\rho_G \sigma} \tag{8.90}$$

Kandlikar (2010) considered the scale effects of tube diameter on the evaporation momentum, viscous, inertia, and surface tension forces to propose a CHF model as an extension of the force balance model developed earlier for pool boiling (Kandlikar, 2001a). The forces were nondimensionalized using the following nondimensional numbers, K_2 (ratio of evaporation momentum to surface tension forces); Weber number, We (ratio of inertia to surface tension forces); and capillary number, Ca (ratio of viscous to surface tension forces):

$$K_{2,CHF} = \left(\frac{q''_{CHF}}{h_{fg}}\right)^2 \left(\frac{D_h}{\rho_V \sigma}\right) \tag{8.91}$$

$$We = \frac{G^2 D_h}{\rho_m \sigma} \tag{8.92}$$

$$Ca = \frac{\mu_L G}{\rho_L \sigma} \tag{8.93}$$

The average density ρ_m in Equation 8.92 is given by the following equation:

$$\frac{1}{\rho_m} = \frac{x}{\rho_V} + \frac{1-x}{\rho_L} \tag{8.94}$$

A particular trend was observed with Weber number, and the correlation scheme was distinguished based on the inertia effects as follows:

1. Low-inertia region (LIR): We < 900
2. High-inertia region (HIR): We ≥ 900

Further, the LIR region was found to be split into two CHF subregions. They are classified as follows:

1. Low-inertia region, lower-CHF subregion (LIR-LC)
2. Low-inertia region, higher-CHF subregion (LIR-HC)

The correlating scheme for CHF over the entire range was given by one of the following two equations depending on the specific range of parameters:

$$K_{2,CHF} = a_1\left(1+\cos\theta_R\right) + a_2\,\mathrm{We}(1-x) + a_3\mathrm{Ca}\left(1-x\right) \tag{8.95}$$

or

$$K_{2,CHF} = a_4\left[a_1\left(1+\cos\theta\right) + a_2\,\mathrm{We}(1-x) + a_3\mathrm{Ca}\left(1-x\right)\right] \tag{8.96}$$

where θ_R is the receding contact angle and $a_1 - a_4$ are the constants. The specific equations applicable in different inertia regions and CHF subregions are given as follows:

Low-inertia region (LIR): We < 900
  High-CHF subregion (LIR-HC): $L/D \leq 140$ Equation 8.95
  Low-CHF subregion (LIR-LC): $L/D \geq 230$ Equation 8.96
High-inertia region (HIR): We ≥ 900
  High-CHF subregion (HIR-HC): $L/D < 60$ Equation 8.95
  Low-CHF subregion (HIR-LC): $L/D \geq 100$ Equation 8.96

The values of constants are as follows:

$$\begin{aligned} a_1 &= 1.03\times10^{-4} \\ a_2 &= 5.78\times10^{-5} \\ a_3 &= 0.783 \\ a_4 &= 0.125 \end{aligned} \tag{8.97}$$

The transition criterion between the macroscale and microscale CHF phenomena is obtained by equating the inertia forces with the viscous forces. The following transition criteria are proposed:

$$\frac{\mathrm{We}}{\mathrm{Ca}} = \frac{a_3}{a_2} = \frac{0.783}{5.78\times10^{-5}} = 13{,}547 \tag{8.98}$$

In terms of the diameter and flow Reynolds numbers, the transition criterion may be expressed as follows:

$$D_{h,transition} = 13{,}547\,\frac{\mu_L}{G}\,\frac{\rho_m}{\rho_L} \tag{8.99}$$

$$\mathrm{Re}_{\mathrm{transition}} = \frac{GD_{\mathrm{h,transition}}}{\mu_{\mathrm{L}}} = 13{,}547\,\frac{\rho_{\mathrm{m}}}{\rho_{\mathrm{L}}} \tag{8.100}$$

The microscale effects begin to become important at diameters or Reynolds numbers given by Equations 8.99 and 8.100, respectively. Further details on the scale effects are described by Kandlikar (2010).

The heat transfer in the post-CHF region depends on the extent of droplet deposition on the tube wall. Beyond a certain temperature, the heater surface may exceed the Leidenfrost temperature and the heat transfer rate by convection would reduce significantly. Correlations by Groeneveld (1973) and Nishikawa et al. (1986) are recommended. Since these correlations are developed for specific fluids, geometries, and operating conditions, extreme caution should be exercised while extending their applicability to parameter ranges beyond their parent database.

8.2.9 Flow Boiling in Compact Heat Exchangers

Flow boiling in compact heat exchangers is extensively employed in chemical, process, air liquefaction, and refrigeration applications. The use of plate fin and plate heat exchangers is common in these applications.

A detailed survey on this topic is presented by Kew and Cornwell (1999). They reviewed a number of available correlations for offset-strip fins, perforated fins, and louvered fins. The correlation schemes presented by Feldman et al. (1996), Kandlikar (1991b), and Wieting (1975) are noteworthy. In general, results reveal that, contrary to the common expectation, the role of nucleate boiling becomes more important in narrow channels found in compact heat exchanger passages when compared to conventional channels.

8.2.10 Flow Boiling Augmentation

Although the heat transfer coefficients during flow boiling are relatively high compared to the corresponding single-phase liquid flows, further enhancements are desired in a number of applications. Many augmentation techniques have been proposed in the literature; a comprehensive review of various techniques for accommodating high heat fluxes is given by Bergles (1997). Among the methods employed, microfin tubes, also called grooved tubes in Japanese and Korean literature, have proved to be quite attractive in flow boiling applications. Tubes of different microfin geometries have been studied in the literature (e.g., Khanpara et al., 1986, 1987, Koyama et al., 1995) and are now routinely applied in refrigeration evaporators. The flow boiling performance of these tubes can be predicted by a number of correlation schemes proposed in the literature (e.g., Kandlikar, 1991b, Kandlikar and Raykoff, 1997).

Structured and porous surfaces that promote pool boiling heat transfer have been successfully applied for flow boiling enhancement as well. The use of such surfaces is common especially in the air separation and cryogenic industries, where very small temperature differences are often employed in the evaporation of air constituents during the separation processes.

Microchannels have received significant attention in both single-phase flow and flow boiling because of their higher performance, including higher CHF. The flow instabilities have been identified as one of the major limitations, but these have been overcome with inlet flow restrictors and artificial nucleation sites. Some of the recent developments in this field include open microchannels with taper and vapor venting designs. A detailed analysis of microchannel flow boiling phenomena is presented by Kandlikar (2014), and the new design configurations are discussed in Kandlikar (2015). These designs are able to dissipate heat fluxes over 1,000 W/cm^2 with a heat transfer coefficient in excess of 500,000 W/m^2 °C.

8.2.11 Enhancement of CHF in Flow Boiling

The techniques to enhance the CHF in subcooled and low-quality saturated boiling regions can be divided into passive and active types. Detailed surveys of various enhancement techniques are presented by Celata and Mariani (1999) and Boyd (1985).

The passive devices consist of twisted tapes and swirl flow devices, helically coiled tubes, surface roughness, and extended surfaces. These devices induce secondary radial and circumferential velocity components over the tube wall causing an increase in CHF. These devices result in significantly higher-pressure drop penalties compared with a smooth tube. The CHF enhancement is 1–3 times the corresponding smooth tube values under the same operating conditions, whereas the pressure drop increase is higher, depending on the specific enhancement technique. The Nariai et al. (1992) correlation is recommended for the prediction of CHF enhancement with twisted tapes:

$$\frac{q''_{CHF}}{q''_{CHF,smooth}} = \left\{1 + 10^{-2}\vartheta \exp\left[\left(-10^{-6}p\right)^2\right]\right\}^{1/6} \tag{8.101}$$

where ϑ is the nondimensional centrifugal acceleration given by

$$\vartheta = \frac{\pi^2 u^2}{2gDTTR} \tag{8.102}$$

where

u is the average flow velocity
D is the tube diameter
TTR is the twist ratio

CHF in the high-quality region resulting from *dryout* can be enhanced by effectively replenishing the heated surface with liquid. Liquid retention in grooves and roughness structures effectively delays the dryout location.

Nomenclature

a,b	Constants in Equation 8.63
A,B	Constants in Equation 8.15
Bo	Boiling number, $= q''/(Gh_{fg})$
c_p	Specific heat constant, J/kg °C
Co	Convection number, $= (\rho_G/\rho_L)^{0.5}\,[(1-x)/x]^{0.8}$
$C_{s,f}$	Fluid–surface effect constant, Equation 8.21
d	Equilibrium break-off bubble diameter, m, Equation 8.26
D	Tube diameter, m
D_b	Bubble diameter, m
D_h	Hydraulic diameter, m
D_{12}	Mass diffusion coefficient of species 1 in a mixture of 1 and 2
F_{Fl}	Fluid–surface parameter accounting for nucleation characteristics of different fluid–surface combinations in Kandlikar (1990) correlation
Fo	Fourier number
Fr	Froude number
Fr_{LO}	Froude number with all flow as liquid $= G^2/(\rho_L g D)$
f	Bubble departure frequency, Equation 8.19
f	Friction factor, Equations 8.58 through 8.60
$f_2(Fr_{LO})$	Froude number multiplier in Equations 8.70 and 8.71
F_D	Diffusion-induced suppression parameter, defined by Equation 8.80
F_{Fl}	Fluid–surface parameter, Equations 8.70 and 8.71, Table 8.3
g	Gravitational acceleration, m/s^2
G	Mass flux, kg/m^2 s
H	Heat transfer coefficient, W/m^2 °C
h_{fg}	Latent heat of vaporization, J/kg
h'_{fg}	Latent heat corrected for vapor superheating, Equations 8.37 and 8.38, J/kg
h_L	Heat transfer coefficient for the liquid, W/m^2 °C
h_{LO}	Single-phase heat transfer coefficient for all flow in the liquid phase at saturation temperature, W/m^2 °C
$h_{L,Sat}$	Heat transfer coefficient for the liquid at the saturation point, W/m^2 °C
h_m	Heat transfer coefficient for the mixture, W/m^2 °C
h_{TP}	Two-phase heat transfer coefficient, W/m^2 °C
$h_{TP\|CBD}$	Two-phase heat transfer in the convective boiling–dominant region, W/m^2 °C
$h_{TP\|NBD}$	Two-phase heat transfer in the convective boiling–dominant region, W/m^2 °C
h^*	Heat transfer coefficient using T_{Sat} as the fluid temperature in the subcooled flow boiling, W/m^2 °C
Ja	Jakob number
K	Boltzmann's constant = 1.38×10^{-23} J/K
K_1	Parameter in Equation 8.16
K_1, K_2	New nondimensional groups defined by Equations 8.89 and 8.90
k_L	Thermal conductivity, W/m °C
l	Mixing length
M	Molecular weight
m''	Total mass flux, kg/m^2 s
Nu	Nusselt number
Nu_{LO}	Nusselt number with all flow as liquid
$Nu_{LO,\,cp,\,LO,\,cp}$	Nusselt number with constant properties and all flow as liquid
p	Pressure, N/m^2
p_{cr}	Critical pressure, N/m^2
p_G	Pressure of the gas inside bubble, N/m^2

p_L	Pressure of the liquid, N/m^2
$p_{Sat,T}$	Saturation pressure over a planar interface, N/m^2
Pr	Prandtl number
q	Heat transfer rate, W
q''	Heat flux, W/m^2
q''_{CHF}	CHF, W/m^2
$q''_{FDB,i}$	Heat flux at the initial point of FDB, W/m^2
q''_{int}	Heat flux at the intersection of the extended single-phase line and the FDB curve, W/m^2
q''_{MHF}	MHF, W/m^2
q''_{ONB}	Heat flux at ONB, W/m^2
q''_{PB}	Heat flux in the partial boiling region, W/m^2
R	Radius
R_b	Radius of a bubble, m
R_C	Cavity mouth radius, m
$R_{C,Crit}$	Cavity radius at the ONB
$R_{C,Max}$, $R_{C,Min}$	Minimum and maximum cavity radii available on a surface, m
Re	Reynolds number
$R(t)$	Bubble growth rate function
$R_c^\star$	Nondimensional cavity radius
$R_{min}^\star$, $R_{max}^\star$	Minimum and maximum radii of active cavities
T	Temperature, °C or K
$T_{Sat,1\|p}$,$T_{Sat,2\|p}$	Saturation temperatures of the pure components at the total system pressure, p, °C
t	Time, s
TTR	Tape twist ratio for twisted tapes
u	Velocity, m/s
v	Specific volume, m^3/kg
V	Volatility parameter, defined by Equation 8.76
V_b	Bubble volume, Equation 8.20 m^3
V_m	Molar volume, m^3/kg mol
X_{1-8}	Nondimensional groups defined in Equations 8.22 through 8.26
x	Equilibrium quality
x_1, x_2	Mass fractions of 1 and 2, respectively, in the liquid phase of a mixture of species 1 and 2
$\tilde{x}$	Molar concentration in Equation 8.29
y	The distance normal to the heater surface to the center of the bubble, m
y_1, y_2	Mass fractions of 1 and 2, respectively, in the vapor phase of a mixture of species 1 and 2

Greek Letters

α	Thermal diffusivity, $= k/(\rho c_p)$, m^2/s
Γ	Liquid mass flow rate per unit film width
Γ	Wall superheat ($T_{Wall} - T_{Sat}$), °C
$\Delta T_{Sat,ONB}$	Wall superheat at the ONB, °C
ΔT_{Sub}	Liquid subcooling ($T_{Sat} - T_L$), °C
$\Delta T_{Sat}^\star$	Nondimensional wall superheat
δ_t	Single-phase thermal boundary layer thickness
ε_m	Eddy diffusivity for momentum transport
ε_h	Eddy diffusivity for heat transport
ϕ	Angle of orientation of the heated surface with respect to the horizontal, deg
ϕ	Association factor in Equation 8.82
φ	Spray distribution parameter for skewness
κ	Mixing length constant
μ_B	Viscosity of the bulk liquid, Ns/m^2
μ_L	Viscosity of the liquid, Ns/m^2
μ_W	Viscosity of the fluid at the wall temperature, Ns/m^2
ξ	Spray distribution parameter for uniformity

θ	Contact angle, deg
θ_r	Receding contact angle, deg
ϑ	Nondimensional centrifugal acceleration, Equations 8.101 and 8.102
ρ	Density, kg/m^3
σ	Surface tension, N/m
ψ	Parameter in Equations 8.86 and 8.87

Subscripts

an	Annular flow
1, 2	Species 1 and 2
b	Bubble
bp	Bubble point
c	Critical state
CHF	Critical heat flux
CBD	Convective boiling–dominant region
conv	Convective boiling component
crit, cr	Critical point for the fluid
dp	Dew point
exit	Exit section
f	Stream core
FDB,*i*	Initial point of FDB
F,c	Convective component of film boiling
F,r	Radiative component of film boiling
Fl	Fluid–surface-dependent parameter in Kandlikar (1990) correlation
fl	Fluid
fg	Latent quantity (vapor property–liquid property)
i	At the interface or initial state
int	Intersection of the extended single-phase line and the FDB curve
L	Liquid
LO	All flow as liquid
G	Gas
MHF	Minimum heat flux
max	Maximum
min	Minimum
NBD	Nucleate boiling–dominant region
NVG	Point of net vapor generation
Nu	Nusselt-type solution
nucl	Nucleate boiling component
0	On a flat surface
ONB	Onset of nucleate boiling
PB	Partial boiling region
r	Receding
F,r	Radiative component of film boiling
F,c	Convective component of film boiling
Sat	Saturation point
Smooth	Smooth tube value
str	Stratified flow
Sub	Subcooling
t	Turbulent flow
tr	Transition flow
T	Thermal layer
TP	Two phase
v	Vapor phase
W	Wall
δ	Edge of liquid film

Superscripts

–	Averaged, average over the entire length or dimensionless quantity
+	Dimensionless quantity
m	Exponent in Equation 8.63, given by Equation 8.66
n	Constant in Equation 8.66
p	Constant in Equation 8.66
*	Nondimensional form
0	Pure component value at infinite dilution, Equation 8.81

9.7 Enhanced Condensation

9.1 Fundamentals of Condensation

9.1.1 Homogeneous Nucleation

Thermodynamically, condensation is defined as the change of phase from vapor to liquid with the release of latent heat. The driving force for condensation is a subcooling of the vapor phase under a metastable condition. As shown in Figure 9.1, assume that a droplet embryo is formed with a radius of a that is larger than the mechanical equilibrium radius or the critical radius a^*. The critical radius is defined by the Laplace–Young equation based on the mechanical equilibrium as follows:

$$p_l - p_g = \frac{2\sigma}{a^*} \tag{9.1}$$

where
p_l and p_g are the liquid- and vapor-phase pressures, respectively
σ is the surface tension coefficient

Under the thermal equilibrium condition $T_l = T_g$, for the vapor phase, Thomson (1871) showed that the actual saturation pressure of the vapor, p_g, surrounding the droplet is increased due to surface tension as given by

$$p_g = p_o \exp\left(\frac{2\sigma v_l M}{a^* R_u T_g}\right) \tag{9.2}$$

$$p_g \approx p_o(1 + 2\sigma v_l / a^* p_o v_g) \tag{9.3}$$

where p_o is the saturation pressure corresponding to T_g on a flat surface. The ratio, p_g/p_o, is called the supersaturation ratio. If T_{Sat} is the saturation temperature corresponding to p_g on a flat surface and $p_l > p_g$, as shown

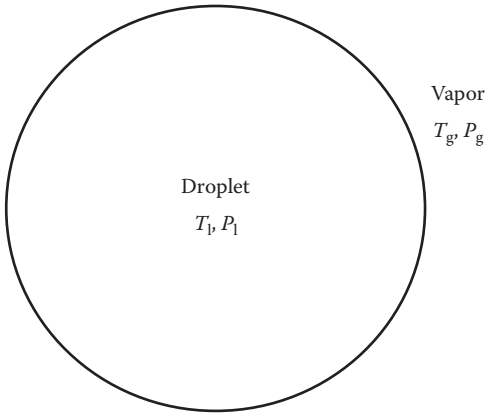

Figure 9.1

Schematic of a droplet embryo in a quiescent vapor environment.

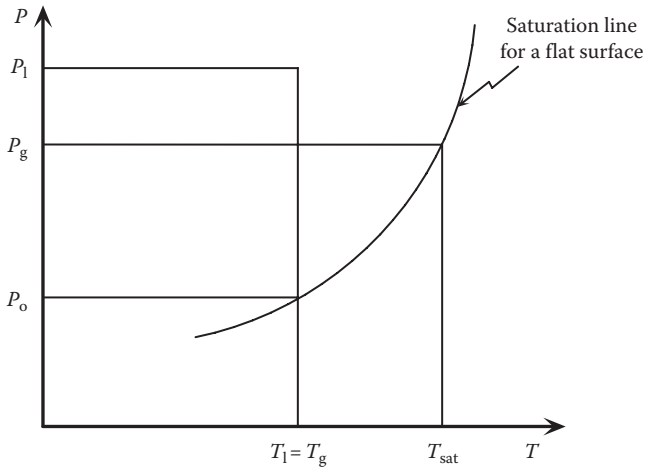

Figure 9.2

Pressure–temperature relationships at saturation.

in Figure 9.2, it is clear that the vapor phase is supersaturated and subcooled because of $p_l > p_g$ and $T_{Sat} > T_g$. With the use of the Clausius–Clapeyron equation, it can be shown that

$$T_{Sat} - T_g \approx \frac{2T_{sat}\sigma v_l}{h_{fg}a^*} \tag{9.4}$$

This provides the degree of subcooling, and it is also called the Gibbs–Thompson condition. As illustrated in Figure 9.3, the initial growth of a droplet embryo is driven by the subcooling condition indicated by Equation 9.4. As the growth continues, the droplet gets larger and the degree of subcooling decreases, which causes the growth rate to decrease.

In an analytical study, Lai (1999) found that the droplet growth is associated with three timescales. The first and second timescales, which are generally small, describe, respectively, the transient temperature distributions of the vapor phase and the droplet phase. The largest timescale controls the droplet growth process. For the case of a large Stefan number, $C_{p,v}(T_{Sat} - T_g)/h_{fg}$, the subcooling effect is dominating, which results in a faster droplet growth. The Gibbs–Thompson effect actually suppresses the droplet growth, and its effectiveness is diminished as time progresses. If the density difference between the liquid and the vapor phases becomes larger, the induced convection effect becomes more relevant.

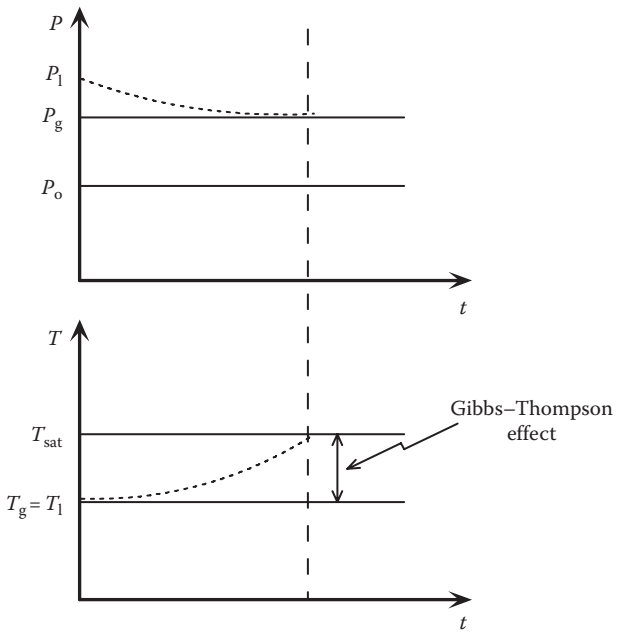

Figure 9.3

Thermodynamics of droplet initial growth.

Oswatitsch (1942) suggested a droplet growth equation for the rate of change of droplet radius with time, which is based on the kinetic theory of gases for droplets smaller than 2 μm:

$$\frac{\mathrm{d}R(t)}{\mathrm{d}t} = \frac{3p_0}{8h_{\mathrm{fg}}\rho_{\mathrm{l}}}\sqrt{\left(\frac{3R_{\mathrm{u}}}{T_{\mathrm{g}}M}\right)\left(T_{\mathrm{Sat}} - T_{\mathrm{g}}\right)} \tag{9.5}$$

For larger droplet growth in the continuum regime, Ford and Lekic (1973) derived an equation for the droplet radius growth rate using conduction and convection heat transfer theories:

$$\frac{\mathrm{d}R(t)}{\mathrm{d}t} = \pi^2 \frac{\alpha\eta}{D_{\mathrm{i}}} \frac{\exp(-\pi^2 Fo)}{[1-\exp(-\pi^2 Fo]^{1/2}} \tag{9.6}$$

where

$$\eta = \left[1 + \frac{C_{\mathrm{p,l}}\left(T_{\mathrm{Sat}} - T_{\mathrm{i}}\right)}{h_{\mathrm{fg}}}\right] - 1 \tag{9.7}$$

and $Fo = 4\alpha_l t/D_{\mathrm{i}}^2$ is the Fourier number, α_{l} the liquid thermal diffusivity, T_{i} the droplet initial temperature, and D_{i} the droplet initial diameter.

9.1.2 Heterogeneous Nucleation

When the nucleation takes place on entrained particulate matter in a vapor environment or on a cold solid surface, the process is called heterogeneous nucleation. There are basically two forms of heterogeneous condensation: dropwise and filmwise condensation. Dropwise condensation usually occurs when the condensate does not wet the surface and, therefore, instead of spreading into a thin film, it takes the shape of droplets. Sometimes, dropwise condensation is just a precursor to film condensation. Filmwise condensation prevails generally on wettable surfaces where a stable condensate removal mechanism is provided. It is well known that dropwise condensation is more efficient in heat transfer than its counterpart of filmwise condensation. According to Rose (2002) in his review of research work on the dropwise condensation,

the detailed mechanism of transition is still not fully understood. Although it is desirable to promote dropwise condensation in order to enhance heat transfer, promoting lasting dropwise condensation under industry conditions remains to be solved despite considerable effort since the early 1990s. More discussions on promoting dropwise condensation are given in Section 9.7.2.

9.2 Condensation on Flat Surfaces

9.2.1 Dropwise Condensation

As stated earlier, dropwise condensation occurs on surfaces that are hard to wet. Usually, this type of surface is associated with high free energy. Droplet embryos first form as a result of nucleation and then these embryos start to grow, which promotes coalescence among small droplets to form larger ones. Then these larger drops are removed by external forces such as gravity or shear. Therefore, from an individual droplet point of view, the process is highly transient and, in general, a cyclic process from one droplet generation to the next. For example, on a cold beer can, when condensed droplets reach sizes that are large enough, gravity force would overcome the surface tension such that droplets would be removed by sweeping down and leave a freshly wiped path for the next generation of droplets to nucleate to start a new cycle.

The transport mechanisms that govern the nucleation, two-phase flow, and heat transfer in dropwise condensation are still in the developmental stage. There are many controversial issues that need to be clarified in the future. Up to this point, there are two basic theoretical models: nucleation theory and film-rupture theory.

The nucleation theory was first introduced by Eucken (1937) and later further developed by Umur and Griffith (1965), Graham and Griffith (1973), Tanaka (1975), and Rose (1988). According to the nucleation theory, the dropwise condensation process starts with very thin liquid film layer and then it breaks up into droplets. These droplets subsequently grow by condensing vapor on their surfaces with the latent heat transported to the surface by conduction. Heat flux is maximum at the vapor–liquid–solid contact line. Following this, droplet–droplet interaction and coalescence produce larger droplets, but the remainder of the surface stays dry.

The film-rupture theory was introduced first by Jakob (1936) and further developed by Welch and Westwater (1961), Silver (1964), and Sugawara and Katsuta (1966). The film-rupture theory claims that vapor condenses on a cold surface and forms microscale thin liquid films. When the film reaches a critical thickness, it would then rupture to form microdroplets.

It is almost impossible to develop a general correlation for the dropwise condensation because of the strong surface property dependence and the condensate removal mechanisms. For the development of a heat transfer correlation, the heat flux is given by

$$q = h\Delta T \tag{9.8}$$

where q is the heat flux in kW/m^2 and ΔT the temperature difference between the vapor and the condenser surface in degrees K. For steam and ethylene glycol, Peterson and Westwater (1966) proposed

$$h = Nu\rho_l h_{fg} k_l (T_{Sat} - T_W)/2\sigma T_{Sat} \tag{9.9}$$

where

$$Nu = 1.46\times 10^{-6} Re_l^{-1.63} \prod_k^{1.16} Pr_l^{0.5} \tag{9.10}$$

in which

$$Re_l = \frac{k_l \left(T_{Sat} - T_w\right)}{\mu_l h_{fg}} \tag{9.11}$$

and

$$\prod_k = -\frac{2\sigma T_{Sat}}{\mu_l^2 h_{fg}} \left(\frac{\partial \sigma}{\partial T}\right) \tag{9.12}$$

with the following limited range:

$$1.75 \le Pr_l \le 23.6$$
$$2\times10^{-4} \le Re_l \le 3\times10^{-2}$$
$$7.8\times10^{-4} \le \Pi_k \le 2.65\times10^{-2}$$

This correlation was recommended only for the fluids with which it was developed. Rose (1999) indicated that because of improvements in experimental quality, recent results from various countries are found to be in reasonably good agreement. For dropwise condensation of pure steam, Rose (1999) suggested the following general correlation that also takes the system pressure into consideration:

$$\dot{q} = T_v^{0.8}\left(5\Delta T + 0.3\left(\Delta T\right)^2\right) \tag{9.13}$$

where

$\dot{q}$ is the heat flux in kW/m^2

T_v is the vapor temperature in Celsius

ΔT is the temperature difference between the vapor and the condenser surface in degrees K

Among the influences on the dropwise condensation heat transfer, there is a controversy in the dependence of the thermal conductivity of the condensing surface. While some studies indicated that thermal conductivity has no influence on the condensation heat transfer (Aksan and Rose, 1973, Rose, 1978), it appears that more studies showed that the dropwise condensation has a strong dependence on the surface thermal conductivity (Tanner et al., 1968, Wilkins and Bromley, 1973, Hannemann and Mikic, 1976). More research in this subject will lead to more fundamental understanding of this important heat transfer process.

9.2.2 Film Condensation

9.2.2.1 Laminar Film

For laminar film condensation on a vertical flat surface, a simplified model was first introduced by Nusselt (1916). The model is based on the following assumptions:

1. The liquid film is laminar and 2D.
2. Thermal properties of the film are constant.
3. Subcooling of the film is negligible.
4. Momentum changes through the film are unimportant.
5. The bulk of the vapor is stagnant, saturated, and free of noncondensables.
6. Interfacial shear is negligible.
7. The heat transfer in the liquid film is dominated by conduction.

The local condensation heat transfer coefficient is defined as follows:

$$h_x = \frac{\dot{q}_x}{\left(T_{sat} - T_w\right)} \tag{9.14}$$

where

$\dot{q}_x$ is the local heat flux

$T_{Sat} - T_w$ is the degree of subcooling. The average condensation heat transfer coefficient over a plate of length L is given as

$$\bar{h}_L = \frac{\bar{\dot{q}}_L}{\left(T_{sat} - T_w\right)} \tag{9.15}$$

where $\bar{q}_L$ is the average heat flux over the entire plate. The local and average heat transfer coefficients for a plate of length L are given by Nusselt (1916) as

$$h_x = \left[\frac{k_l^3 h_{fg} \rho_l (\rho_l - \rho_v) g \sin\theta}{4(T_{Sat} - T_w)\mu_l x} \right]^{1/4} \tag{9.16}$$

$$\bar{h}_L = 0.943 \left[\frac{k_l^3 h_{fg} \rho_l (\rho_l - \rho_v) g \sin\theta}{(T_{Sat} - T_w)\mu_l L} \right]^{1/4} \tag{9.17}$$

Rohsenow (1956) suggested an effective latent heat of condensation to compensate for the liquid subcooling:

$$h'_{fg} = h_{fg} \left[1 + 0.683 \left(\frac{c_{p,l}(T_{Sat} - T_w)}{h_{fg}} \right) \right] \tag{9.18}$$

Sadasivan and Lienhard (1987) introduced a different effective latent heat of condensation that is also a function of the Prandtl number:

$$h'_{fg} = h_{fg} \left[1 + (0.683 - 0.228/Pr_L) \left(\frac{c_{p,l}(T_{Sat} - T_w)}{h_{fg}} \right) \right] \tag{9.19}$$

This is limited for $Pr_L > 0.6$. Many researchers have investigated the validity of the constant thermal property assumption. One acceptable method of including the variation of thermal properties in the liquid film is to use a reference temperature T_r to evaluate the thermal properties. This reference temperature is defined as

$$T_r = T_w + F(T_{Sat} - T_w), \quad 0.25 < F < 0.31 \tag{9.20}$$

One of the assumptions in the Nusselt model allows the neglect of the interfacial shear between the liquid film and the ambient vapor; Koh et al. (1961) investigated this assumption further and found that the interfacial shear is indeed very small for most gases and liquids ($Pr \geq 1$). For condensation of liquid metals, they discovered that the inclusion of the interfacial shear does cause a substantial reduction in heat transfer and suggested the following correction equation:

$$\frac{h}{h_{Nu}} = \left(\frac{1 + 0.68A + 0.02AB}{1 + 0.85B - 0.15AB} \right) \tag{9.21}$$

where

$$\begin{aligned} A &= [c_{p,l}(T_{Sat} - T_w)/h_{fg}] \\ B &= [k_l(T_{Sat} - T_w)/\mu_l h_{fg}] \end{aligned} \tag{9.22}$$

Also, h_{Nu} is the heat transfer coefficient based on the Nusselt model. For laminar film condensation on geometries other than the vertical flat plate, Dhir and Lienhard (1971) introduced the concept of effective gravity for an arbitrary axisymmetric body. Using the coordinates defined in Figure 9.4, Dhir and Lienhard (1971) showed that the local film thickness may be determined by

$$\delta(x) = \left(\frac{4\mu_l k_l (T_{Sat} - T_w) x}{\rho_l (\rho_l - \rho_v) h_{fg} g_{eff}} \right)^{1/4} \tag{9.23}$$

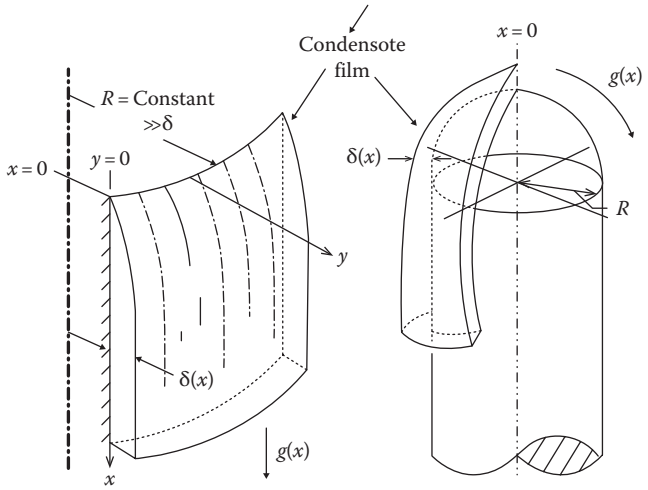

Figure 9.4

Coordinate system for effective gravity model.

where g_{eff} is the effective gravity defined as

$$g_{\text{eff}} = \frac{x\left(gR\right)^{4/3}}{\int_0^x g^{1/3}R^{4/3}\mathrm{d}x} \tag{9.24}$$

The local Nusselt number is therefore given as

$$Nu = \left(\frac{g_{\text{eff}}\rho_1\left(\rho_1-\rho_v\right)h'_{\text{fg}}x^3}{4\mu_1 k_1\left(T_{\text{Sat}}-T_w\right)}\right)^{1/4} \tag{9.25}$$

For example, the average Nusselt number for condensation on a sphere with diameter, D, is equal to

$$\overline{Nu}_D = 0.785\left(\frac{gD^3}{A}\right)^{1/4} \tag{9.26}$$

where

$$A = \frac{\mu_1 k_1\left(T_{\text{Sat}}-T_w\right)}{\rho_1\left(\rho_1-\rho_v\right)h'_{\text{fg}}} \tag{9.27}$$

9.2.2.2 Turbulent Film

As the film thickness increases, the smooth vapor–liquid interface gradually becomes wavy, but the bulk of the liquid film remains laminar. As the thickness increases further, the liquid film eventually becomes turbulent. In order to gage quantitatively the three different regimes, a Reynolds number must be defined first. The local Reynolds number that characterizes the liquid film flow is based on the mean liquid velocity and the hydrodynamic diameter of the 2D liquid film, which is equal to 4δ, where δ is the film thickness. If the liquid film local mass flow rate is represented by the Nusselt model, then the Reynolds number is in the following form:

$$Re_{D_h} = \frac{4g\rho_1\left(\rho_1-\rho_v\right)\delta^3}{3\mu_1^2} \tag{9.28}$$

The three liquid film flow regimes are characterized by the following:

1. $Re_{D_h} \le 30$ (laminar film with smooth interface). In this regime, the Nusselt solution mentioned earlier can be applied.
2. $30 \le Re_{D_h} \le 1800$ (laminar film with wavy interface). Kutateladze (1963) proposed the following equation for this regime:

$$\frac{\bar{h}_L \left(v_l^2/g\right)^{1/3}}{k_l} = \frac{Re_{D_h}}{1.08 Re_{D_h}^{1.22} - 5.2} \tag{9.29}$$

3. $1800 \le Re_{D_h}$ (turbulent liquid film). For the turbulent film, Labuntsov (1957) recommended

$$\frac{\bar{h}_L \left(v_l^2/g\right)^{1/3}}{k_l} = \frac{Re_{D_h}}{58 Pr_l^{-0.5}\left(Re_{D_h}^{0.75} - 263\right) + 8750} \tag{9.30}$$

9.3 Condensation in and on the Tubes

9.3.1 Condensation in a Tube

Condensation in circular tubes is strongly affected by the vapor inlet velocity and the orientation of the tube. For vertical tubes, the flow pattern is in reverse order as that of boiling. As shown in Figure 9.5, the annular flow pattern generally prevails, which is followed by slug flow and then bubbly flow. If the vapor flows upward against the gravity (countercurrent flow), the annular liquid film flowing downward would experience substantial interfacial shear, whereas for cocurrent flows, the interfacial shear is negligible as a result of the large density difference between the vapor and the liquid phases. For horizontal tubes, the annular flow would be maintained if the inlet vapor velocity is relatively high; otherwise, the stratified annular flow would take place because the gravity would tend to drain the liquid condensate in the direction perpendicular to the vapor flow, which would thicken the liquid film along the gravity direction.

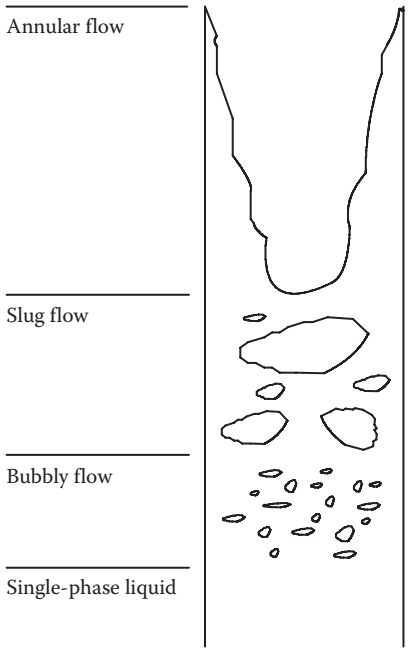

Figure 9.5
Schematic of condensing flow regimes in a vertical tube.

Based on experimental results, Jaster and Kosky (1976) proposed the following criteria for the transition from the initial annular flow to the stratified flow regime:

$$F > 29 \quad \text{annular flow}$$

$$29 > F > 5 \quad \text{transition flow}$$

$$F < 5 \quad \text{stratified flow}$$

The stress ratio, F, is defined as $\tau_w/\rho_l g\delta$, where δ is the liquid film thickness. Jaster and Kosky (1976) also recommended the following for the Nusselt number in the transition flow regime:

$$Nu_{tr} = Nu_{an} + \frac{F-29}{24}\left(Nu_{an} - Nu_{Str}\right) \tag{9.31}$$

The error associated with this equation is of the same order of magnitude as those methods established for annular and stratified flows.

9.3.1.1 Stratified Annular Flow in Horizontal Tubes

For horizontal tubes, when the inlet vapor Reynolds number is <35,000, which corresponds to the mass flow flux of 400 kg/m^2 s for a 1 cm tube, the liquid film is affected by the gravity and the stratified annular flow pattern would be present. Because of the effects of gravity, Chato (1962) proposed a correlation based on the Nusselt film condensation model:

$$h = 0.728K_c\left[\frac{g\rho_l\left(\rho_l-\rho_v\right)k_l^3 h'_{fg}}{\mu_l\left(T_{Sat}-T_w\right)D}\right]^{1/4} \tag{9.32}$$

where h'_{fg} is the effective latent heat of condensation to include the subcooling in the liquid film and is given by

$$h'_{fg} = h_{fg}\left[1+0.68\frac{c_{p,l}\left(T_{Sat}-T_w\right)}{h_{fg}}\right] \tag{9.33}$$

It is noted that Equation 9.32 is identical to the classical Nusselt result for laminar film condensation on a vertical flat plate with height D if K_c is set to 1.295. The physical meaning of K_c is that it is a provision to account for the accumulation of condensate on the bottom of the tube that changes the void fraction. Chato (1962) suggested a value of 0.76 based on the experimental data of R-113.

9.3.1.2 Annular Flow in Horizontal Tubes

As mentioned earlier, when the inlet vapor Reynolds number is >30,000, the annular flow pattern would be maintained along most of the tube length. Near the end of relatively long tubes, the vapor-phase Reynolds number drops substantially such that gravity effects become a factor. Under this situation, the stratified annular flow model mentioned earlier would then describe flow and heat transfer more appropriately.

Heat transfer correlations for condensation in a horizontal tube with an annular flow pattern were first addressed by Ananiev et al. (1961) for single-component pure vapor and smooth tubes. Based on the analogy between the momentum and the heat transport, they proposed that the heat transfer coefficient for the two-phase condensing flow, h, can be correlated with the liquid single-phase forced convection heat transfer coefficient, h_l, as follows:

$$h = h_l\sqrt{\frac{\rho_l}{\rho_m}} \tag{9.34}$$

where the equivalent mixture density, ρ_m, is defined as

$$\frac{1}{\rho_m} = \left(\frac{1}{\rho_l}\right)(1-x) + \left(\frac{1}{\rho_v}\right)x \tag{9.35}$$

and h_l is evaluated based on a correlation for convective-forced convection of single-phase liquid in a circular tube, for example, the Dittus–Boelter-type correlations. Based on the experiments, Boyko and Kruzhilin (1967) found

$$h_l = C\,Re_l^{0.8} Pr_f^{0.43} \left(\frac{Pr_f}{Pr_w}\right)^{0.25} \left(\frac{K_l}{D}\right) \tag{9.36}$$

where $C = 0.024$ and 0.032 for steam condensing on carbon steel tubes and copper tubes, respectively, and Pr_f and Pr_w are the Prandtl numbers evaluated at the stream core and wall temperatures, respectively.

Cavallini and Zecchin (1974) offered the following correlation for saturated vapor inside tubes based on the Reynolds analogy concept and a multiple linear regression analysis:

$$Nu = 0.0344 Re_l^{0.83} \left[1 + x\left(\left(\rho_l/\rho_v\right)^{0.5} - 1\right)\right]^{0.82} Pr_l^{0.35} \tag{9.37}$$

This is suggested for the dimensionless groups and thermal property ratios in the ranges listed as follows:

$$10 < \rho_l/\rho_v < 2{,}000, \quad 0.1 < X < 0.9, \quad 0.01 < \mu_v/\mu_l < 0.1$$

$$15 < Fr = \frac{G\rho_v}{\sqrt{gD}} < 4{,}000, \quad 5{,}000 < Re_f = \frac{GD}{\mu_l} < 5{,}000{,}000$$

$$0.8 < Pr_l < 20, \quad 0.01 < Ja = c_{p,l}\left(T_v - T_W\right)/h_{fg} < 0.2$$

where

G is the total stream mass flux in kg/m^2 s

x is the vapor quality

9.3.1.3 Annular Flow in Vertical Tubes

Chen et al. (1987) divided this problem into two categories: zero shear (cocurrent flow) and high interfacial shear (countercurrent flow) processes. For countercurrent vapor flow, the interfacial shear retards the condensate flow and, therefore, decreases the heat transfer by thickening the liquid film. On the other hand, the cocurrent vapor flow enhances the heat transfer. They suggested the following:

For cocurrent flow,

$$Nu_o = \left[(Nu_{lw})^{n1} + (N\mu_l)^{n1}\right]^{1/n1} \tag{9.38}$$

For countercurrent flow,

$$Nu_x = \left[(Nu_o)^{n2} + (Nu_{hs})^{n2}\right]^{1/n2} \tag{9.39}$$

where all the Nusselt numbers are defined as $(h/k_l)/(v_l^2/g)^{1/3}$. Chen et al. (1987) found that $n1 = 6$ and $n2 = 2$ resulted in the best fit to the reported data. For the laminar wavy flow, Nu_{lw}, Chen et al. (1987) recommended the Chun and Seban (1971) correlation:

$$Nu_{lw} = 0.823 Re_x^{-0.22} \tag{9.40}$$

$$Re_x = \frac{G(1-x)D}{\mu_l} \tag{9.41}$$

For the turbulent film flow, Nu_t, Chen et al. (1987) recommended the following correlation:

$$Nu_t = 0.00402 Re_x^{0.4} Pr_l^{0.65} \tag{9.42}$$

Finally, for the Nusselt numbers for high shear flows, Nu_{hs}, Chen et al. (1987) proposed the Soliman et al. (1968) correlation:

$$Nu_{hs} = 0.036 Pr_l^{0.65} \bar{\tau}_i^{1/2} \tag{9.43}$$

$$\bar{\tau}_i = \frac{\tau_i}{\rho_l (g\nu_l)^{2/3}} \tag{9.44}$$

Chen et al. (1987) proposed the following general equation for the local heat transfer for a vertical cocurrent annular flow:

$$Nu_x = \left[\left(0.31 Re_x^{-1.32} + \frac{Re_x^{2.4} Pr_l^{3.9}}{2.37 \times 10^{14}} \right)^{1/3} + \frac{Pr_l^{1.3} A}{771.6} \left(Re_T - Re_x \right)^{1.4} \right]^{1/2} \tag{9.45}$$

For the case of annular flow in a horizontal tube, this simplifies to

$$Nu_x = 0.036 Pr_l^{0.65} A^{0.5} \left(Re_T - Re_x \right)^{0.7} Re_x^{0.2} \tag{9.46}$$

$$A = \frac{0.252 \mu_l^{1.177} \mu_v^{0.156}}{D^2 g^{2/3} \rho_l^{0.553} \rho_v^{0.78}} \tag{9.47}$$

where Re_T is the film Reynolds number when the total condensation takes place. For the countercurrent flow, the recommended local Nusselt number is

$$Nu_x = \left[\left(0.31 Re_x^{-1.32} + \frac{Re_x^{2.4} Pr_l^{3.9}}{2.37 \times 10^{14}} \right) - \frac{C Pr_l^{1.3}}{771.6} Re_x^{1.8} \right]^{1/2} \tag{9.48}$$

$$C = \frac{0.023 \mu_l^{1.133} \mu_v^{0.2}}{D^2 g^{2/3} \rho_v \rho_l^{0.333}} \tag{9.49}$$

The general correlations by Chen et al. (1987) can be readily incorporated into a condensation model once the interfacial shear is known.

Shah (1989) proposed an alternative formula based on experimental data reported in the literature that includes working fluids of water, refrigerants (R-11, R-12, R-22, and R-113), and organic compounds (methanol, ethanol, benzene, toluene, and trichloroethylene) for vertical, horizontal, and inclined tubes with diameters ranging from 7 to 40 mm:

$$Nu = 0.023 Re_l^{0.8} Pr_l^{0.4} \left[(1-x)^{0.8} + \frac{3.8 x^{0.76} (1-x)^{0.04}}{\left(p_{Sat}/p_c \right)^{0.38}} \right] \tag{9.50}$$

The Shah correlation is valid for the following parameter ranges: $0.002 < p_{Sat}/p_c < 0.44$, $100 < Re_l < 63{,}000$, $1 < Pr_l < 13$, $21°C < T_{Sat} < 310°C$, $3 \text{ m/s} < u_v < 300 \text{ m/s}$, $0 < x < 1$, and $39{,}000 < \dot{m}$ (kg/m^2 h) $< 758{,}000$. The mean deviation of Shah's correlation with 474 data points used in the study is 15.4%.

9.3.2 Mathematical Modeling of Two-Phase Flow and Heat Transfer in Tubes

9.3.2.1 Laminar Film Condensation in a Vertical Tube with Upward Vapor Flow

The goal of the mathematical model is to predict the liquid boundary layer thickness along the tube because it is directly related to the condensation rate. This is accomplished by first addressing the liquid fluid dynamics, then the vapor flow, and finally accounting for the interaction between each along the tube. The following analytical model is based on Seban and Hodgson (1982). All of the Nusselt assumptions, for the vertical flat plate, are applied except that the flow here is an axisymmetric 2D flow that results in an annular flow pattern. Seban and Hodgson (1982) further assumed that the tube radius is relatively large, so the curvature effects were neglected. A schematic representation of the coordinates is shown in Figure 9.6.

9.3.2.1.1 Liquid Layer The momentum equation is

$$\mu_l \frac{d^2u}{dy^2} - \frac{dp}{dx} - \rho_l g = 0 \tag{9.51}$$

After rearrangement,

$$\frac{\mu_l}{\rho_l g}\frac{d^2u}{dy^2} = \left(1 + \frac{1}{\rho_l g}\frac{dp}{dx}\right) = G_p \tag{9.52}$$

It is noted that G_p is a constant. After integration, one obtains the velocity profile as

$$u(y) = \frac{G_p \rho_l g}{\mu_l}\left(\frac{y^2}{2} - \delta(x)y\right) + \frac{\tau_i}{\mu_l}y \tag{9.53}$$

where

τ_i is the interfacial shear stress
δ is the liquid layer thickness

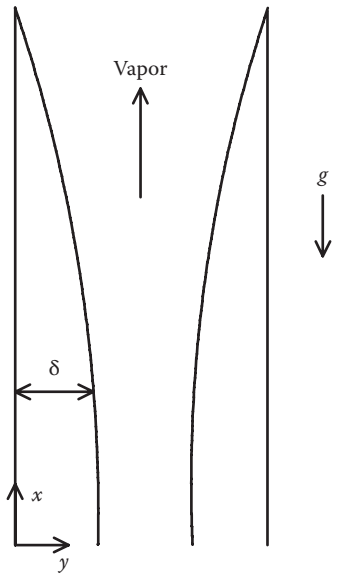

Figure 9.6

Coordinate system for condensation with an upward vapor flow.

This is nondimensionalized as

$$\bar{\delta} = \delta\left(\frac{g}{\nu_l^2}\right)^{1/3}, \quad \bar{y} = y\left(\frac{g}{\nu_l^2}\right)^{1/3}, \quad \bar{u} = \frac{u}{(\nu_l g)^{1/3}} \tag{9.54}$$

The dimensionless velocity profile is therefore given as

$$\bar{u} = G_p\left(\frac{\bar{y}^2}{2} - \bar{\delta}\bar{y}\right) + \frac{\tau_i}{\rho_l g}\left(\frac{g}{\nu_l^2}\right)^{1/3}\bar{y} \tag{9.55}$$

The local Reynolds number is defined by neglecting the pressure drop term, which is $G_p = 1$, as follows:

$$\begin{aligned} Re_l &= \frac{1}{\nu_l}\int_0^{\delta} u\,dy \\ &= N_l\frac{\bar{\delta}^2}{3} - \frac{\bar{\delta}^3}{3} \end{aligned} \tag{9.56}$$

$$N_i = \frac{\tau_i}{\rho_l g}\left(\frac{g}{\nu_l^2}\right)^{1/3} \tag{9.57}$$

The local liquid mass flow rate per unit film width is

$$\Gamma = \rho_l\int_0^{\delta} u\,dy \tag{9.58}$$

The condensation mass flux at a local downstream position, $\dot{m}_c(x)$, is

$$\dot{m}_c = \frac{d(\Gamma)}{dx} \tag{9.59}$$

which is expressed as

$$\dot{m}_c = \mu_l\frac{d(\Gamma/\mu_l)}{dx} = \mu_l\frac{N_2}{\delta} \tag{9.60}$$

for later use. From an energy balance at the vapor–liquid interface, one has

$$\dot{m}_c h_{fg} = \frac{k_l(T_{sat} - T_w)}{\delta} \tag{9.61}$$

Equating Equations 9.60 and 9.61, one has

$$N_2 = \frac{c_{p,l}(T_{Sat} - T_w)}{h_{fg}}\left[\frac{k_l}{\mu_l c_{p,l}}\right] \tag{9.62}$$

9.3.2.1.2 Vapor Layer The detailed velocity profile of the vapor layer is not required to solve the problem if an appropriate friction coefficient is used. First evaluate the friction coefficient of the vapor.

If the vapor were occupying the tube completely in a single-phase flow, the friction coefficient for a fully developed flow would be

$$\frac{c_f}{2} = \begin{cases} \dfrac{8}{Re_V} & \text{for } Re_V < 2000 \quad (9.63) \\ \dfrac{0.04}{(Re_V)^{0.25}} & \text{for } Re_V > 4000 \quad (9.64) \end{cases}$$

Then, with interpolation, one has

$$\frac{c_f}{2} = \frac{(Re_V)0.33}{3050} \quad \text{for } 2000 \le Re_V \le 4000 \tag{9.65}$$

where

$Re_v = (4\dot{M}_V/\pi D\mu_V)$ is the Reynolds number for the single-phase vapor
D is the diameter of the tube
$\dot{M}_V$ is the total vapor mass flow rate

For condensation two-phase flow, the existence of the liquid layer must be accounted for. The vapor Reynolds number is modified as $Re_v = 4\dot{M}_V/\pi D'\mu_V$, where $D' = D - 2\delta$. For the turbulent vapor flow, the single-phase friction factors specified by the previous equations should be multiplied by a quantity that will then produce the effective friction factor $(c_f/2)_E$ to include the liquid layer effects:

$$\left(\frac{c_f}{2}\right)_E = \frac{c_f}{2}(1 + 1400F) \tag{9.66}$$

The value for F is related to F' and is defined as

$$F' = \frac{\sqrt{2}\left(\Gamma/\mu_l\right)^{1/2}}{Re_V^{0.9}}\left(\frac{\nu_V}{\nu_l}\right)\left(\frac{\rho_l}{\rho_V}\right)^{1/2} \tag{9.67}$$

When the liquid flow is laminar, $F = F'$. For low vapor velocities, the factor F must be corrected further since the vapor flow is no longer fully turbulent:

$$\begin{aligned} F &= F'\left[1 - \exp\left(\frac{-\tau_i}{\rho_l g \delta}\right)\right] \\ &= F'\left[1 - \exp\left(\frac{-N_1}{\bar{\delta}}\right)\right] \end{aligned} \tag{9.68}$$

$$F = 0 \quad \text{for } Re_v < 2000 \tag{9.69}$$

The interfacial shear, τ_i, can now be linked to the vapor friction coefficient. The condensation causes a mass flux into the liquid layer, and the interfacial shear stress is affected. The shear stress is

$$\tau_i = \left(\frac{c_f}{2}\right)_E \rho\left(u_V - u_{l\delta}\right)^2 + \dot{m}_c\left(u_V - u_{l\delta}\right) \tag{9.70}$$

where

u_V is the mean vapor velocity based on the total vapor mass flow rate
$u_{l\delta}$ is the liquid velocity at the edge of the liquid film, which can be obtained from Equation 9.55

Equation 9.70 can be nondimensionalized using Equations 9.54, 9.57, and 9.62:

$$N_1 = \left(\frac{c_f}{2}\right)_E \left(\frac{\rho_V}{\rho_l}\right)\left(\bar{u}_V - \bar{u}_{l,\delta}\right)^2 + \frac{N_2}{\bar{\delta}}\left(\bar{u}_V - \bar{u}_{l,\delta}\right) \tag{9.71}$$

If the body force on the vapor flow is neglected ($\rho_V = \rho_l$), Seban and Hodgson (1982) used the integral vapor momentum balance equation, in which the momentum flux term is approximated using u_v as the vapor velocity at the interface instead of $u_v - u_{l,\delta}$ and shows that

$$\frac{1}{\rho_l g}\frac{dp}{dx} = -\frac{4N_1}{\bar{D}'} - \left(\frac{\nu_V}{\nu_l}\right)^2\left(\frac{\rho_V}{\rho_l}\right)\frac{d}{dx}\left(\frac{4\dot{M}_V}{\pi D'\mu_V}\right) \tag{9.72}$$

In general, Seban and Hodgson (1982) concluded that the pressure drop term is negligibly small, which supports the earlier assumption that $G_P = 1$.

For the current case of upward vapor flow in a tube, based on heat and mass transfer coupling and applying Equation 9.60, the liquid layer has the following relationship:

$$\frac{d\left(\Gamma/\mu_l\right)}{d\bar{x}} = \frac{N_2}{\bar{\delta}} \tag{9.73}$$

By differentiating Equation 9.56 with respect to $\bar{\delta}$ and using Equation 9.58, one has

$$\frac{d\left(\Gamma/\mu_l\right)}{d\bar{\delta}} = \left(N_1 + \frac{\bar{\delta}}{2}\frac{dN_1}{d\bar{\delta}} - \bar{\delta}\right)\bar{\delta} \tag{9.74}$$

Combining Equation 9.73 with Equation 9.74, one obtains the governing equation for the liquid film thickness:

$$\frac{d\bar{\delta}}{d\bar{x}} = \frac{N_2}{\left(N_1 + \frac{\bar{\delta}}{2}\frac{dN_1}{d\bar{x}} - \bar{\delta}\right)\bar{\delta}^2} \tag{9.75}$$

The solution procedure is outlined as follows:

1. For a given vapor inlet mass flow rate, $\dot{M}_{V,0}$, at the pipe bottom edge indicated as the starting point of the x coordinate in Figure 9.6, the corresponding condensate flow rate per unit film width, Γ_0, at the same point can be obtained based on an overall mass balance for a steady condition, which means all the vapor is condensed, that is,

$$\Gamma_0 = \frac{\dot{M}_{V,0}}{\pi D} \tag{9.76}$$

   With $\dot{M}_{V,0}$ and Γ_0 known, Equations 9.56 and 9.71 are used to find the corresponding $N_{1,0}$ and $\bar{\delta}_0$ at the bottom edge through an iterative procedure.
2. The next step is to march upward using Equation 9.73. First, choose a small $\Delta\bar{x}$ and then find the condensate flow rate per unit film width, Γ_1, at this new location by using

$$\Gamma_1 = \mu_l\left(\frac{N_2}{\bar{\delta}}\right)\Delta\bar{x} + \Gamma_0 \tag{9.77}$$

3. The corresponding vapor mass flow at this new location is then calculated as

$$\dot{M}_{\mathrm{V},1} = \dot{M}_{\mathrm{V},0} - \pi D\left(\Gamma_0 - \Gamma_1\right) \tag{9.78}$$

Following the same procedure as given in Step 1, one can find $N_{1,1}$ and $\bar{\dot{\delta}}_1$ with known $\dot{M}_{\mathrm{V},1}$ and Γ_1.

4. Repeat Step 2 and march upward to another $\Delta\bar{x}$. Repeating Steps 1 to 3 until $\bar{\delta}$ reaches zero.

Seban and Hodgson (1982) made several sample calculations for specific vapor inlet conditions. They investigated both downward and upward liquid film flow cases. Some of these cases were for an inlet pressure of 900 psia and are related to the operating condition of an industrial steam generating unit. It was reported that for these cases, a complete condensation occurs within a very short height up the tube.

9.3.2.2 Turbulent Film Theory

For annular film flow to take place, the vapor velocity must be high. Therefore, the film is generally in the turbulent or, at least, nonlaminar state. The following is a summary of the theory. The basic assumptions are as follows:

1. The entrainment of vapor by the liquid film is neglected.
2. The film is thin with a smooth interface.
3. The inertia of the liquid film is small.

The schematic representation of the coordinate system is shown in Figure 9.7. From time-averaged turbulence modeling, the shear stress is defined as

$$\tau\left(y\right) = \rho_{\mathrm{l}}\left(\nu_{\mathrm{l}} + \varepsilon_{\mathrm{m}}\right)\frac{\mathrm{d}\bar{u}}{\mathrm{d}y} \tag{9.79}$$

where ε_{m} is the eddy diffusivity for momentum transport. The heat flux is governed by the following equation:

$$\dot{q}\left(y\right) = -\rho_{\mathrm{l}} c_{\mathrm{p,l}}\left(\alpha_l + \varepsilon_{\mathrm{h}}\right)\frac{\mathrm{d}\bar{T}}{\mathrm{d}y} \tag{9.80}$$

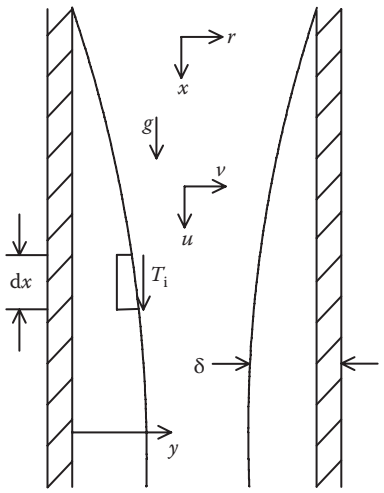

Figure 9.7

Schematic and coordinate system for turbulent film condensation in a tube.

where ε_h is the eddy diffusivity for thermal transport. Using the conventional nondimensional scheme, one has

$$\overline{u}^+ = \frac{u}{\sqrt{\tau_w/\rho_l}}, \quad \overline{u}^+ = \frac{y\sqrt{\tau_w/\rho_l}}{\nu_l}, \quad \overline{y}^+ = \frac{\rho_l c_{p,l}\left(T_w - \overline{T}\right)}{\dot{q}_w}\sqrt{\frac{\tau_w}{\rho_l}}, \tag{9.81}$$

The dimensionless shear stress and heat flux equations become

$$\left(1+\frac{\varepsilon_m}{\nu_l}\right)\frac{d\overline{u}^+}{dy^+} = 1, \quad \frac{\dot{q}}{\dot{q}_w} = \left(\frac{1}{Pr_l}+\frac{\varepsilon_h}{\nu_l}\right)\frac{d\overline{T}^+}{dy^+} \tag{9.82}$$

For the portion where the film is very thin, it is assumed that $\varepsilon_m/\nu_l = 1$, with a no-slip condition at the wall. This leads to the velocity profile of $\overline{u}^+ = y^+$ in the liquid film. On the basis of a mass conservation of the liquid film flow, the following dimensionless equation is obtained as

$$\frac{GD(1-x)}{4\mu_l} = \int_0^{\delta^+} \overline{u}^+ dy^+ \tag{9.83}$$

Using the velocity profile, the dimensionless film thickness is found to be

$$\delta^+ = \sqrt{\frac{1}{2}}Re_{D,l}^{1/2}, dRe_{D,l} = \frac{GD(1-x)}{\mu_l} \tag{9.84}$$

The heat flux is constant across the liquid film, so

$$\frac{\partial}{\partial y}\left[\rho_l c_{p,l}\left(\alpha_l + \varepsilon_h\right)\frac{\partial T}{\partial y}\right] = 0 \tag{9.85}$$

Based on Equation 9.81, the heat flux is therefore constant in the liquid film. After integration and using the boundary conditions, one has

$$\frac{T_{sat} - T_w}{\dot{q}_w/\left(\rho_l c_{p,l}\alpha_l\right)} = \int_0^{\delta} \frac{1}{1 + Pr_l\varepsilon_h/\nu_l} dy \tag{9.86}$$

Following rearrangement, Equation 9.82 becomes

$$\frac{k_l\sqrt{\tau_w/\rho_l}}{h\nu_l} = \int_0^{\delta^+} \frac{1}{1+\left(Pr_l/Pr_t\right)\left(\varepsilon_m/\nu_l\right)} dy^+ \tag{9.87}$$

where $h = \dot{q}_w/\left(T_{sat} - T_w\right)$. Next, the von Karman's mixing length model is adopted for ε_m:

$$\varepsilon_m = l^2\left|\frac{du}{dy}\right|, \quad l = \kappa y \tag{9.88}$$

$$\frac{\varepsilon_m}{\nu_l} = \kappa^2(y^+)^2 \tag{9.89}$$

For the turbulence, the model proposed by Carey (1992) has been used. Carey adopted similar concepts from the general approach for liquid film turbulence:

$$\frac{\varepsilon_m}{\nu_l Pr_t} = \begin{cases} \kappa^2\left(y^+\right)^2/Pr_t & \text{for } 0 \le y^+ \le \delta^+/2 \\ \kappa^2\left(\delta^+ - y^+\right)^2/Pr_t & \text{for } \delta^+/2 \le y^+ \le \delta^+ \end{cases} \tag{9.90}$$

The equation for the $\delta^+/2 \le y^+ \le \delta^+$ region is based on the experimental finding that the eddy diffusivity should approach zero as $(\delta - y)^2$. With the previous information, it may be shown that

$$h = \frac{\kappa k_l \sqrt{\tau_w/\rho_l}}{2\nu_l I}\sqrt{\frac{Pr_l}{Pr_t}} \tag{9.91}$$

where

$$\begin{aligned} I &= \tan^{-1}\left(\sqrt{Pr_l / Pr_t}\,\kappa\delta^+/2\right) \\ &\approx \pi/2 \text{ for large } Pr_l \end{aligned} \tag{9.92}$$

Using the commonly accepted values of $\kappa = 0.4$ and $Pr_t = 0.9$, one has

$$h = 0.134k\sqrt{Pr_l \tau_w/\rho_l/\nu_l} \tag{9.93}$$

The wall shear stress, τ_w, is determined from a force balance:

$$\pi D\tau_w = -\left(\frac{dp}{dx}\right)_f \pi D^2/4 \tag{9.94}$$

The pressure drop due to friction at the wall for two-phase pipe flows is (see Chapter 1)

$$-\left(\frac{dp}{dx}\right)_f = \phi_f^2 \frac{2f_l G^2(1-x)^2}{D\rho_l} \tag{9.95}$$

where

$$\begin{aligned} &\phi_f = \left(1 + \frac{20}{\chi_{tt}} + \frac{1}{\chi_{tt}^2}\right)^{1/2}, \quad \chi_{tt} = \left(\frac{\rho_v}{\rho_l}\right)^{1/2}\left(\frac{\mu_l}{\mu_V}\right)^{0.1}\left(\frac{1-x}{x}\right)^{0.9}, \\ &f_l = 0.05\left(\frac{G(1-x)D}{\mu_l}\right)^{-0.2} \end{aligned} \tag{9.96}$$

With the wall shear stress known, the Nusselt number may be written as

$$\begin{aligned} Nu &= \frac{hD}{k_l} \\ &= 0.134\phi_f\sqrt{f_l}\left[\frac{G(1-x)D}{\mu_l}\right]\sqrt{Pr_l} \end{aligned} \tag{9.97}$$

9.3.3 Condensation on a Plain Tube

As discussed earlier, the laminar condensation on the outside of a horizontal tube can be estimated by the Nusselt theory with the effective gravity modification of Dhir and Lienhard (1971). For a horizontal tube, the average heat transfer coefficient follows Incropera and DeWitt (2002):

$$\bar{h}_D = 0.729\left[\frac{g\rho_l(\rho_l-\rho_V)k_l^3 h'_{fg}}{\mu_l(T_{Sat}-T_w)D}\right] \tag{9.98}$$

This was found to predict the actual heat transfer coefficients on a horizontal single plain round tube quite closely, on the average about 15% lower than the experimental values. The difference is likely attributed to the rippling of the film and early turbulence and drainage instabilities on the bottom side of the tube. In practical industry applications involving condensation on the tube outside surface, the surfaces are typically manufactured with fins to enhance condensation heat transfer, which is discussed in Section 9.7.1.

9.4 Condensation in Minichannels and Microchannels

Aiming to increase the heat transfer performance, reduce the size and weight of components, and reduce the cost of the thermal/fluid systems drives the technology trend of miniaturization over the past decades, with a direct impact now extending into many fields such as electronics cooling, microfluidics, and medical technologies. The increase in the area/volume ratio of the flow passages and the change in the relative importance of different forces create a new class of transport processes that can lead to significant reduction in the device size. In general, according to Kandlikar (2003), the dimensions in the range of 1–3 mm are referred to as minichannels whereas the smaller dimensions in the range of 10–200 μm are said to be microchannels. Kandlikar et al. (2012) gave a review and identified the research needs of heat transfer in microchannels. Condensation heat transfer in microchannels and minichannels has applications in a wide variety of advanced microthermal devices. For example, condensation in microchannels and minichannels is widely used in small devices such as air-cooled condensers for the air conditioning and automotive industry and in heat pipes, thermosyphons, and other applications for system thermal control. Recently, Awad et al. (2014) have provided a comprehensive review of condensation in micro- and minichannels. One can refer to the work by Garimella et al. (2014) for general condensation thermal transport in micro- and minichannels, and also the work by Awad et al. (2014) for condensation in these channels.

9.5 Effects of Noncondensable Gases and Other Secondary Effects

In most of the condensation processes, noncondensables are usually present such as air for those operating in the atmospheric environment. The first comprehensive and detailed study that quantitatively addressed the role of noncondensables was presented by Minkowycz and Sparrow (1966). It is based on the model of Nusselt (1916) except that the environment is a mixture of condensing vapor and noncondensables. Because the vapor–gas phase can no longer be neglected and decoupled from the liquid phase, the coupled boundary layer equations describing continuity, momentum, and energy for both phases were formulated and transformed into similarity variables. The resulting set of coupled nonlinear ordinary equations was solved numerically. To assess exclusively the effects of noncondensable gases, they used the saturated steam–air system with the mixture pressure ranging from 0.5 to 14.7 psia. The results that are based on comparisons with the Nusselt model, where the pure vapor occupies the surroundings, show that the air has a decisive effect in reducing the condensation heat transfer rates. A typical case shows that under 1 atmosphere, when compared with the pure steam condition, a reduction in condensation heat transfer ranging from 35% to 60% for a wall subcooling of 2° to 40° R was found for the air bulk mass fraction as small as 0.5%. In general, when the bulk noncondensable mass fraction increases the condensation heat transfer decreases monotonically. At a given value of noncondensable bulk mass fraction, the heat transfer decreases with increasing wall subcooling except at very small degrees of wall subcooling and large noncondensable bulk mass fractions. The mixture pressure has a strong influence. For a bulk pressure of 0.5 psia, the reduction in heat transfer is from 67% to 83% compared to 35% to 60% for 1 atm.

The physics explains why a small amount of noncondensables have such a detrimental effect on the condensation heat transfer is interesting. The theory is based on the binary convective–diffusive transport in the mixture phase. The net convection flow is moving toward the wall bringing both the vapor and

noncondensables to the liquid surface. Since the noncondensables do not condense, a mechanism must be established to remove them at the same rate as that of arrival during the steady state, thus preventing them from accumulating at the interface. This removal mechanism is basically a diffusion process that sends the noncondensable back to the bulk through a very steep concentration gradient because the diffusion process is much less efficient than the convective process. The requirement for a steep concentration gradient of the noncondensables results in a high noncondensable mass fraction at the liquid–gas interface that drastically reduces the partial pressure of vapor at the interface. The reduction in the vapor pressure at the interface correspondingly decreases the liquid surface temperature, which is the saturation temperature of the condensing vapor. The net consequence is that the temperature difference between the liquid surface and the wall, the condensation driving force, is reduced when compared to the pure vapor case.

The effects of noncondensables discussed earlier are pertinent to a quiescent mixture of vapor and noncondensable gases. Sparrow et al. (1967) investigated the case where a net forced flow field is maintained for the mixture phase, thus resulting in a forced convection laminar boundary layer. Again, a set of coupled nonlinear ordinary different equations was solved numerically and by an integral method. Their results were presented in terms of heat transfer reduction based on the identical system conditions, except that the ambient is composed of pure vapor only. For a mixture pressure of 1 atm, the reduction in condensation heat transfer is only about 2%–5% for the wall subcooling ranging from 2° to 40° R at a noncondensable gas bulk mass fraction of 0.5%. For the low-pressure mixture of 0.5 psia, the reduction in heat transfer is about 3%–10% for the same wall subcooling range and noncondensable gas bulk mass fraction. The reduction becomes substantial at about 40%–55% for the noncondensable gas bulk mass fraction of 10%. The other trends remain similar to those of the quiescent ambient case. Therefore, it is concluded that the forced convection drastically mitigates the noncondensable gas effects on the heat transfer.

Minkowycz and Sparrow (1966) also examined the effects of superheating the mixture phase. In general, for the pure vapor case, the superheating only causes the heat transfer to increase by about 1% at 100° Rankine to 5% at 400° R, whereas for the case of noncondensables, the enhancement in heat transfer due to superheating is more appreciable. For example, with the noncondensable gas bulk mass fraction at 0.5% and a wall subcooling of 10° R, the reductions in heat transfer are 55%, 47%, 43%, and 37% for superheating of 100°, 200°, 300°, and 400° R, respectively. The effect of superheating decreases with decreasing mixture pressure.

Minkowycz and Sparrow (1966) systematically examined the effects of interfacial resistance, diffusion thermo, thermodiffusion, and variable property when noncondensables are present. They concluded that all these effects are of second-order importance.

9.6 Direct Contact Condensation

Direct contact condensation usually refers to vapor condensing on liquid heat sinks that are not attached to a solid surface, for example, condensation on drops, liquid jets, and sheets. For the drop condenser, cold liquid drops are sprayed into the chamber of saturated or superheated vapor. One such design is associated with the emergency cooling system of the nuclear reactor containment. During a main coolant pipe rupture accident, cold water droplets are sprayed into the vapor-filled containment to reduce pressure and temperature by condensing steam.

9.6.1 Condensation on Drops

Lekic and Ford (1980) published a complete study of vapor condensation on a spray of subcooled droplets. They developed a mathematical model that includes the drop size distribution, motion of drop, and heat transfer rate. The model is capable of predicting the average spray temperature as a function of the given spray length. The experimental investigation was also performed where they used three full cone nozzles with different pressure drops. The main results from the experiment are quantified by thermal utilization defined as

$$\varepsilon = \frac{Q_z}{Q_T} \tag{9.99}$$

where

Q_z represents the quantity of heat absorbed per unit time by the spray from nozzle outlet to distance z

Q_T is the maximum amount of heat per unit time that can be absorbed by the spray

The heat transfer Q_z is obtained from

$$Q_z = \frac{\pi}{6}\rho_l h_{fg} \int_0^{D_m} \left(D^3 - D_l^3\right) \mathrm{d}\dot{n} \tag{9.100}$$

where $\dot{n}$ is the number of drops per unit time generated by the nozzle. The following equation provides a relationship between $\dot{n}$ and D_i:

$$\mathrm{d}\dot{n} = \frac{\dot{M}}{\rho_l}\frac{\xi}{\sqrt{\pi}}\frac{D_m}{D_i\left(D_m - D_i\right)}\frac{6}{\pi D_i^3}\exp\left[-\xi^2\left(\ln\frac{\phi D_i}{D_m - D_i}\right)^2\right] dD_i \tag{9.101}$$

where

D is the drop diameter
D_i and D_m are the drop initial diameter and the maximum diameter, respectively
$\dot{M}$ is the mass flow rate of the spray
ξ and ϕ are the spray distribution parameters for uniformity and skewness

Therefore, ε measures the percentage of maximum heat removal capacity. Their experimental results show that the thermal utilization ranges from 0.783 to 0.987 for spray distances of 42 to 356 mm from the nozzle. The model predictions compared well with the experimental results. They concluded that direct condensation is a highly efficient way of condensing pure steam.

Most of the theoretical and analytical investigations were focused on a single droplet. Jacobs and Cook (1978) developed a mathematical model based on pure conduction in the droplet and thin liquid condensate film formed on the droplet surface. The droplet radius history, R_t, is given as

$$\frac{R(t)}{R_i} = \left[1 + \frac{3}{Ja}\int_0^1 \left(\frac{r}{R_i}\right)^2 \frac{\left(T_{r,i} - T_i\right)}{R_i\left(T_{Sat} - T_i\right)}\mathrm{d}r\right] \tag{9.102}$$

where

R_i and T_i are the initial radius and temperature of the drop, respectively
r and $T_{r,i}$ are the radial coordinate and temperature at the radial location r, respectively

Chung et al. (1984a,b) used asymptotic analysis and numerical methods to evaluate the condensation on droplets in the small Reynolds number regime. They included the effects of internal circulation and noncondensable gases. For intermediate and high Reynolds number flows, Sundararajan and Ayyaswamy (1984, 1985a,b) and Huang and Ayyaswamy (1987a,b) have published theoretical and numerical results that address the internal flow field and external boundary layer in addition to the effects of noncondensable gases.

9.6.2 Condensation on Liquid Jets, Liquid Sheets, and Liquid Films

Condensation on jet and sheets has been used in special type condensers. Hasson et al. (1964a) presented a theoretical analysis for vapor condensing on laminar jets. From the same group, Hasson et al. (1964b) experimentally investigated the condensation of steam on laminar water sheets. Later, Taitel and Tamir (1969) extended the study of direct contact condensation by examining the effects of noncondensable gases. For a more complete analysis, Jacobs and Nadig (1987) included the resistance in the condensate that was not addressed in the previous work. They introduced the concept of coolant capacity utilization and produced its relationship with the Graetz number for different noncondensable mass fractions. For example, the percent coolant capacity utilized drops from 100% to 55% for the Graetz number increasing from 0 to 60 at the noncondensable mass fraction of 0.0005. The percent coolant capacity utilized changed from 100% to 30% for the same Graetz number range at the noncondensable mass fraction of 0.1.

9.7 Enhanced Condensation

The enhancement of condensation heat transfer is generally based on the following principles. Because the major heat transfer resistance is associated with the condensate layer, thinning of the condensate film and creating turbulence in the film would accomplish the goal. Increasing the effective condenser surface area such as fluted, finned, corrugated, or wire-wrapped tubes would also enhance the condensation heat transfer. Marto (1988) gave a complete review of the progress made on the enhancement of condensation heat transfer on horizontal integral-fin tubes. It was pointed out that condensate flooding significantly affects the finned tube performance. Heat transfer enhancements are more substantial than the surface area enhancement by adding more fins. Fin spacing has been considered as an important parameter. As the ratio of the surface tension to density of the working fluid is increased, the optimal fin spacing also increases, but the magnitude of the heat transfer enhancement decreases. In cases where the fin shape is important, there is an associated small degree of condensate flooding. When using metals of high thermal conductivities, tall and thin fins are more beneficial. For working fluids of high surface tensions, improvement in the condensate removal may be useful for providing additional heat transfer enhancement. Kedzierski and Webb (1990) proposed a new family of high-performance fin profiles for surface tension–drained condensers that offer improvement over existing commercial fin shapes. They specified each design in terms of the fin tip radius, the fin height, and the fin base thickness. Modern micro-/nanostructured surface fabrication techniques open up new opportunities in innovative engineering surfaces to enhance heat transfer including condensation.

9.7.1 Condensation on an Enhanced Tube

Heat transfer during condensation on the outside surface of a cylindrical tube can be significantly enhanced by using finned tubes due to the increased surface area and thinning of the condensate film by surface tension–driven pressure gradients. Historically, the outside surface enhancement can be loosely categorized into 2D helical ridges and 3D complex surfaces.

9.7.1.1 Condensation on 2D Low Fin Surfaces

Condensation on horizontal low-finned tubes was studied experimentally by Beatty and Katz (1948) who found that the data could be correlated adequately by

$$\overline{h}_{\mathrm{D}} = 0.689\left[\frac{k_{\mathrm{l}}^3\rho_{\mathrm{l}}\left(\rho_{\mathrm{l}}-\rho_{\mathrm{v}}\right)h_{\mathrm{fg}}g}{\mu_{\mathrm{l}}\left(T_{\mathrm{sat}}-T_{\mathrm{w}}\right)}\right]^{1/4}\left(\frac{1}{d_{\mathrm{eq}}}\right)^{1/4} \tag{9.103}$$

where

$$\left(\frac{1}{d_{\mathrm{eq}}}\right)^{1/4} = 1.3\Phi\frac{A_{\mathrm{fin}}}{A_{\mathrm{eq}}}\left(\frac{1}{L}\right)^{1/4} + \frac{A_{\mathrm{root}}}{A_{\mathrm{eq}}}\left(\frac{1}{d_{\mathrm{r}}}\right)^{1/4} \tag{9.104}$$

Also

Φ is the fin efficiency
A_{fin} is the total fin area
A_{eq} is the effective outside area of the finned tube
A_{root} is the plain tube outside heat transfer area based on the root diameter
d_{r} is the root diameter

L is defined by

$$L = \frac{a_{\mathrm{fin}}}{d_{\mathrm{o}}} \tag{9.105}$$

where a_{fin} is the area of one side of one fin:

$$a_{\mathrm{fin}} = \frac{\pi}{4}\left(d_{\mathrm{o}}^2 - d_{\mathrm{r}}^2\right) \tag{9.106}$$

The fin efficiency can be calculated from

$$\Phi = \frac{1}{1 + \frac{m^2}{3}\sqrt{\frac{d_o}{d_r}}} \tag{9.107}$$

where

$$m = H\sqrt{\frac{2}{\left(\frac{1}{h_o} + R_{fo}\right)k_w Y}} \tag{9.108}$$

Also,

$$A_{fin} = \frac{\pi}{2}\left(d_o^2 - d_r^2\right)N_f L \tag{9.109}$$

where

N_f is the number of fins per unit length
L is the finned length of the tube

$$A_{eq} = \Phi A_{fin} + \pi\, d_r L\left(\frac{s}{s+Y}\right) \tag{9.110}$$

And

$$A_{root} = \pi\, d_r L\left(\frac{s}{s+Y}\right). \tag{9.111}$$

It should be noted that these equations, for the calculation of condensation heat transfer on low-finned tubes, are suitable for hydrocarbons, alcohols, and refrigerants with low surface tension as the working fluids, but not suitable for water due to its high surface tension. Water has a high surface tension and the condensate film will bridge the fins with a thick layer of condensate films, significantly reducing the condensation heat transfer.

9.7.1.2 Condensation on 3D Complex Surfaces

The evolution of 2D finned outside surfaces over the last decades to further enhance the condensation heat transfer has led to more complex 3D condensing surfaces, as illustrated in the patents by Withers and Rieger (1974), Chiang et al. (1993), and Thors et al. (1999). These 3D surfaces are formed first by finning a tube outside surface to form 2D fins and followed by notching the extruded fins. With these added secondary or even tertiary fins, the condensation heat transfer is further enhanced not only due to increased surface area but also the thinning of the condensate films and the promoted condensate draining from the condensing surface. Commercially available condenser tubes in the 1990s included the tube Turbo C-II manufactured by Wolverine Tube Inc., which has fins that have been mechanically knurled to produce a saw-tooth fin shape, and the Gewa-SC manufactured by Wieland Metals Inc., which has fins of a Y-shaped cross section. Nowadays, further optimization of the fin structures leads to other variations of 3D condensing surfaces.

Theoretical solutions are problematic owing to the complexity of the condensing surface where the curvature of the fins and the crucial role of the surface tension, which varies in a complicated way over the complicated surfaces, account for major difficulties. Little work has been done on the theoretical analysis of enhancement types other than fins. As a result, invariably the industry resorts to experiments to characterize the heat transfer performance of a condenser tube.

9.7.1.3 Bundle Effect on Condensers

For a vertical tier of N horizontal tubes, Incropera and DeWitt (2002) suggest that the average condensation heat transfer coefficient for the N tubes is $\bar{h}_{D,N} = \bar{h}_D N^{-1/4}$, where N is the number of the tubes in one vertical column of plain tubes. This equation provides a reasonable estimation for N in the range of 20–30. As a result of the more severe inundation for larger bundles, Kern (1958) recommended an exponent of (–1/6) for the plain tube. The decrease in heat transfer is attributed to the increase in the film thickness for the downstream tubes, which is normally called condensate inundation where tubes in the lower portion of the bundle suffer more. For 3D condensing surfaces, which are normally used in practical applications, the effect of inundation varies with different condensing surfaces. Based on the experimentally determined single tube condensation heat transfer where there is zero inundation from tubes above it, Chen (2008) developed a methodology to predict condenser performance by taking into account the condensate inundation over the tubes in the bundle.

Vapor velocity is another factor that affects the overall condensing heat transfer of a bundle. It is well known that the vapor flowing at a high velocity across the tubes can increase the heat transfer coefficient significantly above the theoretical gravity-driven flow model of Nusselt. The general understanding is that the flowing vapor exerts a shear force over the condensate formed on the tube surface, which promotes its removal. The vapor effect on the 3D condensing surfaces is much more complicated. In general, compared with condensation on plain tubes, the vapor effect is smaller for condensation on 3D surfaces. However, very few data actually exist to estimate the significance of the effect, and usually, most of these data are proprietary.

9.7.2 Surface Promoter for Dropwise Condensation

In Section 9.2.1, it was mentioned that dropwise condensation relies on a relatively nonwetting condition between the condensate and the condenser surface for the drops to grow to larger sizes without spreading to liquid films. In most engineering applications, polished metal surfaces that are generally wettable by most liquids are usually used for condensers. Promoters are required to induce the nonwetting condition for dropwise condensation. In general, there are two types of promoters. One is called the additive agent that is sprayed onto the condensing surface or into the vapor phase. The other is coating or plating the condenser surface with the thin layer of materials with high free energy.

9.7.3 Nanostructured Surfaces for Dropwise Condensation

In addition to the additive agent, coating, or plating on the condenser surface to promote dropwise condensation as discussed in 9.7.2, nanostructured surfaces from modern manufacturing technologies have been increasingly studied in recent years to promote dropwise condensation. Examples of these nanostructured surfaces are nanograssed surfaces by Dorrer and Rühe (2008), those with carbon nanotubes by Chen et al. (2007), and those with nanospikes by Narhe and Beysens (2006). Nanostructures on these surfaces convert the surface from wetting to nonwetting, or from superhydrophilic to superhydrophobic, which promotes dropwise condensation and thus enhances condensation heat transfer. Moreover, this interesting phenomenon of wettability switch can be also useful in many compact thermal systems, where the interfacial force plays a more influential role in governing physics. Figure 9.8 shows the dropwise condensation with self-propelled surface by Boreyko and Chen (2009).

Wettability represents an ability of liquid wetting on a solid surface where wetting surface is more favorable to liquid wetting (hydrophilic) and nonwetting surface is unfavorable to liquid wetting (hydrophobic). The wettability can be loosely described by the contact angle at the contact line of a droplet on solid surface as given in Table 9.1. Typically, a surface with $\theta > 150°$ is considered a superhydrophobic surface, where a surface with $\theta < 10°$ is considered a superhydrophilic surface. One droplet deposited on a superhydrophilic surface wets the surface, which is said to exhibit the Wenzel state (Wenzel, 1936). In contrast, one droplet deposited on a superhydrophobic surface curls up with the contact angle $\theta > 150°$, which is said to exhibit the Cassie state (Cassie, 1944).

A stable Cassie state from a superhydrophobic surface is necessary to sustain continuous and rapid removal of condensate from a condenser surface. More studies in engineering superhydrophobic surfaces have been seen in the literature. Chen et al. (2007) achieved continuous dropwise condensation on a biomimetic two-tier texture with short carbon nanotubes deposited on micromachined pillars. Their hexadecanethiol-coated two-tier texture was claimed to surpass lotus leaves in terms of retaining superhydrophobicity. Visualizations of dropwise condensation by Dietz et al. (2010), which showed droplets on a hydrophobic surface, are removed in the form of a number of small droplets with little coalescence.

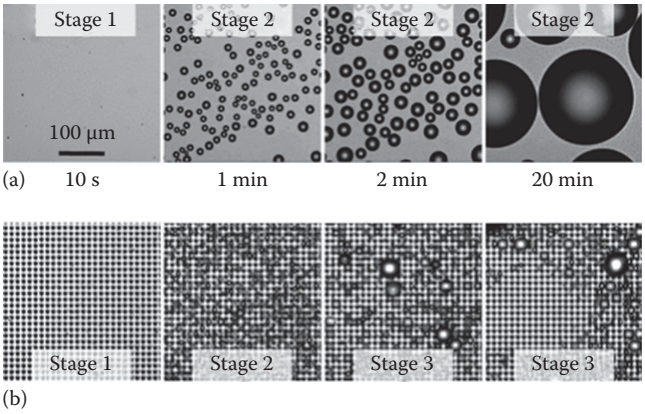

Figure 9.8

Self-propelled dropwise condensation realized by Boreyko and Chen (2009). (a) Dropwise condensation on a smooth hydrophobic substrate and (b) on a rough superhydrophobic substrate where the micropillars are visible.

Table 9.1 Contact Angle and Wettability

		Strength	
Contact Angle	Degree of Wetting	Solid/Liquid	Liquid/Liquid
$\theta = 0°$	Preface wetting	Strong	Weak
$0 < \theta < 90°$	High wettability	Strong	Strong
$90 < \theta < 180°$	Low wettability	Weak	Weak
$\theta = 180°$	Perfect nonwetting	Weak	Strong

Depending on the shape and geometry of nanostructures, a nanostructured surface does not always exhibit superhydrophobicity. Narhe and Beysens (2006) investigated water condensation on a nanostructured surface with nanospikes. Dynamics of water condensate drops was observed to follow three main stages depending on the size of the water drops with respect to the spike feature size. The initial stage is characterized by nucleation of the drops at the bottom (cavities) of the spikes. During the intermediate stage, large drops are surrounded by smaller drops within the neighboring cavities, which persists until coalescence occurs with the central drop. The last stage is characterized by the Wenzel-type drops growing with scaling laws similar to that on a planar surface. Within all stages, condensation on spike surfaces does not exhibit the behavior of superhydrophobicity.

Either a hydrophobic surface or a hydrophobic surface is not sufficient to provide a superior condensing surface. A successful condenser surface necessitates both a wetting surface to facilitate droplet nucleation and a nonwetting surface to promote the removal of condensate drops, which presents a great challenge to design such surfaces. Varanasi et al. (2009) demonstrated the spatial control of heterogeneous nucleation of water drops by manipulating the local nucleation energy barrier and the nucleation rate via the modification of the local intrinsic wettability of a surface. Chen et al. (2011) demonstrated a novel strategy to achieve significant increases in the drop number density from nucleation, drop growth rate, drop departure rate, and surface coverage of small drops, all of which contribute to the enhancement of dropwise condensation heat transfer. The novel strategy includes the use of heterogeneous wettability and hierarchical roughness features in multiscale structures, which enhance both drop nucleation and drop departure on a condensation surface. While promoting dropwise condensation, one issue with nanostructures is the pinning of liquid drops by the nanostructures, which actually is unfavorable for the removal of condensate. To overcome the pinning by the nanostructures, Anand et al. (2012) used an impregnated surface with nanostructures and demonstrated more effective removal of condensate. Whereas much attention has been devoted to dropwise condensation with water, a recent work by Rykaczekski et al. (2014) showed that dropwise condensation can be obtained for low surface tension fluids, such as hydrocarbons, cryogens, and fluorinated refrigerants used in a number of industrial applications, on omniphobic surfaces. More research results in surface engineering are expected to appear in the future.

9.7.4 Electric Field–Enhanced Condensation

Gerstman and Choi (1962) were the first to perform an experiment to demonstrate the enhancement of condensation on a vertical plate by thinning the liquid film with an electrical stress. The idea of using an electric field to enhance the condensation heat transfer was then attempted by Velkoff and Miller (1965). They used Freon-113 vapor condensing on a vertical copper plate. Various electrode geometries and strengths were investigated. It was found that screen electrodes placed parallel to the cold plate generated the largest heat transfer enhancement. Controllable and reproducible increases of 150% were achieved. On the theoretical side, Melcher (1966) was the first to introduce the electrohydrodynamic (EHD) induction pumping based on the electrostatic shear stress at the two-phase interface. Melcher and Taylor (1969) gave a comprehensive review of the EHD-driven convection by a DC or AC field. They also discussed the effects of interfacial instability waves due to the electric field. Jones (1978) further summarized the progress in EHD-enhanced condensation heat transfer. On the basis of the suggestions by Velkoff and Miller (1965), Jones (1978) generalized the following possible mechanisms of EHD-driven condensation:

1. Nucleation sites provided by ions
2. Corona wind to drive ions to heat transfer surfaces
3. Nonuniform electric fields to collect condensate
4. Condensate film surface wave destabilization
5. Electrostatic pumping of condensate
6. Internal mixing of condensate liquid

Miljkovic et al. (2013) recently used an electric field to enhance condensation heat transfer on superhydrophobic nanostructured surfaces. On these superhydrophobic surfaces, after the droplets coalesce, the coalesced droplet experiences a jump as a result of the conversion of excess energy to kinetic energy. The droplet jump results in an increased vapor pressure drop that pulls the droplet back to the condensing surface, thus causing the flooding of the surface. Miljkovic et al. (2013) demonstrated that an externally applied electric field stops coalesced droplets from returning to the original surface that enhances condensation heat transfer on these superhydrophobic surfaces. As more research in this area progresses, innovative technology advancements can be expected, not just limited to new condensing technologies, but also available to other areas such as anti-icing, self-cleaning performance, and thermal diode efficiency.

Nomenclature

c_p	Specific heat constant, J/kg °C
Co	Convection number $(=(\rho_G/\rho_L)^{0.5}\,((1-x)/x)^{0.8})$
D_h	Hydraulic diameter, m
D_{12}	Mass diffusion coefficient of species 1 in a mixture of 1 and 2
D	Tube diameter, m
Fo	Fourier number
Fr	Froude number
Fr_{LO}	Froude number with all flow as liquid $(=G^2/(\rho_L^2 gD))$
G	Gravitational acceleration, m/s^2
G	Mass flux, kg/m^2 s
H	Heat transfer coefficient, W/m^2 °C
h_{fg}	Latent heat of vaporization, J/kg
h_L	Heat transfer coefficient for the liquid, W/m^2 °C
h_{LO}	Single-phase heat transfer coefficient for all flow in the liquid phase at saturation temperature, W/m^2 °C
$h_{L,Sat}$	Heat transfer coefficient for the liquid at the saturation point, W/m^2 °C
h_m	Heat transfer coefficient for the mixture, W/m^2 °C
h_{TP}	Two-phase heat transfer coefficient, W/m^2 °C
h^*	Heat transfer coefficient using T_{Sat} as the fluid temperature in the subcooled flow boiling, W/m^2 °C

Ja	Jakob number
K	Boltzmann constant, k (=1.38 × 10^{-23} J/K)
k_L	Thermal conductivity, W/m °C
l	Mixing length
M	Molecular weight
$\dot{m}$	Total mass flux, kg/m² s
Nu	Nusselt number
Nu_{LO}	Nusselt number with all flow as liquid
$Nu_{LO,cpLO,cp}$	Nusselt number with constant properties and all flow as liquid
$\dot{n}$	Number of drops per unit time
p	Pressure, N/m²
p_{cr}	Critical pressure, N/m²
p_G	Pressure of the gas inside bubble, N/m²
p_L	Pressure of the liquid, N/m²
$p_{Sat,T}$	Saturation pressure over a planar interface, N/m²
Pr	Prandtl number
Pr_L	Prandtl number for liquid
q	Heat transfer rate, W
q''	Heat flux, W/m²
R	Radius
R_b	Radius of a bubble, m
R_C	Cavity mouth radius, m
$R_{C,Crit}$	Cavity radius at the ONB
$R_{C,Max}$, $R_{C,Min}$	Minimum and maximum cavity radii available on a surface, m
Re	Reynolds number
$R(t)$	Bubble growth rate function
R_c^*	Nondimensional cavity radius
R_{min}^*, R_{max}^*	Minimum and maximum radii of active cavities
T	Temperature, °C or K
$T_{Sat,1\|p}, T_{Sat,2\|p}$	Saturation temperatures of the pure components at the total system pressure, p, °C
t	Time, s
TTR	Tape twist ratio for twisted tapes
u	Velocity, m/s
v	Specific volume, m³
V_m	Molar volume, m³/kg mol
x	Equilibrium quality
x_1, x_2	Mass fractions of 1 and 2, respectively, in the liquid phase of a mixture of species 1 and 2
y	The distance normal to the heater surface to the center of the bubble, m
y_1, y_2	Mass fractions of 1 and 2, respectively, in the vapor phase of a mixture of species 1 and 2

Greek Letters

α	Thermal diffusivity (=$k/(\rho c_p)$m²/s)
Γ	Liquid mass flow rate per unit film width
ΔT_{Sub}	Liquid subcooling ($T_{Sat} - T_L$), °C
ΔT_{Sub}^*	Liquid subcooling ($T_{Sat} - T_L$), nondimensional
δ_T	Single-phase thermal boundary layer thickness
ε_m	Eddy diffusivity for momentum transport
ε_h	Eddy diffusivity for heat transport
ϕ	Angle of orientation of the heated surface with respect to the horizontal, deg
φ	Spray distribution parameter for skewness
κ	Mixing length constant
μ_B	Viscosity of the bulk liquid, N s/m²
μ_L	Viscosity of the liquid, N s/m²
μ_W	Viscosity of the fluid at the wall temperature, N s/m²

ξ	Spray distribution parameter for uniformity
θ	Contact angle, deg
θ_r	Receding contact angle, deg
ρ	Density, kg/m^3
σ	Surface tension, N/m^2

Subscripts

An	Annular flow
1, 2	Species 1 and 2
c	Critical state
crit, cr	Critical point for the fluid
dp	Dew point
exit	Exit section
f	Stream core
fl	Fluid
fg	Latent quantity (vapor property–liquid property)
i	At the interface or initial state
L	Liquid
LO	All flow as liquid
G	Gas
MHF	Minimum heat flux
max	Maximum
min	Minimum
NVG	Point of net vapor generation
Nu	Nusselt-type solution
0	On a flat surface
r	Receding
Sat	Saturation point
Smooth	Smooth tube value
str	Stratified flow
Sub	Subcooling
t	Turbulent flow
tr	Transition flow
T	Thermal layer
TP	Two phase
v	Vapor phase
W	Wall
δ	Edge of liquid film

10.4 Discussions: Segregation Phenomenon and Cohesion Effect

10.1 Background and Stress Models

10.1.1 Introduction

Dynamics of grain and power flows has been extensively investigated for their common appearances in industrial processes (gasoline drilling, slurry transportation, surface polishing with fine particles, etc.) and natural events (avalanches, debris flows, sedimentation, etc.). Such flows are, in general, composed of solid constituents of characteristic diameter D greater than 100 nm and within 1–100 nm, respectively. These particles are large enough so that their motion is rather insensitive to disturbances from Brownian motions or thermal energy fluctuations (Rognon et al., 2008, Andreotti et al., 2013) but primarily controlled by the interactions with their neighbors. Grain–grain interactions, in general, are categorized into noncontact near-field cohesion forces and contact forces, including both repulsive collisions and enduring contacts in both elastic recoverable and plastic dissipating modes. Noncontact cohesion force, on the other hand, can result from various mechanisms such as electrostatic force due to frequent surface interaction in humid environment, van der Waals force for materials of high intermolecular potential, and capillary or lubrication force due to thin surface liquid coating.

Unlike conventional fluid or solid continuum at scale several orders of magnitude greater than constituent molecules, separation of flow and grain size scales is not large and particle-level dynamics accumulates to affect grain collective motion at large scale. Based on this understanding, researchers have attempted to develop bulk constitutive models, according to which is the dominating interaction mode in developing continuum governing equations.

Systematic experiments with skillful measuring techniques have been conducted to investigate flow rheology and dynamics with respect to flow conditions so that empirical relations may be formulated. However, such flow information is often limited to averaged properties at flow boundaries due to the discrete and opaque nature of the material. To gain insight from particle-level information, particle-based numerical simulation has become an indispensable research tool that calculates individual grain motions to estimate both rheological properties and transport properties. Along this line, this chapter summarizes some important models and numerical studies for six particular types of steady flows commonly investigated in the literature. The simple linear shear or annular shear flow, inclined flow, and unsteady column collapse are three popular configurations to probe flow rheology and boundary conditions. The other three quasi-steady flows in a rotating drum and on a vertically vibrating bed as well as the discharge from a hopper are commonly studied for

industrial applications. Since extensive reviews and discussions can be found for most flow types except that on a vibrating beds, the rest of this chapter is dedicated to a review for the dynamics of a vibrating bed nearly identical spheres.

10.1.2 Stress Model, Boundary Condition, and Governing Equations

10.1.2.1 Collisional Stress Model

When a granular assembly moves fast at dilute to moderate solid volume concentration, ϕ, most particle–particle interactions are uncorrelated repulsive binary collisions with contact durations much shorter than the timescale associated with bulk shear rate. Such flow is known as a *rapid granular flow* in *collisional regime*. Bulk stress has a collisional part, $\underline{\underline{\sigma}}_c$, and a kinetic part known as the streaming stress, $\underline{\underline{\sigma}}_k = \rho\left\langle\left(\underline{u}_p - \underline{u}\right)\left(\underline{u}_p - \underline{u}\right)\right\rangle$, due to incoherent grain motions (Campbell and Brennen, 1985). Here, $\rho = \rho_p\phi$ is the bulk density depending on the grain intrinsic density ρ_p. Bulk velocity $\underline{u} = \left\langle \underline{u}_p \right\rangle$ is averaged from individual grain velocity $\underline{u}_p$ via a mass- or volume-weighted scheme or a statistical ensemble average, denoted by $\langle\cdot\rangle$, and $\underline{u}_p - \underline{u}$ measures the deviatoric velocity. Except in very dilute flows, $\underline{\underline{\sigma}}_c \gg \underline{\underline{\sigma}}_k$, and the bulk total stress is often approximated by the collisional part in theoretical modeling. Since the dominant micromechanical mechanism resembles how gas molecules interact with each other at a specific thermal state, extensive modeling efforts have been made based on the kinetic theory of dense gas (Ogawa, 1978, Savage and Jeffrey, 1981, Jenkins and Savage, 1983, Jenkins, 1994, Goldhirsch, 2003, etc.). Regardless of the complexity borne in various models, a general form can be expressed as

$$\underline{\underline{\sigma}}_c = \left[C_1 p_T(T) + C_2 \mu_b^\star \nabla \cdot \underline{u} \right] \underline{\underline{I}} + C_3 \mu^\star \underline{\underline{S}}, \tag{10.1}$$

possessing an isotropic normal component and a component that varies with the shear strain rate tensor, $\underline{\underline{S}} = \left[\nabla \underline{u} + \left(\nabla \underline{u}\right)^T \right]/2$, with the superscript T denoting the transpose of a tensor. The coefficients $C_1 \sim C_3$ depend not only on material properties but also on ϕ and other flow properties. The first term in the isotropic component is a *pseudo-thermal* pressure p_T that scales linearly with the *pseudo-thermal* granular temperature $T = 1/3 < (\underline{u}_p - \underline{u})^2 >$ like conventional gases. This similarity in how pressure is related to temperature results from the transport mechanism for momentum flux for both medium is grain collisions and that is why the shear and bulk viscosities $\mu^\star$ and $\mu_b^\star$ also show square root dependence on *T*. By definition, *T* measures the bulk fluctuation energy due to incoherent motion of individual particles from their mean.

One popular collisional stress model is (Lun et al., 1984)

$$\underline{\underline{\sigma}}_c = \left[\rho T\left(1 + 4\eta\phi g_0\right) - \eta\mu_b^\star \nabla \cdot \underline{u} \right] \underline{\underline{I}} - \left(\frac{2+\alpha}{3} \right) \left[\frac{2\mu^\star}{\eta(2-\eta)g_0} \left(1 + \frac{8}{5}\eta\phi g_0 \right) \left[1 + \frac{8}{5}\eta\left(3\eta - 2\right)\phi g_0 \right] + \frac{6}{5}\eta\mu_b^\star \right] \underline{\underline{S}} \tag{10.2}$$

with

$$\mu^\star = \frac{5 m_p \sqrt{T/\pi}}{16 D^2}, \quad \mu_b^\star = \frac{265\phi^2 g_0}{5\pi}\mu^\star \tag{10.3}$$

in which α is a numerical coefficient often assumed to be unity, m_p and *D* are characteristic grain mass and diameter. In Equation 10.2, $\eta = 1/2(1 + e)$ depends on the coefficient of restitution, *e*, for intergrain collisions and $g_0(\phi, \phi_m)$ is the *radial distribution function* that characterizes packing configuration around a single grain and hence depends on both local ϕ and the maximum value ϕ_m at the closest packing.

By this definition, bulk collisional stress is always symmetric and evolves with flow via its dependence on ϕ and *T*. Hence, the momentum conservation equation has to be solved in junction with the conservation equations of mass and pseudo-thermal energy equation as

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \left(\rho \underline{u}\right) = 0 \tag{10.4}$$

$$\rho \frac{D\underline{u}}{\partial t} = \rho \underline{g} - \nabla \cdot \underline{\underline{\sigma}} \tag{10.5}$$

$$\frac{3}{2}\rho\frac{DT}{\partial t} = -\nabla\cdot\underline{q} - \underline{\underline{\sigma}}:\nabla\underline{u} - s \tag{10.6}$$

with $\underline{\underline{\sigma}} \approx \underline{\underline{\sigma}}_c$ and gravity acceleration $\underline{g}$. Additional constitutive relations are needed for the pseudo-thermal flux $\underline{q}$ to account for nonuniform fluctuation energy and rate of dissipation, s, due to inelastic grain interactions in Equation 10.6, and they have been formulated by Lun et al. (1984) as

$$\underline{q} = \frac{\kappa}{g_0}\left\{\left(1+\frac{12}{5}\eta\phi g_0\right)\left[1+\frac{12}{5}\eta^2(4\eta-3)\phi g_0\right]+\frac{64}{25\pi}(41-33\eta)(\eta\phi g_0)^2\right\}\nabla T$$
$$-\frac{\kappa}{g_0}\frac{12}{5}\eta(\eta-1)(2\eta-1)\left(1+\frac{12}{5}\eta\phi g_0\right)\frac{d}{d\phi}(\phi^2 g_0)\frac{T}{\phi}\nabla\phi \tag{10.7}$$

$$s = \frac{48}{\sqrt{\pi}D}\eta(1-\eta)\rho\phi g_0 T^{3/2} \tag{10.8}$$

$$\kappa = \frac{75m\sqrt{T/\pi}}{8\mu^*(41-33\eta)D^2} \tag{10.9}$$

with a pseudo-thermal conductivity κ.

10.1.2.2 Frictional Stress Model

Nonetheless, under the action of gravity, grains tend to rest on their own weight to result in denser flows in which prolonged multiple contacts take place in addition to repulsive binary collisions. Particle elastic deformation, in both normal and tangential directions, and tangential friction with adjacent particles form force chains and cluster-like structures within the bulk. Such internal structures not only provide another micromechanical mechanism for momentum and energy transport but also redistribute and hence sustain external loading to give the bulk plasticity and strength to withstand shear loading. Plugs or basal deposit can further develop within a flow and such phenomenon cannot be captured by the kinetic theory since the modeled predicts a vanishing, instead of diverging, stress model when $\underline{u}$ and hence $\underline{u}'$ and T, μ, and μ_b approach zero.

To address this issue, the deviatoric stress for a slowly deforming dense bulk in the so-called quasi-static regime is often described by the Mohr–Coulomb model as

$$\underline{\underline{\sigma}}_f = P_f\underline{\underline{I}} - \underline{\underline{\tau}}_f = P_f\underline{\underline{I}} - \sin\varsigma P_f\underline{\underline{S}}^\star \tag{10.10}$$

with

$$P_f = tr(\underline{\underline{\sigma}}_f) \quad \text{and} \quad \underline{\underline{S}}^\star = \underline{\underline{S}}/|\underline{\underline{S}}| \tag{10.11}$$

that depends on a quasi-steady friction angle ς. This relation assumes that the stress and strain rate tensor share the same directions of principal axes and the material is incompressible so that $tr(\underline{\underline{S}}) = 0$. The dependence on the *normalized* shear strain rate tensor $\underline{\underline{S}}^\star$ gives a diverging $\underline{\underline{\tau}}_f$ and hence the desired yielding strength when $\underline{\underline{S}}$ approaches zero in slow deformation.

However, the incompressibility assumption inevitably makes $\underline{\underline{\tau}}_f$ independent of changes in ϕ and hence cannot account for the effect of varying ϕ on during deformation—like the Reynolds dilatancy effect upon yielding (Reynolds, 1885). More advanced models have been proposed and one example is the critical-state theory (Wood, 1990, Roux and Radjai, 1998, Radaji and Roux, 2004):

$$\underline{\underline{\tau}}_f = \mu(\psi)P_f\underline{\underline{S}}^{D\star} \tag{10.12}$$

where

$$\underline{\underline{S}}^{D\star} = \underline{\underline{S}}^{D} \Big/ \left|\underline{\underline{S}}^{D}\right| \quad \text{and} \quad \underline{\underline{S}}^{D} = \underline{\underline{S}} - 1/3\, tr\left(\underline{\underline{S}}\right) \tag{10.13}$$

Based on Equations 10.12 and 10.13, the friction coefficient is no longer constant but varies with the *dilatancy angle* ψ. This angle is related to the ratio of the vertical to horizontal relative displacement between two adjacent particle layers and hence depends on local packing configuration and should be positive upon dilation and vice versa. Simple geometric arguments can render a simple relation between ψ and local strain rate tensor as

$$\sin(\psi) = \frac{1}{3} \frac{\mathrm{tr}\left(\underline{\underline{S}}\right)}{\left|\underline{\underline{S}}^{D}\right|} \tag{10.14}$$

where the constant in the denominator should be changed to 2 for a 2D problem. In addition, ψ should further depend on ϕ, and a simple yet feasible linear relation has been proposed (Roux and Radjai, 1998) as

$$\psi = C_4\left(\phi - \phi_c\right) \tag{10.15}$$

with a positive constant C_4 and a critical volume fraction ϕ_c. This critical ϕ_c is the asymptotic value when nearly static packing has undergone sufficient deformation (>1% strain). When $\phi > \phi_c$, $\psi > 0$ and the bulk dilates and vice versa. Equations 10.12 through 10.15 comprise a simple plastic model for granular material under slow deformation, and this model fails when the bulk is under very high confining pressure—often occurs in geophysical events—for which the critical state may change with the bulk quasi-thermal state.

10.1.2.3 Composite Stress Model

With the simplest version of $\underline{\underline{\tau}}_f$ in Equation 10.10, $\underline{\underline{\sigma}}_f$ has been added to $\underline{\underline{\sigma}}_c$ to compose the total stress as the sum: $\underline{\underline{\sigma}} = \underline{\underline{\sigma}}_c + \underline{\underline{\sigma}}_f$ under an *ad hoc* assumption of linear superposition (Savage, 1983b, Johnson and Jackson, 1987). Apart from this, Jenkins modifies the pair interaction model in the kinetic theory to account for long-range interactions through force chains (Jenkins, 1994) so that a transport mechanism faster than that by collisions is added. Some considers the destruction and formation of force chain network as phase transition between mobilized fluid state and arrested solid state to relate the stress tensor to nonlocal functions of velocity field and a structural parameter for the material constituents (Mills et al., 1999, 2000). Another simple yet intriguing model treats force-chain networks as eddies in turbulent flows so that the cluster structure acts like granular eddies to assist transport at a length scale longer than *D* so that $\underline{\underline{\sigma}}$ is modeled by multiplying $\underline{\underline{S}}$ with a flow-dependent viscosity (Ertas and Halsey, 2002). In another work, the bulk is treated as a Herschel–Bulkley type of complex fluid that depends on a hydrostatic normal pressure in the formulation of $\underline{\underline{\sigma}}$ (Balmforth and Kerswell, 2005). The intrinsic biphase behavior inherited in these models promises the success in producing plug flows or a static deposition that is never captured by a model using only the collisional stress.

10.1.2.4 Phenomenological Model Based on μ(I) Rheology Law

Yet, another approach does not distinguish the collision- and friction-induced stress components but employs dimensional analysis to correlate effective friction coefficient, $\mu = |\tau|/P$, to a *dimensionless inertial number I* for incompressible granular flows in uniform shear. Here, μ is the ratio of characteristic tangential to normal stress in the form of the Coulomb-type material due to flow dense nature and *I* is defined as

$$\mathrm{I} = \frac{\left\|\underline{\underline{S}}^{D}\right\| D}{\sqrt{P/\rho}} \tag{10.16}$$

which depends on the second invariant of $\underline{\underline{S}}^{D}$ and mean normal stress *P*. This number represents the ratio of the time for shear-induced streamwise displacement to that for grain transverse movement to adjacent voids under confining *P*. Hence, *I* can be interpreted as a measure of bulk fluidity with respect to settling tendency

so that flows with large I are fast flowing while those with slowly deforming motions are characterized by small I. Empirical $\mu - I$ relation has been sought via laboratory experiments and computer simulations and a conforming trend is discovered for unidirectional steady flows in various simple steady flows (Iordanoff and Khonsari, 2004, MiDi, 2004, Da Cruz et al., 2005, Jop et al., 2006, Forterre and Pouliquen, 2008) as

$$\mu(I) = \mu_s + \frac{\mu_2 - \mu_s}{I_0/I} \tag{10.17}$$

Here, μ_s acts as a bulk static friction coefficient and is associated with the bulk yielding strength as a consequence of lasting frictional contacts and the asymptotic μ_2 characterizes a corresponding value in the collisional regime. Fitted values of $\mu_s = 0.38$ (~tan21°, for the examined glass beads), $\mu_2 = 0.67$(~tan34°), and $I_0 = 0.3$ have been reported to complete the so-called $\mu - I$ rheological relation or frictional law for steady dense granular flows. While μ increases monotonically and nonlinearly with I in Figure 10.1a, the bulk solid volume fraction decreases linearly with I as shown in Figure 10.1b since the flow gets more agitated. A *dilatancy law* has been fitted as

$$\phi = \phi_s - \Delta\phi I \tag{10.18}$$

where ϕ_s is the value for static packing and $\Delta\phi \approx 0.2$ has been fitted for a 3D flow of glass beads. Further details on how these relations are extracted and related to underlying flow physics can be found in Midi (2004), Jop et al. (2006), and Andreotti et al. (2013).

From the algebraic $\mu(I)$ for unidirection flow, a tensorial form for bulk deviatoric stress (with $\underline{\underline{\sigma}} = -p\underline{\underline{I}} + \underline{\underline{\tau}}$) has been proposed as

$$\underline{\underline{\tau}} = \frac{\mu(I)P}{\|\underline{\underline{S}}\|}\underline{\underline{S}} \tag{10.19}$$

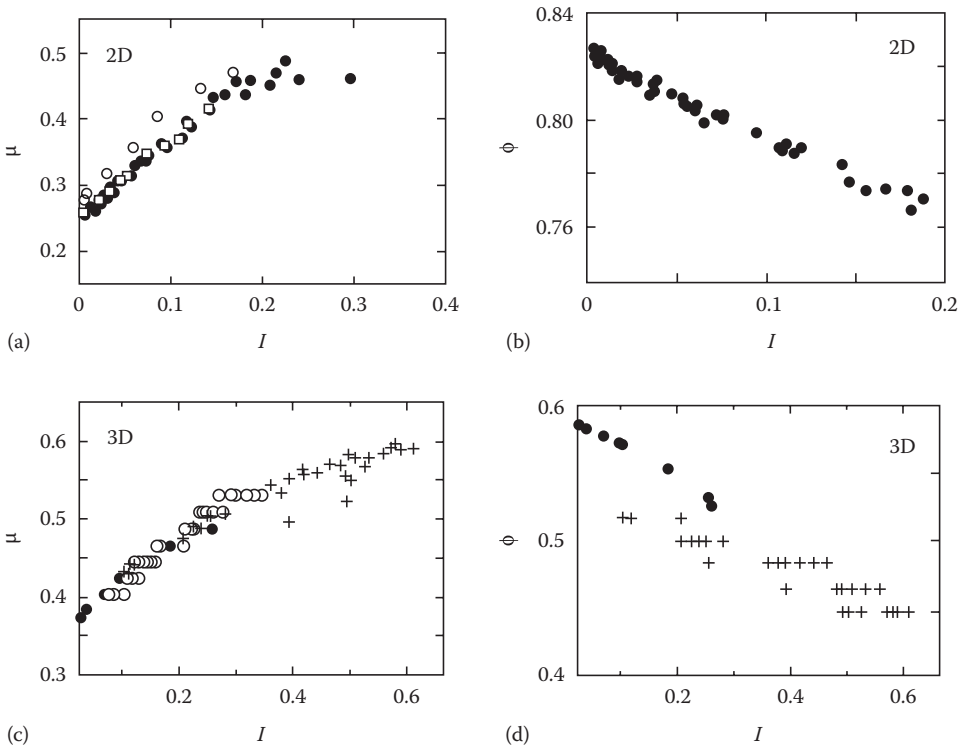

Figure 10.1

The friction law $\mu(I)$ and dilatancy law $\phi(I)$ extracted from 2D (a,b) and 3D systems (c,d). The 3D results in (c) have been fitted into Equation 10.17 for glass beads. (From Andreotti, B. et al., *Granular Media*: *Between Fluid and Solid*, Cambridge University Press, Cambridge, U.K., 2013 and the references therein.)

with

$$\|\underline{\underline{S}}\| = \sqrt{\underline{\underline{S}}\underline{\underline{S}}/2} \tag{10.20}$$

assuming that the principal vectors of $\underline{\underline{\tau}}$ and $\underline{\underline{S}}$ are identical. Both the 2D and 3D rheology laws have been confirmed in flows of various configurations, and researchers have started to investigate how far this simple rheology model can reach when flows are more complex.

The scalar expression in Equation 10.17 is probed in starting and accelerating unidirectional flows over a heap (Jop et al., 2007) and in accelerating and decelerating thin surface flows in a 2D rotating drum (Cortet et al., 2009) and for granular column collapse on a rough plane (Lacaze and Kerswell, 2009). The proposed tensorial form in Equations 10.19 and 10.20 has been incorporated in a 2D incompressible flow solver, and some of the predicted continuum bulk dynamics agree fairly well to either experimental findings or predictions from particle-based simulation methods. For example, the instantaneous surface profile and the final deposit shape from a collapsed column agree to those obtained from a discrete model simulation (Lagrée et al., 2011). The Beverloo law is captured in a rectangular silo and the simulated instantaneous pressure field agrees to the general behavior of a continuum flow (Staron et al., 2014). While these provide supporting evidences for Equation 10.19, it is noted that quantitative comparison on the distribution of bulk velocity is not reported. Further, a recent detailed examination from particle-based simulations reported that unmatched principle stresses for $\underline{\underline{\tau}}$ and $\underline{\underline{S}}$ are slowly creeping bulk in the bed of a 2D rotating drum (Cortet et al., 2009) though the scalar formulation adopting the stress invariants in Equation 10.17 remains valid. Hence, further research on generalizing Equation 10.19 by relaxing the assumptions or by taking into account of nonlocal phenomenon is desired (Kamrin and Bazant, 2007, Pouliquen and Forterre, 2009, Kamrin and Koval, 2012, Shojaaee et al., 2012).

10.1.2.5 Boundary Condition

In addition to these constitutive models, feasible boundary conditions have to be specified so that continuum-like bulk dynamics can be solved via theoretical analysis or numerical simulation. Most common conditions are zero stress at the free surface and vanished velocity (no slip and no penetration) at the solid boundary provided that the flow is sufficiently thick (to validate the continuum-like behavior) or rough (Jop et al., 2005). More complex forms can also be found in the literature for different flow conditions. For example, Johnson and Jackson (1987) consider the transfer of momentum flux between the base and the bulk to propose a more delicate basal condition as

$$\underline{t}\cdot\underline{\underline{\sigma}}\cdot\underline{n} + \frac{\sqrt{3}\pi}{6\phi_m}\Lambda\rho g_0 T^{1/2} u_{SL} = 0 \tag{10.21}$$

with

$\underline{t}$ and $\underline{n}$ denoting the unit vector tangent and normal to the base
u_{SL} is the bulk *basal slip* velocity

The specularity constant factor Λ measures the proportion of the streamwise momentum flux transmitted to the base. The zero stress condition at the free surface has also been modified to account for the normal stress imposed by the overtopping surface particles into the following expression:

$$\underline{\underline{\sigma}}\cdot\underline{n} = \frac{\mathrm{M}\underline{g}}{D^2}\left(\frac{\phi}{\phi_\mathrm{m}}\right)^{2/3} \tag{10.22}$$

in which M is the mass of a layer of grains of unit thickness (a 2D version). As for boundary conditions for the pseudo-thermal energy equation in Equation 10.6, a constant heat influx, $\underline{q}\cdot\underline{n} = q_b$, or constant temperature T is often assigned. Apart from this, there are more advanced models for how basal condition should be related to flow conditions (Artoni et al., 2009a, 2012).

These theoretical models have been applied to describe and explain flow phenomenon, mostly at steady states, and a few are cited in Table 10.1 according to the stress models for six particular types of steady (quasi-steady) flows commonly investigated in the literature. The simple linear shear or annular shear flow, inclined flow, and unsteady column collapse are three popular flow configurations adopted to probe or test flow rheology and boundary conditions. On the other hand, the quasi-steady flows in a rotating drum and

Simple shear flows include 2D linear flows and quasi-2D annular shear; inclined flows treat both uniform and nonuniform cases; rotating drum flows can be both 2D and 3D; vibrating bed flows are limited to vertical shaking only.

on a vertically vibrating bed as well as the unsteady discharge from a hopper are commonly studied for industrial applications.

10.1.3 Depth-Averaged Shallow Flow Model

Apart from these, it should be noted that a depth-integrated shallow flow theory has been developed for thin surface flows down a slope inclined at θ from the horizontal with no-slip boundary condition. The original 2D model (x–y plane, with z pointing out of the page) developed by Savage and Hutter (1989) is dedicated for landslide problems in which significant shearing, fluidization, and density variation are restricted in a thin basal layer (Melosh, 1986). Hence, the flow is approximated as an incompressible plug flow with *depth-averaged* velocity $\bar{u}$ and density $\bar{\rho}$. Limiting to flows of small depth-to-length aspect ratio, ε, the authors first simplify the transverse momentum equation to obtain a hydrostatic pressure distribution that grows linearly with depth from a surface zero. Further integration of mass and x-momentum conservation equations leads to a set of simplified partial differential equations, accurate to the order of ε, as

$$\frac{\partial h}{\partial \mathrm{t}} + \frac{\partial h\bar{u}}{\partial x} = 0 \tag{10.23}$$

$$\frac{\partial \bar{u}}{\partial \mathrm{t}} + \bar{u}\frac{\partial \bar{u}}{\partial \mathrm{x}} = \sin\theta - \varepsilon\cos\theta K_{a/p}\frac{\partial h}{\partial x} - \mathrm{sgn}\left(\bar{u}\right)\cos\theta f_B \tag{10.24}$$

where h is a varying flow height. The action of bulk stress is converted to zero surface friction and a basal friction in the last term of Equation 10.24 in which $f_B = \tan \varsigma_B$ is the friction coefficient in terms of a

basal friction angle ς_B. The additional constant $K_{a/p}$ is the Coulomb-type active and passive earth pressure coefficient, denoted by the subscripts *a* and *p* as

$$\left.\begin{matrix} K_a \\ K_p \end{matrix}\right\} = \frac{2}{\cos^2\varsigma}\left[1 \mp \sqrt{1-\left(1+\tan^2\varsigma_B\right)\cos^2\varsigma}\right] - 1, \quad \text{for} \quad \begin{matrix} \partial\bar{u}/\partial x > 0 \\ \partial\bar{u}/\partial x < 0 \end{matrix} \tag{10.25}$$

This coefficient is the ratio of bulk lateral to normal stress when the bulk dilates or compresses upon yielding. The authors approximate $\overline{u^2} \approx \bar{u}^2$ when handling the convective acceleration term since the velocity profile is nearly blunt since strong shear is localized in a thin basal layer. The set of partial differential equations can be transformed to an *advection–diffusion equation* governing how $h(x, t)$, equivalently the granular mass, evolve in time and space down the slope. For certain types of flows, a *similarity solution* may be found (Liu and Mei, 1989, Ancey et al., 2009, Pudasaini 2011), and numerical solution can always be sought for more complex cases. This scheme succeeded in capturing the primary mode of bulk dynamics in several surface flow problems and hence is also included in Table 10.1 for interested readers.

Besides of theoretical modeling, systematic experiments with skillful measuring techniques have been conducted to explore how each bulk dynamics vary with flow conditions. However, the information is primarily the averaged properties at flow boundaries due to the discrete and opaque nature of the material. To gain an insight from the particle-level information, a particle-based numerical simulation, which calculates individual grain motion to estimate bulk properties, has become an indispensable research tool, especially with the rapid advance of computation capacity. Hence, the fundamentals of one popular scheme—the discrete element method (DEM)—are described briefly in the following to introduce the basic concepts.

10.2 Particle-Based Simulations Using the Discrete Element Method

10.2.1 Introduction

Ever since the first application to granular systems by Cundal and Strack (1979), the DEM has become a powerful simulation tool for both industrial process design and flow physics investigation (Cundall, 1988, Walton, 1993). The motion of individual grain is computed by the conservation of linear and angular momentum under the action of gravity and grain–grain interaction force. Contact models of varying complexity have been proposed to describe the paired interaction force, and the simplest soft-sphere contact model for identical spherical grains is introduced first for easy comprehension.

10.2.2 Soft-Sphere Contact Model

10.2.2.1 Contact Model and Its Parameters

In an inertial reference frame, let $\underline{\mathrm{p}}_i$ denote the position vector for sphere *i* of diameter *D* and mass m_p. Its contact with an adjacent sphere *j* as sketched in Figure 10.2a is determined when the distance between the centers, $|\underline{\mathrm{p}}_{ij}| = |\underline{\mathrm{p}}_j - \underline{\mathrm{p}}_i|$, falls below *D* and a contact normal for sphere *i* is defined accordingly by $\underline{\mathrm{n}}_i = \underline{\mathrm{p}}_{ij}/|\underline{\mathrm{p}}_{ij}|$. The sphere velocity is decomposed with respect to $\boldsymbol{n}$ into a normal and a tangential component as u_{ni} and u_{ti}. Their relative translational and angular motion result in normal and tangential displacement at the contact point as $\delta_\mathrm{n}(t) = \mathrm{D} - |\underline{\mathrm{p}}_{\mathrm{ij}}(t)|$ and $\delta_\mathrm{t}(t) = \sum_1^N u_{rt}(t)\Delta t$ with instantaneous relative tangential velocity at the contact point $u_{\mathrm{rt}} = u_{\mathrm{ti}} - u_{\mathrm{tj}} + 1/2\underline{\mathrm{p}}_{\mathrm{ij}} \times (\underline{\omega}_\mathrm{i} + \underline{\omega}_\mathrm{j}) \cdot \underline{\mathrm{t}}_\mathrm{i}$. Particle rotation at $\underline{\omega}_\mathrm{I}$ or $\underline{\omega}_\mathrm{j}$ is taken into account, and the unit tangent vector $\boldsymbol{t}_\mathrm{i}$ is perpendicular to $\underline{\mathrm{n}}_\mathrm{i}$ according to the right-hand rule. By this definition, $\delta_\mathrm{t}(t)$ represents the total tangential displacement accumulated over *N* constant DEM steps Δt during one contact. The pair interaction force, $\underline{\mathrm{F}}_{ij}$, is decomposed with respect to $\underline{\mathrm{n}}_\mathrm{i}$ and modeled by an elastic and a dissipating force component (Cundall and Strack, 1979, Campbell and Brennen, 1985, Di Renzo et al., 2004, Kruggel-Emden et al., 2007, Luding, 2008, Yang et al., 2013, etc.). The simplest linear spring–dashpot model describes the normal interaction force by the sum of an elastic spring force, $F_{nS} = -k_n\delta_n$, and a damping force, $F_{nD} = -c_n u_{nr}$, with k_n and c_n denoting the normal spring and damping constant and $u_{nr} = u_{nj} - u_{ni}$ being the normal relative velocity. Tangential force also has a recoverable elastic component $F_{tS} = -k_t\delta_t\,\mathrm{sgn}(u_{rt})$ with a spring constant k_t that acts against the sign of relative tangential velocity at the contact point. This force is switched to a dissipative friction of the Coulomb-type $F_{tF} = -f_c(F_{nS} + F_{nD})\mathrm{sgn}(u_{\mathrm{rt}})$ when gross sliding takes place if $F_{tS} \geq F_{tF}$.

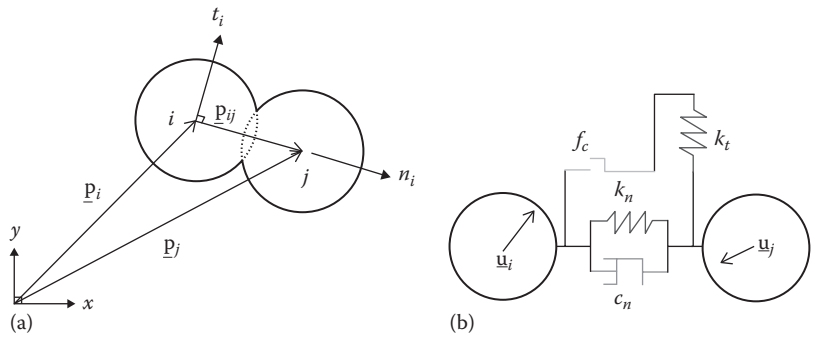

Figure 10.2

(a) Illustration of two contacting spheres at position $\underline{p}_i$ and $\underline{p}_j$ in an inertial reference frame. (b) Illustration of a linear soft-sphere contact model for spheres i and j coming into contact at velocities $\underline{u}_i$ and $\underline{u}_j$: k_n and k_t are the stiffness of the normal and tangential spring, c_n the damping constant, and f_c the sliding friction coefficient.

Here, f_c is the friction coefficient between contacting surfaces. In summary, the normal and tangential force component of $\underline{F}_{ij}$ (with omitted subscript ij) during a contact can be expressed as

$$F_n = F_{nS} + F_{nD} = -\left(k_n \delta_n + c_n u_{nr}\right) \tag{10.26}$$

$$F_t = \begin{cases} F_{tS} = -k_t \delta_t \,\mathrm{sgn}(u_{tr}) & \text{if } F_{ts} < F_{tF} \\ F_{tF} = -f_c F_n \,\mathrm{sgn}(u_{tr}) \end{cases} \tag{10.27}$$

$$\underline{M}_{ij} = 1/2 \underline{p}_{ij} \times \underline{F}_{ij} \tag{10.28}$$

By summing up F_{ij} and M_{ij} from the j concurring contacts, the total force and torque on sphere i are obtained and used to update the sphere's translational and angular velocities as well as displacement.

The next step is to assign the model parameters k_n, k_t, c_n, and f in relation to the grain elastic, plastic, and surface properties so that the simulations give physical bulk quantities. Since the normal displacement in a linear contact model is governed by a second-order differential equation of constant coefficients $m^* d^2\delta_n/dt^2 + c_n d\delta_n/dt + k_n \delta_n = 0$, the analytic solution for $\xi(t)$ can be readily found (Stevens and Hrenya, 2005) as

$$\delta_n(t) = u_{nr}(0) \sqrt{\frac{m^\star}{k_n\left(1-\chi^2\right)}} \exp\left(\frac{-c_n}{2m^\star} t\right) \sin\left(\pi \frac{t}{t_c}\right), \tag{10.29}$$

with the initial conditions upon contact: $\delta_n(0) = 0$ and $d\delta_n/dt(0) = u_{nr}(0)$. In this equation, $m^* = (1/m_i + 1/m_j)^{-1} = m/2$ is the reduced mass, $\chi = c_n/2\sqrt{k_n m^\star}$ is the damping ratio, and the model contact time is specified by the instant when $\delta_n(t)$ returns to zero as

$$t_c = \pi \sqrt{\frac{m^\star}{k_n\left(1-\chi^2\right)}} \tag{10.30}$$

The rebound velocity $d\delta_n/dt(t_c)$ can be used to calculate a coefficient of restitution in relation to the damping ratio as

$$e = -\frac{d\delta_n/dt\big|_{t=t_c}}{u_{nr}(0)} = \exp\left(\frac{-\pi\chi}{\sqrt{1-\chi^2}}\right) \tag{10.31}$$

which characterizes the loss of particle kinetic energy during a contact. By matching e to the experimentally measured value, χ can be specifically determined. A second condition for specifying k_n and hence c_n may

be formulated by matching Equation 10.30 to *Hertzian contact time*, $t_{\text{Hertz}} = 2.86\left(m^*/\sqrt{D^*/2E^*}\right)\left|u_{\text{nr}}(0)\right|^{-1/5}$ (Johnson, 1985), with $D^* = \left(1/D_{\text{i}} + 1/D_{\text{j}}\right)^{-1}$ and $E^{*-1} = (1-\nu_i^2)/E_i + (1-\nu_i^2)/E_j$ depending on the respective radius of curvature, $D_{\text{i}}/2$; Young's modulus, E_i; and Poisson's ratio, ν_{i}, for the contacting surfaces.

As for the tangential spring constant, a popular choice is that derived from elasticity theory (Mindlin, 1949, Mindlin and Deresiewicz, 1953, Cundall and Strack, 1979) by

$$k_t = \frac{2}{2-\nu^*}\left[3G^*(1-\nu^*)a^* F_n\right]^{1/3} \tag{10.32}$$

in terms of averaged Poisson's ratio and shear modulus $\nu^* = \nu_i + \nu_j/2$ and $G^* = G_i + G_j/2$. The friction coefficient f may be assigned to the sliding friction coefficient of the contacting material or according to bulk behavior near yielding. Further discussions will be given shortly in Section 10.2.2.3.

Apart from this possibly the simplest model, different force formulae and components have been adopted in more advanced models (Di Renzo and Di Maio, 2004). For example, a nonlinear Hertzian spring (which scales with $\delta_n^{3/2}$) can replace the linear spring in Equation 10.26 to give more precise description for elastic force–displacement relation during a contact (Stevens and Hrenya, 2005). Additional damping in the tangential direction has also been modeled via a tangential damper and a rolling frictional slider for which tangential damping constant and rolling friction coefficient have to be further assigned.

10.2.2.2 Estimation of Bulk Properties

The bulk local properties can then be estimated from the detailed information of nearby grains by some weighting scheme. For example, an averaging box of volume Δ can be defined at a specific location, and bulk solid volume fraction, velocity field, stress tensor, and granular temperature at the center of the average volume may be calculated as

$$\phi = \frac{\sum_i \Delta_{pi}}{\Delta} \tag{10.33}$$

$$\underline{u} = \frac{\sum_i \Delta_{pi}\underline{u}_{pi}}{\sum_i \Delta_{pi}} \tag{10.34}$$

$$\underline{\underline{\sigma}} = \frac{1}{\Omega}\left[-\sum_i m\Delta_{pi}\underline{u}_{rel}^{ij} \otimes \underline{u}_{rel}^{ij} + \frac{1}{2}\sum_{\substack{i,j \\ i\neq j}} \underline{F}^{ij} \frac{\underline{r}^{ij} \otimes \underline{r}^{ij}}{r^{ij}}\right] \tag{10.35}$$

where

Δ_{pi} is the partial volume of a sphere i included by the averaging box
$\underline{u}_{pi}$ is its instantaneous velocity

The first term on the right-hand side of Equation 10.35 gives the streaming stress due to particle motion in free flights relative to its neighbors, and the second term results from paired contact force, and both are summed over all grains within Δ.

10.2.2.3 Effect of Contact Model and Its Parameters on Bulk Dynamics

A great number of 2D/3D simulations have been conducted to study the constitutive relations for the tangential stress of dry cohesionless grains in a steady simple shear and steady surface flow. Sensitivity tests on the contact model parameters report dynamically similar velocity profiles. Hence, the peak velocity and

the flow transverse length scale have been adopted to scale flow properties bringing merged profiles for dimensionless velocity depth profiles and rheological relations. This leads to the well-known fact that the contact model parameters—as long as they are not vanishingly small or zero—have negligible effects on steady granular flow dynamics (Midi, 2004, Da Cruz et al., 2005).

Nonetheless, when quantitative prediction of flow behavior is desired in addition to its qualitative dynamics, assignment choices of contact model parameters are of concern. A popular remedy is to conduct small-scale experiments to calibrate the parameter constants by examining either properties at the particle size level or the bulk level. Silbert et al. (2001, 2003) assign c_n in a linear contact model by the mean of the measured e and f_c but assigned k_n (with $k_t = 2/7k_n$) to a value 3–5 orders of magnitude smaller than the material true strength to permit larger simulation time step Δt. In reproducing the surface shape and velocity, moving mass, and final deposit of an avalanche-induced 3D granular flow, Teufelsbauer et al. (2009) set k_n and k_t to values of the same order as the material elastic strength, c_n by the measured e, and f_c by the tangent of the interparticle friction. Nonetheless, the authors have to incorporate rolling friction and use a lower solid volume fraction than the measured value to obtain quantitative agreement. When impact force on a rigid downstream wall is examined, the authors report the significance of particle rotation mechanism and refine the switching mechanism between sliding and rolling tangential contact (Teufelsbauer et al., 2011). In another study without rolling friction by Banton et al. (2009), the spring constants and c_n are assigned likewise but f_c is calibrated by bulk static repose angle. Remarkable agreement is reported for the observed and the simulated deposit shapes and satisfying results are obtained for the instantaneous surface geometry (but no quantitative comparison). Also without rolling friction, Valentino et al. (2008) conducted numerical biaxial tests on a unit volume of test sample generated according to the experimental particle properties so that the spring stiffness and f_c are assigned by the simulated bulk stress components.

As commented by many researchers, the friction contact model plays an important role in the governing dynamics of dense flows. Most of the literatures assign f_c either by an intergrain friction coefficient or by a bulk static or nearly yielding property engaging a nearly constant normal load that may exceed the true value if the surfaces are subject to a *time-varying* normal load during a contact. Hence, when tangential interaction alternates between sliding and rolling contact, the mean friction averaged over the contact time can be different from that when pure sliding persists through. Hence, Yang et al. (2013) propose to calibrate f_c by bulk volume discharge rate since this flow property is tight closely to flow dynamics (Pouliquen, 1999b (scaling law.....), Ancey, 2001, Pouliquen and Forterre, 2002) and yet easy to measure in both experiments and simulations upon calibration. Fairly good agreement is obtained for the simulated and the measured motion of individual grains and bulk. More advanced and complex contact models can be found in the literature and the search for a feasible contact model for various applications is still an ongoing research topic (Walton, 1993, Vu-Quoc et al., 2000). In Table 10.2, some references for the six selected flow types are provided to complement the information in Table 10.1, leaving out abundant literature of experimental investigations. The interested readers are always recommended to the comprehensive and informative reviews for the methods and the findings by Hermann and Luding (1998), Yang et al. (2003), GDR Midi (2004), Zhu et al. (2007, 2008), Munjiza et al. (2011), and Paulick et al. (2015). Noticing that updated reviews with in-depth discussions on flow physics can be found for most of the selected flow types except for flows in vibrations beds, the rest of this chapter is prepared to fill in the gap, with a focus on those reported for nearly identical spheres.

10.3 Granular Flows in a Vertical Vibration Bed

10.3.1 Problem Setup

Consider a collection of identical spheres of diameter and density, D and ρ_s, of total mass, M, is packed in a thin box (quasi-2D) of width W to a height of H under the action of gravity g. The box is subject to oscillating vertical displacement of, $z(t) = Z_0F(ft)$, or acceleration at, $A(t) = A_0F(ft)$, with $A_0 = Z_0f^2$ in terms of Z_0 being displacement and acceleration and f being the intrinsic frequency of some periodic function (often sinusoidal) of unit magnitude $F(ft)$. The eight variables (D, ρ_s, W, H, g, M, Z_0, and A_0) involve with three fundamental units (mass, length, and time), and hence, there are five dimensionless parameters pertinent to the dynamic process according to *Buckingham* Π-theory. The commonly used parameters include the *relative acceleration* (or shaking parameter), $A^* = A_0/g$; dimensionless shaking acceleration $\Gamma = Z_0\omega^2/g$ ($\omega = 2\pi f$); aspect ratio of the packed bed, W/H; solid volume fraction,

$\phi = M/\rho_s HW$; and the scaled packing depth, $H^* = H/D$. Other material properties that may come into play in a theoretical model or computer simulation include two elastic modulus—for example, Young's modulus E, Poisson's ratio ν, coefficient of restitution e, and friction coefficient f_c for tangential force upon interparticle sliding.

10.3.2 Dynamics and Flow Physics

10.3.2.1 Transition from Bouncing Bed to Convection Roll

At small excitation amplitudes, the bed moves together with the container as a granular solid and eventually detaches from the base when its inertia balances bulk weight and friction from the container walls. Eshuis et al. (2007) adopt the Rayleigh–Janssen's model (Janssen, 1895, Duran, 2000) to describe the wall friction and determine the detachment acceleration as $\Gamma_\star = 2 - e^{-\Lambda^\star f_{cs} L}$. The exponent represents a decompaction parameter that depends on a coefficient of direction toward the wall, Λ^*; grain static friction coefficient, f_{cs}; and the ratio of material contact area over its projection area, $L = 2(W + W_\perp)H/WW_\perp \approx 2H/W_\perp$. Here, $W_\perp$ denotes the bed transverse width and is much smaller than W for a quasi-2D system. The only fitting parameter $\Lambda^* = 0.15$ is determined. The predicted $\Gamma_\star$ matches well to the measured transition value and grows monotonically with H^* with slight overestimation at smaller shaking amplitude. The free surface of the bouncing bed remains stable and nearly flat.

When Γ is further increased to a threshold value Γ_c slightly above unity ($\Gamma_c = 0.9$–1.2), a thin bouncing bed (roughly $H^* < 3$, Eshuis et al., 2007) is agitated into a dilute cloud of randomly moving particles, showing a transition from *granular solid* to *granular gas*. When the bouncing bed is thick enough, a pair of counterrotating convection roll develops breaking coherent assembly motion and grains are observed to descend at the walls and rise in the center (Faraday, 1831, Laroche et al., 1989). The rising grains near the box center create a central heap with an inclination angle close to, when sufficiently far from the container walls, the material repose angle. Central surface grains then avalanche from the heap apex down the slope and rejoin the descending wall flux to ensure an overall mass conservation. We follow Aoki et al. (1996a) to classify this convection motion as the *downward* mode according to the grain

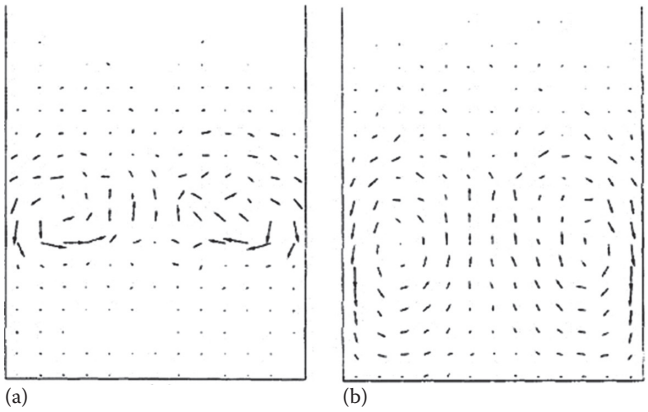

Figure 10.3

Time-averaged velocity vector at $\Gamma = Z_0\omega 2/g = 1.44$ (a) and 2.71 (b) from a 2D particle-based simulation using $e = 0.9$, $Z_0 = 1.1$, $g = 1$, and varying ω. More details regarding the simulation setup can be found in the reference. (From Taguchi, Y.H., *Phys. Rev. Lett.*, 69, 1367, 1992.)

motion next to the wall. This downward convection roll starts to develop beneath the free surface and expands with increasing Γ to fluidize the whole layer as illustrated by the simulated grain velocity vector in Figure 10.3 (2D particle-based simulation, Taguchi, 1992).

Such transition from a coherent bouncing bed has been described by a dynamic model using the analogy to the distinctive response of a single sphere bouncing on a vibrating plate at a critical gravity-scaled acceleration of $\pi(1 - e)/(1 + e)$ (Brennen et al. 1996). Using the same dynamic model, Lan and Rosato (1995) employ an effective bulk restitution coefficient $e_{\text{bulk}} \approx 0.32$ based on the simulated impact and rebound velocity of the assembly and obtain a better agreement to the transition acceleration at $\Gamma_c = \pi(1 - e_{\text{bulk}})/(1 + e_{\text{bulk}}) = 1.66$.

A few mechanisms have been proposed in the literature for the formation of this convection roll. Faraday (1831) has envisioned the effect of interstitial air motion on roll formation almost two centuries ago and wrote: "when the base of the pile loses contact with the plate, it forms a partial vacuum, into which the air round the heap enters with more readiness than the heap itself; as it enters, carries in the powder at the bottom edge with it." When the container decelerates downward from its upper most position (when $A^* < 0$), particles detach from the base into *free flight* creating a small gap at the base that expands and shrinks until the material collides with the base. This basal air gap has lower pressure than the ambient and can entrain air through the comparably loose and thin layer near the lateral walls (packing at a flat boundary is not as dense as internal packing). The grains near the boundary are also more fluidized and collide the base earlier to induce local compaction that in turn squeezes air toward the box center. Condensed stagnant zones hence form at the heap edges on which spheres create an avalanching flow on a bed at the frictional angle as sketched by Laroche et al. (1989) in Figure 10.4. The development of such a local stagnation zone generates successive condensation wave fronts from the container corners at a nearly constant propagation speed (inferred from the base pressure measurement, see Figure 10.5) except very close to the wall. The wave propagation velocity is found to decrease with increasing A^*. This in turn creates horizontal density gradient that drives basal mass fluxes toward the center, as two incoming density waves, which meet and turn up to form the rising central flux under the heap.

Pak et al. (1995) investigated the interstitial air effect on the dynamics of a bed vibrated in concentric cylinders. When the ambient air pressure p decreases below 10–20 torr, the surface elevation decreases monotonically and the heap as well as the convection roll disappears completely when the container wall is made permeable. Similarly, the disappearance of the convection roll was also observed at a lower $p < 10^{-5}$ torr by Laroche et al. (1989) unless the material is agitated in sufficiently narrow containers at high enough frequency that suggests the effect of wall friction and grain–grain interaction.

Besides the induced air stream, grain–grain and grain–wall interaction in response to the external excitation also affect overall bulk dynamics. The base with container pressure measurement suggests that the material does not bounce right after the collision but is brought to a halt by the immense normal impulse upon impact and rise with the container. Bulk kinetic energy is either stored as strain energy or dissipated into

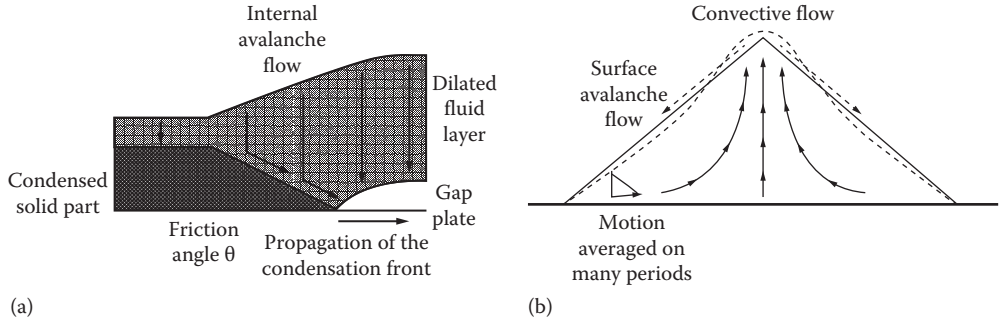

Figure 10.4

(a) Illustration of how the material in free-flight avalanches down an internal slanted stagnant zones at the material friction angle to generate a condensation wave moving toward the container center. (b) The resulting cycle-averaged convection roll (thick arrow) compensated by surface avalanche (dotted arrow) when all the heap material is solidified. (From Laroche, C. et al., *J. de Phys., France,* 50, 699, 1989.)

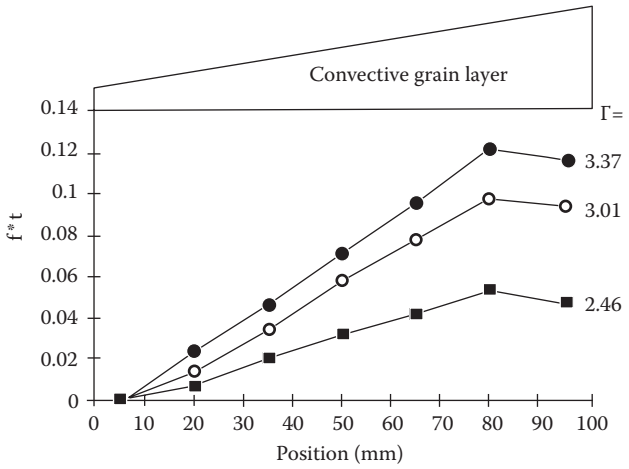

Figure 10.5

Distribution of the collision time of bed material from the container edge toward the convective heap in a bed of $H^* \approx 45$ vibrated at $f = 20$ Hz and different $A^* = 2.46$, 3.01, and 3.37. Note that the authors use the symbol Γ for the relative acceleration but we have changed the plot label to A^* for consistency. (From Laroche, C. et al., *J. de Phys., France,* 50, 699, 1989.)

heat due to inelastic particle interactions. Granulates stay in contact with the container until they resume free flight when the container retrieves from the maximum height at the beginning of next oscillation cycle. Once in free flight, the stress developed upon impact is relaxed but the geometry constraint from the lateral walls restricts the release of horizontal stress. Hence, a higher normal stress is developed at the container walls to induce greater friction that promotes downward granulate motion with the wall (Taguchi, 1992, Wildman et al., 2001). This is why Lan and Rosato (1997) reported from their 3D DEM simulation that the convection velocity grows monotonically with particle-sidewall friction coefficient when the shaking conditions and particle friction coefficient are fixed.

Finally, some authors reported that the central heap configuration is not stable when Γ reaches a certain value above Γ_c and slight asymmetry in the system (container shape, displacement amplitude, packing structure, etc.) can result in transition from a central heap to one that slanted from one wall (Laroche et al., 1989, Wassgren et al., 1996).

10.3.2.2 Reversed Convection and Roll Doubling

10.3.2.2.1 Phenomenon and Mechanism When Γ and A* are further increased above A* = 4.5–5.1 (Aoki et al., 1996a), the layer is not fully condensed before being lifted again so that slight asymmetry in the system can result in unequal wall friction. Knight (1997) reported from experiments the instantaneous profile of the

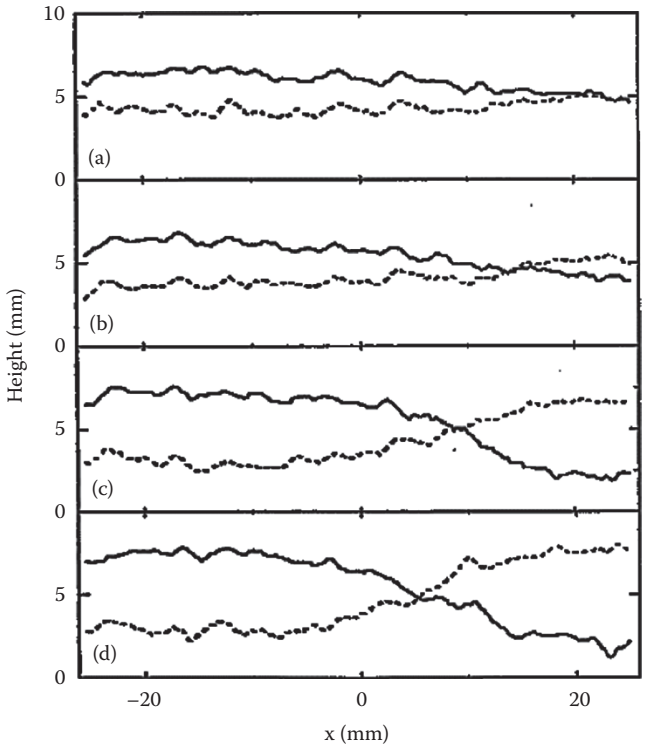

Figure 10.6

Transient development of an internal shear band at the (a) onset of vibration and after (b) 4, (c) 8, and (d) 12 vibration periods for a bed of poppy seeds with $H^* = H/\overline{D} \approx 11.7$, $A^* = 8.7$ and $f = 25$ Hz. The two curves depict the maximum and minimum instantaneous bottom edge of the bed in consecutive vibrations. A mean diameter $\overline{D} \approx 0.85$ mm is estimated here by the mean of the long and short axes of 1 and 0.7 mm of the poppy seeds to scale the bed height. (From Knight, J.B., *Phys. Rev. E*, 55(5), 6016, 1997.)

bottom edge of a bulk at the maximum and minimum elevation during one cycle and the particles exhibited smaller displacement at one wall as shown in Figure 10.6. The intersection of the maximum (thick lines) and the minimum (dashed lines) locates an interface that separates the bed into two adjacent segments in out-of-phase cyclic motions. A shear band develops across the interface and propagates from the right wall toward the container center as the bulk develops into its steady state. The difference between the maximum and minimum bed height at the container center, Δh, grows in time onto a steady plateau (see Figure 10.7a). If lateral boundary effect can be neglected in a large enough container, the steady surface shape across the shear band can be well fitted by $h(x) \sim \tanh(x/x_c)$ where x is the horizontal distance from the shear band and x_c is a length scale of surface curvature (see Figure 10.7b).

Instantaneous particle motions at the shear band can be either positive or negative, but the local cyclic mean is always downward at steady state. At high enough Γ, this internal local flow may reverse the convection roll into the *upward mode* so that particles rise at the container walls but descend in the center, leading to the *DU transition* (defined by Aoki et al. 1996a). The free surface changes accordingly from a central heap to valley as shown by the consecutive experimental images in the left column of Figure 10.8. Unlike the downward mode, convection rolls in the upward mode are stable and can grow with Γ to fluidize more material. When the bed is wide enough or when the shear strength is sufficiently strong, the central shear plane acts as a fictitious wall bisecting the layer and two pairs of convection rolls develop accordingly in each segment as shown in the right column of Figure 10.8. Such roll *doubling bifurcation* (into 2, 4, and 8 pairs) continues with further increment of Γ until a maximum number is reached. The maximum roll number permissible to a granular system is reported to depend on both W^* and H^* and also on particle size and excitation frequency but to a less extent (Aoki et al. 1996a).

Knight (1997) further examines the instantaneous profile of bed bottom edge during the DU transition. The measurements were taken when the container is at its lowest position (dashed line) and at the bed maximum separation from the bed (solid line), and the cycle-averaged bulk velocity distribution within the bed is illustrated. It is interesting to find that when the system goes through the DU transition from

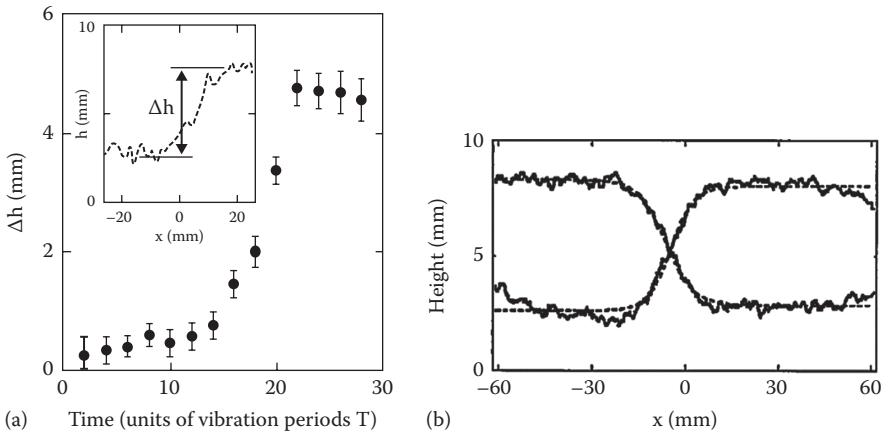

Figure 10.7

(a) Temporal evolution of the deformation amplitude Δh of the bed bottom edge during the shear band development. The inset shows Δh for the dashed curve in Figure 10.6d. (b) Bottom edge of the shaken bed after the development of shear band (following that shown in Figure 10.6). (From Knight, J.B., *Phys. Rev. E*, 55(5), 6016, 1997.)

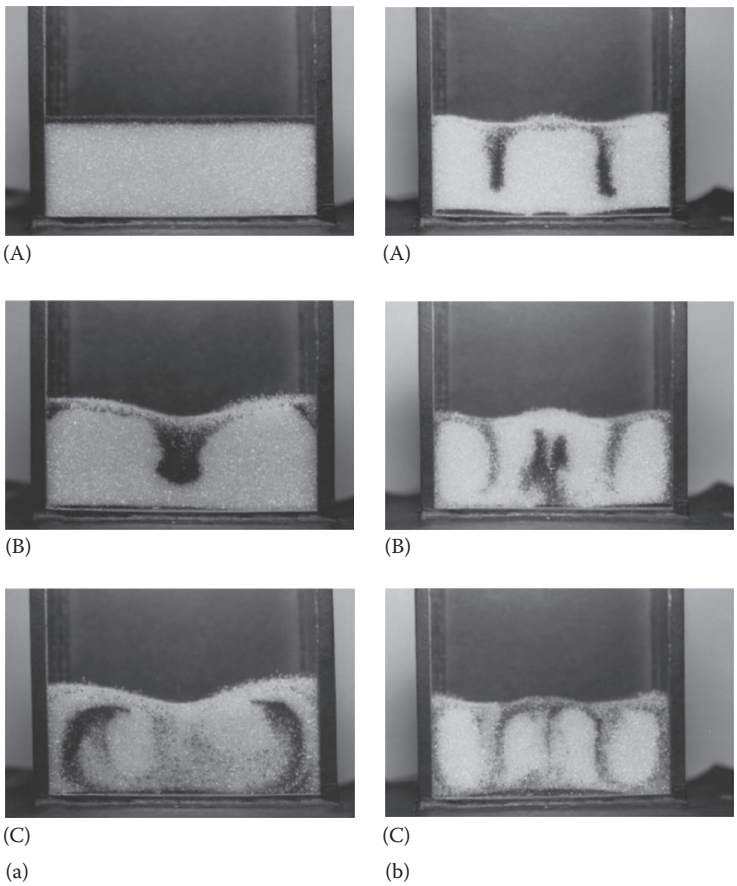

Figure 10.8

Formation of convection rolls of (a) one pair that descends in the center at (A) 0 s, (B) 9 s, and (C) 19 s and (b) two pairs with downward flux in each roll at (A) 9 s, (B) 19 s, and (C) 29 s. Both images are taken for a bed of glass beads of mean diameter $\overline{D} = 0.61$ mm, with initial height $H^* \approx 61$ shaken at $A^* = 5.9$ and $f = 50$ Hz. The glass container has 100 mm width and 30 mm thickness. (From Aoki, K.M. et al., *Phys. Rev. E*, 54(1), 874, 1996.)

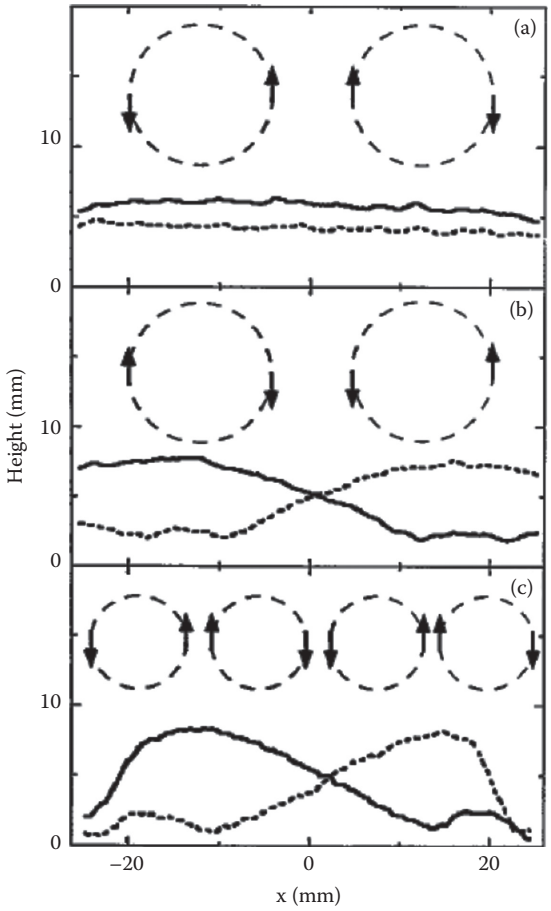

Figure 10.9

(a) Downward convection roll in a bed without internal shear band. (b) The same bed as in (a) but in reverse convection due to the action of an internal shear band. Both (a) and (b) are conducted in the container of smooth walls. (c) Promoted reverse convection in a container with rough walls. The two curves depict the local maximum (—) and minimum (---) bottom edge height when a bed of poppy seeds shaken at $A^* = 8.4$ and $f = 25$ Hz (also used in Figures 10.6 and 10.7). (From Knight, J.B., *Phys. Rev. E*, 55(5), 6016, 1997.)

Figure 10.9a and b, the corresponding changes in the bed profile are from a unified bed motion with a flat boundary to a segment-wise vibration with a step elevation. The incoherent bed segmental motion creates strong shear within the material, and the degree is enhanced in Figure 10.9c when rougher lateral container walls are employed.

Aoki et al. (1996a) also examine how the bed height H^* affects the critical acceleration Γ_{c+} for the DU transition and roll doubling with rising Γ and another critical value Γ_{c-} for the reverse UD transition and the disappearance of convection rolls with decreasing Γ. The results are shown in Figure 10.10a and b for Γ_{c+} and Γ_{c-}, respectively, and deviating Γ_{c+} and Γ_{c-} are observed for roll doubling and cancellation indicating system *hysteresis* at a degree that varies with H^*. For a bed with $H^* > 13$ ($W^* = 128$), DU and UD transition are found at comparable $4.5 < \Gamma < 5.1$ (marked by circles "○"), but deviating Γ_{c+} and Γ_{c-} trends are observed for roll doubling and cancellation indicating strong system hysteresis. This may be attributed to how internal force chains are developed and destroyed in different manners upon acceleration and deceleration. Hysteresis is smaller in the thicker bed, and the multiple rolls (4 and 8 pairs) may disappear abruptly into a single pair (U2) or directly back to downward mode when the bed is too thin due to strong dissipation in the system.

10.3.2.2.2 Surface Pattern and Base Arch In addition to convection rolls, a bulk free surface also develops wavy pattern as a standing wave. When the material collides with the base, an immense normal impulse develops where the bulk exhibits a downward motion so that grains sometimes are observed to bounce from the surface.

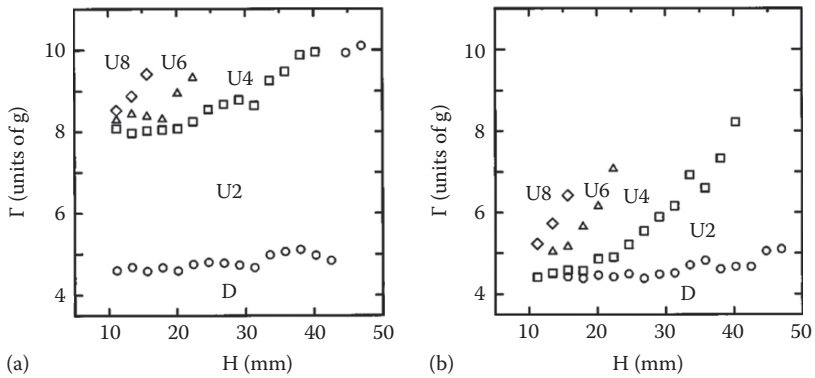

Figure 10.10

Critical Γ for (a) the onset of DU transition and roll doubling and (b) the reverse UD transition and roll reduction as a function of initial bed height H for glass beads of mean diameter $\overline{D} = 0.78$. The acceleration on the y-axis is dimensional, $\Gamma = Z_0(2\pi f)^2$, and can be transformed to the dimensionless shaking acceleration by dividing out the digits by 9.8. The number of rolls is distinguished by different symbols: two (○), four (□), six (△), and eight (◇) with their direction denoted by "D" (downward mode, central heap) and U (upward mode, central valley). (From Aoki, K.M. et al., *Phys. Rev. E*, 54(1), 874, 1996.)

These surface grains fall from the heaps to the valleys during the bed free flight, redistributing the denser regimes so that new heaps form at where the valleys locate in the previous cycle and such alternation continues as demonstrated in Figure 10.11 (3D DEM, Lan and Rosato, 1997). This clearly explains why it takes two vibration cycles for the surface wave pattern to resume its original profile as well-known phenomenon of the *period doubling*. Force chains evolve in the bulk accordingly and form arches near the bed in a wavy pattern similar to that of the free surface as observed in experiments (Wassgren et al., 1996, Lan and Rosato, 1997).

The horizontal distance between adjacent heaps defines half a wavelength, λ/2, which is found to decrease with increasing vibration frequency, f. This is because the lateral distance that grains can relocate during free flight is shortened at higher f. An empirical relation for the nondimensional wavelength has been proposed and confirmed in many systems, following Melo et al. (1994), as

$$\lambda/D = N_\lambda + g_{eff}/Df^2 \tag{10.36}$$

Here, our g_{eff} = 310 cm/s² and N_λ = 11 are reported from a 2D DEM simulation (W* = 200, H^* > 10 from visual inspection, Aoki and Akiyama, 1996b). When a shallow bed of glass beads (H* < 10) are vibrated in a cylinder, standing waves develop as surface stripes or squares and Equation 10.36 has been confirmed in experiments with g_{eff} = 325 cm/s² and N_λ = 5–10 (Metcalf et al., 1997). The dependence of λ on f^{-2} implies that these *surface waves* are gravity waves in nature. When the shaking frequency is further increased to a *crossover frequency* f_X, such wave mode is no longer stable and the trend flattens from $\lambda/D \sim f^{-2}$ to $\lambda/D \sim f^{-1/2}$ as shown in Figure 10.12. Similar bifurcation in surface pattern is also observed in 3D experiments with $f_X \approx 22$ Hz (Metcalf et al., 1997), and the authors attribute it to viscous cutoff effect. The same phenomenon is also reported from a 2D simulation (molecular dynamics) with $f_X \approx$ 30 Hz (Jung and Lee, 2004).

The simulation results are further analyzed to investigate how the wave length of the surface standing wave is correlated to the surface particle lateral displacement, δx, (Jung and Lee, 2004) by examining the distribution function, P(δx). The data averaged over 100 vibration cycles are shown in Figure 10.13a. P(δx) peaks at small δx when $f > f_X \approx 30$ Hz but changes onto a wider spread distribution with a small bump at longer $\delta x \approx \lambda/2$ when $f < f_X$. The probability function is employed to estimate a mean displacement <δx>. The value is normalized by half wavelength, 2 < δx >/λ, and examined with respect to f in Figure 10.13b revealing a sharp change around f_X.

The numerical scheme is also employed to study how the normal component, σ_{xx}, of the collisional and streaming stress vary through the vibration cycle when the bed is shaken below and above f_X. For both excitation, the collisional stress increases sharply at times when the material impacts on the base and then decreases by inelastic and frictional dissipation. At other times, the streaming component exceeds the collisional part for flows at f = 20 Hz since the ballistic surface grains have sufficient time to relax and travel horizontally. In contrast, such horizontal ballistic motion is suppressed when the bed vibrates at a very

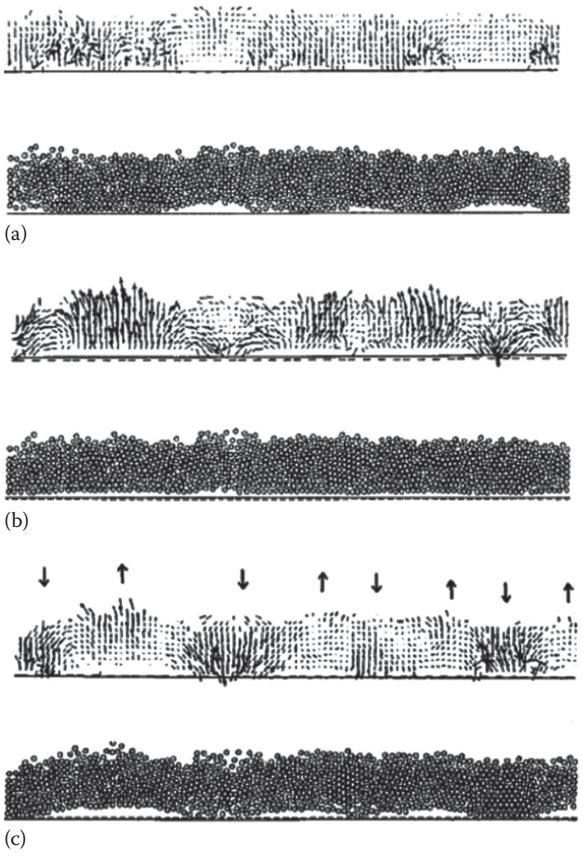

Figure 10.11

Instantaneous velocity vectors and locations of individual spheres shaken at $\Gamma = 10$ ($f = 10$ Hz, $A^* = 0.5$, $W^* = 100$) showing that the bed separates into segments that move out of phase with each other. The time between the snapshot of (a) and (c) is exactly two vibration periods with switched peak and valley locations. Snapshot (b) is taken slightly before the base descends to its equilibrium position (dashed line) in (c) where arch are better formed. (3D DEM, Lan, Y. and Rosato, A.D., *Phys. Fluids*, 9(12), 3615, 1997.)

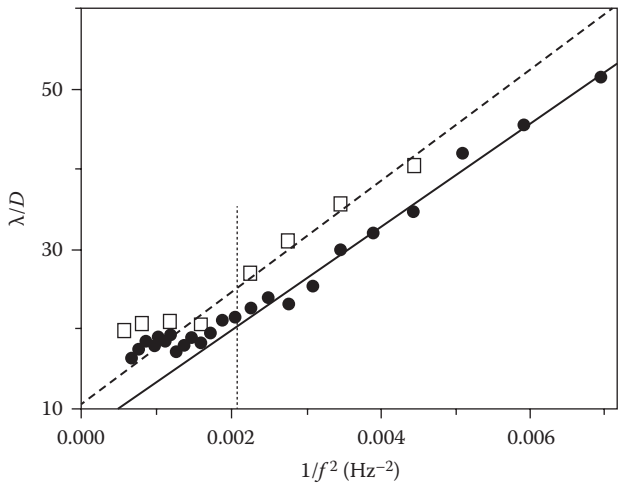

Figure 10.12

Normalized wavelength λ/D examined with respect to $1/f^2$ for system operated at $\Gamma = 3.0$ with $H^* = 8$, $P = 0.04$ Torr (□), and $H^* = 6$, $P = 10$ Torr (●). The crossover frequency for deviating $\lambda/D - 1/f^2$ is determined at 22 Hz as indicated by the dashed line. (From Metcalf, T.H. et al., *Phys. A*, 236, 202, 1997.)

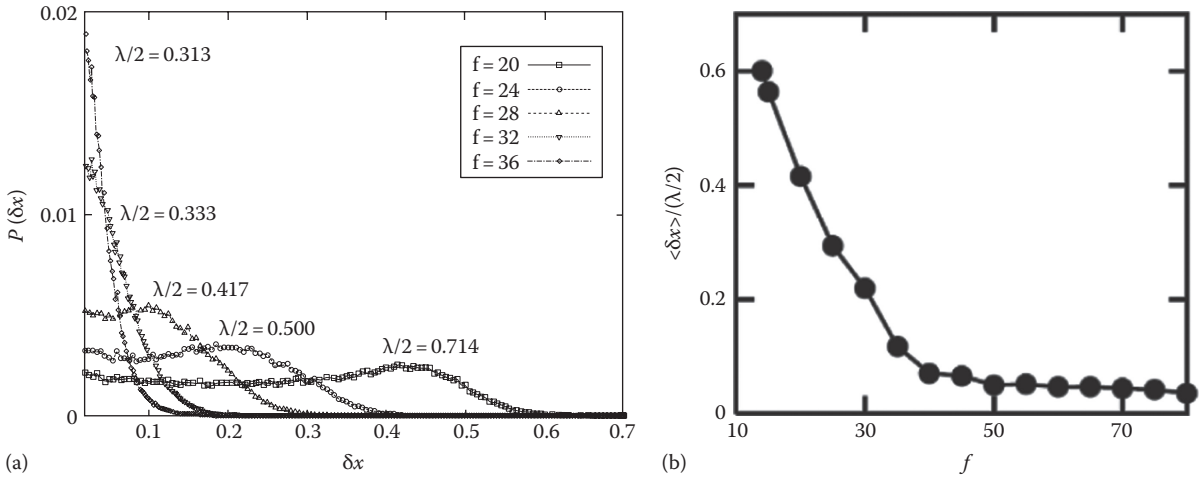

Figure 10.13

(a) The probability distribution function of individual grain horizontal displacement when the bed is shaken at Γ = 2.7. Different distribution profiles are revealed when f is increased beyond the crossover f_X = 30 Hz. Half wavelength of the peak value is indicated. (b) <δx>/(λ/2) increases monotonically when the half wavelength is decreased below f_X = 30 Hz. (From Jung, Y.K. and Lee, J., *Phys. A*, 342, 479, 2004.)

high frequency (>f_X) and the streaming stress is negligible. These observations from detailed grain motions confirm that the changing nature of standing wave when f passes the crossover value should be related to the motion of surface grains.

10.3.2.2.3 Effect of Container Shape Dynamically similar behavior is also observed in a shaking box with outwardly canting side walls at an angle α from the vertical and richer dynamics is reported (Knight, 1997). Since only a portion of the bulk horizontal pressure (with a reduction factor of cos α) acts to induce wall friction during free flight, the net downward friction is reduced. The friction efficacy diminishes with increasing α that combines with the extra room gained next to the walls when approaching the free surface to allow individual grains to exhibit *ratcheting* trajectory. This new type of particle motion dominates at high enough Γ to induce flow reversal as shown by the descended central surface from a cycle-averaged exposure in Figure 10.14a.

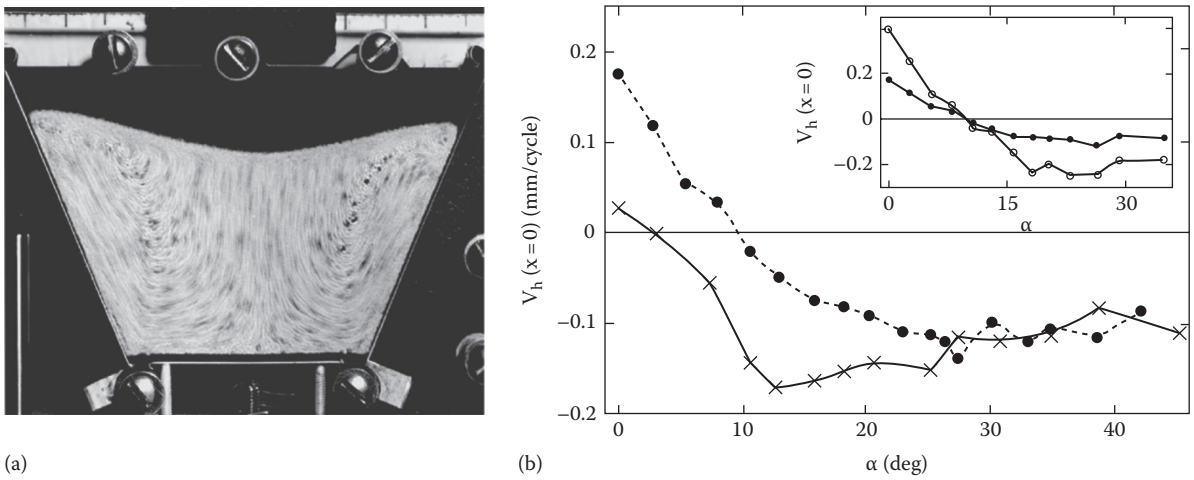

Figure 10.14

(a) Long exposure of flow in a container with walls at Γ = 4.2, 5.6 inclined outward at α = 25° shaken at Γ = 4.2 and *f* = 25 Hz. (b) Cycle-averaged velocity at the center of the convective flow as a function of wall inclination angle with smooth (×) and rough (●) walls, at Γ = 4.2 and *f* = 25 Hz. The inset presents data for rough wall under Γ = 4.2 (●) and 5.6 (○). (From Knight, J.B., *Phys. Rev. E*, 55(5), 6016, 1997.)

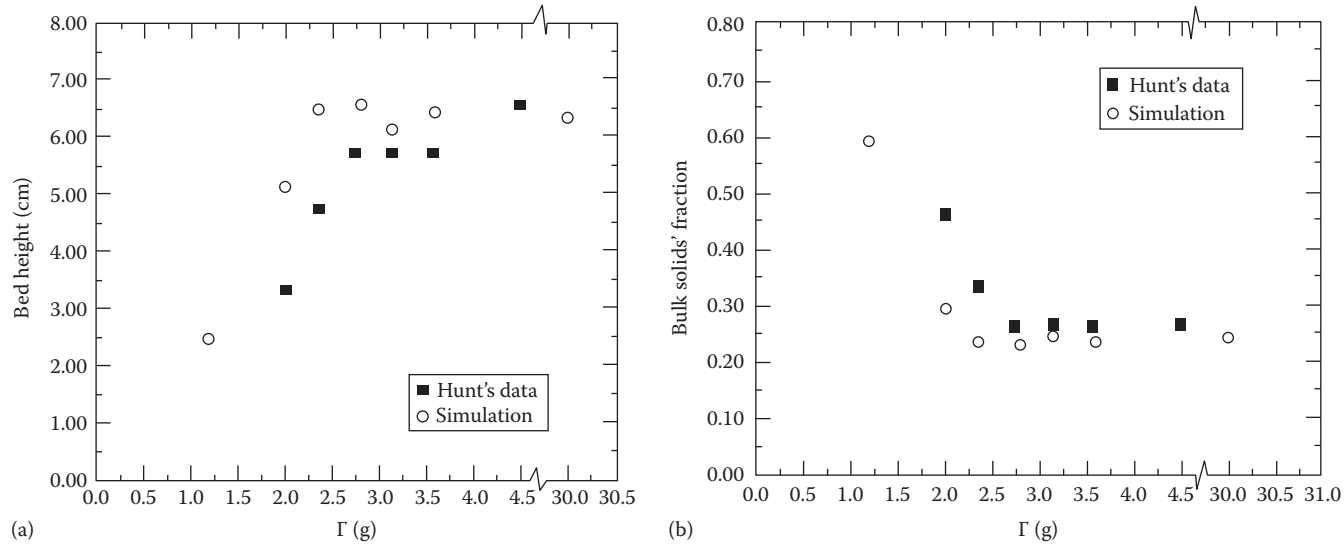

Figure 10.15

Variation of the simulated and the measured (a) system bed height and (b) overall solid volume fraction when G increases from 1.0 to 30. Monotonic rise and drop of T and ϕ is observed when $G > 1$ and both asymptote to constant plateaus when G reaches 3. Note that the authors present the shaking acceleration in units of g and its conversion to the dimensionless value adopted here is straightforward. The simulation results are from 3D DEM using grains of $D = 3$ mm, $\rho_s = 2.49$ g/cm^3, $e = e_w = 0.9$, without surface friction and grain rotation excited at $Z_0 = 5$ mm and $A_0 = 1$–30 g. (From Hunt, M.L. et al., *J. Fluid Eng.*, 116(4), 785, 1994; Lan, Y. and Rosato, A.D., *Phys. Fluids*, 7(8), 1818, 1995.)

Under identical values of Γ, the convective velocity at the container center, V_h, is examined with respect to α in Figure 10.14b and the DU transition angle α_c (zero crossing) is higher in more frictional container, so does the positive V_h in downward mode. Once in upward convection mode, V_h in the more frictional wall becomes smaller owing to degraded ratcheting grain motions. When $\alpha \gg \alpha_c$, the ratcheting mechanism dominates and V_h becomes insensitive to the wall friction as shown by the plateau. The inset of Figure 10.14b shows clearly that increasing Γ does not affect α_c but leads to higher V_h in both downward and upward modes as in the container with vertical walls.

10.3.2.2.4 Overall Dynamics In addition to these detailed observations of surface and bottom shape and individual grain motions, overall flow properties averaged across the bed over a vibration cycle have also been investigated. For example, the bed height is observed to grow abruptly when Γ_c is reached in both simulations (2D DEM [Taguchi, 1992] and 3D DEM [Lan and Rosato, 1995]) and experiments (Hunt et al., 1994) as shown in Figure 10.15a and the corresponding overall ϕ drops accordingly in Figure 10.15b. An overall convection strength in the bed J, as flux across a specific height or velocity at the container center, rises monotonically with Γ (Taguchi, 1992, Lan and Rosato, 1995) and A* (Tai and Hsiau, 2004). These phenomena all indicate that the bulk is better fluidized when Γ exceeds a critical value in which individual grain motion is agitated. Hence, the bulk-averaged granular temperature T shows a sharp rise around $\Gamma = 2 \sim 4$ in both simulation (Lan and Rosato, 1995, Figure 10.16) and experiments (Tai and Hsiau, 2004), and the component in the shaking direction, T_y, is measured to possess greater magnitude than the other component T_x.

10.3.3 Theoretical Modeling

10.3.3.1 Depth Profile of Cycle-Averaged T and ϕ

Apart from systematic experiments and particle-based simulations, theoretical analysis has also been conducted for specific phenomena in vertical vibration bed to consolidate our understanding of the relevant flow physics. For example, Richman and Martin (1992) have developed a model on the kinetic theory framework to describe the depth profiles of cycle-averaged solid volume fraction and granulate temperature in an *infinite* bed of uniform smooth and inelastic spheres. Like most kinetic theory models, the authors assume a Maxwellian velocity distribution function to calculate the ensemble average.

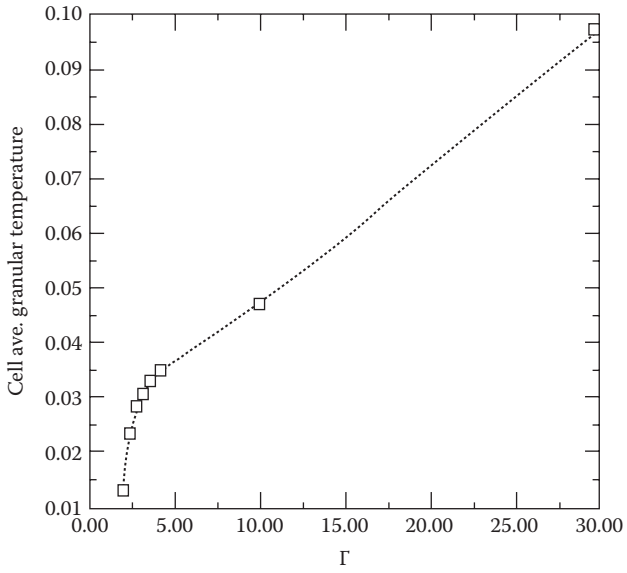

Figure 10.16

Granular temperature increases sharply when Γ increases above 2.0 based on a 3D DEM simulation with details provided in Figure 10.15. (From Lan, Y. and Rosato, A.D., *Phys. Fluids*, 7(8), 1818, 1995.)

The cycle-averaged granulate temperature T decreases monotonically from a maximum bed value onto a minimum plateau near the free surface; a concave depth profile for ϕ is predicted with the midheight maximum occuring at where T approaches its minimum plateau as shown in Figure 10.17. Further, excitation at higher V_b gives higher T (Figure 10.17a vs. c) but lower ϕ (Figure 10.17b vs. d) in dynamically similar depth profiles.

On the same plot, the depth profiles from a 3D DEM simulation with periodic boundary condition under different bed excitation V_b are also presented (Lan and Rosato, 1995). Though it requires much higher A* (>28.3) in the simulation than in real flows to reproduce the analytic T(y) and ϕ(y), it is worth noting that the simulation can capture the critical Γ for bed height expansion and dilatation from the experiment (Hunt et al., 1994). Hence, we infer that the energy dissipation mechanism in the kinetic theory is underestimated, especially when the bulk is not completely fluidized at low acceleration. For example, the effect of enduring frictional contacts and force chain networks on bulk dynamics may be important in denser regimes or when in contact with the vibrating base but is not taken into account in the model.

When the x- and y-components of the deviatoric velocity component, $\underline{u}_p - \underline{u}$, that contributes to total T, namely, T_x and T_y, are examined from simulation data, nearly isotropic Maxwellian (Gaussian with zero mean) is measured when Γ is high enough (A* = 56.5) in Figure 10.18b, confirming the assumption of Maxwellian distribution. Experimental evidences of nearly Maxwellian distribution for the deviatoric velocity when excited above Γc have also been reported (Wildman and Huntley, 2000, Tai and Hsiau, 2004). Nonetheless, asymmetric distribution with a smaller peak at nonzero deviatoric velocity is found at smaller A* = 5.6, in Figure 10.18a, while the other two components show equal and nearly Gaussian profile. This implies non-Maxwellian distribution and the possible failure of the kinetic theory under this flow condition.

10.3.3.2 Upward Convection Roll

In addition to the cycle-averaged quasi-steady depth profiles of T(y) and ϕ(y), the flow during the upward convection has also been modeled, and two different approaches are briefed in the following to shed lights on the underlying physics.

10.3.3.2.1 Acoustic Streaming Model for Averaged Convection Velocity Targeting the phenomenon of upward convection roll velocity, Savage derives an approximate solution on the framework of kinetic theory as the lowest-order asymptotic series solution. Serial assumptions and simplifications have been made

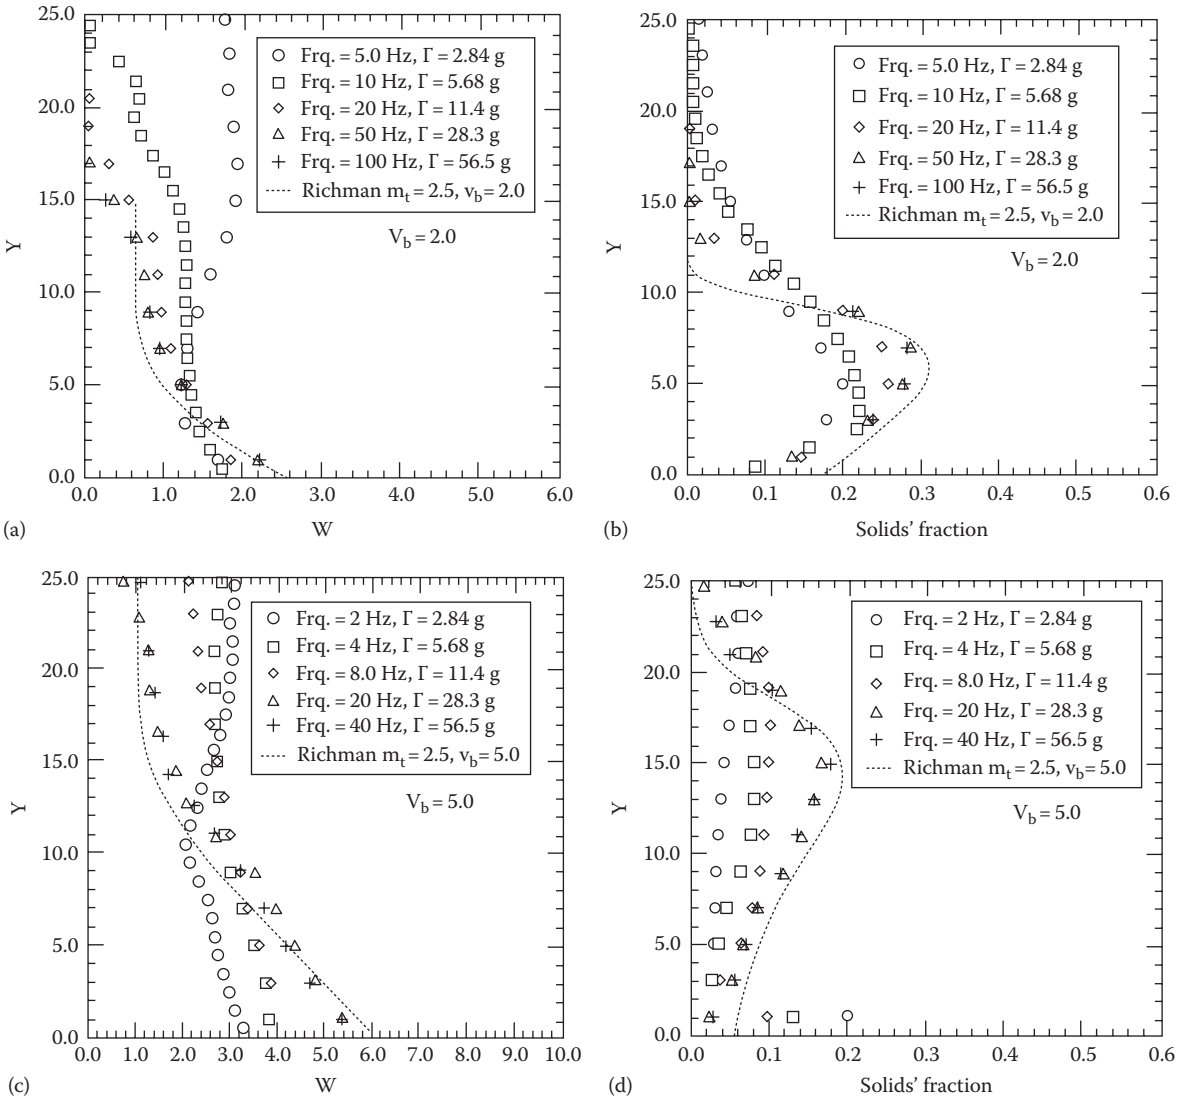

Figure 10.17

Comparison of the predicted and the simulated depth profiles for (a) + (c), granular temperature, and (b) + (d), solid volume fraction using two bed velocities at (a,b) $V_b = 2.0$ and (c,d) $V_b = 5.0$. A range of $\Gamma = 2.84$–56.5 is created in the 3D simulation using grains of $D = 0.1$ cm, $\rho_s = 1.2$ g/cm^3, $e = e_w = 0.9$ without surface friction and grain rotation and a total mass hold up of $m_t = 2.5$. The authors denote granular temperature by W and we have replaced it with T for present symbol consistency. (From Lan, Y. and Rosato, A.D., *Phys. Fluids*, 7(8), 1818, 1995.)

to permit an analytic solution possible. First, simpler constitutive relations are adopted, instead of Equations 10.2, 10.3, 10.7, 10.8, and 10.9, as

$$\underline{\underline{\tau}} = \underline{\underline{\tau}}_c + \underline{\underline{\tau}}_f = \kappa\left[\left(\frac{\sqrt{\pi}\mathrm{T}}{\mathrm{D}} - \frac{2+\alpha}{5}\mathrm{tr}\underline{\underline{\mathrm{D}}}\right)\underline{\underline{\mathrm{I}}} - \frac{2(2+\alpha)}{5}\underline{\underline{\mathrm{D}}}\right] + p_f\left[\underline{\underline{\mathrm{I}}} - \sin\psi\frac{\underline{\underline{\mathrm{D}}}}{\sqrt{1/2\mathrm{tr}(\underline{\underline{\mathrm{D}}}\underline{\underline{\mathrm{D}}})}}\right] \tag{10.37}$$

$$\underline{q} \approx \underline{q}_c = -\kappa\underline{\nabla}T \tag{10.38}$$

$$\kappa = 2\rho_p D(1+e)\phi^2 g_0(\phi)\sqrt{\mathrm{T}/\pi} = \rho DG(\phi,e)\phi g_0(\phi)\sqrt{\mathrm{T}/\pi} \tag{10.39}$$

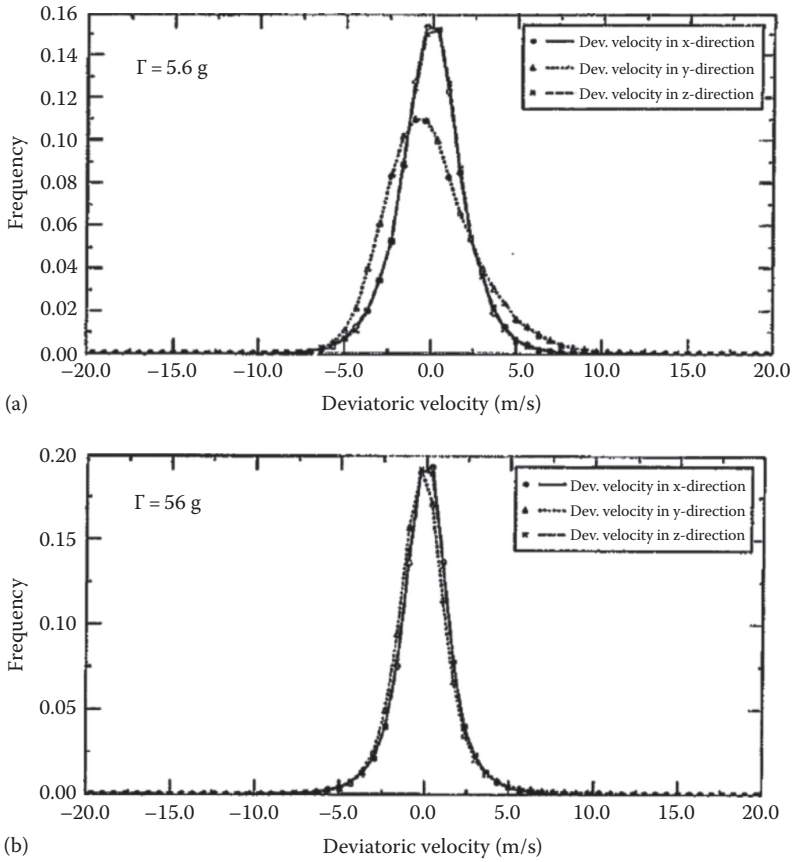

Figure 10.18

Deviatoric velocity distribution at Γ = (a) 5.6 (*f* = 10 Hz) and (b) 56.5 (*f* = 100 Hz) using the same grains of *D* = 0.01 m and $e = e_w = 0.9$ and identical bed velocity $V_b = 2.0$ and total mass holdup $m_t = 2.5$. (From Lan, Y. and Rosato, A.D., *Phys. Fluids*, 7(8), 1818, 1995.)

$$s = \frac{6(1-e)\kappa}{D^2}\left[T - \left(\frac{\pi}{4} + \frac{\alpha}{3}\right)D\sqrt{\frac{T}{\pi}}\,\mathrm{tr}\underline{\underline{D}}\right] \tag{10.40}$$

where $\alpha \approx 1$ and the pseudo-thermal flux due to $\nabla\phi$ is neglected. Savage adopts another radial distribution function, $g_0(\phi) = \left[1 - (\phi/\phi_m)^{1/3}\right]^{-1}$ with $\phi_m = 0.64$ to obtain greater collisional stress that better matches to the experimental results. Note that the streaming stress component is neglected since the bulk concentration is not too low and, likewise, only collision-induced heat flux and dissipation are considered. It is further assumed that there is no static mass under the cyclic base excitation and hence $\psi \to 0$.

Flow variables are then decomposed into a mean and a fluctuating component (denoted by the prime) as

$$\rho = \bar{\rho} + \rho', \quad \underline{u} = \underline{u}_m + \underline{u}', \quad \text{and} \quad T = T_m + T' \tag{10.41}$$

Here, the mean variables with an overhead bar denote a regular average and that with a subscript *m* is from a mass-averaged scheme: $\underline{u}_m = \overline{\rho\underline{u}}/\bar{\rho}$ and $T_m = \overline{\rho T}/\bar{\rho}$. Under the assumption of random fluctuations, $\overline{\rho\underline{u}'} = \overline{\rho T'} = 0$.

Switching to index notation, the mass, momentum, and fluctuation energy conservation equations in Equations 10.4 through 10.6 become

$$\frac{\partial}{\partial t}\left(\bar{\rho} + \rho'\right) + \frac{\partial}{\partial x_j}\left(\overline{\rho u_j} + \overline{\rho u_j'}\right) = 0 \tag{10.42}$$

$$\frac{\partial}{\partial t}\left(\rho u_{mi}+\rho u_j'\right)+\frac{\partial}{\partial x_j}\left(\rho u_{mi}u_{mj}+\rho u_{mi}u_j'+\rho u_i'u_{mj}+\rho u_i'u_j'\right)=\rho g_i-\frac{\partial \tau_{ij}}{\partial x_j} \tag{10.43}$$

$$\frac{3}{2}\frac{\partial}{\partial t}\left(\rho T_m+\rho T'\right)+\frac{\partial}{\partial x_j}\left(\rho T_m u_j+\rho T_m u_j'+\rho T'u_{mj}+\rho T'u_j'\right)=-\tau_{ij}\frac{\partial u_i}{\partial x_j}-\frac{\partial q_j}{\partial x_j}-s \tag{10.44}$$

These *instantaneous* equations are averaged over a vibration cycle to render a set of *mean* governing equations as

$$\frac{\partial}{\partial x_i}\overline{\rho}u_{mi}=0 \tag{10.45}$$

$$\frac{\partial}{\partial t}\overline{\rho}u_{mi}+\frac{\partial}{\partial x_j}\overline{\rho}u_{mi}u_{mj}=\overline{\rho}g_i-\frac{\partial\overline{\tau_{ij}}}{\partial x_j}-\frac{\partial}{\partial x_j}\overline{\rho u_i'u_j'} \tag{10.46}$$

$$\frac{3}{2}\left(\frac{\partial}{\partial t}\overline{\rho}T_m+\frac{\partial}{\partial x_j}\overline{\rho}T_m u_{mj}\right)=-\frac{\partial}{\partial x_j}\overline{\rho T'u_j'}-\overline{\tau_{ij}\frac{\partial u_i}{\partial x_j}}-\frac{\partial\overline{q_i}}{\partial x_j}-s \tag{10.47}$$

Savage reasons that $\partial/\partial x \ll \partial/\partial y$ for flows in a wide bed and assumes, in particular, $u_m \ll u'$ but $\rho \ll \rho'$ and $T' \ll T_m$ for its agitated yet not too dilute state. Based on these flow features, simplification of the instantaneous and mean momentum equation in Equations 10.43 and 10.46 leads to

$$\frac{\partial}{\partial t}\overline{\rho}u_j'+\frac{\partial}{\partial x_j}\left(\overline{\rho}u_i'u_j'\right)=\overline{\rho}g_i-\frac{\partial\tau_{ij}}{\partial x_j} \tag{10.48}$$

$$\frac{\partial}{\partial t}\overline{\rho}u_{mi}+\frac{\partial}{\partial x_j}\overline{\rho}u_{mi}u_{mj}=\overline{\rho}g_i-\frac{\partial\overline{\tau_{ij}}}{\partial x_j}-\frac{\partial}{\partial x_j}\overline{\rho u_j'u_j'} \tag{10.49}$$

where $p_{ij}=\overline{p_{ij}}+p_{ij}'$ and the last term in this equation resembles Reynolds stress in turbulent flows to enhance momentum dissipation. By subtracting Equation 10.48 from Equation 10.49 and further assuming nearly constant mean density $\overline{\rho}\approx\rho_0$ and $\partial/\partial x_j\left[\overline{\rho}\left(u_{mi}u_{mj}-u_i'u_j'\right)\right]$ is much smaller than the rest terms, a linearized equation is obtained for how the fluctuating pressure and velocity are related to each other as

$$\rho_0\frac{\partial u_i'}{\partial t}=-\frac{\partial p_{ij}'}{\partial \mathrm{x_j}} \tag{10.50}$$

Keeping only the dominant terms, the y-component from this equation is

$$\rho_0\frac{\partial \mathrm{v}'}{\partial \mathrm{t}}=-\frac{\partial \mathrm{p}_{yy}'}{\partial \mathrm{y}}=-\frac{\partial \mathrm{p}_T'}{\partial \mathrm{y}}+\frac{9}{5}\frac{\partial}{\partial \mathrm{y}}\left(\kappa\frac{\partial \mathrm{v}'}{\partial \mathrm{y}}\right) \tag{10.51}$$

where p_T' is the fluctuating component of the pseudo-thermal pressure in the first term on the right-hand side of Equation 10.37. Savage then considers the high energy input from the vibrating bed to assume a locally high T and hence negligible transverse variation of κ across most layer thickness (see the definition in Equation 10.39) to write

$$\rho_0\frac{\partial \mathrm{v}'}{\partial \mathrm{t}}=-\mathrm{c}_0^2\frac{\partial \rho'}{\partial \mathrm{y}}+\kappa\frac{9}{5}\frac{\partial^2 \mathrm{v}'}{\partial \mathrm{y}^2} \tag{10.52}$$

Here, $c_0 = \sqrt{\partial p'_T/\partial \rho}$ is a "sound speed" induced by vibration-induced variable fluctuations and Savage has given an estimation as

$$c_0 = \sqrt{\partial p'_T/\partial \rho} = \left[\left(1 + \frac{2}{3}G + \frac{\phi}{G}\frac{dG}{d\phi}\right)GT\right]^{1/2} \tag{10.53}$$

with $G(\phi)$ specified in Equation 10.39. Similarly, the instantaneous mass conservation equation, Equation 10.42, is subtracted from the mean, Equation 10.45, to give

$$\frac{\partial \rho'}{\partial t} = -\rho_0 \frac{\partial v'}{\partial y} \tag{10.54}$$

By eliminating the fluctuating density ρ' in Equations 10.52 and 10.54, a damped wave equation is found for v' as

$$\frac{\partial^2 v'}{\partial t^2} = c_0^2 \frac{\partial^2 v'}{\partial y^2} + \frac{9\kappa}{5\rho_0}\frac{\partial^3 v'}{\partial t \partial y^2} \tag{10.55}$$

When the attenuation is weak, a longitudinal wave solution is found readily as follows:

$$v'(x,y,t) = v_b(x)\cos(\xi y - \omega_{//} t)e^{-\varsigma y} \tag{10.56}$$

with

$$\xi = \omega_{//}/c_0 \quad \text{and} \quad \varsigma = 9\kappa\omega_{//}^2/10\rho_0 c_0 \tag{10.57}$$

In Equations 10.56 and 10.57, $\omega_{//}$ (not to be confused with $\omega = 2\pi f$) and $\xi = \omega_{//}/c_0$ are radian frequency and wave number of the transverse wave going toward the free surface from a bed at a slowly varying velocity distribution $v_b(x)$. It is worth noting that $v_b(x)$ may be interpreted as a way to introduce streamwise non-uniformity to the system to mimic physical property gradient, such as that maintained between coexisting slow denser corner flow and agitated dilute central bulk. Savage prescribes $v_b(x) = V_b\left[1 + \varepsilon N\cos\left(\pi x/W\right)\right]$ with a characteristic V_b, a constant N of order unity, and a small height-to-width ratio, $\varepsilon = H/W$. Further, the approximation of nearly constant density $\overline{\rho} \approx \rho_0$ and κ simplifies the mean continuity equation, the mean stress tensor, and the mean energy equation into the following expressions:

$$\frac{\partial u_{mi}}{\partial x_i} = 0 \tag{10.58}$$

$$\overline{\tau_{ij}} \approx \left[p_{s0} + p_{Tm}\right]\delta_{ij} - \frac{3\kappa}{5}\left(\frac{\partial u_{mi}}{\partial x_j} + \frac{\partial u_{mj}}{\partial x_i}\right) \tag{10.59}$$

$$\frac{dT_m}{dy^2} - \frac{6(1-e)}{D^2}T_m = -\frac{3}{5}\overline{\frac{\partial v'}{\partial y}\frac{\partial v'}{\partial y}} \tag{10.60}$$

where $p_{Tm} = \kappa\sqrt{\pi T_m/D}$ in Equation 10.59 is a pseudo-thermal pressure. The substitution of Equations 10.56 and 10.57 into Equation 10.60 permits a general solution for the mean granular temperature by superposition of the homogeneous solutions, $e^{\pm \beta y}$ with $\beta = 6(1 - e)/D^2$, and the particular solution, $\frac{9}{10}v_b^2\xi^2/(\beta - 4\varsigma^2)e^{-2\varsigma y}$.

Considering that heat flux should go from the constantly agitated bed toward the free surface, the basis solution with positive exponent should vanish, giving the following:

$$T_m(y) = \frac{Ce^{-\sqrt{\beta}y} + \frac{9}{10}\nu_b^2\xi^2}{(\beta - 4\varsigma^2)e^{-2\varsigma y}} \tag{10.61}$$

The unknown constant C is determined later on via stress boundary condition at the bed (see the context following Equation 10.67).

The flow variables are then transformed into dimensionless groups as

$$\begin{aligned} &\mathrm{X} = \frac{x}{W}, \quad \mathrm{Y} = \frac{y}{H}, \quad \mathrm{U} = \frac{u_m}{V_b\varepsilon}, \quad \mathrm{V} = \frac{v_m}{V_b\varepsilon^2}, \\ &\mathrm{P_s} = \frac{p_{s0}}{\rho_0 gH}, \quad \mathrm{T}_\star^{1/2} = \frac{\kappa\sqrt{\pi T_m}}{D\rho_0 gH} \end{aligned} \tag{10.62}$$

so that dimensionless stress components and Reynolds stress are

$$\begin{aligned} &\mathrm{P_{xx}} = \mathrm{P_s} + \mathrm{T}_\star^{1/2} - \mu\varepsilon^3\frac{\partial U}{\partial X}, \quad \mathrm{P_{yy}} = \mathrm{P_s} + \mathrm{T}_\star^{1/2} - \mu\varepsilon^3\frac{\partial V}{\partial Y}, \\ &\mathrm{P_{xy}} = -\frac{1}{2}\mu\varepsilon^3\left(\frac{\partial U}{\partial Y} + \varepsilon^2\frac{\partial V}{\partial X}\right) \end{aligned} \tag{10.63}$$

$$\overline{\rho v' v'} \approx \rho_0\overline{v' v'} = \frac{\rho_0}{2}V_b^2 e^{-2\varsigma Y} \tag{10.64}$$

Solutions are sought in an asymptotic series in expansion with small ε as

$$\begin{aligned} &\mathrm{U} = \mathrm{U}^{(0)} + \varepsilon U^{(1)} + \varepsilon^2 U^{(2)} + \cdots, \quad \mathrm{V} = \mathrm{V}^{(0)} + \varepsilon V^{(1)} + \varepsilon^2 V^{(2)} + \cdots \\ &\left[\mathrm{P_s} + T_\star^{1/2}\right] = \left[\mathrm{P_s} + T_\star^{1/2}\right]^{(0)} + \varepsilon\left[\mathrm{P_s} + T_\star^{1/2}\right]^{(1)} + \cdots \end{aligned} \tag{10.65}$$

The governing equations are then separated into serial sets of equations with increasing order of ε. The zeroth- and first-order governing equations are

$$\begin{cases} \dfrac{\partial \mathrm{U}^{(0)}}{\partial X} + \dfrac{\partial \mathrm{V}^{(0)}}{\partial Y} = 0 \\ \dfrac{\partial}{\partial \mathrm{X}}\left[\mathrm{P_s} + T_\star^{1/2}\right]^{(0)} = 0 \\ \dfrac{\partial}{\partial \mathrm{Y}}\left\{\left[\mathrm{P_s} + T_\star^{1/2}\right]^{(0)} + \dfrac{1}{2}Fe^{-2\varsigma HY}\right\} = -1 \end{cases} \tag{10.66}$$

$$\begin{cases} \dfrac{\partial}{\partial \mathrm{X}}\left[\mathrm{P_s} + T_\star^{1/2}\right]^{(1)} = \dfrac{1}{2}\mu\dfrac{\partial^2 U^{(0)}}{\partial Y^2} \\ \dfrac{\partial}{\partial \mathrm{Y}}\left\{\left[\mathrm{P_s} + T_\star^{1/2}\right]^{(1)} + FN\cos(\pi X)e^{-2\varsigma HY}\right\} = 0 \end{cases} \tag{10.67}$$

where $F = V_b^2/gh$ is a dimensionless number similar to the square of flow Froude number using V_b. Under the stress-free condition at Y = 1, Equation 10.66 can be integrated to yield the following expression:

$$\left[P_s + T_\star^{1/2}\right]^{(0)} = 1 - Y + \frac{1}{2} F e^{-2\varsigma H} \left(1 - e^{-2\varsigma H(Y-1)}\right) \tag{10.68}$$

which is used to determine the only unknown constant C in Equation 10.61 for T_m with the following procedure.

The analysis assumes that, to the first approximation, all the stress at the bed results from particle collisions to obtain $T_\star^{1/2} = 1$ ($P_s = 0$ owing to the earlier assumption of no stagnant layer on the vibrating bed) and hence $T_m = gH/2(1 + e)\phi g_0(\phi)$. Equating this particular value to Equation 10.61 determines C. Likewise, Equation 10.67 can be integrated to give

$$\left[P_s + T_\star^{1/2}\right]^{(1)} = FN \cos(\pi X) e^{-2\varsigma H} \left(1 - e^{-2\varsigma H(Y-1)}\right) \tag{10.69}$$

which is further integrated with Equation 10.67 to give a second-order ordinary differential equation (ODE) for $U^{(0)}$. To specify boundary condition, Savage uses a zero shear stress at the bed, $\partial U^{(0)}/\partial Y|_{Y=0} = 0$, since particles near the bed are well agitated and slide on the smooth bed surface (note that surface friction is not accounted for in this model). A zero total mass flux is further required for the circulating flow as $\int_0^1 U(Y)^{(0)} dY = 0$. The resulting solution is

$$U^{(0)} = \frac{2}{\mu} \pi FN \sin(\pi X) \left\{ \frac{1}{2\varsigma H} \left(Y + \frac{e^{-2\varsigma HY}}{2\delta H} \right) - \frac{1}{2} Y^2 e^{-2\varsigma H} + \frac{1}{6} e^{-2\varsigma H} + \frac{1}{8\varsigma^3 H^3} \left(e^{-2\varsigma H} - 1 \right) - \frac{1}{4\varsigma H} \right\} \tag{10.70}$$

which can be substituted into the continuity equation Equation 10.66 to obtain the leading order vertical velocity profile as

$$\begin{aligned} V^{(0)} = -\frac{2}{\mu} \pi^2 FN \cos(\pi X) \Bigg\{ & \frac{1}{2\varsigma H} \left[\frac{1}{2} Y^2 + \frac{1}{4\varsigma^2 H^2} \left(1 - e^{-2\varsigma HY}\right) \right] \\ & - \frac{1}{6} Y^3 e^{-2\varsigma H} + Y \left[\frac{1}{6} e^{-2\varsigma H} - \frac{1}{4\varsigma H} + \frac{1}{8\varsigma^3 H^3} \left(e^{-2\varsigma H} - 1 \right) \right] \Bigg\} \end{aligned} \tag{10.71}$$

When the coefficient of restitution is set to $e = 0.8$ for typical materials, $\beta^{1/2}$ is of the order of D and much greater than ς^2 so that the second term in Equation 10.61 dominates and $T_m(y)$ decays monotonically but slowly ($\varsigma \ll 1$) from a bed maximum. Savage evaluates a mean value of $D = 1.44$ mm, $\phi = 0.58$, and $\varepsilon N \approx 0.5$ for his experimental materials so that all the coefficients in Equations 10.70 and 10.71 can be evaluated. Figure 10.19 depicts how the predicted velocity components vary across right half of the container and a circulation pattern is clearly captured. Both components grow with the oscillation amplitude but at a rate too fast as compared to real flows. Savage attributes it to the fact that the model does not account for the friction from the container walls (front, back, and side) and internal structure (recall $\psi = 0$) so that frictional stress is underestimated in the model.

10.3.3.2.2 Negative Slip Model for Convection Flow Patterns In a different approach, Bourzutschky and Miller (1995) adopt *compressible* Navier–Stokes equation to approximate the bulk motion and reproduce the downward convection from their numerical solution if a negative apparent wall slip is enforced. Considering that wall friction causes phase delay in local density fluctuations, which relaxes into the bed through inertial transport to cause convection, the authors account for this phenomenon as acoustic wave propagating through the bed. Limiting to small acceleration strength within the parameter space of linear stability

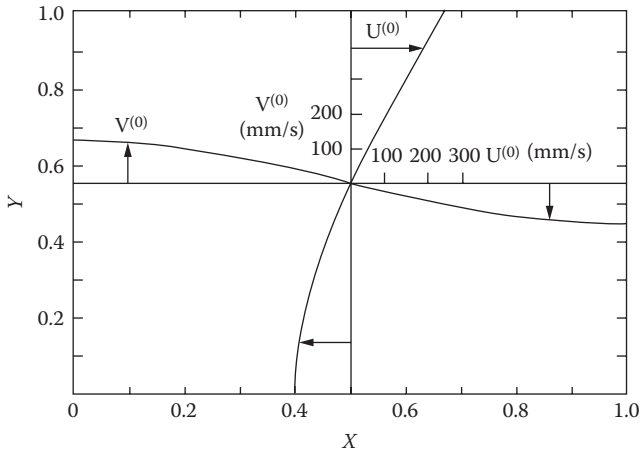

Figure 10.19

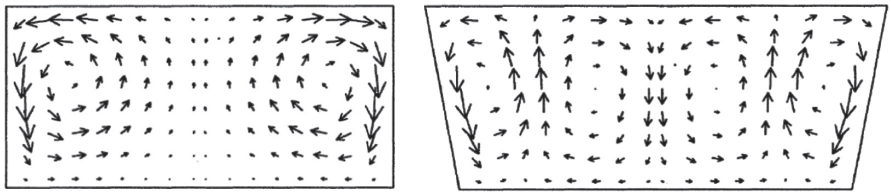
Primary mode of the horizontal and vertical velocity components along a vertical and horizontal line, respectively, at the center of the right half of the container by Equations 10.70 and 10.71 using Z_0 = 3 mm, f = 25 Hz, e = 0.85, and H = 62 mm. The velocity variables used in the reference have been changed to current definition. (From Savage, S.B. and Lun, C.K.K., *J. Fluid. Mech.*, 189, 311, 1988.)

without boundary effect (Peyrel and Taylor, 1983), a linear equation of state $p(\rho) = p_0 + c^2\rho$ is integrated to the conservation equations for mass and momentum as

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \left(\rho \vec{u}\right) = 0 \tag{10.72}$$

$$\rho \frac{\partial \vec{u}}{\partial t} + \rho \vec{u} \cdot \nabla \vec{u} = -\nabla p - \mu \nabla^2 \vec{u} + 4\pi^2 Z_0 \sin\left(2\pi t\right) \underline{e}_y \tag{10.73}$$



where μ is an equivalent bulk viscosity and the gravity is neglected. The last term on the right-hand side of Equation 10.73 is the bed driving force and $\underline{e}_y$ is the unit normal vector. These partial differential equations are subject to no-through flow and tangential slip at the solid walls as

$$\begin{cases} u_n = 0 \\ u_t + \gamma \partial u_t / \partial n = 0 \end{cases} \tag{10.74}$$

with γ being the wall slip. A positive γ in Equation 10.74 enforces a zero tangential velocity outside of the boundary to give the slip tangential velocity at lateral walls and a negative γ results in zero tangential velocity within the flow. The cycle-averaged bulk velocity with no-slip wall always shows downward convection pattern (see Figure 10.20a). When a *negative slip* is assigned, it creates an internal flow localized to the local flow of strong shear similar to the *shear band* reported by Knight (see Figures 10.7 and 10.9) to induce an internal pair convection roll of opposite direction. The flow pattern in a container with outwardly slanting side walls is shown in Figure 10.20b. When no-slip boundary condition always results in downward flow adjacent to the walls, the critical wall inclination angle for roll reversal grows monotonically with the strength of negative wall slip $|\gamma|$. This finding may serve as another evidence that the development of an internal shear band is essential for the UD transition. We may also interpret such wall boundary condition as a different interaction mode between the bulk and the container wall since the DEM simulations have shown that changing only the dissipation mechanism in particle–wall interaction can lead to flow reversal (Taguchi, 1992).

10.3.3.3 Surface Pattern via Stability Analysis

In addition to the convective bulk flow, Deng and Wang (2003) conducted a linear stability analysis of the motion of a uniform layer under uniform vertical vibrations to explain how surface wave (see Figure 10.11)

(a) (b)

Figure 10.20

Cycle-averaged steady velocity field in a shaking bed using unity shaking frequency, $Z_0 = 0.01$, $c = 1$ in the equation of state, $\mu = 0.05$, and negative wall $\gamma = -0.9$. The two cases differ by (α, u_m) = (a) $(0°, 2.4 \times 10^4)$ and (b) $(8°, 1.1 \times 10^{-4})$. (From Bourzutschky, M. and Miller, J., *Phys. Rev. Lett.*, 74(12), 2216, 1995.)

may develop at high enough agitation. The governing equations in Equations 10.4 through 10.6 are completed by substituting the constitutive relations developed by Lun et al. (1984) in Equations 10.2, 10.3, 10.7 through 10.9. They define dimensionless variables using layer thickness, H; grain density and diameter, ρ_p and D; and gravity as

$$\underline{X} = \underline{x}/H, \quad \underline{U} = \underline{u}/\sqrt{gH}, \quad T^\star = T/gD, \quad t^\star = t/\sqrt{Hg},$$
$$M_t = m_t/\rho_p D, \quad Q_t = Q_0/\rho_p (Dg)^{3/2}, \quad \text{and} \quad H^\star = H/D \tag{10.75}$$

in which m_t is the total mass holdup and Q_0 is the energy flux input at the bed. Unlike most works that adopt acceleration strength (Γ or $A^\star$) and bed height ($H^\star$) as the controlling parameters, the authors used the scaled total mass holdup and heat flux. While M_t is linearly correlated to $H^\star$, there is no explicit correlation between Q_t and Γ, but the two have similar influences on the system dynamics that a more agitated bed is obtained with higher Q_t and acceleration strength. The quasi-steady cycle-averaged *base-state* governing equations become

$$H^\star \int_Y^1 \phi dY = f_1(\phi) T^\star - \frac{\pi}{6}\left(\frac{\phi}{\phi_m}\right)^{2/3} \tag{10.76}$$

$$\underline{U}^\star = 0 \tag{10.77}$$

$$\frac{\partial}{\partial Y}\left[f_3(\phi) T^{\star 1/2} \frac{dT^\star}{dY} + f_4(\phi) T^{\star 3/2} \frac{d\phi}{dY}\right] - H^{\star 2} f_5(\phi) T^{\star 3/2} = 0 \tag{10.78}$$

The dependence on ϕ is incorporated into various functions, $f_i(\phi)$, for brevity, and their explicit forms can be found in Table 10.3. Numerical solutions to these coupled equations are solved via iterations by varying a guessed steady flow height and checking if the computed mass hold up, $H^\star \int_0^1 \phi(Y) dY$, is within a chosen tolerance to the assigned M_t. The boundary conditions at the base and the free surface ($Y = 1$) then become

$$\text{At Y} = 0: f_3(\phi) T^{\star 1/2} \frac{dT^\star}{dY} + f_4(\phi) T^{\star 3/2} \frac{d\phi}{dY} = H^\star \left(1 - e_w^2\right) f_3(\phi) f_6(\phi) T^{\star 3/2} - Q_t \tag{10.79}$$

$$\text{At Y} = 1: f_3(\phi) T^{\star 1/2} \frac{dT^\star}{dY} + f_4(\phi) T^{\star 3/2} \frac{d\phi}{dY} = 0 \tag{10.80}$$

The base-state solution can capture many well-known bulk dynamics including the growing bed height with Q_t, midheight maximum of ϕ(Y), monotonic decrease of T(Y), and the pseudo-thermal energy flux J(Y) toward the free surface as shown in Figure 10.21a through d. The authors also report agreement of their T(Y) with that predicted by Richman and Martin (1992) and attribute the difference found in the surface profile of $\phi(Y)$ to the different boundary conditions adopted at the free surface. Via parameter study, the authors

Table 10.3 Dimensionless Functions, $f_i(\phi)$ for $i = 1 \sim 9$ in Equations 10.76 through 10.80, and 10.82 through 10.89

$$f_1(\phi) = \phi\left[1 + 4\eta\phi g_0(\phi)\right],$$

$$f_2(\phi) = \frac{5\sqrt{\pi}(2+\alpha)}{288\eta(2-\eta)}\left[\frac{1}{g_0(\phi)} + \frac{8}{5}\eta\phi\right]\left[1 + \frac{3}{5}\eta(3\eta-2)\phi g_0(\phi)\right] + \frac{8(2+\alpha)\eta\phi^2 g_0(\phi)}{15\sqrt{\pi}},$$

$$f_3(\phi) = \frac{25\sqrt{\pi}}{16\eta(41-33\eta)}\left\{\left[\frac{1}{g_0(\phi)} + \frac{12}{5}\eta\phi\right]\left[1 + \frac{12}{5}\eta^2(4\eta-3)\phi g_0(\phi)\right] + \frac{64}{25\pi}(41-33\eta)\eta^2\phi^2 g_0(\phi)\right\},$$

$$f_4(\phi) = \frac{25\sqrt{\pi}}{16\eta(41-33\eta)}\left[\frac{1}{\phi g_0(\phi)} + \frac{12}{5}\eta\right]\frac{12}{5}\eta(2\eta-1)(\eta-1)\frac{d}{d\phi}\left[\phi^2 g_0(\phi)\right],$$

$$f_5(\phi) = \frac{48\eta(1-\eta)\phi^2 g_0(\phi)}{\sqrt{\pi}}, \quad f_6(\phi) = \frac{\sqrt{3}\pi\phi g_0(\phi)}{4\phi_m f_3(\phi)}, \quad f_7(\phi) = \frac{\pi\phi g_0(\phi)}{2\sqrt{3}\phi_m f_3(\phi)},$$

$$f_8(\phi) = \frac{\pi\phi g_0(\phi)}{2\sqrt{3}\phi_m f_2(\phi)}, \quad f_9(\phi) = \frac{8\eta\phi^2 g_0(\phi)}{3\sqrt{\pi}}$$

[a] Here, $\eta = (1 + e)/2$ as in Equations 10.2 and 10.3.

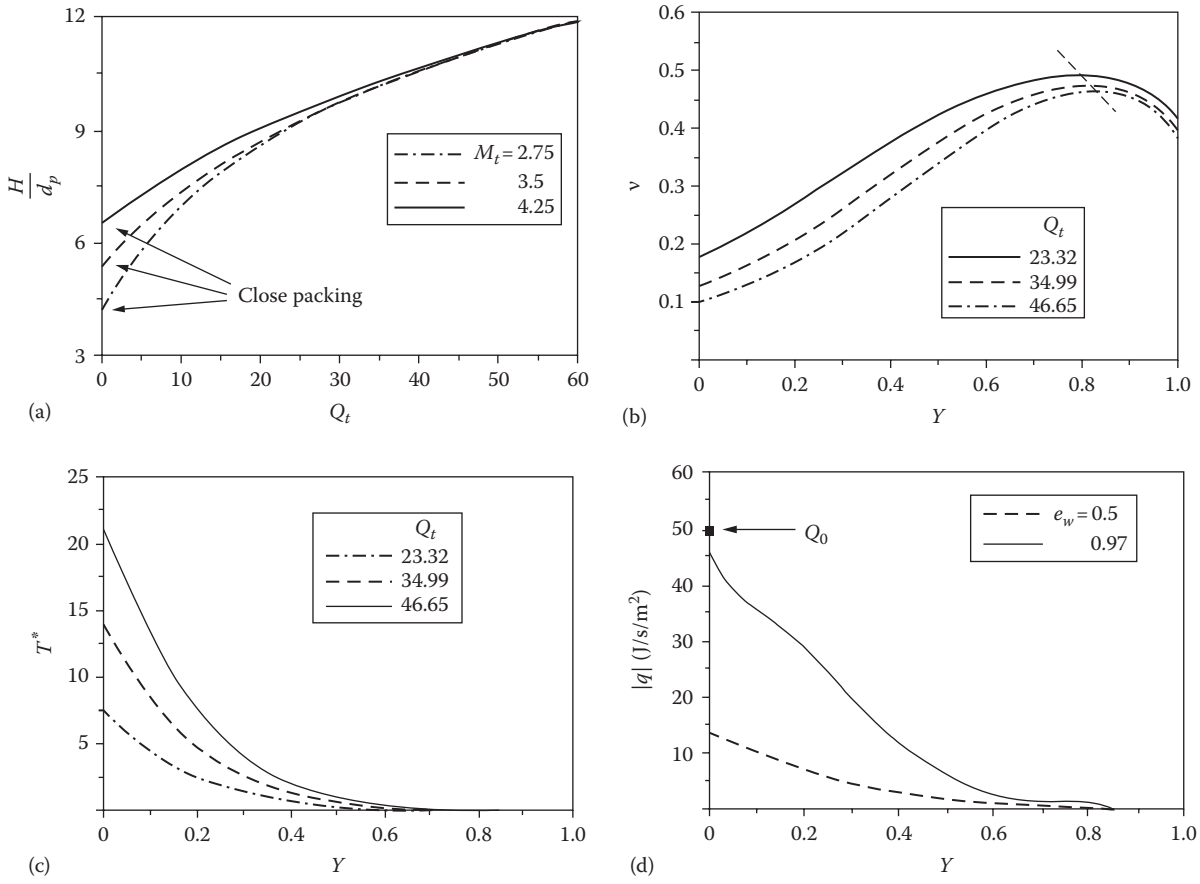


Figure 10.21

(a) Predicted steady-state bed height, H^*, as a function of energy input Q_t; predicted depth profile of (b) solid volume fraction distribution and (c) granular temperature under different Q_t for $M_t = 3.5$. The thin dashed line in (b) locates midheight maximum; (d) depth profile of heat flux using $e_w = 0.5$ and 0.97 for a system operated at (M_t, Q_t) = (4.25, 58.31). (From Deng, R.S. and Wang, C.H., *J. Fluid Mech.*, 492, 381, 2003.)

further conclude that the proportion of dissipated and transported energy depends primarily on the coefficient of restitution between grains (e) and wall (e_w) but not on the operating conditions (M_t and Q_t).

Deng and Wang (2003) then introduce synchronized oscillating perturbations to the base-state solutions—ϕ_0, T_0, and $\underline{U}_0 = 0$ (denoted by a subscript 0)—to describe total variables as

$$\begin{bmatrix} \underline{U} \\ \phi \\ T \end{bmatrix} = \begin{bmatrix} \underline{U}_0 \\ \phi_0 \\ T_0 \end{bmatrix} + \begin{bmatrix} \underline{U}' \\ \phi' \\ T' \end{bmatrix} \quad \text{with} \quad \begin{bmatrix} \underline{U}' \\ \phi' \\ T' \end{bmatrix} = \begin{bmatrix} \underline{U}_e(Y) \\ \phi_e(Y) \\ T_e(Y) \end{bmatrix} \exp(\Omega\tau)\exp(iK_x X)\exp(iK_z Z) \tag{10.81}$$

which is no longer steady and hence subject to Equations 10.4 through 10.6. To conduct the stability analysis, these equations are linearized into

$$\frac{\partial \phi'}{\partial t^\star} + \phi_0 \frac{\partial U'}{\partial X} + \phi_0 \frac{\partial V'}{\partial Y} + \frac{\partial \phi_0}{\partial Y} V' = 0 \tag{10.82}$$

$$\begin{aligned} &-H^\star \phi_0 \frac{\partial U'}{\partial \tau} + H^{\star -1/2} \frac{\partial}{\partial Y}\left[f_2(\phi_0) T_0^{1/2} \right]\left(\frac{\partial U'}{\partial Y} + \frac{\partial V'}{\partial X} \right) - T_0 \left. \frac{\partial f_1}{\partial \phi} \right|_{\phi_0} \frac{\partial \phi'}{\partial X} - f_1(\phi_0) \frac{\partial T'}{\partial X} \\ &+ H^{\star -1/2} T_0^{1/2} \left\{ \left[f_9(\phi_0) + \frac{4}{3} f_2(\phi_0) \right] \frac{\partial^2 U'}{\partial X^2} + f_2(\phi_0) \frac{\partial^2 U'}{\partial Y^2} + \left[f_9(\phi_0) + \frac{1}{3} f_2(\phi_0) \right] \frac{\partial^2 V'}{\partial X \partial Y} \right\} = 0 \end{aligned} \tag{10.83}$$

$$\begin{aligned} &-H^\star \phi_0 \frac{\partial V'}{\partial t^\star} + \left[-H^\star - \frac{\partial}{\partial Y}\left(T_0 \left. \frac{\partial f_1}{\partial \phi} \right|_{\phi_0} \right) \right] \phi' - \left. \frac{\partial f_1}{\partial Y} \right|_{\phi_0} T' - T_0 \left. \frac{\partial f_1}{\partial \phi} \right|_{\phi_0} \frac{\partial \phi'}{\partial Y} - f_1(\phi_0) \frac{\partial T'}{\partial Y} \\ &+ H^{\star -1/2} \left\{ \frac{\partial}{\partial Y}\left[f_9(\phi_0) T_0^{1/2} \right] - \frac{2}{3} \frac{\partial}{\partial Y}\left[f_2(\phi_0) T_0^{1/2} \right] \right\} \frac{\partial U'}{\partial X} \\ &+ H^{\star -1/2} \left\{ \frac{\partial}{\partial Y}\left[f_9(\phi_0) T_0^{1/2} \right] + \frac{4}{3} \frac{\partial}{\partial Y}\left[f_2(\phi_0) T_0^{1/2} \right] \right\} \frac{\partial V'}{\partial Y} \\ &+ H^{\star -1/2} T_0^{1/2} \left\{ f_2(\phi_0) \frac{\partial^2 V'}{\partial X^2} \left[f_9(\phi_0) + \frac{4}{3} f_2(\phi_0) \right] \frac{\partial^2 V'}{\partial Y^2} + \left[f_9(\phi_0) + \frac{1}{3} f_2(\phi_0) \right] \frac{\partial^2 U'}{\partial X \partial Y} \right\} = 0 \end{aligned} \tag{10.84}$$

$$\begin{aligned} &-\frac{3}{2} H^{\star 3/2} \phi_0 \left(\frac{\partial T'}{\partial t^\star} + \frac{\partial T_0}{\partial Y} V' \right) - H^{\star 3/2} f_1(\phi_0) T_0 \left(\frac{\partial U'}{\partial X} + \frac{\partial V'}{\partial Y} \right) \\ &+ \left\{ \frac{\partial}{\partial Y}\left[T_0^{1/2} \left. \frac{\partial f_3}{\partial \phi} \right|_{\phi_0} \frac{\partial T_0}{\partial Y} \right] + \frac{\partial}{\partial Y}\left[T_0^{3/2} \left. \frac{\partial f_4}{\partial \phi} \right|_{\phi_0} \frac{\partial \phi_0}{\partial Y} \right] - H^{\star 2} T_0^{3/2} \left. \frac{\partial f_5}{\partial \phi} \right|_{\phi_0} \right\} \phi' \\ &+ \left\{ \frac{1}{2} \frac{\partial}{\partial Y}\left[f_3(\phi_0) T_0^{-1/2} \frac{\partial T_0}{\partial Y} \right] + \frac{3}{2} \frac{\partial}{\partial Y}\left[f_4(\phi_0) T_0^{1/2} \frac{\partial \phi_0}{\partial Y} \right] - \frac{3}{2} H^2 f_5(\phi_0) T_0^{1/2} \right\} T' \\ &+ \left\{ T_0^{3/2} \left. \frac{\partial f_4}{\partial \phi} \right|_{\phi_0} \frac{\partial \phi_0}{\partial Y} + \frac{\partial}{\partial Y}\left[f_4(\phi_0) T_0^{1/2} \right] + T_0^{1/2} \left. \frac{\partial f_3}{\partial \phi} \right|_{\phi_0} \frac{\partial T_0}{\partial Y} \right\} \frac{\partial \phi'}{\partial Y} \\ &+ \left\{ \frac{1}{2} f_3(\phi_0) T_0^{-1/2} \frac{\partial T_0}{\partial Y} + \frac{3}{2} f_4(\phi_0) T_0^{1/2} \frac{\partial \phi_0}{\partial Y} + \frac{\partial}{\partial Y}\left[f_3(\phi_0) T_0^{1/2} \right] \right\} \frac{\partial T'}{\partial Y} \\ &+ f_4(\phi_0) T_0^{3/2} \left(\frac{\partial^2 \phi'}{\partial X^2} + \frac{\partial^2 \phi'}{\partial Y^2} \right) + f_3(\phi_0) T_0^{1/2} \left(\frac{\partial^2 T'}{\partial X^2} + \frac{\partial^2 T'}{\partial Y^2} \right) = 0 \end{aligned} \tag{10.85}$$

The corresponding boundary conditions become

$$H^{\star} f_8(\phi_0)\phi' U' - \frac{\partial U'}{\partial Y} - \frac{\partial V'}{\partial X} = 0 \tag{10.86}$$

$$V' = 0 \tag{10.87}$$

$$\left\{ \left.\frac{\partial f_3}{\partial \phi}\right|_{\phi_0} \frac{\partial T_0}{\partial Y} + T_0 \left.\frac{\partial f_4}{\partial \phi}\right|_{\phi_0} \frac{\partial \phi_0}{\partial Y} - \left(1 - e_w^2\right) H^{\star} f_3(\phi_0) T_0 \left.\frac{\partial f_6}{\partial \phi}\right|_{\phi_0} - \left(1 - e_w^2\right) H^{\star} f_6(\phi_0) T_0 \left.\frac{\partial f_3}{\partial \phi}\right|_{\phi_0} \right\} \phi'$$

$$+ \left\{ \frac{1}{2} f_3(\phi_0) T_0^{-1} \frac{\partial T_0}{\partial Y} + \frac{3}{2} f_4(\phi_0) \frac{\partial \phi_0}{\partial Y} - \left(1 - e_w^2\right) H^{\star} f_3(\phi_0) f_6(\phi_0) \frac{3}{2} \right\} T' + f_4(\phi_0) T_0 \frac{\partial \phi'}{\partial Y} + f_3(\phi_0) \frac{\partial T'}{\partial Y} = 0 \tag{10.88}$$

$$\left(T_0 \left.\frac{\partial f_1}{\partial \phi}\right|_{\phi_0} - \frac{\pi}{9} \frac{\phi^{-1/3}}{\phi_m^{2/3}} \right) \phi' + f_1(\phi_0) T' + \left[\frac{2}{3} f_2(\phi_0) - f_9(\phi_0) \right] \frac{T_0^{1/2}}{H^{1/2}} \frac{\partial U'}{\partial X}$$

$$- \left[f_9(\phi_0) + \frac{4}{3} f_2(\phi_0) \right] \frac{T_0^{1/2}}{H^{1/2}} \frac{\partial V'}{\partial Y} = 0 \tag{10.89}$$

By extracting the terms involving only the oscillation variables and the variation length scales K_x and K_y, ϕ_e, $\underline{U}_e$, and T_e (also K_x and K_z), a set of ODEs and boundary conditions at the base and the free surface are obtained to form an *eigenvalue problem*. The ODEs are discretized into an equivalent matrix eigenvalue problem and a dispersion relation for the *complex* eigenvalue, $\Omega = \Omega_r + i\Omega_i$, and wave number, K_X (in 2D) and $K_R = \sqrt{K_X^2 + K_Z^2}$ (in 3D), is numerically solved. The result for a 2D flow under the operating condition at $(M_t, Q_t) = (3.0, 19.83)$ and $(4.75, 51.31)$ is shown in Figure 10.22a and b, respectively. The real component Ω_r in the top subplot measures the growth rate of perturbations, and the largest value would dominate the system response. The lower subplot, on the other hand, portrays how the *phase velocity*, $|\Omega_i|/K_X$, of the density wave changes with K_X. At lower excitation (Q_t) in Figure 10.22a, the largest Ω_r (0) occurs in regime I when $K_X = 0$ so that the dominant wave does not vary in the X-direction and the primary bulk motion is in the so-called layer mode as observed in a bouncing bed. When driven at higher Q_t as the results shown in Figure 10.22b, the largest real Ω_r now shifts to regime III with nonzero K_X but zero phase velocity, and hence, a standing wave is obtained and the system is in the so-called stationary mode.

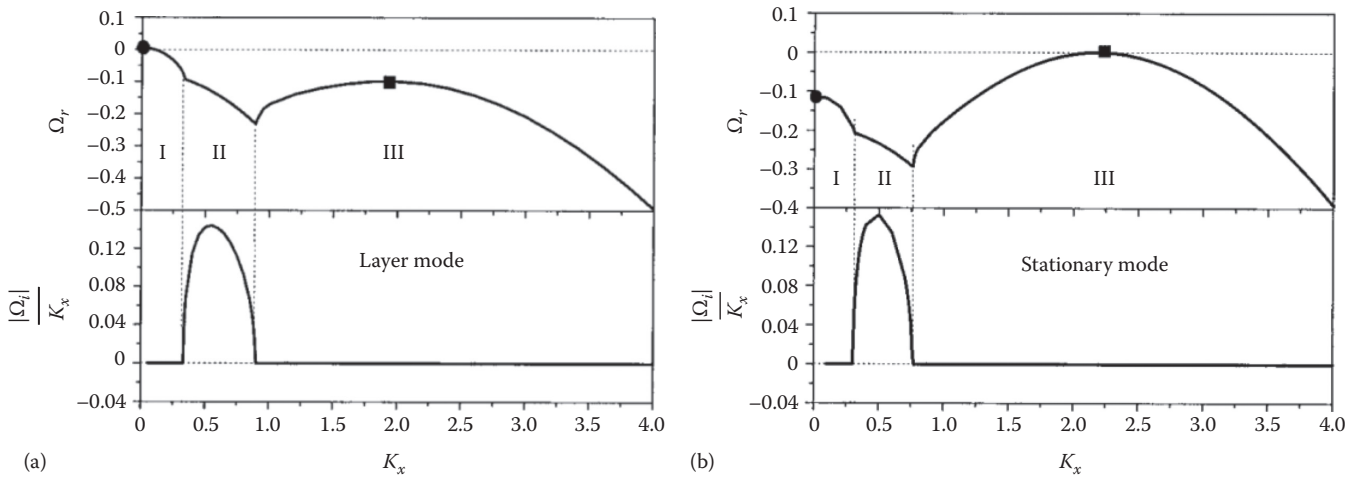

Figure 10.22

Dispersion relation for how the real and the imaginary eigenvalues, Ω_r and Ω_i, change with wave number K_x for a 2D system excited at $(M_t, Q_t) = (a)$ (3.0, 19.83) in the layer mode (largest Ω_r occurs with zero Ω_i) and (b) (4.75, 51.31) in the stationary mode for a standing surface wave with nonzero phase speed Ω_i/K_x. (From Deng, R.S. and Wang, C.H., *J. Fluid Mech.*, 492, 381, 2003.)

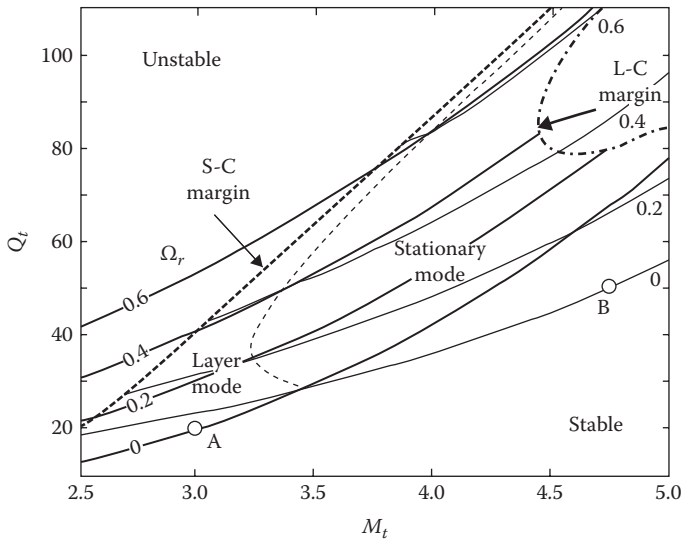

Figure 10.23

Stability diagram by the contours of Ω_r: $\Omega_r < 0$, $\Omega_r = 0$ and $\Omega_r > 0$ correspond to the stable, neutrally stable, and unstable state. The thick solid curve portrays the loci of layer mode with zero Ω_r and phase velocity, as mode in Figure 10.21a, while the thin solid line indicates the standing wave mode with zero Ω_r but positive phase velocity, as the mode in Figure 10.21b. (From Deng, R.S. and Wang, C.H., *J. Fluid Mech.*, 492, 381, 2003.)

By varying Q_t and M_t, the authors locate the contours of constant $\Omega_r = 0$, 0.2, 0.4, and 0.6 for both modes to generate a stability diagram in Figure 10.23. The layer mode (thick solid line) occurs in the left lower corner, while the stationary mode (thin solid line) locates to the right upper corner of the plot. Hence, when subject to identical agitation (Q_t), thin bed (small M_t) develops the coherent layer mode while standing wave structure of incoherent segment motions is found in thicker bed (larger M_t). Further discussions of the stability diagram can be found in the reference.

The dependence of the largest Ω_r in both modes on Q_t and M_t is further investigated in Figure 10.24a, and the system dynamics is always determined by the mode with larger Ω_r. Subject to identical Q_t, the layer mode prevails in thin beds ($M_t < 2.75$) but transits to the stationary mode when the bed is thick

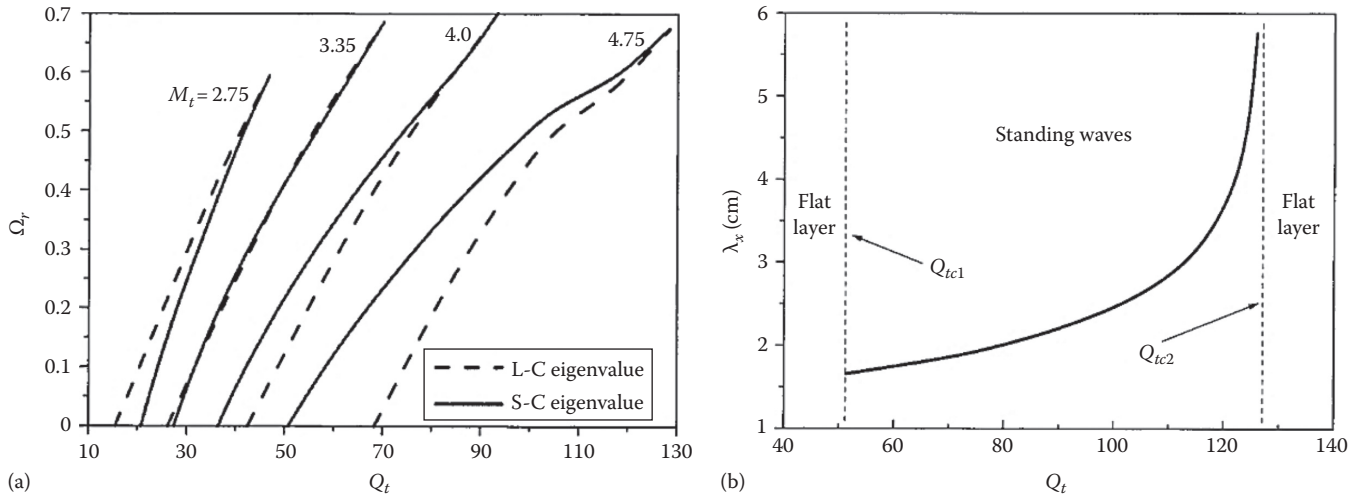

Figure 10.24

(a) Loci of the largest Ω_r in the layer mode (---, L-C) and the stationary mode with standing wave pattern (—, S-C) as a function of energy input Q_t with different M_t. System response is governed by the mode with higher Ω_r under specific Q_t and M_t. (b) Streamwise wave length as a function of Q_t in the standing wave mode. (From Deng, R.S. and Wang, C.H., *J. Fluid Mech.*, 492, 381, 2003.)

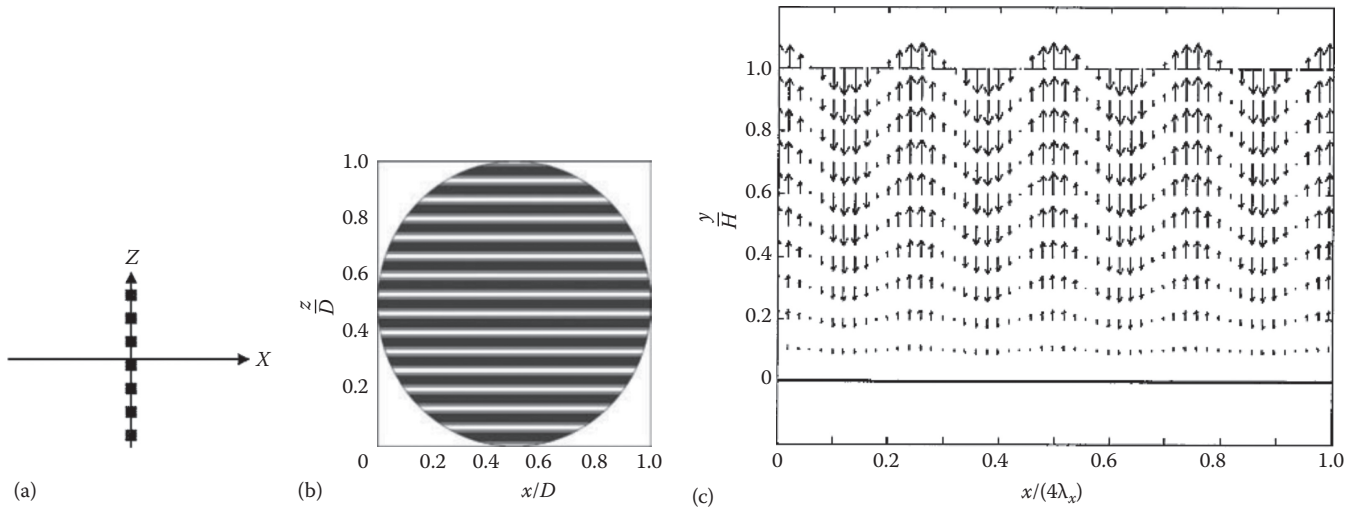

Figure 10.25

Patterns from the 3D stability analysis due to (a) a periodic perturbation along the *Z*-axis and the resulting (b) stripe pattern for $(M_t, \Omega_t) = (4.75, 51.31)$ and $K_x = 2.2$ whose dispersion relation is presented in Figure 10.22b. (c) The corresponding vertical velocity field. (From Deng, R.S. and Wang, C.H., *J. Fluid Mech.*, 492, 381, 2003.)

enough ($M_t > 3$). At a sufficiently large M_t, the stationary mode first appears at a critical Q_{t1} but *disappears* again at a second higher critical Q_{t2} as indicated by the end of the thin solid line marked by the *L-C margin* in the right upper corner of Figure 10.23. When streamwise wavelength λ_X is examined with respect to Q_t in Figure 10.24b, λ_X is found to increase monotonically but slowly when Q_t just exceeds Q_{t1} but the growth rate accelerates when approaching Q_{t2}. When λ_X becomes so large that no wave pattern can be observed in a finite observation window, the flow seems to transit from stationary mode to another mode that will be discussed shortly.

Finally, when perturbations are introduced in both the X- and Z-directions, the authors reveal identical dispersion relations for $\Omega_r - K_X$, $\Omega_r - K_Z$, and $\Omega_r - K$ (with $K^2 = K_X^2 + K_Z^2$), and hence, the system stability response is similar to those revealed from the 2D analysis. The flow response due to small perturbations to the base solution can be constructed from the solution of the eigenvalue problem under specific (M_t, Q_t). For example, when small periodic perturbation in solid volume fraction is introduced along the Z-axis as illustrated in Figure 10.25a, periodic peaks and valleys of $\phi(X, Z)$ form on the surface contour as those horizontal stripes in Figure 10.25b. Meanwhile, the vertical velocity $V_e(Y)$ is found to vary periodically with segments going up and down alternatively as shown in Figure 10.25c, and the magnitude increases monotonically from a basal zero to a surface maximum. When the perturbation is introduced along both axes, a square pattern is found in Figure 10.26a and a hexagon pattern is induced in Figure 10.26b when three perturbations lines of equal included angle are imposed. Note that the principle of superposition of waves has been applied to calculate the net variation at a specific point by linear combination of the local values from each base perturbation. One final remark is that the authors also report that the energy needed to attain the least-stable flow state ($\Omega_r = 0$) increases with decreasing coefficient of restitution (e_w and e) with which the range of the stationary mode is enlarged and the system is stabilized.

10.3.3.4 Phenomenological Model for Granular Leidenfrost Effect

Finally, we would like to relate the transition of the stationary mode to a new mode when $Q_t > Q_{t2}$ to the *granular Leidenfrost effect* experimentally observed by Eshuis et al. (2005, 2007). The authors describe that the highest mode of standing wave becomes unstable when the shaking frequency is beyond a critical level and the bottom layer "evaporates" into a granular gas so that the bulk seems to float atop as shown in Figure 10.27. A phase diagram has been reported by Eshuis et al. (2007) that includes all the dynamics mentioned earlier of a vertically vibrating granular bed with respect to Γ and H^* in Figure 10.28. Special efforts

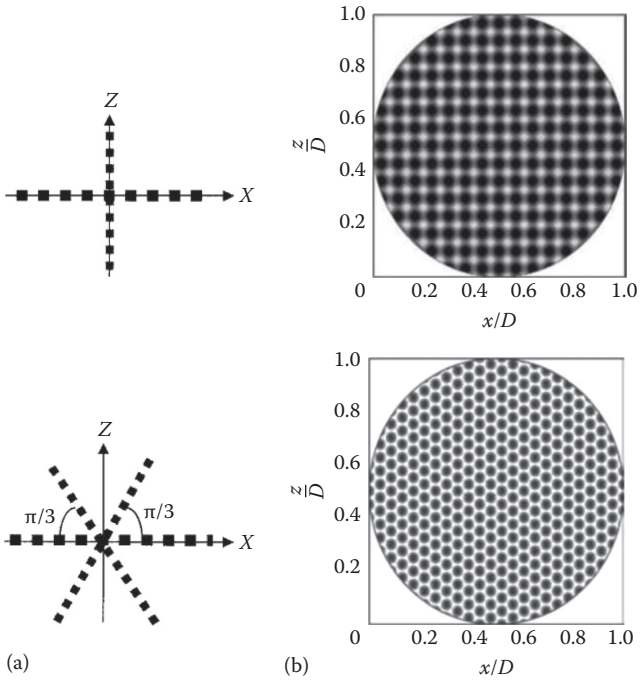

Figure 10.26

Patterns from the 3D stability analysis due to (a) two perpendicular perturbations that result in surface squares and (b) three perturbations with equal included angles that result in surface hexagons. The system is in general identical to that examined in Figure 10.25 and differs only in the how perturbation to base-state solution is applied. (From Deng, R.S. and Wang, C.H., *J. Fluid Mech.*, 492, 381, 2003.)

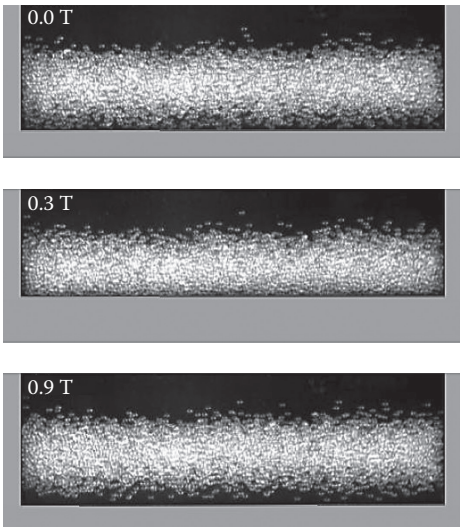

Figure 10.27

Snapshots of the granular Leidenfrost effect for $H^* = H/D = 8.1$ particle layers shaken at $f = 43.0$ Hz and $Z_0 = 3.0$ mm, corresponding to a dimensionless acceleration $\Gamma = 22$. A dense cluster is elevated and supported by a dilute layer of fast particles underneath. The cluster never touches the vibrating bottom, which makes this state distinctively different from the bouncing bed or surface standing wave. (From Eshuis, P. et al., *Phys. Fluids*, 19, 123301, 2007.)

were made to correlate the dimensionless shaking acceleration Γ with the shaking strength $S = \Gamma(A_0/D)$ on the same plot so that the effect of oscillation amplitude relative to the grain diameter may also be evaluated. The phase diagram constructed for the small and large shaking amplitudes, $Z_0 = 2$ and 4 mm (with D = 1 mm), from their experiments shows dynamically similar trends except the disappearance of Leidenfrost regime when larger grains are shaken at milder agitation.

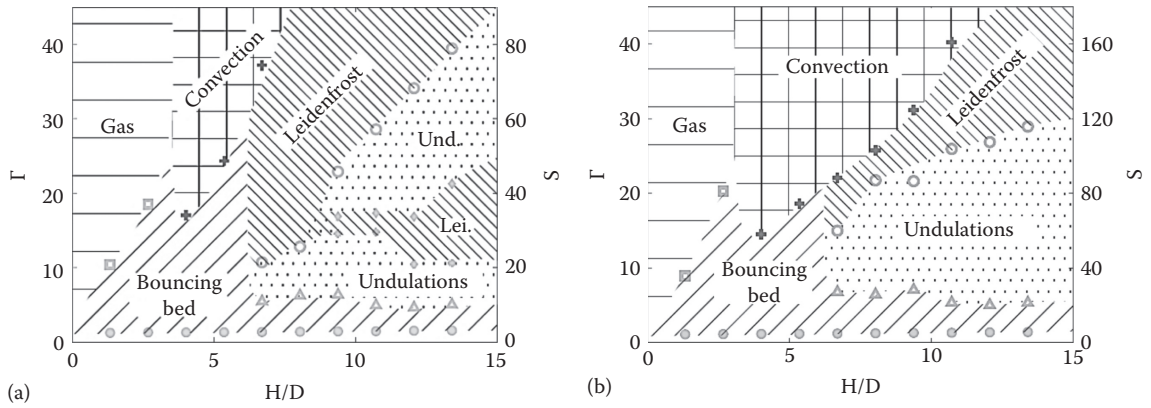

Figure 10.28

Phase diagram of the shallow granular bed ($H^* \approx 8.1$, glass beads of $D = 1$ mm, $\rho_s = 2.6$ g/cm^3, $e \approx 0.95$; thin box of $5D$ thickness and $W^* = 101$) at a shaking amplitude of (a) $a = 2.0$ mm and (b) $a = 4.0$ mm. The "undulation" mode is equivalent to the standing wave mode discussed here. The right axis plots the dimensionless shaking strength $S = \Gamma(Z_0/D)$. (From Eshuis, P. et al., *Phys. Fluids*, 19, 123301, 2007.)

The granular Leidenfrost phenomenon has been successfully captured by a 2D model for a bed that is infinitely long by Eshuis et al. (2005). An equation of state is invoked based on kinetic theory and is incorporated with the balance equations of normal momentum and energy to give

$$p = n\frac{n_c + n}{n_c - n}T \tag{10.90}$$

$$\frac{dp}{dy} = -nm_p g \tag{10.91}$$

$$\frac{d}{dy}\left(\kappa\frac{dT}{dy}\right) = \frac{C_5}{L}\left(1 - e^2\right)nT^{3/2} \tag{10.92}$$

where

n is the number density (number of grains in a control volume)
L is the *mean-free path*
C_5 is a numerical value

These equations are solved numerically with three boundary conditions: constant bed T_0, zero energy flux at the free surface as dT/dy = 0, and conservation of total grain number and the phenomenon is qualitatively captured.

10.4 Discussions: Segregation Phenomenon and Cohesion Effect

All the foregoing contents are for flows of nearly identical grains, the condition of which is rarely met in real flows and grains of dissimilar sizes, densities, geometries, or surface conditions that may separate them and cause segregation. For example, a flow due to landslide often has a surging head primarily composed of large rocks and debris and a thin tail of finer pebbles, soil, and dust. In engineering applications, segregation can assist the separation of different constituent grains in a mixture but, in contrast, can degrade mixing efficiency in other processes. Different segregation mechanisms have been proposed in the literature, and we use this final paragraph to discuss a few and interested readers are referred to the reviews by Bridgewater (1976), Ottino and Khakhar (2000), and Tang and Puri (2004).

When a mixture of large and small grains moves with the presence of gravity, smaller grains fall more easily through the voids to fill the space in deeper layer, the process of which in turn pushes larger grains toward the free surface. The dynamic process can be interpreted as a downward mass flux of small grains

accompanied by an upward flux of large grains so that an overall mass conservation is ensured at each depth. Such a gravity-driven size-induced segregation mechanism is known as the *kinetic sieving* process and the resulting phenomenon can be observed in surface flows down a slope where a layer of coarser grains runs atop and ahead of a basal layer of finer grains (Savage and Lun, 1988, Gray and Thornton, 2005). The same mechanism also explains why larger grains always accumulate at the periphery in a partially filled rotating drum while smaller grains gather near the core (Nityanand et al., 1986, Ottino and Khakhar, 2000, Aranson and Tsimring, 2006). Theoretical models have also been developed for this process by extended kinetic theory of bidisperse mixture (Savage and Lun, 1988, Jenkins and Mancini, 1989, Hsiau and Hunt, 1996), mixture theory (Dolgunin and Ukolov, 1995, Dolgunin et al., 1998, Gray and Thornton, 2005, Gray and Ancey, 2011), statistical theory of cellular automata (Makse et al., 1997, Makse and Einav, 2011), and a depth-averaged model (Boutreux and de Gennes, 1996, Gray and Kokelaar, 2010).

In addition to grain size, other grain properties can come into play to complicate the sieving process and in turn modify the distinct segregation pattern from kinetic sieving (Makse et al., 1997). To name a few, density difference can enhance or counteract size-induced sieving process depending on whether smaller grains possess greater or lower density than larger ones (Drahun and Bridgwater, 1983, Tang and Puri, 2004). Gradient in granular temperature and hence local kinetic stress can create another driving force, especially around regimes of low ϕ, which acts along or against gravity (Ottino and Khakhar, 2000, Berzi et al., 2010). When these mechanisms overcome the sieving process, reverse segregation pattern can even occur such that larger grains are found beneath smaller grains in surface flows or near the core of in rotating drum flows (Nityanand et al., 1986).

Other complication of the segregation process can result from the interplay of different flow processes. For example, while kinetic sieving explains the segregation pattern of surface large grains in vertical vibration beds, a central-rising convection roll may also help to bring large grains to the free surface. After rolling down the heap toward the container walls, these large grains can only remain at the surface since they are too large to be carried by the descending current at the wall (Williams, 1976, Harwood, 1977, Duran et al., 1993, Knight et al., 1993). In addition to bulk convection, segregation may also interfere with local arching effect at the flow boundary (Duran et al., 1994). At times, static deposit may form within a surface flow where local arresting mechanism is crucial to understand the bulk dynamics and hence the segregation pattern, as the case in a heap flow. At high flow rate, the usual deposition process that large grains run faster to the front of an avalanche governs the arresting process, and hence, a typical segregation pattern is developed. Nonetheless, the upslope propagating shock wave may become as effective in bringing the bulk to rest. Hence, large grains may deposit before reaching to the front and the surface over which smaller grains continue to flow downstream to create an alternate inversely graded stripes of large and small grains in a stratification pattern (Makse et al., 1997, Andreotti et al., 2013).

Further, the presence of any near-field noncontact force also modifies grain interactions leading to different bulk dynamics and rheology from that of a dry system. For example, Van der Waal force and electrostatic force are nonnegligible for flows of dry powders for their small sizes (Rietema, 1991, Castellanos, 2005). The presence of a small amount of liquid can result in attracting capillary force between adjacent grains (Mitarai and Nori, 2006) and lubrication force when neighboring solid surfaces are in relative motions (Kim and Karrila, 1991, Pitois et al., 2000, Xu et al., 2007, Simeonov and Calantoni, 2012). Such liquid-induced *cohesion,* in general, helps the grain assembly to resist shear so that a greater angle of repose can develop during heap formation (Albert et al., 1997, Mason et al., 1999, Samandani and Kudrolli, 2001, Tegzes et al., 2002) and in a rotating drum flow (Tegzes et al., 1999, Nase et al., 2001, Bocquet et al., 2002, Chou et al., 2011). Withstanding shear, intergrain cohesion can also result in surface plugs in a surface flow down an incline to destroy the Bagnold profile that explains why the plug size grows with cohesion strength (Brewster et al., 2005). Such phenomenon may further depend on the aggregation of individual grains (Ennis et al., 1991, Yang et al., 2003, Weber et al., 2004, Rognon, 2008), which introduces the bulk to another source of heterogeneity other than the contact-induced force chains. The degree of aggregation depends on the coherence strength as well as local flow conditions (like shear strength and concentration) and hence can interfere with the mixing and segregation process of dissimilar grains (Samandani and Kudrolli, 2000, Samandani and Kudrolli, 2001, Chaudhuri et al., 2006).

Like dry granular materials, the dynamics of cohesive grain assembly has been investigated through particle-based simulation by adding new interaction forces to the contact model (Yang et al., 2003, Zhu et al., 2007, Liu et al., 2011, Marshall and Li, 2014). As for continuum-based theoretical modeling, cohesive collisional flows have been modeled by extended kinetic theory (Kim and Arastoopour, 2002), but it is still an open question of how to incorporate particle-level cohesive interaction to the constitutive models.

For a quasi-static bulk, Nedderman (1992) directly adds a cohesion-induced shear stress c to the Coulomb-type component as $\underline{\underline{\tau}} = (\mu P + c)\underline{\underline{\dot{\gamma}}}/|\underline{\underline{\dot{\gamma}}}|$ in terms of a constant apparent friction coefficient μ and c changes with the particle-level cohesion. Model extension to dense flow regime has also been attempted by de Ryke (2008) using the $\mu(I)$ rheological model of dry flows. Through dimension analysis, Rognon et al. (2008) propose that the bulk frictional coefficient and solid volume fraction should depend on both the inertial number, I, and the cohesion number, η. This new parameter characterizes the ratio of grain-level maximum cohesive force N_c to a typical external load in a particular system. When gravity is the driving force, the cohesion number is equivalent to the Bond number $\eta = Bo = N_c/mg$ (Nase et al., 2001) but changes to $\eta = N_c/PD^{n-1}$ with $n = 2$ or 3 for a 2D or 3D simple shear flow without the presence of gravity. From systematic DEM simulations of plane shear flows, bulk dilatancy law and rheological relation can be expressed as $\phi(\eta,I) = \phi_s(\eta) - a(\eta)I$ and $\mu(\eta, I) = \mu_s(\eta) - b(\eta)I$ in which the fitting coefficients are no longer constant but change with the cohesion intensity η (Rognon, 2008). Such approach dynamically agrees to the findings by Taboada et al. (2006) who attribute cohesive bulk behaviors to different micromechanical mechanisms (the collisional, frictional, and dilational origin) with liquid effects. The variation of $\phi_s(\eta)$, $\mu_s(\eta)$, $a(\eta)$, and $b(\eta)$ with η for flows in different configurations requires further investigations, so does the feasibility of the proposed $\phi(\eta, I)$ and $\mu(\eta, I)$ formulation, which clearly illustrate the research challenges and the richness of powder and grain flows.

Multiphase Flow in Porous Media

John R. Fanchi and John P. Seidle

11.1 Porosity
11.2 Permeability
11.3 Characterizing Porosity and Permeability
11.4 Directional Permeability
11.5 Rock–Fluid Interaction
11.6 Relative Permeability
11.7 Fractional Flow of Two Immiscible Fluids
11.8 Immiscible Displacement
11.9 Reservoir Flow Model Equations

A porous medium is a medium that contains solid material and pore space. Figure 11.1 is a thin section of a rock displaying grains of sand and pores. The solid part of the material is often referred to as the matrix, skeleton, or frame. Porous media are common in nature, commerce, and daily life. Examples include cement, ceramics, soil, rocks, coal filters, packed columns, sponges, and biological tissues.

The factors that influence the flow of single-phase and multiphase fluids through porous media are considered here. In addition, porous media such as coal and shale contain commercial fluids that are extracted through flow in fractures. We discuss the factors at work in these media by discussing multiphase flow in coal.

11.1 Porosity

The porosity ϕ of a porous medium is the volume fraction of its pore space. Bulk volume is the volume of the solid material and the volume of the pore space. In the case of a rock, bulk volume V_B is the sum of pore volume V_P and grain volume V_G:

$$V_B = V_P + V_G \tag{11.1}$$

Pore volume V_P is the volume remaining when the volume of grains V_G is subtracted from the bulk volume:

$$V_P = V_B - V_G \tag{11.2}$$

The bulk volume of the block in Figure 11.2 is HA.

Porosity is the ratio of pore volume to bulk volume:

$$\phi = \frac{V_P}{V_B} = \frac{V_B - V_G}{V_B} \tag{11.3}$$

Porosity has a value that varies from 0 to 1. It is a factor that determines the volume of fluids that can be contained in the porous material.

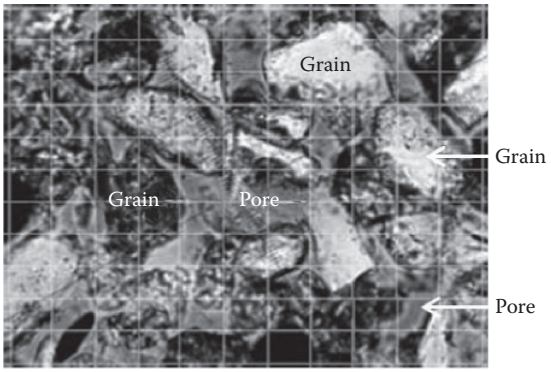

Figure 11.1

Thin section of rock showing pores and grains.

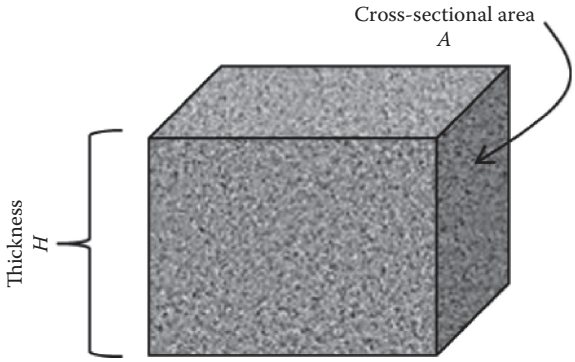

Figure 11.2

Bulk volume of a block or cell.

Pore volume is the product of porosity and bulk volume:

$$V_P = \phi V_B \tag{11.4}$$

11.1.1 Effective Porosity

Two kinds of pores or voids influence flow in porous media: effective pore space and isolated pore space. Effective or open pore space connects enough pores to allow fluid to flow over commercially significant distances such as flow into a wellbore. Effective porosity is the ratio of effective pore volume to bulk volume:

$$\phi_{eff} \equiv \frac{(V_P)_{eff}}{V_B} \tag{11.5}$$

Isolated, "dead," closed, or ineffective pore space consists of pores or voids that are dispersed in the medium and do not allow fluid flow over commercially significant distances. Total porosity is the sum of ineffective porosity and effective (interconnected) porosity. Any further discussion using porosity will assume that porosity is the effective porosity, and the subscript *eff* is omitted.

Fluid flow is possible only in porous media that have connected pore spaces. Porous media that allow fluid flow are called permeable. Permeability is a measure of fluid flow through connected pore spaces and is discussed in greater detail in Section 11.2.

Several porosities are possible in geologic systems. Primary porosity is the original porosity of the medium. The rock porosity changes as a result of the history of the rock. For example, leaching can increase porosity. The resulting porosity is secondary porosity. If breaks or fractures occur in the medium, the pore

space in the fracture is called fracture porosity. The porosity in a relatively large pore space known as a vug is called vuggy porosity.

Porosity can be measured for samples in the laboratory. The porosity of rock can also be measured in the field using well log measurements. Experimental measurements commonly used to determine the porosity of a porous sample include the following:

1. *Imbibition method*: The porous sample is saturated with a preferential wetting fluid by letting the fluid imbibe into the sample under vacuum. The sample is weighed before and after imbibition. The porosity can be calculated from the two weights, the density of the fluid, and the dimensions (bulk volume) of the sample.
2. *Mercury injection method*: A sample is evacuated, and mercury is forced to penetrate into the sample under high pressure. High pressure is needed because mercury will not penetrate the pores of most materials unless pressure is applied. Injection methods that do not rely on mercury have also been developed.
3. *Gas expansion method*: The porous sample is enclosed in a vessel with measured volume V_1 and gas pressure p_1. When the vessel is connected to an evacuated vessel of known volume V_2, the gas expands into this vessel and the gas pressure in the first vessel decreases to a lower value p_2. Applying the ideal gas law to the process mentioned earlier, the effective pore volume V_P of the sample is calculated as

$$V_P = V_B - V_1 - V_2\left(\frac{p_2}{p_2 - p_1}\right) \tag{11.6}$$

   The bulk volume of the sample V_B is determined in a separate measurement.
4. *Density method*: The bulk density of the sample ρ_B and the density of the grains ρ_G in the sample are determined. The total porosity of the sample is calculated as

$$\phi = \frac{V_B - V_G}{V_B} = 1 - \frac{V_G}{V_B} \approx 1 - \frac{\rho_B}{\rho_G} \tag{11.7}$$

11.1.2 Coal Porosity

Coals are characterized by two types of porosity. The first type is associated with the natural fractures (cleats), while the second type, termed *phyteral porosity*, is related to the organic precursors of the coal matrix. Coal cleats (Figures 11.3 and 11.4) are two sets of mutually perpendicular fractures that are, in turn, nominally perpendicular to the coal bedding planes. The first set, termed face cleats, are roughly parallel, thoroughgoing, vertically and laterally extensive, well-developed natural fractures. The butt cleats, perpendicular to the face cleats, are also parallel to one another but are less well developed and shorter, often terminating at a face cleat. Cleat porosity, typical of naturally fractured reservoirs, is on the order of 1% of the bulk volume (Seidle, 2011).

Controls on cleat porosity are poorly understood. Cleating is most pronounced in bituminous coals, but cleat porosity appears to be independent of both coal rank and geologic age. The roles of other parameters such as ash, mineral matter, and maceral population have not been investigated.

The determination of *in situ* coal cleat porosity is difficult. Lab measurements of cleat permeability are often affected by sample size (lab samples are too small to adequately capture the cleat network) and sample preparation (coal rapidly deteriorates when exposed to atmospheric conditions). Laboratory-measured porosities must be reduced due to overburden loads and tectonic stresses to obtain *in situ* values. In practice, cleat porosities are often back calculated from reported water production or reservoir simulation history matches. Cleat porosities determined in this manner typically vary between 0.5% and 2%.

The second type of porosity, phyteral porosity, is relic void space from the original organic material modified during coalification. Phyteral porosity is not linear like cleat porosity nor is it similar to the porosity of conventional sandstone reservoirs formed from nominally spherical sand grains. Pollens, leaves, roots, blossoms, twigs, seeds, and other organic matter in the original swamp are compressed, deformed, and solidified into pores of various sizes, aspect ratios, and connectivity in the coal matrix. A major characteristic of the phyteral porosity seen in coals of all geologic ages and all ranks is the extremely small pore

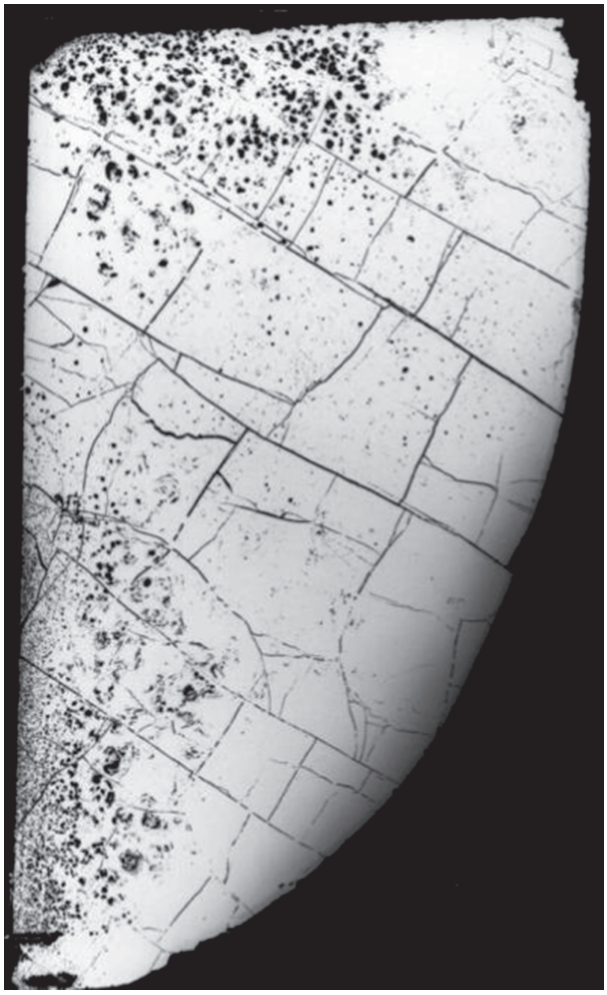

Figure 11.3

Face and butt cleats, Fruitland coal, San Juan Basin, NM. (Courtesy of John Bradley, New Mexico.)

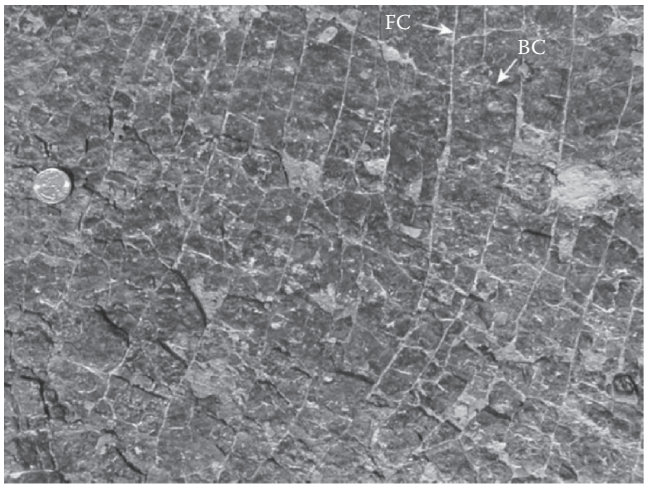

Figure 11.4

Mineral filled face and butt cleats, Warrior Basin, AL. FC, face cleat (systematic joint); BC, butt cleat (cross joint). (Courtesy of George Hampton, Denver, Colorado.)

throats, on the order of 0.5 nm. For comparison, the diameter of a methane molecule is roughly 0.4 nm. Due to these small pore throats, the measurement of coal matrix porosity depends on the method and the material employed.

The imbibition method discussed earlier for porosity measurements in coal is problematic as coal integrity rapidly declines when subjected to a vacuum, yielding erroneously high cleat porosities. Injection pressures required to force mercury into the extremely small pores of a coal often destroy sample integrity, again providing erroneously high matrix porosities. Porosity determined with the gas expansion method depends on the gas employed. Helium gas penetrates the coal matrix more deeply and thoroughly than other molecules, leading to higher porosities, on the order of 7%. In contrast, other gas molecules and injected mercury do not penetrate the matrix so extensively, yielding matrix porosities on the order of a few percent. When the density method is employed, care must be taken to accurately measure coal bulk and grain densities. Assuming a coal with 1% cleat porosity and a bulk density of 1.650 g/cm^3, Equation 11.7 yields a grain density of 1.634 g/cm^3, lower than the bulk density by 0.016 g/cm^3. Clearly, small errors in lab measurements would strongly affect the resulting cleat porosity.

Water transfer between cleat and matrix is minimal at best, leading to the simplified but extremely pragmatic approximation of coals as single porosity reservoirs to water (cleat only) and dual porosity reservoirs to gas (cleat plus matrix). The assumption of an *in situ* coal bed porosity of 1% is often quite adequate for most reservoir engineering calculations.

11.1.3 Porosity Compressibility

Porosity compressibility c_ϕ is a measure of the change in porosity ϕ as a function of fluid pressure p in the pore space. It is defined as

$$c_\phi = \frac{1}{\phi}\frac{d\phi}{dp} \tag{11.8}$$

If porosity compressibility is constant with respect to pressure, porosity ϕ at pressure p can be expressed in terms of porosity ϕ_0 at pressure p_0 as

$$\phi = \phi_0 \exp\left[c_\phi\left(p - p_0\right)\right] \tag{11.9}$$

An approximation to Equation 11.9 is the first-order expansion of the exponential term with respect to pressure difference:

$$\phi \approx \phi_0\left[1 + c_\phi\left(p - p_0\right)\right] \tag{11.10}$$

A typical value of porosity compressibility in sandstone is 3×10^{-6}/psia. It is comparable in magnitude to water compressibility and oil compressibility.

Coal is an organic, reactive, polymeric rock that is highly compressible compared to most reservoir rocks and fluids. The coal matrix is quite rigid, resisting deformation with increasing stress and preventing large changes in the matrix porosity. The high compressibility of a coal is primarily due to narrowing of the cleats with increasing stress. Coal compressibility is difficult to measure in the lab and values reported in the literature range from changes in cleat porosity. As cleating is most pronounced in bituminous coals, cleat compressibility would intuitively peak in these ranks. Available data are insufficient to understand the role of coal rank, geologic age, or composition in coal compressibility. Although not exhaustive, a review of 13 coal cleat compressibilities determined by both laboratory and field methods (Seidle, 2011) showed minimum, median, and maximum values of 3×10^{-4}/psia, 1.3×10^{-3}/psia, and 2.5×10^{-3}/psia, respectively. The eightfold variation in cleat compressibility reflects not only the heterogeneous nature of coals but also the difficulty in measuring this parameter by either laboratory or field methods.

Note the median coal compressibility is more than a hundred times larger than the typical sandstone compressibility reported earlier. In spite of this, the compressibility of a coal deposit is dominated by gas and sorption compressibilities, not cleat compressibility. Dewatering of undersaturated coals is affected by cleat and water compressibilities until reservoir pressure is reduced to the critical desorption pressure and gas is

released off the matrix into the cleats. The estimation of porosity and permeability losses during dewatering of deeply undersaturated coals often requires including at least three terms in the exponential expansion, Equation 11.10.

11.1.4 Saturation and Fluid Volume

The saturation S_ℓ of phase ℓ is the fraction of the volume of pore space occupied by phase ℓ. The sum of the saturations in the pore space must equal one. If the system has N_P phases, the saturation constraint is

$$1 = \sum_{\ell=1}^{N_P} S_\ell \tag{11.11}$$

For an oil–water–gas system, the saturation constraint is $S_o + S_w + S_g = 1$ where the subscripts $\{o, w, g\}$ refer to oil, water, and gas, respectively. The fluid volume of phase ℓ is the product of the saturation S_ℓ of phase ℓ and pore volume:

$$V_\ell = S_\ell V_P = S_\ell \phi V_B \tag{11.12}$$

The volume of fluid in a geologic formation with many contiguous layers depends on gross thickness and net thickness. If we consider the block in Figure 11.2, gross thickness H is the total thickness of the formation and net thickness h is the sum of the thicknesses of the layers in the formation that are permeable. Net thickness is less than or equal to gross thickness. The net-to-gross ratio η_{NTG} is the ratio of net thickness h to gross thickness H:

$$\eta_{NTG} = \frac{h}{H}, \quad 0 \le \eta_{NTG} \le 1 \tag{11.13}$$

The volume V_ℓ of phase ℓ in the permeable intervals is

$$V_\ell = S_\ell \eta_{NTG} HA\phi = S_\ell hA\phi \tag{11.14}$$

for cross-sectional area A.

11.1.5 Tortuosity

The route that a fluid takes through a porous medium can be a straight path or very nonlinear. The property of the rock that measures the length of the path from the entry point to the exit point relative to a straight path is tortuosity. If the path is a straight line, which can occur in a linear fracture, the tortuosity is 1. In most cases, the flow path in a porous medium will be longer than a straight line, so tortuosity is greater than 1. Figure 11.5 illustrates a tortuous path through a porous medium.

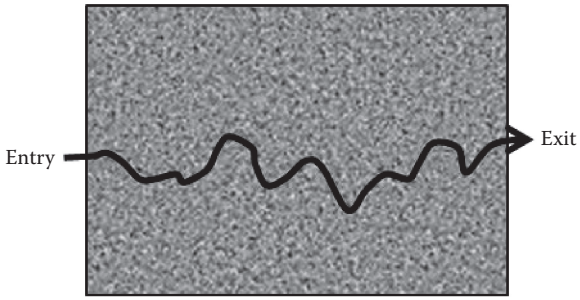

Figure 11.5
Tortuosity.

11.1.6 Specific Surface and Hydraulic Radius

The specific surface S of a porous medium is the pore surface area S_P per unit of bulk volume V_B:

$$S = \frac{S_P}{V_B} \tag{11.15}$$

Pore surface area is the surface area of pores inside the bulk volume. If we assume a medium with porosity ϕ is a packing of spheres with diameter d, the specific surface is (Mavko et al., 2009)

$$S = \frac{3}{2}\frac{(1-\phi)}{d} \tag{11.16}$$

The SI unit of specific surface is 1/m.

Hydraulic radius r_h is the ratio of pore volume V_P to pore surface area S_P (Guéguen and Palciauskas, 1994):

$$r_h = \frac{V_P}{S_P} = \frac{\phi V_B}{S_P} \tag{11.17}$$

Substituting the expression for surface area S_P in Equation 11.15 into 11.17 gives a relationship between hydraulic radius and specific surface S:

$$r_h = \frac{\phi}{S} \tag{11.18}$$

The SI unit of hydraulic radius is m.

11.1.7 Formation Resistivity Factor and Archie's Equation

Processes such as adsorption and desorption, catalysis, and ion exchange depend on specific surface. Formation water, or water in a geologic formation, is brine with a substantial concentration of ionizing molecules, such as sodium chloride and calcium chloride. Mobile ions in a fluid decrease the resistivity of the fluid. Brine usually has more ions in solution than hydrocarbons, so resistivity measurements can be used to indicate the presence of hydrocarbon in a geologic formation. The resistivity R_0 of a porous material saturated with an ionic solution is equal to the resistivity R_w of the ionic solution times the formation resistivity factor F of the porous material:

$$R_0 = FR_w \tag{11.19}$$

Formation resistivity factor F can be estimated using the empirical relationship

$$F(a,m) = a\phi^{-m} \tag{11.20}$$

with two parameters a and m. Parameter a depends on tortuosity and is called the tortuosity factor. Parameter m depends on the degree of consolidation of the rock and is called the cementation exponent. As an example, the cementation exponent m varies from 1.14 to 2.52 and the tortuosity factor a varies from 0.35 to 4.78 (Bassiouni, 1994) for sands.

If a porous medium is partially saturated by an electrically conducting, wetting phase with saturation S_w, the formation resistivity R_t of the partially saturated medium is given by Archie's empirical relationship

$$R_t = R_0 S_w^{-n} \tag{11.21}$$

where n is called the saturation exponent. Note that $R_t = R_0$ when $S_w = 1$. An equation for wetting phase saturation as a function of resistivities and formation resistivity factor is obtained by combining the earlier relationships to obtain Archie's equation:

$$S_w = \left(\frac{FR_w}{R_t} \right)^{1/n} \tag{11.22}$$

Although Archie's equation and its subsequent variations have been widely used to calculate water saturations in sandstone and carbonate reservoirs for over 70 years, it does not give reliable water saturations in coals. Archie's equation is semiempirical and assumes an inert sandstone or carbonate matrix. Coal matrix, which can be considered as a tangle of organic polymers, possesses electrical properties distinct from those of sandstones and carbonates, so it should not be surprising that water saturations and resistivities in coal cannot be described with Archie's equation.

Intentional dewatering of coal beds and recovery of coal gas has been actively pursued for nearly 40 years, yet the determination of water saturation in a coal deposit using wireline logs remains problematic. No logging tool, or combination of tools, can currently assess water saturation of a coal seam. Consequently, water saturations are back calculated from producing gas–water ratios, cumulative produced water and bulk coal porosity, or simulation history matching exercises.

11.2 Permeability

Henri Darcy (1856) found that the flow rate is proportional to the pressure gradient through rock with connected pore space. Permeability quantifies the connectivity of pore spaces. A rock is considered impermeable if there is no connectivity between pore spaces.

Permeability is usually measured using 1D, cylindrically shaped samples. The movement of a single-phase fluid through a cylindrical core of rock is illustrated in Figure 11.6. Fluid flow through the core depends on cross-sectional area A that is normal to the direction of fluid flow, pressure difference Δp across the length Δx of the flow path, and dynamic viscosity μ of the flowing fluid. In the experiment, various flow rates of the fluid are recorded as a function of pressure drop. The permeability is obtained by fitting a straight line to the data points. Theoretically, Darcy's (1856) law for slow (creeping), 1D, horizontal, steady flow of a Newtonian fluid is

$$q = \frac{kA}{\mu} \frac{\Delta p}{L} \tag{11.23}$$

where

q is the volumetric flow rate (cm^3/s)
A is the cross-sectional area of the sample normal to the flow direction (cm^2)
L is the length of the sample in the flow direction (cm)
Δp is the hydrostatic pressure drop (atm)
μ is the viscosity of the fluid (cp)

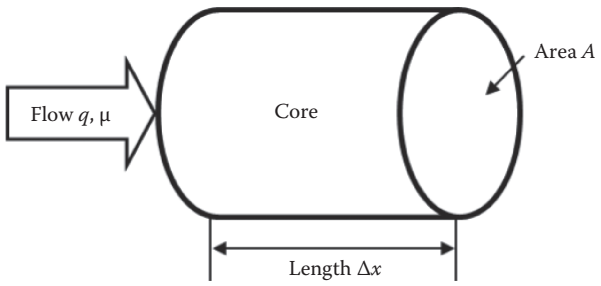

Figure 11.6

Darcy's law for a cylindrical core.

Using these units in Darcy's law gives the practical unit of permeability, darcy (D), with the value

$$1\,\text{darcy} = \frac{(1\,\text{cm}^3/\text{s})(1\,\text{cp})(1\,\text{cm})}{(1\,\text{cm}^2)(1\,\text{atm})} \tag{11.24}$$

The magnitude of permeability typically ranges from 1 millidarcy = 1 md (or 1.0×10^{-15} m^2) to 1 darcy = 1000 md (or 1.0×10^{-12} m^2) for conventional oil and gas reservoirs. Tight gas reservoir permeability is on the order of microdarcies (10^{-3} md) and shale gas reservoir permeability is on the order of nanodarcies (10^{-6} md).

The darcy unit has the dimension of area (L^2) where L is a unit of length. One darcy equals 1000 millidarcies (md). The areal unit (L^2) of permeability can be thought of as a measure of the effective cross-sectional area of a pore throat. A pore throat is the opening that connects two pores. The cross-sectional area of a pore throat tends to increase as grain size increases. Relatively large pore throats imply relatively large values of cross-sectional area transverse to the direction of fluid flow and correspond to relatively large values of permeability.

11.2.1 Darcy's Law

The basic equation describing the fluid flow in porous media is Darcy's law. Darcy's equation for calculating volumetric flow rate q for linear, horizontal, single-phase flow is

$$q = -0.001127\frac{kA}{\mu}\frac{\Delta p}{\Delta x} \tag{11.25}$$

where permeability k is the proportionality constant for the relationship between flow rate and pressure gradient. The minus sign indicates the direction of fluid flow: fluid flows from high pressure to low pressure in a horizontal (gravity-free) system. The constant 0.001127 in Equation 11.23 corresponds to variables expressed in the following oilfield units: volumetric flow rate q (bbl/day), permeability k (md), cross-sectional area A (ft^2), pressure p (psi), fluid viscosity μ (cp), and length Δx (ft). Dynamic viscosity μ is used in Darcy's law. Kinematic viscosity ν is the ratio of dynamic viscosity to fluid density ρ, that is, $\nu = \mu/\rho$.

Departures from the linear relationship between the flow rate and the pressure gradient have been observed. Forchheimer (1901) observed that pressure gradient at high flow rate had the quadratic dependence on the flow rate

$$\frac{\Delta p}{\Delta x} = -\left(\frac{1}{0.001127}\right)\frac{\mu}{k}\left(\frac{q}{A}\right) + \beta\rho\left(\frac{q}{A}\right)^2 \tag{11.26}$$

for fluid with density ρ and turbulence factor β in the non-Darcy q^2 term. The minus sign and conversion factor on the right-hand side (RHS) of Equation 11.26 are inserted to be consistent with the rate convention and units used in Equation 11.25. Equation 11.26 is a special case of the Forchheimer equation.

11.2.2 Superficial Velocity and Interstitial Velocity

Superficial velocity u is the volumetric flow rate q in Darcy's law divided by the cross-sectional area $A_\perp$ normal to flow, as in all other multiphase flow applications (Bear, 1972, Lake, 1989), thus $u = q/A_\perp$ in appropriate units. The actual velocity of fluid moving through tortuous pore space is called interstitial velocity. The interstitial velocity v is the superficial velocity u divided by the porosity ϕ or

$$v = \frac{u}{\phi} = \frac{q}{\phi A_\perp} \tag{11.27}$$

Interstitial velocity is larger than superficial velocity since porosity is a fraction between 0 and 1.

11.2.3 Hydraulic Conductivity

Hydraulic conductivity is used to characterize the ability of water to flow through a porous medium. The relationship between hydraulic conductivity k_H and permeability k is

$$k_H = \frac{k\rho g}{\mu} \tag{11.28}$$

for a fluid with density ρ and viscosity μ. The SI unit of hydraulic conductivity k_H is m/s when permeability k is in m^2, fluid density ρ is in kg/m^3, fluid viscosity μ is in kg/(m · s), and acceleration of gravity g is in m/s^2. Permeability is a property of the porous medium, while hydraulic conductivity depends on the properties of both the porous medium and the fluid.

11.2.4 Darcy's Law for Radial Flow of Liquid

The geometry for radial fluid flow in a porous medium is sketched in Figure 11.7. Darcy's law for steady-state, radial, horizontal, single-phase liquid flow in a homogeneous porous medium with cross-sectional area $A = 2\pi rh$ is

$$q = -\frac{0.00708kh(p_w - p_e)}{\mu B \ln(r_e/r_w)} = -\frac{(0.001127 \times 2\pi)kh(p_w - p_e)}{\mu B \ln(r_e/r_w)} \tag{11.29}$$

where the variables are volumetric flow rate q (stb/day where stb refers to stock tank barrels), inner radius or wellbore radius r_w (ft), outer radius or drainage radius r_e (ft), permeability k (md), thickness h (ft), pressure at inner radius p_w (psi), pressure at outer radius p_e (psi), fluid viscosity μ (cp), and formation volume factor B (rb/stb = reservoir barrel/stock tank barrel). Reservoir barrel is a barrel of volume at reservoir temperature and pressure. Stock tank barrel is a barrel of volume at stock tank temperature and pressure, which is typically surface temperature and pressure. Formation volume factor B is the ratio of volume of fluid at reservoir conditions to volume of fluid at stock tank (surface) conditions. The factor $0.00708 = 2\pi \times 0.001127$ and logarithmic term $\ln(r_e/r_w)$ are due to the change from linear to radial flow. Liquid flow rate q is positive for fluid production $\{p_w < p_e\}$ and negative for fluid injection $\{p_w > p_e\}$.

The outer radius r_e is equated to the drainage radius of a well when analyzing radial flow into a well. The flow rate is less sensitive to an error in the estimate of r_e than a similar error in a parameter like permeability because the radial flow calculation depends on the logarithm of r_e. It is therefore possible to make coarse estimates of the outer radius r_e and still obtain a reasonable value for radial flow rate.

11.2.5 Darcy's Law for Radial Flow of Gas

Darcy's law for the radial flow of gas at reservoir conditions is

$$q_r = -0.006328\frac{2\pi rhk}{\mu_g}\frac{dp_r}{dr} \tag{11.30}$$

where the variables are volumetric flow rate q_r (rcf/day where rcf refers to reservoir cubic feet or cubic feet of volume at reservoir temperature and pressure), radial distance r (ft), permeability k (md), thickness h (ft),

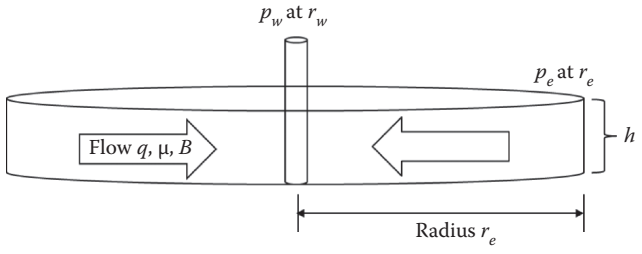

Figure 11.7

Darcy's law for radial flow.

gas viscosity μ_g (cp), and reservoir pressure p_r (psia). Let subscripts r and s denote reservoir and surface conditions, respectively. To convert from reservoir to surface conditions, we divide the gas rate at reservoir conditions by the gas formation volume factor:

$$q_s = \frac{q_r}{B_g} \tag{11.31}$$

where

q_s is the gas rate (scf/day where scf is standard cubic feet or cubic feet of volume at surface conditions)
B_g is the gas formation volume factor (rcf/scf)

Gas formation volume factor B_g is the ratio of the volume of gas at reservoir conditions to the volume of gas at surface conditions. We use the real gas equation of state to express B_g as a function of pressure p, temperature T, and gas compressibility factor Z as

$$B_g = \frac{\text{reservoir volume}}{\text{surface volume}} = \frac{Z_r T_r p_s}{Z_s T_s p_r} \tag{11.32}$$

The flow rate q_s at surface conditions in scf/day is found by combining Equations 11.30 through 11.32 to get

$$q_s = -0.03976 \frac{rhk}{\mu_g} \frac{Z_s T_s p_r}{Z_r T_r p_s} \frac{dp_r}{dr} \tag{11.33}$$

This can be written as

$$q_s = -0.01988 \frac{khT_s Z_s}{p_s T_r \left(\ln \dfrac{r_e}{r_w} \right)} \left[m(p_e) - m(p_w) \right] \tag{11.34}$$

where $m(p)$ is the real gas pseudo-pressure defined by

$$m(p) = 2 \int_{p_{ref}}^{p} \frac{p'}{\mu_g Z} dp' \tag{11.35}$$

where

p_{ref} is a reference pressure
p' is a dummy integration variable

In oilfield units, $m(p)$ has the unit psia^2/cp. Gas viscosity μ_g and gas compressibility factor Z depend on pressure and must be part of the integral. Darcy's law for the radial flow of gas at the standard conditions $Z_s = 1$, $p_s = 14.7$ psia, and $T_s = 60°\text{F} = 520°\text{R}$ is

$$q_s = -0.703 \frac{kh}{T_r \left(\ln \dfrac{r_e}{r_w} \right)} \left[m(p_e) - m(p_w) \right] \tag{11.36}$$

This shows that the flow rate q_s is proportional to the difference in real gas pseudo-pressure.

11.2.6 Permeability Measurements and the Klinkenberg Effect

The permeability of a core can be measured in the laboratory using a permeameter. A core is enclosed in an airtight sleeve, mounted into a steel cell, and a fluid is injected into the cell. The flow rate and pressure drop

across the core are measured and permeability is calculated using Darcy's law. At low flow rates, permeability to gas injection will be larger than permeability to liquid injection due to the slippage of gas molecules along pore walls. The dependence of permeability to gas on the pressure of flowing gas is called the Klinkenberg effect (Klinkenberg, 1941, Satter et al., 2008) and is given by the relationship

$$k_g = k_L\left(1+\frac{b}{\bar{p}}\right) \tag{11.37}$$

where

k_g is the permeability to gas when gas saturation is 100%
k_L is the permeability to liquid when liquid saturation is 100%
$\bar{p}$ is the mean flowing pressure of gas in the flow system
b is the Klinkenberg factor

The Klinkenberg factor b is a positive constant that depends on rock type and type of gas. Consequently, we have the inequality $k_g \geq k_{abs}$ when the factor $\left(1+\frac{b}{\bar{p}}\right) \geq 1$. As $\bar{p}$ increases, the factor $\left(1+\frac{b}{\bar{p}}\right)$ approaches 1 and the permeability to gas k_g approaches the absolute permeability of the rock k_{abs}. The Klinkenberg effect is more significant for gas flow through low-permeability rock than high-permeability rock.

Coals are naturally fractured reservoirs with two sets of mutually perpendicular fractures: face cleats and butt cleats. Both face and butt cleats are perpendicular to the bedding planes. Cleat intensity often varies by bedding plane, but cleat orientation remains nominally constant. Face cleats often cross several bedding planes, while vertical extent of butt cleats is often constrained to a few bedding planes. Face and butt cleat spacing is often on the order of millimeters or centimeters (Figures 11.3 and 11.4).

11.2.7 Coal Permeability

Visualizing coal as a collection of matchsticks with cleat spacing a, in mm, and cleat width b, in mm, lets us express permeability, in md, as (Reiss, 1980)

$$k = \frac{8.444\times10^5 b^3}{a} \tag{11.38}$$

The porosity can be written as (Reiss, 1980)

$$\phi = \frac{2b}{a} \tag{11.39}$$

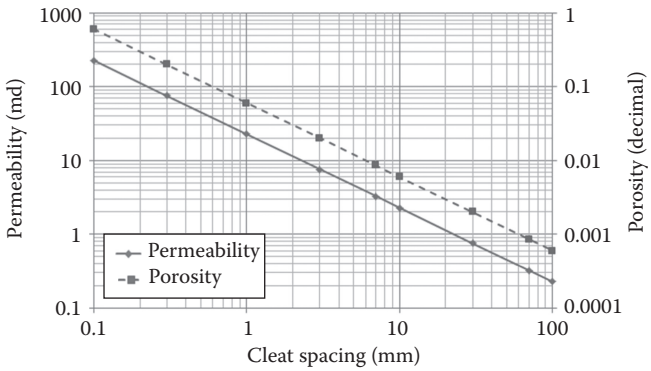

Figure 11.8

Coal permeability and porosity versus cleat spacing.

Assuming a cleat width of 0.050 mm = 50 μm, permeability and porosity are plotted as functions of cleat spacing in Figure 11.8. Cleat spacing on the order of millimeters gives porosities ranging from 0.005 to 0.010 (0.5% to 1%) and permeabilities varying between 2 and 20 md.

11.3 Characterizing Porosity and Permeability

Distributions of porosity and permeability in porous media can be quantified using probability distribution functions (Fanchi, 2000). For example, core plugs are relatively small samples of a geologic formation. Porosity and permeability can be measured in the laboratory using core plugs. Studies of core data have shown that porosity is often normally distributed and permeability is log normally distributed. These distributions are introduced in this section, and some techniques for characterizing porosity and permeability are discussed.

11.3.1 Porosity and Permeability Distributions

The distribution of porosity ϕ can be approximated by the normal, or Gaussian, probability distribution function (pdf) with the form

$$\rho(\phi) = \frac{1}{\sqrt{2\pi}\sigma_\phi} \exp\left[\frac{-(\phi - \phi_{mean})^2}{2\sigma_\phi^2}\right] \tag{11.40}$$

where

$\rho(\phi)$ is the pdf for porosity
ϕ_{mean} is the mean of porosity samples
σ_ϕ is the standard deviation of porosity

The probability P_ϕ that porosity has a value between $\phi - \Delta\phi$ and $\phi + \Delta\phi$ is

$$P_\phi = \int_{\phi-\Delta\phi}^{\phi+\Delta\phi} \rho(\phi')d\phi' \approx \rho(\phi)\Delta\phi \tag{11.41}$$

Figure 11.9 presents a normal probability distribution for a set of cores with average porosity = 0.20 and standard deviation of porosity = 0.05.

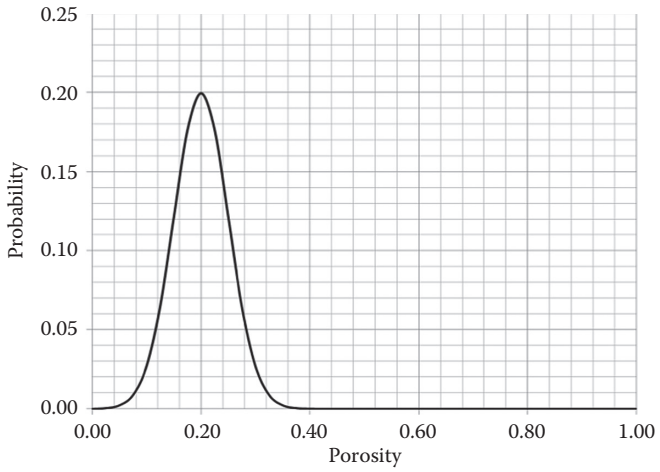

Figure 11.9

Probability distribution for porosity.

The distribution of permeability can be approximated by the normal pdf for the natural logarithm of permeability:

$$\rho(\ln k) = \frac{1}{\sqrt{2\pi}\sigma_k} \exp\left[\frac{-(\ln k - \ln k_G)^2}{2\sigma_k^2}\right] \tag{11.42}$$

where

$\rho(\ln k)$ is the pdf for natural logarithm of permeability
k_G is the geometric mean of permeability samples
σ_k is the standard deviation of permeability

If we have a set of permeability measurements $\{k_1, k_2, \ldots, k_N\}$ for N core samples, the geometric mean k_G of the permeability values is

$$k_G = \left[k_1 k_2 k_3 \ldots k_N\right]^{1/N} \tag{11.43}$$

The standard deviation σ_k is the square root of the variance, which is

$$\sigma_k^2 = \left\langle [(\ln k) - (\ln k_G)]^2 \right\rangle \tag{11.44}$$

where the notation $\langle x \rangle$ denotes the expectation value of variable x.

11.3.2 Permeability Averaging Techniques

Estimates of permeability are needed to make forecasts of fluid flow in porous media. Some practical averaging techniques are presented by Towler (2002), Satter et al. (2008), and Fanchi (2010). For example, the average permeability for flow through a set of parallel beds of differing permeability and thickness (Figure 11.10) can be estimated as a thickness-weighted average

$$k_{ave} = \frac{\sum_{i=1}^{n} k_i h_i}{\sum_{i=1}^{n} h_i} \tag{11.45}$$

where layer i has flow rate q_i, net thickness q_i, and permeability q_i. This is derived from Darcy's law assuming the pressure difference across each layer is the same, and the total flow rate is the sum of the rates in all layers. Equation 11.45 applies to both linear flow and radial flow.

11.3.3 Geostatistics

A fundamental objective of the reservoir characterization process is to distribute rock properties throughout the volume of interest. Geostatistics can be used to characterize a reservoir by determining the statistical distribution of a rock property in space (Hirsche et al., 1997, Kelkar, 2000). Geostatistics, which is also known as spatial statistics, assumes that a spatially distributed property such as porosity is correlated from

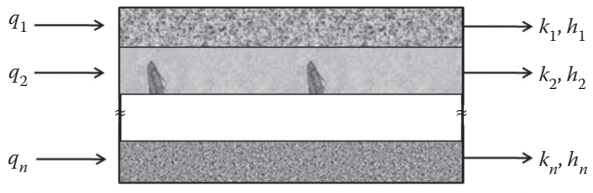

Figure 11.10

Fluid flow through parallel beds.

one point to another in a porous medium. The spatial relationships between data are combined with a geological model to provide a quantitative estimate of a rock property throughout the volume of interest.

The first step in a geostatistical analysis is to gather rock property data. Mathematical algorithms are used to quantify spatial relationships for each rock property. The resulting correlations provide information about the uncertainty associated with the values of rock properties used in different geologic models. Each geologic model is considered a realization, or representation, of the reservoir. A deterministic model of the reservoir is based on a single geologic representation. A stochastic model is a set of realizations obtained from the probability distributions developed during the geostatistical analysis. The first goal of stochastic modeling is to preserve the heterogeneity in a geological system. The second goal is to quantify the uncertainty in the geologic model by generating many possible realizations.

Geostatistics is most successful when data from multiple disciplines are integrated into the reservoir model. The data include thin sections studied under a microscope, laboratory core studies, near-wellbore well log information, and field-scale well test and seismic data. Incorrect reservoir models can occur when basic geostatistical assumptions are violated. For example, geostatistics assumes that rock properties are spatially continuous throughout the region of interest. Inaccuracies can occur if the continuity assumption is invalid by the appearance of a discontinuous change in rock property. Limited well control, biased sampling of well information, and geologic features such as a fault or formation pinch out can disrupt the continuity assumption. Errors may appear in associated maps when the geostatistical assumptions are violated.

11.4 Directional Permeability

Permeability can be a complex function of spatial location and orientation in a gravitational field. The effect of gravity, heterogeneity, and anisotropy on the fluid flow in porous media requires that the simple horizontal, linear form of Darcy's law must be generalized to include gravity and additional spatial dimensions.

11.4.1 Darcy's Law in a Gravitational Field

Fluid flow often occurs in dipping beds and vertical columns of porous media. We modify the 1D form of Darcy's law to include the effect of gravity by writing Darcy's law for single-phase flow in the form

$$q = -\frac{0.001127kA}{\mu}\frac{d\Phi}{dz} \tag{11.46}$$

Pressure is replaced by the potential of phase ℓ

$$\Phi_\ell = p_\ell - \gamma_\ell(\Delta z) \tag{11.47}$$

where

p_ℓ is the pressure of phase ℓ
γ_ℓ is the pressure gradient associated with the gravity term
Δz is the depth relative to a specified datum

The pressure gradient is aligned along the vertical z-axis. Fluid does not flow in the vertical direction when $d\Phi/dz = 0$. Therefore, Equation 11.46 represents the static equilibrium of a fluid column in the presence of a gravitational field and can quantify the movement of fluid when $d\Phi/dz \neq 0$.

The permeability for flow in the direction aligned with the direction of the gravitational field is called vertical permeability. If the fluid flow is in the horizontal plane, permeability is called horizontal permeability. Vertical permeability is usually less than horizontal permeability.

11.4.2 Extension of Darcy's Law to Three Dimensions

Darcy's law in one dimension is extended to three dimensions by writing Darcy's law for single-phase flow as

$$\begin{bmatrix} q_x \\ q_y \\ q_z \end{bmatrix} = -0.001127\frac{A}{\mu}\begin{bmatrix} k_{xx} & k_{xy} & k_{xz} \\ k_{yx} & k_{yy} & k_{yz} \\ k_{zx} & k_{zy} & k_{zz} \end{bmatrix}\begin{bmatrix} \partial\Phi_\ell/\partial x \\ \partial\Phi_\ell/\partial y \\ \partial\Phi_\ell/\partial z \end{bmatrix} \tag{11.48}$$

where the variables are volumetric flow rate q (rb/day), cross-sectional area A (ft^2), fluid viscosity μ (cp), permeability k (md), potential Φ_ℓ of phase ℓ (psi), and Cartesian coordinates x, y, z (ft). Permeability is now treated as a 3 × 3 matrix with nine elements (Fanchi, 2006a). The diagonal permeability elements $\{k_{xx}, k_{yy}, k_{zz}\}$ represent the usual dependence of rate in one direction on pressure differences in the same direction. The off-diagonal permeability elements $\{k_{xy}, k_{xz}, k_{yx}, k_{yz}, k_{zx}, k_{zy}\}$ account for the dependence of rate in one direction on pressure differences in orthogonal directions. The magnitude of the volumetric flow rate is the square root of the sum of the squares of the components q_x, q_y, q_z.

In many cases, it is possible to find a coordinate system $\{x', y', z'\}$ that diagonalizes the permeability tensor. In the diagonal form, the off-diagonal permeability elements $\{k'_{xy}, k'_{xz}, k'_{yx}, k'_{yz}, k'_{zx}, k'_{zy}\}$ are zero and the diagonal permeability elements $\{k'_{xx}, k'_{yy}, k'_{zz}\}$ are nonzero. The diagonal form of the permeability tensor is obtained by a principal axis transformation, and the coordinate axes $\{x', y', z'\}$ are called the principal axes. The flow equations along the principal axes are

$$\begin{aligned} q_{x'} &= -0.001127 \frac{A}{\mu}\left[k_{x'x'}\frac{\partial \Phi}{\partial x'}\right] \\ q_{y'} &= -0.001127 \frac{A}{\mu}\left[k_{y'y'}\frac{\partial \Phi}{\partial y'}\right] \\ q_{z'} &= -0.001127 \frac{A}{\mu}\left[k_{z'z'}\frac{\partial \Phi}{\partial z'}\right] \end{aligned} \tag{11.49}$$

The principal axes in a porous medium can vary from one point to another because of permeability heterogeneity. If the elements of the diagonalized permeability tensor are equal, then

$$k_{x'x'} = k_{y'y'} = k_{z'z'} = k \tag{11.50}$$

and permeability is considered isotropic. If this equation is not true for a particular medium, then flow depends on direction and the medium is anisotropic.

11.4.3 Coal Directional Permeability

Coal deposits should intuitively exhibit directional permeabilities since coal face and butt cleats are visually distinct. Although lab and field studies indicate face and butt cleat permeability contrasts between 2:1 and 17:1, no commercial coal gas development has taken this into account, choosing to space wells based on structure, topography, or culture. Vertical permeabilities of coals are rarely reported but appear to be ten to one hundred times less than horizontal permeabilities. This strong permeability contrast dictates a dominant horizontal flow of gas and water in coal deposits, with minimal vertical flow, primarily through the largest, or "master" cleats, which may extend from floor to roof in thin seams.

11.5 Rock–Fluid Interaction

Multiphase fluid flow in porous media depends on the interaction of the solid material with fluids in the pore space. The focus of this section is on the representation of rock–fluid interactions using physical parameters such as relative permeability and capillary pressure.

11.5.1 Surface Tension and Interfacial Tension

The pressure difference across the interface between two immiscible fluids results in a normal force. The unbalanced force leads to a tension at the interface that is balanced by a force due to the pressure difference when the surface of the interface is curved. The tension between liquids at a liquid–liquid interface is called interfacial tension (IFT), and the tension at a gas–liquid interface is called surface tension. Surface tension may be considered a force per unit length in a surface (dyn/cm, or equivalently, mN/m) or a free energy per unit surface area (erg/cm^2, or equivalently, mJ/m^2).

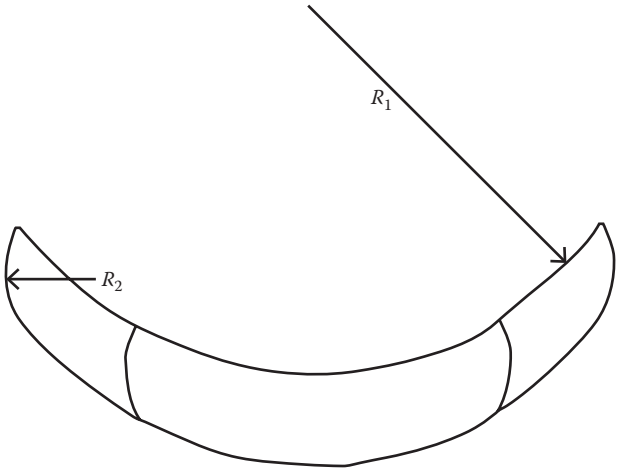

Figure 11.11

Geometry of a curved surface.

In general, two radii of curvature R_1 and R_2 are needed to describe a curved surface (Figure 11.11). The Young–Laplace equation gives the pressure difference Δp across the curved fluid surface or interface:

$$\Delta p = \sigma\left(\frac{1}{R_1} + \frac{1}{R_2}\right) \tag{11.51}$$

where σ is the surface tension. This becomes

$$\Delta p = \frac{2\sigma}{R} \tag{11.52}$$

for a surface where $R_1 = R_2$, such as a sphere. The two radii R_1 and R_2 are infinite for a plane surface, so the pressure difference across a plane surface is zero.

Typical IFT values at an oil–brine interface range from 15 to 40 dyn/cm. Surface tension at a gas–oil interface can vary from 35 to 65 dyn/cm. The surface tension at an air–brine interface can vary from 70 to 100 dyn/cm and tends to be larger than surface tension at a gas–oil interface.

Surface tension and IFT depend on the composition of the two fluids at the interface. The Weinaug–Katz variation of the Macleod–Sugden correlation can be used to estimate surface tension between a liquid and a vapor. The Macleod–Sugden correlation is (Fanchi, 2010)

$$\sigma^{1/4} = \sum_{i=1}^{N_c} P_{chi}\left(x_i\frac{\rho_L}{M_L} - y_i\frac{\rho_V}{M_V}\right) \tag{11.53}$$

where the variables are surface tension σ (dyn/cm), parachor P_{chi} of component i [(dyn/cm)$^{1/4}$/(g/cm^3)], molecular weight of liquid phase M_L, molecular weight of vapor phase M_V, liquid-phase density ρ_L (g/cm^3), vapor-phase density ρ_V (g/cm^3), mole fraction x_i of component i in liquid phase, and mole fraction y_i of component i in vapor phase. The parachor of component i with molecular weight M_i can be estimated using the regression equation (Katz et al., 1943)

$$P_{chi} = 27.0 + 2.75M_i \tag{11.54}$$

for molecular weights up to 100, and the regression equation (Fanchi, 1990)

$$P_{chi} = 10.0 + 2.92M_i \tag{11.55}$$

for molecular weights ranging from 100 to 500.

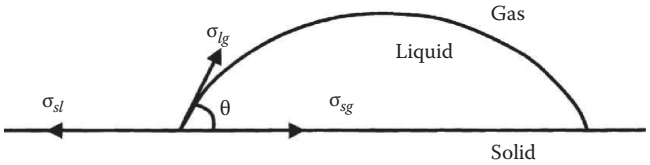

Figure 11.12

Measurement of contact angle.

11.5.2 Wettability

Immiscible fluids compete for space in pores. The configuration of fluids in the pore space is determined by wettability, which is the ability of a fluid phase to be in contact with a solid surface when in the presence of a second immiscible phase. The relative wettability of two fluids in a porous medium is characterized by the contact angle θ and the surface tension (or IFT).

Contact angle θ is defined as the angle between the tangent to the liquid–solid boundary constructed at a point on the three-phase line of contact and the tangent to the gas–liquid boundary constructed at the same point. Figure 11.12 shows a liquid droplet on a solid surface in a gas. The force balance at the point on the three-phase line of contact along the liquid–solid boundary is expressed by Young's equation:

$$\sigma_{sg} - \sigma_{sl} = \sigma_{lg} \cos\theta \tag{11.56}$$

where

σ_{lg} and σ_{sg} are the surface tensions of liquid l and solid s, respectively
σ_{sl} is the IFT between the liquid and the solid

Contact angles are measured on the surface of the denser phase.

The contact angle of a gas–liquid–solid or a liquid–liquid–solid system may have a value between 0° and 180°. It is customary to classify fluids into two categories: wetting fluid and nonwetting fluid. For wetting fluids, $0° \leq \theta \leq 90°$, and for nonwetting fluids, $90° \leq \theta \leq 180°$. Figure 11.13 shows two typical menisci that separate water and gas (or oil) in thin capillaries or pores. The contact angle measured through the water phase in Figure 11.13a is less than 90°, hence the water is the wetting phase and the gas (or oil) is the nonwetting phase. By contrast, the contact angle $\theta > 90°$ in Figure 11.13b, so the water is the nonwetting phase and the gas (or oil) is the wetting phase. The pore surface in Figure 11.13a is a water-wet surface, and the pore surface in Figure 11.13b is as an oil-wet surface.

11.5.3 Capillary Pressure and Capillary Radius

Immiscible fluids in porous media are separated by a curved interface. A pressure difference called capillary pressure p_c exists across the interface. Capillary pressure is the difference in pressure between the wetting and nonwetting phases:

$$p_c = p_{nw} - p_w \tag{11.57}$$

where w and nw represent wetting phase and nonwetting phase, respectively. Capillary pressure is always positive. The pressure difference across the interface is given by Equation 11.51.

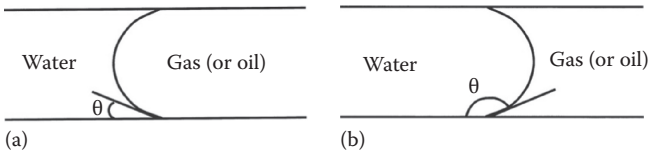

Figure 11.13

Contact angle and wettability. (a) Water wet. (b) Oil wet.

Capillary pressure tends to compress the nonwetting phase relative to the wetting phase. Therefore, pressure in the phase on the concave (curving inward) side of the surface is greater than the pressure in the phase on the convex (curving outward) side. For example, consider the fluid pair consisting of water and gas in Figure 11.13. If water is the wetting phase, the water surface must be concave in shape as shown in Figure 11.13a. By contrast, if water is the nonwetting phase as shown in Figure 11.13b, the water surface is convex in shape and the pressure is higher in the water phase than in the gas phase.

Equation 11.57 is a general form for calculating the pressure difference (or capillary pressure) at any point of a curved interface. The mean radius of curvature r_m of the curved interface with radii of curvature R_1 and R_2 is

$$\frac{1}{r_m} = \frac{1}{2}\left(\frac{1}{R_1} + \frac{1}{R_2}\right) \tag{11.58}$$

The Young–Laplace equation for pressure difference Δp across the curved fluid surface becomes

$$\Delta p = p_c = \sigma\left(\frac{1}{R_1} + \frac{1}{R_2}\right) = \frac{2\sigma}{r_m} \tag{11.59}$$

where σ is the surface tension. If the contact angle of a liquid on the capillary walls is zero, the shape of the interface between two fluids in a cylindrical capillary tube with very small radius is approximately circular. The resulting mean radius of curvature is approximately equal to the radius of the capillary r, and Equation 11.59 simplifies to

$$p_c = \frac{2\sigma}{r} \tag{11.60}$$

In general, the liquid–gas surface or liquid–liquid interface meets the cylindrical capillary wall through contact angle θ, as illustrated in Figure 11.14. If the shape of the interface in a cylindrical capillary tube with radius r is approximately spherical with radius of curvature R, the following geometric relation holds

$$R = \frac{r}{|\cos\theta|} \tag{11.61}$$

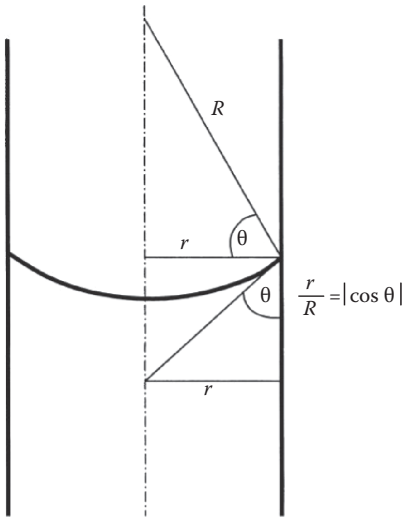

Figure 11.14

Interface between two immiscible fluids in a cylindrical capillary.

and Equation 11.60 becomes

$$p_c = \frac{2\sigma}{r}|\cos\theta| \tag{11.62}$$

This contains the three most important factors in determining the magnitude of the capillary pressure in a porous medium: surface tension σ (or IFT), capillary size *r*, and contact angle θ.

11.5.4 Coal Capillary Pressure

Capillary pressures in coal cleats and matrix differ by one or two orders of magnitude due to the different length scales. Coal cleats are planar with widths ranging from 1 to 100 μm. Coal matrix pores are primarily micropores (diameters less than 2 nm), with some mesopores (diameters between 2 and 50 nm), and a few macropores (diameters greater than 50 nm). Assuming coal cleats are planar and one radius in Equation 11.59 is essentially infinite, cleat capillary pressure can be expressed as

$$p_c = \frac{\sigma}{r}|\cos\theta| \tag{11.63}$$

As the radius is half the cleat width *b*, this expression becomes

$$p_c = \frac{2\sigma}{b}|\cos\theta| \tag{11.64}$$

For bounding calculations, assume water–gas surface tension varies between 70 and 100 dyn/cm and cleat width ranges from 1 to 100 μm. The water–gas interface has a contact angle of zero, making the cosine equal to one. Accounting for dimensions, bounding calculations indicate coal cleat capillary pressures between 0.2 and 29 psi.

Coal matrix pores are formed from organic material but will be considered as spherical pores for bounding calculations. Assuming surface tensions from 70 to 100 dyn/cm, a contact angle of zero, and pore diameters of 2 and 50 nm (radii of 1 and 25 nm), Equation 11.62 gives capillary pressures between 800 and 29,000 psi.

As cleat capillary pressures are on the order of those encountered during coal gas recovery, drainage of the cleats, especially the larger cleats, may be expected. By contrast, coal matrix capillary pressures are so high as to preclude drainage by pressures typically encountered during depletion.

11.5.5 Capillary Pressure and Height of the Interface

The balance of forces between fluid phases in a capillary tube requires that *force up = force down* at the interface between the wetting phase and the nonwetting phase. The upward force is given by

$$\text{Force up} = \sigma|\cos\theta| \times 2\pi r \tag{11.65}$$

where

r is the radius of the capillary tube
θ is the contact angle
σ is the surface tension (or IFT)

Figure 11.15 illustrates the height of the interface between the wetting phase water and the nonwetting phase air in a capillary tube. The downward force due to gravity depends on the difference in density between the wetting fluid with density ρ_w and the nonwetting fluid with density ρ_{nw} in the capillary tube and the height *h* of the interface between the two fluids:

$$\text{Force down} = (\rho_w g - \rho_{nw} g)\pi r^2 h \tag{11.66}$$

where

g is the acceleration of gravity
h is the height of the fluid interface in the capillary tube
πr^2 is the cross-sectional area of the capillary tube

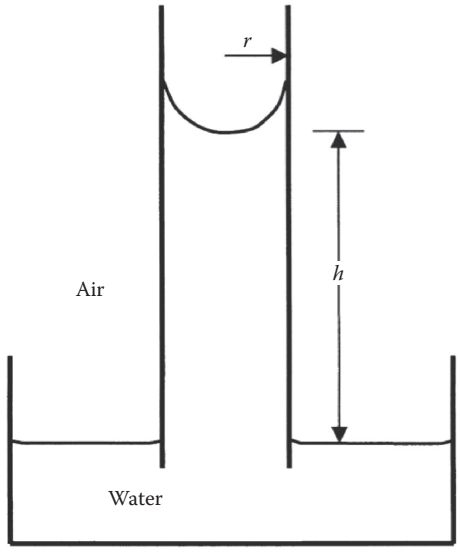

Figure 11.15

Height of the interface in a capillary tube.

The relationship between capillary pressure and height of the interface between the wetting phase and the nonwetting phase can be determined by applying the balance of forces. Capillary pressure P_c can be expressed in terms of force down per unit area as

$$P_c = \frac{\text{force down}}{\pi r^2} = (\rho_w g - \rho_{nw} g)h \tag{11.67}$$

and in terms of force up per unit area as

$$P_c = \frac{\text{force up}}{\pi r^2} = \frac{2\sigma}{r}|\cos\theta| \tag{11.68}$$

Solving Equation 11.67 for h yields the following relationship between capillary pressure P_c and height h of the interface between immiscible wetting and nonwetting phases:

$$h = \frac{P_c}{(\rho_w g - \rho_{nw} g)} \tag{11.69}$$

Equating Equations 11.67 and 11.68 gives a relationship between surface tension (or IFT) and difference in densities between the wetting and nonwetting phases:

$$\sigma = \frac{(\rho_w - \rho_{nw}) rhg}{2|\cos\theta|} \tag{11.70}$$

Equation 11.62 shows that a decrease in capillary radius increases capillary pressure, and Equation 11.69 shows that the increase in capillary pressure increases the height of the interface for a given difference in phase densities. Figure 11.16 illustrates this relationship between capillary radius and interface height.

Using the bounding capillary pressures calculated earlier for coal cleats and matrix gives interface heights in the cleats between 0.5 and 67 ft while interface heights in the matrix 1,800–67,000 ft. Considering that coal seams targeted for coal gas exploitation typically range from a few feet to tens of feet with maybe a few exceptions of 100 ft, seam thickness is often on the order of the cleat interface height. Thus, the thinnest cleats in a seam would be expected to be completely water filled, whereas the widest cleats would have gas–water interfaces present.

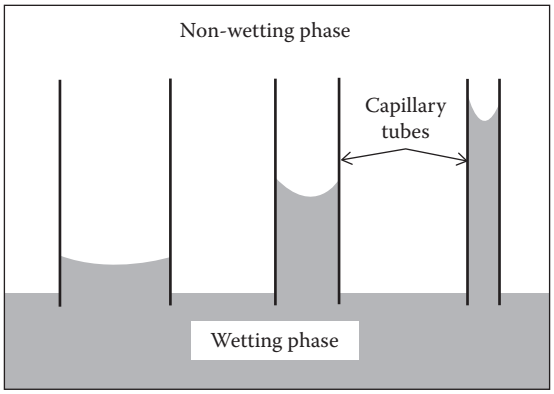

Figure 11.16

Capillary tubes and capillary pressure.

11.5.6 Capillary Pressure Measurement

Laboratory measurements of capillary pressure in reservoir rock can be made using mercury methods, porous-plate methods, and centrifuge methods (Christiansen, 2006). The experiments provide a relationship between capillary pressure P_c and wetting phase saturation S_w. For an oil–water system or an oil–gas system, water is usually the wetting phase.

Figure 11.17 shows several typical features of a capillary pressure P_c versus wetting phase saturation S_w curve:

- The drainage P_c curve starts at $S_w = 100\%$.
- Wetting phase saturation S_w decreases as the nonwetting phase is forced into a porous medium. The threshold or entry pressure is the pressure required to force the first drop of nonwetting phase fluid into the porous medium.
- As pressure increases above entry pressure, more of the nonwetting phase enters the porous medium. Eventually, no further reduction in S_w occurs. The minimum S_w is the irreducible wetting phase saturation, S_{wirr}.
- Capillary pressure increases as the wetting phase saturation decreases during drainage.
- Capillary pressure decreases as the wetting phase saturation increases during imbibition.

The difference in paths between the drainage and imbibition curves is called hysteresis.

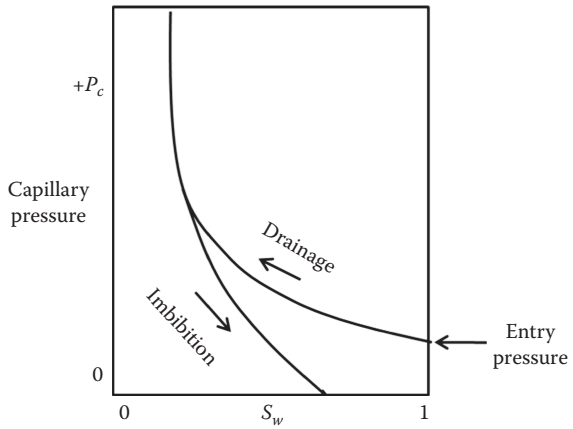

Figure 11.17

Capillary pressure and hysteresis.

Capillary pressure measurements at laboratory conditions should be converted from laboratory conditions to subsurface conditions for fluid flow in geologic formations. The customary correction is

$$P_{c(res)} = P_{c(lab)} \frac{\left(\sigma|\cos\theta|\right)_{res}}{\left(\sigma|\cos\theta|\right)_{lab}} \tag{11.71}$$

where

σ is the surface tension (or IFT)

θ is the contact angle (Amyx et al., 1960, Christiansen, 2006)

Subscripts *lab* and *res* refer to laboratory conditions and reservoir conditions, respectively.

11.6 Relative Permeability

Permeability is a measure of the connectedness of pores in a porous medium. It is necessary to modify permeability when more than one phase is present in the pore space to account for the relative movement of two or more phases in the pore space. Multiphase flow in porous media is simultaneous flow of two or more immiscible fluids, or fluids of limited miscibility, for example, oil and water or air and water. The distribution of the two immiscible fluids flowing simultaneously through a porous sample depends on a number of factors, including saturation, wettability conditions of the pore surface, IFT, fluid viscosities, and pore velocity. Changes in these factors alter the effective permeability of the fluids in the pore space. Relative permeability curves are used to characterize the permeability of a phase as saturation changes during multiphase flow.

11.6.1 Effective Permeability and Relative Permeability

Permeability to single-phase fluid flow through a porous medium depends on the phase and type of fluid flowing through the porous medium. For example, the permeability of air flowing through a core is not the same as water flowing through the same core. We define the permeability of single-phase flow as the effective permeability to that phase. In the case of oil, water, and gas, we have effective permeability to oil k_o, effective permeability to water k_w, and effective permeability to gas k_g.

Two immiscible fluids, such as oil and water or oil and gas, can flow cocurrently through a porous medium. Steady cocurrent flow can be established by injecting both fluids into the porous medium at constant rates and allowing time for the discharge rates to equal the injection rates. Permeability is also affected by the flow of one phase through a porous medium with a residual, immobile second phase. The effect of cocurrent flow of two phases or single-phase flow in the presence of a different phase on the effective permeability is quantified using relative permeability (Ahmed, 2000, Christiansen, 2006, Satter et al., 2008).

Relative permeability is the ratio of effective permeability k_{eff} to reference permeability k_{ref}:

$$k_r = \frac{k_{eff}}{k_{ref}} \tag{11.72}$$

The permeability to air at 100% air saturation is often used as the reference permeability. If we designate the reference permeability as $k = k_{ref}$, the relative permeability of phase ℓ is

$$k_{r\ell} = \frac{k_{\ell eff}}{k} \tag{11.73}$$

where $k_{\ell eff}$ is the effective permeability to flow of phase ℓ.

Relative permeability curves represent the ability of a porous medium to conduct one fluid when other fluid phases are present. The curves are usually plotted as a function of wetting phase saturation as shown in Figure 11.18. The curve labels in the figure depict relative permeability curves for the following conditions: NW-I is the relative permeability of the nonwetting phase during imbibition, NW-D is the relative permeability of the nonwetting phase during drainage, W-I is the relative permeability of the wetting phase during imbibition, and W-D is the relative permeability of the wetting phase during drainage. The arrows in the figure show the direction of wetting phase saturation. Drainage occurs when wetting phase saturation

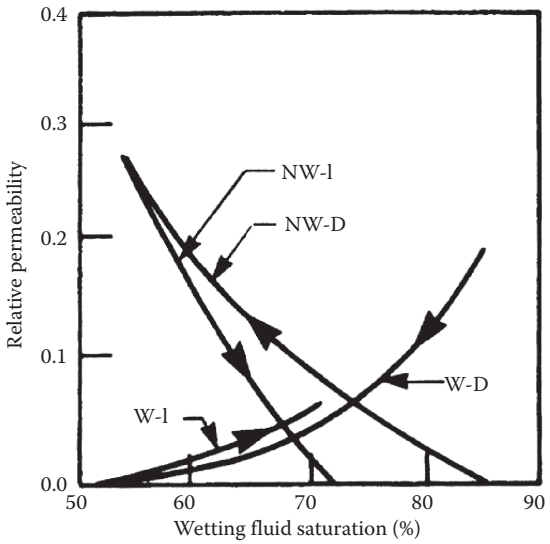

Figure 11.18

Typical relative permeability curves.

decreases, and imbibition occurs when wetting phase saturation increases. The dependence on the history of wetting phase saturation changes is called relative permeability hysteresis.

Relative permeability curves for a porous medium containing two fluid phases are referred to as two-phase relative permeability curves. Relative permeability curves for a porous medium containing three fluid phases are referred to as three-phase relative permeability curves.

The presence of two or more mobile fluid phases reduces the effective permeability, as shown in Figure 11.18. Plots of relative permeability curves for a wetting phase and a nonwetting phase show that the relative permeability of the nonwetting phase (k_{rnw}) goes to 0 before the nonwetting phase saturation S_{nw} reaches 0. This shows that one fluid phase cannot be completely displaced from a porous medium by injecting another phase. The saturation where relative permeability k_r goes to 0 is the end point saturation of the relative permeability curve. The end point saturation for water in an oil–water system is called the irreducible water saturation, S_{wirr} or the connate water saturation S_{wc}. The end point saturation is called residual oil saturation, S_{or} for oil in an oil–water system.

Similar two-phase relative permeability curves can be measured for gas–liquid systems. Gas is the nonwetting phase during two-phase flow of gas and liquid. Critical gas saturation, S_{gc}, is the gas saturation at which gas first begins to flow in a porous medium. Residual or trapped gas saturation (S_{gr} or S_{gt}) is the maximum value of S_g where the relative permeability to gas $k_{rg} = 0$.

11.6.2 Coal Relative Permeability

Gas–water relative permeabilities in coal, as in conventional gas reservoirs, are difficult to predict and are therefore measured experimentally. In addition to the experimental difficulties encountered in measuring relative permeabilities in conventional reservoirs, these measurements in coal are complicated by coal fines shed from the friable, brittle coals, the small cleat porosities, and severe stress and hysteresis effects. Sound and timely collection, preservation, and preparation protocols are critical to obtaining coal samples suitable for gas–water relative permeability measurements.

Coals can hold water chemically bound in the matrix, sorbed to the surface of the coal, and in the cleats. Bound and sorbed water are immobile during depletion of a coal deposit while water drains from the cleats. For engineering purposes, the volume occupied by this cleat water is often characterized as "mobile water" porosity that is defined experimentally as the volume of water that can be displaced by a gas divided by the bulk sample volume. Gas–water relative permeabilities in coals are typically measured across mobile water porosity with a water saturation of one corresponding to fully water filled cleats and a water saturation of zero being associated with fully dewatered cleats. Note that at a mobile water saturation of zero, some immobile water still resides in the smaller coal cleats and matrix. This arbitrarily defined zero water saturation is technically the irreducible water saturation of the coal.

The simplest of the four principal methods of determining gas–water relative permeabilities in coal is to assume they are straight lines that cross, a classic assumption in naturally fractured reservoirs. Second is the laboratory measurement of gas–water relative permeabilities. As seen in Figures 11.19 through 11.21, coal gas water permeabilities vary by coal rank and geologic age (Gash, 1991, Conway et al., 1995, Meaney and Paterson, 1996). Attempts to fit classic Corey curves or other similar equations to gas–water relative data measured on coals have met with limited success. Third, gas–water permeabilities can be calculated from water production data from a well with sufficiently long history. After extrapolating the water rate decline to determine the water estimated ultimate recovery (EUR), division of cumulative water production at any given time by the water EUR yields water saturation. Absolute permeability is estimated from initial water production data, when little, if any gas is present and the water saturation is essentially unity. Effective gas and water perms are calculated from available stabilized gas and water rates and bottomhole or wellhead pressures. Division of effective gas and water permeabilities by the absolute permeability yields the respective gas and water relative permeabilities. Fourth, because of the difficulties encountered in measuring gas–water relative permeabilities in coals and the inaccuracies in estimating them from well performance, many workers choose to regard gas–water relative permeabilities in coal as history match parameters in simulation studies.

11.6.3 Darcy's Law for Multiphase Flow

Darcy's law for single-phase flow is given by Equation 11.48 and expresses the flow rate at reservoir conditions. An equation for calculating the flow rate of phase ℓ in the presence of other phases is obtained by replacing permeability in Equation 11.48 with effective permeability of phase ℓ. Darcy's law for flow of phase ℓ in three dimensions at surface conditions must include the formation volume factor B_ℓ of phase ℓ and relative permeability $k_{r\ell}$ of phase ℓ, thus

$$\begin{bmatrix} q_{\ell x} \\ q_{\ell y} \\ q_{\ell z} \end{bmatrix} = -0.001127 \frac{k_{r\ell}}{\mu_\ell B_\ell} A \begin{bmatrix} k_{xx} & k_{xy} & k_{xz} \\ k_{yx} & k_{yy} & k_{yz} \\ k_{zx} & k_{zy} & k_{zz} \end{bmatrix} \begin{bmatrix} \partial\Phi_\ell/\partial x \\ \partial\Phi_\ell/\partial y \\ \partial\Phi_\ell/\partial z \end{bmatrix} \tag{11.74}$$

where the variables are volumetric flow rate q_ℓ of phase ℓ (stb/day) at surface conditions, relative permeability $k_{r\ell}$, cross-sectional area A (ft²), fluid viscosity μ_ℓ of phase ℓ (cp), formation volume factor B_ℓ of phase ℓ (rb/stb), permeability k (md), potential Φ_ℓ of phase ℓ (psi), and Cartesian coordinates x,y,z (ft). Capillary pressure effects are included in the phase potential Φ_ℓ. Darcy's law for the flow of phase ℓ at surface conditions using the diagonal form of the permeability tensor in three dimensions is

$$\begin{aligned} q_{\ell x'} &= -0.001127 \frac{k_{r\ell}}{\mu_\ell B_\ell} A \left[k_{x'x'} \frac{\partial\Phi_\ell}{\partial x'} \right] \\ q_{\ell y'} &= -0.001127 \frac{k_{r\ell}}{\mu_\ell B_\ell} A \left[k_{y'y'} \frac{\partial\Phi_\ell}{\partial y'} \right] \\ q_{\ell z'} &= -0.001127 \frac{k_{r\ell}}{\mu_\ell B_\ell} A \left[k_{z'z'} \frac{\partial\Phi_\ell}{\partial z'} \right] \end{aligned} \tag{11.75}$$

where $\{x', y', z'\}$ are coordinate axes obtained by a principal axis transformation of the permeability tensor.

11.6.4 Mobility and Relative Mobility

The mobility of phase ℓ in multiphase flow is defined as the ratio of the effective permeability of phase ℓ to the viscosity of phase ℓ:

$$\lambda_\ell = \frac{k_\ell}{\mu_\ell} \tag{11.76}$$

where phase permeability is the product of relative permeability and reference permeability. In an oil–water–gas system, gas has a much smaller viscosity than oil or gas and will have a larger mobility. Oil and water often have comparable viscosities, so the ratio of their mobilities depends on the ratio of their relative permeabilities.

Fluid-phase mobilities for oil, water, and gas phases in an oil–water–gas system are

$$\lambda_o = \frac{k_o}{\mu_o}, \quad \lambda_w = \frac{k_w}{\mu_w}, \quad \lambda_g = \frac{k_g}{\mu_g} \tag{11.77}$$

Total mobility for an oil–water–gas system is the sum of individual phase mobilities:

$$\lambda_T = \lambda_o + \lambda_w + \lambda_g \tag{11.78}$$

It is often useful to determine a minimum in total mobility relative to phase saturation by plotting total mobility versus phase saturation.

The relative mobility $\lambda_{r\ell}$ of phase ℓ is the ratio of relative permeability of phase ℓ to the phase viscosity of phase ℓ:

$$\lambda_{r\ell} = \frac{k_{r\ell}}{\mu_\ell} \tag{11.79}$$

Darcy's law for the flow of phase ℓ in three dimensions at surface conditions given by Equation 11.74 can be expressed in terms of relative mobility as

$$\begin{bmatrix} q_{\ell x} \\ q_{\ell y} \\ q_{\ell z} \end{bmatrix} = -0.001127 \frac{\lambda_r}{B_\ell} A \begin{bmatrix} k_{xx} & k_{xy} & k_{xz} \\ k_{yx} & k_{yy} & k_{yz} \\ k_{zx} & k_{zy} & k_{zz} \end{bmatrix} \begin{bmatrix} \partial\Phi_\ell/\partial x \\ \partial\Phi_\ell/\partial y \\ \partial\Phi_\ell/\partial z \end{bmatrix} \tag{11.80}$$

Darcy's law for the flow of phase ℓ at surface conditions along the x-axis is

$$q_{\ell x} = -0.001127 \frac{\lambda_r k_{xx}}{B_\ell} A \frac{\partial p_\ell}{\partial x} \tag{11.81}$$

where p_ℓ is the pressure of phase ℓ.

11.6.5 Effect of Wettability

The effect of wettability on typical water–oil relative permeability curves is presented in Figures 11.22 and 11.23 for water-wet and oil-wet reservoir formation samples, respectively (Craig, 1971). The most noticeable difference in relative permeability characteristics shown in Figures 11.22 and 11.23 is the water saturation at which water and oil relative permeabilities are equal: the relative permeability curves intersect at water saturations greater than 50% for water-wet rock and less than 50% for oil-wet rock. For rocks with neutral wettability, the relative permeabilities are different from the values measured in systems of strongly water wet or strongly oil wet.

11.6.6 Effect of Interfacial Tension

Four possible occupancy patterns of two fluids in cocurrent steady flow are depicted in Figure 11.24. In Figure 11.24a, both fluids flow in separate channels. Fluid 1 wets the solid surface preferentially and tends to occupy the finer pores in the network. There are thick films of the wetting fluid (not shown in the figure) in the pores, where the nonwetting phase (fluid 2) occupies the central part. The contribution by the thick films to the flow of the wetting fluid is negligible. In Figure 11.24b, both fluids flow in the same pores; the wetting fluid is in the form of thick films (the thickness exaggerated in the figure).

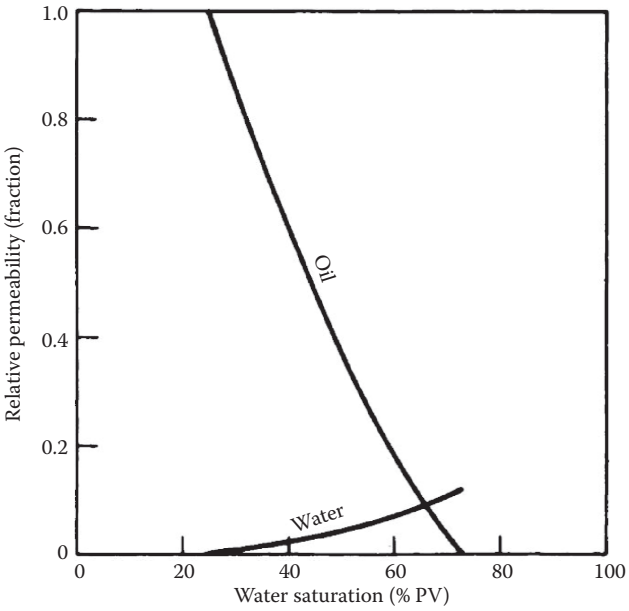

Figure 11.22

Typical water-wet relative permeability curves.

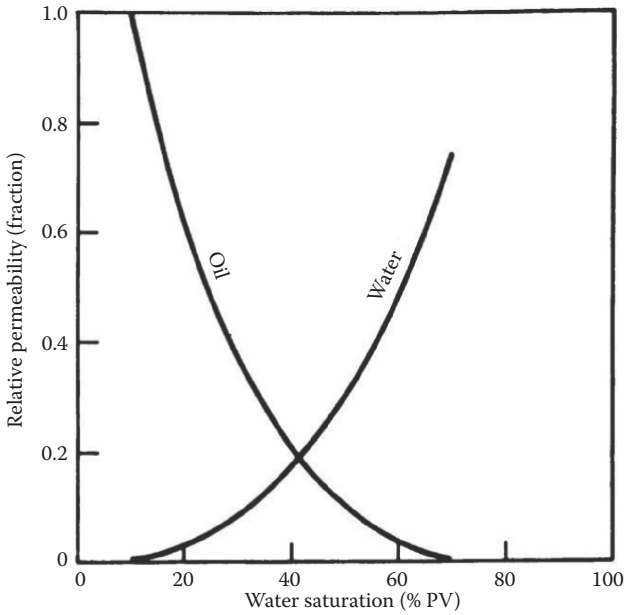

Figure 11.23

Typical oil-wet relative permeability curves.

Such conditions exist at low wetting fluid saturations, where the wetting fluid is no longer continuous in the central parts of the pores.

Figure 11.24c shows the flow pattern in a sample with neutral wettability. There are no thick films of either fluid, and either fluid may fill small as well as large pores. It is conceivable that the two fluids may flow side by side in some pores, as shown in Figure 11.24c. Finally, in Figure 11.24d both fluids flow in the same channel, but one fluid is continuous and the other dispersed. This is the case at low values of the IFT when oil and water form emulsions and it may happen at both low nonwetting phase saturation and high IFTs.

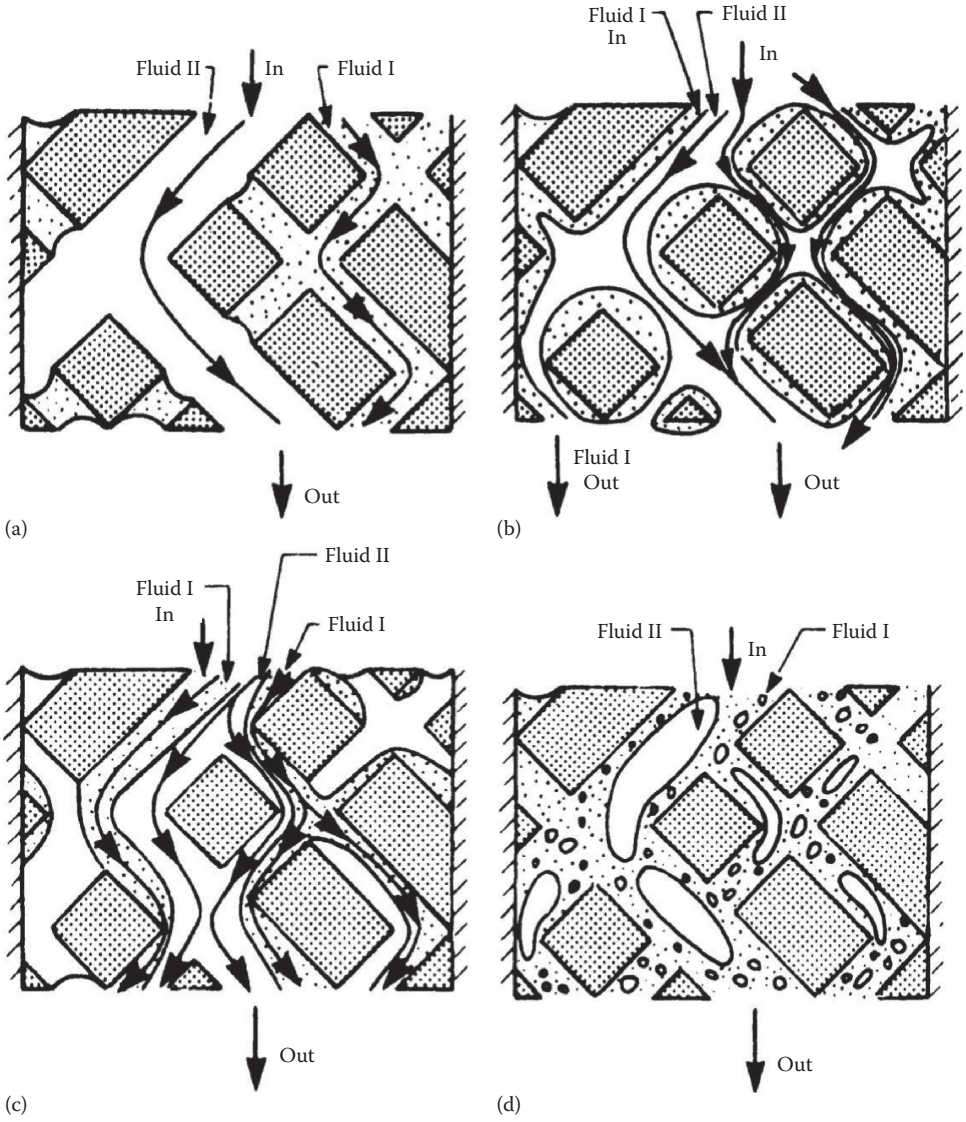

Figure 11.24

Effect of IFT on relative permeability. (a) Fluids flow in separate channels. (b) Fluids flow in same pore space with Fluid I wetting the surface. (c) Fluids flow in same pore space with neutral wettability. (d) Both fluids flow in the same channel with fluid I continuous and fluid II dispersed. (From Dullien, F.A.L., *Chem. Eng. Technol.*, 11, 407, 1988.)

IFTs approximately greater than 1 mN/m usually have a negligible effect on conventional relative permeabilities. For very low IFT systems, however, the networks of the two fluids begin to break up, first in the relatively large pores and then at even lower IFTs and also in the finer pores. Ultimately, an emulsion is formed in the entire pore network (Figure 11.24d) and, at that point, each fluid flows everywhere in proportion to its saturation in the sample. The relative permeability curves become straight diagonal lines for emulsion flows (Figure 11.25).

11.6.7 Effect of Viscosity Ratio

The effect of the viscosity ratio of the two immiscible fluids on the relative permeabilities has been investigated extensively since the work by Leverett (1939). There are two cases to consider. One case is that the relative permeability of a porous medium to a given phase in two-phase flow is dependent only on saturation. A possible explanation is that in cocurrent steady flow under certain conditions each fluid may flow in a separate network of pores, so the two streams do not influence each other (see Figure 11.24a).

The other case is that in low permeability media at low water saturations, when the wetting phase is no longer continuous in the central part of the pores, the lower viscosity of the water may exert a "lubricating effect"

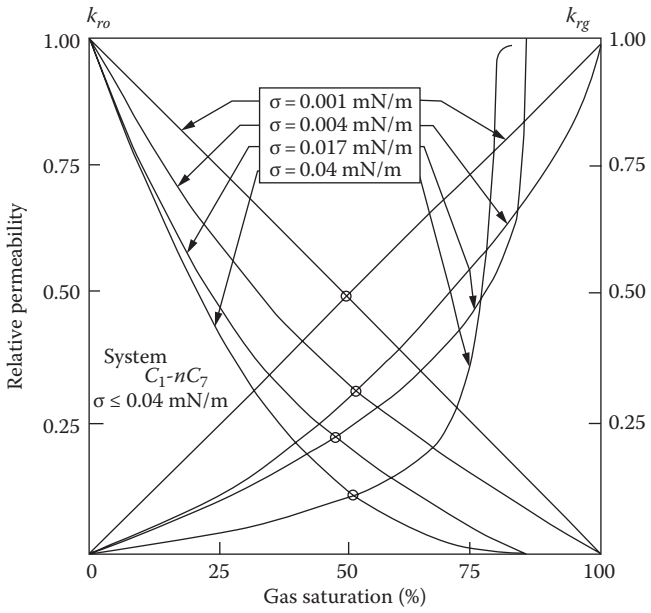

Figure 11.25

Effect of IFT on relative permeability. (From Bardon, C. and Longeron, D., Influence of very low interfacial tensions on relative permeability, Presented at the *53rd Annual Fall Technical Conference and Exhibition*, SPE 7609, SPE of AIME, Houston, TX, 1978.)

on the oil flow under the conditions of steady-state relative permeability measurements. The essence of the lubricating effect is that, as a result of the presence of the lower viscosity fluid (water) near the pore walls, the oil flows at a higher rate than it would if oil instead of water was also present near the wall. Water movement along pore walls provides a moving boundary for oil. Under these conditions, oil relative permeability depends on oil-to-water viscosity ratio, as shown in Figure 11.26 (Odeh, 1959, Danis and Jacquin, 1983).

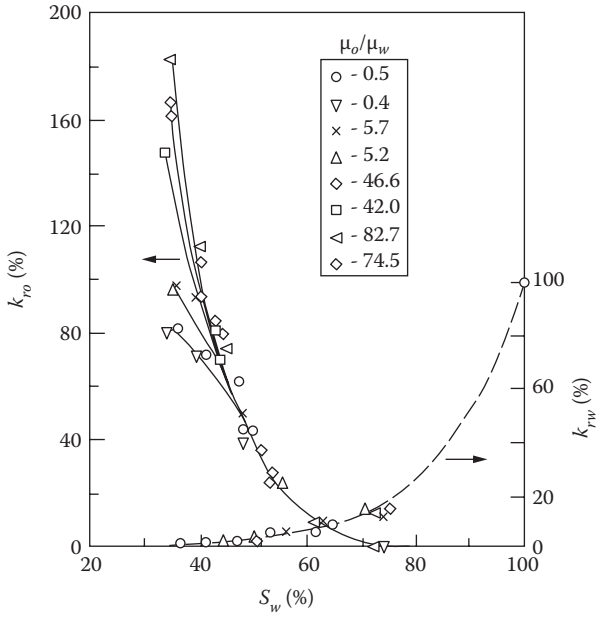

Figure 11.26

Effect of viscosity ratio on relative permeability.

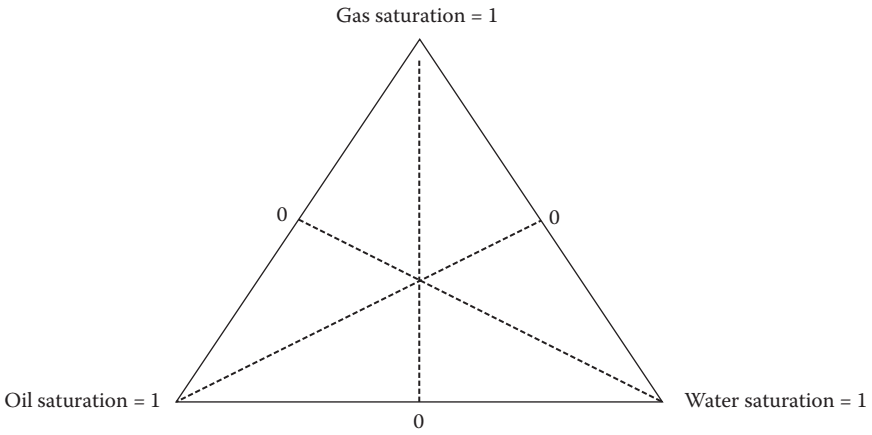

Figure 11.27

Triangle diagram for three-phase relative permeability.

11.6.8 Relative Permeability Correlations

Several correlations exist for two-phase and three-phase relative permeabilities. Correlations are developed from a variety of techniques including empirical correlations based on core flood measurements, statistical models of capillary bundles, and microscopic network models. Correlations should be used in conjunction with laboratory data or when laboratory data are not available.

Three-phase relative permeabilities can be measured in the laboratory using techniques such as steady-state displacement. It is difficult to perform reproducible laboratory measurements over the entire saturation range of interest. Results can be costly and time consuming. Consequently, models of three-phase relative permeability based on two-phase relative permeability curves have been introduced to estimate three-phase relative permeability values. The sensitivity of calculations that depend on three-phase relative permeability is estimated by using different three-phase relative permeability models. Stone (1973) provided two of the most commonly used three-phase relative permeability models. Triangle diagrams are often used to display three-phase relative permeability for an oil–water–gas system. Each axis represents a different phase saturation with a scale ranging from 0 to 1 (Figure 11.27). Three-phase relative permeability is displayed as a set of contours within the triangle diagram.

11.7 Fractional Flow of Two Immiscible Fluids

One of the most important examples of multiphase flow is the flow of a wetting phase and a nonwetting phase through a porous medium. The fractional flow f_w of the wetting phase is

$$f_w = \frac{q_w}{q_T} = \frac{q_w}{q_w + q_{nw}} \tag{11.82}$$

where

q_w is the flow rate of the wetting phase
q_{nw} is the flow rate of the nonwetting phase
$q_T = q_w + q_{nw}$ is the total flow rate

Fractional flow has a value between 0 and 1. A similar equation applies for the fractional flow of the nonwetting phase:

$$f_{nw} = \frac{q_{nw}}{q_T} = \frac{q_{nw}}{q_w + q_{nw}} \tag{11.83}$$

If the only flowing phase is the wetting phase, then $q_{nw} = 0$ and $f_w = 1, f_{nw} = 0$.

An important application of the fractional flow concept is the fractional flow of water f_w in an oil–water system:

$$f_w = \frac{q_w}{q_t} = \frac{q_w}{q_w + q_o} \tag{11.84}$$

where q_w and q_o are water and oil flow rates, respectively. The fractional flow of water is the ratio of water production rate to the total production rate. The fractional flow of oil f_o is related to the fractional flow of water by $f_w = 1 - f_o$.

Fractional flow may be expressed in terms of mobilities. The fractional flow f_w of the wetting phase in a system with a wetting phase and a nonwetting phase is

$$f_w = \frac{q_w}{q_w + q_{nw}} = \frac{1}{1 + \dfrac{q_{nw}}{q_w}} \tag{11.85}$$

The ratio of rates can be determined using Darcy's law. For example, if gravity and capillary pressure are negligible, Darcy's law at the conditions of the porous medium gives

$$\frac{q_{nw}}{q_w} = \frac{-\dfrac{kk_{rnw}A}{\mu_{nw}}\dfrac{\partial p}{\partial x}}{-\dfrac{kk_{rw}A}{\mu_w}\dfrac{\partial p}{\partial x}} = \frac{\dfrac{kk_{rnw}}{\mu_{nw}}}{\dfrac{kk_{rw}}{\mu_w}} = \frac{\lambda_{nw}}{\lambda_w} \tag{11.86}$$

Equation 11.85 becomes

$$f_w = \frac{1}{1 + \dfrac{q_{nw}}{q_w}} = \frac{1}{1 + \dfrac{\lambda_{nw}}{\lambda_w}} \tag{11.87}$$

where λ_w and λ_{nw} are mobilities of the wetting and nonwetting phases, respectively. Equation 11.87 is an expression for wetting phase fractional flow f_w at the conditions of the porous medium. In a geologic reservoir, the fractional flow is calculated using rates and mobilities at reservoir conditions.

11.7.1 Fractional Flow Equation with Capillary Pressure and Gravity

The earlier analysis can be extended to include gravity in the fractional flow equation. The 1D form of Darcy's law with capillary pressure and gravity is

$$\begin{aligned} q_w &= -\frac{kk_{rw}A}{\mu_w}\left(\frac{\partial p_w}{\partial x} + \rho_w g \sin\alpha\right) \\ q_{nw} &= -\frac{kk_{rnw}A}{\mu_{nw}}\left(\frac{\partial p_{nw}}{\partial x} + \rho_{nw} g \sin\alpha\right) \end{aligned} \tag{11.88}$$

where the variables are cross-sectional area A of flow system, reference permeability k, relative permeability to the nonwetting phase k_{rnw}, relative permeability to the wetting phase k_{rw}, capillary pressure $p_c = p_{nw} - p_w$ with nonwetting phase pressure p_{nw} and wetting phase pressure p_w, nonwetting phase density ρ_{nw}, wetting phase density ρ_w, nonwetting phase viscosity μ_{nw}, wetting phase viscosity μ_w, dip angle α of linear flow, and x is the direction of linear flow. We differentiate the capillary pressure function with respect to x

$$\frac{\partial p_c}{\partial x} = \frac{\partial p_{nw}}{\partial x} - \frac{\partial p_w}{\partial x} \tag{11.89}$$

and combine with Equation 11.88 to obtain

$$\frac{\partial p_c}{\partial x} = -\frac{q_{nw}\mu_{nw}}{Akk_{rnw}} - \rho_{nw} g \sin\alpha + \frac{q_w \mu_w}{Akk_w} + \rho_w g \sin\alpha \tag{11.90}$$

Using the total rate $q_t = q_{nw} + q_w$ and density difference $\Delta\rho = \rho_w - \rho_{nw}$ in Equation 11.90 gives, after some rearrangement, the equation

$$\frac{q_w}{Ak}\left(\frac{\mu_{nw}}{k_{rnw}} + \frac{\mu_w}{k_{rw}}\right) = \frac{q_t \mu_{nw}}{Akk_{rnw}} + \frac{\partial p_c}{\partial x} - g\Delta\rho \sin\alpha \tag{11.91}$$

Solving for the fractional flow f_w to the wetting phase gives

$$\begin{aligned} f_w &= \frac{q_w}{q_t} \\ &= \frac{1 + \dfrac{Akk_{rnw}}{\mu_{nw} q_t}\left[\dfrac{\partial p_c}{\partial x} - \left(\rho_w - \rho_{nw}\right) g \sin\alpha\right]}{1 + \dfrac{k_{rnw}}{k_{rw}}\dfrac{\mu_w}{\mu_{nw}}} \end{aligned} \tag{11.92}$$

The general expression for f_w includes the mobility term $(k_{rnw}/k_{rw})(\mu_w/\mu_{nw})$, the capillary pressure derivative $\partial p_c/\partial x$, and the gravity term $(\rho_w - \rho_{nw})g \sin\alpha$. The bracketed term contains capillary pressure and gravity effects. The bracketed term can be neglected if the denominator $\mu_{nw} q_t$ in the term $Akk_{rnw}/\mu_{nw} q_t$ is large enough to make $\dfrac{Akk_{rnw}}{\mu_{nw} q_t}\left[\dfrac{\partial p_c}{\partial x} - \left(\rho_w - \rho_{nw}\right) g \sin\alpha\right] \ll 1$. If the wetting phase is water and the nonwetting phase is oil, the capillary pressure and gravity effects can be negligible when the total flow rate is large. If the wetting phase is water and the nonwetting phase is gas, the capillary pressure and gravity effects may need to be considered at large total flow rate because gas viscosity is small compared to liquid viscosity. Countercurrent flow occurs when the term $1 + \dfrac{Akk_{rnw}}{\mu_{nw} q_t}\left[\dfrac{\partial p_c}{\partial x} - \left(\rho_w - \rho_{nw}\right) g \sin\alpha\right] < 0$ on the RHS of Equation 11.92.

11.8 Immiscible Displacement

The equations for 1D, immiscible flow of a nonwetting phase and a wetting phase in a horizontal, porous medium of constant cross-sectional area A are, respectively,

$$q_{nw} = \frac{k_{rnw} kA}{\mu_{nw}} \frac{\partial p_{nw}}{\partial x} \tag{11.93}$$

and

$$q_w = \frac{k_{rw} kA}{\mu_w} \frac{\partial p_w}{\partial x} \tag{11.94}$$

Total flow q_t is the sum of both flows, that is, Buckley and Leverett (1942) applied this equations and fractional flow concepts to model the advance of a fluid displacement front in an immiscible displacement process.

11.8.1 Buckley–Leverett Theory

The Buckley–Leverett (1942) calculation determines the rate at which an injected wetting phase moves through a porous medium. Flow through a small volume element (Figure 11.28) with length Δx and cross-sectional area A can be expressed in terms of total flow rate q_t given by

$$q_t = q_w + q_{nw} \tag{11.95}$$

The rate of the wetting phase entering the element on the left-hand side (LHS) of the volume element is

$$q_t f_w = \text{entering LHS} \tag{11.96}$$

where f_w is the fractional flow to the wetting phase. The rate of water leaving the volume element on the RHS is

$$q_t \left(f_w + \Delta f_w \right) = \text{leaving RHS} \tag{11.97}$$

The change in wetting phase flow rate Δq_w through the volume element is

$$\begin{aligned} \Delta q_w &= q_t f_w - q_t \left(f_w + \Delta q_t f_w \right) \\ &= -q_t \Delta f_w \end{aligned} \tag{11.98}$$

The change in wetting phase saturation per unit time is Δq_w in Equation 11.98 divided by the pore volume of the element,

$$\frac{\Delta S_w}{\Delta t} = -\frac{q_t}{A\phi} \frac{\Delta f_w}{\Delta x} \tag{11.99}$$

In the limit as $\Delta t \to 0$ and $\Delta x \to 0$, we obtain the differential form

$$\frac{\partial S_w}{\partial t} = -\frac{q_t}{A\phi} \frac{\partial f_w}{\partial x} \tag{11.100}$$

The corresponding equation for the nonwetting phase is

$$\frac{\partial S_{nw}}{\partial t} = -\frac{q_t}{A\phi} \frac{\partial f_{nw}}{\partial x} \tag{11.101}$$

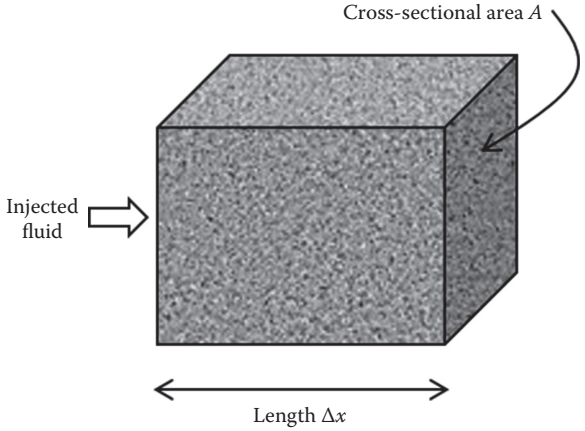

Figure 11.28

Geometry for 1D immiscible displacement.

Assuming fractional flow of the wetting phase f_w depends only on S_w, we obtain the derivative

$$\frac{\partial f_w}{\partial x} = \frac{df_w}{dS_w}\frac{\partial S_w}{\partial x} \tag{11.102}$$

Substituting $\partial f_w/\partial x$ into $\partial S_w/\partial x$ in Equation 11.100 gives

$$\frac{\partial S_w}{\partial t} = -\frac{q_t}{A\phi}\frac{df_w}{dS_w}\frac{\partial S_w}{\partial x} \tag{11.103}$$

Equation 11.103 can be difficult to solve analytically because it is a nonlinear partial differential equation for the general distribution of wetting phase saturation $S_w(x, t)$ in most realistic cases. For example, if water is the wetting phase in rock, water fractional flow is typically a nonlinear function of water saturation.

A simplified approach to solving Equation 11.103 is obtained by tracking the movement of a surface of constant wetting phase saturation. We begin by writing the total differential of $S_w(x, t)$ as

$$\frac{dS_w}{dt} = \frac{\partial S_w}{\partial x}\frac{dx}{dt} + \frac{\partial S_w}{\partial t} \tag{11.104}$$

The derivative $dS_w/dt = 0$ for a surface with constant S_w. If we choose to follow the movement of a surface with constant S_w, we can express Equation 11.104 in the form

$$\left(\frac{dx}{dt}\right)_{S_w} = -\frac{\left(\partial S_w/\partial t\right)}{\left(\partial S_w/\partial x\right)} \tag{11.105}$$

The Buckley–Leverett frontal advance equation is obtained by rearranging Equation 11.103 and substituting the result in Equation 11.105:

$$\left(\frac{dx}{dt}\right)_{S_w} = -\frac{q_t}{A\phi}\left(\frac{df_w}{dS_w}\right)_{S_w} \tag{11.106}$$

The derivative $(df_w/dS_w)_{Sw}$ is the slope of the fractional flow curve. An expression for wetting phase fractional flow f_w as a function of capillary pressure and gravity is given in Equation 11.92. Displacements of one fluid by another in porous media can be analyzed by solving Equations 11.92 and 11.106. This requires the porosity and permeability of the porous medium, fluid viscosities, relative permeability curves, and the capillary pressure curve for the fluids–porous medium system.

11.8.2 Welge's Method

Buckley and Leverett (1942) gave a simplified solution of Equations 11.92 and 11.106 by neglecting the term containing $\partial p_c/\partial x$ in Equation 11.92. Their solution gave multivalued water saturations for the same value of x, which they recognized was physically impossible. Welge (1952) published an approach that is widely used to perform the Buckley–Leverett frontal advance calculation. Welge's approach is best demonstrated using a plot of f_w versus S_w (Figure 11.29).

A line is drawn with its intercept at irreducible wetting phase saturation S_{wirr} and tangent to a point on the f_w curve. The resulting tangent line is illustrated in Figure 11.29 and is called the breakthrough tangent or slope. Wetting phase saturation at the flood front S_{wf} is the point of tangency on the f_w curve. Fractional flow of the wetting phase at the flood front is f_{wf} and occurs at the point of tangency S_{wf} on the f_w curve. Average wetting phase saturation behind the flood front S_{wbt} is the intercept of the main tangent line with the upper limiting line where $f_w = 1.0$. In summary, when the wetting phase exits the volume element, Welge's approach gives the following results:

- The wetting phase saturation at the producing well is S_{wf}.
- The average wetting phase saturation behind the front is S_{wbt}.
- The fractional flow of the wetting phase is f_{wf}.

The Buckley–Leverett procedure is widely available in reservoir engineering software.

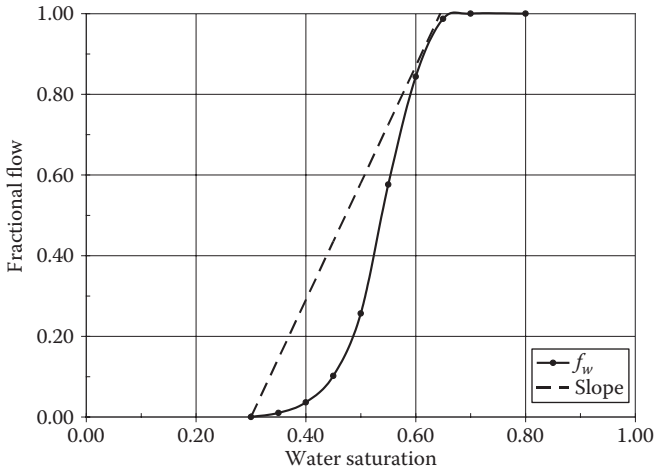

Figure 11.29

Welge's method. (From Fanchi, J.R., *Integrated Reservoir Asset Management*, Elsevier-Gulf Professional Publishing, Burlington, MA, 2010.)

11.8.3 Frontal Advance in a Fracture

Most geologic sediments were deposited in a level plane. Uneven uplift and subsidence over geologic time can break the rock and form natural fractures. Natural fractures affect the fluid flow in a porous medium. Formations with natural fractures are characterized by abrupt changes in porosity and permeability. These changes can result in two physically distinct flow regimes known as the matrix and the fracture. The matrix has a larger porosity and pore volume than the fracture, but a small permeability. Consequently, most of the fluid volume is contained in the matrix while most of the fluid flow occurs in the interconnected fracture volume.

Matrix fluid is usually recovered by flowing into fractures that are open to flow and intersect a production conduit such as a well. The permeability of the fracture when the fracture first formed can be reduced by mineralization. In some cases, there is so much mineralization that the fractures are impermeable are referred to as closed fractures. Open fractures have not undergone mineralization and have the original fracture permeability. Fractures subjected to some mineralization have a permeability that is less than original fracture permeability and are considered partially open. The fluid flow in fractures depends on such factors as fracture permeability, fracture aperture size, orientation of the fracture, net stress on the fracture, and the behavior of the fluids in the fracture.

A model of the displacement of oil by water in a linear, horizontal fracture surrounded by oil saturated matrix rock was given by DeSwaan (1978) as a modification of Buckley–Leverett theory. DeSwaan added a matrix–fracture flow term to Equation 11.101 to get

$$-u\frac{\partial f_{wf}}{\partial x}=\frac{\partial S_{wf}}{\partial t}+\frac{\lambda R_{\infty}}{\phi_f}\int_0^t e^{-\lambda(t-\varepsilon)}\frac{\partial S_{wf}}{\partial \varepsilon}d\varepsilon \tag{11.107}$$

where interstitial velocity $u = q_t/A\phi_f$

f_{wf} is the fractional flow of water in the fracture

S_{wf} is the water saturation in the fracture

ϕ_f is the fracture porosity

ε is a dummy integration variable

The matrix–fracture interaction is represented by the term containing an integral on the RHS of Equation 11.107. The parameters λ and R_∞ are obtained by fitting the equation $R = R_\infty(1 - e^{-\lambda t})$ to a laboratory measurement of oil recovery from a piece of rock surrounded by water. Imbibition of water into the matrix rock does not occur when either λ or R_∞ equal zero. The rate of water imbibition from the fracture

to the matrix increases as λ increases. This increased transfer of water from the fracture to the matrix slows the rate of frontal advance in the fracture. A method for numerically solving Equation 11.107 is presented by Kazemi et al. (1992).

11.9 Reservoir Flow Model Equations

Reservoir flow models play a significant role in designing and assessing the success of a reservoir project. They can be applied to the multiphase flow of fluids in a variety of commercial settings, such as oil and gas reservoirs, coal seams, aquifers, and geothermal reservoirs. The reservoir flow model is an input data set for use in a computer program that simulates the fluid flow based on a set of fluid flow equations. The computer program is often referred to as a reservoir simulator. The set of fluid flow equations is the mathematical representation of the physics incorporated in the reservoir simulator. As an illustration, we consider the multiphase flow of oil and gas in a reservoir. Following Fanchi (2006b), we derive the continuity equation in three dimensions and then develop the equations for a black oil simulator.

A black oil simulator is a computer program that treats the oil and gas phases as two-component systems. The components are a liquid hydrocarbon component and a gaseous hydrocarbon component. The fluid properties (viscosity, density, compressibility, and formation volume factor) are assumed to depend on the two components and pressure. More complex simulators have been developed that include the effects of more components and temperature. The formulation of a black oil simulator illustrates the techniques that are used to develop more sophisticated simulators and has widespread applicability as well. We restrict our attention here to a black oil simulator.

11.9.1 Continuity Equation

Consider the system displayed in Figure 11.30. The block in Figure 11.30 has length Δx, width Δy, and depth Δz. The bulk volume of the block is $\Delta x \Delta y \Delta z$. The symbol J denotes fluid flux. Flux is defined as the rate of flow of mass per unit cross-sectional area normal to the direction of flow. The term *mass* refers to the mass of a component in the fluid. In our case, fluid flows into the block at x with fluid flux J_x and out of the block at $x + \Delta x$ with fluid flux $J_{x+\Delta x}$.

The principle of conservation of mass states that the difference between the mass entering the block and the mass leaving the block is equal to the accumulated mass in the block.

The mass entering the block in a time interval Δt is

$$\left[(J_x)_x \Delta y \Delta z + (J_y)_y \Delta x \Delta z + (J_z)_z \Delta x \Delta y\right] \Delta t = \text{Mass in} \tag{11.108}$$

where the expression includes flux in the x-, y-, and z-directions. The notation $(J_x)_x$ in the first term on the LHS denotes the x-direction flux at location x and $\Delta y \Delta z$ is the cross-sectional area that is perpendicular to the direction of fluid flux. Analogous meanings apply to the remaining terms of Equation 11.108.

The term for mass exiting the block is

$$\left[(J_x)_{x+\Delta x} \Delta y \Delta z + (J_y)_{y+\Delta y} \Delta x \Delta z + (J_z)_{z+\Delta z} \Delta x \Delta y\right] \Delta t + q \Delta x \Delta y \Delta z \Delta t = \text{Mass out} \tag{11.109}$$

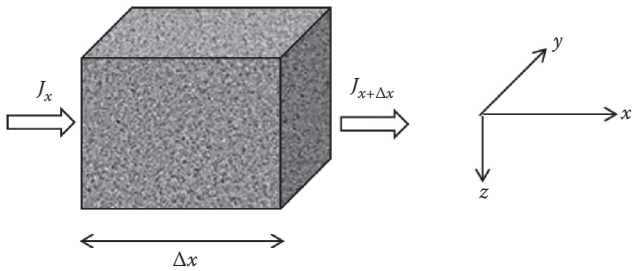

Figure 11.30

Coordinate convention.

A source/sink term q representing the flow of mass into (source) or out of (sink) the block has been added to Equation 11.109. Production is represented by $q > 0$ and injection by $q < 0$. Flow equations may be expressed in terms of volumetric flow rate Q_ℓ for phase ℓ rather than mass flow rate q_ℓ. The flow rates are related by $Q_\ell = q_\ell/\rho_{\ell sc}$ where $\rho_{\ell sc}$ is the density of phase ℓ at standard conditions of pressure and temperature.

The accumulation of mass in the block is the change in concentration of the mass of a component (C) in the block over the time interval Δt. If the concentration C is defined as the total mass of a component in the reservoir block divided by the block volume, then the accumulation term becomes

$$\left[(C)_{t+\Delta t} - (C)_t\right]\Delta x\Delta y\Delta z = \text{Mass accumulation} \tag{11.110}$$

Using Equations 11.108 through 11.110 in the mass balance equation gives

$$\begin{aligned}&\left[(J_x)_x \Delta y\Delta z + (J_y)_y \Delta x\Delta z + (J_z)_z \Delta x\Delta y\right]\Delta t\\ &-\left[(J_x)_{x+\Delta x} \Delta y\Delta z + (J_y)_{y+\Delta y} \Delta x\Delta z + (J_z)_{z+\Delta z} \Delta x\Delta y\right]\Delta t\\ &- q\Delta x\Delta y\Delta z\Delta t = \left[(C)_{t+\Delta t} - (C)_t\right]\Delta x\Delta y\Delta z\end{aligned} \tag{11.111}$$

where

$(C)_t$ denotes the concentration of a component at time t

$(C)_{t+\Delta t}$ is the concentration at time $t + \Delta t$

Dividing Equation 11.111 by $\Delta x\Delta y\Delta z\Delta t$ and rearranging gives

$$\begin{aligned}&-\frac{(J_x)_{x+\Delta x} - (J_x)_x}{\Delta x} - \frac{(J_y)_{y+\Delta y} - (J_y)_y}{\Delta y}\\ &-\frac{(J_z)_{z+\Delta z} - (J_z)_z}{\Delta z} - q = \frac{(C)_{t+\Delta t} - (C)_t}{\Delta t}\end{aligned} \tag{11.112}$$

In the limit as Δx, Δy, Δz, and Δt go to zero, Equation 11.112 becomes the continuity equation for a component in the fluid:

$$-\frac{\partial J_x}{\partial x} - \frac{\partial J_y}{\partial y} - \frac{\partial J_z}{\partial z} - q = \frac{\partial C}{\partial t} \tag{11.113}$$

This is written in vector notation as

$$-\nabla \cdot \vec{J} - q = \frac{\partial C}{\partial t} \tag{11.114}$$

where $\nabla \cdot \vec{J}$ is divergence of flux. A continuity equation for mass is needed for each component of mass in the block.

11.9.2 Black Oil Simulator Equations

Black oil simulators and compositional simulators are the two most common types of computer programs that model fluid flow in reservoirs. Thermal simulators include an energy balance equation that is not considered here. From a physical perspective, black oil and compositional simulators differ in the way they model fluid properties. Compositional simulators use multicomponent equations of state to model fluid properties. Gas and oil properties in a black oil model depend on pressure only. Typical gas and oil properties for a standard black oil model include gas formation volume factor (B_g), gas viscosity (μ_g),

liquid yield (r_s), oil formation volume factor (B_o), oil viscosity (μ_o), and solution gas–oil ratio (R_{so}). We neglect liquid yield in the formulation below later to simplify the presentation. Liquid yield is useful when analyzing condensate reservoirs or reservoirs with hydrocarbon liquid dissolved in the hydrocarbon gas phase. Liquid yield is often included in commercial black oil simulators. Many people prefer to use compositional simulators that provide a more sophisticated model of hydrocarbon fluid properties when modeling condensate reservoirs. Water properties include water formation volume factor (B_w), water viscosity (μ_w), and solution gas–water ratio (R_{sw}).

The flow equations of a black oil simulator are derived from mass conservation and the continuity equation. Fluxes and concentrations are needed for each of the three phases in an oil, water, and gas system. A flux in a given direction can be written as the density of the fluid times its velocity in the given direction. Letting the subscripts *o*, *w*, and *g* denote oil, water, and gas, respectively, the fluxes become

$$\left(\vec{J}\right)_o = \frac{\rho_{osc}}{B_o}\vec{v}_o \tag{11.115}$$

$$\left(\vec{J}\right)_w = \frac{\rho_{wsc}}{B_w}\vec{v}_w \tag{11.116}$$

$$\left(\vec{J}\right)_g = \frac{\rho_{gsc}}{B_g}\vec{v}_g + \frac{R_{so}\rho_{gsc}}{B_o}\vec{v}_o + \frac{R_{sw}\rho_{gsc}}{B_w}\vec{v}_w \tag{11.117}$$

where

R_{so} and R_{sw} are the gas solubilities
B_o, B_w, and B_g are the formation volume factors
sc is the subscript that denotes the standard conditions (usually 60°F and 14.7 psia in oilfield units)
ρ denotes the fluid densities

Liquid hydrocarbon in the form of condensate is not included in this formulation. The velocities in oilfield units are assumed to be Darcy's velocities, and their *x* components are

$$v_{xo} = -k_x\lambda_o\frac{\partial\Phi_o}{\partial x} \tag{11.118}$$

$$v_{xw} = -k_x\lambda_w\frac{\partial\Phi_w}{\partial x} \tag{11.119}$$

$$v_{xg} = -k_x\lambda_g\frac{\partial\Phi_g}{\partial x} \tag{11.120}$$

where

Φ_o, Φ_w, and Φ_g are the oil-, water-, and gas-phase potentials
k_x is permeability in the *x*-direction

Similar expressions can be written for the *y* and *z* components. The relative phase mobility λ_ℓ is defined as the ratio of the relative permeability to the flow of the phase divided by its viscosity:

$$\lambda_\ell = \frac{k_{r\ell}}{\mu_\ell} \tag{11.121}$$

The phase densities are related to formation volume factors and gas solubilities by

$$\rho_o = \frac{1}{B_o}\left[\rho_{osc} + R_{so}\rho_{gsc}\right] \tag{11.122}$$

$$\rho_w = \frac{1}{B_w}\left[\rho_{wsc} + R_{sw}\rho_{gsc}\right] \tag{11.123}$$

$$\rho_g = \frac{\rho_{gsc}}{B_g} \tag{11.124}$$

The concentrations for the oil-, water-, and gas-phase continuity equations are

$$C_o = \frac{\phi\rho_{osc}S_o}{B_o} \tag{11.125}$$

$$C_w = \frac{\phi\rho_{wsc}S_w}{B_w} \tag{11.126}$$

$$C_o = \phi\rho_{gsc}\left[\frac{S_g}{B_g} + R_{so}\frac{S_o}{B_o} + R_{sw}\frac{S_w}{B_w}\right] \tag{11.127}$$

where

ϕ is the porosity

S_ℓ is the saturation of phase ℓ

The gas concentration term in Equation 11.127 accounts for oil (condensate) and water to be dissolved in the gas phase. Saturations satisfy the constraint

$$S_o + S_w + S_g = 1 \tag{11.128}$$

Mass conservation equations for each component in the appropriate phase are given as follows.

Oil component in the oil phase:

$$-\left[\frac{\partial}{\partial x}\left(\frac{v_{xo}}{B_o}\right) + \frac{\partial}{\partial y}\left(\frac{v_{yo}}{B_o}\right) + \frac{\partial}{\partial z}\left(\frac{v_{zo}}{B_o}\right)\right] - \frac{q_o}{\rho_{osc}} = \frac{\partial}{\partial t}\left(\frac{\phi S_o}{B_o}\right) \tag{11.129}$$

Water component in the water phase:

$$-\left[\frac{\partial}{\partial x}\left(\frac{v_{xw}}{B_w}\right) + \frac{\partial}{\partial y}\left(\frac{v_{yw}}{B_w}\right) + \frac{\partial}{\partial z}\left(\frac{v_{zw}}{B_w}\right)\right] - \frac{q_w}{\rho_{wsc}} = \frac{\partial}{\partial t}\left(\frac{\phi S_w}{B_w}\right) \tag{11.130}$$

Gas component in the gas, oil, and water phases:

$$\begin{aligned} &-\frac{\partial}{\partial x}\left(\frac{v_{xg}}{B_g} + \frac{R_{so}}{B_o}v_{xo} + \frac{R_{sw}}{B_w}v_{xw}\right) \\ &-\frac{\partial}{\partial y}\left(\frac{v_{yg}}{B_g} + \frac{R_{so}}{B_o}v_{yo} + \frac{R_{sw}}{B_w}v_{yw}\right) \\ &-\frac{\partial}{\partial z}\left(\frac{v_{zg}}{B_g} + \frac{R_{so}}{B_o}v_{zo} + \frac{R_{sw}}{B_w}v_{zw}\right) - \frac{q_g}{\rho_{gsc}} \\ &= \frac{\partial}{\partial t}\left(\phi\left(\frac{S_g}{B_g} + \frac{R_{so}S_o}{B_o} + \frac{R_{sw}S_w}{B_w}\right)\right) \end{aligned} \tag{11.131}$$

These equations have been simplified by dividing out the constant densities at standard conditions.

Equivalent but more compact forms of the flow equations are presented in terms of vector operators as

$$-\nabla \cdot \frac{\vec{v}_o}{B_o} - \frac{q_o}{\rho_{osc}} = \frac{\partial}{\partial t}\left(\frac{\phi S_o}{B_o}\right) \tag{11.132}$$

$$-\nabla \cdot \frac{\vec{v}_w}{B_w} - \frac{q_w}{\rho_{wsc}} = \frac{\partial}{\partial t}\left(\frac{\phi S_w}{B_w}\right) \tag{11.133}$$

$$-\nabla \cdot \left(\frac{\vec{v}_g}{B_g} + \frac{R_{so}}{B_o}\vec{v}_o + \frac{R_{sw}}{B_w}\vec{v}_w\right) - \frac{q_g}{\rho_{gsc}} = \frac{\partial}{\partial t}\left(\phi\left(\frac{S_g}{B_g} + \frac{R_{so}S_o}{B_o} + \frac{R_{sw}S_w}{B_w}\right)\right) \tag{11.134}$$

The mass conservation equations are nonlinear, partial differential equations that represent the fluid flow in porous media. The equations are discretized using finite difference techniques. The resulting difference equations are solved using matrix solution methods. The mathematical techniques are beyond the scope of this article. They are described in more detail in Batycky et al. (2007) and Gilman and Ozgen (2013).

11.9.3 Reservoir Flow Model Workflows

Reservoir simulators are applied to green fields and brown fields. A green field is an undeveloped field with minimal historical flow data, while a brown field is a developed field. Different flow modeling workflows are used for green fields and brown fields.

Green field and brown field workflows are designed to be systematic procedures for quantifying uncertainty. Green fields have little or no production information to constrain the selection of reservoir realizations or calibrate uncertain model parameters. Each reservoir realization should be a possible representation of reservoir geology. Consequently, it is valuable to have a workflow that can quantify uncertainty. A green field workflow includes gathering data, identifying key parameters and associated uncertainties, generating forecasts of field performance results for a statistically significant distribution of parameters, and generating a probabilistic distribution of field performance results.

Two brown field workflows are currently being used in industry: deterministic reservoir forecasting and probabilistic reservoir forecasting. In deterministic reservoir forecasting, a single reservoir realization is selected and matched to historical performance. Historical performance includes all data about the reservoir, such as seismic data, well log data, well test data, core data, fluid property data, and production data. The uncertainty associated with a deterministic dynamic model can be estimated by evaluating the sensitivity of the model to uncertainties in available data. History match parameters are customarily changed one at a time.

In probabilistic reservoir forecasting, a statistically significant collection, or ensemble, of reservoir realizations is prepared. Reservoir flow models are run for each possible realization, and the results of the model runs are then compared to historical performance of the reservoir. The models that match historical data within a specified set of tolerances are selected as the set of dynamic models that can be used for making predictions. A subset of the ensemble of realizations may be selected for matching to historical data to reduce the number of reservoir flow models that need to be studied. The specific design of a history matching workflow depends on such factors as the objectives of the study, the complexity of reservoir performance, and the availability of history matching technology. More discussion of workflows is presented by Fanchi (2011a,b) and Gilman and Ozgen (2013).

Acknowledgments

The authors thank the publisher for providing material from the corresponding chapter written by M. Dong and FAL Dullien in the first edition (Crowe, 2006).

Turbulence Interactions

John K. Eaton and Ellen K. Longmire

12.1 Introduction
12.2 Particle Motion and Distribution in Turbulent Flow
12.3 Effect of Turbulence on Coupling Forces and Heat Transfer
12.4 Turbulence Modulation

12.1 Introduction

Many of the single- and multiphase flows that we interact with are turbulent. Large-scale flows in nature such as ocean currents, river flows, the atmospheric boundary layer, clouds, and volcanic eruptions are characterized by very large Reynolds numbers and are naturally turbulent with a broad range of eddy length scales. Large fish, birds, and aquatic mammals have turbulent boundary layers and wakes, and flow separation causes turbulence around some smaller animals. In the technological arena, the flows around transport vehicles from motorcycles to airliners are turbulent, as are the flows inside the internal combustion and gas turbine engines powering them. The flows through large-scale industrial equipment such as electric generating plants and chemical processing facilities are almost all turbulent. Considering the built environment, turbulence plays important roles in wind flows through cities, large gas and water pipelines, ventilation ducts, and building interiors.

This chapter discusses the interaction of dispersed particles and droplets with continuous-phase turbulence. Interactions between the particles and the turbulence are almost always important. Some turbulent flows such as dust storms, clouds, particle transport risers, and sediment-laden rivers carry a substantial load of dispersed particles, and the effect of turbulence on particle transport is critical. Turbulence effects on the interphase exchange processes are important in spray combustion and many chemical and food processing systems such as spray dryers. Even in lightly laden flows, particle–turbulence interaction can be important. For example, turbulence may substantially affect the surface deposition of particles such as volcanic ash ingested into jet engines.

There are two important parameters that must be introduced early in any discussion of particle–turbulence interaction. The first is the Stokes number (St) defined as the ratio of the particle aerodynamic time constant to a relevant timescale of the flow. A flow timescale could be based on mean flow parameters. Alternatively, several timescales that characterize the turbulence can be used. For the present discussion, we will use the Kolmogorov timescale, defined as $\tau_k = (\nu/\varepsilon)^{1/2}$. Here, ν is the kinematic viscosity of the fluid and ε is the turbulent dissipation rate. This timescale was chosen because it is unambiguously defined and characterizes the smallest eddies in the flow. We will use the nomenclature St_k to correspond to normalization by

the Kolmogorov timescale, while other normalizations (e.g., a large eddy timescale) would produce different values of the Stokes number. We also introduce a dimensionless particle diameter d_k that normalizes the particle diameter by the Kolmogorov length scale, $\ell_k = (\upsilon^3/\varepsilon)^{1/4}$. This is consistent with the definition of St_k and characterizes the particle size relative to the smallest turbulent eddies.

This chapter covers particle–turbulence interactions for dilute suspensions of particles. Here, the term *particles* can also refer to liquid droplets that are small enough to remain spherical as they interact with the turbulence. Larger droplets that distort and/or break up will have even more complex interactions with the turbulence than are covered here. By dilute we mean that the volume fraction is small enough that the average spacing between particles is many particle diameters. Interparticle collisions may occur, but the particle motion is dominated by interactions with the continuous phase and body forces. Fluidized beds and other dense multiphase flows where the flow dynamics are dominated by collisions will not be discussed, even though some of these flows may be highly turbulent. A particle volume fraction of 0.01 is a rough upper bound for the present regime of interest. Note that the mass loading ratio can be large even at low volume fractions when the continuous phase is a gas. For example, the mass loading ratio for quartz sand particles in air at STP and a volume fraction of 10^{-3} is greater than 2.

We further limit the scope by considering only particle sizes with significant direct particle–turbulence interactions. Very fine particles with Stokes numbers less than around 0.01 are essentially flow tracers, following closely the motion of neighboring fluid elements. Aerosol particles in gas flows and neutrally buoyant dust particles in liquid flows are examples. The turbulent dispersion of such particles can be treated in the same way as turbulent diffusion of heat, contaminant species, or other scalar properties. The particles only affect the turbulence by changing the density or effective viscosity. On the opposite end of the scale, particles with very large St_k and/or d_k are not of interest. If St_k is greater than around 100, the particles move ballistically through the flow and do not respond significantly to the turbulence. Similarly, particles with d_k greater than 10–100 must be treated as moving solid bodies affecting the global flow field. It turns out that many cases of interest both practically and scientifically fall into the range of both St_k and d_k in the range of 0.1–10.

Within our range of interest, there are several different classes of particle–turbulence interactions that may become important. The first class has to do with changes to mass, momentum, and energy coupling between the continuous phase and the particles. These effects are most important when d_k is greater than 1 so that the smallest turbulent eddies are smaller than the particle diameter. For example, heat exchange between particles and fluid usually is calculated using simple correlations for the Nusselt number (hd/k) of a sphere in steady, uniform flow. If the free stream flow around the particle is turbulent with eddy length scales smaller than the particle diameter, the Nusselt number would be considerably higher than indicated by the correlation. For momentum exchange, we must recognize that the particle drag coefficient may be affected by turbulence. Furthermore, local velocity gradients around a particle can create lift so that the composite of aerodynamic lift and drag is not aligned with the instantaneous fluid/particle velocity difference.

The second and broadest class of particle–turbulence interactions involves particle motions induced by the turbulence. Particle dispersion is similar to turbulent scalar transport, in that particle velocities induced by the continuous-phase turbulence act to spread particles away from regions of high mean particle concentration. A related effect is turbophoresis, in which particles move away from regions of high turbulence and accumulate in the regions of low turbulence. This frequently occurs near solid surfaces where fluid turbulence is damped by the wall. Finally, turbulent eddies can induce preferential concentration in which particles are concentrated in clusters with local concentrations much larger than can be accounted for by random particle motions. Similarly, voids in the instantaneous particle concentration field are produced when particles are centrifuged away from vortex cores or local centers of streamline curvature.

The third class of particle–turbulence interactions is turbulence modulation by particles, which is also called the back effect of particles on turbulence. Both increases and decreases in turbulent kinetic energy (TKE) have been observed, and in some cases, the changes are large. Clearly, this effect is strongly coupled to particle dispersion and preferential concentration. For example, if turbulence is strongly attenuated by heavy loading of particles, turbulent dispersion may be substantially reduced.

Finally, the effects of turbulence have to be considered when studying particle collisions. Even in dilute (low volume fraction) flows, particle collisions can be very important. The best example is clouds,

where droplet growth by agglomeration is a critical process leading to precipitation. Turbulence can induce large variations in the velocity of particles within a small region of the flow. This increases the probability of the collisions and also affects the energy of a typical collision. Similarly, preferential concentration can dramatically increase the probability of collisions by concentrating the majority of the particles in a small fraction of the total flow volume.

The following sections cover each of the three types of particle–turbulence interaction discussed earlier. Some areas are better understood than others, and these areas include a more quantitative discussion. Particle–particle collisions including the effects of turbulence are discussed elsewhere in the handbook and are not discussed further in this chapter.

12.2 Particle Motion and Distribution in Turbulent Flow

12.2.1 Overview

To examine the effects of turbulent flow on particles, it is helpful to start from a particle equation of motion. The well-cited equation derived by Maxey and Riley (1983) is

$$\frac{\pi}{6}d_p^3\rho_p\frac{dV_i}{dt}=\frac{\pi}{6}d_p^3\left(\rho_p-\rho_f\right)g_i-3\pi\mu d_p\left(V_i-u_i-\frac{1}{24}d_p^2\nabla^2u_i\right)+\frac{\pi}{6}d_p^3\rho_f\frac{Du_i}{Dt}-\frac{\pi}{12}d_p^3\rho_f\frac{d}{dt}\left[V_i-u_i-\frac{1}{40}d_p^2\nabla^2u_i\right]$$
$$-\frac{3}{2}\pi d_p^2\mu\int_0^t d\tau\left(\frac{d/d\tau\left(V_i-u_i-\frac{1}{24}d_p^2\nabla^2u_i\right)}{[\pi\nu(t-\tau)]^{0.5}}\right),$$

where V indicates the particle velocity, u is the fluid velocity, ρ is the density, g_i is the gravitational acceleration component, and ν is the kinematic viscosity. The subscripts p and f correspond with the particle and fluid phases, respectively. The derivative d/dt represents a time derivative following the particle, while D/Dt denotes the time derivative following a fluid element.

The terms on the right-hand side result from gravitational potential, viscous, pressure gradient, added mass, and Basset history forces on the particle, respectively. It is important to note that, in deriving this equation, Maxey and Riley (1983) assumed an infinite, incompressible fluid (no particle–particle interactions) and that the particle obeyed Stokes drag for a sphere moving through fluid with no disturbances on the order of or smaller than the particle length scale.

If the particle density is much larger than the fluid density as when the continuum phase is a gas, the pressure gradient, added mass, and Basset terms can be neglected leaving a much simpler equation. We can also neglect the third part of the viscous term as typically small compared with the other two parts to get

$$\frac{dV_i}{dt}=g_i+\frac{18\mu}{\rho_p d_p^2}\left(u_i-V_i\right).$$

This equation is linear in V and depends only on viscous and potential (usually gravitational) effects. Also, the equation is still applicable with modified drag coefficients if the particle Reynolds number is not much greater than 1.

In many practical applications, viscous drag is the dominant force acting to accelerate or decelerate particles. The particle inertia is usually assessed based on a time constant τ_p related to the viscous drag. Assuming Stokes flow, this time constant is calculated as the time required for a spherical particle to accelerate from rest to 63% of a constant surrounding velocity. Thus,

$$\tau_p=\frac{d_p^2\left(\rho_f+2\rho_p\right)}{36\mu},$$

where ρ_f is typically negligible in gas flows. The linear equation for particle acceleration and the aerodynamic time constant based on Stokes drag are strictly valid only for particle Reynolds numbers much less than 1, where particle Reynolds number is defined as

$$Re_p = \frac{\rho_f |\boldsymbol{V} - \boldsymbol{u}| d_p}{\mu}.$$

In practice, the simplified equation for particle motion given earlier often is applied for particle Reynolds numbers less than about 10 by applying an empirically derived correction to the drag on the sphere:

$$C_D = \frac{24}{Re_p}\left(1 + 0.15 Re_p^{0.687}\right), \quad \text{with the corresponding corrected } \tau_p = \frac{\rho_p d_p^2}{18\mu}\left(\frac{1}{1 + 0.15 Re_p^{0.687}}\right),$$

where a gas continuum phase is assumed. Various authors define the Stokes number using either the Stokes-derived τ_p mentioned earlier or using a corrected τ_p where the Reynolds number is determined using the average particle slip velocity. There is a misconception in the literature that the use of a Stokes number implies that Stokes drag must be used in evaluating the time constant. However, it is defined that the Stokes number is typically the dominant parameter affecting particle distribution within the fluid. When particle inertia relative to the fluid becomes significant, the particle Reynolds number Re_p also becomes important. First, the drag force is affected by the Reynolds number, and second, when the Reynolds number is sufficiently large, it indicates the presence of individual wakes behind particles that may augment small-scale turbulence (see Section 12.4).

Additional dimensionless parameters of importance can include a Froude number or drift parameter relating gravitational to inertial forces and length scale ratios between the particle diameter and various turbulences or eddy scales. In the following paragraphs, the inertial effects on particle dispersion and preferential concentration are first discussed. Then, the effects of additional forces are discussed in terms of the same phenomena.

Consider a particle with density larger than the surrounding fluid. It will be accelerated or decelerated based on drag interactions. In a turbulent flow, then two effects can result. First, if the local fluid streamlines are curved, fluid elements have an acceleration normal to the flow direction, and particles would tend to take straighter paths than equivalent fluid elements. Second, if the fluid is accelerating linearly, particles will lag the fluid and vice versa. These two components of acceleration have different consequences within the flow, depending on the initial particle distribution and the boundary conditions.

12.2.2 Particle Dispersion

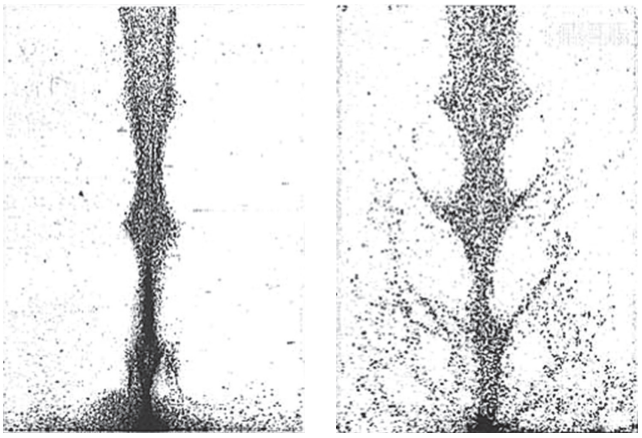
Rigorous studies of mean particle dispersion in the turbulent flow originated with the work of Taylor (1921) and Batchelor (1949), who showed that the dispersion of a single particle in homogeneous, isotropic turbulence is related to the particle's Lagrangian velocity autocorrelation $R_{ij}(t)$ as well as its root-mean-square velocity fluctuations. The Lagrangian velocity autocorrelation, which is measured following a particle trajectory, is defined:

$$R_{ij}(\tau) = \frac{\overline{V_i(t_0) V_j(t_0 + \tau)}}{\overline{v_i' v_j'}},$$

where $\overline{v_i' v_j'}$ represents the particle velocity covariance and the overbar represents an ensemble average based on many particle trajectories. The particle dispersion tensor is then expressed as

$$\overline{X_i X_j(t)} = \overline{v_i' v_j'} \int_0^t \int_0^\tau \left(R_{ij}(\xi) + R_{ji}(\xi)\right) d\xi dt.$$

Since the particle velocity covariance and velocity autocorrelation are typically not known *a priori*, it is unclear from this equation how the mean dispersion varies for different particle time constants and flow geometries.



(a) (b)

Figure 12.1

Laser sheet illumination of particle-laden flow in forced impinging air jet. Flow moves top to bottom. Stokes number based on vortex passage frequency is 1.25 (a) and 0.3 (b). (Images reprinted from Anderson, S.L. and Longmire, E.K., *J. Fluid Mech.*, 299, 333, 1995. With permission.)

Early direct numerical simulations by Squires and Eaton (1991a) and Elghobashi and Truesdell (1992) demonstrated that, in the absence of gravity, "heavy" particles with significant inertia dispersed or "diffused" more rapidly than fluid elements. Also, using model spectra and a representation of dispersion in homogeneous, isotropic, stationary turbulence developed by Reeks (1977), Wang and Stock (1993) and Stock (1996) showed that particles disperse more rapidly than fluid elements for any case with $St_k > 0$.

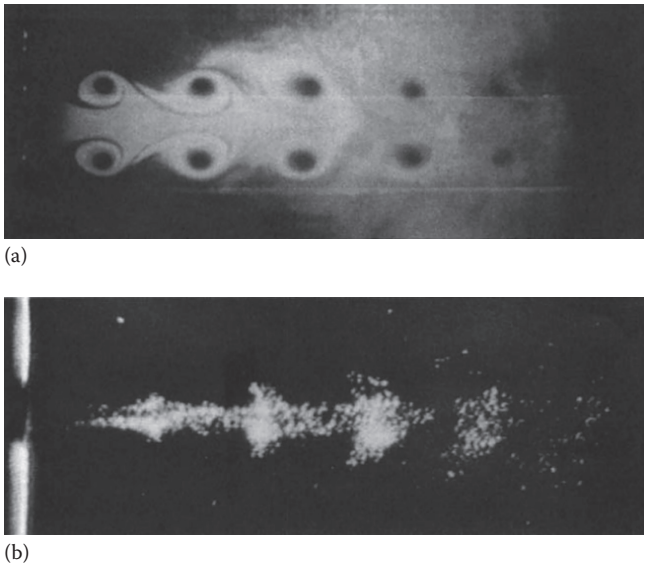
Reeks (1983) derived a term for turbophoretic velocity of particles based on gradients in the fluid velocity covariance (or averaged rms velocity fluctuations):

$$V_{i,turbo} = -\tau_p \frac{\partial(\overline{u_i' u_j'})}{\partial x_j},$$

which corresponded with an earlier one-dimensional derivation by Caporaloni et al. (1975). Here, it can be seen that particles tend to move toward zones of decreasing turbulence intensity. The associated turbophoretic force, which is often discussed in terms of particles approaching walls in boundary layer or pipe flows, clearly increases with both τ_p and the gradient magnitude. References describing the turbophoretic effect include Young and Leeming (1997) and Guha (2008).

In various free shear flows with nonhomogeneous loading of inertial particles, a wealth of experiments and simulations (e.g., Chung and Trout, 1988, Lazaro and Lasheras, 1989, Hishida et al., 1992, Longmire and Eaton, 1992, Tang et al., 1992) demonstrated the importance of coherent eddies to particle dispersion. For example, in free shear layers (Lazaro and Lasheras, 1989) and jets (Longmire and Eaton, 1992) with particles loaded initially in the high-speed stream, particles dragged across the stream by Kelvin–Helmholtz vortices (either 2D or rings) would retain cross-stream inertia longer than fluid elements and thus could be "flung" further into the lower speed stream than the fluid elements. This flinging effect was maximized for Stokes numbers based on large vortex timescales of order 0.3–10. Examples of this phenomenon are shown in Figure 12.1 where the lower Stokes value shown exhibits stronger particle dispersion in the radial direction. At smaller Stokes numbers, particles approximated fluid tracers. By contrast, particles with very large inertia, or larger St, would not couple with the vortices sufficiently and therefore not attain sufficient cross-stream velocity to be "flung," and their cross-stream dispersion would decrease toward zero with increasing St as would occur in the ballistic limit.

12.2.3 Preferential Concentration



Because of their distinct response to fluid accelerations, particles develop inhomogeneous distributions within turbulent flows such that they become preferentially concentrated in some zones and leave voids in other zones. The preferential concentration of particles or droplets is thought to be of great importance

in both environmental and industrial processes where collisions are important, for example, formation of raindrops in clouds (Shaw, 2003), formation of planets (Cuzzi et al., 2001), and production of powdered materials through aerosol and spray processes (Reade and Collins, 2000). Preferential concentration is also important in reacting flows, for example, combustion of liquid drops or particles, or combustion of fuels containing embedded particles. In reacting flows, local reaction rates can depend strongly (and nonlinearly) on particle concentration. Readers are referred to the reviews of Eaton and Fessler (1994), Balachandar and Eaton (2010), and Monchaux et al. (2012) for detailed descriptions of previous experiments and simulations demonstrating and quantifying the effect of preferential concentration in a range of turbulent flows. Neglecting gravity and assuming $\rho_p \gg \rho_f$, Balachandar and Eaton (2010) derived an equation for divergence of particle velocity with the form

$$\nabla \cdot \boldsymbol{V} = -St\left(1-\beta\right)\left(\left\|\boldsymbol{S}\right\|^2 - \left\|\boldsymbol{\Omega}\right\|^2\right) \quad \text{with } \beta = \frac{3\rho_f}{\rho_f + 2\rho_p},$$

where $\|\boldsymbol{S}\|$ and $\|\boldsymbol{\Omega}\|$ are the local strain-rate and rotation-rate tensors, respectively. This equation shows that when $\rho_p > \rho_f$ $\beta < 1$ so that the divergence is negative, hence particles tend to accumulate in the regions of high strain rate. Conversely, the divergence is positive in the regions of high vorticity, and particles tend to vacate these regions. This is a direct consequence of the particle response to the longitudinal and normal accelerations in the fluid mentioned earlier. Examples of long-lasting negative divergence occur in the zones of linear deceleration such as straining zones between vortices in a shear layer (Martin and Meiburg, 1994), between vortex rings in a round jet (Longmire and Eaton, 1992, 1994), or the stagnation zone of an impinging jet (Anderson and Longmire, 1995). In all of these cases, particles accumulate or cluster in these zones when St based on a vortex timescale is of order 0.5–10. Similarly, the locations of vortex cores in these and other flows, which correspond with zones where the divergence of particle velocity is positive, tend to be void of, or have relatively low concentrations of particles. See Figure 12.2 for an example.

Preferential concentration can also occur in turbulent wall–bounded flows such as boundary layers, channels, and pipes. In the near-wall region, where long streamwise streaky structures are prominent and relatively long lasting, particles tend to concentrate in the slow-moving streaks (see, e.g., Brooke et al., 1992, Marchioli and Soldati, 2002, Kaftori et al., 1995a,b, Nino and Garcia, 1996). By directly visualizing particle distributions, Fessler and Eaton (1999) also demonstrated preferential concentration on the centerplane of a fully developed turbulent channel flow.

Much of the previous work examining particle distribution in homogeneous, isotropic turbulence is numerical and assumes dilute particle concentrations such that particles neither interact nor modify the surrounding turbulence. Squires and Eaton (1991b) and Wang and Maxey (1993) showed how zones of high particle concentration coincided with zones of high strain and low vorticity for a range of Stokes numbers. Bec et al. (2006) plotted a relative concentration of particles within rotating regions over a range of St_k, suggesting that the concentrations were the lowest for $St_k \sim 0.7$ and remained somewhat suppressed beyond $St_k = 3$. They further suggested that differences in concentration distribution for $St_k \sim 3$ were caused less by centrifugation out of small vortices and more by the lack of particle response to the smallest scales of fluid velocity fluctuation. In experiments by Wood et al. (2005) and Saw et al. (2008) and in simulations by Monchaux et al. (2010), preferential concentration was maximized for $St_k \sim 1$. An image of the particle distribution for $St_k \sim 1$ in Wood et al.'s experiment is shown in Figure 12.3. As discussed in the review by Monchaux et al. (2012), many questions remain about the lifetime and persistence of particle clusters forming in turbulence, and research is ongoing in this area.

A number of methods have been employed to quantify and characterize the degree of preferential concentration within a fluid volume (see Monchaux et al., 2012 for a comprehensive review). As explained by Fessler et al. (1994), a random distribution of k particles within a volume satisfies a Poisson distribution:

$$p(k) = \frac{e^{-\lambda}\lambda^{k}}{k!},$$

where λ is the average number of particles in the volume. Methods of characterizing preferential concentration therefore usually attempt to measure a deviation from this distribution. Notable methods include box counting (e.g., Fessler et al., 1994, Aliseda et al., 2002), the radial distribution function (RDF) (see, e.g., Sundaram and Collins, 1997, Balkovsky et al., 2001, Zaichik and Alepchenkov, 2009), the correlation dimension (Tang et al., 1992, Fessler et al., 1994, Bec et al., 2007), and Voronoi diagrams (Monchaux et al., 2010). Box counting methods determine a distribution of particle numbers within boxes of uniform size where the box size can be varied over the range of turbulence length scales. Box sizes that are too small or large to correlate with particle number distribution yield Poisson-like distributions, while sizes corresponding to length scales of either particle clusters or voids will yield deviations from the Poisson distribution. The RDF or pair correlation function examines the probability of finding a particle in each of two volumes

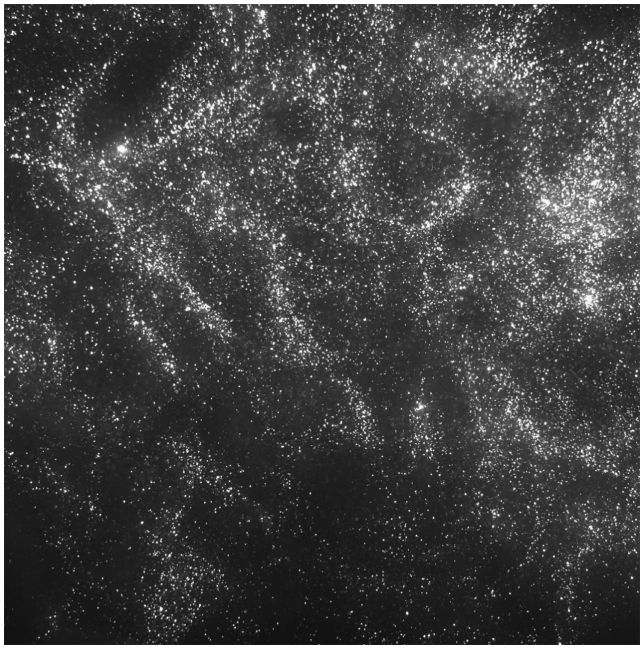

Figure 12.3

separated by a distance r. Similar to box counting methods, this function provides a method to quantify preferential concentration in terms of a range of specific length scales. The RDF has been used directly in collision models (e.g., Sundaram and Collins, 1997).

The correlation dimension involves counting the number of particles N within a radial distance r of a base particle and comparing the slope of N versus r on a log–log plot (see Fessler et al., 1994 for a detailed explanation). The slope is the correlation dimension. If particles are concentrated preferentially, the slope will be reduced from the value associated with a random distribution. The correlation dimension thus yields a single value to quantify the degree of preferential concentration. As explained by Monchaux et al. (2012), the Voronoi diagram method bins the volumes of void space surrounding each particle into a distribution. This method is similar to the correlation dimension, in that no specific length scale such as box size or separation distance is introduced into the distribution.

12.2.4 Gravitational Effects

Stock (1996) gives an excellent review and explanation of gravitational effects on dispersion in homogeneous, isotropic turbulence. To characterize the importance of gravitational effects, he defined a drift parameter:

$$\gamma = \frac{\tau_p g}{u_{rms}},$$

where $\tau_p g$ is the particle settling or drift velocity for $Re_p \ll 1$, and u_{rms} is the rms velocity in the fluid.

In general, the particle diffusivity or rate of dispersion decreases in all directions as the drift parameter increases. This gravitational effect, originally noted by Yudine (1959), is often called the "crossing trajectory effect." Physically, as particle drift velocity increases, particles tend to cross through, rather than remain within, correlated zones of fluid velocity. The particle velocity autocorrelation decreases, and particles are less likely to be dispersed within these zones.

When gravity is present in homogeneous, isotropic turbulence, multiple investigators, starting with Wang and Maxey (1993), found that the presence of turbulence increases the average particle settling velocity. Again, this effect is most prominent for $St_k \sim 1$. The enhanced settling was explained in the following way: particles settling downward are swept preferentially into the downward moving sides of vortical structures (as opposed to the upward moving sides), hence the increase in average settling velocity. This enhancement must also depend on the relative strength of the vortices versus gravity, which can be characterized by the ratio of particle settling velocity to a characteristic fluid velocity. For example, Yang and Lei (1998), who related the settling velocity to the rms fluid velocity as in the γ mentioned earlier, found the strongest enhancement in settling velocity for $St_k \sim 1$ and $\gamma \sim 0.5$. Even though they were dealing with relatively dilute flows (volume fractions $\leq 7 \times 10^{-5}$), Aliseda et al. (2002) found even greater settling enhancement in their experiments than what was predicted in one-way coupled simulations. They argued that turbulence modification and wake interactions within particle clusters would add to the settling enhancement described by Wang and Maxey. Subsequent simulations of Bosse et al. (2006), which employed two-way coupling, were able to duplicate the trend observed by Aliseda et al. (2002).

12.2.5 Basset, Added Mass, and Pressure Gradient Effects

In simulations of homogeneous, isotropic turbulence, Elghobashi and Truesdell (1992) showed that the Basset force was significant for solid particles in gas, although typically an order of magnitude smaller than the drag force. For their density ratio, the added mass and pressure gradient terms were insignificant. By comparing results with and without the Basset term, they found that the Basset force tended to decrease the Lagrangian integral scales and very slightly decrease particle dispersion. Armenio and Fiorotto (2001) simulated the motion of point particles in a turbulent channel flow for a range of density ratios and Stokes numbers. In addition to viscous drag, the particles were subjected to added mass, pressure gradient, and Basset forces, but not gravity. The simulation results showed that all four of the included forces could be significant in liquid/solid flows. However, the three additional force terms did not appear to have any significant effect on particle dispersion compared against a simulation including only viscous drag. More recently, Olivieri et al. (2014) simulated particles in homogeneous, isotropic turbulence subject to both viscous and Basset forces. They found that the Basset force tended to reduce the clustering or preferential concentration of particles. This suppression effect was strongest for $\rho_p/\rho_f \sim 10$ and $St_k = 1$ but was also

significant for $\rho_p/\rho_f = 1000$. For $\rho_p/\rho_f = 1000$, Basset forces tended to be significant for "extreme events" where particle accelerations were especially large.

12.3 Effect of Turbulence on Coupling Forces and Heat Transfer

The critical multiphase interactions in particle-laden flows are the forces applied on the particles by the flow and the heat transfer at the particle surfaces. Typically, these are represented with simple models often selected for ease of implementation. For example, momentum exchange is represented using Stokes drag for a particle in a uniform steady flow, sometimes with a semiempirical correction for finite Reynolds number as discussed in the previous section. Similarly, heat transfer from particles is represented using empirical correlations for the Nusselt number as a function of the particle Reynolds number (c.f. discussion in Jones et al. 2010). These models assume that the flow is quasi-steady and that the unperturbed flow is uniform. The models generally work well when $d_k \ll 1$, but many interesting particle-laden flows have $d_k = \theta(1)$ or greater. For the latter case, small-scale turbulent eddies can significantly affect both the momentum and energy coupling.

The Maxey/Riley equation described in the previous section is believed to correctly represent the effects of unsteadiness, velocity gradients, and pressure gradient on the force applied to a spherical particle in terms of the undisturbed velocity field. However, a particle with $d_k \geq 1$ disturbs at least the smallest eddies in the flow. Furthermore, flow separation from the particle surface occurs when the particle Reynolds number exceeds about 20 and has a strong effect on the applied forces. The separation behavior is probably very sensitive to turbulent eddies with scales near the particle diameter. The experimental study of turbulence effects on particle forces has been inconclusive (see summary in Balachandar and Eaton, 2009) because it is difficult to discriminate such effects from the effects of trajectory bias (Wang and Maxey, 1993) on particle settling velocity. Definitive evidence of the direct effects of turbulence on momentum coupling for small particles has only recently become available with the advent of particle-resolved direct numerical simulations of particle-laden flows (see review in Tenneti and Subramaniam, 2014).

Bagchi and Balachandar (2003) and Burton and Eaton (2005) performed fully resolved simulations of stationary particles in isotropic turbulence with d_k near 1 and particle Reynolds number in the range of 10–100. Bagchi and Balachandar examined streaming turbulence, while Burton and Eaton examined the case with no mean relative velocity, but their conclusions were similar. The mean particle drag was well represented by standard semiempirical drag correlations, but the predicted instantaneous force yielded large errors and the rms force was underpredicted. The model accuracy was not improved by including the added mass and history integral terms from the Maxey–Riley equation. Similar conclusions were reached by Zeng et al. (2008) for the case of a particle suspended at various locations in a fully developed turbulent channel flow.

The case of $d_k > 1$ clearly violates the assumption in the derivation of the Maxey–Riley equation that the particle diameter is much less than any of the flow scales. Detailed examination of the fully resolved simulations shows that eddies are distorted as they interact with particles, and particle wakes are strongly asymmetric. Most models assume that the force on the particle is parallel to the fluid velocity interpolated to the particle center position in the particle frame of reference. However, the asymmetric wakes caused by the turbulence produce perpendicular forces, that is, there is fluctuating lift, even in the absence of large-scale velocity gradients. As the particle Reynolds number increases, another mechanism becomes important. Kim and Balachandar (2012) showed that vortex shedding and consequently lift oscillations begin at a lower Reynolds number in turbulent flows than in uniform flows. For practical simulations that do not resolve the flow around the particles, the addition of a stochastic force to the conventional semiempirical drag law is recommended to represent these effects. Unfortunately, a universal expression for the dependence of this force on particle and turbulence properties is not available.

There has been even less research on the effects of turbulence on interphase heat transfer. Brian et al. (1969) conducted a series of tests on the melting of spherical ice particles in a stirred bath. The turbulence properties were inferred from the known mechanical power input to the bath. They found that the Nusselt number (hd/k_{fluid}), where h is the convective heat transfer coefficient and k_{fluid} is the fluid thermal conductivity, increases slowly with increasing turbulent dissipation rate. This was tested over a range of scales with d_k generally near 1. Bagchi and Kottam (2008) examined the effect of isotropic turbulence on stationary particle heat transfer for $60 < Re_p < 400$ and d_k ranging from 1 to 8. They included cases in which the flow was

isothermal and others with superimposed temperature fluctuations. The turbulence did not affect the mean heat transfer rate that was well represented by the correlation of Feng and Michaelides (2000):

$$\overline{Nu} = 0.922 + \left[RePr\right]^{1/3} + 0.1Re^{2/3}Pr^{1/3},$$

where

Pr is the Prandtl number

Re is the particle Reynolds number based on the mean fluid velocity relative to the particle

When the turbulent inflow was isothermal, instantaneous heat transfer rate fluctuations of up to 20% of the mean were observed. The fluctuations increased with turbulence intensity but were independent of the turbulent length scale. Much larger fluctuations in *Nu* were observed when the inflow field had turbulent temperature fluctuations. These fluctuations arose due to large fluctuation in the heat transfer near the stagnation point.

Overall, much work remains in refining momentum and energy coupling models to correctly represent flows with $d_k \geq 1$. Widely used correlations for particle drag coefficient and Nusselt number in uniform streams are appropriate only when $d_k \ll 1$. Stochastic models can be used to represent the additional fluctuations in force and heat transfer that arise when the particle diameter is comparable to turbulent length scales. However, there are no models that represent the instantaneous force and heat transfer as a function of the local velocity field structure. Future particle-resolved simulations may provide the insight needed to develop such models.

12.4 Turbulence Modulation

12.4.1 Overview

The main focus in this chapter thus far has been on the effects of continuous-phase turbulence on the particle motion, which is the only significant interaction between the particles and the turbulence when the volume fraction of particles is less than about 10^{-6} and dimensionless particle diameters are small. The motions of particles may be computed assuming that they do not have any global effect on the turbulence, and the turbulence may be represented by any model that is valid for the equivalent single-phase flow. This is the case of one-way coupling, meaning that the turbulence affects the particle motion but the particles do not affect the turbulence.

Flows at higher mass or volume loading are in the two-way coupling regime, where the turbulence is modified by the presence of the particles. The carrier-phase turbulence can be characterized by its statistical properties including the TKE, Reynolds stresses, energy spectra, and two-point correlations. The term *turbulence modulation* means that one or more of those statistical properties is modified by the particles. It is common to find modifications in the high-frequency portion of the energy spectrum. This is observed whenever the Stokes number is large enough ($St > 0.1$) that the particles cannot follow the turbulent fluctuations, or when there is a significant mean velocity difference between the phases. However, turbulence modulation is most important when there is significant modification of the TKE. The kinetic energy may be increased (turbulence augmentation) or decreased (turbulence attenuation) relative to the single-phase flow.

We study turbulence modulation because it can be large enough to change the nature of the particle–turbulence interaction, including dispersion of particles, entrainment from particle beds, particle settling velocity, droplet agglomeration rates, and many other aspects of particle-laden flows. Also, the turbulence has a strong influence on scalar transport, frictional losses, and other aspects of the continuous-phase flow. Substantial turbulence modulation typically is observed in systems where the turbulence production due to continuous-phase mean velocity gradients is weak. Examples are decaying grid turbulence, the centerline region of pipe and channel flows, and the outer regions of turbulent boundary layers. For example, Figure 12.4 shows TKE data from the centerplane of a fully developed turbulent channel flow laden with either 150 μm glass or 70 μm copper particles. At the heaviest mass loading ratio of 0.4, the copper particles reduce the turbulence kinetic energy by a factor of more than 7. Note that this loading corresponds to a volume fraction of only 5.5×10^{-5} and a mean particle separation distance of greater than 20 particle diameters. This is a very dilute flow, but the particles nevertheless have a dominant effect on the turbulence behavior. Such large reductions in the turbulence levels can have major effects on particle dispersion, chemical reaction rates within the fluid or at particle surfaces, and transport in the continuous phase.

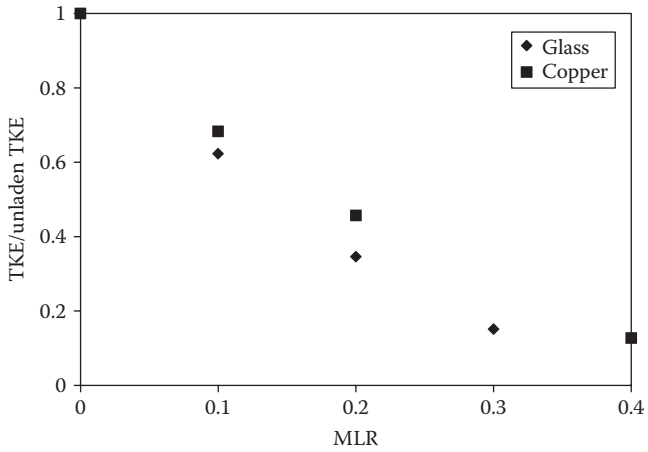

Figure 12.4

Attenuation of TKE as a function of mass loading ratio on the centerplane of fully developed channel flow for 150 μm diameter glass spheres and 70 μm diameter copper spheres. (From Paris, A.D. and Eaton, J.K., Turbulence attenuation in a particle-laden channel flow, Report TSD-137, Department of Mechanical Engineering, Stanford University, Stanford, CA, 2001.)

Turbulence augmentation by particles can be significant when the particle Reynolds numbers are relatively large. Spherical particle wakes become unstable for Reynolds number above about 200 and at even lower Reynolds numbers in turbulent flows (Bagchi and Balachandar, 2003). Regular vortex shedding is observed for Reynolds numbers above about 300 (Sakamoto and Haniu, 1990). The superposition of many unsteady wakes can produce substantial turbulence in the flow. This is most often observed in liquid flows, because particles large enough to have high Reynolds number usually settle out rapidly in gas flows. However, even particles with lower Reynolds number (e.g., $\approx$ 10–100) can generate turbulence by the superposition of randomly positioned and oriented steady wakes. This can be observed in flows where the analogous single-phase flow has very low turbulence intensity, such as particles settling in nominally quiescent fluid.

The degree of turbulence modulation can vary from very small to quite large. Gore and Crowe (1991) reviewed experimental data for the restricted case of particle-laden pipe and jet flows. The percentage change in the streamwise turbulence intensity varied from −90% to +350% over the range of particle and flow parameters examined. While many cases showed substantial modulation, a large fraction of the experiments showed only small changes. The only consistent trend that emerged from the data review was that small particles attenuate turbulence while large particles augment turbulence. They found that the critical particle diameter separating attenuation from augmentation was approximately one-tenth of the scale of the most energetic eddies.

The qualitative rule of thumb developed by Gore and Crowe generally holds, but it does not allow prediction of the degree by which the turbulence will be changed. No general theory or data correlation has emerged that allows reliable prediction of the level or character of turbulence modulation for an arbitrary dispersed multiphase flow. There are several reasons for the lack of progress in this area. First is the difficulty in measuring the carrier-phase turbulence in the presence of a substantial number of particles. Second is the fact that several independent mechanisms may produce turbulence modulation as discussed in the next section. In some flows, two or more of these mechanisms may be active and counteract each other. If the counteracting mechanisms are not recognized, the results may be confusing. Finally, there is the huge parameter space involved. An incompressible, single-phase flow typically is defined by only the geometry and the Reynolds number. The addition of a second phase adds many more parameters, even if the second phase consists of monodisperse round spheres. In that case, additional dimensionless parameters that arise are the particle Stokes number, the dimensionless particle diameter, the particle Reynolds number, and the local particle loading. Of course, even more parameters are important if the particles are polydisperse or nonspherical.

12.4.2 Mechanisms of Turbulence Attenuation and Augmentation

There is no clear consensus on the most important causes of turbulence modulation because different physical mechanisms dominate in different regions of the parameter space. Nevertheless, there are some basic

mechanisms of particle–turbulence interaction that we know play a role in turbulence modulation. All of the known mechanisms require that the particles be large enough that they cannot follow the flow so that there is a substantial instantaneous relative velocity between a particle and the carrier fluid.

One route to turbulence modulation by particles is through the carrier-phase mean velocity. If the mean carrier-phase velocity field is changed by the addition of particles, then the mean strain field and the turbulence production rate also will be changed. For example, if a concentrated stream of high-velocity particles is introduced into a gas flow, a local jet will be formed in the carrier flow due to the drag of the particles applied to the gas. The turbulence production in the jet shear layers is likely to increase the TKE. Presumably, the effects of such large mean flow distortions can be predicted by single-phase turbulence models, so no new understanding of particle–turbulence interaction is needed. On the other hand, this mechanism may be very important in wall-bounded flows where some of the strongest turbulence attenuation has been observed. Turbophoresis tends to concentrate particles near the wall in channel and pipe flows, and particle–fluid mean velocity differences can be large in that region. Therefore, it seems likely that mean velocity changes can occur in the innermost parts of the boundary layer. The region of strongest turbulence production occurs just outside the viscous sublayer due to the steep velocity gradients, so local changes to the mean velocity profile could cause substantial changes in the turbulence. Unfortunately, this is the part of the flow that is most difficult to study either experimentally or by fully resolved simulations, so there is no direct evidence of turbulence modulation due to mean velocity field distortion.

A mechanism for turbulence augmentation when particles are relatively large is unsteady particle wakes. In a uniform carrier stream, the wake of a sphere is asymmetric for Reynolds number above 210 and unsteady for Reynolds numbers greater than 270 (Bagchi and Balachandar, 2002). When there is a mean velocity difference between the particles and the carrier fluid due to gravity or acceleration of the carrier phase, energy is transferred from the particles to small-scale, carrier-phase velocity fluctuations. In most dispersed gas–solid flows, the particle volume fraction is very small and the particle wakes occupy only a small fraction of the flow volume, so the unsteady wake effect creates only minor changes in the turbulence. However, the unsteady wakes are a significant source of turbulence augmentation in some liquid–solid flows where the particle volume fraction is not small and the particle Reynolds number is in the vortex shedding regime. Recent research has shown that these effects can be very complicated. Bellani et al. (2012) studying large particles suspended in the homogeneous turbulence found that spherical particles caused large attenuation of the turbulence while ellipsoidal particles caused far less attenuation. Shao et al. (2012) simulated large particle effects in channel flows and found that the turbulence modification was the largest when particles settled to one wall.

A related mechanism is the superposition of many randomly positioned laminar or "laminar-like" wakes as investigated by Parthasarathy and Faeth (1990) and Chen and Faeth (2001). They investigated turbulence modulation in the absence of shear production, so all the observed turbulence was produced by particle wakes. Chen and Faeth (2001) developed a dimensional correlation that relates the turbulence level to the mean dissipation of energy due to the relative motion of the particles and fluid. For typical multiphase flows, the carrier-phase shear production of turbulence dominates, and laminar wakes are relatively unimportant in setting the level of TKE. However, the superposed effect of the wakes is apparent in several experiments where turbulence spectra were measured. It is common to see a turnup in the spectra at large wave number, which is apparently related to the particle wakes (c.f. Rogers and Eaton, 1991). This effect has also been observed in numerous numerical simulations.

Preferential concentration of particles into specific turbulence structures and preferential sweeping of particles into downflow zones offer two other possible mechanisms of turbulence modulation. A simplified analysis by Eaton and Fessler (1994) showed that particles apply an angular impulse opposing the vortex rotation as they are centrifuged out of a vortex. For Stokes numbers near unity, the ratio of the angular impulse to the initial angular momentum of the vortex is $1.3\phi_m/St_k$, where ϕ_m is the mass loading ratio. This would act to suppress vortices with timescales near the particle time constant. Simulations of homogenous shear flows laden with particles with St_k near unity by Gualtieri et al. (2013) showed that preferential concentration caused the depletion of turbulence in the energy-containing range of the spectrum and augmentation of smaller scales. At high Reynolds numbers, the turbulence has a wide range of time and length scales, so preferential concentration may occur at different length scales depending on the Stokes number. Therefore, the details of turbulence spectrum distortion due to clustering may be Stokes number dependent. Preferential concentration in a gravitational field results in preferential sweeping of particles into downflow zones and a higher than expected average settling velocity (Maxey, 1987). Numerical simulations by Ferrante and Elghobashi (2003) indicate that preferential sweeping at moderate mass loading

creates substantial anisotropy in the turbulence and slows the decay of isotropic turbulence. The preferential concentration causes density variations that lead to buoyancy-induced instability.

The mechanism believed by most to cause turbulence attenuation is the so-called extra dissipation of turbulence by particles. A particle that cannot respond to the turbulent velocity fluctuations exerts a force on the fluid that opposes the relative motion. When the particles are heavy (i.e., have large Stokes numbers) the relative motion is produced mostly by the carrier-phase fluctuations. The cloud of dispersed particles produces a nonuniform force field that instantaneously opposes the carrier-phase velocity fluctuations, thereby extracting energy from the turbulence. Some of the energy taken from the carrier-phase turbulence is transferred to the fluctuating kinetic energy of the particles. However, most goes into producing local flow distortions around each particle. For small particles, the length scales of the flow distortions are small and the corresponding velocity gradients are large, so the local flow distortions are dissipated rapidly by viscosity. Therefore, we see that the particles act as a short circuit of the regular turbulence energy cascade. Energy can be absorbed from the carrier-phase turbulence at any frequency that is too high for the particles to follow. That energy is passed directly to scales comparable to the particle diameter and is dissipated.

An analytical form for the extra dissipation can be derived following Chen and Wood (1985) Berlemont et al. (1990) and Rogers and Eaton (1991). The Navier–Stokes equations for the carrier phase are modified by adding a continuous force field applied onto the fluid by the particles:

$$u_{i,t} + u_j u_{i,j} = -\frac{1}{\rho_f} p_{,i} + \upsilon u_{i,jj} - \frac{1}{\rho_f} F_i \,.$$

Here, indicial notation is used and commas imply derivatives. F_i is the force per unit volume applied by the particles onto the fluid. Assuming a linear drag law and neglecting any other forces, the force field is represented as

$$F_i = \frac{c}{\tau_p}\left(u_i - V_i\right)$$

where

c is the local particle mass concentration
u_i is the continuous-phase velocity
V_i is the particle-phase velocity

A transport equation for the TKE is obtained by applying the Reynolds decomposition, subtracting the mean flow component, squaring the fluctuating component, and averaging. Assuming constant fluid density and particle time constant, the equation is

$$\frac{D}{Dt}\frac{q^2}{2} = P - \varepsilon - \frac{1}{\rho_f \tau_p}\left[\overline{C}\left(\overline{u_i' u_i'} - \overline{u_i' v_i'}\right) + \left(\overline{U}_i + \overline{V}_i\right)\overline{c' u_i'} + \left(\overline{c' u_i' u_i'} - \overline{c' \boldsymbol{u}_i' v_i'}\right)\right].$$

The production term, P, and the dissipation, ε, are identical to their single-phase forms. Also, it is commonly assumed that the second two terms in the square brackets are negligible since they involve correlations of the fluctuating concentration with the fluid and particle velocity fields. The term $\overline{C}/\rho_f \tau_p \left(\overline{u_i' u_i'} - \overline{u_i' v_i'}\right)$ is referred to as the extra dissipation due to particles. There are deficiencies with this analysis, but it gives some idea how turbulence modulation might vary with system parameters. Most obviously, the form of the extra dissipation term suggests that the turbulence attenuation by particles should increase linearly with particle mass loading, a finding that is in rough agreement with experiments. The effect of varying particle time constant is not as obvious, since increases in time constant decrease the leading coefficient but increase the term in parenthesis. The latter is because increasing the Stokes number decreases the particle–fluid velocity correlation $\left(\overline{u_i' v_i'}\right)$. Finally, the equation shows that the extra dissipation term could be negative if the particle velocity fluctuations are large and correlated with the local fluid velocity.

This oversimplified analysis cannot be applied directly because key physical mechanisms have been omitted. In most cases where large turbulence modulation has been observed experimentally, the particles are too large and too widely spaced to be considered as applying a continuous force field onto the turbulence.

An examination of the channel flow case illustrated in Figure 12.4 is instructive. The experiments were performed in air, with a channel half-width of 20 mm, a Taylor microscale of 3000 μm, and a Kolmogorov scale of 170 μm. For the case with the strongest attenuation, the 150 μm particle diameter was comparable to the Kolmogorov length and the 2100 μm average particle spacing was comparable to the Taylor microscale. These values are characteristic of experiments where strong attenuation is observed. In this regime, the particles must be considered as applying local disturbances to the flow rather than a continuous resisting force. Furthermore, the average particle Reynolds numbers in those experiments were 20, which is too high for a linear drag law to be appropriate, but below the range where an unsteady wake or vortex shedding would augment the turbulence.

Experiments have shown that turbulence attenuation can be strong when the dimensionless particle diameter is of order 1 and the particle Reynolds number is below the vortex shedding regime. Generally, models based on the particle analysis earlier strongly underpredict turbulence attenuation in this regime, suggesting that some other mechanism is significantly increasing the turbulence dissipation rate. Simulations that fully resolve all details of the flow around individual particles (Bagchi and Balachandar, 2002, Burton and Eaton, 2005) are casting light on this mechanism. Burton and Eaton simulated a stationary particle with dimensionless diameter of 2 and Re near 20 interacting with homogeneous isotropic turbulence. The dissipation was strongly augmented near the particle surface, and substantial reductions in TKE were observed in a spherical volume roughly five times the particle diameter. Furthermore, snapshots of the turbulence structure showed that eddies with scales up to around 10 times the particle diameter were distorted as they moved around the particle. Highly resolved PIV measurements by Tanaka and Eaton (2010) showed that the dissipation was locally augmented by up to a factor of three near the particles. Unfortunately, widely used large eddy simulation codes augmented by point-force coupling models cannot capture this effect (Segura et al., 2004, Eaton, 2009). While these codes are thought to be accurate for very small particles, modifications such as those under study by Capecelatro and Desjardins (2013) will be needed when the dimensionless particle diameter is comparable to turbulent length scales.

12.4.3 Observations of Turbulence Modulation

Most observations of turbulence modulation have been in simple flows including homogeneous turbulence maintained by external forcing, pipe and channel flows, developing boundary layers, and round jet flows. Generally, the strongest attenuation has been observed in wall-bounded flows where turbulence production is fairly weak except near walls. The brief review in this section concentrates on experiments designed specifically to observe turbulence modulation. In recent years, there has been a proliferation of studies using point-force coupled large eddy or direct numerical simulations to examine homogeneous flows. This technique requires several assumptions that are not strictly valid for typical cases, so the limited sample of results presented here must be used with caution.

12.4.3.1 Homogeneous Gas–Solid Flows

Numerous numerical simulations and a few experiments have examined the case of homogeneous gas phase with dilute loadings of solid particles. Stationary (forced) isotropic turbulence was examined by Squires and Eaton (1990) and Boivin et al. (1998) for particle mass loading ratios ranging from 0.1 to 1.0 and Stokes numbers ranging from 1.3 to 11.4. Both studies indicated substantial turbulence attenuation, with the degree of attenuation increasing with increasing mass loading. The maximum reduction in the TKE was 56%. Squires and Eaton found essentially no effect of varying St_k from about 1.4 to 4.7, while Boivin et al. (1998) found that the attenuation increased monotonically as St_k increased from 1.3 to 11.4 at a mass loading ratio of 0.2. The opposite trend was observed when the mass loading ratio was increased to 1.0. One consistent finding of these studies and many other subsequent works is that the turbulence spectra are distorted, showing attenuation at low frequency and augmentation at higher frequency.

Decaying isotropic turbulence was simulated by Elghobashi and Truesdell (1993), Druzhinin (2001), Druzhinin and Elghobashi (1999), Ferrante and Elghobashi (2003), and Sundaram and Collins (1999). It is difficult to discern any consistent trends from these results. Sundaram and Collins varied the particle diameter and the Stokes number maintaining a constant mass loading ratio of 0.14. They found that the attenuation increased as the Stokes number increased from 1.6 to 6.4. Ferrante and Elghobashi (2003) observed a similar trend for St_k ranging from 0.1 to 5. The overall attenuation levels in the latter case were quite small with a maximum reduction in kinetic energy of 30% at a mass loading ratio of 1.0.

Most of the computations discussed earlier focused on cases without gravity. However, Druzhinin and Elghobashi (1999) and Ferrante and Elghobashi (2003) each ran a case including a body force in the particle equation of motion. In both cases, very substantial turbulence augmentation was observed even though the dimensionless diameters were less than unity.

Some trends can be discerned by combining the results of various homogeneous flow simulations. Figure 12.5 shows the reduction in turbulence kinetic energy as a function of mass loading for selected cases with St_k near 5. Turbulence attenuation was always small (<22%) for mass loadings less than or equal to 20%. Substantial changes to the turbulence were only found for relatively large loadings.

Figure 12.6 shows the turbulence attenuation plotted against St_k for cases in which the mass loading ratio is approximately unity. For the cases of decaying isotropic turbulence, the Stokes number changes with time. A representative value midway through the decay was chosen for the purposes of this plot. There is evidence of a trend of increasing turbulence attenuation with increasing St_k, but the Squires and Eaton (1990) and Boivin et al. (1998) cases for St_k near 1 break with the trend. The differences between these cases

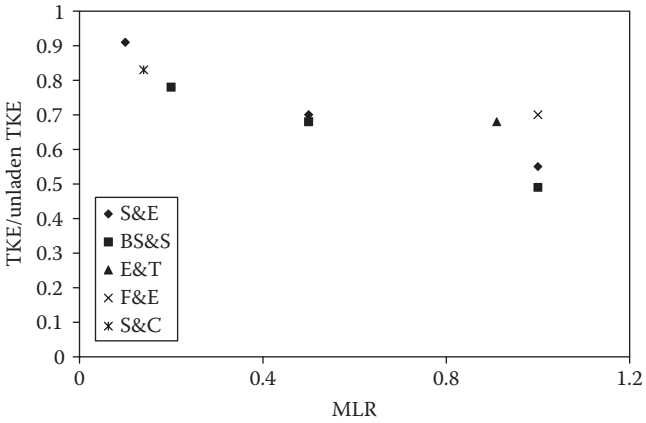

Figure 12.5

Attenuation of TKE in point-force coupled simulations of isotropic turbulence for cases with St_k near 5. (Data from Squires, K.D. and Eaton, J.K., *Phys. Fluids A*, 2, 1191, 1990; Boivin, M. et al., *J. Fluid Mech.*, 375, 235, 1998; Elghobashi, S. and Truesdell, G.C., *J. Fluid Mech.*, 242, 655, 1993; Ferrante, A. and Elghobashi, S., *Phys. Fluids*, 15, 315, 2003; Sundaram, S. and Collins, L.R., *J. Fluid Mech.*, 335, 75, 1999.)

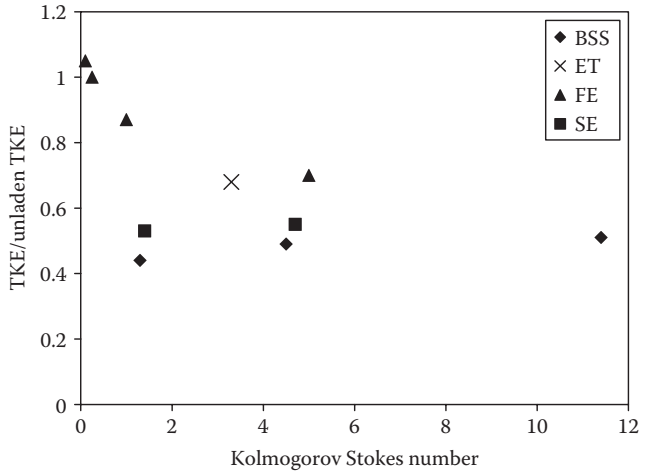

Figure 12.6

Attenuation of TKE as a function of St_k in isotropic turbulence with mass loading ratio near 1. (Data extracted from Boivin, M. et al., *J. Fluid Mech.*, 375, 235, 1998; Elghobashi, S. and Truesdell, G.C., *J. Fluid Mech.*, 242, 655, 1993; Ferrante, A. and Elghobashi, S., *Phys. Fluids*, 15, 315, 2003; Squires, K.D. and Eaton, J.K., *Phys. Fluids A*, 2, 1191, 1990.)

and Ferrante and Elghobashi (2003) are quite large even though the flow and particle parameters are quite similar. This may be due to differences in the implementation of force coupling scheme in the simulation or in the initial conditions for the velocity field. Recent fully resolved simulations by Lucci et al. (2011) on much larger particles found that the Stokes number alone is not adequate to characterize turbulence modification.

Only a few experiments have been reported on modification in particle-laden homogeneous turbulence. Geiss et al. (2001) examined grid turbulence in a downflow wind tunnel. The flow carried a 35% mass loading of 110 μm diameter glass particles. The short paper gives few details on the experiment, but kinetic energy reductions of up to 44% were observed at the most downstream station. Note that this reduction is comparable to the reductions observed in some of the simulations at substantially higher mass loading. Three recent experiments have used specially designed turbulence chambers to examine the effects of particles falling at terminal velocity through homogeneous/isotropic air turbulence. Yang and Shy (2005) used a cruciform apparatus in which turbulence was generated by fans outside the test zone and particles fell through the homogeneous turbulence at their terminal velocity. The volume loading was estimated to be around 5×10^{-6}. Three different particle sizes were used, and all particle diameters were much smaller than the Kolmogorov scale (0.03, 0.06, 0.1). Stokes numbers ranged from 0.36 to 1.9, so preferential concentration was significant in all cases. Terminal velocities ranged from $0.2u_{rms}$ to 0.96 u_{rms}. The particles with the lowest terminal velocity did not significantly change the turbulence, while the large particles produced up to 60% augmentation. There was a clear correlation of increasing augmentation with increasing terminal velocity. Hwang and Eaton (2006) created nearly isotropic turbulence using loudspeaker-driven synthetic jets in the corners of a box. This produced much more energetic turbulence while maintaining small mean velocities. They used glass particles with nondimensional diameters of 1, St_k of 50, terminal velocities at roughly $2u_{rms}$, and estimated mass loadings up to 30%. They observed turbulence attenuation as large as 35%–40%. Tanaka and Eaton (2010) made very high-resolution PIV measurements in the same facility with larger particles (dimensionless d_p = 2.3 and 4.5) at mass loading ratios up to 0.45. Small levels of turbulence modulation were observed, and they concluded that turbulence production in particle wakes was offsetting turbulence attenuation at particle surfaces. Previous measurements had shown reductions in the turbulence dissipation rate in rough proportion to the reduction in TKE. However, the high-resolution measurements by Tanaka and Eaton showed that the overall dissipation rate increases when the high velocity gradients near particle surfaces are resolved. The one consistent feature of all three isotropic turbulence experiments was that the turbulence spectra were augmented at high frequency in agreement with simulations.

12.4.3.2 Wall-Bounded Gas–Solid Flows

The strongest effects of turbulence modification have been observed in wall-bounded flows including pipe flows, channel flows, and boundary layers. Much of the original experimental work on turbulence modulation was done in pipe flows with notable contributions from Lee and Durst (1982), Tsuji and Morikawa (1982), and Tsuji et al. (1984). More recently, considerable effort has been focused on fully developed turbulent channel flows and flat plate boundary layers. Kulick et al. (1994), Paris and Eaton (2001), and Kussin and Sommerfeld (2002) all examined fully developed air channel flows at similar Reynolds numbers. Each experiment covered a reasonably broad range of particle parameters lending new insight into turbulence modulation.

Kulick et al. (1994) conducted experiments in a long vertical downflow air channel flow at a Reynolds number of 13,800 based on the channel half-width and the bulk velocity. Experiments were conducted with 50 and 90 μm diameter glass beads and 70 μm copper beads. The Stokes numbers based on the centerline Kolmogorov timescale were 9, 23, and 50 for the three particle classes. Gas-phase measurements were made using Laser doppler velocimetry with submicron tracer particles that were easily discriminated from the larger dispersed particles. Turbulence modification was small (<10%) for the St_k = 9 particles, substantial for St_k = 23, and very large for St_k = 50. Figure 12.7 reproduced from Kulick et al. (1994) shows the streamwise turbulence intensity profiles for copper beads at various mass loading ratios. The turbulence is attenuated across the entire profile, with the largest attenuation near the centerline.

Paris and Eaton (2001) conducted experiments in the same channel flow facility using phase-discriminated PIV to verify the earlier LDA results for copper beads. They also conducted separate experiments using 150 μm glass beads that had almost the same aerodynamic time constant as the copper. By virtue of their larger diameter, the particle Reynolds numbers were over two times greater for the glass (Re_p = 19 vs. 8). The centerline results, as shown in Figure 12.4, showed similar attenuation levels as observed by Kulick for the copper and larger attenuation levels for the higher Reynolds number glass particles.

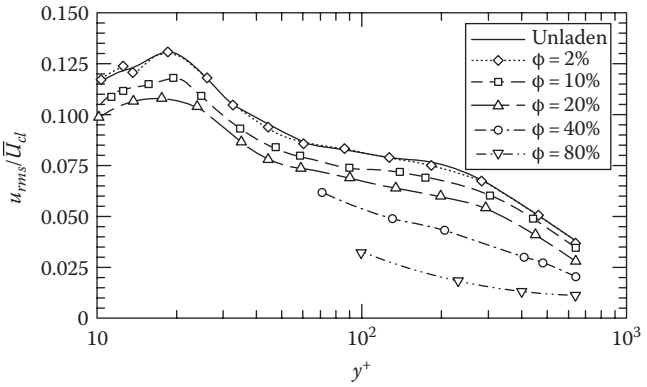

Figure 12.7

Streamwise turbulence intensity in fully developed channel flow laden with 70 micron copper spheres at mass loading ratios from 0 to 0.8. (From Kulick, J.D. et al., *J. Fluid Mech.*, 277, 285, 1994.)

Kussin and Sommerfeld (2002) and Lain et al. (2002) made measurements in a horizontal channel flow for a variety of particle sizes. The half-height Reynolds number was 21,000 and smooth and rough wall cases were examined. Measurements were made using a phase-Doppler anemometer. Unfortunately, the particle size distribution was wide and the flow tracers were large (nominally 4 μm in diameter), so the gas-phase turbulence measurements were contaminated by particle-phase measurements. As a result, the turbulence measurements are quite noisy. Nevertheless, because both the particle size and mass loading ratio were varied over wide ranges, trends were easily observed. Figure 12.8 shows the streamwise turbulence intensity data for Kussin and Sommerfeld's (2002) rough wall cases. The data have been averaged across the channel to reduce noise, normalized by the average value from all cases at zero loading, and squared for comparison to the TKE data presented in other plots. The data are presented for 60, 100, and 195 μm glass beads that have Stokes numbers of 35, 120, and 350 and Reynolds numbers of 7, 23, and 72. All three particle sizes produce substantial attenuation with the degree of attenuation decreasing with increasing particle size. It is interesting to note that the 60 μm particles that produced the largest attenuation in Kussin and Sommerfeld's (2002) experiments have Stokes numbers similar to the 150 μm glass beads that produced the strongest attenuation in the Paris and Eaton experiments.

Kussin and Sommerfeld (2002) also presented measurements with 0.6 and 1 mm diameter glass beads with mass loadings ratios up to 2.0. These cases showed significant turbulence augmentation near the channel centerplane and moderate attenuation near the walls. They concluded that this was a particle Reynolds number effect since the relative velocity between the gas and particles was smaller near the walls than in the channel center region. The particle Reynolds numbers at the centerplane were approximately 350 and 500 for the 0.6 and 1 mm beads, respectively. This indicates that unsteady particle wakes probably played a role

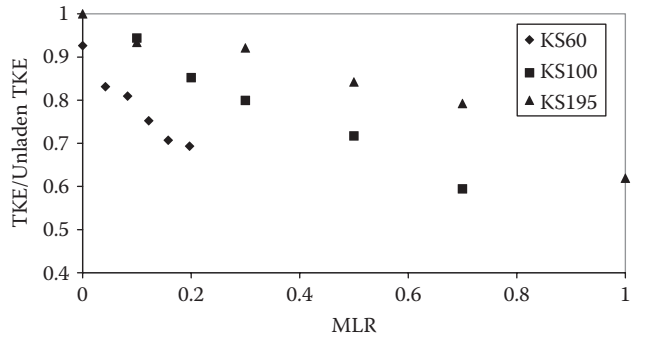

Figure 12.8

Streamwise normal stress ($\overline{u'^2}$) averaged across a fully developed channel and normalized by the averaged stress for an unladen case. Data for three particle sizes are shown. (Data from Kussin, J. and Sommerfeld, M., *Exp. Fluids*, 33, 143–159, 2002.)

in the turbulence augmentation. Hadinoto and Curtis (2009) found a similar behavior in vertical pipe flows laden with relatively large particles at mass loading ratios around 0.5. Large augmentation of the turbulence was observed near the pipe centerline with very little change in the turbulence near the wall.

The channel flow experiments discussed here along with several other wall-bounded flow experiments are beginning to give a fairly consistent picture. Very small particles with St_k less than about 10 do not cause significant changes to the turbulence. As the particle size increases, the particles cannot follow the turbulent fluctuations and turbulence attenuation increases rapidly. Attenuation reaches a maximum around $St_k = 50$. The attenuation can be very large for particles in this size range. As particle size increases further, the effects of superimposed laminar wakes or unsteady wakes begin to have an effect decreasing the overall level of turbulence attenuation, and eventually causing substantial augmentation.

12.4.3.3 Free Shear Flows

The flow geometries and particle parameters for particle-laden jet, mixing layer, and separated flow experiments have varied widely, so it has not been possible to extract trends as was done in the previous two sections. Shuen et al. (1985) and Mostafa et al. (1989) have examined round jets discharging downward into quiescent air. Shuen et al. (1985) examined the far field of a jet discharging from a pipe for a range of particle sizes and mass loading ratios up to 66%. They observed changes in the turbulent stresses of less than 10%. Mostafa et al. (1989) examined the near field of a similar jet at mass loading ratios of 0.2 and 1.0. Detailed comparisons to the unladen turbulence measurements were not presented, but the authors noted a reduction of 40% in the TKE on the jet centerline for a mass loading of 1.0. It is important to note that the jet was supplied from a turbulent pipe flow. Although the jet exit plane was not documented, it is likely that the turbulence level was substantially lower for the particle-laden case than for the single-phase flow.

Free shear flows are subject to the Kelvin–Helmholtz instability that produces large roller vortices. An important issue to understand is how the particles might affect these vortices. A simplified analysis by Yang et al. (1993) showed that particles slow the development of roller vortices. Longmire and Eaton (1992) found little effect of particles on the near-field development of roller vortices for mass loading ratios up to 0.8. This is corroborated by research in backward-facing step flows that have been studied by Maeda et al. (1980), Hishida and Maeda (1991), Hardalupas et al. (1992), and Fessler and Eaton (1999). All of these experiments were conducted in the small particle regime. Some experiments observed almost no change to the turbulence with the others showed either small attenuation or augmentation of the turbulence. Overall, the particle effects on the turbulence are much smaller than in wall-bounded flows probably because the extra dissipation due to particles is overwhelmed by the strong shear production in free shear flows.

Longmire and Anderson (2003) made direct measurements of vortex/particle interaction in an impinging round jet in which the jet was weakly forced to phase lock the dominant vortex ring structures. The jet carried a 4% mass loading of particles with Stokes number of 1.2 based on the vortex ring period. Simultaneous two-phase PIV measurements showed that vortex ring circulation was reduced by around 30% in the impingement zone where the local mean particle loading was elevated by the rapid deceleration of the carrier flow. Also, the velocity difference between the carrier-phase vortices and particles rebounding from the wall was large. This research shows that particles moving with a high relative velocity (hence significant Re_p) can strongly attenuate dominant vortex structures.

12.4.3.4 Liquid–Solid Flows

We consider here cases of solid particles dispersed in liquid flows with relatively low volume fraction so that the flows are not dominated by particle collisions. Typically, liquid–solid material density ratios are between 1 and 5, so the mass loading ratio is very small for dilute volume fractions. Also, the Stokes number is small unless the particles are quite large. The only cases for which turbulence modulation is observed are thus flows in which the particles are large relative to the turbulence scales.

Schreck and Kleis (1993) examined grid turbulence in a downflow water channel laden with particles of $d_k \approx 5$. Volume concentrations were as large as 1.5%. Reductions in the TKE of 20% were observed for the heaviest particles at the largest concentration. Bellani et al. (2012) studied dilute loadings of large ($d_k = 21$) neutrally buoyant particles in homogeneous turbulence produced by opposed arrays of pulsed jets. They found 15% reduction in TKE using spherical particles at a mass loading of 0.0014, but only 3% reduction when the particles were 2:1 ellipsoids. It is apparent from these results that volume fraction rather than mass loading is the critical parameter when considering turbulence attenuation. Lucci et al. (2011) developed fully resolved numerical simulations for spherical particles with the same range of particle size and volume loading

in decaying isotropic turbulence. The five different cases studied all had Stokes number of 61, but particle diameters varying by a factor of 2 and Reynolds numbers around 100. The peak reduction in TKE was only 7.4% while the peak increase in dissipation rate was 16.7% corroborating the air flow experiments of Tanaka and Eaton (2010). Taken together, the five cases showed that no simple parameterization of turbulence attenuation was possible for large particle cases.

Detailed experiments in particle-laden water channel flows have been conducted using PIV in several laboratories. Kiger and Pan (2002) studied a 40 mm wide water channel operated at a Reynolds number of 12,000 and laden with 195 μm diameter glass beads at a mass loading ratio of 0.0006. Relatively small (8%–10%) increases in the turbulence intensity were observed across the channel. Suzuki et al. (2002) used a 40 mm wide, vertical water channel at a very low Reynolds number (Re_h = 2900). The flow was laden with 400 μm ceramic particles at a mass loading ratio of 0.0012. The dimensionless particle diameter was about 2 near the wall, and the particle Reynolds number was on the order of 30. The turbulence was almost unchanged near the wall, but the streamwise turbulence intensity increased by more than a factor of 2 in the channel center.

Sato et al. (2000) examined a similar channel at the same Reynolds number using 190 μm (Re_p = 10) or 400 μm (Re_p = 50) glass beads. The 190 μm particles were smaller than the centerline Kolmogorov scale, while the 400 μm particles were larger. The mass loading ratio was about 0.0004 for the 190 μm particles and 0.00033 and 0.00086 for the 400 μm particles. Data were acquired only near the channel centerline. The smaller particles produced relatively small increases in the kinetic energy, while the larger particles increased the TKE by roughly a factor of 4. Doubling the mass loading for the 400 μm particles had a relatively small effect.

Trends are difficult to discern because of the small number of experiments and resolved simulations examining turbulence modulation in liquid/solid flows. Due to the relatively low density ratio, the particle/turbulence interactions are significant only for relatively large particles that have relatively high Reynolds numbers. Turbulence attenuation can occur due to extra dissipation on the large particle surfaces while turbulence augmentation can occur in particle wakes. The interplay of these effects appears to determine the level (and direction) of turbulence modulation. When attenuation has been observed, the fractional decrease has been substantially less than observed in some air flow experiments.

12.4.4 Simple Parameterization of Turbulence Modulation

There have been several attempts to define a small set of dimensionless parameters that can be used to organize turbulence modulation data and develop predictive correlations. The best known of these is the paper of Gore and Crowe who found that turbulence in simple shear flows is attenuated when the particle diameter is less than 1/10 of the large eddy length scale and augmented for larger particles. This is oversimplistic and does not account for sensitivity to Stokes number, particle density, particle shape, and particle Reynolds number. Even this simple rule of thumb was violated by some experiments performed after the original publication.

Generally, the two-way coupling regime is thought to begin for volume loadings above 10^{-6}. However, the data compilation earlier indicates that turbulence modulation is insignificant for volume loadings less than 10^{-5}. In most experiments where the volume loading has been systematically varied, strong modulation is observed for volume fractions above 10^{-4}. Significant modulation at lower average loadings can occur if the particles are concentrated into specific regions of the flow such as the sublayer in a turbulent boundary layer.

Poelma et al. (2007) proposed a parameter called the Stokes load defined as

$$\Phi_{St} = \frac{\Phi_v \rho_p \eta^3}{3\pi \nu d \tau_k}$$

This is essentially the product of the particle number density and the aerodynamic time constant normalized by the Kolmogorov scales. They found that the decay of isotropic turbulence varied linearly with this parameter. Tanaka and Eaton (2008) nondimensionalized the Reynolds-averaged TKE transport equation and arrived at a parameter they call the particle momentum number:

$$Pa_{St} = StRe_L^2 \left(\frac{\eta}{L} \right)^3$$

where L is an integral scale of the turbulence. Their compilation of pipe and channel flow data showed that attenuation occurs for $3 \times 10^3 < Pa_{St} < 10^5$. Augmentation occurs at both lower and higher particle momentum numbers. The lack of broad success of any of these parameters is probably because there are multiple interacting mechanisms that simultaneously attenuate and augment the turbulence.

Bubble Dynamics and Cavitation

13.1 Bubble Dynamics
13.2 Cavitation

13.1 Bubble Dynamics

Yoichiro Matsumoto and Kazuyasu Sugiyama

13.1.1 Single Spherical Bubble Dynamics

Bubble motion from a surrounding pressure variation is one of the most fundamental gas–liquid two-phase flow problems and is closely related to the macroscale behavior of two-phase flows, the performance of cavitating fluid machinery, and medical ultrasound applications. Of great significance to the analysis of such problems is the prediction of the radial motion of a bubble, namely, its growth and collapse. The bubble motion can be solved exactly by the integration of the conservation equations for mass, momentum, and energy for the gas phase inside the bubble and the liquid phase outside the bubble. Since it is not easy to solve the complete equations in many cases, a polytropic change (isothermal or adiabatic) is assumed for the gas inside the bubble. It is well known that the thermal phenomena inside the bubble can have a significant influence on the bubble motion (Chapman and Plesset, 1971, Nigumatulin et al., 1981, Prosperetti et al., 1988, Kamath and Prosperetti, 1989, Prosperetti, 1991, Takemura and Matsumoto, 1994, Kameda and Matsumoto, 1999). To account for thermal effects, a reduced-order model has been introduced using ordinary differential equations instead of the full conservation equations for mass, momentum, and energy.

13.1.1.1 Direct Numerical Simulation of a Single Bubble

In a single-phase flow, the conservation equations of mass, momentum, and energy are described by partial differential equations (PDEs) if the flow is treated as a continuum. In multiphase flow, these conservation equations are not described by the same set of PDEs, because there are discontinuities between the phases. However, it is possible to describe the governing equations in each phase by PDEs and connect the two phases at the interfaces. The governing equations and boundary conditions at a bubble interface were described by Hsieh (1965). Matsumoto and Takemura (1994) simulated the collapsing bubble motion numerically by using the full equations for mass, momentum, and energy in the gas and liquid phases. Takemura and Matsumoto (1994) calculated the bubble growth caused by an external pressure reduction by taking into account the internal phenomena such as thermal and mass diffusion with mist formation due to homogeneous condensation.

13.1.1.1.1 Governing Equations

A. Gas Phase

1. The mass conservation equations.

– For the gas mixture inside the bubble:

$$\frac{\partial \rho_m}{\partial t} + \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 \rho_m u_{mg}\right) = 0, \tag{13.1}$$

where

$\rho_m = \rho_n + \rho_v + \rho_{lg}$

$\rho_m u_{mg} = \rho_n u_n + \rho_v u_v + \rho_{lg} u_{mg}$, the subscript g denotes the gas phase, l the liquid phase, n the noncondensable gas, v the vapor in the gas phase, and m the mixture condition

Also, the subscript lg denotes the mist inside the bubble and gl the noncondensable gas in the liquid phase), ρ is the density, r the coordinate in the radial direction, and u the radial velocity.

– For the vapor:

$$\frac{\partial \rho_v}{\partial t} + \frac{1}{r^2}\frac{\partial}{\partial r}\left\{r^2\left(\rho_v u_{mg} - \rho_{mg} D_{mg}\frac{\partial c_v}{\partial r}\right)\right\} = -\Gamma, \tag{13.2}$$

where

$\rho_{mg} = \rho_n + \rho_v$

$c_v = \rho_v/\rho_{mg}$

D is the diffusion coefficient

c is the concentration

Γ is the mass of vapor, which changes to mist per unit volume and time

– For the number density distribution function of droplets (Frenkel, 1946):

$$\frac{\partial n(a)}{\partial t} + \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 n(a) u_{mg}\right) + \frac{\partial (n(a) I_a)}{\partial a} = 0, \tag{13.3}$$

where

$n(a)$ is the number density distribution function versus radius of the droplet

I_a is the growth rate of the droplet radius and is given by

$$I_a = \frac{\alpha(p_v - p_s)}{\left(\rho_l \sqrt{2\pi \Re_v T}\right)}, \tag{13.4}$$

where

α is the accommodation factor whose value is estimated to be 0.4 (Hatamiya and Tanaka, 1986)

p is the pressure and subscript s denotes the saturated condition

$\Re$ is the gas constant

T is the temperature

Critical radius r^* and the nucleation rate J are

$$r^* = 2\sigma/\rho_l \Re_v T \ln(p_v/p_s) \tag{13.5}$$

$$J = \left(\frac{2\sigma m}{\pi}\right)^{1/2} \frac{1}{\rho_l}\left(\frac{p_v}{kT}\right)^2 \exp\left(-\frac{4\pi r^{*2}\sigma}{3kT}\right) \tag{13.6}$$

where
- σ is the surface tension
- m is the molecular unit mass
- k is the Boltzmann constant

Γ in Equation 13.2 is defined as

$$\Gamma = \frac{d}{dt}\int \frac{4}{3}\pi\rho_l a^3 n(a)da. \tag{13.7}$$

2. The momentum conservation equation inside the bubble:

$$\frac{\partial}{\partial t}(\rho_m u_{mg}) + \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\rho_m u_{mg}u_{mg}\right)$$
$$= -\frac{\partial p_{mg}}{\partial r} + \frac{4}{3}\frac{\mu_{mg}}{r}\left(\frac{\partial u_{mg}}{\partial r} - \frac{u_{mg}}{r}\right) + \frac{4}{3}\frac{1}{r^2}\frac{\partial}{\partial r}\left\{r^2\mu_{mg}\left(\frac{\partial u_{mg}}{\partial r} - \frac{u_{mg}}{r}\right)\right\}, \tag{13.8}$$

where μ is the viscosity.

3. The energy conservation equation inside the bubble:

$$\frac{\partial}{\partial t}(\rho_n e_n + \rho_v e_v + \rho_{lg} e_{lg}) + \frac{1}{r^2}\frac{\partial}{\partial r}\{r^2(\rho_n e_n u_n + \rho_v e_v u_v + \rho_{lg} e_{lg} u_{mg})\}$$
$$= -\frac{p_{mg}}{r^2}\frac{\partial}{\partial r}\left(r^2 u_{mg}\right) + \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\lambda_{mg}\frac{\partial T}{\partial r}\right) + \frac{4}{3}\mu_{mg}\left(\frac{\partial u_{mg}}{\partial r} - \frac{u_{mg}}{r}\right)^2, \tag{13.9}$$

where
- e is the specific internal energy
- λ is the thermal conductivity

4. The equations of state are as follows:

$$p_n = \rho_n \Re_n T, \tag{13.10}$$

$$p_v = \rho_v \Re_v T. \tag{13.11}$$

B. Liquid Phase

1. The mass conservation equations.
- For the mixture of the liquid:

$$\frac{\partial \rho_{ml}}{\partial t} + \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\rho_{ml}u_{ml}\right) = 0, \tag{13.12}$$

where $\rho_{ml} = \rho_l + \rho_{gl}$, $\rho_{ml}u_{ml} = \rho_l u_l + \rho_{gl}u_{gl}$.
- For the noncondensable gas in the liquid:

$$\frac{\partial \rho_{gl}}{\partial t} + \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\rho_{gl}u_{ml}\right) = \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\rho_{ml}D_{gl}\frac{\partial c_{gl}}{\partial r}\right). \tag{13.13}$$

where $c_{gl} = \rho_{gl}/\rho_{ml}$.

2. The momentum conservation equation for the liquid phase is

$$\frac{\partial}{\partial t}(\rho_{ml}u_{ml})+\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\rho_{ml}u_{ml}u_{ml}\right)$$
$$=-\frac{\partial p_l}{\partial r}+\frac{4}{3}\frac{\mu_{ml}}{r}\left(\frac{\partial u_{ml}}{\partial r}-\frac{u_{ml}}{r}\right)+\frac{4}{3}\frac{1}{r^2}\frac{\partial}{\partial r}\left\{r^2\mu_{ml}\left(\frac{\partial u_{ml}}{\partial r}-\frac{u_{ml}}{r}\right)\right\}. \tag{13.14}$$

3. The conservation equation of energy for the liquid is

$$\frac{\partial}{\partial t}(\rho_l e_l)+\frac{1}{r^2}\frac{\partial}{\partial r}\left\{r^2\rho_l e_l u_l\right\}$$
$$=-\frac{p_l}{r^2}\frac{\partial}{\partial r}\left(r^2u_l\right)+\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\lambda_l\frac{\partial T}{\partial r}\right)+\frac{4}{3}\mu_l\left(\frac{\partial u_l}{\partial r}-\frac{u_l}{r}\right)^2. \tag{13.15}$$

4. The Tait equation is applied with the equations of state in the following form:

$$\frac{p+B}{p_\infty+B}=\left(\frac{\rho}{\rho_\infty}\right)^n, \tag{13.16}$$

where B = 304.9 MPa, n = 7.15 in the case where the liquid is water.

13.1.1.1.2 Boundary Conditions at the Gas–Liquid Interface

1. Boundary conditions for mass conservation
The mass flux due to phase change $\dot{M}_v$ is expressed by the following equation:

$$\dot{M}_v=\frac{\alpha(p_s-p_v)}{\left(\sqrt{2\pi\Re_v T_w}\right)}. \tag{13.17}$$

where the subscript w denotes the bubble wall. The concentrations and gradients of vapor and noncondensable gas in the liquid at the interface are related to $\dot{M}_v$ and $\dot{M}_n$ by the following equations:

$$\dot{M}_v=\frac{D_{mg}\rho_{mgw}\left(\partial c_v/\partial r\right)_w}{1-c_{vw}}+\frac{c_{vw}}{1-c_{vw}}\dot{M}_n, \tag{13.18}$$

$$\dot{M}_n=\frac{D_{gl}\rho_{mlw}\left(\partial c_{gl}/\partial r\right)_w}{1-c_{glw}}+\frac{c_{glw}}{1-c_{glw}}(\dot{M}_v+\dot{M}_{lg}), \tag{13.19}$$

$\dot{M}_{\mathrm{lg}}$ is

$$\dot{M}_{lg}=\begin{cases}0 & (\dot{R}-u_{mg}\geq 0)\\ \rho_{lg}(\dot{R}-u_{mg}) & (\dot{R}-u_{mg}<0)\end{cases}. \tag{13.20}$$

where R is the bubble radius and dot denotes the derivative with respect to time.

2. The boundary condition for the momentum conservation is as follows:

$$-p_{lw}+\frac{4}{3}\mu_l\left(\frac{\partial u_l}{\partial r}-\frac{u_l}{r}\right)_w+\{\rho_{mg}(u_{mg}-\dot{R})(u_{mg}-u_l)\}_w=-p_{mgw}+\frac{2\sigma}{R}+\frac{4}{3}\mu_{mg}\left(\frac{\partial u_{mg}}{\partial r}-\frac{u_{mg}}{r}\right)_w, \tag{13.21}$$

3. The boundary condition for the energy conservation is as follows:

$$\lambda_{ml}\left(\frac{\partial T}{\partial r}\right)_w - \lambda_{mg}\left(\frac{\partial T}{\partial r}\right)_w + \frac{5}{2}(\Re_v - \Re_n)T_w\{(1-c_{vw})\dot{M}_v - c_{vw}\dot{M}_n\}$$
$$= \dot{M}_v\left\{L + \frac{4}{3}\frac{\mu_l}{\rho_{lw}}\left(\frac{\partial u_l}{\partial r} - \frac{u_l}{r}\right)_w - \frac{4}{3}\frac{\mu_{mg}}{\rho_{mg}}\left(\frac{\partial u_{mg}}{\partial r} - \frac{u_{mg}}{r}\right)_w\right\}$$
$$+ \frac{1}{2}\dot{M}_v\left\{(\dot{R}-u_{lw})^2 - (\dot{R}-u_{mgw})^2\right\}, \tag{13.22}$$

where L is the latent heat of the liquid.

The temperature and concentration of the noncondensable gas at the wall in the liquid are

$$T_{lw} = T_{gw}, \tag{13.23}$$

$$c_{glw} = H_n p_{nw}, \tag{13.24}$$

where H_n is Henry's constant.

13.1.1.1.3 Pressure and Temperature Distribution Inside and Outside a Bubble Figures 13.1 and 13.2 show the time histories of the pressure and temperature distribution inside and outside a bubble, and Table 13.1 shows the computational conditions. The pressure surrounding the bubble increases from 10 to 100 kPa stepwise. When the bubble motion starts, the expansion wave propagates outside and the pressure distribution is formed in the liquid phase according to the motion of the bubble interface. At the rebound of the bubble, the pressure peak appears at some distance from the interface and the pressure propagates outward. The pressure inside the bubble is uniform because the speed of sound is much higher than the velocity of the interface. In Figure 13.2, the temperature distribution is uniform in the liquid phase because of the large heat capacity of the liquid. On the other hand, a nonuniform distribution appears in the gas phase, because the temperature rises during the collapse phase as the heat transfers to the liquid at the interface. After rebounding, the temperature inside the bubble decreases to a value less than its initial value. The internal energy of the gas is reduced by thermal diffusion. The heat is trapped and diffuses around the bubble when the gradient of the temperature is negative.

13.1.1.1.4 Effect of Thermal Diffusion on the Bubble Motion Figure 13.3 shows the behavior of the bubbles with different gases inside them under the same conditions as Table 13.1, except for the gas species.

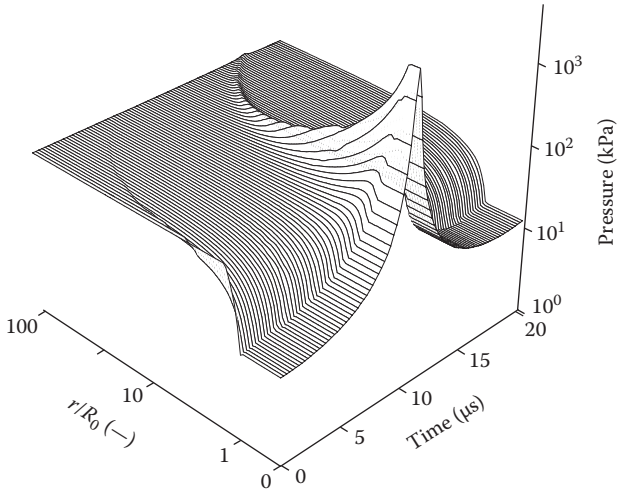

Figure 13.1

Time history of the pressure distribution inside and outside a nitrogen bubble.

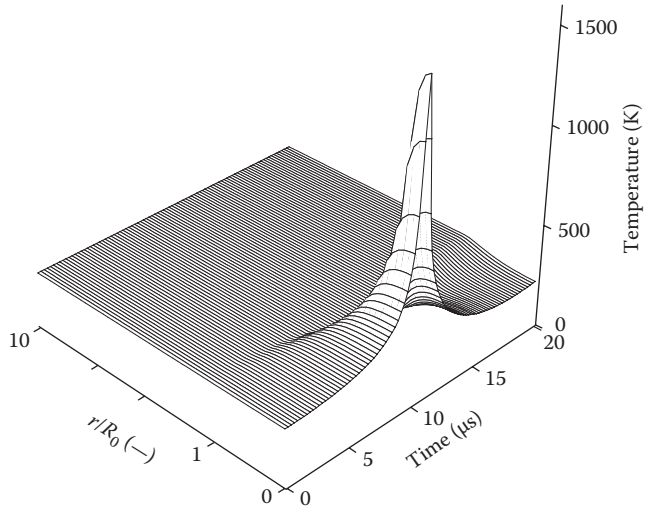

Figure 13.2

Time history of the temperature distribution inside and outside a nitrogen bubble.

Table 13.1 Computational Conditions

Gas phase	Nitrogen
Liquid phase	Water
Initial bubble radius, R_{b0}	100 μm
Initial ambient pressure, p_0	10 kPa
Step increase in ambient pressure	From 10 to 100 kPa
Initial temperature	293 K

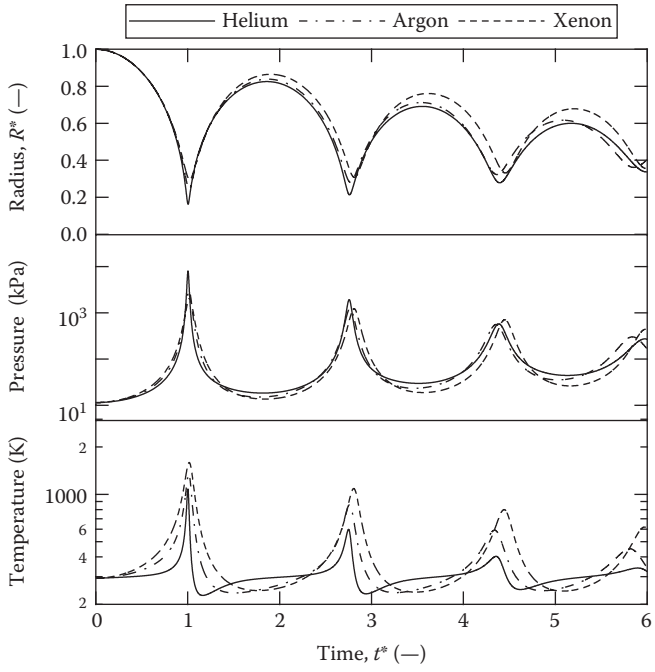

Figure 13.3

Time histories of the bubble radius, pressure at the bubble center, and mean temperature inside the bubble with different gases.

Table 13.2 Properties of the Internal Gas (100 kPa and 293 K)

Gas	Helium	Argon	Xenon
Thermal conductivity (mW/[m·K])	153.5	17.4	5.4
Peclet number, *Pe*	12.3	109.1	347.7

Table 13.2 shows the properties of the internal gas. The Peclet number for the bubbles *Pe* is defined as $Pe = \rho_0 c_{p0} R_0^2 \omega_N / \lambda$, where c_{p0} is the isobaric specific heat and ω_N denotes the natural angular frequency of a bubble, assuming adiabatic changes. Nondimensional length and timescales R^* and t^* are defined as $R^* = R/R_0$, $t^* = t/R_0\sqrt{\rho_{l\infty}/p_{l0}}$, respectively. When the bubble radius takes a maximum or minimum value, the pressure has a minimum or maximum value, respectively. The mean temperature $\left(\text{defined as } T_{mean} = \int_0^R r^2 \rho_g T_g \, dr \Big/ \int_0^R r^2 \rho_g \, dr\right)$ has a maximum at almost the same time as the bubble radius takes a minimum. However, it does not have a minimum when the bubble radius reaches a maximum. This occurs because the heat input has positive or negative values despite the work received from the liquid phase and has a time lag. Therefore, the sum of the work, which the bubble receives per unit time from the liquid phase, and the heat input become zero before the radius attains the minimum or the maximum value. This is the minimum or the maximum point of the temperature.

When the bubble collapses, the work received from the liquid per unit time decreases so rapidly that the temperature takes the maximum at almost the same time as the radius takes the minimum. On the other hand, upon expansion, the bubble supplies work to the liquid phase and the heat flows outward from the gas phase, due to the temperature distribution developed during the collapse phase. Therefore, the temperature decreases rapidly, and the gradient of the temperature at the gas–liquid interface becomes positive. Subsequently, the heat flows inward from the liquid phase and the mean temperature attains the minimum value when the sum of the work received from the liquid per unit time and the heat input become equal to zero.

In the case of a helium bubble (when *Pe* is relatively small), the heat transfers outward through the bubble wall quickly and the bubble shrinks to a smaller size in the collapsing phase. The temperature inside the bubble does not become so high. In the case of xenon (where *Pe* is large), the heat input and output are not large, so the bubble cannot shrink as much and the temperature inside the bubble reaches higher values.

13.1.1.1.5 Bubble Motion and Mist Formation Inside a Bubble Figure 13.4 shows the time histories of the radius, mean temperature, and mean density of mist (a) and the distributions of the temperature, concentration of vapor, and density of mist inside the bubble at several points (b) in the case when the surrounding pressure has a stepwise decrease from 100 to 5 kPa. The other computational conditions are the same as Table 13.1. The bottom figure shows the distributions at the times from A to H indicated in the upper figure. The figures from A to E show the growth period and those from F to H show the collapse period. The abscissa is the nondimensional distance, in which 0 shows the bubble center and 1 shows the bubble wall. As the bubble expands, the temperature inside the bubble decreases at the initial stage and then recovers to the surrounding temperature due to the latent heat released by the formation and growth of mist and the heat penetration from the bubble wall. After that, the temperature is kept almost constant except during the rebounds. The mean density of the mist increases at the beginning of the expansion, and the formation and growth of the mist exert an effect on the bubble motion at that time. After the temperature inside the bubble has become almost constant, the mean density of the mist is also almost constant and the total mass of the mist increases in proportion to the volume of the bubble. The temperature inside the bubble does not become so high at the end of the collapse because energy from the outside is consumed by the mist's evaporation. It is shown that distributions of temperature, vapor concentration, and density of the mist occur and that the distribution of the density of the mist is a rather complicated variable in space due to the slow diffusion process.

13.1.1.2 Reduced-Order Modeling of a Single Bubble

The single bubble motion can be simulated in detail, computing the full equations for the mass, momentum, and energy as outlined in the previous section. However, it is computationally expensive to calculate all equations when many bubbles are treated such as in bubbly flows. Many researchers have developed reduced-order models for the liquid- and gas-phase phenomena.

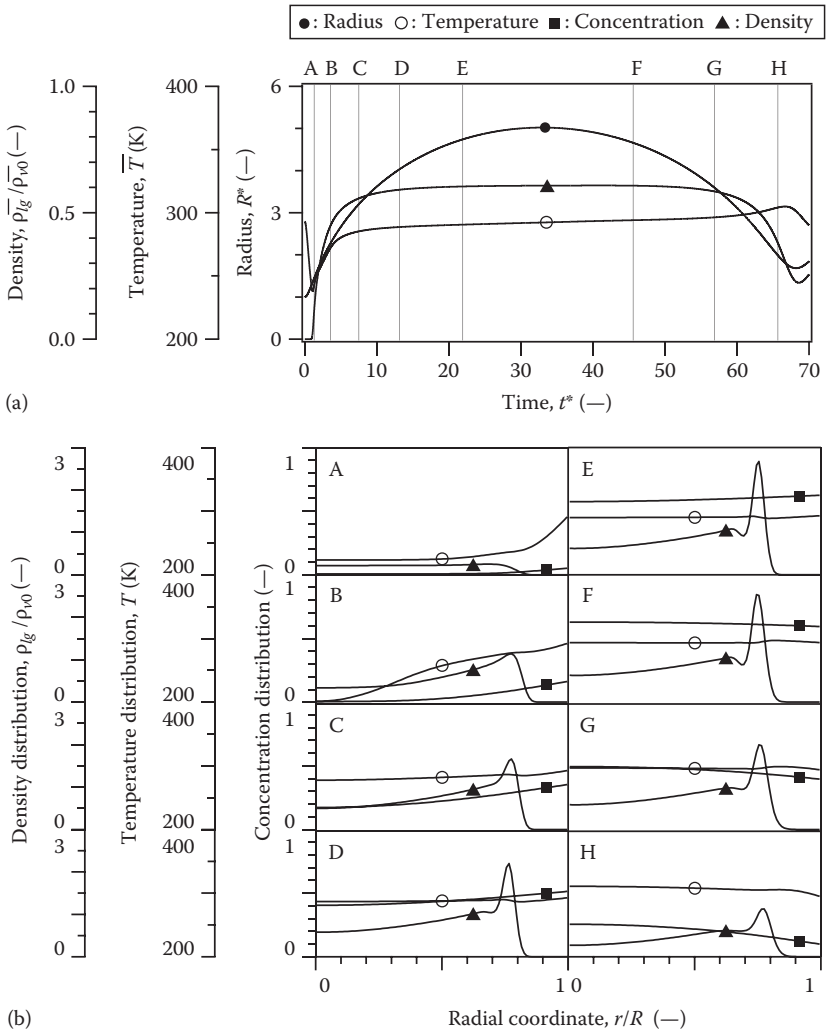

Figure 13.4

Time histories of the bubble radius, mean temperature, and mean density of the mist inside the bubble inside the bubble (a), and the distributions of the temperature, concentration of the vapor, and density of the mist inside the bubble at several points (b) in the case of a nitrogen bubble.

13.1.1.2.1 Effect of Compressibility in the Liquid Phase If the liquid is assumed to be incompressible, the momentum conservation equation can be easily integrated from the bubble wall to infinity and the boundary condition for the pressure can be taken into account. Rayleigh (1917) first considered bubble collapse in a liquid, assuming a vacuum cavity. The effect of the surface tension and viscosity in the liquid was taken into account later, and the Rayleigh–Plesset equation (1949) was defined as shown as follows:

$$R\ddot{R} + \frac{3}{2}\dot{R}^2 = \frac{1}{\rho_l}\left\{p_b - p_\infty - 4\mu_l\frac{\dot{R}}{R} - \frac{2\sigma}{R}\right\}, \tag{13.25}$$

where

p_b is the pressure inside the bubble
p_∞ is the ambient pressure
σ is the surface tension of the liquid

When the velocity of the bubble wall becomes comparable to the speed of the sound in the liquid phase, the compressibility of the liquid has to be considered (Keller and Kolodner, 1956). Thus, the following model with a first-order correction for compressibility is often used:

$$\left(1-\frac{\dot{R}}{c}\right)R\ddot{R}+\frac{3}{2}\left(1-\frac{\dot{R}}{3c}\right)\dot{R}^2=\left(1+\frac{\dot{R}}{c}\right)\frac{1}{\rho_l}\left\{p_b-p_\infty-p_c\left(t+\frac{R}{c}\right)\right\}+\frac{R}{\rho_l c}\dot{p}_b, \tag{13.26}$$

where c is the speed of sound and $p_c(t)$ the variable part of the pressure in the liquid at the location of the bubble center in the absence of the bubble.

A nonequilibrium phase change, such as evaporation and condensation during the collapse phase, is discussed next (Tomita and Shima, 1979, Fujikawa and Akamatsu, 1980). Fujikawa and Akamatsu (1980) derived the equations, which take into account the effects of nonequilibrium behavior at the bubble wall on the bubble motion:

$$\begin{aligned}&R\ddot{R}\left(1-2\frac{\dot{R}}{c}+\frac{\dot{m}}{\rho_l c}\right)+\frac{3}{2}\dot{R}^2\left(1+\frac{4}{3}\frac{\dot{m}}{\rho_l c}-\frac{4}{3}\frac{\dot{R}}{c}\right)\\&-\frac{\ddot{m}R}{\rho_l}\left(1-2\frac{\dot{R}}{c}+\frac{\dot{m}}{\rho_l c}\right)-\frac{\dot{m}}{\rho_l}\left(\dot{R}+\frac{\dot{m}}{2\rho_l}\right)+\frac{p_\infty-p_{l,r=R}}{\rho_l}-\frac{R\dot{p}_{l,r=R}}{\rho_l c}=0,\end{aligned} \tag{13.27}$$

$$p_{l,r=R_b}=p_v+p_g-\frac{\dot{m}^2(\rho_{vi}+\rho_{gi}-\rho_l)}{\rho_l(\rho_{vi}+\rho_{gi})}-2\frac{\sigma}{R}-4\frac{\mu_l}{R}\left(\dot{R}-\frac{\dot{m}}{\rho_l}\right), \tag{13.28}$$

where

$\dot{m}$ is the mass flux caused by the phase change

ρ_{vi} and ρ_{gi} are the density of the vapor and noncondensable gas at the bubble interface, respectively

The nonequilibrium behavior may result in additional cushioning of the bubble collapse.

13.1.1.2.2 Effect of Thermal Phenomena on the Gas Phase The temperature gradient at the bubble wall is used by some researchers instead of calculating the entire temperature distribution inside a bubble. Prosperetti (1991) investigated the thermal diffusive effects and Storey and Szeri (2001) suggested a model in which the bubble interior is assumed to be isothermal when the bubble radius is larger than the equilibrium value and to be adiabatic when the radius is smaller. Shimada et al. (2000) investigated a model, which assumes a homogeneous heat distribution inside a bubble. Toegel et al. (2000) estimated the penetration depth of mass and heat diffusion and calculated the approximated energy flux at the bubble wall. Preston et al. (2007) considered a temperature gradient based on a linear analysis (Prosperetti et al., 1988).

Figure 13.5 shows a comparison of the time history of bubble radii between the isothermal model, the adiabatic model, the reduced-order model, and the direct numerical simulation (DNS). In this case, the reduced-order model of Matsumoto and Beylich (1985) is applied to the governing equations and boundary conditions for the bubble motion, and that developed by Preston et al. (2007) is employed for the temperature gradient at the bubble wall. The gas inside the bubble is air, and the initial bubble radius is 10 μm. The other calculation conditions are the same as Table 13.1. Compared with the DNS, the amplitudes of the bubble motions in the case of isothermal and adiabatic model are too large. In the collapse phase, the bubble radius in the case of the isothermal model is too small because the temperature inside the bubble is assumed to be isothermal and the internal energy of the gas phase does not become high. The bubble in the case of adiabatic model cannot shrink as much as than that of DNS, because the heat inside the bubble does not transfer to the liquid phase. On the other hand, the reduced-order model can capture the DNS-predicted bubble motion well. It is reasonable and efficient to apply such a reduced-order model for the computation of a many-bubble system.

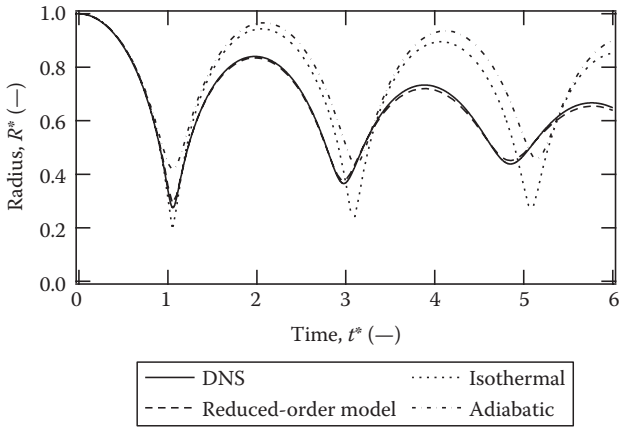

Figure 13.5

Comparison of time histories of radii between DNS and reduced-order model.

13.1.1.3 Nonlinear Behavior and Acoustic Turbulence

13.1.1.3.1 Nonlinear Oscillations of a Microbubble For the dynamics of the bubble in an oscillating field, it is important to take into account the nonlinear phenomena, and many researchers have investigated this topic. Recently, the nonlinear behavior of a microbubble in an ultrasound field has been used for medical ultrasound imaging with microbubble contrast agents. The nonlinear effect was investigated by many researchers (Noltingk and Neppiras, 1950, Neppiras and Noltingk, 1951, Esche, 1952, Borotnikova and Soloukin, 1964, Flynn, 1964, Neppiras, 1969). Lauterborn (1976) simulated the frequency response curve of a bubble (Figure 13.6). This shows the amplitudes of the radial oscillation of a bubble of radius 1.0 μm in water at a mean ambient pressure of 1 bar (100 kPa) plotted as a function of f/f_N for various amplitudes of oscillation. f is a driving frequency, f_N is the natural frequency of the bubble, R_n is a radius at rest, and R_{max} is the maximum radius. The numbers above the peaks indicate the order of the resonance, n/m, and the case $m = 1$, $n = 2, 3, 4$ denotes the higher harmonics and the case $m = 2$, $n = 1$ denotes the subharmonics. The equations that account for the compressibility of the liquid were employed in this calculation. As the amplitude of the ambient pressure grows larger, the superharmonic and subharmonic peak responses become greater. With the increase in the pressure amplitude, these peaks shift to lower frequencies. The influence of the internal phenomena on this nonlinear behavior has also been investigated by Matsumoto and Watanabe (1989).

13.1.1.3.2 Acoustic Turbulence from a Microbubble The bubble motion in an ultrasound field shows chaotic behavior due to the nonlinearity of the oscillation when the sound amplitude is increased. This phenomenon is called "acoustic turbulence" (Lauterborn, 1989). The bifurcation and chaotic behavior of bubble oscillation

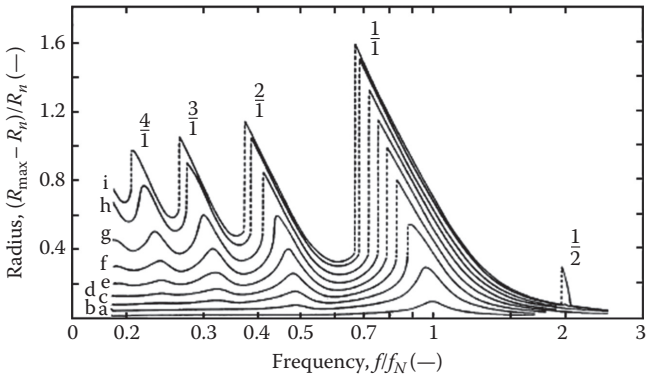

Figure 13.6

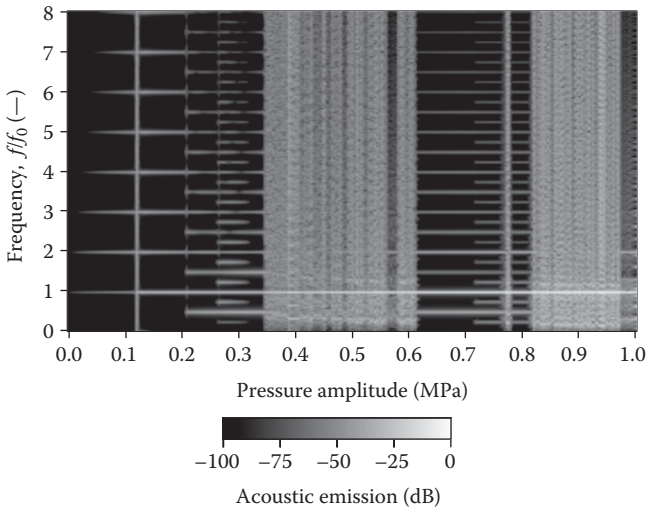

Figure 13.7

Power spectrum of the acoustic pressure from an air microbubble.

have been calculated assuming the interior gas obeys a polytropic relationship, which neglects the thermal dissipation (Lauterborn, 1987).

Figure 13.7 shows the time history of the power spectrum of acoustic pressure from an air microbubble. The bubble motion is simulated for when the ambient ultrasound pressure increases linearly from 0 to 1 MPa in 5000 cycles. The initial bubble radius is 2.0 μm, and the ultrasound frequency is 1 MHz. When the ultrasound driving starts, the bubble begins its oscillation in the fundamental mode. As the ultrasound amplitude increases, the emitted acoustic pressure increases, and it gradually involves nonlinearity with the higher harmonic modes. The bifurcation occurs, and the 1/2 harmonic modes begin to appear in each higher harmonic mode, when the pressure amplitude reaches up to 200 kPa. A further bifurcation appears, and the 1/4 harmonic modes emerge at 250 kPa. After these processes, the bubble oscillation becomes chaotic. When the ambient ultrasound pressure reaches about 600 kPa, nonchaotic oscillations occur for a short time, and then the bubble motion returns to chaotic behavior. In this case, the subharmonic modes are barely visible at this relatively low forcing amplitude.

13.1.2 Bubble Deformation and Fragmentation due to the Collapse

It is well known that the spherical shape of a collapsing bubble is unstable, and it forms a micro-jet that may induce bubble fission. The spherical shape of the bubble is maintained by the surface tension and the viscous force acting on the bubble surface. Deformation will occur when the characteristic anisotropy in the fluid forces overcomes the surface tension and the viscous force. The stability with regard to nonspherical disturbances has been investigated from a hydrodynamic point of view by Birkhoff (1954), Plesset and Mitchell (1956), Brennen (1995, 2002), and Hao and Prosperetti (1999), among others. These analyses essentially examine the spherical equivalent of the Rayleigh–Taylor instability. If the inertia of the gas in the bubble is assumed to be negligible and the viscosity is small enough, then the amplitude, $a_n(t)$, of a spherical harmonic distortion of order n ($n > 1$) will be governed by the equation:

$$\ddot{a}_n + \left[3\frac{\dot{R}}{R} + 2(n+2)(2n+1)\frac{\nu}{R^2}\right]\dot{a}_n + (n-1)\left[-\frac{\ddot{R}}{R} + (n+1)(n+2)\frac{\sigma}{\rho R^3} + 2(n+2)\frac{\nu\dot{R}}{R^3}\right]a_n = 0 \tag{13.29}$$

where ν is the kinematic viscosity.

The coefficients are determined by the dynamic behavior of the bubble radius, $R(t)$. It can be deduced from this equation that the most unstable conditions occur when $\dot{R} < 0$ and $\ddot{R} \geq 0$. These conditions will be

reached just before the rebound of a collapsing bubble. The most stable conditions take place when $\dot{R} > 0$ and $\ddot{R} < 0$, which is the case for growing bubbles as they approach their maximum size.

The fact that the coefficients in Equation 13.29 are not constant in time results in differences from the Rayleigh–Taylor instability for a plane boundary. The coefficient of a is not very different from the case of the plane boundary in the sense that instability is promoted when $\ddot{R} > 0$ while the surface tension and viscosity have stabilizing effects. The primary difference is caused by the $\dot{a}$ term. As the bubble grows, the wavelength on the surface increases, and hence, the growth of the wave amplitude is lessened. The reverse occurs during collapse. It is easily found from Equation 13.29 that the initial acceleration phase of bubble growth in which $\ddot{R} \geq 0$ is unstable with respect to spherical harmonic perturbations of fairly high order, n. However, the remainder of the growth phase during which $\dot{R} > 0$, $\ddot{R} < 0$ is stable with regard to all spherical harmonic perturbations. Therefore, the bubble in the acceleration phase is usually considered to be stable in cavitation experiments. This could be caused either by the briefer acceleration phase or by the greater stabilizing effect of surface tension in smaller bubbles. On the other hand, it is clear from the theory that the bubble may become highly unstable with respect to nonspherical disturbances during stage two because $\ddot{R}$ reaches very large positive values during this rebound phase. The instability appears in several different ways depending on the violence of the collapse and the presence of other boundaries. The instability of the collapsing bubble has been investigated by many researchers (Blake and Gibson, 1987, Tomita and Shima, 1990, Lindau and Lauterborn, 2003). Cavitation bubbles that collapse to a size an order of magnitude smaller than their maximum size inevitably emerge from that collapse as a cloud of smaller bubbles rather than as a single vapor bubble. This fragmentation could be caused by a single micro jet as shown in Figure 13.8 or it could be due to a spherical harmonic disturbance of higher order. The behavior of collapsing bubbles that are filled with a noncondensable gas corresponding with the lower values of $\ddot{R}$ and the instability could be weaker resulting in spherical stability. Thus, acoustically excited cavitation bubbles that contain a substantial amount of gas often remain spherical during their rebound phase. In other instances, the instability is sufficient to cause

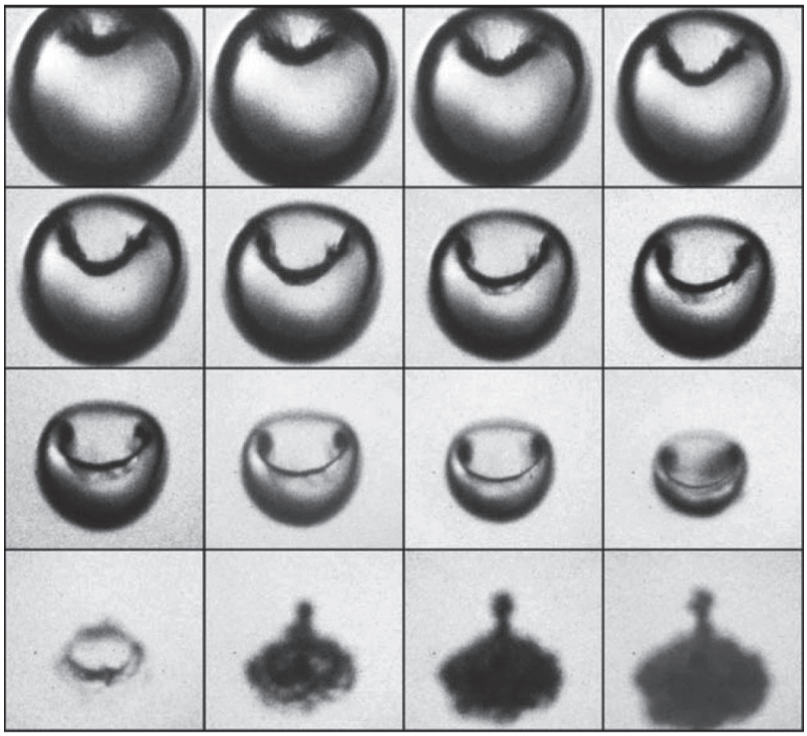

Figure 13.8

Jet and counterjet development at an angle of 45° from above the wall; γ = 2.6 ($\gamma = d/R_{max}$, the distance of the bubble center from the wall at the moment of formation d and the maximum bubble radius R_{max}). Interframe time 1 μs, exposure time 200 ns, R_{max} = 1.5 mm, frame size 1.2 mm × 1.1 mm. (From Lindau, O. and Lauterborn, W., *J. Fluid Mech.*, 479, 327, 2003.)

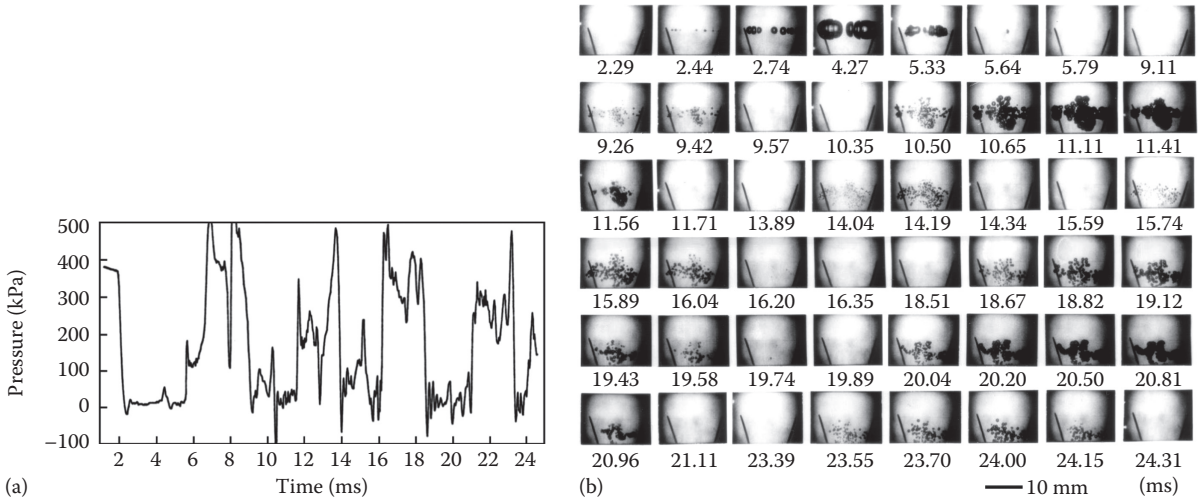

Figure 13.9

Growth and collapse of cavitation bubbles due to decreases and increases in the ambient pressure. The gas content is 2.7 ppm. (a) Pressure in the test section. (b) Snapshots of the cavitation bubbles. (From Matsumoto, Y. and Aoki, M., *Bull. JSME*, 27, 1352–1357, 1984.)

fragmentation. Several examples of fragmented and highly distorted bubbles emerging from the rebound phase are shown in Figure 13.9. The figure shows the dynamic behavior of bubble growth and collapse with the sequential decrease and increase in the surrounding pressure. The first pressure reduction creates cavitation bubbles from a heated thin wire at 2.44 ms, and the bubbles grow under the ambient pressure whose value is almost the same as that of the saturated vapor pressure of the bulk temperature. At 4.27 ms, the pressure increases and the bubbles begin to shrink. Large fluctuations of the pressure are observed due to the interference with the reflected pressure waves from the bubbles and the bottom. Because of nonspherical instability, the bubbles collapse ruggedly into tiny fragments. This creates many small bubbles, and they grow to cavitation bubbles when the ambient pressure decreases at 9.26 ms. With the next intense expansion wave at 10.50 ms, many cavitation bubbles grow from the remaining bubble nuclei, and at 11.11 ms, they are unified into a single bubble whose shape is rugged.

To numerically predict the bubble collapse near a boundary, a boundary integral method based on the potential theory (Blake and Gibson, 1987) has been widely used. This method requires the computational mesh only at the boundary so that the dimension of the problem is reduced. The method has been elaborated to make it possible to predict, for example, the impact due to the formation of the toroidal bubble after jet penetration (Blake et al., 1997) and the role of the heat transfer through the bubble wall (Yuan and Prosperetti, 1997, Yasuda and Takahira, 2003). More recently, owing to the improvement of computational techniques and hardware performance, the finite difference method has also been applied. For instance, Popinet and Zaleski (2002) studied the effect of the viscosity on the jet formation using a front-tracking method, and Johnsen and Colonius (2009) studied the propagation of the shock wave generated at collapse using a shock- and interface-capturing scheme.

13.1.3 Bubble Cloud Dynamics

The cavitating collapse of a bubble cloud generates very high pressure and high temperature. This high pressure reaches 100 MPa–1 GPa in a very short period, and this causes severe erosion, noise, and vibration in hydraulic machines. This high concentration of energy has been utilized recently for biomedical, environmental, and other industrial applications. In particular, the use of microbubbles in high intensity focused ultrasound (HIFU) therapy would enhance the effects of shock wave lithotripsy (Ikeda et al., 2006, Arora et al., 2007) and tissue heating (Coussios and Roy, 2008, Okita et al., 2013).

Many researchers have investigated theoretically and numerically the dynamics of a bubble cloud. There are two approaches: one is to capture the interfacial motion for individual bubble and the other to capture the macroscopic motion of a bubbly mixture using a homogenization technique.

Regarding the former approach, Chahine and Duraiswami (1992) numerically investigated mutual interactions on the dynamics of a multibubble cloud consisting of up to 8 bubbles using a boundary element method (BEM) based on potential theory. They compared their results with analytical results obtained by asymptotic expansions. For the larger systems, Bui et al. (2006) developed a fast algorithm coupled with the BEM, and Wilson et al. (2008) employed a multipole method using surface harmonics. Bremond et al. (2006) described an extended Rayleigh–Plesset equation in consideration of the pressure modification through the surrounding bubbles and made a comparison with the experiments using a patterned surface. Regarding the latter approach, Omta (1987) theoretically and numerically investigated the oscillation and sound emission of a bubble cloud using the averaged equations derived by Biesheuvel and van Wijngaarden (1984). d'Agostino and Brennen (1989) linearized the governing equations for a bubbly mixture together with the Rayleigh–Plesset equation. Shimada et al. (2000) investigated the behavior of cloud cavitation in connection with the cavitation damage using the set of governing equations for the spherical bubble cloud, where the internal phenomena of each bubble and the compressibility of the liquid are taken into account. They concluded that, when the bubble cloud collapses, a very high pressure is emitted from each of the bubbles near the center of the cloud and the variation of the pressure has high frequency.

13.1.3.1 Spherical Bubble Cloud

In this section, the analytical solutions for a spherical bubble cloud are introduced (d'Agostino and Brennen, 1989). The geometry of the spherical cloud is shown in Figure 13.10. The relative motion of the two phases, the mass of the dispersed phase and all the damping mechanisms for the bubble dynamics are neglected, and the liquid is assumed to be inviscid and incompressible. The mass and momentum conservation equations are as follows:

$$\nabla \cdot \mathbf{u} = \frac{\beta}{1+\beta\tau}\frac{D\tau}{Dt} \tag{13.30}$$

$$\rho\frac{D\mathbf{u}}{Dt} = -(1+\beta\tau)\nabla p \tag{13.31}$$

where

β is the number density of bubbles per unit liquid volume
τ is the individual bubble volume
D/Dt indicates the Lagrangian derivative

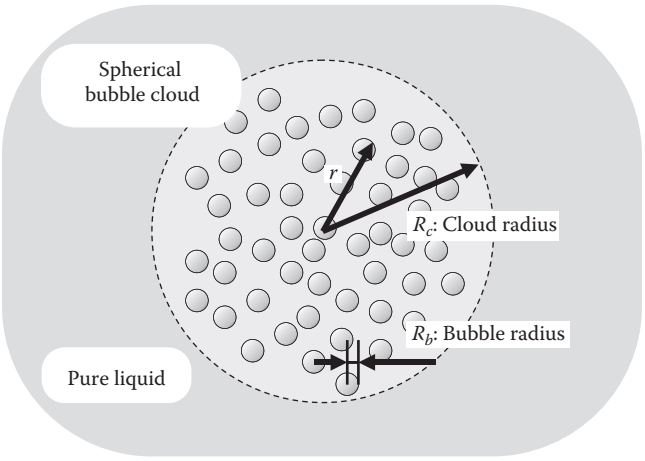

Figure 13.10

Spherical bubble cloud.

The bubble radius, R_b is determined by the Rayleigh–Plesset equation.

$$R_b \frac{D^2 R_b}{Dt^2} + \frac{3}{2}\left(\frac{DR_b}{Dt}\right)^2 = \frac{1}{\rho}\left(p_g + p_v - p - \frac{2\sigma}{R_b}\right) \tag{13.32}$$

where

p_g is the partial pressure of noncondensable gas
p_v is the partial pressure of the vapor
σ is the surface tension

For simplicity, the following assumptions are employed: (1) The bubble cloud is spherical. (2) The mean-flow velocity is purely radial and small. (3) The void fraction is uniform and relatively low inside the cloud. (4) All the bubbles have the same equilibrium radius, R_{b0} (the subscript 0 indicates the unperturbed value). (5) The vapor pressure inside the bubble is constant. (6) The pressure of the noncondensable gas in the bubbles changes isothermally. Let the perturbation of the far-field pressure be defined in the complex plane by the equation: $p_\infty = p_0[1 + \varepsilon \exp(i\omega t)]$ with $\varepsilon \ll 1$. After applying the assumptions and linearizing the Equations 13.30 through 13.32 with the equation $R_b(r,t) = R_{b0}[1 + \varphi(r,t)]$ with $|\varphi(r,t)| \ll 1$, the normalized variation of the bubble radius φ, and the natural frequencies ω_n, are

$$\varphi(r,t) = -\varepsilon \frac{p_0(1-\alpha_0)/\rho R_{b0}^2}{\omega_b^2 - \omega^2}\left(\frac{1}{\cos kR_{c0} - \alpha_0 \sin(kR_{c0})/kR_{c0}}\right)\frac{\sin kr}{kr} e^{i\omega t} \tag{13.33}$$

$$\omega_n^2 = \frac{\omega_b^2}{1 + \left(3\alpha_0(1-\alpha_0)R_{c0}^2/(n-1/2)^2\pi^2 R_{b0}^2\right)} \tag{13.34}$$

$$\omega_b^2 = \frac{3p_{g0}}{\rho R_{b0}^2} - \frac{2\sigma}{\rho R_{b0}^3} \tag{13.35}$$

where,

ω is the frequency of the far-field pressure
ω_b the natural frequency of a single bubble at isothermal conditions
ω_n the natural frequency of the bubble cloud
α the void fraction
R_c the cloud radius
k the wave number in the bubbly flow

The natural frequencies of the spherical bubble cloud will extend to much lower frequencies than that of a single bubble if the initial void fraction, α_0, is much larger than the square of the ratio of bubble size to cloud size $\left(\alpha_0 \gg R_{b0}^2/R_{c0}^2\right)$. Figure 13.11 shows the natural mode shapes of the normalized bubble radius, the pressure, and the bubble concentration per unit liquid volume in the cloud (n = 1–4). The first mode consists of the same phase. Higher modes have n antinodes and $n - 1$ node(s) within the cloud. The envelope is proportional to $1/r$, and the amplitudes at the bubble cloud interface become much smaller in the higher modes.

When the damping effects are included, the attenuation is much greater at the higher frequencies so that the dominant feature of the response is the first mode natural frequency of the cloud. On the other hand, the response at the bubble natural frequency ($n = \infty$) becomes much less significant.

It should be noted that, on the basis of the linearized model (d'Agostino and Brennen, 1989), extended models have been developed. Ando et al. (2011) further developed the model by considering the polydispersity in bubble size and discussed the phase cancellation effect. Grandjean et al. (2012) modelled the void fraction heterogeneities due to the bubble clustering and applied the developed method to predicting the shock wave propagation in bubbly mixture.

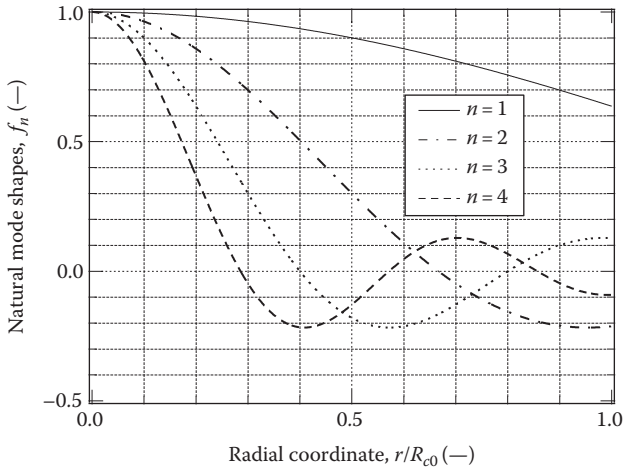

Figure 13.11

Natural mode shapes of the normalized bubble radius, the pressure, and the bubble concentration per unit liquid volume in the cloud (n = 1–4).

13.1.3.2 Spherical Bubble Cloud Model

In the previous section, a theoretical analysis for a spherical bubble cloud was introduced; however, the results are limited to the case in which the volumetric change of the bubbles is very small. In this section, the volumetric change of a spherical bubble cloud is simulated by using the model proposed by Shimada et al. (2000) to illustrate nonlinear response.

13.1.3.2.1 Concept and Assumptions of a Spherical Bubble Cloud Shock waves propagate inside a bubble cloud. Kameda et al. (1996, 1998) clarified that internal phenomena can have a significant influence on shock wave propagation, and in certain cases, the compressibility of the liquid cannot be ignored, depending on the amount of bubble motion. It has been determined that a very high pressure of $O(10^8) \sim O(10^9)$ Pa emerges near the center of the cloud cavitation when it collapses violently. In such a case, the compressibility of the liquid should be taken into account. Therefore, to analyze the collapsing phenomena of a bubble cloud rigorously, the internal phenomena of the individual bubbles and liquid compressibility should be included. Bubbles in the cloud shrink violently so that gases in a bubble cannot be treated as ideal. For simplicity, the ambient temperature rise of the liquid and the mass transfer of noncondensable gases through the bubble wall are not considered. In the numerical simulation, the following assumptions are employed: (1) The bubble cloud and each bubble maintain spherical symmetry as they oscillate. (2) The bubbly liquid inside the cloud is treated as a continuum fluid, whose mass and momentum are assumed to be equal to those of the liquid phase, because the mass in a unit volume of the gas phase is much smaller than that of the liquid phase. (3) Bubbles move with the surrounding liquid. Bubbles are small enough to ignore the slippage between the bubble and the liquid. (4) Coalescence and fragmentation of bubbles in the cloud are ignored. (5) The viscosity of the bubbly mixture is ignored in the cloud because it has little influence on the wave phenomena. (6) The temperature of the liquid in the cloud is constant. (7) The pressure and temperature inside each bubble are uniform except for the thin boundary layer near the bubble wall, compared with the bubble radius. (8) The temperature at the bubble wall is equal to that of the liquid. (9) The mass of the noncondensable gas inside a bubble is constant. (10) Gases inside a bubble obey the van der Waals equation of state. (11) Coalescence and fragmentation of mist inside a bubble are ignored. Then we consider the thermal behavior inside the bubble and the pressure wave phenomena in the bubble cloud, namely, the evaporation and condensation of liquid at the bubble wall, heat transfer through the bubble wall, and the compressibility of the liquid.

The geometry of a spherical bubble cloud is the same as Figure 13.10. A bubble is located at the center of the cloud to avoid a singularity.

13.1.3.2.2 Governing Equations The Keller equation (Keller and Kolodner, 1956) is applied to the equation of motion of the spherical bubble cloud interface (Equation 13.36) to take the compressibility of the surrounding liquid into account.

$$R_c\left(1-\frac{\dot{R}_c}{c}\right)\ddot{R}_c+\frac{3}{2}\left(1-\frac{\dot{R}_c}{3c}\right)\dot{R}_c^2=\frac{1}{\rho_l}\left(1+\frac{\dot{R}_c}{c}+\frac{R_c}{c}\frac{d}{dt}\right)\left(p_w-p_\infty-4\frac{\mu_l}{R_c}\dot{R}_c\right) \tag{13.36}$$

where

R_c is the radius of the bubble cloud
c is the speed of sound in the surrounding liquid
ρ_l is the density of the liquid
p_w is the pressure at the surface of the cloud
p_∞ is the ambient pressure
μ_l is the viscosity of the liquid

In a bubble cloud, the mass and momentum conservation equations of bubbly flow (Equations 13.37 and 13.38) and the conservation equation of the number density of bubbles (Equation 13.39) are also solved. The Tait equation (13.40) is employed as the equation in liquid phase. Thus, the behavior of the bubble cloud is governed by the following set of equations:

$$\frac{\partial(1-\alpha)\rho_l}{\partial t}+\frac{1}{r^2}\frac{\partial}{\partial r}\left\{r^2(1-\alpha)\rho_l u_l\right\}=0 \tag{13.37}$$

$$\frac{\partial(1-\alpha)\rho_l u_l}{\partial t}+\frac{1}{r^2}\frac{\partial}{\partial r}\left\{r^2(1-\alpha)\rho_l {u_l}^2\right\}+\frac{\partial p}{\partial r}=0 \tag{13.38}$$

$$\frac{\partial n_b}{\partial t}+\frac{1}{r^2}\frac{\partial}{\partial r}\left\{r^2 n_b u_b\right\}=0 \tag{13.39}$$

$$\frac{p+B}{p_\infty+B}=\left(\frac{\rho_l}{\rho_{l\infty}}\right)^n \tag{13.40}$$

where

α is the void fraction
u_l is the velocity of the liquid
n_b is the number density of the bubbles

The velocity of a bubble, u_b is assumed to be equal to u_l according to the third assumption. In the Tait equation, B is 304.9 MPa, and n is 7.15 for water.

For each bubble motion, the following phenomena are taken into consideration: the compressibility of the surrounding liquid, the mass and heat transfer through the bubble wall, the evaporation and condensation of the vapor, and mist generation from the vapor inside the bubble (Matsumoto and Beylich, 1985). Equations 13.27 and 13.28 are applied for the dynamic equation for the bubble radius. The energy conservation equation in the gas phase with mist and the nucleation rate equation of mist are also solved.

13.1.3.3 Computational Conditions

In this simulation, the behavior of a spherical bubble cloud, which consists of many microbubbles, is investigated. Such a microbubble cluster may be generated in HIFU applications, which have attracted much attention recently, because they are less invasive than conventional medical treatments. Table 13.3 shows the computational conditions. Acoustic cavitation induced by ultrasound is highly dependent on the ultrasound frequency. In medical applications, a typical frequency of ultrasound is around 0.5–5 MHz. When the ultrasound frequency is 4 MHz, the wavelength is about 0.4 mm in water or tissue. The focal region is considered to be around 2–4 times the wavelength. In this simulation, it is assumed that the region of the bubble cloud

Table 13.3 Computational Conditions

Gas phase	Air
Liquid phase	Water
Initial cloud radius, R_{c0}	0.5 mm
Initial bubble radius, R_{b0}	1 μm
Initial ambient pressure, p_0	101.3 kPa
Initial temperature	293 K
Initial void fraction	0.1%
Amplitude of ambient pressure	10–125 kPa
Frequency of ambient pressure	10 kHz–4 MHz

is 0.5 mm in radius and each bubble radius is 1 μm (the natural frequency is about 4 MHz). The ambient pressure fluctuation is assumed to be a pulse wave, and the frequency of the wave extends from 10 kHz to 4 MHz for amplitudes of 10, 25, 50, 75, 100, and 125 kPa.

13.1.3.4 Frequency Response of a Spherical Bubble Cloud

The bubbles, which are located near the center of the bubble cloud, violently collapse when the bubble cloud oscillates at its resonance frequency. The maximum pressures inside the bubbles and the maximum cloud radii are calculated for various conditions. Figure 13.12 shows the results. The horizontal axis corresponds to the frequency of the ultrasound. The vertical axis corresponds to the maximum pressure inside the bubbles normalized by the amplitude and the maximum cloud radius normalized by the initial radius, respectively.

When the frequency is sufficiently low, around 10 kHz, the normalized maximum pressure is nearly equal to 1. This means that the ultrasound does not focus on the cloud and the attenuation of the bubbly liquid is negligible, corresponding to the long wavelength of the ultrasound. The reason why the normalized maximum pressure inside the bubbles exceeds 1 is the effect of the surface tension. In fact, the normalized maximum pressure in the liquid phase converges to 1 for the same computational conditions. On the other hand, the normalized maximum pressure converges to 0 due to the large attenuation of the bubbly liquid when the frequency is near the natural frequency of a single bubble, which is about 4 MHz. When the frequency range is from approximately 180 to 200 kHz, the bubble cloud resonates and the normalized maximum pressure becomes very high. Furthermore, the normalized pressure becomes higher as the pressure amplitude of the ultrasound becomes greater. The normalized pressure exceeds 2000, which corresponds to 200 MPa, in the case of 100 kPa pressure amplitude at a frequency of 180 kHz. Additionally, in the case of 125 kPa pressure amplitudes, the high pressures appear even for a lower frequency. The maximum pressure exceeds 400 MPa at the frequency range between 50 and 200 kHz. The cloud radius hardly changes in each case. This occurs because the changes of the cloud radius are mainly caused by the volumetric changes of the bubbles in the cloud and the initial void fraction is only 0.1% as shown in Table 13.3.

13.1.3.4.1 Low Pressure Amplitude Cases (Δp = 10 and 25 kPa) The response curves of the maximum pressure in the case of 10 and 25 kPa pressure amplitude are almost the same as those shown in Figure 13.12. Since the cloud shows nearly linear oscillation for these conditions, at first, the ultrasound propagation in these cases is shown. Two different peaks are observed in the response curves of the maximum pressure. One is at 200 kHz and the other is at 600 kHz. Figure 13.13 shows the pressure distributions of the liquid phase over about 0.5 T, at each 0.01 T, where T is the cycle of the ultrasound. The amplitude of the ambient pressure is 10 kPa at a frequency of 200 kHz (left figure) and 600 kHz (right figure). The pressure inside the cloud changes at almost the same phase in the cloud in the 200 kHz case. This is the first resonance mode of a spherical bubble cloud (see Figure 13.11). The first mode frequency is slightly lower than the natural frequency calculated by Equation 13.34 since the damping effects are not considered in that formula. In fact, d'Agostino and Brennen (1989) showed that the natural frequencies become lower when the damping effects are taken into account. In the 600 kHz case, there is one pressure node and the pressure at the center of the cloud is shifted almost π backward from that at the boundary of the cloud. This is the second resonance mode of a spherical bubble cloud (see Figure 13.11). As in the case of the first resonance mode, the frequency is almost the same as the second mode natural frequency (d'Agostino and Brennen, 1989).

13.1.3.4.2 High Pressure Amplitude Cases (Δp = 100 and 125 kPa) When the pressure amplitude becomes greater, the oscillations of the cloud show strong nonlinearity. Figure 13.14 shows the water pressure in the

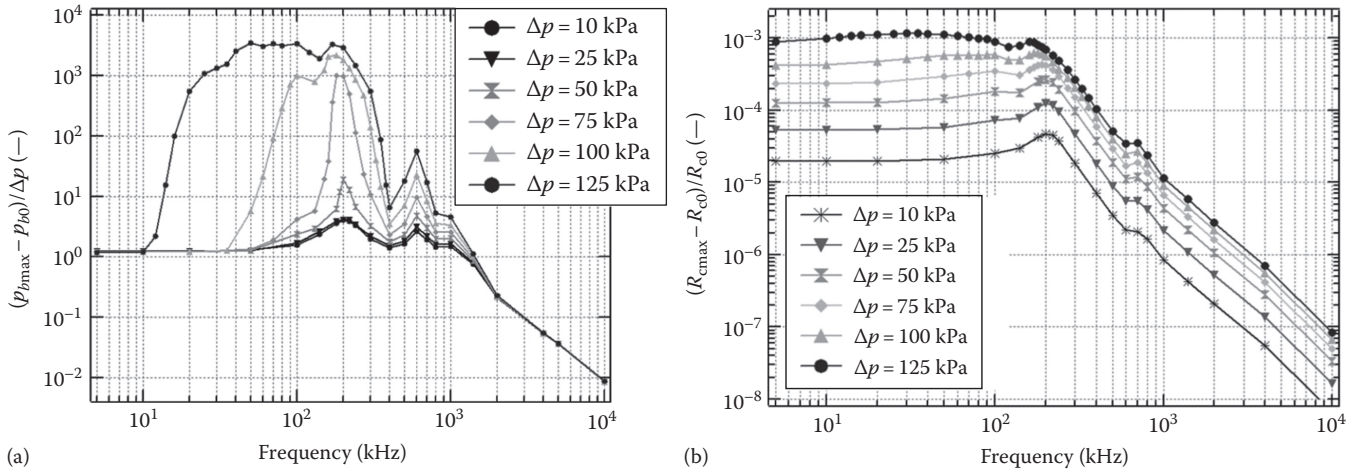

Figure 13.12

Frequency response curves at various amplitudes of the ambient pressure (a: maximum pressure inside the bubbles, b: maximum bubble cloud radius).

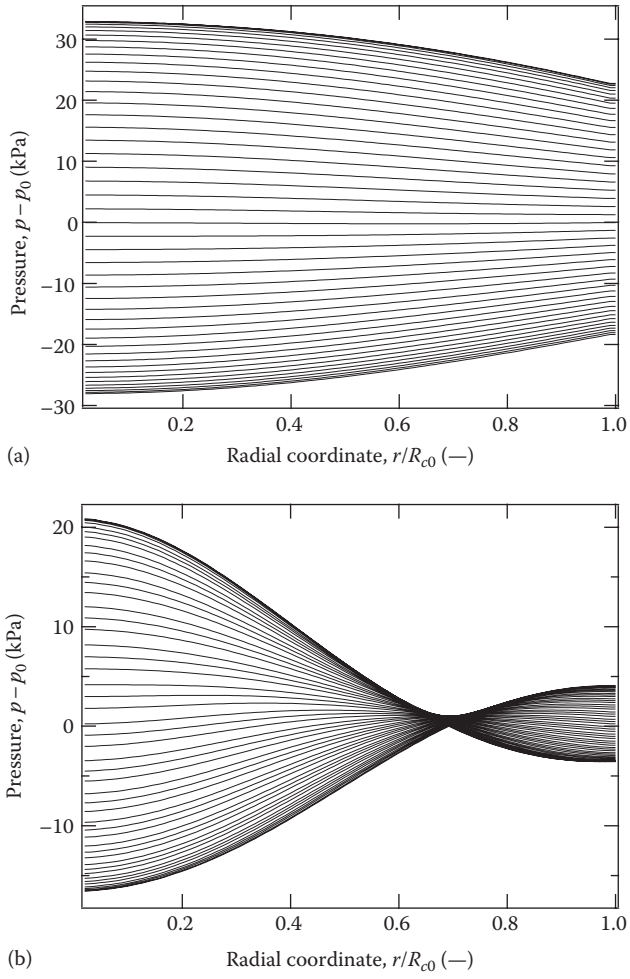

Figure 13.13

Pressure distributions of the liquid phase inside a bubble cloud (a: Δp = 10 kPa, f = 200 kHz, b: Δp = 10 kPa, f = 600 kHz).

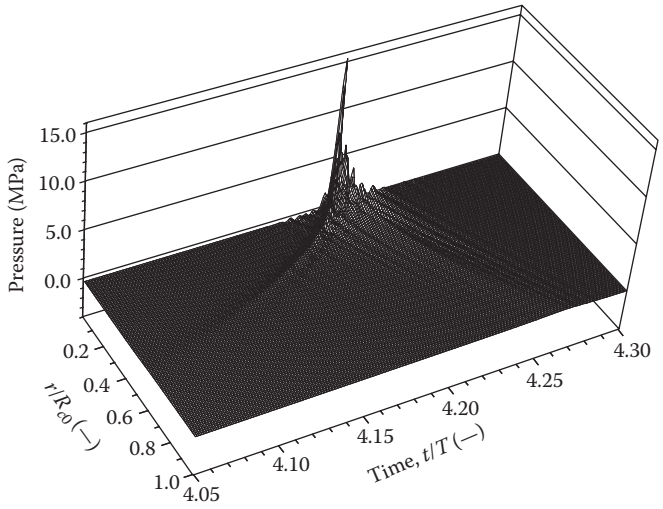

Figure 13.14

Surface plot of the liquid pressure inside a bubble cloud (Δp = 100 kPa, f = 180 kHz).

cloud under the same conditions as the surface plot. The range of the normalized time is from 4.05 T to 4.30 T. In this case, the shock wave is generated inside the cloud by the process of wave focusing. The speed of sound in the bubbly flow strongly depends on the void fraction and is directly dependent on the pressure fluctuations. The sinusoidal pressure wave easily generates the shock wave inside the bubbly liquid. The shock wave in the bubbly liquid causes the collapse of the bubbles so that high energy is concentrated near the center of the cloud. As a result, the normalized pressure becomes much higher when the pressure amplitude becomes significant enough to generate the shock wave. For example, in the case of 100 kPa pressure amplitudes, even when the frequency is much lower, the pressure wave can generate a shock and the high pressures as seen for the 180 kHz case. Additionally, since the high-pressure wave with a high frequency is generated when the bubbles near the center of the cloud collapse, the precursors appear in front of the shock wave before the focusing.

The results indicate that the bubbles inside a bubble cloud violently collapse when the frequency of the irradiated ultrasound is the same or lower than the natural frequency of the cloud for a sufficiently large ultrasound pressure amplitude.

13.2 Cavitation

Steven L. Ceccio

Cavitation is the physical phenomenon associated with the inception, growth, and implosion of cavities (vapor-filled voids or bubbles) in the body of a flowing or a quiescent liquid due to changes in the fluid pressure. Cavitation may occur entirely in the bulk of the liquid or close to solid boundaries of the flow. Cavitation is similar to boiling in the inception and growth of bubbles, except that in the latter bubble formation is due to a rise in liquid temperature, while in the former bubble formation is driven by a drop in the liquid static pressure. Pressure variations in the fluid can be achieved hydrodynamically or acoustically. During vaporous (inertial) cavitation, the cavities are filled mostly with fluid vapor. Vaporous cavitation bubbles are often short-lived and produce a high-intensity acoustic pressure upon collapse. Gaseous cavitation bubbles are filled mostly with noncondensable gases, and these gaseous bubbles may persist for longer periods, collapse much less violently, and produce much less noise and damage compared to vaporous bubbles. Pockets of gas and vapor can form and persist on flowing surfaces, and this is referred to as *partial* or *attached* cavitation. Cavitation *inception* occurs when cavitation is first detected in the flow as the mean pressure in the flow is reduced, and *developed* cavitation describes an advanced stage of cavitation, where the size of the cavity is of comparable magnitude

to a characteristic flow dimension. *Desinence* occurs when cavitation is eliminated through an increase in the mean pressure. Cavitation is undesirable in liquid-handling machinery because it may cause damage to solid surfaces, induce noise and vibrations, and lead to reduction in the mechanical efficiency. Conversely, there are useful scientific and engineering applications that employ cavitation. Comprehensive reviews of this subject can be found in Brennen (1995), Young (1989), and Franc and Michel (2006).

13.2.1 Cavitation Nuclei and Bubble Growth

Liquid water can be brought to evaporation at a constant pressure by raising its temperature. This phase change can also be achieved at a constant temperature by reducing the pressure to the corresponding vapor pressure (e.g., water at 1 atm and room temperature, 25°C, can be brought to boiling by heating to 100°C while keeping the pressure fixed, or by reducing the pressure to vapor pressure, 0.03 atm, while keeping the temperature fixed at 25°C). The process of phase change takes place at a phase boundary in the liquid. If such an interface is not present, the bulk of the liquid can sustain pressures below vapor pressure (or remain liquid at temperatures above the saturation temperature) (Carey, 1992). (See Chapter 3 for a discussion on nucleation and boiling.)

Theoretical predictions based on the van der Waals intermolecular forces of attraction indicate that *pure* water (no dissolved gas or impurities) can withstand high levels of tension corresponding to pressures much less than the vapor pressure (several hundred atmospheres of tension). The fracture of the liquid due to the failure of intermolecular forces is called *homogeneous nucleation*. In most practical applications, these high levels of tension are not approached. Instead, voids or bubbles (cavitation) appear in the liquid as the liquid evaporates at the interface of small gas inclusions or *nuclei*. This process is called *heterogeneous nucleation*, and it is the most common form of cavitation initiation. It is often sufficient to bring the operational pressure to or slightly below the evaporation pressure for these bubbles or voids to appear.

Cavitation nuclei can be present in the body of the liquid or on the surfaces of suspended particles or boundaries that come in contact with it as described in Section 3.1. Cavitation nuclei often exist as small bubbles of gas (a few microns to a few hundred microns) that are in equilibrium with the liquid or as gas-filled miniature pockets on the surfaces of solid particles or solid flow boundaries. Nuclei can also form when dissolved gas in the liquid comes out of solution. The amount and properties of nuclei in the fluid can strongly influence the pressure at which inception occurs. The growth of nuclei can often be approximated by the growth of small spherical bubbles in an unbounded liquid.

The Rayleigh–Plesset equation (Brennen, 1995) describes the dynamics of growth and collapse of a spherical bubble nucleus in an otherwise quiescent, infinite fluid medium. It couples the forces acting on the bubble with the motion of the surrounding fluid:

$$\rho_l\left[a_b\frac{d^2a_b}{dt^2}+\frac{3}{2}\left(\frac{da_b}{dt}\right)^2\right]+\frac{4\mu}{a_b}\frac{da_b}{dt}=\left(p_{\infty,0}-p_v+\frac{2\sigma}{a_{b,0}}\right)\left(\frac{a_{b,0}}{a_b}\right)^{3k}-p_\infty+p_v-\frac{2\sigma}{a_b} \tag{13.41}$$

where the subscript 0 refers to the initial conditions of the bubble. The liquid pressure far away from the bubble is p. The bubble contains both vapor and noncondensable gas of partial pressures, p_v and p_g, respectively. The gas obeys the polytropic gas law. The exponent k is the polytropic gas constant and $k = 1$ for isothermal processes and $k = c_p/c_v$ for adiabatic processes. p_g is equal to the first term on the right-hand side of the equation. In this formulation, the liquid compressibility is neglected (see Section 13.1 for further discussion of bubble physics).

With the left-hand side set to zero, Equation 13.41 describes the quasi-static equilibrium of a bubble (temporal dependence of the bubble radius is negligible). Consider a small bubble (cavitation nucleus) that exists in a quasi-static equilibrium in the body of a liquid. The pressure inside the bubble, p_b, is counteracted by the liquid pressure on the bubble surface, p_l, and by the surface tension forces, or

$$p_g+p_v=\frac{2\sigma}{a_b}+p_l \tag{13.42}$$

where $p_b = p_g + p_v$. When this nucleus experiences a drop in the liquid pressure, such as when it passes through a venturi throat, it may grow quasi-statically from its initial equilibrium radius, $a_{b,0}$, to a larger equilibrium radius, provided that the bubble radius does not exceed the *Blake critical radius*. A bubble exposed to tension will grow unboundedly when its radius is above this critical value given by

$$a_{b,c} = \left[\frac{9km_G T_b K_G}{8\pi\sigma}\right]^{1/2} = \left[\frac{3}{2}\frac{ka_{b,e}^3 p_{g,e}}{\sigma}\right]^{1/2} \tag{13.43}$$

The subscript e refers to the equilibrium state of the bubble. Here, m_G and K_G are the gas mass and gas constant, respectively, and T_b the bubble temperature. An equivalent critical liquid pressure is given by

$$p_{l,c} = p_v - \frac{4}{3}\sigma\left[\frac{8\pi\sigma}{9km_G T_b K_G}\right]^{1/2} = p_v - \frac{4}{3}\sigma a_{b,c} \tag{13.44}$$

In the venturi example, if the liquid pressure drops to or below the critical pressure, the bubble radius will grow explosively to a maximum radius that can be of the order of hundred times its initial size, and the nucleus would then be considered to have cavitated. Figure 13.15a and b shows the response of a nucleus, initially in equilibrium, to a sinusoidal variation in the liquid pressure. Figure 13.15a shows the change in bubble radius when the minimum liquid pressure is above the critical pressure: the bubble radius responds quasi-statically. Next, Figure 13.15b, the tension exceeds the critical pressure. Notice the growth rate of the cavitating nucleus, its violent collapse, and the multiple rebounds. Not all nuclei will lead to cavitation (explosive bubble growth). Only the nuclei that reach the critical radius will cavitate, and these are considered the *active nuclei*.

When a bubble cavitates, its radius will grow asymptotically. Thus, the maximum bubble radius, $a_{b,m}$, is related to the total time that the bubble remains in the region of tension, Δt:

$$a_{b,m} \approx \frac{2}{3}\left(\frac{-p_\infty + p_v}{\rho_l}\right)^{1/2} \Delta t \tag{13.45}$$

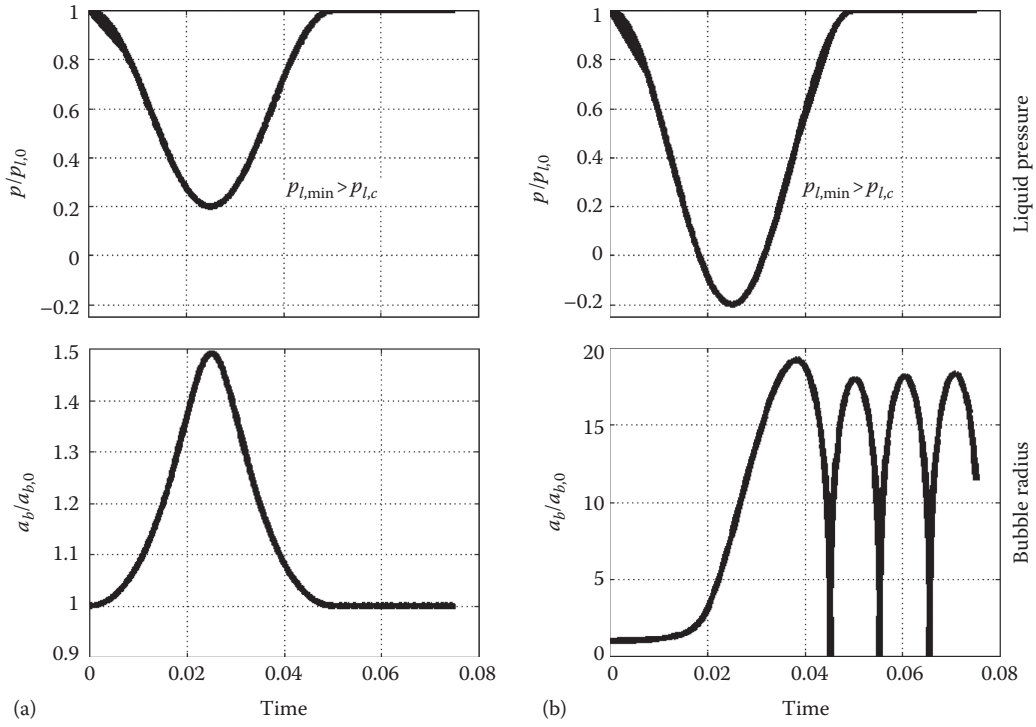

Figure 13.15

Changes in the radius of a bubble as it is exposed to a sinusoidal variation in the surrounding pressure: the minimum pressure is above the critical pressure (a) and below the critical pressure (b).

The nuclei distribution in a flow can be quite variable, depending on the source of the liquid and the upstream flow conditions. Consequently, the characterization of cavitation inception must be accompanied by the measurement of the nuclei content.

Measurement methods for cavitation nuclei can be hydrodynamic, acoustic, or optical (Gindroz and Billet, 1993). Holography and light scattering have been used to detect the presence of cavitation nuclei (Ran and Katz, 1993). In these methods, the optically measured size of detected bubbles is used to infer the critical pressure. The absorption and scattering of acoustic signals is also used to detect and count nuclei (Chahine and Kalumuck, 2003). A direct measurement of the presence of nuclei is achieved when a liquid sample is passed through a region of known low pressure. Nuclei with radii that exceed the critical radius will cavitate. The Blake critical radius is computed from this pressure and presented as the nuclei radius. The event rate of these cavitating bubbles can then be counted by visual observation. Moreover, when a cavitating bubble is convected to a region of higher-pressure downstream, it will collapse producing an acoustic emission. The noise pulses can be detected and counted, giving another independent measurement of the nuclei. Devices that measure nuclei through inducing cavitation events are called *cavitation susceptibility meters* (Ceccio et al., 1991, d'Agostino and Acosta, 1991). The amount of dissolved gas in the liquid will also influence the number of free nuclei and the inception process. Measurements of the total dissolved gas (or of one gas component, such as oxygen) are often reported, but this quantity only indirectly relates to the free gas content.

13.2.2 Collapse of Cavitation Bubbles and Erosion

The collapse of cavitation bubbles is of practical importance because of the associated high potential for damage and noise production. Once a cavitating bubble has reached its maximum radius and encountered a region of higher pressure (either through convection to a high-pressure region or via a change in the mean pressure field), the bubble will start its collapse. During the final stages of bubble implosion, the bubble wall velocity can reach or exceed the liquid speed of sound, and shock waves are produced in the liquid. Liquid compressibility in the vicinity of the bubble cannot be neglected in this instance, and the Rayleigh–Plesset equation (13.41) should be modified to include this effect. One of the existing modifications is the Gilmore equation (Leighton, 1994, Franc et al., 1995) and is given by

$$a_b U \frac{dU}{da_b}\left(1-\frac{U}{c_l}\right)+\frac{3}{2}U^2\left(1-\frac{U}{3c_l}\right)=h\left(1-\frac{U}{c_l}\right)+\frac{a_b U}{c_l}\left(1-\frac{U}{c_l}\right)\frac{dh}{da_b} \tag{13.46}$$

where $U = da_b/dt$, c_l is the liquid speed of sound, and h the enthalpy of the liquid at the bubble wall, with $h = 0$ for the liquid very far away. Whether the bubble wall speed will reach the liquid speed of sound depends on the noncondensable gas mass inside the bubble, which determines the amount of damping of the bubble mechanical energy.

Higher noncondensable gas contents lead to increased damping and result in less violent collapse and reduced possibility for shock pressure production. Experimentally measured values of the pressure levels in the immediate vicinity of spherically collapsing bubbles in water are of the order of hundreds of atmospheres. The intense pressure waves created in the liquid can cause damage to nearby solid surfaces.

A timescale for the bubble collapse is the Rayleigh collapse time, which depicts the time it takes for a vapor-filled spherical bubble to implode from its maximum to its minimum radius, and is given by

$$t_c = 0.915 a_{b,m}\left(\frac{\rho_l}{\Delta p}\right)^{1/2} \tag{13.47}$$

where

$a_{b,m}$ is the maximum bubble radius

Δp is the difference between the liquid static pressure and the vapor pressure

The acoustic emission produced by the collapse of a cavitation bubble is proportional to the mechanical potential energy of the bubble:

$$E_M = \frac{4}{3}\pi a_{b,m}^3 \Delta p \tag{13.48}$$

The collapsing bubble is largely a monopole sound source, with the largest emissions taking place during the rapid volume deceleration and acceleration at the point of minimum bubble volume. The amount of this

energy converted into acoustic energy during bubble collapse is strongly related to the amount of deformation that the bubble undergoes during collapse.

The collapse of the bubble can be influenced by gravity and the presence of free and solid surfaces (Blake and Gibson, 1987). The quantity

$$\gamma = \left(\frac{\rho_l g a_{b,m}}{\Delta p} \right)^{1/2} \tag{13.49}$$

scales the buoyancy force with the force due to the pressure difference across the bubble interface. When $\gamma > 1$, the bubble collapse becomes nonspherical and is characterized by the formation of a jet, where the lower side of the bubble caves inward and upward and penetrates the upper wall of the bubble. A similar jet formation occurs when the bubble collapses near a solid boundary as shown in Figure 13.16. Note that the jet is directed toward the solid surface. Measurements of jet speeds of up to 150 m/s have been observed (Philipp and Lauterborn, 1998, Brujan et al., 2002). The water hammer effect of this jet can induce instantaneous pressures on the surface given by $p_{jet} = \rho_l c_l u_{jet}$, where c_l is the liquid speed of sound and u_{jet} the jet velocity. Jet impact on a nearby solid boundary can lead to very high surface stresses and produce instantaneous pressures on the solid surface exceeding hundreds of bars. These high pressures are capable of inducing surface damage.

Cavitation erosion is caused by the *repetitive* impingement of cavitation-induced pressure pulses on a solid flow boundary and often results from material fatigue. Erosion predictions on metal surfaces have been mostly based on combining the concept of cavitation intensity (frequency of occurrence and levels of peak pressures from collapsing cavities) with one or more representative material properties. Such properties can be the hardness, elastic modulus, tensile strength, or their combinations. An example of such combination is the ultimate resilience, defined as (Hammitt, 1980, Franc, 2009)

$$\text{UR} = \frac{(\text{Tensile strength})^2}{2(\text{Young's modulus})} \tag{13.50}$$

Cavitation intensity depends on the flow conditions and the form of cavitation. Studies on cavitation erosion in metals and alloys often produce scattered results. Erosion measures include mass loss measurements and mean depth of penetration rate (MDPR):

$$\text{MDPR} \sim \rho_l \frac{\eta}{\varepsilon} u^n \tag{13.51}$$

where

η is an energy-transfer efficiency term
ε is related to the material properties
u is the impact speed
n is an exponent

Care should be taken to determine how specific MDPR formulations are derived.

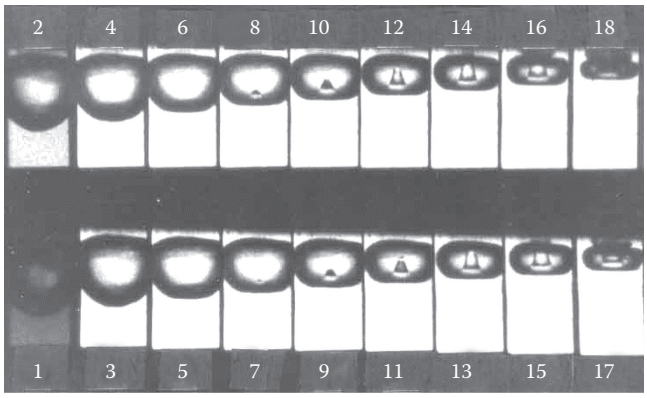

Figure 13.16

A series of images that show the collapse of a cavitation bubble near a solid boundary. The images are with 2 μs time intervals, and each is 1.4 mm wide. Note the formation of the reentrant jet directed toward the wall. (Reproduced from Tomita, Y. and Shima, A., *Acustica*, 71, 161, 1990.)

Despite the scatter in cavitation erosion data, a general trend in erosion behavior can be described as depicted in Figure 13.17 for a ductile metal. There is an *incubation period* (I) before a damage to the surface can be noticed, followed by an *acceleration* of the rate of erosion (II). As the specimen is exposed further to cavitation, the erosion rate will *plateau* (III) for quite some time before it drops, in what is known as the *attenuation phase* (IV). The rate of erosion and the damage properties also depend on the microscopic material structure. For ductile materials that have the potential to store elastically and respond to the

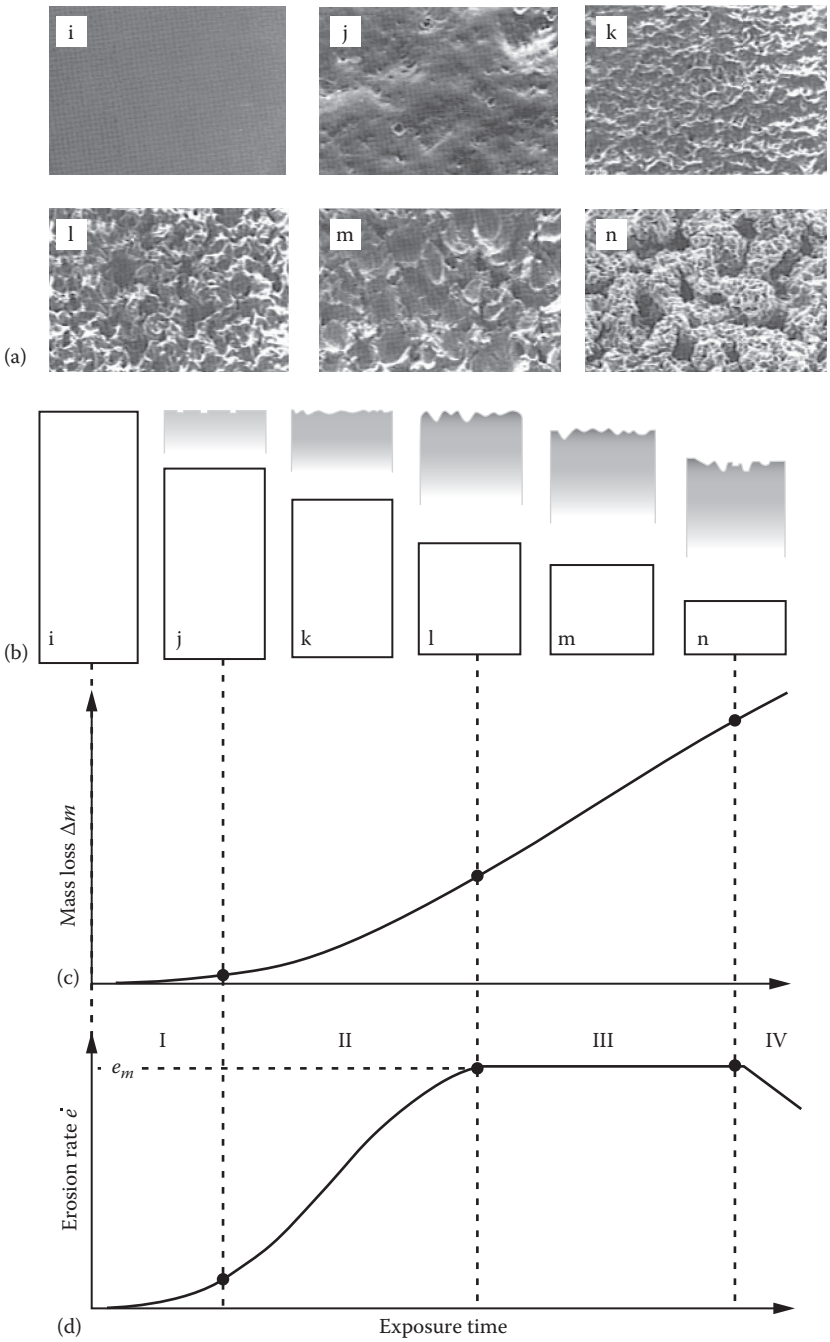

Figure 13.17

Erosion behavior of a ductile alloy with cavitation exposure time: (a) scanning electron microscope images showing the surface appearance; (b) cross-sectional schematics of the pitting behavior; (c) accumulative mass loss; (d) erosion rate showing the four stages of erosion. (From Franc, J.P. et al., *La Cavitation Mecanismes Physiques et Aspects Industriels*, Presses Universitaires de Grenoble, Grenoble, France, 1995. Copyright EDP Sciences, with permission.)

cavitation hammering energy, damage is often due to fragmentation and is in the form of craters. In fragile alloys, erosion often causes cracks and occurs along crystal lines and thus causes more material loss than in ductile metals. And, recent work has extended observations to nonmetallic materials and coatings (Deplancke et al., 2015).

13.2.3 Acoustic Cavitation

Sometimes referred to as vibratory cavitation (low driving frequencies) or ultrasonic cavitation (high driving frequencies), acoustic cavitation describes the growth and collapse of cavitation nuclei due to their exposure to acoustic pressure waves in a liquid (Leighton, 1994). As in many forms of cavitation, the presence of cavitation nuclei is usually required to initiate and sustain the cavitation process. Once the cavitation process is initiated, the collapse of the bubbles and their fragmentation can act as nuclei for new cavitation bubbles. Consider an underwater acoustic horn emitting a sinusoidal pressure signal fluctuating about a mean amplitude. The water will experience compression (high pressure) and rarefaction (low pressure) patterns due to the passage of the wave. If the rarefaction amplitude of the wave drops below the vapor pressure, cavitation can occur. The principle behind the control of acoustic cavitation is the ability to synchronize the acoustic forcing with the dynamics of the bubble in order to achieve the desired effect such as timely bubble growth or collapse. The production of acoustic waves in the liquid can be achieved by magnetostriction type devices or by the more widely used piezoelectric crystal transducers. The electrical input to a piezoelectric element is transformed into displacement of the piezoelectric crystal surface that is then transferred to the liquid in the form of acoustic waves. To achieve acoustic signals of sufficient amplitude for cavitation, acoustic mirrors or acoustic lenses can be used to focus the acoustic energy into a miniature volume. Focusing can also be achieved by using curved emission transducers. The focusing volume is proportional to the emitted acoustic wavelength and inversely proportional to the transducer size.

Pulsed ultrasound refers to the emission of a train of wave packets of fundamental frequency (f_o) and pulse repetition frequency (f). The pulse duration divided by the pulse repetition period ($1/f$) gives the portion of the time that the transducer is actually emitting or the *duty cycle*. Passive acoustic cavitation describes cavitation events induced by the acoustic emissions from other cavitation bubbles.

It can be shown from the Rayleigh–Plesset equation that a bubble acts as spring–damper system. Consider a cavitation nucleus of initial radius (a_o) that is at the focal point of an ultrasonic transducer emitting at a single frequency (f_o) and with peak amplitude P_o. The bubble wall will oscillate under the effect of the forcing acoustic wave, similar to a forced damped oscillator, for *small* bubble oscillation amplitudes. The undamped natural frequency of bubble oscillation in (rad/s) is given by

$$\omega_n = \left(\frac{1}{\rho_l a_{b,e}^2} \left\{ 3k(p_\infty - p_v) + 2(3k-1)\frac{\sigma}{a_{b,e}} \right\} \right)^{1/2} \tag{13.52}$$

The bubble wall motion will be in phase with the forcing pressure if the forcing frequency is less than the bubble natural frequency (resonance). Increasing the forcing frequency above resonance will cause the bubble oscillations to be out of phase with the forcing pressure by 180°. Increasing the driving pressure amplitudes causes the bubble wall motion amplitude to become nonlinear and undergo large volume oscillations, that is, cavitation. The oscillations can be stable (*stable cavitation*) or unstable (*transient cavitation*).

During the growth part of bubble oscillation, the increasing bubble size translates into a drop in the noncondensable gas concentration in the bubble interior below the gas concentration in the liquid. This leads to mass diffusion of the gas from the liquid into the bubble. During the contraction phase of the bubble, the opposite occurs, and gas is diffused from the bubble into the liquid. Due to the larger surface area and thinner concentration boundary layer during the growth phase compared with the contraction phase, there would be a net mass diffusion into the bubble. The overall increase in the gas mass in the bubble interior is called *rectified diffusion* (Blake, 1949, Hsieh and Plesset, 1961). Since the diffusion timescales are usually much larger than the bubble characteristic timescale (Rayleigh time for instance), diffusion can often be neglected. In transient or unstable cavitation, the driving pressure is increased beyond the linear oscillation until the bubble growth becomes unbounded, followed by violent implosion. The bubble may rebound after collapse or it may fragment into multiple fragments. Brennen (2002) suggests that the bubble fission may be due to an instability forming on the bubble wall or due to jet formation. A number of conditions are required for unstable cavitation to occur; one of them satisfies the Blake critical pressure (or radius) threshold.

When the bubble reaches its minimum radius during implosion, the interior pressure and temperature can momentarily reach extremely high levels. Emission of shock waves in the liquid that travel at liquid Mach numbers greater than 1 has been observed (Pecha and Gompf, 2000). Light emission has also been observed from cavitation bubbles collapsing under an ultrasonic pressure field (Holzfuss et al., 1998, Matula et al., 1998, Hilgenfeldt et al., 1999). This phenomenon is known as *sonoluminescence*. Putterman and Weninger (2000) discuss how the high pressures and small minimum bubble volumes during the last stages of collapse result in dramatic increases in the bubble energy density, which is essential for the production of light. The detailed physics of sonoluminescence is still a subject of investigation.

The collapse of cavitation bubbles may cause jet formation and pressure shock waves that have useful noninvasive surgical and lithotriptic effects (Vakil and Everbach, 1993, Coleman et al., 1995, Tran et al., 2003). Ultrasonic cavitation is now commonly used in industrial and electronic component cleaning operations (Niemczewski, 1999, Ferrel and Crum, 2002).

13.2.4 Hydrodynamic Bubble Cavitation

Hydrodynamic cavitation occurs when the flow of a liquid leads to reduction in pressure and cavitation. In these flows, the cavitation number, which is a measure of the level of pressure in the flow, is defined as

$$\sigma = \frac{p_\infty - p_v}{1/2\rho U^2} \tag{13.53}$$

Hydrodynamic bubble cavitation (traveling bubble cavitation) and sheet cavitation (Section 13.2.5) are the two major forms of cavitation that take place on the surface of a hydrofoil or the face of a propeller blade. The operational parameters that give rise to one type or the other can be difficult to predict, and subtle changes in flow conditions (e.g., nuclei content, incident flow angle, boundary layer tripping, or Reynolds number) can lead to the inception or desinence of one or both forms. This underlines the complexity involved in predicting and scaling hydrodynamic cavitation behavior on full-size prototypes from small model tests. The formation of traveling bubble cavitation can lead to significant noise, vibration, and damage if the bubbles collapse on the blade surface.

In traveling bubble cavitation, singly identifiable bubbles can be seen to move in the flow direction while attached to the surface of the blade or hydrofoil. They often have the form of hemispherical caps during the growth phase (Figure 13.18). A closeup examination of traveling bubbles indicates that there is a thin film of liquid separating a bubble from the surface. The dynamics of the boundary layer and its interaction with the bubble have significant impact on cavitation inception, bubble growth, and the consequent cavity collapse (Kuhn de Chizelle et al., 1995).

The growth and collapse of traveling bubbles can be scaled with spherical bubble dynamics for many applications (Ceccio and Brennen, 1991). However, if the bubbles interact with the boundary layer flow, they can be deformed, which reduces the level of noise they emit upon collapse. If many bubbles are present, interaction between the bubbles can become important. These interactions are discussed in Brennen (1995).

13.2.5 Sheet Cavitation

Sheet cavitation occurs when a pocket of gas or vapor forms on a solid surface due to the flow of the liquid (Figure 13.19). Sheet cavitation is often formed when there is wall-flow reversal or boundary layer separation due to an adverse pressure gradient (rising pressure in the flow direction) on the surface. If the cavity

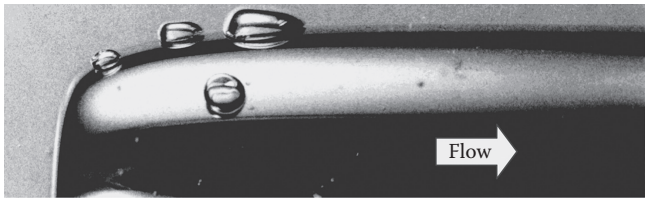

Figure 13.18

Traveling cavitation bubbles over an axisymmetric body of revolution.

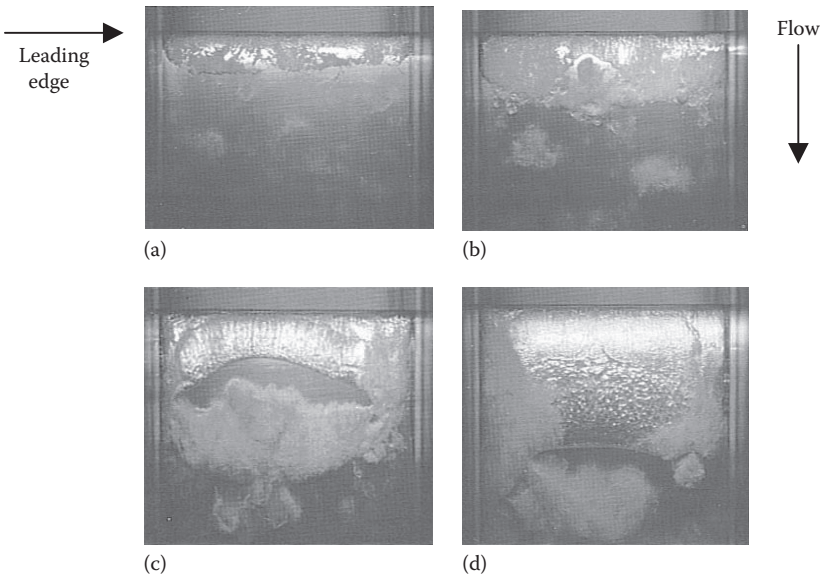

Figure 13.19

Sheet cavitation on a 2D NACA009 hydrofoil: (a) incipient cavitation; (b) developing cavitation; (c) cloud shedding; and (d) cavity refilling.

terminates on the cavitating surface, it is called a *partial cavity*. If the cavity extends beyond the cavitating object into the wake of the flow, it is called a *supercavity*. The shape of the cavity in the detachment region is affected by the type of surface material depending on whether it is hydrophilic or hydrophobic (Leger and Ceccio, 1998). For hydrophilic surfaces, the cavity interface curves downstream forming a forward-facing step, with a recirculation region just upstream. The forward-facing step and the recirculation region are not present on hydrophobic surfaces, and the cavity detachment is close to the boundary layer separation point. Prediction of the cavity detachment point over a given surface can be performed with very good accuracy by invoking the potential flow theory to provide the pressure distribution in the liquid flow. This can then be combined with boundary layer calculations to predict the separation point. Laberteaux and Ceccio (2001a) present such an example.

When a laminar boundary layer separates from the surface, it can become turbulent and reattach to the surface just downstream of the separation point. In this case, the detachment of the sheet cavity is expected to occur in the narrow region between the laminar separation and the turbulent reattachment of the boundary layer, or the "separation bubble". Turbulent boundary layers are more resistant to adverse pressure gradients and separation and can resist the formation of partial cavities. Increased background flow turbulence levels, surface roughness, and surface trips can induce laminar to turbulent boundary layer transition. By artificially tripping the laminar boundary layer on a hydrofoil into turbulence, Arakeri and Acosta (1973) showed that the occurrence of attached cavities could be delayed. Also, if the underlying boundary layer is transitional or turbulent, complex bubble–boundary layer interactions can occur, as shown in Figure 13.20 (Li and Ceccio, 1996).

Franc et al. (1995) map the $\sigma - \alpha$ space of a NACA 16-012 hydrofoil at $Re = 1 \times 10^6$ with relation to the shapes of sheet cavitation occurring on the foil, where α is the angle of attack. For low angles of attack, the laminar boundary layer separation is toward the rear end of the foil, and an attached cavity is formed near the separation point and it extends into the blade wake. Increasing α to a moderate angle of attack leads to the formation of a band of a single hemispherical bubble on the blade surface, which transform with reduction of the cavitation number, σ, into an attached partial cavity terminating on the blade surface. A further reduction in σ forms a supercavity. The interior of partial and supercavities is single-phase vapor (or single-phase gas–vapor mixture). Further increase in the angle of attack α combined with an increase in the cavitation number can cause the attached cavity to become "frothy" or filled with a liquid–vapor mixture, also known as *open* partial cavity. At extreme angles of attack corresponding to stall, the open cavity is not attached to the blade surface anymore except for the leading edge, and cavitation can be noticed in the wake vortices shed in the liquid.

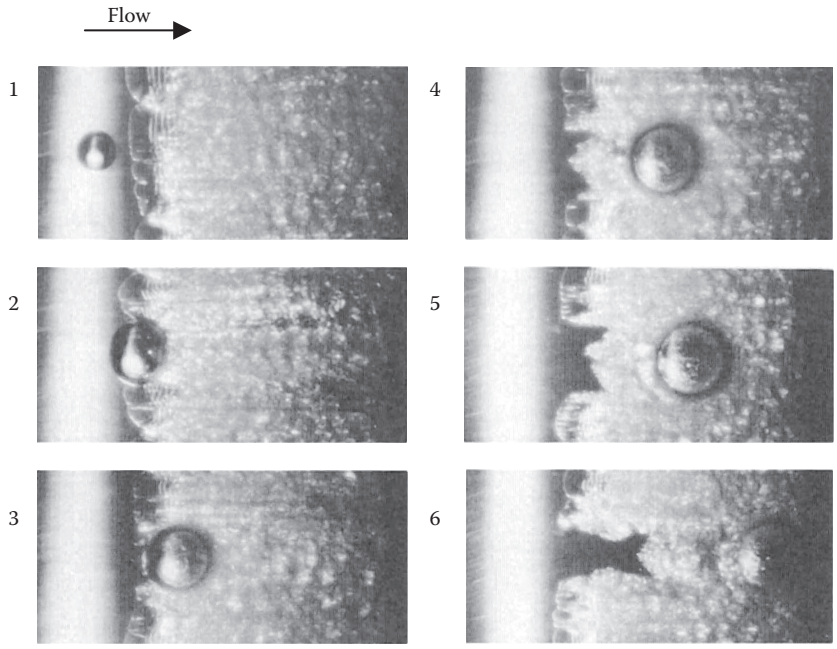

Figure 13.20

Images of several bubbles over a 2D NACA 631A012 hydrofoil. The process of sheet cavity sweeping by the traveling bubble is shown. The bubble does not disturb the cavity, until it has passed downstream, when the sweeping action takes place.

Under certain conditions of Re, σ, and free-stream turbulence levels, a partial cavity can undergo stable or an unstable pulsation. Wade and Acosta (1966) predict that cavities of length, l_c, on a hydrofoil of cord length, c, become unsteady and pulsatile when $(3/4)c < l_c < (4/3)c$. In this pulsatile phenomena, part of the liquid flow that reattaches to the blade surface in the cavity closure region will form a jet that reenters underneath the cavity (jet directed upstream toward the cavity detachment point). When the partial cavity is at its maximum size, the reentrant jet can cause a large portion of the cavity to pinch off and be swept downstream. The bubble cloud will collapse downstream, producing substantial acoustic noise and possible material damage. The small remaining portion of the cavity left attached to the surface will grow smoothly through evaporation and gas diffusion from the liquid to a maximum size, and the cycle repeats. Thick cavities are often unstable and associated with unsteady pulsation. The pulsation phenomena are associated with periodic, strong structural loading, which is undesirable. In stable quasi-steady pulsatile cavities, a Strouhal number (St) can be defined to describe the pulsation:

$$St = \frac{f_p l_c}{U_\infty} \tag{13.54}$$

where

f_p is the pulsation frequency

l_c is the characteristic length

Recent experiments also suggest that the bubbly flows within the sheet cavity can develop condensation shocks that lead to strong cloud shedding (Ganesh et al., 2014).

The Strouhal number for strongly shedding partial cavities is often between 0.2 and 0.4 when l_c is the mean cavity length (George et al., 2000). Laberteaux and Ceccio (2001a,b) studied open partial cavities in detail. They showed that the liquid flow behind the cavity resembled the flow aft of a backward-facing step. The cavities terminated near the point of maximum cavity thickness, and cavitating vortices were shed in the turbulent cavity wake. The collapse of these cavitating vortices is believed to contribute to cavitation damage. The formation of reentrant flow is strongly related to the shape of the cavitating object. Figure 13.21 shows the difference between two cavitating hydrofoils. The first has no spanwise

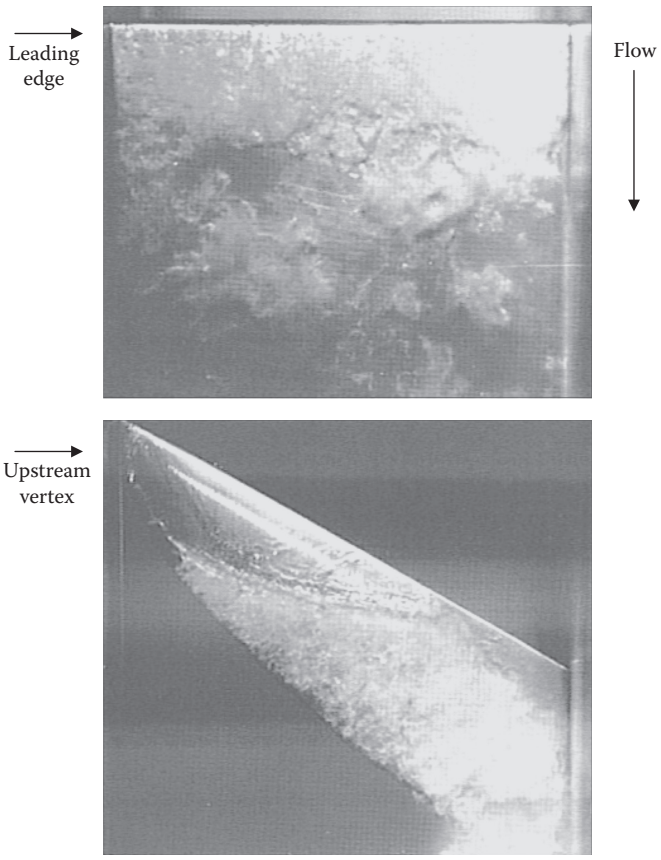

Figure 13.21

Partial cavities on a 2D hydrofoil and on a 3D hydrofoil (swept at 30°). Both hydrofoils have the same section shape.

variation and the second has a swept profile. In the unswept case, the reentrant flow leads to an unstable partial cavity. But the reentrant flow in the swept geometry is deflected in the spanwise direction, producing a stable, closed cavity.

If a partial cavity grows beyond the trailing extent of the cavitating object, it becomes a supercavity. Hydrofoils and propulsors can be designed to form supercavitating on their surface during high-speed operation (Young and Kinnas, 2003). Underwater objects traveling at very high speeds can develop a supercavity that envelope the object, significantly reducing its overall drag (Ceccio, 2010).

13.2.6 Vortex Cavitation

The swirling motion of a vortex requires the presence of a pressure gradient directed away from the center of rotation to counterbalance the centrifugal force. Thus, the pressure in the center of the vortex is lower than the surrounding fluid, and it is possible for the pressure in the core of a liquid vortex to drop below vapor pressure. If nuclei are present in this low-pressure region, they may explosively grow, resulting in *vortex cavitation*. The axial flow inside the vortex core can be slower or faster than the fluid outside the core, which may cause an additional pressure difference. Line vortices often occur near the termination of lifting surfaces, and Figure 13.22 shows developed cavitation occurring in a tip vortex.

The Gaussian vortex, which is a widely used model for concentrated line vortices, is characterized by a zero radial velocity profile and a tangential (azimuthal) velocity profile as a function of radial distance from the vortex center, r, given by

$$u_\theta(r) = \frac{\Gamma_o}{2\pi r}\left(1 - e^{-\eta_l (r/R)^2}\right) \tag{13.55}$$

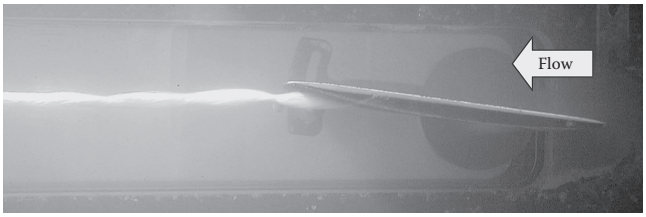

Figure 13.22

Developed tip vortex cavitation from a stationary hydrofoil.

Two parameters are needed to characterize the vortex: its core radius, R, which gives the location of maximum tangential velocity, and its total circulation, Γ_o. The circulation distribution is given by

$$\Gamma(r)=\Gamma_o\left(1-e^{-\eta_l (r/R)^2}\right) \tag{13.56}$$

where $\eta_l = 1.257$ is a constant. The pressure drop at the vortex center is given by

$$p_c = p_\infty - 0.870\rho_1\left(\frac{\Gamma_o}{2\pi R}\right)^2 \tag{13.57}$$

Vortex cavitation is often the first type to appear in hydrodynamic applications. When inception occurs, individual nuclei are captured by the vortex and cavitate. With a further reduction in pressure, the core is filled with a vapor and gas mixture. Based on momentum conservation argument in a Rankine vortex (which has a uniform "top hat" vorticity distribution), Arndt and Keller (1992) predicted the diameter of the vapor-filled region to be 71% of the original liquid vortex core diameter. The inception number is usually *not* equal to the desinence number. This hysteresis pattern is due to the nonlinear bubble dynamics. Vortex cavitation predictions are sensitive to the flow nuclei and dissolved gas content.

The formation of tip vortices results from the pressure difference between the suction side and the pressure side near the tip of a finite-span lifting surface. Prediction of tip vortex cavitation follows the viscous scaling of McCormick (1962). He showed that the tip vortex core radius is scaled with the boundary layer thickness on the blade pressure surface, and this is Reynolds number dependent. In addition, the circulation strength of the tip vortex is related to the lift generated on the lifting surface or the lift coefficient, C_L. Then, the inception cavitation number has the form

$$\sigma_i = KC_L^2 Re^m \tag{13.58}$$

where

K is a scale factor

m is a constant depending on the boundary layer regime (m = 2/5 for a turbulent boundary layer)

In axial pumps and ducted propellers, there is an additional effect due to the confinement gap between the blade tip and the shroud. Other forms of cavitation in concentrated vortices include hub vortex cavitation, which forms on the hub of a propeller or a hydraulic turbine.

Regions of free turbulent shear flow can contain many regions of concentrated vorticity (coherent structures). Shear flow cavitation can form in the high-speed regions of jets, wakes, and separated shear layers. Figure 13.23 shows the cavitating turbulent shear flow associated with a free shear layer. The inception of these flows is often difficult to predict, as it is strongly related to the details of the turbulent flow and nuclei distribution. A recent review of this type of cavitation is found in Arndt (2002).

13.2.7 Cavitation in Hydraulic Machinery

Cavitation can occur in both pumps and turbines. Bubble, sheet, and vortex cavitation have all been observed within these devices, and persistent cavitation can lead to reduction in efficiency, vibration,

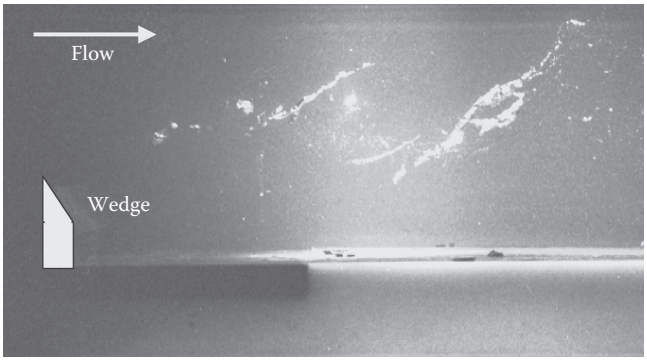

Figure 13.23

Cavitation inception in a turbulent shear flow formed downstream of a wedge.

and erosion damage. The cavitation parameter in hydraulic machinery is usually referred to as the *Sigma Thoma number* and is given by

$$\sigma_T = \frac{H_{sv}}{H} \tag{13.59}$$

where H_{sv} is the net positive suction head (NPSH) and is given by

$$H_{sv} - \frac{1}{g}\left[P_0 - P_v + \frac{1}{2}\rho V_0^2\right] \tag{13.60}$$

with H being the *total head* under which the turbomachinery is operating. If the nondimensional flow rate $Q/2\pi\Omega D^3$ is held constant (analogous to the angle of attack in stationary hydrofoils), then one can write the Thoma number as

$$\sigma_T = \left(\frac{n_s}{S}\right)^{4/3} \tag{13.61}$$

where

$$n_s = \frac{\Omega Q^{1/2}}{(gH)^{3/4}} \tag{13.62}$$

and

$$S = \frac{\Omega Q^{1/2}}{(gH_{sv})^{3/4}} \tag{13.63}$$

where

n_s is the specific speed, while S is the suction specific speed
D is the impeller eye diameter (in m)
Ω is the rotational speed (in rad/s)
Q is the flow rate (in m^3/s)
H and H_{sv} are (in m)

The inlet of a pump or the exit of a turbine are regions of reduced pressure and increased potential for cavitation. Radial flow machines have relatively low specific speeds (high heads and low throughput), and axial machines usually possess high specific speeds (low heads and high throughputs). Knapp et al. (1970) suggest that the flow

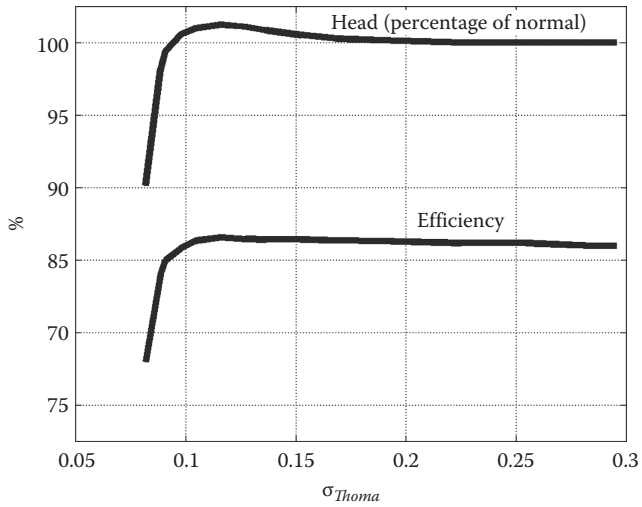

Figure 13.24

Typical pump performance curves at a constant flow rate as a function of the Thoma cavitation number.

in radial machines be treated as flow in passages for cavitation studies, while axial flow machines can be geometrically developed, such that the flow is treated as that over cascade of hydrofoils. They also point out common factors and regions of increased cavitation potential in turbomachinery such as surface discontinuities, junctions between surfaces, gaps, unsteady flows and recirculating regions, and surface roughness effects.

The cavitation performance of turbomachinery is often presented as a plot of specific performance (e.g., specific head rise or specific power output) versus Thoma number. As the Thoma number is decreased to the *inception Thoma number*, cavitation appears, but the performance of the turbomachinery may be only slightly affected. With decreasing Thoma number, cavitation becomes more developed, and the performance of the device will degrade. The *critical Thoma number* is reached when the performance is reduced by a defined fraction from the noncavitating case (e.g., 3%). Further reductions will lead to significant degradation of performance as the *breakdown Thoma number* is reached. Figure 13.24 shows the trends of typical pump performance curves versus the Thoma number.

For marine propellers, the related cavitation number, σ, depends on the advance coefficient $J = U_\infty/(2\pi\Omega D)$ (analogous to the angle of attack in stationary hydrofoils), the thrust coefficient $K_T = T/\rho_l(2\pi\Omega)^2D^4$, and the torque coefficient $K_T = Q/\rho_l(2\pi\Omega)^2D^5$, where T is the thrust and Q the torque.

The degree to which cavitation is developed in turbomachinery can affect various parameters of the device. Incipient cavitation has the possibility of intermittent noise production. In partially developed cavitation, noise, structural vibrations, and damage to surfaces can occur. For fully developed cavitation, where the volume of the cavities becomes significant, mechanical efficiency degradation, head loss, and damage are expected. Figure 13.25 shows vortex, sheet, and cloud cavitation on a model of a marine propeller.

Cavitation is a serious problem in hydraulic systems such as valves because of the potential for damage and vibration (Johnston et al., 1991, Jozsa et al., 1994, Porteiro et al., 1997, Carlson, 2001). Cavitation damage (pitting) has been observed in the liners of diesel engines due to vibratory excitation of nuclei in the liquid (Zhou et al., 1982).

Cavitation can also occur in injector nozzles and fuel pumps in automotive applications. In fuel injection systems, as in diesel engines where the fuel speed is in excess of a 100 m/s, cavitation can occur and cause flow disturbances that can improve the atomization of the injected fuel (Badock et al., 1999, Eisfeld, 2002, Yuan and Schnerr, 2003, Payri et al., 2004).

13.2.8 Cavitation in Biomedical Applications

In contrast with industrial and naval applications where cavitation is most often undesirable because of its erosion potential, the same damaging effects of collapsing bubbles have been implemented as a tool in biomedical applications, namely, surgery and lithotripsy. For example, pulsed ultrasound can be focused with precision on kidney or gall stones. An initial high-intensity pulse is often applied to generate cavitation nuclei and then followed by less intense pulses to drive the bubble nuclei into transient cavitation, that is,

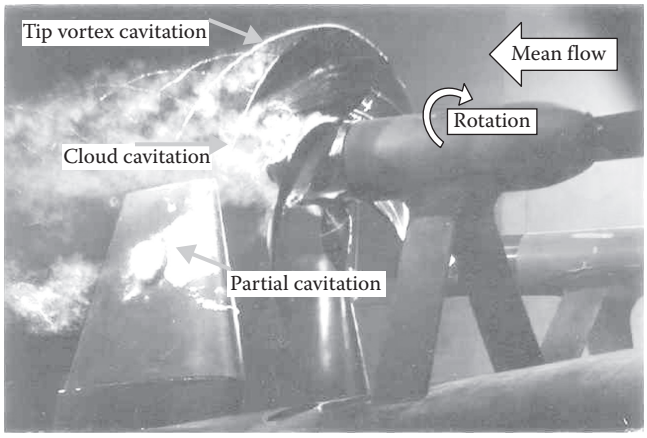

Figure 13.25

Tip vortex cavitation, cloud cavitation, and partial attached cavitation on a model of a marine propeller. (Courtesy of Dr. Y.T. Shen, Naval Surface Warfare Center-Carderock Division, Potomac, MD.)

explosive bubble growth and violent implosion that lead to stone damage. The *in vivo* bubble dynamics are often quite complex. Clouds of bubbles are often created, and the bubble dynamics in these clouds are harder to predict than single bubble dynamics. For instance, the speed of sound in the cloud can be lower than the speed of sound in the liquid alone, and thus, shock wave formation is more likely to occur. The shock can focus in the center of the cloud, leading to an improved lithotriptic effect over single bubble collapse (Brennen, 2003). Ultrasonic focusing can also be used in noninvasive surgery for pulverizing cancer tumors (*necrosis*). Bubble clouds often occur at the focal point. The cloud can backscatter the incoming acoustic pulses, causing increased absorption in the region upstream of the focal point, thus leading to the growth of the lesion (incised tissue) in a direction opposite to the incoming ultrasonic wave. This unintended effect and the resulting pulverization of blood and tissue into a paste have been observed to arrest bleeding in internal organs (*hemostasis*). Jet formation due to cavitation collapse is believed to puncture cell walls and improve drug delivery or allow targeted drug delivery to certain areas such as tumors. Bailey et al. (2003) provide a review of ultrasound in therapy.

Analogous to ultrasound focusing, very short pulses (pico- to nanoseconds) of infrared laser beams from Q-switched YAG (*Yttrium Aluminum Garnet*) or Ruby lasers are focused in laser-eye-surgery procedures into the intended area of the cornea to induce noninvasive, precise surgical effect. A vaporous cavitation bubble grows explosively at the laser focal volume, collapses violently, and generates a shock wave in what is known as optical cavitation, thus producing the surgical effect (Vogel et al., 1986). Additionally, microbubbles are used as contrast agents in ultrasonic imaging. Microbubbles existing in the area under investigation are excited by ultrasonic emissions from an emitting transducer. In response, the bubble volume will oscillate, and the acoustic emissions from the oscillatory motion of the bubble can then be picked by a receiving transducer.

13.2.9 Other Occurrences and Applications of Cavitation

The high pressures and temperatures associated with the collapse of cavitation bubbles have been used to initiate chemical reactions in a process known as *sonochemistry* (Riesz et al., 1990, Suslick, 1997, Beckett and Hua, 2001). These same extreme pressures and temperatures have also been exploited for environmental water purification (*aquasonolysis*) (Madge and Jensen, 2002, Lifka et al., 2003). The formation of radicals upon bubble collapse accelerates the degradation of contaminants through oxidization. Additionally, the shearing effect due to bubble oscillations can break up long-chain molecules. The production of cavitation bubbles near a metal surface can be used to mechanically work the surface in a process known as "shot-less peening." Cavitating jets can be used for this purpose (Soyama and Asahara, 1999).

Last, cavitation can occur in natural processes, for example, when the knuckles are cracked with a popping sound. Head trauma has been associated with cavitation when there is a sudden impact of the cranium (Goldsmith, 2001). *Alpheus heterochaelis* (the "snapping shrimp") uses sound produced by a cavitating jet to stun nearby prey (Versluis et al., 2000). Also, the maximum height of trees may be limited by cavitation during the transpiration of water (Koch et al., 2004).

Nomenclature

Latin

a	Radius
A	Hamaker constant
B	Impact factor
B_e	Transfer number
c_l	Speed of sound in liquid
c_p	Specific heat at constant pressure
Ca	Capillary number
C_D	Drag coefficient
C_L	Lift coefficient
D	Diffusion coefficient
D_j	Jet diameter
e	Specific energy, coefficient of restitution
E	Young's modulus, activation energy
$\dot{E}$	Erosion rate
E_M	Mechanical potential energy
f_p	Pulsation frequency
Fr	Froude number
F	Force vector
g	Acceleration due to gravity
G	Relative velocity vector
h	Enthalpy
h_{fg}	Latent heat of evaporation
H	Total head, hardness
H_{sv}	Net positive suction head
I	Moment of inertia
j_i	Diffusive flux
J	Impulsive force
k	Ratio of specific heats, Boltzmann's constant, spring constant, turbulence energy
k_g	Conductive heat transfer coefficient
K_G	Gas constant
L	Latent heat
m	Molecular unit mass, mass
m_G	Gas mass
M	Mass of abrasive particles
$\dot{M}_V$	Mass flux due to phase change
n	Number density
n	Normal unit vector
N_s	Specific speed
Nu	Nusselt number
Oh	Ohnesorge number
p	Pressure, erosion surface flow stress
q	Charge
q_R	Radiation heat transfer
Q	Volumetric flow rate
r	Radius
$\mathfrak{R}$	Gas constant
R_b	Rayleigh–Plesset bubble radius
R_c	Bubble cloud initial radius
Re	Reynolds number
St	Strouhal number
t	Time
t_c	Collapse time
T	Temperature

u Impact speed
u, v Velocity vector
v_s Solids velocity
W Volume of target material
W_i Molecular weight of species "i"
We Weber number
Y_i Mass fraction of species "i"

Greek Symbols

α Accommodation coefficient, angle of impingement
β Bubble number density
Γ Circulation
δ_n Overlap distance
ε Volume fraction, dissipation rate
ε_o Dielectric constant

14.1 Particle Interactions and Collisions

Yutaka Tsuji

With respect to the particle–particle interactions in multiphase flow dynamics, two phenomena are identified: one is collision and the other is contact. From the viewpoint of physics, collision and contact do not differ much. Collision is merely contact with a short-time duration. However, the approach of modeling is different for each. For collision or contact, two models are normally used: the hard particle model and the soft particle model.

The hard particle model is easy to use but applicable only to the binary collision. The relation between the pre- and postcollision velocities is given explicitly using the coefficient of restitution and friction coefficient. When the particulate phase is dispersed, it is sufficient to consider only simple binary collisions and not multiple collisions.

In the soft particle model, the whole process of collision or contact is solved by the numerical integration of the equations of motion. The computation time is much longer in the soft particle model than in the hard particle model, but the applicability of the soft particle model is wider than the hard particle model. Another important issue is the erosion associated with particle–wall contact. Particle impacting a wall can remove material, the amount depending on the impact velocity, the approach angle, and the properties of the material. Particle deposition and erosion is treated in Chapter 19.

14.1.1 Particle–Particle Interaction

In general, particle–particle collisions are negligible in dilute gas–particulate flows. While this is true in most cases, whether particle–particle collision should be considered or not depend not only on the particle concentration but also on the velocity fluctuation or relative velocity between individual particles. If all the particles move at the same velocity, particles do not collide no matter how high the concentration is. On the other hand, studies (Yamamoto et al., 2001) have shown that the particle–particle collision should not be neglected at volume fractions greater than 10^{-4}, which has been regarded to be sufficiently dilute. Dense and dilute flows are discussed in Section 1.4.5.

When particles collide, they lose kinetic energy due to the inelastic property of the particle material. The case of two spheres (1 and 2) shown in Figure 14.1 is considered here. Section 14.1.1.1 describes the hard sphere model, and Section 14.1.1.2 describes the soft sphere model.

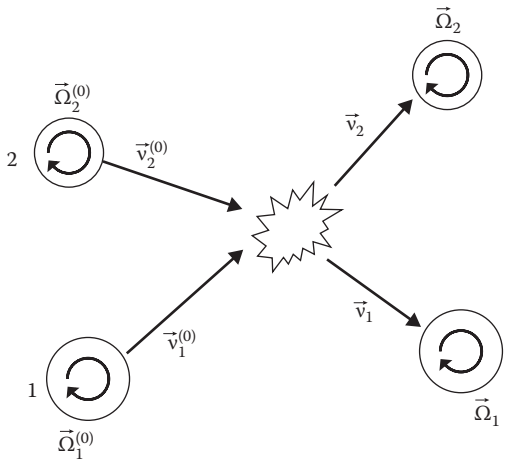

Figure 14.1

Particles colliding.

14.1.1.1 Hard Sphere Model

The hard sphere model is based on the impulsive force, which is defined by integral of the force acting on a particle versus time. If the particles are assumed to be rigid spheres, the impulsive equations are given as follows:

$$m_1\left(\vec{v}_1 - \vec{v}_1^{(0)}\right) = \vec{J} \tag{14.1}$$

$$m_2\left(\vec{v}_2 - \vec{v}_2^{(0)}\right) = -\vec{J} \tag{14.2}$$

$$I_1\left(\vec{\Omega}_1 - \vec{\Omega}_1^{(0)}\right) = a_1\vec{n} \times \vec{J} \tag{14.3}$$

$$I_2\left(\vec{\Omega}_2 - \vec{\Omega}_2^{(0)}\right) = a_2\vec{n} \times \vec{J} \tag{14.4}$$

where

$\vec{n}$ is the normal unit vector directed from particle 1 to particle 2 at the moment of contact
$\vec{J}$ is the impulsive force exerted on particle 1, which acts on particle 2 as the reaction
Subscripts 1 and 2 refer to the two particles
Superscript (0) signifies the values before collision
I is the moment of inertia given by $I = (2/5)ma^2$

In the equations given earlier, the particle mass m, size (radius = a), velocities before collision $\vec{v}^{(0)}$, and positions before collision are given. The unknown variables are the impulsive force $\vec{J}$ and the postcollision velocities $\vec{v}$. The equations given earlier can be solved analytically with some assumptions. The results are shown in Table 14.1. The derivation of the solutions is described by Crowe et al. (2012, pp. 120–124).

14.1.1.2 Soft Sphere Model

14.1.1.2.1 Modeling The basic concept of the soft sphere model is the same as the damping vibration shown in Figure 14.2. The motion of the body with mass m is given by the following differential equation:

$$m\ddot{x} + \eta\dot{x} + kx = 0 \tag{14.5}$$

where

x is the distance from the equilibrium position of the mass
η is the damping coefficient of the dashpot
k is the stiffness of the spring

Table 14.1 Relation between Particle Velocities before and after Collision

	$\frac{\vec{n}\cdot\vec{G}^{(0)}}{\lvert\vec{G}_{ct}^{(0)}\rvert} < \left(\frac{2}{7}\right)\frac{1}{f(1+e)}$	$\frac{\vec{n}\cdot\vec{G}^{(0)}}{\lvert\vec{G}_{ct}^{(0)}\rvert} > \left(\frac{2}{7}\right)\frac{1}{f(1+e)}$
Translation velocity	$\vec{v}_1 = \vec{v}_1^{(0)} - (\vec{n} - f\vec{t})(\vec{n}\cdot\vec{G}^{(0)})(1+e)\frac{m_2}{m_1+m_2}$	$\vec{v}_1 = \vec{v}_1^{(0)} - \left\{(1+e)(\vec{n}\cdot\vec{G}^{(0)})\vec{n} + \frac{2}{7}\lvert\vec{G}_{ct}^{(0)}\rvert\vec{t}\right\}\frac{m_2}{m_1+m_2}$
	$\vec{v}_2 = \vec{v}_2^{(0)} + (\vec{n} - f\vec{t})(\vec{n}\cdot\vec{G}^{(0)})(1+e)\frac{m_1}{m_1+m_2}$	$\vec{v}_2 = \vec{v}_2^{(0)} + \left\{(1+e)(\vec{n}\cdot\vec{G}^{(0)})\vec{n} + \frac{2}{7}\lvert\vec{G}_{ct}^{(0)}\rvert\vec{t}\right\}\frac{m_1}{m_1+m_2}$
Angular velocity	$\vec{\Omega}_1 = \vec{\Omega}_1^{(0)} + \left(\frac{5}{2a_1}\right)\left(\vec{n}\cdot\vec{G}^{(0)}\right)\left(\vec{n}\times\vec{t}\right)f\left(1+e\right)\frac{m_2}{m_1+m_2}$	$\vec{\Omega}_1 = \vec{\Omega}_1^{(0)} - \frac{5}{7a_1}\lvert\vec{G}_{ct}^{(0)}\rvert(\vec{n}\times\vec{t})\frac{m_2}{m_1+m_2}$
	$\vec{\Omega}_2 = \vec{\Omega}_2^{(0)} + \left(\frac{5}{2a_2}\right)\left(\vec{n}\cdot\vec{G}^{(0)}\right)\left(\vec{n}\times\vec{t}\right)f\left(1+e\right)\frac{m_2}{m_1+m_2}$	$\vec{\Omega}_2 = \vec{\Omega}_2^{(0)} - \frac{5}{7a_2}\lvert\vec{G}_{ct}^{(0)}\rvert(\vec{n}\times\vec{t})\frac{m_1}{m_1+m_2}$

e, coefficient of restitution.

f, the Coulomb friction coefficient.

$\vec{G}^{(0)} = \vec{v}_1^{(0)} - \vec{v}_2^{(0)}$, relative velocity of particle centers before collision.

$\vec{G}_c^{(0)} = \vec{G}^{(0)} + a_1\Omega_1^{(0)}\times\vec{n} + a_2\Omega_2^{(0)}\times\vec{n}$, relative velocity of the contact point before collision.

$\vec{t} = \frac{\vec{G}_{ct}^{(0)}}{\lvert\vec{G}_{ct}^{(0)}\rvert}$, unit vector of the tangential direction.

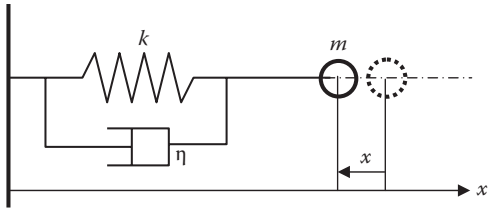

Figure 14.2

Damping vibration.

In the previous equation, the relationship between the force and the displacement is assumed to be linear. The kinetic energy is lost in the dashpot. The work by the dashpot is proportional to the velocity of the mass. There are three modes of motion of the mass depending on the parameters: underdamping, overdamping, and critical damping modes.

In the soft sphere model, the same mechanism is assumed for the particle–particle interaction. Figure 14.3 shows that particle i approaches particle j under the influence of inertia and/or external forces. Particle i at the moment of contact is shown by the dotted line, and the two particles contact at the point C. In the next moment, the contact forces occur between the two particles. Actually, the particles should deform and the

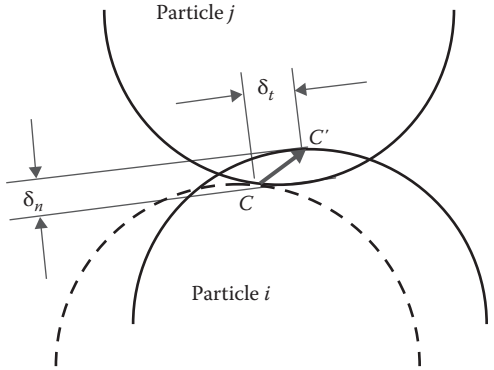

Figure 14.3

Two particles contacting.

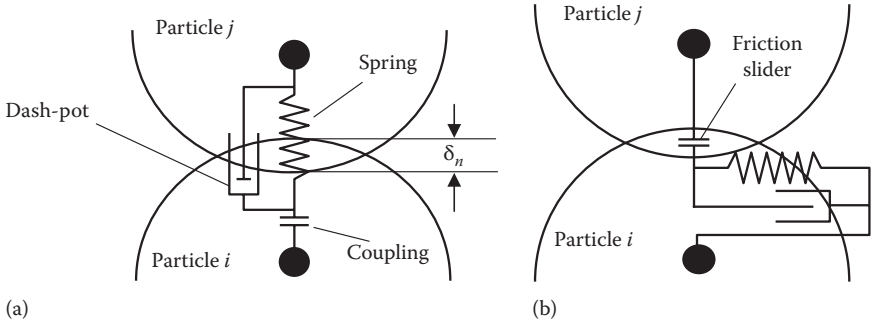

Figure 14.4

Soft sphere model: (a) Normal force. (b) Tangential force.

contact forces could be functions of deformation. In the soft sphere model, the two particles approaching with a relative velocity are made to overlap without changing their shapes. The overlap distance δ is made to correspond to the deformation of the particles. The larger the overlap distance, the larger is the contact force.

A model based on the damping vibration is convenient to express the contact force. Thus, a spring, a dashpot, and other mechanical components are set between particle *i* and particle *j*, as shown in Figure 14.4, where Figure 14.4a corresponds to the case of the normal force and Figure 14.4b to the case of the tangential force. The coupler shown in Figure 14.4a connects the two particles when they are in contact but allows the particles to separate under the influence of repulsive forces. The tangential force is modeled by a spring and dashpot in the same way as the normal force, as shown in Figure 14.4b. If the tangential force exceeds the yield stress, the two particles slide under the application of a normal force and a friction force results. To express this friction force, a friction slider is set in Figure 14.4b. This model for contact forces was proposed by Cundall and Stack (1978). With the soft sphere model, not only can the relationship between pre- and postcollision velocities be obtained but also the forces acting on spheres during contact.

With the hard sphere model, the postcollision velocities are given as functions of precollision velocities and other parameters such as the coefficient of restitution and friction coefficient. The soft sphere model starts with the differential equations. Therefore, variations of momentum and displacement are obtained for arbitrary times as solutions of the differential equations.

The effects of these mechanical components on particle motion appear through the following parameters: stiffness, *k*; damping coefficient, η; and friction coefficient, *f*.

The normal component of the contact force, F_{nij}, acting on particle *i* is given by the sum of the forces due to the spring and the dashpot. If the particles are assumed to be 2D disks, the effect of the spring is linear against the overlap distance and the force F_{nij} is expressed by

$$\vec{F}_{nij} = (-k_n \delta_n - \eta_{nj} \vec{G} \cdot \vec{n}) \vec{n} \tag{14.6}$$

where

δ_n is the overlap distance (displacement of particle caused by the normal force)
$\vec{G}$ is the velocity vector of particle *i* relative to particle *j* ($\vec{G} = \vec{v}_i - \vec{v}_j$)
$\vec{n}$ is the unit vector drawn from the center of particle *i* to that of particle *j*

According to Hertzian contact theory, the normal force varies to the 3/2 power of the displacement in the case of 3D spheres, and therefore, the force F_{nij} acting on particle *i* regarded as a sphere is expressed by

$$\vec{F}_{nij} = (-k_n \delta_n^{3/2} - \eta_{nj} \vec{G} \cdot \vec{n}) \vec{n} \tag{14.7}$$

The tangential component of the contact force, $\vec{F}_{tij}$, is given by

$$\vec{F}_{tij} = -k_t \vec{\delta}_t - \eta_{tj} \vec{G}_{ct} \tag{14.8}$$

where

k_t and η_{tij} are, respectively, the stiffness and damping coefficient in the tangential direction

$\vec{G}_{ct}$ is the slip velocity of the contact point, given by

$$\vec{G}_{ct} = \vec{G} - (\vec{G} \cdot \vec{n})\vec{n} + a_i \vec{\Omega}_i \times \vec{n} + a_j \vec{\Omega}_j \times \vec{n} \tag{14.9}$$

where a_i and a_j are the radii of particle i and particle j, respectively.

Note that the tangential displacement $\vec{\delta}_t$ is a vector and its direction is not equal to the slip velocity vector $\vec{G}_{ct}$ in 3D motion in general. If the following relation

$$\left|\vec{F}_{tij}\right| > f\left|\vec{F}_{nij}\right| \tag{14.10}$$

is satisfied, particle i slides and the tangential force is given by

$$\vec{F}_{tij} = -f\left|\vec{F}_{nij}\right|\vec{t} \tag{14.11}$$

instead of Equation 14.8. Equation 14.11 is the Coulomb-type friction law. The friction coefficient f is measurable and regarded as a parameter that can be given empirically. The vector $\vec{t}$ in Equation 14.11 is the unit vector defined by

$$\vec{t} = \frac{\vec{G}_{ct}}{\left|\vec{G}_{ct}\right|} \tag{14.12}$$

In general, several particles are in contact with particle i at the same time as shown in Figure 14.5. Therefore, the total force and torque acting on particle i are obtained by taking the sum of the forces mentioned earlier with respect to j:

$$\vec{F}_i = \sum_j \left(\vec{F}_{nij} + \vec{F}_{tij}\right) \tag{14.13}$$

$$\vec{T}_i = \sum_j \left(a\vec{n} \times \vec{F}_{tij}\right) \tag{14.14}$$

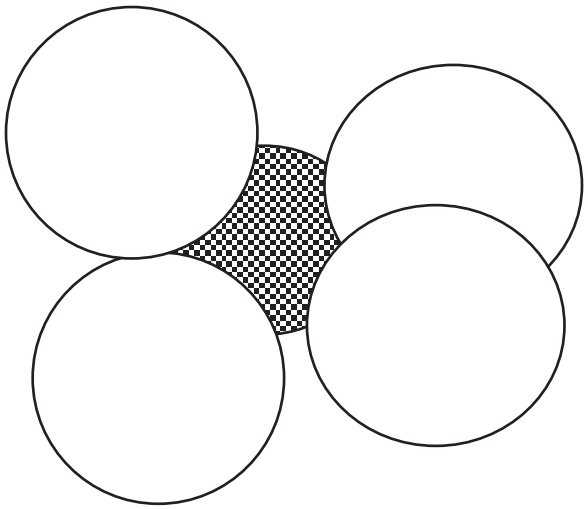

Figure 14.5

Particle with several contact forces.

14.1.1.2.2 Determination of Stiffness k, Damping Coefficient η, *and Friction Coefficient f* The stiffness k_n can be given using the Hertzian contact theory when physical properties such as Young's modulus and Poisson's ratio are known. The stiffness of a sphere is expressed by

$$k_n = \frac{4}{3}\left(\frac{1-\sigma_i^2}{E_i} + \frac{1-\sigma_j^2}{E_j}\right)^{-1}\left(\frac{a_i + a_j}{a_i a_j}\right)^{-(1/2)} \tag{14.15}$$

where

E and σ are Young's modulus and Poisson's ratio, respectively
a is the particle radius
Subscripts i and j denote particle i and particle j, respectively

If particle i and j have the same radius and the same physical properties, the stiffness k_n simplifies to

$$k_n = \frac{\sqrt{2r}E}{3\left(1-\sigma^2\right)} \tag{14.16}$$

The stiffness k_t can be given using the Mindlin theory as

$$k_t = 8\left(\frac{1-\sigma_i^2}{H_i} + \frac{1-\sigma_j^2}{H_j}\right)^{-1}\left(\frac{a_i + a_j}{a_i a_j}\right)^{-(1/2)}\delta_n^{1/2} \tag{14.17}$$

where H_i and H_j are the shear moduli of particle i and particle j, respectively. If both particles have the same properties, the tangential stiffness k_t also simplifies to

$$k_t = \frac{2\sqrt{2r}H}{2-\sigma^2}\delta_n^{1/2} \tag{14.18}$$

where H is related to Young's modulus, E, and Poisson's ratio, σ, as follows:

$$H = \frac{E}{2(1+\sigma)} \tag{14.19}$$

As shown earlier, the stiffness can be determined by material properties. This is the advantage of this model. Unfortunately, it is often difficult in practice to use the stiffness calculated by the Hertzian theory, because the time step Δt for numerical integration is so small that an excessive amount of computational time is needed. It is empirically known that the time step Δt should be <1/10 of the natural oscillation period $2\pi\sqrt{m/k}$ of a mass–spring system. Therefore, in many cases, a small value of stiffness is assumed for convenience of the calculation. In some cases, the results based on a stiffness value much smaller than the actual one are not so different from those based on the precise stiffness value. Fortunately, this is the case for fluid–particle multiphase flows, where fluid forces acting on the particles make the difference in stiffness a minor effect.

14.1.1.2.3 Damping Coefficient Cundall and Strack (1979) proposed the following expressions for the damping coefficients:

$$\eta_n = 2\sqrt{mk_n} \tag{14.20}$$

$$\eta_t = 2\sqrt{mk_t} \tag{14.21}$$

which were derived for the critical damping condition of a single degree-of-freedom system consisting of a mass, spring, and dashpot. The reason for choosing the critical damping condition, as shown in Equations 14.20 and 14.21, can be traced to the requirement that bouncing motion after collision should be damped as soon as possible.

Another method for determining the damping coefficient is based on the idea that the damping coefficient should be related to the coefficient of restitution, which is regarded as a physical property of the particle material. Fortunately, the coefficient of restitution can be measured in a simple experiment.

If the relationship between spring force and displacement is linear, the solution of Equation 14.5 can be used to relate the damping coefficient to the coefficient of restitution (Tsuji et al., 1993). Let us assume that x denotes the distance of particle center from the wall and the particle collides with the wall at time $t = 0$ with the initial velocity $v = v_0$ and initial position of particle center $x = x_0$. The initial velocity is negative. The underdamping solutions are given as follows:

$$\text{Position:} \quad x = \frac{v_0}{q}\sin(qt)\exp(-\gamma\omega t) + x_0 \tag{14.22}$$

$$\text{Velocity:} \quad \dot{x} = \frac{v_0}{q}\exp(-\gamma\omega t)q\cos(qt) - \gamma\omega\sin(qt) \tag{14.23}$$

where

$$\omega = \sqrt{k/m}$$
$$\gamma = \eta/\left(2\sqrt{mk}\right)$$
$$q = \omega\sqrt{1-\gamma^2}$$

The particle position decreases, reaches the minimum value, and recovers to the initial position $x = x_0$ at $t = \pi/q$, which is equal to half of the oscillation period. The particle velocity at $t = \pi/q$ is expressed as

$$v_1 = [\dot{x}]_{t=\pi/q} = -v_0\exp\left(-\frac{\gamma\omega\pi}{q}\right) \tag{14.24}$$

The ratio of v_1 to v_0 corresponds to the coefficient of restitution e:

$$e = \exp\left(-\frac{\gamma\omega\pi}{q}\right) \tag{14.25}$$

From the previous equations,

$$\eta = -\frac{2\ln e}{\sqrt{\pi^2 + \ln e}}\sqrt{mk} \tag{14.26}$$

Tsuji et al. (1992) showed that the damping coefficient η_n for a nonlinear spring is numerically related to the restitution coefficient. According to Tsuji et al. (1992), the damping coefficient η_n is expressed by

$$\eta_n = \alpha\sqrt{mk_n}\delta_n^{1/4} \tag{14.27}$$

where α is a constant related to the coefficient of restitution. The relationship between α and coefficient of restitution e is shown in Figure 14.6. As for the damping coefficient η_t in the tangential direction, the same value as used for η_n is often used for η_t with no firm justification.

14.1.1.3 Cohesive Force

Interparticle forces due to the wetness of particle surfaces, electrostatic charges, and the van der Waals forces are known to cause adhesion of a particle to a wall or to another particle.

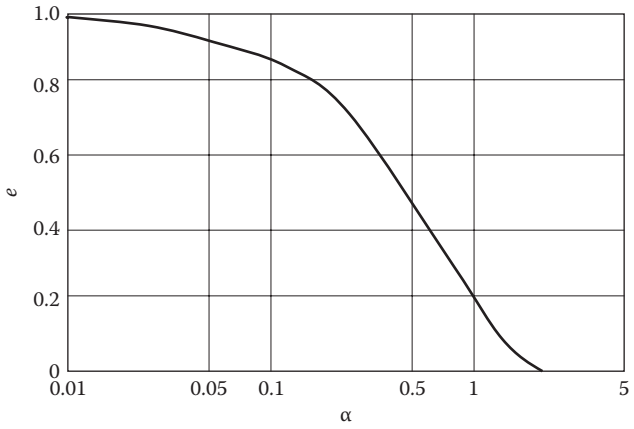

Figure 14.6

Relationship between α and coefficient of restitution *e*.

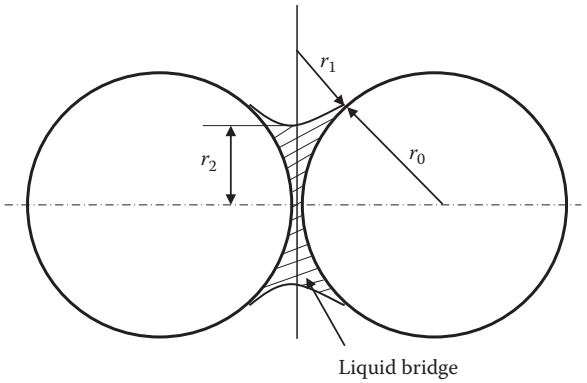

Figure 14.7

Liquid bridge between two spheres.

14.1.1.3.1 Force due to a Liquid Bridge As shown in Figure 14.7, a liquid bridge is formed between particles due to condensation under an environment of high humidity. The liquid surface is concave due to surface tension and the pressure is negative inside the bridge. The force acting on the particle is the sum of the force due to the negative pressure and the cohesive force due to capillarity.

The force due to the liquid bridge F_l is given as follows:

$$F_l = \pi a_2^2 \sigma \left(\frac{1}{a_1} - \frac{1}{a_2} \right) + 2\pi a_2 \sigma \cos\theta \tag{14.28}$$

where

σ is the capillary force (N/m)

θ is the contact angle between liquid and particle surface

The contact angle θ can be assumed to be zero in the case of water. This equation is called the Laplace–Young equation.

14.1.1.3.2 Electrostatic Force Particles in the gas are usually charged and an electrostatic force acts on the particles. Electrostatic force F_e between charged particles is given by the Coulomb formula:

$$F_e = \frac{1}{4\pi\varepsilon_0} \frac{q_1 q_2}{a^2} \tag{14.29}$$

where
q_1 and q_2 are the charges on the particles
ε_0 is the dielectric constant (F/m) in vacuum
a is the distance between particle centers

If the signs of q_1 and q_2 are different, an attractive force acts on the two particles, and if not, the force is repulsive.

The cohesive force acting on the spherical particles in contact with each other is given by

$$F_E = \frac{\pi\sigma_1\sigma_2}{\varepsilon_0} d^2 \tag{14.30}$$

where σ_1 and σ_2 are the charge densities (C/m^2) of the two particles. This equation is derived under the assumption that the particles are charged uniformly and that charging can be regarded as concentrated at the particle centers. The effect of the particle size on the force is larger for the Coulomb cohesive force than for the van der Waals force.

14.1.1.3.3 Van der Waals Forces The van der Waals forces arise from molecular interaction between solid surfaces. This force becomes apparent when very smooth surfaces are brought into contact. To estimate the magnitude of van der Waals forces acting on solid bodies, the contribution of many molecules comprising the surfaces must be considered. Hamaker (1937) carried out calculations for various geometries. The force F between two infinite flat plates with separation is expressed by

$$F = \frac{A_{eff}}{6\pi z^3} \tag{14.31}$$

where
F is the force per unit area
A_{eff} is called the Hamaker constant

The force between the two spheres shown in Figure 14.8 is expressed by

$$F = \frac{A_{eff} d}{12 z^2} \tag{14.32}$$

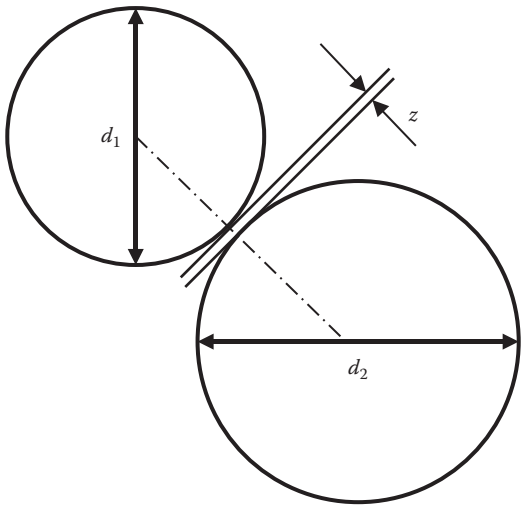

Figure 14.8
Two particles in contact.

Table 14.2 Hamaker Constant

Material	Hamaker Constant [$J \times 10^{20}$]
Water	4.38
Polystyrene	6.15–6.6
Al_2O_3	15.5
Cu	28.4
Au	45.5

where z is the separation distance at the point of contact, which is dependent on the roughness of the sphere and d is

$$d = \frac{d_{p1} \cdot d_{p2}}{d_{p1} + d_{p2}} \tag{14.33}$$

The force between a sphere and a flat plate can be obtained by letting the diameter of one sphere be infinite, that is, $d = d_p$ in Equation 14.33. Table 14.2 shows examples of the Hamaker constant of various materials.

The Hamaker constant between different materials is given by

$$A_{eff\,12} = \sqrt{A_{eff\,11} \cdot A_{eff\,22}} \tag{14.34}$$

where A_{eff11} and A_{eff22} are the Hamaker constants of each material, respectively. This relation is used for *dry* solids. If two solids are separated by a third material between them, the Hamaker constant is expressed by

$$A_{eff\,132} = \left(\sqrt{A_{eff\,11}} - \sqrt{A_{eff\,33}}\right)\left(\sqrt{A_{eff\,22}} - \sqrt{A_{eff\,33}}\right) \tag{14.35}$$

where A_{eff33} is the Hamaker constant of the third material. The Hamaker constant A_{eff33} of air is very small, and thus, Equation 14.35 is reduced to Equation 14.34 in this case. Comparing Equations 14.34 and 14.35, it is found that the attractive force between two solids becomes smaller in water than in air. The equation mentioned earlier means that the sign of the van der Waals force between two solids can be negative, that is, a repulsion force arises if A_{eff33} takes a value between A_{eff11} and A_{eff22}.

14.1.2 Particle–Wall Interaction

The problem of particle–wall interaction is encountered when analyzing gas–particle flows contained within walls such as pipe flows, channel flows, and fluidized beds. The particle–wall interaction falls into two categories: hydrodynamic forces due to proximity of a wall and the purely mechanical interaction in the absence of a fluid. The Saffman lift force due to velocity gradient near the wall is one example of the hydrodynamic interaction. Another example is the fluid force acting on a particle approaching the wall in the normal direction. This interaction is observed when the case of two approaching particles is addressed. Assuming the diameter of one particle to be infinitely large, the particle–particle interaction is reduced to the particle–wall interaction. A hydrodynamic interaction of this type can prevent a particle from making contact with the wall. The postcollisional velocity of the particle is also affected by this interaction. This hydrodynamic interaction can be neglected if the particle inertia force is so large that collision takes place in a time small compared to the hydrodynamic relaxation time of the particle.

The treatment of the mechanical behavior associated with the particle–wall mechanical interaction depends on the inertia of the particle. When a massive particle collides with a wall, it rebounds but loses kinetic energy due to friction and inelasticity. For a very small particle approaching a wall, molecular forces become dominant compared with the inertia force. As a result, the particle is captured by the wall due to cohesion forces (Section 14.1.1.3.3) and neither rebounds nor slides along the wall. Energy loss due to wall collision is considered in Section 14.1.2.1, where the analysis is based on a single spherical particle and a smooth wall. The energy loss at walls is readdressed in Section 14.1.2.2, where the case of a nonspherical particle impacting a rough wall is considered.

14.1.2.1 Momentum and Energy Exchange at Walls

Two models are used to deal with particle–wall collision: the hard sphere model and the soft sphere model, as in the case of particle–particle collisions. The soft sphere model is based on the integration of differential equations. So, variation of velocities from the moment of contact to detachment is calculated step by step in the soft sphere model. Thus, not only the relationship between the pre- and postcollisional velocities is obtained but the instantaneous motion during the whole collision process is obtained as well. The soft sphere model is explained in detail in Section 14.1.1.2.

The hard sphere model is based on the impulsive equations, which are the integrated forms of the equations of motion. Thus, the hard sphere model considers momentum difference between precollision and postcollision. Concerning the hard sphere model, there are a few approaches depending on the definition of the coefficient of restitution, which is described in detail in this section.

The difference in momentum between two instants of time is equal to the impulsive force acting on the particle during that time period:

$$m\left(\vec{v}^{(2)} - \vec{v}^{(1)}\right) = \vec{J} \tag{14.36}$$

where

$\vec{v}^{(1)}$ and $\vec{v}^{(2)}$ are the velocities at time 1 and time 2, respectively

J is the impulsive force acting on the particle during the period between the two times

The difference in angular momentum is expressed as

$$I\left(\vec{\Omega}^{(2)} - \vec{\Omega}^{(1)}\right) = -\vec{r} \times \vec{J} \tag{14.37}$$

where

$\vec{\Omega}^{(1)}$ and $\vec{\Omega}^{(2)}$ are the angular velocities at time 1 and time 2, respectively

I is the moment of inertia of the particle

The impulsive force is defined by integral of the force versus time when the force acts on the body. Equations 14.36 and 14.37 are not sufficient to determine the relationship between the pre- and postcollisional velocities. Auxiliary equations are necessary to close a set of equations. The auxiliary equations originate from the concept of the coefficient of restitution and friction coefficient.

Next, move on to the definition of the coefficient of restitution e. The definition of e is somewhat arbitrary, and there are a few definitions available in the literatures. Consider a particle colliding with a wall as shown in Figure 14.9. The symbol $\vec{v}$ denotes the translation velocity. The velocity vector has two components: longitudinal component (x-component) and the component normal to the wall (y-component). The suffixes (0) and (2) denote the precollision velocity and postcollision velocities, respectively. The following definitions have been used in general:

$$\text{Definition (1)} \quad e = \frac{\left|\vec{v}^{(2)}\right|}{\left|\vec{v}^{(0)}\right|} \tag{14.38}$$

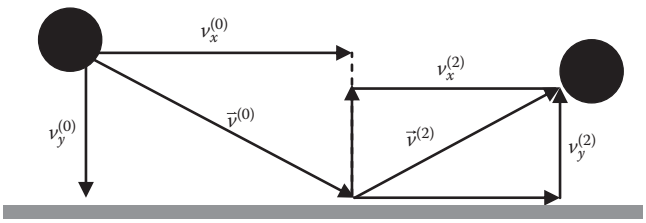

Figure 14.9

Particle colliding a wall.

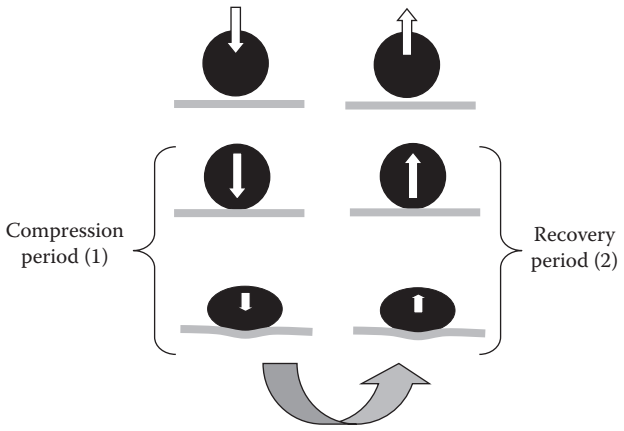

Figure 14.10

Compression and recovery periods in collision process.

$$\text{Definition (2)} \quad e = \frac{v_y^{(2)}}{v_y^{(0)}} \tag{14.39}$$

$$\text{Definition (3)} \quad e_x = v\frac{v_x^{(2)}}{v_x^{(0)}} \cdot e_y = \frac{v_y^{(2)}}{v_y^{(0)}} \tag{14.40}$$

$$\text{Definition (4)} \quad e = \frac{J_y'}{J_y} \tag{14.41}$$

where J_y and J_y' are the normal components of impulses acting on the particle during the collision period. J_y and J_y' are explained as shown in Figure 14.10. The process of collision is divided into two periods, one in which the material is compressed and the other in which the compression is released. J_y and J_y' are the y-components of the impulsive force during the compression and recovery periods, respectively. Among these four definitions, the second definition is used most widely. However, if this definition is adopted, the value of the coefficient for nonspherical particles depends on the location of the contact point between the particle and the wall. If the restitution coefficient is regarded as a property of the material, its value should not depend on the location of the contact point. From this point of view, a reasonable definition for the coefficient of restitution is given by Equation 14.41. If the particle is a sphere, it is found that the impulse ratio J_y'/J_y is equal to the velocity ratio $v_y^{(2)}/v_x^{(0)}$.

Consider a 3D collision of a spherical particle with a smooth flat wall, as shown in Figure 14.11. The velocities $\vec{v}^{(0)}$ and $\vec{\Omega}^{(0)}$ are the precollision translation and angular velocities, respectively. The corresponding postcollision velocities are expressed by $\vec{v}^{(2)}$ and $\vec{\Omega}^{(2)}$. The y-axis is normal to the wall and the x-axis and z-axis are in the plane of the wall. The subscripts x, y, and z signify component directions. If the

Condition	$\frac{v_y^{(0)}}{\lvert\vec{v}\rvert} < -\frac{2}{7f(e+1)}$	$-\frac{2}{7f(e+1)} < \frac{v_y^{(0)}}{\lvert\vec{v}\rvert} < 0$
Translation velocity	$v_x = \left(\frac{5}{7}\right)\left(v_x^{(0)} - \frac{2a}{5}\Omega_z^{(0)}\right)$	$v_x = v_x^{(0)} + \varepsilon_X f(e+1)v_y^{(0)}$
	$v_y = -ev_y^{(0)}$	$v_y = -ev_y^{(0)}$
	$v_z = \left(\frac{5}{7}\right)\left(v_z^{(0)} + \frac{2a}{5}\Omega_x^{(0)}\right)$	$v_z = v_z^{(0)} + \varepsilon_Z f(e+1)v_y^{(0)}$
Angular velocity	$\Omega_x = \frac{v_z}{a}$	$\Omega_x = \Omega_x^{(0)} - \frac{5}{2a}\varepsilon_Z f(e+1)v_y^{(0)}$
	$\Omega_y = \Omega_y^{(0)}$	$\Omega_y = \Omega_y^{(0)}$
	$\Omega_z = -\frac{v_x}{a}$	$\Omega_z = \Omega_z^{(0)} + \frac{5}{2a}\varepsilon_X f(e+1)v_y^{(0)}$

coefficient of restitution e and kinetic (sliding) friction f are known, the postcollision translation and angular velocities can be obtained by solving the impulsive equations. The results are shown in Table 14.3. In this table, ε_X and ε_Z are factors indicating the proportion of the velocity in each component direction, that is, the direction cosines of the approaching velocity in the x- and z plane. The factors ε_X and ε_Z satisfy the relation:

$$\varepsilon_x^2 + \varepsilon_z^2 = 1 \tag{14.42}$$

In the analysis, the Coulomb friction law is assumed for kinetic (sliding) friction:

$$J_\tau = -f \cdot J_n \tag{14.43}$$

where

J_τ and J_n are the tangential and normal components of the impulsive forces, respectively
f is the friction coefficient

The derivation of the results is described in Crowe et al. (2012, pp. 140–149).

14.1.2.2 Nonspherical Particles and Rough Walls

When the coefficients of restitution e and dynamic friction f are given as physical properties of the particles, the postcollisional velocities can be expressed in terms of the precollisional velocities. The relation between these velocities for the case of a spherical particle and smooth wall is shown in Table 14.3. This relationship is useful for calculating particle trajectories in a field enclosed by walls. However, in some cases, the trajectory calculation in multiphase flows is not as straightforward as it might be. The coefficient of restitution e defined by Equation 14.41 must be less than unity. If trajectory calculations were made for a long horizontal pipe or duct, particles repeatedly colliding with the wall would ultimately lose their vertical velocity component and slide along the wall, as shown in Figure 14.12a. To avoid such an unrealistic result, the irregularity of collisions must be considered. If this irregularity is neglected, large particles cannot be suspended in the carrier fluid. Fluid dynamic forces, such as Magnus or shear lift forces, and fluid turbulence acting on the particles are sufficient to suspend small particles. However, the mechanism responsible for suspending large particles in horizontal pipes is the irregular bouncing of the particles against the wall. In general, the irregularity is caused by particle shape (nonspherical particles) and/or roughness of the wall. In practice, both mechanisms are operative. Several models with regard to the irregular bouncing have been proposed. Those models are classified into two types: one in which the irregularity is attributed to the nonsphericity of the particle (Matsumoto and Saito, 1970a, Tsuji et al., 1989, 1991) and the other to wall roughness (Matsumoto and Saito, 1970b, Tsuji et al., 1987, Sommerfeld and Zivkovis, 1992, Frank et al., 1993, Sommerfeld and Huber, 1999).

In the following paragraphs, the nonspherical model is described first and then the rough wall model. If the problem is two dimensional, the treatment is relatively easy, because the cross-sectional shape of the

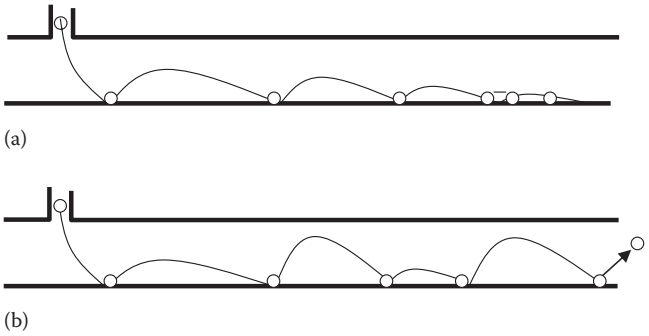

Figure 14.12

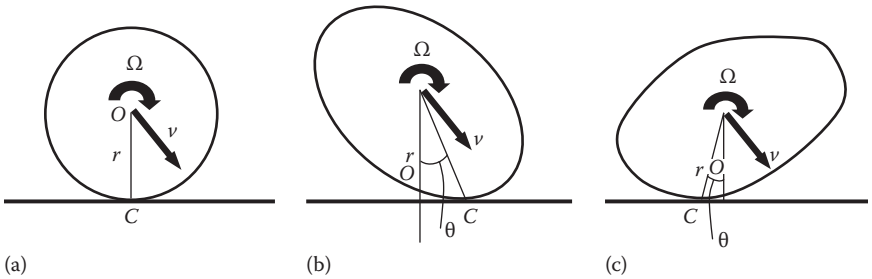

Figure 14.13

Contact point between particle and wall: (a) circular particle, (b) ellipse, and (c) arbitrary shape.

particle is limited to the circle, ellipse, or an arbitrary shape. As shown in Figure 14.13, the distance between the particle center of gravity O and the contact point C depends on the incident attitude of the particle, which does not change in the case of a spherical particle. A set of values for r and θ shown in Figure 14.13b and c describes any particle shape. Impulsive equations are formed for a set of values for r and θ. In the numerical simulation, a pair of values for r and θ is chosen by random numbers. The postcollisional velocities are obtained from solutions of the impulsive equations.

It is difficult to deal, in a rigorous way, with the collision of an arbitrary 3D, nonspherical particle having three components of translational and angular velocities. The complexity of the problem is reduced by using some assumptions. Examples of such assumptions are explained in Tsuji et al. (1991).

The wall roughness model for irregular bouncing is shown in Figure 14.14. The choice of wall roughness is arbitrary. Several configurations could be considered, such as a wavy pattern and a combination of inclined plates. The calculation for a spherical particle bouncing on the rough wall is simpler than that for a nonspherical particle on a flat wall if the pattern of roughness is specified, because the results shown in Table 14.3 can be used with some modifications. In the rough wall model, the point at which the particle collides with the wall is assumed to be on an inclined plane. Each inclined plane has its own coordinate system. The relationship between the coordinates, with and without an inclination angle, is easily described by

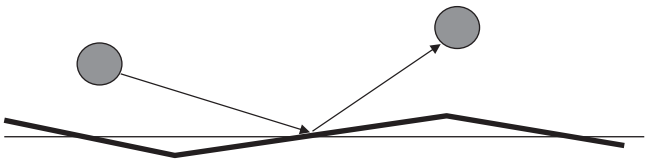

Figure 14.14

Particle collision with a rough wall.

using a matrix. Once particle velocities are transformed by the usual linear transformation technique into the coordinates corresponding to the inclined plane, the results shown in Table 14.3 can be used to obtain the postcollisional velocities. After this, the postcollisional velocities based on the coordinate on the inclined plane are retransformed into the original coordinate system. As with the nonspherical particle model, the rough wall models make it possible for the particles to move along with a bouncing motion in long, horizontal pipes or ducts.

Predicting the impact–rebound relations for particles with sharp edges, such as quartz particles, would be very difficult. Experiments (Tabakoff, 1982) with quartz particles impacting on an aluminum surface show that for a given impact angle, there is a distribution of rebound angles. In this case, it is more pragmatic to use a Monte Carlo method with the measured distribution of rebound angles to model particle-surface impact.

14.2 Droplet Breakup, Coalescence, and Wall Impact

Cameron Tropea and Ilia V. Roisman

The usual description of spray transport involves the solution of the mass and the momentum balance equations for the liquid phase (droplets) and of the ambient gas flow as well as the forces associated with the droplet/gas interactions (drag forces). The details and various approaches to such modeling can be found in Chapter 12. The phenomena considered in this chapter include droplet breakup due to the interaction with

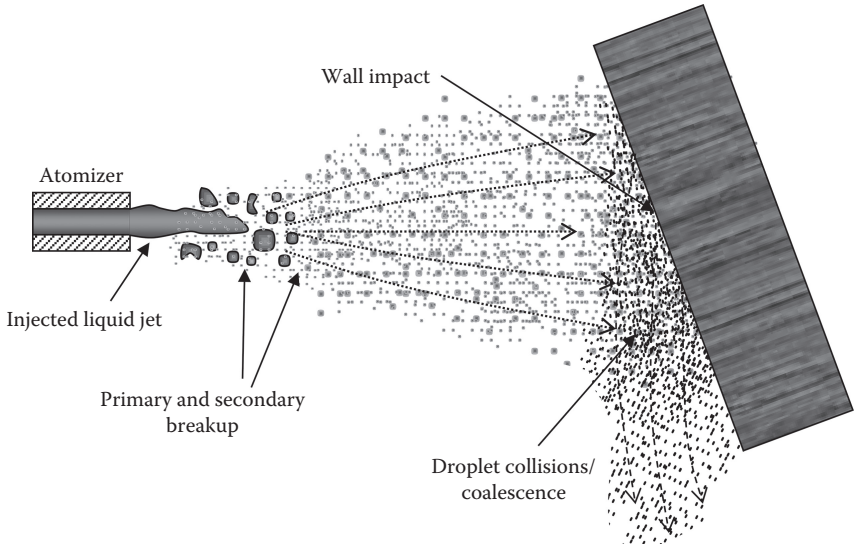

Figure 14.15

Sketch of spray atomization, transport, and wall impact.

the airflow and collisions with another drop or with a wall. In Figure 14.15, the spray atomization, transport, and wall impact are shown schematically, involving these phenomena. They lead to the alterations in the distributions of the drop diameters and velocity in a spray. Accounting for such alterations significantly complicates the modeling of spray transport, considerably extending the numerical simulations, and therefore, in many numerical simulations, the effect of the drop breakup and coalescence is assumed negligibly small and neglected. However, drop fragmentation in the near-atomizer region determines the average drop diameter in the overall spray and therefore cannot be neglected. The secondary breakup of drops can be caused by the interaction of a spray with a high-speed gas jet or by a shock wave. The effect of binary collisions becomes significant in the region of the interaction of two (or more) sprays, in the case of the propagation of very dense spray, or in the near-wall region (where the impacting spray interacts with the spray of the secondary droplets produced by spray/wall impact). When a spray impacts onto a substrate, part of the droplet volume deposits on it and forms a thin fluctuating liquid film. Another part of the spray volume rebounds and creates a flow of secondary droplets. One of the key elements in the creation of such secondary spray is the drop impact onto a wall, also described in this chapter.

The common feature of the phenomena described in this chapter is the significant change of the drop shape due to the impact with another drop (binary drop collisions), its deformation and breakup by ambient airflow, or the impact onto a dry or wetted substrate, as illustrated in Figure 14.16.

The main parameters determining the drop deformation and breakup are the Reynolds number, $Re = DU/\nu$, and the Weber number, $We = DU^2/\sigma$, where D is the drop diameter, U is the characteristic velocity, ν is the kinematic viscosity, and σ is the surface tension. If both these numbers are large ($Re \gg 1$, $We \gg 1$), the droplet deformation is inertia dominated. The drop deformation often leads to the creation of an expanding, relatively thin free liquid sheet (lamella) bounded by a rim, formed due to capillary forces (see Figure 14.17a). In other cases, the drop deformation leads to the appearance of the fingerlike jets ending with a droplet, as shown schematically in Figure 14.17b.

These forms appear due to capillary forces. The rim velocity differs from the velocity of the liquid in the lamella. The motion of the rim is determined by the capillary forces, the internal viscous stresses, the inertia of the liquid entering the rim from the lamella, and the aerodynamic drag force. The simplest case of the motion of the rim bounding a steady uniform liquid sheet was analyzed in Taylor (1959). In this case, the capillary force per unit length, 2σ, is balanced with the inertia of the liquid entering the rim, $\rho w_{rim}^2 \delta$, where δ is the thickness of the lamella. The relative rim velocity w_{rim} is expressed in the form

$$w_{rim} = \sqrt{\frac{2\sigma}{\rho\delta}} \tag{14.44}$$

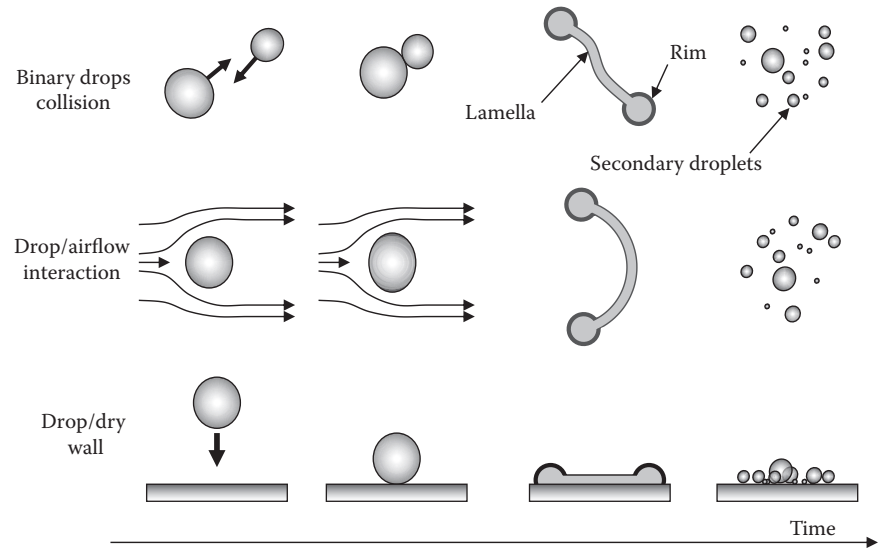

Figure 14.16

Successive stages of drop deformation and breakup due to the binary drop collision, drop/airflow interaction, and drop/wall impact.

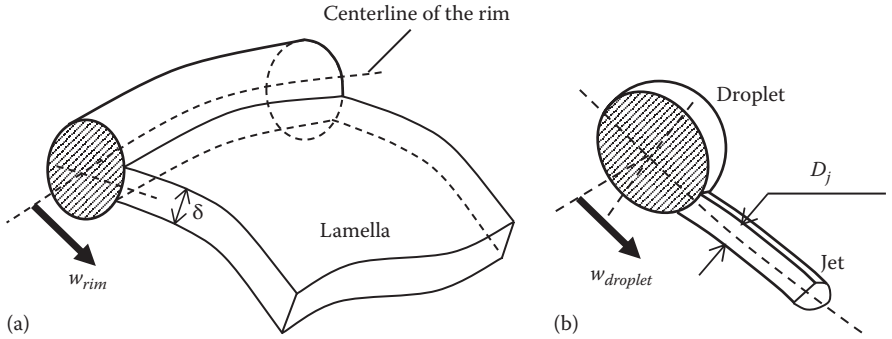

Figure 14.17

Capillary effects at the free boundary: (a) Element of rim bounding a liquid sheet. (b) Droplet appearing at the end of a liquid jet.

The analysis of the droplet appearing at the end of a free liquid jet (Figure 14.17b) is very similar. The momentum equation of this droplet appearing at the end of a steady jet of diameter D_j expresses the balance of the inertia of the liquid entering the droplet from the jet, the capillary forces, and the pressure in the jet due to surface tension. The relative droplet velocity is

$$w_{droplet} = \sqrt{\frac{2\sigma}{\rho D_j}} \tag{44.45}$$

14.2.1 Droplet Breakup Mechanisms

The main topics when studying drop breakup are the regimes of the breakup, the time of breakup, and the outcome: size, number, and velocities of the secondary droplets. We distinguish here two main directions for such studies:

1. Aerodynamic breakup, which is important for the description of sprays, associated with the drop suddenly exposed to a high-speed gas flow or breakup by a shock wave propagating in the ambient gas. The velocity of the drop relative to the velocity of the ambient gas flow and corresponding pressure gradients at the drop surface are the main reason for the breakup.

2. The breakup in a viscous flow, with the application to the rheology of emulsions, when the drop deforms and breaks up mainly due to the shear stresses appearing in the ambient viscous liquid.

In addition, there are many specific cases of drop impact, which will not be described in detail in this chapter, for example, the deformation and breakup involving non-Newtonian drops or flows (Ha and Leal, 2001), in an electric field (Ha and Yang, 1998), in a turbulent fluid flow (Sevik and Park, 1973), and in an acoustic field (Yarin et al., 2002).

14.2.1.1 Regimes of the Aerodynamic Drop Breakup

The typical dimensionless parameters used in the description of the aerodynamic breakup are the Reynolds number, $Re_g = \rho_g w D/\mu_g$, and the Weber number, $We_g = \rho_g w^2 D/\sigma$, based on the properties of the ambient gas, as well as the Ohnesorge number, $Oh = \mu_l/\sqrt{\rho_l D\sigma}$, where w is the relative droplet/gas velocity. These parameters determine the degree of the drop deformation and the mode of the drop breakup.

The first attempt to classify the various regimes of drop breakup using the Weber number, We_g, and Ohnesorge number, Oh, was made by Hinze (1955). A more detailed map of these regimes at various Ohnesorge numbers has since been created on the basis of extensive experimental studies of a drop breakup (Hinze, 1955, Hsiang and Faeth, 1992, 1995). Most of the observations show that the critical We_g numbers, corresponding to the regime thresholds, are almost independent of the Ohnesorge number if it is small ($Oh < 0.1$). Increasing the Weber number leads to an increase in drop deformation. At some critical Weber number, the drop breaks up. Several main regimes of breakup shown schematically in Figure 14.18 can be observed:

Bag breakup, shown in Figure 14.18a, takes place in the range $12 < We_g < 15$ at $Oh < 0.1$. In this regime, the lamella deforms and takes an expanding bag-like shape. At some time instant, the lamella disintegrates. The rim then breaks up due to the Rayleigh capillary instability.

At higher relative velocities, $80 < We_g < 350$ at $Oh < 0.1$, the main drop deformation takes place in the thin boundary layer of the frontal surface of the drop. The flow in the liquid layer leads to *boundary layer stripping* (Hinze, 1955, Ranger and Nicholls, 1969, Delplanque and Siringano, 1994). The resulting thin liquid film then disintegrates in the airflow (Figure 14.18b). This mechanism is also called "shear breakup." An alternative description of the drop breakup mechanism in this range of relative velocities, called "stretching/thinning breakup," is given by Liu and Reitz (1997, 2000). In these studies, the main source of drop deformation is associated with the low-pressure region near the drop equator. The pressure gradient along the drop surface leads to the drop stretching in the plane normal to the direction of the airflow. The edges of the obtained lamella are thin because the inertial forces in the film significantly exceed capillary forces. Such a film is then deflected in the direction of the gas flow (Figure 14.18c).

If the relative velocity is so high such that the gas Weber number exceeds 350 ($We_g > 350$), the droplet deforms very quickly and takes the form of wavy thin sheet. This sheet then breaks up into ligaments and secondary droplets: *catastrophic breakup* shown in Figure 14.18d (Hwang et al., 1996).

Note that the phenomena of drop breakup cannot always be classified by the aforementioned regimes. Some studies are devoted to the investigation of *multimode regimes*, mainly in the range between the bag breakup and shear breakup. In the articles written by Pilch and Erdman (1987) and Joseph et al. (1999), the bag-and-stamen breakup at $50 < We_g < 100$ was mentioned. The description and temporal parameters of bag/plume and plume/shear breakup regimes can be found by Dai and Faeth (2001).

The best fit for the threshold of breakup regimes and the degree of drop deformation by a shock wave based on the experimental data from Hsiang and Faeth (1995) for $Oh < 2 \times 10^{-4}$ is obtained in Schmehl (2003a,b) in the following forms:

$We < 0.6(1 + 0.8Oh^{0.8} + 9 \times 10^{-5}Oh^{2.4})$	Deformation <5%, no breakup	$Oh < 6 \times 10^2$
$We = 1.1(1 + 0.7Oh^{0.85} + 1.5 \times 10^{-4}Oh^{2.4})$	Deformation 10%, no breakup	$Oh < 6 \times 10^2$
$We = 2.3(1 + 0.75Oh^{0.8} + 2.5 \times 10^{-4}Oh^{2.4})$	Deformation 20%, no breakup	$Oh < 6 \times 10^2$
$3(1 + 15Oh^{1.2}) < We < 13(1 + 1.7Oh^{1.4})$	Drop oscillations, no breakup	$Oh < 3 \times 10^{-1}$
$13(1 + 1.7Oh^{1.4}) < We < 35(1 + 0.65Oh^{1.4})$	Bag breakup	$Oh < 4$
$35(1 + 0.65Oh^{1.4}) < We < 80(1 + 0.6Oh^{1.5})$	Multimode breakup	$Oh < 15$
$80(1 + 0.6Oh^{1.5}) < We$	Shear breakup	$Oh < 6$

The increasing drop viscosity slows the rate of drop deformation; however, the maximum drop deformation is virtually not affected by the Ohnesorge number.

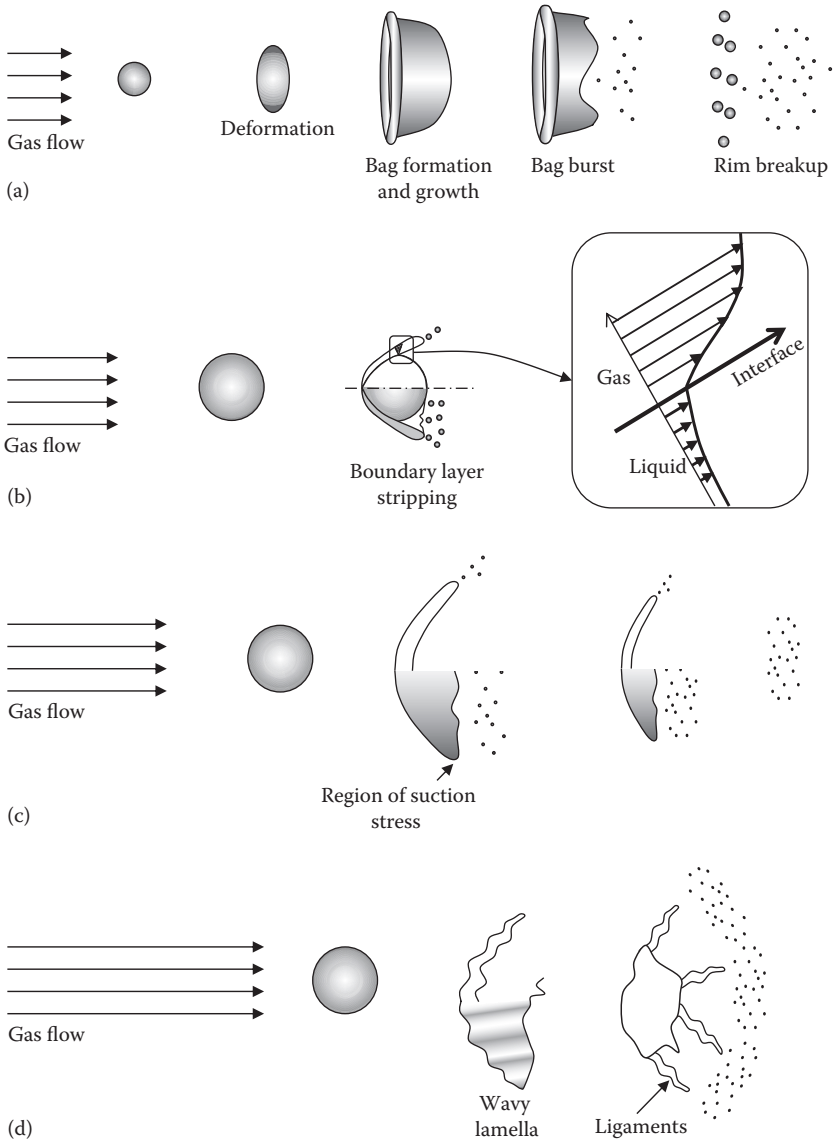

Figure 14.18

Mechanisms of aerodynamic breakup. (a) Bag breakup. (b) Shear breakup. (c) Stretching/thinning breakup. (d) Catastrophic breakup.

The axisymmetric shape of the drop deformed by a shock wave can be approximately described by two dimensions: its length L in the axial direction and its diameter D. The empirical expression for the degree of the maximum drop deformation by a shock wave is given in Hsiang and Faeth (1995):

$$\left(\frac{D}{L}\right)_{\max} = (1 + 0.007We^{1/2})^3 \tag{14.46}$$

The temporal behavior of the drop during the breakup process is illustrated in Figure 14.19 using the characteristic shear breakup time defined by Ranger and Nicholls (1969):

$$t^* = \frac{D_0}{w_0}\sqrt{\frac{\rho_l}{\rho_g}} \tag{14.47}$$

where D_0 and w_0 are the initial drop diameter and the initial relative velocity to the gas, respectively. The gray area corresponds to the time intervals at which a drop breaks up and generates secondary droplets.

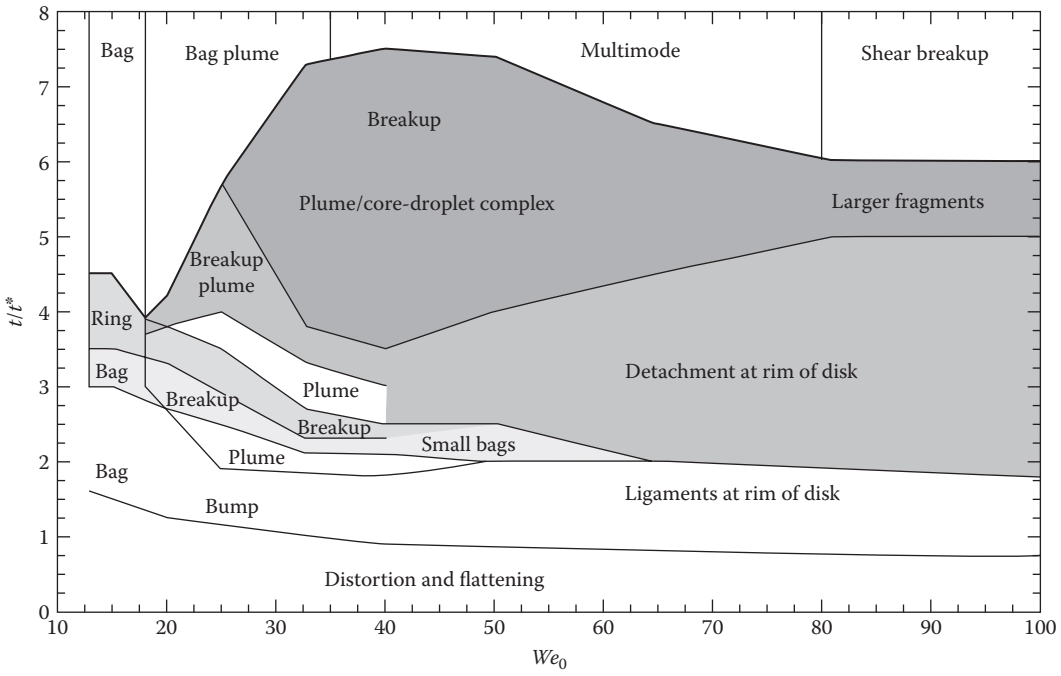

Figure 14.19

Stages of droplet deformation and breakup for various regimes of aerodynamic breakup ($Oh < 0.1$). (Adapted from Schmehl, R., Modeling droplet breakup in complex two-phase flows, in *Proceedings of International Conference on Liquid Atomization and Spray Systems ICLASS-2003*, Italy, July 13–18, 2003b.) (The experimental data are from Dai, Z. and Faeth, G.M., *Int. J. Multiphase Flow*, 27, 217, 2001; Krzeczkowski, S.A., *Int. J. Multiphase Flow*, 6, 227, 1980; Wiezba, A., *Exp. Fluids*, 9, 1329, 1990.)

14.2.1.2 Aerodynamic Breakup Outcomes

The secondary droplets obtained by drop breakup are usually in a relatively wide range of diameters and velocities. The Sauter mean diameter (SMD), D_{32}, is one of the most convenient integral parameters characterizing the drop size. This parameter has been modeled by Hsiang and Faeth (1992) as a function of the size of the viscous boundary layer appearing on the front surface of the drop. The resulting expression for small Ohnesorge number ($Oh < 0.1$) is

$$D_{32} = 6.2 D_0 Oh^{1/2} We_g^{-1/4} \tag{14.48}$$

In an article by Schmehl (2003a), an alternative empirical correlation for the SMD has been proposed, fitting the collected experimental data more precisely:

$$D_{32} = 1.5 D_0 Oh^{0.2} \left(\frac{1 + 1.7 Oh^{1.4}}{We_g} \right)^{0.25} \tag{14.49}$$

Hsiang and Faeth (1992) have found that the diameters of the droplets (excluding the size of the parent drop) can be described well using the universal root normal distribution function with the $D_{0.5}/D_{32} = 1.2$, where $D_{0.5}$ is the mass median diameter. The definitions of various mean diameters can be found in an article by Lefebvre (1989).

For breakup events that occur in the range of $12 < We < 80$ (bag breakup and multimode breakup), the correlation of Wert (1995) can be used:

$$D_{32} = \frac{0.32\sigma}{u_{rel}^2 \rho_g} \left[We (t_{tot} - t_{ini}) \right]^{2/3} \tag{14.50}$$

where

t_{ini} is the dimensionless initiation time after which a drop is deformed beyond an ellipsoidal shape

t_{tot} is the dimensionless total time for the complete breakup process

An empirical correlation for the initiation time has been proposed by Hsiang and Faeth (1992):

$$t_{ini} = \frac{1.6}{1 - Oh/7}, \quad We < 10^3 \; Oh < 3.5 \tag{14.51}$$

For the total breakup time t_{tot}, the correlation is given by Pilch and Erdman (1987):

$$t_{tot} = 6(We - 12)^{-1/4}, \quad 12 < We < 18$$

$$t_{tot} = 2.45(We - 12)^{1/4}, \quad 18 < We < 45$$

$$t_{tot} = 14.1(We - 12)^{-1/4}, \quad 45 < We < 351$$

$$t_{tot} = 0.766(We - 12)^{1/4}, \quad 351 < We < 2670$$

$$t_{tot} = 5.5 \quad 2670 < We < 10^5$$

The next parameter characterizing the breakup outcome is the velocity of the fragments. Their velocity changes during the breakup period due to the drag force applied from the ambient gas flow. The deceleration associated with this drag depends on the fragment's size, yielding a velocity-dependent distribution. The velocity distribution of fragments at the instant when the breakup process is completed is given in Hsiang and Faeth (1993) in the following form:

$$\frac{w_0}{w} = 1 + 2.7\left(\sqrt{\frac{\rho_g}{\rho_l}}\frac{D_0}{D}\right)^{2/4} \tag{14.52}$$

In this empirical correlation, w and D are the relative velocity and the diameter of the fragments, respectively, and w_0 is the initial relative velocity of the drop.

14.2.1.3 Breakup in a Viscous Flow

The interest in the phenomenon of drop breakup in a viscous flow comes from problems of mixing, blending, and dispersion and from the studies of rheology and formation of emulsions. A drop located in the viscous flow deforms, stretches, and then, if the velocity gradient reaches some critical value, breaks up. For the description of the dynamics of the drop deformation and breakup in viscous flows, see the reviews by Stone (1994) and Eggers (1997).

The governing parameters determining the deformation and breakup of drops in a viscous flow are the viscosity ratio, $\lambda = \mu_l/\mu_g$; the density ratio, $\beta = \rho_l/\rho_g$; the capillary and Reynolds numbers, $Ca = G\mu_g D_0/\sigma$; and $Re = \rho_g G^2 D_0/\mu_g$, where G is the magnitude of the velocity-gradient tensor. However, the drop breakup depends not only on the instantaneous flow conditions but also on its history (Grace, 1982, Bently and Leal, 1986). Quick changes in flow conditions enhance drop breakup.

Four mechanisms of drop breakup in a viscous flow are shown schematically in Figure 14.20 (Stone, 1994).

Capillary breakup (Tomotika, 1935, Mikami et al., 1975, Tjahjadi et al., 1992) takes place when the diameter of the threadlike drop is so small that it is broken by a growing capillary waves. The drop can also break near the middle of the thread (Barthes-Biesel and Acrivos, 1973). Such *necking breakup* leads to the formation of two similar droplets. *End pinching* (Taylor, 1934, Grace, 1982, Stone and Leal, 1989a,b, Stone et al., 1989) is the breakup of the threadlike (or fingerlike) drop near the droplet appeared at its end (see also Figure 14.17b). The addition of surfactants to the fluid of a deforming, low-viscosity ratio drop ($\lambda < 0.1$) can lead to the *tip streaming* (de Bruijn, 1993, Ha and Yang, 1998). Tip streaming was also observed in the experiments with the deformation of viscoelastic drops (Milliken and Leal, 1991).

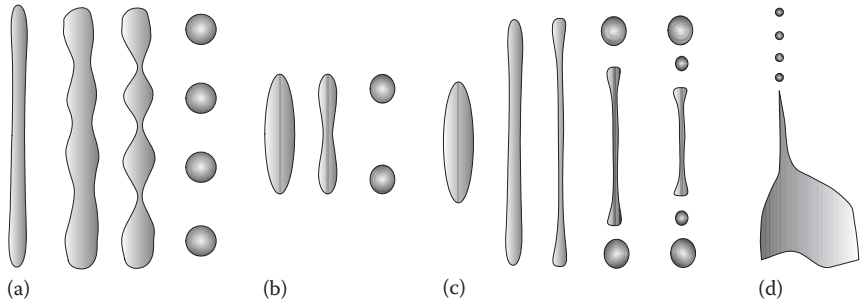

Figure 14.20

Modes of drop breakup in a viscous flow. (a) Capillary breakup. (b) Necking. (c) End pinching. (d) Tip streaming. (Adapted from Stone, H.A., *Annu. Rev. Fluid Mech.*, 26, 65, 1994.)

The shape of the drop deforms under the action of stresses generated by the outer flow. This deformation increases as the capillary number grows. The stable solution for the shape of the deformed drop in an extensional flow has been obtained by Acrivos and Lo (1978) for inviscid drops

$$h(z)=\frac{D_0}{8Ca}\left[1-\left(\frac{z}{10D_0Ca^2}\right)\right] \tag{14.53}$$

and the asymptotic value for the critical capillary number for the viscous drop is

$$Ca_{cr}\lambda^{1/6}=0.148 \tag{14.54}$$

This is valid for the small viscosity ratio ($\lambda \ll 1$).

14.2.2 Binary Drop Collisions

A collision of two drops is shown schematically in Figure 14.21, where also the main geometrical parameters of the collision are determined: the separation distance between the droplet centers χ and the collision angle $\psi = \arcsin[\chi/(R_1 + R_2)]$. The relative velocity is denoted as w. The main dimensionless parameters governing the binary drop collision phenomena include the Weber number, $We = \rho_l w^2(R_1 + R_2)/\sigma_l$; the impact parameter $B = \chi/(R_1 + R_2)$ (see the studies of Ashgriz and Poo, 1990, Jiang et al., 1992, Qian and Law, 1997); the drop diameter ratio, $\Delta = R_1/R_2 < 1$; and the Reynolds number.

The influence of the viscosity of the fluid on the binary collision in vacuum, particularly on the temporal evolution of the drop size, was investigated by Willis and Orme (2003). They found that higher Reynolds number corresponds to higher characteristic times of the drop deformation.

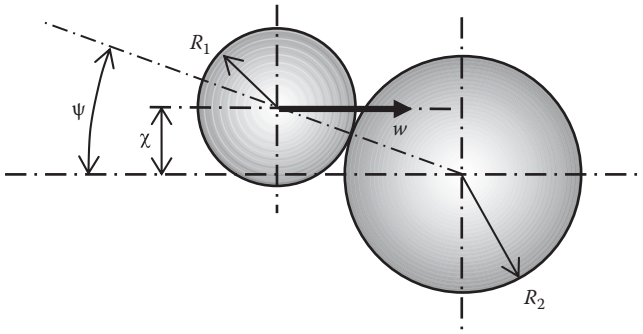

Figure 14.21

Sketch of a binary drop collision.

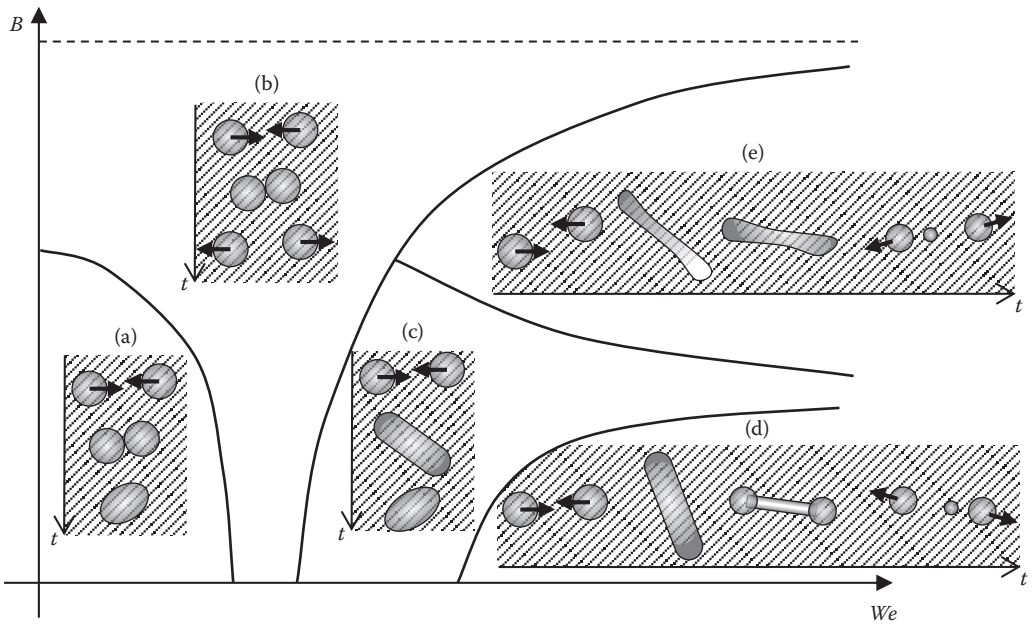

Figure 14.22

Regimes of hydrocarbon droplets: (a) Coalescence. (b) Bouncing. (c) Coalescence. (d) Reflexive separation. (e) Stretching separation. (Adapted from Qian, J. and Law, C.K., *J. Fluid Mech.*, 331, 59, 1997, $\Delta = 1$.)

A detailed study of the collision of drops of the same diameter can be found in an article by Qian and Law (1997). Several regimes of collision are observed in this work: coalescence, bouncing, coalescence, stretching separation, and reflexive separation. These regimes are shown schematically in Figure 14.22.

At relatively high Weber numbers, when the phenomenon is inertia dominated, the near head-on collision (regimes (c) and (d)) can be subdivided into several main stages, similar to the stages of the impact of a drop onto a dry wall (see Section 14.2.3): initial drop deformation leading to the formation of a relatively thin expanding liquid film, bounded by a rim. This rim expands and then recedes. The kinetic energy of the drop is accumulated in the rim at the instant when it merges. This kinetic energy leads to the creation of stretching nearly cylindrical jet bounded by two droplets. The liquid from the jet enters these two droplets. If the time of the jet breakup is smaller than the time of the droplets merging, the collision leads to separation; otherwise, it ends with coalescence.

At relatively small values of the Weber number, the phenomenon is governed by the behavior of the film of the ambient liquid/gas in the gap between the approaching drops. It is known that the expression for the pressure in this film is singular if its thickness approaches zero. The drops will coalesce if the film drains to a thickness comparable with the characteristic distance associated with the van der Waals force (Chesters, 1991).

The stretching separation regime corresponds to nonsymmetric collision of two drops at high Weber number. Such impact produces a stretching filament, which breaks up by *end pinching* (Eggers, 1993, Brenn et al., 2001).

The regimes shown in Figure 14.22 definitely do not reflect all the variety of the considered phenomena. For example, collision of two drops of $\Delta = 1/4$ observed in an article by Podvysotsky and Shraiber (1984) yields the penetration of the smaller drop into the larger, following by the creation of a relatively long jet behind the bigger drop. This jet then breaks up into several secondary droplets.

Among the models describing the critical parameters corresponding to the separation/coalescence threshold are the models of Park (1970), based on the balance of the surface forces in the neighborhood of the contact of two drops and the forces associated with the angular momentum. In an article by Brazier-Smith et al. (1972), the kinetic energy of rotation of the drop obtained by coalescence is accounted for. The energy balance of the collided drops leads to the following expression for the critical impact factor:

$$B_{cr} = \left[\frac{24[1+\Delta^2-(1+\Delta^3)^{2/3}](1+\Delta^3)^{11/3}}{5We\Delta^5(1+\Delta)^2} \right]^{1/2} \tag{14.55}$$

The criterion for the reflexive separation based on the energy balance of the system is obtained by Ashgriz and Poo (1990) in the form

$$We > 3\frac{\Delta(1+\Delta^3)^2}{\Delta^6 C_1 + C_2}\left[7(1+\Delta^3)^{2/3} - 4(1+\Delta^2)\right] \tag{14.56}$$

where

the parameters $C_1 = 2(1-C_3)^2(1-C_3^2)^{1/2} - 1$

$C_2 = 2(\Delta - C_3)^2(\Delta^2 - C_3^2)^{1/2} - \Delta^3$

the parameter C_3 is defined as $C_3 = B(1 + \Delta)/2$

$\Delta < 1$

This expression is obtained by the simplified approximation of the shape of the deformed drop by a disk.

Their model for critical Weber number of the stretching separation is

$$We = \frac{4(1+\Delta^3)^2\left[3(1+\Delta)(1-B)(\Delta^3 C_4 + C_5\right]^{1/2}}{\Delta^2\left[(1+\Delta^3) - (1-B^2)(C_4 + \Delta^3 C_5\right]} \tag{14.57}$$

where

$$C_4 = \begin{cases} 1 - \dfrac{1}{4\Delta^3}(2\Delta - \tau)^2(\Delta + \tau) & \text{for } \tau > \Delta \\ \dfrac{\tau^2}{4\Delta^3(3\Delta - \tau)} & \text{for } \tau < \Delta \end{cases}, \quad C_5 = \begin{cases} 1 - \dfrac{1}{4}(2-\tau)^2(1+\tau) & \text{for } \tau > 1 \\ \dfrac{\tau^2}{4(3-\tau)} & \text{for } \tau < 1 \end{cases}$$

with the parameter τ being $\tau = (1 - B)(1 + \Delta)$.

Qian and Law (1997) have also considered the energy balance of two colliding drops with the same diameter. They have accounted for the energy loss during collision due to viscous dissipation. Their result yields the linear dependence of the critical Weber number corresponding to the separation/coalescence threshold on the Ohnesorge number. Their result for the best fit to the existing experimental data is given in the form

$$We_{cr} = 30Oh + 15 \tag{14.58}$$

with the Ohnesorge number being defined as $Oh = 16\mu_l/\sqrt{\rho_l R \sigma_l}$.

14.2.3 Drop–Wall Impact

Many processes involving drop and sprays also involve their impact onto a surface. Universal relations describing the outcome of drop/wall impact do not exist simply because of the large number of influencing parameters:

- Reynolds number and Weber number of incident drop
- Surface orientation (normal/inclined)
- Surface structure (rough/smooth) and chemical composition (hydrophobic/hydrophilic)
- Dry or wet surface, including the hydrodynamics of the liquid film in the case of a wet surface
- Surface temperature

Obviously, additional properties of the impinging drop may also be of importance, such as boiling point, heat of vaporization, or contact angle with the surface.

Understanding drop–wall impact represents a key technology for some processes, for example, ink jet printing or near net-shape manufacturing, where solidification must also be accounted for (Madejski, 1983, Poulikakos and Waldvogel, 1996, Liu and Orme, 2001). Very-high-speed drop impacts can even lead to

damage or erosion of the solid surfaces, like turbine blades or airplane surfaces. In such ultrahigh-speed drop impacts, compressibility is one important factor, leading to the propagation of shock waves in the drop and in the target material (Lesser and Field, 1983, Korobkin, 1997). However, drop/wall impact is also an elemental part of spray/wall impact, which itself is an essential process in many technologies: spray cooling, spray painting, fuel injection, drop separators, etc.

In the following discussion, the phenomenon of drop impact has been divided into impact onto dry surfaces and onto liquid films. In the former case, the wettability may become important, whereas in the latter case, the hydrodynamics of the liquid film must be considered. A very good collection of papers dealing with various specific aspects influencing drop impact phenomena can be found in an article by Rein (2002).

14.2.3.1 Wetting of a Dry Surface: Static and Dynamic Contact Angles

The stationary shape of a drop on a dry solid surface depends on its volume, density, and surface wettability property, described by a static (or equilibrium) contact angle θ_e, defined in Figure 14.23. In the case of a smooth, homogeneous, rigid surface, this angle depends on the surface (or interface) free energy of the solid–gas interface, σ_{sv}; of solid–liquid interface, σ_{sl}; and of the liquid–gas interface, σ(surface tension). The equilibrium condition at the contact line leads to *Young's relation*:

$$\cos\theta_e = \frac{\gamma_{sv} - \gamma_{sl}}{\gamma} \tag{14.59}$$

The wetting of the substrate is total, $\theta_e = 0$, if the right-hand side of (14.57) is larger than 1. The surface is partially wettable if the absolute value of the RHS of (14.57) is smaller than 1, yielding the value of the equilibrium contact angle in the range $0 < \theta_e < \pi$. Within this range, hydrophobic ($\theta_e > \frac{\pi}{2}$) and hydrophilic ($\theta_e < \frac{\pi}{2}$) surfaces can also be distinguished.

When the liquid spreads on the substrate under action of gravity and capillary forces (spontaneous spreading) or due to inertial forces (forced wetting), the position of the contact line moves and the apparent dynamic contact angle θ_d differs from the static one. The dynamic contact angle depends on the contact line velocity U_c if the capillary number $Ca = U_c\mu/\sigma$ is relatively small. This dependence is shown schematically in Figure 14.24. The sign of U_c is positive if the contact line moves toward the gas phase. Two distinct branches of the curve $\theta_d = \theta_d(U_c)$ are considered in relation to the direction of motion of the contact line: the advancing dynamic contact angle for $U_c > 0$ and receding contact angle for $U_c > 0$.

Next, the static advancing, θ_a, and static receding, θ_r, contact angles can be defined as two different limits of the dynamic contact angle as the velocity U_c approaches zero:

$$\theta_a = \lim_{U_c \to +0} \theta_d(U_c), \quad \theta_r = \lim_{U_c \to -0} \theta_d(U_c)$$

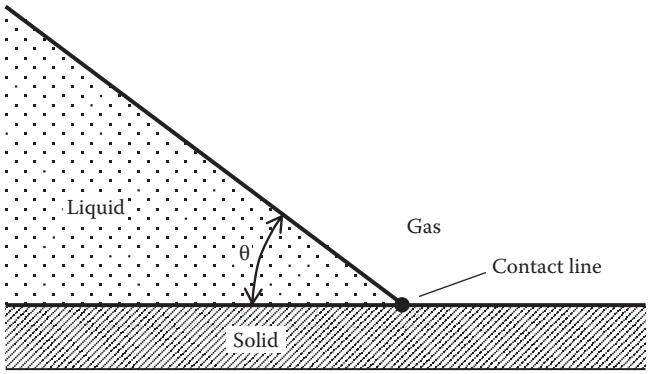

Figure 14.23

Sketch defining the contact angle and the contact (or triple) line.

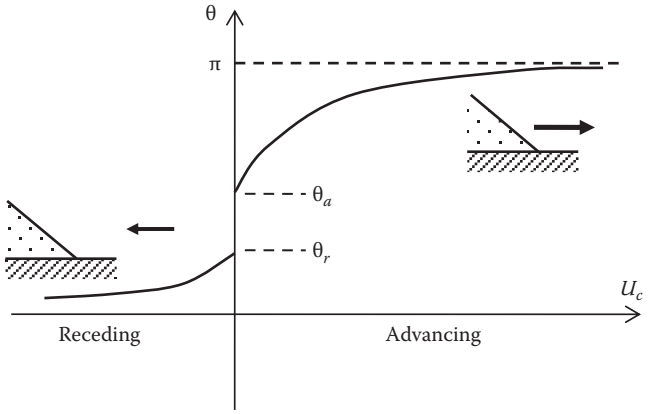

Figure 14.24

Hysteresis of the dynamic contact angle.

The hysteresis in the values of θ_a and θ_r is related to the microstructure of the surface (roughness, chemical nonhomogeneity), the presence of impurities in the liquid, and the substrate. The contact angle of the liquid in the steady state can thus vary in the range $\theta_r < \theta < \theta_a$.

The dynamic contact angle at $\theta_e \approx 0$ and $Ca \ll 1$ depends on the capillary number Ca only (Hoffman, 1975). An empirical correlation for the dynamic contact angle for such cases is given by Voinov (1976) and (Tanner, 1979) in the form

$$\theta_d \sim Ca^{1/3} \tag{14.60}$$

which is known as the "Hoffman–Voinov–Tanner law" (Kistler, 1993).

More generally, the dynamic contact angle may also depend on the hydrodynamics of the liquid behind the contact line and two main approaches to the problem of dynamic contact angle are considered to date: the hydrodynamic approach (with the most general analysis in Cox (1986)) and molecular-kinetic approach (introduced in Blake, 1968, Blake and Haynes, 1969). See the detailed reviews of the wettability phenomena and modeling in Kistler (1993) and Blake (1993). More recent work can be found in Blake et al. (1999).

Some biological or micro- and nanostructured surfaces are extremely hydrophobic. Barthlott and Neinhuis (1997) studied the morphology of lotus plant leaves, revealing a self-cleaning property through rain, fog, or dew (the lotus effect). Considerable effort is presently being spent on producing synthetic water-repellent surfaces with prescribed surface morphologies. Onda et al. (1996) produced a fractal alkylketene dimmer, reaching an apparent contact angle of 174° in their experiments. Bico et al. (1999) and Richard and Quéré (2000) have investigated a single drop impact onto such highly hydrophobic surfaces, observing that the drop can fully bounce after impact on such surfaces.

Spontaneous drop spreading is analyzed in the theoretical works of Hocking and Rivers (1982), Dussan and Chow (1983), Pozdikidis (1990), and Reznik and Yarin (2002). The inertial effects in such low-speed drop impacts are small in comparison with the capillary forces and viscous drag. At higher impact speeds, inertia and viscous forces can no longer be neglected, and this situation is considered in the following section.

14.2.3.2 Drop Impact onto a Dry Substrate

The phenomenon of drop impact onto a dry substrate can be subdivided into several main phases, as shown in Figure 14.25. The first phase is the initial drop deformation during which the drop shape transforms from a nearly spherical shape to a thin liquid film (lamella) expanding on the wall. The duration of this first phase is approximately $t_{init} \sim D_0/U_n$, where D_0 is the initial drop diameter and U_n is the normal component of the impact velocity. During the second phase of drop impact, the spreading lamella is bounded by a rim, formed by capillary forces. The formation of this rim leads to the typical pizza-like shape of a spreading drop. The position of the rim determines the size and the shape of the wetted spot on the substrate. At some time instant, $t = t_{max}$, the size of the wetted spot reaches a maximum. Then, if the substrate is partially hydrophobic, the drop begins to recede, leading to the third phase of drop impact. At some further time

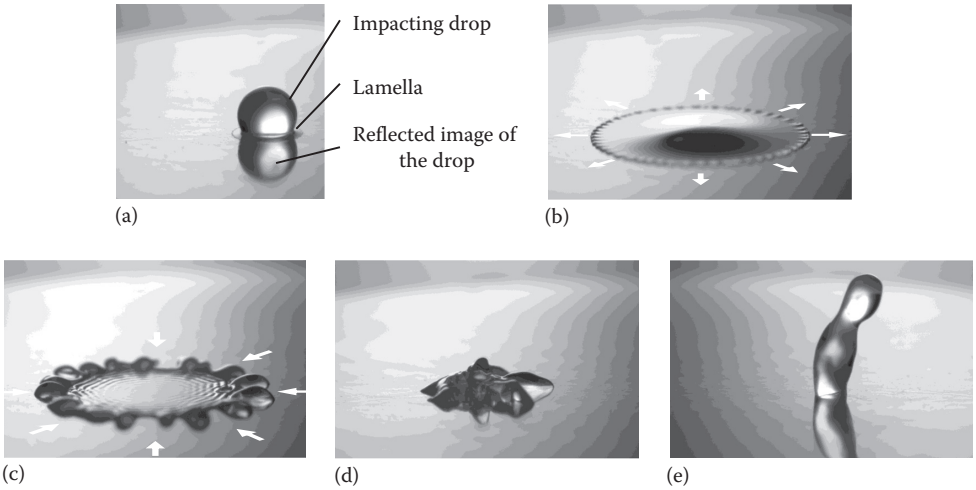

Figure 14.25

Stages of single drop impact onto a dry, partially wettable substrate.

instant $t = t_{merg}$, the rim merges. If the kinetic energy of the rim at the time instant $t = t_{merg}$ is high enough, the rim merging process can lead to the appearance of a fingerlike central jet ejected from the surface.

If the Reynolds and the Weber numbers are high, the first phase of the initial deformation and the spreading of the drop are dominated by inertia. The evolution of drop diameter during these two phases and the value of the maximum spread diameter are almost independent of the static contact angle (Rioboo et al., 2002). The receding of the drop is in contrast caused by forces associated with the wettability.

In each stage of impact, the drop can lose its stability and break up. The experimental studies of drop impact are focused mainly on the determination of various outcomes of the impact event (see Hartley and Brunskill, 1958, Levin and Hobbs, 1971, Stow and Stainer, 1977, Stow and Hadfield, 1981, Mao et al., 1997, Range and Feuillebois, 1998). The influence of the surfactants added to the liquid on the evolution of the diameter of the spreading drop has been studied by Mourougou-Candoni et al. (1999).

A number of different outcomes of drop impact are classified in an article by Rioboo et al. (2001) (see Figure 14.26). A *prompt splash* occurs at high impact velocities onto a rough surface during the first stage of initial drop deformation. A number of jets are formed in the region of the contact line as the result of its perturbations by the wall roughness. These jets then break up into secondary droplets. The mechanism of *corona splash* after a drop impact onto a dry wall is not yet completely clear. It can be caused either by air entrainment into the contact line region or by the bending instability of a lamella spreading radially on the substrate. This type of splash is more typical for the high-speed drop impact onto a wetted wall. At some time instant, this lamella (initially planar) begins to deform and eject a nearly cylindrical, uprising

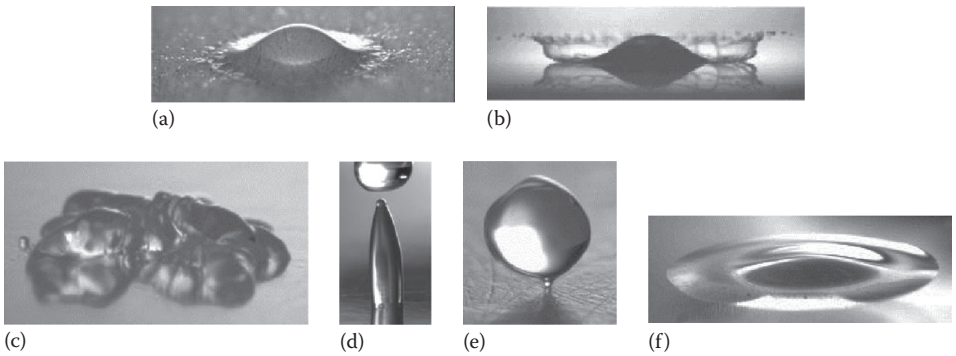

Figure 14.26

Classification of different outcomes of drop impact onto a dry substrate. (The images are from Rioboo, R. et al., *Atomization Sprays,* 11, 155, 2001.)

crown-like sheet. A number of small jets then appear at the edge of this sheet, subsequently breaking up into secondary droplets. The drop can also break up during its receding phase. This *receding breakup* is caused by a disjoining of the contact line due to the local wall microstructure or chemical inhomogeneity. The *partial rebound* occurs when the duration of the central jet stretching is longer than the time required for its capillary breakup. Drop impact onto a highly hydrophobic surface can lead to the complete *rebound*. If the parameters of drop impact are below the splashing threshold, it *deposits* on the surface without breakup.

An empirical relation for the splashing threshold was obtained by Mundo et al. (1998). It was assumed that drop will not splash if

$$K = WeOh^{-0.4} < 657 \tag{14.61}$$

However, more recent parametric studies of drop of variable liquids indicate that the well-known relation (14.59) is not precise and the *K*-number does not describe the splashing threshold well. It is valid probably for relatively narrow range of impact parameters. More generalized expression for the corona splash threshold can be found in Roisman et al. (2015):

$$Ca \geq 0.067 + 0.60Oh^{0.15} \quad \text{at 1 bar} \tag{14.62}$$

is a necessary condition for splash, where the capillary number is based on the drop impact velocity, $Ca = U\mu/\sigma$. Equation 14.62 is recommended for use, since it is based on the analysis of a high number of experiments collected from different sources. The *K*-number is more relevant to the impact of a drop onto a wetted substrate, the case considered in the next section.

The splashing threshold depends also on the ambient pressure. Pressure reduction can lead to a significant increase in the threshold velocity (Xu et al., 2005). Still, no consensus exists on the physical mechanisms leading to the dependence of the splashing threshold on the properties of the ambient gas.

Moreover, it was shown by Roisman et al. (2015) that the prompt splash on rough and porous substrates is determined not on the average roughness but on the characteristic slope of the substrate surface structures. They have introduced an average threshold Weber number for splash

$$We_{\text{average}} = 10.2(Rpk/Rsm)^{-0.83} \tag{14.63}$$

where

Rpk and *Rsm* are the standard parameters characterizing substrate roughness
Rpk is an average height of protruding peaks above the roughness core profile
Rsm is the mean width of a roughness element

14.2.3.3 Drop Impact onto a Wetted Wall

Numerous studies of the drop impact onto a liquid film have led to similar data concerning the splash threshold, drop shape, crown propagation, fingering of the rim, etc. (Levin and Hobbs, 1971, Macklin and Metaxas, 1976, Cossali et al., 1997, 2004).

Depending on the impact parameters and the film thickness, several impingement regimes have been determined. The collision can result in *sticking, rebound, deposition*, and *splash* (Stanton and Rutland, 1996) as shown in Figure 14.27. In an article by Cossali et al. (1997), two types of the splash were observed: *corona splas*h (when the impact results in the creation of a crown-like sheet, which then breaks up) and *prompt splash* (when small secondary droplets are ejected from the region where the drop contacts the free surface of the film). Also, the formation of a central fingerlike jet was observed in the case of high-velocity impact into a deep pool or onto a relatively thick film (Ogũz and Prosperetti, 1990).

The stick regime occurs when the nearly spherical drop adheres to the film. The condition for the stick regime, $We < 5$ in Stanton and Rutland (1996), is based on the experimental results of the studies by Rodrigues and Mesler (1985), Walzel (1980), and Jayaratne and Mason (1964).

The rebound regime occurs in the Weber number range $5 < We < 10$ (Rodrigues and Mesler, 1985).

For the Weber number higher than 10, the deposition of the impinging drop takes place when the parameters of the impact are below the splash threshold.

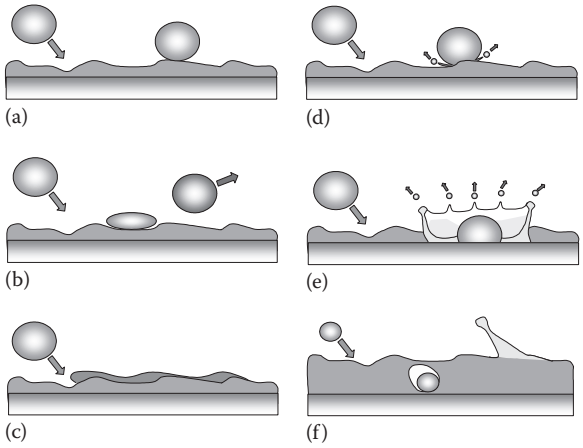

Figure 14.27

Single drop impact onto a wetted surface.

The splash threshold represents the conditions at which secondary droplets are first observed and takes a form similar to Equation 14.59, with empirical modifications for the liquid film (Cossali et al., 1997, Samenfink, 1997, Mundo et al., 1998, Wang and Chen, 2000).

Cossali et al. (1997) have obtained images of a splashing drop, showing the details of the crown formation, and jetting. The following empirical relation for the critical *K*-number depending on the dimensionless film thickness δ (scaled to the drop diameter) has been proposed:

$$K = 2100 + 5800\delta^{1.44} \quad \text{for } 0.1 < d < 1 \quad \text{and} \quad Oh > 7 \times 10^{-3} \tag{14.64}$$

Note that in spite of the fact that the *K*-number is a parameter having "round" powers of *We* and *Oh*, it is completely empirical.

Ogũz and Prosperetti (1990) have studied the impact of a single drop into a deep pool or relatively thick liquid film. The main subjects of this experimental, theoretical, and numerical study were the crater expansion in the liquid pool, bubble entrapment, and the creation of the central jet. The dominant factors influencing the phenomenon are the inertia of the liquid, capillary forces, and gravity. Bubble entrainment takes place in the range of parameters

$$41.3\, Fr^{0.179} < We < 48.3\, Fr^{0.247} \tag{14.65}$$

where

$Fr = U^2/(gD_0)$ is the Froude number

g is the acceleration due to gravity

These upper and lower bounds are obtained by fitting the experimental data.

14.2.3.4 Theoretical Modeling of Drop Impact

Modeling of drop impact phenomena involves description of an unsteady flow governed by inertia, capillary forces, and viscous drag. In the case of the drop impact onto a dry wall also, the forces associated with the wettability are important.

One parameter characterizing drop impact onto a dry wall is the maximum spread diameter. Most of the models are based on the energy balance of the drop: Collins et al. (1990), Chandra and Avedisian (1991), Pasandideh-Fard et al. (1996), Fukai et al. (1995), and Mao et al. (1997). In all of these approaches, the drop shape is assumed to be a disk at the instant when the drop diameter reaches its maximum value. Moreover, the total kinetic energy of the drop at this instant is assumed to vanish.

Other feature of drop impact is the instability of lamella, leading to its breakup, which has been studied by Kim et al. (2000) and Fedorchenko and Chernov (1999).

In the study of normal impact of a drop onto a dry, partially wettable wall (Roisman et al., 2002), the temporal evolution of the drop diameter—its spreading and receding—is determined by the motion of a

torus-like rim, bounding a thin radially expanding film (lamella). The equations of motion of the film are obtained from its mass and momentum balance.

One important result of the studies of drop impact onto a stationary uniform liquid film is the temporal expansion of the radius R_{cr} of the crown. The dependence $R_{cr} \sim \sqrt{t}$ is obtained by Yarin and Weiss (1995) describing the base of the crown as a kinematic discontinuity in the liquid film. In recent work (Trujillo and Lee, 2001), this theory is modified, taking into account the effect of the viscous forces. In Roisman and Tropea (2002), the theory of the formation of the uprising sheet and its shape, valid for the general, nonaxisymmetric case, is developed. All these models are developed for the case of drop impact onto relatively thin films ($\delta < 0.5$).

If the impact Weber and Reynolds numbers are much higher than unity, the evolution of the lamella thickness in time does not depend on viscosity and surface tension (Roisman et al., 2009). An exact solution for the flow generated by drop impact has been obtained by Roisman (2009). Among important results from this solution is an expression for the maximum spreading diameter

$$D_{\max} \approx 0.87 Re^{1/5} - 0.40 Re^{2/5} We^{-1/2} \tag{14.66}$$

and for the minimum (residual) thickness of the lamella

$$h_{res} = 0.79 Re^{-2/5} \tag{14.67}$$

15.10 Scrubbers
15.11 Barrier-Type Separators
15.12 Bag Filters
15.13 Liquid-Phase Particle Separation (Hydrocyclone)

The operation to separate dust from a fluid stream is referred to as particle collection. It has been utilized to recover valuable materials from many chemical processes and to remove air pollutants consisting of particulate matter from exhaust streams before exiting to the atmosphere. In this operation, it is essential to produce a sufficiently large relative velocity between the particles and the fluid. Hence, many types of collectors have been developed and used to accomplish the tasks mentioned. In this chapter, the principles and features of particle separation and typical particle collectors are described. Particle separation in a hydro-cyclone is also described in Section 15.13, because the separation process of particle is similar in both liquid and air.

15.1 Separation Efficiency and Grade Efficiency

Chikao Kanaoka

Separation (overall) efficiency is the ratio of the amount of dust collected to the total amount of dust entering the collector in a given period of time. However, it is difficult, practically, to determine the separation efficiency of an actual dust collector. The efficiency is calculated by one of the following three methods using inlet and outlet dust flow rates, dust concentration, and gas flow rate, as shown in Figure 15.1.

1. Efficiency evaluation using the dust flow rate at the inlet and outlet ducts:

$$\mathfrak{E}\begin{cases} = \dfrac{\dot{m}_{in} - \dot{m}_{p,out}}{\dot{m}_{in}} = 1 - \dfrac{\dot{m}_{out}}{\dot{m}_{in}} \\ = \dfrac{c_{p,in}\dot{V}_{in} - c_{p,out}\dot{V}_{out}}{c_{p,in}\dot{V}_{in}} = 1 - \dfrac{c_{p,out}\dot{V}_{out}}{c_{p,in}\dot{V}_{in}} \\ = \dfrac{c_{p,in,N}\dot{V}_{in,N} - c_{p,out,N}\dot{V}_{out,N}}{c_{p,in}\dot{V}_{in,N}} = 1 - \dfrac{c_{p,out,N}\dot{V}_{out,N}}{c_{p,in}\dot{V}_{in,N}} \end{cases} \tag{15.1}$$

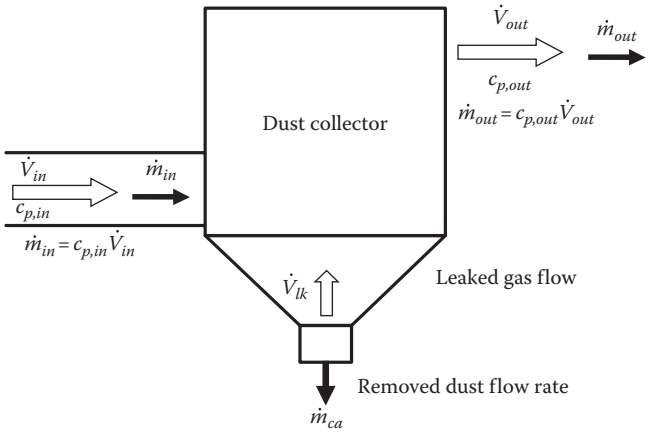

Figure 15.1

Symbols relating the performance of dust collector.

where

$\dot{m}$ is the mass flow rate of dust (kg/s)
c_p is the dust concentration (kg/m^3)
$\dot{V}$ is the volume flow rate of the gas (m^3/s)
The subscripts "in" and "out" refer to the inlet and outlet, respectively
N refers to the standard conditions (dry basis, 0°C, 1 atm)

Without gas leakage and temperature change, the efficiency expression becomes

$$\mathfrak{E} = 1 - \frac{c_{p,out}}{c_{p,in}} = 1 - \frac{c_{p,out,N}}{c_{p,in}} \tag{15.2}$$

2. Efficiency evaluation using the dust flow rate in the inlet duct and the amount of dust removed per unit time in the collector, $\dot{m}_{ca}$:

$$\mathfrak{E} = \frac{\dot{m}_{ca}}{\dot{m}_{in}} \tag{15.3}$$

3. Efficiency evaluation using the dust flow rate at the outlet and the amount of dust removed per unit time in the collector:

$$\mathfrak{E} = \frac{\dot{m}_{cat}}{\dot{m}_{ca} + \dot{m}_{out}} \tag{15.4}$$

Although the separation efficiency can be determined by any of the aforementioned methods, Equations 15.1 and 15.2 are the only methods viable in practice.

Dust particles approaching the collector are polydisperse, and their size distribution depends on the source. The separation efficiency of each individual particle depends on its size, because the particle is separated by a separation mechanism that depends on a physical property related to its inertia and operational conditions. Hence, separation efficiency for a given particle size is called "grade efficiency," "partial separation efficiency," or "fractional efficiency." The separation efficiency for a whole particle size range is a sum of the individual grade efficiencies accounting for the particle size distribution. This is called "overall separation efficiency."

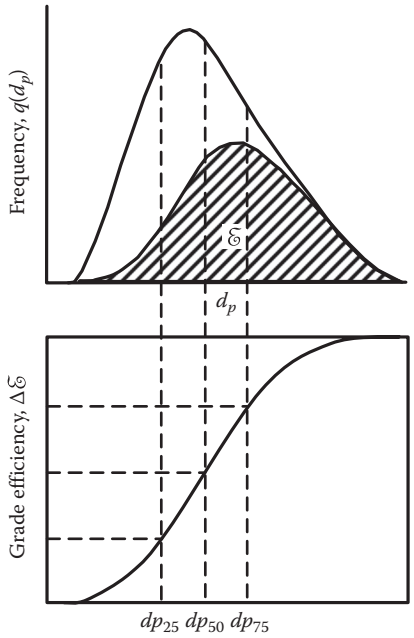

Figure 15.2

Relation between overall separation efficiency and grade efficiency.

The overall separation efficiency $\mathfrak{E}$ is expressed schematically by the hatched area in Figure 15.2 and in terms of grade efficiency $\Delta\mathfrak{E}$ and particle size distribution $q(d_p)$ as

$$\mathfrak{E} = \int_0^{d_p} \Delta\mathfrak{E}\left(d_p\right) q\left(d_p\right) \mathrm{d}d_p \tag{15.5}$$

Since $\Delta\mathfrak{E}(d_p)$ can be calculated for a given dust collector as a function of particle properties and operational conditions, the overall separation efficiency of the dust collector can be estimated without any measurement by knowing the particle size distribution.

The total separation efficiency of dust collectors in series is expressed by

$$\mathfrak{E}_T = 1-(1-\mathfrak{E}_1)\left(1-\mathfrak{E}_2\right)\ldots\left(1-\mathfrak{E}_n\right) \tag{15.6}$$

where

$\mathfrak{E}_T$ is the separation efficiency of the overall system
$\mathfrak{E}_1, \mathfrak{E}_2, \ldots, \mathfrak{E}_n$ are the separation efficiencies of the elemental collectors
n is the number of dust collectors

Hence, when the separation efficiency of each elemental collector is the same, $\mathfrak{E}_T$ is expressed as

$$\mathfrak{E}_T = 1-\left(1-\mathfrak{E}\right)^n \tag{15.7}$$

15.2 Classification of Particle Separation Systems

Chikao Kanaoka

Dust removal equipment can be classified as dry or wet collectors depending on whether the collection medium is liquid or solid. They are also classified according to industrial dust collectors or air filters, depending on inlet dust concentration, which, for industrial collectors, is usually several orders of magnitude higher

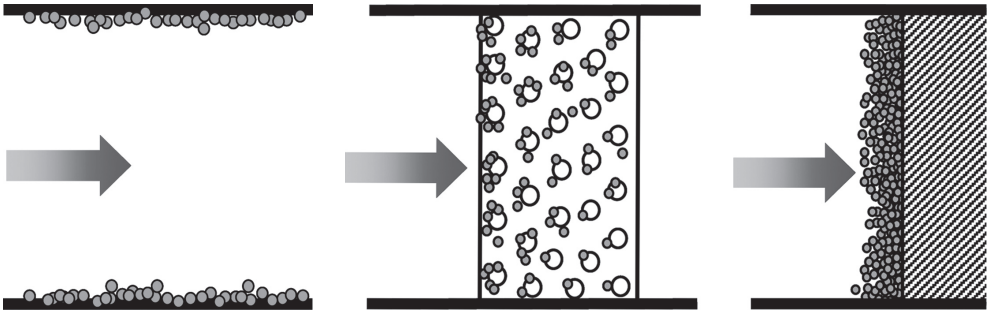

Figure 15.3

Classification of dust collector according to gas flow and collection mechanisms.

than for air filters. When they are classified according to the gas flow and dust collection mechanism, every dust collector belongs to one of the categories shown in Figure 15.3 (Kanaoka et al., 1997):

1. *Flow-through-type dust collectors*: This type of collector utilizes the external force perpendicular to the mean gas flow to remove particles from the flow. Hence, the flow does not change with time and removal performance and pressure drop of the system are always the same. Gravitational dust collector, cyclone, and electrostatic precipitator (ESP) all belong to this collector type.
2. *Obstacle-type dust collectors*: This type of collector captures dust on obstacles inside the equipment. When solid particles are captured by a solid obstacle, the collected particles remain on the obstacle, which results in an increase in both collection performance and flow resistance with time. This also makes the release of captured particles from the obstacles difficult. Therefore, this type of dust collector is normally used as a disposable type of collector. Air filter, granular bed filter, louver-type dust collector, and venturi scrubber belong to this collector type.
3. *Barrier-type dust collectors*: This type of collector uses a permeable medium for the gas but not for the dust, so that the dust is captured and accumulated on the surface. To maintain a continuous operation of this type of dust collector, the accumulated dust has to be removed when the pressure drop becomes too high. Bag and ceramic filters are the typical dust collectors of this type.

Table 15.1 summarizes general features of dust collectors. Compared with the other collectors, the bag filter shows the highest collection performance, but the collector size has to be large, as its lowest filtration

Table 15.1 General Features of Dust Collectors

Type	Removable Particle Size (μm)	Pressure Drop (Pa)	Maximum Temperature (°C)	Inlet Concentration (g/m³)	Initial Capital Cost	Remarks
Flow-through type						
Gravitational collector	>20	50–150	1000	50>	Low	Predust collector
Cyclone	>1	2,000>	1000	500>	Middle	Convenient
ESP	>0.02	300>	400	20>	Highest	Not for explosive material
Obstacle type						
Scrubber	>0.2	10,000>	1000	100>	Middle	Requires waste water treatment
Air filter	>0.01	500>	100	0.01>	Low	For building and house
Air cleaner	>1	1,000>	50	1>	Low	Engine and compressor
Granular bed	>1	10,000>	1000	50>	High	Good for hot gas cleaning
Barrier type						
Bag filter	>0.01	2,000>	250	20>	High	Not good for condensable material
Ceramic filter	>0.01	50,000>	1000	50>	Highest	Good for hot gas cleaning

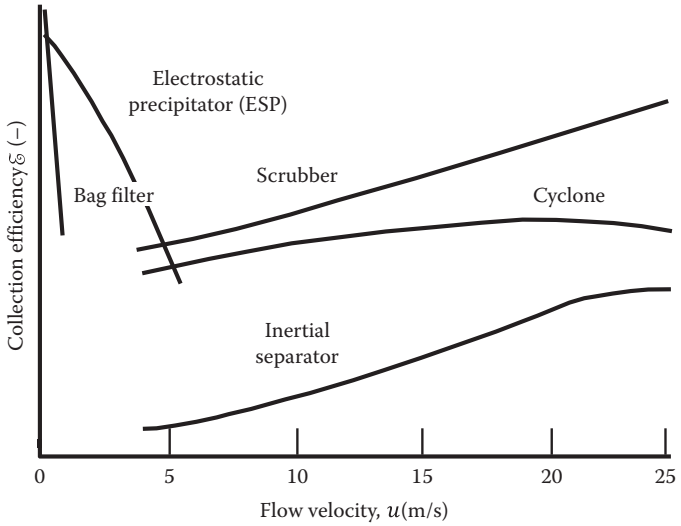

Figure 15.4

A rough sketch of separation performance for various dust collectors.

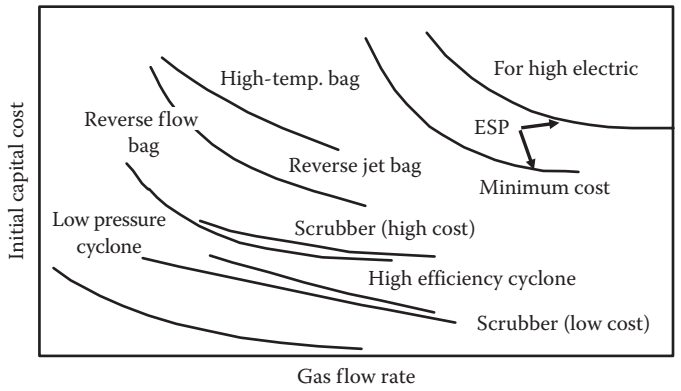

Figure 15.5

Relationship between initial capital cost and dust collector type.

velocity is of the order of 1 m/min. Furthermore, its highest operating temperature is limited to 250°C because of the poor thermal durability of the filter material.

The ESP can treat gases as high as 1 m/s with a very low pressure drop. However, its collection performance depends on the electrical properties of dust particles. Figures 15.4 and 15.5 show the collection efficiency of dust collectors in relation to gas velocity and the initial capital cost of the equipment as a function of the handling gas flow rate. The total annual cost to operate a dust collector is usually the lowest at a gas velocity that differs from the velocity for best performance. Hence, one has to have criteria for the selection of dust collectors.

15.3 Flow-Through-Type Separators

Chikao Kanaoka

This type of collector utilizes the external force perpendicular to the mean gas flow to remove particles from the flow. The flow does not vary with time. Hence, the collection performance and pressure drop of the system are also essentially constant with time.

15.3.1 Separation Efficiency

15.3.1.1 Separation for Laminar Flow

When dust particles collect into a rectangular-shaped dust collector with height H, width W, and length L, as shown in Figure 15.6, the separation efficiency of the collector can be obtained as follows. For simplicity, the gas flow is assumed as laminar and the only force acting on particles is in the direction perpendicular to the gas main flow. Then the particle motion in the collector can be expressed by

$$v_x = \frac{\mathrm{d}x}{\mathrm{d}t} = u(y) \tag{15.8}$$

$$v_y = \frac{\mathrm{d}y}{\mathrm{d}t} = -v_{mig} \tag{15.9}$$

where

v_x and v_y are the particle component velocities in the x and y directions
$u(y)$ is the gas velocity in the flow direction
v_{mig} is the migration velocity of the particle determined from the force balance between the applied external force and fluid drag force

The migration velocities due to different external forces are summarized in Table 15.2.

The particle trajectory can be obtained by integrating

$$v_{mig}\,\mathrm{d}x = -u(y)\mathrm{d}y \tag{15.10}$$

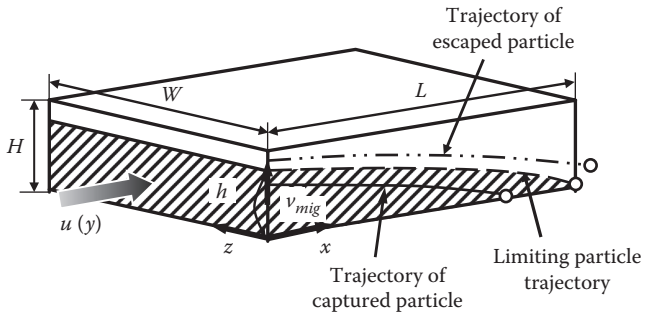

Figure 15.6

Concept of flow-through-type dust collector.

Table 15.2 Migration Velocity by External Force

External Force		Migration Velocity v_{mig}
Gravitational	$\frac{\pi}{6}(\rho_p - \rho_f)d_p{}^3 g$	$\frac{Cc(\rho_p - \rho_f)d_p^2 g}{18\mu}$
Centrifugal	$\frac{\pi}{6}(\rho_p - \rho_f)d_p^3 \frac{u_\theta^2}{r}$	$\frac{Cc(\rho_p - \rho_f)d_p^2}{18\mu}\frac{u_\theta^2}{r}$
Electrostatics	neE	$\frac{CcneE}{3\pi\mu d_p}$

with the initial condition at $y = h$, $x = 0$. Three typical trajectories are illustrated in Figure 15.6. The shapes of these trajectories are the same, but each trajectory shifts horizontally, depending on the inlet height. The lowest trajectory that intersects the bottom plate and the intermediate one reaches at the exit of the collector, while the highest trajectory passes through the collector. In other words, those particles that impact the collector plate and lie below the intermediate trajectory are collected, but those particles higher than the intermediate trajectory are not collected. Hence, the intermediate trajectory is regarded as the "limiting particle trajectory" and the separation efficiency of this dust collector is defined as the ratio of particle flow rate below the limiting particle trajectory (hatched area in the Figure 15.6) to the total particle flow rate entering the collector:

$$\mathfrak{E} = \frac{c_p W \int_h^0 u(y)\mathrm{d}y}{c_p W \int_H^0 u(y)\mathrm{d}y} = \frac{W \int_0^L -v_{mig}\,\mathrm{d}x}{-\dot{V}} = \frac{WLv_{mig}}{\dot{V}} = \frac{A_c v_{mig}}{\dot{V}} \tag{15.11}$$

where

$\dot{V}$ is the flow rate of treated gas

$A_c = WL$ is the area where particles deposit, namely, the total collection area of the collector

Equation 15.11 has been derived based on the assumption that the flow is laminar (without turbulent mixing). Therefore, it is applicable for any flow through the dust collector so long as the flow is laminar.

15.3.1.2 Separation for Turbulent Flow

The situation becomes different when flow inside the collector is turbulent, and it is very difficult to obtain an analytical expression except for the following two extreme cases: (1) complete mixing across the cross section of the collector, that is, uniform concentration throughout the cross section and (2) complete mixing in the whole collector, that is, uniform concentration everywhere in the collector.

For the first case, the concentration change along the mean flow direction can be obtained from the mass balance as follows:

$$c_p uWH - (c_p - \Delta c_p)uWH = c_p v_{mig} W\,\mathrm{d}x \tag{15.12}$$

$$\mathfrak{E} = 1 - \frac{c_{p,out}}{c_{p,in}} = 1 - \exp\left(-\frac{A_c v_{mig}}{\dot{V}}\right) \tag{15.13}$$

In the second case, the particle concentration in the equipment and outlet is the same and the separation efficiency becomes

$$\mathfrak{E} = 1 - \frac{1}{1 + A_c v_{mig}/\dot{V}} = \frac{A_c v_{mig}/\dot{V}}{1 + A_c v_{mig}/\dot{V}} \tag{15.14}$$

The calculated separation efficiency for each case is shown in Figure 15.7. As seen from the figure, the separation efficiency increases with $A_c v_{mig}/\dot{V}$ for any flow condition, but it is the highest for laminar flow. In other words, the presence of turbulence decreases the collection efficiency. Any actual flow is between these two extreme cases, and thus, separation efficiency of each dust collector can be approximated by knowing the turbulent intensity and $A_c v_{mig}/\dot{V}$.

From Figure 15.7, the separation efficiency $\mathfrak{E}$ becomes higher when v_{mig} and A_c become larger and $\dot{V}$ smaller. In practice, the flow rate is usually given so as to enhance the separation efficiency; either v_{mig} has to be increased or A_c made larger, that is, increasing the size of the dust collector.

Furthermore, it is remarkable that Equations 15.11, 15.13, and 15.14 were derived without any restrictions, other than types of gas flow, that is, laminar and turbulent. This suggests that they are applicable for all flow-through-type dust collectors such as gravity, centrifugal force, electrostatic force, and so on. Equation 15.13 is sometimes called the "Deutsch equation" for ESPs.

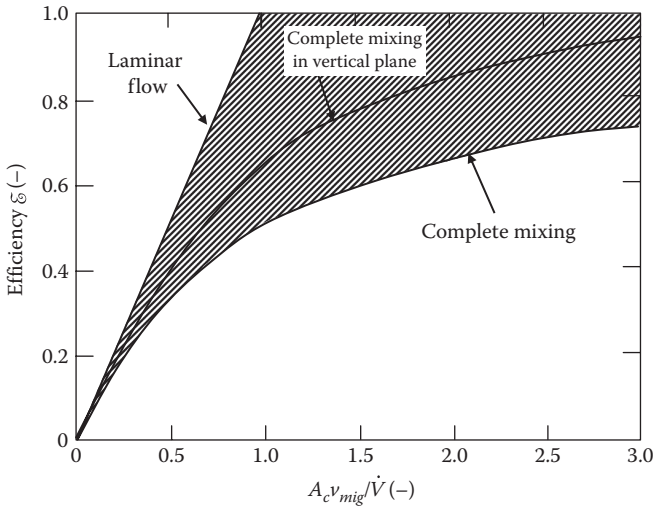

Figure 15.7

Separation efficiency of a flow-through-type dust collector at different flow conditions.

15.4 Gravitational Collectors

Chikao Kanaoka

The gravitational dust collector is the most typical flow-through-type dust collector and separates particles by the difference in the gravitational settling velocity between particles. Figure 15.8 shows some typical dust collectors. Figure 15.8a is the box-type settling chamber and Figure 15.8b is the multiplate-type collector. As indicated earlier, the separation efficiency increases as $A_c v_{mig}/\dot{V}$ becomes large. In the multiplate-type collector, several horizontal trays are installed to shorten the vertical migration distance to separate the particles and thus increase the separation area in keeping with increasing $A_c v_{mig}/\dot{V}$. In both the cases, to improve the gravitational effect, the cross-sectional area of the collector is enlarged to operate at a low gas velocity. Gas velocity in this type of collector is usually 1 m/s, and thus the pressure drop is low (of the order of 100–1000 Pa). However, discharging the separated particles and cleaning the equipment are difficult tasks to perform in practice.

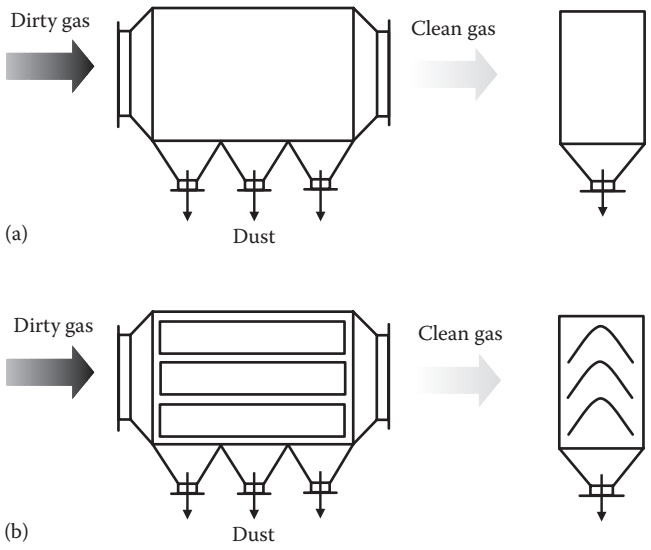

Figure 15.8

Typical gravity dust collector. (a) Gravity settling chamber, (b) multistage settling chamber.

15.5 Centrifugal Separation: Dry Cyclones

Hideto Yoshida and Kunihiro Fukui

Cyclones are widely used for separating powders. Recently, excellent performance with cut size below 0.5 μm has been obtained by Iinoya et al. (1990, 1992, 1993). The optimization of the cyclone dimensions in each part is, however, mainly determined by experiment, because the analyses of fluid flow and particle motions are very complicated. Numerical calculations of fluid flow and particle motions in the cyclone have been conducted by Ayers et al. (1985), Zhou and Soo (1990), Yamamoto et al. (1993), and Yamamoto and Kitamura (1994), but their calculations are conducted by assuming axisymmetrical flow. To model the complicated flow field in the cyclone, it is necessary to do the numerical calculation in three dimensions. Yoshida et al. (1991) have reported such calculations.

Centrifugal acceleration is created either by airflow in cyclone-type classifiers or by the mechanical revolution in air separators. Two types of centrifugal separators are in practical use: the forced vortex type and the free vortex type. For the forced vortex type, a variety of centrifugal classifiers are available. Changing the rotational speed in the separator controls the cut size. On the other hand, the conventional cyclone falls into the free vortex type. Changing the inlet velocity can control the cut size. Compared to the forced vortex type, the range of cut size variation in the conventional free-vortex-type cyclone is small. However, Yoshida et al. (1993) have shown that it is possible to change the cut size over a wide range by using special designs of the conventional cyclone separator.

In this section, recent results using a three-dimensional simulation for the performance of a dry cyclone are presented. The predicted fluid flow pattern and particle trajectories in the cyclone are compared with experimental results. The effects of using blow-down and an apex cone on particle collection efficiency are also shown. Recent results for submicron classification using an improved-type cyclone are also presented.

15.5.1 Classification Theory of Cyclones

Cyclones are widely used in industrial applications. If N is the number of revolutions required for the particle to reach the wall, the particle residence time is

$$\tau_{res,r} = \frac{2\pi RN}{u_{in}} \tag{15.15}$$

In Figure 15.9, R is the cyclone radius and u_{in} is inlet fluid velocity. The radial velocity of the particle toward the wall is represented by

$$v_{rad} = \tau \frac{u_{in}^2}{R} \tag{15.16}$$

The value of τ, the particle velocity response time, defined by

$$\tau = \frac{\left(\rho_p - \rho_f\right) d_p^2}{18\mu} \tag{15.17}$$

is used in the calculation. Assuming that those particles initially at a distance of x from the wall are collected, the time it takes for the particle to reach the wall is

$$\tau_{res,x} = \frac{x}{v_{rad}} = \frac{xR}{\tau u_{in}^2} \tag{15.18}$$

By using Equations 15.15 and 15.18, one has

$$\frac{xR}{\tau u_{in}^2} = \frac{2\pi RN}{u_{in}} \tag{15.19}$$

$$\tau = \frac{x}{2\pi N u_{in}} \tag{15.20}$$

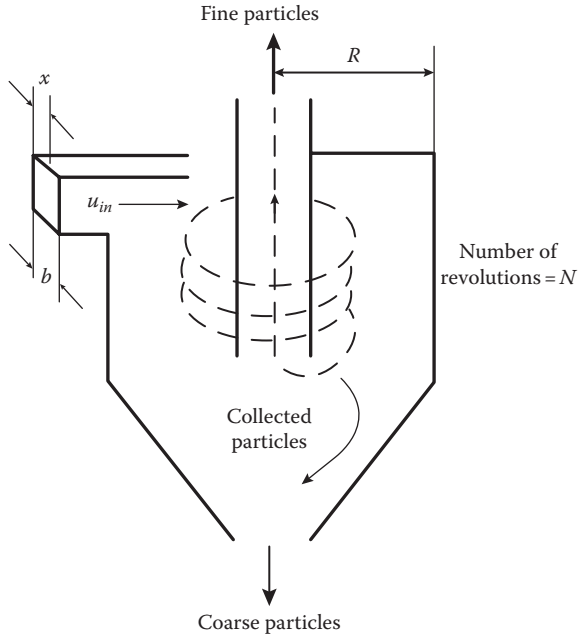

Figure 15.9

Simplified model of cyclone separator.

If the inlet width of the cyclone is b, the fractional separation efficiency is given by

$$\Delta\mathfrak{S} = \frac{x}{b} = \frac{2\pi u_{in}\left(\rho_p - \rho_f\right)d_p^2}{18\mu b} \tag{15.21}$$

Then, the cut size, which is the particle size corresponding to $\Delta\mathfrak{S} = 0.5$, is

$$d_{p,cut} = \sqrt{\frac{9\mu b}{2\pi N u_{in}\left(\rho_p - \rho_f\right)}} \tag{15.22}$$

The value of N can vary from 3 to 8, depending on the cyclone configuration.

Leith and Licht (1972) proposed estimating cut size by using the various dimensions of cyclone separator. A more detailed information regarding cyclone performance is obtained from recent results of numerical simulation.

15.5.2 Numerical Calculations

A 3D numerical simulation of the cyclone separator has been performed by Yoshida et al. (1993, 1994). The flow fields were modeled and particle trajectories calculated according to the methods described in Chapter 2. Two approaches were used in the numerical simulation: In the direct-method approach, a constant (eddy) viscosity was assumed and different values were tried as reflected by using three Reynolds numbers: 3,000, 5,000, and 10,000. The Reynolds numbers are based on the inlet velocity and diameter of the cyclone. The second approach was to use the $\kappa - \varepsilon$ turbulence model.

The component of the fluid velocity in the $r - z$ plane at different circumferential angles is shown in Figure 15.10. The definition of the circumferential angle θ is defined in Figure 15.10. In this figure, the flow Reynolds number in the cyclone is 5000. It is found that the flow field depends on the circumferential angle and the assumption of axial symmetry of the flow in the cyclone is not always correct. For example, the velocity vectors just below the exit tube point toward the central axis in the case of $\theta = 3.8°$, but point in the opposite direction in the case of $\theta = 183.8°$. The downward velocity components near the conical wall (region A) are large and the down-flow (region A) and up-flow (region B) are in close proximity near the entrance of the dust box. It might be thought that a small particle located near the cyclone wall moves downward, but close to the entrance to the dust box, and the particle may be entrained in the up-flow velocity and go out to the exit tube. The calculations also show upward velocity components in the upper part of the dust box.

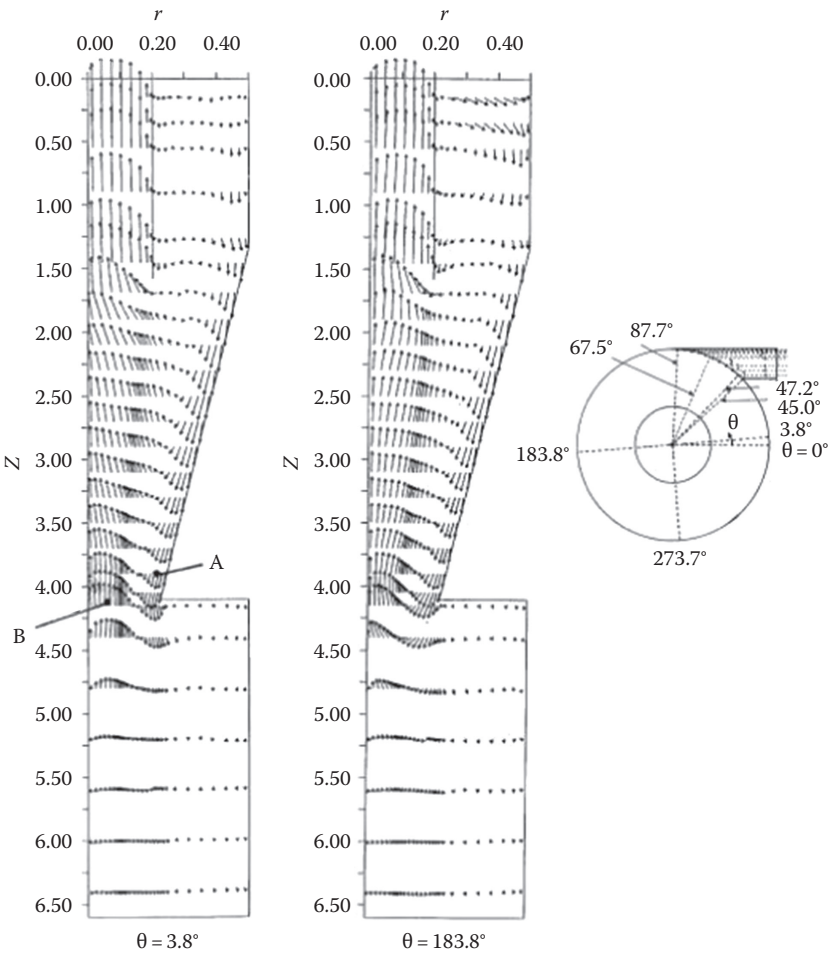

Figure 15.10

Fluid velocity distribution in the *r–z* plane at two circumferential angle (*Re* = 5000).

The predicted particle trajectories for different particle diameters projected on a plane are shown in Figure 15.11. It was assumed that the particles are collected when they contact the wall surface. The large particles (d_p = 2.4 μm) are collected on the conical wall, but some smaller particles (d_p = 2.0 μm) enter into the dust box and then move out of the cyclone because of the upward axial velocity component. If the particles are much smaller (d_p = 0.8 μm), they do not enter the dust box, but move around the vortex finder and exit the cyclone.

The experimental data for partial separation efficiency obtained by Iinoya and Nakai (1969) are shown in Figure 15.12.

The Stokes number *St* is defined in this case as

$$St = \frac{Cc\rho_p d_p^2 u_{in}}{9\mu D} \tag{15.23}$$

where

Cc is Cunningham's slip correction factor
D is the cyclone diameter
u_{in} is the inlet velocity

The test particles were latex, Kanto loam (d_p = 1.8 μm), and stearic acid. The experimental results are compared with the numerical calculations. The solid line indicates calculated results of the direct method and the dotted line is the result when turbulence is included (κ − ε model). The experimental flow Reynolds number is higher than 40,000. The experimental data agree well with the predicted results when the turbulence model is used.

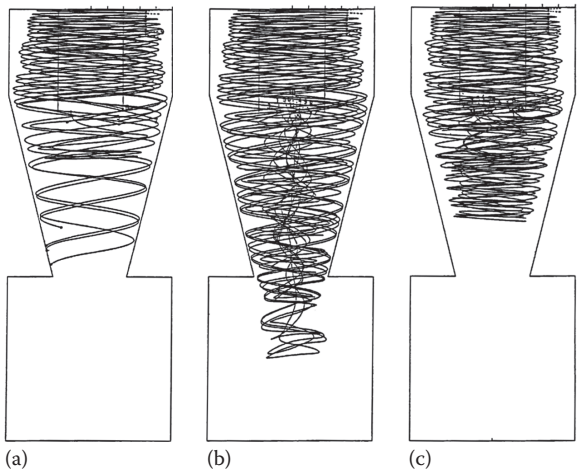

Figure 15.11

Particle trajectories in a cyclone: (a) d_p = 2.4 μm, (b) d_p = 2.0 μm, (c) d_p = 0.8 μm.

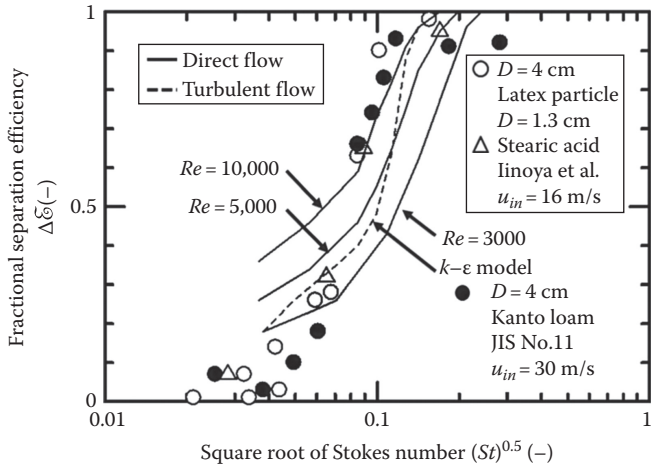

Figure 15.12

Fractional separation efficiency data compared with calculated results.

15.5.3 Effect of Blow-Down

Numerical and experimental studies of fractional separation efficiency under blow-down conditions were carried out by Yoshida et al. (1995). With the blow-down method, a portion of fluid is discharged from the dust box. With the blow-up method, particle-free fluid is introduced into the dust box. The blow-down and blow-up ratios are defined as follows:

$$B_d = \frac{\dot{V}_d}{\dot{V}_{in}} \quad B_u = \frac{\dot{V}_u}{\dot{V}_{in}} \tag{15.24}$$

where

$\dot{V}_{in}$ is the inlet flow rate
$\dot{V}_d$ is the discharge from the dust box
$\dot{V}_u$ is the additional-flow rate into the dust box

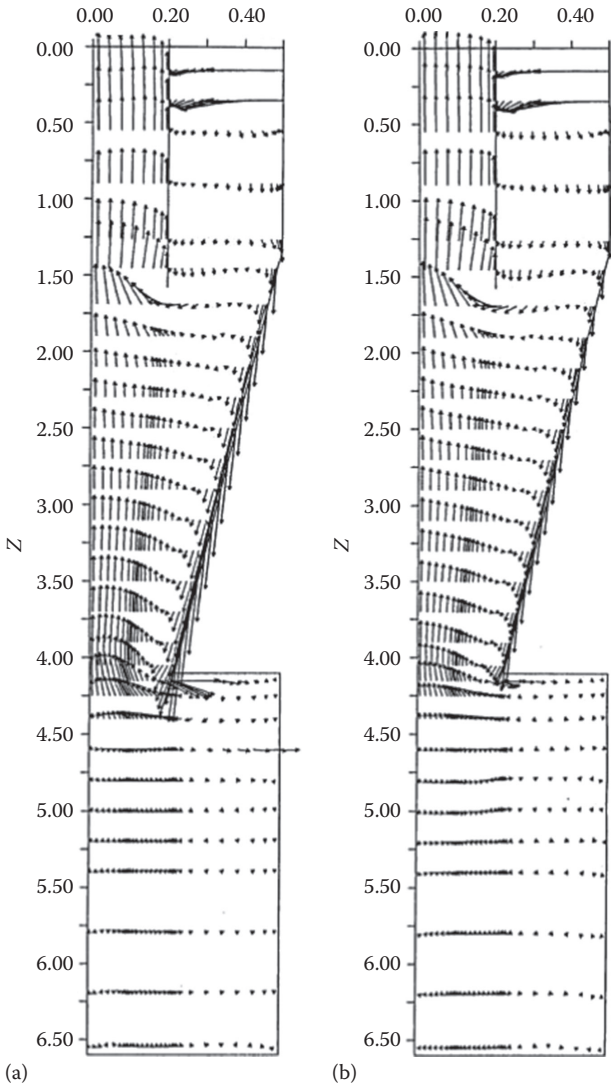

Figure 15.13

Fluid velocity distributions (a) with and (b) without blow-down.

Fluid velocity vectors with and without blow-down are shown in Figure 15.13. The $\kappa - \varepsilon$ turbulence model was used in numerical calculations. The blow-down flow is located at the upper part of the dust box. In this case, the blow-down ratio is 10%. In the case of blow-down, the downward velocity components near the conical wall are larger than without blow-down. With blow-down, small particles collected on the cyclone wall move downward near the conical wall and the particles are more likely to enter the dust box.

The effects of the circumferential angle of the particle starting position on predicted particle trajectories are shown in Figures 15.14 and 15.15. The particle diameter was 0.8 μm, and the three initial circumferential angles were 47°, 65°, and 88°. These circumferential angles correspond to different starting positions for the particles in the inlet duct, as shown in Figure 15.10. The results for blow-down and no blow-down are shown in Figures 15.14 and 15.15, respectively. With blow-down, some of the particles are collected near the blow-down hole in the dust box. On the other hand, nearly no particles are collected without blow-down.

The correlation between fractional separation efficiency and the square root of half value of Stokes number for both blow-down and no blow-down case is shown in Figure 15.16, where it is also observed that the experimental data agree well with the numerical predictions. It is found that the partial separation efficiency with blow-down approaches the value of blow-down ratio as the Stokes number decreases. Iinoya et al. (1993) found that submicron classification is possible by the use of a specially designed cyclone.

Particle trajectories for different initial circumferential angle (with blow-down).

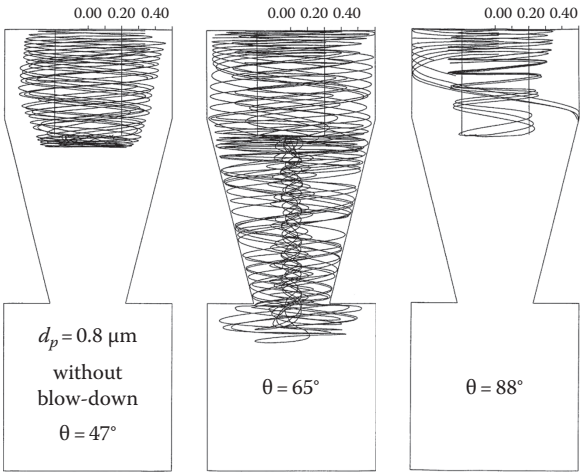

Figure 15.15

Particle trajectories for different initial circumferential angle (without blow-down).

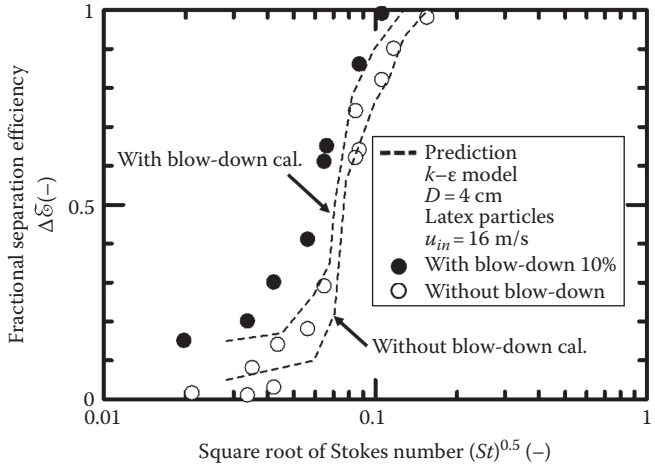

Figure 15.16

Fractional separation efficiency with and without blow-down.

15.5.4 Cut Size Control by Use of a Free-Vortex-Type Classifier

The use of a movable circular slide plate, shown in Figure 15.17, is effective in controlling the cut size in a gas cyclone. Data for classification performance obtained by Yoshida et al. (1993, 1994) are shown in Figure 15.18. Using a movable slide plate and employing the blow-down method, the cut size changes to small size region. Both methods are effective in decreasing the cut size. The effect of an apex cone located at the upper part of the dust box is expected to decrease the cut size and to increase the collection efficiency.

The fluid vectors predicted by Yoshida et al. (2001) are shown in Figure 15.19. The two cases with and without an apex cone are examined. Using the apex cone, it is possible to decrease the magnitude of the fluid velocity component in the upper part of the dust box. As a result, it is possible to reduce re-entrainment of particles from the dust box to the vortex finder.

The predicted particle trajectories with and without the apex cone are shown in Figure 15.20. Particle re-entrainment is not observed with the apex cone. The cut size of cyclones with an apex cone is smaller than that without an apex cone, as demonstrated in Figure 15.21. By using the apex cone, it is possible to move the cut size into fine particle size region.

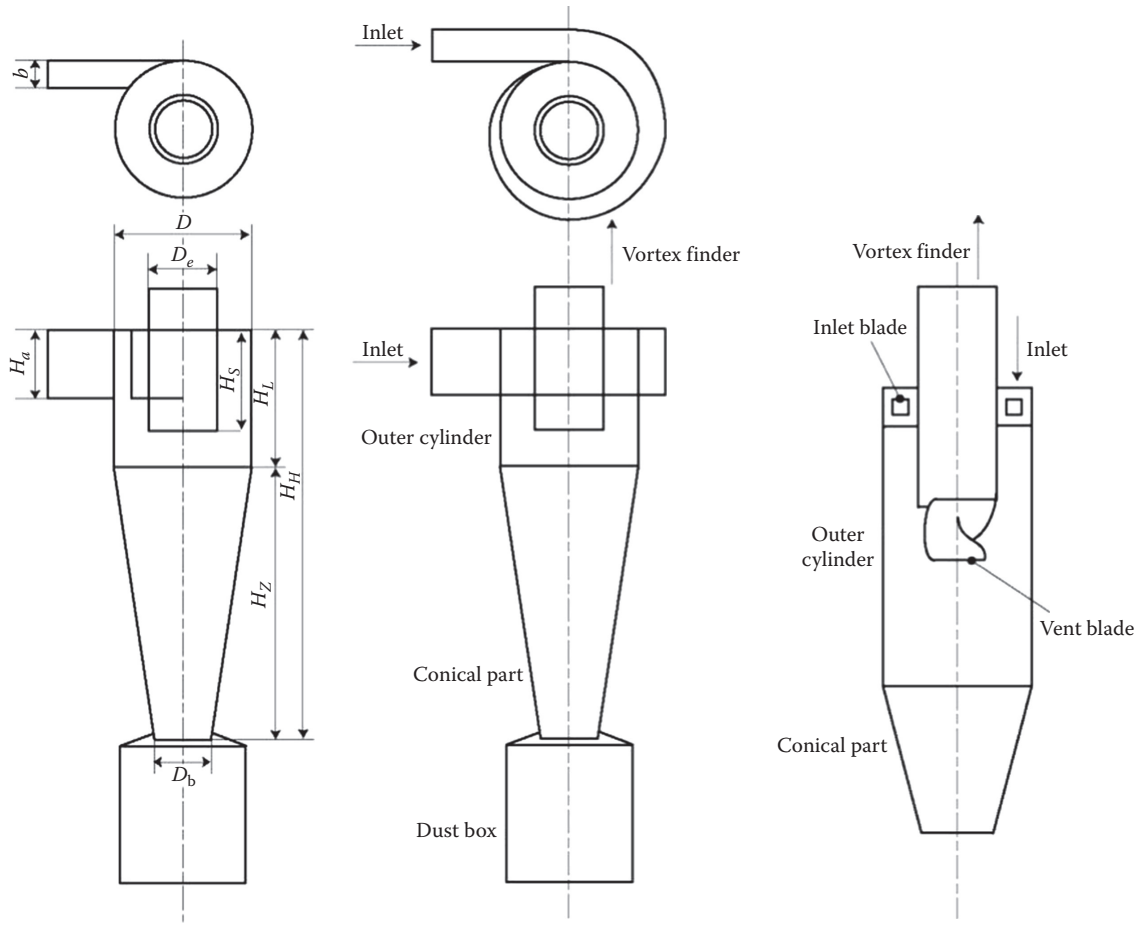
15.5.5 Estimation Method of Pressure Drop and Classification Performance

Many studies have been devoted to the optimization of the overall cyclone design and that of individual components, and as a result, cut sizes have reached the submicron order with improved separation accuracy (Fukui et al., 2011). Figure 15.22 shows the typical flow inlet systems and dimensional ratios of cyclone separators. The cyclone separator can be divided into three types roughly, according to the systems needed to insert the flow into the cyclone. They are the tangential inlet, the scroll inlet, and the axial flow inlet configurations.

The pressure drop of the cyclone mainly consists of three losses: pressure losses at the inlet part, fluid friction losses caused by the vortex flow in the cyclone, and pressure losses at the vortex finder. In many cases, the last term affects the pressure drop most strongly. The pressure drop of the cyclone is usually approximately proportional to the square of the inlet velocity u_{in}. The pressure drop of the cyclone when the dust is not loaded, ΔP_0, can be calculated by the following equation:

$$\Delta P_0 = Eu\frac{\rho_f u_{in}^2}{2} \tag{15.25}$$

Here, the variable Eu, which is called Euler number, can be determined predominantly by the cyclone geometry. It was reported that the variable Eu can be given as follows (Shepherd and Lapple, 1939):



$$Eu = 16\left(\frac{K_a K_b}{K_e^2}\right) \tag{15.26}$$

$$Eu = 11.3\left(\frac{K_a K_b}{K_e^2}\right)^2 + 3.33 \tag{15.27}$$

where K_a, K_b, and K_e are ratios of length to the cyclone diameter D, defined in Figure 15.22, respectively. These equations suggest that the pressure drop depends little on the cyclone size and also on the dimensional ratios.

It is well known that the cyclone pressure drop decreases with increasing concentration of the loaded powder. The following equation was proposed as the empirical formula, which gives the cyclone pressure drop ΔP when the concentration of loaded powder is equal to c_p (Briggs, 1946):

$$\Delta P = \Delta P_0\left(1 - 0.0086\sqrt{c_p}\right) \tag{15.28}$$

	$K_a = H_a/D$	$K_b = b/D$	$K_s = H_S/D$	$K_e = D_e/D$	$K_L = H_L/D$	$K_H = H_H/D$	$K_B = D_b/D$
Yoshida (a)	0.60	0.20	0.85	0.50	1.0	5.0	0.40
Yoshida (b)	0.50	0.24	1.39	0.44	2.08	9.72	0.50
Stairmand	0.50	0.20	0.50	0.50	1.5	4.0	0.38
Lapple	0.50	0.25	0.63	0.50	2.0	4.0	0.25
Barth	0.53	0.13	0.73	0.33	0.69	2.58	0.33

Figure 15.22

Typical inlet systems and configurations for cyclone separator. (a) Tangential inlet, (b) scroll inlet, (c) axial inlet.

Since the actual airflow in the cyclone contains the complicated secondary flow, the turbulent fluctuation, the instability aspect of the vortexes, and so on, it is very difficult to estimate the particle motion and the classification performance of the cyclone exactly. However, many models, which evaluate the classification performance, have been proposed based on the simplified and idealized velocities and forces acting on the particle. Some estimation formulae can successfully give the accurate cut size and fractional separation efficiency.

Most popular formulae for 50% cut size calculation are listed in Table 15.3. Lapple's model (Lapple, 1950) correlates the number of revolutions N with the cyclone configurations in Equation 15.22. On the other hand, regarding Barth's model (Barth, 1956), 50% cut size is calculated by two specified tangential velocities u_{ti} and u_{tw} defined by him. Iozia's model (Iozia and Leith, 1989) also uses the specified maximum tangential velocity $u_{t\max}$.

Table 15.3 Estimation Equations for the 50% Cut Size of Cyclone Separator

Lapple's model	$d_{p,50} = \sqrt{\dfrac{9\mu b}{2\pi N C_c u_{in}(\rho_p - \rho_f)}}$, $N = \dfrac{H_L + (H_H - H_L)/2}{H_a}$
Barth's model	$d_{p,50} = \sqrt{\dfrac{9\mu u_{ti} D_e}{C_c u_{tw}^{\ 2}(\rho_p - \rho_f)}}$
Iozia's model	$d_{p,50} = \dfrac{1}{u_{t,max}} \sqrt{\dfrac{9\mu H_a b u_{in}}{\pi z_c (\rho_p - \rho_f)}}$
	$u_{t,max} = 6.1 u_{in} (K_a K_b)^{0.61} K_e^{-0.74} K_H^{-0.33}$, $d_{cr} = 0.47 D (K_a K_b)^{-0.25} K_e^{1.4}$
	$z_C = H_H - H_S \ (d_{cr} < D_b)$
	$z_C = (H_H - H_S) - \left(\dfrac{H_H - H_S}{K_b - 1}\right)\left(\dfrac{d_{cr}}{D_b} - 1\right) \ (d_{cr} < D_b)$

The fractional separation efficiency $\Delta\mathfrak{E}(d_p)$ of most cyclones can be approximated by the following equation with the 50% cut size $d_{p,50}$ and the slope exponent β:

$$\Delta\mathfrak{E}(d_p) = \frac{1}{1 + (d_{p,50}/d_p)^{\beta}} \tag{15.29}$$

Equation 15.29 is the empirical estimation equation for β reported by Iozia and Leith (1989). The partial separation efficiency curve can be obtained by the 50% cut size calculation in Table 15.3, and Equations 15.29 and 15.30:

$$\ln\beta = -0.62 - 0.87\ln(d_{p,50} \cdot 10^3) + 5.21\ln(K_a K_b) + 1.05\{\ln(K_a K_b)\}^2 \tag{15.30}$$

Further, the formulae for the direct calculation of the fractional separation efficiency have been also proposed, and some of the popular ones are listed in Table 15.4 (Dietz, 1981, Clift et al., 1991).

Figure 15.23 shows the fractional separation efficiency curves estimated by various models for a cyclone separator 72 mm in diameter with the real experimental data. Though the estimated results are not in absolute agreement with the experimental ones, these models can predict them practically with satisfactory accuracy.

As listed in Tables 15.3 and 15.4, the classification performance of the cyclone decreases with the cyclone size. The cut size of the cyclone is usually proportional to the square root of the cyclone size D approximately. In order to collect the particles from large amount of the dust-loaded airflow without reducing the collection efficiency, the multicyclone system where many small size cyclones are contained in parallel is useful. A schematic diagram of the multicyclone is shown in Figure 15.24.

Table 15.4 Formulae for the Partial Separation Efficiency Curve

Clift's model	$\Delta E = 1 - \exp\left[-\dfrac{(\rho_p - \rho_f)}{9\mu}\left(\dfrac{2 d_p u_{in}}{D}\right)^2 t_{res}\right]$
Diez's model	$\Delta E = 1 - \left\{K_0 - \left(K_1^{\ 2} + K_2\right)^{0.5}\right\} \exp\left[-\dfrac{2\pi(2K_S - K_a)}{K_a K_b} St\right]$
	$K_0 = \dfrac{1}{2}\left\{1 + K_2\left(1 + \dfrac{K_a K_b}{\pi K_l St}\right)\right\}$, $K_1 = \dfrac{1}{2}\left\{1 - K_2\left(1 + \dfrac{K_a K_b}{\pi K_l St}\right)\right\}$
	$K_2 = K_e^{\ 2\gamma}$, $K_l = 2.3 D_e (H_a b D)^{-1/3}$
	$\gamma = 1 - (1 - 0.67 D^{0.14})\left(\dfrac{T}{283}\right)^{0.3}$

15.6 Electrostatic Precipitators

Hisao Makino and Naoki Noda

15.6.1 Principles of Electrostatic Precipitators

The ESP is utilized as a dust collector in large-scale plants, such as thermal power plants, because it has high collection efficiency and is capable of handling large flue gas volume flow rates.

In the EPS, dust particles in the flue gas are charged by a corona current and removed by the electric field. There are two types of ESP: one stage and two stage. In the one-stage ESP, dust charging and separation are performed simultaneously, whereas in the two-stage type, particle charging is performed in the first stage, and collection of the charged particles is performed in the second stage. The one-stage ESP, shown in Figure 15.25, is the most common. This type of ESP with flat-plate collection electrodes is easy

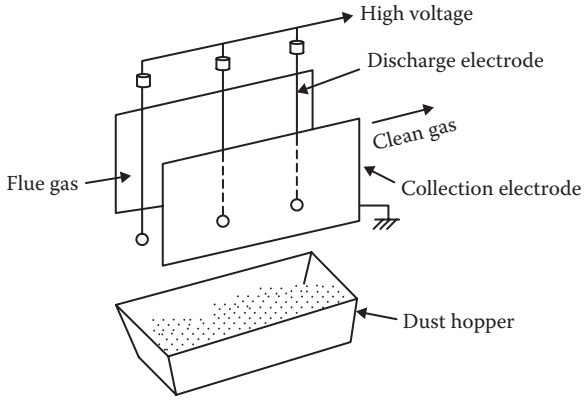

Figure 15.25
Outline of ESP.

to scale up. The wire discharge electrodes are centered between two parallel flat collection electrodes. The pressure drop in the ESP is very low compared to the fabric filter or granular bed. The ESP is suitable for dust collection in large-scale facilities.

A negative high voltage is applied to the discharge electrodes and the collection electrodes are grounded. The negative ions generated by the corona discharge at the electrodes collide with the dust particles in the flue gas to charge the particles. The particles then move toward the collection electrodes by the electric mobility due to the electric field formed between the discharge and collection electrodes. The collected dust particles are released to the hopper under the ESP. The particles adhering to the discharge and collection electrodes are dislodged by tapping the electrodes, which then fall into the hopper.

15.6.1.1 Particle Charging

In the ESP, the dust particles are charged by the ions in the field generated by corona discharge. The amount of charge is determined by particle size, electric field strength, corona current density, and residence time. The mechanisms responsible for particle charging are field and diffusion charging. The particle charge acquired by one of the following two mechanisms may be given by the following expressions:

$$\text{Diffusion:} \quad q_e = \frac{d_p \kappa T}{2e^2} \ln\left(1 + \frac{\pi d_p \overline{G}_i n_i e}{2\kappa T} t\right) \tag{15.31}$$

$$\text{Field:} \quad q_e = \left[1 + \frac{2(\varepsilon_0 - 1)}{\varepsilon_0 + 2}\right] \frac{E d_p^{\,2}}{4e} \cdot \left(\frac{\pi e B_i n_i t}{1 + \pi e B_i n_i t}\right) \tag{15.32}$$

where

$\overline{G}_i$ is the mean thermal mobility of ions (4.5×10^4 cm/s)
n_i is the concentration of ions
ε_0 is the dielectric constant
B_i is the electric mobility of ions (1.4 cm^2/s/V)

The relationship between particle charge and particle size is shown in Figure 15.26. In diffusion charging, the particle charge is not affected by the electric field strength and tends to increase linearly with particle size. In field charging, the particle charge increases with an increase in electric field strength and tends to increase linearly with the square of the particle size. In general, diffusion charging is most effective for fine particles less than 1 μm in diameter, while the field charging is most effective for particles greater than 1 μm.

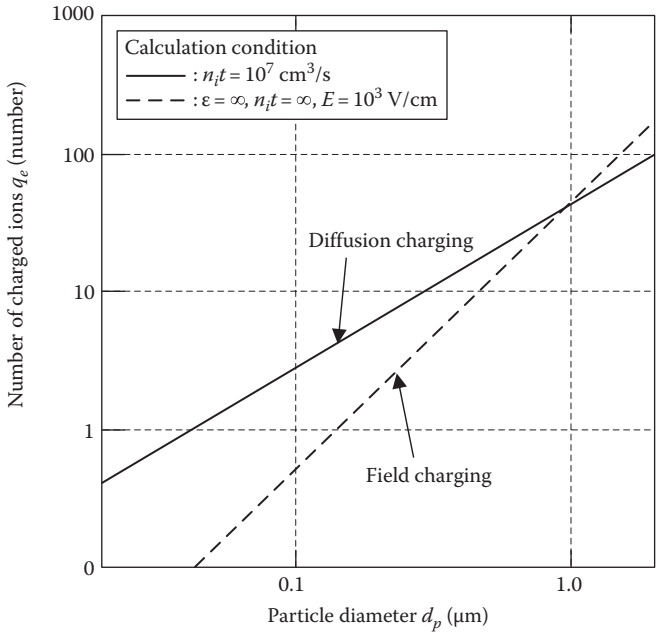

Figure 15.26

Number of charged ions and particle diameter. (From Kanaoka, C. et al., Principle and equipment of dust collectors, *Fundamentals in Aeorsol Science*, Nikkan Kogyo Shinbun, Tokyo, Japan, 1997, pp. 24–99.)

Since it is necessary to charge particles as much as possible in a short period of time, high electric field strength and high current density are required. The charging methods utilized are DC charging, AC charging, and the pulse charging.

1. *DC charging*: The dust particles are charged in a DC electric field. This charging method is the most common. In this method, the ions move in the same direction and the applied voltage is limited to prevent arc discharge, and hence the charging efficiency is reduced for high-resistivity particles.
2. *AC charging*: The dust particles are charged in the AC electric field. The direction of ion movement alternates constantly. In this method, the particles are charged by ion motion from two directions. Thus, it is more effective for the high-resistivity particles than the DC charging method.
3. *Pulse charging*: This type of charging adds the high-voltage pulse to the DC charging type. However, in this type, the DC charging voltage is applied at lower voltage than in the usual simple DC charging method in order to control arc discharge. The maximum voltage in the pulse charging can be higher than in the usual DC charging method, and the voltage increases with a decrease in the pulse period. Using this method, a high and uniform ion density can be achieved, with no restriction on the shape of the discharge electrode or dust adhesion to the electrode. It is suitable for high-resistivity particles.

The most effective charging method depends on the resistivity of dust particles. The electric mobility in the DC charging method is higher than that in pulse charging for particles with electric resistivity less than $10^9\ \Omega \cdot \mathrm{m}$, while the reverse trend is observed for the high-resistivity dust particles.

15.6.1.2 Electric Mobility of Particles

Under the condition of a uniform electric field in the ESP, the electric mobility (velocity) of charged particles toward the collection electrode is expressed by the following equation (Michaelides, 2006):

$$v_e = \frac{Ccq_eE}{3\pi\mu d_p} \tag{15.33}$$

where
q_e is the particle charge
E is the electric field strength
Cc is the Cunningham correction factor (see Section 1.3)

A suitable expression for the later was obtained by Kanaoka et al. (1997), which is derived from the equation given by Takahashi (1978):

$$Cc = 1 + \left\{1.25 + 0.42\exp\left(-\frac{0.435 d_p}{\lambda_m}\right)\right\}\frac{2\lambda_m}{d_p} \tag{15.34}$$

where
d_p is the particle diameter
λ_m is the mean free path of the gas molecules which, in turn, is given by

$$\lambda_m = 0.709\nu_e\left(\frac{\pi\mathfrak{M}}{\mathfrak{R}_u T}\right)^{1/2} \tag{15.35}$$

where
$\mathfrak{M}$ is the molecular mass
ν_e is the kinematic viscosity
T is the gas temperature
$\mathfrak{R}_u$ is the gas constant

Several expressions for Cc, which are suitable for a wide range of particle sizes, may be found in Michaelides (2014).

15.6.1.3 Collection Efficiency

The collection efficiency of ESP is generally expressed by the following equation, called the Deutsch equation:

$$\mathfrak{E} = 1 - \exp\left(-\frac{A_c \nu_e}{\dot{V}}\right) \tag{15.36}$$

where
A_c is the area of the collection electrodes, which is the product of the length and height of the collection electrode
ν_e is the mobility of charged particles
$\dot{V}$ is the volume rate of flue gas

This equation is developed on the basis of assumptions of uniform electric field, monodisperse particle size, and a locally uniform dust concentration. However, in an actual ESP, the situation is quite different and therefore, this equation is useful only as an estimate of the tendency of collection efficiency.

The overall collection efficiency of a practical ESP is approximately 99%, and the fractional collection efficiency, $\Delta\mathfrak{E}$, which is the collection efficiency for the respective particle size, has a minimum value in the range of particle size of 0.1–1.0 μm, as shown in Figure 15.27. In this figure, p represents the penetration efficiency using

$$p = 1 - \Delta\mathfrak{E} \tag{15.37}$$

The reason for the minimum fractional collection efficiency can be explained as follows: According to Equation 15.34, the Cunningham correction factor increases with a decrease in particle size, but the charge

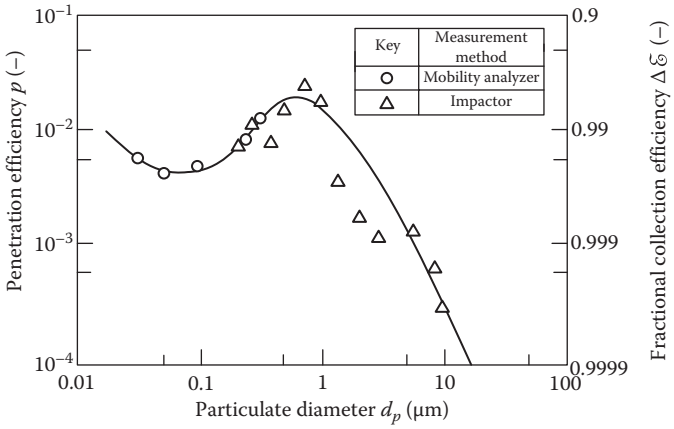

Figure 15.27

Fractional collection efficiency of ESP.

on the particle q increases with an increase in particle size, as shown in Figure 15.26. For particles less than 1 μm, the particle charge accumulation varies linearly with the particle size, but for particles greater than 1 μm, the charge increases with the square of the particle size. Therefore, the fractional collection efficiency shows a minimum value at the particle size in the range of 0.1–1.0 μm.

15.6.2 Characteristics of Electrostatic Precipitators

15.6.2.1 Effect of Collection Conditions

15.6.2.1.1 Influence of Dust Resistivity As the dust particles accumulate at the collection electrodes, they discharge electrons. The performance parameters of the ESP, such as collection efficiency, applied voltage, and corona current, depend on the dust resistivity, ρ_d, as shown in Figure 15.28. In the regions of $\rho_d < 10^2$ $\Omega \cdot$m, and $\rho_d > 5 \times 10^8$ $\Omega \cdot$m, the collection efficiency is low. On the other hand, in the region of 10^2 $\Omega \cdot$m $< \rho_d < 10^8$ $\Omega \cdot$m, the collection efficiency is high. This tendency is explained as follows:

In the case of $\rho_d < 10^2$ $\Omega \cdot$m, when the dust particles accumulate at the collection electrodes, they discharge the electrons immediately and are charged to the same electrostatic potential by the electrostatic conductor. Then the dust particles are re-entrained in the direction of the discharge electrode, and the collection efficiency is decreased. In the case of $\rho_d > 5 \times 10^8$ $\Omega \cdot$m, it is difficult for dust particles to discharge on

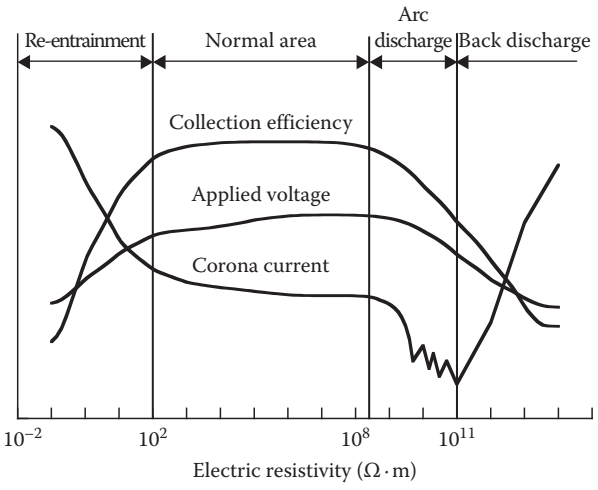

Figure 15.28

Collection characteristics and electric resistivity. (From Kanaoka, C. et al., Principle and equipment of dust collectors, *Fundamentals in Aeorsol Science*, Nikkan Kogyo Shinbun, Tokyo, Japan, 1997, pp. 24–99.)

the collection electrodes and the electrons are stored in the dust layer; hence, the applied voltage is decreased by the dust layer. In addition, as the effective electric field strength becomes lower, the collection efficiency decreases. If ρ_d becomes higher than $10^{11}\ \Omega \cdot m$, back discharge ensues and the collection efficiency is significantly decreased.

In the case of $10^2\ \Omega \cdot m < \rho_d$, $5 \times 10^8\ \Omega \cdot m$, the discharge rate of dust particles is moderate and the collection efficiency remains high.

The resistivity ρ_d is affected by dust properties, temperature, humidity, etc. The relationship between ρ_d of coal ash and the temperature for various humidity conditions is shown in Figure 15.29. The resistivity has a maximum value in the temperature range 100°C–200°C, except under condition of 0% humidity. At the same temperature condition, the resistivity becomes higher with a decrease in humidity, because of the following considerations:

In the low-temperature region, the coal ash particles adsorb moisture from their surroundings and form a water layer on the particle surfaces. Ions can move easily through this water layer, and hence the resistivity is reduced. This layer becomes thicker with a decrease in temperature and an increase in humidity; therefore, the resistivity becomes lower. On the other hand, in the high-temperature region, there is no surface water layer and the electrical conduction must take place through the particles. In this case, the electric resistivity decreases with an increase in temperature. Overall, the resistivity is determined by a combination of these mechanisms, showing maximum values in the temperature range between 120°C and 160°C depending on the humidity.

15.6.2.1.2 Space between Collection Electrodes The space between the collection electrodes is usually set to be 250–300 mm. However, if a sufficient corona current can be achieved, a wider space between collection electrodes can help to maintain or improve the collection efficiency. From Deutsch's equation (Equation 15.36), one notes that to maintain a high collection efficiency, it is necessary to increase the mobility of the particles v_e, because with the wider spacing, the number of electrodes (and collection area) is decreased for space-limited systems.

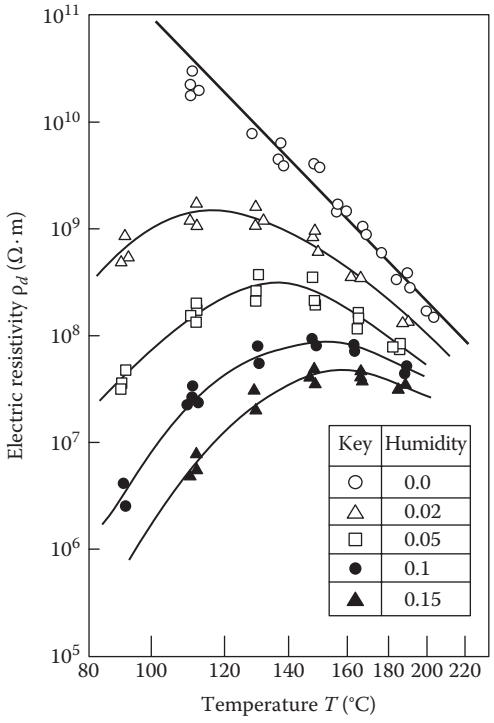

Figure 15.29

Electric resistivity of fly ash. (From Kanaoka, C. et al., Principle and equipment of dust collectors, *Fundamentals in Aeorsol Science,* Nikkan Kogyo Shinbun, Tokyo, Japan, 1997, pp. 24–99.)

15.6.2.2 Dust Collection of Low-Resistivity Particles

An example of low-resistivity dust is the ash from the residual oil combustion, which is in an environment of high humidity. The relationship between applied voltage and collection efficiency for the ash from residual oil combustion is shown in Figure 15.30. The collection efficiency of the ESP increases with an increase in applied voltage, and saturates at 30–40 kV. The collection efficiency is affected by the gas temperature and becomes higher with an increase in gas temperature at the same applied voltage.

The flue gas density decreases with an increase in gas temperature and the corona current increases with a decrease in gas density. On the other hand, as the applied voltage decreases with an increase in gas temperature, the collection efficiency decreases for the same corona current. By these trends, it is evident that collection efficiency is directly related to corona power, which is the product of the applied voltage and corona current, regardless of the gas temperature, as shown in Figure 15.31. This is due to the fact that the properties of the

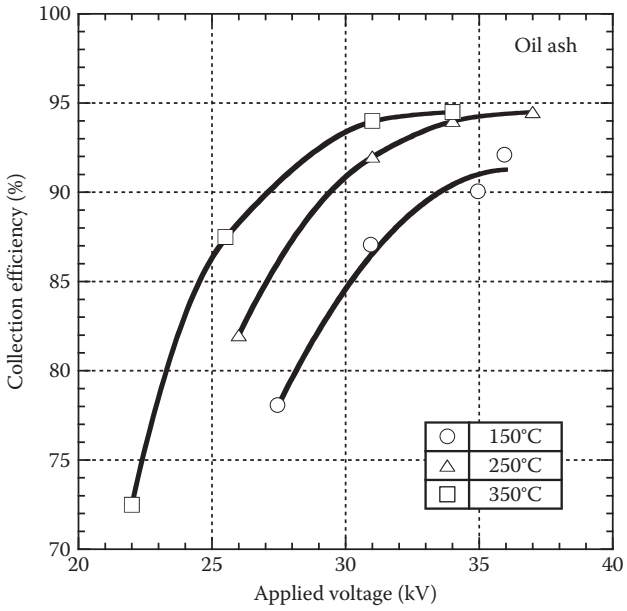

Figure 15.30

Applied voltage and collection efficiency. (From Kanaoka, C. et al., Principle and equipment of dust collectors, *Fundamentals in Aeorsol Science*, Nikkan Kogyo Shinbun, Tokyo, Japan, 1997, pp. 24–99.)

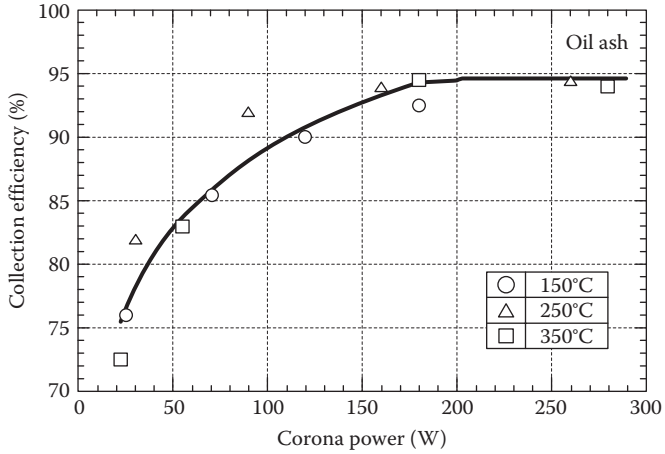

Figure 15.31

Influence of corona power on collection efficiency. (From Kanaoka, C. et al., Principle and equipment of dust collectors, *Fundamentals in Aeorsol Science*, Nikkan Kogyo Shinbun, Tokyo, Japan, 1997, pp. 24–99.)

ash from residual oil combustion remain constant with changes in gas temperature. In other words, if the dust properties are held constant, the collection efficiency of an ESP can be estimated based on corona power.

15.6.2.3 Dust Collection of High-Resistivity Particles

Ash produced by the combustion of pulverized coal is an example of high-resistivity dust. The relationship between corona current density and collection efficiency of an ESP for pulverized coal ash is illustrated in Figure 15.32. The collection efficiency increases with an increase in the current density and saturates at 0.3 mA/m^2, which is the typical operational condition at a coal-fired plant. If the gas velocity is increased, the collection efficiency decreases owing to the lower residence time of the flue gas in the precipitators.

The effect of gas temperature on the collection efficiency is shown in Figure 15.33. For the same corona current density, the collection efficiency decreases with an increase in gas temperature. The reason for this trend is as follows: When the gas temperature decreases, the corona current becomes higher owing to the decrease in gas density and the resistivity of the fly ash. Equivalently, for the same corona current density, the applied voltage becomes lower with an increase in gas temperature and the collection efficiency decreases. The relationship between the applied voltage and the corona current is shown in Figure 15.34, which indicates that at higher gas temperature, the corona current becomes higher at the same applied voltage.

The relationship between corona power, which is the product of the applied voltage and the corona current, and collection efficiency is shown in Figure 15.35. For the same corona power, the collection efficiency decreases with an increase in gas temperature, in contrast to the residual oil combustion ash. This is due to the fact that the resistivity of coal ash decreases with an increase in gas temperature and the applied voltage becomes lower, because of the higher corona current.

In a conventional pulverized coal combustion boiler, the ESP is operated at approximately 150°C. At this temperature, the maximum value of the resistivity of the coal ash is achieved. The collection efficiency for various kinds of coal is shown in Figure 15.36. The collection efficiency depends on coal properties, that is, the collection efficiency for high resistivity ash is lower. Improvements in technology to deal with the decrease in the collection efficiency for high electric resistivity ash are very important to flue gas cleanup.

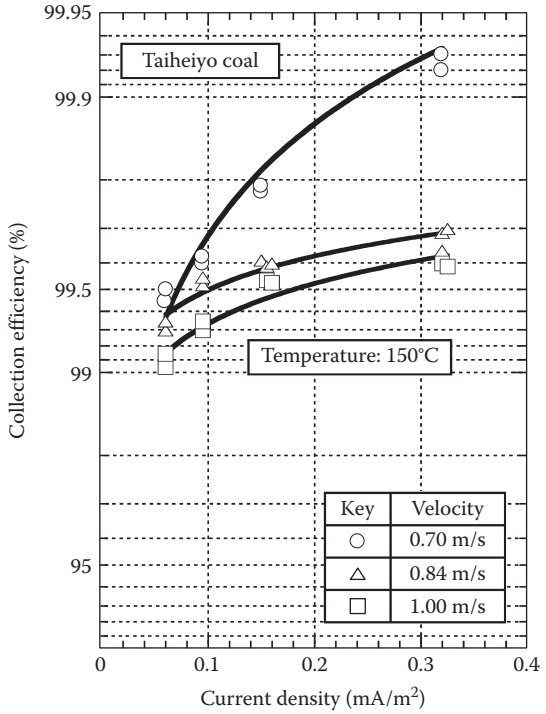

Figure 15.32

Influence of corona current density on collection efficiency. (From Kanaoka, C. et al., Principle and equipment of dust collectors, *Fundamentals in Aeorsol Science*, Nikkan Kogyo Shinbun, Tokyo, Japan, 1997, pp. 24–99.)

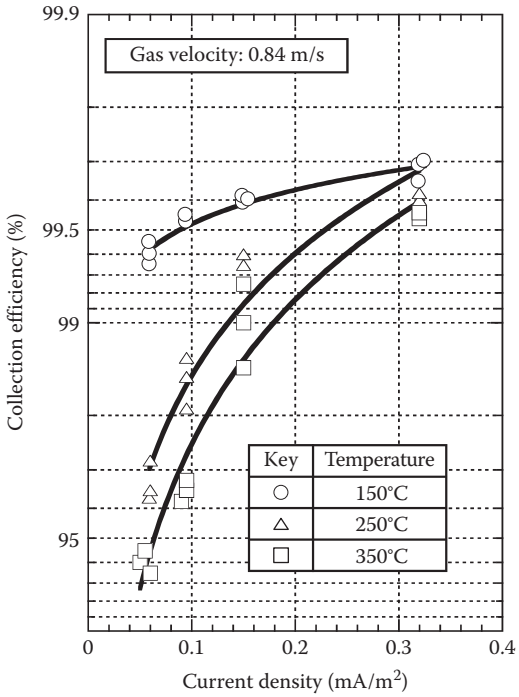

Figure 15.33

Influence of temperature on collection efficiency. (From Kanaoka, C. et al., Principle and equipment of dust collectors, *Fundamentals in Aeorsol Science*, Nikkan Kogyo Shinbun, Tokyo, Japan, 1997, pp. 24–99.)

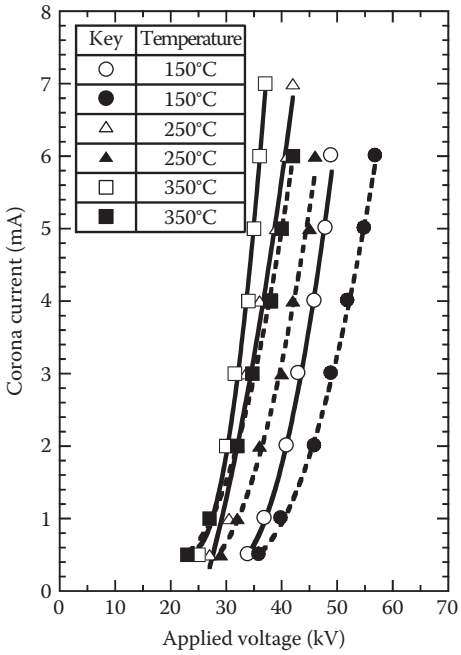

Figure 15.34

Applied voltage and corona current. (From Kanaoka, C. et al., Principle and equipment of dust collectors, *Fundamentals in Aeorsol Science*, Nikkan Kogyo Shinbun, Tokyo, Japan, 1997, pp. 24–99.)

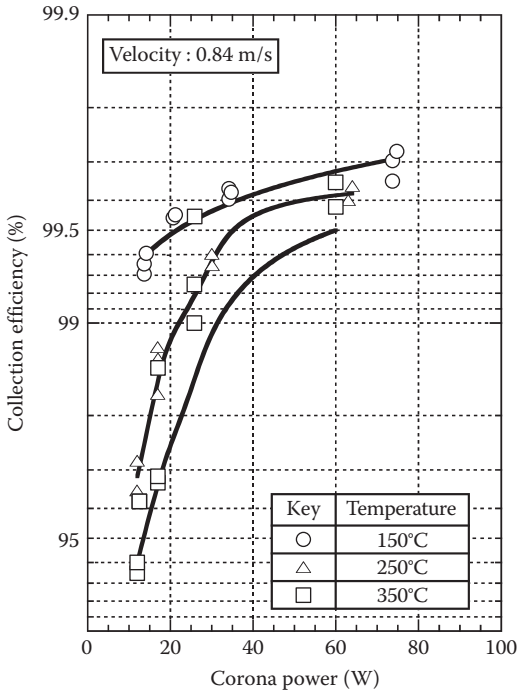

Figure 15.35

Corona power and collection efficiency. (From Kanaoka, C. et al., Principle and equipment of dust collectors, *Fundamentals in Aeorsol Science*, Nikkan Kogyo Shinbun, Tokyo, Japan, 1997, pp. 24–99.)

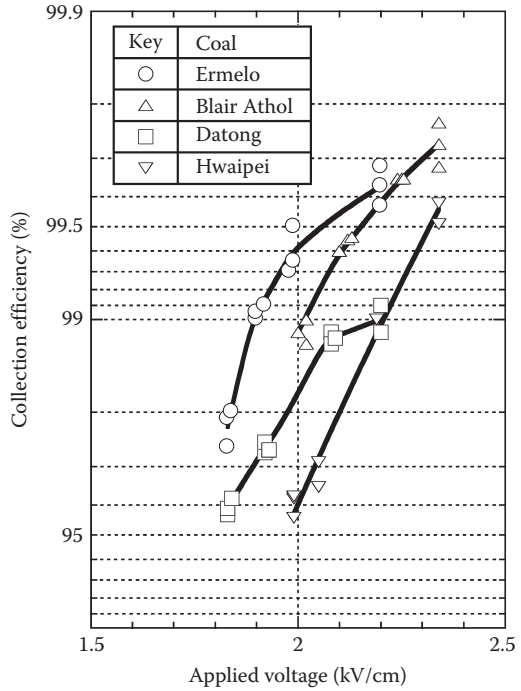

Figure 15.36

Collection efficiency of various kinds of coal.

One such approach is the high-temperature ESP operating at 350°C. This ESP utilizes the fact that the resistivity of coal ash is reduced at higher temperature. Although the gas volume increases with an increase in gas temperature and the corona power increases with an increase in corona current, the high-temperature ESP can use the higher corona power for high electric resistivity ash, because arc discharge is suppressed as shown in Figure 15.37.

Another method to reduce dust resistivity is to inject SO_3. When the SO_3 concentration in flue gas is high, a liquid layer is formed on the surface of the ash particles by the condensation of SO_3, and the collection efficiency is improved due to the decreased resistivity of the ash. The effect of SO_3 concentration on the collection efficiency and the dust concentration at the ESP outlet is shown in Figure 15.38. With increasing SO_3 concentration, the collection efficiency becomes higher and the dust concentration at the ESP outlet decreases.

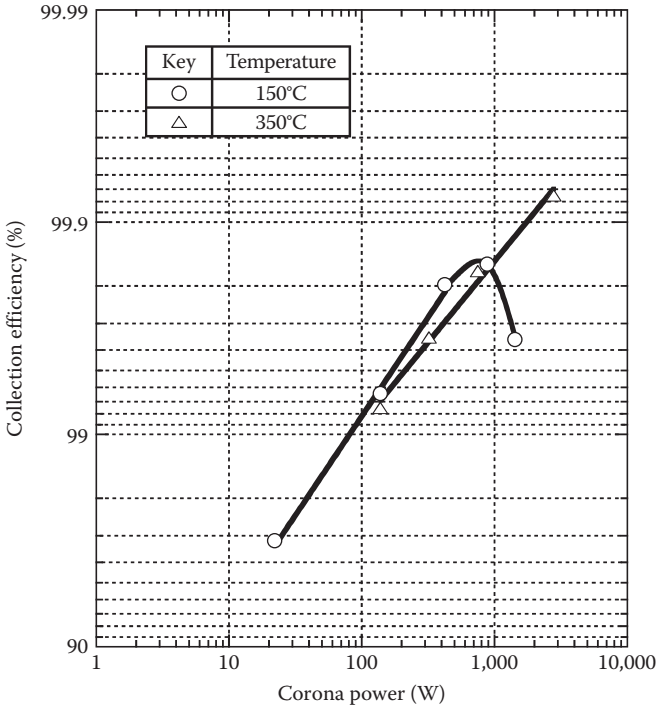

Figure 15.37

Influence of gas temperature on collection efficiency.

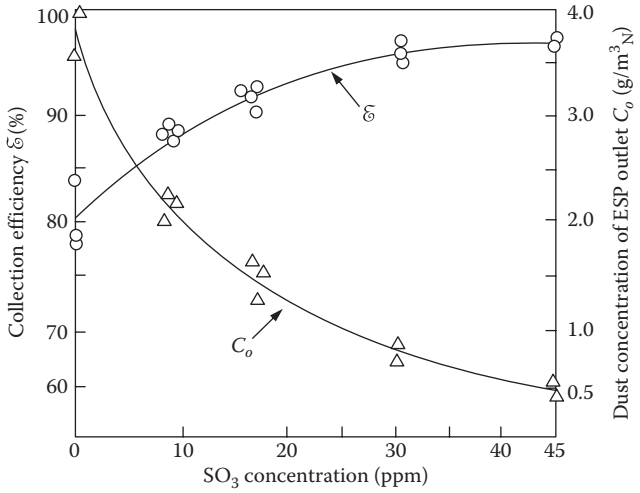

Figure 15.38

Improvement of collection efficiency of ESP by SO_3 injection.

When the operating temperature of the ESP is reduced, the dust resistivity decreases due to the formation of the liquid layer on the surface of the ash particles. The method that utilizes this trend is a new development in advanced low temperature ESPs which operate below 100°C. The relationship between gas temperature and the collection efficiency is shown in Figure 15.39. The collection efficiency is remarkably improved below 120°C. In the future, this type of ESP will be the choice for high-resistivity ash.

On the other hand, since the reduction in collection efficiency for ESPs operating with high-resistivity ash is due to the dust layer adhered on the collection electrodes, methods to minimize this problem are being developed. One of the techniques is a moving collection electrode in which the dust is removed by a brush. Another is the semiwet-type ESP in which the dust layer is removed by washing with water. These two methods offer potential for performance improvement.

The electric resistivity of the ash is affected by the ash composition in addition to operating conditions of ESP including the operation temperature. So, the relationship between collection efficiency and ash composition has been investigated. Bickelhaupt proposed the estimation method of the electric resistivity of ash from the ash composition, particularly Na, K, Ca, and S contents. The relationship between collection efficiency and the content of these elements is shown in Figure 15.40. Although the content of Ca and S in ash does not have a big effect on the collection efficiency of ESP, the content of Na and K in ash has a remarkable correlation with the collection efficiency. Of the two, Na has better correlation than K. Considering these results, the relationship between collection efficiency and the factor of 2Na + K in ash shown in Figure 15.41 has been derived. The collection efficiency of the ESP increased drastically by increasing the value to 2Na + K in ash at 130°C. And the content of Na and K in ash has a small effect on collection efficiency at 90°C in comparison with 130°C. This tendency indicates that the collection efficiency for the particles with high internal electric conduction is affected strongly by the concentration of Na and K in ash at 130°C. On the other hand, collection efficiency at 90°C has been influenced significantly by surface electric conduction more than internal conduction. Therefore, as shown in Figure 15.42, the collection efficiency at 90°C is affected by the moisture concentration and becomes higher, depending on the increase of moisture concentration in flue gas.

Relationship between the value of 2Na + K in fly ash and the collection efficiency.

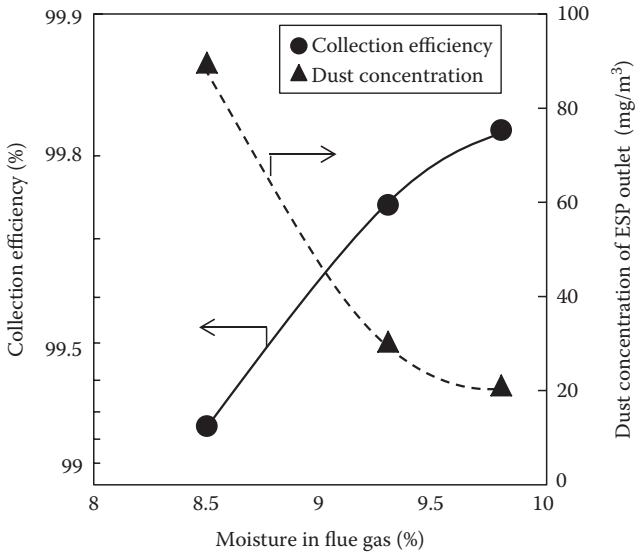

Figure 15.42

Relationship between moisture content in flue gas and the performance of ESP at 90°C.

15.7 Obstacle-Type Separators

Chikao Kanaoka

As described in Section 15.2, this type of collector captures dust particles on each individual obstacle in the system, that is, capturing particles by creating a relative velocity between the gas and particle. Most of the dust collectors belong to this category. Many different shapes and designs to create a relative velocity and enhance particle collection have been developed for this type of equipment.

As shown in Figure 15.43, when a dust-laden gas enters the dust collector with a cross-section A and length L, and obstacles are packed into the collector with a packing density $(1 - \varepsilon)$, the separation efficiency can be derived by considering the mass balance in the differential thickness Δx as follows:

$$uAc_p - uA\left(c_p + \Delta c_p\right) = \eta nA\frac{u}{\varepsilon}c_p\Delta x \tag{15.38}$$

where

n is the number of obstacles in Δx

u is the imposed gas velocity

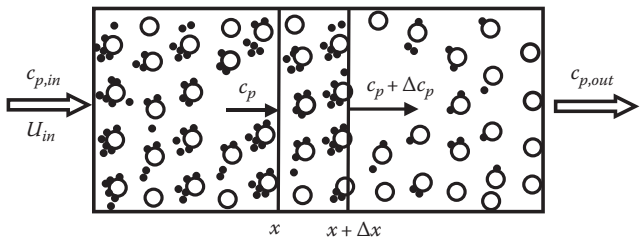

Figure 15.43

A schematic representation of dust collection.

Furthermore, η is the collection efficiency of a single collection obstacle (body) defined by the following equation:

$$\eta = \frac{\dot{m}_c}{\dot{m}_{c,in}} \tag{15.39}$$

where

$\dot{m}_c$ is the rate at which particles are collected on the obstacle

$\dot{m}_{c,in}$ is the flow rate of particles in the area projected by the obstacle

For the case of cylindrical and spherical collectors, the collection efficiency is

$$\eta \begin{cases} = \dfrac{c_{p,in} u 2Y}{c_{p,in} u d_c} = \dfrac{2Y}{d_c} & \text{cylinder} \\ = \dfrac{c_{p,in} u\left(\pi Y^2\right)}{c_{p,in} u\left(\pi d_c^2/4\right)} = \left(\dfrac{Y}{d_c/2}\right)^2 & \text{sphere} \end{cases} \tag{15.40}$$

This is schematically illustrated in Figure 15.44. As may be seen in the figure, the single body efficiency is defined as the ratio of the upstream area of limiting trajectory to the projected area of the collection body. The limiting trajectory is thus the critical particle trajectory that defines collection efficiency. Particles within the limiting trajectory are collected, but particles beyond the limiting trajectory are not collected. The separation efficiency of the collector E is obtained by integrating Equation 15.38 as follows:

$$\mathfrak{E} = 1 - \exp\left(-C\frac{1-\varepsilon}{\varepsilon}\eta L\right) \tag{15.41}$$

where

L is the packed thickness of the filter, that is, length

ε is porosity of the collector

$(1 - \varepsilon)$ is the packing density of the obstacles

The constant C is the constant determined by the shape of obstacle, that is, $C = 4/d_c$ for a cylindrical collector and $3/(2d_c)$ for a sphere. The symbol d_c is the nominal size of the obstacle.

In Equation 15.41, constants other than η are determined from the equipment and shape of single collection obstacle, such that $\mathfrak{E}$ can be estimated if η is specified for a given collector and operational conditions. The collection efficiency for obstacles with different shapes is calculated, as shown in Figure 15.45. In this figure, St is the Stokes number defined by

$$St = \frac{C\rho_p d_p^2 u}{9\mu d_c} \tag{15.42}$$

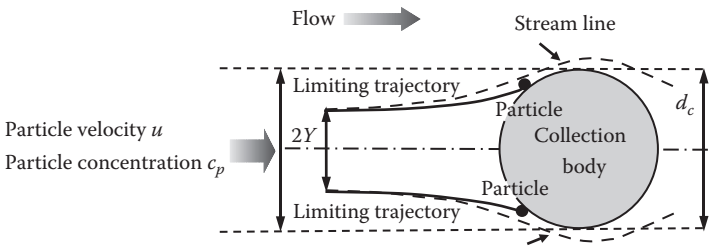

Figure 15.44

Definition of single body collection efficiency.

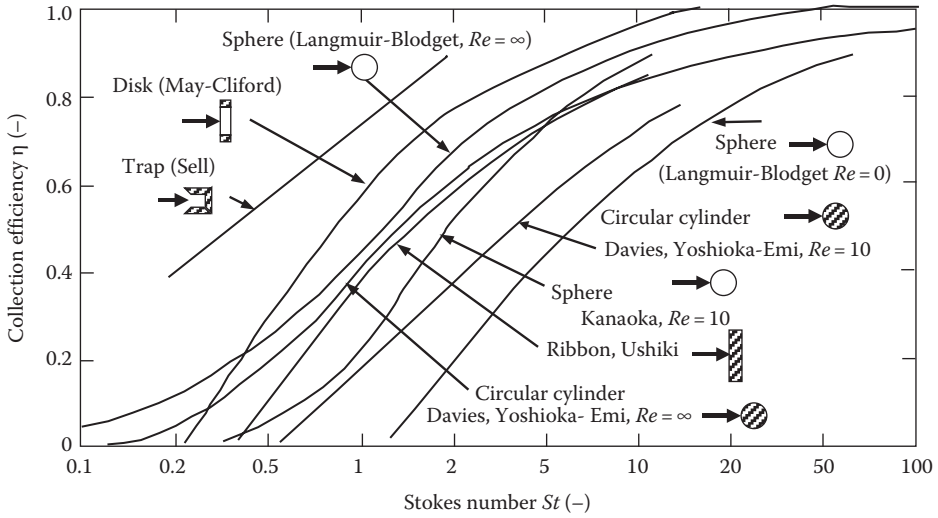

Figure 15.45

Calculated collection efficiencies for single collecting obstacles. (From Kanaoka, 1997.)

where

Cc is the Cunningham's slip correction factor
ρ_p is the particle density
d_p is the particle diameter
d_c is the representative size of the collecting body
u is the gas velocity
μ is the gas viscosity

15.8 Inertial Dust Collectors

Chikao Kanaoka

The inertial dust collector is one of the typical obstacle dust collectors and separates particles based on the difference in the particle trajectory and gas streamlines, as shown in Figure 15.46. Various obstacles are designed to create a relative velocity between particle and gas flow. Typical obstacles are shown in Figure 15.47. The Louver-type dust collector, shown in Figure 15.48, intensifies the inertial effect by a large inclination angle and a small gap between blades.

In practical applications, inertial collectors are used mainly to separate mist rather than solid particles.

15.9 Air Filters

Chikao Kanaoka

The air filter is one of the most reliable and efficient methods for dust collection and is mainly used at low dust concentrations. Particles are captured inside the filter, and hence, this type of particle collection system is referred to as depth filtration.

An air filter is mainly used to purify the air in local environments, such as hospitals, manufacturing lines, working spaces, residential and commercial buildings, etc. In these environments, the dust concentration is usually lower than 10 mg/m^3 and the particle size is less than several micrometers. Hence, packed filter materials, especially fibrous mats, are used for this purpose. The porosity of a filter mat is generally

higher than 85%; hence, particles are captured on individual fibers in the filter. The filter efficiency $\mathfrak{E}$ can be calculated from the single fiber collection efficiency for a given filtration condition as follows:

$$\mathfrak{E} = 1 - \exp\left(-\frac{4}{\pi} \frac{1-\varepsilon}{\varepsilon} \frac{L}{d_c} \eta \right) \tag{15.43}$$

where d_c, ε, $(1-\varepsilon)$, and L are the fiber diameter, porosity, fiber packing density, and filter thickness, respectively.

Although particles are collected on a fiber by a combination of effects, the mechanisms of inertia, Brownian diffusion, interception, and gravity are predominant in mechanical filtration. The electrostatic force becomes important when either fibers or particles or both are electrically charged or an external electrical field is applied.

Many theoretical and empirical expressions have been proposed for each collection mechanism. Figures 15.49 through 15.51 show typical single fiber collection efficiencies by different mechanisms and

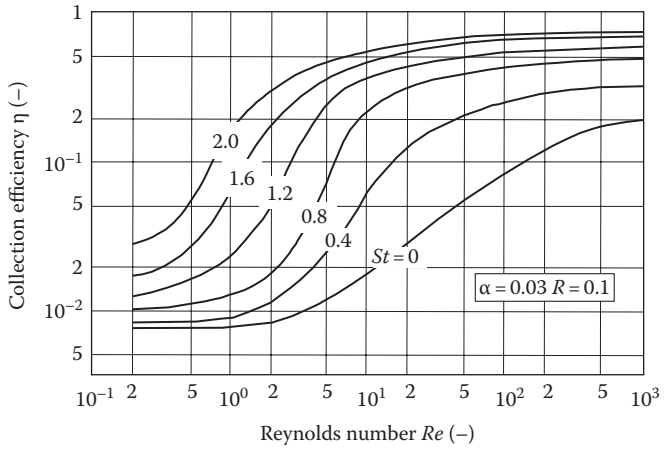

Figure 15.49

Calculated single fiber collection efficiency by inertia and interception effect. (From Emi, H. et al., *J. Chem. Eng. Jpn.*, 10, 148, 1977.)

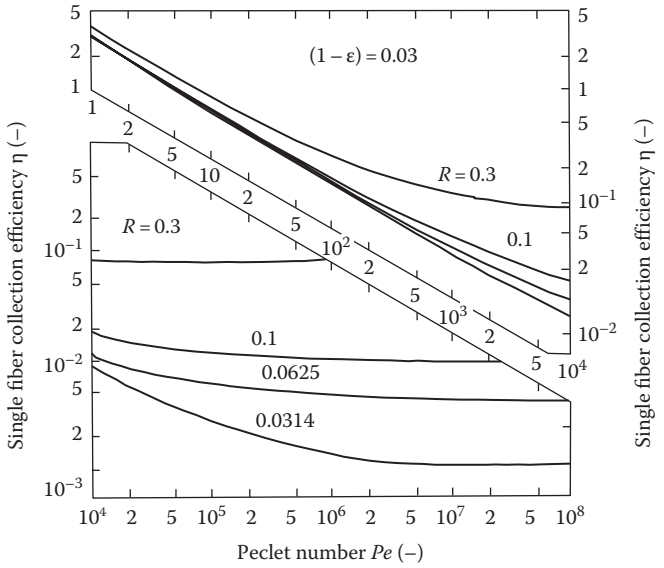

Figure 15.50

Calculated single fiber collection efficiency by diffusion and interception. (From Kanaoka, C., *J. Soc. Powder Technol. Jpn.*, 25, 469, 1988.)

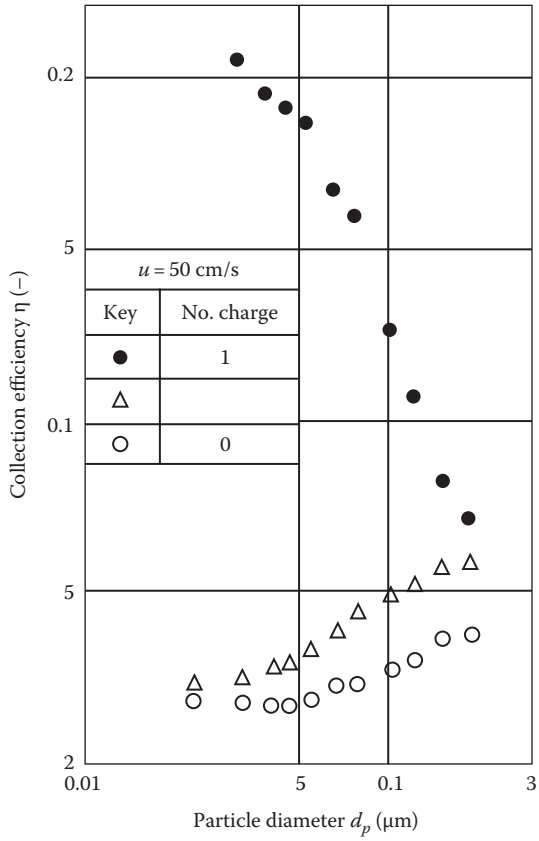

Figure 15.51

Experimental collection efficiency of particles at different charging state by an electret fiber. (From Emi, H. et al., *Particulate Sci. Technol.*, 5, 161, 1987.)

Figure 15.52 provides the efficiency chart obtained by taking inertia, Brownian diffusion, interception, and gravity into the account simultaneously. It is clear from the figure that there exists a particle size or a filtration velocity, which gives minimum efficiency, corresponding to the transition region for different mechanisms.

Filter performance, such as collection efficiency and pressure drop, changes with time and state of particles, as shown in Figures 15.53 and 15.54. These changes are caused by the shadowing effect of already captured particles on the collection of incoming particles, as shown in Figures 15.55 through 15.57. Figure 15.58 summarizes the general morphologies of captured particles by this collection mechanism.

There are two types of air filters: disposable and renewable. For the former type, fiber materials, such as glass, metal, and natural and synthetic fibers, are packed loosely in a frame or are formed into a mat structure. Since captured particles accumulate inside the filter, the pressure drop increases with filtration time, such that a zigzag structure is adopted to increase the filtration area to lengthen its service life. It is finally replaced when the pressure drop reaches a certain level to avoid an increase in the operational cost.

High-efficiency particulate air (HEPA) and ultralow penetration air (ULPA) filters are types of paper filters composed of very fine fibers, less than 1 μm on average. They are defined as the filters that collect 0.3 μm particles at an efficiency higher than 99.7% and 0.1 μm particles at higher than 99.9997%, with a pressure drop that does not exceed 12.7 mm H_2O at their specified flow rate, usually 2.5 cm/s. Therefore, HEPA and ULPA filters are used to create highly purified environments, which are necessary in the semiconductor industry, the precision machine industry, and so on. Penetration curves for HEPA and ULPA filters vary convexly with particle size and the maximum appears around 0.1 μm (i.e., the collection efficiency of the filter is poorest around this particle size at the conventional filtration condition

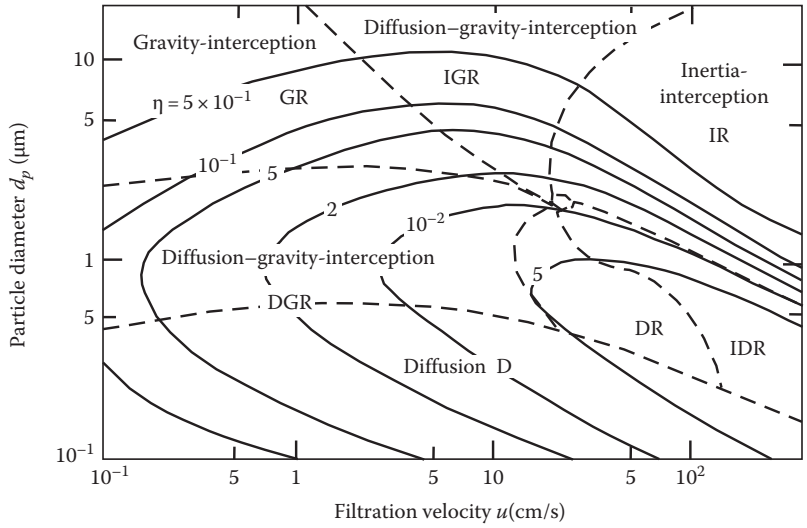

Figure 15.52

and decreases as the filtration velocity increases), as shown in Figure 15.59. Hence, the filter collection performance can be roughly evaluated by measuring the efficiency around this size range.

An electrostatic fibrous filter is another type of air filter that utilizes electrostatic force to remove particles. An electrostatic attractive force becomes effective when either fiber or particle is charged, but not when both of them are charged with the same polarity. Therefore, several types of electrostatic fibrous filters have been designed, depending on the charging state of fiber and particle. In general, an electrostatic fibrous filter is superior in collection performance to a mechanical fibrous filter but difficult to operate stably. The electret filter is a stable electrostatic fibrous filter, because it is composed of fibers with permanent dipoles and is capable of collecting particles at a high efficiency in the initial filtration stage. However, the efficiency decreases with filtration time owing to dust loading. This drawback has to be eliminated in practical use.

Experimental penetration of HEPA filter. (From Emi, H., *Aerosol Engineering*, Yokendo Publisher, Tokyo, Japan, 1984, p. 186.)

15.10 Scrubbers

Chikao Kanaoka

The scrubber is the generic name for a group of dust collectors utilizing liquid droplets or a liquid film as collecting media. Most of them can be classified into obstacle-type dust collectors.

The most important difference between this group and the so-called dry type is that the collection of dust particles is carried out in two operational steps: the capture of the dust by liquid component and then separation from the liquid by some other means. Since a liquid medium is used, this type of collector can be used for the collection of mist particles, even under hot gas conditions. Furthermore, the simultaneous separation of dust and gaseous material is also accomplished. However, the collector consumes a large amount of liquid. Also, secondary treatments of the collected liquid, the resulting sludge, and so on are required. This type of equipment is used only when a cheap and abundant amount of water is available or when a dry-type collector cannot be utilized.

Scrubbers can be classified into four types as shown in Figure 15.60: (a) the water reservoir type, (b) the pressurized water type, (c) the packed tower type, and (d) the forced rotary type. Their performance is summarized in Table 15.5.

As seen from Figure 15.60 and Table 15.5, scrubbers are in general relatively simple in structure. However, their performance is very good. Most scrubbers are capable of removing particles several micrometers in diameter with little difficulty. However, it is rather difficult to separate particles finer than 1 μm, except with a venturi scrubber operating at very high speed.

As described earlier, droplets are often used in the scrubber and their space density is not very high. Therefore, single sphere collection efficiency, shown in Figure 15.45, is directly applicable to the prediction of the separation efficiency of the scrubber. However, both the dust particle and collecting droplet

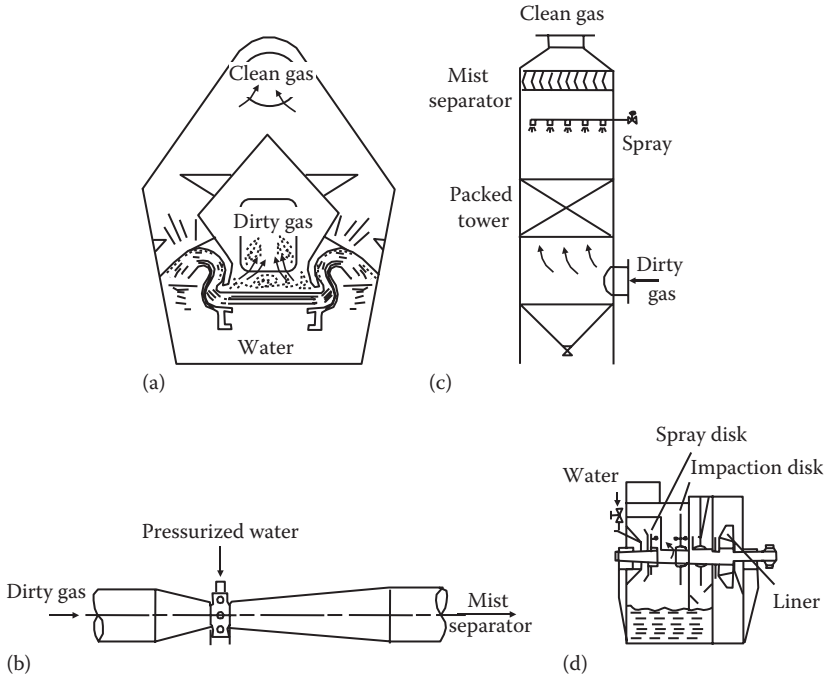

Figure 15.60

Typical scrubbers. (a) Water reservoir type; (b) pressurized water type; (c) packed tower type; (d) forced rotation type.

Table 15.5 Typical Scrubber

	Gas Velocity (m/s)	Gas Volume Flow Rate (m^3/min)	Pressure Drop (Pa)	Liquid–Gas Ratio (L/m^3)	Separation Diameter (μm)
Water reservoir type					
Rotoclone	20–30	1,000	500–1,500	0.1–0.3	0.5
Pressure water type					
Cyclone scrubber	1–2	5,000	500–2,000	0.5–5	1
Venturi scrubber	40–100	10,000	2,000–20,000	0.3–1	0.1
Packed tower type					
Spray scrubber	1–2	1,000	100–500	0.1–1	3
Packed tower	1–2	1,000	1,000–3,000	1–10	1
Forced rotary type					
Theisen washer	1–5	1,000	2,000–4,000	0.5–2	0.2

move in the air and the collection takes place only when there is a relative velocity between them, which does not last very long. Separation efficiency of the collector is expressible by the following equation.

$$\mathfrak{E} = 1 - \exp(-Rem \cdot \mathfrak{L}) \tag{15.44}$$

where

$\mathfrak{L}$ is the liquid–gas ratio

Rem is the dimensionless parameter for the amount of particles captured by a single collecting body (water droplet) defined by

$$Rem = \frac{3\int_0^X \eta \, dx}{2d_w} \tag{15.45}$$

where X is effective collection length of the collector in the water droplet diameter.

Figure 15.61 shows the calculated *Rem* versus collector diameter d_w for a venturi scrubber with a throat velocity of 80 m/s and $X = 1$ m.

As seen from the figure, *Rem* decreases with increasing droplet size for diffusion but displays a maximum for droplet sizes greater than 0.5 μm for inertial collection. The maximum *Rem* for inertial collection can be explained by trends in collection efficiency with the Stokes number and the Reynolds number defined as follows:

$$St = \frac{C\rho_p d_p^2 \Delta u}{9\mu d_w}, \quad Re = \frac{\rho_p d_w \Delta u}{\mu} \tag{15.46}$$

where Δu is the velocity difference between the droplet and the fluid. As the water droplet diameter increases, the velocity difference increases and the Reynolds number and the Stokes number go through maximum values. As seen from Figure 15.45, the collection efficiency will increase and approach an asymptotic value near unity. The value for *Rem* first increases with collection efficiency, reaches a maximum, and decreases as the water droplet diameter becomes larger. The same trend is not observed from the small droplets, because they are in the lower Reynolds number range.

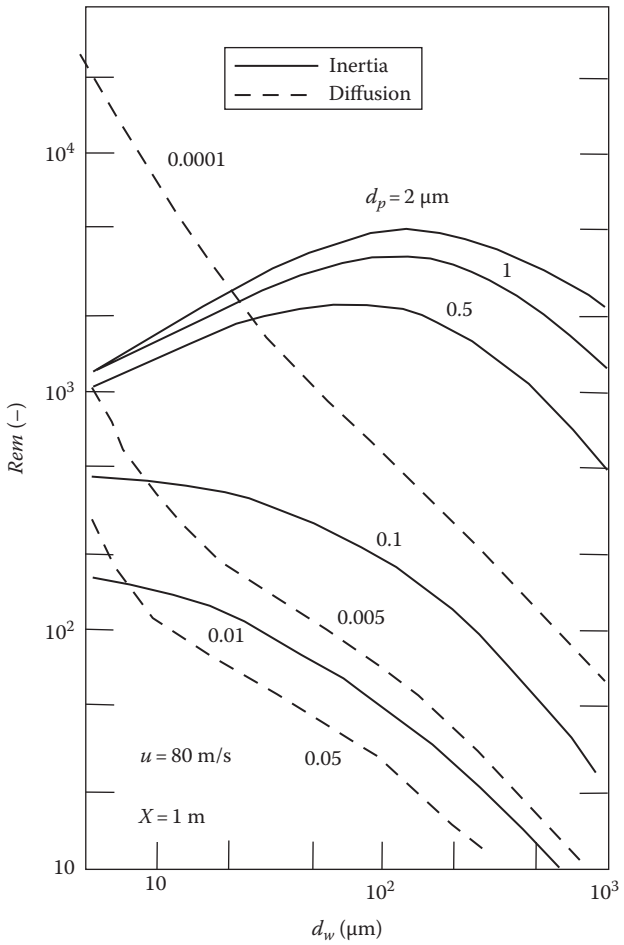

Figure 15.61

Dimensionless amount of particles captured by a droplet in a venturi scrubber. (From Morishima, N., Study on the venturi scrubber, PhD thesis, Osaka City University, Osaka, Japan, 1967.)

15.11 Barrier-Type Separators

Chikao Kanaoka

As described earlier, this type of collector uses a permeable medium for the gas, but not for the dust, and is used to separate dust at high concentrations. Hence, the most pronounced feature of dust collectors of this type is almost perfect particle collection, regardless of size, except just after the dislodgement of accumulated particles on the barrier. This occurs because most of the particles are collected due to the particles captured earlier by a sieving effect. This type of collection is usually referred to as surface or cake filtration. The bag filter is the most common barrier-type dust collector. Recently, the ceramic filter has become popular for high-temperature dust cleaning.

15.12 Bag Filters

Chikao Kanaoka

15.12.1 Collection Mechanism

The bag filter is commonly made of fabric in a cylindrical "bag" shape. Consequently, this type of filter is called a bag filter. The designation "fabric" filter is also popularly used. Figure 15.62 shows the typical shape of the bag filter.

Although any type of fiber with a different weave, such as woven and nonwoven, can be used as a filter material, synthetic fibers such as polyester, polypropylene, nylon, and glass fibers are most often employed owing to their strong resistivity to gas and dust.

The collection of particles by a fabric depends on the weave of the fabric, that is, woven or nonwoven. For a woven fabric, initially (or after cleaning), the particles are captured on fibrils in the texture by inertia, interception, diffusion, and so on. After the texture is filled with captured particles, the capture area expands to the whole fabric surface and forms a very coarse dust layer of porosity ranging between 80% and 85%. At this stage, particles are mainly captured by the sieving effect, because particles have to go through the openings in the layer, the size of which is of the same order as the particles. Hence, the collection performance is not affected by the particle size and is usually very high.

Nonwoven fabric consists of independent fibers, and hence, the porosity is much higher than that of woven fabric with same weight. Therefore, it can operate at higher flow rates than woven fabric and the

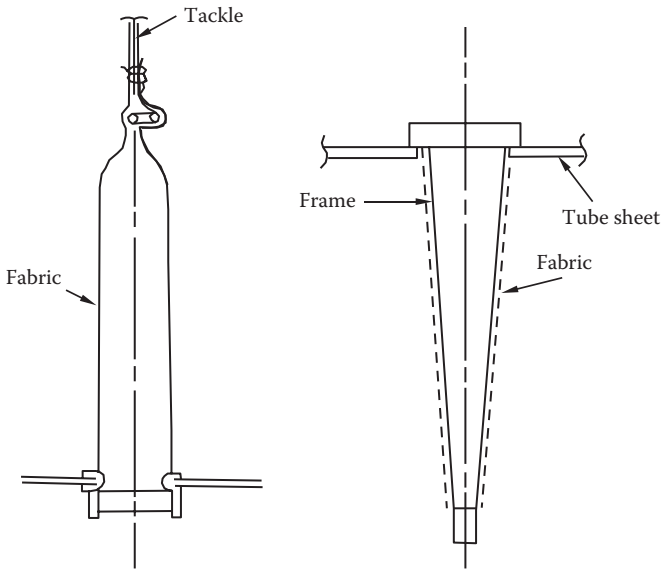

Figure 15.62

Typical shape of bag filter element.

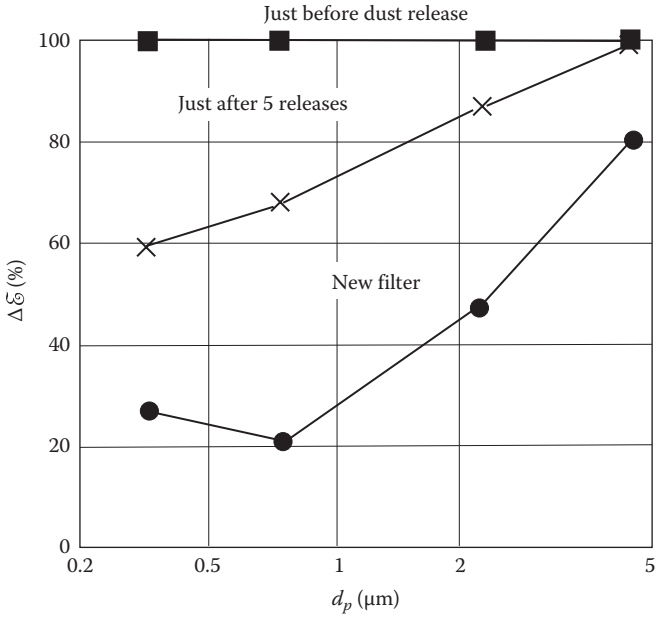

Figure 15.63

Grade efficiency of a singed polyester filter element. (From Kanaoka, C., *Industrial Pollution Control Technologies and Regulations*, Maruzen, Tokyo, Japan, 2003, p. II250.) Fabric: singed polyester nonwoven felt, fiber diameter: 14 μm mass: 600 g/m^2, particle: JIS No.11 test dust (coal flyash, mean diameter 1.5 μm), filtration velocity 3 cm/s, pressure drop of fabric for cleaning: 2 kPa, cleaning air pressure: 100 kPa, duration of air injection: 200 ms.

particle collection behavior is more or less similar to that of an air filter in the initial stage. In this case, the collection behavior after the formation of dust layer is not much different from that of the woven fabric.

As mentioned earlier, the dust release from the fabric is carried out repeatedly either after some prescribed time interval or when the filter pressure drop reaches a predetermined value, above which continuous operation cannot be maintained. However, a small amount of dust remains in the fabric after the release action and forms a primary dust layer, which plays an important role in dust collection in bag filtration. This can be seen from Figure 15.63, which shows the grade efficiency of a flat nonwoven felt just before and after dust release at different cleaning cycles. As seen from the figure, the grade efficiency before dust cleaning is almost 100%, regardless of particle size, but after cleaning it is considerably lower but increases with the number of cleanings, suggesting the formation of the primary dust layer. Once the primary layer is formed, the collection efficiency of the filter does not radically decrease even after cleaning.

Figure 15.64 shows the change measured for outlet dust concentration as a function of dust load. The dust load is the product of the particle concentration, filtration velocity, and time and represents the total incoming particle mass per unit filter area. As seen from the figure, the outlet concentration decreases with time, but the decrease rate is higher for slow filtration velocity and the final stabilized dust concentration is more than two orders of magnitude different, despite the fact that the filtration velocity varied only one order of magnitude. This suggests the possibility of pinhole formation in the dust layer at the faster filtration velocity and thus fairly large penetration of particles from the holes.

15.12.2 Pressure Drop

Pressure drop of a bag filter ΔP is expressed by the sum of the pressure drop in the fabric and the dust accumulated on the fabric as

$$\Delta P = \Delta P_f + \Delta P_d = \left(\zeta_f + \zeta_d m_d\right)\mu u \tag{15.47}$$

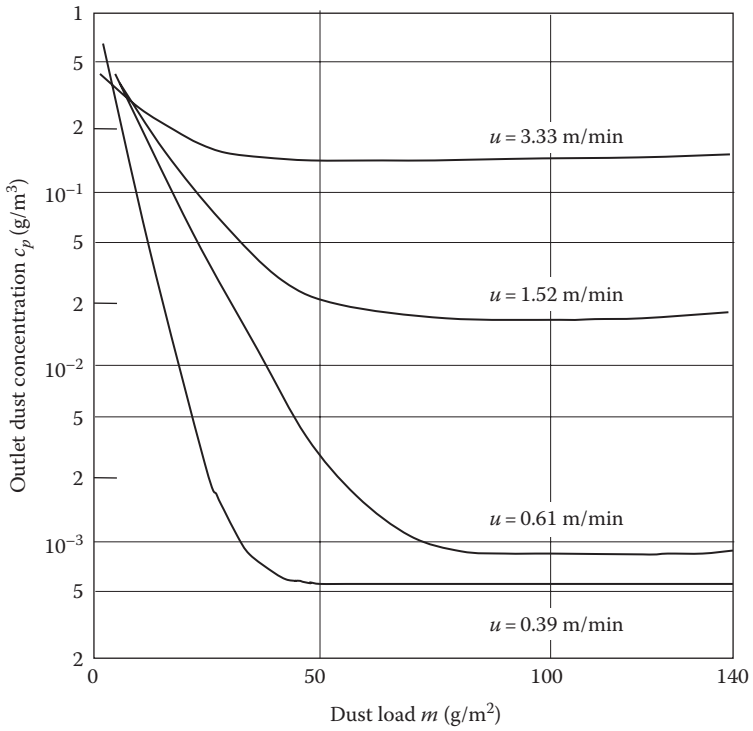

Figure 15.64

Time change of outlet dust concentration at different filtration velocities. (From Chaing, T. and Ostop, R.P., EPA-666/9-82-005C, 1982, p. 261.)

where

ΔP is the pressure drop of a dust loaded fabric (Pa)
ΔP_f and ΔP_d are the pressure drops through the fabric and covering dust layer
ζ_f is the resistance coefficient of the fabric (1/m)
ζ_d is the specific resistance of dust layer (m/kg^2)
m is the dust load (kg/m^2)
μ is the gas viscosity (Pa·s)
u is the filtration velocity (m/s)

At the initial stage of the filtration, ΔP_f of a woven fabric is usually very low and thus negligible. However, it may not be negligible for a very thick nonwoven fabric. Under dust-loaded conditions, the porosity of the fabric decreases so that pressure drop increases as $\Delta P \propto u^n$ where n ranges between 1.5 and 2. The flow through the dust layer is usually laminar, such that the pressure drop ΔP_d is proportional to the filtration velocity and is expressed by the following Kozeny–Carman equation:

$$\Delta P_d = \frac{180(1-\varepsilon)m_d \mu u}{d_{ps}^2 \varepsilon^3 \rho_p} \tag{15.48}$$

where

ε is the porosity
d_{ps} is the specific surface diameter (m^2/m^3)
ρ_p is the particle density (kg/m^3)

15.12.3 Methods of Dislodging the Dust Particles

The collected dust particles accumulate on the fabric surface and increase the pressure drop. Hence, the accumulated dust has to be dislodged to maintain continuous operation. The dislodging categorizes the bag filters into mechanical shaking, reverse flow, and pulse jet types, as shown in Figure 15.65.

The dislodging method can be further categorized as intermittent or continuous dislodging. The mechanical shaking and reverse flow type filters belong to the intermittent category and pulse jet type to the continuous category. With the intermittent type, the gas flow has to be suspended during dislodging; so, the bag house is divided into several compartments so that the entire house does not have to be shut down during cleaning. With the pulse jet type, the cleaning can be performed without ceasing operation, since the injection of intense cleaning air is only needed for a short time. Table 15.6 summarizes the classification of bag filters and their features.

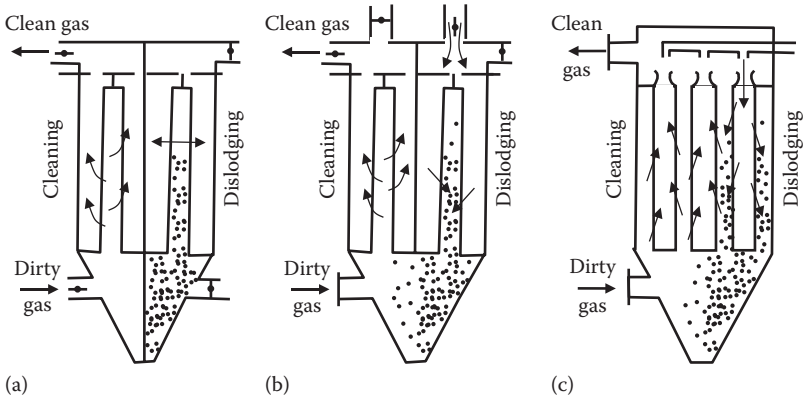

Figure 15.65

Schematics of bag filters. (a) Mechanical shaking type, (b) reverse flow type, (c) pulse jet type.

Table 15.6 Classification of Bag Filter and Feature

Cleaning Mode	Filter			Filtration Side	Filtration Velocity (m/min)	Temperature (°C)	Remarks
	Weave	Shape	Material				
Mechanical shaking		Cylinder		Inside	0.6–1.6	~200	General purpose: Applicable for any gas flow rate and temperature range.
	Woven		Synthetic fiber				Reliable cleaning performance. Suitable for the collection of fume.
Pulse jet	Nonwoven	Envelope	Synthetic	Outside	1~2	~100	Small size collector less than several 10 m^3/min.
		Cylinder	fiber	Outside	1~4	~200	Dust cleaning can be carried out without stopping gas flow.
							Gas flow fluctuation is small. Suitable for small gas flow rate.
							Applicable for high concentration and abrasive dust.
							Applicable for higher filtration velocity.
	Woven	Cylinder	Glass fiber	Outside	0.5~1.5	~250	High resistivity for hot gas. Large filtration area.
	Nonwoven	Cartridge	Synthetic fiber or paper	Outside	0.3~1	~140 ~450	Applicable to low dust concentration, requiring high separation performance like air purification.
	Sintered	Cylinder	Metal fiber Ceramic	Outside	0.5~1.5	~1000	High-temperature gas cleaning.
Reverse flow	Woven or nonwoven	Cylinder	Synthetic fiber	Inside	0.6~1.2	~200	Widely used in cement and iron refining industries.
			Glass fiber		0.3~1	~250	Suitable for high-temperature fume like carbon black, noniron refinery, and so on.
	Nonwoven	Envelope	Synthetic fiber	Outside	1~2	~140	Suitable for large gas flow rates.

15.13 Liquid-Phase Particle Separation (Hydrocyclone)

Hideto Yoshida

The principle of liquid–solid separation is the same as gas–solid separation. Recently, wet separation has been used for producing ceramic particles and in recycling processes. The following should be considered in the wet separation:

1. Particle dispersion control is easy compared to gas–solid separation.
2. A drying or dewatering process is necessary to separate particles from the liquid.
3. The particle inertia is comparable to the fluid inertia.
4. The viscosity of the slurry decreases with increasing temperature, and the particle sedimentation velocity increases as the slurry temperature rises.

15.13.1 Hydrocyclones

Hydrocyclones are widely used in many industrial processes. Experimental studies of the separation efficiency and pressure drop of a hydrocyclone have been reported by Bradley (1958), Yoshioka and Hotta (1955), and Yoshioka (1962). Several flow-controlling methods at the outlet pipe of a hydrocyclone have been proposed by Yamamoto and Jiao (1997) and Chu et al. (2002). Also, a prediction of the flow within a hydrocyclone was made using several turbulence models by Petty and Parks (2001). The performance of axial flow-type hydrocyclone was studied by Sineath and Della Valle (1959). The performance between conical and cylindrical hydrocyclone was examined by Chine and Ferrara (1997).

The characteristics of hydrocyclones are

1. The size of hydrocyclones is small compared to other types of wet classifiers.
2. The cut size decreases with an increase in inlet velocity or with a decrease in the cyclone diameter.
3. The pressure drop is in the range of 0.1–0.5 MPa, depending on the operating conditions.

The general flow pattern in the standard hydrocyclone is shown in Figures 15.16 through 15.66. The coarse particles are collected in the under-flow exit and the fine particles in the over-flow exit. The ratio of inlet volume flow rate to under-flow volume flow rate is referred to as the under-flow ratio, B_d. The normal operating conditions for a hydrocyclone are as follows:

1. Cyclone inlet velocity $u_{in} = 2 \sim 10$ m/s
2. Cyclone diameter $D_c = 1 \sim 30$ cm
3. Pressure drop $\Delta P = 0.1 \sim 0.5$ MPa
4. 50% cut size $d_{p,cut} = 5 \sim 50$ μm
5. Under-flow ratio $B_d = 5\ \% \sim 20\%$

The details of the standard cyclone in Japan (Yoshioka, 1962) with each dimension scaled with the cyclone diameter D_c are also shown in Figure 15.66. The bottom diameter of the conical section is relatively small compared to a gas-cyclone. As the under-flow rate increases, a fluctuating air core is sometimes observed near the axis. In order to improve the sharpness of classification, the air core region should be in a stable state.

Measurements of the tangential velocity distribution for different axial positions obtained by Ohashi and Maeda (1958) are shown in Figure 15.67. The tangential velocity profiles are similar to a gas-cyclone. Solid body rotation occurs near the axial part and a near free vortex profile, represented by the following equation, is created in the outer region:

$$u_\theta r^n = C \tag{15.49}$$

The maximum tangential velocity occurs at about 60% of the vortex finder diameter, and the index n in the aforementioned equation varies from 0.7 to 0.9.

A typical separation efficiency curve obtained using the standard hydrocyclone is shown in Figure 15.68. The fractional separation efficiency approaches the under-flow ratio B_d as the particle diameter decreases.

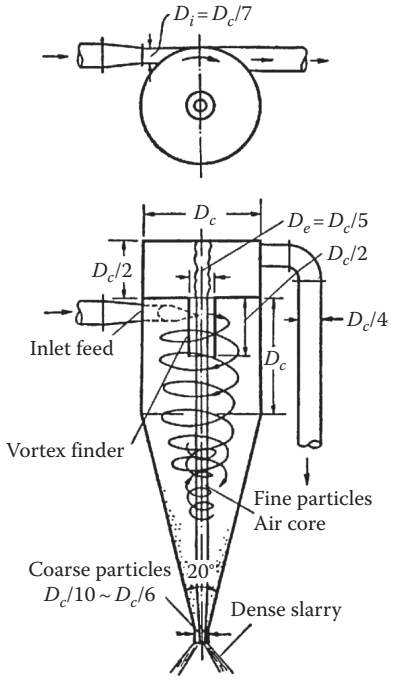

Figure 15.66

Standard hydrocyclone and flow pattern.

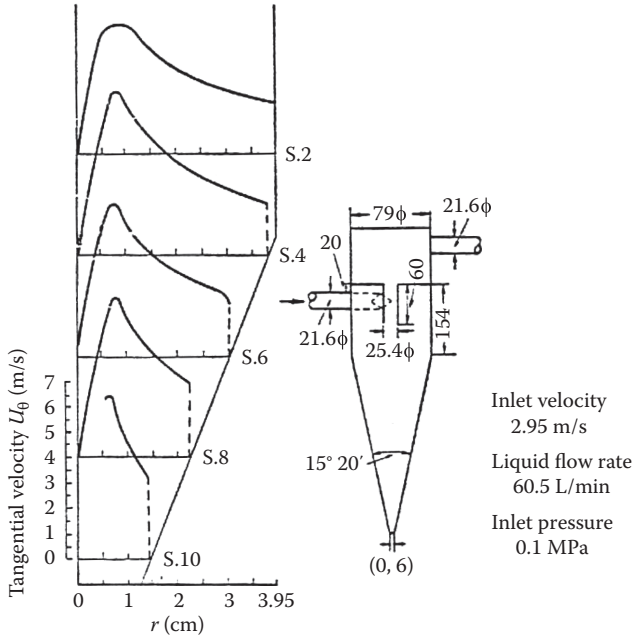

Figure 15.67

Tangential liquid velocity distribution.

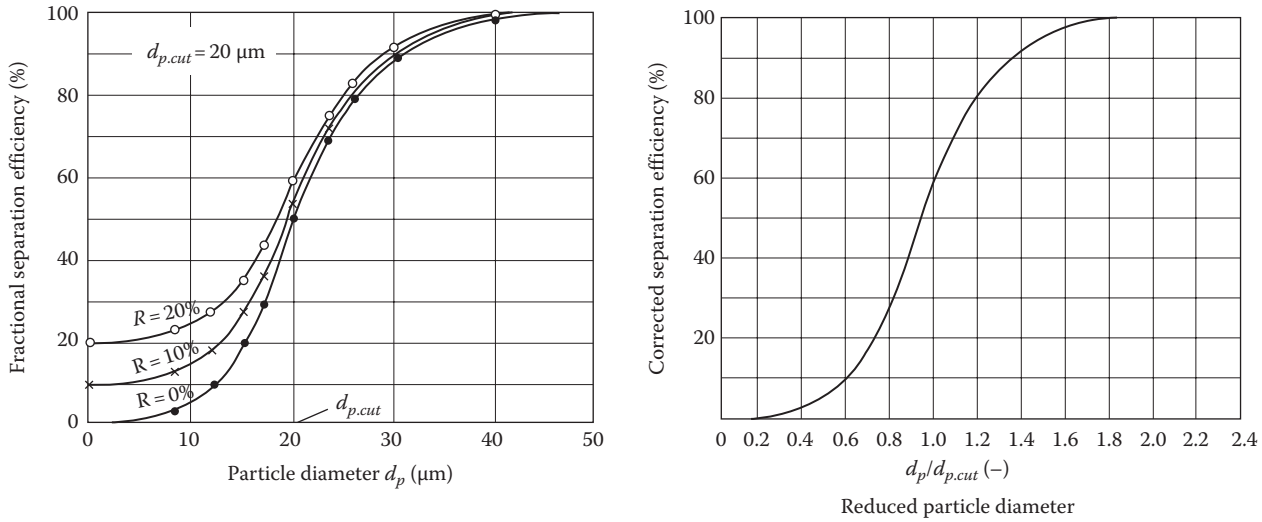

Figure 15.68

Fractional separation efficiency and corrected one.

The experimental data for fractional separation efficiency, $\Delta\mathfrak{E}$, shown in the figure are normalized for different under-flow ratio conditions using

$$\Delta\mathfrak{E}_c = \frac{\Delta\mathfrak{E} - B_d}{1 - B_d} \tag{15.50}$$

where $d_{p,cut}$ denotes a 50% cut size under B_d is zero. The normalized fractional separation efficiency shown in Figure 15.68 can be represented approximately by the following equation:

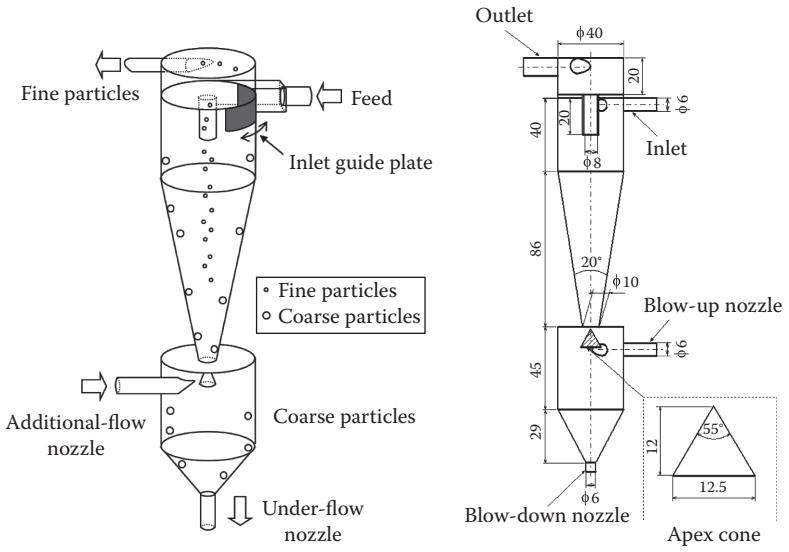
$$\Delta\mathfrak{E}_c = 1 - \exp\left\{-\left(\frac{d_p}{d_{p,cut}} - 0.115\right)^3\right\} \quad 0.02 \le \Delta\mathfrak{E}_c \le 0.98 \tag{15.51}$$

15.13.2 Control of Cut Size

In order to improve the cut size control easily, the modified hydrocyclone shown in Figure 15.69 has been developed by Isshiki et al. (1997) and Yoshida et al. (2001a). The inlet of the hydrocyclone is fitted with a movable guide plate. The apex cone at the inlet of under-flow side is also attached. Both under-flow and additional-flow methods similar to the gas-cyclone are used to increase classification sharpness in the fine sizes. Using the additional-flow method, pure fluid without particles is introduced in the additional-flow nozzle shown in Figure 15.69. Using the under-flow method, the under-flow is discharged in the under-flow nozzle. In order to decrease the 50% cut size, a movable guide plate, shown in Figure 15.70, was used. Under constant feed rate conditions, the inlet velocity u increases with a decrease in inlet width b_e. The inlet width ratio, G_{eff}, defined by the following equation, is used as a control parameter:

$$G_{eff} = \frac{b_e}{b} \tag{15.52}$$

For the standard case, the value of G_{eff} is unity. Because of increased centrifugal force and the small radial sedimentation distance, small particles are easily collected for the case of a small inlet width. Typical experimental results using the guide plate are shown in Figure 15.71. The 50% cut size decreases from 10 to 7 μm as the inlet width ratio decreases under a constant inlet flow rate. The fractional separation efficiency approaches 0.1 for a particle diameter less than about 5 μm. In order to increase classification sharpness in the small particle diameter region, under-flow and additional-flow methods were used simultaneously.



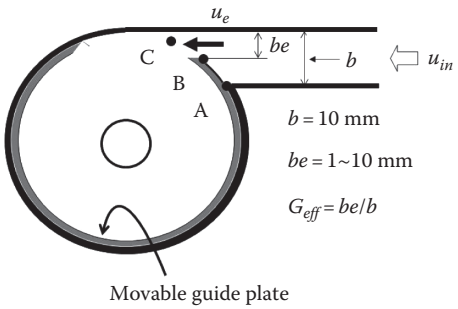


Figure 15.69

Experimental apparatus of a hydrocyclone.

G_{eff} (–)	1.00	0.75	0.50	0.25
u_e (m/s)	1.4	2.1	2.8	3.5

Figure 15.70

Cross section of cyclone with a guide plate.

Some experimental results for the fractional separation efficiency are shown in Figure 15.72. In this case, the under-flow method, additional-flow method, and a movable guide plate were used. The additional-flow ratio was 30%, the under-flow ratio was 10%, and the inlet width ratio was changed from 1 to 0.1. The 50% cut size changes from 35 to 10 μm as the inlet width ratio decreases from 1 to 0.1. The fractional separation efficiency in this case approaches zero as the particle diameter decreases.

15.13.3 Effect of Inlet Slurry Temperature

The viscosity of the slurry decreases with increasing fluid temperature. It would be expected that the cut size would be reduced when the inlet slurry temperature is increased. Yoshida et al. (2004) examined the effect of inlet slurry temperature on cut size change of hydrocyclone. A comparison between the calculated and experimental fractional separation efficiencies for conditions of high slurry temperature is shown in Figure 15.73. For a given value of the fractional separation efficiency, the particle diameter corresponding to the reference temperature of 20°C changes according to the following expression:

$$d_p(T) = d_p(20)\sqrt{\frac{\left(\mu/(\rho_p - \rho_f)\right)_{T°C}}{\mu/(\rho_p - \rho_f)_{20°C}}} \tag{15.53}$$

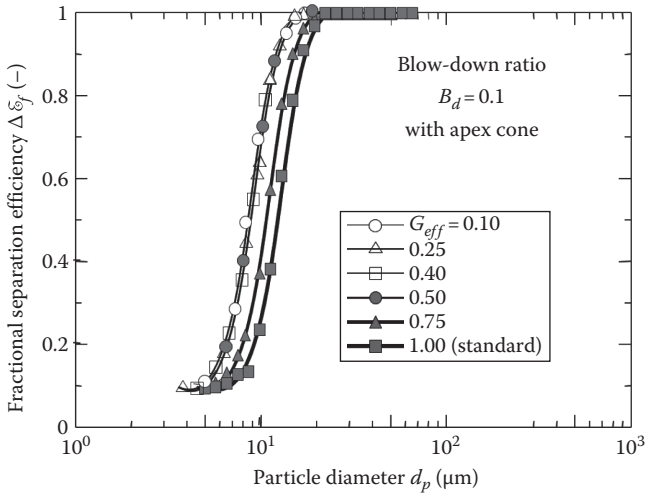

Figure 15.71

Classification performance using inlet guide plate and under-flow method.

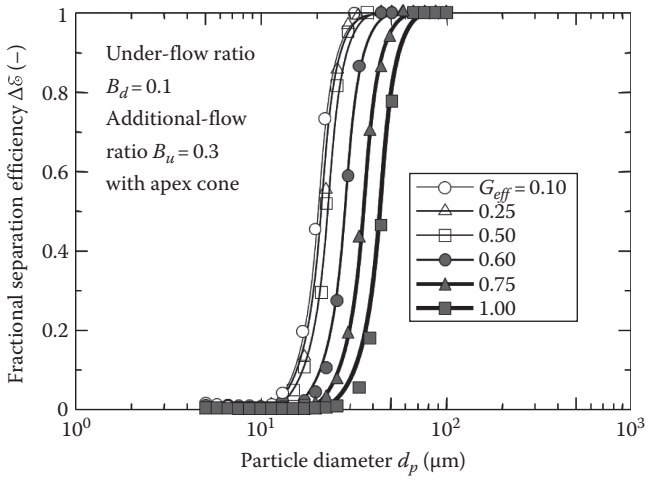

Figure 15.72

Classification performance using inlet guide plate, under-flow, and additional-flow method.

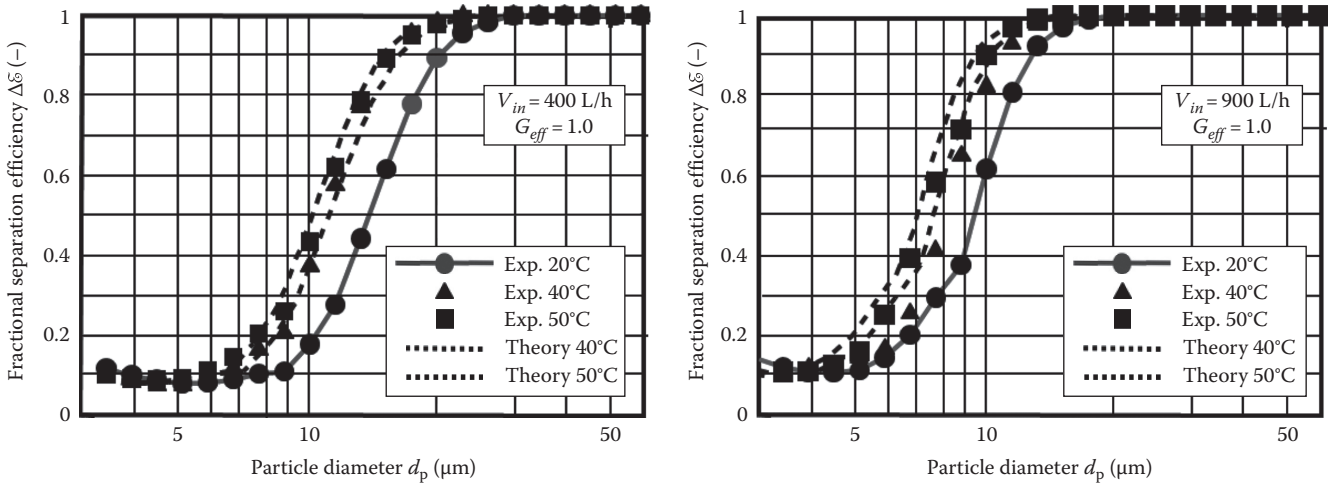

Figure 15.73

Comparison between predicted and experimental fractional separation efficiencies.

Based on the experimental data at 20°C, the fractional separation efficiency for high-temperature conditions can be estimated. The experimental data are in good agreement with the results calculated using this equation. In order to decrease the 50% cut size, the use of an inlet guide plate and an increase in slurry temperature are recommended for practical applications.

Nomenclature

Latin

A	Cross-section area of a dust collector
A_c	Total collection surface area
B_d	Blow-down ratio
B_i	Electric mobility of ions (=1.4 $cm^2/s/V$)
B_u	Blow-up ratio
b	Inlet width of cyclone
b_{eff}	Width of inlet duct
C	Constant with dimension
Cc	Cunningham's slip correction factor
c_p	Particle concentration
$c_{p,in}$	Particle concentration at inlet
$c_{p,out}$	Particle concentration at outlet
D	Cyclone diameter
$\mathfrak{D}$	Diffusion coefficient of particle
D_b	Diameter of discharge duct
D_e	Diameter of vortex finder
d_c	Diameter of a single collector
d_p	Particle size or particle diameter
$d_{p,50}$	50% cut size
$d_{p,cut}$	Cut size
$d_{p,cut}$	Cut size at $R_d = 0$ hydrocyclone
$d_{p,cut}(T)$	Fractional separation efficiency at T°C
d_w	Droplet diameter
E	Electric field strength
$\mathfrak{E}$	Collection efficiency
e	Elementary electric charge
Eu	Euler Number
G_{eff}	Inlet width ratio defined by 15.28
$\overline{G}_i$	Mean thermal mobility of ions (=4.5×10^4 cm/s)
g	Acceleration of gravity
H	Height of the collector
Ha	Inlet height of cyclone
H_H	Total height of cyclone
H_L	Height of cyclone outer cylinder
H_S	Height of vortex finder
H_Z	Height of cyclone cone
h	Inlet height of particle
h_t	Interfiber interval
K	Ratio of length to cyclone diameter defined in Figures 15.16 through 15.22
L	Length of dust collector
$\mathfrak{L}$	Liquid–gas ratio
$\mathfrak{M}$	Molecular mass
$\dot{m}_c$	Mass flow rate collected at dust collector
$\dot{m}_{ca}$	Rate at which particles are collected
m_d	Dust load
m_d	Dust load

$\dot{m}_{in}$	Mass flow rate at inlet
$\dot{m}_{out}$	Mass flow rate at outlet
$\dot{m}_u$	Flow rate of particles in the area projected by obstacle
N	Number of revolution of particle in a cyclone
n	Number of dust collector in series
n	Number of charges on a particle
n	Index for vortex motion
n_i	Ion concentration
ΔP	Pressure drop
ΔP_0	Pressure drop at $c_p = 0$
ΔP_d	Pressure drop due to dust load
ΔP_f	Pressure drop due to fabric
p	Penetration (=1 − ΔE)
Pe	Peclet number (=$d_c u/D$)
$q(d_p)$	Frequency (density) of particle size distribution
q_e	Electric charge on a particle
R	Cyclone radius
$\mathscr{R}$	Interception parameter (=d_p/d_c)
$\mathfrak{R}_u$	Gas constant
r	radius
Rem	Dimensionless parameter defined by 15.44
Re	Reynolds number
S	Total collection surface area
St	Stokes number
T	Gas temperature
u	Fluid velocity
u_{in}	Inlet gas velocity
$\dot{V}$	Gas flow rate
$\dot{V}_b$	Discharge from the dust box
$\dot{V}_{in}$	Inlet flow rate
$\dot{V}_{out}$	Gas flow rate at inlet and outlet
$\dot{V}_u$	Additional-flow rate into the dust box
v_{rad}	Radial velocity of particle to the wall
V_c	Volume of one collection obstacle
v_e	Electric mobility (velocity) of a charged particle
v_{mig}	Migration velocity of particle to the collection wall
v_x, v_y	x-directional particle velocity
v_y	y-directional particle velocity
W	Width
x	Distance from the wall at the entrance of cyclone
X	Effective collection length of a collector
Y	Income height of limiting particle trajectory shown in Figure 15.44

Greek

β	Slope exponent in Equation 15.29
ε_p	Porosity
ε_0	Permittivity
ζ_d	Specific resistance of dust layer
ζ_f	Resistance coefficient of fabric
η	Single body collection efficiency
λ_m	Mean free path of gas molecules
μ	Viscosity
ν	Kinematic viscosity
ρ_p	Particle density

ρ_f	Fluid density
τ	Velocity response time defined by 15.17 relaxation time
τ_{res}	Particle residence time
τ_x	Time to travel from x to reach to collection wall

Subscripts

c	Collector
ca	Captured
d	Dust
f	Fabric
in	Inlet
lk	Leakage
mig	Migration
N	Dry basis at 0°C, 101.3 kPa
out	Outlet
p	Particle
T	Total
t_i	Tangential direction in Table 15.3
t_w	Tangential direction in Table 15.3
θ	Circumferential

16.3 Biomimetics and Bioinspiration

16.1 Airflow and Particle Deposition in the Upper Respiratory Airways

Goodarz Ahmadi and Omid Abouali

16.1.1 Introduction

The human respiratory system is composed of the upper airways including nasal cavity, throat, larynx, and pharynx and the main body of lung including trachea, main bronchus, and lower bronchial tree, down to the alveolar cavities. This rather complex system provides the supply of oxygen to the blood stream while removing the carbon dioxide. The main role of the upper airways is to condition the inhaled air, including respiration, heating, and humidifying the inhaled air. Another important function of these organs is preventing particles from entering the lungs. The filtering task of the upper airways becomes more important when the breathing of toxic particles through upper airway leads to unhealthy responses (Kreuzer et al., 2000, Balásházy et al., 2003).

16.1.1.1 Anatomy of Human Airway System

The human respiratory system consists of upper airways, including nasal and oral cavity, pharynx, and larynx, and lower airways, including trachea, bronchi, bronchioles, and pulmonary alveoli as shown schematically in Figure 16.1. Air enters from nose or mouth and passes into the pharynx and then flows through the larynx into the trachea and then to the primary bronchi. The bronchioles successively bifurcate about 23 times until they reach the alveoli. In the alveolar cavities, gas exchange with the cardiovascular system occurs.

Figure 16.2 shows a schematic of the nasal cavity that extends from the naris (nostril) to the entrance of nasopharynx. The nostril is the external opening of the nasal passage through which air is inhaled and exhaled. The funnel region following the nostril is the vestibule that extends to the nasal valve region. The nasal passage has its minimum cross-sectional area at the nasal valve region; therefore, the axial component of airflow velocity is the highest in this region. The nasal valve region is connected to the main airway region that has a complex geometry and includes turbinate regions. At the end of the main airway and the beginning of nasopharynx, the left and right nasal cavities merge together and form one passage. Figure 16.2 also shows the inferior, middle, and superior turbinates. One of the functions of the turbinates is to help humidify and thermally condition the inhaled air. In addition, they remove particulate pollutant form the air. The thin wall that is dividing the nose in the center is called the septum. The regions between turbinates and the lateral side of the passage are the inferior meatus, middle meatus, and superior meatus regions.

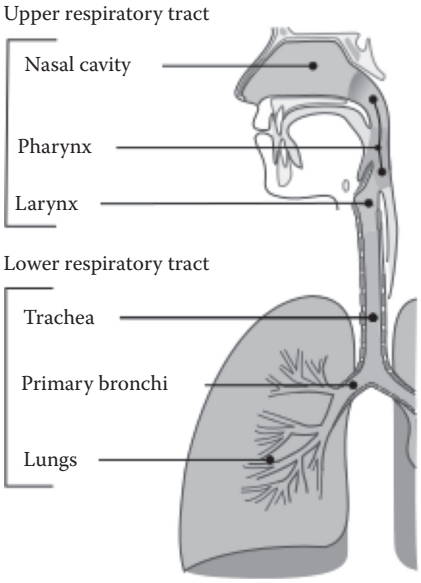

Figure 16.1

Schematic of the human airway system. (From http://en.wikipedia.org/wiki/File:Illu_conducting_passages.svg.)

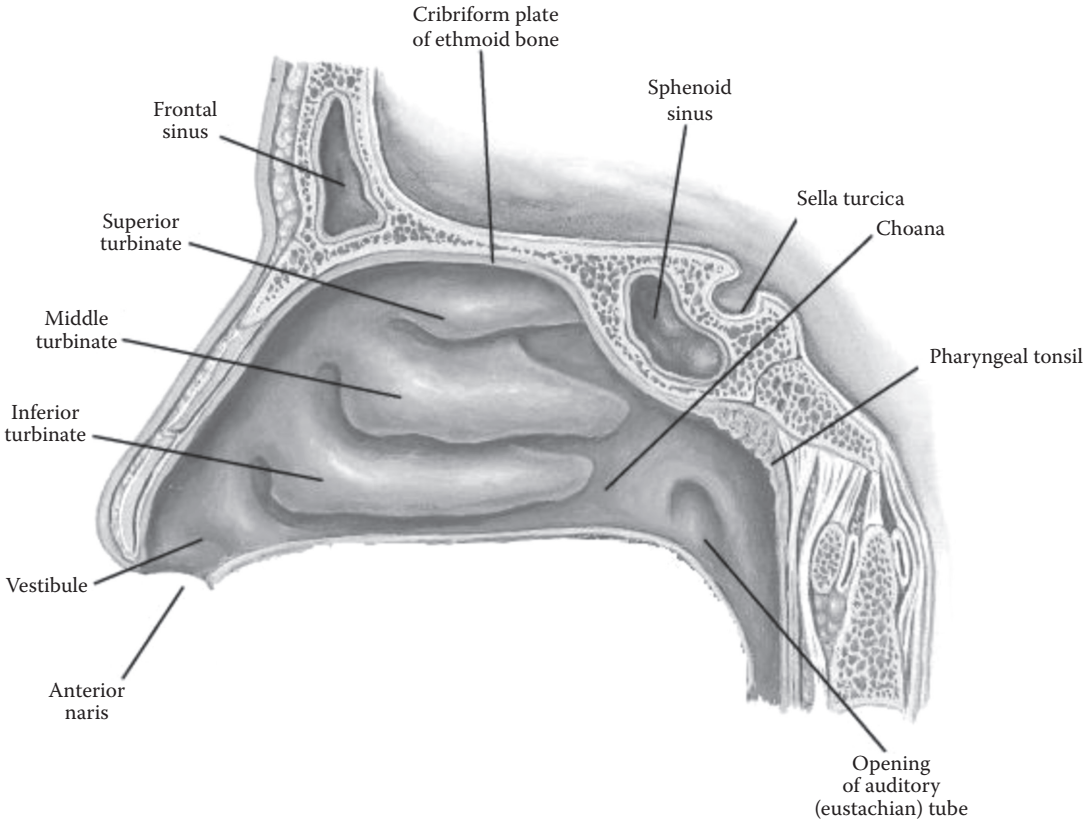

Figure 16.2

Anatomy of a nasal airway. (From http://www.earnosethroatdoctor.net/nose/nose-anatomy2/.)

The sinuses are hollow cavities that are connected in the skull. There are four types of sinuses as shown in Figures 16.3 and 16.4:

1. The maxillary sinuses, which are the largest sinuses of the nasal airway located in the cheekbones
2. The frontal sinuses, which are in the low center of the forehead
3. The ethmoid sinuses, which are between the eyes, at the nasal bridge
4. The sphenoid sinuses, which are located in bones behind the nasal cavity

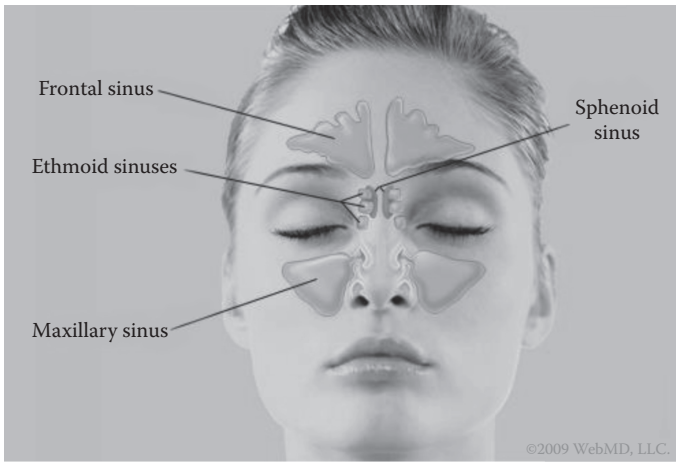

Figure 16.3

Frontal view of a human face showing the locations of the paranasal sinuses: frontal, ethmoid, sphenoid, and maxillary sinuses. (From http://www.webmd.com/allergies/picture-of-the-sinuses.)

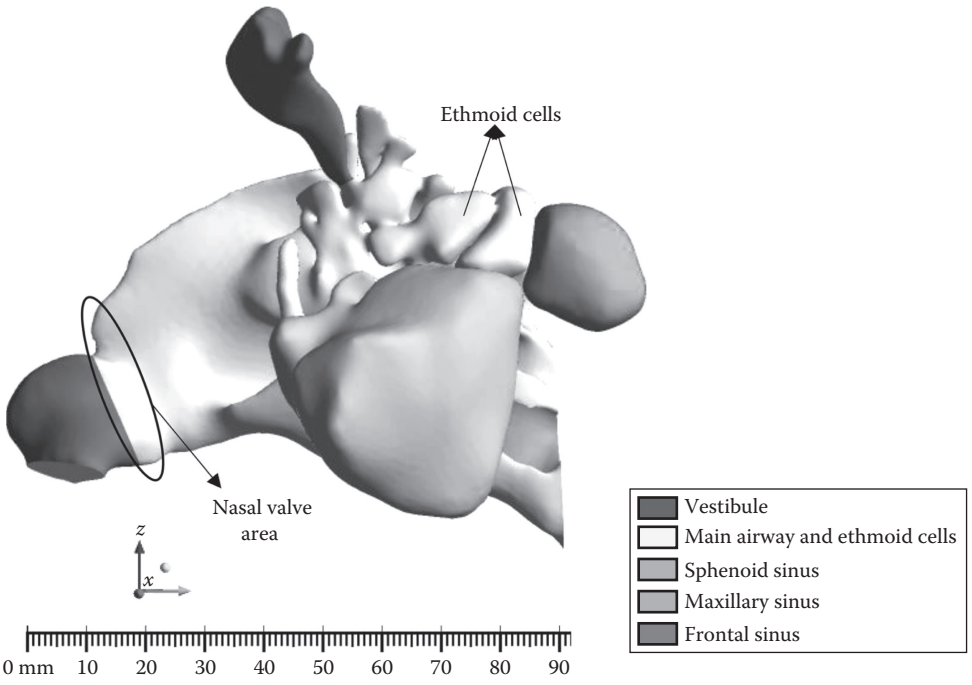

Figure 16.4

A 3-D view of the nasal cavity with all sinuses.

The sinuses walls are lined with mucosa and for a normal person are empty except for a thin layer of mucus. The purpose of the sinuses is not quite clear. It is believed that sinuses have the effect on humidifying the inhaled air and also enhancing the human voices.

16.1.2 Survey of Literature

Understanding the process of inhalation of aerosols has attracted considerable attention because of its significance to human exposure to particulate pollutants and transmission of infectious diseases. Deposition of inhaled particles in the airway passages has been of serious health concerns. These particles include dust, microorganisms, photochemical smog, and other irritants. From the toxicological point of view, all particles that are smaller than 10 μm in diameter can be biologically active and could cause allergic responses and even cancers in susceptible individuals (Cheng, 2003, Heyder, 2004). According to the studies of Frampton (2001), Donaldson et al. (2000), and Oberdorster (2001), fine and especially ultrafine particles are more likely to be harmful and toxic compared to micrometer-sized particles of the same material, and deposition of these ultrafine particles in the lungs can contribute to serious pulmonary diseases such as lung cancer. The sources of these fine aerosols include diesel exhaust 5–500 nm (Kittelson 1998), cigarette smoke (140–500 nm) (Keith, 1982, Bernstein, 2004), and radioactive decay (1–200 nm) (ICRP, 1994). In addition, some of these ultrafine aerosols are biologically active, such as avian flu and SARS, which typically range from 20 to 200 nm (Mandell et al., 2004).

On the other hand, for therapeutic inhalation drug delivery, it is important to make sure particle deposition occurs at targeted areas. Some pharmaceutical aerosols are larger than 20 μm in order to maximize their deposition in nasal cavity and upper airways before entering the lungs. On many other cases, particles smaller than 5 μm (Suman et al., 2006) and sometimes in the submicrometer size range are used in order to make sure of their passage through the upper airways and the delivery of the drug into the lung (Longest and Hindle, 2010). Thus, estimating the fraction of particles of different sizes and physical properties that penetrate into the lung and predicting the distribution of deposited particles in different regions of the human airways are of considerable interest not only to determine what reaches the lung but also to quantify the dose to the upper airways for both health risk and therapeutic effectiveness of inhaled particles. Estimating the regional deposition fraction (DF) of pharmaceutical aerosols is important for treating localized respiratory tract infection. For an acceptable average drug dose, it is still important to be aware of the regional deposition rates since a high local drug dose may cause tissue injuries or initiate a new disease. Thus, understanding the regional particle deposition in human upper airway and the fraction of particles entering the lungs is very important for controlled pulmonary drug delivery.

16.1.2.1 Eulerian and Lagrangian Approaches

Although particles are carried by the breathing air through the respiratory system, their trajectories differ from the airflow streamlines due to their inertia and effects of various forces. The most important forces are gravity, drag, and Brownian motion. Particles are then deposited on the walls of the airway by sedimentation, impaction, and/or diffusion mechanisms (Heyder, 2004). There are two methods for analyzing particle transport and deposition, namely the Lagrangian and the Eulerian methods. The Eulerian approach is more efficient for ultrafine particles when the Brownian excitation is dominant, while the Lagrangian approach is more suitable for dilute suspension of larger particles for which the inertia is important.

All earlier studies suggest that in inertial regime ($d_p \geq 1$ μm), particle deposition increases as particle diameter and airflow rate increases, although there are some differences in the estimated values of DF between different studies even when those estimates are for models constructed from a single set of medical images. This is partly due to the small relative dimension of the airway so that slight differences in the model geometry significantly affect the DF of particles. In addition, variability of the airway of different subjects results in variation of the aerosol deposition under seemingly identical conditions (Wang et al., 2008, Garcia et al., 2009). The differences between evaluated DFs for airway of the same human subject may arise from resolution of magnetic resonance imaging (MRI) or computed tomography (CT) scan images, number of coronal images used for producing the 3-D geometry of the airways, and different techniques of replica cast fabrication.

16.1.2.2 Realistic 3-D Models

Two decades ago, numerical models of the airflow and particle deposition in airway system were limited to simplified and even 2-D models. With improvement of the numerical algorithms and the advances in computer technologies, the numerical solutions for real 3-D geometries of the respiration system have become available. In particular, the computational fluid dynamics (CFD) approach has now matured to the extent that is being widely used to simulate the flow fields in complex configurations and, more recently, the airflow in human airways. In addition, recent advances in developing computer models for complicated geometries provide the opportunity to generate realistic 3-D models for human airways in rather short times. Therefore, the details of airflow and transport of pollutants and aerosols in the respiratory system of individual people can be predicted.

16.1.2.3 Abnormality

CFD models for the airflow dynamic and particle deposition are not limited to healthy human airways; in the past decade, using CFD for studying the respiration systems with different types of abnormalities and performing virtual surgeries and evaluating the outcome of the medical operation in advance have attracted considerable attention. Recent advances in computational modeling allow the creation of models for individual patients with specific abnormalities. In addition, the computational modeling results can be obtained in several days rather than several months that were previously required. Thus, CFD provides the opportunity to predict the details of respiratory airflow and the corresponding transport of gaseous chemicals, aerosols, heat, and water vapor in the airway of an individual patient before and after operations.

Abnormal nasal airways could occur due to the presence of deviation and/or obstruction in the bony or cartilaginous septum of the nasal passage. Deviation in the nasal airways is a common disease that makes septoplasty one of the most frequently performed operations in the nasal airway. The current standard rhinometric measurements provide information on the total nasal airflow rate, pressure drop, and nasal cross-sectional area but cannot reveal changes in the patterns of local airflow. Such general data are inadequate for quantifying the functional impact of nasal obstruction and the effectiveness of the subsequent surgical outcomes. For example, the long-term outcomes of septoplasty are still not quite satisfactory, and a large percent of the patients continue to complain about nasal obstruction following the operation. CFD can be used as a tool for virtual surgery to test various scenarios and for selecting the proper procedure for the optimal outcome of the operation before the surgery (Zachow et al., 2006, Zhao and Dalton, 2007, Ozlugedik et al., 2008, Moghadas et al., 2011). In addition, understanding particle deposition in the human respiratory system is important in connection to odorant delivery rates (Zhao et al., 2004) and therapeutic drug delivery (Inthavong et al., 2008a) of local airflow. Chronic rhinosinusitis (CRS) is another common disease affecting many patients around the globe. When medical management of CRS fails, endoscopic sinus surgery (ESS) is the recommended treatment. Uncinectomy and middle meatal antrostomy (MMA) are fundamental steps in functional ESS (FESS). Uncinectomy involves detachment and removal of the uncinate process, which is a thin, sickle-shaped structure that covers the entrance to the maxillary sinus. MMA means dissection of the medial wall of the maxillary sinus for better exposure of the cavity of this sinus. Uncinectomy and MMA affect the nasal passages' anatomy and may lead to substantial changes in airflow; consequently, the inhaled particle deposition pattern in the nose could also change. From a clinical point of view, it is desirable to perform a virtual surgery in advance of the actual surgery to assess the potential changes in the nasal airflow and the associated aerosol particle deposition pattern and filtration. In addition, the virtual surgery would allow for testing various alternatives and for optimal surgical planning.

Drug delivery devices for airways play an important role in the health issues of human respiratory system. Inthavong et al. (2008) determined critical parameters for the study and design of effective nasal drug delivery devices by taking images of droplet formation from a nasal spray device in an experimental setup. They found that the critical parameters are particle size, diameter of spray cone at a breakup length, and the spray cone angle. They transported the obtained data into initial particle boundary conditions for particle flow simulation within the nasal cavity by using CFD. The results from this qualitative study aim to assist the pharmaceutical industry to improve the design of nasal spray devices. Inthavong et al. (2011) added the nasal spray device in their computational model. They compared the subsequent airflow patterns and its effects on particle deposition, with and without a spray device.

16.1.2.4 Particle Shape

Another concern for particle deposition in the human airway is the shape of the particles. In earlier works, typically the particles are assumed to be spherical, but in reality many natural and man-made particles are nonspherical. For example, although the use of asbestos fibers has been banned, there are still many old buildings that have asbestos-based heat insulation. In addition, new fibrous materials such as vitreous fibers (MMVFs) are currently being manufactured for many applications. It has been shown that some MMVFs may have adverse carcinogenic effects similar to that of asbestos (Cavallo et al., 2004). Therefore, potential risk of lung diseases related to fiber inhalation is still a serious health issue. The adverse effects of particulates also depend on the region of the airway in which the particles/fibers deposit. Thus, the knowledge of regional deposition of fibers in the respiratory tract is of considerable importance. Regional deposition is not likely to be studied in in vivo or even in vitro experimental investigations. In contrast, the computational modeling approaches have the capability to conveniently estimate the regional deposition pattern of aerosols including fibrous particles. In particular, the location of peak deposition in different parts of the respiratory tract can be identified.

16.1.2.5 Upper Respiratory System

In this section, a survey of the earlier work on the upper human respiratory system addressing the noted points is presented. Numerous experimental and numerical studies of the airflow dynamic and the associated particle deposition in the nasal cavity have been reported in the literature. The work of Keyhani et al. (1995), Subramaniam et al. (1998), Zhao et al. (2004), Weinhold and Mlynski (2004), Zachow et al. (2006), and Wen et al. (2008) are some examples of recent numerical studies of the nasal airflows. Computer simulations of particle transport and deposition in the nasal passages were reported by Zamankhan et al. (2006), Shi et al. (2007), Liu et al. (2007, 2010), Xi and Longest (2008), Wang et al. (2009), Se et al. (2010), Moghadas et al. (2011), and Abouali et al. (2012), among others. While most of these numerical studies were restricted to the nasal passages from nostrils to the end of nasopharynx, some others, such as the work of Martonen et al. (2002) and Farhadi Ghalati et al. (2012), included those about the larynx, pharynx, and trachea and/or first bronchial branches. More recently, considerable attention was given to the regional deposition of particles in the respiratory system (Jayaraju et al., 2007, Mylavarapu et al., 2009, Wang et al., 2009, Xi et al., 2011, Abouali et al., 2012, Farhadi Ghalati et al., 2012, Tavakoli et al., 2012, Ghahramani et al., 2014, Dastan et al., 2014).

16.1.2.6 Experimental Studies

Hahn et al. (1993), Schreck et al. (1993), Kelly et al. (2000), and Doorly et al. (2008) performed the experimental investigation of the airflow in the nasal cavity. Experimental results indicated that the nasal airflow was laminar up to a breathing rate of about 24 L/min (Hahn et al., 1993). Later, Kelly et al. (2000) found that for their nasal models the airflow is laminar for airflow rate up to about 15 L/min.

Many experimental studies on particle transport through human nasal passages were also reported in the literature. Strong and Swift (1987), Cheng et al. (1988), and Swift et al. (1992) measured the capture of ultrafine particles in the human nasal passage. Cheng et al. (1993, 1996), Swift and Strong (1996), and Cheng (2003) presented empirical relations for deposition efficiency in the human nasal passage. Kelly et al. (2004a,b) measured the particle deposition in a nasal cavity replica model with different surface qualities. These included a stereolithography (SLA) nasal replica model with greater surface roughness and a Viper nasal replica model (manufactured with a Viper Si2 machine) with a smooth surface. They suggested that the surface quality does not significantly affect the nasal deposition efficiency of nanoparticles. However, the microparticle deposition efficiency strongly depends on the surface roughness. Numerous experimental studies have been performed to measure the total nasal deposition, both in vivo and in vitro using human volunteers. While these provide the most physiologically realistic approach, they are inevitably limited by the number of flow rates and particle sizes that can be used and the data are associated with the intersubject variability. The nasal replica casts, however, offer the opportunity for detailed measurements of the nasal passage and can be studied for a wide range of flow rates and particle sizes. There are, however, limitations on the level of surface finish in the manufacturing process, which affects the airflow and the deposition of micron-sized particles and/or sometimes smaller particles. Schroeter et al. (2011) categorized the sources that cause differences in the estimated DF into *wall roughness* and *surface smoothness*. Accordingly, the term "wall roughness" is used to denote the surface resolution of the rapid prototyping machine used to fabricate the airway replica casts and is normally excluded in numerical approaches, while the term "surface smoothness" is used to describe surface irregularities due to coarse imaging data and poor interpolation between consecutive cross sections in sectional anatomic data. That is, the DF in nasal cavities is strongly affected by the model developing procedure for

both experimental and numerical studies, in addition to the interindividual differences between human subjects. As a result, although it was tried to reduce the data of different cases to a single graph (Wang et al., 2008, Garcia et al., 2009), generally, validation can be done only with the trend of the data.

16.1.2.7 Oral Upper Airway

The airflow structure and particle deposition in oral airway were also studied numerically by many researchers. Most of these studies utilized a simplified model of the oral airway (Zhang et al., 2002, 2005, Kleinstreuer and Zhang, 2003). Jayaraju et al. (2007) and Tavakoli et al. (2012), however, reported the results of their numerical studies for the airflow field and particle deposition in realistic geometries of human oral airway. Cheng et al. (1999) investigated the effects of breathing rate and particle size on the deposition pattern in a human oral airway cast. The airway replica included the oral cavity, pharynx, larynx, trachea, and three generations of bronchi. Except for the oral cavity, all the other airway portions of the cast were made from a cadaver. For micrometer particle sizes, they reported that the deposition efficiency is a function of the Stokes number and concluded that impaction is the dominant deposition mechanism. Grgic et al. (2004) presented regional and total deposition measurements in several realistic mouth and throat geometries and reported the effects of intrasubject and intersubject variations in geometry on both total and regional deposition efficiencies. They showed when the total deposition data from all different geometries are plotted versus Stokes number, all the graphs collapse onto a single curve. They found that the mouth area is the most effective filter for capturing the inhaled aerosols. Verbanck et al. (2011) studied both inspiratory and expiratory deposition efficiencies of microparticles in realistic upper airway geometry both experimentally and numerically. They found that expiratory and inspiratory deposition efficiency curves were almost identical. But the regional deposition efficiency in the upper airway model was different during inspiration and expiration, with preferential deposition, respectively, in oral and pharyngeal regions. Zhang and Kleinstreuer (2011) presented a CFD analysis of airflow and nanoparticle deposition in the combined nasal–oral–tracheobronchial airway model. They found that the change from nasal to oral breathing markedly influenced the regional deposition pattern in the upper airways. Also, the change in breathing route noticeably affects the deposition rates in the regions from pharynx to bronchial airways for nanoparticles less than 5 nm. However, the effect on the regional deposition of larger nanoparticles (>5 nm) beyond the pharynx region is small.

16.1.2.8 Tracheobronchial Airways

The airflow and particle deposition in tracheobronchial airways and lung have also been the subject of a lot of studies in the past three decades. A brief review of some of the pertinent recent work is provided in this section. Zhang et al. (2002) simulated the airflow and particle transport under the 3-D transient laminar flow conditions for a symmetric triple bifurcation lung airway model (i.e., Weibel's generations G3–G6). Three inhalation conditions related to rest, light, and moderate activities were analyzed for ranges of inhaled particles with Stokes numbers, $St < 0.2$. They reported particle deposition patterns in the triple bifurcations. Zhang et al. (2005) presented their numerical simulation results for microparticle and nanoparticle deposition for a simplified human airway model covering the mouth to the planar airway generation G3 under different inspiratory flow conditions. They presented their results in the form of deposition patterns, local concentrations, and segmental averages. Li et al. (2007) studied the particle deposition in the human tracheobronchial airways considering a more realistic computational model under transient condition. Their airway model consisted of trachea to the third bifurcation generation. Adding the trachea rings and accounting for the nonsymmetric behavior of the bifurcations were the new changes to their earlier simple airway model. The results showed that the relation between particle-release positions at the trachea inlet and the particle depositions at specific lung sites are mainly affected by the complex airway geometry and the airflow rate magnitude. Inthavong et al. (2010) studied the micron particle deposition in a tracheobronchial airway model under different breathing conditions. They developed a realistic computational model of a human tracheobronchial airway from CT scans. They found that a deep inhalation with a breathhold of 2 s increases the deposition in the first few airway generations, but it does not necessarily increase the deposition up to the sixth branch generation. Also, their results showed that the breathhold allows the deposition by sedimentation, which could assist in targeted local deposition. Longest et al. (2012) compared the metered dose inhaler (MDI) and dry powder inhaler (DPI) aerosol deposition using in vitro experiments and a new stochastic individual path (sip) model of the conducting airways. Their airway model consisted of the mouth–throat and tracheobronchial trees. They found that the drug delivery to the tracheobronchial region using the MDI is approximately two times more compared with that for the DPI.

16.1.2.9 Nasal Upper Airways

The numerical analysis of the respiratory flow pattern in a realistic nasal human upper airway was presented by Wang et al. (2009). The airway model in their work consisted of the nasal cavity, pharynx, larynx, and trachea fabricated based on the CT images of a healthy volunteer and also the triple bifurcation based on Weibel's model. Mylavarapu et al. (2009) developed an anatomically accurate human upper airway model constructed from multiple MRI axial scans. They used this model to conduct detailed CFD simulations during expiration to investigate the airflow in the airway regions where obstruction could occur. They also measured the pressure and velocity experimentally in a physical model prototype. The airway model in their work consisted of the nasal cavity, pharynx, and larynx and the inlet section of trachea. Xi et al. (2011) evaluated the transport and deposition of respiratory aerosols in a nasal–laryngeal airway model based on MRI head images of a 5-year-old boy. Recently, Farhadi Ghalati et al. (2012) developed a more comprehensive and realistic model, which covered the upper airways from nasal cavity to the end of trachea, and performed a series of numerical analysis of local deposition of micro-/nanoparticles. Knowledge of the localized and subregional particle deposition rates may be helpful in specifying the site of the highest possibility for respiratory lesions. Current risk assessment approach uses the spatially averaged dose overbroad regions of the respiratory tract (G. U.S. General Surgeon report, 2006, Foos et al., 2008). But the concentrations of particulate matter for localized deposition may exceed area-averaged values by several orders of magnitude resulting in the formation of dosage hot spots (Xi and Longest, 2007, 2008). It is important to identify these deposition hot spots for which formation of cancer is more probable. That is, the information of local deposition could be useful for health risk assessment because a high local dose may cause tissue injuries or initiate a disease process (Kim et al., 1996), whereas the average dose could be still negligibly small.

16.1.2.10 Virtual Surgery

There have been a number of papers in literature that studied the effect of pathological conditions in patients. The presence of polyps, swelling, atrophy, or resection of turbinates and enlarged adenoids in the nasal airflow were studied using cadaver models by Tonndorf (1939), Proetz (1951), and Swift and Proctor (1977). Grützenmacher et al. (2006) inspected the presence of compensatory hypertrophy of turbinates. Chung and Kim (2008) applied digital particle image velocimetry procedure to study the consequence of turbinate modification on the airflow patterns during respiration. In addition, they studied the airflow patterns in both nasal cavities of a patient with an asymptomatic deviated nasal septum. Ozlugedik et al. (2008) inspected both the effects of septal deviation and concha bullosa on nasal airflow, as well as the aerodynamic changes induced by virtual septoplasty and partial lateral turbinectomy. Chen et al. (2009) carried out a CFD study to provide information on the aerodynamic consequences of nasal septal deviation on the turbulent airflow patterns and their related physiological functions. Moghadas et al. (2011) investigated numerically the effect of septal deviation on the flow patterns and deposition of micro-/nanoparticles in the realistic human nasal airways before and after septoplasty. Their study showed that CFD provides a suitable tool for predicting the airflow and particle deposition patterns in the nasal passages that specific surgical interventions would produce. Thus, it is expected that CFD could help the medical professional to optimize the selection of surgical interventions for specific patients.

Although in the past decade numerous computational simulations of airflow and particle deposition patterns in the nasal cavity were reported in the literature, in most cases, the sinuses were not included in the numerical model. In fact, the number of papers in the literature discussing the airflow in the nasal airways including the sinuses is very few. Lindemann et al. (2005) simulated the intranasal airflow after radical sinus surgery during inspiration. They performed an aggressive virtual operation on the CT scan model of the nose, which included a bilateral model of the human nose with maxillectomy, ethmoidectomy, and resection of the lateral nasal wall and the turbinates. They concluded that aggressive sinus surgery led to disturbed intranasal airflow patterns and a reduction of the effective surface area in relation to the nasal volume. Zachow et al. (2006) presented their airflow simulations using CFD for a highly detailed anatomy of a nasal airway including the frontal and paranasal sinuses. They showed that a very small part of the airflow entered the sinuses. Using CFD modeling of one volunteer patient's nose pre- and postoperative, Zhao et al. (2006) showed significant improvement in postsurgical ortho- and retronasal airflow and odorant delivery rate to olfactory neuroepithelium (by a factor of 1000 times), which correlated well with olfactory recovery. Ethmoid and sphenoid sinuses were included in their computational model, and it was shown that the airflow velocity within the sinus is quite low, confirming the limited effect of the sinus on the overall nasal airflow field. Xiong et al. (2008) utilized CFD techniques to construct a numerical simulation of nasal

cavity airflow pre- and postvirtual functional endoscopic surgery (FESS). A virtual FESS intervention was performed numerically on the normal nasal model using the Fluent™ software. In the post-FESS model, they found an increase in airflow distribution in the maxillary, ethmoid, and sphenoid sinuses and a 13% increase through the area connecting the middle meatus and the surgically opened ethmoid. Xiong et al. (2011) used CFD to compare nasal airflow after two different surgical interventions, which involved opening the paranasal sinuses, excising the ethmoid sinus, and excising or preserving the uncinate process, in a cadaveric head model. They concluded that the preservation of the uncinate process may significantly reduce the alteration of nasal cavity airflow dynamics after FESS for CRS. Abouali et al. (2012) constructed realistic 3-D computational models of the human nasal passage for pre- and postvirtual uncinectomy and MMA. They showed that after maxillary sinus endoscopic surgery, the maxillary sinus ventilation changes dramatically and the deposition of inhaled nano-/microparticles in the sinus increases. Kim et al. (2013) reviewed methods and challenges for developing patient-specific CFD models of nasal airflow. They described several CFD case studies for deviated nasal septum (decision for surgery), turbinectomy, and maxillary sinus ventilation (simulated and postsurgery) on patient-specific 3-D models of nasal cavity. They concluded that while using CFD for diagnosis and outcomes of nasal surgery has considerable potential, the challenges will be the standardizations of the methodology for creating 3-D airway models and the CFD procedures.

16.1.2.11 Turbulence Effects

Another challenge in the numerical modeling of the airflow and particle transport in human airway system is accounting for the flow turbulence effects. Small particles in a turbulent airflow stream are significantly influenced by the turbulence fluctuating velocities leading to the so-called turbulence dispersion. For a reliable analysis of particle trajectories, these fluctuations should be calculated and the corresponding instantaneous flow velocity should be evaluated. The most accurate approach for evaluating the fluctuation velocity in turbulent flows is the direct numerical simulation (DNS), and that is followed by the large eddy simulation (LES) method. For DNS, the Navier–Stokes equation is solved using sufficiently fine grids that can resolve the Kolmogorov scales (smallest length and time scales of turbulence) to capture the smallest eddies and highest frequencies of turbulence. DNS, however, requires extensive computational resources and so far has been used for very simple geometries such as channels and pipes (Nasr et al., 2009). When the grid size is somewhat larger than the Kolmogorov length scales, the LES method is used, where scales larger than the grid are resolved and the effect of subgrid scale fluctuations are modeled. However, the LES is also computationally expensive and also requires accounting for the effects of turbulence subgrid scale fluctuations. While some investigators (e.g., Liu et al., 2007, 2010, Salmanzadeh et al., 2010, Dehbi, 2011) used LES in their analysis, most researchers used the Reynolds averaged Navier–Stokes (RANS) equations and a turbulence model. In these cases, the effect of turbulence fluctuations on particle dispersion needs to be included. The RANS models were used by many previous investigators. For example, Katz et al. (1999) and Stapleton et al. (2000) used the standard k–ε model and Renotte et al. (2000) used the RNG, k–ε model. Some researchers tried to first validate the models for similar but simpler flow fields and then apply them to more complex flows. For example, Zhang and Kleinstreuer (2003) tested different two-equation turbulence models and recommended the use of the standard k–ω model with low-Reynolds-number (LRN) corrections for LRN flows, which includes laminar to turbulent transition. The application of the standard k–ω model can also be found in the work of Matida et al. (2004), Grgic et al. (2006), Ball et al. (2008), Tavakoli et al. (2009), and Alexopoulos et al. (2010). The SST k–ω is another k–ω-based turbulence model that was used by Liu et al. (2007, 2010) and Jayaraju et al. (2007, 2008). Earlier, Li and Ahmadi (1995) emphasized the importance of anisotropy of turbulence fluctuations near the wall on particle deposition and used an anisotropic nonlinear turbulence model for analyzing particle deposition in the first lung bifurcation. However, in many studies, the isotropic models including the LRN k–ε model that was developed by Launder and Sharma (1974) was used.

As noted before, the RANS models compute the mean flow field, as well as the root mean square (RMS) turbulence fluctuations. To include the turbulence dispersion effects on particle trajectories, the fluctuating velocity field at the location of particles needs to be evaluated. Typically, the discrete random walk (DRW) and the continuous random walk (CRW) models are used. In DRW models, which are also known as the eddy interaction models, it is assumed that each particle has a succession of interactions with turbulent eddies that have limited life and length scales and the fluctuating velocities can be found from turbulent quantities of the eddies. The original form of this model was proposed by Gosman and Ioannides (1983) and was used by a number of researchers such as Katz et al. (1999), Jayaraju et al. (2007, 2008), Kleinstreuer and Zhang (2003), and Liu et al. (2007, 2010) in order to take into account the turbulent fluctuations effect

on particle dispersion in respiratory systems. It should be noted that the use of the original DRW model for inhomogeneous and anisotropic turbulent flows can lead to unrealistic results and the particle deposition would be overestimated since this model shows a tendency for small particles to concentrate near the walls, especially in the diffusion-dominated flows (Mehel et al., 2010). In fact, when this model is combined with turbulent RANS models, it is assumed that the flow is homogenous and isotropic. One major issue with the k-ε and k-ω turbulence models is that they are based on the Boussinesq approximation that assumes that the turbulence fluctuation field is isotropic. Therefore, the use of k–ε or k–ω models in combination with the DRW model leads to unphysical particle dispersion predictions. Tian and Ahmadi (2007) showed that the use of this model even in combination with anisotropic Reynolds stress models (RSMs) can lead to overprediction of particle deposition rate in simple duct flows. However, some investigators tried to use a modified version of this model to take into account turbulence anisotropy (Matida et al., 2004, Zhang et al., 2004, 2005, Inthavong et al., 2006, 2009, Tian and Ahmadi, 2007).

While DRW models describe fluctuating velocities as piecewise constant functions of flow properties, CRW models compute the fluctuation velocities as continuous functions. These models were also extensively used in homogeneous turbulent flows where statistically averaged turbulent properties are position independent. For inhomogeneous flows, Durbin (1983, 1984) and Thompson (1984) suggested the use of the normalized form of the Langevin equation. Dehbi (2008) improved the method and applied it for predicting turbulent dispersion of particles in idealized mouth–throat geometry (Dehbi, 2011).

For modeling the particle transport and deposition in the respiratory systems, the most critical step is the determination of the airflow regime. Like many other flow fields, transition from laminar to turbulent flow regime in the respiratory tract does not occur at a specific flow rate and depends on various factors. In other words, because of the anatomical differences, the flow regime for a given breathing rate may be turbulent in the respiratory tract of a person, while it could be laminar in the airway passages of another person. Jayaraju et al. (2007) studied the flow field in a real mouth–throat model and showed that even for a moderate breathing rate of 15 L/min, the flow is in turbulent regime especially after the glottis. On the other hand, Hahn et al. (1993) concluded that the flow is laminar for a flow rate of less than 12 L/min in a single nasal passage. Also Doorly et al. (2008) reported some instability in the flow field for the flow rate of 12 L/min in a single passage for an inspiratory jet entering the nasal cavity, but they observed a relatively undisturbed laminar flow within most of the cavity. Furthermore, the type of flow may vary with time over a dynamic inhalation/exhalation cycle. While the onset of transition from laminar to turbulent regime depends primarily on Reynolds number, it also varies with the flow geometry (which is somewhat different for different subjects). Nevertheless, it is certain that for flow rates of 30 L/min and more, the transition from laminar to turbulence occurs and the flow field should be simulated using a turbulence model.

16.1.2.12 Surrounding Effects

Another challenge in the study of the inhalation of air and aerosols is the important effects of the surrounding environment including the subject facial feature. In most numerical investigations, a detached airway system with either a uniform pressure or uniform inlet airflow velocity was considered and the external environment to the body was not included in the computational model. It is, however, generally known that many parameters such as air ventilation conditions, ambient airflow speed and temperature, and even people positions affect the inhalation process and particle deposition in the respiratory track. Understanding the effect of external environment and facial features on the human exposure to particulate matter has attracted some attention in the recent years. Kennedy and Hinds (2002) used a full-sized and a torso mannequin and studied particle inhalation through nose and mouth during breathing. Se et al. (2010) studied the effect of human facial feature on particle inhalation and the total deposition in human airways using CFD for a rather crude mannequin model. In their experimental studies, Berry and Froude (1989) and Baldwin and Maynard (1998) paid attention to the air environment calm. They defined the calm air as a condition where the wind speed rarely exceeds 0.3 m/s. Using a mannequin, Hsu and Swift (1999) measured the inhalability of ultra large aerosol in a calm air environment under different breathing conditions. They showed that the breathing condition and age do not significantly affect the aspiration ratio and suggested an empirical correlation for inhalability for the nasal breathing. In their work, torso mannequins of an adult and a child were exposed to nonspherical airborne particles. Several volume flow rates corresponding to human activity condition (rest, moderate, and heavy exercise) were studied. Daia et al. (2006) measured the nasal inhalability of aerosol particles under the calm air condition for ten subjects exposed to different inspiratory flow rates. Comparison of in vivo and mannequin measurements suggested that the natural convection from the human body could affect the particle motions in calm air and cause slightly higher

inhalability for particles smaller than 50 μm. Li et al. (2012) simulated airflow around a simplified mannequin model and investigated effects of facial features on nostril velocity profile. Then, they used the resulted velocity profile as an inlet boundary condition for their nasal cavity flow study. They reported that the facial features affect only a small region in front of the face (10–20 mm) and result in a nonuniform velocity profiles at the inlet of the nostril that may affect the particle inhalation. Inthavong et al. (2012) integrated the human upper airway into a mannequin that was placed inside a room, facing different airflow speeds. Their study provided a better understanding of the air and particle flow patterns near a mannequin exposed to different environmental conditions. In a detailed study, Taylor et al. (2010) investigated the effect of the inflow condition on the numerical simulation of steady nasal inspiration. They compared the cases of (1) uniform velocity profile, (2) a tapered pipe inflow, and (3) a model that fully replicates the external environment and the internal nasal airways. Investigating the airflow inside the nasal airway, they found that a tapered pipe inflow provides a better approximation for the natural inflow than a uniform velocity profile applied to the nares. Recently, Inthavong et al. (2013) investigated the source and trajectories of deposited particles in the upper respiratory system using a computational model that combined the mannequin and respiratory airway in an indoor environment for free stream airflow velocities of 0.05, 0.2, and 0.35 m/s, which is common in an indoor environment. A more recent research in this area was performed by Naseri et al. (2014). They developed a 3-D realistic computational model of the airway system integrated into a standing male mannequin and simulated the external and internal airflows simultaneously. Their results showed when the upper airway is integrated into the mannequin, the airflow focuses the particles toward the central part of the nostril. As a result, the regional deposition of inhaled particles differs markedly from those predicted for detached airways.

16.1.2.13 Fibrous Particle Transport and Deposition

Another issue for the respiratory flow simulations is handling the nonspherical shape of inhaled particles. It should be pointed out that particles in many cases are highly elongated and cannot be approximated as spheres. Suspensions of fibrous particles occur in many industrial applications such as composite material production, paper industry, and chemical and food processing industries. Understanding the motion and transport of fibrous particles with high aspect ratio has attracted the attention of a few researchers in the past. Accordingly, for elongated particles, the orientation and rotation of the fibers need to be included in the analysis. Fan and Ahmadi (1995a,b) studied numerically the effects of shape, aspect ratio, and density of ellipsoidal fibers on their dispersion and deposition in turbulent flow fields. Asgharian and Ahmadi (1998) studied the motion and deposition of fibers in a simplified model of small human airways, while Kvasnak and Ahmadi (1996), Tian et al. (2012), and Zhang et al. (2001) studied fiber transport and deposition in ducts.

Deposition of fibrous particles in nasal cavities, however, has received comparatively less attention, and there is rather limited number of related experimental and numerical studies in the literature. Experimental researchers (Su and Cheng, 2005, Su et al., 2008) investigated the regional fiber deposition in a human airway replica. Wang et al. (2008) conducted an experimental investigation on fibrous particle deposition in several human nasal cavities and studied the effects of particle shape, flow rate, and the nasal geometry on their deposition patterns. For non-Brownian fibers, they showed that the increase in flow rate and fiber length increases the deposition efficiency; therefore, they concluded that the inertial impaction is primarily deposition mechanism. They also noted the dependence of the deposition pattern on the nasal airway geometry. Inthavong et al. (2008) studied numerically the deposition of fibers in both right and left cavities of an adult person. They used the modified drag equation of Haider and Levenspiel (1989) (HL) for the cylindrical fibers. The HL model uses a spherical particle simulation approach with a shape factor for the nonspherical particle. Recently, Dastan et al. (2014) performed simulations of fibrous particle deposition in different realistic human nasal cavities. The coupled translational and rotational equations of motion of ellipsoids were solved and the fiber transport and deposition in the nasal passages were analyzed. They showed that when the DF results and the Stokes-based and pressure-based impaction parameters (IPs) are compared, the results of the different cases for various nose models collapse roughly to a single curve.

16.1.2.14 Targeted Deposition

A new concept that has attracted the attention of researchers is the targeted deposition of particles in the airway using a magnetic field. This idea has the potential for applications to lung cancer treatment. Ally et al. (2006) experimentally studied the factors affecting magnetic retention of particles in the upper airways

using in vitro and ex vivo models. Their results indicated that particle size and aggregation as well as the apparent viscosity of the mucus layer at low shear rates affect the particle retention. Dames et al. (2007) were the first to actually perform targeted aerosol delivery to the lung in mice. They used superparamagnetic iron oxide nanoparticles (nanomagnetosols, i.e., aerosol droplets in addition to a target-directed magnetic gradient field). They also provide a theoretical analysis of the process using computer simulations. They also emphasized that the major challenge for using this technology for humans is the scale-up of the magnetic gradient field for the human lung. Nevertheless, they concluded that targeted inhalation therapy with use of magnetic targeting of nanomagnetosols could be possible in the future. Martin and Finlay (2008) experimentally showed that using magnetic field alignment, deposition of high-aspect-ratio aerosols in small airway bifurcations can be enhanced. The measurements were done in vitro in a physical model of a small bifurcating airway of the lung. In this approach, there is no need for generating a gradient in the magnetic field strength, which decreases the amounts of magnetic material compared to the active drug. The magnetic deposition of aerosols composed of aggregated superparamagnetic nanoparticles was experimentally verified and also simulated with a CFD model by Xie et al. (2010). They showed that the CFD simulations could help design the systems for selective drug delivery in vivo as a function of magnetic properties and aerosol characteristics.

16.1.2.15 Accounting for Unsteady Breathing

The breathing cycle is clearly an unsteady process in which airflow rate increases during the inhalation cycle and decelerates and reverses during the exhalation phase. One major limitation of many of the earlier studies on the respiratory flow modeling and particle deposition is ignoring the effect of unsteadiness of the breathing process. As noted by Doorly et al. (2008), most of the earlier studies have used the mean flow rate averaged over the inhalation breathing cycle. Therefore, the acceleration and deceleration of airflow in the breathing process were not considered. The steady airflow simplification at a constant inhalation rate has also been used for simulation of transport and deposition of particles. Although a given flow rate may occur at certain instant of breathing, the breathing rate is certainly periodic. Therefore, the accuracy of the assumption of steady airflow needs to be understood and verified. Indeed, the time variation of airflow during breathing is known to affect the deposition of microparticles in the nasal cavity that is dominated by inertial impaction. Zhang et al. (2002) reported that the deposition of microparticles in the bronchial airway bifurcation under cyclic airflow was higher compared with the case that the equivalent mean flow was used. This trend was also observed by Grgic et al. (2006) for the human mouth–throat model. Häußermann et al. (2002) observed a reverse trend in total deposition of microparticles in a nasal cavity cast. Their results showed much higher deposition rate for 1.7 and 3 μm particles at constant flow rates compared to that periodic human breathing. Li et al. (2007) studied numerically microparticle deposition in the human tracheobronchial airways due to transient inspiratory breathing patterns. They found that the particle DF is a time varying function following the inhalation waveform. In addition, their numerical results showed that the local deposition efficiencies are higher in the cyclic case compared with those in the steady case. Jiang and Zhao (2010) performed both steady and unsteady CFD simulations for a rat nasal model under realistic breathing and sniffing flow rates. They investigated the transient nature of the airflow, as well as nanoparticle transport and deposition patterns in the nasal cavity and the olfactory region. They found that the total deposition efficiency of nanoparticle during cyclic breathing is lower than that for the steady flow model. While the results of some of the earlier studies are contradictory, they suggest that the use of the steady assumption for analyzing nasal particle transport and deposition during cycling breathing may not be accurate, and for more detailed assessment of the toxicological and therapeutic impact of particle inhalation, an unsteady flow and particle tracking are needed. Detailed CFD studies for the comparison of microparticle deposition in the human nasal cavity for cyclic breathing and the equivalent steady flow are rather scarce.

Zubair et al. (2012) presented a discussion of the limitations of CFD modeling of nasal airflow. Neglecting the mucous layer and other vital anatomical features was noted as some common limitation. They suggested using appropriate CT or MRI data for constructing the CFD models. In addition, the use of the entire upper airway and pull-flow boundary conditions was recommended.

The summary of this section shows there has been increasing interest in computational analysis of airflow and particle transport and in the human respiratory system in the past three decades, and numerous publications have appeared in the literature. Tu et al. (2013) published a book on computational fluid and particle dynamics in the human respiratory system, which is a good reference for researchers as well as graduate students interested in this field.

16.1.3 Computational Methodology

The recent methodology for the computational study of airflow and particle transport in human respiratory airways consists of five main steps: the first step is taking the CT or MRI images of the subject airways. Patient-specific models are obtained in this fashion as needed. The existing medical images taken in routine clinical procedures can also be used when they have sufficient resolution and cover the entire airway of interest. Figure 16.5a shows a sample medical image of a section of the upper airways. For the reconstruction of the airway models, the CT images are preferable, but a complete set of images of sections of the entire airway is needed. The CT and MRI image is usually in Digital Imaging and Communications in Medicine (DICOM) format.

The second step is constructing 3-D computational model of the airway from the CT or MRI medical images. A sample reconstructed volume is shown in Figure 16.5b. In-house codes and/or commercial image processing software such as Mimics (Materialise, Ann Arbor, United States) and Amira (Mercury Computer Systems, Inc., United Kingdom) can be used for this purpose. The commercial Mimics and Amira have

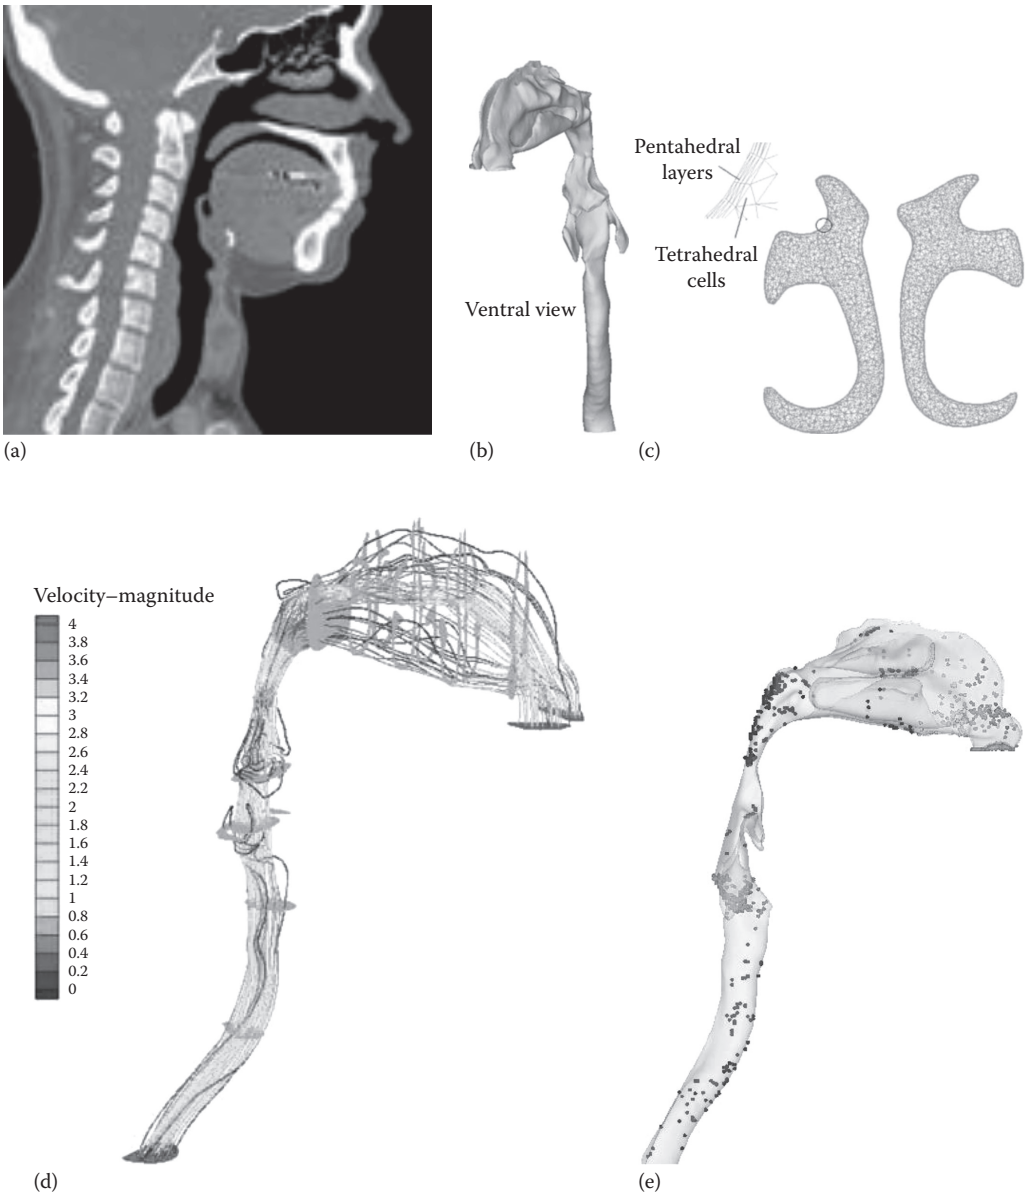

Figure 16.5

Steps for developing a computational fluid dynamics model of human airway system. (a) Medical image. (b) 3D model. (c) Mesh generation. (d) Flow field simulation. (e) Particle deposition analysis.

been widely used for the construction of complicated 3-D anatomical models for medical and biological applications. Alternatively, the CT scan images with DICOM format are processed by MATLAB® software to identify the boundary coordinates of the airway walls. Then, the resulting surface is imported into CAD software (CATIA) or mesh generator tool and the airway surface and volume are created and used for the CFD study. Additional details of these steps may be found in Chapter 3 of the recent book by Tu et al. (2013).

The third step is the grid generation for the created computational volume of the airway. Since most segments of human airways are anatomically complicated, typically unstructured grids have been used in the earlier work. For a better approximation of the velocity gradients and particle deposition, a combination of the pentahedral layers in vicinity of the walls and tetrahedral cells in other regions as shown in Figure 16.5c may be more appropriate. Gambit, ICEM, and ANSYS Workbench are among the software tools that are used for mesh generation. The fourth step is solving the governing equations for the flow dynamics and then the particle motions for evaluating the airflow field and transport and deposition of particles in the airway. ANSYS-Fluent™ has been widely used as flow solver in many of the reported works. ANSYS-CFX™ is also another commercial flow solver that has been used in the earlier numerical studies of the respiratory system. Some researchers have used their own in-house code as solver. The open, source code, OpenFOAM software has also been gaining popularity as a solver and is being used for respiratory applications.

The last step is the postprocessing of the obtained results and their analysis and interpretation. The postprocessing for the flow properties, such as providing contour plots for velocity magnitude, pressure, and turbulence kinetic energy and dissipation rate, as well as path lines, is usually done within the flow solvers (Fluent or CFX) or with use of other software such as Tecplot. Tecplot is a CFD postprocessing tool graphical presentation of the simulation data. Figure 16.5d shows sample particle path lines colored with velocity magnitude. Figure 16.5e shows the particle deposition pattern in the upper airways.

Within these major steps, some additional interesting tasks may be done as needed. For example, a virtual surgery can be performed. That is, under the supervision of a physician, appropriate changes in the image processing software such as Mimics and Amira can be before developing the 3-D surface model of the airway.

16.1.4 Governing Equations

For respiratory deposition, typically the concentration of particles is dilute and the assumption of one-way coupling is used. That is, the fluid flow carries the particles, but the effect of particles on the flow is negligibly small and is neglected. Under this condition, the airflow field is first simulated and the resulting velocity fields are used for analyzing the particle motions. In this case, the interactions of particle are negligible and each particle can be tracked independently. Exhaustive reviews of computational modeling of single-phase fluid flows in laminar and turbulent flow regimes through solving the Navier–Stokes and RANS equations, in conjunction with some turbulence model, are available in the literature (e.g., Tu et al., 2013). Therefore, here only the governing equations for particle motions are outlined.

16.1.4.1 Microparticle Transport Equation

Simulations of the microparticle transport and deposition are usually performed by the Lagrangian trajectory analysis approach. In this method, the individual particles are tracked within the flow field. The primary advantage of this approach is that the effect of forces such as gravity, drag, and inertia are directly considered. In particular, the Lagrangian approach is well suited for microparticles for which the inertia has a noticeable effect on their motion. The second law of Newton governs the dynamic of particle motion:

$$\frac{du_i^p}{dt} = \frac{1}{\tau}\frac{C_D \mathrm{Re}_p}{24}(u_i - u_i^p) + F_i^L + g_i + n_i(t) \tag{16.1}$$

where

u_i^p is the particle velocity
u_i is the fluid velocity
F_i^L is the lift force per unit mass
g_i is the acceleration due to gravity
$n_i(t)$ is the Brownian force per unit mass
τ is the particle relaxation time given by

$$\tau = \frac{Sd^2 C_c}{18\nu} \tag{16.2}$$

where
d is the particle diameter
ν is the gas kinematic viscosity
S is the particle-to-fluid density ratio
C_c is the Cunningham slip correction given as

$$C_c = 1 + \frac{2\lambda}{d}\left(1.257 + 0.4e^{-\frac{1.1d}{2\lambda}}\right) \tag{16.3}$$

where λ is the gas mean free path.

The first term on the right-hand side of Equation 16.1 is the drag force that is typically the dominant force for microparticles. Here, C_D is the drag coefficient, which is given as (Hinds, 1982)

$$C_D = \frac{24}{\mathrm{Re}_p}\left(1 + 0.15\mathrm{Re}_p^{0.687}\right) \quad \text{for } \mathrm{Re}_p < 400 \tag{16.4}$$

where Re_p is the particle Reynolds number given by

$$\mathrm{Re}_p = \frac{\rho^p d\left|u^p - u\right|}{\mu} \tag{16.5}$$

where
d is the particle diameter
μ is the gas dynamic viscosity

While the drag coefficient given by Equation 16.4 is reasonably accurate for applications to aerosol motion, there are a number of expressions with various degree of accuracy in the literature. For example, Clift et al. (1978) suggested the use of

$$C_D = \frac{24}{\mathrm{Re}_p}(1 + 0.1315\mathrm{Re}_p^{\omega}) \quad \text{for } \mathrm{Re} < 20 \tag{16.6}$$

with the exponent given as

$$\omega = 0.82 - 0.05(\log_{10}\mathrm{Re}_p) \tag{16.7}$$

Recently, Barati et al. (2014) suggest a highly accurate expression for the drag force acting on a spherical particle.

The expression for the shear lift force in Equation 16.1 is given as

$$F_i^L = \frac{2K\nu^{1/2}d_{ij}}{Sd(d_{lk}d_{kl})^{1/4}}(u_j - u_j^p) \tag{16.8}$$

where
$K = 2.594$ is the constant coefficient suggest by Saffman (1968)
d_{ij} is the deformation rate tensor expressed as

$$d_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) \tag{16.9}$$

The trajectory of the particle, $x_i(t)$, is obtained by integrating the velocity vector equation. That is,

$$\frac{dx_i}{dt} = v_i \tag{16.10}$$

Equations 16.1 and 16.10 are used to compute the trajectories of individual particles when the flow velocity is known. When the airflow is in the turbulent regime, however, the fluid fluctuating velocities should be estimated and added to the mean flow velocity for the particle trajectory analysis.

For the Lagrangian model, the DF is computed based on the number of deposited particles and the number of particle entering the domain. That is, the DF for a region i is defined as

$$\mathrm{DF}_i = \frac{\text{Number of particles depositing in region } i}{\text{Number of particles entering the geometry inlet}} \tag{16.11}$$

16.1.4.2 Stochastic Fluctuation Velocity Models

As noted before, small particles in a turbulent airflow stream are influenced by the turbulence fluctuating velocities that lead to their turbulence dispersion, which is the key factor in their spreading and deposition. When RANS models are used, for accurate analysis of particle transport in turbulent flow, these fluctuation velocities should be evaluated so that the corresponding instantaneous flow velocity is used in the evaluation of drag and other relevant forces. The RANS models typically provide the mean flow and mean square values fluctuation velocities and/or kinetic energy of turbulence. Some stochastic models are then used to generate the fluctuation velocities using the turbulent kinetic energy and/or Reynolds stresses. Two main models that are commonly used in the literature are outlined here.

16.1.4.2.1 DRW Model The well-known DRW model for describing fluctuation velocities was introduced by Gosman and Ioannides (1983). The DRW also referred to as the eddy lifetime model is used in some commercial codes such as ANSYS-Fluent. In this model, the fluctuating velocities, which are piecewise constant functions, are computed from the following equation:

$$u_i' = \lambda_i \sigma_i \tag{16.12}$$

where

λ_i is a normally distributed random number

σ_i is the RMS velocity fluctuation in ith direction

When an isotropic two-equation turbulence models is used, then this becomes

$$\sigma_i = \sqrt{\tfrac{2}{3}k} \tag{16.13}$$

where k is the kinetic energy of turbulence. In using (16.13), clearly it is assumed that the RMS velocity fluctuations for different directions are equal. This could be an issue for near-wall flows, where the fluctuating velocity in the normal direction is significantly smaller compared with the streamwise direction. The importance of anisotropy of turbulence for estimating particle deposition was noted in the earlier works (Li and Ahmadi, 1992, He and Ahmadi, 1999). While using most researches used the isotropic RAND models, some (Matida et al., 2004, Zhang et al., 2005, Li et al., 2007) used damping functions to correct the anisotropy behavior of normal Reynolds stresses near the walls based on DNS data. He and Ahmadi (1999) and Tian and Ahmadi (2007) used the Reynolds stress turbulence model and captured the anisotropy of the normal Reynolds stresses directly. In these studies, the significance of quadratic variation of wall-normal velocity fluctuation close to the wall for correct evaluation of particle velocity was emphasized.

In the DRW model, the particle is assumed to interact with the eddy over the smaller of the eddy lifetime and the particle-eddy crossing time. When this time is reached, a new value of the fluctuation velocity is obtained by using a new value of random number λ_i in Equation 16.12 (Fluent, 2006). The eddy lifetime is estimated as

$$\tau_e = C_L \frac{k}{\varepsilon} \tag{16.14}$$

where C_L is a constant. Also, the particle-eddy crossing time is expressed as

$$t_{cross} = -\tau \ln\left(1 - \frac{L_e}{\tau\left|u - u^p\right|}\right) \tag{16.15}$$

where

τ is the particle relaxation time defined in Equation 16.2

L_e is the eddy length scale, which is given as

$$L_e = \left(C_\mu\right)^{3/4} \frac{k^{3/2}}{\varepsilon} \tag{16.16}$$

16.1.4.2.2 CRW Model The CRW models are based on solving a Langevin equation to generate a Gaussian random field with appropriate means and variances. The model is also referred to as filtered white nose model and was first introduced by Thompson (1987) and used by others (He and Ahmadi, 1999). Accordingly, the instantaneous flow velocity u_i is evaluated by solving the following Langevin equation:

$$\frac{du_i}{dt} = -\frac{u_i - \overline{u_i}}{T_L} + \left(\frac{2\overline{u_i'^2}}{T_L}\right)^{1/2} \xi_i(t), \tag{16.17}$$

where

$\overline{u_i}$ is the mean flow velocity

$\overline{T_L}$ is the particle Lagrangian integral time scale

$\overline{u_i'^2}$ is the mean square fluctuation velocity in ith direction

$\xi_i(t)$ is a Gaussian white-noise random process

The particle Lagrangian time scale is generally not available, and the Eulerian flow time scale (eddy lifetime) given by Equation 16.14 is typically used. The solution to Equation 16.17 leads to a Gaussian random field with appropriate mean, variance, and time scale. The CRW model given by 16.17 has been implemented in commercial codes such as ANSYS-Fluent.

In order to account for the inhomogeneous turbulence fluctuations, the generalized Langevin equation, including the drift correction term, is used. That is, (Iliopoulos et al., 2003)

$$\frac{du_i}{dt} = -\frac{u_i - \overline{u_i}}{T_L} + \left(\frac{2\overline{u_i'^2}}{T_L}\right)^{1/2} \xi_i(t) + \frac{1}{2(1+Stk)} \frac{\partial \overline{u_i'^2}}{\partial x_i} \delta_{i2}, \tag{16.18}$$

In this equation, the last term is the mean drift correction term for a flow with x_2 being in wall-normal direction. More detail of the upgraded model can be found in the studies by Dehbi (2008) and Ghahramani et al. (2014).

16.1.4.3 Mass Diffusion of Nanoparticles

Nanoparticle transport and deposition are dominated by their Brownian motion. The Lagrangian trajectory analysis approach becomes inefficient for cases that the particle deposition rates very low and/or whenever a very large number of particles need to be traced for accurate estimate of local deposition characteristics. Therefore, the nanoparticle transport and deposition were usually computed by a Eulerian/diffusion approach. This approach treats the particles as a continuum field and neglects the particle inertia effects. The Eulerian/diffusion model is suitable for the sub-100 nm particles because of their very low inertia. The primary advantage of the Eulerian/diffusion model approach is in its simplicity that it can rapidly evaluate the deposition rates. In this method, the steady form of the convective–diffusive equation governing the mass transport of nanoparticles is used. That is, (Friedlander, 2000)

$$\frac{\partial(u_j C)}{\partial x_j} = \frac{\partial}{\partial x_j}\left[(D + D_t)\frac{\partial C}{\partial x_j}\right] \tag{16.19}$$

where

C is the nanoparticle concentration

D is the Stokes–Einstein diffusion coefficient of nanoparticles, which is given as

$$D = \frac{k_B T C_c}{3\pi\mu d_p} \tag{16.20}$$

where

$k_B = 1.38 \times 10^{-23}$ J/K is the Boltzmann constant

T is the absolute temperature of air

C_c is the Cunningham correction factor given in Equation 16.3

In Equation 16.19, D_t is the turbulent diffusion coefficient and needs to be included for turbulent flows in conjunction with a turbulence model.

For the Eulerian model, the DF of nanoparticles in region i of a passage is the ratio of the rate of mass deposition on the walls of the region to the inlet mass flow rate. That is,

$$\left(\mathrm{DF}_i\right)_{nano-particles} = \frac{\dot{m}_{w,i}}{\dot{m}_{in}} \tag{16.21}$$

In a computational model, the total mass deposition can be evaluated using

$$\dot{m}_{w,i} = \sum_{j=1}^{N} -\rho A_j (D + D_t)\frac{\partial C}{\partial n}\Big|_{w,j} \tag{16.22}$$

where

N is the number of cells adjacent to the walls in region i

n is the wall-normal direction

A_j is the area of the each cell face adjacent to the walls in the region

Note that on solid walls D_t is zero.

16.1.4.4 Equations of Motion of Ellipsoidal Fibers

The equations governing the motion of ellipsoidal fiber were described in the literature (Gallily and Eisner, 1979, Fan and Ahmadi, 1995a,b, Dastan and Abouali, 2013). Here, a summary of key equations is presented.

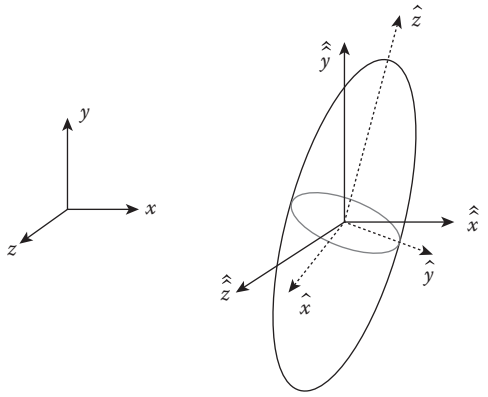

Figure 16.6

Three different coordinate systems used in description of fiber motion.

In comparison to the spherical particles, the equations governing the motion of nonspherical particles are more complex because of the coupling between the translational and rotational motions. Figure 16.6 shows the three different coordinate systems that are typically used to describe the motion of ellipsoidal particles. The inertial coordinate system is given by $\mathbf{x} = [x, y, z]$. The particle coordinate system denoted by $\hat{\mathbf{x}} = [\hat{x}, \hat{y}, \hat{z}]$ is attached to the particle with its origin at the mass center of the particle and its axes along the principal axes of the ellipsoids. Typically, the $\hat{z}$ axis of the particle frame is selected to be along the major axis of the ellipsoid. The third coordinate system $\hat{\hat{x}} = [\hat{\hat{x}}, \hat{\hat{y}}, \hat{\hat{z}}]$ is a comoving coordinate system with its origin at the mass center of the particle (similar to the origin of the particle coordinate) with its axes parallel to the axes of inertial coordinate system. The transformation matrix between these two coordinate systems can be expressed in terms of Euler four parameters $(\varepsilon_1, \varepsilon_2, \varepsilon_3, \eta)$ (Goldestein, 1980). That is,

$$A = \begin{bmatrix} 1-2\left(\varepsilon_2^2+\varepsilon_3^2\right) & 2\left(\varepsilon_1\varepsilon_2+\varepsilon_3\eta\right) & 2\left(\varepsilon_1\varepsilon_3-\varepsilon_2\eta\right) \\ 2\left(\varepsilon_2\varepsilon_1-\varepsilon_3\eta\right) & 1-2\left(\varepsilon_3^2+\varepsilon_1^2\right) & 2\left(\varepsilon_2\varepsilon_3+\varepsilon_1\eta\right) \\ 2\left(\varepsilon_3\varepsilon_1+\varepsilon_2\eta\right) & 2\left(\varepsilon_3\varepsilon_2-\varepsilon_1\eta\right) & 1-2\left(\varepsilon_1^2+\varepsilon_2^2\right) \end{bmatrix} \tag{16.23}$$

The translational and rotational equations of motion of a nonspherical particle in a general flow field are given as

$$m^p \frac{d\mathbf{v}}{dt} = \pi\mu a \hat{\hat{\mathbf{k}}}\left(\mathbf{u}-\mathbf{v}\right) + m^p\mathbf{g} + m^p\mathbf{F}^{\mathbf{L}} \tag{16.24}$$

$$I_{\hat{x}} \frac{d\omega_{\hat{x}}}{dt} - \omega_{\hat{y}}\omega_{\hat{z}}\left(I_{\hat{y}} - I_{\hat{z}}\right) = T_{\hat{x}}^h \tag{16.25}$$

$$I_{\hat{y}} \frac{d\omega_{\hat{y}}}{dt} - \omega_{\hat{z}}\omega_{\hat{x}}\left(I_{\hat{z}} - I_{\hat{x}}\right) = T_{\hat{y}}^h \tag{16.26}$$

$$I_{\hat{z}} \frac{d\omega_{\hat{z}}}{dt} - \omega_{\hat{x}}\omega_{\hat{y}}\left(I_{\hat{x}} - I_{\hat{y}}\right) = T_{\hat{z}}^h \tag{16.27}$$

where m^p, $\mathbf{v}$, $I_{\hat{i}}$, and $\omega_{\hat{i}}$, respectively, are the particle mass, particle mass center velocity vector, particle moment of inertia, and particle angular velocity. Here, μ and a are the fluid viscosity and the ellipsoid

semiminor axis, respectively. The forces included in the translational equation of motion given by (16.24) are the hydrodynamic drag force, the gravitational force, and the lift force. The other forces, such as the added mass and Brownian forces for inertial fibers, are neglected. In Equation 16.24, the flow resistance tensor $\hat{\hat{\mathbf{k}}}$ is given by

$$\hat{\hat{\mathbf{k}}} = \mathbf{A}^{-1}\hat{\mathbf{k}}\mathbf{A} \tag{16.28}$$

where

A is the transformation matrix given by Equation 16.23

$\hat{\mathbf{k}}$ is a diagonal matrix that the diagonal elements are given by

$$k_{\hat{x}\hat{x}} = k_{\hat{y}\hat{y}} = \frac{16\left(\beta^2 - 1\right)}{\left[(2\beta^2 - 3)/(\sqrt{\beta^2 - 1})\ln\left(\beta + \sqrt{\beta^2 - 1}\right) + \beta\right]} \tag{16.29}$$

$$k_{\hat{z}\hat{z}} = \frac{8\left(\beta^2 - 1\right)}{\left[\dfrac{2\beta^2 - 1}{\sqrt{\beta^2 - 1}}\ln\left(\beta + \sqrt{\beta^2 - 1}\right) - \beta\right]} \tag{16.30}$$

Here, β is the fiber aspect ratio (the ratio of semimajor axis to semiminor axis, $\beta = (b/a) > 1$).

The shear-induced lift acting on an arbitrary shaped particle is given by Harper and Change (1968). That is,

$$f^L = \frac{\pi^2 \mu a^2}{\nu^{1/2}} \frac{\dfrac{\partial u_x}{\partial y}}{\left|\dfrac{\partial u_x}{\partial y}\right|^{1/2}} (\hat{\hat{K}} \cdot L \cdot \hat{\hat{K}}) \cdot (u - v) \tag{16.31}$$

where

$$L = \begin{bmatrix} 0.0501 & 0.0329 & 0.00 \\ 0.0182 & 0.0173 & 0.00 \\ 0.00 & 0.00 & 0.0373 \end{bmatrix} \tag{16.32}$$

Here, a simple shear flow is considered.

The components of hydrodynamic torque acting on an ellipsoidal particle under creeping flow condition are given by Jeffery (1922). These are

$$T_{\hat{x}}^h = \frac{16\pi\mu a^3 \beta}{3\left(\beta_o + \beta^2 \gamma_o\right)}\left[\left(1 - \beta^2\right) d_{\hat{z}\hat{y}} + \left(1 + \beta^2\right)\left(w_{\hat{z}\hat{y}} - \omega_{\hat{x}}\right)\right] \tag{16.33}$$

$$T_{\hat{y}}^h = \frac{16\pi\mu a^3 \beta}{3\left(\beta^2 \gamma_o + \alpha_o\right)}\left[\left(\beta^2 - 1\right) d_{\hat{x}\hat{z}} + \left(1 + \beta^2\right)\left(w_{\hat{x}\hat{z}} - \omega_{\hat{y}}\right)\right] \tag{16.34}$$

$$T_{\hat{z}}^h = \frac{32\pi\mu a^3 \beta}{3\left(\alpha_o + \beta_o\right)}\left(w_{\hat{y}\hat{x}} - \omega_{\hat{z}}\right) \tag{16.35}$$

where the nondimensional parameters α_o, β_o, and γ_o are given as

$$\alpha_o = \beta_o = \frac{\beta^2}{\beta^2 - 1} + \frac{\beta}{2\left(\beta^2 - 1\right)^{3/2}} \ln\left[\frac{\beta - \sqrt{\beta^2 - 1}}{\beta + \sqrt{\beta^2 - 1}}\right] \tag{16.36}$$

$$\gamma_o = -\frac{2}{\beta^2 - 1} - \frac{\beta}{\left(\beta^2 - 1\right)^{3/2}} \ln\left[\frac{\beta - \sqrt{\beta^2 - 1}}{\beta + \sqrt{\beta^2 - 1}}\right] \tag{16.37}$$

and $d_{\tilde{i}\tilde{j}}$ and $w_{\tilde{i}\tilde{j}}$ are, respectively, the fluid deformation rate and spin tensors in the particle coordinate system.

The time rate of changes of the Euler parameters is given by

$$\begin{bmatrix} \frac{d\varepsilon_1}{dt} \\ \frac{d\varepsilon_2}{dt} \\ \frac{d\varepsilon_3}{dt} \\ \frac{d\eta}{dt} \end{bmatrix} = \frac{1}{2} \begin{bmatrix} \eta\omega_{\hat{x}} - \varepsilon_3\omega_{\hat{y}} + \varepsilon_2\omega_{\hat{z}} \\ \varepsilon_3\omega_{\hat{x}} + \eta\omega_{\hat{y}} - \varepsilon_1\omega_{\hat{z}} \\ -\varepsilon_2\omega_{\hat{x}} + \varepsilon_1\omega_{\hat{y}} + \eta\omega_{\hat{z}} \\ -\varepsilon_1\omega_{\hat{x}} - \varepsilon_2\omega_{\hat{y}} - \varepsilon_3\omega_{\hat{z}} \end{bmatrix} \tag{16.38}$$

When the mass center velocity is know, the particle position is obtained by integrating Equation 16.10.

The details of the discretization and numerical solution of the fiber equation of motion, as well as the identification of the fiber touch point on the walls, may be found in the earlier works of Fan and Ahmadi (2000), Zhang et al. (2001), Tian and Ahmadi (2012), and Dastan and Abouali (2013).

16.1.4.4.1 HL Model HL (1989) developed an empirical equation for the drag coefficient of nonspherical particles by a curve fitting on the available data from previous researchers. In this approach, the nonspherical particles are treated as spherical particles with an equivalent volume diameter and the use of a shape factor for the drag force. The shape factor (sphericity) is defined as

$$\phi = \frac{s}{S} \tag{16.39}$$

where

s is the surface of a sphere having the same volume as the particle

S is the actual surface of the particle

HL (1989) suggested the following drag coefficient correlation:

$$C_D = \frac{24}{\mathrm{Re}_p}\left(1 + A\,\mathrm{Re}_p^B\right) + \frac{C\,\mathrm{Re}_p}{D + \mathrm{Re}_p} \tag{16.40}$$

where Re_p is the particle Reynolds number based on the relative velocity and volume equivalent diameter and

$$\begin{aligned} A &= \exp(2.3288 - 6.4581\phi + 2.4486\phi^2) \\ B &= 0.0964 + 0.5565\phi \\ C &= \exp(4.905 - 13.8944\phi + 18.4222\phi^2 - 10.2599\phi^3) \\ D &= \exp(1.4681 + 12.2584\phi - 20.7322\phi^2 + 15.8855\phi^3) \end{aligned} \tag{16.41}$$

The drag force acting on the particle then is given as

$$F_D = 3\pi\mu\, d_{eq} C_D \frac{\mathrm{Re}_p}{24}\left(\mathbf{u} - \mathbf{u}^{\mathbf{p}}\right) \tag{16.42}$$

Using this on the right-hand side of Equation 16.24 or Equation 16.1, the translational motion of nonspherical particles can be calculated. It should be pointed out that the HL model ignores the coupling between translational and rotational motions of elongated particles.

16.1.5 Sample CFD Models of Human Upper Airway Systems

In this section, some examples of the recent computational models of upper airway systems are presented.

16.1.5.1 Micro- and Nanoparticle Transport and Deposition in Human Upper Airways

Micro- and nanoparticle transport and deposition in the upper airways were studied by Farhadi Ghalati et al. (2012) using a computational modeling approach. To construct the airway model study, the CT scans of a 24-year-old healthy female subject were used. The scans, which were provided by TABA Medical Imaging Center, are obtained while the person was in a supine position. Imaging was helical and performed using a CTI whole body scanner (GE Medical Systems) with the following parameters: 0.625 mm slice increment, 24.20 cm field of view, 120 kV peak, and 99.00 mA. Under the supervision of a specialist, the boundary between the airway mucosa and air in the upper respiratory tract was defined in the CT scan slices. Figure 16.7 shows some samples of the coronal and sagittal cross sections of the nasal and upper airways. To reconstruct the 3-D model consisting of nasal cavity, pharynx, larynx, and trachea, the boundaries were imported into a CFD preprocessor software tool (GAMBIT). The boundaries are connected to each other to create a smooth surface and form the volume. An unstructured tri-/tetrahedral hybrid volume mesh was generated inside the airway passage. A grid size of approximately 2,600,000 cells was obtained after the grid independency test. The 3-D model for the total volume of the upper airways is shown in Figure 16.8.

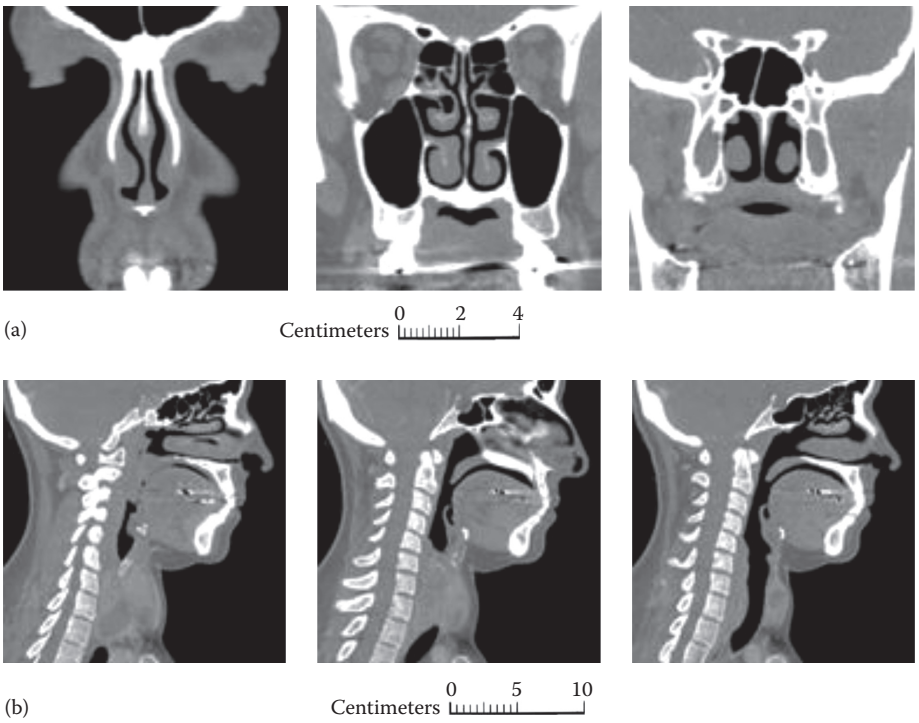

Figure 16.7

Samples of (a) coronal and (b) sagittal cross sections of the nasal and upper airways.

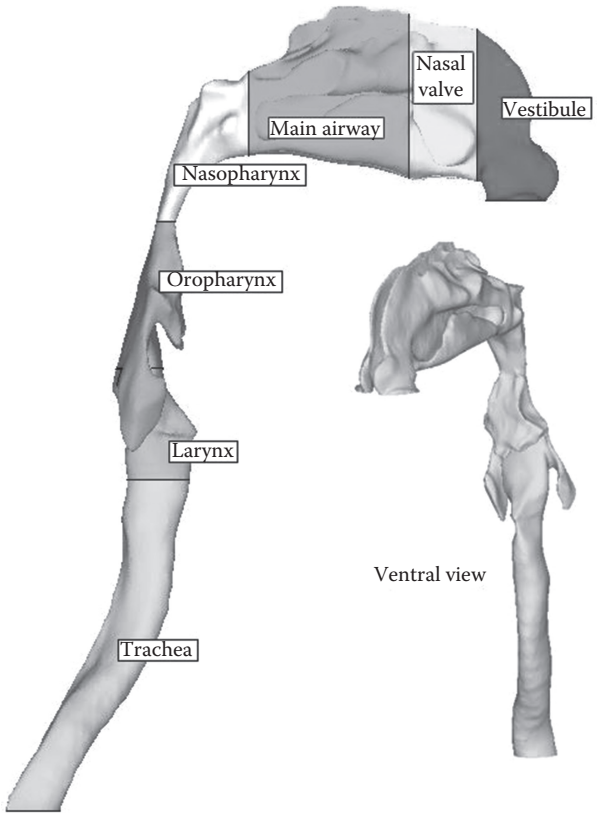

Figure 16.8

The developed 3-D model of the nasal upper airway.

A series of computer simulations was performed for various breathing rates. Sample results for the mean airflow velocity magnitude contours for a breathing rate of 10 L/min are shown in Figure 16.9. It is seen that air enters uniformly from the nostril into the vestibule region and then experiences an almost 90° turn. As a result, due to the centrifugal force effect, the streamlines tend to move toward the upper part of the nasal cavity. This part of the nasal passage, however, has relatively small cross-sectional area; therefore, the air flows mainly in the middle part of this section as seen in Figure 16.9a. After reaching to the nasal valve region shown in Figure 16.9b, the airflow mostly passes through the middle meatus area (Figure 16.9a and b). A small amount of airflow passes through the superior meatus and olfactory region. Additional details of airflow structures in human nasal cavity were described by Doorly et al. (2008).

As the airflow enters the nasopharynx, it turns 90° again to the vertical downward direction and the centrifugal force effect moves the peak airflow toward the upper part of the pharynx as shown in Figure 16.9e. Then, the flow becomes almost fully developed as shown in Figure 16.9f. At the end of the nasopharynx region, the cross-sectional area of the passage reaches to its minimum value and the airflow velocity becomes its maximum value of about 4 m/s as shown in Figure 16.9g. Figure 16.9h clearly shows a high-velocity jet in the pharynx region, which flows along the posterior pharyngeal airway. The velocity distributions in the larynx and trachea shown in Figure 16.9i thorugh k are significantly influenced by the presence of jet flow exiting the pharynx.

Figure 16.10a shows the predicted deposition efficiency versus IP. The IP is defined as

$$\mathrm{IP} = d_p^2 Q \ (\mu\mathrm{m}^2\ \mathrm{cm}^3/\mathrm{s}) \tag{16.43}$$

where Q is the inhaled air volume flow rate in cm^3/s. Figure 16.10a shows that the deposition rate of microparticles increases with the increase in either the particle diameter or inhalation flow rate as the inertial effect is the main mechanism for deposition of these particles. This figure also shows that the curves for various breathing rates nearly coincide with each other, which is as expected for plots

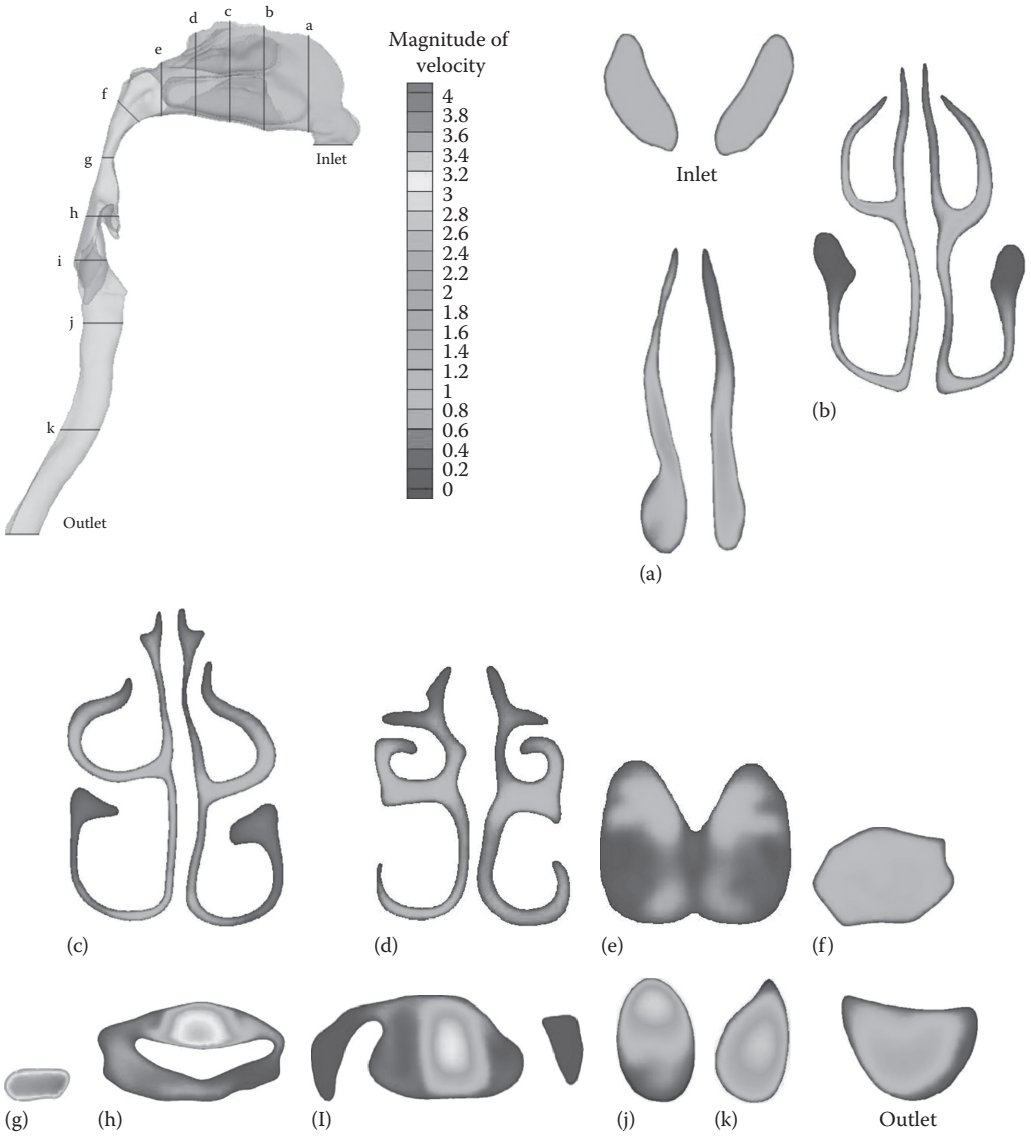

Figure 16.9

Velocity (m/s) contours in different sections for breathing rate of 10 L/min. Cross sections of a–e are in the nasal cavity, f and g are in the nasopharynx, h is in the oral pharynx, i is in the larynx, and j and k are in the trachea.

versus the IP. The experimental data of Kelly et al. (2004a) are also reproduced in Figure 16.10a for comparison. It is seen that while the trend of the predicted deposition curve is similar to that of the experimental data, there are marked differences between the numerical results and the experimental data that were for different subjects. Schroeter et al. (2011) showed that the particle deposition reported by Kelly et al. (2004a) was for a replica model developed from low-resolution MRI images, which led to high deposition rates compared with those for a smooth nasal passage. Golshahi et al. (2011) also found that when the deposition efficiency was reported versus the IP for different anatomical airway passages, there was a wide scatter in the data.

Long ago, Hounam et al. (1971) suggested the use of the deposition parameter that included the pressure drop ΔP across the nasal airways instead to reduce the scatter due to the interpersonal differences, which was confirmed by Golshahi et al. (2011). The disposition parameter (DP) defined as

$$DP = d_p^2 \Delta P \ (\mu m^2\, Pa) \tag{16.44}$$

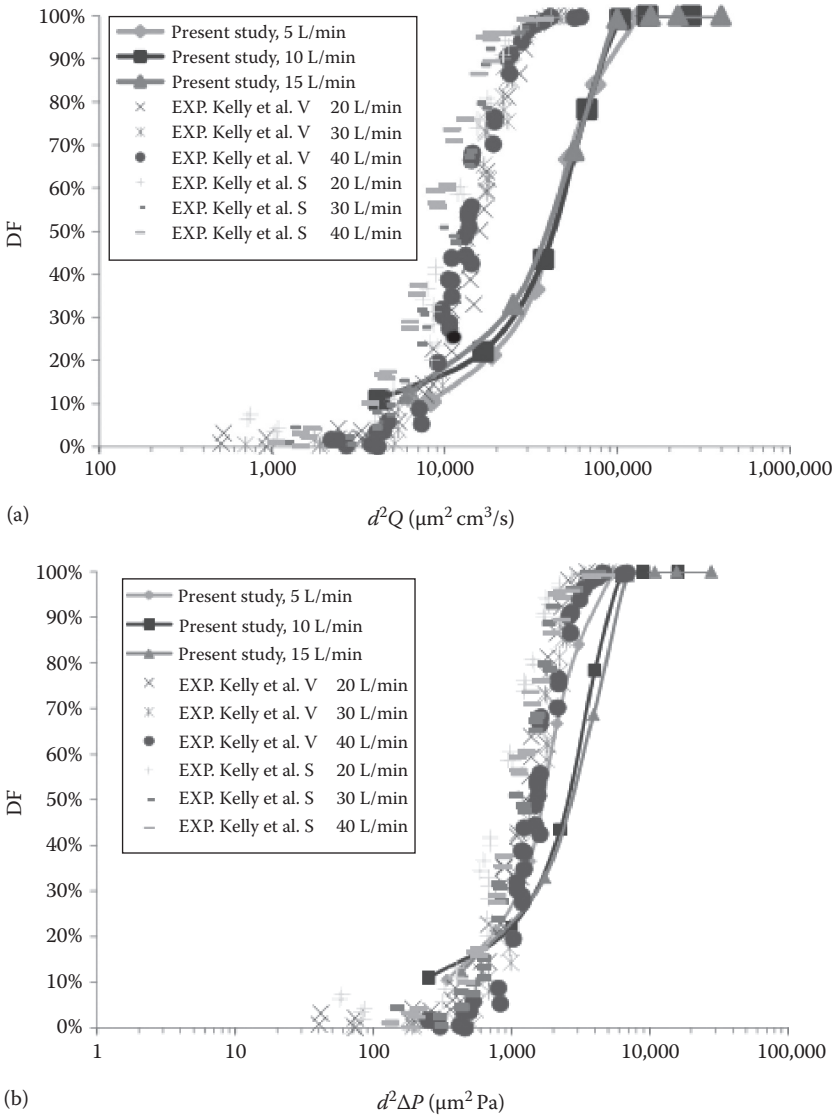

Figure 16.10

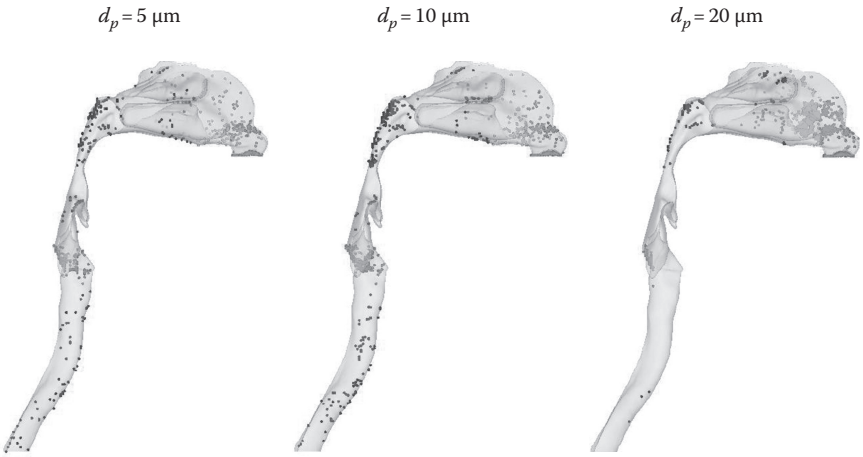
Comparison of the computational model predictions with the experimental data of Kelly et al. (2004a), for microparticle deposition in the nasal cavity and nasopharynx at breathing rates of 5, 10, and 15 L/min (a) versus the impaction parameter (b) versus the deposition parameter. Letters S and V refer to the SLA and Viper nasal replica models in their work.

is used for this purpose. Figure 16.10b compares the numerical and experimental DFs when plotted versus the deposition parameter. It is seen that the scatter in the deposition data reduces significantly and the computational model prediction shows a good agreement with the experimental data. The small differences between the simulation results and the experimental data are due to the anatomical and geometrical differences of the nasal passages of different subjects.

Figure 16.11 shows the spatial deposition patterns for particles with aerodynamic diameters of 5, 10, and 20 μm in the realistic geometry of human upper airway system for a breathing rate of 10 L/min. The corresponding total DFs for these particles as extracted from Figure 16.10 are, respectively, 16.6%, 31.4%, and 86.2%. It is clearly seen that the deposition rate increases as the particle diameter increases. This is due to the result of their higher inertia that makes the impaction process more efficient. Figure 16.11 shows that the 5 μm particles, which have low inertia, penetrate deep into the larynx and trachea regions, while the 20 μm particles are mainly trapped in the vestibule and nasal valve with very few reaching the pharynx, the larynx, and the trachea region. The 10 μm particles are also captured mainly in the nasal passage and the larynx area, with some penetrating deeper into the upper airway system. In addition, Figure 16.11 shows there are



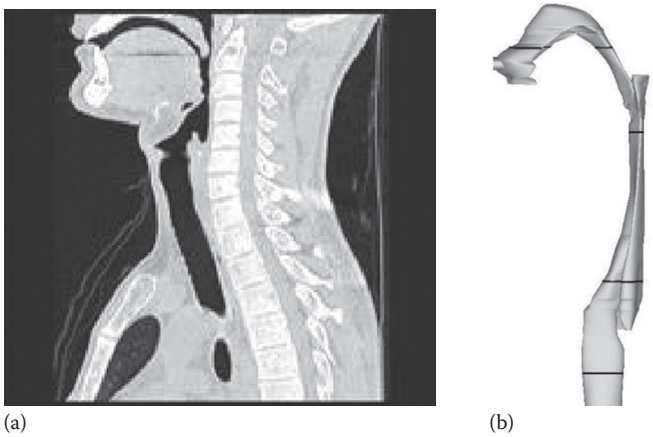


Figure 16.11

Deposition patterns in different passages for 5, 10, and 20 μm particles at a breathing rate of 10 L/min.

regions of the airway that are more susceptible to the accumulation of deposited particles. Here, it seems there are at least four spots. The first is the end of the vestibule region where the flow turns 90° into the nasal valve with sharp variation in the passage size. As mentioned before, the centrifugal force causes the particle to deviate away from the flow streamlines and move toward the upper part of the passage, leading to their deposition on the nasal wall. The second area of concentrated deposition is the top of the middle meatus. In this region, complexity of the geometry is the main reason for particle deposition on the middle meatus wall. The third zone is the nasopharynx wall where there is another 90° bend in the airway passages, and the fourth site is at the beginning of the larynx. There is an abrupt decrease in the cross-sectional area and the air passage becomes narrow, leading to the higher flow velocity. Consequently, the higher inertia of particles prevents them to follow the airflow streamlines, causing the particles to deposit on the larynx wall.

16.1.5.2 Microparticles Transport and Deposition in Realistic Geometry of Human Oral Upper Airways

The transport and deposition of microparticles in human oral airways were studied by Tavakoli et al. (2012), among others. The 3-D geometry of human upper airways is first constructed from CT scan images of a healthy male volunteer subject. Figure 16.12a shows the midsagittal plane of the images of the upper airways of the subject. Reconstructed 3-D geometry of the oral upper airway is shown in Figure 16.12b.

(a) (b)

Figure 16.12

(a) CT scan image of the upper airways (sagittal view). (b) Reconstructed 3-D geometry of the oral upper airway.

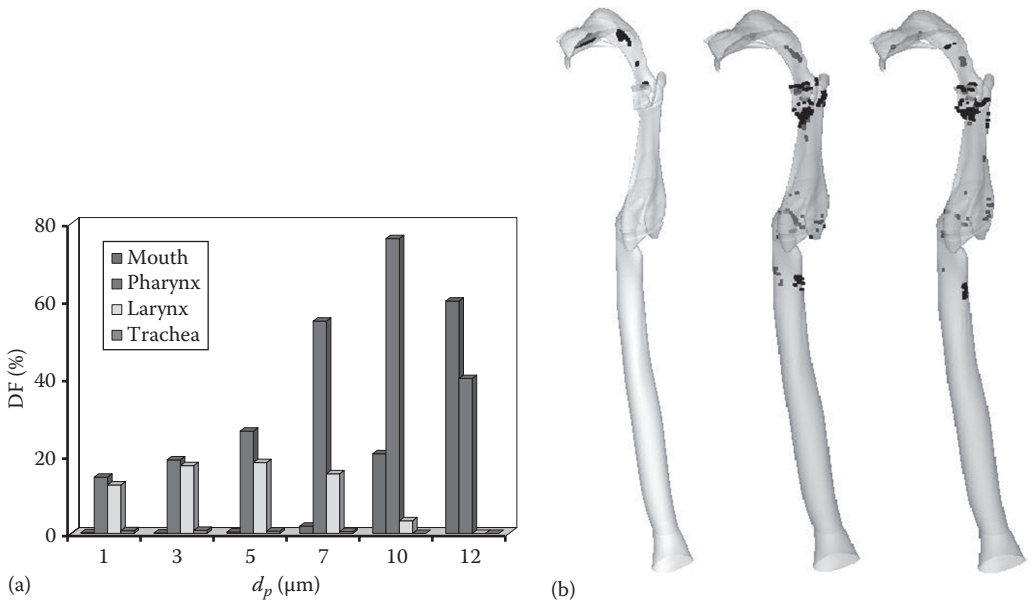

Figure 16.13

(a) Local deposition fraction of microparticles for a breathing rate of 30 L/min. (b) Deposition patterns of 3, 7, and 16 μm particles on the walls of the upper airways during the mouth breathing rate of 30 L/min.

Figure 16.13 shows local DF of microparticles in the mouth, pharynx, larynx, and trachea for the flow rate of 30 L/min. The particles with smaller diameters penetrate deeper into the upper airways and get into the larynx and trachea, while larger particles are captured in the upper parts including the mouth and pharynx. Figure 16.13 shows that large micron-sized particles are predominantly captured in the mouth region. This trend was also reported by Cheng et al. (1999) in their experimental study of mouth breathing. The use of realistic geometry of airway passages is important as the earlier numerical simulations of Zhang et al. (2002) and Tavakoli et al. (2009) using idealized geometry of upper airways for mouth breathing were not able to predict the same trend.

Figure 16.13b shows the spatial deposition patterns of 3, 7, and 16 μm particles in the human upper airways for a breathing rate of 30 L/min. It is seen that most particles are deposited in the pharynx and the inlet of the larynx. This is because of the sufficiently high particle inertia for this relatively high breathing. Figure 16.13b shows that all 16 μm particles are trapped in the mouth region for the 30 L/min flow rate.

16.1.5.3 Computational Modeling of Septal Deviation Effect on Deposition of Nano- and Microparticles in Human Nasal Passage

The effects of surgical correction of septal deviation on particle deposition in human nasal passage were studied by Moghadas et al. (2011) using a computational modeling approach. The adult male subject has actually gone through a real septoplasty surgery. The coronal cross sections of both sides of the nasal cavities obtained by CT scan images of the subject were used to construct smooth airway passages for the pre- and postoperative cases. The coronal cross sections were 2 mm apart and the resolution of the images was 512 × 512 pixels. The postoperative CT scan was taken three months after the septoplasty. The images before the septoplasty were acquired as a part of routine clinical procedure, and the images after the septoplasty were obtained with the approval of ethics and human subject committee.

Figure 16.14 shows the pictures of the axial CT scans of cross sections of the nasal passage. The differences between the left and right cavities for the earlier operation can be clearly seen from this figure. The major deviation is located in the main airway region. Septal deviation started at about 30 mm from the nose tip, in the nasal valve region where the cross-sectional area of the airway begins to decrease. At a distance of 46 mm from the nose tip, the deviation divides the right airway in two separated pathways. This separated segment continues to 50 mm away from the nostril. Deviation decreases the cross-sectional areas and the total volume of the passage, which causes breathing problems for the patient. The two separated pathways reunite at a distance of 72 mm from the nose tip, but the shape of the reconnected pathway is different from the left nasal cavity. The deviation ended at the beginning of the nasopharynx region.

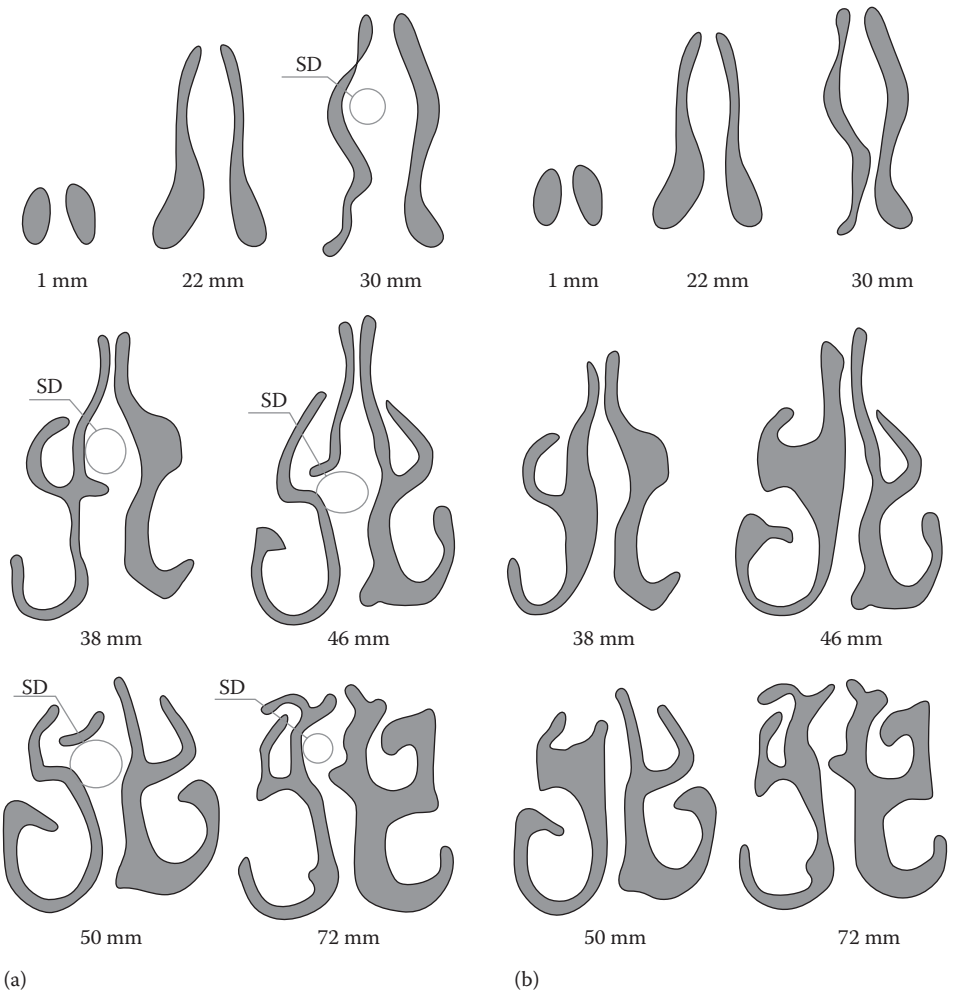

Figure 16.14

Nasal coronal cross sections at various distances from the nostril (a) before and (b) after operation. SD refers to the septal deviation.

Figure 16.14 shows that the two separated pathways of the right-side airway are merged into a single airway after septoplasty and the right cavity looks more like a normal nasal airway postoperatively. It should be pointed out that some parts of the nasal passages might be blocked by the mucus buildup. These can change the shape of the nasal cross sections during different scanning times. The blockage due to the mucus buildup in the scanned pictures can be identified and removed.

The 3-D geometry of human nasal airways can be constructed similar to the procedure described earlier. Here, CT scan images for the subject with septal deviation in the right cavity are processed to form the boundary surfaces of the nasal cavities walls. The 3-D nasal airway volume is exported to the mesh generation software to produce the computational grid. The generated unstructured computational grid includes roughly 800,000 tetrahedral elements for each passage. Several finer computational grids are also used to investigate the effect of grid refinements on the computational results. It is shown that the numerical results are grid independent for a computational grid with about 600,000 cells or more. The initially generated grid typically has high skewness because of the complexity of the nasal passages. Care should be taken to decrease the skewness of the grid, which results in a better convergence of the numerical solutions and decreases the corresponding residual computational errors. For simulation of the airflow and particle transport and deposition, flow solver software (such as ANSYS-Fluent) may be used.

Monodispersed particles in the range of 1–50 μm are injected into the nasal airway, and their transport and deposition for different pressure drops in the range of 10–20 Pa are evaluated. Comparisons of the model predictions for the variation of deposition efficiency with the IP for different nasal passages for a pressure drop of 10 Pa with the experimental data of Kelly et al. (2004a) are shown in Figure 16.15.

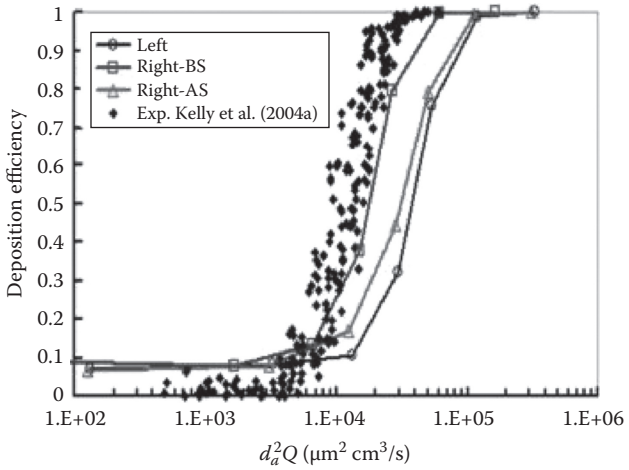

Figure 16.15

Deposition efficiency versus the impaction parameter for different nasal passages for a pressure drop of 10 Pa. (Comparison with the experimental data of Kelly, J.T. et al., *Aerosol Sci. Technol.*, 38, 1063, 2004a.)

The IP as defined in Equation 16.43 has been used extensively to correlate the nasal deposition efficiency of microparticles. The S-shape variation of the deposition efficiency is clearly seen from this figure. The model predictions for the normal left nasal passage and postoperative right cavity, however, are somewhat lower than the experimental data, while the predicted deposition efficiency for the preoperative right passage is in the range of the experimental data. As noted before, differences between the simulation results and the experimental data are due to the anatomical and geometrical differences of the nasal passages.

This study is for a patient with one abnormal nasal passage, while the experimental data are for normal nasal passages. Interestingly, the healthy left passage and the postoperative right cavity exhibit roughly identical trends. This shows that the operation corrected the abnormal passage to behave like the healthy passage. It is also possible that the left nasal passage of the patient may have had anatomically changed to compensate for the right blocked passage. Thus, the left passage may also have some differences with the nasal cavities of typical healthy people. In addition, as noted before, the fabricated experimental models typically have rough surfaces, while the computer model has smooth walls. This could be another reason for the differences seen.

It should also be pointed out that the deposition efficiency reported by Kelly et al. (2004a) is for two nasal chambers, but the presented simulation results are for single nasal passage to clarify the differences between the right nasal passage before and after the septoplasty. For the same pressure drop, Figure 16.15 also shows that the preoperative right cavity has a markedly higher DF compared with the postoperative one. For example, for IP = 26,733 μm² cm³/s, the deposition efficiency is 79% for the right preoperative cavity, 44% for the right postoperative passage, and 35% for the left nasal cavity. That is, there is a difference of 35% between the right preoperative and the normal left cavity, and it decreases to 12% after the septoplasty. The reason for the significant increase in the deposition in the right abnormal nasal cavity is that the septum deviation blocks the airflow and turns the streamlines sharply and thus increases the inertia impaction effect.

16.1.5.4 Micro- and Nanoparticle Deposition in Human Nasal Passage Pre- and Postvirtual Maxillary Sinus Endoscopic Surgery

Use of CFD in conjunction with virtual surgery could provide physicians with an important tool for evaluating the performance of various options before performing actual corrective airway surgery. Abouali et al. (2012) studied the virtual endoscopic surgery of maxillary sinus and the variation of the micro- and nanoparticle deposition in human nasal passage pre- and postoperation. A realistic 3-D model of the nasal cavity including paranasal sinuses was developed. The coronal cross sections for the left side of the nasal cavity and sinuses obtained by CT scan images of an adult male were used for developing a nasal airway model for the pre- and postoperative cases. The resolution of CT scan images was 512 × 512 pixels, and the coronal cross sections were 0.625 mm apart. The images were acquired as a part of routine clinical procedure. Under the supervision of a rhinologist, the boundary between the airway mucosa and air in the upper respiratory tract was defined in the CT scan slices. In addition, the uncinectomy and MMA were performed virtually by the rhinologist by removing the uncinate process and a part of the medial wall of the maxillary sinus on the coronal cross sections.

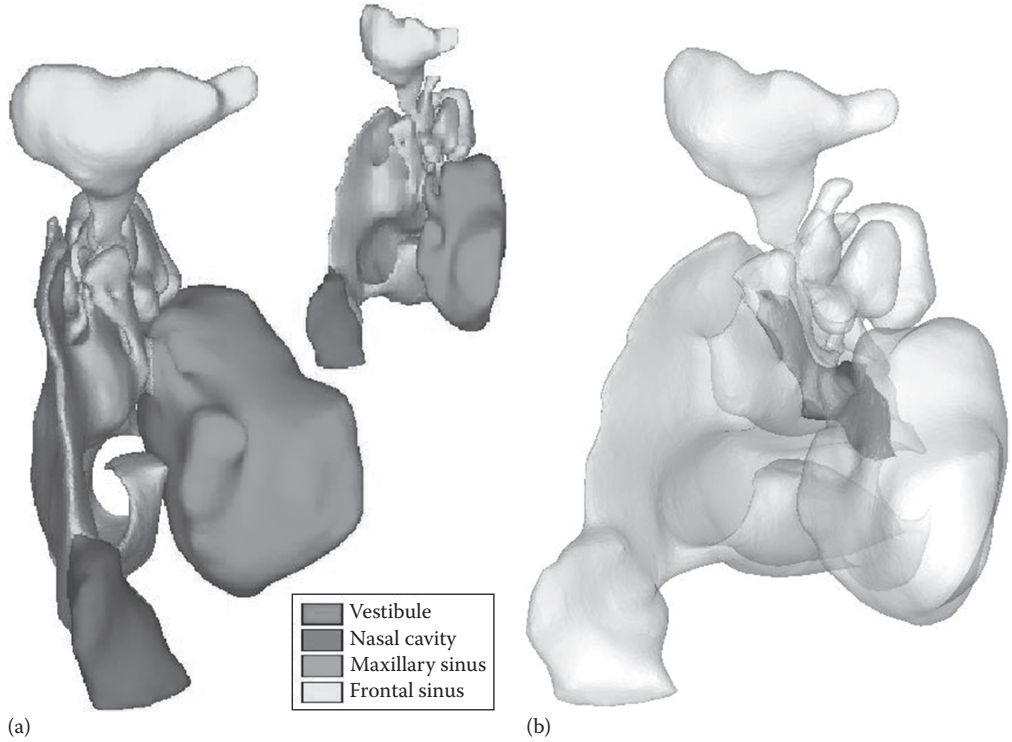

Figure 16.16

(a) Schematic of a constructed model of the left nasal airway and maxillary and frontal sinuses of a male patient. (b) The uncinate process and the removed part of medial wall of the maxillary sinus for the left nasal cavity are highlighted.

To reconstruct the 3-D model consisting of the nasal cavity and maxillary and frontal sinuses, the boundaries were imported into a CFD preprocessor software. The boundaries were connected to create smooth surfaces and form the volume. Figure 16.16a shows the schematic of the constructed model for the left nasal airway and maxillary and frontal sinuses. For clarity, the nasal vestibule, nasal cavity, and maxillary and frontal sinuses are colored differently in this figure. The uncinate process and part of the medial wall of the maxillary sinus that were usually removed in FESS are highlighted in Figure 16.16b. Figure 16.17 shows the streamlines of the inhaled air for a flow rate of 4 L/seen that none of the streamlines that start from the nostril enter the maxillary sinus before the operation. After uncinectomy and MMA, however, the airflow field inside the maxillary sinus changes dramatically, and part of the main airflow through the nasal passage enters the sinus. That is, the maxillary sinus ventilation changes significantly after the operation.

To compare the local deposition of microparticles for pre- and postoperation cases, monodispersed 1, 10, and 20 μm particles are released at the inlet of the nostril, and their trajectories are analyzed. For volume flow rates of 10 L/min, the corresponding deposition patterns are shown in Figure 16.18. This figure shows that practically no particle enters into the maxillary sinuses before the operation. After uncinectomy and MMA, however, some 1 and 10 μm particles enter into the maxillary sinus and deposit on the sinus wall. That is, the uncinate process and medial wall of the maxillary sinus are highly effective in preventing the microparticles to enter the maxillary sinus. It is also seen that almost no 20 μm particles reach the inside wall of the maxillary sinus even after uncinectomy and MMA. This implies that even the increased airflow into the maxillary sinus is not strong enough to move the 20 μm particles into the sinus. It should be noted here that no microparticle enters into the frontal sinus before or after the operation.

A quantitative description on the effect of uncinectomy and MMA on the microparticle deposition in the maxillary sinus is presented in Figure 16.19. DFs of microparticles in the size range of 1–25 μm for breathing rate of 10 L/min are shown in this figure before and after the operation. It is seen that a very small fraction (less than 0.1%) of the entering microparticles into the nasal cavity deposit on the maxillary sinus before ESS. This small fraction of particles also deposits at the opening of the maxillary sinus and none of them deposits on the inside wall of the maxillary sinus as seen in Figure 16.18. Uncinectomy and MMA increase the number of microparticles entering into the maxillary sinus by tenfold. The deposition pattern, however,

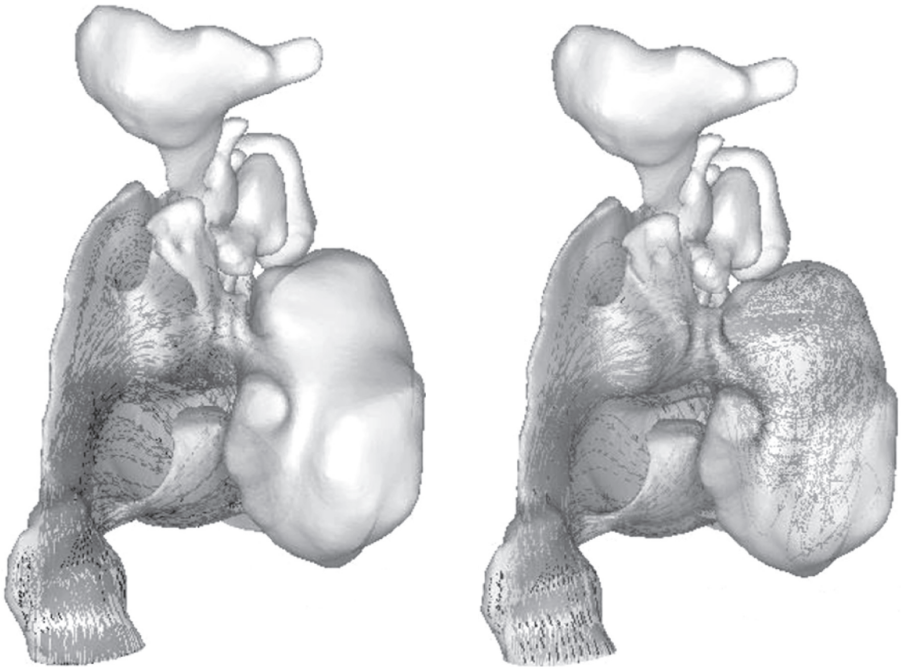

Figure 16.17

Streamlines of airflow (a) before and (b) after surgery for $Q = 4$ L/min.

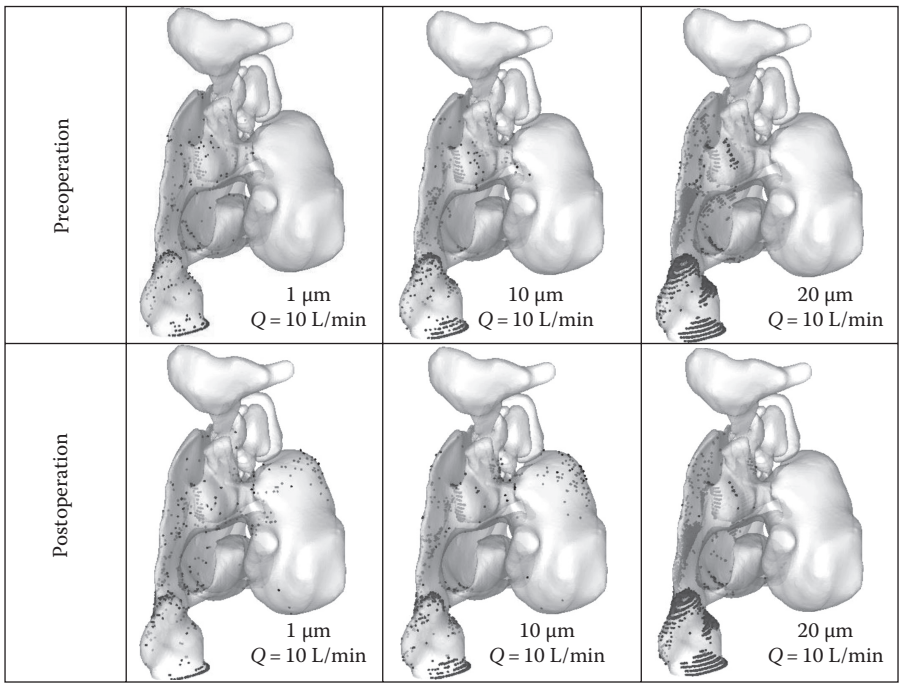

Figure 16.18

Microparticles deposition patterns on the nasal passage and maxillary sinus walls.

varies depending on particle size and breathing rates. For all the studied flow rates (not shown here), the maximum deposition in the maxillary sinus is highest for 10 μm particles.

The presented results provide a better understanding of the consequence of uncinectomy and MMA on therapeutic nasal drug delivery and exposure to inhaled pollutants. In particular, the simulation results show that the therapeutic spray droplets can penetrate the maxillary sinus after the operation. Thus, this treatment can be more

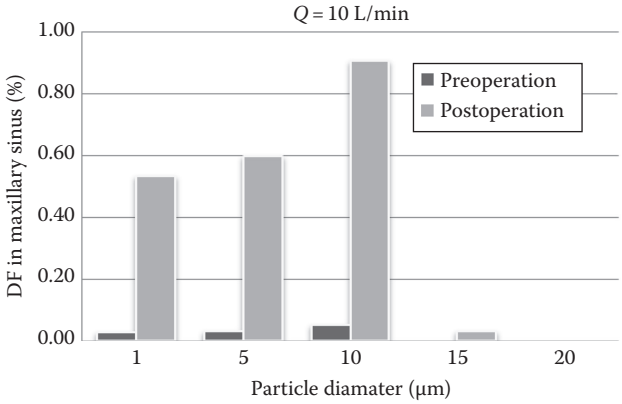

Figure 16.19

Pre- and postoperation deposition fractions in the maxillary sinus for a breathing rate of 10 L/min.

effective in curing allergic sinusitis and similar diseases. At the same time, however, allergens that can trigger the allergic symptoms in sinuses can also reach the sinuses and deposit on their walls. The size of allergens in the form of microparticles that causes most allergic symptoms ranges from 1 to 80 μm, with smaller particles under 50 μm more easily inhaled. Most of pollens that trigger allergic symptoms are in the size range of 15–40 μm, and the present simulations show that the probability of allergens reaching the maxillary sinus increases after uncinectomy and MMA. Thus, the occurrence of persistent maxillary sinus diseases after uncinectomy and MMA may be a consequence of increased deposition of allergens. As noted before, this operation for the presently studied case does not change the transport processes in the nasal valve or the main airway regions.

As mentioned before, a Eulerian diffusion model was used for studying the dispersion and deposition of nanoparticles in the nasal cavity and sinuses. Figure 16.20 shows the nanoparticle deposition flux contours on the walls of the nasal cavity and sinuses in the left passage for 1, 5, 10, and 20 nm particles with a breathing rate of 4 L/min. The particle deposition fluxes are nondimensionalized with respect to the inlet flux. That is, the nondimensional flux is evaluated as $-D(\partial C/\partial n)/U_iC_i$, where U_i and C_i are, respectively, the velocity and concentration at the inlet and n is the normal direction to the passage walls. Figure 16.20 clearly shows that, before the operation, almost no nanoparticles enter the sinuses and/or deposit on the sinus walls. Some nanoparticles, however, penetrate through and deposit on the walls of the maxillary sinus after the uncinectomy/MMA. No deposition of nanoparticles in the frontal sinus occurs before or after the operation. As mentioned before, the uncinate process studied in this work does not include the opening of the frontal sinus. Therefore, no change in the flow filtration and particle deposition in the frontal sinus occurs.

To provide a more detailed insight on the deposition of nanoparticles in the maxillary sinus, the DFs for flow rates of and 10 L/min are shown in Figure 16.21. Here, simulations are performed for particle diameters of 1, 3, 5, 10, and 20 nm. This figure shows that the DF of 1 nm particles increases after the uncinectomy and MMA operation for flow rates of 10 L/min. At a flow rate of 10 L/min, the DF is highest for 1 nm particles. After the uncinectomy and MMA, for 10 nm particles or smaller, the DF is at least 1%. No 20 nm particles enter the maxillary sinus before the operation, but after surgery about 0.5% of 20 nm particles deposit on the sinus wall. Although the DF of nanoparticles in the maxillary sinus is generally small compared with that in the main nasal passage, a comparatively significant increase is observed after the operation.

For a constant breathing rate, Figure 16.21 also shows that the nanoparticle deposition flux increases as the particle size decreases. Furthermore, for a fixed size, the particle deposition decreases as the flow rate increases. These trends are as expected since the Brownian diffusion is the dominant mechanism for nanoparticle deposition.

16.1.5.5 Regional Particle Depositions in the Upper Airway of a Standing Mannequin

There have been concerns on the effect of surrounding conditions including the geometric facial features on respiratory deposition. Recently, Naseri et al. (2014) reported the results of their study on the effect of external environment on the inhalation deposition. In particular, the assumption of uniform velocity and uniform particle concentration that are commonly used for the computer modeling of respiratory systems was examined.

The breathing mannequin used by Naseri et al. (2014) is shown in Figure 16.22. The mannequin resembles a typical male subject (Huston, 2009, Zhuang et al., 2010). The external computational domain is a 4 m side cube with the mannequin standing at its center as shown in Figure 16.23a. This computational

domain is expected to be sufficiently large to eliminate the boundary effects. Based on the performed grid sensitivity, a grid of about 5.5 million cells was sufficient to achieve mesh-independent solutions. To assess the importance of including the mannequin body and external environment in the computational study of particle deposition in human airways, a 3-D model of the upper airways is connected to the mannequin and included in the computational domain. The airway model is the same as the one used in the example shown in Section 16.5.1. The attachment of the 3-D airway model to the mannequin is shown in Figure 16.23b.

For a breathing rate of 7 L/min, Figure 16.24 shows the path lines of inhaled air from the environment around the mannequin. The path lines are colored by velocity magnitude. It is seen that the peak velocity occurs in the pharynx region where the cross-sectional area is minimum. Sharp changes in the path lines occur in the nasal cavity and in the oropharynx region before the trachea. The detail of the airflow field a detached upper airway can be found in the work of Farhadi Ghalati et al. (2012).

Figure 16.25 shows the total particle deposition in the upper airways from nostril to the trachea, defined as TDF = N_d/N_{total}, where N is the number of particles that is deposited in the airway and N is total number of particles that entered the upper airway at the nostril. This figure compares the simulation results for the case of a separate airway with the case of an airway connected to the mannequin in a calm environment. For the case of separate airway, the particles are injected into the nostril with a uniform distribution. For the case of the airway of a mannequin, the particles are distributed uniformly around the mannequin in the computational domain. The effect of presence of mannequin body and face and external environment depends on both the breathing rate and particle diameter. For a breathing rate of 7 L/min, Figure 16.25

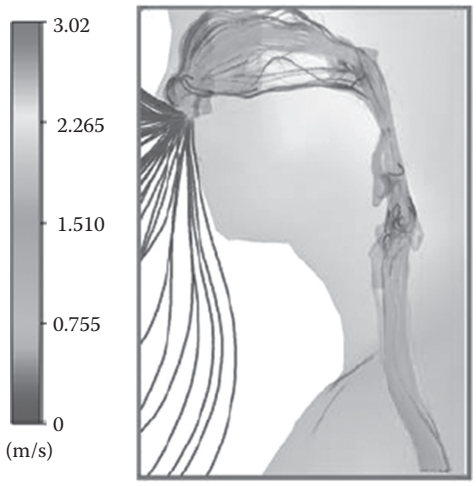

Figure 16.24

Path lines of inhaled air colored with velocity magnitude for the breathing rate of 7 L/min.

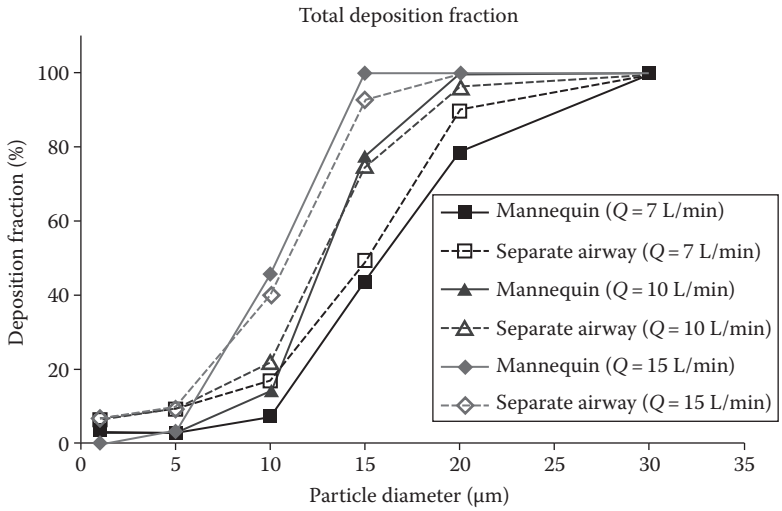

Figure 16.25

Comparison of the total deposition fractions in the detached upper airways with those in the airways attached to the mannequin.

shows that including the body of the mannequin and external environment in the computational model reduces the total deposition in the upper airway compared with that for the separated airway. But for higher breathing rates (10 and 15 L/min) and large particles, the effect reverses and the total DF for some particle size range increases. At a breathing rate of 10 L/min for particles with diameters of 10 μm or smaller, releasing the particles around the mannequin decreases the DF. For higher flow rate of 15 L/min this phenomenon is observed for particles with diameters of 5 μm or smaller.

Figure 16.26 shows the distribution of 2 μm particles at the nostrils when they have a uniform concentration in the surrounding environment. It is seen that particle distributions of inhaled particles at the nostrils are nonuniform. In addition, the particle distributions at the nostrils are different. This is perhaps due to the differences in the left and right nasal passages leading to different flow rates for the two sides of the nose. The simulation results show that the airflow rate through the right nasal passage in this case for a breathing rate of 10 L/min is about 73% of the left passage, and it drops to below 70% for low breathing rate of 7 L/min. It appears that the flow resistance of the left nasal passage for this subject is lower than that for the right one and this leads to a higher flow rate through the left nostril.

Another important observation is that the inhaled particles from the surrounding are concentrated in the high-velocity regions at the nares. In fact due to the presence of mannequin face and body and different

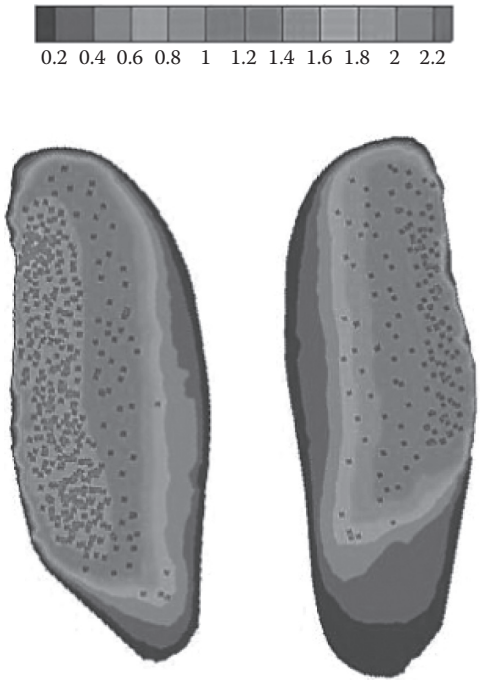

Figure 16.26

Distribution pattern of 2 μm particles released uniformly around the mannequin at the nostrils for a 7 L/min breathing rate. The contours show the velocity magnitude.

resistances of nasal passages, a nonsymmetrical airflow forms at the nostrils. This flow focuses the particles in the regions of high velocity at the nares. For the detached airway model, typically the particles are introduced uniformly at the inlet of the nostril. These different initial distributions lead to the differences in the particle deposition predicted by the two models.

To study the regional deposition, a sample result for the trachea is presented here. Figure 16.27 shows the regional DF for the trachea region, which is generally low. The simulation results of the separated airway model predict the peak DF of the 15 μm particles for the three inhalation rates studied. For the airway model attached to the mannequin, however, the peak deposition occurs for 10 μm particles. For the airway in the integrated mannequin model, the effects of the external environment and geometric features of the mannequin face shift the peak DF in the trachea region toward smaller particles.

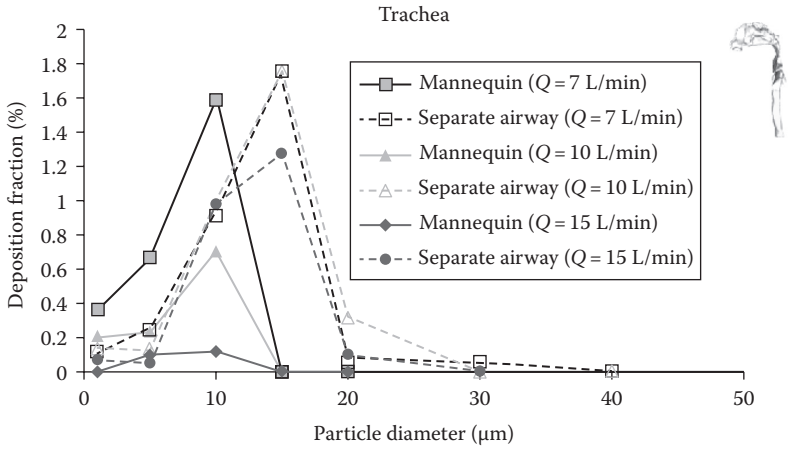

Figure 16.27

Comparison between the regional deposition fractions in the trachea of the separate upper airway and the airway in the mannequin.

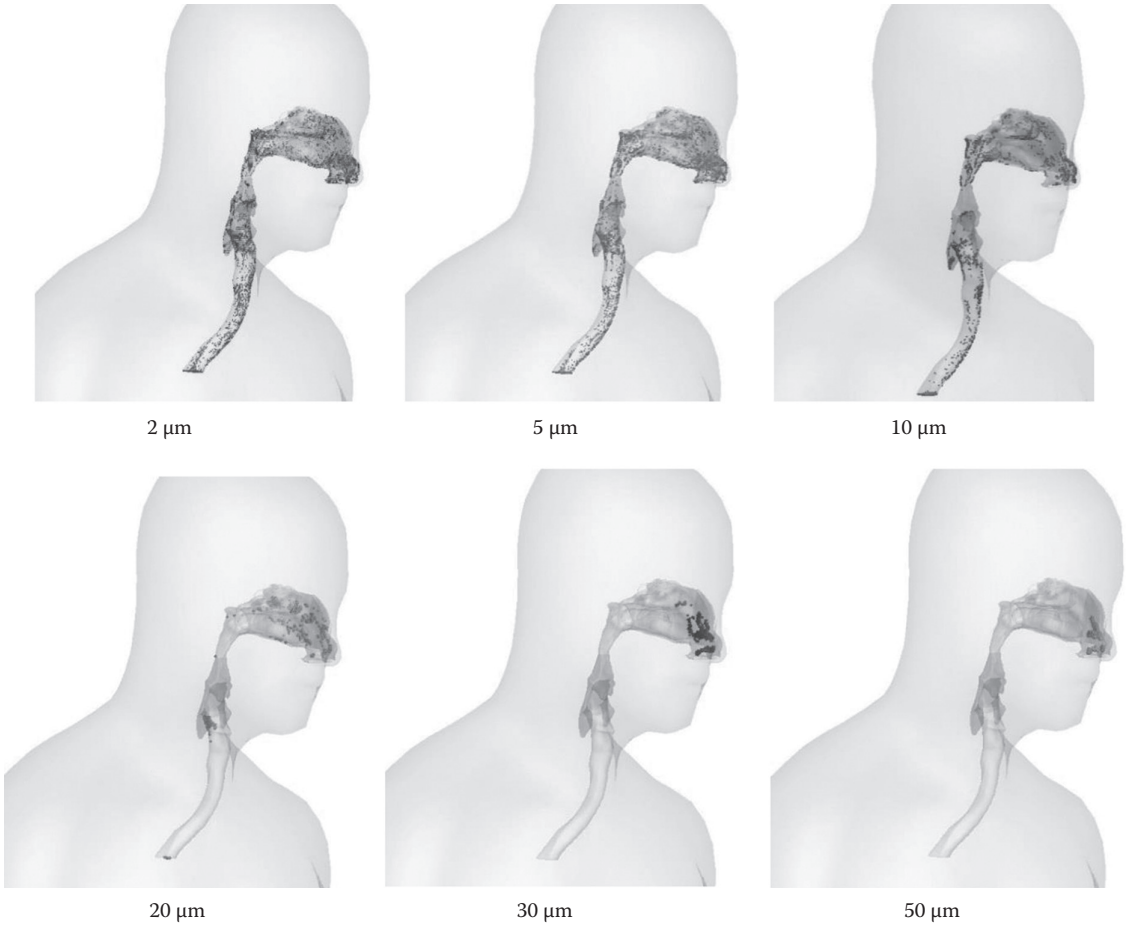

Figure 16.28

Particle deposition patterns in different regions of human upper airways for the breathing rate of 7 L/min.

Figure 16.27 also shows that generally the DF decreases with the increase in the inhalation rate. This might seems counterintuitive as the inertia deposition is the main mechanism for these particle sizes. However, it should be remembered that for higher flow rates the particles are filtered out in earlier sections of the nasal airway and a smaller number of particles have the chance to reach the trachea region. This observation is consistent with the very low DF for large particles in the trachea region.

Figure 16.28 shows the spatial deposition pattern for 5, 10, 20, 30, and 50 μm particles in the human upper airways for a breathing rate of 7 L/min. As expected, smaller particles penetrate deeper into the upper airway and reach the larynx and the trachea regions. All particles with sizes equal or larger than 30 μm are filtered out in the vestibule. Particles with diameters of 10 μm or smaller could reach into the trachea region for low breathing rates. The larynx, because of its rather complex geometry, is a hot spot for the deposition of particles passing through the upper airways.

16.1.5.6 Dispersion of Microparticles in Turbulent Airflows in Upper Airways

Recently, Ghahramani et al. (2014) reported the influence of airflow turbulence on the motion and deposition of microparticles in the upper airways. Accordingly, for a breathing rate of 45 L/min, the airflows in the passages of the upper airways are typically in the state of turbulent motion. The airway model used here is similar to that shown in Section 16.5.1. The velocity magnitude contours of and the turbulence intensity contours at various sections of the airway are shown in Figure 16.29. While the airflow is turbulent, the general pattern of the flow is similar to the laminar flow case at low breathing rate described in Section 16.5.1. The air enters from the nostril into the vestibule region and then turns sharply. The bulk of the airflow passes through the middle part of the passage. Here, however, because of the curvature in the flow passage, turbulence intensity increases significantly as shown in Figure 16.29b. In addition, secondary flows also occur in this part of passage that has

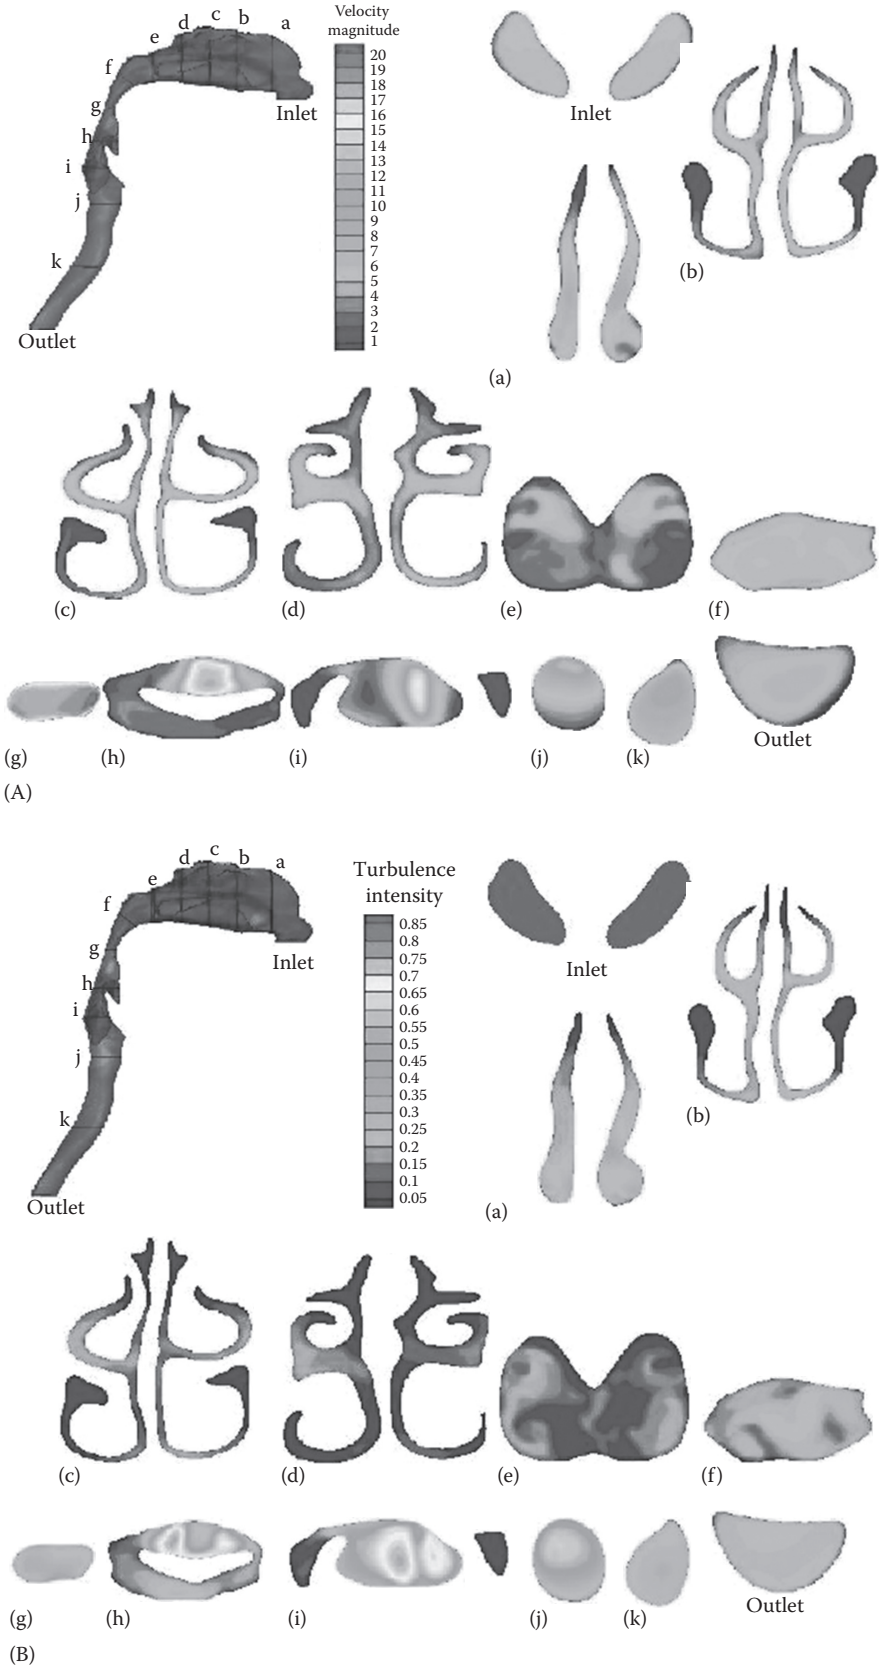

Figure 16.29

Airflow conditions at various sections of airways for a breathing rate of 45 L/min. (A) Velocity magnitude contours. (B) Turbulence intensity contours.

considerable effect on particle deposition. In the nasal valve and the main airway regions, similar to the laminar flow case, the airflow mainly passes through the middle meatus area as can be seen in Figure 16.29b through d. Again only a small fraction of airflow passes through the superior meatus and olfactory regions. In this region, the turbulent intensity decreases and in some parts the flow regime becomes laminar. Thus, while the bulk of the flow is in the turbulent flow regime, there are areas that are in the laminar regime. Therefore, it is important to use a suitable low Reynolds turbulence model, which can predict the relaminarization process appropriately.

In the nasopharynx region, as shown in Figure 16.29e through g, the turbulence intensity and secondary flows increase again. This is because of the presence of a significant curvature and sharp cross-sectional area reduction of the passage. Figure 16.29g shows that the velocity magnitude reaches its highest value at the end of the nasopharynx region. This section has the minimum cross-sectional area, which is about one-third of the area at section f. Therefore, the pressure drop in the nasopharynx region is quite high such that the average pressure at the end of nasopharynx is lower than its corresponding value at the outlet of trachea. In the oropharynx, due to the increase of the flow area, the velocity magnitude decreases, but the turbulent intensity continues to increase because of significant changes of the geometry as seen in Figure 16.29h. The curvature of the flow passage in the larynx causes the turbulent intensity to reach its highest value in this part of the airway (sections i and j, Figure 16.29b). In the trachea, the flow develops gradually, the turbulent intensity decreases, and the velocity magnitude variation diminishes.

For a better understanding of turbulence dispersion effects, particle tracking simulations were performed using the DRW and CRW stochastic models described, respectively, in Sections 16.1.4.2.1 and 16.1.4.2.2, and the results for the particle DF versus IP are presented in Figure 16.30, as well as the Stokes number, and are compared with the available experimental data. In addition, the case that the effect of turbulence fluctuation velocity was neglected and only the mean flow field was used for particle tracking is also plotted in Figure 16.30 for comparison.

This figure shows that the two stochastic methods for simulating the fluctuation velocity lead to roughly the same particle DF for high-inertia particles. In addition, the model predictions with the use of CRW model for low-inertia regime are also reasonable. For particles with low and moderate inertia, the DRW model prediction highly overpredicts the deposition rate. When the effect of turbulent dispersion is ignored and only the mean flow velocity is used, Figure 16.30 shows that the model prediction continuously underpredicts the DF, except perhaps for the very-low-inertia particles for which the DF is quite low. This implies that while turbulence has a significant effect on small particle dispersion, it does not significantly enhance the deposition of low-inertia particles. This figure clearly shows that deposition of particles with midrange inertia is clearly enhanced by turbulence fluctuations. The DRW model, however, markedly overpredicts the DF in this range.

Figure 16.31 shows the deposition pattern for 2.5, 5, and 10 μm particles in the realistic geometry of human upper airway system for a breathing rate of 45 L/min. The total DFs for these cases are, respectively, 17.9%, 66.3%, and 99.3%. It is also seen that particles of different sizes follow different deposition patterns. While a significant fraction of low-inertia particles with $d_p < 5$ μm can penetrate into the larynx and trachea regions, most of the high-inertia particles with $d_p > 10$ μm are captured in the vestibule and nasal valve regions. For these large particles, the inertia is high and the inertial impaction effects are quite effective. Moreover, as can be seen from the figure, some regions are more susceptible for the accumulation of deposited particles. Interestingly, these regions are similar to those described in Section 16.5.1 for the laminar flow analysis model. These accumulation regions are the vestibule, the top of middle meatus, the nasopharynx wall, the entrance to the oropharynx, and the back of the larynx regions.

Figure 16.32 shows the deposition patterns of 10 μm particles for the breathing rates of 30, 45, and 60 L/min. It is seen that the particle DF increases as the breathing rate increases. This trend is as expected since the impaction process dominates the deposition in the upper airways. In fact, the IP, which is the main factor for particle deposition, is directly proportional to the volume flow rate. Another important parameter that is increased by increasing the flow rate is the airflow turbulence, which enhances the turbulent dispersion of particles and consequently their deposition on the walls. However, when compared with the results shown in Figure 16.31, it is seen that the flow rate effect on particle deposition is comparatively less than the particle diameter effect. The stronger effect of particle size is due to the fact that the IP depends on the square of particle diameter compared with the linear dependence on the flow rate.

For the range of the studied inhalation flow rates described in Figures 16.31 and 16.32, the regional DF is highest in the nasal cavity compared with the other parts of the airway. Beyond the nasal cavity, the larynx and pharynx also capture a large number of the particles. Comparing the regional particle deposition patterns shown here to those that were reported by Frahadi Ghalati et al. (2012), who analyzed particle dispersion under strictly laminar flow regime (described in Section 16.5.1), two major differences are noticeable: While

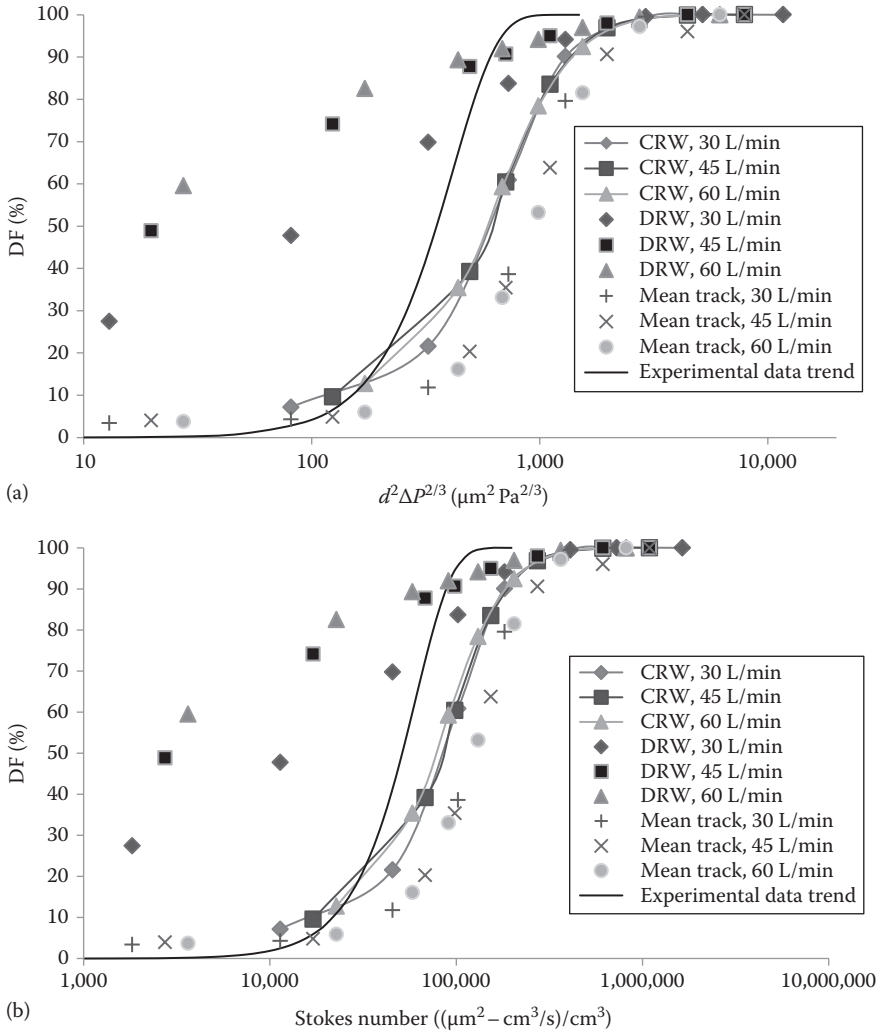

Figure 16.30

a large fraction of microparticles in the size range of $d_p \sim 10$ μm reach the lung under laminar flow condition, the majority of these particles are filtered out under the turbulent airflow condition. In fact, for high activity breathing rates of $Q \sim 45$ L/min, almost no particles larger than 10 μm enter the lung. Moreover, although a large fraction of small particles pass the nasal cavity, there is moderate chance for their deposition in the pharynx and the larynx in turbulent airflows due to the increased turbulence intensity in the glottis; however, under laminar flow condition, the possibility of small particle deposition in the pharynx and the larynx is not high.

16.1.5.7 CFD Simulation of Total and Regional Fiber Deposition in Human Nasal Cavities

Dastan et al. (2014) presented a recent study on elongated particle deposition in nasal passages. A summary of their work is presented in this section. Three different single-passage nasal cavities are investigated. The first cavity, which will be referred as "case A," is the same as the cavity that was discussed in Section 16.5.4 for which the effects of maxillary sinus surgery were studied (Abouali et al., 2012). Here, only the left nasal cavity with the ethmoidal sinus is considered for the fiber transport and deposition analysis. The second and third nasal cavities considered here are the right and left nasal cavities of an adult healthy female, which is the same as the model that was used in Section 16.5.1 (Farhadi Ghalati et al., 2012). In the earlier section, the upper airway to the end of the trachea was modeled, while in here the main nasal cavity from nostril to the beginning of nasopharynx is used for fiber transport and deposition analysis. These right and left cavities are referred to, respectively, as "case B" and "case C" in the discussion.

16.1.5.7.1 Equivalent Diameter A number of equivalent sphere diameters for fibrous particle deposition in different configurations were introduced by a number of researches in the past (Fan and Ahmadi, 1995b, Balásházy et al., 2003, Inthavong et al., 2008, Tian et al., 2012, Wang et al., 2008). Clearly, the appropriate form of the equivalent diameter depends on the main deposition mechanism, such as inertial impaction, diffusion, or gravitational sedimentation. For relatively large microfibers, in addition to gravity, the inertial impaction is the main mechanism for their deposition in airway passages. Using the point force approximation method, Wang et al. (2008) suggested different expressions for equivalent aerodynamic diameters for fibers moving parallel to the flow, normal to the airflow direction, and with random orientation. These are

$$d_{eq_parallel} = 3a\sqrt{\frac{\rho^p}{\rho^f}[\ln(2\beta) - 0.80685]} \tag{16.45}$$

$$d_{eq_normal} = \frac{3}{2}a\sqrt{2\frac{\rho^p}{\rho^f}[\ln(2\beta) + 0.19375]} \tag{16.46}$$

$$d_{eq_random} = a\sqrt{6\frac{\rho^p}{\rho^f}[\ln(2\beta) - 0.30685]} \tag{16.47}$$

where ρ^p and ρ^f are, respectively, the particle density and the density of water.

Fan and Ahmadi (1995b) suggested the use of Stokes diameter for the presentation of ellipsoidal fiber deposition results. That is,

$$d_{Stk} = 6a\sqrt{\frac{2\beta}{k_{\dot{x}\dot{x}} + k_{\dot{y}\dot{y}} + k_{\dot{z}\dot{z}}}} \tag{16.48}$$

where $k_{\dot{i}\dot{i}}$ are the elements of resistant tensor given in Equations 16.29 and 16.30. For incorporating the effect of particle density, the equivalent aerodynamic diameter corresponding to the Stokes diameter given by (16.48) is given as

$$d_{eq_Stk} = 6a\sqrt{\frac{2\beta\rho^p}{\rho^f\left(k_{\dot{x}\dot{x}} + k_{\dot{y}\dot{y}} + k_{\dot{z}\dot{z}}\right)}} \tag{16.49}$$

The goal of introducing the equivalent diameter and IP is to collapse the data to a narrow curve and make it possible to compare the results of nonspherical particle deposition with those of spherical particles. Figure 16.33 shows the variation of total DF of fibrous and spherical particles versus IP for the nasal passage of case A for a breathing rate of Q = 10 L/min. The IP given by $\text{IP} = d_{eq}^2 Q$ is calculated using different equivalent diameters given by Equations 16.44 through 16.49. It is seen that among the four noted equivalent diameters, the use of the equivalent aerodynamics diameter given by Equation 16.49 collapses the simulation results of fibers on those of spherical particles. Therefore, the equivalent aerodynamic diameter given by Equation 16.49 is used for presentation of data in the rest of the current example.

The total DF of fibrous particles for a range of fiber radii and aspect ratios for different nasal passages are evaluated, and the results are plotted versus the IP with the equivalent diameter given by Equation 16.49 in Figure 16.34. The case of $\beta = 1$ corresponding to spherical particles is also included in these simulations. In the majority of cases, it was assumed that the density of fibers is ρ^p = 1000 kg/m^3 (density of water). However, the results of fiber deposition with density of ρ^p = 2000 kg/m^3 for the case A and breathing rate of Q = 10 L/min are also presented in Figure 16.34 for comparison. It is seen that using the equivalent aerodynamic diameter and presenting the results versus the IP leads to collapsing of the DF results to roughly a

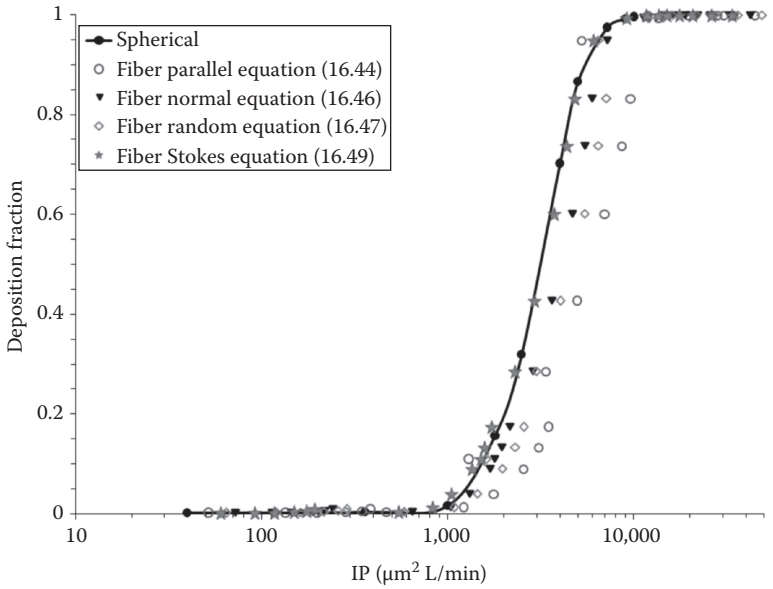

Figure 16.33

Variations of simulated deposition fractions of fibrous and spherical particle versus IP for different equivalent diameters in the nasal cavity of case A for a breathing rate of Q = 10 L/min. (The sizes of particles are in the ranges of $1 \le a \le 15$ μm and $1 \le \beta \le 80$. Particle density is the same as water.)

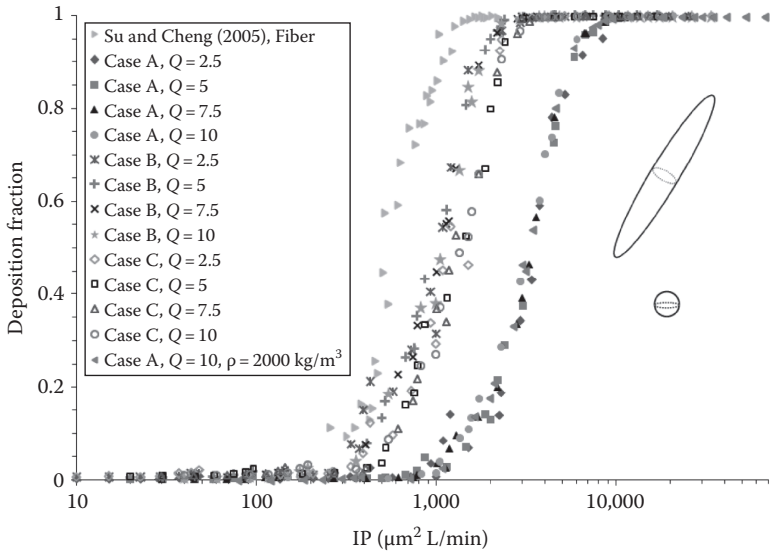

Figure 16.34

Total fibrous particle deposition for the range of $1 \leq a \leq 15$ μm and $1 \leq \beta \leq 80$ and unit density versus impaction parameter for different noses studied. The values of flow rates, Q, are in L/min for single nasal passage. The experimental data of Su and Cheng (2005) for fiber deposition are also reproduced in this figure for comparison.

single graph for each studied nasal passage. However, the intersubject variability between the nasal passages significantly affects the fiber deposition. As expected, the anatomy of the nasal cavity markedly affects the deposition rates of fibers as well as of spherical particles. Variations in the anatomy of the nasal passages are associated with the changes in the pressure drop for a given flow rate. The higher pressure drop in the nasal cavity is due to small effective cross section and leads to an increase in fiber deposition. The experimental data of Su and Cheng (2005) for fiber deposition are also presented in Figure 16.34 for comparison. This figure shows that the experimental DF for the nasal passage used by Su and Cheng is markedly higher than the simulated results. That again shows that the IP cannot reduce the intersubject variations and the differences among the DF values for different nasal cavities still remain.

Figure 16.35 shows the spatial deposition pattern of fibers for case A for a flow rate of $Q = 5$ L/min. It is seen that as the IP increases, the DF increases. This figure also shows that as the IP increases, the regional deposition pattern also changes to an extent. In particular, fibers with high IP deposit heavily in certain region of the nose where sharp changes in flow direction occur.

For nasal passage A, Figure 16.36 compares the DF predicted by the fiber model (solving the coupled translational and rotational equations of motions of ellipsoids) with the HL model described in Section 16.1.4.4.1. It is seen that the HL model follows the trend of the fiber simulation results. The HL model results are, however, somewhat scattered compared with the fiber model and the corresponding simulation results do not collapse onto a single curve. In addition, for the range of the parameter in this figure, the HL model overestimates the DF by factor of about 2. While the HL model is a much simpler model and reduces the computational time, it does not account for the actual physics of the fiber motion in the airflow and does not provide accurate estimates for the fiber DFs.

16.1.6 Conclusions

In this chapter, a review of recent literature on respiratory flow and deposition is presented. Fundamentals of particles and fiber transport and deposition are outlined and particular attention is given to recent advances in computational modeling of nano- and microparticles as well as fiber transport and deposition in human upper airways. Sample results on transport and deposition processes in nasal cavity, throat, larynx, and pharynx, as well as trachea and main left and right bronchus, are presented. Both nasal and oral breathing conditions are discussed. An example of effects of septoplasty surgery on particle deposition in human nasal passage is presented. The particle transport and deposition for pre- and postmaxillary sinus endoscopic surgery are also discussed. The effects of the surrounding environment including the facial features, as well as turbulent airflow

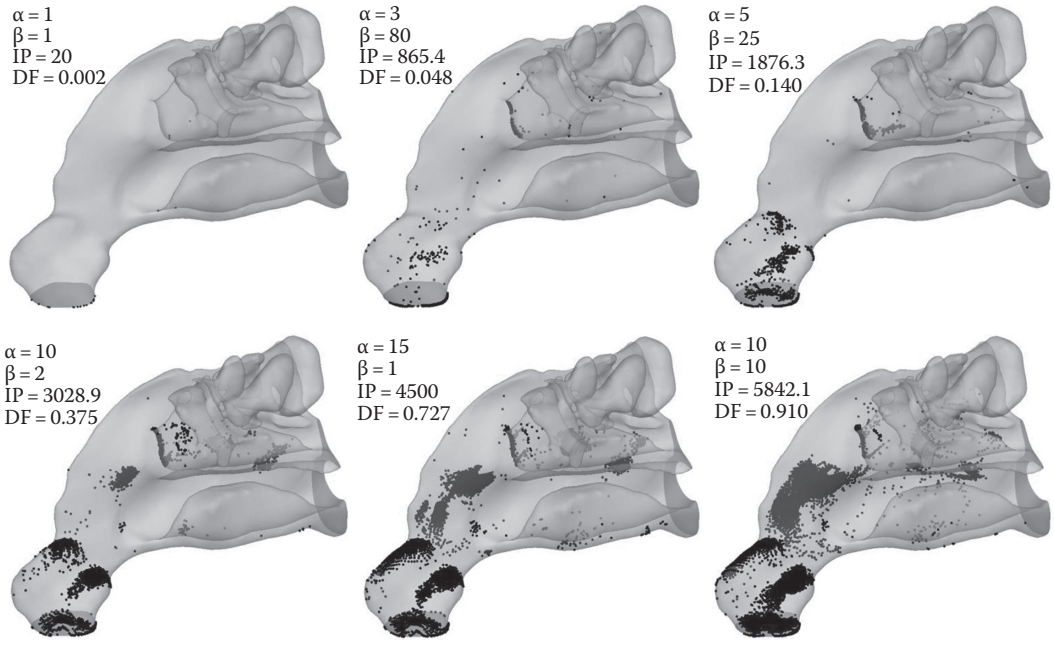

Figure 16.35

Spatial distribution of deposition pattern of fibers in the nasal passage A for a flow rate of $Q = 5$ L/min. Fiber radius, a, is in μm and IP is in μm^2 L/min. DF stands for the total deposition fraction.

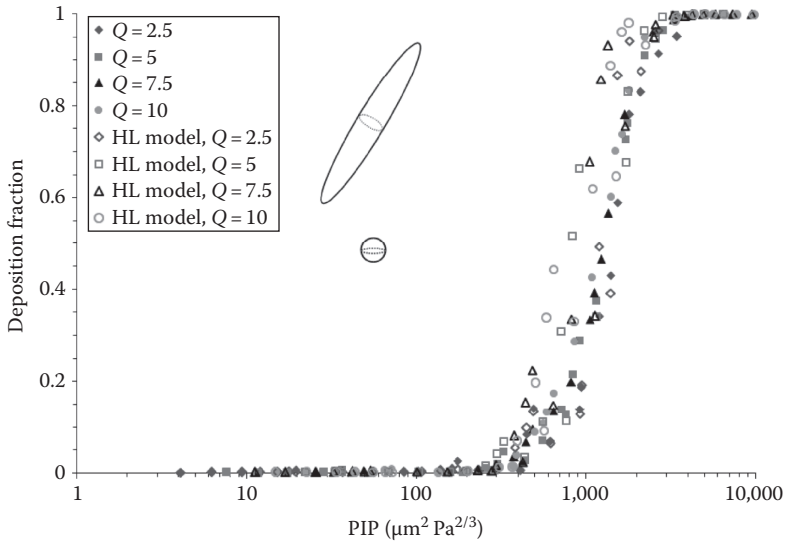

Figure 16.36

Comparison of deposition fractions predicted by the fiber model with those of the HL model for the nasal cavity of case A. The values for flow rate, Q, are in L/min per single passage and the fiber sizes are in the range of $1 \le a \le 15$ μm and $1 \le \beta \le 80$ with unit density.

on the respiratory deposition, are also studied. The motion and deposition of fibrous particle in the upper airways are discussed. The following are the presented results:

- The molecular diffusion and turbulence are dominant for deposition of nanometer size particles and the deposition rate increases as particle diameter decreases.
- For particles larger than a few microns, the impaction is the dominant deposition mechanism and the deposition rate increases with the particle size.

- Computer simulations for spherical and fibrous particles are in good agreement with the available experimental data.
- The computational model could be became a useful tool for performing virtual surgery for testing various options.
- Surrounding environment and facial features markedly affect the regional particle DF in the upper airways.
- The concentration of inhaled aerosol at the nostril is not uniform.

16.2 Blood Flow

Shu Takagi, Kazuyasu Sugiyama, and Satoshi Ii

16.2.1 Introduction of Blood Flows as Dispersed Multiphase Flows

Blood flow is a dispersed phase flow, in which red blood cells (RBCs) are the main component of the dispersed phase. RBCs occupied 35%–50% of the total blood volume and there are 10–40 trillion RBCs in a human body. This means that there are approximately 5 million RBCs in 1 mm^3 blood. As is well known, RBC has a biconcave shape and its size is about 8 μm in long axis and 2 μm in short axis. The red color of blood is due to the presence of RBCs and from the aforementioned fact the blood flow can be recognized as a dense dispersed phase flow.

In many situations, blood flow is assumed to be Newtonian fluid that has a larger viscosity than that of pure water. In other situations, they are often assumed to be non-Newtonian. This different approximation highly depends on the vessel diameter. That is, if the vessel diameter is large enough, blood is assumed to be Newtonian since the size of RBCs is negligible compared with the scale of the macroscopic flow structure. Reducing the vessel size down to the O(100 μm) diameter, the size of RBCs becomes more important and the blood flows start showing non-Newtonian behavior. That is, the velocity fluctuations due to the presence of RBCs give the nonlaminar (nonparabolic) velocity profile by the pseudo-turbulence effect even in the laminar flow regime. Furthermore, reducing the vessel size to the scale of capillary vessels, which has less than 10 μm diameter, the vessel diameter becomes comparable with the size of RBCs. In this situation, the blood should not be treated as non-Newtonian fluid of homogeneous media which is expressed by the constitutive equations of the non-Newtonian fluid. In principle, the flows in capillary vessels should be treated as dispersed multiphase flows where the dispersed phase of RBCs is treated individually in blood plasma, since the idea of spatial averaging is not available in this scale. Although the behavior of RBCs is mainly discussed so far, not only the RBCs but also other blood cells, such as white blood cells, platelets, and also drag delivery agents regarded as artificial blood cells, need to be treated in the same manner. Therefore, reducing the vessel size, the characteristics of blood as multiphase flow become more important. Compared with spherical blood cells such as neutrophil, RBCs are highly deformable and can move smoothly into the small vessels. In this chapter, the important characteristics of blood flows in microcirculations are explained in the next section. Then, the modeling of blood cells and the results of numerical simulations for blood flows containing blood cells are also explained.

16.2.2 Apparent Viscosity and Fåhræus–Lindqvist Effect

To express the flow resistance in the vessel, the apparent viscosity is often used as an indicator. The apparent viscosity, which is also known as effective viscosity, gives the pressure drop along the tube. It simply expresses the relative pressure drop to that of blood plasma without RBCs. Due to the dispersed multiphase flow nature of blood with RBCs, the apparent viscosity is always larger than 1.0, since the dispersed phase generates the extra energy dissipation. The apparent viscosity dependence on the vessel diameter is not simple. There is a good review paper by Freund (2014). This figure is shown in Figure 16.37. The horizontal axis is vessel (tube) diameter, and the vertical axis corresponds to apparent (effective) viscosity. It is shown that decreasing the vessel diameter from larger size to about 10 μm, the apparent viscosity gradually decreases. Furthermore, decreasing the diameter, the viscosity rapidly starts increasing. This complicate behavior comes from the relative size of the vessel diameter to the size of RBCs. If a vessel diameter becomes comparable or smaller than the RBC size, the RBCs need to be highly deformed to pass through the vessels and this causes the drastic increase of the apparent viscosity. In the case for the vessel diameter from 10 to 30 μm, the reduction of the apparent viscosity in the smaller diameter is due to the change of RBC positioning. It is easily seen in Figure 16.37. For the smaller diameter less that about 10 μm, RBCs form train-like structure, that is, a single RBC moves at the center for vessel and flows continuously. For the vessel larger than 15 μm, slipper-like shape RBCs flow in the core region of the vessel. It is noted that RBCs are trying to flow in the center of the pipe due to the shear-induced lift effect. Since RBCs are flowing in the center of the pipe, there exists the blood plasma layer close to the vessel walls. This plasma layer ends up with the reduction of average hematocrit value in the smaller vessel.

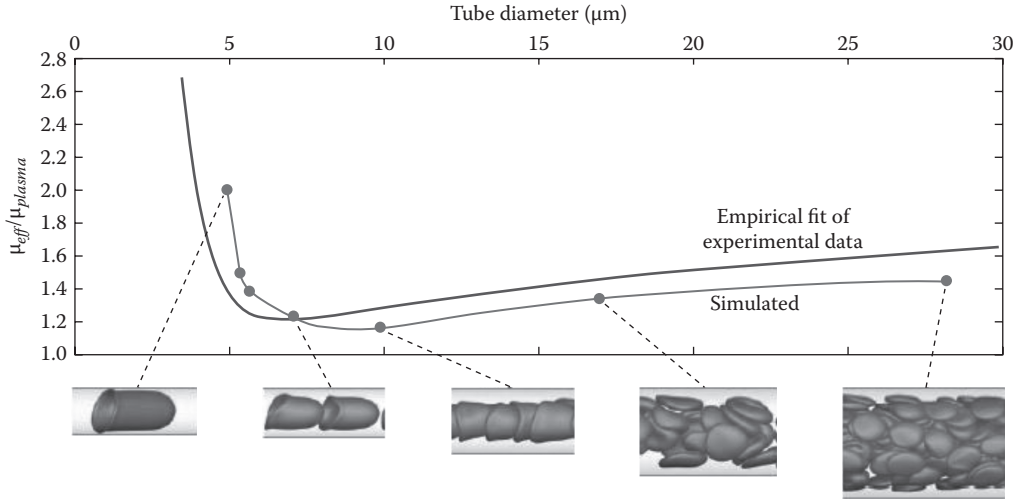

Figure 16.37

Relation between effective viscosity and vessel diameter. (From Freund, J.B., *Annu. Rev. Fluid Mech.*, 46, 72, 2014.)

This is called the Fåhræus effect. And the reduction of hematocrit value gives the reduction of apparent viscosity in the smaller diameter for the vessel of 10–30 μm diameter. This is called the Fåhræus–Lindqvist effect.

16.2.3 Modeling of Blood Cells

Biological cells have lipid bilayer membranes. Since the lipid molecules of the lipid bilayer can easily move around in the membrane, the lipid bilayer membrane is often modeled as 2-D fluid membrane. Furthermore, since the distance between two neighborhood lipid molecules hardly changes, the membrane is assumed to be incompressible. Hence, the lipid bilayer membrane is modeled as a 2-D incompressible fluid deformable in 3-D space. Following this concept, Helfrich (1973) developed the model of lipid bilayer membrane. He considered the effect of bending rigidity and gave the following energy functional E to express the mechanical energy of the membrane:

$$E = \frac{1}{2}k_b \int (c_1 + c_2 - c_0)^2 dA + k_G \int c_1 c_2 \, dA + \lambda \int dA + \Delta P \int dV \tag{16.50}$$

where

k_b is the bending rigidity
c_1 and c_2 are the principal curvatures of the membrane
c_0 is the spontaneous curvature
dA and dV are the microsurface and microvolume elements of the membrane

Under the expression of Equation 16.50, λ and ΔP are the Lagrangian multiplier to impose the constraints of the surface area and the volume constant. The integral $k_G \oint c_1 c_2 \, dA$ term is related to the surface integration of the Gaussian curvature: product of principle curvature. This term keeps constant if there is no breakup or topological changes of the cell shape, through the well-known Gauss–Bonnet theorem in differential geometry. An artificial cell-like structure covered by lipid bilayer membrane is called liposome. A liposome can be used as a drag delivery agent by encapsulating drags inside. The membrane of a liposome is often modeled by this Helfrich model.

Actual living cells including blood cells have not only lipid bilayer membrane but also a protein network structure called cytoskeleton underneath the lipid bilayer. This cytoskeleton structure gives the strength of membrane under the strong shear flow. Due to the presence of cytoskeleton structure, the membrane of blood cells no longer behaves as fluid membrane. It behaves as an elastic material and a hyperelastic membrane model is often introduced to describe the cell membrane. For example, one of the well-known membrane models for RBCs are called the Evans–Skalak (1980) model and the constitutive equation of membrane is given by the following expression:

$$\boldsymbol{\tau}_s = \frac{E_s}{\left(\Lambda_1 + 1\right)^2}\mathbf{B}_s + \left(E_s\Lambda_1 - C_s\frac{\Lambda_2 + 1}{\Lambda_1 + 1}\right)\mathbf{P}_s \tag{16.51}$$

where

$$\Lambda_1 = J_s - 1, \quad \Lambda_2 = \frac{\mathrm{tr}(\mathbf{B}_s)}{2J_s} - 1, \tag{16.52}$$

where

E_s is the shear modulus

C_s is the area dilation modulus

16.2.4 Numerical Method for Solving Blood Flow Containing RBCs

16.2.4.1 Overview of Standard Methods to Simulate Blood Flows

There are several ways to simulate blood flows containing many RBCs. One of the standard methods is using the boundary element method (BEM) for Stokes flow. As mentioned, the presence of blood cells becomes important in the microcirculation, where the flow Reynolds number is very small. So, the Stokes flow assumption is applicable in many situations. The other approach to simulate extra-large number of RBCs is by the lattice Boltzmann method. Both methods and simulated results are explained in detail in the book by Pozrikidis (2010).

In coupled methods for a fluid and elastic membrane typified by the immersed boundary (IB) method (Peskin, 1972, 2002), the Lagrangian description is employed for the membrane motion, whereas the Eulerian description is employed for the fluid. However, there is an open question for the numerical stability in a long time run without any numerical stabilization. For that reason, rather than using the Lagrangian particles, field variables to identify the membrane interface are introduced and utilized for interaction between the fluid and membrane on the Eulerian mesh. Cottet and Maitre (2006) introduced the level-set function to identify the interface; in addition, the membrane stretching or variation of the surface area was obtained from the information of the level-set function. As a result, the membrane force was successfully obtained on the Eulerian mesh without using the interfacial material points. However, since the constitutive law of the membrane elasticity is limited to a model that only involves a variation of the surface area, it has not been applied yet to more general membrane models that depend on the principal strains.

16.2.4.2 Full Eulerian Formulation of the Dispersed Multiphase Blood Flow

In this subsection, the numerical method to solve blood flows containing many blood cells is explained as a fluid–membrane interaction problem. Here, the full Eulerian equation formula is introduced and finite difference approach is introduced to solve the discretized equations.

A novel full Eulerian fluid–membrane interaction method has been proposed by Ii et al. (2012a,b), as an extension of the general idea by Sugiyama et al. (2011). It is assumed that a closed membrane is immersed in a field Ω, where inner and ambient regions Ω_1 and Ω_2 are filled with the incompressible Newtonian fluids ($\Omega = \Omega_1 \cup \Omega_2$). A material phase to describe each fluid is expressed by a smoothed volume fraction volume of fluid (VOF) function ϕ, which extends from 0 to 1 within a few computational meshes. Then a membrane transition region Γ defined as $|\nabla\phi| \leq \varepsilon$, where $|\nabla\phi|$ is regarded as a smoothed delta function (e.g., Brackbill et al., 1992) and ε is an arbitrarily value depending on the mesh size, is introduced as in Figure 16.38.

By making use of a basic theory on the finite deformation (Skalak et al., 1973, Barthés-Biesel and Rallison, 1981), a set of governing equations with a mixture formulation is given as follows in the Eulerian frame:

$$\nabla \cdot \mathbf{v} = 0, \quad \mathbf{x} \in \Omega \tag{16.53}$$

$$\rho\left(\partial_t \mathbf{v} + \mathbf{v} \cdot \nabla \mathbf{v}\right) = -\nabla p + \nabla \cdot (\mu(\nabla \mathbf{v} + \nabla \mathbf{v}^T)) + |\nabla\phi|\,\mathbf{f}_s, \quad \mathbf{x} \in \Omega \tag{16.54}$$

$$\partial_t \phi + \mathbf{v} \cdot \nabla \phi = 0, \quad \mathbf{x} \in \Omega \tag{16.55}$$

$$\partial_t \mathbf{B}_s + \mathbf{v} \cdot \nabla \mathbf{B}_s = \mathbf{B}_s \cdot \nabla_s \mathbf{v} + \nabla_s \mathbf{v}^T \cdot \mathbf{B}_s, \quad \mathrm{x} \in \Gamma \tag{16.56}$$

$$\partial_t J_s + \mathbf{v} \cdot \nabla J_s = J_s \nabla_s \cdot \mathbf{v}, \quad \mathbf{x} \in \Gamma \tag{16.57}$$

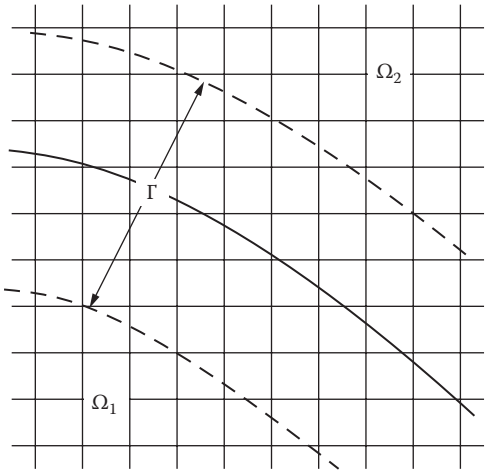

Figure 16.38

The compactly supported or smoothed interface region Γ immersed in the Cartesian mesh.

$$\partial_t \kappa_R + \mathbf{v} \cdot \nabla \kappa_R = 0, \quad \mathbf{x} \in \Gamma \tag{16.58}$$

where

$\nabla_s = \mathbf{P} \cdot \nabla$ is the *surface* gradient operator with a surface projection tensor $\mathbf{P} = \mathbf{I} - \mathbf{nn}$, where $\mathbf{n}$ is a unit normal vector of a membrane surface

$\mathbf{B}_s = \mathbf{P} \cdot \mathbf{B} \cdot \mathbf{P}_R$ the *surface* left Cauchy–Green deformation tensor (subscript R denotes a reference coordinate)

J_s the surface Jacobian (i.e., ratio A/A_0 between an initial surface area A_0 and current area A)

κ_R the reference mean curvature

$\mathbf{f}_s$ the surface singular force (force per area) of the membrane given by the expression

$$\mathbf{f}_s = \nabla_s \cdot \left(\tau_s + \tau_b \right), \tag{16.59}$$

where $\boldsymbol{\tau}_s$ is an in-plane stress tensor, for example, the neo-Hookean material (Barthés-Biesel and Rallison, 1981)

$$\tau_s = \frac{E_s}{3\left(\Lambda_1 + 1\right)} \left(\mathbf{B}_s - \frac{1}{\left(\Lambda_1 + 1\right)^2} \mathbf{P}_s \right) \tag{16.60}$$

and the Evans–Skalak material for RBC given in Equation 16.51

$$\tau_s = \frac{E_s}{\left(\Lambda_1 + 1\right)^2} \mathbf{B}_s + \left(E_s \Lambda_1 - C_s \frac{\Lambda_2 + 1}{\Lambda_1 + 1} \right) \mathbf{P}_s \tag{16.61}$$

Here

$$\Lambda_1 = J_s - 1, \quad \Lambda_2 = \frac{\mathrm{tr}(\mathbf{B}_s)}{2J_s} - 1 \tag{16.62}$$

E_s is the shear modulus

C_s is the area dilation modulus used

$\boldsymbol{\tau}_b$ is a bending stress tensor proposed by Pozrikidis (2001), that is, $\boldsymbol{\tau}_b = \mathbf{q}_s \mathbf{n}$

$$\mathbf{q}_s = \left(\nabla_s \cdot \mathbf{m}_s \right) \cdot \mathbf{P}, \quad \mathbf{m}_s = K_s \left(\boldsymbol{\kappa}_s - \kappa_R \mathbf{P} \right) \tag{16.63}$$

where

K_s is the bending modulus

$\boldsymbol{\kappa}_s = \nabla_s \mathbf{n}$ the Cartesian curvature tensor

The outward unit normal vector defined as $\mathbf{n} = -\nabla\phi/|\nabla\phi|$ and $\boldsymbol{\kappa}_s$ (and also κ_R) are calculated in the Eulerian meshes. A set of PDEs is discretized by the finite difference/volume manner, and the SMAC algorithm (Amsden and Harlow, 1970) is employed to couple with the pressure and velocity fields with the staggered arrangement. For more detailed description on the numerical methods, one may consult Ii et al. (2012a,b).

The updating equation of the VOF function $\phi_s(\mathbf{x}, t)$ is derived from the advection equation (16.52). From a numerical point of view, an accurate treatment is necessary to numerically obtain the flux $\mathbf{v}\phi_s$ in a conservative form without the numerical dissipation and oscillation. In other words, an accurate approximate function $F(\mathbf{x}, t)$ is desirable for the indicator function $I_s(\mathbf{x}, t)$. In the discretization, the approximate function $F(\mathbf{x}, t)$ is piecewisely reconstructed in a single mesh ijk, that is, F_{ijk}. In the present Eulerian FSI method especially for the coupling with the membrane including a diffusive membrane region, a numerical method is required to ensure that the diffusive transition region between respective material phases (fluid and solid regions or inner/outer fluid region of the membrane) is without numerical dissipation over time. In order to satisfy solving such a requirement, a continuous interface capturing method, namely, MTHINC method (Ii et al., 2012c) extended from Xiao et al. (2005), has been proposed. In this method, the (multidimensional) hyperbolic tangent function is utilized for the approximation of the cell-wise indicator function.

16.2.4.3 Results of the Numerical Methods and Discussion

For the sake of validation, a shear-induced deformation problem for a spherical capsule obeying the neo-Hookean law (Equation 16.39) is simulated. A capsule with a diameter of $d = 2$ is located on a computational domain, $[-4, 4] \times [-2, 2] \times [-4, 4]$. An opposing velocity of $\pm V$ that results in a shear rate $\gamma = 2V/H_z$, where $H_z = 8$ is a vertical height of the domain, is imposed on each top/bottom wall in z direction. The periodic boundary conditions are imposed on other x and y directions. The viscosity $\mu(=\mu_1=\mu_2)$ is given by the Reynolds number $\mathrm{Re} = \rho\gamma d^2/(4\mu)$, and the membrane stiffness is given by capillary number $Ca = \gamma d/(2E_s)$. In this test, $\rho = 1$, $\gamma = 1$, and $\mathrm{Re} = 0.001$ are fixed; therefore, the membrane stiffness only depends on the capillary number Ca. Here, the bending force is neglected and the capillary number is varied as 0.0125, 0.025, 0.05, 0.1, and 0.2. Numerical results at steady state with a mesh size $\Delta x = d/32$ are shown in Figure 16.39, where the time increment $\Delta t = 0.0025$ is used. It is confirmed that the deformation becomes larger as the capillary number increases.

The time history of a deformation parameter $D = (l - s)/(l + s)$, where l and s denote the semimajor and semiminor axes of an ellipse fitting to an obtained interface in *shear plane*, that is, x–z cross section passing through $y = 0$, is shown in Figure 16.40. The mesh lengths $\Delta x = d/16$ and $d/32$ are employed, where the time increments $\Delta t = 0.005$ and 0.0025 are used. In this regard, numerical solutions given by the IB method (Eggleton and Popel, 1998) and the BEM (Pozrikidis, 1995) are also shown. As compared with the well-validated results of the IB method and BEM, the present results converge to the reference solutions by increasing the spatial resolution.

16.2.4.4 Suspension of Red Blood Cells and Platelets in a Capillary Tube

Human blood is composed of biological cells (erythrocyte, leukocyte, and thrombocyte, i.e., RBC, white blood cell, and platelet), proteins and plasma. In particular, the deformable RBC highly occupies a blood, where its volume ratio ranges from 30% to 50%; thus, the dynamic motions of the multiple RBCs play an important role in a capillary vessel when its size (or diameter D) is comparable to a RBC size (diameter

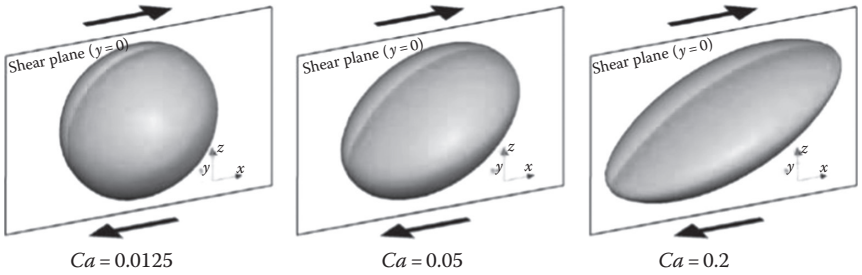

Figure 16.39

The fully developed deformed surface of the neo-Hookean membrane subjected to the linear shear flow for various capillary numbers $Ca = 0.0125$, 0.05, and 0.2. The *shear plane* indicates a plane at $y = 0$, and the arrows indicate a schematic of the imposed shear velocities. (Reproduced from Ii, S. et al., *J. Biomech. Sci. Eng.*, 7, 72, 2012b.)

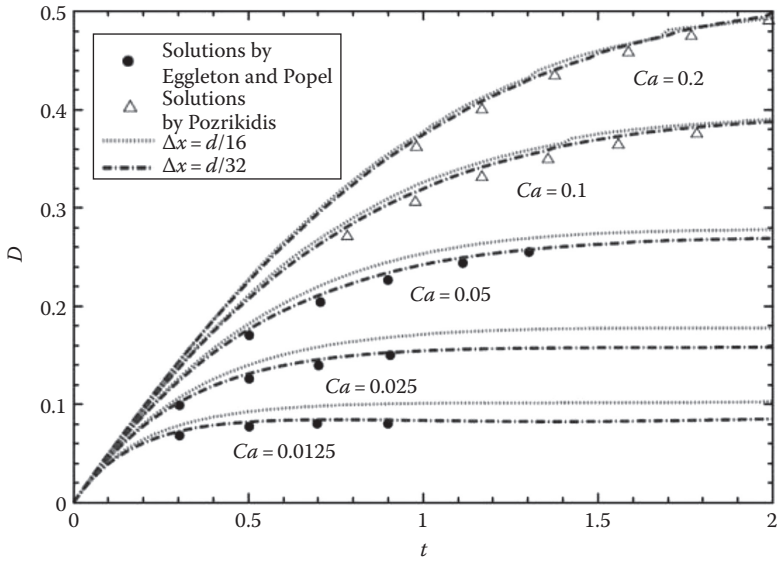

Figure 16.40

Deformation parameter D versus time t for various capillary numbers Ca = 0.0125, 0.025, 0.05, 0.1, and 0.2. The lines are the present solutions with the mesh sizes of $\Delta x = d/16$ and $d/32$, the filled circles indicate the solutions by means of the IB method by Eggleton and Popel (1998), and the open triangles show those of the boundary element method by Pozrikidis (1995). (Reproduced from Ii, S. et al., *J. Biomech. Sci. Eng.*, 7, 72, 2012b.)

$d \sim 8$ μm). In such a small vessel, the blood is no longer a Newtonian fluid due to the presence of the high-density RBCs. When the vessel size D is close to the RBC size d for $D > d$, it has been observed that a flow rate increases even if a same driving pressure is enforced, that is, commonly known as the Fåhræus–Lindqvist effect (Fåhræus and Lindqvist, 1931). Due to a hydrodynamic effect, the deformable RBCs axially aggregate and the RBC-rich core region is created around an axial center, resulting in a cell-free layer (or plasma occupying layer) near the vessel wall. In a primary stage of the thrombus formation (or blood clotting) that stops the bleeding in homeostatic mechanism, the platelets immediately accumulate on an injured vessel wall. Therefore, it is quite important to know how many platelets are confined and drift in the cell-free layer.

A suspension flow of the multiple RBCs and platelets in an elastic capillary vessel is studied using a blood flow analysis based on a full Eulerian approach. To simplify the analysis, the platelet is regarded as an elastic solid with a stiff elastic modulus, whereas the RBC is treated as an elastic membrane obeying an adequate constitutive law with experimentally given parameters (Hochmuth and Waugh, 1987).

A suspension of the RBCs and platelets is enclosed by the elastic vessel tube with a radius of D = 20 μm, obeying the solid material of the neo-Hookean law (Equation 16.17). Here, 30 RBCs are randomly distributed to simulate a pertinent hematocrit H_t of approximately 20%. The Evans–Skalak model (Equation 16.40) and Pozrikidis bending model (Equation 16.42) are employed for the RBC. Meanwhile, 10 platelet-like elastic solids are randomly distributed within a range of $r_c \leq 8$ μm (r_c is a centroid of the platelet in a radial direction) to reveal how the centrally located platelets behave due to the presence of the RBCs. Initial shapes of the RBC and platelets are biconcave discoids (Evans and Fung, 1972) and spheroid, respectively. A flow is induced by a pressure gradient as a body force, and a periodic boundary condition is imposed on a streamwise direction x. Wall boundary conditions are employed for both the spanwise and vertical directions, y and z, respectively. Computational conditions are referred to Table 1 (Ii et al., 2012b).

Snapshots of numerical results at t = 7.5, 30, and 75 ms are shown in Figure 16.41. It is found that the initially distributed RBCs are mixed over time. Each of the RBCs has a different shape such as a parachute shape or slipper one reported in both a numerical simulation (Zhao et al., 2010) and an experiment (Gaehtgens et al., 1980). The deformed RBCs aggregate into large masses around the axial center due to a hydrodynamic effect, causing a plasma phase near the wall, which the so-called cell-free layer.

To clarify the development of the cell-free layer, a spatial occupancy of the RBCs in a streamwise direction x is plotted in Figure 16.42. It is confirmed that the cell-free layer (or nonexisting region of the RBC near the wall) becomes larger and a RBC-rich core region is created around a tube center over time. It has been reported that the RBC-rich core region is sufficiently created at t = 87.5 ms in a 2-D simulation (Zhang et al., 2008), in which the computational conditions are totally different (i.e., 2-D and 3-D, rigid parallel plate and

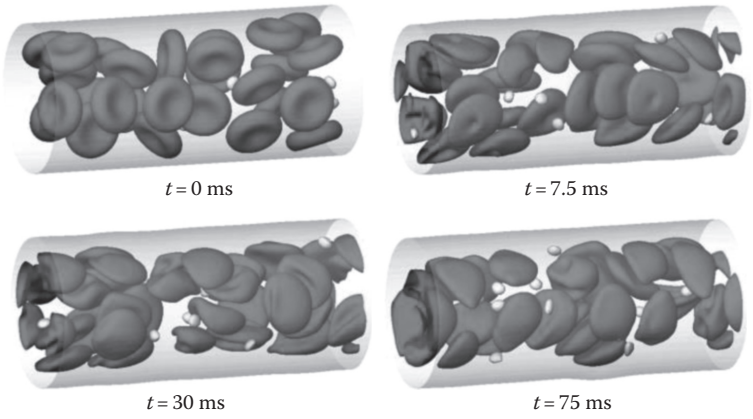

Figure 16.41

elastic tube, $H_t \approx 30\%$ and $H_t \approx 20\%$). Nevertheless, the present result is physically comparable to the result by Zhang et al. (2008) in terms of a time constant for creating the RBC-rich core region. In a bounded flow subjected to a pressure gradient, it is known that a laterally located RBC follows a tank-treading motion due to a strong shear rate near the wall (Zhang et al., 2008, Zhao et al., 2010, Crowl and Fogelson, 2010, 2011). This tendency has been also reported by Doddi and Bagchi (2009) of which simulation employs a parallel plate in 3-D. However, the present result is given by a specific configuration (1 initial distribution); therefore, further discussions for the development of the RBC aggregation will be necessary using various initial distributions.

Trajectories of the respective platelets in a radial direction are plotted in Figure 16.43a. Each platelet moves in a flow undergoing a fluctuation in a radial direction. Such a fluctuation seems to be large around the tube center ($r \leq 4$ μm). It is considered that the axially aggregating RBCs push out the platelets together with the plasma, and the laterally migrated platelets drift with lesser fluctuations. Taking the distribution of the RBCs into account, it is assumed that the RBC-rich core region induces a mixing effect of the flow, which results in a higher fluctuation in respect to the medially located platelets, whereas the cell-free layer restricts the radial motions of the laterally located platelets. Furthermore, a specific separation is observed between the axial center ($r \leq 4$ μm) and near the wall (6 μm $\leq r \leq$ 8 μm) for $t \leq 75$ ms. In the 2-D simulation results (Crowl and Fogelson, 2010, 2011), this separation has relevance to the multiple behaviors of the RBCs playing the tank-treading motions near the wall, and they could perform a kind of barrier to restrict

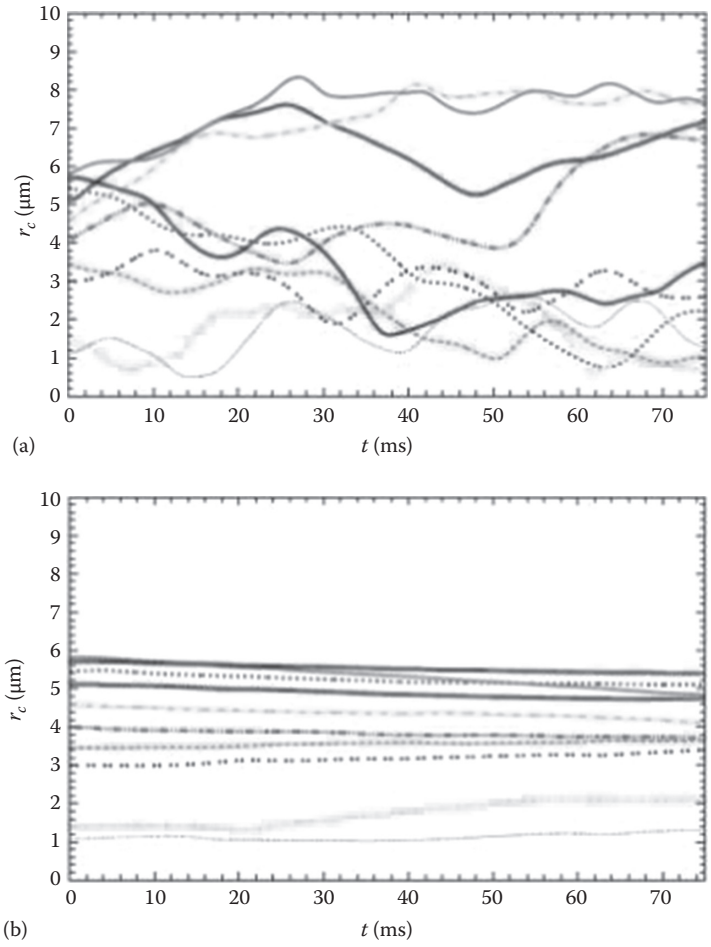

Figure 16.43

Trajectories of the respective 10 platelets in a radial direction. (a) The result with the suspension of the RBCs. (b) The result with the pure plasma. (Reproduced from Ii, S. et al., *J. Biomech. Sci. Eng.*, 7, 72, 2012b.)

the radial drift of the platelet from the sides to the center. In the present simulation, it is not clear by what this separation is triggered because the number of platelets is only 10 and the simulation is run with 1 initial configuration. Nevertheless, it is considered that the radial fluctuation comes from the motions of the RBCs. To clarify it, we carried out a computation without taking account of the RBCs. The platelet trajectories are shown in Figure 16.43b. In a situation without the RBCs, the radial fluctuation of the platelet only comes from the platelet motion itself. Therefore, the platelets straightforwardly drift in the flow with less radial fluctuation for $t \leq 75$ ms. It, therefore, appears that the dynamic motion of the platelets is strongly affected by the motions of the RBCs.

16.2.5 Modeling of Platelet Adhesion at the Initial Stage of Thrombosis

Thrombosis is regarded as one of the most important diseases, which cause the myocardial and cerebral infarctions. It is a very complicated disease affected from molecular-scale protein–protein interaction to continuum scale in blood flow. Initially, platelets start aggregate at the injured wall, where von Willebrand factor (vWF) is attached. The glycoprotein, GPIb-α, on platelet membrane starts showing ligand–receptor-type interaction with this vWF and platelets start aggregating around this spot. From this stage, complicated activation process of platelets and interactions with the blood, vessel walls, RBCs, fibrin, etc. occur and they end up with the blockage of the vessels. The numerical model for conducting the initial stage of thrombus formation is explained here. To analyze this process, we used the full Eulerian fluid–membrane coupling method explained earlier, which is a further extension of the full Eulerian fluid–structure coupling method (Sugiyama, 2011). This method is coupled with the results of a stochastic Monte Carlo simulation on GPIb-α and vWF interactions. The basic concept of this multiscale thrombosis simulator is shown in Figure 16.44.

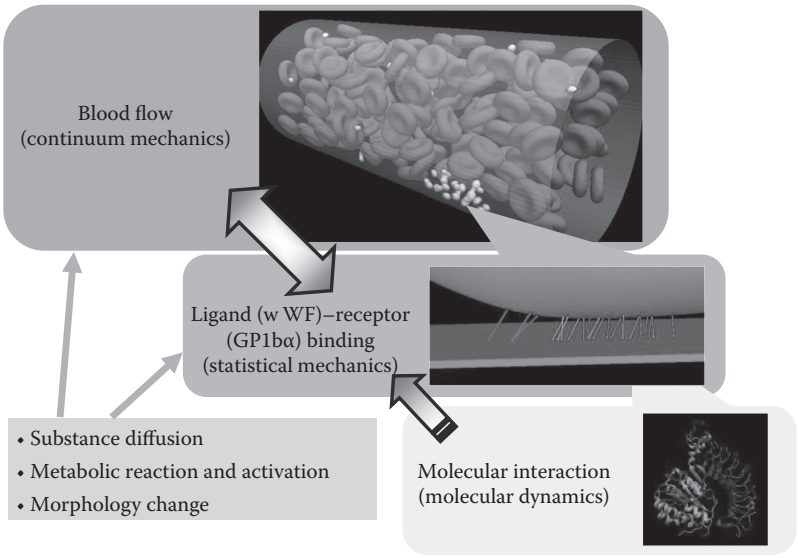

Figure 16.44

Multiscale modeling on the platelet adhesion.

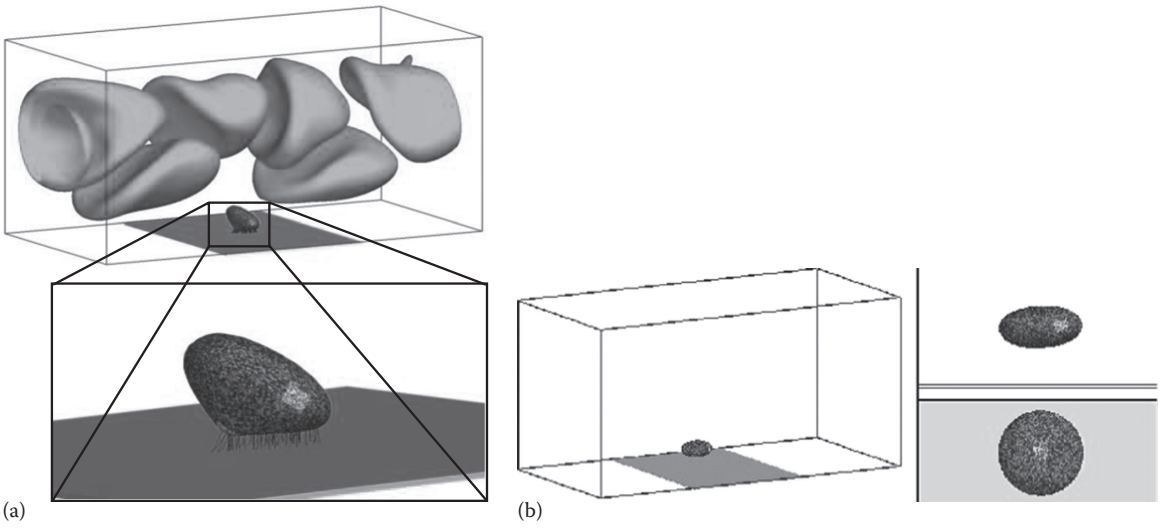

Figure 16.45

Effect of RBCs on platelet adhesion (a) with RBCs and (b) without RBCs (no adhesion).

The pressure-driven flows including the multiple RBCs and platelets in a circular tube were carried out. Figure 16.45 illustrates the time evolution of the shape of RBCs and platelets. It is well known that, in actual blood flows, RBCs tend to flow in the center of the vessels with large deformation constructing the so-called blood plasma layer and that small platelets tend to flow in this plasma layer. It was observed that once the platelets are coming closer to the vessel wall, they stay there. It is rarely observed that they go back to the center region of vessels. Next, the effect of RBCs on the adhesion of platelets is shown in Figure 16.45b. It is very interesting to see that the platelet that is initially located slightly away from the vessel wall does not come to adhere on the wall without RBCs. This is because the platelets flow with the plasma and have a low probability to come close to the vessel wall. On the other hand, in the presence of RBCs, platelets are much easier to adhere on the wall because RBCs produce the velocity fluctuation in the normal direction of the wall. This simulation results support the fact that thrombus does not glow without the presence of RBCs. In summary, in the present simulation, the molecular-scale interaction between platelets and vascular endothelium is taken into account through the molecular dynamics

simulations and the kinetic Monte Carlo simulations. Then, the interacting force obtained from the kinetic Monte Carlo simulation is coupled with the continuum scale simulation. The results illustrate that platelets are much easier to aggregate on the wall in the presence of red blood.

16.2.6 Summary

In this section, blood flows are explained with emphasis on their characteristics as dispersed multiphase flows. From the medical application point of view, microcirculation system is very important since the mass and heat transfer to the cells are given there. The blood flow behavior in microcirculation is no longer assumed to be neither Newtonian Fluid nor non-Newtonian. The behavior of each blood cell needs to be taken into account to understand the essential role of the blood flows in microcirculation systems. Due to an overwhelming number of RBCs, the fluid mechanical characteristics of blood flows in microcirculation systems are dominated by the behavior of RBCs. The several previous studies related to the blood flows in microcirculation concerns mainly about the behavior of RBCs. But from the medical point of view, the behaviors of other cells, white blood cells and platelets, are also very important. Further investigation of coupling effect between fluid mechanics and biochemical reactions inside and outside of these flowing cells is highly expected.

16.3 Biomimetics and Bioinspiration

Yoshimichi Hagiwara

16.3.1 Introduction

Biomimetics, biomimicry, and bioinspired engineering have recently emerged as keywords in engineering. These new technologies have been developed by physicists, chemists, biologists, and engineers. Table 16.1 shows examples of biomimetic or bioinspired products and systems. To date, the origins of these products have been limited to some parts of higher animals, lower animals, and plants under normal temperatures.

16.3.2 Stressors

Creatures do not usually exhibit their special abilities clearly except at times when the environment changes from its normal state. When a creature suffers, due to an external stimulus, it will be in a state of stress. These external stimuli are called stressors. Various stressors have been studied (Murofushi, 2005). The present study classifies these stressors into

1. Physical, chemical, and biological types
2. For each type, a cell level, an immobile level (such as plants and small insects), and a mobile level (such as animals) (Hagiwara, 2008)

Table 16.2 shows typical stressors in each of these categories. The creatures are threatened when the quality or quantity of the stressors exceeds a threshold. The special functions and materials of creatures appear in the defense reactions of these creatures when escaping from such situations. Thus, these functions and materials can be good hints for biomimetics and bioinspired engineering.

Table 16.1 Examples of Biomimetic Products

	Products	Origins
New surfaces	Hook-and-loop fasteners	Seeds of burdock
	Adhesive tapes	Gecko feet
	Oil-stain-free tiles	Snail shells
	Packaging foils	Lotus leaves
New shapes	Automobile body	Boxfish
	Low-noise, high-efficiency blades of wind turbine generators	Chest fins of humpback whales
	Propeller fan of air-conditioner exterior unit	Wings of eagles and albatrosses
	Sirocco fan	Wings of dragonflies
New processes	Shield tunneling method	Motion of shipworm
	Ceramics production	Abalone shells
New systems	Ventilation of office building complexes	Termite mounds
	Front nose of bullet trains	Beaks of kingfisher

Table 16.2 Various Stressors

	Cell or Organ Level	Immobile Level (Plants, Fungi, and Bacteria)	Mobile Level (Fish, Birds, and Mammals)
Physical type	Heating	Heating	Heating
	Freezing	Freezing	Freezing
	Drying	Drying	Drying
	High pressure	Flame	Flame
	Ultraviolet rays	Ultraviolet rays	Sound
			Electric current
Chemical type	High ion concentration	Strong acid or base	Medicine
	Oxygen concentration	Oxygen concentration	Toxins
	Medicine	Oils	Oxygen concentration
		Heavy metals	
Biological type	Bacillus	Bacillus	Bacillus
	Virus	Harmful insects	Virus

In the following sections, we explore research concerning both multiphase flow and biomimetic technologies. We focus on momentum and heat transfer phenomena without strong stressors in the first three subsections, while we focus on the phenomena with the strong stressors (drying and freezing) in the last two subsections.

16.3.3 Capillary Flow

Capillary flow is very efficient for heat and mass transfer in animals. The RBCs are the dispersed phase of the capillary flow. Hassanipour and Lage (2010) carried out heat transfer experiments for water flow with the particles of encapsulating phase-change material, and these experiments were inspired by alveolar capillaries. They obtained heat transfer enhancement due to the mixing of the particles.

16.3.4 Skin Separation

The surfaces of fast-swimming dolphins are affected by the high shear force of water. Thus, small pieces of skin surfaces (submillimeter in dimension) are peeled off continuously. These small pieces of skin affect the small eddies near the skin surfaces. Nagamine et al. (2004) carried out DNS for turbulent water flow near the compliant wall including the separation of pieces of the surface with time. Each piece of skin surface consisted of a cluster model of beads and connecting springs, representing the stratum cornea of dolphin skin (see Figure 16.46). The computational results showed that the compliant wall contributes to drag reduction. When the separation rate of the small pieces of skin surface is high particularly due to the flow acceleration, the separation modifies near-wall turbulence and decreases the shear stress.

16.3.5 Superhydrophobic Surfaces

Some plants have hairy exteriors, which are superhydrophobic. The surfaces of such exteriors are composed of dual micro-/nanoscale features. Neinhuis and Barthlott (1997) showed that the leaf epidermis of many highly water-repellent plants including lotus contain waxy bumps (papillae), approximately 10 μm wide, 10 μm high, and 20 μm apart, covered with nanoscale, waxy tubules. Not only the waxy tubules but also air trapped between the bumps contributes to the water repellency. Since only approximately 5% of the bump surfaces make contact with the droplets surfaces, water droplets on these leaves form near spherical shapes (see Figure 16.47a) that easily roll off, carrying with them foreign particles, such as dust (McHugh, 2010). Thus, the surfaces have self-cleaning effects.

Various methods have been explored to fabricate artificial surfaces that mimic these plant surfaces: separation of multicomponent mixtures (Shirtcliffe et al., 2007), lithography (Dorrer and Rruhe, 2006), crystal growth (Tavana et al., 2006), plasma deposition (Satyaprasad et al., 2007), and electrodeposition (Shirtcliffe et al., 2005). Various materials were used for these studies. The highest values of static contact angles, θ, for water droplets placed on the surfaces in these references were in the range of θ =160°–170°, which is nearly equal to or higher than that in the cases of the surfaces of water-repellent plants including lotuses. In some of these studies, not only the static contact angles but also the advancing contact angle and receding contact

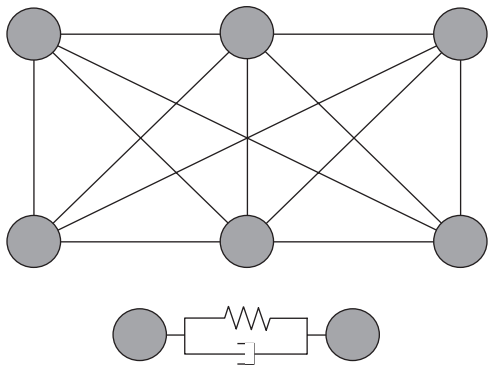

Figure 16.46

A bead–spring–dashpot model representing an aggregated fibrous part of strata corneas: the fibrous parts are replaced by thirteen connecting springs with dashpots and the nodes in the aggregated fibrous parts of corneas are replaced by six beads of the same density as that of the fluid. The bead radius is $0.3\nu/u_\tau$, the shortest spring length is $4.9\nu/u_\tau$, the spring constant is $30\rho\nu u_\tau$, and the dashpot coefficient is $7.4\rho\nu^2/u_\tau$, where ρ is the fluid density, ν is the fluid kinematic viscosity, and u_τ is the friction velocity.

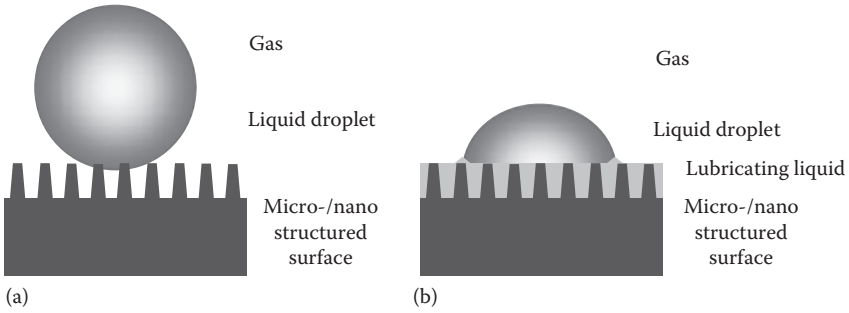

Figure 16.47

Comparison of liquid droplets on micro-/nanostructured surfaces: (a) three-phase system and (b) four-phase system. The gas–liquid–solid three-phase system is seen in lotus leaves, while the gas–liquid–liquid–solid four-phase system is seen in pitcher plants.

angle were discussed (Dorrer and Rühe, 2006, McHugh and Sohal, 2010). The discussion of these angles is useful for the understanding of droplet motion and heat transfer in spray and mist flow.

Recently, another type of superhydrophobic surfaces has been focused on: micro-/nanostructured surfaces with lubricating liquids. Wong et al. (2011) created porous surfaces infiltrated with perfluorinated liquids. These surfaces were inspired by the *Nepenthes* pitcher plants, whose inner surfaces are so slippery that insects cannot crawl up. Wong et al. obtained (1) negligible contact-angle hysteresis for the droplets of low-surface-tension liquids, (2) extreme pressure stability, and (3) optical transparency. Similarly, Solomon et al. (2014) carried out drag measurements for the laminar flow of glycerol aqueous solution over micro-/nanostructured surfaces impregnated with lubricating liquids. The drag reduction was found to depend on the ratio of the solution viscosity to the lubricant viscosity. Anand et al. (2012) conducted experiments on the dropwise condensation on the nanotextured surfaces impregnated with Krytox oils. Novel contact-line morphology of the condensate droplets could be observed due to the four-phase contacting system (Smith et al., 2012, also see Figure 16.47b). It was shown that condensate droplets became highly mobile. This lead to a continuous sweeping effect that cleared the surface for fresh nucleation and resulted in enhanced condensation.

16.3.6 Combination of Surfaces of Different Hydrophobicity

Some insects and plants living in dry areas have special surfaces for collecting water. The tenebrionid beetle living in the Namib Desert collects drinking water from early-morning fog by using its elytra surfaces (Parker and Lawrence, 2001). The peaks of the bumps of the elytra surfaces are smooth and hydrophilic, while the other areas of the surfaces have microstructures coated in wax, and are hydrophobic. The fog water droplets settle on the peaks, forming big droplets, and they are then blown to the hydrophilic peaks. Eventually, the big droplets at the peaks are detached and roll down the tilted surface to the beetle's mouth. Zhai et al. (2006) mimicked the structure by creating a hydrophilic surface with superhydrophobic coatings.

In the heat transfer of spray and mist flow, periods for the liquid contact with the heating surfaces are necessary. When the surface temperature of the horizontal heating wall is low, the deposited droplets form a liquid film. The sensible heat transfer in the liquid film is predominant. Higher heat transfer occurs with thinner films and faster film motion. Thus, the controls of thickness and motion of the liquid film are required. Yamagishi et al. (2010) created a new functional surface that consisted of a nanostructured superhydrophilic area and another hydrophilic area. They observed the liquid film on this surface and measured the temperature on the surface. Figure 16.48 shows the time changes in the temperature of wetted surfaces of a bare glass plate (hydrophilic) (Plate (a)) and a glass plate with the new surface (Plate (b)). The surface temperature reaches the lowest value when the first droplet collides with the surface. In the case of Plate (a), the temperature increases with time, but it drops slightly when the following droplets are added. This shows that the liquid film formed by the droplets is heated regardless of the deposition of successive cool droplets. Thus, the liquid film becomes a form of thermal resistance. On the other hand, the temperature recovers more noticeably until t = 22 s in the case of Plate (b). This is because the droplet moves immediately after the part of it comes into contact with the superhydrophilic part. Even during this period, however, the peak temperature decreases gradually. This suggests that a small amount of liquid still remains after the droplet moves. In the period of t = 22–36 s, the temperature does not change remarkably. This shows that the amount of remaining liquid is still small and that it does not become a form of thermal resistance during

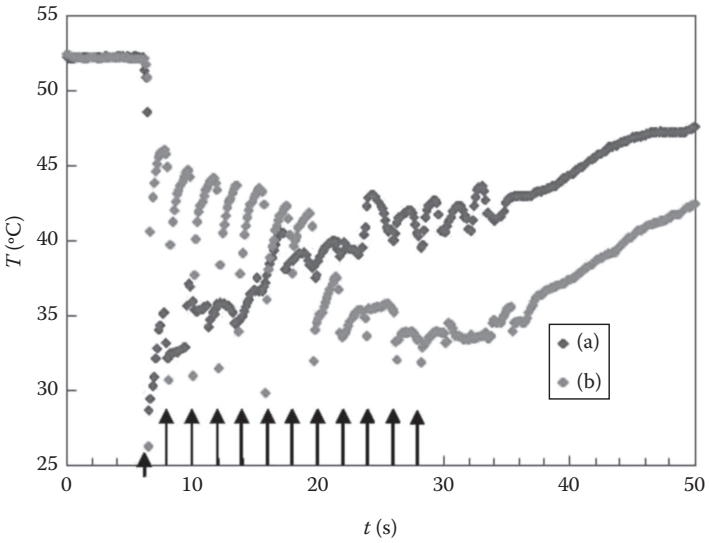

Figure 16.48

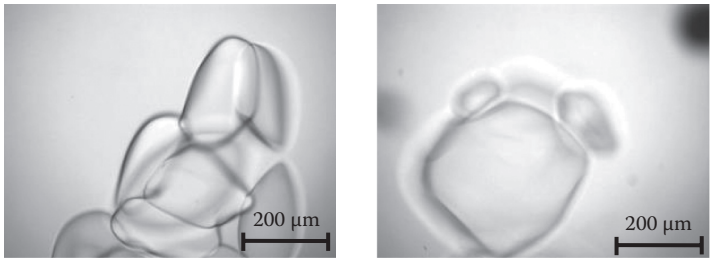
Time changes in the temperature of wetted surfaces of a bare glass plate (hydrophilic) (Plate (a)) and a partially modified glass plate (Plate (b)). The chemical-bath deposition method was adopted for the surface modification. Approximately 30% of the surface is covered with numerous pins of nanoorder sizes. This modified part is superhydrophilic. The heat flux was $q_w = 356$ W/m^2. The heat flux from the plate surface to the air was measured by using a heat flux meter. Fifteen droplets of 350 μL in total volume were dropped every 2 s. The arrows in this figure depict the instants of dropping. The surface temperature, *T*, was measured with an infrared camera. A calibration was carried out between the temperature measured with the infrared camera and that measured with a thermocouple attached to the plate surface.

the period. Thus, the local, instantaneous heat transfer coefficient in the case of the new surface was higher than that of the hydrophilic surface after 22 s (Yamagishi et al., 2010).

Betz et al. (2013) and Takata et al. (2013) carried out experiments on pool boiling from the hybrid surfaces of hydrophilic areas and hydrophobic areas. They obtained the pool boiling enhancement and high heat transfer characteristics in specific cases.

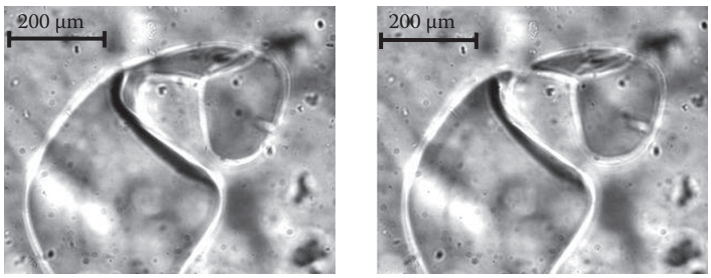


16.3.7 Ice Growth Inhibitors

Some species of fish, insects, plants, fungi, and bacteria have an ice growth inhibitor called antifreeze protein or antifreeze glycoprotein. In the experiments on solutions of these antifreeze substances under thermodynamically quasi-equilibrium states, the freezing point is depressed, while the melting point is retained (Fletcher et al., 1999). Thus, at a temperature between the two points, ice crystals do not grow in a regular way but form peculiar shapes.

Experiments were also carried out for the unidirectional freezing of protein solutions under thermodynamically nonequilibrium states. Furukawa et al. (2005) observed a serrated interface pattern. Hagiwara and Yamamoto (2012) measured the temperature field noninvasively and showed that the balance of heat flux near the bottom edge of the serrated interface was obtained by taking account of heat convection due to high-concentration regions of antifreeze protein, not only protein adsorption to the interface but also the heat conduction/convection contributed to the modification of ice growth.

The antifreeze protein is also effective for the modification of ice particle motion in ice slurry flow. Onishi et al. (2012) measured the motion of ice particles in ice slurry flow in a horizontal minichannel (the cross-sectional area of which was 1×0.7 mm^2). It was found that adding antifreeze protein attenuated the aggregation of ice particles in the flow (see Figure 16.49). A second finding was that the velocity of cluster of ice particles in the saline solution with the protein was lower than that in the saline solution only. This is because a small cluster resulted from the ice/protein interaction being transported near the upper wall of the channel where the mean flow velocity is low.



Taira et al. (2014) carried out the observation of the ice slurry in the flow of a mixture of saline solution and preheated protein solution. It was found that cracks appeared on the surface of the ice particles (see Figure 16.50). Furthermore, it was found that the velocity and volume of the ice particle clusters are much higher in the case of the preheated protein solution than those in the case of unheated protein solution.

(a) (b)

Figure 16.49

Typical images of clusters of ice particles in the ice slurry flows: (a) in the case of the saline solution (the concentration is c = 0.90 wt%) and (b) in the case of the equal-volume mixture of saline solution and the antifreeze protein solution (the concentration is c = 0.25 mg/mL). The focus was on the midplane of the horizontal minichannel. When the antifreeze protein solution was added, the ice particles became square and the clusters of ice particles became small. This proves that antifreeze protein inhibits the aggregation of ice particles.

(a) (b)

Figure 16.50

Time change in the shape of a cluster of ice particles in the case of the mixture of saline solution and the heated antifreeze protein solution (heated at 80°C for 3 h): (a) t = 0 s and (b) t = 2.12 s. The cluster, in which the ice particles were adsorbed, broke due to the protein and protein aggregates.

The modification of protein structure and the protein aggregates (submicron in dimension) due to the preheating of the protein solution are thought to be the reasons for these changes (Miyamoto et al., 2016).

16.3.8 Concluding Remarks

We have exposed the readers to several biomimetic or bioinspired pieces of research related to multiphase dispersed flows. In-depth discussion on various aspects of this topic will take place in the near future and will result in significant inventions and products.

Fluidized Bed Reactors

17.1 Hydrodynamics of Fluidization
17.2 Heat and Mass Transfer
17.3 Applications of Fluidized Bed Reactors

17.1 Hydrodynamics of Fluidization

John R. Grace

17.1.1 Key Properties Affecting Fluidization Hydrodynamics

Fluidization occurs when gas or liquid is forced to flow vertically through a bed of particles at such a rate that the buoyed weight of the particles is completely supported by the drag force imposed by the fluid. The particles are then able to move relative to one another. When fluidization occurs, the bed of particles gains the appearance and many properties of a true liquid or fluid. The term "fluidization" reflects this conferring of fluid-like properties onto the solid particles, much as the term liquefaction is used to denote the act of making liquid or conferring liquid properties.

Most applications of fluidized beds are for cases where the fluidizing fluid is a gas rather than a liquid. Hence, except where liquid-fluidized and gas–liquid–solid (three-phase) beds are considered explicitly in the following sections, this chapter is devoted to consideration of fluidized beds where the fluidization is caused by upward flow of a gas.

As detailed in Section 17.3, fluidized beds have many applications. These take advantage of a number of useful features such as low-pressure drops (relative to packed beds), temperature uniformity, excellent surface-to-bed heat transfer, the ability to accommodate a wide range of particle properties, and the capability of handling limited quantities of liquids (e.g., sprayed reactants). Desirable (in some cases necessary) properties of particles and gas for fluidized beds are delineated in Table 17.1. Observing the guidelines with respect to desirable properties will generally lead to good-quality fluidization. It is sometimes possible to extend the range of particle properties, which can be fluidized. For example, the ability to fluidize fine-powders can be enhanced by such means as gentle vibration or stirring, high velocity to cause elementary particles to agglomerate into particles of more favorable sizes, using a tapered bed (larger cross section with increasing height), or some combination of these factors (Deiva et al., 2002).

Geldart (1973) proposed a popular classification scheme for particles fluidized in air under atmospheric conditions. Four powder groups were suggested in order to distinguish broad types of behavior. These four groups (A, B, C, and D) are frequently referred to in the literature. Boundaries between adjacent groups for fluidization by air at room temperature and atmospheric pressure are shown in Figure 17.1. Later, this classification was extended (Grace, 1986a) to cover gases other than air as well as operating temperatures and pressures other than atmospheric. The characteristics of the four groups and criteria to distinguish

Table 17.1 Desirable Properties of Particles and Gases for Gas–Solid Fluidization

Property	Desirable Range	Comments
Particle properties		
Mean diameter[a]	50 μm to 1.6 mm	Finer particles are too cohesive; coarser ones give less desirable fluidization properties.
Size distribution[b]	Neither too narrow nor too broad, e.g., 90th to 10th decile ratio 5–25	Too narrow distribution gives less desirable fluidization properties; too broad a distribution results in particle segregation.
Density	Wide range of values possible, but uniform from particle to particle	Density differences among particles can cause segregation; very low-density materials (e.g., <500 kg/m^3) may be difficult to retain in the bed.
Shape	Rounded and with length-to-thickness ratio no larger than ~3	Avoid extreme shapes like disks and needles, which inhibit fluidization; sharp corners and edges can cause excessive wear of surfaces.
Surface roughness	Smooth	Some roughness is tolerable.
Surface stickiness	Avoid sticky surfaces	Stickiness causes agglomeration and fouling.
Attrition resistance	Usually strong as possible	Particles typically spend hours in the bed; they must withstand the stresses of the bed.
Hardness	Avoid resilience, but also excessive hardness	Compressible particles give excessive interparticle forces; very hard ones tend to cause excessive wear of the equipment components.
Gas properties		
Density	No restriction, but higher value improves properties	High pressure results in improved fluidization characteristics.
Viscosity	No restriction	
Relative humidity	Typically 10%–90%	Below ~10% RH, electrostatics may well be excessive; above ~90%, capillary forces tend to be dominant.

[a] The mean diameter is conventionally defined as $1/\Sigma\,(x_i/d_{pi})$, where x_i is the mass fraction of particles of mean size d_{pi}, usually obtained from the arithmetic average sieve opening in a sieve analysis.

[b] Note that the size distribution in the bed at any point will, in general, differ from the feed or original size distribution due to factors such as attrition, elutriation, and agglomeration.

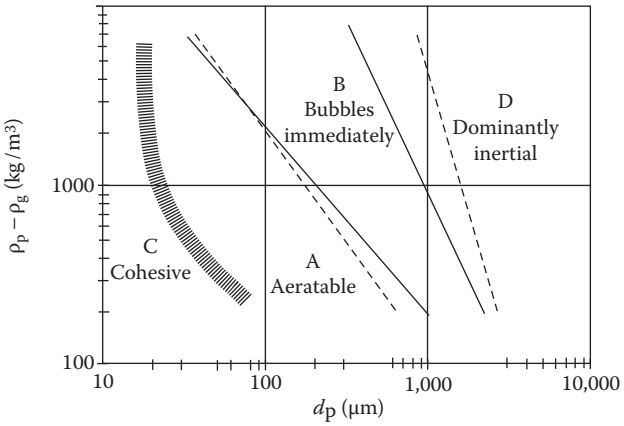

Figure 17.1

Geldart powder groups for fluidization by air at room temperature and atmospheric pressure. CA boundary is typical, but varies with properties such as moisture content of the particles. Solid lines give AB and BD boundaries as suggested originally by Geldart (1973). Dashed lines are AB and BD boundaries from Equations 17.1 and 17.2, respectively.

them are summarized in Table 17.2. Group C particles are usually inappropriate for fluidization due to excessive interparticle forces, whereas groups A, B, and D can be fluidized and used in practical applications. Criteria to distinguish among the powder groups are as follows.

CA boundary. This boundary can be thought of as dividing systems where interparticle forces are so strong that normal fluidization is impossible from those where unaided fluidization is possible, despite significant interparticle forces. It is the most difficult boundary to predict since it depends on a number of nonhydrodynamic factors, such as electrostatic charges and relative humidity, which can affect interparticle forces, primarily caused by van der Waals forces. There is no generally applicable equation. For useful discussion, see Visser (1989). For a review of interparticle forces in fluidized beds, see Seville et al. (2000). In recent

Table 17.2 Powder Groups and Their Key Characteristics

Group	Mnemonic	Example	Key Features	Interparticle Forces Relative to Weight–Buoyancy	Typical Particle Size (μm)
C	Cohesive	Flour	Fluidize poorly due to strong interparticle forces; show channeling	Dominant	<30
A	Aeratable	Fluid cracking catalyst	Excellent fluidization; small bubbles; deaerate slowly when gas flow stopped; high bed expansion, rapid particle mixing	Appreciable	~30–100
B	Bubble readily	Normal sand	Deaerate quickly when gas is shut off; large bubbles; intermediate solids mixing	Negligible	~100–800
D	Dominantly inertial	Peas	Deaerate quickly when gas is shut off; large bubbles; relatively poor solids mixing	Negligible	>800

Sources: Geldart, D., *Powder Technol.*, 7, 285, 1973; Grace, J.R., *Can, J. Chem. Eng.*, 64, 353, 1986a.

years, there has been considerable interest in fluidizing nanoparticles, involving formation of agglomerates, which then act like primary particles (e.g., Zhu et al., 2005, van Ommen et al., 2010).

AB boundary. The AB boundary distinguishes systems where interparticle forces are significant (but not dominant, group A) from those (group B) where interparticle forces do not play a significant role. Data for this boundary for various gases, including air, and for different temperatures and pressures have been correlated (Grace, 1986a) by

$$Ar_{AB} = \left| \frac{g\rho_g(\rho_p - \rho_g)d_p^3}{\mu_g^2} \right|_{AB\ boundary} = 1.0\times10^6\{(\rho_p - \rho_g)/\rho_g\}^{-1.275} \tag{17.1}$$

BD boundary. This boundary separates systems where the flow through the particles is dominated by viscous forces from those where inertial effects are dominant. The boundary between groups B and D can therefore be based on whether the flow through the particulate phase is laminar or turbulent, leading (Grace, 1986a) to

$$Ar_{BD} = \left| \frac{g\rho_g(\rho_p - \rho_g)d_p^3}{\mu_g^2} \right|_{BD\ boundary} = 1.45\times10^5 \tag{17.2}$$

17.1.2 Flow Regimes and Their Transitions

Gas-fluidized beds show a number of distinct flow regimes. The principal ones appear schematically in Figure 17.2 for increasing superficial gas velocity and a column of high height/diameter ratio equipped to return essentially all of the particles entrained from the top. A corresponding flow regime diagram is shown in Figure 17.3 for cases where the column is large enough that the slug flow regime (see Section 17.1.5) is never reached. This form of regime diagram is convenient because the abscissa is simply a dimensionless particle diameter, whereas the ordinate is a dimensionless superficial gas velocity. Approximate boundaries between the powder groups introduced in the previous section are also shown in the figure. Details of the transitions between the flow regimes are considered in the rest of this section.

17.1.2.1 Minimum Fluidization

Consider a bed of solid particles in a cylindrical containing vessel whose bottom is permeable, with gas forced upward through it. The details of the base plate, usually called a "distributor," "distribution plate," or "grid," are considered in Section 17.1.10. As noted earlier, fluidization requires that the pressure drop across the beds matches the buoyed weight of the particles, so that

$$\frac{dP}{dz} = -(\rho_p - \rho_g)(1 - \langle\varepsilon\rangle_A)g \quad \text{or} \quad \Delta P_{bed} = (\rho_p - \rho_g)(1 - \langle\varepsilon\rangle_{av})gH \tag{17.3}$$

where $\langle\varepsilon\rangle_A$ and $\langle\varepsilon\rangle_{av}$ are the volume fraction of gas (usually called "voidage") averaged over the cross-sectional area and the entire bed volume, respectively, while H is the expanded bed depth. If one neglects

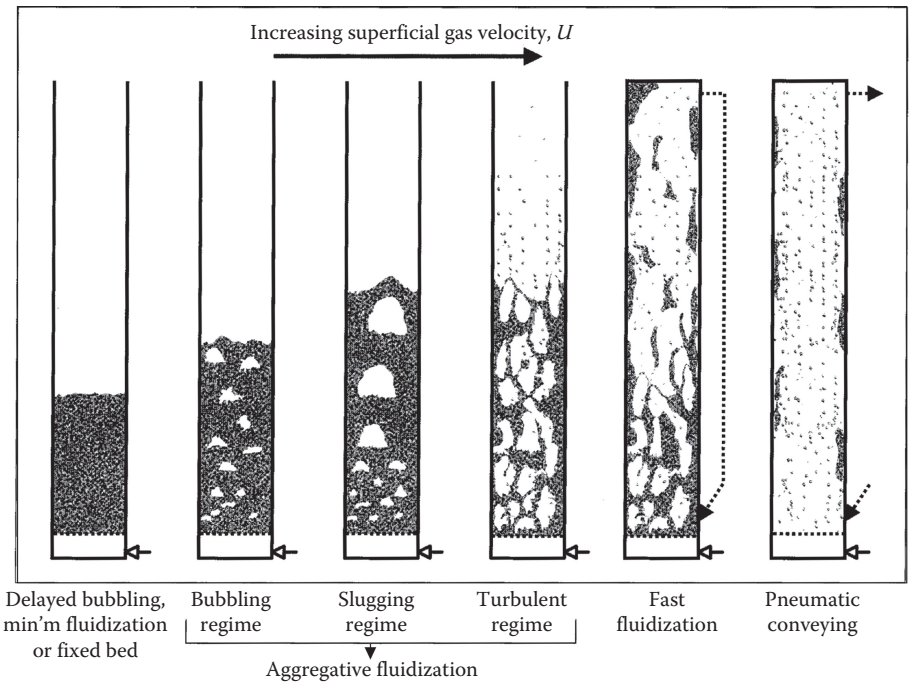

Figure 17.2

Schematic representation showing appearance of flow regimes relevant to gas–solid fluidization.

contributions of wall friction and acceleration to the pressure drop, as it is usually possible to do, this equation should apply no matter what the flow regime. In effect, the time-mean pressure varies as in a static liquid of density $(\rho_p - \rho_g)(1 - \langle\varepsilon\rangle_A)$. In practice, Equation 17.3 is generally accurate for well-fluidized materials in cylindrical columns (with vertical walls). Except in high-density circulating fluidized beds (CFBs) (see Section 17.1.7.2), where wall friction and acceleration terms can be appreciable, deviation by more than approximately ±5% from Equation 17.3 usually indicates "channeling" (i.e., the gas finds fissures or other fixed passages through stationary particles) or other poor gas distribution in the column. Note that Equation 17.3 is also valid for liquid-fluidized beds with the gas density, ρ_g, then replaced by the liquid density, ρ_l.

Pressure drops in fixed beds are commonly predicted by the Ergun equation

$$\Delta P_{\text{fixbed}} = \frac{150\mu_g U(1-\langle\varepsilon\rangle_{av})^2}{\psi^2 d_p^2 \langle\varepsilon\rangle_{av}^3} + \frac{1.75\rho_g U^2(1-\langle\varepsilon\rangle_{av})}{\psi d_p \langle\varepsilon\rangle_{av}^3} \tag{17.4}$$

where

U is the "superficial gas velocity" (total gas volumetric flow rate divided by total column cross-sectional area)

Ψ is a particle shape factor called the sphericity, defined as the surface area of a volume-equivalent sphere divided by the true external surface area of the particle

Transition from a fixed bed to a fluidized bed occurs when the pressure drop across a loosely packed fixed bed reaches the value given by Equation 17.3. Hence, one can estimate the superficial velocity, U_{mf}, at the transition between a fixed and fluidized bed, called the "minimum fluidization velocity," by solving the quadratic equation obtained when the right-hand sides of (17.3) and (17.4) are equated. The result is then an equation of the form

$$Re_{mf} = \frac{\rho_g d_p U_{mf}}{\mu_g} = \sqrt{C_1^2 + C_2 Ar} - C_1 \tag{17.5}$$

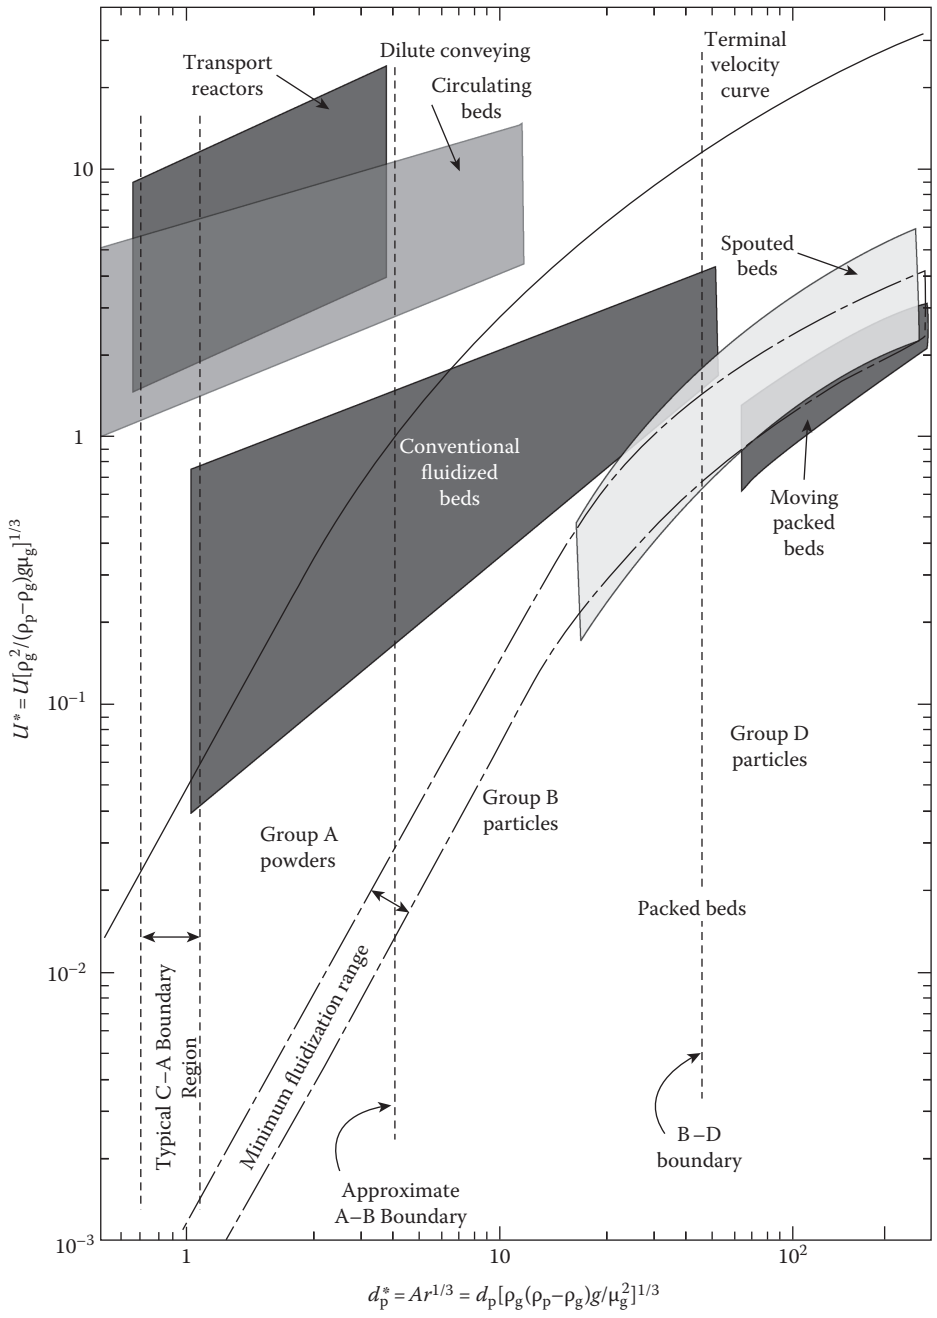

Figure 17.3

Dimensionless flow regime map for upward gas flow through solid particles diagram. Column diameter is assumed to be significantly larger than any bubbles formed, so that slug flow regime is excluded in this diagram. (Adapted from Grace, J.R., *Can. J. Chem. Eng.*, 64, 353, 1986a.)

where

$$Ar = \frac{g\rho_g(\rho_p - \rho_g)d_p^3}{\mu_g^2} \tag{17.6}$$

Different values of the constants, C_1 and C_2, are available in the literature, with the most popular being $C_1 = 33.7$ and $C_2 = 0.0408$, as recommended by Wen and Yu (1966). Typically, this equation predicts the minimum fluidization velocity no better than within approximately ±25%, so it is best to measure it

experimentally whenever possible. The most common method of measurement requires that the pressure drop across the bed be recorded as the superficial velocity is increased stepwise through U_{mf} and beyond; U_{mf} is then taken at the intersection of the straight lines corresponding to the fixed-bed and fluidized-bed portions of the graph obtained when ΔP_{bed} is plotted against U on log–log coordinates. While measuring U_{mf}, it is important to also determine the bed voidage at minimum fluidization, ε_{mf}, requiring that one find the mass, M_p, of the particles, the bed height, H_{mf}, at minimum fluidization, and the particle density, ρ_p, with

$$\varepsilon_{mf} = 1 - M_p/\left(\rho_p A H_{mf}\right) \tag{17.7}$$

Figure 17.4 plots minimum fluidization velocities for particles of different mean diameters and densities fluidized by air at room temperature and atmospheric pressure, based on Equations 17.5 and 17.6 with the C_1 and C_2 values given. As expected, U_{mf} increases with increasing particle diameter and increasing particle density.

Equation 17.5 can be simplified when the particles are either small (low Ar) or large (high Ar). With the C_1 and C_2 values specified earlier, then

$$\text{for } Ar < 10^3: \quad Re_{mf} = 6.1\times10^{-4} Ar \quad \text{or} \quad U_{mf} = 0.00061\frac{g(\rho_p - \rho_g)d_p^{\,2}}{\mu_g} \tag{17.8}$$

$$\text{for } Ar > 10^7: \quad Re_{mf} = 0.202 Ar^{0.5} \quad \text{or} \quad U_{mf} = 0.20\sqrt{\frac{g(\rho_p - \rho_g)d_p}{\rho_g}} \tag{17.9}$$

In all of these expressions, d_p is the mean particle diameter, as defined in the footnote of Table 17.1. Equations 17.5 through 17.9 can also be used for liquid-fluidized beds with ρ_g replaced by ρ_l. Equations 17.8 and 17.9 are important not only because they are useful in their own right for small and large particles, respectively, but also because they show the influence of key variables on U_{mf}. For example, for small particles fluidized by gases, pressure is seen to have virtually no effect, whereas U_{mf} decreases with increasing temperature,

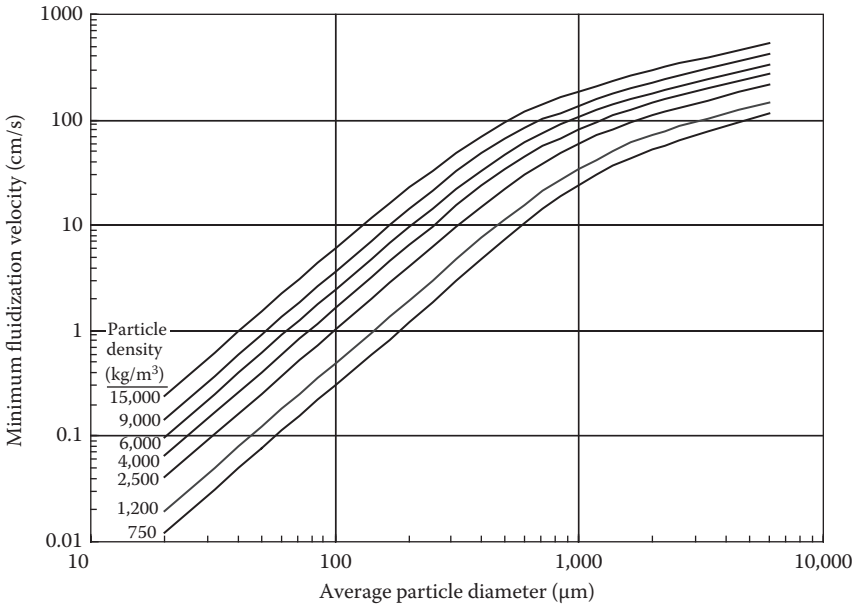

Figure 17.4

Minimum fluidization velocity vs. particle diameter for particles of different densities fluidized by air at atmospheric temperature and pressure.

and it is proportional to the square of the mean particle diameter. On the other hand, for large particles, U_{mf} decreases with an increasing pressure for gas fluidization, increases with increasing temperature, and is proportional to the square root of the mean particle diameter. Equations 17.8 and 17.9 are also notable, because they are identical, except for the coefficients, to expressions for terminal settling velocities of small and large spherical particles of diameter d_p in Newtonian fluids. For small spherical particles ($Ar < 10^3$), Stokes law replaces 6.1×10^{-4} in Equation 17.8 by 1/18, meaning that the terminal settling velocity is approximately 90 times U_{mf}, suggesting a relatively wide range for fluidization before significant entrainment of particles occurs. For large particles ($Ar > 10^7$), where the coefficient in a terminal-velocity equation (Clift et al., 1978) of the form of Equation 17.9 is 1.73, the corresponding V_s/U_{mf} ratio is only 8.6.

17.1.2.2 Overview of Flow Regimes

As the superficial gas velocity, U, is increased stepwise beyond U_{mf} for a bed of solid particles, one encounters a number of different flow regimes. In the most general case, they are in order of increasing U:

- Bubble-free bed expansion (Section 17.1.3)
- Bubbling fluidization (Section 17.1.4)
- Slug flow (Section 17.1.5)
- Turbulent fluidization (Section 17.1.6)
- Fast fluidization and dense suspension upflow (DSU) (Section 17.1.7)

These flow regimes are shown diagrammatically in Figure 17.2, together with dilute pneumatic conveying, reached at even higher gas velocities.

17.1.2.3 Minimum Bubbling Velocity

For particles in groups B and D of the Geldart classification (see Section 17.1.1), bubbling begins as soon as U exceeds U_{mf}. The minimum bubbling velocity, U_{mb}, is then equal to U_{mf}. For group A powders, on the other hand, there is an appreciable gap between these two. Since interparticle forces play a role in determining U_{mb}, correlations in terms of purely hydrodynamic quantities are not very successful. A dimensional correlation due to Abrahamsen and Geldart (1980) gives

$$U_{mb} = 2.07 \exp\{0.176\chi\} \frac{d_p \rho_g^{0.06}}{\mu_g^{0.347}} \tag{17.10}$$

where

χ is the fraction by mass of particles finer than 45 μm (from a sieve analysis)
d_p is again the mean particle diameter defined as in the footnote of Table 17.1

Note that U_{mb} cannot be less than U_{mf}, so that if the value calculated from Equation 17.10 < U_{mf} obtained from Section 17.1.2.1, then set $U_{mb} = U_{mf}$ from Equations 17.5, 17.8, or 17.9.

17.1.2.4 Minimum Slugging Velocity

Slugs are gas bubbles large enough for their volume-equivalent diameters to exceed about 50% of the column diameter. In order for slug flow to occur in fluidized beds, several conditions must be satisfied:

- The ratio of expanded bed depth to column inside diameter (H/D) must be sufficient to give the bubbles enough distance in which to coalesce to voids of a size large enough to be considered slugs. This requires (Darton et al., 1977)

$$\frac{H}{D} \geq 3.5\left(1 - N_{or}^{-0.5}\right) \tag{17.11}$$

- The maximum stable bubble diameter for the particle/gas system (see Section 17.1.4.1) must be of the same order as D or greater.

If both these conditions are met, the superficial gas velocity at minimum slugging is (Stewart and Davidson, 1967)

$$U_{ms} = U_{mf} + 0.07\sqrt{gD} \tag{17.12}$$

For columns of noncircular cross section, D is replaced by the hydraulic diameter, $D_h = 4A/P_c$, where P_c is the column perimeter. This substitution works less well when the width-to-thickness ratio falls outside the range of ~0.4–2.5.

17.1.2.5 Onset of Turbulent Fluidization

Turbulent fluidization occurs when, as U is increased, a point is reached where the bubbles or slugs, instead of continuing to increase in size, begin to break down. The "critical velocity," U_c, which demarcates the onset of the turbulent fluidization flow regime, is usually determined experimentally as the superficial gas velocity at which the standard deviation of pressure fluctuations reaches a maximum. Unfortunately, U_c tends to vary also with level in the bed. Moreover, gage pressure readings lead to different values of U_c than differential pressure measurements. Gage signals register fluctuations from distant locations (including those due to bed surface oscillations and bubble formation), as well as local features, whereas differential signals filter out most information arising from outside the interval between the pair of pressure taps across which the pressure readings are being recorded.

Most correlations of U_c are of the form

$$Re_c = \frac{\rho_g d_p U_c}{\mu_g} = B\,Ar^{\eta} \tag{17.13}$$

Values of $B = 0.565$ and $\eta = 0.461$ are recommended based on a wide range of data for absolute pressure fluctuations (Bi et al., 2000). However, equations of this form fail to include the influence of H/D ratio, which can be significant for relatively shallow beds. A correlation (Ellis et al., 2004) taking this into account and covering columns up to a diameter of 1.6 m is

$$Re_c = \frac{(H/D)^{0.43} Ar^{0.74}}{\sqrt{4.2(H/D)^{0.86} + 3.1Ar^{0.33}}} \tag{17.14}$$

17.1.2.6 Onset of Fast Fluidization Flow Regime

As the superficial gas velocity is increased further, a superficial velocity, called the transport velocity, U_{tr}, is reached where there ceases to be a "bed," that is, there is so much entrainment that there is no distinct upper bed surface. Massive recycling of solids is then required to maintain a large number of particles in suspension. Particles are carried upward in the core of the column and then descend as streamers and clusters along the outer wall. The transition to fast fluidization corresponds to onset of "significant entrainment" and can be predicted (Bi et al., 1995) from

$$Re_{se} = 1.53Ar^{0.5} \quad \text{or} \quad U_{se} = 1.53\sqrt{\frac{g(\rho_p - \rho_g)d_p}{\rho_g}} \tag{17.15}$$

This equation is of the same form as Equation 17.9, which, as noted, is also identical to the expression for terminal settling velocities of large spheres, except for its different constant coefficient. For cases (which only occur for relatively large particles) where the U_{tr} predicted from Equation 17.15 is less than the corresponding terminal settling velocity, V_s, of particles of mean size, U_{tr} should be taken to be equal to V_s.

17.1.2.7 Onset of Dense Suspension Upflow

DSU occurs when, in addition to having a large superficial gas velocity, there is also a high net particle circulation flux, G_s, sufficient to cause the time-mean flux of solids to be upward over the entire column cross

section and the solid's volume fraction is 7% or more (Grace et al., 1999). The transition condition where this occurs is a function of both U and G_s. Kim et al. (2004a) suggest that the onset occurs at

$$\frac{U_{DSU}}{\langle\varepsilon\rangle_A V_s} = 22.8\left\{\frac{G_s}{\rho_p(1-\langle\varepsilon\rangle_A)V_s}\right\}^{0.59} Ar^{-0.20} \tag{17.16}$$

Since the cross-sectional average voidage, $\langle\varepsilon\rangle_A$, varies with height, as discussed in Section 17.1.7.1, regions of fast fluidization and DSU can coexist in the same column.

17.1.2.8 Transition from Fast Fluidization to Dilute Pneumatic Conveying

At high gas velocities and solids holdups $\lesssim$7%, particles are conveyed upward throughout the entire crosssection of a riser column, and the dilute pneumatic conveying flow regime is reached. This condition again demarcates termination of fast fluidization. The transition superficial velocity has been correlated (Kim et al., 2004a) by

$$\frac{U_{DPC}}{\langle\varepsilon\rangle_A V_s} = 1160\left\{\frac{G_s}{\rho_p(1-\langle\varepsilon\rangle_A)V_s}\right\}^{-0.90} Ar^{-0.20} \tag{17.17}$$

As in the previous case, it is seen that this transition is a function of the cross-sectional average voidage, which varies with height in risers, so that transition can again occur within the riser (part way up).

17.1.3 Particulate and Bubble-Free Fluidization

Almost all liquid-fluidized beds expand smoothly without bubbles when the superficial velocity of the fluidizing fluid is increased beyond U_{mf}. This has commonly been called "particulate" or homogeneous fluidization, in contrast to so-called aggregative fluidization (involving division into distinct dilute and dense regions or phases), which occurs for almost all gas-fluidized beds, including all those of practical importance. Particulate beds, gently and homogeneously fluidized by liquids in this manner, are also sometimes referred to as "expanded beds." In practice, the expansion is not perfectly homogeneous, but regions of somewhat increased and decreased voidage propagate slowly enough that beds of practical height can be considered to be homogeneous. An extensive review of liquid fluidization was published by Epstein (2003b). As already noted, the pressure drop, U_{mf}, and ε_{mf} can be predicted by the same relationships as for gas-fluidized beds in Section 17.1.2.1, with the gas density ρ_g replaced by the liquid density ρ_l. The bed expansion can be predicted from the relationship

$$H = H_{mf}\frac{1-\varepsilon_{mf}}{1-\langle\varepsilon\rangle_{av}} \tag{17.18}$$

where the volume-average bed voidage (or liquid fraction) is estimated from an empirical equation suggested by Richardson and Zaki (1954):

$$\langle\varepsilon\rangle_{av} = \left\{\frac{U}{kV_s}\right\}^{1/n} \tag{17.19}$$

with the exponent n and the coefficient k obtained from empirical relationships (Khan and Richardson, 1989)

$$\frac{4.8-n}{n-2.4} = 0.043Ar^{0.57} \quad \text{and} \quad k = 1-1.15\left\{\frac{d_p}{D}\right\}^{0.6} \tag{17.20}$$

These equations are derived from experimental data covering a broad range of conditions, $0.01 < \rho_l d_p V_s/\mu_l < 7000$ and d_p/D up to 0.2. Caution should be exercised for voidages greater than about 0.85 where significant deviations can occur (Epstein, 2003b).

As we have seen in Section 17.1.2.3, gas-fluidized beds of group A particles experience a range of conditions for which $U_{mf} \leq U < U_{mb}$, where the bed expands without bubbles. Since the interstitial gas travels more slowly than bubbles would rise in the same beds, the expansion is greater for given values of U in this range than would be the case if U were to have exceeded U_{mb}. While this range is also often referred to particulate fluidization, there are significant differences between gas-fluidized beds in this range and liquid-fluidized beds (Martin, 1983). The most notable difference is that interparticle forces play a significant role in gas-fluidization case, whereas they are of little or no importance for liquid-fluidized beds.

Bubble-free gas fluidized beds are of little practical importance because of the low gas velocities. However, it is helpful to be able to predict the bed expansion at the minimum bubbling point. Abrahamsen and Geldart (1980) give

$$\frac{H_{mb}}{H_{mf}} = \left(\frac{U_{mb}}{U_{mf}}\right)^{0.22} \tag{17.21}$$

with U_{mf} and U_{mb} obtained from the relationships and procedures described earlier.

17.1.4 Bubbling Fluidization

This section considers the hydrodynamics of the bubbling flow regime, which extends from U_{mb} (Section 17.1.2.3) at the lower limit to either U_{ms} (Section 17.1.2.4) or U_c (Section 17.1.2.5), depending on whether or not slug flow is encountered before reaching the turbulent fluidization flow regime. The bubbles, also often called "voids," form in gas-fluidized beds, because a homogeneous bed is unstable to perturbations once $U \geq U_{mb}$. The bubbles themselves are analogous to spherical-cap bubbles in liquids (Clift et al., 1978). Surrounding the bubbles is a "dense-phase," composed of particles and interstitial gas, acting (Grace, 1970) like a non-Newtonian liquid with an effective viscosity of order 0.1–1 Pa·s, 2–3 orders of magnitude greater than the viscosity of liquid water. As shown in Figure 17.5, the resulting bubbles are well rounded, with total included wake angles (Rowe and Partridge, 1965) of ~200°–260°. The wake approximately completes the base of the sphere, and plays a very important role in determining solids mixing, as discussed in the following. Note that the boundaries of bubbles, unlike those of bubbles in liquids, are permeable. Given the lower pressure at the top of the bubble than at the bottom, an observer riding upward with the bubble on its inside would experience an updraught, often referred to as "throughflow." This plays a vital role in determining mass transfer between the bubbles and surrounding dense phase, while

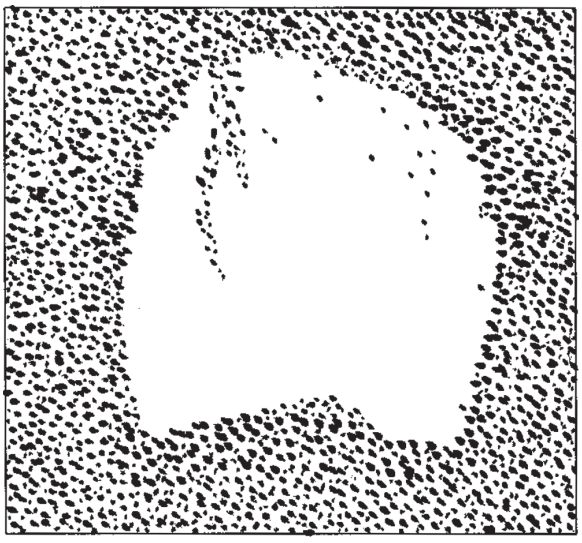

Figure 17.5

Shape of a typical isolated bubble in a three-dimensional fluidized bed. (Based on x-ray photograph of Rowe, P.N. and Partridge, B.A., *Trans. Inst. Chem. Eng.*, 43, 157, 1965.)

stabilizing the roof of the bubble against collapse. Note that there is no load-bearing arch on the bubble roof (Rowe, 1964). In fact, the voidage around the periphery tends to be a little higher than elsewhere in the dense phase (Lockett and Harrison, 1967).

17.1.4.1 Bubble Properties and Bed Expansion in Freely Bubbling Bed without Tubes

The volumetric flow accounted for by the displacement of bubbles or voids rising in the bed can be written as follows:

$$\dot{V}_b = Y(U - U_{mf})A \tag{17.22}$$

Originally, it was assumed that $Y = 1$, and this simple equation, implying that all the gas beyond that required to just fluidize the bed travels as bubbles, is commonly referred to as the "two-phase theory of fluidization." The literature data obtained by many laboratories using various experimental techniques have indicated, however, that Y is usually <1 in practice. Typically, one can assume $Y \approx 0.8$ for group A particles, ~0.7 for group B solids, and ~0.3 for group D particles.

There are a number of empirical and semiempirical equations for predicting the mean bubble size as a function of height in fluidized beds. The approach due to Darton et al. (1977) usually works well for cylindrical columns without any internal tubes or baffles. This considers chains of bubbles rising from the distributor and coalescing pair-wise up the bed. The mean bubble diameter as a function of height, z, is then given (Darton et al., 1977) by

$$D_b(z) = \frac{0.54\left(U - U_{mf}\right)^{0.4}\left(z + 4.0\sqrt{A_c}\right)^{0.8}}{g^{0.2}} \tag{17.23}$$

where A_c is the area of the distributor plate per orifice in the distributor. This equation is intended for cases where bubbles form right at the gas distributor and where the particles are large enough (essentially group B and D solids) that negligible bubble splitting occurs. For group A solids, bubbles commonly reach a "maximum stable diameter," where there is a dynamic equilibrium between bubble coalescence and splitting. This imposes an upper limit on the bubble diameter. The maximum stable bubble diameter can be estimated (see Grace, 1982) by

$$D_{bmax} = 2.0(V_s^e)^2/g \tag{17.24}$$

where V_s^e is the terminal settling velocity of a particle of diameter $2.7d_p$ in the fluidizing gas at the same pressure and temperature as in the bed. An alternative approach, which accounts for bubble splitting as well as coalescence, was suggested by Horio and Nonaka (1987). As suggested by these authors, the height coordinate, z, should be taken from the termination of gas jets in cases where vertical jets form at the distributor (see Section 17.1.10).

Once the mean bubble diameter has been estimated as a function of height from Equation 17.23, subject to the constraint imposed by Equation 17.24, it is then possible to calculate the corresponding bubble rise velocity from

$$U_b(z) = 0.71\sqrt{gD_b(z)} + (U - U_{mf}) \tag{17.25}$$

The first term accounts for the velocity of rise of a spherical-cap bubble with a typical wake angle, whereas the second term corrects, in an approximate manner, for bubble interaction effects inside the bed (Grace and Harrison, 1969).

With the estimates of bubble volumetric flow, that is, $\dot{V}_b$, and rising velocity, that is, U_b, from above, it is now possible to predict the expansion of the bubbling bed, aided by the common assumption that the dense phase retains the same voidage as at minimum fluidization, that is, ε_{mf}. In the next two relationships, it is also assumed that a negligible fraction of the particle inventory is displaced into the freeboard, cyclones, and return system. If this is not the case, then one needs to correct the H_{mf} below to use an effective value, which accounts only for particles in the dense bed (i.e., below the expanded bed surface). An iterative procedure

is then required to estimate the bed expansion: Firstly, guess a value of ε_b, the fraction of dense bed volume occupied by bubbles. Then, calculate a first estimate of the expanded bed depth as

$$H = \frac{H_{mf}}{(1-\varepsilon_b)} \tag{17.26}$$

Next calculate the mean bubble diameter at $z = H/2$ using Equation 17.23 or 17.24, whichever gives the smaller value. Then find the corresponding bubble rise velocity, $U_{b|z=H/2}$, from Equation 17.25. Hence, find a new estimate of ε_b from

$$\varepsilon_b = \dot{V}_b / [A U_{b|z=H/2}] \tag{17.27}$$

If this value is within a chosen tolerance of the original guess, it is accepted; H is then specified as the value calculated previously from Equation 17.26. Otherwise, calculate a new estimate of H from Equation 17.26 using the most recently calculated value of ε_b and proceed as earlier. Generally, three or four iterations should be sufficient to give a good estimate of the bed expansion and other mean bubble properties calculated via this procedure.

Once the bubble properties have been calculated in this manner, it may also be useful to estimate the mean frequency of bubbles passing any level:

$$f_b = \dot{V}_b / V_b \quad \text{with} \quad V_b = \text{bubble volume} = (\pi/6) D_b^3 \tag{17.28}$$

One of the important features, however, of bubbling fluidized beds is that the bubbles are not uniformly distributed across the cross section of the column, even on a time-averaged basis. Instead, as shown both by experimental results and coalescence models show that, the bubbles tend to become depleted near the outer wall, with the maximum frequency and bubble volumetric flow initially occurring about one mean bubble diameter in from the outer wall, and then this position migrates inward toward the axis of the column as bubbles grow and the slug flow regime is approached (Grace and Harrison, 1969, Werther, 1974).

17.1.4.2 Influence of Tubes and Baffles on Bubbling and Bed Expansion

The procedure described earlier for estimating bed expansion and bubble properties applies to cases where there are no internal heat-transfer tubes or other fixed surfaces inside the column. In any section of the column containing an array of horizontal tubes, bubbles can be assumed to grow by coalescence according to Equation 17.23 until they reach either the diameter given by Equation 17.24 or the minimum center-to-center tube separation distance, whichever is smaller. If the array terminates before the top of the bubbling bed, then growth beyond the latter limit will recommence, but of course with the limit imposed by the maximum stable size, Equation 17.24, still in place. In such cases, the expansion is predicted by estimating ε_b separately for each section—that is, below the array of tubes, inside the tube bundles, and above the tubes—and then applying a procedure analogous to that described earlier to balance the total in-bed inventory of solids with the sum of the solids within all of the individual sections.

For vertical tubes or other baffle geometries and configurations, there are no reliable methods for prediction of the evolution of bubble size, and hence the bed expansion. In general, bubbles are smaller when baffles are present as the internal fixed surfaces limit bubble coalescence (Grace and Harrison, 1971), and baffles may also promote bubble splitting. Hence, bed expansion is usually increased by the presence of fixed internal surfaces, with the degree of increase depending strongly on the extent to which the mean bubble size is reduced.

17.1.4.3 Solids Mixing and Motion in a Bubbling Bed

The dominant mechanism by which solids are dispersed in bubbling fluidized beds involves displacement of particles by bubble wakes and due to the "drift" caused by the bubbles. These displacements are illustrated schematically in Figure 17.6. In the case of wake transport, particles are gathered in the wake at the bottom (back) of rising bubbles and transported upward, with occasional shedding of clumps or fragments of particles along the way (Rowe et al., 1965). In the case of drift, particles undergo net displacement outside the wake due to the passage of bubbles. This displacement is upward near the bubble axis, and downward at several bubble radii from

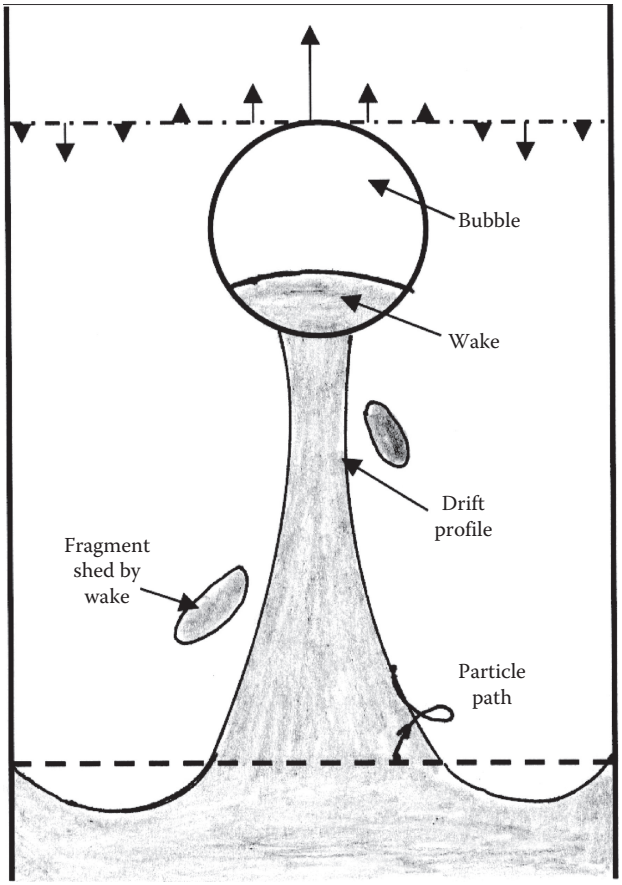

Figure 17.6

Schematic showing particle wake transport and drift due to passage of bubble. Arrows at top indicate relative vertical components of particle velocity across the bed just ahead of the approaching bubble.

the axis, just as in the case of drift net displacement caused by a sphere passing in potential flow through a fluid (Baeyens and Geldart, 1973). Let f_w represent the volume of the wake divided by the volume of the corresponding bubble. Some experimental results for f_w are shown in Figure 17.4 based on x-ray photography of bubbles in fully three-dimensional fluidized beds (Rowe and Partridge, 1965). An effective drift fraction may be defined in a similar manner, with experimental results (Baeyens and Geldart, 1973), suggesting that this is approximately $1.6f_w$. Hence, the upward mass flux of particles due to the rise of bubbles at any level in the bed can be estimated as

$$G_s = 2.6\rho_p(1-\varepsilon_{mf})f_w\dot{V}_b/A \tag{17.29}$$

where

$\dot{V}_b$ is obtained from Equation 17.22

f_w can be estimated based on x-ray photographs of bubbles reported by Rowe and Partridge (1965)

A characteristic mixing time, sometimes called a "turnover time," can then be estimated as the average time for the inventory of particles in the bed to travel through one cycle, from the bottom of the bed to the top and back again to the bottom, leading to

$$t_{mix} = \frac{H_{mf}}{\left\{2.6f_wY\left(U-U_{mf}\right)\right\}} \tag{17.30}$$

Experimental results indicate that homogeneity is effectively achieved in two to three mixing times. For most fluidized beds of practical importance, t_{mix} turns out to be on the order of 10–100 s, whereas particles usually spend much longer times in the bed. Hence, the particles are quickly blended in the vertical direction and perfect axial mixing can commonly be assumed. As long as bubbling is well established, that is, ($U - U_{mb} > \sim 0.1$ m/s), and the distributor has been well designed, height-wise classification by size of particles whose diameters are within an order of magnitude of the mean particle diameter is unlikely to be a problem. Nonuniform particle densities are more likely to give rise to vertical segregation (Rowe and Nienow, 1976). However, vigorous bubbling is usually sufficient to prevent segregation of particles whose densities are within ~30% of each other.

For larger density differences, for example, for biomass particles in beds of sand, the spatial distribution of the two species depends on circulation patterns and is a complex function of the superficial gas velocity, species concentrations, and particle shape (Zhang et al., 2009, Fotovat et al., 2014).

These results refer to vertical mixing (often referred to as axial dispersion). Commonly the literature describes the mixing process in terms of an axial dispersion coefficient, defined by analogy with molecular diffusion, and having the same units (m^2/s) as molecular diffusivity. However, molecular diffusion involves small random steps, clearly differing from the large bubble-generated (and hence deterministic) displacements that dominate the mixing process in bubbling fluidized beds. As a result, axial dispersion coefficients vary widely and are not very useful in practice, except as a gross means of comparing data and seeing trends, as in the review by van Deemter (1980), which provides useful data on mixing in industrial-scale fluidized beds.

Particle transport by bubbles also provides the principal mechanism for horizontal (or radial) solids mixing in bubbling beds. When bubbles that are not perfectly aligned vertically interact and coalesce, gas and particles are displaced horizontally. In addition, particles are displaced horizontally when bubbles erupt at the dense bed surface, resulting in splashing and spraying of particles into the freeboard. Typically, the magnitudes of mixing coefficients are about an order of magnitude less in the horizontal direction than in the vertical direction. Although dispersion models are still strictly inappropriate in this case, as for axial mixing, they are often used (van Deemter, 1980), and the objection to their use for radial (or lateral) dispersion is less than for vertical (axial) dispersion coefficients since the displacement steps are smaller and less ordered.

An issue of considerable importance in bubbling fluidized beds is the establishment of gross overall particle circulation patterns, associated with the bubble coalescence pattern referred to, whereby bubbles initially become more concentrated near the outer wall, and then the region of increased bubbling migrates inward toward the axis of the bed with increasing height. Since bubbles carry particles upward in their wakes and propel particles upward by drift, the nonuniform radial distribution of bubbling leads to nonuniform solid's movement. On a time-mean basis, the patterns then tend to be as indicated in Figure 17.7. As shown, there is a relatively weak cell near the bottom where particle motion is primarily upward near the wall and

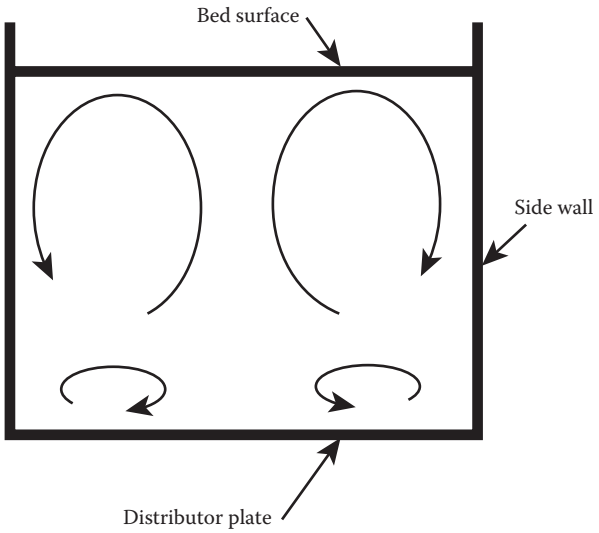

Figure 17.7

Typical time-mean solids motion ("gulf-streaming") in bubbling beds.

downward near the center. In bubbling beds of height/diameter ratio of about 1 or more, this then gives way to a stronger up-the-center, down-the-outside time-mean circulation pattern. These patterns, often referred to as "gulf-streaming," are self-reinforcing, as bubbles tend to be pulled into the upflow regions, where the bubbles are already more abundant, as they rise from the distributor. However, it is important to note that the pattern at any instant may differ significantly from the time-mean patterns.

17.1.4.4 Gas Mixing and Gas–Solid Contacting in a Bubbling Bed

Gas mixing patterns are strongly influenced by solids motion (May, 1959) and also by the two-phase nature of the bed. Since particles are transported upward by bubbles and the bubbles are nonuniformly distributed, as we have seen earlier, particles must travel downward in other parts of the column to maintain the bed of solids in place. Wherever particles descend with a vertical component of velocity larger than the interstitial velocity relative to particles, which is given approximately by U_{mf}/ε_{mf}, the local absolute velocity of gas elements is directed downward toward the distributor plate. Hence, the regions of net downward flow of particles indicated in Figure 17.7 can also be regions where, in a time-mean sense, gas elements are carried downward (Latham et al., 1968, Kunii and Levenspiel, 1991). This is one factor contributing to axial dispersion of gas in bubbling fluidized beds, and it can even lead to true "backmixing," that is, displacement of gas upstream (downward).

Gas dispersion is also affected by the fact that bubbles travel in general with velocities that differ, usually widely, from the interstitial gas velocity. For example, for group A solids, the bubble velocity is typically on the order of 0.6–1.2 m/s, compared with interstitial gas velocities relative to the particles of order 0.01 m/s or less. Hence, even if elements of gas in the dense phase are not descending, they are certainly rising much less quickly than gas elements associated with bubbles. Interphase mass transfer diminishes this effect to some extent, but differences in gas velocities between the two phases contribute in a major way to substantial deviations from plug flow. While gas mixing deviates considerably from plug flow, the residence time distribution is also far from that corresponding to perfect mixing (Gilliland and Mason, 1952, van Deemter, 1980, Kunii and Levenspiel, 1991). The fact that bubbles are widely distributed in size, and hence in rising velocity (see Equation 17.25), further contributes to nonuniform gas residence times of gas elements in the bed. Yet another contributor is that the "throughflow" component of gas velocity, defined earlier, tends to increase as bubbles elongate while bubbles are interacting and coalescing (Levy and Dorfman, 1995, Grace, 2002). Axial mixing can be significantly reduced by the addition of horizontal baffles (Overcashier et al., 1959).

Reactor models for bubbling beds must take into account the difference in gas–solid contacting, axial dispersion, and gas velocity between the dense phase and bubble phase. A simple two-phase bubbling bed model (Grace, 1986b) that covers the major factors assumes stagnant gas in the dense phase and plug flow in the bubble phase. A small proportion of the bubble phase volume, on the order of 0.1%–1%, is assumed to be occupied by particles. Interphase mass transfer is predicted by a semiempirical equation due to Sit and Grace (1981):

$$k_{bd} = \frac{U_{mf}}{3} + \left\{ \frac{4 D_{AB} \varepsilon_{mf} U_b}{\pi D_b} \right\}^{0.5} \tag{17.31}$$

where D_{AB} is the molecular diffusivity of the reacting component. Mole balances are then written for each phase. For example, for a first-order gas-phase reaction, the mole balance for the bubble and dense phases, respectively, is

$$U \frac{dC_{Ab}}{dz} + k_{bd} a_b \varepsilon_b (C_{Ab} - C_{Ad}) + k_r \varphi_b C_{Ab} = 0 \tag{17.32}$$

$$k_{bd} a_b \varepsilon_b \left(C_{Ad} - C_{Ab} \right) + k_r \varphi_d C_{Ad} = 0 \tag{17.33}$$

where

C_{Ab} and C_{Ad} are bulk gas concentrations in the bubble and dense phases at height z
k_r is a first-order kinetic rate constant
$a_b \approx 6/D_b$ is the interphase area per unit volume, whereas φ_b ($\approx 0.001–0.01\varepsilon_b$)
φ_d ($\approx (1 - \varepsilon_b)(1 - \varepsilon_{mf})$) are the fractions of the total dense bed volume occupied by solids associated with the bubble and dense phases, respectively

The bubble diameter, D_b, is usually taken at $z = 0.4H$, that is, at 40% of the expanded bed depth.

With the boundary condition $C_A = C_{A0}$ at $z = 0$, these equations can be integrated to estimate the concentration at the top ($z = H$) of a bubbling bed:

$$C_{AH} = C_{A0} \exp\left\{\frac{-k_r^\star [k_{bd}^\star(\varphi_b + \varphi_d) + k_r^\star \varphi_b \varphi_d]}{k_{bd}^\star + k_r^\star \varphi_d}\right\} \tag{17.34}$$

where $k_{bd}^\star$ and $k_r^\star$ are dimensionless interphase mass transfer and kinetic rate constants defined by

$$k_{bd}^\star = \frac{k_{bd}\alpha_b \varepsilon_b H}{U} \quad \text{and} \quad k_r^\star = \frac{k_r H}{U} \tag{17.35}$$

This simple model illustrates how conversions depend on both interphase mass transfer and chemical kinetics, with the former usually being the rate-determining step. Effectively, some of the gas bypasses the bed by short-circuiting through the bubbles, which, because they are much more dilute and usually travel much faster, are much less effective for reaction than an equal volume of dense phase. Mass transfer resistance within the individual phases is seldom important for gas-phase reactions, but can be important, especially for gas-solid reactions and large (e.g., Geldart group D) particles.

This reactor model can be readily extended to non-first-order kinetics and to multiple reactions; some analytical solutions are available for simple cases (Grace, 1986b). It can also be extended to account for more complex kinetics, axial dispersion in one or both phases, and gas-solid reactions, with numerical solution definitely then being required to solve the resulting set of equations.

17.1.4.5 Entrainment

When bubbles burst at the surface of fluidized beds, clumps of bed particles are ejected into the freeboard region (region between bed surface and top of column). The velocities of the ejected particles are of the same order as the bubble rise velocities. When coalescence is in the process of occurring just as two bubbles reach the bed surface, especially energetic bursts of particles can occur, with the initial vertical component of particle velocity in the freeboard approximately doubled. Most evidence suggests that ejected particles come predominantly from the wake of the bubbles, rather than from the nose. As a result, some particles from deep within the bed can find themselves quickly dispersed in the freeboard, where they may escape altogether with the exit gas stream, or be disengaged and land at some other horizontal position on the bed surface, thereby contributing to lateral mixing. Because small particles experience more drag relative to their weight than larger ones, the finer material is preferentially lost from the bed. This process of preferentially losing finer material from the mixture is often called "elutriation." The overall particle size distribution in the bed is also, of course, influenced by other factors such as agglomeration, attrition, and growth or shrinkage in particle size as a result of chemical reactions occurring in the reactor.

Two quantities are generally used to characterize the entrainment. The "transport disengaging height," usually abbreviated TDH, is the effective freeboard height (measured from the surface of the dense bed below) beyond which there is negligible variation in the entrainment flux. In other words, any ejected particles, which, due to gravity, are able to reverse their direction of motion and return to the dense bed, do so within the TDH. In practice, the TDH is the freeboard height usually provided by fluid bed designers, as any greater height results in a negligible decrease in entrainment, whereas a shorter freeboard increases the carryover from the bed. Experimental evidence shows that the TDH is a strong function of both the gas velocity and the column diameter. A graphical correlation by Zenz and Othmer (1960) is commonly used to provide a conservative estimate of the TDH. This correlation is plotted in SI units in Figure 17.8. Several other approaches are also available to predict the TDH, as summarized by Geldart (1986) and by Werther and Hartge (2003). More recent data by Chen et al. (2010) show fair agreement with the Zenz approach, and these authors provide a new predictive model.

The other quantity of importance with respect to particle carryover is the entrainment flux above the TDH as a function of particle size. This is needed to estimate the efficiency of cyclones or other gas–solid separation devices downstream of the bed, and hence to estimate the overall entrainment from the complete system. There are many empirical correlations, which can be used to predict the specific rate constant, $K_i^\star$

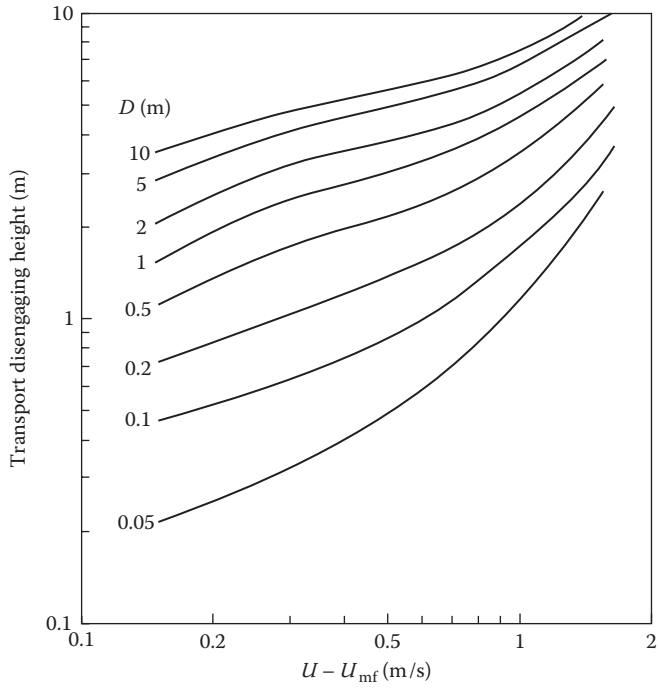

Figure 17.8

Transport disengaging height correlation. (Adapted from Zenz, F.A. and Othmer, D.F., *Fluidization and Fluid—Particle Systems*, Reinhold Publishing Corp., New York, 1960.)

(also called the elutriation constant by some authors). $K_i^\star$ is defined in such a way that the flux of particles in a narrow size range of mean diameter d_{pi} is given by

$$G_{si} = m_i K_i^\star \tag{17.36}$$

where m_i is the mass fraction of particles in the i^{th} size interval. Available approaches and correlations for $K_i^\star$ differ widely, commonly by orders of magnitude, in their predictions (Chew et al., 2015). Summaries of these correlations have been published (Geldart, 1986, Werther and Hartge, 2003). It is important to choose an approach, which was derived for particles and conditions as similar as possible to those of interest. This makes it very difficult to predict entrainment with any degree of accuracy. A correlation based on an extensive range of materials and operating conditions, including data on units up of 1 m in diameter and data obtained at high temperature and pressure (Choi et al., 1999), gives

$$\frac{K_i^\star d_{pi}}{\mu_g} = Ar_i^{0.5} \exp\left\{6.92 - 2.11F_g^{0.303} - \frac{13.1}{F_d^{0.902}}\right\} \tag{17.37}$$

where

$$F_g = g d_{pi}\left(\rho_p - \rho_g\right) \quad \text{and} \quad F_d = C_D \rho_g U^2/2 \tag{17.38}$$

Entrainment at the bed surface itself can be approximated (Wen and Chen, 1982) by

$$G_{so} = 9.6A\left(U - U_{mf}\right)^{2.5} g^{0.5} \rho_g^{3.5} \mu_g^{-2.5} \tag{17.39}$$

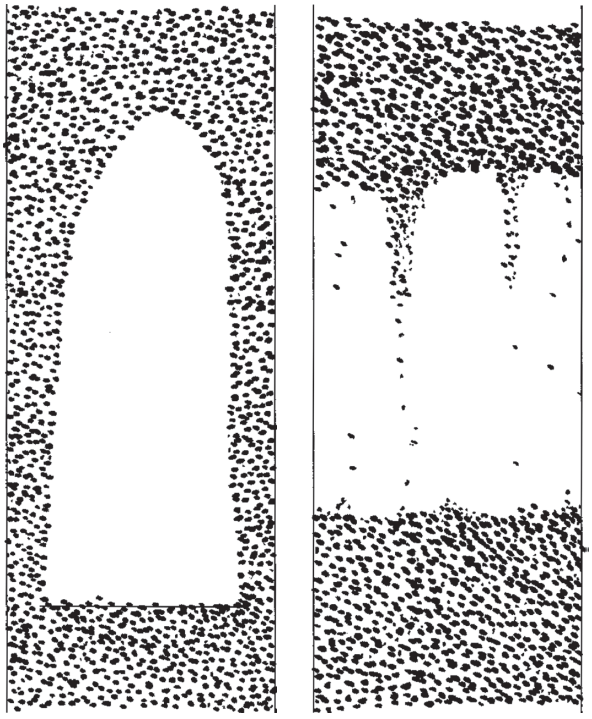
Below the TDH, the particle flux decays approximately exponentially with height, with

$$G_{si} = m_i K_i^{\star} + G_{so} \exp\{-\alpha_i z'\} \tag{17.40}$$

where z' is the vertical coordinate measured from the bed surface. The decay constant, α_t, was found (Wen and Chen, 1982) to vary from 3.5 to 6.4 m^{-1}, and can be taken as 4.0 m^{-1} in the absence of specific information.

Solids entrained by the outlet gas are usually passed through at least one stage of cyclones and other separators to remove as many particles as possible. Vertical standpipes are employed to return the captured solids to the bottom of the dense bed. To prevent short-circuiting of gas in the wrong direction up the standpipe, trickle valves are commonly installed at the exit of the standpipe.

17.1.5 Slugging Fluidization



The conditions required for slug flow are summarized in Section 17.1.2.4. These conditions are most likely to apply at high H/D ratios in vessels of relatively small diameter. They are satisfied in many laboratory and pilot units, but are unlikely to be applicable in vessels of commercial scale. A useful review of slugging in fluidized beds was provided by Hovmand and Davidson (1971).

Slugs are bullet-shaped voids, rounded at the top and almost flat at the bottom, as shown in Figure 17.9a. In most cases, they rise nearly symmetrically in the column, though asymmetric slugs clinging to the wall are sometimes observed. Once continuous slugging has become established, the interslug spacing, that is, the separation distance between the bottom of one slug and the nose of the next slug, typically reaches ~ 2D. The flow is then fully developed and the length of slugs, ℓ_s, can be estimated from the quadratic equation

$$\ell_s/D - 0.495\left(\ell_s/D\right)^{0.5}\left(1+\beta\right) + 0.061 - 1.94\beta = 0 \tag{17.41}$$

where

$$\beta = \frac{U - U_{mf}}{U_{si}} \geq 0.2 \quad \text{and} \quad U_{si} = 0.35\sqrt{gD} \tag{17.42}$$

(a) (b)

Figure 17.9

Shapes of slugs: (a) axisymmetric round-nosed slug; (b) square-nosed slug.

The velocity of each slug is approximately given by

$$U_s = U_{si} + \left(U - U_{mf}\right) \tag{17.43}$$

The frequency with which slugs pass a given level and also reach the upper bed surface is then

$$f_s = \frac{U_s}{\left(\ell_s + 2D\right)} \tag{17.44}$$

In slugging beds, the upper surface rises smoothly as the top slug approaches and then falls sharply as each slug breaks the upper surface. The maximum expanded bed height for slugging beds, achieved just as each slug breaks the surface, is approximately

$$H_{max} = H_{mf}\left(1 + \beta\right) \tag{17.45}$$

Like bubbles, slugs have wakes at the bottom, but these are stunted relative to wakes of bubbles of similar volume. As a result, both solids mixing and gas mixing are less for slugging beds than for comparable bubbling beds in which wall effects play a minor role.

These equations provide good estimates of the major hydrodynamic properties of most slugging fluidized beds where $H \gg D$. Results for gas and solids mixing and models for chemical reaction are also available for this flow regime (Hovmand and Davidson, 1971).

Another mode of slug flow, usually called "square-nosed slugging," is also sometimes encountered in columns of small diameter. In this case, the slugs are relatively flat both at top and bottom, as indicated in Figure 17.9b. These slugs rise relatively slowly as particles rain from the top surface (roof) of each slug. Square-nosed slugs are usually attributable to relatively large d_p/D ratios or large, rough, or cohesive particles, coupled with smooth-walled columns. This mode has no useful features, nor can it be scaled up with confidence. Therefore, it should be avoided in practice and is not pursued further here.

17.1.6 Turbulent Fluidization

When the superficial gas velocity reaches U_c (see Section 17.1.2.5), there is a transition to the turbulent fluidization flow regime. The turbulent regime bridges between the bubbling (or slugging) regime, where bubbles (or slugs) are dispersed in a continuous dense phase of particles and interstitial gas, and the fast fluidization regime, where particles streamers and clusters are dispersed in a continuous dilute suspension of particles in gas. While voids appear in the turbulent fluidization flow regime, they are much more transitory in nature, irregular in shape, and generally smaller than the bubbles and slugs encountered in the bubbling or slugging flow regimes. Hence, the distinction between a dense phase and a dilute phase is generally unnecessary for the turbulent flow regime. The turbulent flow regime turns out to be especially favorable for carrying out chemical reactions and certain physical operations. An extensive review of the turbulent flow regime was published by Bi et al. (2000).

17.1.6.1 Hydrodynamics of the Turbulent Fluidization Flow Regime

The overall mean (spatial- and time-average) voidage in the turbulent flow regime is generally in the range 0.65–0.75, intermediate between that in bubbling and fast fluidization. There is little variation in the axial direction until one approaches the bed surface. Because of surging and eruption of voids, the upper surface is indistinct, and hence, the time-mean expanded bed depth is commonly inferred from pressure profiles, ideally involving a series of pressure taps extending from low in the bed to well into the freeboard region. X-rays and γ-rays can also be employed for this purpose. Radial profiles of local time-team voidage show significantly higher values in the core of the column than near the outer wall. A correlation (Wang and Wei, 1997) that accounts for this variation is

$$\varepsilon = 1 - \left(1 - \langle\varepsilon\rangle_A\right)\left\{0.908 + 0.276\left(r/R\right)^4\right\} \tag{17.46}$$

Data on axial and radial voidage variations are summarized by Bi et al. (2000).

The local flow structure within turbulent fluidized beds is complex, as demonstrated by a number of different characterization techniques including spectral analysis, chaos analysis, and wavelet analysis. Whichever of these techniques is used, the character of the profiles for the turbulent regime tends to be quite distinctive (Bai et al., 1999). For cases where the turbulent regime is preceded by slug flow (usually restricted to group B or D solids), there is local intermittency between periods of slug-flow-like behavior and fast-fluidization-like structures. However, when turbulent fluidization is preceded by bubbling (generally encountered with group A solids), the structure is more homogeneous.

Given the relative homogeneity of turbulent fluidized beds and the transient nature of voids, internal baffles are generally not required. When vertical or horizontal heat-transfer tubes are present, they tend to influence the hydrodynamics less than for the bubbling bed flow regime.

17.1.6.2 Gas and Solids Mixing

Since mixing within the turbulent flow regime occurs by much smaller and more random steps than in bubbling fluidized beds, it is more appropriate to apply models based on the analogy with molecular diffusion. The axial dispersion coefficient for the gas, $D_{g,ax}$, has been correlated (Bi et al., 2000), based on data from a number of studies, by

$$Pe_{g,ax} = \frac{UH}{D_{g,ax}} = 3.47 Ar^{0.149} Re^{0.0234} Sc^{-0.231} \left(\frac{H}{D}\right)^{0.285} \tag{17.47}$$

There are relatively few data available with respect to radial gas mixing in the turbulent flow regime. The results, which are available, indicate that radial mixing is again about an order of magnitude smaller than axial mixing. Hence, one can take $D_{g,r} \approx 0.1 D_{g,ax}$ as a first approximation.

Solids mixing in turbulent beds have received only limited attention. Recommended correlations are

1. For group A particles (Lee et al., 1991):

$$D_{s,ax} = 0.365 Re_D^{-0.368} \left[g(U - U_{mf}) D^4 \right]^{1/3} \tag{17.48}$$

2. For group B particles (Lee and Kim, 1990):

$$Pe_{s,ax} = \frac{UH}{D_{s,ax}} = 4.22 \times 10^{-3} Ar \tag{17.49}$$

One may again assume that radial or lateral mixing coefficients are an order of magnitude less than for the corresponding axial dispersion. Overall, solids mixing is generally large enough that temperature gradients are small within turbulent fluidized beds, similar to bubbling beds.

17.1.6.3 Mass Transfer and Chemical Reaction

Given the broad spectrum of local voidages, rapid disintegration and reforming of voids, and the lack of a coherent two-phase structure in the turbulent flow regime, interphase mass transfer is unlikely to provide a significant resistance when considering chemical reactions in turbulent fluidized beds. Hence, single-phase axially dispersed reactor models can be used (e.g., Foka et al., 1996) to predict the conversion and selectivity of gaseous components. The axial dispersion coefficient for the gas can then be estimated from Equation 17.47. Reaction in the freeboard region may be significant, requiring that it also be estimated. Note also that it may be important to make allowance for the radial variation of void fraction when modeling turbulent fluidized-bed reactors.

The simple axially dispersed plug flow approach has been extended (Thompson et al., 1999, Abba et al., 2003) to consider gradual transitions between the flow regimes rather than assuming regime-specific reactor models with step changes at the regime boundaries. In this approach, probabilistic averaging is performed so that, as U increases, the probability of bubbling falls from nearly unity, whereas the probability of turbulent fluidization increases to nearly unity and then falls, and the probability of fast fluidization is initially 0, but ultimately approaches unity.

17.1.6.4 Entrainment

There are many empirical equations in the technical literature, which purport to predict rates of entrainment. However, these can differ by many orders of magnitude in their predictions (Chew et al., 2015), and none of correlations these can be regarded as reliable. This is likely, at least in part, because none of these correlations take electrostatic charging into account, which can alter entrainment rates, as well as downstream separation and flow in the bed itself as the departure of charged particles leaves behind charges of opposite polarity. A correlation that appears to be somewhat more reliable than others for entrainment above the TDH of particles from turbulent fluidized beds (Tasarin and Geldart, 1998) is

$$K_i^* = 14.5\rho_g U^{2.5} \exp\{-5.4 V_{si}/U\} \tag{17.50}$$

The TDH can be predicted using Figure 17.8 or alternatively from correlations in the literature (Wen and Chen, 1982, Baron et al., 1988).

17.1.7 Fast Fluidization and Dense Suspension Upflow

Fast fluidization is usually encountered with group A and B solids at superficial gas velocities >1.5 m/s. To maintain continuous operation, particles must be continuously fed to the bottom of the vertical shaft to replace those carried over from the top. Whereas lower velocity fluidization flow regimes have a relatively dilute freeboard region to disengage particles ejected at the bed surface, there is no bed surface, and hence no "bed," nor is there any freeboard region, in the fast fluidization flow regime. Instead, particles are conveyed upward, individually and as loose clusters, through the entire column height. Efficient gas–solids separators (usually cyclones, but occasionally inertial separators) are relied upon to capture entrained particles and return them via a standpipe or "downer" (Li et al., 2004) to near the bottom of the main column or riser. The overall configuration, including the riser (where the main gas–solid contacting and chemical reaction[s] take place), the gas–solid separator(s), standpipe, and any nonmechanical or mechanical valves in the recirculation line, constitutes the CFB system. A typical CFB configuration is shown schematically in Figure 17.10b. Note that the H/D ratio is usually $\gg 1$, especially for small-scale systems.

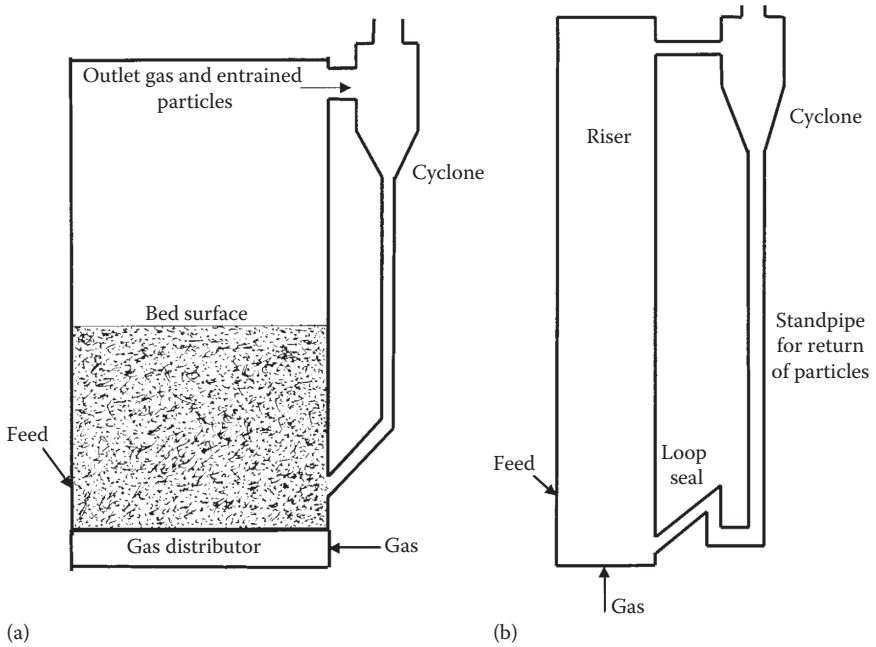


Figure 17.10

Typical equipment configurations of (a) dense (bubbling, slugging, or turbulent) fluidized beds and (b) circulating fluidized beds.

17.1.7.1 Hydrodynamics of the Fast Fluidization Flow Regime

The riser of a CFB system is usually operated in the fast fluidization flow regime. Since, as indicated in Figure 17.10b, the exit at the top of the riser is usually at one side, while the return of solids to the bottom of the riser also involves asymmetric re-entry; flow at the top and bottom of a CFB riser is generally not symmetric about the axis. On the other hand, axisymmetric flow (in risers of circular cross section) or planar symmetry (in risers of rectangular cross section) can commonly be assumed throughout the middle portion of the riser.

To a first approximation, the acceleration and wall friction terms in the momentum equation for flow in CFB risers can be neglected for fast-fluidized beds relative to the gravity terms. It is then possible to derive an approximate profile of axial density from the axial pressure profile since, with $\rho_p \gg \rho_g$,

$$1-\langle\varepsilon\rangle_A \approx -\frac{1}{g\rho_p}\frac{dP}{dz} \tag{17.51}$$

The cross-sectional average voidage within a fast-fluidized bed is generally lowest near the distributor plate, increasing with height, reaching a plateau approximating fully developed conditions at some distance above the bottom, and then varying again toward the top outlet. When the top is constricted (i.e., the area of the exit is less than that of the riser), there tends to be an increase in solids concentration (decrease in voidage) near the exit, whereas a very open or smoothly tapered exit tends to cause an increase in voidage toward the top. The various shapes of axial voidage profile and the influence of various operating variables on them were summarized nicely by Bai et al. (1992). Some typical axial profiles of solids holdup are plotted in Figure 17.11. The main variables, in addition to the exit geometry, are the net solids circulation flux, G_s, and the superficial gas velocity, U. With increasing G_s, U, ρ_p, or d_p, the solids' holdup ($=1 - \langle\varepsilon\rangle_A$) increases, and there is more likely to be an upturn in the axial solids' holdup profile near the top exit. This arises because the top of the column acts as a crude inertial gas–solid separator, in which the particles have more difficulty in negotiating the turn into the exit duct if they are larger, denser, moving more quickly, or present in greater numbers.

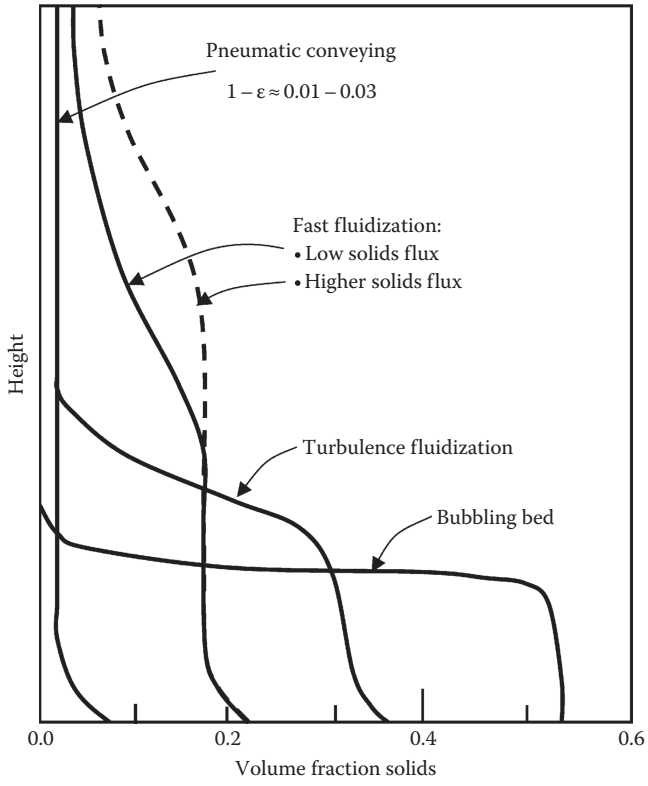

Figure 17.11

Typical solids holdup profiles in bubbling, turbulent, fast fluidization, and dilute pneumatic conveying flow regimes.

Expressions that can be used to estimate the limiting cross-sectional average voidages, ε_d in the lower dense region and ε^* at the top exit, were given by Bai and Kato (1999).

One first calculates the saturation carrying capacity, G_s^{sat}:

$$\frac{G_s^{sat} d_p}{\mu_g} = 0.125 \left(\frac{U}{\sqrt{g d_p}} \right)^{1.85} Ar^{0.63} \left(\frac{\rho_p - \rho_g}{\rho_g} \right)^{-0.44} \tag{17.52}$$

and

$$\varepsilon' = 1 - G_s / \left[\rho_p \left(U - V_s \right) \right] \tag{17.53}$$

For $G_s < G_s^{sat}$ one then calculates

$$\varepsilon_d = 1 - \varepsilon' \left\{ 1 + 6.14 \times 10^{-3} \left(\frac{G_s}{\rho_p U} \right)^{0.23} \left(\frac{\rho_p - \rho_g}{\rho_g} \right)^{1.21} \left(\frac{U}{\sqrt{gD}} \right)^{-0.383} \right\} \tag{17.54}$$

and

$$\varepsilon^* = 1 - 4.04 \left(1 - \varepsilon' \right)^{1.214} \tag{17.55}$$

On the other hand, when $G_s \geq G_s^{sat}$,

$$\varepsilon_d = 1 - \varepsilon' \left\{ 1 + 0.103 \left(\frac{\rho_p U}{G_s} \right)^{1.13} \left(\frac{\rho_p - \rho_g}{\rho_g} \right)^{-0.013} \right\} \tag{17.56}$$

and

$$\varepsilon^* = 1 - \left(1 - \varepsilon' \right) \left\{ 1 + 0.208 \left(\frac{\rho_p U}{G_s} \right)^{0.5} \left(\frac{\rho_p - \rho_g}{\rho_g} \right)^{-0.082} \right\} \tag{17.57}$$

These relationships provide estimates of the voidages in the lower dense region and at the top of the column. Between the bottom region and the top, the voidage varies, asymptotically approaching ε_d when approaching the lower dense zone and ε' as the top exit is approached. Hence, these relationships facilitate estimation of the full axial voidage profiles.

The solids' holdup in fast fluidization is much higher toward the outer wall, where there are descending streamers, than in the core of the riser, where there is upward motion of gas and widely dispersed particles. Except near the solids' entry or re-entry ports and asymmetrically located exit ports, the radial profile of time-mean voidage can then be predicted (Issangya et al., 2001) by

$$\varepsilon = \varepsilon_{mf} + \{ \langle \varepsilon \rangle_A - \varepsilon_{mf} \} \langle \varepsilon \rangle_A^{-1.5 + 2.1 (r/R)^{3.1} + 5.0 (r/R)^{8.8}} \tag{17.58}$$

For columns of rectangular or square cross section, the corners are regions of decreased voidage and more prominent solids' downflow (Zhou et al., 1995).

Solids' velocities are upward throughout most of the cross section of the column, but downward velocities are experienced at the wall, with a time-mean value of approximately (Griffith and Louge, 1998)

$$v_{sw} = -36 \sqrt{g d_p} \tag{17.59}$$

The negative sign in this equation indicates that the solids are traveling downward on average at the wall of the riser when the fast fluidization flow regime is present. This downward velocity corresponds to dense streamers or clusters of elongated lens-shapes, descending jerkily along the outer wall of the riser. The thickness of the wall layer subject to net downward flow of solids has been correlated (Kim et al., 2004b), covering a broad range of conditions by

For $U^{\star}_{slip} < 6.5$,

$$\frac{\delta_w}{D^{0.85}(U^2/g)^{0.15}} = 1.73(U^{\star}_{slip})^{0.21}\left\{\frac{U}{\sqrt{gd_p}}\right\}^{-0.97}\left\{\frac{\rho_p[1-\langle\varepsilon\rangle_A]}{\rho_g\langle\varepsilon\rangle_A}\right\}^{0.16} \tag{17.60}$$

For $U^{\star}_{slip} \geq 6.5$,

$$\frac{\delta_w}{D^{0.85}(U^2/g)^{0.15}} = 0.53(U^{\star}_{slip})^{-0.32}\left\{\frac{G_s}{\rho_p[1-\langle\varepsilon\rangle_A U]}\right\}^{-0.55}\left\{\frac{\rho_p[1-\langle\varepsilon\rangle_A]}{\rho_g\langle\varepsilon\rangle_A}\right\}^{-0.70} \tag{17.61}$$

where

$$U^{\star}_{slip} = \left\{\frac{\rho_g{}^2}{g\mu(\rho_p-\rho_g)}\right\}^{1/3}\left[U - \frac{G_s\langle\varepsilon\rangle_A}{\rho_p[1-\langle\varepsilon\rangle_A]}\right] \tag{17.62}$$

The time-mean particle velocity is upward everywhere, except for this outer wall layer, reaching a maximum at the axis of the column. Radial profiles of solids flux are similar to those of time-mean local particle velocity, positive (upward) and at a maximum at the axis of the column, and negative (downward) at the outer wall. Gas velocity profiles are difficult to measure, but follow similar trends. However, the gas motion is upward relative to the particles.

In some CFB processes such as combustion of solid fuels, secondary gas is fed from the sides of the column through nozzles or orifices at some height well above the principal gas distributor. The resulting gas jets tend to disrupt the downward-moving wall layers. Moreover, the region of lower gas velocity below the secondary nozzles tends to be denser and somewhat isolated from the region above the secondary nozzles. If these secondary jets are introduced tangentially, the resulting swirl tends to cause an increase in solids' holdup near the outer wall due to centrifugal forces.

17.1.7.2 Dense Suspension Upflow

Downward flow of particles in streamers and clusters at the wall, a major feature of the fast fluidization flow regime, no longer occurs when the solids' flux is sufficiently high, typically beyond ~200–300 kg/m^2 s. Instead, the time-mean particle and gas motion is upward throughout the entire cross section, with ~7%–20% or more of the overall cross-sectional area occupied by particles. This flow regime has been called dense suspension upflow or DSU (Grace et al., 1999). It is encountered in fluid catalytic cracking (FCC) and other catalytic processes where there are group A solids combined with high solids throughputs. The transition to the DSU flow regime is covered in Section 17.1.2.7. As noted there, the DSU and fast fluidization flow regimes can coexist, occupying different portions of the same riser.

While there is no net local downflow in the DSU flow regime and the flow is generally more homogeneous, there are still marked radial gradients, with much higher time-average voidages near the axis of the riser than near the wall (Issangya et al., 2000, Liu et al., 2003). The voidage can approach ε_{mf} at the wall. Equation 17.58 can again be used to predict the radial voidage variation as it is based on DSU data, in addition to data from the fast fluidization flow regime. Particle velocities also reach a maximum at the axis of the column, approaching, or even exceeding, 2U. Local solids fluxes are typically 1.5–2.5 G_s at the axis of the column, falling to close to 0 at the wall. Local fluctuations in voidage are strongly correlated with local fluctuations of particle velocity (Liu et al., 2003), so that it is not possible to obtain time-mean solids fluxes from time-mean voidages and particle velocities.

17.1.8 Spouted Beds

Spouted beds provide an alternative to fluidized beds for relatively coarse particles (larger than about 1 mm in diameter). The geometry of a typical spouted bed is shown in Figure 17.12. This generally involves a single

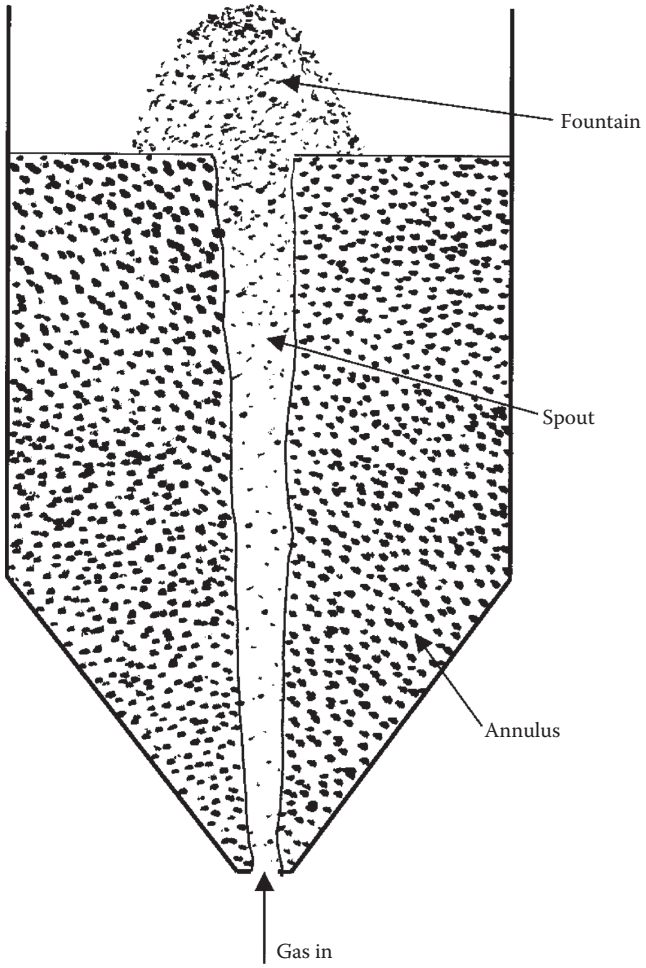

Figure 17.12

Schematic of typical spouted bed.

central orifice at the bottom and a conical section at the base, leading to a vessel of cylindrical cross section at the top. However, there are many variants on this geometry, including flat-bottomed vessels, completely cylindrical and completely conical vessels, columns of rectangular cross section equipped with slot orifices, and reactors equipped with nonporous or porous draught tubes, extending over most of the height of the particles. It is also possible to have multiple orifices (leading to multiple spouts) and a hybrid of spouting and fluidization (called a "spout-fluid bed"). For comprehensive reviews of spouted beds, see Mathur and Epstein (1974) and Epstein and Grace (2011).

A spouted bed is composed of three separate regions: a relatively dilute spout (or jet) region above the orifice extending right up to the bed surface, a surrounding moving-packed-bed annulus region, and a fountain region above the bed surface, where particles travel upward through a certain distance from the top of the spout and then rain back under gravity onto the surface of the annulus. Systematic solids' circulation occurs as particles descend in moving-packed-bed flow through the annulus, are entrained from the spout–annulus interface into the upward jet of gas in the spout where they are accelerated upwards and carried through the top of the spout, and thence return in the fountain to the top surface of the annulus.

Unlike a fluidized bed where all of the particle weight-minus-buoyancy is supported by drag from the fluid, in a spouted bed only part is provided by drag, with the rest of the weight of particles in the annulus borne by particles below. Hence, the pressure drop across a spouted bed is lower, typically by 25%–30%, than in a corresponding fluidized bed. This lower pressure drop results in lower energy costs and therefore constitutes one of the advantages of spouted beds. Other advantages are that the gas and particle motion are more systematic and predictable than in fluidized beds. Disadvantages are that narrower particle size distributions tend to be needed, that scale-up is only possible over a much lower range of column diameters, that particle–particle

contact is more likely to cause agglomeration, and that the range of gas velocities, which can be used, is less broad than for fluidized beds.

Typically, a spouted bed is constrained by certain limits for good operation. In order for a coherent spout to form, the ratio d_{or}/d_p should not exceed about 25, while the ratio D/d_{or} must be greater than ~3 for coarse particles or ~10 for relatively fine materials. The included angle of a conical base should generally be at least 40°.

The minimum spouting velocity is usually predicted by an early correlation proposed by Mathur and Gishler (1955):

$$U_{mS} = \left(\frac{d_p}{D}\right)\left(\frac{d_{or}}{D}\right)^{1/3}\sqrt{\frac{2gH(\rho_p - \rho_g)}{\rho_g}} \tag{17.63}$$

Unlike the minimum fluidization velocity U_{mf} (Equation 17.5), U_{mS} depends on the bed depth, H, and on the equipment used (via the orifice diameter, d_{or}). For relatively large columns where $D > 0.5$ m, the right-hand side of Equation 17.63 should be multiplied by $2D$ (with D in meters) to compensate empirically for systematic underestimation by the original correlation.

The maximum spoutable bed depth, beyond which it is not possible to obtain spouting, can be predicted from the correlation

$$H_m = \frac{D^2}{d_p}\left(\frac{D}{d_{or}}\right)^{2/3}\frac{568b^2}{Ar}\times\left\{\sqrt{1+35.9\times10^{-6}Ar}-1\right\}^2 \tag{17.64}$$

where the empirical constant b can be taken as 1.11 for room temperature conditions and 0.9 for elevated temperatures. It can be shown by differentiation that H_m reaches a maximum at $Ar = 223{,}000$, corresponding typically to $d_p \approx 1$–1.5 mm.

Once spouting has been achieved, the pressure drop across the bed, ΔP_S, is approximately 65%–70% of that across a fluidized bed of the same particles of the same depth, and the axial pressure distribution can be approximated (Lefroy and Davidson, 1969) by

$$\frac{dP}{dz} = \frac{-\Delta P_S}{2H}\pi\sin\left(\frac{\pi z}{2H}\right) \tag{17.65}$$

The flow of gas through the dense annulus at height z can be estimated by a result derived by Mamuro and Hattori (1968):

$$\frac{U_a}{U_{mf}} = 1-\left(1-\frac{z}{H_m}\right)^3 \tag{17.66}$$

This relationship works well, even when $H < H_m$ and for a wide range of particle sizes. The fraction of the total flow that passes through the annulus at any height, z, is then given by $(U_a/U)[1\ 2\ (d_S/D)^2]$, where d_S is the spout diameter, which in turn can be estimated from an empirical dimensional correlation proposed by McNab (1972):

$$d_S = 2.0\left(\rho_g U\right)^{0.49} D^{0.68}\rho_b^{-0.41} \tag{17.67}$$

where ρ_b is the bulk density of the particulate material. In practice, the spout diameter varies with height, with the shape varying, for example, diverging continuously or necking. This equation should therefore be regarded as predicting a longitudinal average spout diameter.

The voidage in the annulus can be approximated as being uniform and equal to the packed-bed value, which for the relatively coarse particles of interest is also nearly equal to ε_{mf}, the voidage at minimum fluidization, with a typical value of 0.41–0.43. The voidage in the spout starts out at 1 at $z = 0$ and then decreases approximately linearly with increasing height, z. The depth of the annulus under operating conditions is

generally very nearly the same as the depth of the same bed of particles without any flow through it. The fountain height can be estimated (Grace and Mathur, 1978) from the semiempirical equation:

$$H_f = \frac{\rho_p \left(\varepsilon_{SH}^{0.93} v_{oSH}\right)^2}{2g(\rho_p - \rho_g)} \tag{17.68}$$

where ε_{SH} is the voidage in the spout at the bed surface, that is, at $z = H$ and v_{oSH} is the particle velocity in the spout on the column axis at the same level. Several models are available for predicting the latter two quantities, and the particle circuit times and trajectories (Mathur and Epstein, 1974, Epstein and Grace, 2011).

When spouted beds are employed as chemical reactors, they have better gas–solid contact in the annulus than in the spout. Hence, two-region models are required to predict gas conversions, with a molar balance at the bed surface to estimate the overall composition of the gas at that level. This approach is analogous to the two-phase models for fluidized-bed reactors discussed in Section 17.1.4.4. Allowance may also be made for additional gas–solid contact in the fountain region. When the particles are reacting (e.g., in spouted-bed combustion or gasification of solid fuels), mole balances for the gas must be coupled with those for the solid phase. The particles can usually be assumed to be perfectly mixed.

Spout-fluid beds are intermediate between spouted beds and fluidized beds. These units, in addition to the spouting gas (or liquid) introduced through a central orifice, a fraction of the total fluid is also introduced around the outer periphery at the bottom, for example, distributed over a lower conical surface. This generally helps to avoid particle agglomeration, improves the distribution of gas between the annulus and spout regions, increases the solids circulation rate, and reduces temperature gradients in the annulus. Various flow regimes exist, depending on geometry, total flow rate, and whether or not the auxiliary gas injected at the bottom is sufficient to fluidize the particles.

17.1.9 Three-Phase Fluidization

Gas–liquid–solid fluidization is practiced in some biochemical reactors and in certain chemical processes where solid particles need to be contacted with both liquid and gas, for example, in hydrotreating of liquid hydrocarbons by gaseous hydrogen in the presence of solid catalyst particles. A thorough review of three-phase fluidized beds (covering their fundamentals as well as their applications) was published by Fan (1989). Many contacting modes and geometries are possible. This brief section only deals with cases where the gas and liquid are both introduced at the bottom and travel cocurrently upward in a cylindrical column without any draught tube or other internal surfaces.

There is considerable extra complexity due to having three distinct phases (gas, liquid, and solid) interacting with each other. Some of the simpler results are presented here. First, the sum of the holdups of the individual phases must be unity, that is,

$$\varepsilon_s + \varepsilon_l + \varepsilon_g = 1 \tag{17.69}$$

Since wall friction and acceleration effects are usually negligible, the hydrostatic pressure gradient in the bed can be written as

$$\frac{dP}{dz} = -\left\{\rho_p \varepsilon_s + \rho_l \varepsilon_l + \rho_g \varepsilon_g\right\} g \tag{17.70}$$

The gas contribution ($\rho_g \varepsilon_g$) term in the brackets can usually be ignored relative to the other terms on the right-hand side. If the pressure gradient is measured experimentally, then a third equation is needed to solve for the three unknown holdups. Frequently, this is obtained as a fair approximation by assuming that all of the particles stay in the bed and that the solids holdup is independent of height, that is,

$$M_p = \rho_p \varepsilon_s AH \tag{17.71}$$

where

M_p is the mass of particles present
H is the expanded bed height

The minimum fluidization condition depends on the flow of both gas and liquid. If the gas flow is fixed at some low value, the liquid minimum fluidization velocity, U_{lmf}, can be predicted by a gas-perturbed liquid model (Zhang et al., 1995), in which the primary role of the gas is assumed to be the occupation of space, causing an increase in the velocity of liquid due to the smaller area available for liquid flow. The best agreement is provided (Lee et al., 2003) when the buoyancy is based on the gas–liquid mixture (rather than the liquid alone) and when allowance is made for a decrease in voidage, observed experimentally, when gas is added to a bed of particles through which liquid is percolating. The resulting equation, analogous to Equation 17.5 for two-phase systems, is

$$Re_{lmf} = \frac{\rho_l d_p U_{lmf}}{\mu_l} = \sqrt{C_1^2 + C_2 Ar'(1-\alpha_{mf})^3} - C_1 \tag{17.72}$$

where

$$Ar' = \frac{\rho_l(\rho_p - [\rho_g \alpha_{mf} + \rho_l(1-\alpha_{mf})]g d_p^3)}{\mu_l^2} \tag{17.73}$$

and α_{mf} is the gas holdup expressed on a solids-free basis at minimum fluidization, which can be predicted from the empirical correlation of Yang et al. (1993):

$$\alpha_{mf} = \frac{0.16 U_g}{\varepsilon_{mf}(U_g + U_l)} \tag{17.74}$$

The observed variation in voidage at minimum fluidization due to gas addition is accounted for by the empirical equation

$$\varepsilon_{mf} = \varepsilon_{mf|U_g=0}\left\{1 - 0.34(1 - U_{lmf}/U''_{lmf}) + 0.22(1 - U_{lmf}/U''_{lmf})^2\right\} \tag{17.75}$$

where U_{lmf} and U''_{lmf} are the liquid superficial velocities at minimum fluidization for three-phase (gas–liquid–solid) and two-phase (liquid–solid) fluidization, respectively. Equations 17.72 through 17.75 are solved simultaneously to yield values of the three unknowns: α_{mf}, ε_{mf}, and U_{lmf}. The Wen and Yu (1966) values of the constants, that is, $C_1 = 33.7$ and $C_2 = 0.0408$, are recommended, as in Section 17.1.2.1. Experimental values of the voidage at minimum fluidization without any gas present are recommended whenever they are available; otherwise, one can employ the correlation of Limas-Ballesteros (1980):

$$\varepsilon_{mf/U_g=0} = \frac{0.42}{\psi^{0.376}} \tag{17.76}$$

where Ψ is the particle sphericity. A similar approach can be used to predict minimum fluidization velocities of inverse fluidization (where the particle density is less than the liquid density) and three-phase systems where the liquid flow is far less than that required to fluidize the solids (Zhang et al., 1998).

When three-phase fluidization has been achieved, it is difficult to obtain accurate predictions of behavior, due to factors such as different flow regimes, the wide range of possible properties and operating conditions, and the role of wettability and surfactants. In practical systems, the liquid phase may be non-Newtonian in nature, further complicating the predictions. Fan (1989) provides a useful summary of the empirical and semiempirical methods available to predict properties such as solids, gas, and liquid holdups, solids holdup in the freeboard region, and bed expansion.

The most successful models for predicting three-phase bed hydrodynamics are heavily based on bubbles and their wakes. Small bubbles are spherical or nearly so. With increasing size, they become ellipsoidal and wobbly, ultimately undergoing a transition to spherical-cap bubbles, whose wakes approximately complete the spheres of which the bubbles form the tops. These wakes (Fan and Tsuchiya, 1990), carried at the back of rising bubbles, are responsible for a number of key behavioral aspects of three-phase systems:

1. They transport liquid and solids rapidly in an upward direction, accounting for much of the rapid axial mixing and transport of both liquid and solids.

2. The rapid transport of liquid in the wake can explain a surprising feature of some three-phase systems, where the introduction of gas bubbles into a liquid–solid system actually causes a decrease in bed expansion. Several criteria are available (Fan, 1989) for when bed contraction, rather than expansion, occurs upon the addition of gas.
3. When the bubbles reach the bed surface, their wakes transport solid particles right into the freeboard region, often leading to significant carryover.

17.1.10 Practical Considerations for Gas–Solid Systems

Important aspects of particle and gas properties are covered in Table 17.1. This section briefly considers some of the important aspects of equipment design and operation. More design tips and details are provided in major texts and information sources on fluidization (Zenz and Othmer, 1960, Hetsroni, 1982, Davidson et al., 1985, Geldart, 1986, Pell, 1990, Kunii and Levenspiel, 1991, Grace et al., 1997, Yang, 2003).

The most important design variable for fluidized beds is the gas distributor (see Figure 17.10a). This should (1) provide a pressure drop across it of approximately 30%, and definitely not less than 10%, of that across the fluidized solids above it; (2) distribute the gas uniformly over the cross section above it, typically requiring that the gas entry points should not be more than 100 mm apart; (3) damp out pressure fluctuations from the blower or compressor; (4) not cause "sand blasting" (erosion) of surfaces or excessive attrition, typically meaning that entry velocity of the gas should not exceed 30–50 m/s and the jet should not impinge directly on fixed surfaces such as vessel walls or heat-transfer tubes; (5) support the dead weight of the bed when the gas is shut off; (6) not cause weeping or dumping of solids into the windbox below (due to pressure fluctuations); and (7) not become blocked by particles or deposits. Many geometries are used in practice including nozzles, tuyeres, downward-facing orifices, and shrouded orifices.

Jet penetration into a zone that does not contain bubbles can be predicted by correlations due to Merry (1971, 1975).

Vertical jets:

$$L_j = 5.2 d_{or} \left(\frac{\rho_g d_{or}}{\rho_p d_p} \right)^{0.3} \left\{ 1.3 \left(\frac{u_{or}^2}{g d_{or}} \right)^{0.2} - 1 \right\} \tag{17.77}$$

Horizontal jets:

$$L_j = d_{or} \left\{ 5.25 \left(\frac{\rho_g u_{or}^2}{(1-\varepsilon_{mf})\rho_p g d_p} \right)^{0.4} \left(\frac{\rho_g d_p}{\rho_p d_{or}} \right)^{0.2} - 4.5 \right\} \tag{17.78}$$

Jet penetration is reduced if the region into which the jet penetrates contains bubbles. In some cases, gas may be introduced in a downward direction, or obliquely downward. Penetration is then considerably reduced, but at the expense of higher particle attrition. It is especially important to assure excellent dispersion and mixing in cases where liquid must be sprayed into the bed or where the particles are wet or sticky. In such cases, high gas velocities coupled with uniform gas distributors and a lack of locations where particles can sit without being immediately set into motion are important to maintain the continuity of fluidization and to prevent defluidization, hot spots, and fouling.

Attrition of particles in fluidized beds may occur due to impact of particles with fixed surfaces or with other particles (e.g., in jets or in cyclones), due to abrasion wearing away surface roughness, due to rapid heating causing thermal stresses, or due to some combination of these factors. Standard tests are available to test the friability of particulate materials. Particle growth may occur as a result of elutriation of fines from the vessel, agglomeration (e.g., due to sintering), deposition, or chemical reaction.

Pressure taps and other orifices installed along the walls of the column should be purged, with gas entering at a linear velocity of not less than 0.5 m/s, to prevent particles from entering. Common instrumentation includes pressure transducers (both gauge and differential) and thermocouples. Both mean values

and fluctuations can be employed to warn about local defluidization and to provide indications of the flow regime and hydrodynamic behavior of the bed (e.g., see van Ommen et al., 2011, Issangya et al., 2013).

When heat-transfer surfaces or other fixed surfaces are immersed in fluidized beds, they should be either vertical or horizontal, not inclined, as oblique surfaces cause short-circuiting of gas up the underside. Fixed surfaces should be separated by at least 20 particle diameters (and preferably $50d_p$) to avoid channeling in the gap, causing defluidization of the region and local bypassing, which reduce gas–solids contacting in the neighborhood. Natural frequencies of bubbles in fluidized beds are usually of order 1 Hz. It is important to design tubes and other surfaces with their natural frequencies well outside this range. Convective heat-transfer coefficients between fixed surfaces and fluidized beds are usually of order 300–500 W/m^2 K for bubbling beds of group A materials, and 200–300 W/m^2 K for group B materials or fast-fluidized beds of group A materials.

Scale-up of fluidized beds is often based on experience rather than first principles. Scaling rules summarized by Glicksman et al. (1994) can sometimes be used to provide hydrodynamic scaling based on geometric and dynamic similarity, with matching of key dimensionless groups between the model and full-scale unit. Dimensionless quantities to be matched include *Ar*, a particle Reynolds number, Froude number, density ratio ρ_p/ρ_g, particle sphericity, and dimensionless particle size distribution. For scale-up of difficult chemical processes in fluidized beds, a common approach is to build a series of units of different scale, beginning with a unit of minimum diameter 100–150 mm and progressing through a substantial pilot plant scale unit to the full-scale unit.

Nomenclature

a_b	Bubble interfacial area per unit volume of bubbles, m^{-1}
A	Cross-sectional area of column, m^2
A_c	Area of distributor per orifice, m^2
Ar	Archimedes number defined by Equation 17.6, dimensionless
Ar'	Modified Archimedes number defined by Equation 17.73, dimensionless
b	Empirical constant in Equation 17.64, dimensionless
B	Empirical constant in Equation 17.13, dimensionless
C_1,C_2	Empirical constants in Equation 17.5 and 17.72, dimensionless
C_{Ab}	Concentration of reactant A in bubble phase, mol/m^3
C_{Ad}	Concentration of reactant A in dense phase, mol/m^3
C_D	Drag coefficient, dimensionless
d_{or}	Orifice diameter, m
d_p	Mean particle diameter, m
d_{pi}	Diameter of *i*th particle size fraction, m
d_S	Spout diameter, m
D	Column diameter, m
D_{AB}	Molecular diffusivity of reacting or tracer gas, m^2/s
D_b	Bubble diameter, m
$D_{g,ax}$	Gas axial dispersion coefficient, m^2/s
D_h	Hydraulic diameter of column, m
$D_{s,ax}$	Solids axial dispersion coefficient, m^2/s
f_b	Bubble frequency, s^{-1}
f_w	Bubble wake fraction (= volume of wake/volume of bubble), dimensionless
F_d	Drag force/unit area defined by Equation 17.38, kg/m s^2
F_g	Gravity force per unit area defined by Equation 17.38, kg/m s^2
g	Acceleration due to gravity, m/s^2
G_s	Net solids flux through column, kg/m s^2
G_{so}	Upwards flux of solids at dense bed surface, kg/m s^2
G_{si}	Entrainment flux of solids of fraction *i* above the TDH, kg/m s^2
H	Expanded bed depth, m
H_f	Fountain height above spouted bed, m
H_m	Maximum spoutable bed depth, m
H_{mf}	Bed depth at minimum fluidization, m

k	Empirical constant in Equation 17.19, dimensionless
k_{bd}	Bubble-to-dense-phase interphase mass transfer coefficient, m/s
$k_{bd}^{\star}$	Dimensionless interphase mass transfer coefficient defined by Equation 17.35, dimensionless
k_r	First-order gas-phase reaction rate constant, s^{-1}
$k_r^{\star}$	Dimensionless first-order rate constant defined by Equation 17.35, dimensionless
L_j	Jet penetration distance into the fluidized bed, m
l_s	Slug vertical length, m
m_i	Mass fraction of particles belonging to the ith size fraction, dimensionless
M_p	Total mass of particles in the bed, kg
n	Empirical constant index, dimensionless
N_{or}	Number of orifices in the gas distributor, dimensionless
Nu	Nusselt number, dimensionless
P	Local pressure, Pa
P_c	Inner perimeter of fluidization column, m
$Pe_{g,ax}$	Peclet number for axial gas dispersion defined by Equation 17.47, dimensionless
$Pe_{s,ax}$	Peclet number for axial solids dispersion, dimensionless
Pr	Prandtl number, dimensionless
r	Radial coordinate, m
R	Radius of column, m
Re	Reynolds number based on particle diameter ($=\rho_g d_p U/\mu_g$), dimensionless
Re_c	Reynolds number corresponding to onset of turbulent regime, Equation 17.13, dimensionless
Re_D	Reynolds number based on column diameter ($=\rho_g DU/\mu_g$), dimensionless
Re_{lmf}	Reynolds number defined in Equation 17.72, dimensionless
Re_{mf}	Reynolds number defined in Equation 17.5, dimensionless
Re_{se}	Reynolds number corresponding to U_{se} ($-\rho_g d_p v_T/\mu_g$), dimensionless
Sc	Schmidt number for gas, dimensionless
Sh	Sherwood number, dimensionless
t_{mix}	Characteristic solids mixing or turnover time, s
u_{or}	Gas velocity through orifice into fluidized bed, m/s
U, U_g	Superficial gas velocity, m/s
U_a	Superficial velocity in annulus of spouted bed, m/s
U_b	Bubble rise velocity, m/s
U_c	Superficial gas velocity at onset of turbulent fluidization, m/s
U_{DSU}	Superficial gas velocity at onset of DSU, m/s
U_l	Superficial liquid velocity, m/s
U_{lmf}	Superficial liquid velocity at minimum fluidization, m/s
U''_{lmf}	Superficial liquid velocity at minimum liquid–solid fluidization, m/s
U_{mf}	Superficial gas velocity at minimum fluidization, m/s
U_{ms}	Superficial gas velocity at minimum slugging, m/s
U_{mS}	Superficial gas velocity at minimum spouting, m/s
U_{se}	Superficial gas velocity at significant entrainment, m/s
U_{si}	Velocity of rise of a single isolated slug, Equation 17.42, m/s
$U_{slip}^{\star}$	Dimensionless slip velocity defined in Equation 17.62, dimensionless
v_{oSH}	Velocity of particles on axis of spouted bed at $z = H$, m/s
v_{sw}	Time-mean particle velocity at wall of riser, m/s
v_T	Particle terminal settling velocity, m/s
V_b	Bubble volume, m^3
V_b	Volumetric flow accounted for by displacement of bubbles, m/s
V_s	Terminal settling velocity of particles, m/s
V_s^e	Terminal settling velocity of particles of diameter d_p in the fluid in question, m/s
V_{si}	Terminal settling velocity of particles in the ith size fraction, m/s
Y	Coefficient modifying two-phase theory of fluidization, Equation 17.22, dimensionless
z	Vertical height coordinate measured from gas distributor, m
z'	Vertical height coordinate measured from surface of dense bed, m

Greek Letters

α_i	Decay constant in Equation 17.40 for entrainment in TDH, m^{-1}
α_{mf}	Gas holdup/(gas + liquid holdup) at minimum fluidization, dimensionless
β	Dimensionless gas velocity for slug flow defined by Equation 17.42, dimensionless
ΔP	Pressure drop, Pa
ΔP_{bed}	Pressure drop across dense fluidized bed, Pa
ΔP_{fixbed}	Pressure drop across fixed bed, Pa
ΔP_{mf}	Pressure drop across fluidized bed at minimum fluidization, Pa
ΔP_S	Pressure drop across spouted bed, Pa
ε	Local time-mean voidage
ε'	Voidage defined by Equation 17.53, dimensionless
ε^*	Voidage at top exit of riser, Equations 17.55 and 17.57, dimensionless
$\langle\varepsilon\rangle_A$	Voidage averaged over cross-sectional area, dimensionless
$\langle\varepsilon\rangle_{av}$	Voidage averaged over entire bed
ε_b	Fraction of bed volume occupied by bubbles, dimensionless
ε_d	Voidage in dense phase region at bottom of riser, dimensionless
ε_g	Gas holdup = fraction of bed volume occupied by gas, dimensionless
ε_l	Liquid holdup = fraction of bed volume occupied by liquid, dimensionless
ε_{mf}	Bed voidage at minimum fluidization, dimensionless
ε_s	Solid holdup = fraction of bed volume occupied by particles, dimensionless
ε_{SH}	Spout voidage at top of spout (i.e., at $z = H$), dimensionless
η	Constant index in Equation 17.13, dimensionless
μ_g	Gas viscosity, kg/m s
μ_l	Liquid viscosity, kg/m s
ρ_b	Bulk density of particulate material, kg/m^3
ρ_g	Gas density, kg/m^3
ρ_l	Liquid density, kg/m^3
ρ_p	Particle density, kg/m^3
φ_b	Fraction of bed volume occupied by particles associated with bubble phase, dimensionless
φ_d	Fraction of bed volume occupied by particles associated with dense phase, dimensionless
χ	Mass fraction of particles, which are finer than 45 μm, dimensionless
Ψ	Particle sphericity, dimensionless

Abbreviations

ATP	Atmospheric-topped bitumen
BGPG	Biomass gasification and power generation
CFB	Circulating fluidized bed
CFBC	Circulating fluidized bed combustor
DSU	Dense suspension upflow
FCC	Fluid catalytic cracking or fluid cracking catalyst
FFB	Fixed fluidized bed
GIEC	Guangzhou Institute of Energy Conversion
GLSFB	Gas–liquid–solid fluidized beds
GLSCFB	Gas–liquid–solid circulating fluidized beds
LSCFB	Liquid–solid circulating fluidized beds
LSFB	Liquid–solid fluidized beds
PCFBC	Pressurized circulating fluidized-bed combustor
PFBC	Pressurized fluidized-bed combustor
QC	Quick contact
RFCC	Residue fluid catalytic cracking
RTD	Residence time distribution
SFB	Stationary fluidized-bed
SFB	Stationary fluidized bed combustor
SINOPEC	Chinese National (Sino) Petroleum Enterprises Corporation

TDH	Transport disengagement height
TCC	Thermofor catalytic cracking
UOP	Universal Oil Products Company
VTP	Vacuum-topped bitumen

Subscripts

AB	Boundary between group A and B solids
BD	Boundary between group B and D solids
b	Bubble
d	Dense phase
g	Gas
l	Liquid
p	Particle
s	Solid particles, slug
S	Spout, spouted bed

17.2 Heat and Mass Transfer

Bo Leckner

17.2.1 Bed to Surface Heat Transfer

Heat is transferred across various kinds of surfaces:

1. Bed internal heat transfer: fluidization gas ↔ bed material
2. External heat transfer to surfaces in or above the bed: fluidization gas and bed material ↔ heat-receiving surfaces in contact with the bed material

In this section, external heat transfer in dense or dilute particle suspensions will be discussed. Internal heat transfer will be treated in Section 17.2.2.

Heat transfer in fluidized beds has been summarized in several reviews, such as those of Zabrodsky (1966), Gelperin and Einstein (1971), Botterill (1975), Saxena (1989), Kunii and Levenspiel (1991), Baskakov and Filippovsky (1991), and Molerus and Wirth (1997). Heat transfer, especially in CFB, has been treated in the proceedings of the Conference on CFB. Furthermore, reviews related to CFB have been published by Basu and Nag (1996), Breitholtz and Leckner (1997) and Glicksman (1997).

The heat-transfer coefficient h W/m^2, deg for heat exchange between the bed and a heat-transfer surface of area A (m^2) in contact with the bed is defined by the heat flow expression

$$Q = hA\left(T_\mathrm{b} - T_\mathrm{w}\right) \tag{17.79}$$

where T_b and T_w (°C or K) are the bulk bed and wall temperatures. As an approximation, the radiative (index r) and convective (index c) constituents of heat transfer from gas (gc) and particles (pc) are often assumed to be additive. The heat-transfer coefficient then becomes

$$h = h_r + h_{gc} + h_{pc} \tag{17.80}$$

Sometimes, the gas and particle convective constituents are treated together as $h_c = h_{gc} + h_{pc}$. Data on thermal properties are normally taken at the average of surface and bed temperature.

17.2.1.1 Heat Transfer in the Dense, Bubbling Fluidized Bed

17.2.1.1.1 Correlations Related to Maximum Heat Transfer The bed is fluidized between the minimum fluidization velocity, here expressed in terms of a Reynolds number, Re.

$$Re_{mf} = \frac{Ar}{1400 + 5.22Ar^{1/2}} \tag{17.81}$$

and the terminal velocity of a single particle

$$Re_t = \frac{Ar}{\left(18 + 0.61Ar^{1/2}\right)} \tag{17.82}$$

according to empirical correlations (Aerov and Todes, 1968), incorporating Ergun's correlation (Equation 17.5) for minimum fluidization velocity under the assumption that the voidage is $\varepsilon = 0.4$, where *Ar* is the Archimedes number, a relationship between gravity and drag force representing the particle size, and *Re* is the particle Reynolds number related to the superficial velocity.

Figure 17.13 shows the heat-transfer coefficient in beds consisting of monosized particles of various sizes. The beds are fluidized between minimum fluidization and terminal velocities. The particle convective heat transfer to a surface in the bed increases when the velocity rises from the minimum fluidization velocity and reaches a maximum due to the enhancement of heat transfer following an increase in the movement of the bed. Despite further agitation of the bed caused by the increase in velocity toward the terminal velocity, the particle convective heat-transfer coefficient decreases after the maximum due to a simultaneous increase in voidage. Superimposed on the particle convective heat transfer, there is a contribution from the gas flowing through bubbles and particulate phase in the form of a gas convective heat-transfer constituent. The gas convection heat transfer is very small at low velocities (small particle sizes), but for large particles the particle convective heat transfer is small and the gas convective heat transfer is high. The gas convection is often disregarded for small particles (less than a millimeter), but must be considered for large particles (larger than a millimeter).

Figure 17.13 is designed on the basis of a model of Martin (1984). Heat transfer takes place between minimum fluidization velocity, given by Equation 17.81, and terminal velocity given by Equation 17.82. Furthermore, the

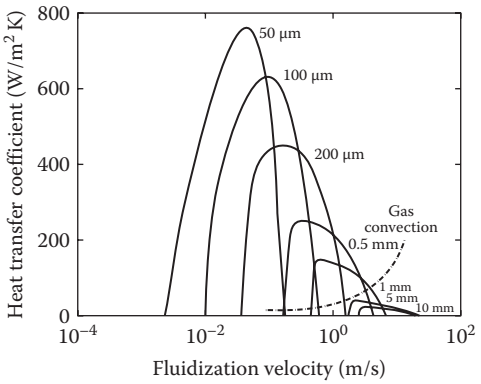

Figure 17.13

Schematic representation of the particle (lines) and gas convective (dashed) heat-transfer coefficients vs. fluidization velocity (log scale) in dense, bubbling fluidized beds of different particle sizes, each bed consisting of monosized particles. (Plotted according to a model for fluidization in air at 25°C and ρ_p = 2500 kg/m³.)

heat-transfer maxima for each particle size follow Equation 17.84. Obviously, the small heat transfer in the fixed bed at lower velocities than that of minimum fluidization is neglected. Likewise, the use of the terminal velocity as an end point is an approximation. The particle suspension in the bed becomes more dilute as the velocity increases (the voidage increases), but there should be some bed left even at the terminal velocity, especially for small particles where clustering makes a suspension endure higher velocities than the terminal velocity of a single particle. The terminal velocity as an end point makes the curves bend more severely at high velocities than what is shown in measurements. However, two aspects should be observed: (1) the scale is logarithmic and that compresses the diagram somewhat, (2) the gas convection should be added to the particle convection, and at higher temperatures also the thermal radiation, to get the resulting total heat-transfer coefficient. These effects would make the curves fall less steeply.

In the surveys on heat transfer in dense, bubbling beds, as mentioned in the reviews quoted above there are many correlations and modeling efforts describing the detailed behavior of heat transfer. The result of one of these models illustrates the general behavior of the heat-transfer coefficient, as shown in Figure 17.13. However, the situation in a fluidized bed is complex and the multitude of efforts has led to a qualitative understanding of the phenomena rather than to a generally valid predictive description. In the following, a simplified approach is preferred and the presentation will focus on the most reliable data, namely, those of the maximum heat-transfer coefficient, for which correlations are available. The maximum heat-transfer coefficient of a rounded fixed object in the interior part of a dense, bubbling fluidized bed, joining the maximum points shown in Figure 17.13, has been determined empirically and expressed as a function of the Archimedes number. One such correlation (Varygin and Martyushin, 1959) is as follows:

$$Nu_{c,max} = 0.86 Ar^{0.2} \left(30 < Ar < 10^5\right) \tag{17.83}$$

where

$Nu_c = h_c d_p / k_{air}$

k_{air} is the thermal conductivity of air

For other gases, h_c should be multiplied by $(k_g/k_{air})^{0.6}$. The location of the maximum can be described according to Aerov and Todes (1968) and Gelperin and Einstein (1971):

$$Re_{opt} = \frac{Ar}{\left(18.0 + 5.22 Ar^{1/2}\right)} \tag{17.84}$$

The optimum fluidization velocity is in the range between the terminal and minimum fluidization velocities, as seen in Figure 17.13 and in a different way in Figure 17.14. The maxima determined empirically are quite wide and the optimum velocity is not as exactly described by experimental data as may be the impression from Figures 17.13 and 17.14.

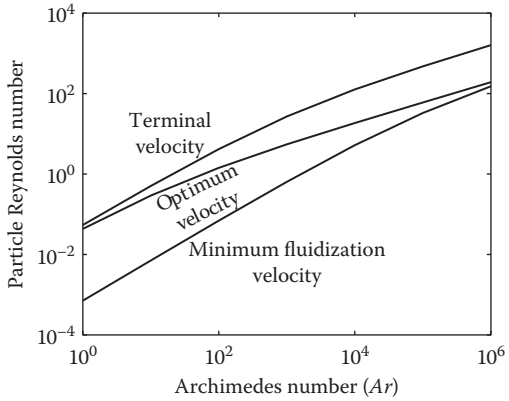

Figure 17.14

The minimum, terminal, and optimum fluidization velocities for different particle sizes (Ar) according to Equations 17.81, 17.82, and 17.84.

Equation 17.83 can be written as

$$h_{c,max} \sim d_p^{-0.4} \rho_p^{0.2} k_g \mu_g \rho_g^{0.2} \tag{17.85}$$

which can be compared with the well-known Zabrodsky (1966) formula, expressed in SI units, valid for objects of sizes between 0.010 and 0.060 m and bed particles between 0.00006 and 0.001 m at room temperature:

$$h_{c,max} = 35.7 d_p^{-0.36} \rho_p^{0.2} k_g^{0.6} \tag{17.86}$$

Both formulae show an approximately equal impact of bed particle size. The thermal conductivity of gas has a different power, which means that the temperature dependence could be different in the two representations. This is not the case, however, as the gas density term in Equation 17.83 provides an additional temperature influence. None of the expressions consider the impact of specific heat of the bed material. As seen from the packet model, Equation 17.98, both density and specific heat of the particles are important, since they account for the transport of heat by particles to the wall. However, the properties of materials reveal that specific heat and density are correlated for most conceivable bed materials. Therefore, in empirical formulae, such as Equations 17.83 and 17.86, the particle density also represents the specific heat.

Similar expressions for vertical and horizontal tube bundles in a fluidized bed have been given by Gelperin and Einstein (1971, Table 10.3, p. 516). The relationship for horizontal in-line tubes is

$$Nu_{d,max} = 0.79 Ar^{0.22} (1 - D/s_h)^{0.25} \tag{17.87}$$

where

D is the tube diameter

s_h is the horizontal distance between the centers of the tubes

In fluidized-bed applications, there is a connection between Re and Ar, as seen from Equations 17.81, 17.82, and 17.84, and these dimensionless numbers can be interchanged in heat-transfer expressions. It is likely that dimensional expressions such as Equation 17.86 also can be transformed into a dimensionless form. For instance, Zabrodsky (1974) tentatively expressed Equation 17.86 in the same form as Equation 17.83 yielding $0.88 Ar^{0.213}$. With Archimedes number, gas density is introduced in Equation 17.83, and therefore, the correlation becomes sensitive to pressure, which was not included in the database used to establish the relationship. Although pressure may have some impact on gas convection and also to some extent on particle convection (Martin, 1984), this impact may be too strong in Equation 17.83 owing to the gas density term, and this form of relationship is therefore applicable only at atmospheric pressure unless supported by heat-transfer measurements at other pressures. However, within its range of applicability, the simpler dimensional relationship, Equation 17.86, could be applied to pressurized situations also, if gas convection is not dominant.

For larger particles, the impact of the gas flow is relatively important, and a gas convective constituent should be added to the particle convection term (Baskakov et al., 1973):

$$Nu_{gc} = 0.009 Ar^{0.5} Pr^{0.33} \tag{17.88}$$

This equation has already been plotted in Figure 17.13.

Figure 17.15 summarizes the details given. The simple relationships, Equations 17.83 and 17.86, include gas convection, but in their range of validity $Ar < 10^6$, gas convection is insignificant. Only at $Ar > 10^7$, gas convection dominates heat transfer.

The total maximum heat transfer can be expressed by a simple Archimedes number relationship over a wide range of particle size, such as proposed by Baskakov (1985)

$$Nu_{max} = 0.85 Ar^{0.19} + 0.006 Ar^{0.5} Pr^{0.33} + h_r d_p / k_g \tag{17.89}$$

valid in the temperature range of 20°C to 1300°C for Ar from 10^2 to 10^9 at atmospheric pressure. More refined expressions of the same kind, also considering pressure, have been presented by Borodulya et al. (1991).

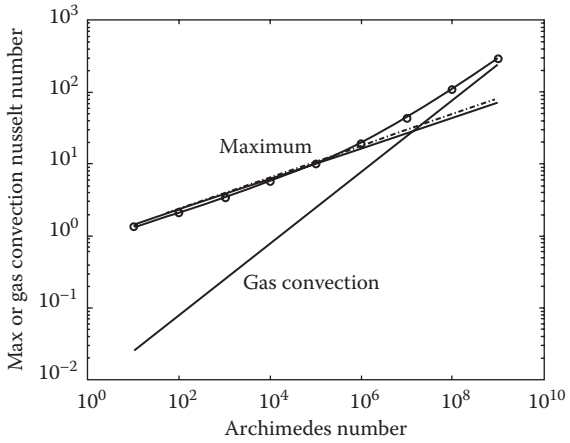

Figure 17.15

Total maximum heat transfer compared to gas convective heat transfer. The straight line, representing maximum heat transfer, is Equation 17.83 and the dashed one is Zabrodsky's formula (Equation 17.86). Gas convection is plotted according to Equation 17.88. The curve denoted by circles is Baskakov's relationship (Equation 17.89) without radiation.

The definition of the additive radiative component of heat transfer between the bed and the surrounding wall is straightforward. Assume a heat-exchanging volume of gas and particles, surrounded by a wall of area A. Then, the radiation heat flow Q_r can be written as

$$Q_r = h_r A\left(T_b - T_w\right) = \varepsilon A\sigma\left(T_b^4 - T_w^4\right) \tag{17.90}$$

where

T_b and T_w are the temperatures of the bulk of the bed and the wall expressed in K
σ is the Stefan–Boltzmann's constant (W/m^2 K^4)
ε is the resulting emissivity

Equation 17.90 yields the definition of the radiative heat-transfer coefficient

$$h_r = \varepsilon\sigma\left(T_b + T_w\right)\left(T_b^2 + T_w^2\right) \tag{17.91}$$

This definition has the consequence that h_r depends on the temperature conditions in each case of application in the range from one extreme ($h_r = 4\varepsilon\sigma T_b^3$ when $T_b = T_w$) to another ($h_r = \sigma\varepsilon T_b^3$ when $T_b \gg T_w$). For an enclosure or a semi-infinite plane-parallel layer, the resulting emissivity can be written as

$$\varepsilon = \frac{1}{1/\varepsilon_b + 1/\varepsilon_w - 1} \tag{17.92}$$

where ε_b and ε_w are the emissivities of bed and wall. The emissivity of the wall can be obtained from handbooks on radiation properties, although it is still an open question if the walls in fluidized beds are more polished by the particles than the materials in general and may have another emissivity for that reason. Owing to the "Hohlraum" effect of the space between the particles, the emissivity of the dense bed, ε_b, is higher than that of the surface of the particles ε_s. According to Borodulya and Kovensky (1983),

$$\varepsilon_b = \varepsilon_s^{0.48} \tag{17.93}$$

which is one of several expressions leading to the same result, as analyzed by Baskakov and Leckner (1997). All data needed for the radiative transfer calculation (T_b, T_w, A, ε_b, and ε_w) are normally available, but still the calculation cannot be carried out since the temperature of the particle layers adjacent to a

heat-transfer surface may differ from the bed temperature, more in the case of small particles than in beds of large particles. Therefore, Equation 17.90 represents the maximum radiative transfer and the actual value is normally lower. Various modeling approaches have tried to describe this reduction of the radiative transfer. For simplified estimates, Baskakov (1985) has suggested maintaining Equation 17.91 as it is and introducing an empirically defined effective emissivity $\varepsilon_{eff} = \varepsilon_b$ to take the variations into account; examples are found in the source quoted. For bed temperatures between 1000 and 1500 K and voidages of $0.3 > \varepsilon_b > 0.6$, and in the absence of more general expressions, an even more simplified relationship has been proposed by Baskakov: $h_r = 7.3\sigma\varepsilon_b\varepsilon_w T_w^3$. The choice of the wall temperature to represent radiative exchange is obviously a considerable approximation and is mostly valid for beds of small particles where the particles close to the wall approach wall temperature. For large particles, on the other hand, the particle temperature is close to the bulk bed temperature, as these particles need more time to cool down after reaching the wall layer. In Schlünder et al. (1987), similar simplifications are found; for instance, it is proposed to use the arithmetic mean between wall and bed temperature as a representative radiation temperature in Equation 17.90.

17.2.1.1.2 Correlations, General The quoted reviews present many correlations describing heat transfer to an element (like a tube) in a fluidized bed. The correlations are not necessarily related to the maximum heat transfer but can cover the rising branch seen in Figure 17.13 or the postmaximum branch or both. Here only one example will be presented: one of the best-known correlations is that of Vreedenberg (1958) related to a horizontal tube. It has been analyzed and criticized by many. For instance, Grewal (1979), observing that the correlation lacked a term ρc_p to express the thermal capacity of the fluidized suspension, proposed an extension of the correlation in addition to an expression for voidage. Andeen and Glicksman (1976) had the opinion that the correlation should consider the influence of voidage instead of just allowing the heat transfer to increase monotonically with velocity, and they suggested the following modification:

$$Nu_D = 900(1-\varepsilon)Pr^{0.3}\left(\frac{uD\rho_s}{\mu}\frac{\mu^2}{d^3\rho_s^2 g}\right)^{0.336} \tag{17.94}$$

Andeen and Glicksman derived an expression for voidage based on a form proposed by Leva (1957)

$$\varepsilon = \frac{1}{2.1}\left(0.4 + \left(\frac{200u\mu}{d^2\rho_s g}\right)^{0.33}\right) \tag{17.95}$$

Grewal used the same starting point (Leva) but fitted the expression to his own extensive measurements:

$$\varepsilon = \frac{1}{2.1}\left[0.4 + \left[4\left(\frac{u\mu}{d^2\rho_s\phi_s^2 g}\right)^{0.43}\right]^{0.33}\right] \tag{17.96}$$

A plot of Equation 17.94 using the voidages of Equations 17.95 and 17.96 is compared with the maximum heat-transfer coefficients according to Gelperin and Einstein's (1971) Equation 17.84 in Figure 17.16.

Figure 17.16 illustrates a few properties of this type of correlations. It is obvious that the original Vreedenberg correlation did not catch the maxima, just as was observed by Andeen and Glicksman (1976) whose improved correlation does reflect the maximum heat transfer. On the other hand, the same correlation (Equation 17.94) employing the voidage correlation of Grewal (Equation 17.96) is more similar to the original Vreedenberg correlation and it does not fall off at high velocities, not even qualitatively describing a maximum. Grewal (1979) himself found that his own correlation (a modified Vreedenberg equation) with his voidage description gives the best fit to available data among the various correlations investigated.

The conclusion is that even though the determination of the velocity at maximum heat transfer can be slightly uncertain, especially at high velocities where there is a substantial contribution of gas convection, correlations describing the maximum heat transfer seem more reliable than the correlations trying to catch

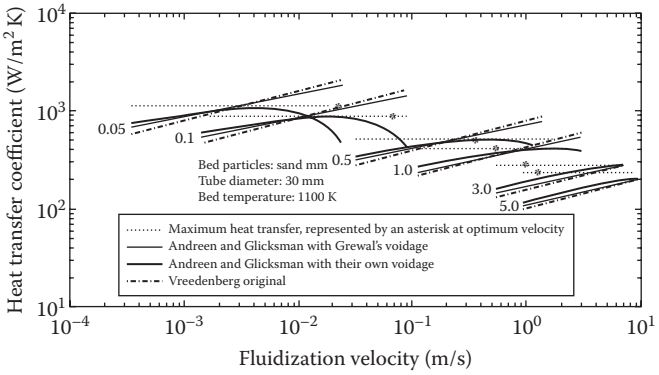

Figure 17.16

Comparison between Vreedenberg's (1958) and Andeen and Glicksman's (1976) correlations of heat transfer to a tube with their own representation of voidage (the thicker curve, showing a maximum) and that of Grewal (1979), and the maximum heat-transfer coefficient from Gelperin and Einstein (1971) for infinite tube distance (s_h) and six bed-particle sizes (from 0.05 to 5 mm). The plot is made considering temperature-dependent gas properties, but it exceeds the range covered by the test data of the correlations. Each set of curves represents the given particle size and ranges from the minimum fluidization velocity to the terminal velocity of a single particle.

the variations with velocity in the rising branch where the development of voidage with velocity, particle size, and geometry play significant roles. The two voidage correlations quoted both use Leva's work as a starting point but nevertheless lead to different results if used as independent expressions. In tube bundles, the voidage conditions may differ even more from available voidage expressions, as reflected by pictures shown on bubbles in a two-dimensional bed containing various tube packings and subject to various velocities, Leckner (1998). This has been little studied and only some correlations on the influence of tube configurations of the kind shown in Equation 17.87 are available in the literature.

17.2.1.1.3 Heat-Transfer Mechanisms The steep rise in heat transfer from the value at minimum fluidization to the maximum value is caused by the increased movement of the bed in the vicinity of the heat-transfer surfaces as a consequence of the stirring action of bubbles. Heat transfer to a surface and the fluid dynamic behavior of the bed are strongly linked. The fluid dynamics change with the position within a bed and depend on several conditions, such as fluidizing velocity, bed material, and size of the containing vessel. This has made it difficult to establish generally valid heat-transfer relationships. The correlations, differ from each other and give different results, showing the complexity of the situation. In Figure 17.17, a striking example is given, illustrating the difficulty involved in the application of heat-transfer correlations, while it also explains the mechanisms of heat transfer. Figure 17.17a shows the resulting heat-transfer coefficients, measured with a heat-transfer probe on a vertical water-cooled wall of a fluidized-bed combustor with a 10 m^2 cross section, operated with sand as bed material at 850°C bed temperature. The heat-transfer coefficient increases from the air-distributor plate, forming the bottom of the bed, to the surface of the bed (which is located above the bed height at rest, given in the figure) during operation at various fluidization velocities. Above the surface of the bed, in the splash zone, the heat-transfer coefficient decreases again with height. Figure 17.17b shows material loss from the heat-transfer steel tubes of the wall owing to erosion by the bed material in the same boiler and on the same wall where the heat-transfer measurements were made.

The similarity between heat transfer and erosion illustrates the mechanism of heat transfer. At the surface of the bed, there is a vigorous movement and the wall is frequently exposed to high-temperature particles. The bed material flows downward along the wall and the agitation declines, although the bed as a whole is vividly fluidized and the air supply nozzles are active. Changes in the fluidization velocity in the range of 1.4–2.2 m/s did not markedly change the conditions. The particle layers close to the wall transfer their heat to the wall and cool, thereby reducing the heat-transfer potential. Heat is transferred by exchange of bed material from the hot core of the bed to the wall. If there is only little or almost no exchange of bed material, the material close to a surface attains the temperature of the surface, and eventually heat transfer takes place only by thermal conduction. The thermal conductivity of stagnant bed material is low, and in this case, when the bed material serves as an insulating agent, heat transfer declines.

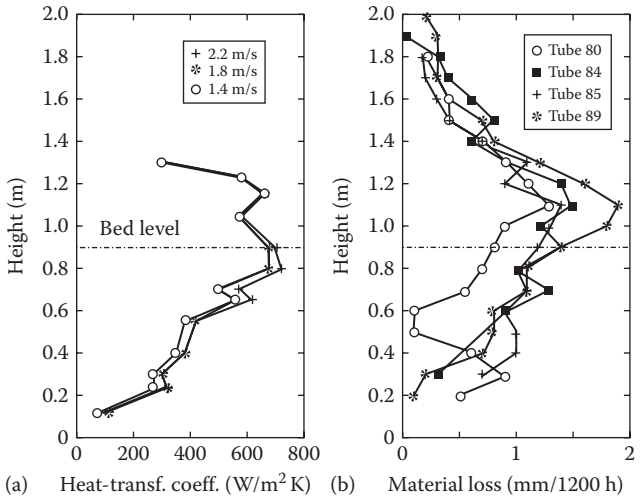

Figure 17.17

Heat transfer to a wall of a stationary fluidized-bed boiler at various fluidization velocities (symbols) (a) compared with erosion on the same membrane tube wall after 1200 h of operation (b). Conditions: bed temperature 850°C; average particle size 0.55 mm. Bed level is the level at rest. (The heat transfer data are from Andersson, B.-Å. and Leckner, B., Bed-to-wall heat transfer in a 10 m² bubbling fluidized bed, in Macías Machín, A. and Winter, G. (Eds.), *Proceedings of Congreso Europeo de Fluidisación*, Universidad de Las Palmas de Gran Canaria, Vol. 1, 1994, pp. 251–260; the erosion data are from Leckner, B. et al., Operational results from the 16 MW FBB at Chalmers University, *Third International Fluidised Conference*, The Institute of Energy, London, U.K., 1984, Paper Disc/16/134–143.)

The heat-transfer correlations presented are for large objects in the central parts of a fluidized bed, a different surrounding compared to a surface element on the sidewall of the bed.

17.2.1.1.4 Models Heat transfer can be modeled together with fluid dynamics and combustion, but here only the classical semiempirical approaches will be summarized. The most general set of semiempirical heat-transfer models describes the exchange of bed material at a heat-transfer surface as a packet of hot bed material, which is brought to the surface by the movements of the bubbles. The packet remains at the surface for a certain contact time, while its temperature approaches that of the heat-transfer wall, and is then replaced by a new packet from the core of the bed. A simplified version of the energy equation describes the thermal behavior of the packet, considered as a semi-infinite continuum with effective thermal properties:

$$\left(\rho c_p\right)_b \partial T/\partial t' = k_{pb}\partial^2 T/\partial x^2 \tag{17.97}$$

where

$\rho_b = \rho_p(1 - \varepsilon)$, ε is the voidage
c_{pb} and k_{pb} are the specific heat and thermal conductivity of the packet
x is a coordinate oriented normal to the surface

The primed values t' and h' denote current time and heat-transfer coefficient, whereas t is the total residence time of a packet at the surface and h is the time-average heat-transfer coefficient. The time-dependent solution of Equation 17.97 for constant wall temperature and with the packet initially at core temperature is

$$h'_{i,c} = \frac{k_{pb}}{x_m}\left(1 + 2\sum_{n=1}^{\infty}\exp\left[-\frac{n^2\pi^2 k_{pb}t'}{x_m^2\left(\rho c_p\right)_b}\right]\right)$$
$$\cdots = \sqrt{\frac{k_{pb}\left(\rho c_p\right)_b}{\pi t'}}\left(1 + 2\sum_{n=1}^{\infty}\exp\left[-\frac{n^2 x_m^2\left(\rho c_p\right)_b}{k_{pb}t'}\right]\right) \tag{17.98}$$

This equation has two equivalent solutions: the first converges fast for long times and the second for short and intermediate times. Truncation gives an approximate expression for short and intermediate times:

$$h'_{i,c} = \frac{\sqrt{k_{pb}(\rho c_p)_b}}{\sqrt{\pi t'}}, \quad \text{i.e., } Nu_{i,c} = 1/(\pi Fo)^{1/2} \tag{17.99}$$

whereas for very long times

$$h'_{i,c} = h_c = k_{pb}/x_m, \quad \text{i.e., } Nu_{i,c} = 1 \tag{17.100}$$

where

$Nu_{i,c} = h'_{i,c}x_m/k_{pb}$ is the Nusselt number of the packet and the dimensionless time

Fo is the Fourier number, defined as $Fo = k_{pb}t'/(c_{pb}\rho_b d_p^2)$

For very short times or large particles, this solution leads to unreasonably high heat transfer, and the heat-transfer resistance $1/h'_{i,c}$ approaches zero. Therefore, a time-independent contact resistance in the form of a gas layer close to the surface is introduced:

$$\frac{1}{h_k} = \frac{\varphi d_p}{k_g}, \quad \text{i.e., } Nu_k = \frac{1}{\varphi} \tag{17.101}$$

where

k_g is the thermal conductivity of the gas adjacent to the surface

φd_p indicates the width of the gas layer in terms of particle diameters

Now, the total particle convective heat-transfer resistance becomes

$$\frac{1}{h'_{pc}} = \frac{1}{h_k} + \frac{1}{h'_{i,c}} \tag{17.102}$$

Baskakov (1964) integrated Equation 17.97 considering the gas gap and obtained the heat-transfer coefficient

$$h'_{pc} = h_k \exp\left[\frac{h_k^2 t'}{k_{pb}(\rho c_p)_b}\right] \operatorname{erf}\left[\sqrt{\frac{h_k^2 t'}{k_{pb}(\rho c_p)_b}}\right] \tag{17.103}$$

Time averaging for the total residence time t of a packet at the wall yields

$$h_{pc} = \frac{1}{t}\int_{t=0}^{t} h'_{pc}\,dt = 2\sqrt{\frac{k_{pb}(\rho c_p)_b}{\pi t}} - \sqrt{\frac{2k_{pb}(\rho c_p)_b}{\pi t h_k}} \ln\left[1 + \sqrt{\frac{\pi t h_k^2}{k_{pb}(\rho c_p)_b}}\right] \tag{17.104}$$

Similar expressions for various boundary conditions have been given by Gelperin and Einstein (1971). This type of expressions is somewhat inconvenient for engineering calculation and a simpler relationship is preferred:

$$h_{pc} = \frac{1}{1/h_k + 1/h_{i,c}} \tag{17.105}$$

where the time-average emulsion heat-transfer coefficient during time t is

$$h_{i,c} = 2h'_{i,c} = 2\frac{\sqrt{k_{pb}(\rho c_p)_b}}{\sqrt{\pi t}} \tag{17.106}$$

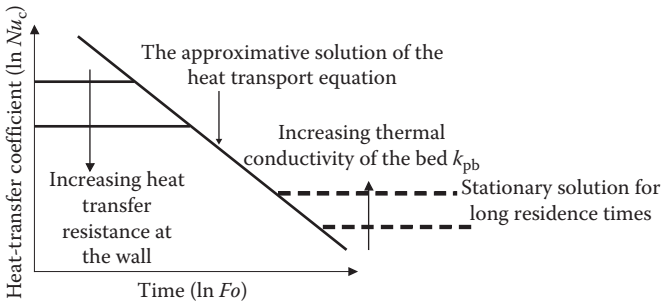

Figure 17.18

The particle convective heat-transfer coefficient as a function of residence time of a packet at the heat-transfer surface.

It has been shown (Fang et al., 1995b) that the deviation between Equation 17.104 and the simplified expression is less than 5%.

Figure 17.18 illustrates the limitations of the simplified solution of the heat-transfer equation, Equation 17.105. At very short times or large particles, the heat-transfer coefficient is limited by the resistance in the gas layer, Equation 17.101, and for hypothetically long residence times, it approaches the limit of pure conduction through a stagnant particle suspension of thickness x_m and thermal conductivity k_{pb}, given by Equation 17.100. The impact of the particles depends on particle size. In the case of very large particles (larger than 1 mm), the resistance of the gas layer becomes more important than that in the emulsion. For smaller particles, the thermal residence time of the emulsion is important, and the coefficient tends to be represented by the sloping part of the relationship shown in Figure 17.18. The packet model explains the particle convective heat-transfer mechanisms at a heat-transfer surface, but the resistance coefficient φ in Equation 17.101, the thermal conductivity of the packet (its density), and its residence time at the surface require further modeling.

If the heat-transfer surface is exposed to bubbles during a fraction of time f_0, the heat-transfer coefficient can be written as

$$h_c = \left(h_{gc,bubbles} + h_{r,bubbles}\right) f_0 + \left(h_{pc} + h_{gc,emulsion} + h_{r,emulsion}\right)\left(1 - f_0\right) \tag{17.107}$$

where the two terms represent the heat-transfer coefficients during the passage of a bubble and during the presence of the particle emulsion. In the common case when gas convection is small and radiation is negligible. Using Equation 17.105, Equation 17.107 can be written as

$$h_c = \frac{\left(1 - f_0\right)}{\left(1/h_k + 1/h_{i,c}\right)} \tag{17.108}$$

The significance of the various terms can be understood from the aforementioned discussion. Here only two extreme cases will be illustrated: those of small and large particles. In the case of small particles, Equation 17.107 results in

$$h_c = h_{r,bubbles} f_0 + h_{i,c}\left(1 - f_0\right). \tag{17.109}$$

In this case only radiation through bubbles and heat conduction through the emulsion (the sloping part of the curve in Figure 17.18) play significant roles as constituents of the heat-transfer coefficient. In the other extreme case, that of large particles, heat conduction through the emulsion is less important than the thermal resistance of the gas gap. Moreover, in this case, the particles at the wall are not essentially cooled and radiation from both emulsion phase and bubbles is important at high temperatures. With radiation and gas convection expressed for the total time, the result for large particles becomes

$$h_c = h_k\left(1 - f_0\right) + h_{gc} + h_r \tag{17.110}$$

The packet model has been the starting point for most fluidized-bed heat-transfer modeling. However, other ways of modeling have also been followed, where the heat exchange between the row of particles adjacent to a wall and the wall is regarded as most important for the heat transfer (Zabrodsky, 1966). An example of such an approach is the model developed by Martin (1984), who regarded the transport of heat by particles moving at an average velocity toward a heat-transfer surface. As in the case of the packet model, particles exchange their heat while remaining for some time at a heat exchange surface, but the thermal conduction in the particle emulsion is disregarded. The principal mechanism of heat transfer is through the gas film between a particle and a wall, and to some extent heat transport within a particle. The unknown parameters in Martin's model are related to the voidage of the bed, and for practical application of the model, a description of bed expansion is needed. A simplified version of this model has been used to illustrate the heat-transfer behavior in Figure 17.13. In the design of this figure, the bed voidage was supposed to vary linearly with the fluidization velocity

$$\varepsilon = \varepsilon_{mf} + (1-\varepsilon_{mf})(u-u_{mf})/(u_t-u_{mf}) \tag{17.111}$$

where $\varepsilon_{mf} \approx 0.4$. The velocities at minimum fluidization u_{mf} and terminal velocity u_t were obtained from Equations 17.81 and 17.82, respectively. The coarse simplification of the description of bed voidage makes the curves more rounded at velocities exceeding the optimum velocity than seen from the measurements. In reality, the curves are flatter, and a heat-transfer coefficient of $0.8h_{max}$ is often recommended for rough calculations over a wide range of velocities above the optimum one. The absence of particles at terminal velocity and, as a result, zero particle convective heat transfer (seen in Figure 17.13) is a consequence of the simplifying assumptions introduced for the present purpose. They are not necessary limitations of the model. A more realistic description of bed expansion in the high-velocity range would improve the result. However, the model assumes that the particles remain in contact with the wall, and it is not intended for the high-velocity modes of fluidization occurring when the bed is being converted into a circulating system.

17.2.1.2 Heat Transfer in the Disperse Suspension of the Circulating Fluidized Bed

17.2.1.2.1 General Conditions The high-velocity fluidized bed, extending in a riser reactor, consists of a dense bottom bed (if there is sufficient bed material in the riser), a transition zone, and a transport zone. The bed material is recirculated from a particle separator (e.g., a cyclone) back to the bottom bed, and hence, the device is called a CFB. Heat transfer in CFB is most common in combustors, and this is the application to be treated here. In a furnace for combustion, heat-transfer surfaces are found on the walls and inside the upper part of the CFB furnace (riser). In some cases, external heat exchangers containing horizontal tube bundles in low-velocity bubbling fluidized beds are connected to the cyclone return. In the CFB riser, the suspension densities are lower and the gas velocities are higher than in a noncirculating, bubbling, bed. Owing to the high velocity, erosion on the heat-transfer surfaces is potentially severe, and there are restrictions, both on the fluidization velocity and on the allocation of heat-transfer surfaces.

The orientation of the surfaces in the CFB riser should be parallel to the principal direction of the particle flow, and the surfaces should be located where the particle density is low, although, then the rate of particle-related convective heat transfer is also low. In the dense bed, often present in the bottom zone of the CFB riser, the conditions are analogous to those in the bubbling bed, but this region is not of interest for heat transfer because erosion makes it impossible to locate heat transfer tubes there; the walls of this zone are refractory lined to protect the tubes. Work on heat transfer in CFB has focused on the transport zone in the upper part of the furnace.

The heat-transfer surfaces of combustors normally consist of membrane tubes (Figure 17.19), exposed for heat transfer from where the bottom refractory ends and up to the top of the riser. In larger furnaces, there are also internal surfaces, such as "wing walls," inside the upper part of the riser, or extending all the way from the bottom to the top of the furnace, again, allocated parallel to the main flow of particles and protected from erosion in critical places. The heat-transfer surface is the entire area exposed to the particle suspension, but for tube walls, it may be expressed as projected surface area if the radiation from a distant suspension of gas and particles or from a flame is important. At a given heat-transfer rate, the coefficient h depends on whether it is related to the projected or to the total surface. The ratio of total and projected area is always less than $\pi/2$ for tube walls, as can be realized from geometrical reasons (see Figure 17.19).

The heat transfer between suspension and wall is affected both by the density of the suspension and by the temperature. Close to the heat-transfer walls, there is a falling film of particles forming particle and thermal boundary layers with higher suspension density and lower temperature than in the core of the riser.

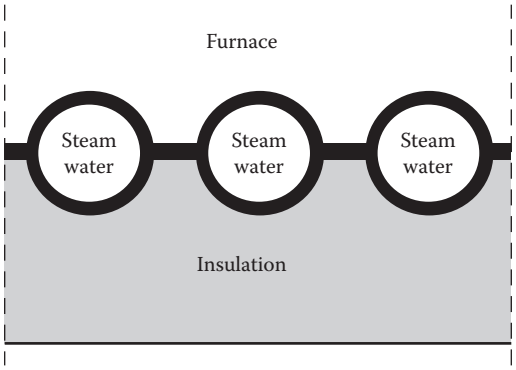

Figure 17.19

Cross section of three tubes of a membrane tube wall.

The boundary layer not only transfers heat by convection, it also participates in the radiative transfer of heat between the bed and the wall. Much of the radiative transfer originates in the hot core, but this radiation is partly absorbed by the particles in the wall layer and reaches the wall only after attenuation (Werdermann and Werther, 1994). The wall layer is colder than the core and its own emission is limited. Heat-transfer correlations are normally related to the average particle density of the cross section ρ_{av}, since this quantity is relatively easy to evaluate from measured pressure drops $\mathrm{d}P/\mathrm{d}z$ along the riser's height z under the assumption that the particles are carried by the gas. Formally, the average density over the cross section is expressed by integration of the local suspension density ρ_b over the cross section A_c of the riser as

$$\rho_{av} = A_c^{-1} \int \rho_b \mathrm{d}A_c = -1/g \; \mathrm{d}P/\mathrm{d}z \tag{17.112}$$

where the suspension density is

$$\rho_b = (1-\varepsilon)\rho_p + \varepsilon\rho_g \tag{17.113}$$

where ρ_p and ρ_g are the densities of particles and gas, respectively. With the exception of the thermal boundary layers, the time-average temperature of the suspension ("the bed temperature"), T_b, is usually constant in the riser. Only in large risers and at part load there may be a small fall of T_b with height and in the corners. An example of a thermal boundary layer is seen in Figure 17.20, where the temperature starts to fall at about 0.1 m from the wall. The measurements were made in a 14 m high CFB furnace with a cross section of about 2.2 m^2. Similar results have been obtained in other CFB furnaces. The shape of the temperature curves is similar at all heights, which reveals that heat is supplied to the boundary layer at almost the same rate as it is removed to the wall. In Figure 17.20, the wall temperature is 200°C, and very close to the wall (<3 mm from the fin), there is obviously a temperature fall from about 500°C to 200°C that can only be explained by the existence of a gas gap, free from particles, close to the wall. The temperature gradient reveals that more than half of the resistance to convective/conductive heat transfer may be found in this gas gap and that the remaining resistance is in the particle suspension of the boundary layer.

The vertical heat-transfer surfaces in a CFB are polished but not severely eroded. Therefore, it can be assumed that the particles touch the walls occasionally, and that the gas gap has at least an average size of the order of a particle diameter (in contrast to the dense bubbling bed where the particles are in closer contact with the walls). The thinnest conceivable dimensionless thickness is that of a gas lens between a particle resting on the wall and the wall $\varphi = 1/6$, where the thickness is $\delta_g = \varphi d_p$ (cf. Equation 17.101). Another geometrically defined limit is that formed by a cubic, expanded, arrangement of particles, assuming that the particle volume fraction at the wall is three times the cross-sectional average volume-fraction:

$$\varphi = \left(\frac{\pi}{\left(18\left(1-\varepsilon_{av}\right)\right)} \right)^{1/3} \tag{17.114}$$

These geometric relationships are compared with various measurements or fits in Figure 17.21.

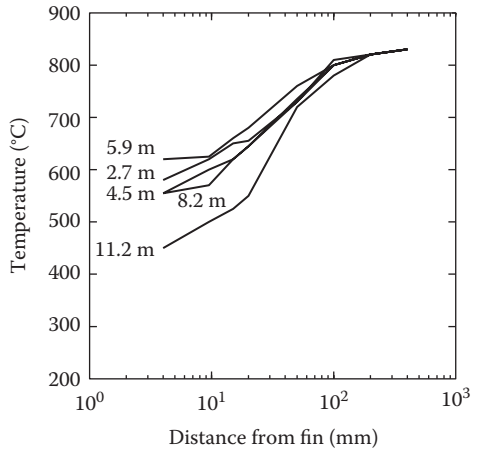

Figure 17.20

Thermal boundary layer measured in a 12 MW CFB boiler at various distances from bottom of the furnace. Conditions: particle size 260 μm; fluidization velocity 4 m/s; bed temperature 850°C. (From Leckner, B. et al., Boundary layers–first measurements in the 12 MW CFB research plant at Chalmers University, in Anthony, E.J. (Ed.), *Proceedings of the 11th International Conference on Fluidized Bed Combustion*, ASME, New York, 1991, pp. 771–776.)

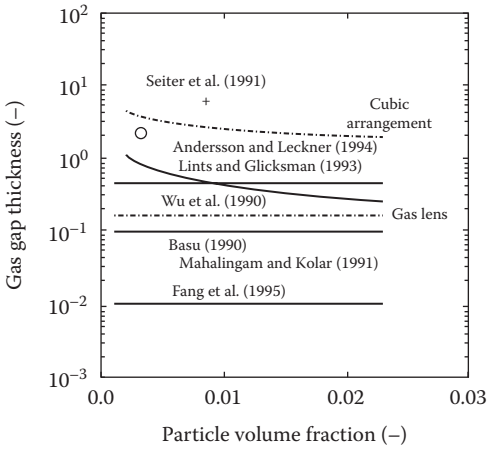

Figure 17.21

Measured and fitted dimensionless gas-gap thickness $\varphi = \delta_g/d_p$ vs. cross-section average solid volume fraction. Theoretical limits set by a gas lens $\varphi = 1/6$ and a cubic packing, Equation 17.114, are marked with dashed lines. (From Breitholtz, C. and Leckner, B., *Trends Heat Mass Momentum Transfer*, 3, 85, 1997. With permission.)

The temperature in the boundary layer varies with time, as illustrated in Figure 17.22. The figure shows simultaneous variations in the boundary layer temperature measured by six thermocouples inserted at various distances from the fin of the membrane tube of a CFB furnace. The variations in temperature are obviously due to high-temperature, streamers of particles, occasionally brought to the wall region from the hot core of the riser, remind on the packets occurring in the dense bubbling bed. These irregularities cause corresponding fluctuations in heat transfer. The temperature in the core is even (at 0.28 m from the wall in Figure 17.22 and further into the core of the suspension), without thermal disturbances. It can be assumed that the temperature variations are accompanied by density variations, as observed visually. The density variations are complex and also contain higher frequencies than the temperature fluctuations shown in Figure 17.22, which are filtered by the thermal inertia of the thermocouples used. Wu et al. (1991) have shown that the fast density variations correspond to variations in the heat transfer to a wall. An intermittency index γ has been defined (Brereton and Grace, 1993) to characterize the density fluctuations at a

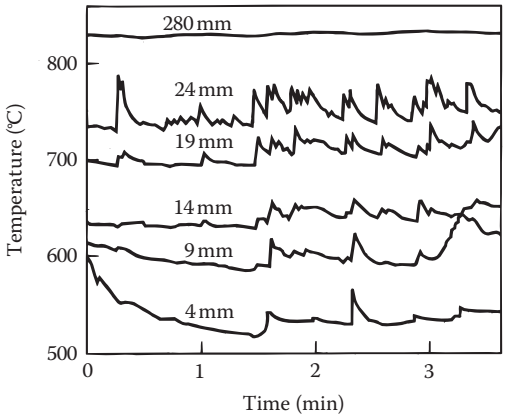

Figure 17.22

Example of simultaneous temperature variations in the boundary layer at various distances from the fin of a membrane tube wall 11.2 m above the bottom in the same case as Figure 17.20. (From Leckner, B. et al., Boundary layers–first measurements in the 12 MW CFB research plant at Chalmers University, in Anthony, E.J. (Ed.), *Proceedings of the 11th International Conference on Fluidized Bed Combustion*, ASME, New York, 1991, pp. 771–776.)

given point, represented by the standard deviation of the density fluctuation σ for two cases with identical time-mean densities

$$\gamma = \frac{\sigma \text{ under the actual conditions}}{\sigma \text{ for a fully segregated flow}} \tag{17.115}$$

This index is zero for a homogeneous flow and unity for a flow consisting of particle swarms of the same volume fraction as a bed at minimum fluidization velocity. In model representations, the particle suspension is often regarded as having a high intermittency index, in the extreme case consisting of a discrete probability of presence of particles, f_c, the coverage factor, indicating how much the wall is covered by particles, and $(1 - f_c)$ is the uncovered part of the wall. In terms of probability distribution, such a fully segregated flow would have a bimodal distribution of particle density and an intermittency index of unity, but measured distributions are continuous around a maximum. They are far from bimodal (Breitholtz and Leckner, 1997, Johnsson et al., 1997), and the intermittency index is below 0.5 (Brereton and Grace, 1993, Johnsson et al., 1997). Hence, although there are density fluctuations in the medium, they are not as distinct as assumed in some models; they are actually gradual variations against a background of a finite concentration of particles.

The description of heat transfer in CFB risers can be roughly separated into four, sometimes combined, approaches:

1. Gas and particle convection are evaluated separately as average values and added to radiation according to Equation 17.80.
2. Particle convection is assumed to take place when a dense streamer is present and gas convection (if not neglected) and radiation are considered during the remaining time.
3. Comprehensive (more or less) modeling, in some cases, allowing the mechanisms to be interrelated.
4. Correlations.

17.2.1.2.2 Addition of Radiative and Convective Heat Transfer (Approaches 1 and 2) It is often assumed that the wall is covered by particles in the form of streamers during a fraction of time f_c, and uncovered during the rest of the time $(1 - f_c)$. The resulting heat-transfer coefficient h is composed of a contribution from convection h_c (or h_{pc}) and radiation $h_{r,w}$ from the boundary layer during coverage f_c, and of radiation from the core of the bed h_r during the particle-free time $(1 - f_c)$. Gas convection may have some minor effect when the wall is uncovered. The heat-transfer coefficient can then be written as

$$hA = f_c\left(h_{pc} + h_{rw}\right)A + \left(1 - f_c\right)\left(h_r A_{proj} + h_{gc} A\right) \tag{17.116}$$

where radiation from distance is received by the projected surface A_{proj} and convective and radiative heat transfer from the streamers, seen from the wall, is received by A, the total surface area. However, the wall coverage f_c is not known. Normally, the terms $h_{r,w}$ and h_{gc} are small and can be neglected. The particle convective coefficient h_c (h_{pc}) consists of two resistances in series

$$\frac{1}{h_c} = \frac{1}{h_k} + \frac{1}{h_l} \tag{17.117}$$

where the resistance in the particle boundary layer is $1/h_l$ and the resistance in the gas film at the wall

$$\frac{1}{h_k} = \frac{\delta_g}{k_g} \tag{17.118}$$

represents the influence of a gas gap between the wall and the suspension (cf. Equation 17.101), with the thickness $\delta_g = \varphi d_p$. The heat transport through the remaining part of the particle wall layer can be expressed as

$$h_l = \frac{k_s}{\delta_s} \tag{17.119}$$

implying that the transfer mechanism is conduction across a particle suspension with the thickness δ_s, promoted by the irregular movement in the bed material having an effective suspension conductivity k_s. Alternatively, heat is transferred by the movements of the particle suspension and the heat-transfer mechanism is assumed to consist of displacement of streamers of particles transferring heat from the core to the wall, similar to the packets of the noncirculating dense bubbling bed (Equation 17.99). Glicksman (1997) and Basu and Nag (1996) have conducted surveys on various approaches of this type. The streamers are parts of the suspension that approach the wall. They are characterized by having higher density than that of the surrounding suspension and are treated like the packets of particles formed by the agitation of bubbles in the dense bed.

In the aforementioned formulation, some factors are known: k_g (thermal conductivity of gas), δ_g (Figure 17.21), the contribution of radiation $(f_c h_{rad,w} A + (1 - f_c) h_{rad} A_{proj})/A \approx 50$ (W/m² deg), (further discussed in connection to Figure 17.25) and δ_s (thermal boundary layer thickness), but essential parameters such as f_c and k_s require additional modeling. Glicksman (1997) has reviewed available information about the various parameters involved.

Radiation in CFB is described by the same expressions as for the noncirculating bed, but at the lower particle concentration of the CFB, radiation attains longer pathlengths. For the calculation of the effective emissivity of the suspension ε_b, two cases can be considered:

1. Combustion gases with low suspension density, for example, in a CFB during low-load operation or in the freeboard of a noncirculating fluidized bed combustor (FBC). In this situation, the influence of boundary layers can be disregarded.
2. Combustion gases with, relatively seen, high suspension density: for example, a CFB boiler under normal load conditions. The boundary layers are important.

Case 1: When the particle concentration is small, scattering of radiation from particles can be neglected, but both combustion gases and suspended particles contribute to the bed emissivity

$$\varepsilon_b = 1 - \left(1 - \varepsilon_g\right)\left(1 - \varepsilon_p\right) = \varepsilon_g + \varepsilon_p - \varepsilon_g \varepsilon_p \tag{17.120}$$

where

ε_g is the emissivity of the combustion gases H_2O and CO_2, which can be evaluated according to standard radiation correlations (Modest, 2003)

ε_p is the emissivity of a particle suspension calculated for the same pathlength L as for the gases, knowing the radiation cross section of particles C_p

$$C_p = \varepsilon_s n \pi d_p^2 / 4 \tag{17.121}$$

and the number of particles

$$n = \frac{\rho_{av}}{\rho_p \pi d_p^3/6} \tag{17.122}$$

where

d_p is the particle diameter
ρ_p is the particle density
ρ_{av} is the bulk bed density along the path considered
ε_s is the emissivity of the surface of the particles

With these relationships, the resulting emissivity of the particle suspension becomes

$$\varepsilon_b = 1 - \exp\left(-C_p L\right) \tag{17.123}$$

For an enclosure with surface A and volume V, the mean pathlength L is calculated according to Hottel and Sarofim (1967) as

$$L = 3.5V/A \tag{17.124}$$

Contributions to the radiative flux from the surface of the bed and from other surfaces also have to be included, according to standard procedures (Modest, 2003).

Case 2: When the particle concentration is high, the gas contribution can be neglected, but scattering in the particle suspension should be considered. The bed emissivity is $\varepsilon_b = \varepsilon_p$, calculated considering scattering (Brewster, 1986):

$$\varepsilon_p = \left[\frac{\varepsilon_s}{(1-\varepsilon_s)B}\left(\frac{\varepsilon_s}{(1-\varepsilon_s)B} + 2\right)\right]^{1/2} - \frac{\varepsilon_s}{(1-\varepsilon_s)B} \tag{17.125}$$

For isotropic scattering ($B = 0.5$) or for diffusely reflecting particles ($B = 0.667$) and a particle surface emissivity ε_s, this formula is represented as in Figure 17.23. Baskakov and Leckner (1997) have shown that several independent derivations of effective emissivity give similar results, among others, Equation 17.93.

At high particle concentration, when the wall layers are substantial, radiation and convection are not simply additive. Radiation from the core of the suspended bed ($\varepsilon_b \sigma T_b^4$) is reduced by the colder, relatively dense, wall layer. One approach has been (Breitholtz and Leckner, 1997) to express radiation from an isothermal medium at bed temperature compared with that affected by a boundary layer, employing the radiation heat transport equation. The result of this operation yields a correction to the maximum radiative heat-transfer coefficient by an empirical coefficient "the radiation efficiency," η, defined in analogy with Steward et al. (1995) and using the definition Equation 17.91

$$h_r = \eta \varepsilon \sigma \left(T_b + T_w\right)\left(T_b^2 + T_w^2\right) \tag{17.126}$$

where the emissivity ε is given by Equation 17.92. The radiation efficiency accounts for absorption of radiation by the wall layer and reduction in emission due to the fall in temperature close to the wall. Figure 17.24 shows the radiation efficiency determined by means of data sets obtained from the literature. Although there might have been inconsistencies in some of the data, it is seen that, at low suspension density, the impact of the wall layer is small (similar to Case 1) and the radiation efficiency is almost equal to unity, but with an increase in suspension density, the wall layers become more important and reduce the contribution of radiation to almost half its value in a suspension without wall layers.

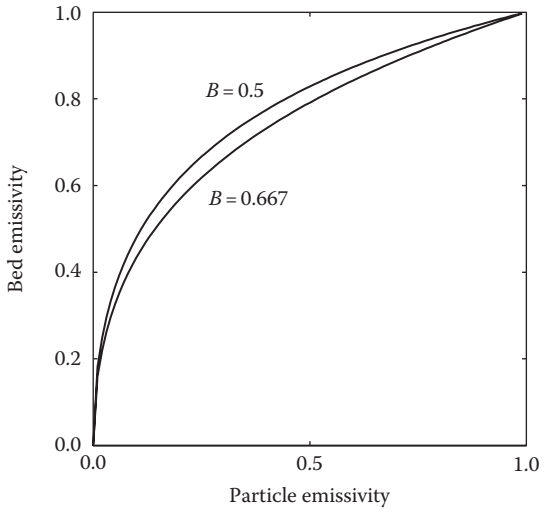

Figure 17.23

Effective bed emissivity vs. particle surface emissivity considering scattering (Equation 17.125).

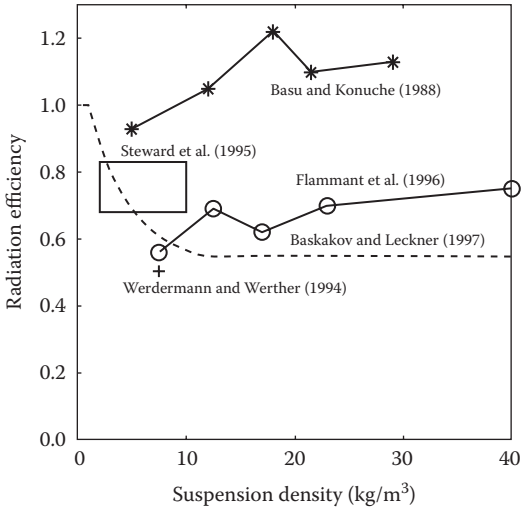

Figure 17.24

Radiation efficiency evaluated for a few experimental results. (From Breitholtz, C. and Leckner, B., *Trends Heat Mass Momentum Transfer*, 3, 85, 1997. With permission.)

The radiation efficiency is presented as a function of suspension density only. Implicitly, this relates to density and thickness of the wall layer. The influence of bed and wall temperatures remains to be further investigated.

17.2.1.2.3 Modeling (Approach 3) Comprehensive modeling involves the energy equation using the flow field from the continuity and momentum equations and considering mass and species balances related to chemical reactions. Although the developments in computer technology opens up new possibilities, most approaches related to heat transfer in fluidized bed have been simplified and are often similar to the models previously developed for bubbling fluidized beds. Assumptions commonly found in the literature can be summarized as follows:

1. Heat transfer between gas and particles is high. This allows the assumption of equal particle and gas-phase temperatures, and an emulsion phase energy equation using lumped thermal properties can be formulated rather than a particle and a gas-phase equation.

2. The main direction of the particle flow is along the wall, and the convective flows in other directions are relatively small and are neglected (but the transport of material to and from the wall layer implies a horizontal component).
3. The temperature gradient is large in the horizontal direction and negligible along the wall (Figure 17.20). Therefore, the conductive, dispersive, and radiative heat flows in the directions along the wall can be omitted from the equations.
4. Despite the obvious coupling of conduction and radiation toward the wall, in many models, these phenomena are treated separately.
5. Because of the low temperature in the wall layer, combustion is slow and heat release from chemical reactions is neglected there.
6. The density of the gas phase is much lower than that of the particle phase and gas convection can be neglected.
7. A thermal conductivity k_{pb} can be defined for the particle suspension.

As a result of these approximations, the energy equation becomes equal to Equation 17.97, and the same solution, Equation 17.98, is obtained, now with strands instead of packets transporting heat to the surface. The problem with high heat-transfer rates at short contact times requires the same solution as for the bubbling bed, and a particle convective heat-transfer coefficient is defined according to Equation 17.102. The fraction of time that the surface is not covered by bubbles $(1 - f_0)$ is now replaced by the wall coverage f_c of strands. To use these relationships, the thickness of the gas gap, the density of the strands, the descending velocity of the particles, or the residence time and length, all have to be known. This requires further modeling or empirical information. Several efforts have been made according to the approach described: for instance, by Wu et al. (1990), Basu (1990), Lints and Glicksman (1993), Fang et al. (1995a), Wang et al. (1996).

There is a striking resemblance between the modeling of the streamers falling along a surface in a CFB and the packets of particles induced by bubbles in a dense, bubbling bed bringing heat to a wall. In both cases, the thermal conduction of the particle suspension has an influence. On the other hand, it was mentioned that Martin's model of heat transfer in a bubbling bed focused attention on the gas gap and on the particles close to the wall, neglecting the transfer in the suspension itself. There are a number of CFB heat-transfer models that follow the same idea and treat single particle behavior at the wall and the influence of the gas gap (e.g., Farag and Tsai, 1993, Goedicke and Reh, 1993, Wirth, 1995).

Breitholtz and Leckner (1997) compared a number of available models of both kinds with two cases represented by average measurement data using similar physical properties: one under ambient conditions and the other was a hot case. The results from the various models showed a scatter of ±75%. In some comparisons, agreement between models was found, but for quite different reasons. Hence, judging available models as a group, it seems that modeling of CFB is not yet a well-established technique and the heat-transfer coefficient can only be reliably modeled in special cases when the importance of the particle boundary layer is small, that is, in the upper part of a CFB and in the freeboard of a noncirculating fluidized bed, where the particle suspension is not dense and absorption of radiation is small; otherwise, at present, empirical correlations have to be used.

17.2.1.2.4 Correlations (Approach 4) The collection of experimental results from various literature sources, presented by Basu and Nag (1996), shows a set of highly scattered data, which gives an impression of experimental difficulties in determining heat transfer in CFB. The variation between data sets is greater than the variation of the parameters studied. In contrast to a noncirculating bed, the CFB is a system, which, in addition to the impact of bed material and gas parameters, is affected by the size of the fluidized-bed vessel (wall effects) and by the operation of the circulating loop. Narrow, hot units have to be heated through the walls (because the wall surface to volume ratio makes heat losses important in small devices), and then the thermal wall layers differ from those of larger units where the walls are cooled; the conditions for thermal radiation heat transfer are different in small and large equipment. Moreover, it has been pointed out (Wu et al., 1989, Nag and Moral, 1990) that the length of the heat-transfer surface is important in research rigs where heat-transfer probes and inserts of limited size are used to measure heat transfer and a thermal boundary layer is formed on the measuring device (on the contrary, in a boiler, thermal boundary layers are already formed). Above a length of a meter or two, this effect is negligible. Hence, it is not a concern in commercial-size equipment, but it has influenced early measurements in research installations. Furthermore, in small research units, radiation from the surrounding walls may contribute unintentionally to the measured heat transfer.

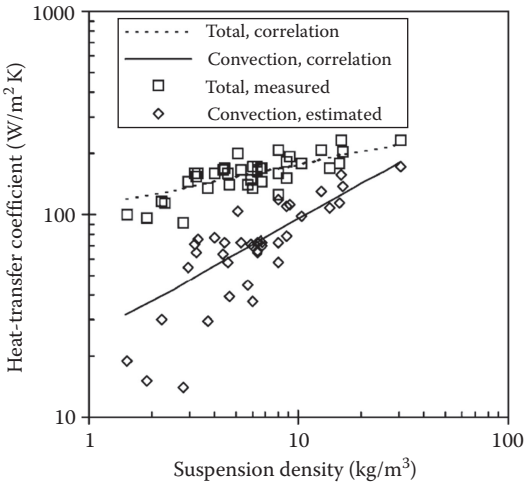

Figure 17.25

Total (convection and radiation) heat-transfer coefficients measured under hot conditions, averaged over the entire heat-receiving wall vs. cross-sectional average suspension density averaged over the corresponding furnace height. The lower curve represents the convective component. (From Breitholtz, C. et al., *Powder Technol.*, 120, 41, 2001.)

To simplify comparison, Breitholtz et al. (2001) classified the available results into two groups: results from boilers operating under hot conditions and results from laboratory-scale units run under ambient conditions. In both cases, long heat-transfer surfaces were used for measurements. This reduced the differences between the results in each of the two groups, but the scatter is still considerable. There are only a few results available from measurements of total heat-transfer coefficients in boilers. (e.g., as shown by Andersson and Leckner (1992), measurement by heat flux meters through holes in a boiler wall is very convenient, but quite unreliable because of the disturbance of the particle wall layer by the hole in the wall and by the variability of heat transfer in the boundary layer; it is difficult to determine a representative measurement value, because it depends on the location of the probe's surface). The data selected from boilers, related to the projected wall surface area (see Figure 17.19), presented as averages over the heat-transfer walls and related to the suspension density averaged over the corresponding furnace volume, have been represented in Figure 17.25 (upper line, "total") by

$$h = 110\rho^{0.21}(\mathrm{W/m^2\,deg}) \tag{17.127}$$

An implicit conclusion from Equation 17.127 is that within the scatter of available data only suspension density was found to be important for CFB heat transfer. This must be interpreted in the context of the evaluation, namely, for the heat-transfer situation in combustors, that is, a bed of sand, limestone, or ashes, operated at a temperature around 850°C and a heat-receiving surface consisting of boiler tubes at a temperature of 200°–500°C and with bed materials with sizes between 200 and 300 μm, in the various cases investigated.

There is a general agreement that the suspension density is a predominant influencing parameter, but often (Basu and Nag, 1996), a power of 0.5 is mentioned instead of 0.2, which was found for the boilers. There are three important aspects in relation to this issue: (1) the value given in Equation 17.127 is a furnace-averaged value and therefore, the slope is low; (2) there is a considerable scatter between various observations (e.g., as seen in Figure 17.25); and (3) radiation is included, which will reduce the power, because radiation is most influential at low suspension densities, and its impact is reduced as particle concentration increases.

In the diagram of Figure 17.25, also the convection constituent h_c is plotted. The convection is obtained from the difference between the measured total heat-transfer coefficient (the upper relationship in Figure 17.25) and the calculated radiative heat-transfer coefficient according to Equation 17.126, using the operational data from the various test cases and assuming that the two heat-transfer constituents are additive.

As a result, the convective heat-transfer coefficient (the lower line in Figure 17.25) becomes

$$h_c = 25\rho^{0.58}(\mathrm{W/m^2\,deg}) \tag{17.128}$$

valid for boiler conditions and $2 < \rho < 40$ kg/m^3). The data points decrease from the trend for $\rho < 10$ and approach a convective heat-transfer coefficient of $h_c \approx 10$ at very low densities, a value that is in the same order as the convective heat-transfer coefficient of gas in an entrance region of a duct (Breitholtz et al., 2001).

If scaled with $Nu_{amb} = Nu_{hot}$, the derived convective heat-transfer coefficients from Figure 17.25 agree with heat-transfer coefficients measured under ambient conditions, Breitholtz et al. (2001) (provided that the thermal conductivity in Nu_{hot} is taken at an average value between bed and wall, which is just a little above the end temperature of the gas gap).

In the upper part of a CFB furnace, the suspension density is low and radiation dominates. Baskakov and Leckner (1997) argued that in such a case the total heat-transfer coefficient should approach the radiative one, which should be around 125 W/m^2 deg at $T_w = 340$°C and $T_b = 850$°C (Equation 17.91), and about 100 W/m^2 deg for the wall temperature $T_w = 200$°C. It was also found that, due to the shielding effect of the colder boundary layer, the radiative contribution declined as accounted for by the radiation efficiency, and at suspension densities of above 25 kg/m^3 the radiation contribution was only about 50 W/m^2 deg (a radiation efficiency of $\eta \approx 0.5$). In investigating several cases, a curve describing the radiation efficiency η, like the one in Figure 17.24, was obtained by Breitholtz et al. (2001).

In summary, the total average heat-transfer coefficient can be obtained from Equations 17.126 and 17.128 as

$$h = h_c + h_r \tag{17.129}$$

by means of data from CFB boilers of thermal sizes between 10 and 300 MW. The expression allows for estimates of the influence of wall and bed temperatures on the heat transfer.

17.2.1.3 Concluding Remarks

Much work on heat transfer in fluidized beds, and in CFB in particular, was motivated by application in combustors. However, it was found during the 1980s that erosion on heat-transfer surfaces prevented the use of surfaces in contact with a dense bed of a combustor. It is still possible, though, to apply heat-transfer surfaces in dense fluidized beds if the velocity is low and erosion is minimized, such as in external heat exchangers of CFB boilers. There is an essential difference between tube bundles in a dense bubbling bed and the vertical surfaces in the transport zone of a CFB: in addition to erosion and the much higher heat-transfer coefficient in the dense bed, there is an obvious influence of particle size, whereas in the riser of the CFB, the contact between wall and suspension is less intensive, and consequently also the influence of particle size is small. In fact, there is no marked influence of particle size observed within the scatter of the experiments (Figure 17.25), except in refined laboratory-scale experiments (Sundaresan and Kolar, 2002). However, the particle size affects the heat transfer indirectly through the particle density ρ_{av}. For similar conditions (a given pressure drop over the furnace and a given fluidization velocity), smaller particles result in higher ρ_{av} in the upper part of the CFB riser than with larger particles, which remain to a larger extent in the bottom region below the heat-transfer surface. In CFB, heat transfer depends on particle size indirectly through the fluid dynamics.

17.2.2 Gas–Particle Heat and Mass Transfer

17.2.2.1 General

This section deals with heat and mass transfer across the surface of the particles in a fluidized bed. As seen from the point of view of the fluidized bed, this is internal heat and mass transfer. Accounts have been given by Gelperin and Einstein (1971), Kunii and Levenspiel (1991), Agarwal and La Nauze (1989), Tsukada and Horio (1992), Prins (1987), Palchonok (1998), and Di Natale et al. (2013).

Following the analogy between heat and mass transfer, the convective part of is these processes is expressed in a similar form:

$$Nu = f\left(Re, Pr\right) \quad \text{for heat transfer} \tag{17.130}$$

$$Sh = f\left(Re, Sc\right) \quad \text{for mass transfer} \tag{17.131}$$

The Sherwood number $Sh = k_m x_0/\mathscr{D}$ for mass transfer is defined similar to the Nusselt number $Nu = hx_0/k_g$ with the mass transfer coefficient k_m and gas diffusivity $\mathscr{D}$ instead of the heat-transfer coefficient h and

thermal conductivity k_g of the surrounding gas. There is an analogy between heat and mass transfer, and the fields of temperature and concentration coincide if the Lewis number $Le = \alpha/\mathscr{D} = Sc/Pr$ is equal to unity, where $\alpha = k_g/(\rho_g c_{pg})$ is the thermal diffusivity. The characteristic dimension x_0 is, except for some cases, the diameter of the particles. Most work presented in the literature concerns spherical particles and this form is also treated here. As will be pointed out, the analogy between heat and mass transfer is not complete. For instance, radiation may affect heat transfer but not mass transfer. Also, in a fluidized bed, the neighboring particles interact in different ways with an active particle for heat and for mass transfer.

In addition to Equations 17.130 and 17.131, there are boundary conditions. For heat transfer at a particle surface (index *w*; *n* is a direction perpendicular to the surface)

$$k_g\left(\partial\left(T - T_o\right)/\partial n\right)_w = h\left(T_w - T_o\right) \tag{17.132}$$

or in dimensionless form

$$\left(\frac{\partial \Theta}{\partial N}\right)_w = Nu \tag{17.133}$$

where

$N = (n/x_0)$ is the dimensionless coordinate

$\Theta = (T - T_o)/(T_w - T_o)$ is the dimensionless temperature, and the Nusselt number is

$$Nu = \frac{hx_0}{k_g} \tag{17.134}$$

Similar boundary conditions can be formulated for mass transfer. In the following, only empirical relationships will be treated.

17.2.2.2 A Spherical Particle in Single-Phase Flow

The conduction heat transfer across a spherical surface of radius r under steady-state conditions in a stagnant medium can be written as illustrated in Figure 17.26:

$$Q = 4\pi r^2 k_g \, \mathrm{d}T/\mathrm{d}r \tag{17.135}$$

Integrated between the temperature $T = T_w$ at $r = R$ (the surface of the sphere) and $T = T_o$ at $r = R_o$, a fictitious surface outside the sphere, and combined with the definition of the heat-transfer coefficient h (Equation 17.79), this becomes

$$Q = \frac{4\pi R k_g}{(1 - R/R_o)}(T_w - T_o) = 4\pi R^2 h (T_w - T_o) \tag{17.136}$$

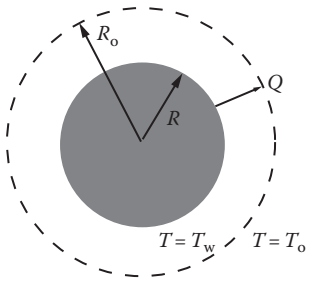

Figure 17.26

The heat flow Q leaving a sphere of radius R and a boundary layer of radius R_o.

When R_o tends to infinity, $hR/k_g = 1$ or $Nu = 2$ if Nu is based on the diameter of the sphere. If the sphere is also exposed to convective heat transfer, the following relationship is obtained:

$$Nu = 2 + f\left(Re, Pr\right) \tag{17.137}$$

A similar derivation yields $Sh = 2$ for mass transfer, and

$$Sh = 2 + f\left(Re, Sc\right) \tag{17.138}$$

These relationships are valid for heat and mass transfer to or from single particles and will be applied here to the special case of particles in fluidized beds. The Frössling–Ranz–Marshall equations are well-known relationships for heat and mass transfer to spheres in single-phase flow

$$Nu = 2 + 0.69\ Re^{0.5} Pr^{0.33} \tag{17.139}$$

$$Sh = 2 + 0.69\ Re^{0.5} Sc^{0.33} \tag{17.140}$$

Two classes of problems to be considered are (1) transfer between an entire bed and the gas flowing through the bed and (2) transfer between the gas and certain, active, particles contained in a bed of passive, inert particles. An example of the latter class is a bed of sand or ash for conversion (pyrolysis, gasification, or combustion) of fuel particles. These active fuel particles usually constitute only a few percent of the total bed.

17.2.2.3 Heat and Mass Transfer to a Bed of Particles

In a fluidized particle bed, one would expect more or less the same relationships for heat and mass transfer as for single particles, but this is apparently not the case as shown by Figure 17.27, where the shaded area (4) is the region of published, measured heat and mass transfer data related to particle beds and (3) represents Equations 17.139 and 17.140 for a single particle in single-phase flow. (The other curves in the figure will be

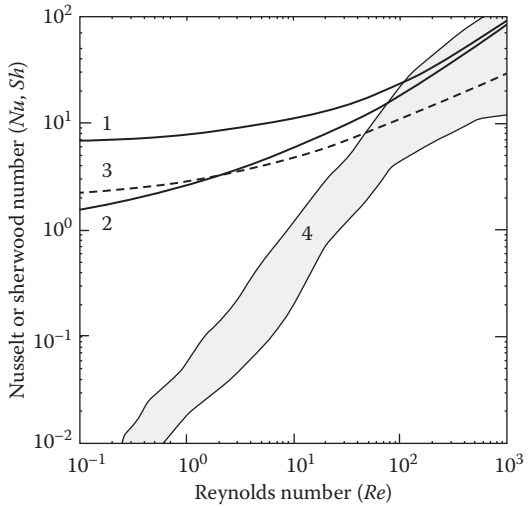

Figure 17.27

Heat and mass transfer coefficients as a function of velocity or particle size: (1) Equation 17.143 for heat transfer and (2) Equation 17.144 for mass transfer are compared with (3) a sphere in single-phase flow (Equations 17.139 and 17.140). The shaded region (4) represents various sets of published data from entire beds. *Ar* in Equations 17.143 and 17.144 has been calculated from Re_{mf} (Equation 17.81), assuming $\varepsilon = 0.4$ and $Pr = Sc = 0.7$. (Adapted from Palchonok, G.I. et al., Effect of turbulence on heat and mass transfer in the freeboard region of stationary and circulating fluidized beds, in Fan, L.-S. and Knowlton, T.M. (Eds.), *Fluidization IX*, Engineering Foundation, New York, 1998b, pp. 413–420.)

further treated below.) Only at higher velocities the coefficients of the various cases are on the same level. For small particles and low velocities the overall coefficients of an active bed appear to be much lower than those of single particles.

This discrepancy is explained by the resistance to gas transfer in fine particle beds (low *Re*), where most of the gas passes the bed through the bubble phase, while the flow through the emulsion phase, where the particles are contained, is much smaller. Thus, the overall resistance at the surface of a particle includes the additional resistance caused by the transfer from the bubble phase to the particulate phase. Furthermore, due to the extremely large specific area of beds of small particles, the gas in the particulate phase reaches saturation (it reaches the state of the particles) already close to the gas distributor, making the transfer potential in the upper part of the bed very small. These two factors result in great deviations of the actual gas property profiles from the log-mean value assumed in the evaluation of most measurements. Consequently, low, measured, overall heat and mass transfer coefficients for an entire fluidized bed are obtained (the shaded region) at the same time as the actual coefficient of a single small particle in the bed is much higher.

For larger particles, the gas flow through the particulate phase is larger and the flow through the entire bed is closer to plug flow (the high *Re* region in Figure 17.27). Therefore, the particles are exposed to the representative gas properties to a greater extent. Furthermore, the flow reaches farther into the bed before saturation. A detailed account of these phenomena is found in Kunii and Levenspiel (1991).

The large surface area encountered by a gas is one explanation for difficulties in interpretation of experimental data. A further explanation related to fixed beds, where the same phenomenon is observed, was given by Wakao and Kaguei (1982) to be due to the neglect of the axial dispersion in the evaluation of experimental results, a transport constituent that becomes increasingly important at low velocities (small particles, low *Re*).

As a consequence of the fast transfer, in most practical applications, the description of heat and mass transfer to the particles in a bed is not important. The problem of design of a bed is converted to what Gelperin and Einstein (1971) called the "thermal balance problem." This means that a heat or mass balance across the bed is sufficient in most design tasks. Only in special cases, for instance, very thin beds, where gas and particle conditions may not have reached equilibrium, the heat and mass transfer in the bed needs to be considered.

17.2.2.4 Heat and Mass Transfer to Active Particles in a Fluidized Bed of Inert Particles

Fuel converted in a fluidized bed forms active fuel particles surrounded by inert bed particles. Usually, the amount of fuel particles in the bed is such that every fuel particle is completely surrounded by inert particles and by gas at the given concentration and temperature, as illustrated in Figure 17.28. The particles are assumed to remain in the particulate phase where the superficial velocity is of the order of minimum fluidization velocity u_{mf}, and hence, there is a direct relation between the Reynolds number (velocity) and the particle size via the Archimedes number according to Equation 17.81. The temperature of the inert particles is practically the same as that of the gas, whereas the temperature of the active particles may differ from that

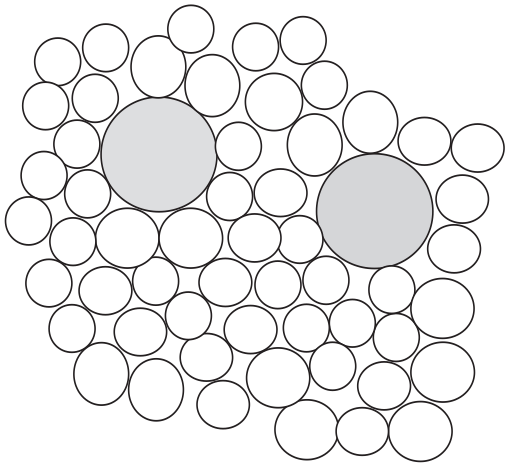

Figure 17.28

Two large, active particles surrounded by smaller, inert particles.

of the surrounding inert bed particles due to release or consumption of heat by some activity, such as chemical reaction in the particle or on its surface.

Depending on the size of the active particle d_a relative to that of the inert particles d_i, two extreme and one intermediate case can be distinguished: $d_a/d_i \gg 1$, $d_a/d_i \approx 1$, and $d_a/d_i \ll 1$. Baskakov et al. (1987) and Palchonok (1998a) established relationships for large active particles and for those of the same size as the inert particles and then proposed to interpolate between these extreme cases to obtain the heat and mass transfer data for active particles of the intermediate size.

Large active particles surrounded by smaller inert particles ($d_a/d_i \gg 1$) can be represented by correlations valid for maximum heat and mass transfer from gas and particle convection to large objects fixed in a fluidized bed (see Equations 17.83, 17.88, and 17.89) based on the size of the inert particles (index i):

$$Nu_{i,large} = 0.85 Ar_i^{0.19} + 0.006 Ar_i^{0.5} Pr^{0.33} \tag{17.141}$$

$$Sh_{i,large} = 0.009 Ar_i^{0.5} Sc^{0.33} \tag{17.142}$$

$Nu_{i,large}$ is the maximum Nusselt number obtained at optimum fluidization velocity according to Equation 17.84. This Nusselt number is assumed to be valid also for higher velocities. Naturally, there is no particle convection that contributes to mass transfer, and the first term of Equation 17.141 is not included in Equation 17.142. The information regarding the gas-convective term is originally gained from mass transfer experiments (Baskakov et al., 1973). (The small, insignificant differences in the coefficients in Equations 17.141 and 17.142 arise from slightly different fits to data at different times of publication.)

For active particles, which are nearly equal in size to the surrounding inert particles ($d_a/d_i \approx 1$), the heat and mass transfer has been represented by (Palchonok et al., 1992)

$$Nu_1 = 6 + 0.117 Ar_i^{0.39} Pr^{0.33} \tag{17.143}$$

$$Sh_1 = 2\varepsilon_{mf} + 0.117 Ar_i^{0.39}\, Sc^{0.33} \tag{17.144}$$

Index 1 is used to indicate that the dimensionless numbers are related to inert or active particles of about the same size. The gas convection term (the second term on the right-hand side) is based on numerous sets of measured data, among others those of Palchonok and Tamarin (1983 and 1985) and the analogy between heat and mass transfer. The first term represents the limiting case at low velocities (for small inert particles, small Ar), where heat and mass transfer are different. The mass transfer is about similar to the single-phase case, approximately corrected for the occlusion caused by the surrounding inert particles through the term ε_{mf}, the voidage at minimum fluidization velocity (Avedesian and Davidson, 1973). In heat transfer, there is no similar occlusion. On the contrary, the surrounding inert particles exchange heat both with the active particle and the gas. In this case, the integration of the heat conduction equation, Equation 17.136, is not carried out to infinity as for single-phase flow, but only to a limit represented by an equivalent spherical space containing the nearby gas. The space is $\varepsilon_{mf} d_p^3$ and part of the gas lenses between the active particle and the six neighboring particles $6(\pi d_p^3/24)$ (the gas lens is that between a cylinder $\pi d_p^3/8$ and a half-sphere, or alternatively, $6\varepsilon d_p^3/6$ can be used) in a cubic arrangement (Palchonok et al., 1992). This yields approximately the number 6, seen in Equation 17.143, a number that agrees with several sets of measurement data. A similar expression was presented by Baskakov et al. (1987):

$$Nu_1 = 10 + 0.23 Ar_i^{0.33} Pr^{0.33} \tag{17.145}$$

where the integration was carried out for a spherical gas shell in a cubic packing of particles, as explained by Zabrodsky (1966) and Gelperin and Einstein (1971). The difference between Equations 17.143 and 17.145 is small in practical applications, which are usually far from the limiting values at low velocities.

Equations 17.143 and 17.144 are compared with the correlation for single-phase heat and mass transfer to a sphere in Figure 17.27, and the limiting expressions for heat and mass transfer (Equations 17.143, 17.141 and 17.144; 17.142) are shown by the thick dashed (heat transfer) and solid (mass transfer) curves in Figure 17.29.

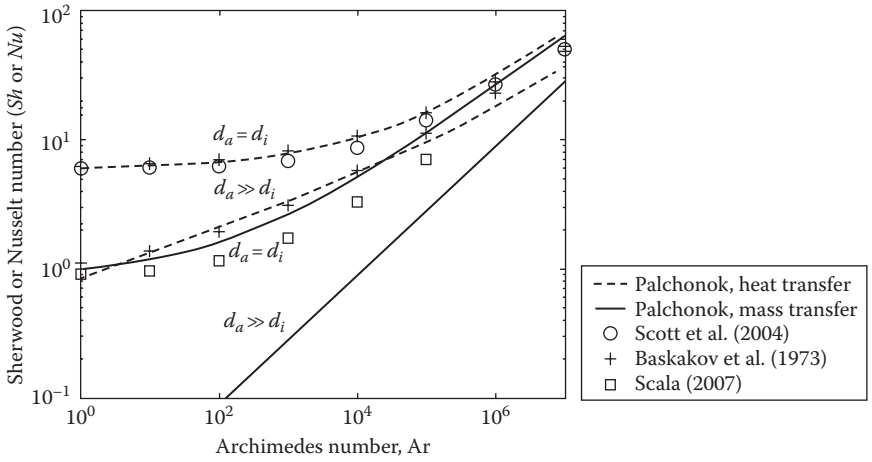

Figure 17.29

Heat and mass transfer in terms of Nusselt and Sherwood numbers at $d_a = d_i$ according to Equations 17.143 and 17.144 compared with some data from literature. The corresponding large active particle limits $d_a \gg d_i$ according to Equations 17.141 and 17.142 are also shown.

Interpolation between $Nu_{i,large}$ or $Sh_{i,large}$ and Nu_1 or Sh_1 yields heat and mass transfer coefficients Nu_i and Sh_i for spherical particles of an intermediate size $d_a/d_i \geq 1$:

$$\left(Nu_i - Nu_{i,large}\right)/\left(Nu_1 - Nu_{i,large}\right) = \left(d_i/d_a\right)^{2/3} \tag{17.146}$$

$$\left(Sh_i - Sh_{i,large}\right)/\left(Sh_1 - Sh_{i,large}\right) = \left(d_i/d_a\right)^{2/3} \tag{17.147}$$

The interpolation is based on available experimental data from literature, which are fitted within a range of ±30% (Palchonok, 1998a). However, there are several data sets that show greater deviation. The reasons for deviation have not yet been explained, and there are matters of discussion, such as the fact that Equation 17.141 describes the conditions at optimum velocity and beyond, whereas some heat transfer tests were carried out at lower velocities. Mass transfer does not seem to be affected by the fluidization velocity.

Scott et al. (2004) and, from the same department, Collier et al. (2004) investigated heat transfer to active particles and came up with the expression (with only some minor differences between the two publications):

$$Nu_a = 2 + 1.0 Re_{mfa}^{0.6} \left(d_a/d_i\right)^{0.26} \tag{17.148}$$

for $100 < Re_{mf,a} < 830$ and $0.2 < d_a/d_i < 2.72$. In this formula, the Prandtl number is not explicitly given and the velocity in Re is u_{mf} instead of u_{mf}/ε_{mf}, the actual interstitial velocity. Moreover, the constant term is 2, compared to 6 or 10 as derived by Palchonok et al. (1992) and Baskakov et al. (1987). Collier et al. (2004) paid particular attention to this matter and extrapolated their data to $Re = 0$ in order to determine the corresponding value. Despite considerable scatter in the data, the authors decided after discussion that the value of 2 was most relevant for the inclusion in Equation 17.148. Subsequently, Zhou et al. (2009) modeled numerically some of the cases investigated by Collier et al., including also $Re = 0$ and differentiating between convection and conduction. For a case of $d_a = d_i$ (Figure 10 in Zhou et al. (2009)), it is possible to derive $Nu(Re = 0) \approx 6$.

Also for mass transfer, alternative expressions have been derived, generally having the form, inspired by Equation 17.140:

$$Sh_a = 2\varepsilon_{mf} + 0.69 Re_{mf,a}^{0.5} Sc^{0.33} \tag{17.149}$$

where

Sh_a is related to d_a

$Re_{mf,a} = u_{mf} d_a/(\varepsilon_{mf}\nu)$

Several variants of this relationship have been proposed. Hayhurst and Parmar (2002) found that their own measurements were close to Equation 17.149 "but only for larger reacting spheres" (i.e., active particles larger than 3 mm). Scala (2007) carried out a comprehensive study in a slugging bed and concluded that Equation 17.149 fitted "excellently" his experimental data. He also concluded that the adequacy of using u_{mf} and ε_{mf} in Re "strongly suggests that the active particles only reside in the dense phase and never in the bubble/slug phase." This statement is not in agreement with Agarwal and co-workers (1988) whose model was based on the idea that the active particles were present both in the bubble and the particle phase. However, there is no doubt that Scala's data fit Equation 17.149 within the range of parameters investigated by him (100 μm $< d_i <$ 1.4 mm; 1.0 mm $< d_a <$ 10.0 mm) with the only uncertainty declared by Scala being the theoretical foundation of the limiting term $2\varepsilon_{mf}$. In the review of Di Natale et al. (2013), a comparison between various representations is made, stating that the results of Equation 17.147 deviate from Equation 17.149.

These correlations have been compared in Figure 17.29 for the special case $d_a = d_i$ at 450°C and $Pr = Sc = 1$. In this comparison, a number 6 has been imposed on the heat-transfer correlations instead of 10 or 2. Moreover, the correlations have been used as formulas beyond the ranges supported by measurement data. The data of Baskakov et al. (1987) (+) coincide rather well with Palchonok's curves, Within the range of data support ($10^2 < Ar < 10^5$), the results of Scala (2007) are lower than those of Palchonok, as stated by Di Natale et al. (2013). When adjusted to 6, Equation 17.148 (o) coincides rather well with Palchonok's data for heat transfer.

In conclusion, there are differences between the various data sets, but agreement is also found, especially if the value of 2 is adjusted to 6 in the heat-transfer correlations. Because of the analogy between heat and mass transfer, the results from heat and mass transfer measurements support each other.

Very small active particles (index a) tend to be carried by the gas through the space between the larger inert particles, constituting the bed. They can be assumed to behave like particles in a single-phase flow (cf. Equations 17.139 and 17.140), exposed to a velocity equal to their terminal velocity:

$$Nu_a = 2 + 0.6 Re_{at}^{0.5} Pr^{0.33} \tag{17.150}$$

$$Sh_a = 2 + 0.6 Re_{at}^{0.5} Sc^{0.33} \tag{17.151}$$

In this case, the terminal velocity of the active particle is equal to or smaller than the gas velocity $u_{mf}/\varepsilon \geq u_{at}$. This yields the Reynolds number in the convective terms of Equations 17.146 and 17.147 according to $Re_{at} = Ar_a/(18 + 0.61 Ar_a^{1/2})$ from Equation 17.82. Normally, these terms are very small, and the limiting Nusselt or Sherwood numbers approach 2 as long as the small particles do not severely interact with the bed particles. The correlations for small particles are related to their dimension d_a.

17.2.2.5 Active Particles above a Dense Bed

The previous account concerns particles in a dense, bubbling fluidized bed. Less information is available about particles in the freeboard or in the disperse phase of a CFB. There are some ways to solve this problem. First, it should be mentioned that in a CFB converter a great deal of the particles remains in the bottom bed and can be handled by the relationships mentioned in the previous section for a dense, bubbling bed. The particles carried away are small, and the surrounding particle loading of inert particles is also small; the voidage ε is almost equal to unity. Hence, the correlations for single-phase flow can be employed. These particles are exposed to a velocity that can be represented by the terminal velocity of a single particle (the velocity of the ascending particle relative to the gas). Refinements, such as accounting for clustering, are not likely to play a key role due to the high bed voidage.

A large, fixed object (a cylinder or a sphere), on the other hand, is subjected to the flow of particles and gas from the bed and particles returning from the space above the dense part of the bed down to the bed. There are some experiences from a CFB and from the splash zone of bubbling noncirculating beds related to heat transfer in this situation, as illustrated in Figure 17.30. The measured heat transfer is higher than the heat transfer to an object in an undisturbed single-phase flow, represented by the solid lines in the figure, and can be written as follows for a sphere ($Nu_{min} = 2$) or for a cylinder ($Nu_{min} = 0$).

$$Nu = Nu_{min} + 0.89 Re^{0.5} Pr^{0.33} \tag{17.152}$$

The additional contribution of radiation, if any, can be described by the relationships presented in the section on heat transfer.

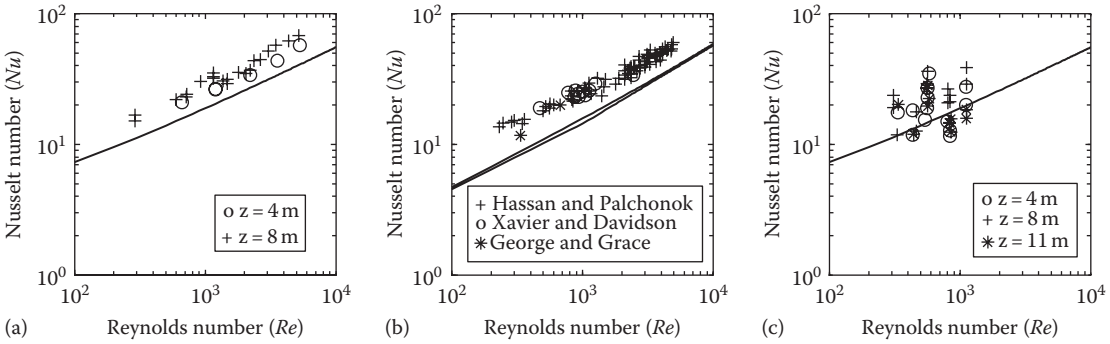

Figure 17.30

Convective heat transfer to a fixed object located at various distances z above the dense, bottom bed (a) in a cold experimental CFB rig, (b) in the splash zone of a bubbling bed, and (c) in a CFB boiler with radiation subtracted. The measurements are compared with the correlations for spheres and cylinders in a single-phase flow (Equation 17.139 in Figure [a] and [c]). The data in (b) are compared with the correlations of Douglas and Churchill (1956) and of Zhukauskas (1990) for a cylinder. (From Palchonok, G.I. et al., Effect of turbulence on heat and mass transfer in the freeboard region of stationary and circulating fluidized beds, in Fan, L.-S. and Knowlton, T.M. (Eds.), *Fluidization IX*, Engineering Foundation, New York, 1998, pp. 413–420.)

Nomenclature

Latin symbols

A	Area, m^2
C	Radiation cross section, 1/m
c_p	Specific heat capacity, J/kg, K
$\mathscr{D}$	Diffusivity, m^2/s
D	Tube diameter, m
d	Particle diameter, m
f_0	Fraction of time, –
f_c	Coverage factor, –
g	Acceleration of gravity, m/s^2
h	Heat-transfer coefficient, W/m^2, deg
h_l	Heat transfer through the particle wall layer, W/m^2, deg
k	Thermal conductivity, W/m, deg
k_m	Mass transfer coefficient, m/s
L	Pathlength, m
n	Number, normal direction
Q	Heat flow, W/m^2
R,r	Radius, m
s_h	Horizontal distance between tube centers, m
P	Pressure, Pa
T	Temperature, K
t	Time, s
u	Velocity, superficial gas velocity, m/s
V	Volume, m^3
z,x	Coordinates, length, m

Greek symbols

α	Thermal diffusivity, m^2/s
δ	Thickness, m
ε	Voidage
ϵ	Emissivity
η	Radiation efficiency
ρ	Density, kg/m^3

σ	Standard deviation, Stefan–Boltzmann's constant, W/m^2, K^4
ν	Kinematic viscosity, m^2/s
μ	Dynamic viscosity, kg/m, s
φ	Fraction of particle size, shape factor

List of Dimensionless Numbers

$Ar = \frac{g d_p^3 (\rho_p - \rho_g)\rho_g}{\mu^2}$	Archimedes number
$Fo = \frac{kt}{c_p \rho d^2}$	Fourier number
$Nu = \frac{hd}{k_g}$	Nusselt number, where d is a dimension
$Pr = \frac{\mu c_{pg}}{k_g}$	Prandtl number
$Re = \frac{ud}{\nu}$	Reynolds number, where d is a dimension
$Sc = \frac{\mu}{\rho_g D}$	Schmidt number
$Sh = \frac{k_d d_p}{D}$	Sherwood number

Indices

a	Active
air	Air
av	Average
at	Active particle at terminal velocity
b	Bed
c	Convective, cross section
eff	Effective
g	Gas
gc	Gas convective
h	Horizontal
i	Instantaneous, inert
k	Contact (resistance)
l	Layer
m	In x_m, thickness of stagnant particle suspension, mass transfer
max	Maximum
mf	Minimum fluidization
mf,a	Active particle at minimum fluidization velocity
opt	Optimum
p	Particle, packet
pc	Particle convective
proj	Projected (surface)
r	Radiative
s	Particle suspension, surface, solids
t	Terminal
w	Wall
∞	Far away, limiting case
1	Index indicating equality in size of active and inert particles
1	Of the same size
0	Characteristic

17.3 Applications of Fluidized Bed Reactors

Jesse Zhu and Yi Cheng

17.3.1 Fluidized Bed Reactors

Fluidized beds as chemical reactors offer many unique advantages such as large interfacial surface area between fluid (gas or liquid) and the particles, high fluid-particle contact efficiency, excellent heat transfer, uniform temperature, and the abilities to handle a wide range of particle properties and a large quantity of particulate materials (Davidson et al., 1985, Geldart, 1986, Kunii and Levenspiel, 1991, Kwauk, 1992, Zhu et al., 2000). Added benefits for the high-velocity circulating fluidized beds include higher gas and solids throughput, more uniform residence time distributions for both gas and solids phases, higher turndown ratio, and the possibility to realize two different reactions in the riser and the solid's downflow return system (Grace et al., 1997). Please also refer to Sections 17.1 and 17.2 for more details.

Fluidized bed reactors include gas–solid, liquid–solid, and gas–liquid–solid fluidized bed reactors, in terms of the fluid-particulate systems. In terms of reactor scheme and operation, there are the so-called stationary fluidized beds (SFBs) or fixed fluidized beds (FFBs), where the particles essentially stay in the fluidized bed, and the so-called CFBs where particles are mostly entrained out of the fluidized beds but at the same time recirculated back to or fresh particles added to the same fluidized beds. SFBs are often called conventional fluidized beds since they were the first realized and used in various industry applications. In gas–solid systems, SFBs include particulate fluidized beds, bubbling fluidized beds, slugging fluidized beds, and turbulent fluidized beds, which are also called fluidization regimes, as detailed in Section 17.1. In liquid–solid systems, the SFBs primarily have one operating regime, the particulate fluidization regime, where the particles are uniformly suspended in the upflowing liquid. In the stationary gas–liquid–solid three-phase fluidized beds, there are three main operating regimes: the dispersed bubble regime, the coalesced bubble regime, and the slug regime (Fan, 1989). Since all CFBs have a dense phase of particulate materials in the bed, they are also referred to as dense phase fluidized beds, in contrast to dilute phase fluidized beds referring to s (CFB).

In CFBs, the fluidizing gas or liquid (or the two combined) velocity is high enough to entrain all particles out of the bed and to retain enough particles in the bed so as to keep a fluidized bed, particles (either recycled or fresh) need to be fed into the bottom of the fluidized beds. In the CFBs, there are also different regimes: the fast fluidization regime and the pneumatic transport regime (Grace et al., 1997), and in terms of the operating conditions, there are low-density (or low-flux) CFB and high-density (or high-flux) CFB, with the latter referring to higher suspension density and high particle flux operations (Zhu and Bi, 1995, Pärssinen and Zhu, 2001, Wang et al., 2004). A new type of fluidized bed reactor, the circulating turbulent fluidized bed (CTFB), was proposed recently, which is shown to have both the benefits of high reaction intensity from the turbulent fluidized bed and suppressed gas and solids dispersion from the CFB (Zhu and Zhu, 2008, Qi et al., 2009, Zhu, 2010). There is also the cocurrent gas–solid downflow operation where both gas and particles are flowing downward in the downer column (Zhu et al., 1995, Cheng et al., 2008).

There are also special types of fluidized bed reactors, such as the spouted bed reactor (Mathur and Epstein, 1974), which has been broadly included in the fluidized bed literature by tradition, although it can also be considered as another multiphase reactor. In a spouted bed, gas (or liquid) is injected from the bottom through a central nozzle into the bottom of a normally cylindrical vessel to form a high-velocity upflow stream of gas (or liquid) and particles in the central region (the spout) and a slow downward moving layer of particles between the central spout and the wall (the annulus). In this pattern, a gross internal particle circulation is created, which gives special features such as the ability to handle larger or sticky particles, making the spouted bed very useful in certain physical operations such as drying and particle coating. Another example is pneumatic transportation, which originated earlier than the concept of fluidized beds. With the development of CFB reactors, however, the distinctions between a CFB reactor and a transport reactor have become less clear (Bi et al., 1995). Associated with pneumatic transportation are particle spray and elutriation, which are normally not separately considered in the fluidized bed literature.

In a broad sense, the application of fluidization technology dates back to the ancient times when peasants winnowed their grains. After the grain particles were swung up, a relative upflow of gas stream was created when the particles fall down. In such a "fluidized" state, the "upflow" gas preferentially segregates the lighter shells from the heavier seeds so as to achieve separation. The first record on application of fluidization technology was perhaps in an ancient Chinese book entitled "Applying the Principles Learned from the Nature" in 1637, where Song (1637) described a process to separate sands out of grain through vibrating winnowing pans in a certain fashion.

Table 17.3 Fluidized Bed Reactors and Their Properties

Type of Fluidized Bed Reactor	Fluidizing Medium	Typical Particle Size	Typical Gas/Liquid Velocity
Bubbling bed	Gas	Medium–large	Low
Slugging bed	Gas	Medium–large	Low
Turbulent bed	Gas	Small–medium	Medium
Circulating turbulent bed	Gas	Small–medium	Medium–high
Circulating riser	Gas	Small	High
Circulating downer	Gas	Small	Medium–high
Spouted bed	Gas	Very large	Low
Liquid–solid bed	Liquid	Medium–large	Low
Gas–liquid–solid bed	Gas and liquid	Medium–large	Low
Liquid–solid circulating bed	Liquid	Small–medium	High
Gas–liquid–solid circulating bed	Gas and liquid	Small–medium	High
Inverse bed	Liquid	Small–medium	Low

The first modern application of a fluidized bed reactor was a stationary, dense-phase gas–solid fluidized bed reactor (Winkler, 1922), operated for coal gasification in Germany to produce synthesis fuel from coal. Over the last 80 years, the concept of such low-velocity "conventional" fluidized bed reactors has been significantly expanded with the development of new types of fluidized bed reactors, including high-velocity circulating or riser fluidized bed reactor by increasing the fluid velocity (Yerushalmi, 1976), to liquid–solid and gas–liquid–solid three-phase fluidized reactors by changing the fluidizing agent (Fan, 1989, Zhu et al., 2000, Epstein, 2003), and to cocurrent downflow downer fluidized bed reactors by changing the direction of the fluid/particle flow (Zhu et al., 1995, Cheng et al., 2008). Experimentally tested but not yet in application is the inverse fluidized bed reactors where lighter particles are fluidized inversely by heavier fluid (Karamanev and Nikolov, 1992, Sang, 2013). The various types of fluidized bed reactors are listed in Table 17.3.

The numerous applications of fluidized bed technology can be classified at least in two manners. The first is by reaction type. For gas–solid systems, they can be divided into four categories:

1. Gas catalytic reaction, where both reactants and products are in gas phase, but the reaction takes place on the surface of a solid catalyst. This is the most frequently encountered application, counting for majority of all fluidized bed applications. Examples of such reactions are the FCC process, and many catalytic synthesis reactions.
2. Gas-phase reaction with solids as heat carriers, where both reactants and products are in gas phase, but the solids are required as heat carriers to either provide the heat for the reaction or carry out the heat produced by the reactions. This is very useful for highly exothermic and endothermic reactions, because solid particles have very high heat capacity.
3. Gas–solid reaction, where both gas and solids are the reactants and the products contain either only gas phase or a combination of both gas and solids. Examples are coal and biomass combustion and gasification.
4. Physical process that involves a gas and particles, where no chemical reaction occurs. A typical example is fluidized bed drying.

A similar classification like the gas–solid systems can also be used for liquid–solid and gas–liquid–solid fluidized beds, but it may not be necessary at this stage given the limited number of applications. Applications of liquid–solid fluidized beds (LSFBs) and three-phase fluidized beds can often be found in hydrocarbon processing and the mineral process industry, and more recently in the biochemical, pharmaceutical, and food industry and the environmental area.

The second manner of classification is to group by the areas of applications in different industrial processes, including

1. Hydrocarbon processing
2. Catalytic synthesis
3. Roasting and calcination
4. Metallurgical processes
5. Materials processing, sprays, and coatings

6. Combustion, gasification, pyrolysis, and incineration
7. Biochemical and environmental processes
8. Pharmaceutical and food processes
9. Physical processes

This section is primarily structured in the first manner, but the type of application for each example in terms of the second classification is clearly referred in the description. Given the limited space, only the most commonly encountered processes and those of special features are included in this section. There are also many potential applications of fluidized beds. A selected few important potential applications, especially those in the late stage of development, are also described.

17.3.2 Catalytic Gas-Phase Reactions

17.3.2.1 Fluid Catalytic Cracking

Fluidized catalytic cracking or fluid catalytic cracking (FCC) for short was the second major application of fluidized bed technology after coal gasification by Winkler in the 1920s and was the largest application of fluidized bed technology for over 60 years, with over 400 units worldwide (Chen, 2011), just surpassed by fluidized bed coal combustion in the last 10 years. The FCC process uses a solid catalyst to crack down the long chain of vaporized heavy oil or residues from the crude and other sources and convert them to light products such as gasoline, kerosene, diesel, and light olefins. Since crude oil on average contains less than 10% gasoline with poor octane value, FCC becomes the critical process in meeting the demands for a higher gasoline fraction (over 50% in North America) plus a higher octane value. FCC is therefore often called the heart of a refinery (Avidan, 1992, Murphy, 1992, Reichle, 1992).

Some numbers provided in a 1997 review (Avidan, 1997) show the enormous economic impact of FCC on petroleum refining and hence on worldwide economy:

1. There are about 350 FCC units operating worldwide. The total worldwide capacity of FCC units is over 2.4 million tonnes/day (16 million barrels/day).
2. The uplift across the FCC unit (difference between the value of products and feed) can be as high as $US10 per barrel.
3. The total inventory of FCC catalyst in the average FCC unit is 300 tonnes. The daily catalyst makeup rate to the typical vacuum gas oil feed FCC unit is 4 tonnes, whereas the daily makeup rate to a residue processing FCC unit can be as high as 30 tonnes.
4. Over 450,000 tonnes of FCC catalyst are manufactured every year, representing a $US600 million business worldwide. The total catalyst manufactured worldwide is approximately 1200 tonnes/day corresponding to a surface area of 380,000 km^2 if laid as single layer particles, the size of Egypt, each year.

Cracking of crude oil to lighter hydrocarbons dated back to the early twentieth century (Royal Dutch Shell, 1983). In 1916, the first catalytic cracking process was carried out in a commercial scale with aluminum chloride as the catalyst. Since the catalyst was too costly, this process did not continue for long. In the 1930s, Houdry obtained an effective catalyst from natural clay and invented the Houdry process. Both were fixed bed processes, which had a long residence time and required cyclic operations for catalyst regeneration. Such processes also required salt bath heat exchangers, which are costly and only partially effective for temperature control. In 1941, the thermofor catalytic cracking (TCC) moving bed process went on operation where the cracking reaction and catalyst regeneration were for the first time realized in two separate vessels with the catalyst particles circulated between the two vessels initially by bucket elevators and later by pneumatic transport.

Because the fixed/moving-bed operation had many limitations in terms of solids handling and transportation, heat addition/removal, gas–solid contact, and process capacity etc., the Standard Oil of New Jersey (now Exxon) began to develop a new FCC process in the late 1930s, with their first commercial unit on line in 1942 (Jahnig et al., 1980). Figure 17.31 sketches the typical early FCC design, the EXXON Model IV, which has two dense phase fluidized beds: one as cracking reactor and one as catalyst regenerator. The reactor runs in the temperature range of 480°C–550°C and the regenerator in the range of 550°C–600°C. The catalyst used was the synthetic amorphous silica-alumina catalyst and the average particle size of FCC is 55–80 μm. The much smaller particle size than that in the fixed bed operation gives much more surface area for the cracking reaction. Figure 17.32 shows an alternative design of the dense phase FCC, the UOP stacked unit.

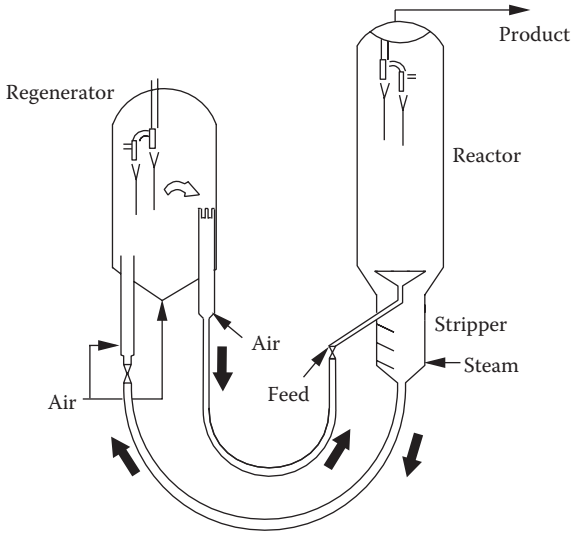

Figure 17.31

Exxon dense-phase fluidized bed FCC, Model IV.

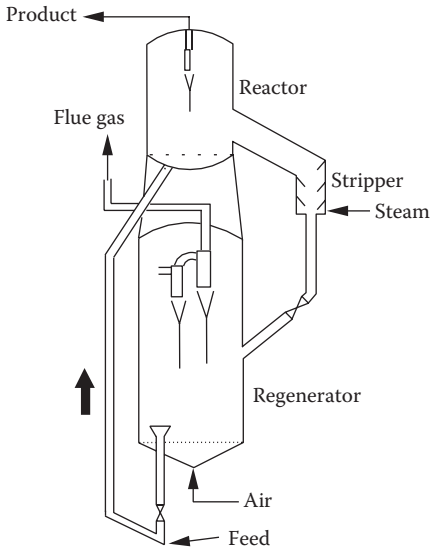

Figure 17.32

UOP stacked dense-phase fluidized bed FCC.

During the operation, the regenerated hot catalyst particles flow into the bottom of the reactor with the feed (crude oil or other heavy residue) injected into the transport line at a position near the bottom entrance to the reactor. The feed vaporizes upon contacting the hot catalyst and the catalytic cracking reaction takes place inside the reactor. Cracking yields lighter products, which leave the reactor in gas phase from the top of the reactor. During the cracking process, rejected carbon deposits onto the catalyst, causing it to deactivate. The deactivated catalyst particles are then circulated to the regenerator, after passing through a steam stripping section below the reactor. The stripping section or the stripper is either a moving bed or a gently fluidized bed with a very low steam rate and its main function is to displace the products adsorbed on the catalyst. The stripper commonly contains baffles to promote staging as significant axial mixing encountered in most SFBs leads to unit inefficiency. The deactivated catalyst is regenerated in the regenerator by burning off the carbon accumulation, before being circulated back to the reactor. During the regeneration, the temperature of catalyst is also increased by this exothermic combustion process, accumulating substantial heat in the catalyst. The hot catalyst then carries the heat

to the reactor, supplying the energy necessary for the endothermic catalytic reaction. Because of fluidization, catalyst particles can be transported easily in the loop between the two units. Both the reactor and the regenerator were reported to operate in the bubbling regimes in the early times. However, it is likely that most of them were operated in the turbulent fluidization regime given the relatively high gas flowrate, although not reported as such since the concept of the turbulent fluidized bed was not proposed until the early 1970s (Kehoe and Davidson, 1971).

The advantages of the FCC process are the excellent gas–solid contact, the much improved heat transfer, the large interfacial area with the reduction of particle size, and the large and controllable solids circulation between the two units. There are also at least two additional key advantages that distinguish the FCC from other fluidized bed processes: The first key advantage is that the reaction and regeneration is completed in one cycle with catalyst particles freely circulated between the two units. This solves the problem of quick catalyst deactivation and allows the process to continue. FCC is classified as a gas-phase catalytic reaction, because the solid particles are the catalyst that does not change its form during the process. The second key advantage is the realization of self-heat sufficiency by using the heat of carbon combustion in the regenerator to supply the heat required for the endothermic cracking reaction. This also gives the feature of a "gas-phase reaction with solids as the heat carrier" as in the first classification. With the second classification by areas of application, FCC clearly belongs to hydrocarbon processing.

While having many advantages, the dense phase FCC process has at least two distinct disadvantages: (1) The residence time of the gas phase in the reactor cannot be controlled precisely, leading to overcracking of the product, and (2) the residence time of the catalyst is also not uniform in the reactor and the presence of deactivated catalyst severely affects the selectivity. With the development of the more active zeolite catalyst by Mobil, the new "riser-cracker" was commercialized in the early 1960s. This new FCC replaces the dense-phase fluidized bed reactor with a transport riser reactor within which the gas velocity is sufficiently high to entrain the particles upward while the cracking reaction takes place. A typical riser FCC unit, the Shell FCC unit, is given in Figure 17.33a. The riser reactor significantly narrows the residence time distributions for both gas and solid phases so that overcracking is reduced and selectivity is increased. The high-velocity operation, in combination with the more active zeolite catalyst, also shortens the reaction time, further enhancing the formation of liquid products and reducing coke formation. The new zeolite catalyst also allows the increase of the regeneration temperature to about 700°C or higher, enhancing the combustion efficiency with more CO burnings and providing a better heat balance. The zeolite catalyst has an average particle size of 50–75 μm and the particles usually have a wide size distribution from 1 to 130 μm (Avidan and Shinnar, 1990), with sufficient fines under 45 μm to ensure excellent fluidity.

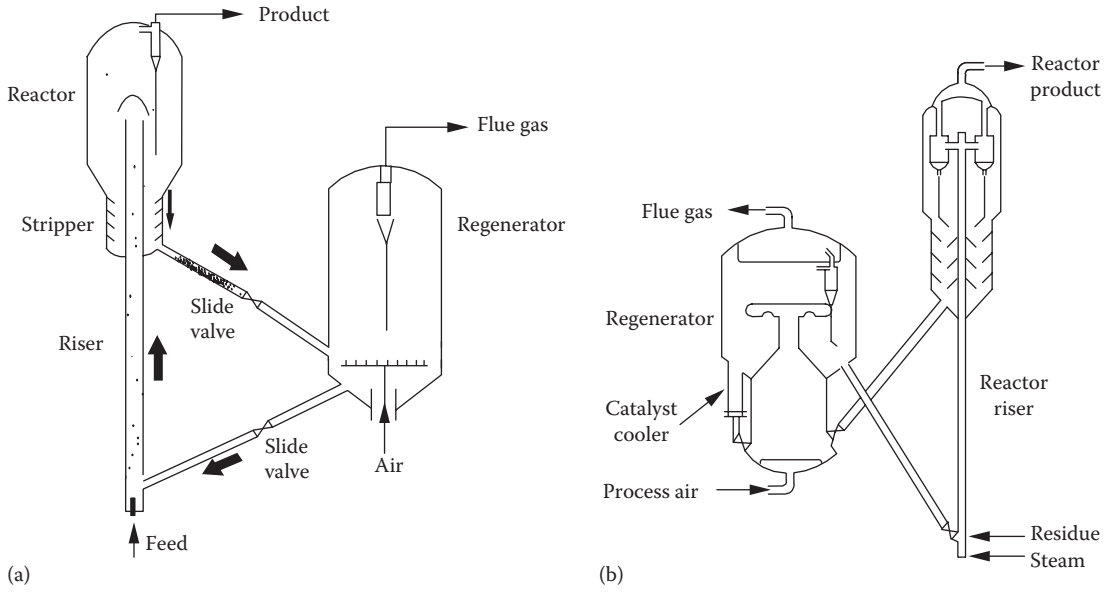

Figure 17.33

(a) Shell riser FCC. (b) SINOPEC riser RFCC.

Typical yields from a modern FCC (Avidan et al., 1990) operated in North America are (all weight %)

Fuel gas	4%
Dry gases $(C_3's + C_4's)$	13%
Gasoline	50%
Light cycle oil	20%
Heavy cycle oil	7%
Coke	6%

The highly endothermic cracking reaction significantly reduces the molecular weight of the feed to yield much more valuable products. The moderate temperature (500°C–550°C) ensures the preference of a more selective catalytic cracking over the less selective thermal cracking. By changing the temperature and other operating conditions, the relative fractions of the different product components can be adjusted to reflect the market requirements. (Avidan et al., 1990).

In recent years, the demand for more light products has led to the cracking of heavier feed. This is sometimes referred to as residue fluid catalytic cracking (RFCC). RFCC requires "deeper" cracking under a higher catalyst/oil ratio. In addition, the heavier feed produces more carbon on the deactivated catalyst, increasing the load of the regenerator. Many new regenerators have been designed to accommodate such a change, featuring two-stage combustion, larger unit, additional catalyst cooler, etc. The catalyst cooler is another external fluidized bed heat exchanger connected to the regenerator, where excess heat from the regenerator can be optionally removed out of the system. This becomes an essential feature for RFCC, since the heat from carbon combustion is normally more than that required for the cracking reaction. It is also used to control the regenerator and the reactor temperatures. The RFCC unit by SINOPEC is shown in Figure 17.33b as an example.

Although the modern FCC coupled by the CFB riser reactor and the turbulent bed regenerator is dominating the world FCC technology, they are not free from some inherent problems. In a typical riser, there is significant radial segregation with higher solids concentration and lower gas and particle velocities near the wall, and, lower solids concentration and higher gas and particle velocities in the center. This reduces the gas–solids contact efficiency, and also causes axial dispersion of the two phases and therefore nonuniform residence time distributions for the gas and solids. The gas dispersion causes overcracking and solids dispersion causes a reduction of selectivity. Solids acceleration at the riser bottom and gas–solids separation at the riser top both also lead to the requirement of longer reaction time.

To overcome this problem, the concept of a cocurrent gas–solid downer was proposed as a quick-contact reactor. In the downer, the radial gas and solids segregation existing in the riser is minimized due to the along-gravity flow directions of both gas and particles. The patent by Texaco appears to be the first to publish this downer concept (Gross, 1983, Gross and Ramage, 1983). Later, Murphy (1992) reviewed the evolutionary design changes of FCC processes and pointed out that the future FCC will involve high temperature, short residence time cracking, and dispersed phase regeneration. He then proposed the use of a downer for cracking reaction and a riser for catalyst regeneration, as shown in Figure 17.34. The Quick Contact (QC) reactor tested by Stone and Webster (Gartside, 1989) and the short contact-time fluidized reactor tested by Bergougnou et al. (1994), though mainly developed for thermal cracking, are both downer reactors that can also be used for FCC. Later on, bench-scale pilot studies by Deng et al. (2002a) show the excellent properties of the downer reactor, which have led to a significant improvement in selectivity, but similar pilot studies by Talman et al. (1999) reveal that the actual conversion in their downer reactor is less than that expected from a pseudo homogeneous reactor. The latter was further confirmed by recent studies of Li et al. (2013) and Wang et al. (2014), which directly compare the performance of a pilot scale pair of riser and downer using ozone decomposition reaction, where the downer is shown to be much more closer to plug flow than the riser but is yet not an ideal plug flow reactor. Associated with hot model studies are many hydrodynamic studies, such as those of Zhang et al. (2001), Luo et al. (2007), Qi et al., (2008), and Wang et al. (2014), as well as those reviewed by Cheng et al. (2008), most showing favorable characteristics of the downer reactor. In the longer run, it is evident that the downer is superior to the riser for the FCC process. Results from a 0.2 b/d demonstration downer unit in Saudi Arabia, operated at a high reaction temperature (above 550°C), short contact time, and with a high C/O ratio, have reported enhanced gasoline and light olefins production, reduced back-mixing, and suppressed thermal-cracking reactions (Maadhah et al., 2000). Based on these results, a 30 b/d demonstration unit was later on built near a Saudi refinery.

17.3.2.2 Catalytic Synthesis: Fischer–Tropsch Process

Fischer–Tropsch (F-T) process is the collective name for a group of synthetic reactions that synthesize CO and H_2 to form hydrocarbons of longer chains under high temperature and pressure. This is a strong exothermic reaction. The application of fluidized beds in the F-T process has been an ongoing competition between the SFB and the CFB and important lessons can be learned from the evolution of this process.

The application of fluidized bed in the F-T process started with a sad story regarding the failure of the first such attempt in the United States in the 1950s (Kunii and Levenspiel, 1991). It was the hydrocol process that aimed at the production of high-grade gasoline from cheap natural gas. It was a dense (bubbling) phase fluidized bed (SFB) of iron catalyst with cooling tube banks immersed in the bed to remove the heat (Zenz and Othmer, 1960). Although laboratory experiments were very promising (90% conversion), the 5 m ID commercial unit had much lower conversion. One key reason was attributed to the group C iron catalyst particles, which results in poor fluidization quality including channeling, poor gas–solid contact, and poor mixing. The operation was then abandoned later, with the added consideration of the rising natural gas price.

At the same time, the South African Synthetic Oil Limited (Sasol) was asking Kellogg to develop a new reactor for the same process. At that time, Kellogg has been heavily involved in a consortium of companies to develop the FCC reactors, the first generation of which was a CFB (Shingles and McDonald, 1988). The story was that Kellogg decided to try the CFB approach since they already had the detailed design for FCC, which was then shelved because of the low activity of the amorphous silica-alumina catalyst. The pilot study was a success and CFB was chosen as the Sasol Synthol reactor. The first commercial Sasol reactor, Sasol 1, was in production in 1955 and this was also the first application of CFB in industry, although it turned out later that there is no need to have a CFB, but a more carefully designed SFB would suffice.

The Sasol Synthol reactor is schematically shown in Figure 17.35. It is more like a loop reactor, but has most of the essential features of CFB. The feed is pushed into the bottom of the riser where the F-T reaction takes place. Heat exchangers are located in the middle portion of the riser to remove the heat produced by the reaction. The product is then separated from the recirculating catalyst and the catalyst is returned to the bottom of the standpipe to restart the cycle. The reaction temperature is above 320°C, and the pressure is 10–17 bars. The reactor side gas velocity needs to be above a critical velocity of 1.2 m/s, below which the operation becomes unstable. The voidage on the reactor side is around 0.90 at the bottom to 0.97 at the top (Shingles and McDonald, 1988). A series of scale-ups after the first commercial unit have increased the single unit capacity by several times. Shingles and McDonald (1988) provide a detailed account of the initial startup experience of the first Sasol reactor and the subsequent scale-ups to Sasol 2 and Sasol 3 reactors.

The main reason for using a fluidized bed for the F-T process is the high heat-transfer rate that ensures a nearly uniform reaction temperature. However, because catalyst deactivation is not an issue and there

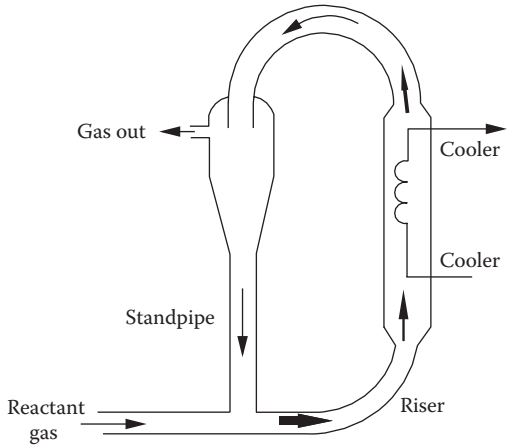

Figure 17.35

Sasol Synthol CFB Fischer–Tropsch reactor.

is no need to remove and return the catalyst continuously, the particles are in complete mixed mode in the Sasol reactors. In this case, a turbulent fluidized bed reactor, an SFB, should suffice and actually is better given the lower cost. While Sasol did make a quick comparison between a CFB and a SFB back in the 1950s, Shingles and McDonald (1988) suggested that the comparison was not made properly, since different particle sizes were used for the two types of reactors. At that time, little was known about the turbulent fluidized bed, so that its positive influence on the F-T process was left to be discovered 30 years later (Silverman et al., 1986).

The competition between the SFB and the CFB on the application of F-T process now finally has a "verdict" with the turbulent bed winning the race. An important lesson is that there is no need to "overkill" and CFB is not necessarily better if not needed. The latter is often mistakenly portrayed to students and young engineers as always being superior when they read the vast literature that describes the benefits of CFB.

17.3.2.3 Other Catalytic Reactions

Besides the F-T process, there are also a number of catalytic gas-phase processes that have been realized in fluidized bed reactors. In most of these cases, the catalyst does not deactivate quickly; that is, there is no need to change the catalyst frequently so that these catalytic reactions take place in SFBs. One key feature for gas-phase catalytic reactions is the large thermal effect of the reactions, and in this regard, fluidized beds are superior to fixed beds, because a uniform temperature can be easily maintained in the fluidized beds. Another key feature for catalytic gas-phase reactions is that the reaction rate is usually very high. As a result, almost all such catalytic reactions employ the turbulent fluidized bed, given the advantages of a smaller particle size that gives a higher gas–solid contact area, the reduction of bubble size, the high gas throughput, and reduced gas backmixing in the turbulent fluidized beds. Some of the reactions may have been reported to operate in the bubbling fluidized beds, due to the fact that the turbulent fluidization regime was not separately defined until the earlier 1970s (Kehoe and Davidson, 1971). Even if some of the earlier catalytic reactors did operate in the lower gas velocity bubbling regime, the operators have learned quickly through online experience that increasing the gas velocity most likely benefits both the yield and the productivity as the bed transfers from the bubbling to the turbulent regime.

Such catalytic gas-phase reactions include the productions of phthalic anhydride, acrylonitrile, aniline, ethylene dichloride, polyethylene, and polypropylene. Some of the processes are illustrated in Figure 17.36. Kunii and Levenspiel (1991) and Yerushalmi (1982) have given a good review for several of these processes with detailed reaction conditions so that an extensive review is not repeated here. Some common key features required for these fluidized bed reactors include good feed nozzle design for liquid feed, uniform gas distribution, efficient heat exchangers, and excellent gas–solid separation. Makeup of the catalyst may also be needed during the process due to catalyst attrition and carryovers.

A point worth mentioning is that the addition of proper internal baffles can enhance these catalytic reaction. Horizontal baffles lead to more staging for the gas flow and can normally increase the conversion and yield. Some more exotic baffles have also been used, which are believed to provide more benefits to certain

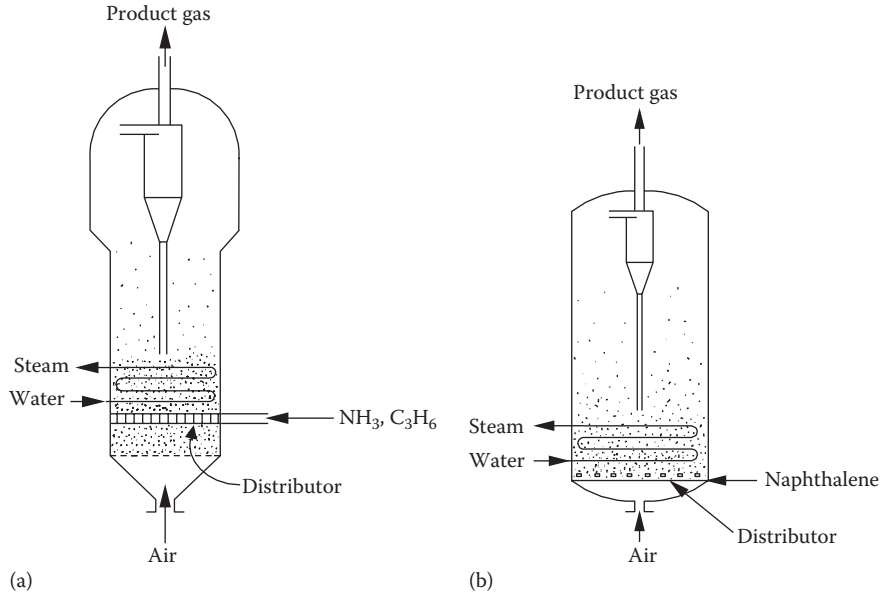

Figure 17.36

(a) Fluidized bed reactor for the production of acrylonitrile. (b) Fluidized bed reactor for the production of phthalic anhydride.

reactions. For example, the installation of pagoda baffles led to a significant increase of both conversion and yield for the production of phthalic anhydride from the oxidation of naphthalene (Yu, 1994). The reason for the success is that the pagoda baffles lead to an earlier transition to the turbulent fluidization regime at lower gas velocities, providing a better fluidization quality (Jin et al., 1986).

17.3.3 Noncatalytic Gas-Phase Reactions

17.3.3.1 Thermal Cracking

The purpose of thermal cracking is to produce light olefins. This is often achieved in a tubular furnace reactor, where the feed is cracked in tubes going through a high-temperature furnace. Currently, most of the world's ethylene is produced in this manner. However, the coke produced in the cracking process deposits on the tube inner wall and blocks up the reactor, so that the feeds to the tubular reactors are limited to light hydrocarbons such as ethane, naphtha, and kerosene, which are much more expensive than the heavier feed such as crude.

A fluidized bed reactor can be used to achieve the same process to crack light hydrocarbons into olefins, with the required heat for the reaction provided by burning additional fuel oil, or burning partially either the feed or the product. Kunii and Levenspiel (1991) described two such processes developed by Luigi and Fujinagata in the 1950s. In these earlier processes, sand particles are used as the heat carrier, and the reaction and heating take place in two different fluidized beds, with the sand circulating in between to transfer the heat generated from a combustion process to the endothermic cracking reactor. The entire concept is similar to the FCC process, but there are no catalyst particles and the reaction temperature is much higher in the range of 700°C–750°C.

The real benefit of using a fluidized bed is the direct cracking of crude oil or heavy oil to lower olefins. This will alleviate the pressure on the use of light hydrocarbons for the ever-increasing demands for light olefins. Such a process, like the FCC process, produces rejected carbon. The carbon deposition, while bad for the tubular reactors, can be turned into a benefit in a fluidized bed process as burning the deposited carbon on the heat carrier particles in a separate fluidized bed can produce the required heat for the endothermic thermal cracking. A similar setup as that of an FCC unit can be envisaged, either with two turbulent fluidized beds or two circulating fluidized beds or a combination of both, for the thermal cracking. In comparison with FCC, this would represent a "deeper" cracking of crude to lighter olefins than the mainly gasoline-kerosene product stream from FCC.

While there have been several encouraging developments on pilot studies for such a deep cracker, there appears to be no commercial application yet. Kunii and Levenspiel (1991) reported two earlier efforts by

BASF (Badische Anilin und Soda-Fabrik) and by MITI (Ministry of International Trade and Industry) in Japan, at 36 and 120 tonnes/day capacity to produce light olefins directly from crude. Both are pilot studies with two dense phase fluidized beds (SFB) with coke particles circulated between the reactor and the combustor. About 25% wt ethylene and 11% wt propylene are produced in both cases at a reaction temperature of 750°C. The lower conversion appears to be the reason that hinders the further development of these fluidized units.

The relatively low conversion may be caused by the backmixing of gas and the long residence time, therefore overcracking in the two pilot reactors mentioned. In response to this problem, Stone and Webster developed a QC reactor, starting from the 1970s (Gartside, 1989). This is a downer reactor with a very short contact time (as low as 200 ms) and very uniform residence time distributions for both gas and solids, permitting "the quick controlled contacting and separation of the fluidizable solids with a feedstock." The process is completed with an entrained bed combustion system to provide the heat required for thermal cracking. Alumina is used as the inert particles. A semicommercial demonstration unit was operated in the early 1980s, with flow capabilities of 34 tonnes/day hydrocarbon feed and 1200 tonnes/day of solids operated at temperatures ranging from 650°C to 1000°C, to show the feasibility of the downer concept. The system comprises a short downer reactor, a rapid mixer, and a quarter turn quick gas–solid separator. The reported reaction residence time from the point of oil-catalyst initial contact to the point of product quench including solids separation can be as low as 200 ms. No conversion rate is given, but it is believed to be higher than that of the SFB units.

Fluidized bed reactors also permit the possibility of adding catalyst into the unit, to further promote the cracking reaction, as initially suggested by Gartside (1989). This route combines the thermal and catalytic cracking and can increase the cracking efficiency. Deng et al. (2002b) have used this concept in a so-called downer catalytic pyrolysis process in a pilot downer reactor, for light olefins production from heavy feeds. Their results show that high olefins yields can be obtained at the temperature of 659°C and a residence time of 0.75 s, with the total yields of ethylene, propylene, and butylenes just over 50%wt. The added benefit to the combined catalytic/thermal cracking is the flexibility to adjust the relative ratio of ethylene, propylene, and butylenes, by switching catalysts that favor either ethylene or propylene/butylenes production. Increasing the temperature boosts the production of ethylene and decreasing the temperature promotes the production of propylene and butylenes. Such flexibility is extremely useful to respond to the changing demands of industry.

17.3.3.2 Coking

Coking is a process that converts heavy residual petroleum stocks into lighter and more valuable products. It is essentially a thermal cracking process at high temperature, but happens at the "higher end" in terms of molecular weight, compared to the thermal cracking discussed in the last section. This is an extremely important process in the petroleum industry, to convert very heavy stocks into lighter fractions. One situation is the need to crack heavy bitumen from oil sand to yield synthetic crude and the other is to crack the heavy residue matters left over from the atmospheric and/or vacuum distillation of crude or other feedstocks. When such cracking occurs, long-chain hydrocarbons break down into smaller molecules by rupture of carbon-to-carbon bond. Because the number of hydrogen atoms present in the parent molecules is insufficient to provide the full complement for each carbon atom, some carbon is rejected to form coke, hence the name "coking." As such, coking is a so-called carbon-rejection process.

There are two such coking processes using fluidized beds: the fluid coking process and the flexi coking process. Among the world's largest fluid cokers are the three in Alberta, Canada, operated by Syncrude, where hot atmospheric topped bitumen (ATB), vacuum topped bitumen (VTB), and residue are cracked or broken down into lighter products (Syncrude, 2012). High temperatures in the coking reactors cause the long-chain molecules to thermally crack in a bubbling fluidized bed of coke. The high temperature comes from the recirculating coke that has been heated in accompanying coker burner. The lighter liquid products, primarily naphtha and gas oils, are sent to hydrotreaters for sulfur and nitrogen removal. The coking reaction also produces sour fuel gas, which is sent to amine treaters for hydrogen sulfide removal. The resulting sweet fuel gas (much like natural gas) is used as an energy source throughout the upgrading and utilities operations. The coking reaction also produces coke, some of which is burned to produce heat for the high temperatures in the reactor. Excess coke is mixed with water and transported to coke cells in the mine area to be stored for potential future use. The two larger fluid cokers were designed to process 72,900 barrels of bitumen a day, but currently are able to process over 110,000 barrels of bitumen/day as a result of continuous improvement efforts (Syncrude, 2012).

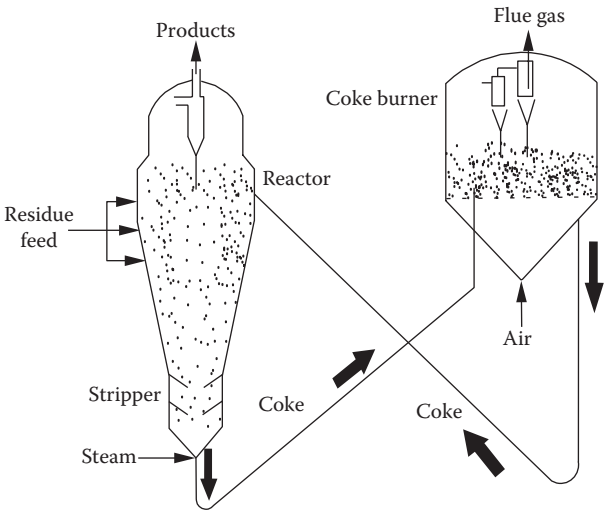

Figure 17.37

A typical fluid coking unit.

A typical fluid coker similar to that operating at Syncrude is shown in Figure 17.37. The reactor (480°C–550°C) operates in the bubbling fluidization regime with large bubbles produced mainly as a result of the formation of lighter products. The residue is fed into the reactor through nozzles from the side and a small amount of steam is injected from the bottom to maintain the fluidization at the bottom and also to displace any product desorbed on the coke particles as they travel down through the stripper at the bottom of the coker, before being transported to the coke burner. Part of the coke particles are combusted in the burner (590°C–700°C) to heat up the coke particles, which are then returned to the reactor to supply the heat required for the coking reaction. The remaining coke is discharged as a by-product. The coke particles are of Geldart type B particles with an average size close to 200 μm, which is maintained by a balance between the growth of particle size due to coke deposition and the reduction of particle size by attrition. Operation with Geldart type B particles leads to a bubbling bed with large bubbles. Cracked products vaporize inside the reactor and escape quickly in the form of large bubbles. Large bubbles are not favorable in most fluidized bed reactors, since they cause by-pass of reactant. In fluid coking, however, large bubbles become desirable, because they can quickly carry the products out of the reactor to minimize the residence time of the vapor products, which in turn avoids overcracking. The large bubbles also ensure vigorous mixing between the wet coke particles covered by the injected liquid and dry coke particles to ensure uniformity in the reaction and also to avoid the wet particles from sticking to each other. All fluid cokers also have a reversed cone shape to accommodate the vapor product formed during the process. Since only a very small amount of steam is supplied from the bottom of the reactor to fluidize the coke particles, the cross section of the reactor needs to be small in the bottom but gradually increases to maintain a relatively constant fluidization velocity as the products vaporize.

Flexi coking, an Exxon technology as shown in Figure 17.38, is similar to fluid coking but with the addition of a coke gasifier at the end of the line to produce boiler fuel, after sulfur removal (Yerushalmi, 1982). In this case, hot coke for the cracking reaction is usually provided by the particles from the gasifier rather than the combustor.

17.3.4 Gas–Solid Reactions

Fluidized bed gas–solid reactions have many applications. Such reactions take place in either a dense-phase SFB or a dilute-phase CFB, making use of the special characteristics of fluidized beds, such as excellent heat and mass transfer, the uniform temperature distribution, and the ability to handle a large quantity of solids and a wide range of solid materials. Coal utilization is a major part of such fluidized bed G-S reactions. The fact that the world's coal reserves are significantly larger than those of oils and natural gas renders them very important both as fuel and as feedstock for chemicals and other materials. Fluidized coal combustion and gasification have been shown to have many advantages. In more recent years, sustainable development and environmental concerns have also led to a large wave of increased utilization and consumption of biomass materials, in incineration and gasification.

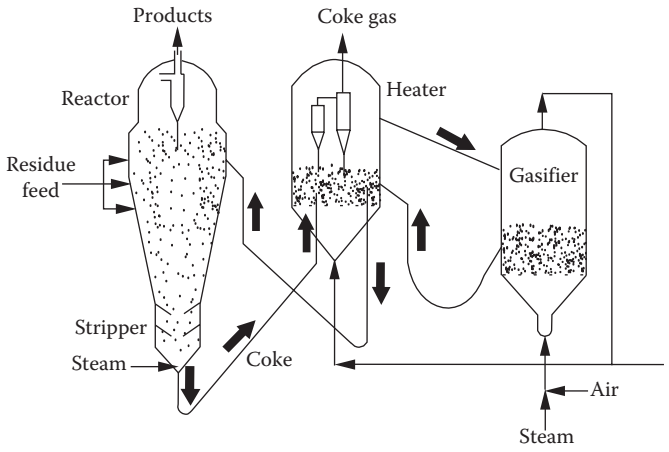

Figure 17.38

Flexi coking unit by Exxon.

17.3.4.1 Coal Combustion

Fluidized bed combustion is now the largest application of fluidized bed technology, both in the number of units and in the scale, with 600 MWe boilers being started recently. In an FBC, coal particles are suspended in an upflowing gas stream (normally air or oxygen enriched air) with a large amount of inert particles that help in stabilizing the combustor temperature and facilitating excellent heat transfer. In an FBC, a coal particle experiences the following process: After a coal particle is fed into the FBC, its temperature rises as the inert particles at higher temperature transfer heat to this colder coal particle. For a short period of time, volatile matters are released and are burned at or beyond the coal particle. Then the remaining solid combustible matters, mainly char, start to be oxidized (burned) with the generation of heat, while the particle is "floating" and move around inside the fluidized bed, leaving behind noncombustible matters such as ash. The char oxidation step takes by far the longest time during the combustion.

The FBC has many advantages, including

- Efficient and large-scale operation
- Very easy to maintain a uniform temperature
- Low-temperature operation, 750°C–900°C
- Very high heat-transfer rate
- Suitable for burning a wide variety of fuels, including low-grade coals and other low-end combustible materials
- No moving parts inside the combustor
- In situ capture of sulfur pollutants
- Lower emission of nitrogen oxides, especially in circulating fluidized bed combustors (CFBCs)

Coal particles contain mainly volatiles, char, and ash, with their relative quantities varying with the type of coal: Anthracite contains the least amount (a few percept) of volatiles and lignite can contain as high as over 50% volatiles. The ash in the coal is a mixture of adventitious ash and inherent ash, which is in the form of very small particles (typically 2 μm size), bound within the coal pieces (Howard, 1983). Most of the adventitious ash is removed in the coal cleaning plant, so that the treated coals have lower sulfur and ash contents and higher calorific values than the untreated coal. In most developed countries, only treated coal is combusted given the tight environmental control.

The following details are given for the volatiles and their combustion properties (Howard, 1983):

1. The volatilization process is not a simple physical vaporization, but the consequence of chemical reactions.
2. The volatiles given off are hydrocarbon gases arising from irreversible chemical reactions, that is, thermal decomposition, which occur when the coal is heated. Condensation and further cooling of these gases will not reconstitute their original chemical and physical form.

3. Volatiles are mostly emitted from the interior of the coal particle from which they seep out to the exposed surface.
4. The chemical reactions may be exothermic.
5. There is no clearly defined temperature at which the volatiles are released, but the higher the surface heat flux into the coal particles, the shorter the time taken for all the volatiles to be given off.
6. The volatiles burn in much the same way as liquid fuel vapors burn, with a flame located a short distance away from the solid surface. The flame provides heat to the particle surface to assist further volatilization until all the volatiles have been evolved.
7. The evolved hydrocarbon gases may not burn completely in the region around the coal particle, but often appear as a smoky yellow flame and deposit shoot on the surfaces downstream.
8. Incompletely burnt volatiles can only be burned to completion if they passed through a high-temperature zone containing excess oxygen.

One key advantage of the fluidized bed coal combustion is that it operates at low temperature, 750°C–900°C, minimizing the volatilization of alkali metals in the fuel and avoids any sintering of the coal ash and sand materials. This partially results from the uniform temperature in a fluidized bed, which is facilitated by the presence of inert particles, mostly sand or ash from coal combustion, plus sorbent particles. The inert particles form the majority of the fluidized bed materials as the coal particles only constitute no more than 10% of the bed materials. The large quantity of inert particles act as a huge heat sink that quickly takes away the heat produced by combustion, transfers a large amount of heat to the heat exchangers, and maintains excellent temperature uniformity. They also act as a heat source to rapidly heat up the cold coal particles fed into the system. Sand particles are usually used as the initial inert materials, which are then gradually replaced by ash from the combustion. Depending on the ash content and the size range of the ash produced, addition of makeup bed materials may be required from time to time. Finer ash leaves the combustor through the cyclone as fly ash and larger sized ash is collected from the bottom drain of the combustor.

Another important advantage of fluidized bed combustion is the ability to capture sulfur within the combustor using low cost sorbent. Sulfur exists in almost all types of coals, varying from less than 1% up to 10%, in the form of pyrites (FeS_2) and organic sulfur compounds. When coal is burned, sulfur is released as sulfur dioxide and, to a smaller extent, as sulfur trioxide, both are air pollutants that form acid rain. The most common way to remove sulfur oxides is to add lime either in the form of limestone (calcium carbonate) or in the form of dolomite (combined calcium and magnesium carbonate) into the FBC where they react with the released sulfur to form calcium sulfate ($CaSO_4$). With this method, sulfur is *fixed* in calcium sulfate, which is then removed with ash. The retention of sulfur by lime in FBCs has the advantage of not requiring a separate gas-scrubbing plant, easier handling and disposal of spent sorbent, and greater overall thermal efficiency. Lime sorbent can be fed into the combustor either with the coal (premixed) or separately.

Another major pollutant of fluidized bed combustion is nitrogen oxides, including nitrogen monoxide and nitrogen dioxide, also collectively called NO_x, plus nitrous oxide. Nitrogen monoxide and dioxide are sources of acid rain, and nitrous oxide induces ozone decomposition in the stratospheric layer. Nitrogen oxides in FBCs come from the nitrogen in the fuel, typically 0.5%–2% by mass. The formation of NO_x is a complex process, but it is clearly known that increasing temperature and the excess air both favor the formation of NO_x due to the increased oxidation rate. Therefore, the low temperature of FBCs helps to limit NO_x formation. However, either low temperature or limited excess air ratio alone is currently not enough for the stationary (bubbling) fluidized bed combustors (SFBCs) to meet the more stringent NO_x emission standard. In this regard, the CFBC is much more advantageous given its ability to create separate reducing and oxidizing zones inside the combustor.

CFBCs emerged as a better alternative to bubbling bed combustors in the late 1970s and early 1980s. A typical CFBC is shown in Figure 17.39. CFBC has a large diameter riser where most combustion occurs. Flue gas and entrained particles are separated in the cyclone on top of the solids return pipe. Collected solids including inert particles, sorbent, and unburnt char are gathered in the return pipe, and then further recirculated to the bottom of the riser combustor. Air is divided into two streams: the primary stream is fed into the riser through the bottom air distributor to fluidize the particles in the bottom region and the secondary air is fed lower midway in the riser to further entrain particles upward and to bring the combustion to completion. Coal and limestone are fed into the bottom region of the riser and so are the returned solids from the return pipe. The splitting of airflow results in a lower gas velocity in the bottom region of the riser.

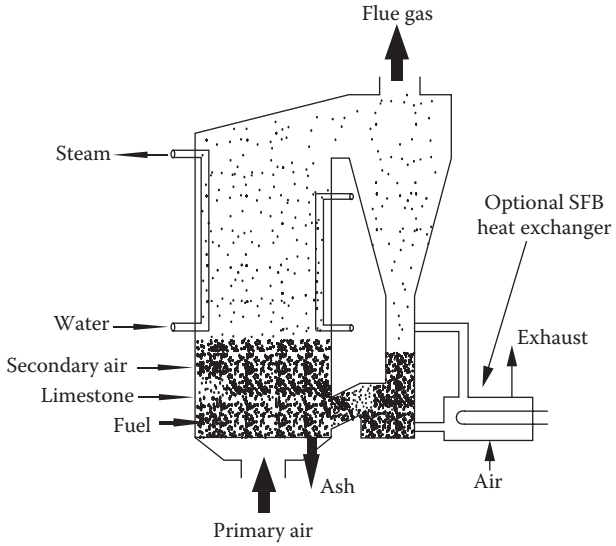

Figure 17.39

A typical circulating fluidized bed combustor.

This creates a bubbling fluidized bed in the bottom, which significantly enhances lateral solids mixing to quickly mix the coal, sorbent, and the returned solids. The bubbling bed also ensures excellent heat transfer to heat up the newly fed coal and sorbent particles. The temperature in the riser is normally 750°C–900°C, and the temperature in the return pipe is 100°C–200°C lower. Major heat transfer is through the membrane wall of the riser and more heat transfer through the fluidized bed heat exchangers in the return pipe, plus possible additional fluidized bed heat exchangers. The bed materials have a size range of 100–300 μm, but the coal and sorbent are usually fed in much larger sizes, in the range of several millimeters. The larger size permits the newly fed and cold coal and sorbent to remain in the bottom bubbling bed region, so that there is sufficient time for them to heat up and to react. As the reactions continue and their temperature rises, the larger particles are broken down into smaller fractions and then entrained into the upper region for continued and higher temperature combustion. The ability to feed larger particles directly is another clear advantage of the fluidized bed, as it eliminates the energy-intensive crashing process upstream, such as those required for pulverized coal combustion.

The partial feeding of the total amount of air required for combustion into the bottom region creates a reducing zone there, which favors the formation of N_2 over the formation of NO_x from the released nitrogen from the fuel. The temperature in the bottom region is also lower, again favoring the reduction of NO_x formation. In addition, the low gas velocity and the larger coal particle size both increase the residence time of the newly fed coal in the bottom bubbling region, to ensure all volatiles, including most of the fuel nitrogen, are released in the bottom reducing region. All of these factors favor the reduction of NO_x emission, making CFBC more preferable than SFBC. Above the point of the secondary air injection, the temperature rises and an oxidizing region forms, to promote fast combustion. However, NO_x emission is not affected, since most fuel nitrogen has been consumed at this time.

Such staging effect also increases the combustion efficiency, by maintaining a higher temperature in the upper region of the riser. Excellent heat transfer is ensured by operating the riser combustor at lower gas velocity (compared to most other CFBs) to promote particle reflux near the wall, creating a dense particle annulus for better bed-to-wall heat transfer. CFBC also provides better gas–solid contact efficiency for the combustion.

Overall, CFBC has several advantages over SFBC:

- High combustion efficiency
- Adjustable primary-to-secondary air flow ratio
- Significantly reduced NO_x emission
- Separate control of air and particle feeds
- Higher turndown ratio

As a result, CFBC has quickly replaced SFBC in the past few decades as the industry standard for fluidized bed combustion. However, SFBC is still used for some small-scale combustors given its low construction cost, and for some special purpose combustors.

Prior to the 1980s, many SFBC of different designs have been commercialized all over the world. For example, China had over 2000 small SFBC in operation in the 1980s. An excellent comprehensive review on the application of SFBC has been provided by Highley and Kaye (1983). Given the rapid replacement of SFBC by CFBC, those design features are not detailed here.

CFB combustion is the fastest growing application of CFB technology and has recently overtaken FCC, to become the largest application of CFB technology. Both capacity and number of CFB boilers in use are increasing drastically in the past 20–30 years. Approximately 600 CFB boilers are either in operation or under construction. The CFB combustor has surpassed the bubbling bed firing system not only by total unit capacity, but also by the number of plants. Now, atmospheric CFB plants stand for about two-thirds of the total installed capacity worldwide. The demand also triggered a fast increase in unit size (Jacobs, 1999). Reh (1999) reported that the boiler companies such as ABB Combustion Engineering, Lurgi and Foster Wheeler Power Systems were pursuing several projects in the 250–400 MWe capacity range at the turn of the century, while Electricité de France (EdF) was planning to scale up its atmospheric CFBC into the 600 MWe capacity range. Yue et al. (2014) reported the world's largest 600 MW CFBC being put into operation in 2013.

A pressurized fluidized bed combustor (PFBC) has the added benefit to also employ the high-pressure flue gas to drive a gas turbine to form the combined cycle power generation, giving higher thermal efficiency. However, operating at higher pressure causes many problems so that PFBC has not been widely used. In connection with the recent development of CFBC, pressurized CFBC may still represent the future direction of fluidized bed combustion, although the current economy does not make PCFBC profitable.

There are also two new trends in the development of FBC. Firstly, in an effort to reduce the emission of greenhouse gas such as CO_2, oxy-fuel combustion has been proposed (Buhre et al., 2005, Kosowska-Golachowska et al., 2011). In an oxy-fuel combustor, coal particles are burnt in the presence of pure or enriched oxygen and recycled flue gas, without nitrogen, so that the flue gas leaving the combustor is highly enriched in CO_2, allowing easy CO_2 sequestration. The second trend is to utilize the supercritical phenomena to improve the water-steam efficiency for supercritical circulating fluidized bed combustion (SCFBC) (Xin et al., 2002, Wu et al., 2004, Yue et al., 2014).

17.3.4.2 Coal Gasification

Coal gasification is the first industrial application of fluidization technology in modern history. The concept was first envisaged by Fritz Winkler (1922) in his German patent in 1922. In 1926, the first Winkler commercial unit began its operation with four additional units added by 1929 (Squires, 1983). In the gasifier, a fluidized bed of coal particles was suspended by a gas mixture of air and steam, or more often a gas mixture of oxygen and steam, to produce raw gas for the chemical industry, such as ammonia synthesis. The temperature is about 800°C–900°C, and the thermal power is up to 100 MW.

As shown in Figure 17.40, the Winkler gasifier is a relatively simple unit, with gas entering from the bottom and product leaving from the top. The coal, crushed to about 10 mm and dried of surface moisture, is fed by a screw feeder into the dense phase. The products are mainly carbon monoxide and hydrogen, sometimes with a minor quantity of methane. When air is used, the products are diluted by nitrogen. The energy required for gasification is supplied by the partial oxidation of coal. There is usually an expanded section above the particle bed to allow the return of ejected particles through bubble eruption and a cyclone is usually there as well to catch and recycle fine carbon particles. In the later models, some additional air or oxygen was injected into the freeboard region, to increase the carbon efficiency by burning off the fine carbon particles there. The resulting temperature rise in the freeboard increases the decomposition of produced methane to the desired CO and H_2. Both primary and secondary gases are injected through nozzles to increase the contact efficiency. Compared to modern technology, the Winkler gas producer is inefficient because of its high oxygen consumption and its large (over 20%) carbon loss through dust carryover. Given the abundance of cheap petroleum and natural gas in the 1950s, most Winkler gasifiers went out of service due to poor economy. Kunii and Levenspiel (1991) reported that all Winkler units were shut down in the 1950s, while Yerushalmi (1982) seemed to suggest that a few Winkler units were still in operation in the 1980s.)

From the 1970s, the oil crises raised the importance of coal, so that a number of companies started to develop new coal gasifiers. There are a number of benefits of coal gasification over straight combustion, including a higher electricity efficiency through the gas-turbine-steam-turbine binary cycle via gasification

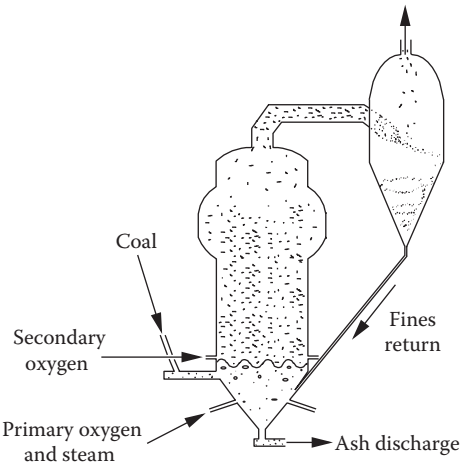

Figure 17.40

A typical Winkler gasifier.

than the conventional steam turbine system via combustion only. Gasification also provides clean gaseous fuels and raw chemicals for synthesis. For example, in the Sasol Synthol process described in Section 17.3.2, the syn-gas for the F-T process was supplied by coal gasification.

However, there are a number of inherent limitations for fluidized bed gasification of coal (Yerushalmi, 1982), including

1. The operating temperature is limited, with the highest temperature limited by the sintering temperature and the lowest by the reactivity of coal.
2. Carbon fines are produced within the fluidized bed, giving rise to problems such as loss of carbon through entrainment.
3. Loss of carbon through purging of ash.

These limitations implied that the complete gasification cannot be achieved in a single-stage fluidized bed operating below the sintering temperature. Therefore, the development of new fluidized bed gasifiers needs to overcome these problems. Many designs include multiple stages to increase the efficiency of carbon use. Unfortunately, there appears to be no commercialization of the fluidized bed gasifier to date, although numerous studies including many pilot studies have been carried out. Kunii and Levenspiel (1991) summarized the various routes and concepts of fluidized bed gasifiers, and pointed out, although the development has been much slower than expected, the fluidized bed route is still beneficial for large-scale production of fuel gas for binary cycle power plants.

17.3.4.3 Incineration of Solids Wastes

Fluidized bed incinerators are mainly used for the elimination of harmful materials and for the utilization of heat value in the wastes. Examples of the subject materials are solids municipal and industrial wastes, saw dust, plastic wastes, dried sewage sludge, and special wastes such as hospital wastes. Electricity generation may be a good use of the energy produced. Fluidized bed incineration is similar to fluidized bed combustion in their structure and in that both fluidized beds are composed of mainly inert particles with the combustible wastes fed into the fluidized bed in the dense phase. However, there are special issues that must be considered for the incineration of wastes:

1. Pretreatment—Some solids waste may contain large objects that need to be crushed or removed, some have high moisture content that need to be at least partially removed, some contain too many noncombustibles such as glass and metal that need to be screened out.
2. Combustibility, flame stability, auxiliary fuel, and cofiring—Not all waste materials have enough heating value, good combustibility, and/or flame stability, so that auxiliary fuel(s) may be needed to cofire the incinerator (Sondreal et al., 2001). Most common cofiring fuels are coal and natural gas.

In most cases, a cofiring facility is normally required although not necessarily always used, because it is needed when switching waste materials and during start-up and the period when the waste supplies are short if a continuous energy supply is required.

3. Variations in waste compositions—Certain solids wastes such as municipal wastes can have their compositions fluctuating. The incinerator must be designed to handle such variations in the change of heating values, ash content, moisture, etc. In this regard, the standby of cofiring is essential to maintain good operation of a fluidized bed incinerator.
4. Feeding—Special attention is needed to feed the different solids wastes. If multiple wastes are to be burned in the same unit, the feeding device must be versatile enough to handle all situations.
5. Secondary air injection—As in coal combustion, secondary air injection may be beneficial for certain cases. This, however, changes with the type of solids wastes and the type of fluidized beds adopted (SFB or CFB).
6. Temperature—Temperature is another key factor. In addition to those issues discussed in Section 17.3.4.1 related to coal combustion, there may be additional factors coming into play. For example, the temperature needs to be high enough to decompose certain harmful constituents.
7. Emission control—Other than the acid rain cursors of SO_2 and NO_x encountered in coal combustion, other harmful gases such as chlorine and bromine might be released during the combustion of, for example, plastic wastes. Dioxins are an even worse issue. Special measures need to be taken to eliminate these harmful gases or trap them in the flue gas.
8. Heavy metals and other toxic solid contents, residue solids disposal—Some wastes contain much higher fractions of heavy metals such as vanadium, lead, and mercury and can cause long-term damages. The containment of those heavy metals must be solved before the incineration of those materials. A related issue is the residue solid's disposal: the presence of heavy metals makes it much harder.

17.3.4.4 Gasification and Pyrolysis of Biomass

Sustainable development requires the use of renewable energy and biomass provides the main renewable energy resource (Bridgwater and Peacocke, 2000, Bridgwater, 2003). Biomass includes grain husk and stalk, sawdust, grass, and wood especially wood from short rotation forestry. There are three methods that can utilize the energy contained in the biomass: combustion, gasification, and pyrolysis. Direct combustion provides heat for use in heating, for steam production and electricity generation; gasification provides fuel gas for combustion for heat or in an engine or turbine for electricity generation, or raw materials for the chemical industry; and pyrolysis provides a liquid fuel that can substitute for fuel oil and that can produce a range of specialty and commodity chemicals. Combustion of biomass using a fluidized bed is currently not competitive, unless the feeds are the wastes, such as that from pulp and paper, and agricultural and forestry industries (Bridgwater, 2003). The nature of biomass combustion is similar to those discussed in the previous sections.

Gasification is the (thermochemical) conversion of biomass to a gaseous fuel by heating in a gasification medium such as air, oxygen, or steam. It is advantageous over combustion because the gaseous fuel is easier and more versatile to use and can also be standardized in its quality. The main reactions are partial/complete combustion and water gas shift reaction, to convert the carbon to CO, CO_2, and H_2, plus some methane. Gasification starts from driving out the moisture, followed by a pyrolysis process to yield gas, vaporized tars or oils, and char residue, and then the much slower process to gasify the solid char, pyrolysis tars, and pyrolysis gases. Alkali metals present in wood ash can act as a catalyst to accelerate the reactions.

Bubbling fluidized bed and CFB both can be used for biomass gasification. Both have good temperature control and high reaction rates, but both have high particulate content in the product gas and high carbon loss with the ash. CFB has the additional advantage of increased process efficiency, more operational flexibility, and better emission control.

The financial assessment of biomass gasification, however, is not always favorable and is very sensitive to many factors. Biomass is of low-energy density and is not produced centrally. In developed countries, the high cost of collecting and transporting the biomass may make the gasification process cost-inhibitive, but the potential of being paid to take biomass wastes should help greatly enhance the economics of power generation. However, biomass gasification can be economically viable in developing countries, where the cost of biomass at feed is much less expensive. Wu et al. (2002) concludes that their 1 MW unit is still profitable if the cost of biomass is less than US$25 per metric ton.

In China, there is an abundance of biomass but a lack of electricity, especially in the rural areas. In the past two decades, the Guangzhou Institute of Energy Conversion has been demonstrating the BGPG (biomass

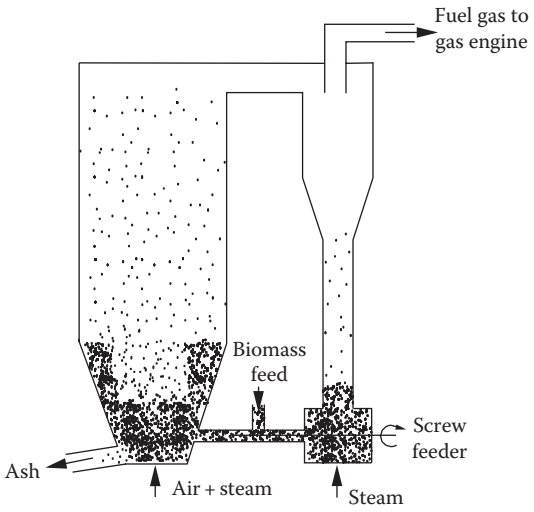

Figure 17.41

CFB biomass gasifier developed by GIEC, for the BGPG process.

gasification and power generation) concept using one 1 MW CFB unit in Fujian Province to gasify rice husk (Yin et al., 2002) and another 1.2 MW CFB unit in Sanya to gasify saw dust (Wu et al., 2002). Taking the 1.2 MW CFB as an example, the unit is a simple CFB gasifier as shown in Figure 17.41, with sawdust fed into the bottom region of the riser through a screw feeder. The solid's recirculation rate is not very high so the riser diameter is significantly larger than the diameter of the return column under the primary cyclone. The product gas passes through a simple scrubber to remove ash and tar, before being burned in four parallel gas engines (Wu, 2010). They (Wu et al., 2002, Yin et al., 2002, Wu, 2010) reached the conclusion that BGPG can reach reasonable efficiency at certain scale and provide a high-quality power supply to the users. It is especially suitable for rural areas in developing countries where such simple and robust technology can assist in the development of rural economies by providing electricity produced from local sources of biomass. Larger units are planned for full commercialization.

The use of a catalyst can further increase the efficiency and therefore the economy of biomass gasification (Sutton et al., 2001). It can also lower the reaction temperature. Asadullah et al. (2002a,b) reported a catalytic gasification process developed for the gasification of wood powder to proceed completely at lower temperature in the presence of a$Rh/CeO_2/SiO_2$ catalyst.

Pyrolysis is a thermal decomposition process in the absence of oxygen. When the reaction is controlled within a short period of time, in the order of milliseconds, more valuable liquid products can be obtained. The liquid products continue to decompose to lighter hydrocarbons of less value, if the reaction continues. Thus, it is very important to control the short reaction time and such a pyrolysis process is therefore called fast pyrolysis. In this process, the critical issues are to bring the reacting biomass particles quickly to the optimum process temperature and minimize its exposure to the intermediate temperatures that favor formation of charcoal and to quickly stop the reaction at the desired time.

Bergougnouet al. (1994) proposed a short contact-time fluidized reactor developed for the ultrapyrolysis of biomass and heavy oil. The design is very similar to the QC concept by Stone and Webster (Gartside, 1989) that the process is realized in a downer reactor. Preheated hot inert solids (sands) and the biomass are injected separately into the top of the downer where vigorous heat transfers quickly bring the biomass to the reaction temperature. While flowing cocurrently downward, pyrolysis proceeds quickly, within about 500 ms. At the bottom of the downer reactor, the products are quickly separated from the sands and quenched.

Based on the aforementioned concept, Ensyn developed a rapid thermal pyrolysis (RTP) process in the 1980s for fast pyrolysis, to produce gaseous and liquid fuels and chemicals of high value (Graham and Huffman, 1995). Instead of a downer, an upflowing riser reactor is used to facilitate rapid and uniform contacts between the biomass and the hot recirculated sand at the riser entrance. Before feeding to the reactor, biomass is comminuted to approximately 6 mm and dried to no more than 10% moisture. At the riser top, the products pass through two cyclones to separate solids and the vapor after the cyclone is rapidly quenched to stop further decomposition of the thermally unstable liquid intermediates of the pyrolysis.

The aforementioned process was commercialized in 1989 to produce food flavorings and additives (Graham and Huffman, 1995). There were later on eight such plants in operation in the 1990s. A variety of feeds including cellulose, wood, lignin, agricultural residues, heavy oils, heavy distillates, asphalt, and bitumen can be processed (Bridgwater and Peacocke, 2000). It may be possible to burn the produced "bio-oil" in an internal combustion engine.

Another technology from the University of Waterloo in Canada uses a SFB for fast pyrolysis instead of a CFB and bench-scale experiments seem to indicate they can achieve the same performance as in CFB (Scott et al., 1985, 1999).

The liquid "bio-oil" contains valuable chemicals and can be easily stored and transported. It can be used as alternative liquid fuel and/or as chemical feedstock because it contains a significant fraction of useful organic chemicals. However, there are still many challenges, such as higher cost, incompatibility with conventional fuels, high viscosity, chemical instability, lack of standards for use and distributions, and the variations in its quality (Bridgwater, 2003).

17.3.4.5 Mineral and Metallurgical Processes: Roasting and Calcination

Another area of application of fluidized bed reactors is in the mineral and metallurgical process. The use of fluidized bed for roasting started in the late 1940s in Ontario Canada for roasting arsenopyrite and to obtain a cinder suitable for gold production by cyanidation (Kunii and Levenspiel, 1991). The roaster is a simple one-stage SFB operated most likely in the bubbling fluidization regime. Air is usually the fluidizing medium, which also supplies the oxygen and the roaster is usually operated at high temperature. The advantages of using fluidized beds for roasting are the excellent mass transfer, uniform temperature, and the ability of continuously adding and withdrawing the particles. Many roasting processes have been realized in fluidized beds, such as the roasting of pyrites, pyrrhotite, zinc sulfide, copper and cobalt concentrates, and other various sulfide and sulfate. Readers are referred to Yerushalmi (1982) for a more comprehensive review on the application fluidized bed roaster, given the limited space here.

Calcination is another important gas–solid reaction. For example, calcination of aluminum hydroxide is an essential step for the production of aluminum, since only completely dehydrated alumina can be fed into the electrolytic cells. Calcination of calcium carbonate is another example. Again, calcination in fluidized bed is to make better use of the special features of the fluidized bed. The added advantages of CFBs can also be utilized. In the late 1960s, Lurgi commercialized the world's CFB calciner, the so-called fast fluidized bed alumina calciner (Reh, 1971, 1986). As shown in Figure 17.42, the CFB calciner has a very similar structure as a CFB combustor. Aluminum hydroxide is fed into the bottom dense region of the riser. Natural gas or fuel oil is fed into the riser to provide the high temperature for calcination. The air is also split into primary

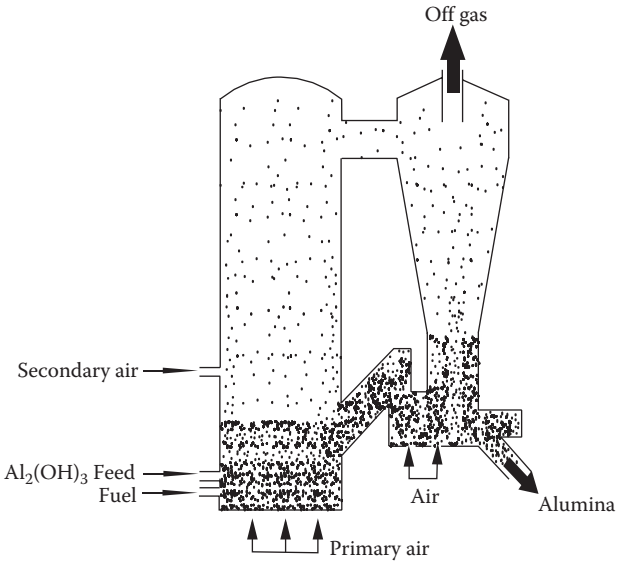

Figure 17.42

Lurgi's CFB calciner.

and secondary streams, with the purpose of creating a dense phase at the bottom to accelerate the heat transfer from the hot bed materials to the newly fed cold $Al_2(OH)_3$ particles and to promote lateral mixing. If not counting the Sasol CFB for F-T process, which could have been better served by a turbulent fluidized bed, the Lurgi CFB alumina calciner would have been the first commercial CFB reactor.

17.3.5 Physical Operations

There are many examples of using fluidized beds for physical operations, where no chemical reaction occurs. These processes use one or more of the special features of the fluidized beds:

- The large interfacial surface area between the fluid and the particles for excellent gas–solid contact, due to the small particle size
- The excellent heat transfer between the gas and particles given the vigorous relative movement between the fluid and the particles
- The excellent heat transfer between the gas–solid suspension and the heat exchanger surfaces
- The uniform temperature from the excellent heat transfer and gross movement of particles
- The ability to handle a large quantity of particulate materials
- The flexibility to fluidize a wide range of particle properties

17.3.5.1 Drying

Fluidized bed dryers have been applied in many industries, such as the food and agriculture industry, the pharmaceutical industry, and the chemical process industry. During a drying process, a significant amount of heat needs to be transferred from air (as in most cases) to the particles and a significant amount of mass (steam) needs to be transferred from the particles back to the air stream. Fluidized beds are very efficient dryers because they have the ability to rapidly provide a large amount of heat and to quickly take away a large amount of vapor. These essential features ensure the excellent use of energy, which is the biggest concern in all nonspecialty drying processes. Aside from excellent heat and mass transfers, fluidized beds also contain the following special features, which make them specially suitable for most drying processes:

1. Fluidized beds have a very uniform and well-controlled temperature. This allows the drying temperature to be raised very close to the maximum allowed temperature for most efficient drying, without worrying about localized overheating. This is particularly useful for drying heat-sensitive particles, such as grains and pharmaceutical products where overheating will permanently damage the materials.
2. Fluidized bed dryers can handle a very large quantity of particulate materials, with easy feeding and product withdrawal. This helps to ensure a continuous and large-scale operation.
3. The vigorous movements of particles inside the fluidized bed promote the uniform drying of all particles and over all surfaces of each particle. This is in favor of more uniform drying products.

The drying process usually has two stages: The first is the constant rate stage when the moisture on the particle surface is being taken away. During this stage, the driving force, the difference between the moisture content in the air stream and that on the particle surface, remains the same, so that the drying rate remains the same. The second drying stage is the reducing rate stage that removes the hard-to-dry moisture contained inside the particles. The first stage is fast and requires a large amount of airflow to provide the heat for evaporation and to remove the steam, while the second stage is slower and requires a longer drying time. Obviously, it is best that the drying process can be designed to suit the needs of both stages.

Figure 17.43 sketches a basic fluidized bed dryer design where hot air passes through the fluidized bed and leaves from the top, and wet particles enter from one side of the fluidized bed and the dry particles leave from the other side. When this is run in a continuous mode, it will not be most efficient, since the particles are well mixed in such a dense-phase fluidized bed. Some wet particles can quickly bypass the dryer, while others may stay in the bed for too long, causing underdried and overdried particles. In order to ensure the drying is complete, the residence time of the particles has to be significantly increased, leading to a much larger unit and the waste of energy through increased airflow. A significant portion of the hot air also tends to pass through the bed as bubbles, bypassing the dryer, leading to a less efficient use of energy.

To increase the uniformity of the solids products in a continuous drying process, it is useful to create some staging effect to prevent the drier particles from remixing (backmixing) with fresh wet particles. Figure 17.44 illustrates several alternative designs of fluidized bed dryers. Figure 17.44a and b show two

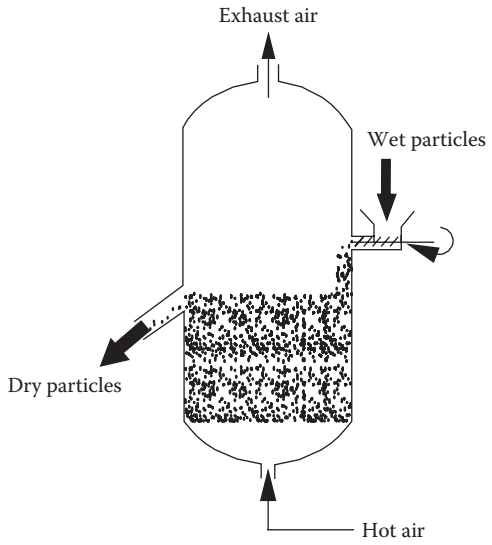

Figure 17.43

A typical fluidized bed drier.

examples of staged drying operations: one with vertical staging and one with horizontal staging. Such staging reduces solids' bypassing and therefore increases drying efficiency. The vertical one with countercurrent flow is more efficiency than the horizontal one with crosscurrent flow for energy use. Figure 17.44c and d are two special designs that accommodate closely the features of the two drying stages. In Figure 17.44c, the two fluidized beds are operated at different hot air velocities: the one on the right at a higher air flowrate to quickly take away the moisture on the particle surface in a relatively short time, the one on the left at much lower air flowrate but with much longer residences of both air and solids, plus staging to remove the moisture inside the particles. A similar method (Figure 17.44d) is to realize the first stage in a riser where the air-particle mass transfer is very high and a very high air velocity can be used to quickly remove the moisture on the particle surface, and then to realize the second stage in a vertically staged fluidized bed at air velocity not much above the minimum fluidization with horizontal baffles to ensure uniform and longer residence time distribution of the particles.

17.3.5.2 Heat Exchangers

Fluidized beds are excellent heat exchangers given the high heat-transfer rate and the huge heat capacity of solid particles. Such a process is usually realized in a set-up similar to a shell-tube heat exchanger where the fluidized particles are usually in the shell side of the exchanger. For example, fluidized bed heat exchangers have been used to take away the large amount of heat generated from chemical reactions. Because of the high heat-transfer rate and large heat capacity, such fluidized bed heat exchangers are highly efficient. Because of higher solids concentration, most fluidized bed heat exchangers are dense-phase SFBs rather than CFBs, given the much higher heat capacity of the solids.

Fluidized beds with inert particulate materials can also be used to maintain a constant temperature for some operations. For instance, it can act as a temperature bath that encases a chemical reactor. It can also be used as a heat sink to provide a well-controlled and uniform temperature source with high heat capacity. Kunii and Levenspiel (1991) mentioned the use of such a fluidized bed to rapidly quench and temper hot metalware to a definite temperature so as to obtain the desired properties of an alloy.

There are also the direct contact heat exchanges inside the fluidized bed. For example, hot flue gas can be used to warm up sand particles that are to be added into the combustor as makeup materials in fluidized bed combustion. This also happens during the start-up of fluidized bed coal combustion when hot air, obtained from the burning of natural gas, for example, is first passed through the FBC to heat up the bed materials to a certain temperature, before coal particles can start to burn on themselves. Similarly, air or other gas can be used to fluidize hot particulate materials in product line to recover the residue heat.

Fluidized bed heat exchangers can also be used as a heat exchanger within a chemical process that already utilizes the fluidized bed. For example, as discussed in Section 17.3.2.1, a catalyst cooler is an essential

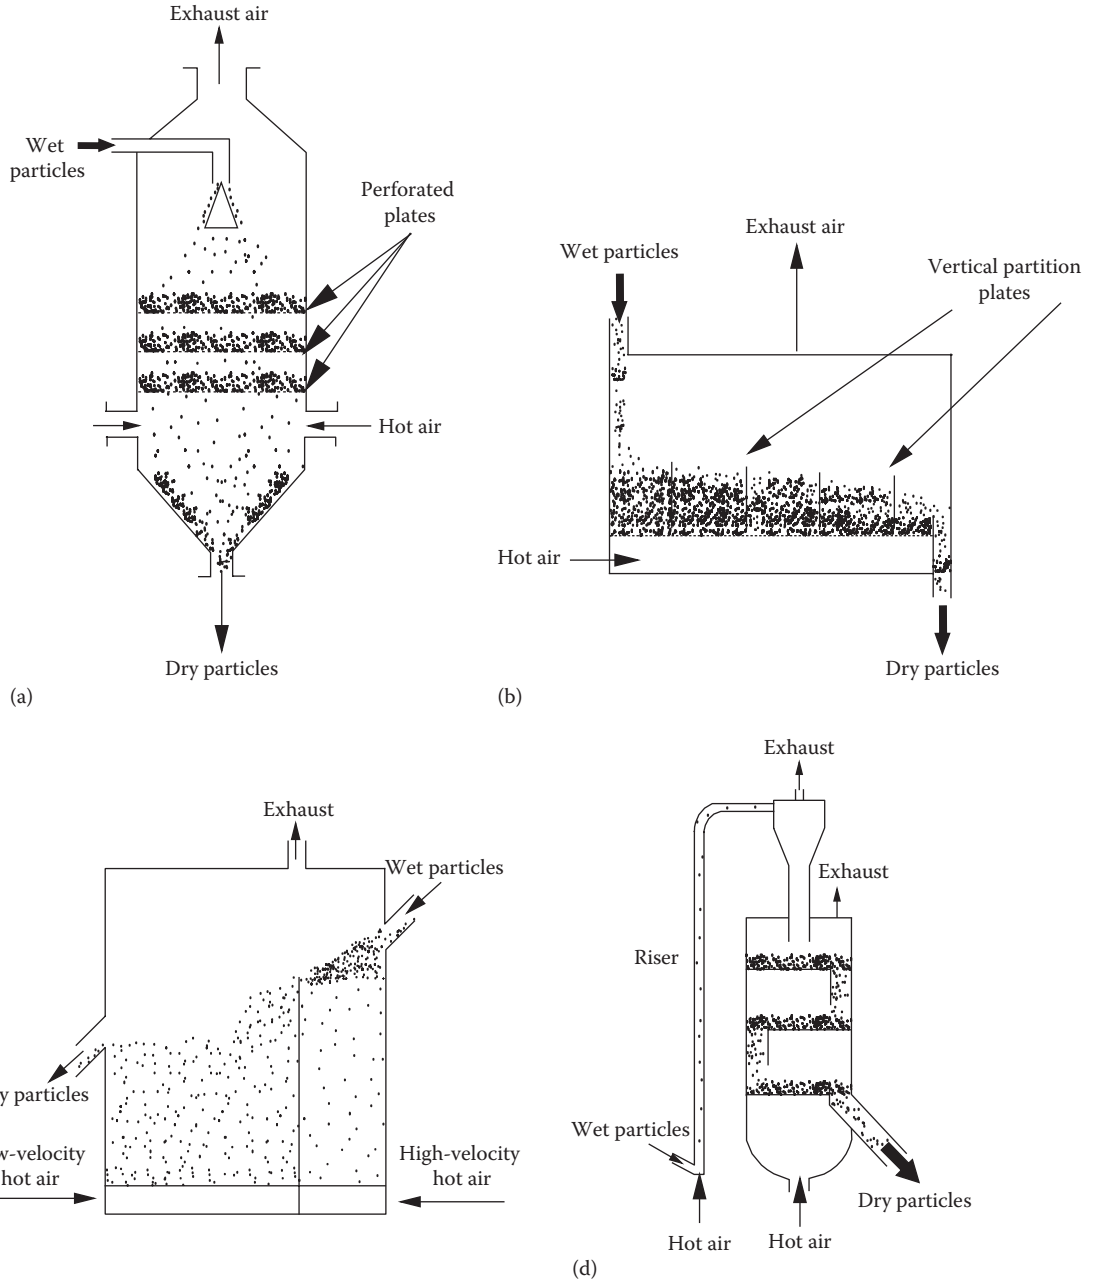

Figure 17.44

(a) Vertically staged fluidized bed drier. (b) Horizontally staged fluidized bed drier. (c) Two-stage SFB fluidized bed drier. (d) Two-stage CFB-SFB fluidized bed drier.

component of modern RFCC , to take away the extra heat from the combustion in order to maintain the heat balance. In combustors, besides the heat exchanger installed inside the fluidized bed combustion chamber, additional dense-phase fluidized bed(s) can also be installed in the solid's return loop to take away extra heat if required.

There are some additional distinct advantages of fluidized bed heat exchangers and two examples are given here.

1. They can be kept at a relatively high temperature, which is difficult to maintain by gas or liquid. For example, to maintain a highly endothermic chemical reaction inside a reactor at 350°C, it is required to have an efficient heat exchanger that can maintain at a constant temperature just slightly higher. This was mostly realized using molten salt since the evaporation temperatures of the most

commonly used gases and liquids are not in this range. However, molten salt causes many problems such as corrosion. Fluidized beds, with sand, for example, are now being used to replace such molten salt heat exchangers.

2. The heat-transfer rate can be easily adjusted in most fluidized bed heat exchangers. Their heat-transfer capacity can be "turned up" or "turned down" almost instantaneously by increasing or decreasing the fluidization gas. As the fluidizing gas velocity increases in a dense-phase fluidized bed, there are more gross movements of solids and therefore higher heat-transfer rates. Such fluidized bed heat exchangers can also be easily "turned off" and "turned on" by shutting off and restarting the fluidization gas, without having to stop any other operations.

17.3.5.3 Fluidized Bed Coating

Coating of particles with a thin layer of film can be realized in a fluidized bed. In such a process, the particles to be coated are first fluidized, with air or with inert gas if needed, and the coating materials, usually in solution, are sprayed into the fluidized bed. Because of the vigorous movement of the particles and the gross flow pattern in the fluidized bed, particles are uniformly coated. Very often, spouted beds are preferentially used for particle coating. Given the gross particle circulation, particles, which get sticky after being sprayed by the coating solution, can still be nicely circulated in the spouted bed. The spouted bed is also a better choice when handling large particles. Figure 17.45 shows three examples of fluidized/spouted bed coaters.

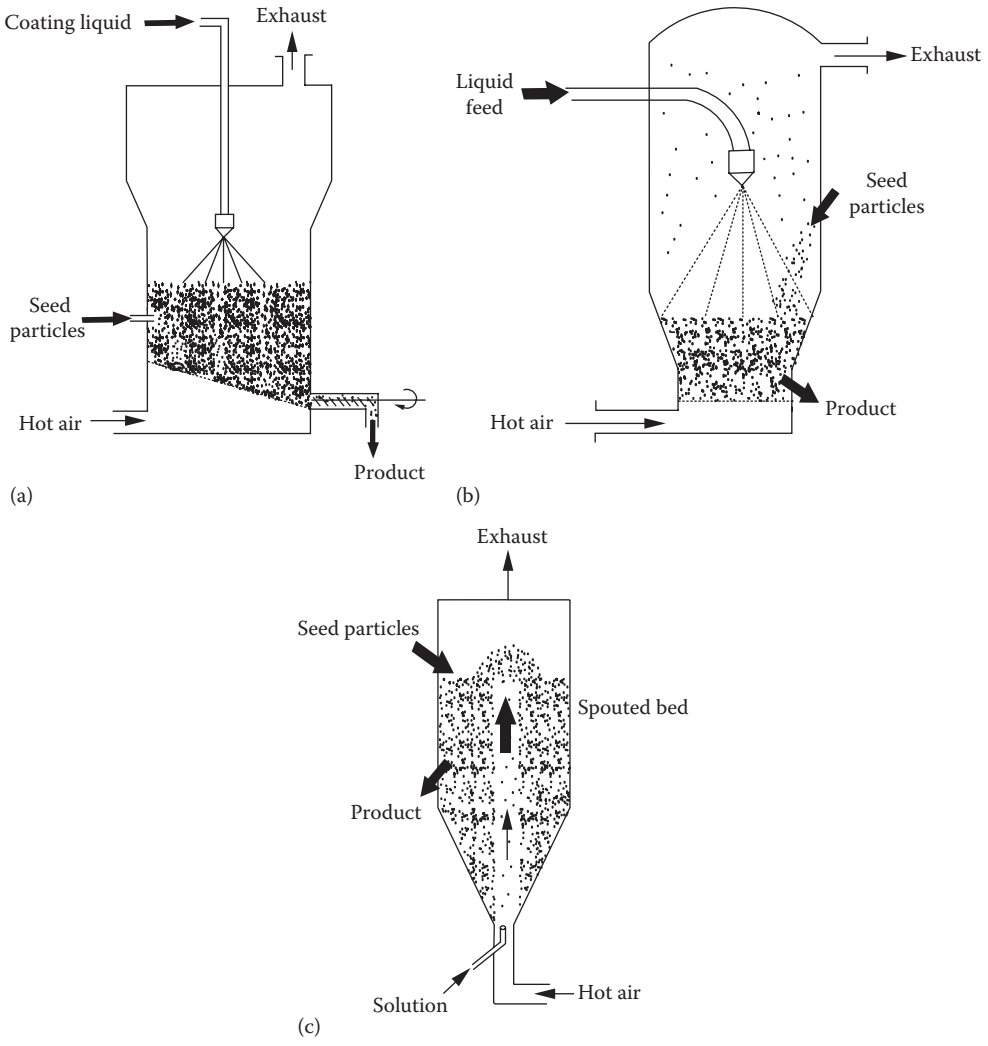

Figure 17.45

(a and b) Fluidized bed coaters. (c) Spouted bed coater.

Particle coating has many industrial applications, including coating the small pellets for pharmaceutical capsules to realize controlled drug release profile.

17.3.5.4 Powder Coating

Powder coating is a process where the materials initially in powder form are coated onto larger objects such as dishwasher racks, filing cabinets, and automotive parts. The powder materials can be thermoplastic or thermosetting. Thermoplastic materials are usually used for simple indoor parts with less stringent requirement. When applying thermoplastic coating, the thermoplastic powder is fluidized with cold or warm air and the heated metal part such as a dishwasher rack is dipped into the bed for a short period of time, normally a few seconds, and then quickly removed. A uniform thermoplastic coating is thus formed onto the dishwasher rack, making it a nice final product.

Thermosetting powder coating is used much more widely and also much more durable than thermoplastic powder coatings. In the thermosetting powder coating process, pigment, resin, and other materials are first dry-mixed together and then put through an extrusion process to homogenize the materials. The solid paint chips from the extrusion are then grinded down to about 30–60 μm to be used as the paint powder.

There are two methods to apply the paint powder onto workpieces, both using electrostatics. The first method is fluidized bed coating, where the air is electrically charged when flowing through the plenum with a high voltage electrode. The parts are then dipped into the fluidized bed of paint powder and the powder forms a thin layer on the parts' surface caused by electrostatic adhesion. The parts are then transported to an oven for curing. This procedure is simple but limited to continuous coating of simple parts of similar size and shape.

The mostly widely used powder coating process, over 90%, is the electrostatic spraying method. A typical powder spray booth with accessories is given in Figure 17.46. Paint powder is first put into the fluidized feed hopper from which the powder is "picked up" by the Venturi effect using a high-velocity airflow in the transport line. At the end of the air transport line is the spray gun, which produces an air and particle flow mixture, projecting toward the parts that are conveyed in the direction perpendicular to the powder flow. The powder, now charged by the high-voltage electrode at the tip of the powder spray gun, preferentially flows onto the earthed metal parts and cling onto them. The coated parts are then conveyed by the continuous conveyor to the oven for solidification (curing). Particles not adhered to the parts are sucked into the solids separation system, typically with cyclones and bag house filters, and the paint particles collected are recycled back to the feeder.

There are many significant advantages of electrostatic spraying powder coating over regular solvent-based coating. First, it eliminates the use of a solvent, which not only eliminates the associated emission problem but also realizes cost savings. The second key advantage is that any unused paint can be recycled and reused. Therefore, dry powder coating has developed very quickly and is replacing solvent coating at an unprecedented rate. However, due to the use of Geldart A powders, the surface quality of powder coating is not very smooth so that powder coating has not been used for high end products such as automobile bodies. While the use of much finer Geldart C paint powder should lead to a much better surface quality, the problem of powder agglomeration makes the results even worse, preventing the use of powder coating

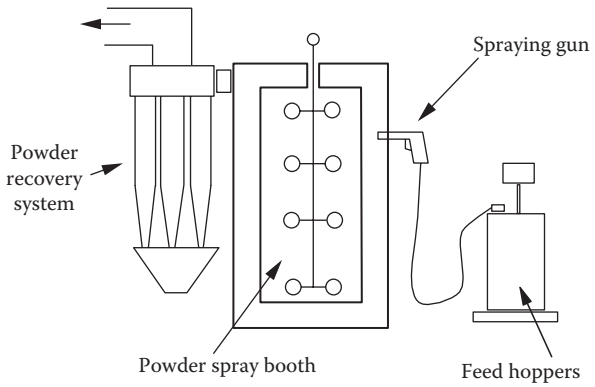

Figure 17.46

The powder coating process.

from being used for high-end products. A new technology has been invented at the authors' university that can essentially eliminate the interparticle forces. Using this new technology, Geldart C particles are made to flow freely, just like Geldart Group A particles. This new technology has now been commercialized in a local company to produce high-end powder coating products.

It is with the use of fine Geldart C particles that this fine powder coating has been extended to coat pharmaceutical tablets (Zhu et al., 2010, 2011). Horizontally rotating coating pans that are currently used for liquid coating are directly adopted for powder coating, so that major change of equipment is not required. Coating powder is made by direct mixing of the ingredient particles, typically including the functional polymer, the pigment, and other additives such as plasticizers. After preheating the tablets in the tumbling coating pan, a thin layer of liquid plasticizer may be first sprayed onto the tablets, to reduce the glass transition temperature as well as to create a moisturized surface for easy adhesion of the coating powder. Then, coating powder was sprayed, followed by curing—this process cycle may be repeated to increase the coating level when required, typically for functional release profiles. This technology has now been fully demonstrated with industry size pilot runs, for all major functional coating profiles, that is, immediate release (Qiao et al., 2010a), sustained release (Qiao et al., 2010b), and enteric release (Qiao et al., 2013). Once commercialized, this will represent the fourth generation of pharmaceutical coating, after sugar coating, organic solvent coating, and aqueous coating, with clear benefits over its predecessors: significantly reduced energy use, environmentally more friendly, and shorter processing time. Additional benefits include reduced coating level to achieve the same functional coating due to the more consolidated film formed by powder coating (Zhu et al., 2010).

17.3.6 Other Fluidized Bed Reactors and Applications

Besides the various gas–solid fluidized bed reactors discussed earlier in this section, there are also other types of fluidized bed reactors, namely, the spouted bed and spout-fluid bed reactors, the LSFB reactors, and the gas–liquid–solid three phase reactors. Given the limited space of this handbook, only the special features are highlighted here, while the readers are directed to key references for more details.

17.3.6.1 Spouted Beds

The spouted bed is essentially a fluidized bed with purposely made "mal-distribution" of gas. All fluidizing gas enters in a central nozzle from the bottom of the bed, which has reversed cone shape, and all the special features of the spouted bed trace back to the central nozzle. As outlined in Section 17.3.1, particles in the spouted bed flow rapidly upward in the spout, reach the top fountain, and then move down slowly in the annulus. Most gases pass through the bed in the central spout and there may be a gas downflow in the annulus as gas is dragged downward by the particles. The gross internal particle circulation inside the spouted bed gives rise to several additional features and it is these features that lead to the application of spouted beds.

First of all, the gross solid's circulation and the more vigorous particle movement allow the spouted bed to handle larger and sticky particles. This makes the spouted bed very useful in certain physical operations such as drying and particle coating, as the gross and vigorous internal circulation prevents the particles from sticking to each other. As a matter of fact, the invention of spouted bed was directly associated with the drying of Canadian wheat (Mathur and Gishler, 1955). Mathur and Epstein (1974) reviewed most of the early applications of spouted beds, including drying and particle coating. There were also a period of time during the 1980s and early 1990s that spouted beds have been studied for coal combustion and gasification, which, however, appears to have not led to commercialization. There were also studies on pyrolysis in spouted beds with and without draft tubes (Huff and Vasalos, 1998, Aguado et al., 2002), and the spouted bed with a more "complete" draft tube is also referred to as an "internal CFB" (Milne et al., 1994).

Spouted beds are also finding applications in new areas such as the food industry (Dewettinck, and Huyghebaert, 1999, Gibbs et al., 1999) and pharmaceutical industry (Jono et al.,, 2000) to coat beads and pellets. In the food industry, encapsulation with thin film of polymers provides specific properties that the natural product does not offer. For example, encapsulation can separate the reactive components within a mixture, mask undesirable flavors, protect unstable ingredients from degradation (due to heat, moisture, air and light), provide controlled and/or delayed release and reduce hygroscopicity, and change the characteristic of the original material (such as flowability, compressibility, dust reduction and density).

17.3.6.2 Liquid–Solid Fluidized Beds

LSFBs have very uniform liquid–solid suspension. Unlike a gas–solid fluidized bed where excess fluidizing gas beyond minimum fluidization forms bubbles, which lead to bypassing of reactant and many other

problems, "excess" liquid in LSFB merely leads to higher bed expansion. Such phenomenon is referred to as particulate fluidization (Kwauk, 1992) and provides many benefits: very uniform contact between the two phases throughout the entire fluidized bed and the ability to adjust the liquid–solid ratio inside the bed by changing the liquid fluidization velocity.

The modern applications of LSFB appear to date back to the 1960s. The more traditional applications of liquid–solid fluidized beds include classification of particles by size and density, backwashing of granular filters, crystal growth, adsorption, ion exchange, and electrolysis with both inert and electrically conducting fluidized particles (Epstein, 2003). Another area of applications is leaching and washing (Kwauk, 1992). More recent applications of the LSFB are in the bioindustry and wastewater treatment industry. A recent review paper by Epstein (2003) provides an excellent collection of applications of LSFBs.

Worth special mentioning is the emergence of the liquid-solid circulating fluidized beds (LSCFBs) as a new liquid–solid reactor, which gives added benefits over the traditional LSFB (Zhu et al., 2000). The added features include more uniform residence time distribution, better mass transfer, the independent control of solid's concentration, the higher turndown ratio, and the possibility of accommodating two reactions/processes in the same LSCFB unit. LSCFB has found potential applications in the chemical industry (Liang and Zhu, 1997), the biotech industry (Lan et al., 2002), and the wastewater treatment industry (Nakhla et al., 2007, Zhu et al., 2010). By early 2015, LSCFB has been successfully demonstrated commercially by Renix at London, Canada, for an ionic exchange process.

17.3.6.3 Gas–Liquid–Solid Three-Phase Fluidized Beds

Gas–liquid–solid fluidized beds (GLSFB) or three-phase fluidized beds may be considered as LSFBs with the additional injection of gas. The GLSFB is generally divided into two phases: the gas or bubble phase and the fluidized dense phase where there are only liquid and solids. In a GLSFB, bubbles form as soon as the gas is injected, since, unlike in the gas–solid fluidized bed, the gas phase is not present in the dense phase. Interaction between the gas phase and particles is mostly indirect through the liquid phase. Generally speaking, a GLSFB is more uniform than a gas–solid fluidized bed but less uniform than an LSFB. In the stationary GLSFB, there are three main operating regimes: the dispersed bubble regime, the coalesced bubble regime, and the slug regime (Fan, 1989). The dispersed bubble regime under higher liquid velocity is more uniform than the coalesced bubble regime under higher gas velocity. This also reflects the point that a "gas-driven" fluidized system is less uniform than a "liquid-driven" fluidized system.

GLSFBs also have many applications. The more traditional applications are in the petrochemical industry for upgrading heavy stocks such as hydrocracking and hydrotreating. Applications in fermentation and pharmaceutical industry also have a long history. More recent applications in the past 20–30 years are seen mostly in the biotech industry and wastewater treatment industry. A very thorough review has been provided by Fan (1989).

Nomenclature

Abbreviations

ATB	Atmospheric topped bitumen
BGPG	Biomass gasification and power generation
CFB	Circulating fluidized bed
CFBC	Circulating fluidized bed combustor
FCC	Fluid catalytic cracking or fluid cracking catalyst
FFB	Fixed fluidized bed
GIEC	Guangzhou Institute of Energy Conversion
GLSFB	Gas–liquid–solid fluidized beds
GLSCFB	Gas–liquid–solid circulating fluidized bed
LSCFB	Liquid–solid circulating fluidized bed
LSFB	Liquid–solid fluidized beds
PCFBC	Pressurized circulating fluidized bed combustor
PFBC	Pressurized fluidized bed combustor
QC	Quick contact
RFCC	Residue fluid catalytic cracking
RTD	Residence time distribution

SFB	Stationary fluidized bed
SFB	Stationary fluidized bed combustor
SINOPEC	Chinese National (Sino) Petroleum Enterprises Corporation
TCC	Thermofor catalytic cracking
UOP	Universal Oil Products Company
VTB	Vacuum topped bitumen

Nanofluids

Efstathios E. Michaelides and Yulong Ding

18.1 Overview
18.2 Definition of the Effective Transport Properties
18.3 Effective Viscosity
18.4 Effective Thermal conductivity
18.5 Additional Augmentation of the Convective Heat Transfer Coefficients
18.6 Natural Convection
18.7 Boiling with Nanofluids
18.8 Effective Diffusivity
18.9 Specific Heat Capacity
18.10 Conclusions and General Observations

18.1 Overview

Nanofluids are heterogeneous suspensions of nanoparticles in common fluids, which are typically called *base fluids*. Nanofluids exhibit significantly altered heat and mass transfer characteristics and have become the subject of investigations of numerous research projects since 1995. Several sets of experimental data indicate that the addition of very small quantities of nanoparticles in the base fluids has the following effects on the heat and mass transfer characteristics of the mixture:

1. Increases, in many cases, the effective thermal conductivity of the suspensions
2. Increases, in many cases, the convective heat transfer coefficients
3. In general, decreases the pool boiling coefficients, enhances the convective boiling coefficients, and enhances significantly the critical heat flux (CHF)
4. Increases significantly the mass transfer coefficient
5. Increases the viscosity and friction factor
6. Increases the specific heat capacity in some cases

Figure 18.1 depicts the ratio of the thermal conductivities of the nanofluid to that of the base fluid, k_e/k_f, as a function of the volumetric fraction of solids. This ratio is often referred to as the *relative conductivity* of the nanofluid. The figure is a compilation of several sets of experimental data from the literature with the most typical nanoparticles (Eastman et al., 2001, Xie et al., 2002, 2011, Das et al., 2003, Chopkar et al., 2006, 2008, Liu et al., 2006, Turanov and Tolmachev, 2009). The two lines represent typical trends with a metallic nanofluid and an oxide nanofluid.

The following conclusions may be drawn from this figure:

- The percentage conductivity enhancement is significantly higher than the percentage concentration increase of the particles. A very low concentration of particles (less than 1%) may cause more than 20% enhancement of the thermal conductivity.

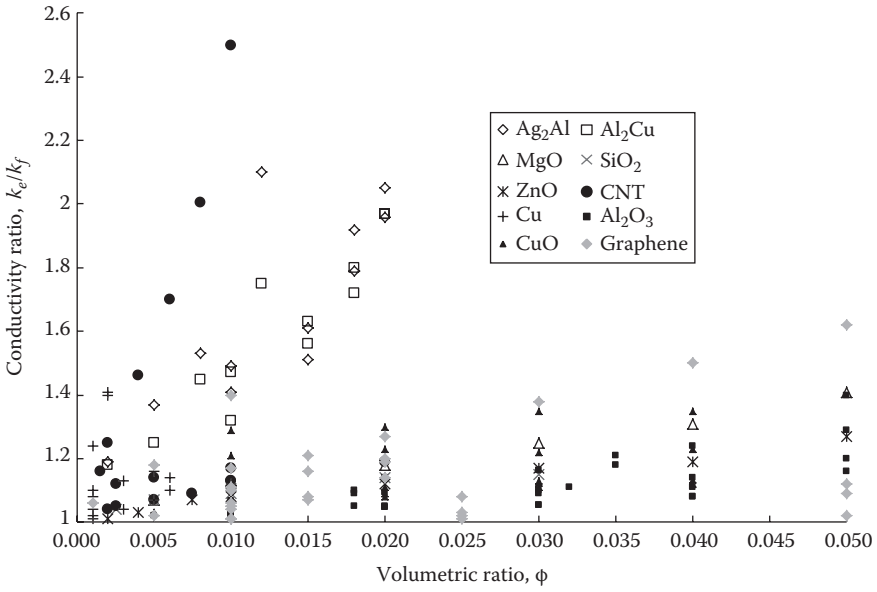

Figure 18.1

Effective thermal conductivity enhancement of several nanofluid systems.

- The thermal conductivity enhancement depends primarily on the type of particles: nanofluids with particles, such as carbon nanotube (CNT), Ag_2Al, and Al_2Cu, exhibit significantly higher effective conductivities, while the effective conductivities of nanofluids with Al_2O_3 nanoparticles are, in general, significantly lower.
- There are diminishing returns to adding more particles beyond a concentration of approximately 1%: the effective conductivity increase is not simply proportional to the volumetric ratio.

Because of their very high relative conductivity, CNT and metallic nanofluids are considered to be excellent heat transfer media. This, and the expectation that nanofluids with desired internal structure and transport properties may be specifically designed by using suitable nanoparticles and surfactants, has sparked a tremendous research interest in these suspensions. It must be noted that this discussion does not take into account the penalty due to viscosity and pressure drop increase, which may outweigh the benefits of the thermal conductivity enhancement. The following sections present a succinct summary of the transport properties of the experimental and analytical results pertaining to nanofluids.

18.2 Definition of the Effective Transport Properties

All the transport properties have been defined in homogeneous fluids as the ratios of a flux and the corresponding conjugate force (Onsager, 1931). For example, the viscosity of a homogeneous, Newtonian fluid has been defined at every point of the fluid in terms of the shear stress and the velocity gradient:

$$\tau = \mu\left(\frac{\partial u}{\partial y}\right) \tag{18.1}$$

Similar expressions yield the thermal conductivity and the diffusivity of homogeneous media. In the case of anisotropic and homogeneous materials, the transport properties are vectorial quantities but are still well defined at every point of the homogeneous medium from the tensors of the fluxes and conjugate forces (Michaelides, 2014).

Nanofluids are heterogeneous media at a scale of the order of magnitude of the nanoparticle size, composed of nanoparticles immersed in the base fluid. As such, there are two geometric domains in a nanofluid: the domain occupied by the solids and the domain occupied by the fluid. It is clear that if Equation 18.1 is to be applied for the viscosity of a nanofluid at two different points, the first inside the base fluid and the

second inside a nanoparticle, one would obtain two different values: the first is close to the viscosity of the pure base fluid and the second is very large (infinite, since the nanoparticle moves as a rigid body and the velocity gradient inside this particle is zero). None of the two values describe accurately the flow behavior of the entire heterogeneous suspension, the nanofluid. Therefore, both values are useless or meaningless to the scientist or the engineer. A more useful property in this case is the *effective viscosity* of the heterogeneous mixture, which includes the effects of the solid particles on the motion of the fluid. The effective viscosity is derived from an extension of the definition of the homogeneous fluid viscosity according to Equation 18.1 and pertains to the velocity gradients that are defined on a scale much larger than the scale of the particles: An average velocity gradient may be defined at any point (x, y, z) in the heterogeneous mixture using a length scale, δy, which is significantly larger than the size of the particles ($\delta y \gg \alpha$) and the velocity difference of the suspension, δu, at the ends of the segment. At this length scale, δy, the fluid–solids suspension may be approximated as a homogeneous fluid and the corresponding velocity difference, δu, as well as the average shear stress, τ, may be measured experimentally. Hence, the effective viscosity of the heterogeneous mixture, μ_e, at the point (x, y, z), which is the midpoint of the segment δy, is defined according to the expression:

$$\gamma \equiv \frac{\delta u}{\delta y} \quad \text{and} \quad \mu_e = \frac{|\tau|}{|\gamma|} \left(\delta y \gg \alpha\right) \tag{18.2}$$

Because of the condition $\delta y \gg \alpha$, Equation 18.2 defines the viscosity property at all points (x, y, z) of the heterogeneous mixture, regardless of whether these points are within the fluid or the solid domains.

This definition of the effective viscosity as a transport property of heterogeneous media is implicit in all the analytical derivations of expressions for the viscosity of heterogeneous mixtures as functions of particle concentration (e.g., Einstein, 1906, 1911, Brinkman, 1952, Batchelor, 1977). In the case of nanofluids, where the size of the particles is very small, this definition is convenient to use locally because the defining length scale, δy, is very short in comparison to the length scales of the pertinent fluids. Experimental and numerical studies prove that the so defined viscosity of the heterogeneous mixtures is uniform in suspensions where the particles are uniformly distributed and is independent of the size of δy, provided that δy is greater than the equivalent of 20 particle radii. Because of this, the effective viscosity of homogeneous suspensions is widely used in engineering flow calculations. If the particles are nonuniformly distributed, for example, in a sedimentation column, the effective viscosity is also nonuniform and, in general, it is a monotonically increasing function of the particle volumetric fraction, ϕ. In nonuniform suspensions, the function $\mu_e(\phi)$ may be also used in engineering calculations to determine the flow behavior of the suspension.

Similar definitions apply to the effective thermal conductivity and the effective diffusivity of heterogeneous materials. As with the effective viscosity, the numerical value of these effective transport properties is relatively easily measured or deduced from other measurements, provided that the measuring instrument does not disturb the particle distribution (Michaelides, 2014). The effective transport properties are routinely used in scientific and engineering calculations.

18.3 Effective Viscosity

18.3.1 Analytical Results

The now famous study by Einstein (1906), with the later correction (Einstein, 1911), was the beginning of the analytical studies on the viscosity of heterogeneous suspensions. He used a molecular model that treats the particles as noninteracting spheres, performed a first-order asymptotic analysis, and, after a correction, derived (Einstein, 1911) the following expression for the effective viscosity:

$$\mu_e = \mu_f (1 + 2.5\phi) \tag{18.3}$$

Brinkman (1952) extended the analysis by Einstein by including the fluid velocity field modification due to the presence of the spheres and derived the expression:

$$\mu_e = \mu_f \frac{1}{(1-\phi)^{2.5}} \tag{18.4}$$

A couple of decades later, Batchelor (1977) extended further this analysis to include the effects of the Brownian motion and the hydrodynamic interactions of pairs of spherical particles. Batchelor's expression is

$$\mu_e = \mu_f(1 + 2.5\phi + 6.5\phi^2) \tag{18.5}$$

It is apparent that the last three expressions yield very similar results for nanofluids that typically have low concentrations, $\phi \leq 5\%$. In cases where aggregation occurs, both the effective particle size and the volumetric concentration are needed for the calculation of the effective suspension viscosity (Chen et al., 2007b).

The only approach that differs significantly from the method used by the Einstein equation is the one by Happel (1957), who accounted for the interactions of particles under creeping flow conditions. He also stipulated that the additional tangential stress due to the presence of the particles vanishes far from the particles. With these modifications to the theory, he derived a higher coefficient for the parameter ϕ:

$$\mu_e = \mu_f(1 + 5.5\phi) \tag{18.6}$$

Among the other analytical studies on fluid–solid suspensions, Krieger and Dougherty (1959), Frenkel and Acrivos (1967), and Lundgren (1972) derived expressions in terms of the maximum allowable packing, which are applicable at higher particle concentrations. The expressions by Krieger and Daugherty (1959) and Lundgren (1972) reduce to the Einstein expression at the very low concentrations that are characteristic of low particle concentration nanofluids. The expression by Frenkel and Acrivos (1967) is only applicable to dense heterogeneous mixtures.

It must be noted that all these studies pertain to spherical particles. Elongated particles, spheroids, and ellipsoids cause a significantly higher enhancement of the effective viscosity (Kuhn and Kuhn, 1945, Michaelides, 2014). For example, spheroidal particles with aspect ratio $E = 20$, which are randomly distributed in a fluid, have an effective viscosity:

$$\mu_e = \mu_f(1 + 39\phi) \tag{18.7}$$

Nanofluids are composed primarily of irregular, elongated particles or long fibers and, for this reason, the experimentally observed effective viscosity of these heterogeneous mixtures is higher than the analytical expressions that are based on the spherical particle model.

18.3.2 Experimental Data and Correlations

The addition of solid particles in a homogeneous fluid, either gas or liquid, has always an enhancing effect on the viscosity of the fluid because of the following two effects:

1. The particles move as rigid bodies with uniform velocity and disrupt locally the velocity profile of the fluid. In order to accommodate the entire fluid velocity gradient, the velocity gradients in the fluid part of the suspension become sharper. The increased strain in the interstitial fluid between the particles causes higher stress at the same overall velocity gradient and this manifests itself as a higher effective viscosity.
2. In a velocity gradient, there is an additional momentum transfer in the direction perpendicular to the gradient, which is due to the solid particles and is similar to the molecular momentum transfer that defines the viscosity at the molecular level (Michaelides, 2014). This momentum transfer always increases the effective viscosity of the suspension.

Pak and Cho (1998) conducted one of the early studies on the effective viscosity and measured the viscosity and thermal conductivity of metal oxide (TiO_2 and Al_2O_3) aqueous nanofluids. Their results show that the coefficient of the volumetric fraction (the intrinsic viscosity) is significantly higher than the Einstein value of 2.5. The experimental data of this study were cast in correlation forms by Buongiorno (2006), who derived the following expression for the alumina–water nanofluids:

$$\mu_e = \mu_f(1 + 39.11\phi + 534\phi^2) \tag{18.8}$$

The viscosity of the titania (TiO_2)–water nanofluids was correlated by the expression

$$\mu_e = \mu_f(1 + 5.45\phi + 108\phi^2) \tag{18.9}$$

Another set of experimental data that determined intrinsic viscosity values significantly higher than 2.5 is that by Wang et al. (1999), with alumina nanoparticles in water and ethylene glycol base fluids. They observed viscosity enhancements in the range 20%–30% at $\phi = 0.03$ and close to 80% at $\phi = 0.07$. They also observed that the measured viscosity values depended on the method of preparation of the nanofluids. A comparison of the data sets by Wang et al. (1999) and by Pak and Cho (1998) shows that the measured viscosity values in the latter study are significantly higher. Wang et al. (1999) attributed this discrepancy to the different methods of preparation of the nanofluids, but there is also a question as to whether or not some of the nanofluids that were used by Pak and Cho (1998) were Newtonian fluids (Michaelides, 2014). The experimental data by Wang et al. (1999) were correlated by Maiga et al. (2005) by the equation

$$\mu_e = \mu_f(1 + 7.3\phi + 123\phi^2) \tag{18.10}$$

Das et al. (2003) also measured the effective viscosity of nanofluids at several temperatures and shear rates. The following conclusions may be derived from this study:

1. The alumina–water nanofluids were Newtonian in the range $0 < \phi < 0.04$.
2. The viscosity of the nanofluids decreased with increasing temperature.
3. The viscosity of the nanofluids increased with increasing volumetric fraction, ϕ.

The magnitude of the viscosity enhancements observed by Das et al. (2003) is close to 50% at $\phi = 0.04$, which implies that their data agree with the Wang et al. (1999) study rather than the Pak and Cho (1998) study.

Another experimental study by Chen et al. (2007a,b) with TiO_2 nanoparticles in ethylene glycol determined a higher value for the coefficient of ϕ, 10.6. The correlation developed in the study is

$$\mu_e = \mu_f(1 + 10.6\phi + 112\phi^2) \tag{18.11}$$

The experiments by Chen et al. (2007a,b) extend to higher volumetric fractions, close to 10%. It is apparent from Equation 18.11 that at the high volumetric ratios, the contributions of the two powers of ϕ are comparable. However, at the volumetric fractions of 1%–2%, which are typical of nanofluids, the term in ϕ contributes significantly higher to the value of the effective viscosity than the term in ϕ^2.

The experimental study by Nguyen et al. (2007) is the only one where the first coefficient agrees with the Einstein expression:

$$\mu_e = \mu_f(1 + 2.5\phi + 150\phi^2) \tag{18.12}$$

The authors of this study observed a hysteresis in the effective viscosity experiments, which is more likely due to particle aggregation and a slightly non-Newtonian behavior of their nanofluids.

A group of authors including Nguyen et al. (2007), Tseng and Chen (2003), and Tseng and Lin (2003) followed the functional form of the viscosity correlation by Mooney (1951), who stipulated that the viscosity of concentrated suspensions is well correlated by an exponential function of the form:

$$\mu_e = A\mu_f \exp(B\phi) \tag{18.13}$$

The values of the coefficients A and B vary significantly in these four studies. For example, the coefficient pairs (A, B) derived by Nguyen et al. (2007) for a water–Al_2O_3 nanofluid are (0.904, 14.8), while coefficient pairs (A, B) derived by Tseng and Lin (2003) for water–TiO_2 nanofluids are (13.47, 35.98).

Numerical calculations show that the last set of coefficients gives very high values for the effective viscosity that may not be realistic for Newtonian suspensions (Michaelides, 2014). In general, the exponential form of the correlation function is not recommended to be used for the following reasons:

1. The form originally has been derived for concentrated suspensions (Mooney, 1951), while all nanofluids are very dilute suspensions.
2. The exponential function $e^{B\phi}$ varies sharply with ϕ. Small errors in the calculation of the volumetric fraction result in high errors of the effective viscosity value. For example, in the expression by Tseng and Lin (2003), a 0.005 error in ϕ, causes a 20% error in the effective viscosity value.
3. The polynomial form is supported by most analytical studies for dilute suspensions and nanofluids are dilute suspensions.

A glance at all the correlations and the viscosity values they generate proves that there is a significant disagreement among the several experimental studies on the functional form as well as on the actual values of the viscosity of nanoparticle suspensions, even when the nanoparticles are of the same type. While each correlation represents fairly well the data it emanates from, correlations that are based on different data sets disagree significantly. The significant disagreement of the experimental data on the viscosity of nanofluids highlights some of the difficulties in designing cooling systems that use nanofluids as coolants.

The results of the experimental investigations suggest that the effective viscosity of nanofluids depends strongly on the shape of solid particles and this is corroborated by the analytical studies. Since most nanoparticles are not spheres, the analytical expressions that were derived for spheres would not be accurate for nanofluids. Some investigators have also suggested that different correlations apply to the same nanoparticle materials that are composed of different particles sizes. Such investigations derived correlations relating the viscosity to the particle *diameter*. This complicates the issue for the determination of the effective viscosity because

1. Aggregation and break-up processes continuously change the apparent *diameter* of the particles in a nanofluid. The aggregation mechanism is associated with interparticle forces, whereas the break-up mechanism is mostly associated with fluid shearing, particle–particle, and particle–wall collisions.
2. Given the size distributions of all nanoparticles, the particle "diameter" is not unique and is very difficult to measure.
3. Most nanoparticles are not spherical for one length scale value to describe their "size" or "diameter." The "size" issue is examined in more detail in Michaelides (2013, 2014) as well as in Chapter 1 of this handbook.
4. In shearing flows, nanofluid experiences different shear rates at different positions of the fluid field. This implies different break-up forces.

18.3.3 Non-Newtonian Behavior

The defining characteristic of non-Newtonian fluids is that their viscosity is not only a function of two independent properties, for example, T and P, but also of the local value of the shear, γ. This implies that the viscosity of non-Newtonian fluids is not an equilibrium material property, but a property that is associated with the local shear. For this reason, it is called the "effective viscosity" even in single-phase non-Newtonian fluids and is denoted by a different symbol, η. In addition to being a function of two thermodynamic properties, η is also a function of the rate of shear: $\eta = \eta(T, P, \gamma)$.*

Krieger and Dougherty (1959) were the first to examine the rheology of fluid–solid suspensions, composed of micro- and nanoparticles in liquids. They analyzed several sets of experimental data and determined that the local strain is best represented by a dimensionless shear Peclet number: $Pe = \mu_f \alpha^3 \gamma / k_B T$, which is a measure of the ratio of the shear force to the Brownian force. Figure 18.2 shows a typical dependence of the effective viscosity of a nanofluid on the rate of shear, γ, at constant T and P. The data in the figure pertain to polystyrene nanoparticles with sizes in the range 108–180 nm in deionized water and were obtained by Krieger (1972).† The effective viscosity of the suspension is typically made dimensionless by the dynamic

* As with the Newtonian fluids and the dynamic viscosity μ, η is also a weak function of the pressure, P.
† At the time of these publications the terms "nanofluid" and "nanoparticles" had not yet been adopted. The experimental data and the conclusions pertain to what are now called "aqueous nanofluids."

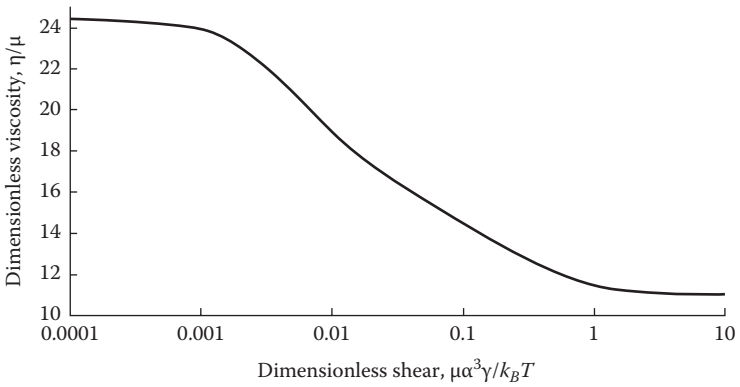

Figure 18.2

Shear dependence of the effective viscosity of a nanofluid. Qualitative behavior using data from Krieger (1972).

viscosity of the base fluid, which is usually a Newtonian fluid, η/μ_f. The following observations may be drawn from this figure about the function η:

1. Since it is known that the viscosity of the base fluid is a function of the temperature and a very weak function of the pressure, $\eta = \eta(\gamma, T)$.
2. The function $\eta(\gamma)$ has two asymptotic limits: one at the low and one at the high values of the shear, η_0 and η_∞.
3. Both asymptotic limits, η_0 and η_∞, are significantly higher than the viscosity of the base fluid, μ_f.
4. The value of the effective viscosity at high shear rates is by orders of magnitude lower than the effective viscosity at the lower shear rates.

The behavior of particulate mixtures to exhibit significantly lower effective viscosities at high shear rates has been called *shear thinning*. The local concentration and configuration of the particles within the base fluid matrix and the particle behavior and interactions during the shearing process are the main parameters that contribute to shear thinning (Russel et al., 1989, Probstein, 1994).

The formation of weak gel structures and the phenomenon of shear thinning have been observed in several experiments with nanofluids: Among these, the experimental study by Kim et al. (2011) on alumina–water nanofluids confirmed that several nanofluids composed of deionized water and alumina nanoparticles exhibit the rheological characteristics of Newtonian fluids at low volume fractions ($\phi \leq 2\%$), but showed a strong non-Newtonian behavior, including shear thinning at slightly higher volume fractions ($3\% \leq \phi \leq 5\%$). Two representative curves from the data of Kim et al. (2011) are shown in Figure 18.3, where it may be seen that the dilute nanofluid with $\phi = 1\%$ exhibits the typical behavior of a Newtonian fluid, since

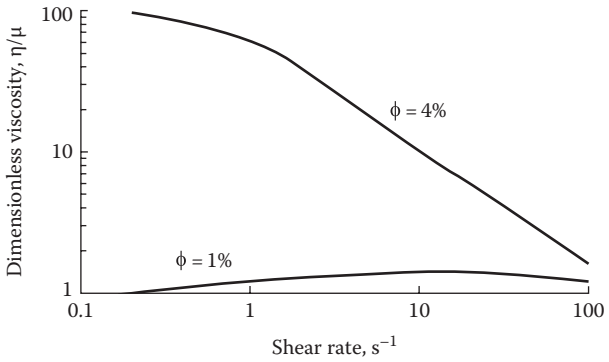

Figure 18.3

Rheological behavior of a water–alumina nanofluid at two different solids concentrations. (Data from Kim, S. et al., *J. Appl. Phys.*, 110, 034316, 2011.)

the ratio η/μ_f remains almost constant and approximately equal to 1 (within the experimental uncertainty of the data) at shear rates that span three decades. On the contrary, the nanofluid composed of the same materials with $\phi = 4\%$ exhibits strong non-Newtonian behavior: the effective viscosity, η, of this nanofluid reaches values close to 100 times higher than the base fluid viscosity, μ_f, at the lower shear rates. The same nanofluid shows very strong shear thinning behavior and its effective viscosity is reduced to approximately $4\mu_f$ at the higher rates of shear. One of the observations in the study by Kim et al. (2011) is that the particles in nanofluids within the range $3\% \leq \phi \leq 5\%$ aggregated, and the entire solutions formed gel-like structures. This explains the very high values of η at the low shear rates.

The study by Kim et al. (2011) also provides a great deal of information and insight on the method of preparation and treatment of the nanofluids that were used in the experiments. It was observed that the preparation process and time-to-settle for the nanofluid played a major role in the values of its effective viscosity. The experiments showed that the milling process of the nanoparticles and the amount of time the solution was left undisturbed had a significant effect on the observed characteristics and the rheological behavior of the nanofluids. For example, an alumina–water nanofluid with $\phi = 4\%$ was milled extensively for 5 h and when tested immediately after, it exhibited Newtonian behavior. When the same nanofluid was left undisturbed for 6 days, it exhibited strong non-Newtonian behavior with $\eta/\mu_f = 80$ at the lower shear rates of the experiments. These observations strongly suggest that, during the time the nanofluid was at rest, the alumina nanoparticles aggregated and the suspension formed a weak gel. The structure of the gel was temporarily broken by the milling process, but was restored when the mixture remained undisturbed for a prolonged time.

The formation of particulate structures and networks that conduct heat and also impede the flow in these experiments is supported by the observation that the effective viscosity of the gels increased significantly when the pH of the solution was modified sufficiently to cause an increase of the electrostatic forces between particles: for example, a change of the pH from 4 to 11 in a mixture of 5% particle concentration caused the dimensionless viscosity, η/μ_f, to increase by three orders of magnitude. Similarly, a dilute nanofluid with $\phi = 1\%$, behaved as a Newtonian fluid at the low pH range, but exhibited gel-like structure and non-Newtonian behavior with $\eta/\mu_f = 6000$ when the pH increased from 4 to 7 (Kim et al., 2011).

18.3.3.1 Viscosity of CNT Nanofluids

The experimental evidence with CNT (either single-walled or multiwalled) nanofluids proves that these suspensions are non-Newtonian, even when the volumetric ratio, ϕ, is very low. Ding et al. (2006) presented some of the early rheological data on aqueous CNT nanofluids and showed that their effective viscosity is a strong function of the rate of shear, γ, and of their volumetric ratio, ϕ. Two sets of data from this study are shown in Figure 18.4. The following observations may be drawn from this figure:

1. The rate of shear alters the viscosity of the nanofluid by five orders of magnitude.
2. The suspension reaches the high shear rate asymptotic value, η_∞, at shear rates between 1,000 and 10,000 s^{-1}.
3. The value of η_∞ is significantly higher than the viscosity of the base fluid (water).

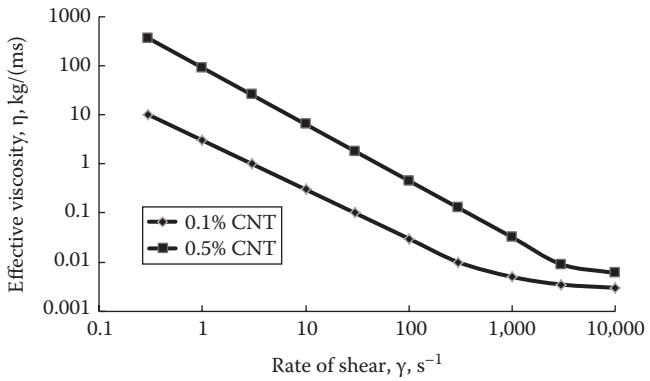

Figure 18.4

Selected aqueous CNT effective viscosity data at 25°C by Ding et al. (2006).

One of the reasons for the non-Newtonian behavior of CNT nanofluids is the addition of surfactants or dispersants, which are typically polymeric materials with long molecular chains. The chemical formula, the relative amount of the surfactants, the pH, and the treatment of the heterogeneous suspensions with ultrasound waves (sonification) influence significantly the effective viscosity of nanofluids that are formed. Yang et al. (2006) made a detailed report on the effect of surfactant concentration as well as on the time and energy of sonification for the effective viscosity of olefin-based CNT nanofluids. Their observations show that, even at the very low values of ϕ (0.12%), the CNT nanofluids exhibited distinct non-Newtonian behavior. One may easily conclude from the data of this study that the concentration of the surfactant affected significantly the effective viscosity of the suspension at the low shear rate, but not at the high shear rate: The effective viscosity of the nanofluid reached a minimum at the surfactant concentration 3% by weight, where the lowest effective viscosity was measured (Yang et al., 2006, Michaelides, 2014). Ding et al. (2006) also allude to the effect of the surfactants in their study of aqueous CNT nanofluids: in the absence of nanoparticles, the surfactant–water solution exhibited non-Newtonian behavior and its effective viscosity depended on the pH of the solution.

It must be noted that there have also been observations on the shear thickening of suspensions of nanoparticles particularly for nonspherical nanoparticles at relatively high concentrations. This is not typical to nanofluids and is therefore not discussed further in this chapter.

18.4 Effective Thermal conductivity

Early experimental work on CNT nanofluids (Choi et al., 2001) reported that the addition of a small fraction of CNTs in engine oil increased the thermal conductivity of the base fluid by a factor of 2–3. Such conductivity enhancements represent significant increases of the convective heat transfer coefficients. Because of this, nanofluids hold the promise to become the heat transfer media of the future. The magnitude of thermal conductivity enhancement was initially characterized as "anomalous" and sparked immense scientific interest during the first decade of the twenty-first century. Several laboratories throughout the globe experimented with different types of base fluids and nanoparticles. Among the most common base fluids that were investigated are water, engine oil and other oils, and ethylene glycol. Among the nanoparticles that were investigated are aluminum oxide (Al_2O_3), copper oxides (both CuO and Cu_2O), single-walled and multiwalled CNTs, copper (Cu), and gold (Au).

18.4.1 Experimental Studies

The more recent experiments show rather convincingly that several other types of nanofluids enhance only moderately the thermal conductivity of the base fluid. Typical enhancements with oxide nanofluids are in the range 5%–50% (Kakaç and Pramuanjaroenkij, 2009, Michaelides, 2013). However, a few studies, conducted typically with metallic and CNT nanoparticles, reported thermal conductivity enhancements close to 100% or above (Chopkar et al., 2006, 2008). The highest increases of thermal conductivity have been observed with suspensions of CNTs—both single-walled and multiwalled—and with metallic nanoparticle suspensions. The lowest enhancements were observed with oxides of nanoparticles, such as TiO_2 and Al_2O_3.

From the several experimental studies, it is apparent that the most important parameters of the conductivity enhancement phenomenon in nanofluids are

1. The type and properties of the nanoparticles
2. The nominal *size* of the nanoparticles
3. The type of the base fluid
4. The volumetric fraction of the nanoparticles
5. The pH and the type of surfactants used to stabilize the nanofluid and prevent aggregation

The thermal conductivity enhancement of the same nanofluid system (same base fluid and particles) is not consistent among all the data sets. This is apparent in the several sets of Al_2O_3 and Cu nanofluids, which differ significantly between different studies. Figure 18.5, which shows the relative conductivity of several CNT nanofluids (Choi et al., 2001, Biercuk et al., 2002, Xie et al., 2003, Liu et al., 2005, Ding et al., 2006), also demonstrates this point. From the discrepancy among different data sets, one may conclude that while the type and concentration of nanoparticles is a major determinant of the thermal conductivity enhancement, variables other than these two also play an important role. The identification and quantification of the effect of such variables is important in engineering studies for the design and optimization of reliable and effective heat transfer media using nanofluids.

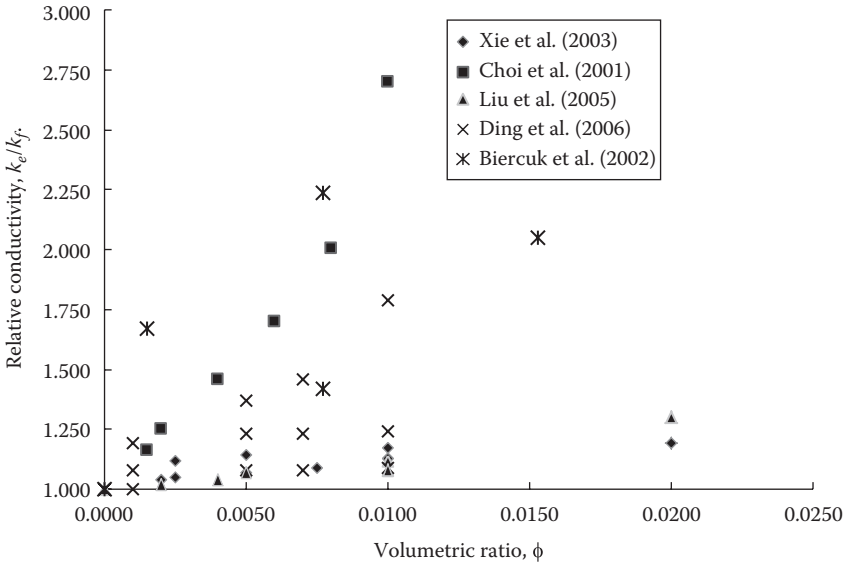

Figure 18.5

Thermal conductivity data for several CNT nanofluid sets.

18.4.2 Analytical Expressions and Correlations

In his study of electricity, Maxwell (1881) derived an expression for the effective electrical conductivity of a heterogeneous mixture with spherical particles. Because of the analogy in the thermal and electrical conduction processes, this expression is also valid for the effective thermal conductivity of heterogeneous mixtures, such as nanofluids. When written in terms of the thermal conductivities of the fluid and solid spheres, the effective thermal conductivity, or Maxwell's equation becomes

$$k_e = k_f\left[1+\frac{3\left(k_s-k_f\right)\phi}{\left(k_s+2k_f\right)-\left(k_s-k_f\right)\phi}\right] \tag{18.14}$$

where

k_f is the conductivity of the base fluid
k_e is the effective conductivity of the suspension
ϕ is the volumetric fraction of the nanoparticles

Later, Bruggeman (1935) and Hamilton and Crosser (1962) extended this expression to short cylinders and irregular particles. It must be noted that at the limit of very high solids conductivity ($k_s \gg k_f$) Equation 18.1 and the similarly obtained analytical expressions yield the following asymptotic expression:

$$k_e = k_f\left[1+\frac{3\phi}{1-\phi}\right] \tag{18.15}$$

It is apparent that the last approximate expression does not include the effect of the very high conductivity of the solid particles ($k_s \gg k_f$). Of particular interest in the study of the thermal conductivity of nanofluids, and especially nanofluids with CNTs, is the analytical study by Nan et al. (1997), who derived an expression for the conductivity of composite materials with high-aspect ratio fibers. They later derived a simplified expression, applicable to nanofluids with high-aspect ratio CNTs, at low solids concentrations ($\phi \ll 1$), which is as follows (Nan et al., 2003):

$$k_e = \frac{3k_f+\phi k_s}{3-2\phi} \approx k_f+\frac{\phi k_s}{3} \tag{18.16}$$

Because $k_s \gg k_f$, it follows that the addition of very small amounts of CNTs—materials that have thermal conductivities that could be as high as 3000 W/m K—may triple the conductivity of the suspension even at volumetric concentrations close to 1%. This largely explains the significant enhancement of the thermal conductivity of CNT nanofluids that was observed by the early researchers and proves that most of the observed thermal conductivity enhancement is not "anomalous."

Several researchers have tried to explain the observed high conductivity of nanofluids using models for the Brownian motion of particles. An analytical study (Xuan et al., 2006) used the mechanism of the stochastic movement of the particles and used the Langevin equation to describe the fluctuations of nanoparticle suspensions. Thus, Xuan et al. (2006) modeled the "heat transfer chain" between nanoparticles and base fluid and, superimposed the effects of the Brownian motion to the effective conductivity expression by Maxwell:

$$k_e = k_f\left[1+\frac{3\left(k_s-k_f\right)\phi}{\left(k_s+2k_f\right)-\left(k_s-k_f\right)\phi}\right]+\frac{9\phi h_c k_B T}{8\pi\rho_s\alpha^4} \tag{18.17}$$

where h_c is the convective heat transfer coefficient between the fluid and the particles that also includes the interfacial resistance to heat transfer. It must be noted that this is a heuristic expression, not supported by detailed analysis.

Among the other expressions, a correlation of several sets of experimental data of aqueous nanofluids resulted in the following expression (Khanafer and Vafai, 2011):

$$\frac{k_e}{k_f} = 1+1.0112\phi+2.4375\phi\frac{47}{d_s}-0.0248\phi\frac{k_s}{k_w} \tag{18.18}$$

where

d_s is the diameter (size) of the particles in nm

k_w is the thermal conductivity of water, $k_w = 0.613$ W/m K.

18.4.3 Mechanisms of Thermal Conductivity Enhancement

The plethora of experimental data on the enhanced conductivity of nanofluids also resulted in several analytical and experimental studies on the mechanisms of the enhanced conductivity. The following chief mechanisms have been suggested for the enhanced conductivity of nanofluids:

1. The significantly higher thermal conductivity of the particles
2. The shape (spheres, fibers, irregular) of the particles
3. The Brownian motion of the particles including the mass of fluid that follows the movement of the particles
4. The development of aggregates and chains that form highly conductive paths in the nanofluid or contribute to the development of such paths
5. Significant changes of the thermodynamic properties of the fluid at the solid–fluid interface and the formation of a "solid layer"
6. The electric charge on the surface of the particles
7. Transient local heat transfer effects
8. Preparation and surfactants

The effects and possible contributions of these mechanisms are summarized in the next sections.

18.4.3.1 Particle Conductivity

The thermal conductivity of the bulk materials of solid nanoparticles is typically higher than the conductivity of the base fluid by three orders of magnitude, as may be seen in Table 18.1. The table lists the thermal conductivities of several materials commonly used as base fluids and solids materials. Although the thermal conductivities of individual nanoparticles are lower than that of the bulk materials when the nanoparticle size is smaller than the mean free path of the energy carriers, the nanoparticles are still expected to have a much higher thermal conductivity than the base liquids. Because of the significantly higher conductivities

Table 18.1 Thermal Conductivities of Several Materials Common in Nanofluids

Solids	k_s (W/m K)	Liquids	k_f (W/m K)
Silver (Ag)	427	Water	0.613
Copper (Cu)	395	Ethylene glycol	0.253
Aluminum (Al)	237	Engine oil	0.145
CNTs	3200–3500	Alcohol	0.115
Brass	120	Glycerol	0.285
Nickel	91		
Quartz (single crystal)	12–7		
Alumina (Al_2O_3)	39		

of the solids, the addition of even a small fraction of particles ($\phi \sim 1\%$) to the base fluid would result in a substantial increase of the thermal conductivity of the liquid–solids mixture.

Because of this mechanism, effective conductivity enhancements have been observed in almost all experimental and analytical studies, regardless of the type, shape, and volume fraction of the particles used. A similar enhancement has also been observed in composite materials where there is no apparent flow.

The very high values of thermal conductivity of nanofluids, which were observed in the early experiments, have led a few authors to characterize the enhancement of the thermal conductivity of nanofluids as "anomalous." The experimentally observed early conductivity enhancements were in the range 100%–180% and were most commonly observed with CNT nanofluids. CNTs have very high aspect ratios (100–1000) and their thermal conductivities are of the order of 2000 times more than the conductivity of water. One of the characteristics of long spheroids and fibers is that the conduction within the heterogeneous mixture is significantly higher in the directions of their long axes and the effective conductivity is more accurately modeled by Equation 18.16. It is rather unfortunate that the results of the earlier studies with fibrous solid particles (CNTs) were compared to analytical models of spheres and short cylinders Equations 18.14 and 18.15, which yield significantly lower values for the thermal conductivity of the heterogeneous suspension. This led to the characterization of the thermal conductivity of nanofluids as "anomalous." A benchmark study led by Buongiorno (2009), which was conducted with the participation of 34 laboratories worldwide, concluded that the observed heat transfer enhancement with nanofluids is not "anomalous," and that 86% of the available experimental data are explained by one of the pertinent equations or their approximations, for example, Equations 18.14 and 18.16.

18.4.3.2 Particle Shape and Orientation

It is apparent from the analytical studies that the shape of the particles plays a significant role in the conductivity of the nanofluid. All the analytical and experimental studies indicate that the effective conductivity of heterogeneous mixtures is significantly higher with elongated rather than with spherical particles (Michaelides, 2013a, 2014). Since elongated particles, such as spheroids and fibers, have a longer dimension, where heat is conducted at a higher rate, the aspect ratio and the orientation of the elongated particles are important parameters in the calculation of the thermal conductivity of these heterogeneous mixtures.

The importance of particle orientation in relation to the direction of heat flow is easily demonstrated by the following example (Michaelides, 2013a, 2014): let us consider the heat transfer between two parallel plates with a liquid–solid heterogeneous mixture and let us assume that all the solid particles are packed together (have fused) in a single layer. The two fluid–particle configurations will yield two extreme orientation cases that correspond to the upper and lower limits of heat conduction:

1. The fused particle layer is parallel to the direction of heat transfer.
2. The fused particle layer is perpendicular to the direction of heat transfer.

The two limit cases are depicted in Figure 18.6, where the "fused" particle layer is portrayed in gray. The heat flux is in the same direction as that of the temperature difference, ΔT. The volumetric fraction of the solids is ϕ. Hence, the dimensionless thickness of the particle layer is ϕ, and that of the liquid layer $1 - \phi$.

In the first case (A) where the orientation of the particle layer is perpendicular to the temperature gradient, the induced heat flux, q, is conducted from one plate to the other and causes temperature differences

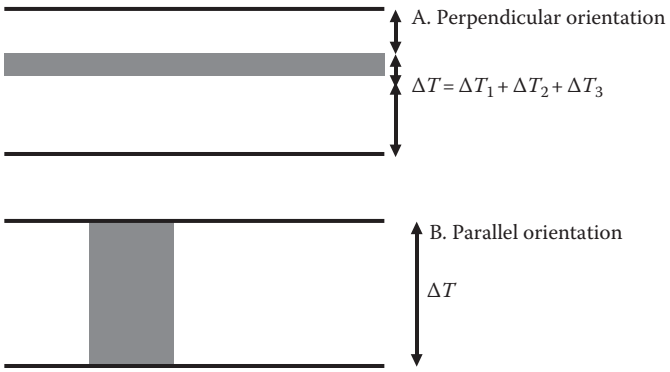

Figure 18.6

The two limiting cases of particle orientation in a liquid.

ΔT_1, ΔT_2, and ΔT_3 in the three layers between the plates, as shown in the figure. From elementary considerations of heat conduction between the two plates, we obtain the following expression for the temperature differences in the case (A):

$$\Delta T_1 + \Delta T_3 = \frac{qL(1-\phi)}{k_f} \quad \text{and} \quad \Delta T_2 = \frac{qL\phi}{k_s} \tag{18.19}$$

The sum of the three temperature differences is equal to the total temperature difference, ΔT, and, hence, we have

$$\Delta T = q\left[\frac{L(1-\phi)}{k_f} + \frac{L\phi}{k_s}\right] \tag{18.20}$$

Given that $q = k_e \Delta T$, Equation 18.20 yields the following expression for the effective conductivity of the medium between the two conducting plates:

$$\frac{1}{k_e} = \frac{1-\phi}{k_f} + \frac{\phi}{k_s} \tag{18.21}$$

Nanofluids typically have very low volumetric fractions of solids ($\phi \ll 1$) and the conductivity of the nanoparticles is much higher than the conductivity of the fluid $k_s \gg k_f$. Under these conditions, the last expression may be approximated as

$$(k_e)_{\phi \ll 1} = k_f(1+\phi) \tag{18.22}$$

In the second case (B), where the orientation of the solid particle layer is parallel to the temperature gradient, the total heat flux is equal to the sum of the heat fluxes in the two layers:

$$q = \left[k_f(1-\phi) + k_s\phi\right]\frac{\Delta T}{L} \tag{18.23}$$

This expression yields the following equivalent conductivity for the heterogeneous mixture:

$$k_e = k_f(1-\phi) + k_s\phi \tag{18.24}$$

For typical nanofluids, where $k_s \gg k_f$, and $\phi \ll 1$, the last equation may be approximated as

$$(k_e)_{\phi \ll 1} = k_f + \varphi k_s \tag{18.25}$$

It is apparent from Equations 18.22 and 18.25 that when particle layers are formed within the fluid, which are perpendicular to the direction of the heat flux, the effective conductivity of the heterogeneous medium does not increase significantly. When the particle layers are formed parallel to the temperature gradient, the effective conductivity of the medium increases linearly with the volumetric fraction and the thermal conductivity of the fibers. The study (Eapen et al., 2010) showed that most of the available experimental data for nanofluids fall within these "classical" limits.

18.4.3.3 Formation of an Interfacial Solid Layer

A few early studies on nanofluids (Keblinski et al., 2002, Yu and Choi, 2003) suggested that a "solidified" liquid layer composed of a few molecular layers of the base fluid is formed on the surface of the solid particles. With this layer, the nanoparticle becomes a composite material and consists of the nanoparticle, which has conductivity k_s, and the solidified layer, whose conductivity is approximately the same as the conductivity of the solid phase of the base fluid k_{sf}. When $k_{sf} > k_f$, the presence of the solidified layer enhances the conductivity of the entire particle. However, for this enhancement to be significant, the ratio of the conductivities of the formed "solid" to the nanoparticle conductivity, k_{sf}/k_s, must be higher than 0.02 and the relative thickness of the interfacial layer, $\delta\alpha/\alpha$, must be less than 0.05 (Michaelides, 2014). In the case of aqueous nanofluids, for which the conductivity of ice is $k_{sf} = 2.2$ W/m K, the first condition is not satisfied with most of the fluid–particle systems listed in Table 18.1. Similar considerations with other nanofluids lead to the conclusion that the formation of the solid layer alone does not explain the vast majority of the experimental observations.

The thickness of the "solid nanolayer," around 43 nm magnetic alumina nanoparticles in water, was measured by an NMR technique to be 1.4 nm (Gerardi et al., 2009). This layer of relatively immobile water molecules is equivalent to five water molecule layers formed on the surface of the nanoparticles. However, the independent measurement of the thermal conductivity of this nanofluid revealed that the formation of this interfacial layer had no effect on the measured effective conductivity of the nanofluid. Molecular dynamics (MD) simulations, which probe into the structure and the properties of interphasial molecular layers, also do not support the theory, especially in the case of the hydrophobic carbon atoms that comprise the CNTs (Din and Michaelides, 1998, Xue et al., 2004).

18.4.3.4 Electric Surface Charge and pH

It is well known that electric charges and the value of the liquid pH do not have an appreciable effect on the transport properties of pure fluids, including the base fluids used with nanofluids. Any effect of these variables on the thermal conductivity of nanofluids could only work for aqueous-based suspensions and must take place through mechanisms that act on the shape and structure of the particles, primarily clustering, aggregation, and the formation of other forms of structures that facilitate the transfer of thermal energy. An extensive experimental investigation by Lee et al. (2006) on the influence of the surface charges of the nanoparticles on the effective thermal conductivity of suspensions concluded that surface charges influence significantly the effective thermal conductivity by altering the structure of the nanofluid. Departures from electric neutrality for the nanoparticles, which appear as high zeta potential measurements, produce higher stability of the suspension overall, and better dispersion of the particles within the base fluid. All of these mechanisms have an enhancing effect on the thermal conductivity of the suspensions.

The structure of the suspension and the zeta potential effect may partly explain the disparities between some sets of experimental data, where researchers used surfactants that alter the electric surface charge of the nanoparticles and the internal structure of the suspensions (Jung and Yoo, 2009, Michaelides, 2014). Two independent studies, which examined the effect of the pH of the base fluid, found significant changes in the effective thermal conductivity of the suspensions. These were attributed to the altered shapes of the nanoparticle aggregates and modifications of the internal structure of the nanofluid (Fan and Wang, 2011, Wamkam et al., 2011).

18.4.3.5 Brownian Movement

The Brownian movement of nanoparticles in the base fluid is the primary mechanism for the "microconvection," which causes agitation in nanofluids—a mechanism that always contributes to higher heat and mass transfer in fluid systems. For this reason, several studies have been undertaken to quantify the effects of the Brownian movement on the thermal conductivity of nanofluids. Since the Brownian movement and the resulting microconvection are difficult to observe experimentally, most of the studies on this mechanism

are analytical and numerical. However, not all of the authors arrive to the same conclusions and several have disagreed significantly on the importance of the Brownian movement on the nanofluid conductivity.

At first, when examining the mechanisms of higher thermal conductivity, one must consider that the two effects of the higher particle conductivity and particle shape account for a large part of the observed higher effective conductivity of nanofluids: 86% of the experimental data in the international benchmark study (Bungiorno, 2009) are explained to within a 15% experimental error by these two effects. Therefore, the Brownian movement and other effects may explain a smaller portion of the data and may help to reduce the uncertainty of the experimental measurements.

Secondly, it is known that the Brownian movement and the associated fluid movement cause "agitation" in the fluid and that all forms of such agitation facilitate the transport of energy and mass. For example, agitation by turbulence and the turbulent motion of larger particles is a major contributor to heat and mass transfer of gas–particle systems (Pfeffer et al., 1966, Michaelides, 1986). The Brownian-induced agitation in the fluid is of lesser magnitude than turbulent agitation and is expected to have a lesser (but not vanishing) effect on the heat transfer coefficient. The benchmark study leaves open the possibility of lesser contributions by other mechanisms, and the Brownian movement is very likely the principal mechanism among them.

Thirdly, the effect of the Brownian movement of particles gives an excellent explanation for the very high dependence of the conductivity of nanofluids on temperature (Das et al., 2003, Li and Peterson, 2006). The increased Brownian movement at higher temperatures and the associated fluid microconvection is touted by most researchers as the main mechanism for the significant temperature effect. The acceptance of the Brownian movement as the primary mechanism for the high dependence of the thermal conductivity on the temperature by the vast majority of researchers is in itself an indication that the Brownian movement is a contributing mechanism to the enhanced effective thermal conductivity of nanofluids, but most likely, a mechanism of lesser importance than particle concentration, shape, and conductivity.

18.4.3.6 Transient Motion of Particles

The transient effects of particulate motion are generated by the Brownian movement and are related to the following (Maxey and Riley, 1983, Michaelides, 2006):

1. The movement of the *virtual* or *added mass* of the base fluid that accompanies the motion of the particles
2. The mass of the fluid that rushes in to replace the volume of the moving particles and the fluid volume of the added mass
3. The contribution of the history term on the heat transfer from the particles

All three effects contribute to the enhancement of the microconvection or fluid "agitation," which leads to higher heat transfer. It must be noted that the Brownian movement of the particles is caused by the motion of the fluid molecules (thermal motion), but manifests itself through the motion of the particles, which have significantly higher inertia than that of the fluid molecules and significantly higher characteristic timescales. It is most likely that the effects of the transient motion would materialize at timescales that span the range of the characteristic timescales of particles. For 10 nm copper nanoparticles in water, the characteristic timescales are approximately 2.0×10^{-10} s, while the timescales of the fluid molecules are of the order of 10^{-14} s. Hence, the Brownian movement of particles and the associated transient particle and fluid movement would not be expected to play a major role in the effective thermal conductivity of the suspension, which is associated with the molecular momentum and energy transfer at the molecular timescales. The Brownian movement and the transient effects are expected to have a more significant influence on the convective heat transfer coefficient of the suspensions, a subject that is treated in Section 18.5.

18.4.3.7 Particle Distribution and Aggregation

Single particles, clusters, and aggregates form structures and layers that may significantly enhance the conductivity of the suspension, even when the volumetric concentration of particles does not change. For example, when two or more spherical particles aggregate, the resulting composite particle is longer. All the theoretical models prove that the formation of longer particles, and especially formation of linear chains of particles, brings the effective thermal conductivity of the suspension closer to that of fibrous nanoparticles, whose contributions to the thermal conductivity of the suspension are given by Equation 18.16 rather than Equation 18.14. This happens because a fraction of the elongated particles is always oriented in the direction of the temperature gradient and, thus, creates conducting paths. Several experimental and numerical

studies on particle aggregation that have observed the formation of highly conducting "paths" or "bridges" support this mechanism of effective conductivity enhancement (Prasher et al., 2006, Timofeva et al., 2007, Philip et al., 2008, Kondaraju et al., 2010).

18.4.3.8 Preparation and Surfactants

The method of preparation of nanofluids and the specific chemicals used as surfactants influence significantly the formation of clusters and aggregates, and the particle distribution within the suspension. Every laboratory, which chemically manufactures nanoparticles, may use their own methods for the stabilization of their respective nanofluids, but the methods are typically not reported in the literature. Some of the methods are even proprietary. Mechanical methods, such as milling and shearing the nanofluid, have been used extensively to produce stable nanofluids. Electromechanical methods, such as the application of ultrasonic waves (sonification or ultrasonification), have also been used extensively to disperse the nanoparticles and prevent them from aggregating and forming a sediment. Chemical methods are routinely used with a variety of surfactants: examples are sodium laurate, sodium dodecyl benzene sulfonate, sodium dodecylsulfate, and gum Arabic acid. A review of the stability and properties of nanofluids (Ghadimi et al., 2011) provides an extensive list of surfactants and stipulates that "…choosing the right surfactant is the most important part of the [preparation] procedure." The choice of chemical surfactants is typically accomplished by a trial and error method.

Oftentimes, the amount or concentration of the surfactants is close or even higher than the concentration of the nanoparticles. This implies that the surfactant must be considered as a component that affects the thermodynamic and transport properties of the mixture. When the actual concentration of the surfactants in the heterogeneous mixture is not high enough to have its own influence, the effect of the surfactants and the method of preparation of nanofluids on the effective conductivity is realized via the size and shape mechanism as in Section 3.3.2.

It must also be noted that surfactants and dispersants often have a lower thermal conductivity than the base liquid. The use of these additives is expected to reduce the effective thermal conductivity of the nanofluid suspension.

18.4.3.9 Other Mechanisms

From the large number of experimental investigations, it follows that a few other mechanisms and parameters have an influence on the transport properties of nanofluids. Among these are

1. Magnetic fields and magnetic nanoparticles, which most likely work via the particle aggregation/distribution mechanism (Philip et al., 2008, Younes et al., 2012)
2. The amount of fluid "trapped" within the volume defined by the boundary of irregular particles (Cherkasova and Shan, 2010, Fantoni et al., 2010)
3. Velocity discontinuity (slip) and thermal discontinuity at the fluid–particle interface (Feng et al., 2012, Feng and Michaelides, 2012)

A purely statistical study (Sergis and Hardalupas, 2011) surveyed the results of 141 nanofluid experimental studies and performed a statistical analysis on the heat transfer enhancement mechanisms. Among the observations of this statistical study are

1. The Brownian movement of the particles—by itself or in combination with other mechanisms—is reported as a significant mechanism for the heat transfer enhancement by approximately 70% of the researchers.
2. Thirty-three percent of the research studies stated that the Brownian motion is the only mechanism for the observed enhancement.
3. The four leading mechanisms or combination of mechanisms promulgated by the researchers were
   - Brownian motion (solely), 33%
   - Interfacial layer formation, 22%
   - Brownian motion with diffusion and aggregation, 11%
   - Brownian motion with thermophoresis, 9%*

* It must be noted, however, that the actual cause of thermophoresis is the Brownian movement of particles in a temperature gradient. Thermophoresis and Brownian movement are not independent phenomena.

18.5 Additional Augmentation of the Convective Heat Transfer Coefficients

Nanofluids as heat transfer media are to be used in channels of all sizes to remove heat by convection from a hotter surface (e.g., from an electronic component). The primary parameter of interest in convection heat transfer applications is the convective heat transfer coefficient, h_c, which is typically given by a closure equation in terms of the Nusselt number:

$$\dot{Q} = h_c A \Delta T \quad \text{with } h_c = Nu \frac{k_e}{L_{ch}} \tag{18.26}$$

where L_{ch} is the characteristic dimension of the heat transfer system. The Nusselt number is typically a function of the Reynolds and Prandl numbers [$Nu = f(Re, Pr)$] and is given by an empirical equation. It is apparent from Equation 18.26 that if the thermal conductivity of a heat transfer medium increases, the convective coefficient increases proportionately.

Several experiments that measured independently the thermal conductivity and the convective coefficients of nanofluids in laminar flows concluded convincingly that the increase of the convective heat transfer coefficient is significantly higher than the simple relationship of Equation 18.26 (Li and Xuan, 2002, Wen and Ding, 2004). These experiments concluded that there is an augmentation* of the convective coefficient, h_c, in addition to the heat transfer enhancement that follows the increased effective thermal conductivity of the nanofluid. Most experimental studies indicate that the additional augmentation increases with the volumetric fraction, ϕ, but the relationship is not linear.

Figure 18.7 shows representative data (Li and Xuan, 2002, Wen and Ding, 2004, Ding et al., 2006, Hojjat et al., 2010) of the convective heat transfer augmentation as the ratio of Nu_{obs}/Nu_e and Re for nanofluids composed of Al_2O_3 nanoparticles in water. Nu_{obs} is the experimentally measured Nusselt number and Nu_e is the Nusselt numbers calculated analytically using the effective conductivity of the nanofluid ($Nu = h_c L_{ch}/k_e$) and the pertinent Reynolds and Prandl numbers. It is observed in this figure that, even though the trend of the ratio Nu_{obs}/Nu_e versus Re is not very clear, the data consistently demonstrate that this ratio is greater than 1, sometimes by as much as 60%. This general observation implies that other than the increased conductivity of the nanofluids, there is an additional increase of h_c, which augments the convective heat transfer and needs to be accounted for in design calculations.

The vast majority of the experimental studies on the convective heat transfer coefficient for laminar flows show that there is such an additional heat transfer augmentation. On the contrary, the

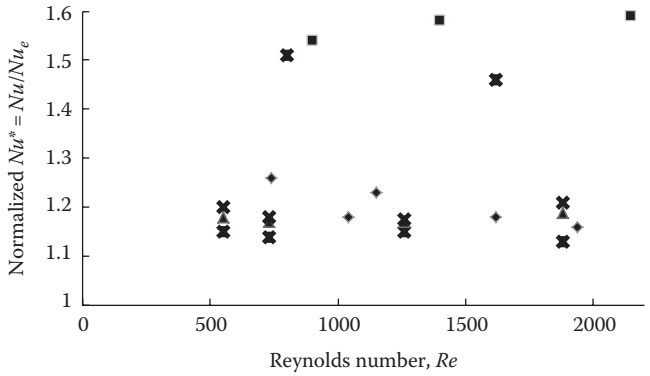

Figure 18.7

Normalized Nusselt numbers for several types of nanofluids. (Data from Li, Q. and Xuan, Y., *Chin. Technol. Sci. Ser. E*, 45, 408, 2002; Wen, D. and Ding, Y., *Int. J. Heat Mass Transfer*, 47, 5181, 2004; Ding, Y. et al., *Int. J. Heat Mass Transfer*, 49, 240, 2006; Hojjat, M. et al., *Korean J. Chem. Eng.*, 27, 1391, 2010.)

* In order to differentiate the two phenomena, the term "augmentation" is used for the observed increase of the heat transfer coefficient and the term "enhancement" for the increase of the thermal conductivity.

experimental evidence with turbulent flow measurements is not clear: a few experimental studies observed some measure of an augmentation in the range 10%–20% (Xuan and Li, 2003, Torri and Young, 2009), while most of the other studies did not observe any augmentation, within the limits of the experimental uncertainty, and concluded that the ratio Nu_{obs}/Nu_e is approximately equal to 1 (Williams et al., 2008, Prabhat et al., 2012).

The most likely explanation for the observed augmentation of the convective heat transfer coefficient, above and beyond the values calculated by the enhanced thermal conductivity of the nanofluid, is the fluid microconvection, which is induced by the Brownian movement of the particles. The microconvection includes the transient effects of the fluid movement due to the added mass and history of the particles (Michaelides, 2006, 2013b), as well as the movement of the masses of fluid that rush in to fill the void left by the particles in their original positions and rush out to allow the particles to move in their final positions (Michaelides, 2013b, 2014). The apparent absence of such augmentation in the turbulent heat transfer regime corroborates this mechanism: the magnitude of turbulent velocity fluctuations and the "agitation" of the fluid caused by turbulence are by far higher than that of the Brownianly induced microconvection process. Therefore, in turbulent flows, the contribution of the microconvection to the value of the convective heat transfer coefficient would be negligible and almost vanishing. On the contrary, any systematic lateral velocity fluctuations in laminar flows contribute significantly to the overall laminar heat transfer coefficient.

18.6 Natural Convection

The addition of nanoparticles in a base fluid has the following effects on the process of natural (free) convection (Michaelides, 2014). Some of the effects promote and some inhibit the flow instabilities that generate and maintain the natural convection process:

1. Increase of the effective fluid viscosity (inhibiting).
2. Local instability damping on the solid surface of the particles (inhibiting).
3. Interactions with the heating surface. Depending on the nature of particles and the interactions, this may have either a promoting or an inhibiting effect.
4. Particle sedimentation. This induces long-range fluid currents and promotes instabilities (promoting).
5. Increase of the effective fluid conductivity (promoting).
6. Chemically active nanoparticles, which are sources or sinks of energy, may cause local thermal and flow instabilities around the particles (promoting).

It appears from these observations that there is not a clear and simple mechanism for the enhancement or reduction of the overall heat transfer coefficients in a natural convection process when nanoparticles are added to the base fluid. This is reflected in the sets of experimental data, which are divided in the overall effect: Some of the experimental data show enhancement and others reduction of the natural convection and the Nusselt numbers associated with it. The picture of the natural convection studies with nanofluids is not clear: on one hand, almost all of the analytical studies (e.g., Shukla and Dhir, 2008, Tsou, 2008) and a few experimental studies (e.g., Okada and Suzuki, 1997) advocate that there is an enhancement of the natural convection heat transfer coefficients, when nanoparticles are added to the base fluid. On the other hand, several experimental studies (e.g., Putra et al., 2003, Wen and Ding, 2005) show that there is a clear and systematic reduction of the natural heat transfer coefficients. More accurate and better documented experiments, where the size and distribution of the nanoparticles are also measured, are needed to improve our understanding of the effect of nanoparticle addition on the natural convection process with nanofluids.

It must be emphasized that a possible earlier onset of natural convection with nanofluids may cause a significant error with the popular (and otherwise accurate in homogeneous systems) method of thermal conductivity measurement using a transient hot wire (THW) instrument. One of the fundamental assumptions of the operation of the THW instrument is that conduction only occurs during the time of the measurements and that the onset of natural convection does not takes place during the effective thermal conductivity measurement. An onset of natural convection earlier than that of the base fluid in a THW instrument results in significantly higher and erroneous value of the "measured" thermal conductivity with nanofluids (Michaelides, 2014).

18.7 Boiling with Nanofluids

18.7.1 Pool Boiling

The addition of nanoparticles in base fluids, which are used for boiling applications, has the following promoting and inhibiting effects (Michaelides, 2014):

1. Nanoparticles provide additional nucleation sites.
2. Nanoparticles—especially at higher concentrations—may deposit, cover, and deactivate a fraction of the nucleation sites on the heated surface.
3. Nanoparticles, left behind during evaporation, deposit on the heating surface and change the characteristics of the surface.
4. The surfactants added for the stability of nanoparticles in suspensions also modify the surface tension of the base fluid. This affects the bubble formation and lift-off.
5. Nanoparticles enhance the microlayer evaporation on the heated surfaces.
6. Nanoparticles alter, sometimes significantly, the thermal and transport properties of the base fluid.

Most of the experimental data on nanofluid nucleate boiling indicate that the presence of nanoparticles decreases the pool boiling heat transfer coefficient of base fluids. Typical pool boiling experimental results with the addition of metal oxide nanoparticles are shown in Figure 18.8. The Nukiyama curve (Nukiyama, 1934), which characterizes the boiling of a homogeneous fluid, is also shown in the figure.

Most of the experimental studies with nanofluids indicate that the addition of metal oxide nanoparticles in a base fluid causes a reduction of the pool boiling heat transfer coefficient (Das et al., 2003, Bang and Chang, 2005, Kim et al., 2007). On the other hand, most of the experimental studies with metallic and CNT nanoparticles indicate an increase of the pool boiling heat transfer coefficient (Witharana, 2003, Park and Jung, 2007). While a more detailed study on the pool boiling coefficients may be needed, a tentative conclusion on the subject, based on the published studies, is that the addition of oxide nanoparticles decreases the pool boiling heat transfer coefficient, while addition of metallic and CNT nanoparticles enhances the pool boiling heat transfer coefficient.

18.7.2 Convective Boiling

Convective or forced boiling occurs in channels, where the nanofluid is forced to flow, usually by a pump. The main differences between pool boiling and convective boiling are

1. The vapor is advected downstream and does not stay close to the nucleation site to be detached slowly by buoyancy.
2. Because the volume and cross-sectional area of the channel are restricted, the liquid and vapor phases arrange themselves in one of the flow regimes that characterize the vapor–liquid (or gas-liquid) two-phase flow.
3. There is frictional pressure drop along the channel that affects the saturation temperature. In most applications though, the pressure drop is very low and has a minimal effect on the heat transfer in the channel.

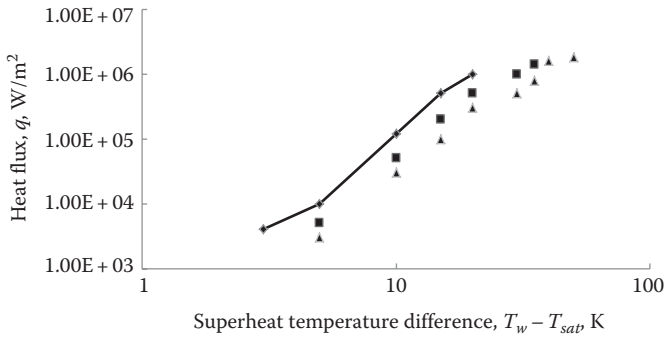

Figure 18.8

Typical experimental data of pool boiling with nanofluids: The pool boiling heat transfer coefficient is the ratio $q/(T_w - T_{sat})$ and is lower than that obtained from the Nukiyama curve. The CHF is enhanced significantly.

The formation of the known vapor–liquid flow regimes—annular, churn, bubbly, etc.—(Bergles et al., 1981) in convective boiling determines the flow and thermal conditions at the boundaries of the channel and, hence, the friction factor and the convective heat transfer coefficient. The mass and volume of the vapor phase increase along the flow direction because of the heat influx, evaporation, and (by a small amount) pressure reduction. There is not a general expression with a high accuracy that is applicable to this type of boiling, but a working and fairly accurate suggestion (Whaley, 1987) is that the heat flux for convective boiling is equal to the sum of the single-phase boiling and the pool boiling heat flux for the liquid:

$$q_{CB} = q_{NB} + q_l \tag{18.27}$$

For most fluids, $q_{NB} \gg q_l$, and, hence, the approximation $q_{NB} \approx q_{CB}$ is often used.

A recent study that was conducted for nanofluids (Chehade at al., 2013) presents several of the more recently developed correlations for the heat transfer coefficients on the convective boiling of liquids in channels. One may conspicuously observe in the data in this study the very high disagreement among the available correlations for liquid flow alone: The uncertainty associated with the experimental correlations for the base fluids is more than 50%. Under the light of this observation, it is reasonable to conclude that the uncertainty for nanofluids would be even higher.

Unlike pool boiling, the preponderance of experimental evidence on the heat transfer coefficients for convective heat transfer points to the enhancement of the convective heat transfer coefficient with the addition of nanoparticles. Of the several experimental studies that were consulted, none observed a reduction of the convective boiling heat transfer coefficient without a clear explanation for the reasons of reduction (Michaelides, 2014). Most of the experimental studies indicate a significant enhancement, or at least no deterioration of the convective boiling heat transfer coefficient (Peng et al., 2009, Rana et al., 2013). A few experimental studies observed significant enhancements of more than 50% (Boudouh et al., 2010). The following mechanisms are responsible for the enhancement of the convective boiling heat transfer coefficients:

1. Channel boundary modification with increased number of nucleation sites.
2. Increase of bubble–surface contact angles
3. Inhibition of the formation of long-lasting dry vapor patches by higher concentrations of deposited particles at the bubble–surface interface
4. Increased frequency of bubble departure from the nucleation sites
5. Formation of larger bubbles

Because of the very high boiling heat transfer coefficients, nanofluids have been touted as the heat transfer media with convective boiling in microchannels. A cause of concern with this application is the long-term reliability of such cooling systems: as the base fluid evaporates, nanoparticles deposit close to the exit of the channel and cause channel blocking, something that has been observed in one of the failed experiments in this area (Faulkner et al., 2003). One may guard against partial or total blocking of the cooling channels by restricting the fraction of base fluid that evaporates.

Since one of the important nanofluid applications is the cooling of miniature electronic components, well-coordinated experiments are needed in the future that will determine under what conditions (types of nanoparticles, base fluid, volumetric fraction, flow conditions, shape of channels, etc.), there is significant enhancement, and what are the optimum conditions for the consistent and reliable removal of heat by nanofluid boiling in micro-channels.

18.7.3 Critical Heat Flux (CHF)

The onset of CHF occurs with the formation and lateral expansion of dry vapor patches on the heated surfaces, including heated microchannels. The process of vapor expansion spreads the vapor patches sideways, joins two or more vapor patches, and creates thin vapor layers over large parts of the heating surface. Because particles do not evaporate with the fluid, they are trapped inside the liquid layer at the heated

surface, a process that creates higher particle concentrations adjacent to the dry patches. The increased concentration of particles has three effects on the vapor phase:

1. Restricts the sideways expansion of the vapor patch, by forming a solid residue that obstructs the spreading of vapor.
2. Maintains, through the interfacial surface tension, thin interstitial liquid layers between the individual particles and between particles and the heating surface.
3. The presence of particles close to the heated surface disturbs the shape of the meniscus at the vapor–liquid interface, thus creating a "structural disjoining pressure," which increases the wettability and inhibits the spreading of the dry patches (Wen, 2008).

All three mechanisms are averse to the spreading of vapor pockets and bubbles. Therefore, one would expect *a priori* that the addition of any small particle, including nanoparticles, to a base fluid would enhance the CHF by modifying the structure of the heated surface and the particle concentration close to this surface. This is corroborated by all the experimental studies on CHF with nanofluids.

All the experimental data of CHF indicate that the addition of nanoparticles—to both pool boiling and convective boiling—increases the CHF of base fluids, sometimes by a factor of 2 or 3 (Milanova and Kumar, 2008, Park et al., 2009). This trend is also illustrated in Figure 18.8, where the CHF increases from approximately 1,000,000 W/m^2 to 1,800,000 W/m^2 (this is not entirely obvious due to the logarithmic scale of the diagram). Significant increases in the CHF have been observed even when the volumetric ratio of the solids is very low, for example, in the range $10^{-6} < \phi < 10^{-5}$. The significant CHF enhancements were observed with all types of nanoparticles (metallic, metal oxides, CNTs, etc.) and with several types of heating surfaces (plates of copper, aluminum, stainless steel; wires of copper, steel, Ni–Cr alloy). General observations from the several experimental studies on CHF are (Michaelides, 2014)

1. CNT nanoparticles cause the highest CHF enhancement, followed by metal nanofluids and oxide nanofluids.
2. CHF enhancement in convective boiling is lower than that of pool boiling.
3. The vapor bubbles departing from the heating surface were significantly larger in the nanofluid experiments than in the pure base fluid experiments. This implies that the nanoparticles or, most likely, the surfactants used for their stabilization modified significantly the surface tension of the water.
4. The heating surfaces were modified by the deposition of a layer of particles, which sometimes formed a thin, solid porous layer.

Surface heat fluxes achieved with boiling fluids (typically of the order of 10^6 W/m^2) are significantly higher than heat fluxes with single-phase fluids. For this reason, boiling heat transfer media, and in particular boiling nanofluids, are touted as the cooling media that may achieve surface fluxes close to 10^7 W/m^2, to be used with the next generations of microelectronic devices (Faulkner et al., 2003). An important consideration in this application is that the surface temperature be kept under 130°C at all times including fast transient processes. The high CHF of nanofluids provides a significant safety margin, which may ensure that the temperature of the heated surface does not exceed the design value.

A glance at Figure 18.8 illustrates this advantage of nanofluids and corroborates the promise of nanofluids as potentially reliable heat transfer media in electronic devices: the base fluid boiling curve (solid line) shows a CHF of 1,000,000 W/m^2 with superheat 20°C. The experimental data (diamonds) extend to a CHF of 1,800,000 W/m^2 with higher superheat, close to 50°C. The difference in the superheat (30°C) is not prohibitively high for a thermal system with higher reliability. One may actually design a cooling system using this nanofluid to operate at a heat flux of 1,400,000 W/m^2 with a superheat 40°C. Such a system would have an adequate safety margin (400,000 W/m^2) before the CHF is exceeded and the electronic components fail.

18.8 Effective Diffusivity

Diffusion is the movement of mass at the molecular level and involves the transfer of a species within a fluid (gas or liquid) and a solid. For nanofluids, let us consider the diffusion of a species, *A*, in a nanofluid composed of a base fluid, *F*, and a single type of nanoparticles, for example, the diffusion of oxygen in an

alumina–water nanofluid. From the beginning, it is recognized that the diffusion process of the species A is much faster in the fluid domain than in the solid. The diffusion process within the solids is very slow and, without any loss of accuracy, the flux of the species A into the solid matrix may be assumed to vanish. This implies that the diffusivity of species A into the solid, D_{AS}, vanishes, while the diffusivity of the species A into the base fluid, D_{AF}, is finite. As with the other transport properties, we introduce an operational definition of the effective diffusivity of the mixture that applies not at a specific point of the nanofluid but at a domain, which is much larger than the characteristic dimension of the nanoparticles:

$$D_{ANe} = \frac{|J_A|}{\left|\frac{\delta n_A}{\delta x}\right|} \left(\delta x \gg \alpha\right) \tag{18.28}$$

where

J_A is the mass flux

n_A is the concentration of the species A

The value obtained from this mathematical operation is the effective diffusivity of species A in the nanofluid, D_{ANe}, defined at the midpoint of the segment δx. Experimental and numerical studies prove that the diffusivity of the heterogeneous mixtures is uniform in nanofluids where the particles are uniformly distributed and is independent of the size of the segment, δx, provided that the latter is greater than the equivalent of 20 nanoparticle radii. If the particles are nonuniformly distributed in the suspension, the effective diffusivity is also nonuniform and, in general, it is a monotonic function of the particle concentration, ϕ.

It must be noted that of interest in the mass transfer applications is the mass transfer coefficient of the nanofluid, h_{AN}, which is defined in terms of the mass transfer equation:

$$\dot{m} = h_{AN} A_c \left(\Delta c\right) \tag{18.29}$$

where

Δc is the difference of the concentration of the species A at the two ends of the instrument

A_c is the cross-sectional area through which the mass is transferred

The mass transfer coefficient is calculated in general through the Sherwood number:

$$Sh = \frac{2\alpha h_{AN}}{D_{ANe}} \tag{18.30}$$

The latter is obtained from empirical correlations, which have been typically obtained from heat transfer experiments using the analogy of heat and mass transfer (Michaelides, 2014).

18.8.1 Analytical Results

The solid particles with vanishing diffusivity are impediments to the diffusion of mass in solid–fluid mixtures. For this reason, it is expected that the effective diffusivity of nanofluids would be lower than the diffusivity of the base fluid. This is corroborated by all the analytical studies on the subject: Joensson et al. (1986) conducted an analysis for the self-diffusion of small molecules in colloidal systems and derived the following expression, for the ratio of the effective diffusivity of the suspension to the diffusivity of the base fluid:

$$\frac{D_{ANe}}{D_{Af}} = \frac{1}{1+0.5\phi} \tag{18.31}$$

Cussler (2009) conducted a more detailed analysis and derived the expression:

$$\frac{D_{ANe}}{D_{Af}} = \frac{1-\phi}{1+0.5\phi} \tag{18.32}$$

The two expressions are expected to be applicable to nanofluids. For nanoparticles, where $\phi \ll 1$, the results from the last two expressions are virtually identical. The same may be said for the expression derived by von Meerwal et al. (1990), who used a model based on the formation of a solid interfacial layer. It is apparent from all the analytical studies that the effective diffusivity of nanofluids—where typically $\phi < 0.05$—is slightly lower than the diffusivity of the base fluid.

18.8.2 Experimental Methods and Results

Several experimental studies on the effective diffusivity of nanofluids produced results markedly different than the analytical solutions: Olle et al. (2006) used a liquid chemical reactor with a small beaker to measure the mass transfer rates of oxygen in aqueous ferric (Fe_3O_4) nanofluids. They observed that the mass transfer coefficients of oxygen, h_{ON}, increased significantly when nanoparticles were added to the water. The mass transfer coefficient, h_{ON}, in these experiments increased up to 60% with the addition of nanoparticles at $\phi = 0.04$. Olle et al. (2006) also used a chemical method for the determination of the mass transfer coefficients, during which the oxygen in the beaker was constantly depleted by a reducing reactant. In the oxygen depletion experiments, they observed h_{ON} enhancements of up to 600%. They also observed that there were diminishing returns with the increase of the volumetric fraction of nanoparticles; that is, the function h_{ON} increases monotonically with ϕ, but the slope of the function progressively decreases.

The data by Krisnamurthy et al. (2006) showed a more dramatic increase of the mass transport coefficient of nanofluids. They used an optical method to observe the diffusion of a fluorescent dye in deionized water with Al_2O_3 nanoparticles, up to volumetric fractions of $\phi = 0.01$. Their results show significant increases of the diffusion coefficients, up to 14 times (1400%) at $\phi = 0.005$.

However, one of the first experimental studies on the mass diffusion with nanoparticles by Wen et al. (2005), which was conducted with an internal loop airlift reactor, reported that the mass transfer coefficient of gases was reduced when TiO_2 nanoparticles were added to the base fluid.

Another study by Kang et al. (2008) used a liquid film absorption process and two aqueous nanofluids with iron (Fe) and CNTs. They observed mass transfer coefficient enhancements in the range 50%–150%. Their results indicate that the CNT nanofluids exhibited significantly higher mass transfer enhancements than the Fe nanofluids.

An increase of the effective diffusivity with the addition of Cu nanoparticles is also indicated by the data obtained in the study by Li et al. (2006). The study was conducted with a refrigerant and Cu nanoparticles. One of the conclusions of this study is that the time of formation of the hydrofluorocarbon-134a hydrates, which is important in energy storage systems, decreased significantly and monotonically with the addition of small amounts of Cu nanoparticles.

Ozturk et al. (2010) conducted an experiment with a fluorescent dye in a microfluidic device that allows two nanofluid streams to flow in parallel. Their observations showed that there was *complexation*—formation of composite particles—of the dye molecules and the nanoparticles along the interface of the two streams and this affected significantly the experimental data. The complexation effect of the Ozturk et al. (2010) study is the same as the *grazing effect* that was observed in slurry flows and was documented by Kars et al. (1979). In the latter study, fine slurry particles adsorbed preferentially a gas solute from a gaseous stream and rapidly transferred it to the suspension, thus showing a very high mass transfer coefficient for the slurry. The grazing effect and the study by Ozturk et al. (2010) for nanofluids raise an important question on the use of optical methods with dyes for the determination of mass transfer coefficients and nanofluid diffusivity: The introduction of a dye in the nanofluid introduces a different type of molecules in the experiment that may not be inert with respect to the species whose diffusion/transfer is to be measured. The dye molecules may react with one or more of the species in the experimental setup, thus giving diffusion results for nanoparticles that are different from those, for which the experiment was designed. In such experiments, the instrument (dye) affects the measurement and this means that the experimental data must be interpreted under a different light.

However, the study by Veilleux and Coulombe (2010), who carefully minimized all dye–nanoparticles interactions, observed a 10 times larger dye diffusion in Al_2O_3 nanofluids than in the base fluid. It is unlikely that complexation has played a role in the last experiments. All the data of this study imply that the addition of the nanoparticles enhances significantly the diffusivity of the nanofluid. A similar study of nanofluids in a refrigerant base fluid by Kim et al. (2006) observed that the addition of very small amounts ($\phi < 0.001\%$) of Cu, CuO, or Al_2O_3 nanoparticles in binary water–ammonia and water–2-ethyl-1-hexanol mixtures increased the mass transfer coefficients of bubble columns by as much as 530%.

In two separate studies by Komati and Suresh (2008, 2009), several types of liquid reactors were used, including a capillary reactor, to measure the mass transfer of CO_2 and O_2 in a variety of reacting and non-reacting liquids laden with magnetic ferrous oxide (Fe_3O_4) nanoparticles. The two studies consistently reported mass transfer enhancements between 200% and 300%. By carefully controlling their experimental setup, they ruled out any complexation or catalytic effects due to the nanoparticles in their experiments. The authors promulgated the hypothesis that a "zone of convective disturbance" (microconvection) is the most likely cause of the observed enhanced mass transfer coefficients.

The study by Turanov and Tolmachev (2009) was conducted with an NMR instrument and measured the self-diffusion coefficient (SDC) of water in colloidal silica (SiO_2) nanofluids. The experiments indicated that the SDC of water actually decreased with the addition of the SiO_2 nanoparticles. The decrease was more than 30% at $\phi = 0.225\%$, a value that is significantly higher than the values predicted by the effective medium theory. Turanov and Tolmachev (2009) attributed the low diffusivities on the formation of solid-like interfacial layers around the nanoparticles.

Another study that did not observe significant changes in the diffusivity of nanofluids is that by Subba-Rao et al. (2011). They used a fluorescence correlation spectroscopy (FCS) method that transforms the signal from the fluorescence process and measures only the random movement of the diffusing species. Nanoparticle–dye interactions and complexation were excluded by the appropriate processing of the data. By this method, they measured the diffusion coefficients, not the mass transfer coefficients. The results of the study show that the diffusion coefficients of both SiO_2 and Al_2O_3 nanofluids do not vary appreciably from the diffusion coefficients of the pure base fluid, up to volumetric fractions close to 2%. The observed slight decrease of the diffusion coefficients in these data agrees with the heterogeneous suspension diffusion models of Equations 18.31 and 18.32, within the range of the experimental uncertainty of the data.

A more recent experimental study where significant mass transfer enhancement was observed is that by Manikandan et al. (2012). They used a stirred-tank cylindrical reactor with oxygen sparged in the tank (sparging is the bubbling of a gas in a liquid or a suspension). Their nanofluids were aquatic suspensions of ferrous oxide, Fe_2O_3. Manikandan et al. (2012) observed mass transfer coefficient enhancements up to 63%, even though the maximum volumetric fraction of the nanoparticles was very low, less than 0.0065%.

An interesting effect of technological importance is the dependence of the diffusivity on the viscosity. The effect was first studied by Perez and Sandall (1974) with colloidal particles: Higher viscosity impedes the diffusion and advection of any species within a fluid and causes lower molecular diffusivities in nanofluids as well as lower mass transfer coefficients. For non-Newtonian nanofluids at low shear rates, whose viscosity may become extremely high, this is a characteristic that impedes significantly the mass transfer of any species within the nanofluid. Park et al. (2006) studied the mass transfer of CO_2 in aqueous SiO_2 nanofluids that exhibited non-Newtonian behavior. Their results show that there was a clear decrease of the mass transfer coefficient, h_{AN}, and this was attributed to the higher viscosity of the nanofluid. The mass transfer coefficient in these experiments improved significantly with the addition of 2% 2-amino-2-methyl-1-propanol (AMP). This compound is a surfactant, which is known to reduce the viscosity of the nanofluid.

The results of the last set of experiments raise the possibility of modifying the mass transfer coefficient and viscosity of nanofluids at will, by increasing or reducing the concentration of the surfactants. This will have significant technological implications in the administration of pharmaceuticals in the blood stream as well as in medical testing processes.

18.8.3 Observations and Conclusion on the Effective Diffusivity

It is apparent that there is a great deal of disagreement resulting from the experimental data on the diffusivity and the transfer of mass: while some studies have observed enhancements by factors as high as 16, other experimental studies indicate no enhancement, and some even indicate a small reduction. It is also apparent that some experiments measured the molecular diffusivity of the species, while others measured the mass transfer coefficients and from these deduced the effective diffusivity. It is rather unfortunate that very few studies make a distinction between the two.

A careful examination of the experimental results reveals that almost all the studies, which have observed significant enhancement, used a liquid reactor or simple optical methods, where the nanofluid flows freely and there is ample evidence of advection (Michaelides, 2014). These studies actually measured the convective mass transfer coefficient, h_{AN}. Most of the studies that concluded there is no enhancement, and actually determined the diffusivity of a species within the nanofluid, D_{AN}, or the self-diffusion coefficient. These studies used techniques such as NMR or permeable membranes, where

advection is restricted, or sophisticated versions of the optical methods such as the FCS, which eliminate the advection effects by the processing of the signal.

A careful examination of the experimental data indicates that the molecular diffusivity of the species remains almost constant and may actually decrease when nanoparticles are added to the base fluid. This is most likely due to obstruction by the particles and the higher viscosity. The data also show that the mass transfer coefficients, which account for both the diffusion and the advection of a species, are invariably increased, when nanoparticles are added to the base fluid and the measuring instrument allows for the unhindered particle motion as well as the microconvection process that follows the Brownian movement. This implies that the addition of nanoparticles primarily causes mass advection and this has a significant impact on the mass transfer within the nanofluid. Almost all the studies, where enhancement of the convective mass transfer coefficients was observed, attribute this enhancement to the Brownian movement of the particles and the associated microconvection.

The molecular diffusion process is a very slow molecular process in comparison to the other transport processes (Michaelides, 2014). Any type of fluid advection, however slow or weak, has the potential to contribute significantly to the mass transfer process. Wherever they are not suppressed, the Brownian movement and the accompanying unsteady microconvection of the base fluid enhance significantly the mass transfer process. In addition, other forms of mass transfer, for example, from catalysis, chemical reactions, or complexation, which may take place with the addition of the nanoparticles, also contribute to the increased mass transport.

The observed low diffusivities in several experiments do not detract from the usefulness of nanofluids as effective mass transfer media. The objective of all pertinent technological applications is the enhancement of the overall mass transfer, not only of the molecular transfer *per se*. For this reason, it is the enhancement of the convective mass transfer coefficient, h_{AN}, of a species that matters in engineering systems and not the effective diffusivity, D_{AN}, of the species. If the overall mass transfer of the base fluid increases by the addition of small amounts of reacting or nonreacting nanoparticles, nanofluids may prove to be very inexpensive media to improve the operation of the microfluidic devices, such as the "lab on a chip" type of systems. An additional advantage may be the possible control of the rate of mass transfer by the addition or removal of surfactants.

18.9 Specific Heat Capacity

The specific heat capacity of a material is an equilibrium thermodynamic property and represents the capability of the material to store heat. It also affects the convective heat transfer coefficient of a fluid. There have been very limited studies on the specific heat capacity of the nanofluid suspensions and the results of these studies are not always in agreement: Zhou and Ni (2008) measured this property for aqueous nanofluids containing alumina nanoparticles and found that the specific heat capacity decreases with increasing nanoparticle concentration. This is in agreement with the conventional model of heterogeneous mixtures, which is based on the thermal equilibrium of the constitutive materials (Gibbs, 1878, Michaelides, 2014). The experimental results are also in agreement with a recent molecular modeling study by Rajabpour (2013).

Shin and Banerjee (2010) measured the specific heat capacity of eutectic salts of $LiCO_3$ and K_2CO_3 containing 1% by weight of silica nanoparticles and observed a specific heat capacity enhancement in the range 19%–24%. The addition of silica nanoparticle to the $BaCl_2$–NaCl–$CaCl_2$–LiCl eutectic mixture also resulted in 14.5% enhancement in the specific heat (Shin and Banerjee, 2011). The authors proposed three mechanisms to explain the observed significant enhancement:

- Nanoparticles have higher surface energy per unit mass than the bulk solid. The surface atoms in the lattice of nanoparticle are less constrained, due to the lesser number of bonds. Because the bonds may be considered as springs, the surface atoms vibrate at a lower natural frequency and higher amplitudes, resulting in higher surface energy.
- The extremely high surface area per unit mass of the nanoparticles causes an increase in the interfacial thermal resistance between the nanoparticles and the surrounding liquid molecules. This higher interfacial thermal resistance may cause the vibrational energy between nanoparticle atoms and the interfacial molecules to store additional energy.
- The existence of a semisolid layer, which depends on the surface energy of the nanoparticles, that has higher heat capacity than the bulk liquid and may thus increase the specific heat capacity of the nanofluid suspension.

Similar mechanisms have also been used to explain the enhanced thermal conductivity of the nanofluids as detailed in Section 18.4, but they have not been validated. Also, the mechanisms do not explain the observed reduction in the specific heat observed by Zhou and Ni (2008). Two preliminary observations/conclusions that may be drawn from the limited experimental and analytical data on the heat capacity are

1. The aqueous nanofluids have reduced specific heat capacity, whereas molten-salt-based nanofluids show heat capacity enhancement.
2. The heat capacity measurements of the aqueous nanofluids were performed at temperatures that are close to the ambient temperature (certainly below the boiling point of water), whereas the molten-salt-based nanofluid measurements were performed at high temperatures (a few hundred degree Celsius).

18.10 Conclusions and General Observations

The addition of nanoparticles in base fluids modifies significantly the transport properties of these fluids. The addition of nanoparticles increases the effective viscosity in almost all cases, and the thermal conductivity of the fluids in most cases, sometimes by a factor of 2 or 3. Higher enhancements were observed for the mass transfer coefficient of some nanofluids—on the order of a factor of 10—even though the effective diffusivity may slightly decrease.

The higher thermal conductivity enhancements were observed with fibrous CNT and metallic nanofluids, which also tend to use the most expensive nanoparticles. Most of the experimental results on oxide nanofluids, which utilize less expensive nanoparticles, indicate that the thermal conductivity enhancement is modest, in the range of 5%–50%. The primary mechanism for the enhancement of the thermal conductivity is the significantly higher conductivity of the solid nanoparticles and in particular of elongated, fibrous nanoparticles. Electric surface charges, particle aggregation, and surfactant choices influence the thermal conductivity of the suspension by affecting the shape and distribution of the nanoparticles. The Brownian movement of the nanoparticles has a rather minor effect on the thermal conductivity. However, the Brownian movement of the particles and the associated microconvection of the fluid have significant effects on the mass transfer process.

In addition to the observed thermal conductivity enhancement, nanofluids also exhibit an augmentation of the convective heat transfer coefficient, above the values that are expected from the observed thermal conductivity enhancement. This augmentation occurs in laminar flows only and is most likely due to the microconvection and the transient effects caused by the Brownian movement of the nanoparticles.

Regarding boiling with nanofluids, the preponderance of experimental evidence is that the pool boiling and convective boiling coefficients are reduced with the addition of all types of nanoparticles. However, the CHF of the suspension increases, often by a factor of 2 or 3. Despite the lower boiling heat transfer coefficients, the CHF enhancement is very significant for the design of thermal systems with boiling nanofluids, because it provides a safety factor that is crucial to the design of electronic cooling systems.

It must be noted that all the reliable experimental observations of the heat and mass transport processes using nanofluids indicate that there is nothing "anomalous" with these suspensions. The high transport coefficients are readily explained with known mechanisms of heterogeneous suspensions, of which the most important are the type, the shape, and the distribution/configuration of nanoparticles. Similarly, the very high mass transfer coefficients are readily explained by the microconvection process. The successful manipulation of the shapes of particle aggregates, the artificial formation of particle structures, the optimized distribution of nanoparticles in base fluids, and the addition or removal or appropriate surfactants may create heat and mass transfer media in the future that are far superior to the base fluids.

Although little attention has been paid to the specific heat capacity of nanofluids, it is a very important property that has significant effect on heat transfer. Limited work so far shows that the specific heat capacity of aqueous-based nanofluids decreases with increasing nanoparticle concentration, while that of molten-salt-based nanofluids increases, sometimes significantly.

Acknowledgments

The research presented in this chapter was partially supported by the Tex Moncrief chair at TCU and by a DOE grant through the National Energy Technology Laboratory to UTSA (DE-FE0011453). The authors are thankful for this support.

Spray Systems

Udo Fritsching and Xing-gang Li

19.1 Atomization
19.2 Spray Behavior
19.3 Spray Impact
19.4 Spray Applications

19.1 Atomization

19.1.1 Introduction

Atomization and spraying of liquids (e.g., pure liquids, solutions, suspensions and emulsions, or melts) is a classical process engineering unit operation. The process of liquid atomization has applications in numerous industrial branches, such as in chemical, mechanical, aerospace and civil engineering, as well as in material science and technology and metallurgy, food processing, pharmaceuticals, agriculture and forestry, environmental protection, medicine, and others.

Within atomization, the bulk fluid (continuous liquid phase) is transformed into a spray system (dispersed phase/droplets). The disintegration process itself is caused either by intrinsic (e.g., potential) or extrinsic (e.g., kinetic) energy, where the liquid, which is typically fed into the process in the form of a liquid jet or sheet, is atomized either due to the kinetic energy contained in the liquid itself by the interaction of the liquid sheet or jet with a (high-velocity) gas, or by means of mechanical energy delivered externally, for example, by rotating devices.

The main purpose of technical atomization processes is the generation of a dramatically increased gas/liquid interface in the dispersed multiphase system. All transfer processes across the gas/liquid phase boundary directly depend on the driving potential difference of the exchange property (heat, mass, or momentum) and the size of the exchange surface. This gas/liquid contact area in a dispersed spray system is correlated with the integral sum of the surfaces of all individual droplets within the spray. Increasing the relative interphase area in a dispersed system intensifies momentum, heat, and mass transfer processes between gas and liquid. The total flux of exchange within spray systems thereby is increased by several orders of magnitude.

Applications of atomization techniques in process technology or chemical engineering processes can be divided into

- Impact-related spray processes
- Spray structure–related processes
- Particle (powder) production in spray processes

In impact-related spray processes, the spray typically impinges onto a solid surface or onto a liquid or semi-liquid material deposited by the spray. The spray may be used for coating, preform build-up, or hot surface

cooling applications. In spray structure–related processes, the main aim of the spray process is to produce dispersed spray droplets of a defined size, for example, for powder production or spray combustion.

Some examples for spray process applications in engineering following this subdivision can be given as follows:

- For *impact-related spray applications* within the continuous fine spatial distribution of a liquid continuum, for example, in the field of coating applications:
  - Corrosion protection of (metal) surfaces by spray coating applications
  - Coating applications for technical specimen and parts for use in private or industrial applications including surface protection and color (paint) applications
  - Crop and plant protection by applying agricultural chemicals
  - Protection coatings by thermal spray applications (like plasma- or flame-spraying of particles) for ceramic or metallic coatings in the metal industry
  - Spray granulation or coating of particles (e.g., in pelletizers or in fluidized beds), for example, for pharmaceutical or food industry applications
  - Spray cooling in aluminum and steel manufacturing (e.g., in strip or slab casting) or in heat treatment of metallic specimen
- For utilizing the spray structure and properties of liquids or particulate solids by gas/droplet/particle exchange processes (*spray structure–related spray process*) within
  - Solid particle separation or chemical gas cleaning (e.g., desulphurization) from exhaust gases, for example, in conventional power plants (wet scrubbers, see Section 15.10)
  - Gas conditioning processes, for example, for room air-conditioning (moisture control)
  - Reaction processes within fuel applications for energy conversion in furnaces within pyrolysis process, automotive, airplane or aerospace turbine, or fuel jet applications
- For utilizing the intense heat and mass transfer rates in sprays for solid particle production (particle product–related atomization process)
  - Thermal exchange processes, for example, for rapid cooling and solidification purposes of fluid melts in powder generation
  - Coupled mass and thermal transfer processes, for example, within spray drying of solutions (or spray crystallization) in food or diary industry or chemical mass products production
  - Particle generation for additive manufacturing processes
- In the combination of the aforementioned impact-, spray structure-, and particle product-related spray process applications within
  - Droplet-based manufacturing technologies, for example, for rapid prototyping and 3D printing
  - The generation of specimen and preforms by spray forming of metals

Each technical process couples several subprocesses in a complex away. Therefore, the complete process (in a first analysis approach) is to be subdivided into individual process steps for further analysis. In this context, a common subdivision of a technical atomization and spray process into modular subprocesses is performed. From the viewpoint of multiphase flow analysis, a typical subdivision for the atomization and spray process is illustrated in Figure 19.1. The sketch shows a (relatively rough) subdivision of a general atomization and spray process into four main subprocesses as

- *Media delivery*: The internal liquid flow in the atomizer and delivery (and possible mixing) of atomization media and energy, typically liquid and gas
- *Atomization*: The process of fluid disintegration or fragmentation, from the continuous delivery of the fluid or melt and the necessary supporting materials (like gases or additives), to the primary resulting spray structure and droplet/ligament spectrum from the atomization process
- *Spray*: The establishing and spreading of the spray, to be described as a dispersed multiphase flow process with momentum, heat, and mass transfer, and possible chemical reactions in all phases, and the exchange between the phases, as well as a possible secondary disintegration process of fluid ligaments or coalescence of droplets
- *Impact*: The impact of the spray droplets onto a solid or liquid surface and compaction and possible film formation of the impacting fluid or melt mass as well as the build-up of a remaining layer or preform

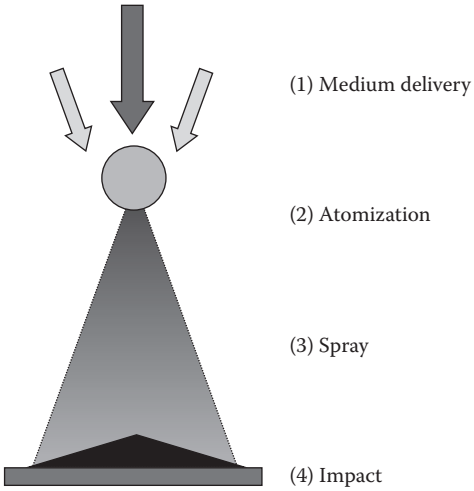

Figure 19.1

Subdivision of atomization and spray process into subprocesses.

A common viewpoint for analysis of all atomization and spray processes is to be seen from multiphase flow analysis with integral heat and mass transfer. Spray processes typically involve two-phase flows of liquid and gas, or even three-phase flow of solid, liquid, and gas (e.g., within atomization of slurries and suspensions or within (solidifying) melt atomization or within composite particle production).

19.1.2 Atomization Principles

The type of atomization principle or atomizer to be used for a specific application depends on the operational parameters to be tackled. Here, the material properties of the liquid to be atomized play an important role. Liquid material properties of importance are (in the order of significance): viscosity, surface tension, and density. These parameters may typically differ by several orders of magnitude. Some typical examples of spray liquid properties are given in Table 19.1. From the overall amount of atomized liquids, fuel and water (or water mixtures) are the most commonly used ones. Metal and ceramic melts are used for powder production and highly viscous liquids are, for example, found in chemical process technology (e.g., paints). The viscosity of these liquids varies up to six orders of magnitude. In addition, material properties typically are not constant within an atomization process. Especially for viscosity, liquids may show non-Newtonian (e.g., shear-dependent) viscosity behavior, for example, for slurries, or temperature-dependent behavior (melts). Therefore, the type of atomizer to be used for a specific application depends on

- The liquid feed material properties
- The targeted liquid throughput
- The spray characteristics to be achieved (e.g., droplet sizes or spray cone shape or spray cone opening angle)

Table 19.1 Material Properties for Atomization Liquids

Liquid	Density ρ (kg/m^3)	Surface Tension σ (kg/s^2)	Dynamic Viscosity μ (kg/ms) × 10^3
Fuel (benzine)	660	0.017	0.27
Water	1000	0.073	1.0
Melt (copper)	7800	1.31	3.12
Melt (iron)	8000	1.83	5.0
Fuel (oil)	830	0.026	20.1
Melt (ceramic)	5000	0.5	1,000
High-viscosity liquid	1000	0.035	20,000

19.1.3 Atomizer Types

Most common for characterization of atomization principles is a subdivision by means of the energy used for the disintegration of the liquid. Here, energy from the liquid itself may be used (pressure), or energy from external media like gas energy (pneumatic), mechanical energy (rotation), or electrical or acoustic energies are used Table 19.2.

19.1.3.1 Pressure Atomizer

The pressure atomizer (single fluid atomizer) is the most common used type of atomizer at all (by number) in technical applications. Main characteristic of this atomizer type is the ejection of a (pressurized) fluid through a small opening at high speeds into a (almost quiescent) gas atmosphere. The energy for atomization is carried by the liquid itself, and the potential energy is transferred into kinetic energy of the liquid. The liquid discharge geometry is either of straight simple type (circular round or flat stream) or swirling type (annular sheet). Pressure atomization typically is used for low viscosity fluids. A principal sketch of a pressure atomizer is illustrated in Figure 19.2a, a pressure swirl atomizer is shown in Figure 19.2b. For the latter, the swirl is generated either by tangential inlet ports and fluid delivery into the atomizer (right part in Figure 19.2b) or by, for example, insert of a vaned swirl generator on top of the atomizer (left part). Due to the swirling liquid flow and the resulting pressure distribution, a hollow air core is produced in the center of the atomizer chamber by suction and the liquid discharges as a swirling annular film from the atomizer. The simplex pressure nozzle produces a full cone or flat sheet spray, the swirl pressure atomizer typically produces a hollow cone spray. Drawbacks in the application of the pressure atomizer are the necessity of pressurizing the liquid (which may be difficult in some cases) and the relatively coarse spray droplet sizes as well as low mass flow rates (Walzel and Musemic, 2013).

19.1.3.2 Pneumatic Atomizer

Pneumatic atomizers (twin-fluid atomizers) typically use the kinetic energy of a pressurized gas that interacts with the liquid surface to disintegrate the liquid. Here, atomizers with external and internal mixture of

Table 19.2 Power Demand of Various Liquid Atomization Principles as per Mass of Liquid

Type of Atomizer	Power Demand (W/kg)
Simple pressure	2–4
Pressure swirl	2–4
Pneumatic twin fluid	50–60
Rotary	15

gas and liquid are to be distinguished. Both principles are shown in Figure 19.2c and d. Within internal mixing atomizers, gas and liquid are mixed in a premixing chamber and the gas/liquid mixture is ejected from the atomizer orifice directly. In twin-fluid atomizers with external mixing, the gas interacts with the liquid outside of the atomizer. Twin-fluid atomizers typically produce a full cylindrical spray cone with relatively small droplets at high liquid mass flow rates.

19.1.3.3 Rotary Atomizer

Within rotary atomization, the liquid typically is fed onto a rotating surface, where it spreads under the action of centrifugal forces. From the rim of the rotating device, for example, a liquid film is ejected at fairly high speeds that disintegrate into droplets. The rotating device as illustrated in Figure 19.3a may be of flat disk, cup, or slotted (vaned) wheel shape. Because the liquid in a rotary atomizer is not flowing through any tiny passages, this kind of atomizer is typically used in process industries where possible nozzle blockage by the fluid (or slurry) may cause major problems. The main drawback of the simple rotary atomizer is the possible slip between liquid and solid surface, thereby limiting the use of this device. This problem is solved in a practical way by using rotating wheels with vanes or channels.

Atomization with narrow drop size distribution width (low span) can be obtained with laminar operated rotary atomizers (so-called LAMROT). In this atomizer concept, the liquid feed is distributed into laminar open channel flows through multiple larger bore holes in the rotating wheel (cup or cylinder). After detachment, the liquid forms thin threads in a very controllable manner, that will be elongated and attenuated by centrifugal acceleration. The bore channels are only partially filled by the flowing liquid, thus exhibiting small hydraulic diameters compared to the bore-hole diameter. Additional attenuation of the threads leads to small drop sizes compared to the detachment diameter. The controlled thread breakup is caused by capillary instability (Rayleigh breakup), leading to narrow distributed droplets. Thereby, small drops are achieved by atomizers with large bores (Schröder and Walzel, 1998, Mescher et al., 2013).

19.1.3.4 Ultrasonic Atomizer

Ultrasonic atomizers either use directly the acoustic energy in a gaseous atmosphere or indirectly the vibrational energy of an ultrasonic excitated surface. Within ultrasonic standing wave atomization, a resonant standing acoustic wave is produced by a system of two opposing ultrasound transducers (or a single transducer and an opposing reflector) that are separated by a distance of a multiple of the half wavelength (typically 1.5–5 λ, i.e., 25–85 mm at a typical frequency of 20 kHz). The acoustic energy in the resulting resonant wave is used to disintegrate the liquid stream that is poured into the center of the standing wave. This principle is illustrated in Figure 19.3b. Main advantage of this atomizer type is the possibility of disintegrating highly viscous liquids (due to its specific disintegration mechanism, see Sections 19.1.5.1.6 and 19.1.8.1); its disadvantage is the limitation to relatively small mass flow rates.

In another type of ultrasonic atomization, vibrating surfaces are used to build fast oscillating capillary waves on the surface of the liquid covering the vibrating solid (see Figure 19.3c). The oscillating liquid ejects

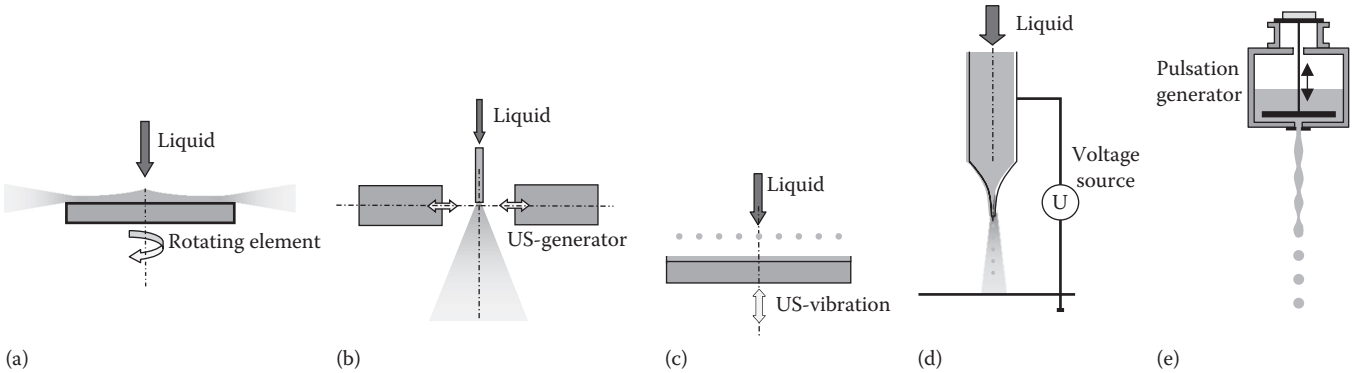

Figure 19.3

(a) Rotary (spinning disk) atomizer. (b) Ultrasonic atomizer (USWA). (c) Ultrasonic capillary wave atomization. (d) Electrostatic atomization. (e) Monosized droplet generation (here: jet excitation by vibrating plunger).

droplets from the wave tips. This device produces especially narrow droplet size distributions at small overall droplet sizes, but is limited to small liquid throughputs.

Ultrasonic gas atomization is a twin-fluid atomization process that uses a resonance cavity in the gas delivery path to generate fluctuating gas flow behavior at the nozzle exit (velocity and pressure fluctuations). The gas fluctuations support the atomization process, especially when their main fluctuating frequency is corresponding to the frequency of the fastest growing instability wave of the liquid stream or jet (e.g., see, Hartmann nozzles in Yule and Dunkley 1994). A direct excitation of the liquid flow may be performed to enhance the natural instability of the liquid jet (see, e.g., Chavez and Obermeier, 2002).

19.1.3.5 Electrostatic Atomizer

Within electrostatic atomization, an electrically charged liquid is accelerated in an electric field, thereby forming an accelerating tiny liquid jet (e.g., Taylor cone) that finally breaks down into fine droplets at the tip, as shown in Figure 19.3d. The achieved yield is relatively low (~1 kg/h). Typical electric potential is in the order <100 kV. Narrow-sized droplets at sizes down to the submicron scale may be produced by electrostatic atomization at very small quantities (Michelson, 1990, Lohmann, 2000).

Within coating applications also, the charging of the droplets in an electric field is used to additionally accelerate the droplets toward a (grounded) target and to spray-coat shadow areas. Thereby, the overspray amount of the process (particles that are deflected around the target, e.g., by aerodynamic effects) is minimized and a sufficient yield of the spray process is achieved. The atomization itself in this case may be performed, for example, by a rotary atomizer.

19.1.3.6 Monosized Droplet Generation

In several applications as in inkjet printing, the need is for droplets or particles of almost identical size (Walzel et al., 2001, Armster et al., 2002). Here, droplet generators that control the disintegration behavior and instability mode of liquid jets or sheets obtain a proper solution. The principal characteristic of a monosize droplet generator is illustrated in Figure 19.3e. An emerging liquid jet is excited (e.g., by mechanical vibration or acoustic excitation) at its most unstable wavelength. The disturbance generates waves of uniform size that leads to continuous breakup of the liquid jet into identical droplets. For increasing the overall mass yield, several individual jets may be combined within a single generator. Another possibility for (almost) monosized drop generation is the controlled breakup of a liquid within rotary atomizer in the ligament formation mode (see the following). Here also, perforated cylindrical elements are used.

19.1.3.7 Prefilming Hybrid Atomizer

The efficiency of an atomization process can be optimized by increasing the specific liquid surface energy before atomization (Lefebvre, 1980). Within twin fluid (gas) atomization, the fragmentation must take place in a region where the velocity difference between the atomization gas and the liquid is highest. Therefore, the liquid must be transformed and transported into an area where the maximum velocity difference occurs. These aspects can be realized in a prefilming hybrid atomizer where the disintegration process can be subdivided into two steps: a prefilming and a gas atomization step. During the prefilming step, a large specific liquid surface area is generated to prepare an efficient secondary disintegration step by gas atomization.

The prefilming hybrid atomizer concept is based on a combination of a single-fluid rotary prefilming concept and an external mixing twin-fluid atomizer, as shown in Figure 19.4a. Within this specific design, the feed material is first spread out by a spinning disk operated in sheet formation mode so that a free-flowing liquid film is formed in the vicinity of the rotary disk. The prefilm is conveyed into the most effective atomization zone by the local gas flow and subsequently atomized by a high-speed gas flow from the external mixing gas atomizer. This configuration allows the generation of a high velocity difference between the atomization gas and the liquid film. The prefilming hybrid atomizer design can be used for disintegrating highly viscous liquids and melts at high throughputs that produce a considerably low droplet size. For atomizing viscous melts, the atomization gas may be heated to prevent fiber-particle formation. See Czisch and Fritsching (2008a) and Fritsching and Uhlenwinkel (2012).

A different hybrid atomization process for particle production was developed to hybridize effectively gas atomization with centrifugal atomization in Liu et al. (2002) and Minagawa et al. (2005). In this hybrid atomizer configuration, the melt spray from an external mixing twin fluid nozzle impinges onto a rotating disk, resulting in a controlled film that finally acts as centrifugal atomizer for fine droplets with narrow particle size distribution within metal particle production.

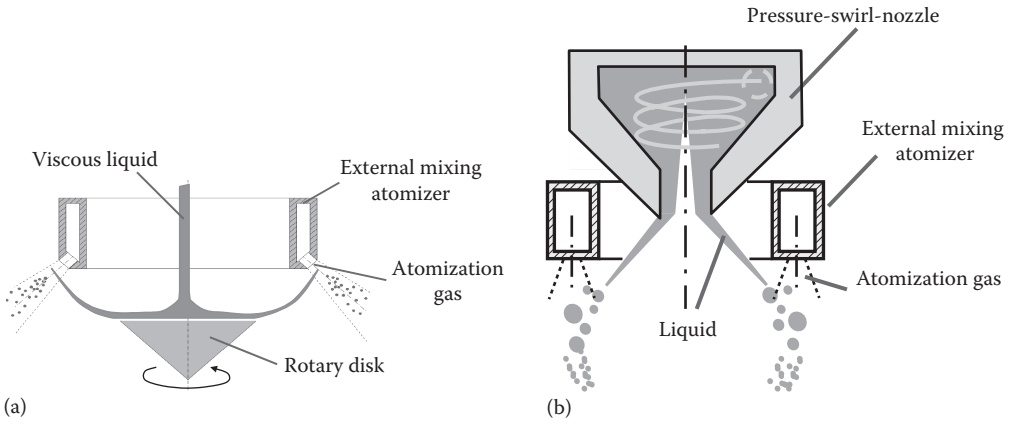

Figure 19.4

(a) Sketch of the prefilming hybrid atomizer: rotary atomizer plus external mixing twin-fluid atomizer. (From Czisch, C. and Fritsching, U., *Mater. Sci. Eng. A*, 477, 21, 2008a. With permission.) (b) Sketch of the pressure gas atomizer: pressure swirl atomizer plus external mixing twin-fluid atomizer. (Adapted from Achelis, L., Drall-Druck-Gas-Zerstäubung von Metallschmelzen, Dissertation, Universität Bremen, Shaker-Verlag, Aachen, Germany, 2009. With permission.)

Pressure gas atomization (PGA) is another prefilming hybrid atomization process that combines pressure swirl atomization as a prefilming step and gas atomization. Within the PGA process, the feed material initially enters a pressure swirl atomizer and leaves the nozzle exit as a conical hollow cone film due to its swirl and centrifugal forces; as the second step, an external mixing gas atomizer is employed to disintegrate the liquid film, ligaments, and any large droplets. The hollow cone film/spray is surrounded by the external mixing gas atomizer. Due to the high velocity gas flow from the external mixing gas atomizer, the hollow cone film/spray from the prefilming process is atomized into small droplets, which are mainly guided to the centerline of the atomizer axis. In Figure 19.4b, the principle of the pressure gas atomizer is illustrated. This atomizer design can be used to produce, for example, fine powders with small median diameters and narrow size distributions. See Uhlenwinkel et al. (2002), Lagutkin et al. (2004), Achelis and Uhlenwinkel (2008), Achelis (2009), Fritsching and Uhlenwinkel (2012), Li et al. (2011), and Li (2014).

19.1.4 Some Global Atomization and Spray Definitions and Characteristics

An initial division of atomization principles has to be done on account of the specific energy input for atomization. The energy supplied to the atomizer is given by

$$E = E_A + E_K + E_L \tag{19.1}$$

where

- E_A is the surface energy of the liquid, that is, the energy used to overcome the resistance or surface-tension forces during disintegration of the liquid into droplets
- E_K is the kinetic energy, that is, the energy used to accelerate the liquid and droplets in the spray
- E_L is the energy loss, that is, due to friction in the atomizer

The efficiency of atomization is given by

$$\eta = \frac{E_A}{E} \tag{19.2}$$

The efficiency of atomization depends mainly on the type of atomizer, the droplet size distribution in the resulting spray, and the physical properties of the liquid. For all conventional atomizers, this efficiency is very small, namely, in the order of less than 0.1%. Pressure atomizers have the relatively best efficiency (e.g., 5% for generation of droplets of 100 μm size, but even much smaller when the mean droplet size in the spray is lower). Even the kinetic energy that is needed to obtain the radial dispersion momentum of a spray,

respectively the droplets (spray cone angle), is at least one order of magnitude higher than the resulting surface energy of the spray.

Another measure for characterization of an atomization process is the approximate energy demand for atomization of a specific liquid amount, as listed in Table 19.2. Here, also pressure atomization is most efficient.

Atomization and spray process analysis is done by means of theoretical, numerical, and experimental approaches. From these results, characterization of atomization and spray processes most successfully is done in terms of nondimensional analysis based on characteristic numbers. For atomization and spray processes, the most important characteristic numbers are

$$\text{The density ratio: } M = \frac{\rho_g}{\rho_l} \tag{19.3}$$

$$\text{The viscosity ratio: } N = \frac{\mu_g}{\mu_l} \tag{19.4}$$

$$\text{The liquid Reynolds number: } \mathrm{Re}_l = \frac{\rho_l u_l d_l}{\mu} \tag{19.5}$$

$$\text{The liquid Weber number: } \mathrm{We}_l = \frac{\rho_l u_l^2 d_l}{\sigma} \tag{19.6}$$

$$\text{The aerodynamic (gas) Weber number: } \mathrm{We}_g = \frac{\rho_g u_{rel}^2 d_l}{\sigma} \tag{19.7}$$

$$\text{The Ohnesorge number Oh (or Laplace number Lp): } \mathrm{Oh} = \frac{\sqrt{\mathrm{We}_l}}{\mathrm{Re}_l} = \frac{\mu_l}{\sqrt{\rho_l \sigma d_l}} = \frac{1}{\sqrt{\mathrm{Lp}}} \tag{19.8}$$

$$\text{The momentum ratio: } I = \frac{\rho_g u_g^2}{\rho_l u_l^2} \tag{19.9}$$

$$\text{The gas (air) to liquid mass flow ratio: } ALR = \frac{\dot{m}_g}{\dot{m}_l} \tag{19.10}$$

Atomization processes yield a spray containing a certain range of droplet sizes. These drop size spectrum is identified by suitable size distribution functions. A general description of particle size distribution functions has been discussed in Section 1.3. Here, in addition, only the most spray relevant size parameters will be given. A spray typically is characterized by

1. A suitable droplet size distribution function
2. The (mean) size parameter
3. The relative width of the distribution (distribution parameter)

For description of the drop size distribution in sprays, either the probability density function (PDF) $q_i(d)$ and/or the cumulative distribution function $Q_i(d)$ are used. Most common is a fit of the drop size distribution by means of (1) the log-normal distribution function, (2) the Rosin–Rammler distribution function, or (3) the Nukiyama–Tanasawa distribution function. A discussion of statistical parameters for classifying size and various size distribution functions are presented in Chapter 1. As typical mean droplet size for these functions, either the arithmetic number mean diameter d_{10} or the arithmetic volume mean diameter d_{30} is used. An important spray characteristic parameter to describe drop size distributions in sprays is the volume to surface area mean diameter d_{32} (Sauter mean diameter [SMD]), that is, the drop diameter with the same total volume to surface area than the entire spray (important for all spray-related atomization processes).

In addition, characteristic spray droplet sizes may be identified as: the modal diameter d_m (corresponding to the most probable drop size in the spray, or peak value of the pdf), and the mass median diameter $d_{0.5}$ (or MMD) that divides the drop size distribution into two identical halves by mass. The width of the drop size distribution may be characterized by the standard deviation (geometric or logarithmic) or by the span value of the distribution:

$$\text{Span} = \frac{d_{0.9} - d_{0.1}}{d_{0.5}} \tag{19.11}$$

19.1.5 Internal Flow in Atomizers

From the viewpoint of multiphase flows in atomization and spray processes, the various kinds of atomization principles that have been illustrated before vary in the type, shape, and form of the gas/liquid interface prior to atomization. The liquid disintegration process is caused by acting forces in or on the liquid. Disintegration is more easily achieved if the liquid is fed into the atomization area in the form of a thin jet or sheet because here the liquid jet already has its highest surface energy and thus greatest instability potential.

19.1.5.1 Liquid Flow

19.1.5.1.1 Pressure Atomizer For simplex pressure atomizers, the overall characteristic of the single-phase (liquid) flow in the atomizer is described by the pressure drop and the state of the liquid at the nozzle exit. The former is described by the discharge coefficient C_D as

$$m_l = C_D A_0 \sqrt{(2\rho_l \Delta p_l)} \tag{19.12}$$

The discharge coefficient depends on the geometry of the atomizer outlet as well as on fluid material properties (Roach et al., 2001, Schneider et al., 2001) and liquid Reynolds number (Lefebvre, 1989). For Reynolds numbers below 10,000, and for a length to diameter ratio l/d_0 between 2 and 120 for the nozzle orifice, the discharge coefficient may be linearly correlated by Lichtarowicz et al. (1965)

$$C_D = 0.827 - 0.0085 \frac{l}{d_0} \tag{19.13}$$

The flow state of the liquid (jet) at the exit of the atomizer depends on the flow field in the atomizer and the orifice. Typically, spray nozzles are of compact size, with short orifices (l/d_0) to minimize the pressure loss. The degree of turbulence in the fluid is determined by the flow state upstream of the orifice and by disturbances generated in the converging region and in the orifice itself. A laminar to turbulent transition within the orifice is unlikely, though the Reynolds number may exceed the typical transition value in tubes (Re = 2300). Though in typical atomizer configurations, maximum Reynolds numbers of up to Re = 10,000 may be achieved, these high values occur only on a very small length scale, where the laminar/turbulent transition of the flow is not realistic. In the investigation on the influence of nozzle geometry on the critical intake length of fluid jets within pressure atomization, van de Sande and Smith (1976) derived a critical Reynolds number Re_{crit} for transition of the flow configuration from the laminar to the turbulent state as follows:

$$Re_{crit} = 12{,}000 \left(\frac{l}{d_0} \right)^{-0.3} \tag{19.14}$$

This critical Reynolds number is typically not reached in atomizer configurations. However, the local distribution and degree of turbulence may strongly influence the atomization process. Based on the description of Giffen and Muraszew (1953), the state of the jet at the atomizer exit may be described as illustrated in Figure 19.5. The jet profile may be either fully developed laminar (Figure 19.5A), or a developing boundary layer profile (Figure 19.5B), or turbulent (Figure 19.5b). Also, the liquid jet may include a turbulent core (Figure 19.5c) or vice versa, and the jet may exhibit a turbulent or disturbed outer shell (e.g., from vortex shedding from edges or cavitation at the wall inside the nozzle (Figure 19.5d). Especially the case of a turbulent outer liquid surface structure of the jet will influence the development of surface instabilities and waves at the liquid/gas interface when the surface wavelength is in the order of the natural instability wavelength. In this case, turbulence may inhibit or promote the disintegration process.

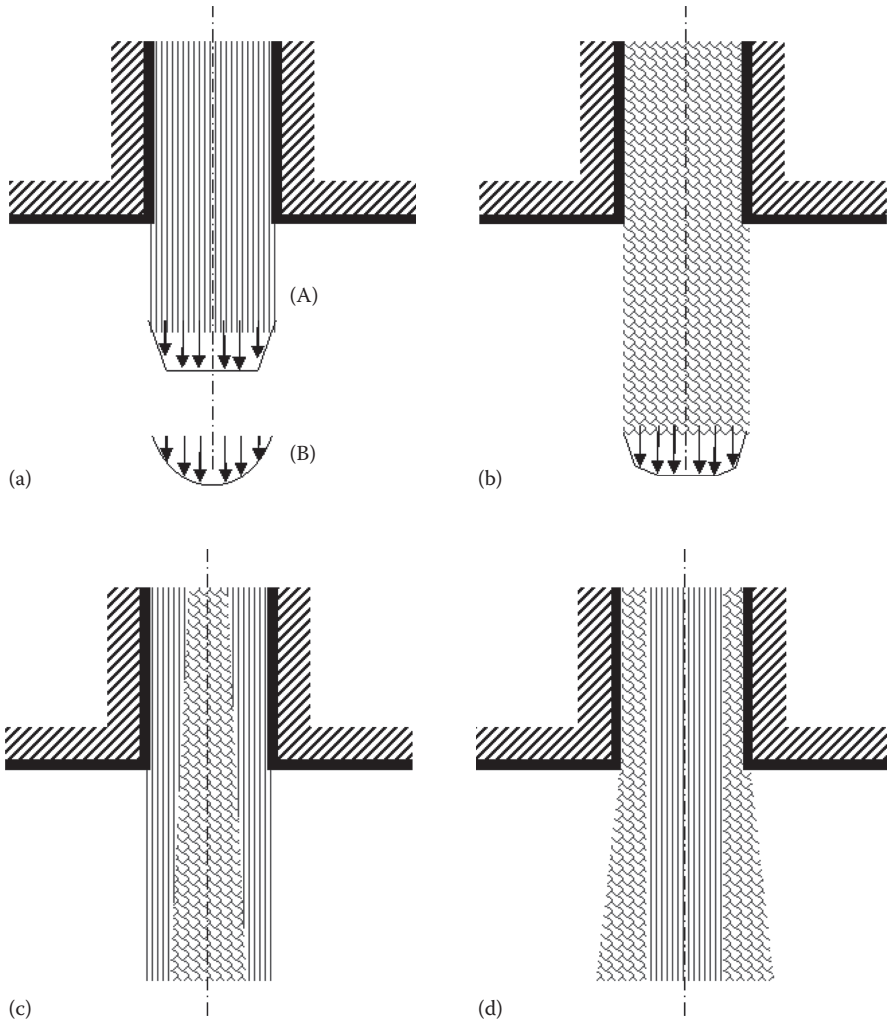

Figure 19.5

Liquid jet condition at the exit of an atomizer: (a) laminar, (b) turbulent, (c) turbulent core, and (d) turbulent shell.

For a pressure film atomizer, Heukelbach and Tropea (2001) have shown that turbulence may have a stabilizing effect on the disintegration of the free film. As long as the velocity fluctuations remain below a certain value (i.e., below 50% in the near-wall region and below 5% in the central flow region), turbulence stabilizes the disintegration process. This result has been explained by the increased vorticity of the turbulent flow, which produces additional shear stresses. These may be interpreted as increased turbulent viscosity, stabilizing the flow. Only if the disturbance level is beyond a certain threshold value, the disruptive forces of the fluctuations seemed to overcome the stabilizing effects, even exceeding the effect of aerodynamic forces. For a cylindrical jet, Mansour and Chigier (1994) found that in the absence of aerodynamic effects, turbulent jets are as stable as laminar jets. Marked differences however were found in the breakup behavior and droplet formation patterns of both laminar and turbulent jets.

19.1.5.1.2 Pneumatic Atomizer Typical atomizer configurations are spraying vertically downward in the direction of gravity. Here, the geometrical shape of the liquid jet in the gravity field and liquid velocity change prior to disintegration is of importance. When neglecting surface tension and frictional effects within and on the liquid jet behavior, the velocity distribution of a cylindrical falling jet is

$$u_l = \sqrt{u_0^2 + 2gx} \tag{19.15}$$

and, therefore, the jet diameter can be calculated as

$$\frac{d}{d_0} = \left(1 + \frac{2gx}{u_0^2}\right)^{-0.25} \tag{19.16}$$

This is independent of the liquid density. By adding surface-tension effects to this one-dimensional analysis (see Anno, 1977, Schröder, 1997, Schneider and Walzel, 1998), a nonlinear relation is achieved, describing the fluid jet contour behavior in a gravity field as a function of the nozzle distance:

$$\frac{d}{d_0} = \left[1 + \frac{2gx}{u_0^2} + \frac{4\sigma(d - d_0)}{\rho u_0^2 d d_0}\right]^{-0.25} \tag{19.17}$$

Numerical evaluation of this correlation is shown in Figure 19.6 for the jet contour of a liquid jet for different values of the surface tension, including $\sigma = 0$ N/m (without surface-tension effects), $\sigma = 0.0725$ N/m (surface tension of water), and $\sigma = 1.83$ N/m (surface tension of a molten steel). Two different Reynolds numbers of the jet are plotted. From this analysis, it is apparent that the effect of surface tension is to slow down the decrease of the liquid jet diameter for small Reynolds numbers. The jet diameter as a function of distance from the nozzle increases with increasing surface tension.

In case of a fully developed parabolic (laminar) velocity profile of the liquid jet at the nozzle exit, Middleman (1999) derived an approximate solution of the decreasing jet diameter (neglecting surface-tension effects) as follows:

$$\frac{d}{d_0} = \left(\frac{4}{3} + \frac{2gx}{u_0^2}\right)^{-0.25} \tag{19.18}$$

A numerical calculation of an exiting fluid jet having a velocity profile, taking into account friction, gravity, and surface tension, has been performed by Duda and Vrentas (1967) for Reynolds numbers Re > 200. Their results indicate that flattening of the developed velocity profile in the jet due to the low tangential stresses on the jet surface is very slow. As shown in Fritsching (2001), a two-dimensional numerical simulation of the liquid jet behavior (taking into account additional frictional effects and velocity profiles in the liquid jet due to the interaction with surrounding gas) produces only small deviations from the analytical solution.

19.1.5.1.3 Pressure Swirl Atomizer *Air core*: Halder et al. (2002) found that below a certain Reynolds number (Re_{l1}) at the inlet of the nozzle the liquid flows full through the nozzle without the formation

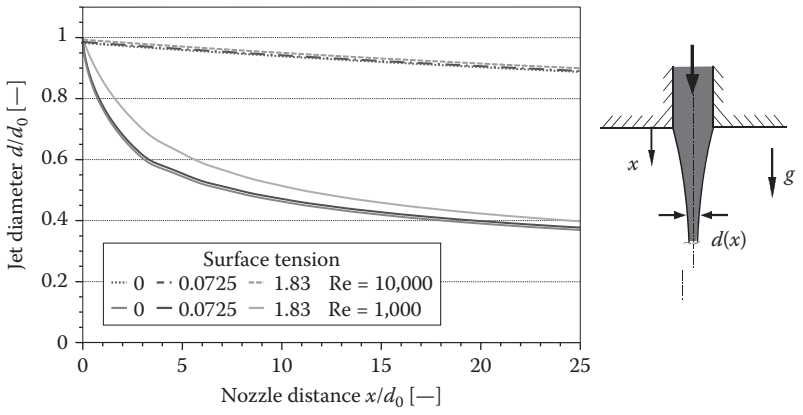

Figure 19.6

Dimensionless jet diameter of a free-falling circular liquid jet in gravity field, effect of density and surface tension.

of an air core, while above a certain Reynolds number (Re_{l2}) the formation of a fully developed central air core of cylindrical shape takes place in the nozzle. The inlet Reynolds number in Halder et al. (2002) takes the form

$$\mathrm{Re}_l = \frac{\rho_l \dot{Q} D_p}{\mu A_p} \tag{19.19}$$

where

$\dot{Q}$ is the total liquid flow rate through the nozzle
A_p is the total area of tangential entry ports

A transition flow with the development of a central air core takes place within the nozzle in between two limiting inlet Reynolds numbers. These two limiting Reynolds numbers are found to be an inverse function of the ratio of orifice to swirl chamber diameter (D_0/D_s) and a direct function of the ratio of tangential entry port to swirl chamber diameter (D_p/D_s). The terms on the nozzle geometry are defined in Figure 19.7. The fully developed central air core is cylindrical in shape with a sudden bulging in diameter at the entrance to the orifice. The air core diameter in both converging and orifice sections of the nozzle increases with an increase in the inlet Reynolds number at its lower range, while it becomes independent of the inlet Reynolds number at its higher range. Halder et al. (2002) gave the empirical correlations between the air core diameter and the pertinent dimensionless controlling parameters as follows:

$$\frac{D_{a1}}{D_0} = 0.42\left(1 - e^{-1.45\times10^{-4}\,\mathrm{Re}_l}\right)\alpha^{0.002}\left(\frac{D_0}{D_s}\right)^{0.735}\left(\frac{D_p}{D_s}\right)^{-0.765}\left(\frac{L_0}{D_s}\right)^{-0.111} \tag{19.20}$$

and

$$\frac{D_{a2}}{D_0} = 0.338\left(1 - e^{-1.45\times10^{-4}\,\mathrm{Re}_l}\right)\alpha^{0.073}\left(\frac{D_0}{D_s}\right)^{0.424}\left(\frac{D_p}{D_s}\right)^{-0.732}\left(\frac{L_0}{D_s}\right)^{-0.252} \tag{19.21}$$

where D_{a1} and D_{a2} are the air core diameters in both converging and orifice sections of the nozzle, respectively. The size of the air core determines the effective flow area at the discharge orifice and thus controls the coefficient of discharge (C_D). If the sheet thickness (h_0) at the orifice is known, the ratio of the air core area at the nozzle exit to the orifice area, X, is given by

$$X = \left(1 - \frac{2h_0}{D_0}\right)^2 \tag{19.22}$$

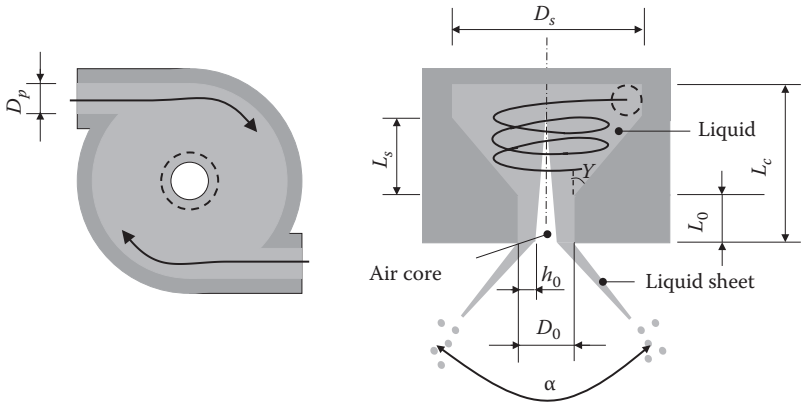

Figure 19.7

Schematic of pressure swirl nozzle together with main geometric parameters. (From Li, X.G., Modeling and simulation of the gas-atomization process of metal melts for metal-matrix-composite production, Dissertation, Universität Bremen, Shaker-Verlag, Aachen, Germany, 2014. With permission.)

Atomizer constant: The atomizer constant (K), which is found to correlate with some performance parameters like discharge coefficient (C_D), liquid film thickness (h), and spray angle (α), is defined as

$$K = \frac{A_p}{D_s D_0} \tag{19.23}$$

where A_p is the total area of tangential entry ports.

Discharge coefficient: The relation of liquid-mass-flow rate ($\dot{M}_l$) and injection pressure differential (Δp_l, i.e., the difference between the driving pressure on the liquid p_l and the ambient in the spray chamber p_a) is correlated by the discharge coefficient (C_D) of the nozzle:

$$C_D = \frac{4\dot{M}_l}{\pi D_0^2 \sqrt{2\rho_l \Delta p_l}} \tag{19.24}$$

where ρ_l is the density of the liquid. Analytical and empirical correlations for the discharge coefficient are summarized in Table 19.3. The correlation in Rizk and Lefebvre (1985) considers only the influence of the nozzle geometry. In Ballester and Dopazo (1994), the injection pressure differential as a factor is taken into account together with the nozzle geometry. In other correlations, the physical properties like liquid viscosity (μ_l) and liquid density (ρ_l) are also involved. The terms on the nozzle geometry are defined in Figure 19.7.

Film thickness: The liquid film inside a swirl nozzle is formed by the centrifugal force of swirling liquid and its thickness is one of the crucial factors governing the film development and atomization process. In fact, the liquid film thickness at the nozzle exit is one of the important input parameters for most of swirl spray atomization models. Suyari and Lefebvre (1986) derived an equation with regard to the effect of the pressure difference (Δp_l), liquid properties, and nozzle diameter (D_0). Badami et al. (2004) suggested an analytical equation, taking into account the nozzle diameter (D_0) and spray angle (α) as main parameters. Kim et al. (2006) modified the correlation in Suyari and Lefebvre (1986) by introducing the effect of the ratio of nozzle length to diameter (L_0/D_0). The experimental results in Moon et al. (2010) indicate that the liquid

Moon et al. (2010)	$h = 0.97 A_p^{0.08} \left(\frac{\mu_l D_0}{\rho_l}\right)^{0.25} \left(\frac{L_0}{D_0}\right)^{0.76} (\tan\gamma)^{-0.12}$, when $\Delta p_l \geq 2$ MPa

film thickness at high injection pressure differential is mainly dependent on the ratio of nozzle length to diameter (L_0/D_0) and independent of the injection pressure differential and the increase in L_0/D_0 ratio causes thicker liquid film thickness. The analytical and empirical correlations for the sheet thickness in terms of flow parameters are summarized in Table 19.4.

Spray angle: The spray cone angle (α) determines the coverage and dispersion of the spray in the surrounding environment. An increase of spray cone angle (α) with the injection pressure differential (Δp_l) is confirmed by most of experimental observations based on types of fluid viscosities and different nozzle geometries (Mulhem et al., 2006a, Achelis, 2009, Musemic et al., 2010). An increase in swirl ratio $S = \pi(D_s - D_p)D_0/(8A_p)$ leads to an increase of the sheet velocity in tangential direction at the nozzle orifice, resulting in a larger spray angle (Musemic et al., 2010). The spray cone angle decreases with increasing atomizer constant (K) (Ballester and Dopazo, 1994). An increase in the orifice length/diameter ratio (L_0/D_0) reduces the spray cone angle (Musemic et al., 2010). An increase in liquid viscosity reduces the spray cone angle (Mulhem et al., 2006a). Analytical and empirical correlations for the spray cone angle in pressure swirl atomization are summarized in Table 19.5.

A way to influence the film formation and the spray and ligament opening angle at the orifice of a pressure swirl atomizer by utilizing the Coanda effect (jet deflection at curved interface) has been illustrated by Kamplade et al. (2013). The liquid film angle deflection and thus the spray by the Coanda orifices mounted to a pressure swirl nozzle has been characterized by geometrical parameters as the Coanda curvature radius R_c/D (versus the orifice diameter) and by the flow or pressure Reynolds number. In general, under proper conditions, it is shown that much higher spray angles than with sharp edged nozzles can be achieved.

Discharge velocity: The discharge velocity, that is, the sheet velocity at the nozzle exit, can be obtained based on the mean flow velocity, which depends on the injection pressure differential Δp_l (Eslamian and Ashgriz, 2011):

$$U = K_v \sqrt{\frac{2\Delta p_l}{\rho_l}} \tag{19.25}$$

Table 19.5 Analytical and Empirical Correlations for the Spray Cone Angle α (in SI units)

References	Correlation
Giffen and Muraszew (1953)	$\sin\left(\frac{\alpha}{2}\right) = \frac{(\pi/2)C_D}{K(1+\sqrt{X})}$
Rizk and Lefebvre (1985)	$\alpha = 6K^{-0.15}\left(\frac{\Delta p_l D_0^2 \rho_l}{\mu_l^2}\right)^{0.11}$
Ballester and Dopazo (1994)	$\alpha = 16.156 K^{-0.39} D_0^{1.13} \mu_l^{-0.9} \Delta p_l^{0.39}$
Rivas et al. (2014)	$\sin\left(\frac{\alpha}{2}\right) = \frac{2\sqrt{2}X}{(1+\sqrt{X})\sqrt{1+X}}$

where K_v is given by the empirical correlation:

$$K_v = \frac{C_D}{(1-X)\cos(\alpha/2)} \tag{19.26}$$

where
C_D is the discharge coefficient
X is the ratio of the air core area at the nozzle exit to the orifice area
α is the spray angle

The axial component of the discharge velocity can be derived by the following equation:

$$U_z = \frac{\dot{M}_l}{\rho_l \cdot \pi h(D_0 - h_0)} \tag{19.27}$$

where
D_0 is the diameter in the nozzle exit area
h_0 is the initial sheet thickness

And then the average swirling velocity at the nozzle exit can be obtained by

$$U_t = \sqrt{U^2 - U_z^2} \tag{19.28}$$

19.1.5.1.4 Rotary Atomizer The film thickness at the rim of a rotating disk has been analyzed using several approaches by solving the equations of motion for the liquid film. Based on the local velocity difference between the angular film and the solid disk velocity, Nikolaev et al. (1967) derived the resulting film thickness. Bruin (1969) analyzed the simplified Navier–Stokes equation using complex functions and Matsumoto et al. (1973) obtained a numerical solution from the Navier–Stokes equations. Their results as well as experimental results (see Lefebvre, 1989) are in principle agreement and may be empirically correlated in terms of the dimensionless film thickness versus the dimensionless liquid flow rate by

$$\frac{t}{(\mu_l/\rho_l\omega)} = -14.5\left(\frac{\dot{Q}}{2\pi R^2(\mu_l\omega/\rho_l)^{0.5}}\right)^2 + 6.72\frac{\dot{Q}}{2\pi R^2(\mu_l\omega/\rho_l)^{0.5}} + 0.2 \tag{19.29}$$

19.1.5.1.5 Internal Mixing (Effervescent) Twin-Fluid Atomizer In the narrowest cross-section (typically in the exit) of an internal mixing, effervescent atomizer for the gas–liquid mixture critical mass flow is observed (Chawla, 1969, 1985, Chawla and Böckh, 1971, Buckner and Sojka, 1991, Whitlow and Lefebvre, 1993, Lund et al., 1993, Sovani et al., 2001). The term critical condition in this context stands for the critical mixture exit velocity (Mach number Ma = 1), the so-called choked nozzle condition. In a gas/liquid two-phase medium, the speed of sound is markedly less than that in either of the individual phase. As an example, Chawla (1985) notes that the minimum speed of sound in an air/water mixture at standard temperature and pressure is 20–30 m/s, as compared to 300 and 1500 m/s in the individual air and water phases, respectively. Since a two-phase flow through a nozzle chokes at a significantly lower velocity than that at which a single-phase flow would choke, a two-phase flow will experience a steep pressure jump at the nozzle exit, even at relatively low flow velocities and low injection pressures. Since atomization quality is greatly enhanced by the sudden pressure drop at the nozzle exit, it is possible to achieve good atomization with two-phase flows even at low flow rates and low injection pressures. Furthermore, due to its low sonic velocity, a two-phase flow can remain choked while flowing through orifices larger than those required for a single-phase flow. As a result, a two-phase flow can provide good atomization even with exceptionally large exit orifices. The lower sonic velocity of a two-phase mixture and the consequent pressure jump at the atomizer exit is an advantage that effervescent atomization shares with other internal-mixing twin-fluid atomization techniques (Sovani et al., 2001).

The total mass flow rate through the nozzle and the loading (mass flow ratio of gas and liquid, GLR) also depends on the actual state of the mixture within the nozzle throat as will be described here. Leaving the nozzle, the gas flow expands and the liquid is dispersed into ligaments and droplets. The atomizer efficiency and temporal and spatial distribution of droplet diameters and droplet velocities depend on the total pressure in front of the nozzle, the volumetric flow rate of liquid and gas, as well as on the spatial and temporal distribution of gas and liquid at the nozzle exit. These distributions are affected by the two-phase flow structure inside the mixing chamber and the nozzle. Chin and Lefebvre (1993) as well as Lörcher (2003), Lörcher et al. (2003), Kim and Lee (2001), Jedelsky and Jicha (2008), and Shepad (2011) and Jedelsky (2013) analyzed experimentally the flow regimes inside of an internal mixing atomizer and in its exit, where bubbly, slug, annular, or dispersed flow regimes with GLR increase are found (see Chapter 3). Their findings for the different flow regimes have been incorporated in the general flow maps, for example, of Oshinowo and Charles (1974). In Jedelsky and Jicha (2008) and Jedelsky (2013), modified Baker's map for vertical downward two-phase flow with transformed coordinates has been used to describe different internal two-phase flow patterns, as shown in Figure 19.8. The coordinates in the map are

$$X = k_x \cdot GLR \cdot \lambda \cdot \psi \quad \text{and} \quad Y = \frac{k_y \dot{m}_g}{\lambda} \tag{19.30}$$

where k_x and k_y are constants needed for conversion from Imperial system to SI system. The other parameters are

$$\lambda = \left(\frac{\rho_g}{\rho_a} \cdot \frac{\rho_l}{\rho_w} \right)^{1/2} \quad \text{and} \quad \psi = \frac{\sigma_w}{\sigma_l} \left(\frac{\mu_l}{\mu_w} \cdot \left(\frac{\rho_w}{\rho_l} \right)^2 \right)^{1/3} \tag{19.31}$$

where ρ, σ, and μ are density, surface tension, and dynamic viscosity, respectively. The subscripts *g*, *l*, *a*, and *w* denote atomizing gas, atomized liquid, air, and water, respectively.

However, as these general flow maps have been derived for a fully developed two-phase flow, the flow regimes inside the internal mixing atomizer do not fit well into these general schemes. Here, the atomizer and mixing chamber lengths are too small to achieve fully developed flow conditions.

Model developments for the different flow regimes in an effervescent atomizer are to be found in Lörcher (2003), Lörcher et al. (2003) and the transition between the modes has been characterized in Kim and Lee (2001), Jedelsky and Jicha (2008), and Shepad (2011). The spray from an effervescent atomizer has been

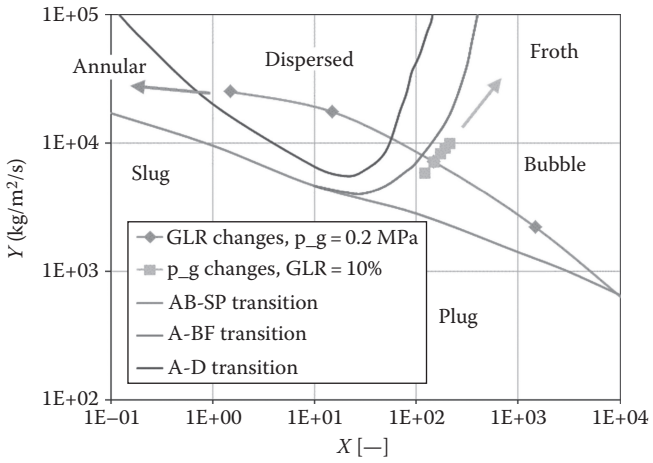

Figure 19.8

Modified Baker's map for vertical downward two-phase flow with transformed coordinates with marked influence of operational conditions on the two-phase flow regimes. Arrows show direction of regime change, while the appropriate values increase. AB-SP: line defining transition between bubble and plug or annular and slug pattern, A-BF: transition between annular and bubble-froth pattern, A-D: transition between annular and dispersed pattern. (Adapted from Jedelsky, J., Some aspects of effervescent atomization: Experimental study, Short version of Habilitation thesis, Brno University of Technology, Brno, Czech Republic, 2013.)

investigated by Whitlow and Lefebvre (1993), Jicha et al. (2002), Luong and Sojka (1999), Jedelsky and Jicha (2008), Liu et al. (2011), and Shepad (2011).

The critical pressure $p_{2,c}$ in the nozzle exit can be correlated by Churchill and Usagi (1972)

$$\left(\frac{p_2}{p_0}\right)_c = \left[\left(\frac{\kappa+1}{2}\right)^{4\kappa/3(\kappa-1)} + \left(\frac{\kappa}{2}\frac{1-\alpha_0}{\alpha_0}\right)^{4\kappa/3(\kappa+1)}\right]^{-3/4} \tag{19.32}$$

The discharge coefficient and the critical mass flow rate at the exit have been empirically correlated, for example, with gas to liquid mass ratio (GLR) by Chen and Lefebvre (1994), Landwehr et al. (1999), Kim and Lee (2001), and Ochowiak et al. (2010). Lörcher (2003) found the best agreement with the simulation results of Richter (1983) and the analytical expression of Leung and Epstein (1990). From the corresponding critical pressure and mass flow rate at the nozzle exit, the void fraction and mean velocities at the exit can be derived.

The comparisons between the two-phase flow structures inside the mixing chamber and the spray structures exiting the nozzle have been performed by Kim and Lee (2001), Jedelsky and Jicha (2008), and Shepad (2011). Figure 19.9 shows how the spray appears under different internal flow regimes. For a relatively small amount of

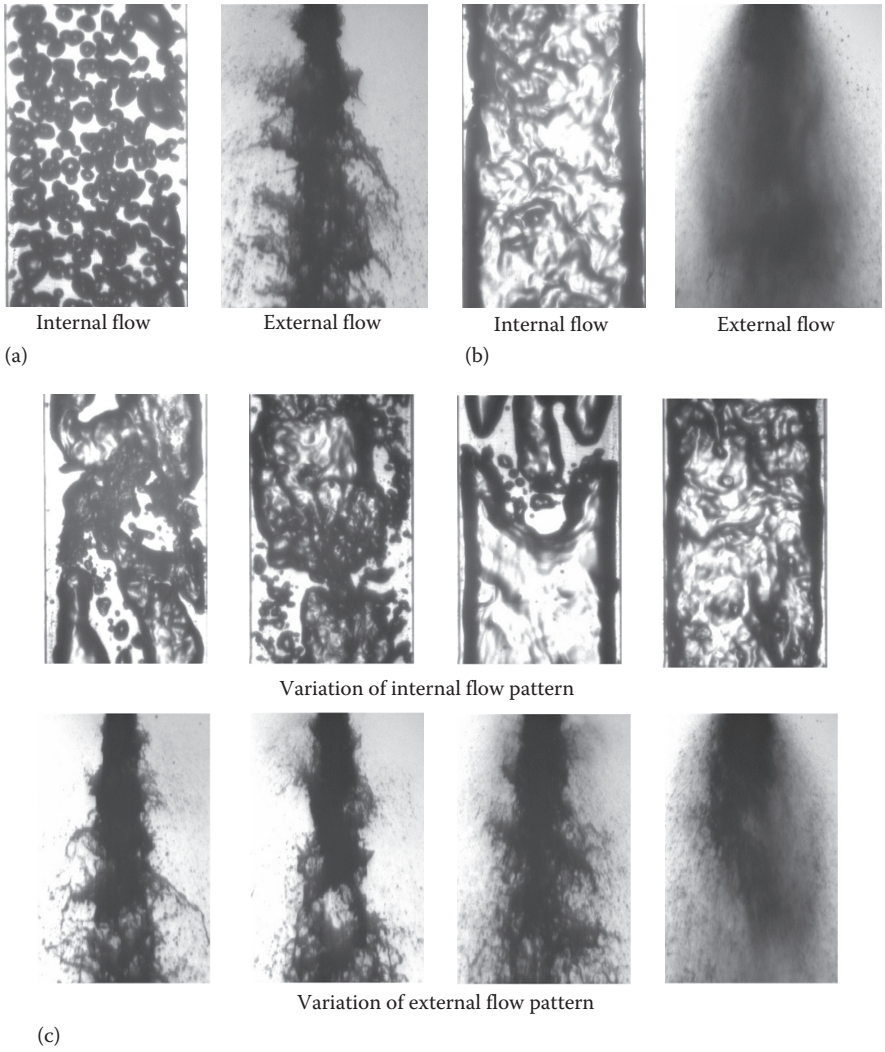

Figure 19.9

Internal vs. external flow characteristics in different regimes, Δp = 0.4 MPa, D_0 = 1.6 mm: (a) bubbly flow, GLR = 0.003; (b) annular flow, GLR = 0.111; (c) intermittent flow, GLR = 0.017. (Adapted from Kim, J.Y. and Lee, S.Y., Dependence of spraying performance on the internal flow pattern in effervescent atomizers, *Atom. Sprays*, 11, 735, 2001. With permission.)

air (GLR = 0.003, Figure 19.9a), the internal flow regime is bubbly and the spray has intermittent disruptions. In the bubbly flow regime, the discharged air/liquid mixture disintegrates into drops through the processes of bubble expansion and ligament breakup. When the internal flow is annular, due to the large amount of gas (GLR = 0.111), the spray breaks up relatively close to the nozzle exit, as evident in Figure 19.9b. In the annular flow regime, the liquid annulus disintegrates into fine drops by aerodynamic interaction due to high relative velocity between the core gas and the liquid film. At GLRs in between the bubbly and annular flow regimes, there is an internally intermittent regime (i.e., slug flow regime) where the unsteadiness of the internal flow structure is observed, and thus, the spray characteristics fluctuate with variation of the internal flow structure. In the slug flow regime, the bubble expansion/ligament disintegration and the annulus disintegration modes appear alternately, and this effectively produces the spectrum of spray characteristics, as shown in Figure 19.9c, demonstrating the unsteadiness of the spray. The spray unsteadiness can be identified by sampling time-dependent droplet velocity and size measurements using phase/Doppler particle analyzer (PDPA) (Hardalupas and Horender, 2001), or based on measurements of pressure fluctuations in the atomizer mixing chamber (Jedelsky and Jicha, 2008), or by analysis of droplet arrival statistics (Edwards and Marx, 1995, Heinlein and Fritsching, 2006, Liu et al., 2011).

19.1.5.1.6 Ultrasonic Standing Wave Atomizer (USWA) Within a typical application of the USWA technique, a cylindrical liquid jet is poured into a node of the standing acoustic wave (Lierke et al., 1988). Here the liquid surface interacts with the acoustic field, resulting in a force on the liquid surface, regarded as sound radiation pressure. The sound radiation pressure is a result of the temporal averaged difference of surface pressure to ambient pressure and, therefore, the local temporal averaged density increases (Langevin sound radiation pressure). Its distribution on a spherical surface was first calculated by King (1934). The sound radiation pressure leads to a deformation of the cylindrical jet into a disk-shaped film (see Figure 19.10). In addition, suction forces act at the rim of the disk. This suction makes the USWA process ideal for disintegration of viscous liquids. The liquid velocity in the disk is increasing when the liquid moves from the center toward the rim of the disk, thereby the sheet thickness decreases. The liquid velocity distribution inside the disk has been derived theoretically by Hansmann (1996) and has been compared to experimental results, as illustrated in Figure 19.10. The liquid disintegrates at the rim of the disk when the film becomes thin and instability occurs.

19.1.5.2 Gas Flow

Analysis of the gas flow field in atomizer configurations is to be done in external mixing twin-fluid atomizers especially to identify the disintegration potential in terms of the operation conditions (gas pressure, nozzle arrangement, etc.). The geometric configuration and arrangement of the gas jet system as well as the

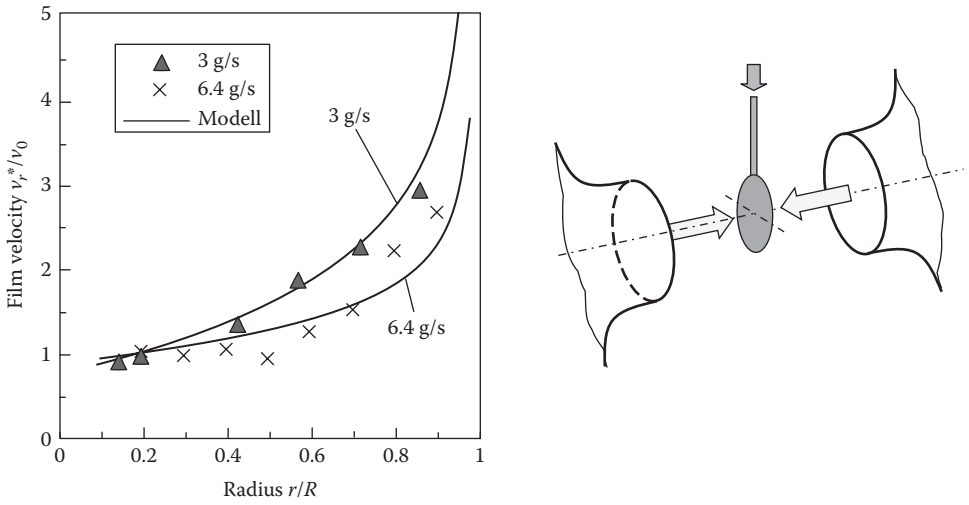

Figure 19.10

Film formation and radial film velocity in ultrasonic standing wave field. (Adapted from Hansmann, S., Einfluss von Stoff- und Betriebsparametern auf die Zerstäubung hochviskoser Flüssigkeiten im Ultraschall-Stehwellenfeld, Dissertation, Universität Bremen, Bremen, Germany, 1996.)

geometry or contour of the individual gas nozzles may be adapted for suitable application of the atomization gas (Espina and Piomelli, 1998a,b, Heck, 1998, Dielewicz et al., 1999, Espina, 1999, Czisch et al., 2003, Zeoli and Gu, 2006, Czisch and Fritsching, 2008b).

The gas flow behavior in front of an external mixing twin-fluid atomizer may have an influence on fundamental atomization parameters like the liquid mass flow rate (yield) or the resulting drop size distribution in the spray. The typical concentric gas flow configuration in an atomizer results in a pressure change in the central liquid feed area that causes variations in the pressure ratio between the liquid feed (or reservoir) and the pressure level in front of the liquid exit. Some possible arrangements of the nozzle tip in an external mixing twin-fluid atomizer are illustrated in Figure 19.11 (Anderson and Figliola, 1988), together with the corresponding measurements of the orifice pressure (also called aspiration pressure) in the gas-only flow field (without liquid atomization). Typical technical atomizers are constructed to give a suction pressure (lower pressure than ambient) at the liquid delivery port rather than overpressure. Also, the arrangement and number of discrete jets or the configuration of the gas nozzle as an annular slit nozzle result in different aspiration pressure behavior (see Lohner et al., 2003). If the spacing between the individual jets is large enough and the interaction between the jets is small, pressure equalization takes place and in between the discrete jets, the aspiration pressure effect is decreased. For a slit nozzle, the aspiration pressure effect tends to a maximum.

Depending on the individual gas jet nozzle contour, underexpansion, overexpansion, or ideal expansion (within a Laval nozzle contour) may be achieved (Sizov, 1999). The gas jet exit condition has a major influence on the jet behavior. In the gas nozzle exit, overexpanded jets in principle contain the highest exit momentum at a constant mass flow rate. This jet configuration is of special interest to achieve a gas kinetic energy maximum in the atomization area (in order to achieve the maximum slip velocity between gas and fluid). The results of a comparison of simulation data for overexpanded, underexpanded, and ideally expanded circular gas jets are illustrated in Figure 19.12. The velocities on the jets centerlines are plotted versus the nozzle distance for constant gas pre-pressure (p_0 = 5.5 bar abs.) and mass flow rate. For the latter, the gas nozzle exit areas of the three jets are different, calculated from isentropic flow conditions. Therefore, the exit area is highest for the overexpanded jet at identical conditions. Because the overexpanded jet also delivers the highest exit gas velocity, the resulting exit momentum in this case is highest (at constant mass flow rates). But downstream of the nozzle exit, the underexpanded jet has the highest velocity values after the first shock cell in the transonic region, especially immediately behind the shock fronts. For analysis of the atomization potential of the three different gas flow configurations, the behavior further downstream in the far field is important. In the subsonic free jet region, the ideally expanded jet shows the highest velocity values on the centerline. For ideally expanded jet behavior without any shock structures, the highest potential for atomization purposes is achieved in the far field.

Figure 19.13a and b shows the simulated gas flow field (velocity contours and vectors) in an external mixing (close-coupled) atomizer configuration (Zeoli and Gu, 2006). The gas exit geometry is an annular slit configuration where the gas emerges from a concentric ring slit nozzle. As the high-pressure gas enters the nozzle, the sharp

angle with the nozzle causes a detachment of the flow from the wall and a recirculation flow is generated around the corner of the throat. An oblique shock is formed inside the nozzle and reflected by the outer surface of the feeding tube. At the exit, the gas flow expands through a series of Prandtl–Meyer expansion waves and recompression shocks to match the atmospheric pressure inside the atomization chamber and the high-velocity gas continuously overshoots the equilibrium position as the external layer of the jet communicates with the jet core by sound/pressure waves, which is slower than the supersonic flow. The gas flow separation at the corner of the melt tube generates a recirculation vortex under the melt exit hole. The recirculation zone is distinguished from the high velocity gas with the sonic lines. The gas flow in the center of the recirculation zone moves toward the feeding tube and turns outward radially as it moves close to the tip. When the gas flow comes into contact with the sonic boundary, it is pushed inward and flows downstream. Inside the recirculation zone, a turbulent layer separates upstream and downstream flows. At the end of this recirculation zone, there is a stagnation front, where the gas velocity falls to around zero. About 15 mm behind the stagnation point, there is a mach disk (normal shock) and the corresponding velocity drop is more clearly depicted in Figure 19.13c.

Figure 19.14 shows on the left (a) the simulated gas flow field (velocity contours) in an external mixing (free-fall) atomizer configuration for different gas exit boundary conditions. The gas exit geometry is an annular slit configuration where the gas emerges from a concentric ring slit nozzle. The left part of the Figure 19.14a shows an underexpanded gas flow, and the right part shows the result for the ideal expanded case; both cases have been calculated for identical mass flow rates. In the underexpanded case, a shock cell structure in the gas jet is in front of the nozzle. Using ideally expanded gas jets in atomizer jets increases the velocity potential, as seen in Figure 19.14b (right side). Comparison of the gas velocities on the atomizer centerline illustrates that approximately 50–100 mm below the nozzle, where the primary disintegration of the liquid takes place, an increase of the gas velocity of approximately 10%–20% is achieved.

Figure 19.15 shows a sketch of a conventional external mixing free-fall atomizer. This atomizer design combines two separate gas nozzle systems, namely, a primary gas nozzle and a secondary gas nozzle, both concentrically surrounding the central jet (Fritsching and Bauckhage, 1992). The secondary gas nozzle is the main atomization unit, from which the concentric gas jets impinge onto the central liquid jet that is disintegrated due to instabilities from the shearing action of the secondary gas flow and its relative velocity (Markus et al., 2002). The atomization area is located underneath the secondary gas nozzle (Heck, 1998, Lohner et al., 2003).

Depending on the atomizer design and operation conditions, the inclined secondary gas flow jets may lead to the formation of a recirculation gas flow area underneath the secondary gas nozzle. If the intensity of the recirculation flow is reasonably strong, liquid ligaments or droplets may be transported back to the atomizer body. Here, these sticking fragments may clog the gas and/or liquid orifices and negatively influence or even stop the atomization process. Therefore, a primary gas nozzle or a controlled entrainment gas flow may be employed in a free-fall atomizer to suppress the recirculation of the gas. The primary gas flow is coflowing to

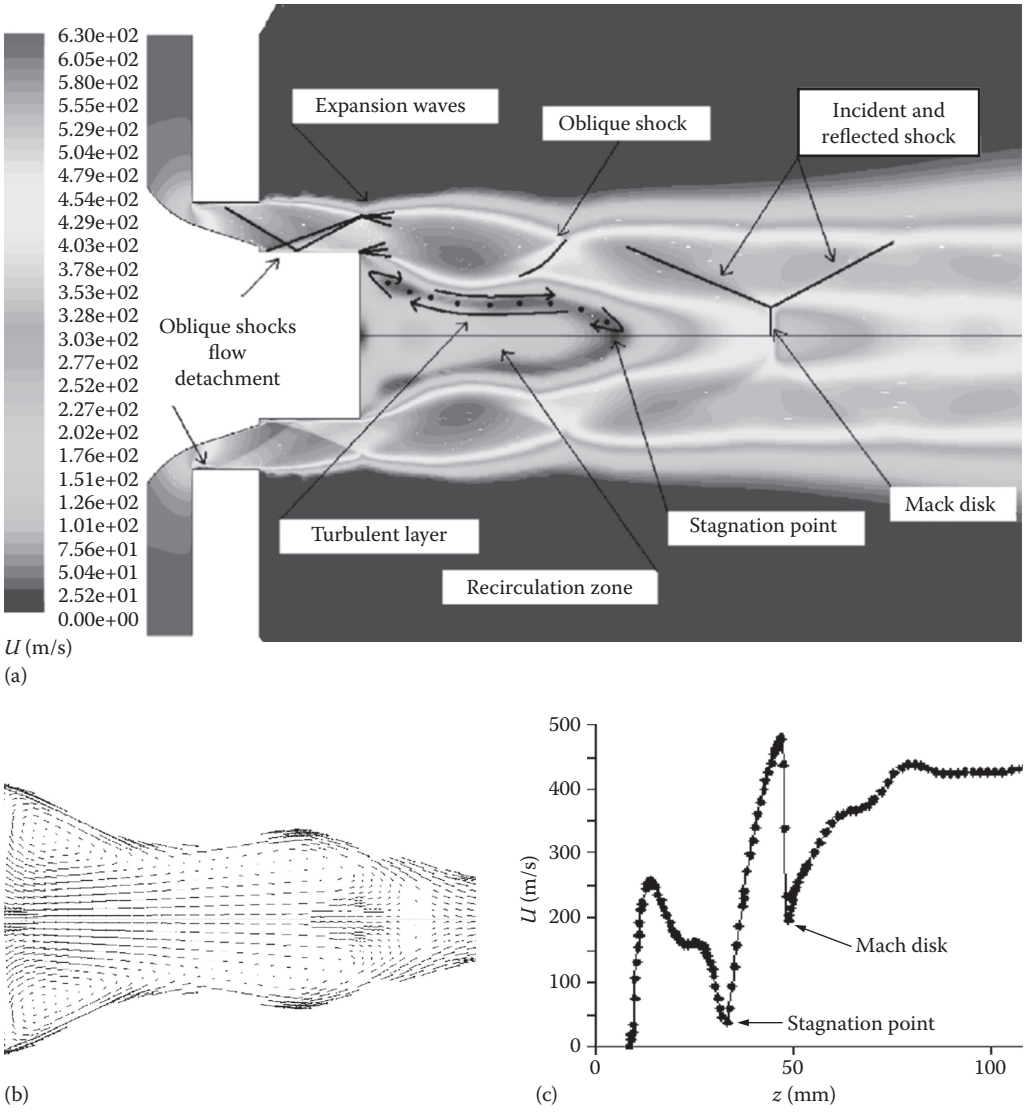

Figure 19.13

Gas flow field simulation for an external mixing (close-coupled) atomizer: (a) velocity contour plot; (b) velocity vector depicting flow recirculation under the melt exit; (c) gas velocity along symmetry axis. (Adapted from Zeoli, N. and Gu, S., *Comput. Mater. Sci.*, 38, 282, 2006. With permission.)

the liquid jet, thereby guiding the liquid into the atomization area. The influence of the primary gas flow on the flow structure in a free-fall atomizer was numerically investigated by Czisch and Fritsching (2008b). In Figure 19.16a, the influence of the primary gas pressure at constant secondary gas pressure (p_0 = 0.5 MPa, rel.) is shown in terms of gas streamlines. Two different operating conditions are to be distinguished, separated by the centerline in the figure. On the left of the figure, the gas flow field is illustrated with primary and secondary gas flow. A reasonable recirculation flow can be seen only close to the primary gas orifice, but no recirculation flow is present underneath the secondary gas nozzle. On the right of the figure, the gas flow field is illustrated when only the secondary flow is applied but no primary gas flow. The shown streamlines illustrate an intense recirculation flow area located from underneath the secondary gas nozzle up to the primary gas nozzle. Figure 19.16b presents the axial gas flow velocity on the centerline of the atomizer at constant secondary gas pressure (p_0 = 0.5 MPa, rel.) for varying primary gas pressures. It can be found that at constant secondary gas pressure the intensity of the gas recirculation underneath the secondary gas nozzle decreases with increasing primary gas pressure, and for primary gas pressures exceeding 0.025 MPa, the recirculation gas flow underneath the secondary gas nozzle is suppressed (no negative velocities in that area). However, the intensity of the recirculation close to the primary gas nozzle increases with increasing primary gas pressure.

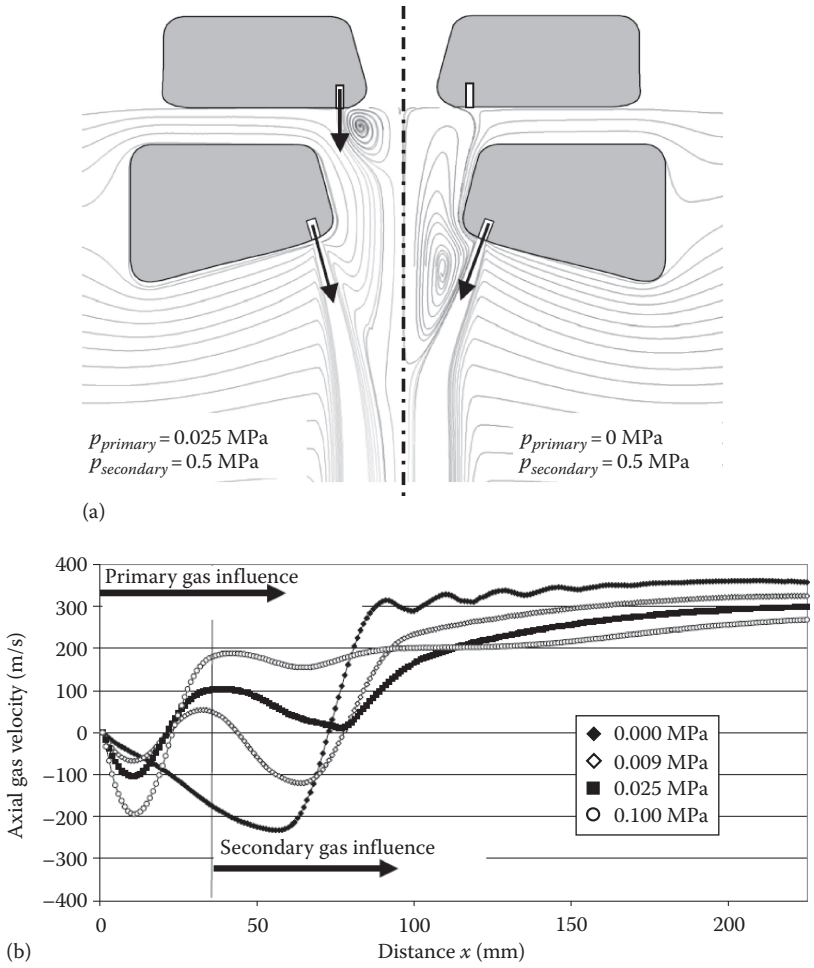

Figure 19.16

(a) Flow field of a conventional free-fall atomizer at different operating conditions. (b) Axial gas velocity on the center-line at varying primary gas pressures (see secondary gas pressure). (From Czisch, C. and Fritsching, U., *Atom. Sprays*, 18, 511, 2008b. With permission.)

During operation of the free-fall atomizer, the gas mass flow rates of both gas nozzle systems are controlled by the primary and secondary gas pressures, respectively. An intense recirculation flow may be generated if the pressure ratio between the primary and the secondary gas nozzle is improperly adjusted. The applicable maximum gas pressure of the primary gas nozzle is limited by initial disturbances that may be generated on the liquid jet before reaching the atomization area. Therefore, the secondary gas pressure is limited also because the secondary gas mass flow rate determines the necessary primary gas mass flow rate for prevention of recirculation. This coupling of the two nozzle systems limits the applicability of the free-fall atomizer (Heck et al., 2000, Bergmann et al., 2001a, Fritsching, 2004).

To improve the operating conditions and to overcome limitations of the free-fall atomizer, a Coanda-flow ring device was developed and installed inside the secondary gas flow (Czisch and Fritsching, 2008b). The applied flow device utilizes the Coanda effect (Wille and Fernholz, 1965) and the injector principle to influence the local atomization gas direction. Within the confined flow device, the secondary gas flow is deflected in the downward direction, the entrainment mass flow is increased, and, therefore, a primary gas nozzle is not necessary for suppression of gas recirculation.

In Figure 19.17a, the flow field of the free-fall atomizer without primary gas application is illustrated as streamline distribution (left) and local static pressure distribution (right) at a secondary pressure of 0.5 MPa (rel.). A recirculation flow field generated underneath the secondary gas nozzle is visible. The area with highest pressure is located where the atomization gas streams impinge onto the centerline. The local static pressure exceeds 50 kPa in this area. Figure 19.17b shows the flow situation of a free-fall atomizer without

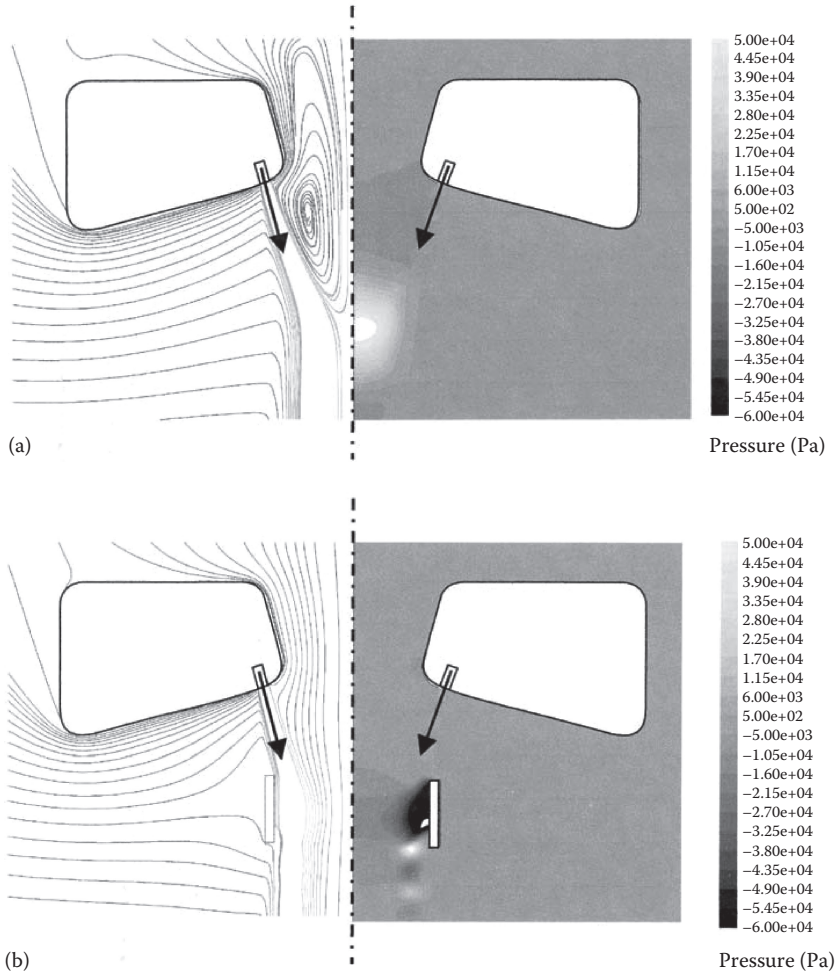

Figure 19.17

(a) Flow field (left) of and pressure distribution (right) of a conventional free-fall atomizer generated only by the secondary gas flow. (b) Flow field (left) of and pressure distribution (right) of a conventional free-fall atomizer generated only by the secondary gas flow but with installed Coanda-flow device. (From Czisch, C. and Fritsching, U., *Atom. Sprays,* 18, 511, 2008b. With permission.)

primary gas application but with the installed Coanda-flow ring device at a secondary gas pressure of 0.5 MPa (rel.). On the left, the flow field is illustrated by its streamline distribution; on the right, the static pressure distribution is displayed. No recirculation flow field is generated in this case. On the right, it can be seen that at the entrance of the installed Coanda-flow device, an underpressure area is generated. Depending on the negative pressure ratio between the underpressure area close to the atomization zone and the environmental gas pressure, the gas flow is deflected downward. Thus, the total gas mass flow rate increases through the liquid passage of the secondary nozzle by suppressing the recirculation completely. The maximum underpressure within the Coanda-flow device exceeds –60 kPa for the given secondary gas pressure.

Figure 19.18 shows the axial velocity on the centerline of the atomizer versus the varying secondary gas pressure without applying primary gas flow but with applying the Coanda-flow ring. There is almost no effect on the axial gas velocity with increasing gas pressure until the gas passed the installed flow device. Up to this point, the flow is completely dominated by the entrained gas flow from outside. After the gas flow passes the Coanda-flow device, the axial gas velocity increases with increasing secondary gas pressure. Thus, it is possible to achieve a recirculation free gas flow in a free-fall atomizer configuration by using the Coanda-flow device.

Figure 19.19a shows a photograph of the atomization area without the Coanda-flow device at secondary gas pressure 0.5 MPa (rel.) and without primary gas application. Obviously, an unstable atomization occurs where droplets are transported from the atomization area upward toward the atomizer body due to the generated

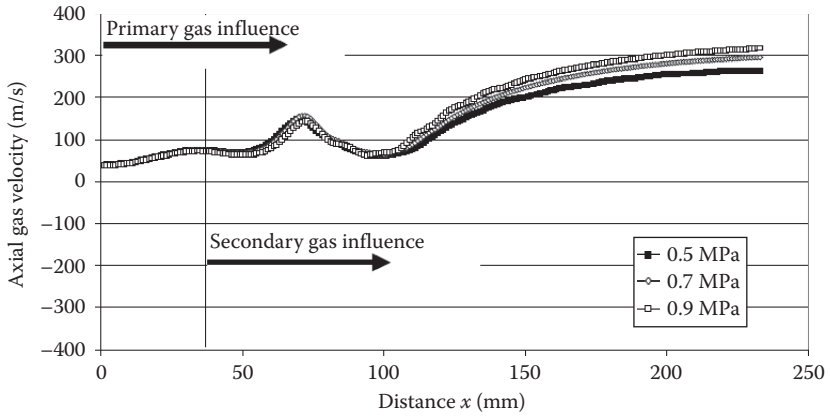

Figure 19.18

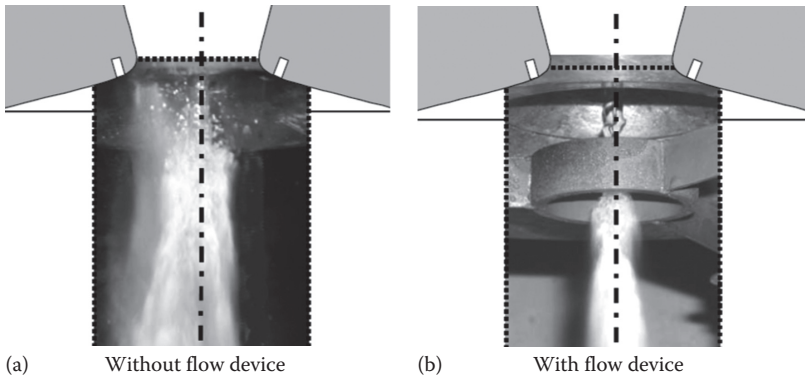

Figure 19.19

(a) Model experiments without Coanda-flow device. (b) Model experiments with Coanda-flow device (p_{sec} = 0.5 MPa, no primary gas, liquid mass flow rate 435 kg/h.) (From Czisch, C. and Fritsching, U., *Atom. Sprays*, 18, 511, 2008b. With permission.)

recirculation flow. The instability of the atomization is visible even as three-dimensional structure (asymmetric). When the Coanda-flow device is installed (Figure 19.19b), the atomization at secondary gas pressure 0.5 MPa (rel.) and without primary gas becomes stable, that is, no major recirculation in the atomization area occurs. Advantages of the flow-adapted atomizer design with Coanda-flow device are a reduction in gas consumption, as well as the potential of generation of small particles (Czisch and Fritsching, 2008b).

19.1.6 Primary Atomization

19.1.6.1 Flow Regimes and Flow Maps

For a first classification of liquid fragmentation in various configurations, the disintegration behavior of a liquid jet or sheet is subdivided into different atomization modes depending on the boundary conditions. As a result of several investigations, the disintegration behavior of a liquid has been globally classified, regimes have been identified, and interfaces between the different regimes have been correlated.

19.1.6.1.1 Single-Fluid (Pressure) Atomization This case holds for a liquid jet emerging into a quiescent gaseous atmosphere. Some examples for water atomization in a pressure nozzle are illustrated in Figure 19.20. Ohnesorge (1936) in an early investigation divided the breakup regimes of a circular liquid jet into three areas, depending on the liquid Reynolds number and a dimensionless number that

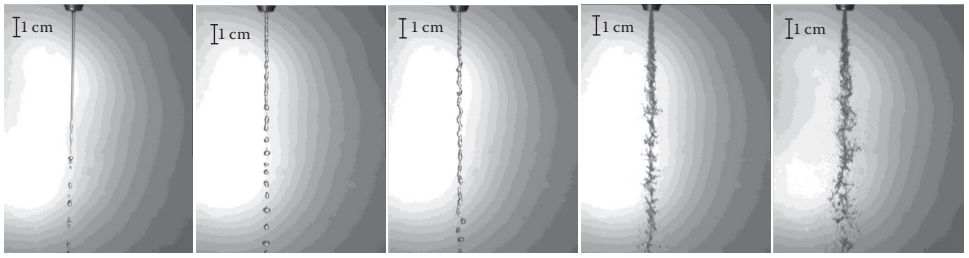

Figure 19.20

Disintegration of a liquid jet in pressure atomization, water, d_l = 1.5 mm.

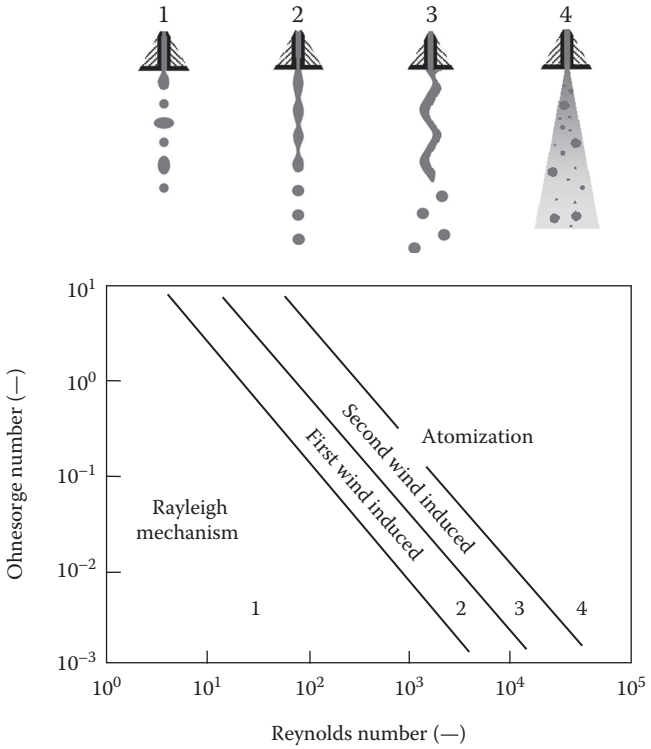

Figure 19.21

Primary fragmentation modes of a liquid jet in pressure atomization. (Adapted from Reitz, R.D., Mechanisms of breakup of round liquid jets, PhD thesis, Princeton University, Princeton, NJ, 1978.)

only contains liquid properties, later referred to as the Ohnesorge number (Oh) (Figure 19.21). These regimes have been further detailed, for example, by Haenlein (1932) and Reitz (1978).

1. At low Reynolds numbers, the jet disintegrates due to surface-tension effects (*Rayleigh regime (a)*, symmetric or varicose instability) into fairly identical droplet sizes.
2. At intermediate Reynolds numbers, drop formation is influenced by aerodynamic forces (non-axisymmetric Rayleigh breakup). These forces cause symmetric (*first wind induced mode (b)*) and asymmetric (*second wind induced mode (c)*, asymmetric or sinusoidal instability) wave growth of the gas/liquid interface that finally leads to jet disintegration.
3. At higher Reynolds number, the jet disintegrates almost spontaneously at the nozzle exit. This mode is called the *atomization regime (d)*.

The transition line from the Rayleigh mode to the aerodynamic mode is identified by

$$\mathrm{We}_l = \frac{1.74\times10^4}{\mathrm{Re}^{0.5}} \tag{19.33}$$

and the transition line between aerodynamic disintegration and the atomization mode is characterized as

$$\mathrm{We}_l = \frac{9.4\times10^5}{\mathrm{Re}^{0.5}} \tag{19.34}$$

19.1.6.1.2 Twin-Fluid Atomizer The first map of breakup regimes for a liquid jet in a coaxial gas flow was introduced by Faragó and Chigier (1992). Hopfinger (1998) introduced the momentum ratio between gas and liquid as an additional parameter (see also Lasheras and Hopfinger, 2000). The main disintegration modes are characterized in Figure 19.22, and some examples are illustrated in Figure 19.23.

1. At small aerodynamic Weber numbers, the jet mainly breaks up due to Rayleigh instabilities (*axisymmetric and nonaxisymmetric Rayleigh mode*).
2. If the Weber number is increased, ligaments are formed. The surface tension acts now at smaller scales. Owing to its smaller radius of curvature, the tip of the ligament recedes and a bulge is formed that may be blown up by the gas to form a membrane. This breakup regime is called the *membrane mode*.
3. At further increasing Weber numbers, the size of the ligaments decreases and the breakup occurs in the form of fibers (*fiber mode*).

Not enough data at present are available to identify the interfaces between the different regimes.

19.1.6.1.3 Pressure Swirl Atomizer In a pressure swirl atomizer, the liquid leaves the nozzle exit as a swirling conical sheet. The sheet disintegration proceeds differently depending on the action of the dominant forces on the sheet. As described in Fraser and Eisenklam (1953), Horvay (1985), Walzel (1982, 2012), Löffler-Mang, 1992, and Broll (2006), four modes of disintegration can be identified (see Figure 19.24), referred to as rim (or edge contraction), perforated, wave, and turbulent sheet disintegration, respectively, corresponding

(c) Perforation-dominated breakup. (Adapted from Prabhakaran, V.S. et al., Effect of temperature on atomization in gas centered coaxial injection systems, 2009, http://web.nmsu.edu/~sashi/iisc.pdf, date of access: 2013-06-20.) (d) Turbulent breakup. (From Sivakumar, D. and Kulkarni, V., *Exp. Fluids*, 51(3), 587, 2011. With permission.)

to different combinations of liquid inertia, liquid viscosity (μ_l), surface tension (σ), aerodynamic forces, and turbulence of the sheet. Different breakup modes usually coexist.

Walzel (2012) derived an upper limit for rim disintegration as

$$k^{1/2}\mathrm{We}_l < 370 \tag{19.35}$$

where $k = hz/A$ is the sheet number related to the sheet thickness h at some distance z from the nozzle exit and the cross-sectional area A of the nozzle exit. We_l is liquid Weber number based on the diameter at the liquid-nozzle exit (see Equation 19.6). Rim disintegration occurs at the edge of the film, where rims are formed due to the surface-tension-induced contraction and subsequently disintegrate into relatively large droplets. During the whole process, Rayleigh–Plateau (R-P) instability plays a dominating role. Figure 19.24a shows the rim-dominated breakup of a conical water sheet. The edge of the sheet is characterized by a relatively thicker fluid layer and goes through an asymmetric capillary instability (R-P instability). As soon as a drop is pinched off from the rim, the thickness of the rim suddenly drops to the sheet thickness. The sheet is pushed upward by the increased surface-tension forces due to the changed curvature at the rim, reducing the length of the sheet. A small perforation can be found on the intact liquid sheet.

For $k^{1/2}\mathrm{We}_l > 370$, the sheet begins to oscillate. With increasing distance, the quickly growing amplitudes of disturbances cause the sheet disintegration. Liquid ligaments are formed by contraction from the broken sheet and these ligaments subsequently break up into drops, as shown in Figure 19.24b. The majority of the breakup models explain this disintegration process based on aerodynamic sheet stability concepts (see Fraser et al., 1962, Dombrowski and Johns, 1963, Senecal et al., 1999, Nonnenmacher and Piesche, 2000, Mehring and Sirignano, 2004). These models assume the instabilities arising from the aerodynamic stimulation in the ambient gas (Kelvin–Helmholtz instabilities) lead to the sheet disintegration under conditions of low turbulence. However, the oscillations on the air core/liquid interface may also play an important role in the sheet disintegration by affecting the liquid surface inside the nozzle. The existence of helical waves on the surface of the liquid core inside the nozzle has been confirmed in experiments (Cooper and Yule, 2001, Donjat et al., 2003). These disturbances on the air core/liquid interface cause variations in liquid film thickness inside the nozzle. This effect may be in turn transported to the outside conical sheet and manifested by low amplitude three-dimensional waves appearing on the outside conical sheet, giving mechanism of disintegration into droplets. Low-frequency bands of disturbances on the outside conical sheet, which are in the same magnitude as on the air core/liquid interface inside the nozzle, were observed in experiments (Donjat et al., 2003, Landwehr et al., 2006).

Under conditions of low turbulence, experiments also indicate the formation of significant perforations on the sheet as a relevant mechanism of disintegration. The formation of perforations has been ascribed to a variety of cases including suspended solid particles, entrained air bubbles, drop impingement, and wave interactions (Spielbauer and Aidum, 1994). Figure 19.24c shows a typical perforation-dominated breakup of a conical hot-water sheet (82°C) formed by a gas-centered swirl coaxial atomizer. The perforations grow larger as the film extends radially and, finally, the ligaments between the perforations collapse into droplets. The waves on the intact sheet can also be observed as well as the contraction at the edges of perforations.

Turbulent sheet disintegration takes place due to the strong internal turbulence and/or the strong aerodynamic action of the ambient gas. In practice, the term liquid atomization is understood to mean turbulent sheet disintegration. Figure 19.24d shows the turbulent breakup of a conical water sheet from a gas-centered swirl coaxial atomizer. In the rim, wave, and perforated disintegrations, an intact axisymmetric liquid sheet can be observed. Such a feature is absent in the turbulent breakup where the liquid mass is fragmented into ligaments and droplets in the very near region of the orifice exit.

19.1.6.1.4 Rotary Atomizer The flow configuration and liquid condition (and therefore the effective atomization mode) at the rim of a rotating disk, where the fluid is continuously fed to the disk center, depends on the liquid flow rate, the disk rotational speed and size, and the liquid physical properties. A general division may be done based on the liquid feed rate as has been done by Hinze and Milborn (1950). For rotary atomization, the liquid Weber number is expressed as

$$\mathrm{We}_l = \frac{\rho_l \omega^2 d^3}{\sigma} \tag{19.36}$$

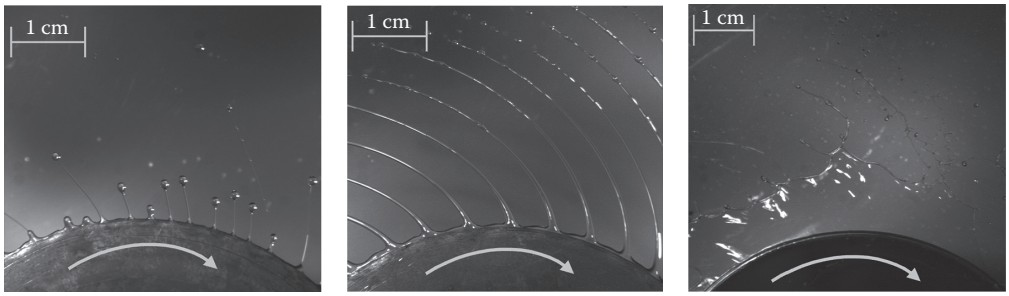

Figure 19.25

Main liquid disintegration modes in rotary atomization.

Main fragmentation modes in rotary atomization are illustrated in Figure 19.25 and may be analyzed as follows:

1. At low liquid flow rates, the liquid spreads out across the disk surface and is centrifuged off in the form of droplets with a narrow size spectrum. This mode is called the direct *drop formation mode (a)*.
2. If the flow rate is increased, ligaments are formed along the periphery that afterward are disintegrated into droplets. This mode is termed the *ligament formation mode (b)*. The number of ligaments increases with increasing flow rate up to a maximum value; beyond this maximum, it remains constant, regardless of flow rate. The thickness of the ligaments increases with flow rate.
3. With continuing increase in flow rate, a condition is finally reached where the ligaments have attained their maximum number and size and can no longer accommodate the flow of liquid. A thick film is produced that extends outward to some distance beyond the cup rim. When this film disintegrates into ligaments, it does so in an irregular manner, which results in a wider droplet size distribution. This disintegration mode is termed the *film formation mode (c)*.

For analysis of a wide range of liquid properties within rotary atomization, Brauer (1971) introduced as additional parameter the fluid number K_F

$$K_F = \frac{\rho_l \sigma^3}{\mu_l^4 g} \tag{19.37}$$

and the volume flow rate number

$$\dot{Q}^\star = \frac{\dot{Q}_l^2 \rho_l}{d^3 \sigma} \tag{19.38}$$

The breakup map for rotary atomization on a spinning disk is illustrated in Figure 19.26. The dimensionless ordinate and abscissa are labeled as

$$\Pi_y = \mathrm{We}^{0.5}\ \mathrm{Oh}^{0.922}\ K_F^{0.491}; \quad \Pi_x = \frac{\dot{Q}^{\star\ 0.5}}{\mathrm{Oh}^{0.47}\ K_F^{0.295}} \tag{19.39}$$

Transition between the individual breakup regimes is characterized in terms of the volume flow rate number, the liquid Weber number, and the Ohnesorge number by

$$\dot{Q}^\star\ \mathrm{We}_l^{0.25}\ \mathrm{Oh}^{0.835} < 2.08 \times 10^{-5} \tag{19.40}$$

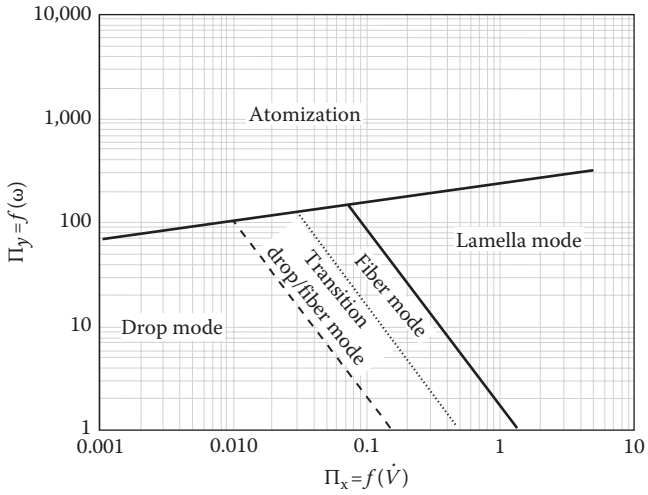

Figure 19.26

Disintegration modes map in rotary atomization. (Adapted from Brauer, H., *Grundlagen der Einphasen-und Mehrphasenströmungen*, Sauerländer Verlag, Frankfurt, Germany, 1971.)

for the transition from drop formation mode to ligament formation mode and

$$\dot{Q}^{*}\,\mathrm{We}_l^{0.6}\,\mathrm{Oh}^{0.835} > 1.77 \tag{19.41}$$

for the transition from fiber formation to film formation mode.

19.1.6.2 Continuous Jet Length

The continuous jet breakup length is an important parameter characterizing the atomization process that determines the region of the liquid jet where the liquid (at least in the center of the jet) remains as a continuous medium. The breakup length is taken as the distance from the nozzle exit to the breakup point. The general behavior of the breakup length versus the liquid jet velocity is illustrated in Figure 19.27. The initial part of the curve is described as the dripping region of the jet. From point A to point B, the laminar

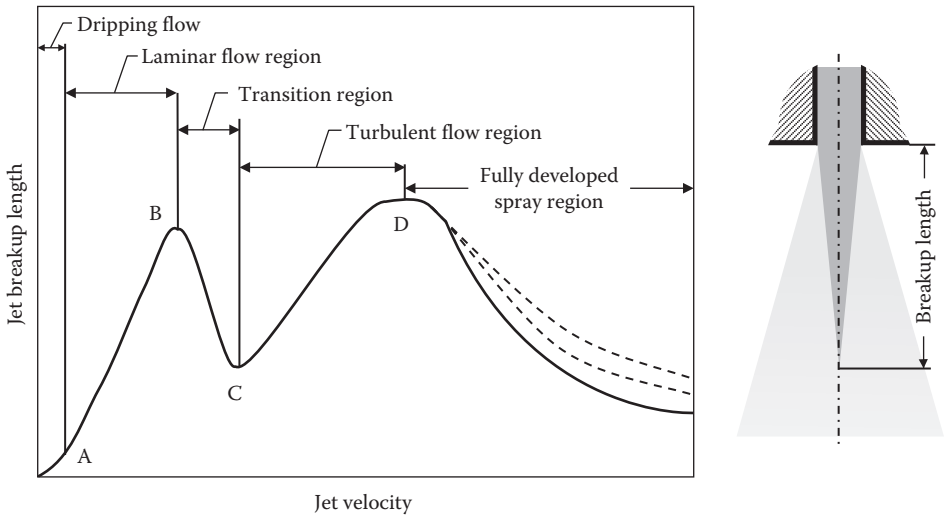

Figure 19.27

Breakup length in different modes.

flow region is located, where symmetric Rayleigh instabilities prevail. Here, the breakup length is linearly increasing and has been empirically determined as (Grant and Middleman, 1966)

$$\frac{L}{d_0} = 19.5\,\mathrm{We}_l^{0.5}(1+3\,\mathrm{Oh})^{0.85} \tag{19.42}$$

The upper point B indicates the transition from varicose to sinusoidal breakup mode. It has been correlated from experiments by Grant and Middleman (1966) for a laminar (fully developed) velocity exit profile of the jet as

$$\mathrm{Re}_{crit} = 3.25\,\mathrm{Oh}^{-0.28} \tag{19.43}$$

In the transition region B to C, the breakup length decreases. When the fluid at the nozzle exit is already in a turbulent flow stage and/or aerodynamic interaction between the liquid jet and the gas dominates the breakup, from point C to D, the jet breakup length increases with increasing velocity (see Walzel, 1980b, 1990, 1999). Here, Grant and Middleman (1966) proposed the empirical relationship

$$\frac{L}{d_0} = 8.51\,\mathrm{We}^{0.32} \tag{19.44}$$

The behavior of the liquid jet breakup length at jet velocities beyond point D is not uniquely defined yet but in general tends to decrease.

19.1.6.3 Stability Analysis

A cylindrical fluid element in a quiescent gaseous atmosphere is inherently unstable. Small perturbations of the surface (at wavelengths $\lambda > \pi d_l$) will always tend to grow. The first stage of the liquid jet disintegration process in atomization is described by an initial perturbation of the liquid/gas interface and next by the growth of surface waves of/on the liquid. Instability itself, for example, is promoted by the formation of the surface tension, leading to a local pressure distribution on the phase boundary depending on the local liquid surface curvature. A first quantitative analytical description of this process has been successfully given by Rayleigh (1878). In his contribution, a derivation of the fundamental system of describing energy conservation equations (by neglecting viscous contributions) and solution of the resulting equation system is performed. Rayleigh's analysis is limited to the case of sinusoidal initial perturbations of small amplitude. The liquid jet that is affected by surface-tension forces will become unstable only in the event of any axisymmetric disturbance whose wavelength satisfies the following equation:

$$\lambda_\delta < \pi d \tag{19.45}$$

For asymmetrical disturbances, the system is always stable. Rayleigh showed that the exponential growth of the fastest growing disturbance is given by

$$q_{\max} = 0.97\left(\frac{\sigma}{\rho_l d^3}\right)^{0.5} \tag{19.46}$$

and the corresponding wavelength of the fastest growing wave is

$$\lambda_{opt} = 4.51d \tag{19.47}$$

A spherical drop forms from the separate ligament (cylinder of length $4.51d$) due to surface-tension force at equal volumes and finally the resulting drop size becomes

$$d_p = 1.89d \tag{19.48}$$

This relation is used, for example, in droplet generators to produce monosized droplets by excitation of the liquid jet at its most unstable wavelength-corresponding frequency (see Figure 19.20).

Weber (1931) investigated in continuation of Rayleigh's work the viscous system. He neglected inertial effects and this solution is also only valid for small initial perturbations. He also found an exponential growth of small perturbations at unstable wavelengths. The ranges of process parameters and liquid properties in real atomization processes afford the inclusion of viscous effects (boundary layer) of the gas flow field. The upper limit for which the inviscid assumption in the instability process can be made with tolerable error in the case of a planar liquid sheet has been derived by Cousin and Dumouchel (1996). The result is summarized in terms of a limiting dimensionless number. The influence of viscous forces on the jet disintegration can be neglected if the dimensionless number M_c is

$$M_c = \frac{\mu_l \rho_g^2 u_{rel}^3 h_f}{\rho_l \sigma^2} < 10^{-3} \tag{19.49}$$

where the properties of the gas (subscript g) and of the liquid (subscript l), the relative velocity between gas and liquid u_{rel}, and the liquid film thickness h_f are used.

Starting from the pioneering works of Rayleigh and Weber, the following analytical stability analyses also are generally limited by one or more basic simplifying assumptions, such as the neglect of viscosity effects of either gas and/or liquid, the partial neglect of inertial effects, or the limitation of small initial perturbation amplitudes.

Investigations of jet instability processes in the area of small perturbation wavelengths (aerodynamic interaction and liquid disintegration), based on the linearized conservation equations and partially neglecting inertial effects and gas viscosity (neglecting the gas boundary layer), were performed for the first time by Taylor (1949, 1959). If, in addition, the liquid viscosity is neglected, this result leads to the classical case of the aerodynamic fluid disintegration based on Kelvin–Helmholtz instability.

A stability analysis that is independent of the ratio of wavelength to jet diameter λ_d/d has been performed by Mayer (1993) based on the contributions of Taylor (1949) and Reitz (1978). The reference system in this analysis moves with the fluid velocity u_l and the results are related to the relative velocity between gas and liquid $u_{rel} = u_g - u_l$. The complex formulation is based on a perturbation of the basic flow in the form of a surface wave with the amplitude

$$\eta_s = \text{real}\left(\eta_0 e^{ikx+im\theta+\omega t}\right) \tag{19.50}$$

where

$k = 2\pi/\lambda_d$ is the wave number

m is the mode of the perturbation

the parameter $\omega = \omega_r + i\omega_i$ is the complex growth rate of the perturbation

The real part of the complex growth rate $\text{Re}(\omega) = \omega_r$ describes the reaction function of the liquid jet by external excitation and the behavior of the perturbation. For negative growth rates $\omega_r < 0$ the perturbation will be damped out, positive growth rates $\omega_r > 0$ will lead to an exponential growth of the initial wave. In this derivation, the linearized flow conservation equations for gas and liquid are solved, based on the introduction of the stream function ψ and the velocity potential ϕ and the related perturbation formulations. Here, the velocity distribution of the gas is neglected, resulting in a velocity jump at the phase boundary between liquid and gas. The solution of the equation system is

$$\omega^2 - 2\frac{\mu_l}{\rho_l}k^2\omega\frac{I_1'(kr_0)}{I_0(kr_0)}\left[1 - \frac{1kl}{k^2+l^2}\frac{I_1(kr_0)}{I_0(kr_0)}\right] = \frac{l^2-k^2}{l^2+k^2}\frac{I_1(kr_0)}{I_0(kr_0)}\left\{\frac{\sigma k}{\rho_l r_0^2}\left[1-(kr_0)^2\right] + \frac{\rho_g}{\rho_l}\left(u_{rel} - \frac{i\omega}{k}\right)\frac{K_0(kr_0)}{K_1(kr_0)}\right\} \tag{19.51}$$

This contains the modified Bessel functions I_n and K_n of nth order and their derivatives I', as well as $l^2 = k^2 + \omega/\nu_l$. From the general solution in Equation 19.50, some specific cases can be derived, which will be discussed in the following.

19.1.6.3.1 Large-Wavelength Area When aerodynamic effects are neglected as well as the fluid viscosity, the gas density and also the relative velocity between fluid jet and gas flow field, the classical solution of Rayleigh (1878) is obtained:

$$\omega^2 - \frac{\sigma}{\rho_l r_0^2} k\left[1-(kr_0)^2\right]\frac{I_1(kr_0)}{I_0(kr_0)} = 0. \tag{19.52}$$

In this equation, I_0 and I_1 are the Bessel functions of zero and first order. As already mentioned, perturbations with wavelengths $\lambda > \pi d_l$ are unstable, resulting always in positive growth rates. If in the total unstable wave spectrum only the particular wavelength with maximum growth rate is considered (the fastest growing wave of all unstable waves, maximum of the instability function), the analysis ultimately leads to the classical case of the Rayleigh disintegration of a liquid jet.

19.1.6.3.2 Small-Wavelength Area In the case of an inviscid flow, the area of small wavelengths is the classical Kelvin–Helmholtz instability as derived by Bradley (1973a,b) for the excitation of the primary disintegration process in the area of small wavelengths within coaxial atomization of liquids.

In the limiting case of very small wavelengths ($\lambda \ll d_l$), the solution of the instability problem leads to

$$\left(\omega + 2\nu_l k^2\right)^2 + \frac{\sigma}{\rho_l}k^3 - 4\nu_l^2 k^2\sqrt{k^2\frac{\omega}{\nu_l}} + \xi_g(\omega + iu_{rel}k)^2\frac{\rho_g}{\rho_l} = 0. \tag{19.53}$$

Introduced in this solution is an assumption for the viscosity influence of the gas flow on jet stability, which has been derived by Sterling and Schleicher (1975). These authors found that accounting for boundary layer effects of the gas flow field stabilizes the wave growth. This can be taken into account as a damping effect of the perturbation pressure on the liquid jet surface. The factor ξ_g is related to this influence where

- $\xi_g = 1$ corresponds to inviscid gas flow
- $\xi_g = 0.8$ accounts for a turbulent boundary layer profile of the gas flow field at the phase boundary between liquid and gas.

In a similar way, Miles (1957, 1958, 1960, 1961) already has taken into account the turbulent boundary layer character of the gas flow field at the phase boundary. By neglecting the gas viscosity, the turbulent logarithmic velocity profile in the fully turbulent region is expressed in terms of a suitable pressure distribution on the wavy liquid surface (see also Bürger et al., 1989, 1992).

Generally from the analyses of aerodynamic disintegration behaviors, the influence of surface tension is found to have a stabilizing effect (shifting of the maximum unstable wavelength towards lower values) and the influence of fluid viscosity is characterized as having a damping effect (lowering of the amplitude of the growth rate while keeping constant the value of the wavelength with maximum growth rate). Increasing the relative velocity between gas and liquid phase always has a destabilizing effect.

The instability of a liquid/gas phase boundary of a jet or sheet is divided into several modes, which are to be described by their specific spatial growth function. Besides the symmetric mode ($m = 0$) of wave growth of phase boundaries, the liquid jet may tend to a long waved oscillatory movement (asymmetric jet oscillations, see Figure 19.28). By neglecting the gas and liquid viscosities and the region of high relative velocities between gas and liquid, a stability analysis of the first asymmetric mode ($m = 1$) of a liquid jet has been given by Levich (1962):

$$\omega^2 + \rho_g k^4 r_0^2 u_{rel}^2\frac{(\ln(kr_0/2))}{2\rho_l} - \frac{\sigma k^2}{2\rho_l r_0}\left(1 - m^2 - k^2 r_0^2\right) = 0. \tag{19.54}$$

In the case of a planar liquid sheet, Hagerty and Shea (1955) have shown that an inviscid fluid shows higher values of the growth rate in the asymmetric mode than in the symmetric mode. Here, the asymmetric mode is always dominant.

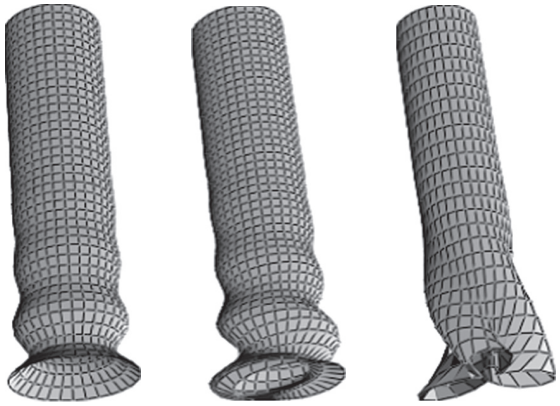

Figure 19.28

Instability modes of a circular liquid jet.

A comparison of the initial stability for laminar and turbulent liquid jet conditions has been made by Mansour and Chigier (1994). The growth rates of initial disturbances have been found to be the same for both laminar and turbulent conditions in agreement with the analysis of Weber (1931). For laminar flow conditions, the optimum wavelength corresponding to the fastest-growing disturbance is $\lambda_{opt} = 4.45 d_0$, which is in agreement with the theoretical value from Weber´s solution of the stability problem. For turbulent flow conditions, $\lambda_{opt} = 9.2 d_0$ has been found, which is approximately twice the optimum wavelength calculated in theory.

Despite the relatively crude assumptions and simplifications, which have to be made to apply linear stability analyses, the use of linear theory has a number of advantages when used as a first step for general analysis of fluid atomization process. First, the linear stability analysis is based on simple assumptions and second, the mathematical efforts for the solution are quite small. This makes the handling of this method easy. Linear stability analyses deliver general stability criteria and trends for the liquid/gas system under investigation and allow calculation of wavelengths and growth rates that mainly cover the disintegration process. An overview of classical solutions for the system of linear ordinary differential equations in the frame of linear stability analyses has been given by Markus et al. (2000). But, as will be described in the following, in comparison to experimental results in technical applications, linear stability analysis typically overpredicts the wavelength by up to one order of magnitude (Markus et al., 2000, Klein et al., 2002).

Nonlinear stability analyses, taking into account some of the simplifications necessary to carry out linear theories, have been reported in the literature for some actual cases and geometrical boundary conditions. The resulting system of conservation equations is solved in the sense of stability analysis using a perturbations approach or by numerical analysis with discrete perturbations (see, e.g., Shokoohi and Elrod, 1987, Dumouchel, 1989, Rangel and Sirignano, 1991, Panchagnula et al., 1998).

For illustration, the results of a linear stability analysis based on these assumptions for a coaxial twin-fluid atomizer with external mixing and the reference system water/air with a liquid jet diameter of $d_l = 2$ mm will be discussed. The results in terms of growth rates for the symmetric mode ($m = 0$, short wave length perturbations) and the asymmetric case ($m = 1$, long wave length perturbations) are shown in Figure 19.29 and 19.30, respectively, for a variation of the relative velocity between coaxial atomizer gas and central liquid. The principal influence of process parameters on the phase boundary excitation can be shown. The relative maximum of each growth rate curve stands for the fastest growing wavelength. Comparing the symmetric mode and the asymmetric mode in this example shows that here the symmetric perturbations always yield higher growth rates than the asymmetric ones. Therefore, the symmetric jet behavior should finally lead to disintegration of the jet in this case. This result cannot be confirmed by experimental studies for these boundary conditions (Faragó and Chigier, 1992, Hardalupas et al., 1997). Hardalupas et al. (1997), experimentally analyzing the spray from a similar type of nozzle, found only a small number of droplets that are immediately sheared from the phase boundary at small wavelengths. These droplets make only a small contribution to the resulting spray; therefore, the results of the stability analysis here need to be scrutinized or extended to more realistic boundary conditions. In addition, the linear evaluation from Figure 19.30 also

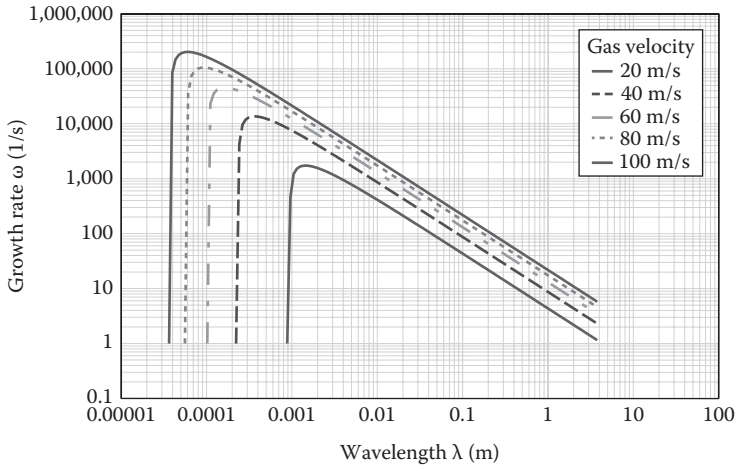

Figure 19.29

Instability growth rates of varicode mode in twin-fluid atomization of circular water jet (d_l = 2 mm, m = 0).

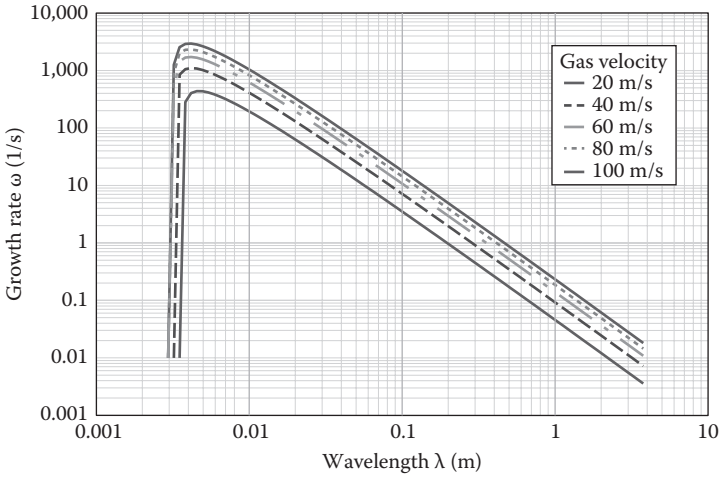

Figure 19.30

Instability growth rates of asymmetric mode in twin-fluid atomization of circular water jet (d_l = 2 mm, m = 1).

indicates that the wavelengths having the maximum growth rate show only a small dependence on the relative velocity between fluid and gas. This result is confirmed by experimental atomization investigations by Hardalupas et al. (1997).

The behavior of the jet changes for varying liquid properties. Here, especially liquid metals show remarkable differences as these have high surface tension at comparably low viscosity. Comparison of different modes of stability for a jet of molten metal in a coaxial gas flow has been discussed by Markus et al. (2000) based on the solution of the stability problem provided by Li (1995). Results for growth rates of different metal melts are shown in Figure 19.31a and results for the three basic modes of instability (m = 0, 1, and 3) for a molten steel jet are illustrated in Figure 19.31b. The results are calculated for a jet diameter of d_l = 4 mm moving at a velocity of u_l = 2 m/s in a coaxial gas flow at a constant velocity of u_g = 100 m/s. The influence of material properties on melt jet stability is observed in the left. Here, mainly the effect of the surface tension, increasing from tin (σ = 0.544 N/m) via copper (σ = 1.31 N/m) to steel (σ = 1.83 N/m), can be observed. Increasing values for surface tension result in decreasing Weber numbers, which finally also result in smaller amplitudes of the growth rate. In the same way, the dominant wavelength of jet disintegration increases. In comparison to water jets, the growth rates for molten metal jets are much lower. Here, somewhat higher energies (relative gas velocities) are needed to achieve atomization characteristics similar to water atomization. At higher relative velocities, the higher instability modes become more significant.

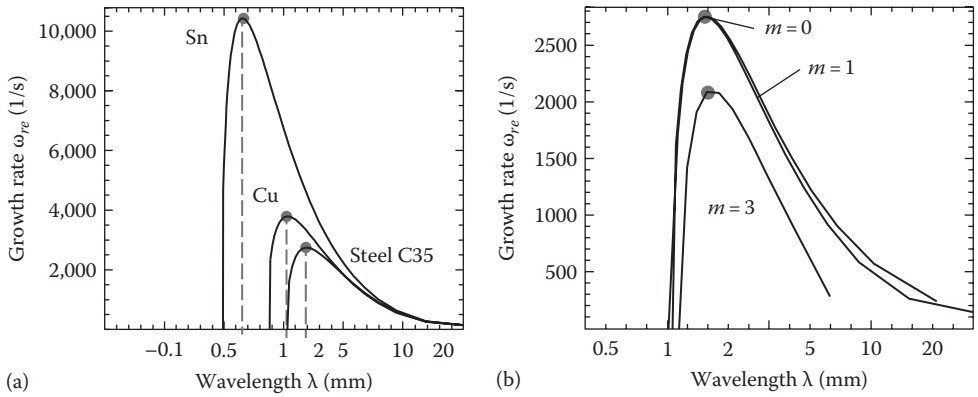

Figure 19.31

Stability curves for liquid metal jets (From Markus et al., 2002. With permission.), (a) Different metal melts and (b) basic instability modes.

Maximum growth rates in this case are observed for the symmetric mode $m = 0$; the asymmetric growth mode $m = 1$ has almost identical growth rates, while higher modes show maximum growth rates at much smaller values (see Figure 19.31b).

A comparison of calculated growth rates and wavelengths with high-speed video pictures for primary perturbation of tin and steel melt jets in Markus et al. (2000) have shown that the theoretical calculated wavelengths are smaller than observed in the experiments by one order of magnitude. This same trend has also been found by comparing experiments and direct numerical simulations (DNSs) and the results from linear theory for atomization of liquid sheets, for example, by Klein et al. (2002). However, a superposition of different modes with adapted growth rates (which do not match those in Figure 19.31) results in a quite good representation of the relevant processes of the primary perturbations of the liquid tin melt jet just in front of the exit of the atomizer nozzle. In Figure 19.32a, a picture of a primary excitation of a tin melt jet within a twin-fluid atomizer is compared to a simulated picture of the superposed three main instability modes in Figure 19.32b.

Superposition of instability modes (a) and comparison with experiment (b). (From Markus et al., 2002. With permission.)

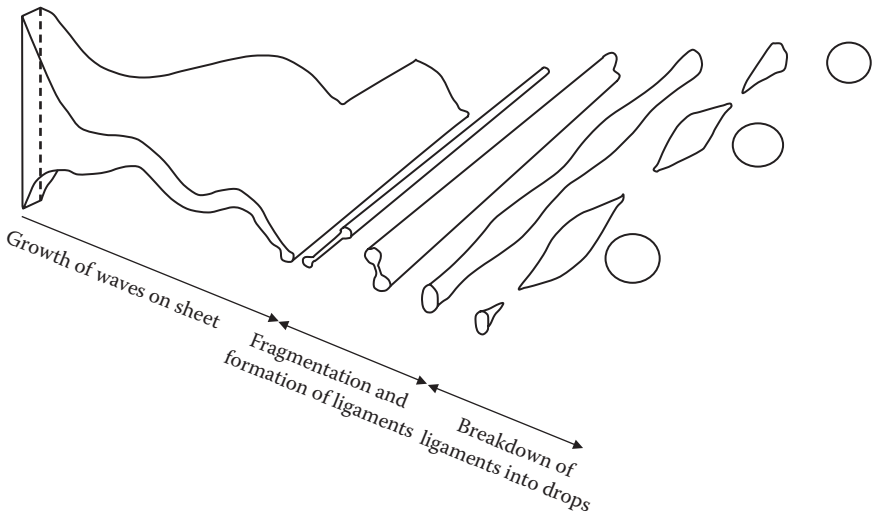

Figure 19.33

Principle of aerodynamic disintegration of a planar liquid jet. (Adapted from Dombrowski, N. and Johns, W.R., *Chem. Eng. Sci.*, 18, 203, 1963.)

In the introduced initial models for gas/liquid interface instability, the focus is on the excitation and initial growth of surface perturbations on/of the liquid jet. In a further step of fragmentation analysis, it needs to be defined when (or where) a growing liquid element is separated from the excited liquid jet (primary droplet or ligament formation). An initial analysis for derivation of the jet disintegration model and a correlation equation for the resulting droplet size distribution have been performed by Dombrowski and Johns (1963). These authors discuss (for the plane liquid jet emerging from a planar slit nozzle) the aerodynamic disintegration behavior, as illustrated in Figure 19.33. Starting from the growth of an instability on the interface, at first in longitudinal direction plane, liquid elements or ligaments are separated from the jet, which are deformed to cylindrical elements further downstream. In the next step, these cylindrical ligaments disintegrate due to capillary instabilities (Rayleigh) into the fragments that form the resulting droplet structure in the initial spray by the action of surface tension.

Additional refinements of such fundamental models for primary disintegration within twin-fluid atomization are based on a more detailed analysis of the liquid stripping mechanism from the liquid surface and the description of the most relevant wavelengths at highest growth rates. Here, the work of Berg et al. (1995) and Bürger et al. (1989, 1992) provide useful and detailed correlations. These authors observed, in agreement with Jeffrey (1924), that the gas flow field interacting with the wave in its critical condition results in a stripping mechanism just on the wave crest and not on the whole wave volume, while the mean height of the wave in its temporal average remains practically unchanged. A principal sketch of this model is shown in Figure 19.34. The turbulent boundary layer character of the gas flow is taken into account using a linear stability analysis of the liquid jet as in the model of Miles (1957). Starting from an energy balance at the wave crest, where the work done by the gas flow on the wave crest

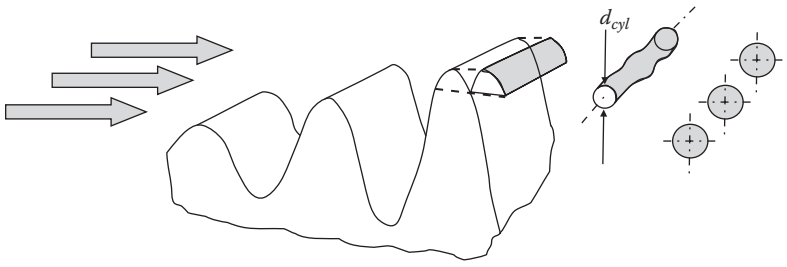

Figure 19.34

Stripping of a liquid fragment from the wave crest of a liquid sheet. (Adapted from Bürger, M. et al., *Powder Metall. Int.*, 21(6), 10, 1989.)

is related to the free surface energy that is created by the newly generated liquid surface, the critical wave height for stripping $\Delta h = \eta_{ab} - \eta_B$ is calculated as follows:

$$\Delta h = \frac{4\sigma}{C_d \rho_g u_{rel}^2} \tag{19.55}$$

In this model, a resistance coefficient C_d is introduced for the gas flow at the wave crest. This coefficient takes either a constant value (Bürger et al., 1984) or, alternatively, is derived from the local pressure distribution at the wave geometry (Bürger et al., 1992). In the latter, the resistance coefficient depends on the local height of the wave. The basic height of the wave η_B is taken as constant with a value of half of the wavelength (length to height ratio of the wave is $l/d = 2$). From this value, the variable diameter of the stripped liquid elements (in the case of a cylindrical element) d_{cyl} is derived.

A two-stage liquid fragmentation model based on stability theory has been introduced by Fritsching (2001) for coaxial twin-fluid atomization (round liquid jet) and a similar model for ring film disintegration by Lund et al. (1993). These models combine a stability analysis in the first stage, resulting in primary fragmentation of the liquid stream with a Rayleigh breakup model to derive the final drop size distribution in the spray. Input parameters of the models have been obtained by experimental and/or numerical flow field studies.

As a refinement of a modeling approach for liquid disintegration, the primary liquid fragmentation process has been coupled directly into a two-phase flow simulation in the disintegration area. Here, the behavior of both phases is simultaneously analyzed based on full conservation equations. In the first step, the stepwise stripping of fluid elements from the central jet is calculated. From this, the resulting decrease of the liquid mass within the remaining liquid jet is obtained. The contribution of the stripped fluid ligament to the successive fragmentation process and the resulting drop size distribution are calculated. In the next step, the development of the now reduced liquid jet diameter is directly related to the local gas flow field at that particular location. The stripped fluid drops and ligaments are introduced as source terms for mass and momentum in the calculation of the multiphase flow field. The continuation of the fragmentation process leads to successive stripping and smaller jet diameter. The coupling and interaction between the phases is treated in this manner. The calculated local drop size contributions of the discrete stripping events are combined to yield the final droplet size distribution in the spray. The initial configuration of the spray after atomization is derived in this way. An ongoing further fragmentation of these droplets due to secondary atomization processes is not taken into account and, therefore, the finest droplets in the calculated droplet size distribution are underrepresented (see Section 19.1.7).

19.1.6.3.3 Liquid Instability Sheet Atomization (LISA) Model A commonly used breakup model for liquid sheet fragmentation in CFD codes is the LISA model proposed by Senecal et al. (1999) and Schmidt et al. (1999). The LISA model was developed based on aerodynamic sheet stability concepts (see Figure 19.33). In the LISA model, the initial film thickness (h_0) and the injection velocity is estimated based on mass conservation, nozzle dimensions, and discharge efficiency. The model takes into account the effects of liquid viscosity, surface tension, and the surrounding gas. The LISA model assumes that wave oscillations on the liquid sheet cause its breakup into ligaments and finally into droplets. The calculated breakup length of the liquid sheet and the size of the resulting drops using a linear instability analysis can be used as a starting point of an integral spray model.

In the LISA model, the sheet is assumed to be broken into ligaments when the wave amplitude (η) reaches the local sheet thickness (h). The breakup length (L) for long waves is given by

$$L = U_{abs}\left(3\ln\left(\frac{\eta_b}{\eta_0}\right)\right)^{2/3}\left(\frac{J\sigma}{(\rho_g/\rho_l)^2 U_{rel}^2 \rho_l}\right)^{1/3} \tag{19.56}$$

and for short waves by

$$L = \frac{U_{abs}}{\omega_{max}}\ln\left(\frac{\eta_b}{\eta_0}\right) \tag{19.57}$$

where η_0 and η_b are the initial disturbance amplitude and the amplitude at the breakup point, respectively, the quantity $\ln(\eta_b/\eta_0)$ is given a value of 12, J is a constant, ω_{max} is the maximum wave growth rate, and U_{abs} and U_{rel} are the absolute sheet velocity and liquid/gas relative velocity, respectively.

For long waves in the limit of ($\rho_g/\rho_l \ll kh/2$), ω_{max} is given by

$$\omega_{max} = \max\left[-2\frac{\mu_l}{\rho_l}k^2 + \sqrt{4\left(\frac{\mu_l}{\rho_l}\right)^2 k^4 + \frac{\rho_g}{\rho_l}\frac{2U_{rel}^2 k}{h} - \frac{2\sigma k^2}{\rho_l h}}\right] \tag{19.58}$$

If short waves are assumed for high-speed sheets and ($\rho_g/\rho_l \ll 1$), ω_{max} is given by

$$\omega_{max} = \max\left[-2\frac{\mu_l}{\rho_l}k^2 + \sqrt{4\left(\frac{\mu_l}{\rho_l}\right)^2 k^4 + \frac{\rho_g}{\rho_l}U_{rel}^2 k^2 - \frac{\sigma k^3}{\rho_l}}\right] \tag{19.59}$$

The wave number k is related to the wavelength by $k = 2\pi/\lambda$. The transition from a long wavelength regime to a short wavelength regime is found to occur at a gas Weber number of $We_g = 27/16$. The gas Weber number is based on the liquid velocity, gas density, and half sheet thickness. Below the critical Weber number, instability due to long waves is dominant, while at higher Weber numbers, short waves occur with a wave rate growth independent of the sheet thickness.

In the LISA model, ligaments are assumed to form from the sheet fragmentation at the point of breakup. For the case of long waves, it is assumed that the ligaments are formed from tears in the sheet twice per wavelength and the resulting diameter is given by

$$d_L = \sqrt{\frac{4h_b}{K_s}} \tag{19.60}$$

where K_s is the most unstable wave number and given by

$$K_s = \frac{\rho_g U_{rel}^2}{2\sigma} \tag{19.61}$$

On the other hand, for short wave growth, it is assumed that the ligaments are formed from tears in the sheet once per wavelength and the resulting diameter is given by

$$d_L = \sqrt{\frac{8h_b}{K_s}} \tag{19.62}$$

where K_s is given by Equation 19.59. The film thickness at the point of breakup (h_b) can be calculated from the breakup length (L), the spray cone angle (α), and the radial distance from the centerline to the midline of the sheet at the nozzle exit (R_0) as

$$h_b = \frac{R_0 h_0}{R_0 + L\sin(\alpha/2)} \tag{19.63}$$

If it is assumed that breakup occurs when the amplitude of the unstable waves is equal to the radius of a ligament, one drop will be formed per wavelength. The drop diameter based on a mass balance is given by

$$d_d = 1.88 d_L (1 + 3\mathrm{Oh})^{1/6}, \quad \text{with } \mathrm{Oh} = \frac{\mu_l}{(\rho_l \sigma d_L)^{1/2}} \tag{19.64}$$

where Oh is the Ohnesorge number.

19.1.6.3.4 Stability of Threads in Cross-Flow Fragmentation of gravity-stretched laminar threads in gas cross-flows at low gas-relative velocities was experimentally investigated by Mescher et al. (2012), where axisymmetric threads emerging from vertically arranged and completely filled circular nozzles are significantly attenuated due to gravity until breakup occurs. The influence of the liquid flow rate, the liquid properties, and the gas cross-flow were chosen close to a typical technical application of stretched threads, that is, at the laminar operated rotary atomization (LAMBOT) process. Viscosity and liquid flow rate were confirmed to be important influences on the breakup process. Intensified gas cross-flows were found to lead to a decreasing breakup length (as shown in Figure 19.35), this is consistent with the theory for cylindrical jets. However, the mean drop size was found to increase at higher gas-relative-velocities, this is in contradiction to the theory for cylindrical jets. The increase of the drop size can be explained by larger breakup diameters of the threads due to shorter breakup lengths at higher gas-relative-velocities. The drop size is a function of both the dominating wave number (representing the breakup wavelength) and the breakup diameter. On the one hand, increased gas-relative-velocities should lead to higher dominating wave numbers and thus, theoretically, to smaller droplets. On the other hand, the breakup length decreases due to the faster growth of perturbations. For almost cylindrical jets, the influence of cross-flow intensities on the breakup wavelength may dominate. In contrast, stretched threads still significantly attenuate close to the breakup point. A distinctly increased breakup diameter occurs for a reduced breakup length. Then, the alteration of the breakup wavelength may be overcompensated and larger drops can be observed. In the range of low gas-relative-velocities, an increasing diameter of the shorter threads could be identified to cause the larger drops. At high cross-flow intensities and especially for thin threads, a fully altered nonaxisymmetric breakup mode (or wind-induced breakup) occurs. The critical gas Weber number ($We_{g,crit}$), characterizing the transition between different breakup modes, is related to the nondimensional volumetric liquid flow rate ($\dot{V}_l^\star$) and the nondimensional viscosity ($\mu^\star$):

$$We_{g,crit} = 1.92\dot{V}_l^{\star 0.15}\mu^{\star -0.39}, \quad \text{with } \dot{V}_l^\star = \dot{V}_l\left(\frac{g^3\rho_l^5}{\sigma^5}\right)^{0.25} \quad \text{and} \quad \mu^\star = \mu\left(\frac{g}{\rho_l\sigma^3}\right)^{0.25} \tag{19.65}$$

where

g is the gravitational acceleration
ρ_l is the liquid density
μ is the liquid viscosity
σ is the surface tension

The span of the DSD (drop size distribution) also increases at higher gas-relative-velocities. Correlations for the breakup length ($L^\star$), the mass-median drop size ($d^\star$), and the span of the DSD were formulated:

$$L_0^\star = 48.24\dot{V}_l^{\star 0.732}(1 + 0.679\mu^\star)^{2.375} \tag{19.66}$$

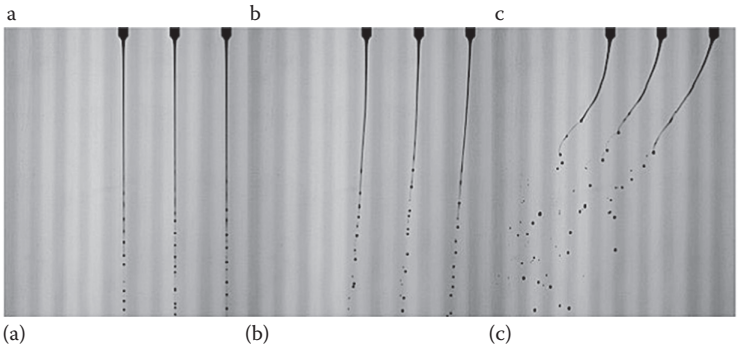

Figure 19.35

Backlight images of thread breakup in gas cross-flow. Experimental parameters: three nozzles of an inner diameter of D = 10 mm were mounted. The impact angle of the gas cross-flow was α = 90°. Glycerol/water mixture, viscosity: μ = 140 mPa s, volume flow rate per nozzle 4.4 L/h, gas Weber numbers: (a) 0, (b) 0.3, and (c) 3.3.

$$L^\star = L_0^\star - 12.56(1+\dot{V}_l^\star)^{0.996}(1+\mu^\star)^{-0.538}\mathrm{We}_g^{0.249(1+\mu^\star)^{1.906}} \tag{19.67}$$

$$d^\star = 1.043\dot{V}_l^{\star 0.259}\mu^{\star 0.038}(1+139.65\mathrm{We}_g)^{0.248(1+4.12\times10^5\mu^\star)^{-0.206}} \tag{19.68}$$

$$\mathrm{span} = (1.616 - \exp(-5.446\mathrm{We}_g - 0.605))\cdot(0.099\mu^{\star 0.364}\mathrm{We}_g + 0.183\mu^{\star -0.128}) \tag{19.69}$$

Here, the nondimensional breakup length ($L^\star$), the nondimensional mass-median drop size ($d^\star$), and the gas Weber number (We_g) are based on the capillary length $L_c = (\sigma/\rho_l g)^{0.5}$.

Kamplade et al. (2014) investigated the breakup of initially nonaxisymmetric laminar threads from open channel flow and from oval nozzles under the influence of gas cross-flows. The results indicate qualitative agreement to the investigation based on axisymmetric laminar threads (Mescher et al., 2012). The comparison to circle nozzles showed that the breakup length is significantly shorter for threads from open channel flow and from oval nozzles, possibly due to the stronger deformation of the nonaxisymmetric threads. Moreover, a lower critical We_g for the transition between the axisymmetric and the wind-induced breakup is observed for the nonaxisymmetric threads.

Gramlich et al. (2011) investigated the perturbations on gravity-stretched threads subject to gas cross-flows by means of linear stability analysis. The dispersion relation is derived as follows:

$$\begin{aligned}&\frac{(\bar{W}K_z-\Omega_T)^2}{K_z}\frac{s^2+K_z^2}{s^2-K_z^2}\frac{I_0(K_z\bar{R}_s)}{I_1(K_z\bar{R}_s)}-\frac{\rho_g}{\rho_l}\frac{K_1(K_z\bar{R}_s)}{K_1'(K_z\bar{R}_s)}\left(\Omega_T+\frac{2}{\bar{R}_s}\bar{U}_{g,rel}-K_z\bar{W}_{g,rel}\right)^2\\&-\frac{2i(\bar{W}K_z-\Omega_T)}{\mathrm{Re}}\left[\frac{-2K_z^2}{s^2-K_z^2}\left(s\frac{I_0(s\bar{R}_s)}{I_1(s\bar{R}_s)}-\frac{1}{\bar{R}_s}\right)+\frac{s^2+K_z^2}{s^2-K_z^2}\left(K_z\frac{I_0(K_z\bar{R}_s)}{I_1(K_z\bar{R}_s)}-\frac{1}{\bar{R}_s}\right)\right]+\frac{1}{\mathrm{We}}\left(\frac{1}{\bar{R}_s^2}-K_z^2\right)=0\end{aligned} \tag{19.70}$$

where

$s^2 = K_z^2 + i\,\mathrm{Re}(\bar{W}K_z - \Omega_T)$ is the dispersion parameter

$I_0(K_z\bar{R}_s)$ and $I_1(K_z\bar{R}_s)$ are the modified Bessel's functions of the first kind

$K_1(K_z\bar{R}_s)$ is the modified Bessel's function of second kind with its derivative $K_1'(K_z\bar{R}_s)$

Dimensionless numbers $\bar{W}$, $\bar{U}_{g,rel}$, and $\bar{W}_{g,rel}$ are time-averaged liquid axial velocity, radial relative velocity, and axial relative velocity, respectively, scaled by the initial liquid axial velocity ω_0; dimensionless numbers $\bar{R}_s$ and Z are the time-averaged jet radius and distance along the jet axis, respectively, scaled by the initial jet radius r_0. Complex quantities $K_z = K_r + iK_i$ and $\Omega_T = \Omega_r + i\Omega_i$ are the spatial and temporal wave functions, respectively. The real parts with their derivatives $K_{r,z} = dK_r/dZ$ and $\Omega_{r,T} = d\Omega_r/dT$ are the wave number and the circular frequency of the oscillation, respectively, whereas the imaginary parts K_i and Ω_i characterize the spatial and the temporal growth or decay of the perturbation, respectively. T is the dimensionless time as $T = t\omega_0/r_0$. The wave with the critical wave number $K_{r,Z,crit}$, resulting in maximum growth of the disturbance $\Omega_{i,\max}$, leads to breakup of the jet into droplets. For the spatial stability analysis, the spatial growth rates $K_{i,Z}$ are determined for fixed values of the angular frequency $\Omega_{r,T}$. The drop size results from the volume-equivalent jet segment with the axial extension λ and the time-averaged cross-sectional area at the breakup point for both temporal and spatial instability:

$$\frac{d}{d_0} = \frac{1}{2}\sqrt[3]{\frac{12\pi}{K_{r,Z,crit}}(\bar{R}_s\big|_{Z=L})^2} \tag{19.71}$$

19.1.6.4 Direct Numerical Simulation

Recent investigations describe the complex behavior of the liquid jet and the gas/liquid interface, including the primary fragmentation process in atomization, using DNS of the multiphase flow system (see, e.g., Mayer, 1993, Lozano et al., 1994, Zaleski et al., 1995, Zaleski and Li, 1997, Lafaurie et al., 1998, Scardovelli and Zaleski, 1999, Klein et al., 2001, 2002, Zaleski and Boeck, 2003, Menard et al., 2007, Desjardins et al., 2008, Desjardins, 2009, Gorokhovski and Herrmann, 2008, Shinjo et al., 2010, Zhu et al., 2013, Zhu, 2014).

The progress in DNS of liquid atomization and liquid fragmentation processes as well as in elementary liquid processes, such as liquid interface coalescence, is tremendous. Appropriate length and time scales are increasingly resolved. The success of fundamental research in this area is mainly driven by tremendously increasing computer power; however, carrier of the progress is the successful cooperation of related disciplines such as physics, chemistry, engineering, and mathematics, respectively.

19.1.6.4.1 Single-Fluid Formulation Direct numerical simulations (DNSs) of liquid atomization and liquid fragmentation processes are based on the continuum approach through integrating the single-fluid Navier–Stokes (NS) equations and identifying the gas/liquid interface at each time. The goal of such a DNS is to resolve all time and length scales, solving the governing equations directly. Because most primary atomization applications occur at low Mach numbers and the two fluids involved are immiscible, the flow is governed by the unsteady Navier–Stokes equations in the variable density, incompressible limit

$$\frac{\partial \rho \vec{U}}{\partial t} + \vec{U} \cdot \nabla \rho \vec{U} = -\nabla p + \nabla \cdot (\mu(\nabla \vec{U} + \nabla^T \vec{U})) + \rho \vec{g} + \vec{F}_s \tag{19.72}$$

$$\nabla \cdot \vec{U} = 0 \tag{19.73}$$

where

U is the velocity
ρ is the density
p is the pressure
μ is the dynamic viscosity
g is the gravitational acceleration
F_s is the surface-tension force, which is a singular force active only at the location of the phase interface Γ

There are three different approaches to model the surface-tension force in this context.

The first approach is the continuum surface force (CSF) method (Brackbill et al., 1992) defined as

$$\vec{F}_s = \sigma \kappa \vec{n}_f \delta(\vec{x} - \vec{x}_f) \tag{19.74}$$

where

κ is the mean curvature of the phase interface
n_f is its normal vector
δ is the delta function concentrated on the phase interface

The second approach is the continuous surface stress (CSS) model (Lafaurie et al., 1994, Gueyffier et al., 1999, Scardovelli and Zaleski, 1999) where the surface-tension force is expressed as the divergence of a surface-tension tensor:

$$\vec{F}_s = -\nabla \cdot ((\mathrm{I} - \vec{n} \otimes \vec{n}) \sigma \delta(\vec{x} - \vec{x}_f)) \tag{19.75}$$

The discretization of the delta function in both CSF and CSS models usually spreads the surface-tension force into a small neighborhood normal to the phase interface. To avoid an interface thickness, an alternative is to use the ghost-fluid method (Kang et al., 2000, Tanguy and Berlemont, 2005, Hong et al., 2007), in which the surface-tension force is acting though the pressure jump condition at the phase interface,

$$[p]_\Gamma = \sigma \kappa + 2[\mu]_\Gamma \vec{n}^T \cdot \nabla \vec{U} \cdot \vec{n} \tag{19.76}$$

and a discretization of the delta function is thus not required.

Interface capturing models (Gorokhovski and Herrmann, 2008, Ashgriz, 2011) are usually applied to obtain the gas/liquid interface evolution and topology by solving an advection equation of an indicator (Φ) that can be attributed to the interface:

$$\frac{\partial \Phi}{\partial t} + \vec{U} \cdot \nabla \Phi = 0 \tag{19.77}$$

The normal vector and curvature are computed from the indicator function using the following formulas:

$$\vec{n}_f = \nabla\Phi, \quad \vec{n} = \frac{\nabla\Phi}{|\nabla\Phi|}, \quad \text{and} \quad \kappa = -\nabla\cdot\vec{n} \tag{19.78}$$

Within interface capturing scheme, two principal methods are the volume of fluid (VOF) method (Hirt and Nichols, 1981, Scardovelli and Zaleski, 1999) and the level set (LS) method (Osher and Sethian, 1988, Sethian, 1996, Osher and Fedkiw, 2002).

19.1.6.4.2 Volume of Fluid (VOF) Method In the VOF method, a volume fraction (f) is defined in each cell as the fraction of the cell containing liquid. If the cell is completely filled with liquid, then $f = 1$, and if it is filled with gas, then its value should be $f = 0$. At the location of the gas/liquid interface, the value of f is between 0 and 1 ($0 < f < 1$). Therefrom, the physical properties in the governing equations can be expressed as

$$\rho = \rho_l f + \rho_g (1-f) \quad \text{and} \quad \mu = \mu_l f + \mu_g (1-f) \tag{19.79}$$

Discontinuity in f propagates according to Equation 19.77, where Φ is replaced with f. In a physical sense, the equation implies mass conservation of one phase in the mixture. The gas/liquid interface needs to be reconstructed in each cell since interface information is lost when the interface is represented by a volume fraction field. Gopala and van Wachem (2008) give a useful comparison between different interface sharpening and reconstruction algorithms in a variety of CFD codes. In general, the geometric piecewise linear interface calculation (PLIC) method (Zaleski et al., 1995, van Wachem and Schouten, 2002) is commonly used because of its accuracy and applicability for complex flows. In the PLIC method, the interface is approximated by a straight line of approximate inclination in each cell. A typical reconstruction of the interface with a straight line in a cell, which yields an unambiguous solution, is perpendicular to an interface normal vector $\boldsymbol{n}_f$ and delimits a fluid volume matching the given volume fraction f for the cell. In the open-source CFD code OpenFOAM, the interface compression scheme of Weller (2008) and Wardle and Weller (2013) has been implemented as interface sharpening methodology, which adds an additional "artificial" compression term to the LHS of the volume fraction transport equation (Equation 19.77 replacing Φ with f).

19.1.6.4.3 Level Set (LS) Method In an LS method, a continuous function F is defined as the signed distance between any point of the domain and the interface. The function F is set to zero at the interface, is positive on one side, and negative on the other. Solving the advection equation (19.77), where Φ is replaced by the LS function F, determines the evolution of the interface. However, as the front propagates, high velocity gradients can produce wide spreading and stretching of the LS, and F will no longer remain a distance function. A reinitialization algorithm is thus applied to keep F as the signed distance to the interface. An iterative procedure is proposed by Sussman et al. (1998) to maintain F as a distance function.

The major drawback of the LS method is that it does not inherently conserve liquid mass. Since liquid volume errors are proportional in size to the employed grid resolution, grid refinement strategies, such as the refined level-set grid (RLSG) method (Herrmann, 2008) and structured adaptive mesh refinement (AMR) (Nourgaliev and Theofanous, 2007), can be employed to reduce their influence. An alternative to grid refinement is to augment and correct the LS function by an additional numerical scheme,, for example, coupling LS and VOF (CLSVOF) (Sussman and Puckett, 2000, van der Pijl et al., 2005). The main concept of the CLSVOF method is to benefit from the advantage of both LS and VOF methods: mass loss is limited through the VOF method and a fine description of interface properties is kept with the LS method.

19.1.6.4.4 DNS of Primary Atomization Such complete three-dimensional, transient, direct numerical analyses, from initial liquid jet deformation to the primary fragmentation of the liquid jet, are based on modeling approaches such as the VOF method (Nichols et al., 1980) in combination with surface reconstruction methods (Brackbill et al., 1992) like the PLIC method (Zaleski et al., 1995). The primary liquid fragmentation and also the simultaneous coalescence of fluid elements are analyzed in this way. Typically, the excited fragmentation of a planar liquid sheet in a parallel gas flow field is observed in a three-dimensional calculation. In Figure 19.36, a sequence of a result from a fragmentation simulation from Zaleski and Li (1997) is shown. The calculation has been performed for a liquid Reynolds number $\mathrm{Re}_l = 200$, a liquid

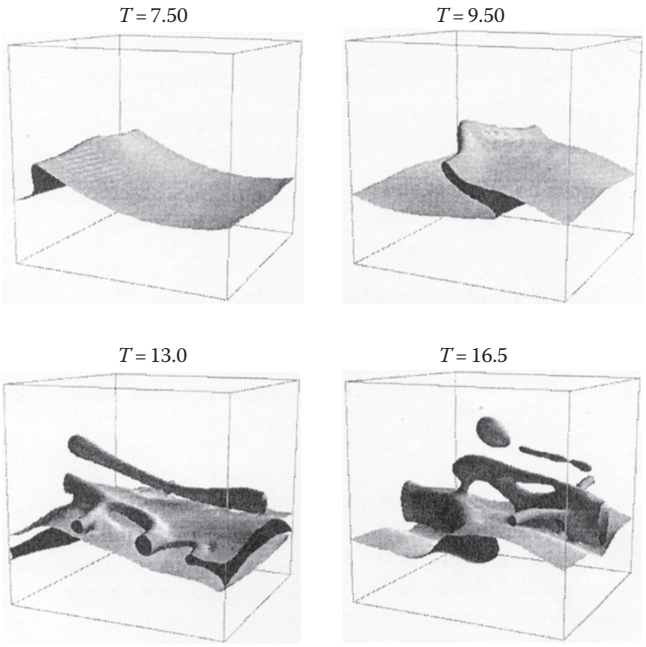

Figure 19.36

DNS of liquid jet fragmentation, $Re_l = 200$, $We_l = 300$, $\rho_l/\rho_g = 10$. (Adapted from Zaleski, S. and Li, J., Direct simulation of spray formation, in *Proceedings of ICLASS-'97*, Seoul, Korea, August 1997, pp. 812–819.)

Weber number of $We_l = 300$ at an artificially low density ratio between liquid and gas of $\rho_l/\rho_g = 10$ (at higher density ratios no stable solutions are achieved). From the tip of the evolving wave, a finger-type ligament is formed, which is stripped off in a later stage from the main liquid jet and is deformed and stretched into the main flow direction to form a cylindrical fluid element. This unstable fluid element is fragmented later on as a result of capillary instabilities. This disintegration results in smaller fragments of different sizes. It is interesting to note that a result of this simulation is that a primary fluid ligament results from initial fragmentation that is orientated in the direction of the main flow (fingering in flow direction). In contrast to this result, the former classical aerodynamic fragmentation models such as Dombrowski and Johns (1963) (see Figure 19.33) used a stripped-of fluid ligament orientated perpendicular to the main flow direction.

A direct numerical calculation (in two dimensions) of the dynamics of phase boundaries of a planar liquid sheet has also been performed based on the VOF method by Lafaurie et al. (1998) and Klein et al. (2002). In their contributions, some major effects of liquid parameters like density ratio, viscosity ratio, and capillary effects on the primary fragmentation mechanism are discussed based on simulation results and comparisons to experimental results.

Zhu et al. (2013) and Zhu (2014) performed DNSs on the primary breakup of inelastic non-Newtonian liquid (PVP solution) jets into stagnant air, with a high liquid/gas density ratio $\rho_l/\rho_g = 871$. The VOF method is employed together with CSS model. The range of the investigated nondimensional quantities covers: Reynolds number (Re_l): 492–1,312, Weber number (We_l): 5,867–41,719, and Ohnesorge number (Oh): 0.1557. The non-Newtonian viscosity is described by modified power law model. Three different destabilizing factors, including inlet velocity profile, inlet Reynolds number, and inflow turbulence, are considered. Compared to Newtonian jets with a similar viscosity, the size of streamwise vortices within the liquid phase is relatively smaller, while the number of vortices is greater. Meanwhile, streamwise contrarotating vortex pair (CVP) and even triple vortex structures are observed in the liquid phase. Two different regimes of ligament formation have been observed. One is caused by the Rayleigh capillary instability, while the other is a result of stretching. A specific shear thinning breakup mechanism, the cavity breakup, is detected, which gives a novel perspective for the analysis of jet disintegration.

Menard et al. (2007), Lebas et al. (2009), and Shinjo et al. (2010) have successfully employed the CLSVOF method in 3D DNS of the primary atomization of a turbulent liquid jet into stagnant air. In Menard et al. (2007) and Lebas et al. (2009), the ghost-fluid method is used to model the surface-tension force, while in Shinjo et al. (2010), the CSF method is applied. These DNSs have been performed with very fine grid

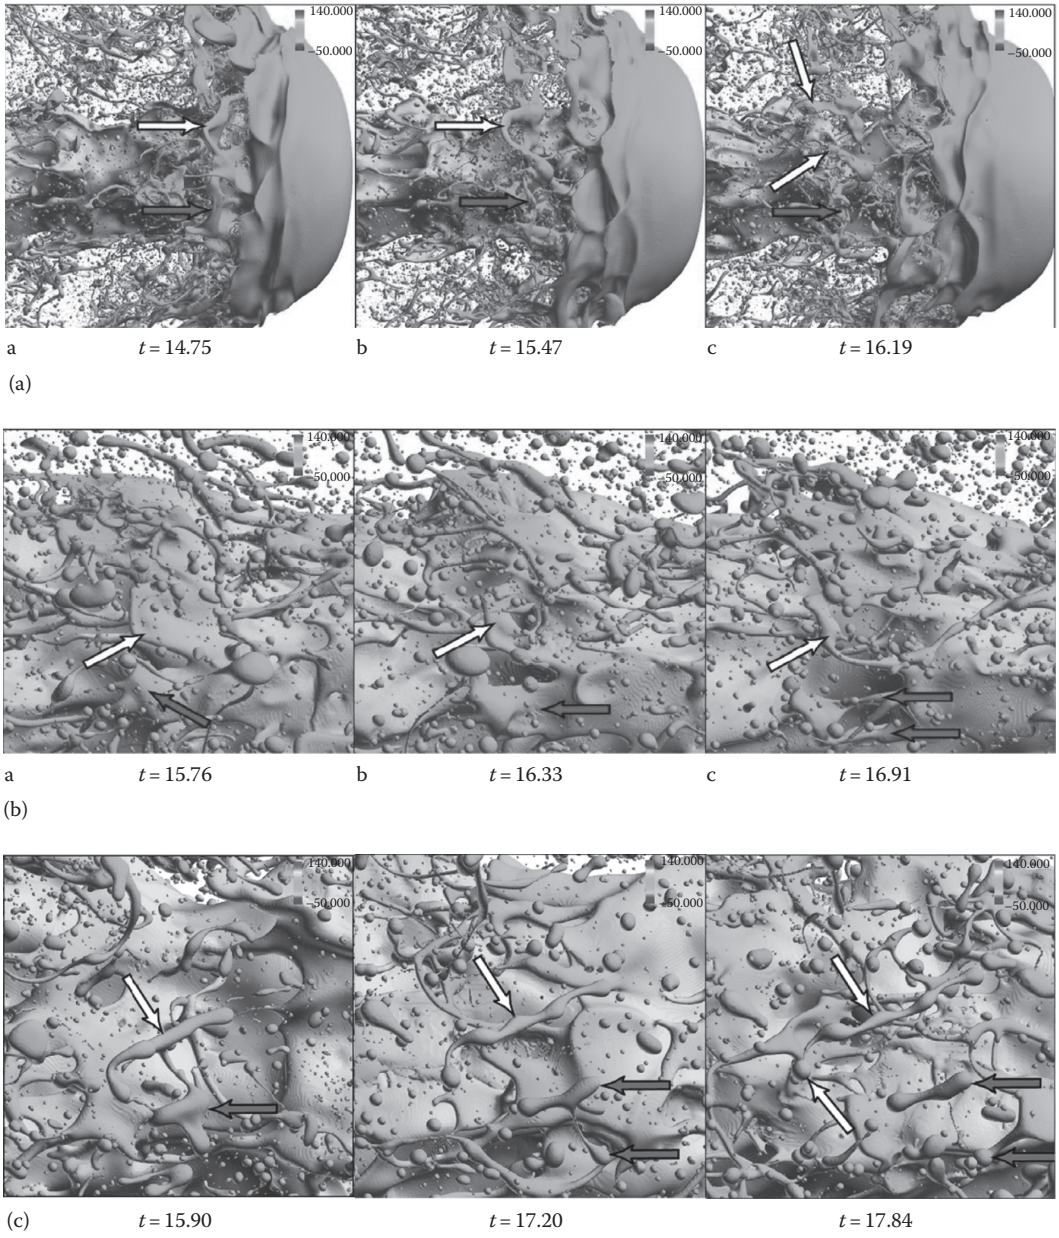

Figure 19.37

(a) Ligament formation from tip edge. (b) Ligament formation from liquid core. (c) Droplet formation from ligament. The greyscale/color indicates the axial velocity in m/s. The flow is from left to right. Bulk liquid Reynolds number $Re_l = 1{,}470$ and bulk liquid Weber number $We_l = 141{,}000$. Nondimensional time $t = t_{real}/(D/U_l)$ with nozzle diameter $D = 0.1$ mm and liquid injection velocity $U_l = 100$ m/s. (Adapted from Shinjo, J. and Umemura, A., *Int. J. Multiphase Flow*, 36, 513, 2010. With permission.)

resolution (grid spacing 0.35–2.36 μm). Therefrom, more detailed information in liquid atomization process can be revealed. Shinjo et al. (2010) found that ligament formation occurs both from the liquid jet tip roll-up (Figure 19.37a) and the liquid core surface (Figure 19.37b). In Figure 19.37a, the mushroom-shape tip is created due to the lateral liquid spread by impingement against the stagnant gas and roll-up by the initial Rayleigh–Taylor (R–T) instability; from the mushroom tip edge, quasi-axisymmetric (or ring-like) ligaments (indicated by the grey arrow) and streamwise ligaments (indicated by the white arrow) are generated alternately. In Figure 19.37b, crests are formed on the liquid core due to surface instability and breakup into ligaments: in the case indicated by the white arrow, the crest breaks up into only one ligament; while in the case indicated by the grey arrow, the central part of the flat crest soon becomes thinner than the rim, and

then a hole is created and grows due to contracting motion by surface tension in the central region of the flat crest, finally resulting in the formation of two ligaments. Shinjo et al. (2010) pointed out that shear from local vortices plays an important role in the ligament formation, and ligaments are created when $We_g \sim O(1)$, where We_g is the local gas Weber number of a ligament based on the baseline radius of the ligament. In Figure 19.37c, droplet formation occurs from the ligament tip mostly by the short-wave mode (as indicated by the grey arrow), and surface capillary wave propagation is clearly observed (as indicated by the white arrow). Recollision of ligaments and droplets often happens and enhances next breakup:

19.1.6.5 Large Eddy Simulation (LES)

In a DNS, the goal is to reduce epistemic uncertainty by resolving all necessary time and length scales inherent in the flow and thus eliminating the need to model the effect of any unresolved scales (Gorokhovski and Herrmann, 2008). In a single-phase turbulent flow, the smallest length scale that must be resolved is the Kolmogorov length scale. Multiphase flows add an additional smallest length scale that requires resolution, the size of the smallest liquid structure. This implies the DNS of primary atomization with a limited domain size, simple geometries, and low turbulent Reynolds numbers.

Reynolds-averaged Navier–Stokes (RANS) formulation can be introduced in industrial solvers. In this case, almost any configuration may be resolved, but much information concerning the liquid properties remains unknown, and the accuracy of the results may be quite low in some situations. Some RANS studies of primary atomization process based on VOF interface capturing can be found in Rivas et al. (2014) and Li and Fritsching (2014a). In Rivas et al. (2014), a 3D numerical simulation of the internal flow in a conical swirl atomizer, as well as the initial water-sheet formation near the nozzle exit, was performed based on the VOF approach and the standard k–ε turbulence model. Because of the low grid resolution, only some macroscopic phenomena such as flow field (velocity and pressure) at the entrance to swirl chamber and the cone angle of the conical sheet after the nozzle exit have been described. In Li and Fritsching (2014a), the formation of a swirling conical sheet and its fragmentation near the nozzle exit were numerically investigated based on the VOF approach, the k–ω SST (shear stress transport) turbulence model, and the AMR technique. The liquid sheet evolution and breakup after the nozzle exit have been described based on a 3D simulation, while more details about spray characteristics such as droplet size and droplet velocity have been extracted from a 2D-axisymmetric simulation. Figure 19.38 exhibits the temporal evolution of a swirling conical sheet of liquid tin (Sn) from the 3D simulation, which indicates two kinds of instabilities existing in the sheet surface: one grows in the longitudinal direction, while the other in the circumferential direction. The latter wavelength (several millimeters) is one order of magnitude larger than the former (hundred micrometers). The ligament formation can be observed. The interconnected ligaments form cellular structures (or perforations), and finally disintegrate into droplets. With the propagation of the liquid sheet, the number of computational cells has increased from ~3.5 million in the base grid to ~12 millions at t = 4.5 ms.

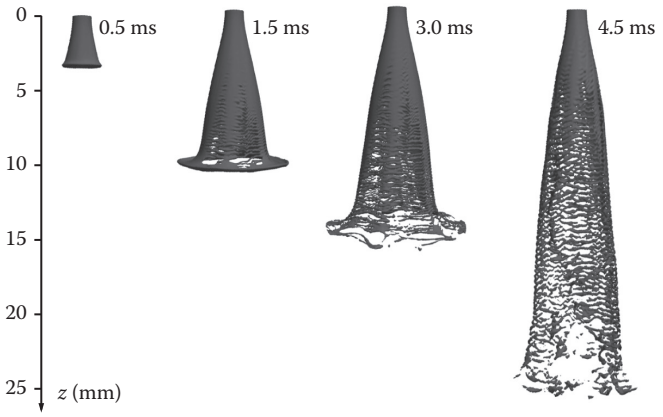

Figure 19.38

3D simulation: temporal evolution of a swirling conical sheet of melt tin (Sn) from a pressure swirl nozzle, Δp_l = 0.6 MPa, D_0 = 1.3 mm. (Adapted from Li, X.G. and Fritsching, U., Multiscale modeling and simulation in spray processing of composite particles, in *Proceedings of Second International Symposium on Multiscale Multiphase Process Engineering*, Hamburg, Germany, September 24–27, 2014b.)

To overcome those difficulties encountered in DNSs and RANS simulations, the current trend in turbulence modeling is the development of LESs. LES is a promising technique between industrial RANS solvers and academic DNS solvers. It solves the largest scales of the flow while the impact of the smallest scales (or the subgrid scales) is modeled. The LES studies of primary atomization process based on interface tracking/capturing schemes can be found in de Villiers et al. (2004), Bianchi et al. (2007), Corbinelli et al. (2010), Desjardins et al. (2013), Xiao et al. (2014), and Tian et al. (2015). In Desjardins et al. (2013), a conservative LS method is used for interface capturing, while in Xiao et al. (2014), a CLSVOF method coupled with ghost fluid method is used. Other studies use VOF interface capturing:

$$\frac{\partial \bar{\Phi}}{\partial t} + \bar{u}_i \cdot \frac{\partial \bar{\Phi}}{\partial x_i} = -\left(\overline{u_i \frac{\partial \Phi}{\partial x_i}} - \bar{u}_i \frac{\partial \bar{\Phi}}{\partial x_i} \right) \tag{19.80}$$

When a usual LES formalism is applied to the interface capturing equation (19.77), an unresolved term appears on the right-hand side of the resulted equation (19.80) and a model is necessary to account for the unresolved subgrid correlation between the velocity and the phase function. However, all the LES studies discussed consider standard subgrid scale (SGS) models for the momentum conservation equation but not for the interface equation. Thus, the impact of the subgrid flow properties on the droplet formation process is neglected and only the large-scale instabilities participate in the spray formation.

Chesnel et al. (2011a) carried out a priori analysis of the subgrid to evaluate the order of magnitude of the contributions of these terms to the flow evolution, where a DNS by use of the CLSVOF method was applied as a reference. The results show that the interface evolution is not mainly controlled by large-scale convection phenomena, and the subgrid contribution results in globally up to 10% of the resolved contribution. Thus, it is necessary to take into account the impact of the small scales on the interface propagation. Furthermore, at the interface level close to the injection, the order of magnitude of the subgrid correlations strongly increases. Therefore, a closure of the interfacial subgrid term has been proposed by Chesnel et al. (2011a,b) based on a scale similarity assumption to close all the subgrid unresolved terms in comparison with a Smagorinsky formulation (Smagorinsky, 1963).

19.1.6.6 Multiscale Simulation Coupling ICM and LPT

The primary atomization of a liquid jet into small droplets is a multiscale phenomenon, in which the size of the smallest droplet is often three orders of magnitude smaller than the diameter of the atomizing liquid jet. DNS with interface tracking/capturing schemes is very useful in understanding fundamental physics of atomization. However, the range of scales that can be covered by DNS with computing ability today is still often much smaller than practical applications. For example, even with a mesh resolution of 0.35 μm (Shinjo and Umemura, 2010), the finest scales of the flow are still not resolved. To optimize the computational cost, some studies use an AMR (Fuster et al., 2009, Agbaglah et al., 2011), but there is still a numerical cut-off scale. To resolve this multiscale challenge in atomization simulation, coupled Eulerian–Lagrangian multiscale models have been proposed by Tomar et al. (2010), Herrmann (2010), Hecht et al. (2013), Osmar et al. (2013), Ling and Zaleski (2014), and Grosshans et al. (2014). In these multiscale models, interface capturing method (ICM) (the Eulerian approach), such as VOF, LS, and CLSVOF methods, describe the large scales of gas/liquid interface during atomization, while the Lagrangian particle tracking (LPT) approach is employed to model the droplets smaller than the Eulerian grid size. The purpose of the coupling procedure is to identify separated regions Ω_d of liquid in gas fulfilling certain criteria, to remove these from the interface capturing representation, and to insert them into a Lagrangian framework, preserving their volume V_d, center of mass x_d, and momentum $\rho_d u_d$:

$$V_d = \int_{\Omega_d} d\vec{x}, \quad \vec{x}_d = \frac{1}{V_d} \int_{\Omega_d} \vec{x}\, d\vec{x}, \quad \text{and} \quad \vec{u}_d = \frac{1}{V_d} \int_{\Omega_d} \vec{u}(\vec{x}) d\vec{x} \tag{19.81}$$

where ρ_d is the constant liquid density. The removal criteria can be based on the derivation assumptions of typical Lagrangian spray models, that is, that individual drops be small and nearly spherical. The size criterion can be expressed in terms of a thresh volume V_{cut} (e.g., the grid volume), in that only those separated liquid structures with volume $V_d < V_{cut}$ are candidates for removal. The shape criterion can be expressed in

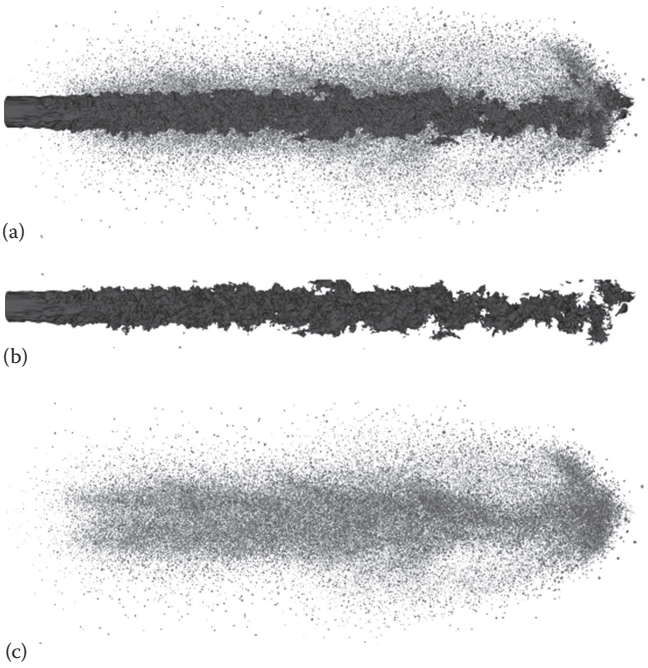

Figure 19.39

Atomization of turbulent liquid jet 20 μs after start of injection. Liquid core and spray (a), tracked phase interface of liquid core (b), and Lagrangian tracked spray (c). Injection Reynolds number $Re_l = 5{,}000$ and Weber number $We_l = 17{,}000$. (Adapted from Herrmann, M., *J. Comput. Phys.*, 229, 745, 2010. With permission.)

terms of an eccentricity measure threshold e_{cut}. Different formulations of eccentricity measure are given by Herrmann (2010) and Hecht et al. (2013), respectively. The Lagrangian to Eulerian transfer has also been considered by Herrmann (2010) in some situations where Lagrangian drops may grow due to drop/drop collisions or move from grid regions of low resolution into that of high resolution so that the drop's size becomes significantly larger than the local grid spacing. The multiscale coupling approach links DNS of the liquid core and the dense spray regime to the LPT simulation of the dilute spray regime. Compared with a full DNS, the computational cost will be reduced by this coupling approach as the unresolved droplets, which are computational expensively tracked in DNS, are only tracked in the LPT frame if these droplets are judged to satisfy Eulerian to Lagrangian transfer criteria. Hecht et al. (2013) pointed out that the transformation between Eulerian droplets and Lagrangian droplets may cause some difficulties to conserve some physical quantities of the system.

Figure 19.39 shows the atomizing liquid jet, the remaining tracked phase interface geometry, and the transferred Lagrangian drops from multiscale simulation of the primary atomization of a turbulent liquid jet at 20 μs after injection into still compressed air under conditions relevant to diesel engine systems (Herrmann, 2010). The injector diameter and the mean injection velocity are $D = 100$ μm and $U = 100$ m/s, respectively. The multiscale simulation has been performed for a liquid Reynolds number $Re_l = 5{,}000$ and a liquid Weber number $We_l = 17{,}000$ at a liquid/gas density ratio $\rho_l/\rho_g = 34$. The RLSG method proposed in Herrmann (2008) has been used to track gas/liquid interface during atomization. In Figure 19.39, roughly 403,000 drops have been transferred into the Lagrangian spray model. Diameters of these transferred drops range from the submicron size up to 10.8 μm. The total computer time per time step needed to identify and remove separated structures is less than 1% of the total computer time of a single time step, which demonstrates the high efficiency of the multiscale atomization model and its applicability to realistic problems.

In Tomar et al. (2010), the multiscale simulation of atomization of a liquid jet by a high-speed coaxial gas flow has been performed based on coupled VOF and LPT approach for a high liquid/gas density ratio of 100 and a high momentum ratio ($M = \rho_g U_g^2/(\rho_l U_l^2)$) of 16. The PDFs of the droplets are derived, which indicates two mechanisms of droplets formation, namely, by primary atomization of the jet and another by breakup of bigger fragments of liquid emerging downstream. The smallest droplets interact with the bigger lumps of liquid downstream, leading to a shift in the droplet size distribution to large droplet sizes.

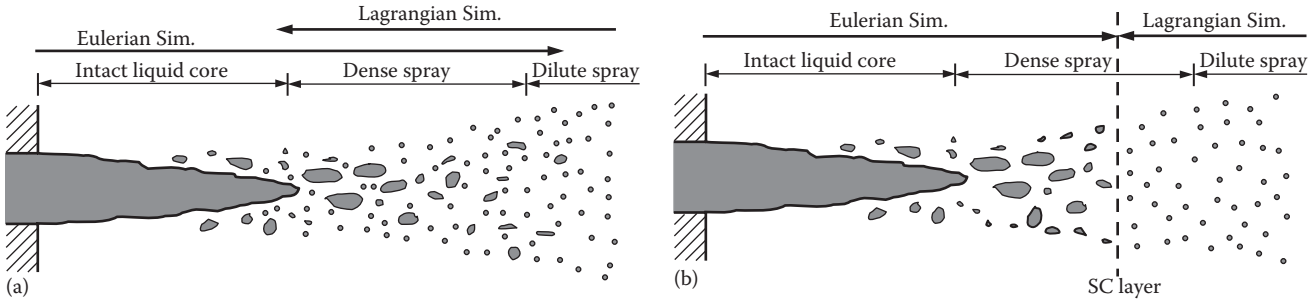

Figure 19.40

Schematic of coupled Eulerian–Lagrangian approaches for liquid atomization: (a) direct coupling approach, DCA; (b) statistical coupling approach, SCA.

Grosshans et al. (2014) categorize coupled Eulerian–Lagrangian approaches into direct coupling approach (DCA) and statistical coupling approach (SCA), as shown in Figure 19.40. In the DCA, each droplet that leaves the Eulerian simulation is injected individually in the LPT simulation, as in Tomar et al. (2010), Herrmann (2010), Hecht et al. (2013), Osmar et al. (2013), and Ling and Zaleski (2014), and both Eulerian and Lagrangian simulations covering the whole spray development are performed in parallel in a same physical domain (or an overlapped physical domain). However, in the SCA, only the statistical distribution of the droplet field properties is transferred from Eulerian to Lagrangian simulation instead of transferring each droplet individually. Compared with the DCA, this leads for two reasons to a computational significantly faster method:

1. In the SCA, the Eulerian simulation has to be run only until statistical convergence of the droplet distributions and not during the whole spray development. A layer, called the statistical coupling (SC) layer, is introduced close to the outlet of the Eulerian simulation (see Figure 19.40b). This layer has to be positioned far enough downstream from the injector, so that the spray is diluted enough to be simulated with the LPT approach. The liquid mass passing through the layer is analyzed. The statistical parameters of the droplet distributions at this layer are extracted from the Eulerian simulation and applied as starting conditions for the LPT simulation. In the SCA, the Eulerian simulation and the LPT simulation can be performed in different physical domains. According to the nature of the numerical methods, the time step and the grid size of the Eulerian simulation by interface capturing schemes are at least one order of magnitude smaller than the ones of LPT simulation. Thus, the computational time of a droplet traveling a certain distance in the Eulerian domain is several orders of magnitude larger than in the LPT domain. In the DCA, the computational time during the whole multiscale atomization simulation is determined by the Eulerian simulation.
2. In the DCA, each droplet in the particle cloud in the LPT simulation is tracked individually. The large number of droplets in a practical spray cannot be handled on individual bases. In the SCA, the droplets can be tracked in the LPT simulation using the stochastic parcel method. Here, a number of droplets are grouped in one parcel. All the droplets within the parcel are assumed to have the same properties, such as same size, position, velocity, temperature, distortion, and composition. Using the stochastic parcel method makes the description of a complete spray process feasible in the SCA.

For statistically stationary sprays, the accuracy of the SCA is only marginally lower than that of the DCA (Grosshans et al., 2014). The drawback of the SCA compared with the DCA is that the coupling layer is fixed in space. Therefore, it cannot be at the ideal position for all liquid structures to be transferred from the Eulerian to the LPT simulation. Another drawback of the SCA is that it cannot deal with transient sprays.

Based on the principle of the SCA, Li and Fritsching (2014a) performed integral process modeling and simulation of PGA of molten metal for powder production. The primary disintegration of swirling conical liquid sheets of the molten metal is described by the VOF approach, while the subsequent droplet spray process is simulated through the LPT approach by taking into account the secondary breakup of produced droplets as well as other in-flight spray phenomena. The characteristics of liquid sheet fragmentation such as breakup length, primary droplet size, and velocity are derived and applied as the

initial conditions for the droplet spray process simulation. The coupled atomization and spray simulation obtained a good prediction of the (MMD) of the metal powder produced by the PGA process.

19.1.6.7 Eulerian–Lagrangian Spray Atomization Model

The Eulerian–Lagrangian spray atomization (ELSA) model, initially proposed by Vallet et al. (2001) and further developed by Blokkeel et al. (2003), Lebas et al. (2005, 2009), Ning et al. (2009), and Chesnel et al. (2011b), is based on an Eulerian approach, which is more suitable for the description of the dense zone of the spray and its atomization. Within the diluted spray region, the ELSA model could switch to the traditional Lagrangian description of the liquid phase. The ELSA model considers the situation of high-speed turbulent sprays where Reynolds and Weber numbers are high, and it proposes a turbulent mixing process between the liquid and surrounding gaseous phases as a single-phase turbulent fluid flow with mean properties. Therefrom an assumption similar to the Kolmogorov hypothesis has been invoked: large-scale features of the flow are supposed to be independent of viscosity and surface tension at high Reynolds and Weber numbers; small-scale features do depend on viscosity and surface tension (Vallet et al., 2001). The separation of the large-scale flow features from the atomization process occurring at smaller scales allows the direct simulation of the large-scale bulk transport of the liquid, while unresolved turbulent transport is modeled using standard closures such as those used in Reynolds-averaged turbulence models (Vallet et al., 2001, Lebas et al., 2009) or LES models (Chesnel et al., 2011b). The small-scale atomization is modeled by solving a transport equation for the evolution of gas/liquid interface density Σ, which is defined as the quantity of gas/liquid interface per unit volume (m^{-1}).

The key formulae in the ELSA model are summarized as follows. Mean liquid volume fraction is denoted ($\overline{Y}$) and mean liquid mass fraction ($\tilde{Y}$) is defined as

$$\tilde{Y} = \frac{\overline{\rho Y}}{\overline{\rho}} \tag{19.82}$$

where $\overline{\rho}$ is the mean density of the mixture, which is obtained as

$$\overline{\rho} = \rho_l \overline{Y} + \rho_g (1 - \overline{Y}) \quad \text{or} \quad \frac{1}{\overline{\rho}} = \frac{\tilde{Y}}{\rho_l} + \frac{1 - \tilde{Y}}{\rho_g} \tag{19.83}$$

with the liquid density (ρ_l) and the gas density (ρ_g). The Favre averaged mean velocity $\tilde{U}$ is expressed in terms of $\tilde{Y}$ as

$$\tilde{U} = \tilde{U}_l \tilde{Y} + \tilde{U}_g (1 - \tilde{Y}) \tag{19.84}$$

and the equation of state

$$\overline{p} = \frac{(1 - \tilde{Y})\overline{\rho} R T_g}{1 - \tilde{Y} \cdot \overline{\rho}/\rho_l} \tag{19.85}$$

Neglecting terms that are related to the viscosity and the surface tension in accordance to the hypothesis of high Reynolds and Weber values, the transport equations for the mean mixture properties are written as

$$\frac{\partial \overline{\rho}}{\partial t} + \frac{\partial \overline{\rho} \tilde{U}_j}{\partial x_j} = S_{EL}^{\tilde{Y}} \tag{19.86}$$

$$\frac{\partial \overline{\rho} \tilde{U}_i}{\partial t} + \frac{\partial \overline{\rho} \tilde{U}_j \tilde{U}_i}{\partial x_j} = -\frac{\partial \overline{p}}{\partial x_i} - \frac{\partial \overline{\rho u_i'' u_j''}}{\partial x_j} + S_{EL}^{\tilde{U}_i} \tag{19.87}$$

To track the dispersion of the liquid phase, this set of equations is completed by Favre averaging the transport equation for the liquid mass fraction

$$\frac{\partial \overline{\rho} \tilde{Y}}{\partial t} + \frac{\partial \overline{\rho} \tilde{U}_j \tilde{Y}}{\partial x_j} = -\frac{\partial \overline{\rho u_j'' Y''}}{\partial x_j} + S_{EL}^{\tilde{Y}} \tag{19.88}$$

where $S_{EL}^{\tilde{Y}}$ and $S_{EL}^{\tilde{U}_i}$ are the sink or source terms due to the droplet generation or absorption when the transition from Eulerian to Lagrangian formulation is activated. The turbulent stress tensor in Equation 19.87 can be closed with a classical or modified k–ε model. Concerning the liquid turbulent diffusion in Equation 19.88, the gradient law approximation (Lebas et al., 2009) can be applied:

$$\overline{\rho u_j'' Y''} = -\overline{\rho}\frac{\nu_t}{\mathrm{Sc}}\frac{\partial \tilde{Y}}{\partial x_j} \tag{19.89}$$

where

ν_t is turbulent kinematic viscosity
Sc is Schmidt number

A transport equation for the gas/liquid interface density ($\tilde{\Omega} = \overline{\Sigma}/\overline{\rho}$) is postulated by analogy with the flame surface density

$$\frac{\partial \overline{\rho}\tilde{\Omega}}{\partial t} + \frac{\partial \overline{\rho}\tilde{U}_j\tilde{\Omega}}{\partial x_j} = \frac{\partial}{\partial x_j}(\overline{\rho}\tilde{\Omega}(\tilde{U}_j - \tilde{U}_{j,\Gamma})) + S_{EL}^{\tilde{Y}} + \overline{\rho}\dot{\tilde{\Omega}}_s \tag{19.90}$$

The first term on the right-hand side of Equation 19.90 represents the turbulent flux of interface, which reflects the difference between the interface velocity and the global mixture velocity. It is often closed using a turbulent diffusion term as follows:

$$\overline{\rho}\tilde{\Omega}(\tilde{U}_j - \tilde{U}_{j,\Gamma}) = \overline{\rho}\frac{\nu_t}{\mathrm{Sc}}\frac{\partial \tilde{\Omega}}{\partial x_j} \tag{19.91}$$

which is similar as that for the closure of the liquid turbulent diffusion term in Equation 19.89. In Chesnel et al. (2011b) where the ELSA model is extended to the LES, the scale similarity assumption has also been proposed to close the turbulent interface flux. The third term on the right-hand side of Equation 19.90 is a source term accounting for the production and/or destruction of the interface area due to the turbulent mixing between liquid and gas, the mean shear stress, breakup, coalescence, and vaporization. The mathematical formulation of the source term is detailed in Lebas et al. (2009).

Together with the mean liquid mass fraction, the gas/liquid interface density can be used to calculate the local SMD (D_{32}) of the spray (Vallet et al., 2001):

$$D_{32} = \frac{6\overline{\rho}\tilde{Y}}{\rho_l\overline{\Sigma}} \tag{19.92}$$

In general, the ELSA model can give an accurate description of the mixing-controlled phenomena such as spray penetration, dispersion, and vaporization processes (Lebas et al., 2009, Ning et al., 2009, Garcia-Oliver et al., 2013), but cannot well describe the droplet-related phenomena, for example, the SMD of the spray (Vallet et al., 2001, Garcia-Oliver et al., 2013).

19.1.7 Secondary Atomization

Secondary breakup in sprays is defined as the disintegration of larger droplets and ligaments into smaller droplets. The breakup of a single droplet in a gas is caused by either relative velocity, turbulence, or shock structure interaction, respectively. The main features of binary droplet collisions are presented in Chapter 14.

19.1.7.1 Droplet Breakup Mechanism

The secondary atomization of drops (drop fragmentation) is a multiphase flow process that is common for a wide variety of spray systems. Since the goal of many atomization processes is to control the final droplet size distribution, one of the most important reasons to study secondary atomization is to determine the conditions that lead to appropriate fragment sizes. Numerous studies of dilute sprays and isolated droplets have been performed in order to increase the understanding of secondary atomization mechanism. In-depth reviews on secondary atomization can be found in Krzeczkowski (1980), Pilch and Erdman (1987), Faeth et al. (1995), Chryssakis and Assanis (2008), and Guildenbecher et al. (2009). Shock tube (Gelfand et al., 1973, Faeth, 1990, 2002, Faeth et al., 1995, Hsiang and Faeth, 1992, 1993, 1995, Ruff et al., 1992, Tseng et al., 1992, Chou et al.,

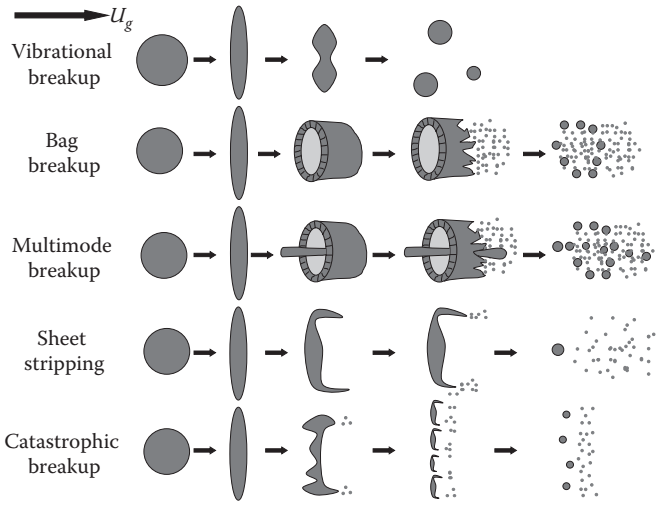

Figure 19.41

Typical modes of drop breakup. (From Li, X.G., Modeling and simulation of the gas-atomization process of metal melts for metal-matrix-composite production, Dissertation, Universität Bremen, Shaker-Verlag, Aachen, Germany, 2014. With permission.)

1997, Chou and Faeth, 1998, Dai and Faeth, 2001, Aalborg et al., 2003) and continuous jet methods (Lane, 1951, Taylor, 1963, Reitz, 1986, Hwang et al., 1996, Lee and Reitz, 2000, Liu and Reitz, 1993, 1997, Schmelz and Walzel, 2003, Cao et al., 2007, Zhao et al., 2010) have been employed to study the secondary breakup process. Both methods attempt to subject droplets to a step change in velocity.

Different flow conditions lead to different breakup modes. Figure 19.41 shows five typical breakup modes for Newtonian drops. From top to bottom, the modes are termed vibrational, bag, multimode (often called bag-and-stamen), sheet stripping (thinning), and catastrophic breakup, respectively.

Vibrational breakup is caused by the amplification of droplet oscillation when surface tension acts to restore the drop to its initial spherical shape. This breakup mode does not always occur and proceeds much more slowly than the other modes. It produces only a few fragments whose sizes are comparable to those of the parent drop.

During bag breakup, separation of the flow around a deformed drop (thin disk) leads to a positive pressure difference between the leading stagnation point and the wake. This tends to blow the center of the drop downstream, resulting in a thin hollow bag. The bag will first break, forming a large number of small droplets; thereafter the rim will break into few larger droplets.

Multimode breakup is a transitional regime, which resembles a combination of bag- and striping-type breakup. Bag formation accompanied by the presence of a core drop results in the formation of a long ligament in the center of the bag, which is referred to as a stamen or plume. Like bag breakup, the bag is the first to break up, followed by the rim and the stamen. Multiple sized fragments are produced.

Joseph et al. (1999) attributed the bag formation during both bag and multimode breakup to RT instability, and suggested that when the diameter of a drop was less than the critical wavelength of RT instability, the drops could not be fragmented by RT instability. Zhao et al. (2010) investigated the effect of RT wave number (k_{RT}) in the region of maximum cross-stream dimension on drop breakup morphology. The RT wave number is defined as the ratio of maximum cross-stream dimension to RT instability wavelength, $k_{RT} = d_{\max}/\lambda_{\max}$. The bag breakup occurred at $k_{RT} = 0.5774$–1, bag-stamen breakup at $k_{RT} = 1$–2, and dual-bag breakup (Cao et al., 2007) at $k_{RT} = 2$–3. Girin (2014) analyzed the role of inertial mass force and drop deformation in drop fragmentation, and raised the temporal and spatial conditions for drop breakup: (1) the period of the steady existence of the inertial force field should be large enough to ensure the proper instability development and (2) the lateral drop deformation exceeds the characteristic length of the fastest growing wave. Depending on the characteristic wavelength, selection mechanism between different breakup modes is built.

In a sheet striping (thinning) regime, the droplet is deformed into a thin disk from which a thin sheet is successively drawn from the periphery of the droplet because of Kelvin–Helmholtz (KH) waves, which is caused by the shear forces in the relative parallel motion at the common interface. The sheet evolves into

ligaments, which disintegrate into small droplets until the droplet is completely fragmented or until it has accelerated to a point where the aerodynamic effect is negligible, leaving a stable diameter of the core droplet.

In a catastrophic breakup regime, both RT and KH instabilities are involved. At first, RT waves due to the normal forces at the gas/liquid interface are grown on the surface of the parent droplet, which causes the droplet fragmentation into large child drops. KH waves are developed on the surface of the child droplets, resulting in a fragmentation mode equal to sheet stripping.

In secondary atomization, the aerodynamic force deforms the drop, causing it to fragment. This deformation is resisted by the surface tension (σ) and drop viscosity (μ). The aerodynamic Weber number We (Equation 19.7) and the Ohnesorge number Oh (Equation 19.8) are employed when describing secondary atomization process. We forms the ratio of the disrupting aerodynamic force to the restorative surface-tension force and Oh represents the ratio of the viscous force to the surface-tension force. A larger We indicates a higher tendency toward fragmentation, while a higher Oh indicates a lower tendency toward fragmentation. Several studies have considered the definitions and conditions for the onset of various deformation and breakup modes of drops in an Oh-We diagram (see Brodkey, 1967, Gelfand et al., 1973, Pilch and Erdmann, 1987, Samenfink et al., 1994, Simpkins and Bales, 1972, Chou et al., 1997, Chou and Faeth, 1998, Dai and Faeth, 2001, Kolev, 2002, Schmehl, 2003). The relation between transitional We and Oh is shown in Figure 19.42. It can be found that for Oh < 0.1, significant drop deformation begins at Weber numbers of roughly unity and the transition We is essentially constant, whereas Oh becomes important for Oh > 0.1 (Gelfand 1996, Nigmatulin, 1990). This can be interpreted by considering that for small Oh, the liquid viscous forces are small and the aerodynamic drag forces can only be balanced by surface-tension effects. However, as the liquid viscosity increases, liquid viscous forces stabilize the gas dynamic forces. At the lowest We region, droplets are not subject to secondary breakup, but they deform and obtain the shape of oblate spheroids, which may significantly affect their aerodynamic drag properties (Triebnigg, 1929, Taylor 1963, Low and List, 1982). With increasing We, three important outcomes appear in sequence: bag breakup, multimode breakup, and sheet thinning breakup. Schmehl (2003) presented the Oh–We functions characterizing the onset of different drop deformation degrees and breakup regimes in Figure 19.42, as

$$\mathrm{We}=\begin{cases}0.6(1+0.8\mathrm{Oh}^{0.8}+9\times10^{-5}\,\mathrm{Oh}^{2.4}),\ \text{defromation 5\%, no breakup, Oh}<600;\\ 1.1(1+0.7\mathrm{Oh}^{0.85}+1.5\times10^{-4}\,\mathrm{Oh}^{2.4}),\ \text{defromation 10\%, no breakup, Oh}<600;\\ 2.3(1+0.75\mathrm{Oh}^{0.8}+2.5\times10^{-4}\,\mathrm{Oh}^{2.4}),\ \text{defromation 20\%, no breakup, Oh}<600;\\ 3(1+15\mathrm{Oh}^{1.2}),\ \text{drop oscillations, no breakup, Oh}<0.3;\\ 13(1+1.7\mathrm{Oh}^{1.4}),\ \text{bag breakup, Oh}<4;\\ 35(1+0.65\mathrm{Oh}^{1.4}),\ \text{multimode breakup, Oh}<15;\\ 80(1+0.6\mathrm{Oh}^{1.5}),\ \text{sheet thinning breakup, Oh}<6.\end{cases}\tag{19.93}$$

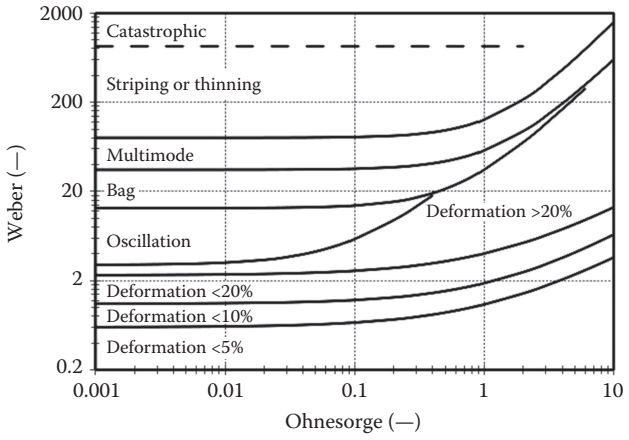

Figure 19.42

Drop deformation and breakup regime map based on Hsiang and Faeth (1995), We = 850 for onset of catastrophic breakup according to Chryssakis and Assanis (2008).

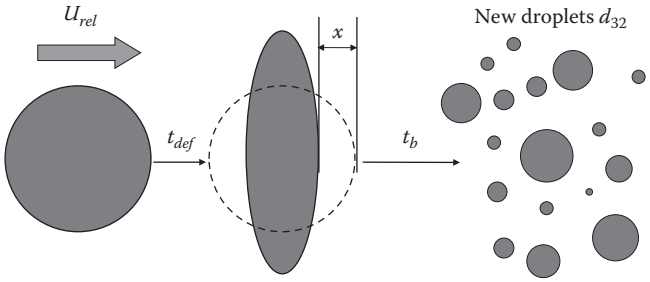

Figure 19.43

Sequential deformation and breakup of a droplet.

At critical conditions, initially the droplet deforms to a disk that finally breaks up into smaller droplets, as illustrated in Figure 19.43. The total breakup time consists of the deformation time t_{def} and the breakup time $t_{breakup}$. The latter describes the time where no further fragmentation occurs.

19.1.7.2 Semiempirical Breakup Models

For computations of the droplet breakup process, models are used that include the following:

- Breakup criteria if the droplet breaks up or not
- An estimation of the deformation time t_{def} and the breakup time $t_{breakup}$
- the resulting droplet size distribution (e.g., in terms of d_{32})
- the spatial distribution of the resulting droplets and their velocities after breakup

In the semiempirical breakup model, the time it takes to deform and disrupt a droplet is described by the characteristic breakup time:

$$t^\star = \frac{d_d}{U_{rel}}\sqrt{\frac{\rho_d}{\rho_g}} \tag{19.94}$$

The initial deformation of a droplet into a disk shape is similar for all breakup modes. The duration of this initial phase is estimated as $t_{def} = 1.6t^\star$ by Hsiang and Faeth (1992). Thereafter, the droplet will fragment depending on the breakup modes. As proposed in Pilch and Erdman (1987), the correlations of $t_{breakup}$ for different intervals of Weber numbers can be formulated as

$$\frac{t_{breakup}}{t^\star} = \begin{cases} 6(\mathrm{We}-12)^{-0.25}, & 12 \le \mathrm{We} < 18 \\ 2.45(\mathrm{We}-12)^{0.25}, & 18 \le \mathrm{We} < 45 \\ 14.1(\mathrm{We}-12)^{-0.25}, & 45 \le \mathrm{We} < 351 \\ 0.766(\mathrm{We}-12)^{0.25}, & 351 \le \mathrm{We} < 2670 \\ 5.5, & \mathrm{We} \ge 2670 \end{cases} \tag{19.95}$$

To account for the viscosity effects observed for Oh > 0.1, a corrected Weber number is used in these relations for the low Oh-number range only (Schmehl, 2000):

$$\mathrm{We}_{corr} = \frac{\mathrm{We}}{1+1.077\mathrm{Oh}^{1.6}} \tag{19.96}$$

When a droplet breaks up, it results in a group of new droplets with a certain size distribution and mean diameter. The SMD d_{32} is computed for bag breakup and multimode breakup from the following relation:

$$\frac{d_{32}}{d_d} = 1.5\mathrm{Oh}^{0.2}\ \mathrm{We}^{-0.25} \tag{19.97}$$

where d_d is the initial droplet diameter. The volume distribution of the child-droplet fragments can be described by a presumed distribution, for example, a root-normal distribution or a log-normal distribution. The MMD $d_{50,3}$ and SMD for the distribution are related by

$$\frac{d_{50,3}}{d_{32}} = 1.2 \tag{19.98}$$

Sheet stripping breakup is characterized by continuous film stripping, leaving a larger core droplet at the end of the breakup process. In the computational model, the maximum stable diameter (d_s) of this droplet is evaluated by

$$d_s = \frac{12\sigma}{\rho_g U_{rel}^2} \tag{19.99}$$

The fine fraction of the droplet fragments is distributed as in bag and multimode breakup regimes based on a reduced SMD $d_{32,red}$, which is derived from the SMD d_{32} given by Equation 19.97 and the maximum stable diameter d_s by Equation 19.99, as follows:

$$d_{32,red} = \frac{4d_{32}d_s}{5d_s - d_{32}} \tag{19.100}$$

Other commonly used droplet breakup models include those based on droplet deformation dynamics and those based on the instability growth on the droplet surface. The former include Taylor analogy breakup (TAB) model, as well as its extensions such as Enhanced TAB (ETAB) and cascade atomization and droplet breakup (CAB) models. The latter include wave breakup model and KH-RT hybrid breakup model.

19.1.7.3 TAB, ETAB, and CAB Model

The TAB model (O'Rourke and Amsden, 1987) treats the oscillation of a distorting droplet with the analogy of a spring-mass system. The external force is represented by aerodynamic force while the restoring force of the spring by the surface tension (σ). The liquid viscosity (μ_l) represents the damping force. Setting $y = 2x/r$, where x is the displacement of the droplet equator from its spherical (undisturbed) position and r is the undisturbed droplet radius (see Figure 19.43), the governing equation of droplet deformation is

$$\ddot{y} = \frac{C_f}{C_b}\frac{\rho_g}{\rho_l}\frac{U_{rel}^2}{r^2} - \frac{C_k\sigma}{\rho_l r^3}y - \frac{C_d\mu_l}{\rho_l r^2}\dot{y} \tag{19.101}$$

where

ρ denotes the density
U_{rel} is the relative droplet-gas velocity
the subscripts g and l denote the gas or liquid properties, respectively

As suggested in O'Rourke and Amsden (1987), the values of the dimensionless constants C_b, C_f, C_k, and C_d are 0.5, 1/3, 8, and 5, respectively. It is argued in the TAB model that a necessary condition for droplet breakup is reached when $We_g > We_{crit}$, where the critical Weber number is experimentally determined as $We_{crit} = 6$. The gas Weber number used in TAB, ETAB, and CAB model is based on the droplet radius, that is, $We_g = \rho_g U_{rel}^2 r/\sigma$. For an inviscid liquid, this condition is met when $y(t) > 1$. The breakup time is taken to be the smallest positive root of the deformation equation $y(t) = 1$. By balancing the deformation energy and surface energy before and after breakup, the expression for the Sauter mean radius (r_{32}) of the child droplets after breakup can be derived as

$$\frac{r}{r_{32}} = 1 + \frac{8K}{20} + \frac{\rho_l r^3}{\sigma}\left(\frac{6K-5}{120}\right)(\dot{y})^2 \tag{19.102}$$

where K is a constant that must be evaluated experimentally by measuring droplet sizes. O'Rourke and Amsden (1987) suggest a value of $K = 10/3$. It is assumed that the product droplets are neither distorted nor

oscillating, that is, $y = \dot{y} = 0$. The TAB model also predicts a velocity of the product droplets normal to the path of the parent droplet, approximately by $U_\perp = \dot{x}$.

The effect of deformation on droplet motion can be significant. For example, at maximum deformation typical at the onset of breakup, drag forces on the droplet are increased by a factor of 4 for steady disturbance and 13 for shock loading due to the droplet-distortion-induced increase in drag coefficient C_d and the cross-sectional area of the droplet (Hsiang and Faeth, 1995). Therefore, when the droplet is deformed into a disk, the drag coefficient needs to be changed accordingly. The distortion parameter y can be used to modify the drag coefficient to account for the droplet deformation by using the relation

$$C_{d,y} = C_{d,sphere}(1 + 2.63y) \tag{19.103}$$

proposed by Liu et al. (1993), where $C_{d,y}$ is the drag coefficient for the deformed droplet and $C_{d,sphere}$ is that of the initially spherical droplet.

The ETAB model developed in Tanner (1997) maintains the droplet deformation dynamics of the TAB model, that is, droplet breakup occurs when the normalized droplet distortion y exceeds the critical value of 1. However, for each breakup event, the ETAB model assumes that the rate of product droplet generation is proportional to the number of the product droplets. From this, the rate of droplet creation, in conjunction with the mass conservation principle, leads to the basic ETAB law

$$\frac{d\bar{m}(t)}{dt} = -3K_{br}\bar{m}(t) \tag{19.104}$$

where $\bar{m}(t)$ denotes the mean mass of the product droplet distribution. The breakup constant K_{br} depends on the breakup regime (bag or stripping breakup) according to the gas Weber number as follows:

$$K_{br} = \begin{cases} k_1\omega, & \mathrm{We}_g \le \mathrm{We}_{trans} \\ k_2\omega\sqrt{\mathrm{We}_g}, & \mathrm{We}_g > \mathrm{We}_{trans} \end{cases} \tag{19.105}$$

with $k_1 = 2/9$, $k_2 = 2/9$ and $\mathrm{We}_{trans} = 80$ (Tanner, 1997). The droplet oscillation frequency ω is given by

$$\omega^2 = C_k\frac{\sigma}{\rho_l r^3} - \left(\frac{C_d\mu_l}{2\rho_l r^2}\right)^2 \tag{19.106}$$

with $C_k = 8$ and $C_d = 5$ (O'Rourke and Amsden, 1987). With an assumption of a uniform product droplet size distribution, Equation 19.104 becomes

$$\frac{r_{new}}{r} = e^{-K_{br}t} \tag{19.107}$$

where r_{new} and r are the radii of the product and parent droplets, respectively. As in the TAB model, after breakup of a parent droplet, the initial deformation parameters of the product droplets are set to $y = \dot{y} = 0$. Also, the product droplets are initially supplied with a velocity component perpendicular to the path of the parent droplet with a value $U_\perp = A\dot{x}$, where A is a constant determined by balancing the deformation energy and surface energy before and after breakup, as follows:

$$A^2 = 3\left[1 - \frac{r}{r_{32}} + \frac{5C_d\mathrm{We}_g}{72}\right]\frac{\omega_0^2}{\dot{y}^2} \tag{19.108}$$

where C_d is the aerodynamic drag coefficient and $\omega_0^2 = 8\sigma/(\rho_l r^3)$. For inviscid, large Weber droplets with initial deformation conditions $y(0) = \dot{y}(0) = 0$, one obtains the relation

$$A^2 = \frac{5C_D}{4} + \frac{18(1 - r/r_{32})}{\mathrm{We}_g} \tag{19.109}$$

For a breakup of a droplet with $We_g = 250$, $C_D = 0.5$, and $r_{32}/r = 0.65$, Equation 19.109 yields $A \approx 0.77$. As in the TAB model where $A = 1$, this radial velocity contributes to the radial expansion of the spray.

The CAB model proposed by Tanner (2004) is a further development of the ETAB model. In the CAB model, the breakup condition is determined by means of the droplet deformation dynamics of the TAB model, and the definition of the rate of droplet creation follows the pattern of the ETAB model (Equation 19.104). However, the individual droplet breakup regions, which, in the ETAB model, were restricted to either bag ($We_{crit} < We_g < We_{b,s}$) or stripping breakup ($We_{b,s} < We_g < We_{s,c}$) have been extended to include the catastrophic breakup regime ($We_{s,c} < We_g$) to accommodate the disintegration of the high-speed droplets. Correspondingly, the breakup constant K_{br} for each breakup regime can be expressed as

$$K_{br} = \begin{cases} k_1\omega, & We_{crit} < We_g < We_{b,s} \\ k_2\omega\sqrt{We_g}, & We_{b,s} < We_g < We_{s,c} \\ k_3\omega(We_g)^{3/4}, & We_{s,c} < We_g \end{cases} \tag{19.110}$$

where the droplet oscillation frequency ω is given by Eq. s-34. In Tanner (2004), the regime-dividing Weber numbers are taken to be $We_{b,s} = 80$ and $We_{s,c} = 350$, and the constant $k_1 = 0.05$ is determined, whereas the values for the constants k_2 and k_3 are chosen such that K_{br} is continuous at the regime-dividing Weber numbers, $We_{b,s}$ and $We_{s,c}$. The way to deal with the velocity of the product droplets in the CAB model is same as that in the ETAB model.

19.1.7.4 Wave and KH-RT Hybrid Breakup Model

The wave breakup model or the Kelvin–Helmholtz (KH) breakup model, developed by Reitz and Diwakar (1987) and further improved by Reitz (1987), assumes that breakup is caused by KH instability on the surface of a cylindrical "blob" of liquid. Under the assumption that the size of the striped-off product droplets is proportional to the length of the fastest growing wave, the wave model postulates that a parent parcel with radius, r, breaks up to form new droplets with radius, r_{new}, as follows:

$$r_{new} = B_0\Lambda_{KH} \tag{19.111}$$

where

Λ_{KH} is the wavelength corresponding to the KH wave with maximum growth rate (Ω_{KH})

B_0 is a constant equal to 0.61

Linear analysis of KH instabilities on a round liquid jet gives the frequency of the fastest-growing wave (Ω_{KH}) and its corresponding wavelength (Λ_{KH}) as follows:

$$\Omega_{KH} = \frac{0.34 + 0.38We_g^{1.5}}{(1+Oh)(1+1.4(Oh\sqrt{We_g})^{0.6})}\sqrt{\frac{\sigma}{\rho_l r^3}} \tag{19.112}$$

$$\Lambda_{KH} = \frac{9.02r(1+0.45\sqrt{Oh})(1+0.4(Oh\sqrt{We_g})^{0.7})}{(1+0.865We_g^{1.67})^{0.6}} \tag{19.113}$$

The definitions of gas Weber number (We_g) and Ohnesorge number (Oh) can be found in Equations 19.7 and 19.8, respectively, but with a substitution of droplet diameter with droplet radius in both equations. During breakup, the parent parcel reduces in diameter due to the loss of mass. The rate of change of the radius of the parent parcel is calculated using

$$\frac{dr}{dt} = \frac{r - r_{new}}{\tau_{KH}} \tag{19.114}$$

where τ_{KH} is the breakup time defined by

$$\tau_{KH} = \frac{3.726B_1 r}{\Omega_{KH}\Lambda_{KH}} \tag{19.115}$$

The constant B_1 has been given a variety of values between 1.73 and 60 (Patterson, 1997, Patterson and Reitz, 1998).

In the KH-RT hybrid atomization model (Patterson, 1997, Patterson and Reitz, 1998, Beale and Reitz. 1999), the wave model is employed to predict the primary breakup of the intact liquid core of a liquid jet. The secondary breakup of individual droplets is modeled with the wave model in conjunction with the RT accelerative instability model. The hybrid model is allowed to grow KH instability and RT instability simultaneously, and the fastest growing instability leads to a droplet breakup event. In the RT model, the frequency of the fastest growing wave is given by

$$\Omega_{RT} = \sqrt{\frac{2}{3\sqrt{3\sigma}} \frac{[-g_t(\rho_l - \rho_g)]^{3/2}}{\rho_l + \rho_g}} \tag{19.116}$$

where g_t is the acceleration in the direction of travel and is defined by $g_t = \mathbf{g} \cdot \mathbf{j} + \mathbf{a} \cdot \mathbf{j}$, where $\mathbf{a}$ is the droplet acceleration, and $\mathbf{j}$ is the unit vector tangent to the droplet trajectory. The corresponding wavelength is

$$\Lambda_{RT} = 2\pi C_{RT} \sqrt{\frac{3\sigma}{-g_t(\rho_l - \rho_g)}} \tag{19.117}$$

where C_{RT} is an adjustable constant set equal to 0.1 (Beale and Reitz, 1999). The RT waves are only allowed to form on the droplet when the diameter of the droplet is larger than the wavelength of the fastest growing disturbances (i.e., $d > \Lambda_{RT}$). The radii of new droplets are given by

$$r_{new} = \frac{\Lambda_{RT}}{2} \tag{19.118}$$

The breakup time in the RT model is calculated using

$$\tau_{RT} = \frac{C_\tau}{\Omega_{RT}} \tag{19.119}$$

where C_τ is a constant usually equal to unity beyond the breakup length, and is equal to 9.0 within the breakup length.

19.1.7.5 Empirical Extension of Droplet Deformation Model

In many application scenarios, the time scale of deformation and breakup is comparable to or larger than the characteristic scales of the gas flow fluctuations, that is, the relative velocity varies significantly during the deformation and breakup process (Schmehl, 2004). In these cases, the deformation and breakup process and the resulting characteristics of secondary fragments do not depend only on instantaneous local flow situations but also on the variation of aerodynamic forces during the disintegration process. As an empirical extension of dynamic droplet deformation model, the breakup model proposed by Bartz et al. (2010) takes into account the temporal evolution of the aerodynamic loading of the droplet. A critical deformation is used as breakup criterion. The actual disintegration process is described empirically.

In Bartz et al. (2010), the subcritical deformation as well as the initial deformation phase during breakup is computed by the nonlinear Taylor analogy breakup (NLTAB) model (Schmehl, 2002). The NLTAB model is a nonlinear variant of the TAB model and is based on the experimental observation that the droplet deformation airflows can be represented by spheroidal (oblate and prolate) shapes. The NLTAB model describes the droplet deformation dynamics in terms of the nondimensional equator coordinate y, which is defined as the ratio of the cross-stream diameter to the spherical diameter $y = D/D_0$. By balancing the kinetic energy of the deformation with the surface energy change, the work performed by the surface pressure and the energy dissipation in the droplet on the time scale $T = t/t^*$ (t^*, the characteristic breakup time, see Equation 19.94), the NLTAB model gives the governing equation of the droplet deformation as

$$\frac{\pi^2 + 16/y^6}{\pi^2 + 16} \frac{d^2y}{dT^2} - \frac{48}{\pi^2 + 16} \frac{1}{y^7} \left(\frac{dy}{dT} \right)^2 + \frac{40}{\mathrm{Re}_{def}} \frac{1}{y^2} \frac{dy}{dT} + \frac{20}{\mathrm{We}_g} \frac{1}{S_0} \frac{dS}{dy} = \frac{2C_2}{y} \tag{19.120}$$

where the Reynolds number Re_{def} is given by

$$\mathrm{Re}_{def} = \frac{U_{rel} D_0}{\mu_l} \sqrt{\rho_g \rho_l} \tag{19.121}$$

and the term relative to the normalized rate of surface change can be expressed by the polynomials of the nondimensional equator coordinate y as follows:

$$\frac{1}{S_0}\frac{dS}{dy} = \begin{cases} 9.98y^3 - 30.34y^2 + 33.94y - 13.58, & 0.5 < y < 1; \\ 0.67y^3 - 4.01y^2 + 9.21y - 5.67, & 1 \le y < 2.3. \end{cases} \tag{19.122}$$

where S_0 is the initial surface of the undeformed droplet and C_2 is an adjustable constant. The aerodynamic drag coefficient C_d of the droplet is determined from a linear interpolation between the drag coefficient of a spherical droplet and a disk shaped droplet, that is,

$$C_d = fC_{d,sphere} + (1-f)C_{d,disc}, \quad \text{with } f = 1 - E^2 \tag{19.123}$$

where E is the droplet aspect ratio defined as $E = 1/y^3$ (Schmehl, 2002).

The linear equation of the TAB model (Equation 19.101) can be reformulated according to the notation of Schmehl (2002, 2004) into

$$\frac{d^2y}{dT^2} + \frac{40}{\mathrm{Re}_{def}}\frac{dy}{dT} + \frac{64}{\mathrm{We}_g}(y-1) = 2C_2 \tag{19.124}$$

The TAB model suggests $C_2 = 2/3$. The critical deformation, $y_c = 1.5$, is reached at a critical Weber number $\mathrm{We}_c = 12$.

Schmehl (2004) performed calculations of the maximum nondimensional equator coordinate for shock-loaded droplets with Oh < 0.1 using the NLTAB model. At the onset of bag breakup for a critical Weber number of $\mathrm{We}_c = 13$, a maximum deformation of

$$y_c \approx 1.8 \tag{19.125}$$

is found. Experimental data from Kim (1977) confirm this critical deformation. Aalburg et al. (2003) performed DNSs of shock-loaded droplets. They concluded that the critical deformation noted in Equation 19.125 is a good estimate of the critical deformation at the onset of breakup for a large range of Ohnesorge numbers.

For higher We_g, the maximum nondimensional coordinate reaches higher amplitudes before breakup. By analyzing experimental data for shock-loading conditions (Dai and Faeth, 2001), it can be concluded that the maximum nondimensional coordinate of disintegrating droplets reaches maximum amplitude

$$y_{\max} \approx 2.1, \quad \text{for } \mathrm{We}_g > 20 \tag{19.126}$$

In Bartz et al. (2010), droplet deformation is modeled by the NLTAB model until a maximum deformation nondimensional coordinate ($1.8 < y_{\max} < 2.1$) is reached. After that, the droplet deformation and breakup process is modeled based on the empirical data from experiments in a shock tube. Therefore, a corresponding shock loading state is calculated when the maximum deformation is reached. The initial gas Weber numbers corresponding to the shock loading state are derived and taken into Equation 19.95 to obtain the total breakup time. Fragment sizes resulting from secondary atomization can be predicted by a global statistical atomization product model as proposed in the semiempirical breakup model or by the detailed atomization product model, which Bartz et al. (2010) obtained by analyzing the experimental data from Chou et al. (1997), Chou and Faeth (1998), and Dai and Faeth (2001). The detailed atomization product model accounts for the volume fraction of the fine droplets produced by the fragmentation of the bag during bag and bag-plume breakup.

Bartz et al. (2011) presented the comparison of droplet trajectories for bag breakup, as illustrated in Figure 19.44. The trajectory of the droplet in the experiment is plotted as a solid line with circles.

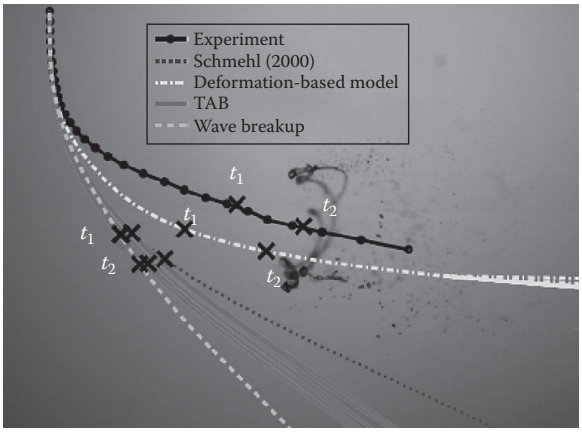

Figure 19.44

Comparison of trajectories for bag breakup, makers denote droplet position at t_1 (fragmentation of the bag) and t_2 (fragmentation of the rim); high-speed-image at t_2 in the background; $We_{max} = 15$. (Adapted from Bartz, F.O. et al., Model comparison for single droplet fragmentation under varying accelerations, in *Proceedings of ILASS-Europe 2011*, Estoril, Portugal, September 5–7, 2011.)

The time when the fragmentation of the bag begins, t_1, and a time t_2 during the fragmentation of the rim are marked. The trajectory predicted with the semiempirical model of Schmehl (2000) is displayed as a dotted line. As stated before, in this model, the characteristic times are calculated based on the instantaneous Weber number at the time step when We_c is first exceeded. The breakup time is overestimated, and fragmentation begins at a location, which is not in the field of view. Trajectories calculated with the TAB model are displayed as solid lines. The droplet exceeded the critical deformation at an early stage and then fragments are released. The trajectories deviate from the experimental trajectory. The calculation using the wave breakup model did not predict fragmentation. As stated earlier, the physics behind this model is only valid for high We. The droplet trajectory as well as the temporal evolution of the trajectory predicted with the deformation-based model showed a better agreement to experimental results than predictions with the other models.

The results based on a semiempirical breakup model (Markus and Fritsching, 2003b) are illustrated in Figure 19.45. Here, atomization in a twin-fluid gas atomizer configuration is studied. In this direct numerical approach, each particle has been tracked throughout the flowfield. Droplet deformation and breakup are considered. If a ligament/droplet breaks up, all daughter droplets created are further tracked. The gas velocity distribution is based on measurements. Figure 19.45 shows a typical cumulative droplet size

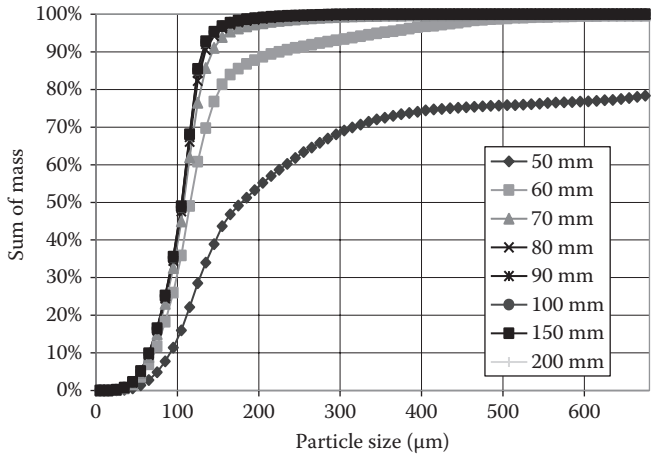

Figure 19.45

Secondary drop fragmentation in liquid spray: evolution of the drop size distribution versus the distance to the atomizer nozzle. (From Markus and Fritsching, 2003b. With permission.)

distribution at increasing distances from the atomizer. Most droplets are created in a short distance behind the region of the primary breakup. Then, the droplets are accelerated and spread out due to turbulence.

19.1.8 Special Liquids

19.1.8.1 Highly Viscous Liquids

Atomization of very viscous liquids (i.e., at dynamic viscosities above 1 Pa s) is a difficult task as these liquids exhibit a certain resistance to the primary deformation process. In this context, prefilming of the liquid stream is a possibility to enhance the size of the gas/liquid interface area prior to the atomization process and therefore contribute to the efficiency of the primary fragmentation mechanism. Prefilming of the liquid stream may be achieved by

- Geometrical arrangement of the liquid feed (in twin-fluid atomization)
- Centrifugal forces (in rotary or pressure-swirl atomization)
- Pressure forces (in ultrasonic standing wave atomization [USWA])

In a variant of the effervescent atomizer (internal mixing), Campanile and Azzopardi (2003) used a mixing chamber that was designed to create annular liquid flow in the nozzle to enhance interaction between gas and liquid (see Figure 19.46). Newtonian liquids at viscosities up to 50 Pa s have been atomized with air. The liquid mass flow rate was approximately 50 kg/h. In Figure 19.47, spray patterns in the fragmentation area are to be seen. For higher viscosities, the liquid is more pronounced to form fibers within primary fragmentation. In Figure 19.47, the MMD achieved at liquid viscosities of 5 and 50 Pa s is illustrated. Typical droplet sizes achieved are in the range of several millimeters. From a model based on the observation that ligaments are formed from the annular film rim acting against surface tension, which tends to form a new liquid surface, the optimum wavelength for lateral instability is

$$\lambda_{opt} = 2\pi\sqrt{\frac{3\sigma}{\rho_l A_c}} \quad \text{where } A_c = \frac{1}{\rho_l}\frac{dp}{dx} + g \tag{19.127}$$

By taking into account the effects of viscosity and compressibility, especially for very viscous liquids at higher air velocities, the model is in good agreement with measured particle sizes.

Effervescent atomization of PVP K30 aqueous solutions was investigated by Schröder et al. (2013). The shear viscosity of PVP K30 solutions increases with increasing mass fraction. The breakup of PVP K30 solutions is changed significantly by their viscosity. With increasing viscosity, the breakup

With permission.)

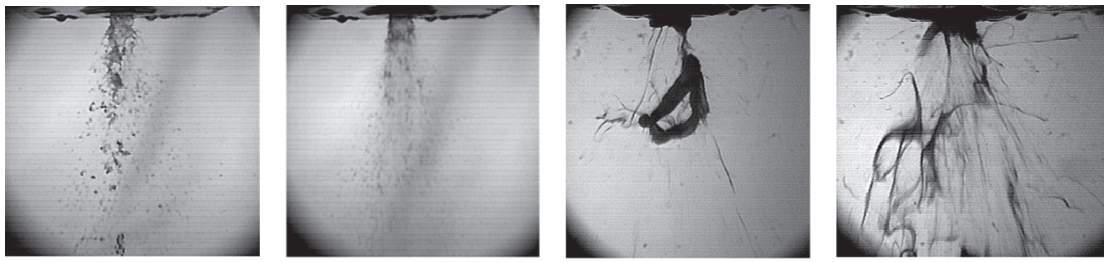

Figure 19.47

Fragmentation process and spray pattern in viscous liquid atomization: for liquid viscosity = 0.001 Pa s and liquid superficial velocity = 0.15 m/s, (a) gas superficial velocity = 51 m/s, (b) gas superficial velocity = 116 m/s; for liquid viscosity = 5 Pa s and liquid superficial velocity = 0.15 m/s, (c) gas superficial velocity = 70 m/s, (d) gas superficial velocity = 256 m/s. (From Campanile, F. and Azzopardi, B.J., Atomisation of very viscous liquids, in *Proceedings of International Conference on Liquid Atomization and Spray Systems ICLASS 2003*, Sorrento, Italy, 2003. With permission.)

changes from complete breakup into drops directly at the nozzle orifice outlet to an incomplete breakup with ligaments present, as shown in Figure 19.48. The corresponding SMD and the standard deviation (representing the width of the drop size distribution) increase with increasing viscosity as well. The air-to-liquid ratio by mass (ALR) has comparably less impact on the breakup at the nozzle orifice outlet, as shown in Figure 19.48. Nevertheless, an increasing ALR results in decreasing SMDs and standard deviations. The atomizer geometry (by changing nozzle orifice length) has a minor impact on the breakup and the resulting drop size distribution.

The application of the atomizing media (gas) from inside of an annular liquid sheet results in a radial droplet size variation in the spray that shows increasing drop size values with increasing radius (Lohner et al., 2003). On the other hand, typical twin-fluid atomizers with external mixing show decreasing droplet sizes at the outer side of the spray with increasing radius. The reason in both cases is as follows: the specific gas velocity distribution and the kinetic energy of the gas are partially absorbed by the dispersed phase. Based on these results, a prefilming atomizer with inner and outer atomization has been proposed for highly viscous liquids, as shown in Figure 19.57 (later in the chapter). This atomizer essentially is a combination of an external mixing atomizer and the internal atomizer. The aim is that by this design the gas/liquid

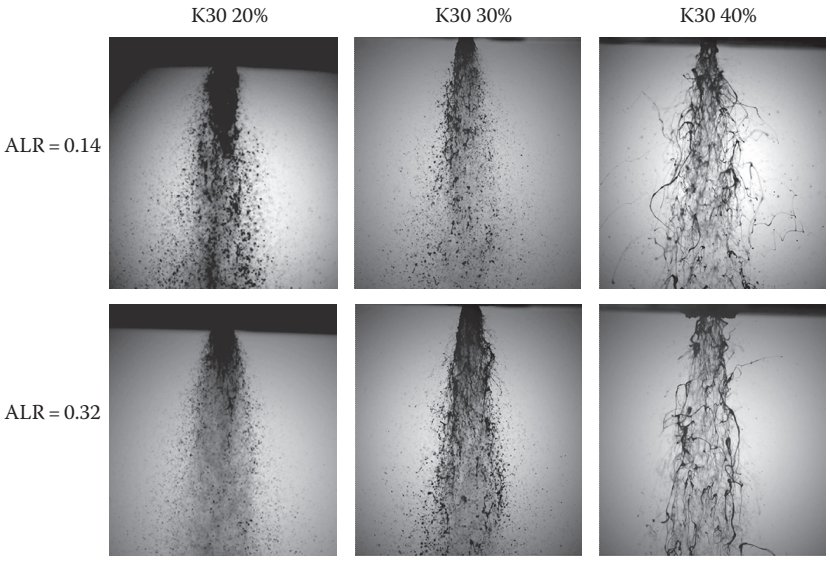

Figure 19.48

The diameter of the liquid jet at the nozzle orifice outlet is 1.5 mm. (Adapted from Schröder, J. et al., *Atom. Spray*, 23(1), 1, 2013. With permission.)

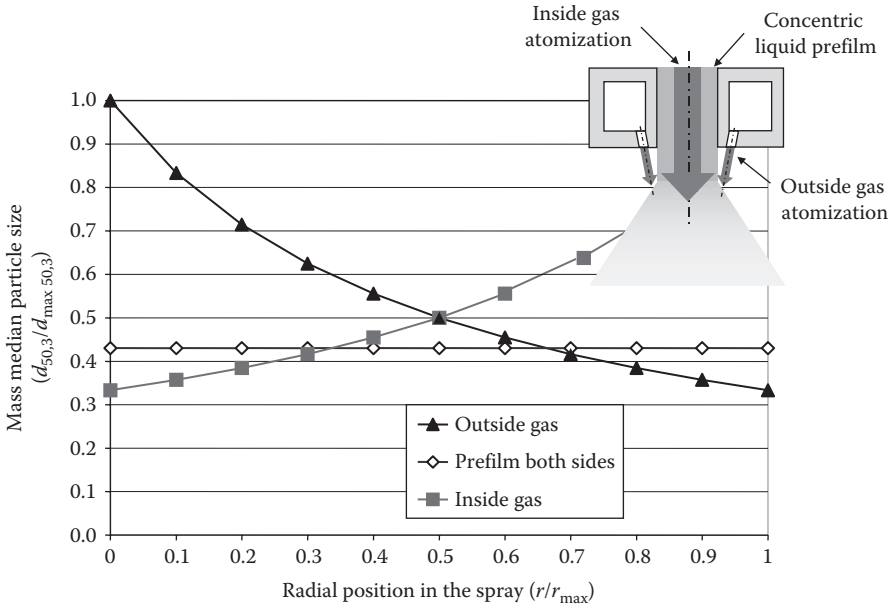

Figure 19.49

Atomizer configuration for viscous liquids and high throughputs, radial droplet size distribution in spray. (From Lohner, H. et al., Impact of gas nozzle arrangement on the flow field of a twin fluid atomizer with external mixing, in *Proceedings of International Conference on Liquid Atomization and Spray Systems ICLASS 2003*, Sorrento, Italy, 2003. With permission.)

contact area is increased for fragmentation of viscous liquids and that a more homogeneous particle size distribution across the spray cross section can be obtained compared to the other two individual atomizers described before. In Figure 19.49, the principal behavior for the radial distribution of the mean droplet sizes in the spray is shown. The mass median particle size is nearly constant when the pressure ratio between the inside and the outside nozzles is unity, as has been verified in experiments (Lohner et al., 2003).

As described in Section 19.1.3, the USWA process is a very suitable method for atomization of highly viscous liquids. The sound radiation pressure within the resonant ultrasound field between two opposing sonotrodes leads to a deformation of the cylindrical feed liquid jet into a disk-shaped film (see Figure 19.10), thereby accelerating the liquid radially outward. At the rim of the disk, additional suction forces are acting. Here, the sheet becomes unstable and disintegrates into droplets/ligaments. The tensile forces in the sheet support the disintegration process at the rim of the disk especially for viscous liquids. In Figure 19.50, a comparison of a liquid atomization photo and a direct simulation of the primary fragmentation process within the USWA process is illustrated (Reipschläger, 2002, Reipschläger et al., 2002). The MMD achieved with USWA atomization of a Newtonian viscous liquid (up to 10 Pa s), as measured by Hansmann (1996), is shown in Figure 19.51 as a function of the liquid throughput.

19.1.8.2 Melts (Polymers, Minerals, or Metals)

Melts of polymers, metals, and glass or ceramic materials are atomized for powder production or coating/preforming applications. In the atomization process of molten materials, in addition to their typically difficult material properties,* the atomization process must ensure that sufficient thermal energy is available in the area close to the atomizer in order to prevent liquid fragments that may get in contact with the atomizer from sticking and freezing. Here, typical process problems in melt atomization arise (Bauckhage et al., 2001). Also, for achieving almost spherical particles, the cooling and solidification of the liquid fragments after atomization needs to be finished after a sufficiently high residence time in the molten stage for the liquid droplets (solidification time < spheroidization time). In addition to the thermal-related freezing problem within the melt nozzle, chemical- or metallurgical-related problems in melt delivery systems are also found frequently in applications. Problems may arise from melt/tundish reactions or melt segregational effects from diffusion.

* Polymer solutions or melts typically are highly viscous and show non-Newtonian flow behaviour, metal melts have high surface tensions, and ceramic melts have high viscosities that drastically change with melt temperature.

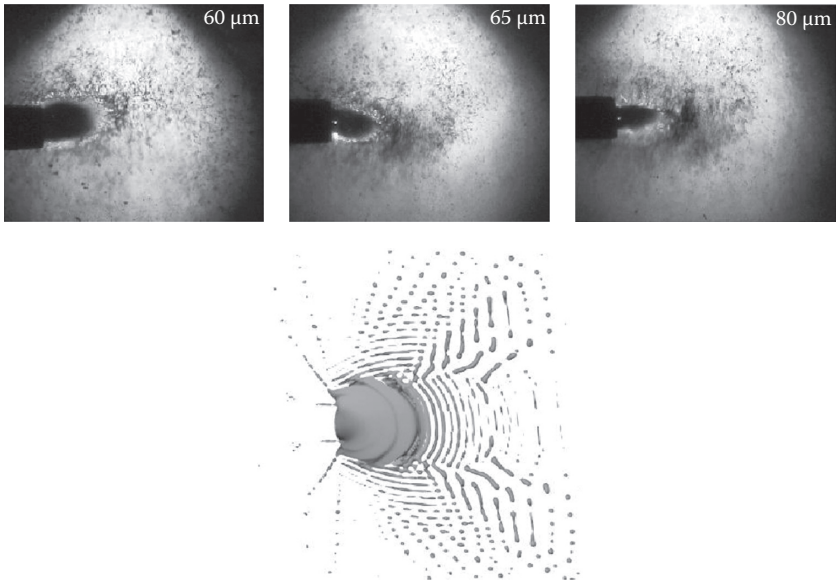

Figure 19.50

Atomization process in USWA, comparison of experiment and simulation. (From Reipschläger, O. et al., Modelling and simulation of the disintegration process in ultrasonic standing wave atomizers, in *Proceedings of 18th Annual Conference on Liquid Atomization and Spray Systems ILASS Europe*, Zaragoza, Spain, 2002. With permission.)

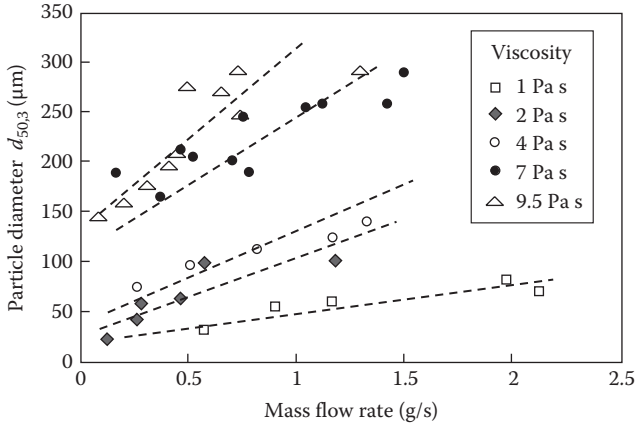

Figure 19.51

MMD within viscous fluid disintegration by USWA. (Adapted from Hansmann, S., Einfluss von Stoff-und Betriebsparametern auf die Zerstäubung hochvoskoser Flüssigkeiten im Ultraschall-Stehwellenfeld, Dissertation, Universität Bremen, Bremen, Germany, 1996.)

Polymer melts may be sufficiently atomized by using the USWA technique (Reipschläger, 2002, Reipschläger et al., 2002) or gas atomization (Watkinson et al., 2001). The energy requirement to overcome the effect of viscosity and surface tension in atomization may be expressed by the ratio of liquid Weber and Reynolds numbers as follows:

$$\frac{E_\mu}{E_\sigma} = \frac{\mu_l u_{rel}}{\omega} = \frac{\mathrm{We}_l}{\mathrm{Re}_l} \tag{19.128}$$

Typically, this ratio is below 1 for a steel melt and above 1000 for polymers.

Mineral melts like glass or slags (e.g., from blast furnace process) have a high viscosity and a low surface tension compared to other melts. When these types of melts are conventionally atomized under cold conditions,

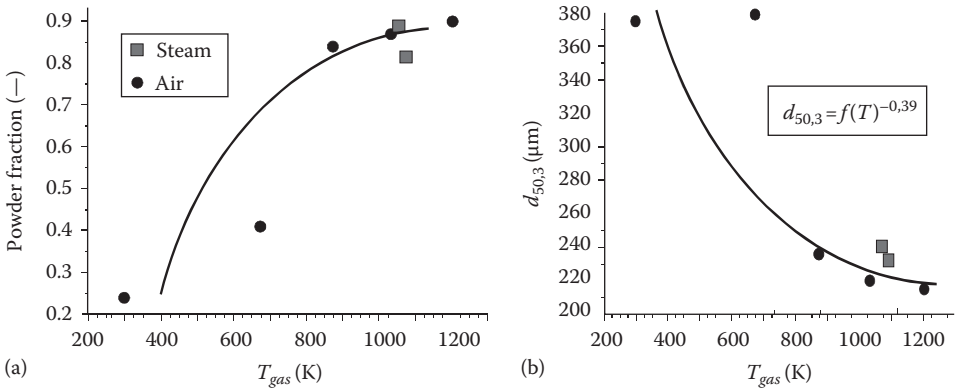

Figure 19.52

(a) Powder fraction and (b) mass median particle size for mineral melt atomization at increased gas temperatures. (From Lohner, H., Zerstäuben von Mineralscmelzen mit Heißgas, Dissertation, Universität Bremen, VDI-Verlag, Düsseldorf, Germany, 2003. With permission.)

the material characteristics lead to a fiber product or at least to a product with a high fiber content instead of a particle product because the viscosity steadily and dramatically increases with decreasing temperature within the atomization process. Thus, it is possible to disintegrate the melt stream into ligaments, because of the high temperature and the low viscosity at the beginning of the atomization process. However, as the temperature of the ligaments decreases and the viscosity increases rapidly, the ligaments cannot be disintegrated further into smaller particles in the secondary atomization step. Therefore, the ligaments remain in a fiber state. To prevent the early termination of the atomization after the first fragmentation step and to allow further disintegration of the ligaments, one possibility is to increase the atomizing gas temperature. The lower temperature difference between the hot atomizer gas and the melt results in a lower heat transfer. Thus, the melt stays longer in a liquid state at low viscosity and the atomization process can finish and finally the fragments spheroidize into globular particles. Figure 19.52a shows as an experimental result the continuous decrease of the fiber content of a gas atomized ceramic melt with increasing gas temperature (Lohner, 2003, Lohner et al., 2005). An external mixing twin-fluid atomizer was used, where a maximum gas temperature of 1000°C could be achieved. In Figure 19.52b, it is evident that in addition to the decrease of the particle size, the efficiency of the atomization process increases with increasing gas temperature (the gas mass flow rate at constant gas pressure is decreasing with increasing gas temperature, see also Strauss, 1997). Here, the MMD of the powder fraction decreases with increasing gas temperature. From an energetic point of view, Strauss and Dunkley (2000) showed that the particle diameter at constant gas pressure and increasing gas temperature should vary as follows:

$$d = KT^{-0.25} \tag{19.129}$$

This correlation has been validated in (molten metal) atomization trials (Strauss and Dunkley, 2000). Experiments for a ceramic melt have shown an exponent that is approximately −0.4 (Czisch et al., 2003).

It has been shown by Lohner (2003) and Lohner et al. (2005), that in the case of hot gas atomization of a viscous ceramic melt, the velocity difference between melt and gas has a primary effect on the atomization process. The kinetic energy of the gas (ρu^2) is constant (for constant gas pressure) with increasing gas temperature. Therefore, assuming a constant surface tension, the aerodynamic Weber number We_g is constant and not a function of the gas temperature:

$$We_g = \frac{\rho_g \cdot \Delta u^2 \cdot D_l}{\sigma} = \text{const.} \tag{19.130}$$

The influence of the increasing shearing action between the melt jet and the gas flow with increasing gas temperature and constant gas pressure is formulated in the gas Reynolds number Re_g formed with the relative velocity Δu between gas flow and melt jet. By rearrangement, the gas Reynolds number may be written as

$$Re_g = \frac{\rho_g \cdot \Delta u \cdot D_l}{\mu} = \frac{\rho_g \cdot \Delta u^2}{\mu(\Delta u / D_l)} \tag{19.131}$$

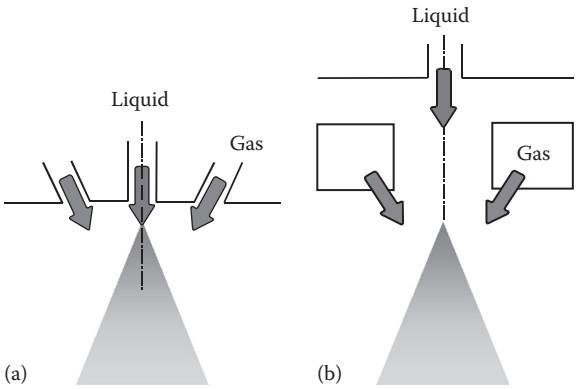

Figure 19.53

Twin-fluid atomizer: (a) close-coupled and (b) free-fall atomizer principles.

Several atomization mechanisms and devices are used for disintegration of *molten metals*, an overview has been given by Lawley (1992), Bauckhage (1992), Yule and Dunkley (1994), Liu (2000b), and Nasr et al. (2002). Especially, twin-fluid atomization by means of (inert) gases or liquids (water) is used because of

- The possibility of high throughputs and disintegration at high mass flow rates
- The high heat transfer rates for rapid cooling of the melt droplets
- The direct delivery of kinetic energy to accelerate the droplets (for compaction purposes)
- The minimization of oxidation by use of inert gases

In most gas atomization cases with external mixing, the central melt jet stream is surrounded by a gas flow from a single (slit) jet configuration or a set of discrete gas jets, which are flowing parallel or inclined toward the melt stream. The coaxial atomizer gas usually exits the atomizer at high pressures with a high kinetic energy. Two main configurations and types of external mixing twin-fluid atomizers need to be distinguished as they result in different fragmentation characteristics. The first one is the confined or close-coupled atomizer and the second is the free-fall atomizer (Figure 19.53). The gas flow in the close-coupled atomizer immediately covers the flowing melt jet. Within the confined atomizer, the distance between gas exit and melt stream is smaller than in the free-fall arrangement, where the melt jet moves a certain distance in the direction of gravity before the gas flow impinges onto the central melt jet; therefore, the close-coupled configuration generally results in higher atomization efficiencies (in terms of smaller particles at identical energy consumption). But the confined atomizer type is more susceptible to freezing problems of the melt at the nozzle tip. This effect can be due to the extensive cooling of the melt by the expanding gas flow, which exits in the close-coupled type near the melt stream and contributes to rapid cooling of the melt at the tip of the melt nozzle. The thermal-related freezing problem is most important directly in the initial phase of the spray process when the melt stream is initiated and exits the nozzle for the first time. At that point, the nozzle tip is still cool and needs to be heated first either externally or by the hot melt flow.

In a close-coupled atomizer, the liquid/melt typically is prefilmed at the nozzle face due to the action of the gas recirculation from the concentric arrangement (see Figure 19.54 adapted from Ünal, 1987, 1989). Modeling the fragmentation process of metal melts within a close-coupled atomizer arrangement has been derived by Antipas et al. (1993) and Liu (1997). Based on experimental observations of fragmentation processes within atomization in close-coupled atomizers (Ünal, 1987, Anderson and Figliola, 1988, Anderson and Terpstra, 2002, Ting et al., 2002), it is assumed that (at least under general conditions) the emerging fluid from the atomizer is moving from the tundish exit as a radial film at the lower side of the nozzle tip toward the gas jets delivery area. The local liquid film thickness τ_f is derived from a Couette flow analogy as follows:

$$\tau_f = \left[\frac{\mu_l}{\mu_g} \frac{\dot{m}_l}{\pi \rho_l r} \left(\frac{du_g}{dz} \right)^{-1} \right]^{0.5} \tag{19.132}$$

At the outer edge of the wetted nozzle tip, the liquid film is influenced by the gas flow field and is reflected into the main gas flow direction. From this point on, the liquid moves as a free concentric ring configuration

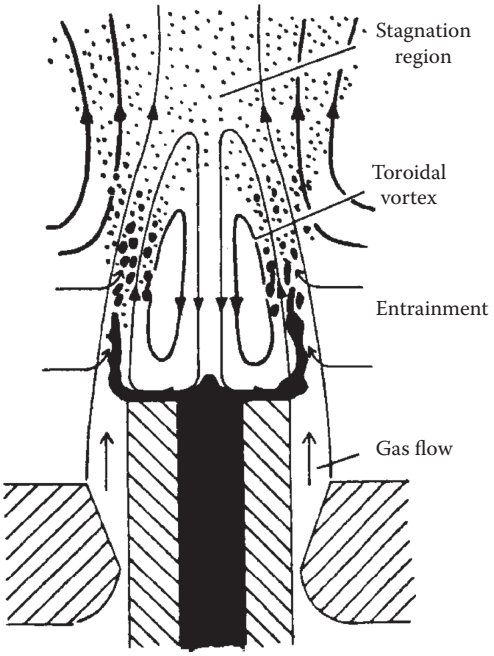

Figure 19.54

Flow field configuration in atomization area of close-coupled atomizer. (Adapted from Ünal, A., *Metall. Trans.*, 20B, 613, 1989.)

in the direction of the gas streamlines. In this area, the liquid film is fragmented after a certain distance in a primary fragmentation process into droplets. The characteristic distance from the atomizer to the fragmentation point is derived from empirical data as

$$L_f = 1.23\,\tau_f^{0.5}\,\mathrm{We}_f^{-0.5}\,\mathrm{Re}_f^{0.6} \tag{19.133}$$

Here, the film Weber number We_f and the film Reynolds number Re_f are derived using the local film thickness τ_f and the relative velocity between gas and liquid u_{rel} respectively the film velocity u_f:

$$\mathrm{We} = \frac{\tau_f \rho_g u_{rel}}{2\sigma}; \quad \mathrm{Re} = \frac{\tau_f \rho_l u_g}{\mu_l} \tag{19.134}$$

Developments for understanding fragmentation of a metal melt in a close-coupled atomizer during atomization have been introduced by Ting et al. (2002). These authors discuss especially the effect of the aspiration pressure on the flow of gas and liquid at gas pressures up to 5.5 MPa. The atomization gas flow field results in a fluctuating pressure distribution at the melt outlet. Based on gas dynamic assumptions for the gas flow field in the nozzle vicinity for increasing gas pressures, these authors finally conclude that for increased gas pressures, an oscillating flow field of the gas may occur. This effect will result in the temporal occurrence of central orthogonal shock structures in front of the nozzle. Based on this observation, a fragmentation process model is developed, which predicts, for gas pressures exceeding a configuration dependent threshold value, a pulsating flow field configuration of the melt flow at the nozzle tip (see Figure 19.55) and therefore highly transient atomization behavior.

19.1.8.3 Solid/Liquid Suspensions

The atomization of solid/liquid suspensions is important in chemical, food, and pharmaceutical industrial applications (e.g., for paints, paper coatings, printing inks, ceramics, cosmetics, detergents) and in energy conversion (coal water slurries). In typical technical suspensions, the solid particle size may range from 1 nm to 1 mm, while the solid concentration may be up to 70 weight/volume %, depending on the specific application. The presence of solid particles in the carrier liquid, which may lead to plugging and/or wear-out of the atomizer material, introduces an additional criterion for the selection of a specific atomizer type (pressure, twin-fluid, or rotary) for suspension atomization.

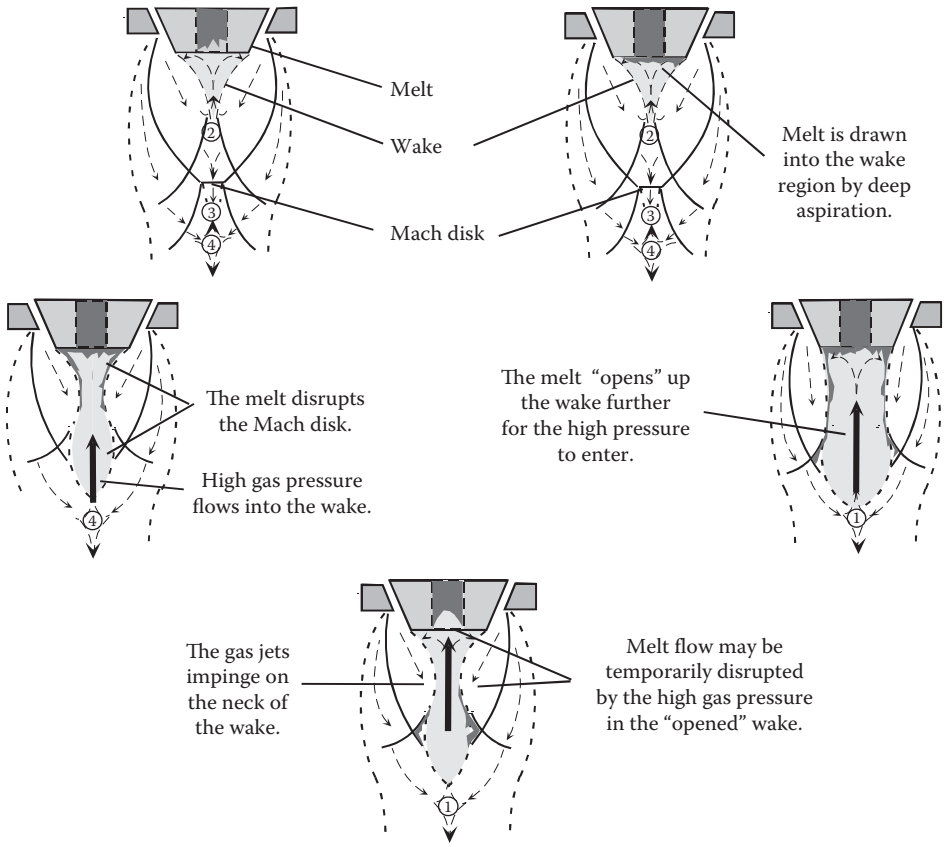

Figure 19.55

Pulsating melt flow in close-coupled atomization. (From Ting, J. et al., *Mater. Sci. Eng. A*, 326(1), 110, 2002. With permission.)

Interactions between the three different phases (solid particles, liquid, and gas) as well as the non-Newtonian rheological properties of the suspension, which strongly depend on the solid particles, play an important role in the disintegration process of suspensions. These parameters make an extension of basic fragmentation theories of pure liquids for analysis of suspension atomization processes difficult. Theoretical work on this subject has been presented by Parthasarathy (1999), who studied the breakup of two-dimensional slurry sheets subjected to gas flow using linear spatial stability analysis for the case of a dilute slurry and a dense slurry. Schütz et al. (2003) used the semi-empirical Carreau–Yasuda model to describe the flow behavior of a suspension in a mathematical–physical model to calculate the resulting mean droplet diameter in suspension spray produced by a hollow-cone nozzle. In the case of suspension disintegration, experimental research dominates the research effort (see, e.g., Dombrowski and Fraser, 1954, Shirley et al., 1987, Glaser, 1989, Kurt et al., 2002, Mulhem et al., 2002, 2003a,b, 2006a,b, Shimizu et al., 2002, Gramlich and Piesche, 2012, Jedelsky, 2013).

The most important parameters controlling the formation process of the droplet in a suspension spray are the atomization energy, the capillary pressure, the cohesion forces between the solid particles, and the suspension viscosity. While the atomization energy depends on the type of the atomizer, the other parameters are strongly influenced by the solid particle size and concentration. The adhesion forces and suspension viscosity increase with decreasing solid particle size and increasing solid particle concentration in the suspension. Therefore, the droplet formation process becomes difficult in the case of a suspension containing small solid particles and/or high solid concentrations.

The influence of the solid particle characteristics and the carrier liquid properties on suspension atomization in film formation atomization processes (e.g., by means of hollow-cone nozzles, flat spray nozzle, or rotary atomization) is reported by Schütz et al. (2003), Glaser (1989), Kurt et al. (2002), and Mulhem et al. (2006a,b). In the film formation process, the breakup length of the suspension sheet is shorter than the breakup length of the comparable pure carrier liquid sheet due to the disturbance of the liquid surface by the particles. The solid particle size and density affect the perforation mechanism in the dilute suspensions.

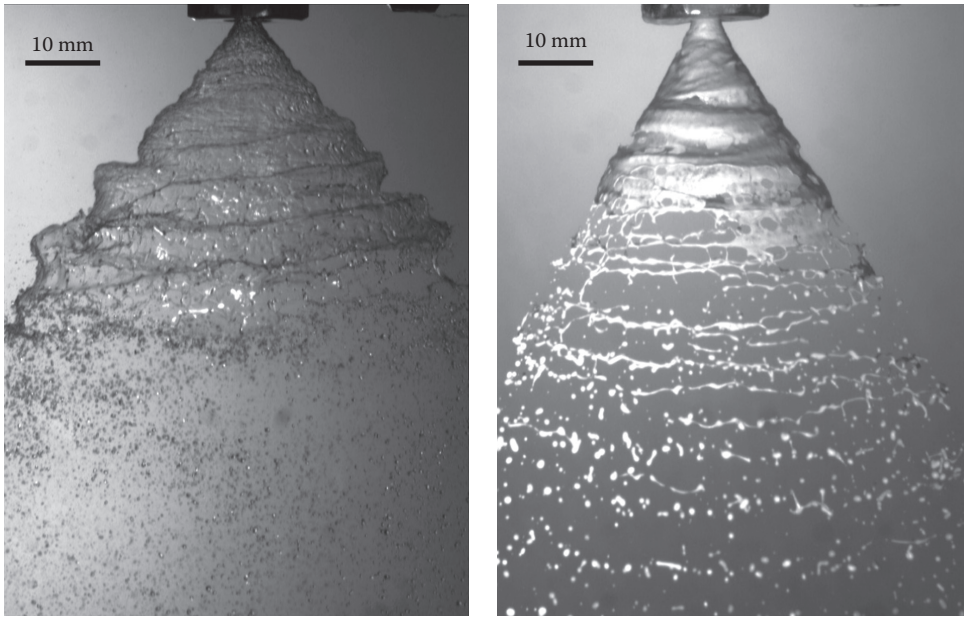

Figure 19.56

Hollow cone lamella for different process fluids: (a) water; (b) clay/water-suspension (30 v.%). (Adapted from Mulhem, B. et al., Break-up of hollow cone and flat suspension lamellae of pressure atomizers, in *Proceedings of ICLASS 2006*, Kyoto, Japan, August 27–September 1, 2006a.)

In this case, solid particles with high relaxation time (large diameter or high density) cannot follow the turbulent fluctuations in the liquid sheet that leads to increase in the velocity difference between the particles and the liquid. Accordingly, the perforation mechanism is promoted by the solid particles. Figure 19.56 shows photographs of the breakup process of the hollow cone sheet of two different process fluids, water and clay/water suspension (30 v.%). By adding solid particles to the basic process fluid, its flow behavior changes, that is, it becomes shear-thinning rather than Newtonian as for the pure carrier liquid. The photographs show that the hollow cone liquid sheets will disintegrate into ligaments and drops according to aerodynamic waves. However, the formation of perforations or cell structures is obvious on the suspension film.

Gramlich and Piesche (2012) investigated the breakup of particle-laden liquid jets or threads in a centrifugal field. Despite an increase in volume concentration of particulate materials from 4.5% to 20%, the variation of the atomization characteristics like drop size is not significant, possibly because of the suspension containing relatively fine particulate materials (particulate materials: 6.55–22.5 μm vs. droplets: 200–2000 μm).

Effervescent atomization of suspension is reported by Jedelsky (2013). Effervescent atomizers have larger orifice than conventional atomizers, and thus can avoid clogging or abrasion during the atomization of suspension, especially for suspension containing large solid particles. The interactions among the three different phases (gas, liquid, solid) occur during the disintegration process.

19.1.9 Drop Size Correlations in Sprays

19.1.9.1 Theoretical Analysis

Approaches for general theoretical descriptions of drop size distributions resulting from atomization processes can be based on statistical approaches and tools, which derive a PDF in relation to the process to be analyzed. The maximum entropy formalism (MEF) is statistical tool that delivers partial information for a specific process (based on a number of compulsatory conditions) by transformation into a suitable distribution function. An MEF is a statistical tool and does not contribute any physical aspects to the analysis of the fragmentation processes. Fundamental model developments in the area of applying MEF to the analysis of fragmentation processes of liquids and the derivation of the resulting droplet size distributions in sprays have been done by Sellens (1989), Sellens and Brzustowski (1985), and Li and Tankin (1987). Their approaches have been further

developed by Ahmadi and Sellens (1993) and Cousin and Dumouchel (1997). The fundamental idea of this modeling is the description of a PDF of the particle size distribution $q_r(d)$ from the Shannon entropy (uncertainty) Sha:

$$\mathrm{Sha} = -k_S \int_0^\infty q_r(d) \ln(q_r(d)) d(d) \tag{19.135}$$

where k_s is a constant, to be determined by the dimensionality of the specific process under investigation.

The MEF allows the prediction of the droplet size PDF, depending on a number of mathematical constraints. These constraints are described based on a number of known conservation properties of the process and their distribution and are equivalent to the moments of different orders of the distribution. Without further limitations, a number of different PDFs fulfill a given set of constraints. The MEF describes the best-fit solution for which entropy reaches a maximum value. Cousin et al. (1996) describe the resulting number density-based particle size distribution of a pressure swirl atomizer from this formalism as

$$q_0(d) = \frac{p^{(p-1)/p}}{\Gamma_S(1/p) d_{p0}} e^{(-d^p/p d_{p0}^p)} \tag{19.136}$$

containing the Gamma function Γ_s. The determination of input parameters like p and d_{p0} in aforementioned derivation is done either based on specific singular measurements (Ahmadi and Sellens, 1993) of moments of a measured spray particle size distribution or by a primary analysis of the fragmentation process based on linear stability analysis (Cousin and Dumouchel, 1997). For an atomization process where the principal mode of the disintegration process is constant (constant fragmentation mode), the resulting particle size distribution in terms of a mean or characteristic particle size and the particle size distribution width can be determined by this method. Applications are described by Malot and Dumouchel (1999), and Prud'homme and Ordonneau (1999). For application within ultrasonic liquid atomization, refer to Dobre and Bolle (1998).

Another model is the approach of Platzer and Sommerfeld (2003). It originates from a structural effects theory based on the work of Naue and Bärwolf (1992) as detailed by Hartmann (1993), and provides functions for drop size and volume distribution. In contrast to conventional MEF models, no mean drop diameter needs to be provided as input parameter. The SMD and the drop size distribution are calculated iteratively using only known geometrical information and operating conditions. This is done assuming a structure formation process that is a function of the critical Weber number. Some varying functions are derived, differing in the number of drops in each class and in the function of the critical Weber number describing the number of classes formed. The complete spray model from internal and primary fragmentation flow to the spray structure simulation is described. The two-fluid model including the prediction of the drop size distribution is used for the first part and the Euler/Lagrange method for the second part.

A two-stage modeling approach of atomization may be based on primary fragmentation in the first step from stability analysis, and ligament fragmentation described as a Rayleigh breakup process in the second step. A model for liquid fragmentation for coaxial twin-fluid atomization (round liquid jet) has been introduced by Fritsching (2001) and a similar model for annular ring film disintegration by Lund et al. (1993). The description of the gas and liquid state prior to atomization within these models has been derived by means of experimental and/or numerical flow field studies. Mean drop size correlations in the initial spray are derived.

19.1.9.2 Empirical Drop Size Correlations

A large number of empirical correlations for drop size distributions in sprays have been derived (Lefebvre, 1989, Bayvel and Orzechowski, 1993, Liu, 2000b, Walzel, 2012, Walzel and Musemic, 2013). These drop size correlations typically fit only a specific atomizer type (respectively atomization principle) and a certain (narrow) range of boundary conditions or disintegration modes. The boundary conditions include the geometric constraints of the atomizer design and operational parameters such as liquid properties, flow rates, pressures, and others. The characteristic droplet size in the spray spectrum (typically given as mean, median or Sauter diameter) is either correlated in terms of dimensionless numbers or in terms of direct material and operational properties. A few of those correlations discussed before with respect to some different atomizer types are given in Table 19.6. The analysis of the drop size distribution width and correlation in a spray is given in few cases only.

Table 19.6 Examples of Empirical Droplet Size Distributions for Various Atomizer Types

Application	Drop Size	Source
Pressure Atomizer	$d_{32} = 47\frac{d_0}{u_0}\left(\frac{\sigma}{\rho_g}\right)^{0.25}\left[1+331\frac{\mu_l}{(\rho_l\sigma d_0)^{0.5}}\right]$	Tanasawa and Toyoda (1955)
Pressure swirl atomizer	$d_{32} = 2.25\sigma^{2.25}\mu_l^{0.25}\dot{m}_l^{0.25}\Delta p_l^{-0.25}\rho_g^{-0.25}$	Lefebvre (1983)
Hybrid atomizer (pressure swirl gas atomizer)	$d_{50,3} = 1.45(1+\dot{M}_l/\dot{M})(360/\alpha)^{0.37}$ $\cdot\left(A\left(\frac{\sigma}{\rho_g U_g^2}\right)^{0.6}\left(\frac{\rho_l}{\rho_g}\right)^{0.1} h_0^{0.4} + B\left(\frac{\mu_l^2 h_0}{\sigma\rho_l}\right)^{0.5}\right)$, $A = 0.07$ and $B = 0.01$	Achelis (2009)
Twin-fluid atomizer (external)	$d_{32} = 0.585\left(\frac{\sigma}{\rho_l u_{rel}^2}\right)^{0.5} + 53\left(\frac{\mu_l^2}{\sigma\rho_l}\right)^{0.225}\left(\frac{\dot{Q}_l}{\dot{Q}_g}\right)^{1.5}$	Nukiyama and Tanasawa (1939)
Twin-fluid atomizer (internal, bubbly flow regime)	$d_{32} = \left[0.023ALR\frac{\rho_l RT_a}{\sigma(\kappa-1)}\left(1-\left(\frac{p_a}{p_c}\right)^{(\kappa-1)/\kappa}\right)+\frac{2.35}{d_0}\right]^{-1}$	Kim and Lee (2001)
Twin-fluid atomizer (internal, annular flow regime)	$d_{32} = 0.14\, d_0\, f\left(\alpha,\frac{\rho_g}{\rho_l}\right)\left(\frac{\rho_g j_g^2 d_0}{\sigma}\right)^{-0.5}$ $f\left(\alpha,\frac{\rho_g}{\rho_l}\right) = \frac{\alpha\sqrt{1-\alpha}}{1-\sqrt{\frac{\rho_g}{\rho_l}\left[\frac{1+75(1-\alpha)}{\sqrt{\alpha}}\right]^{0.5}}}$	Kim and Lee (2001)
Rotary atomizer (drop mode)	$d_{32} = \frac{27}{n_z}\left[\frac{\sigma}{2\rho_l r}\left(1+0.003\frac{\dot{Q}\rho_l}{2r\mu_l}\right)\right]^{0.5}$	Tanasawa et al. (1978)
Rotary atomizer (fiber mode)	$d_{32} = 0.119\frac{\dot{Q}^{0.1}\sigma^{0.5}}{n_z(2r)^{0.5}\rho_l^{0.4}\mu_l^{0.1}}$	Tanasawa et al. (1978)
Rotary atomizer (fiber mode)	$d = (d_0/2)\sqrt[3]{(12\pi/K_{r,Z,crit})(\bar{R}_s\,\vert_{Z=L})^2}$	Gramlich et al. (2011)
Rotary atomizer (film mode)	$d_{32} = 15.6\frac{\dot{Q}^{0.5}}{n_z}\left[\frac{\sigma}{(2r)^2\rho_l}\right]^{0.4}$	Tanasawa et al. (1978)
USWA	$d_{50,3} = 0.53\dot{Q}^{0.27}d_0^{-0.24}\mu^{0.69}\rho_l^{-0.21}p_{max}^{-0.97}\rho_0^{0.48}c_0^{0.97}$	Hansmann (1996)

19.1.9.3 Suspension Atomization

Some correlations for suspension droplet sizes in sprays generated using different atomizer types are summarized in Table 19.7.

The experimental results of Son and Kihm (1998), using laser diffraction particle analysis and assuming a Rosin–Rammler-type droplet size distribution (RRSB) in the spray, showed that the SMD (d_{32}) of coal-water-slurry (CWS) containing smaller coal particles is larger than the SMDs of CWS containing larger coal particles. The separation of the solid particles from each other in the suspension spray has to be controlled by the solid particle characteristics. Mulhem et al. (2003a, 2006b) confirm this assertion experimentally in the case of twin-fluid suspension atomization. Figure 19.57 shows a bimodal droplet size distribution of suspension spray containing large solid particles $d_{50,3}$ = 94 µm (right) and a monomodal droplet size distribution of suspension spray containing small solid particles $d_{50,3}$ = 6 µm (left).

The influence of the solid particle characteristics and the carrier liquid properties on suspension atomization for the case of a twin-fluid suspension atomization process may be summarized as follows. In the case of suspension containing *large solid particles*, the solid particles tend to separate from the carrier liquid (Glaser, 1989, Mulhem et al., 2003a, 2006b). Dry solid particles are being seen in the spray, their characteristic diameter independent of the atomization energy, and pure carrier liquid drops, which disintegrate further with

Table 19.7 Drop Size Correlations for Suspension Atomization

Application	Drop Size	Sources
Internal mixing twin-fluid atomizer	$\frac{d_{50,3}}{d} = \left[\left(A\cdot(\mathrm{We}_g)^{-x} + B\cdot(\mathrm{Oh})^{2x}\right)\right]\left[1+\frac{1}{ALR}\right]^{y}$ $\mathrm{We}_g = \frac{\rho_g u_g^2 d_F}{\sigma}$; $\mathrm{Oh} = \frac{\mu_l}{\sqrt{\rho_l \sigma d}}$; $ALR = \frac{\dot{m}_g}{\dot{m}_l}$ A, B, x, y: parameters depend on coal-slurry coal particles: $d_{50,3} \le 32$ µm, $Cp \le 72$ wt%	Shirley et al. (1987)

increasing atomization energy, as shown in Figure 19.58. The solid particle size in the suspension influences the resulting diameter of the pure carrier liquid drops, which is explained as a result of reducing the volume of the liquid bridge between the solid particles by decreasing the solid size in the suspension. Investigation of the influence of solid particle concentration on the atomization of suspension containing large solid particles showed only a small influence on the resulting pure liquid diameter. The diameter of the carrier liquid drops in the spray increases with increasing viscosity of the carrier liquid.

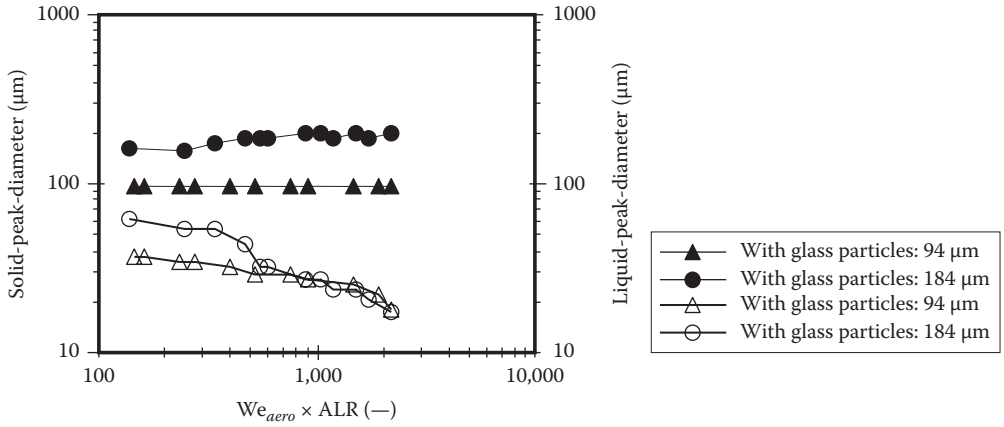

Figure 19.58

Peak of the logarithmic particle size distribution for suspension atomization containing large solid particles. (From Mulhem et al., 2003b. With permission.)

In the case of suspension spray containing relatively *small solid particles*, the large cohesion forces between the particles prevent the liquid/solid separation process. The majority of the droplets in the spray are suspension droplets. The suspension droplets behave like pure liquid droplets, taking into account the change in material properties due to the particles. That means, the suspension droplets may disintegrate into smaller ones with increasing atomization energy. The diameter of the suspension drops in the spray is comparable to the diameter of carrier liquid drops (Isenschmid, 1992). The droplet diameter in the suspension spray increases with increasing solid concentration.

Mulhem et al. (2006b) defined a limit of the separation process within a twin-fluid atomizer (external mixing), assuming that the separation process can take place if the droplet diameter produced by twin-fluid atomization at the given operational parameters equals or is smaller than the solid particle diameter in the suspension. This critical process condition is expressed as

$$0.21 d_l \left(\frac{\mu_l}{\sqrt{\sigma \rho_l d_l}} \right)^{0.0622} \left(\frac{\rho_g d_l}{\sigma} ALR \right)^{-0.4} U_{rel}^{-0.8} \leq \left(\frac{9}{2} \frac{1-\varepsilon_a}{\varepsilon_a} \frac{\sigma}{\rho_g} \right) \frac{1}{U_{rel}^2} \tag{19.137}$$

In this equation, the term on the left represents the mean droplet diameter in the liquid spray, and the term on the right represents the solid particle diameter in the atomized suspension. Other parameters in this equation include liquid viscosity (μ_l), surface tension (σ), liquid density (ρ_l), liquid-nozzle exit diameter (d_l), air density (ρ_g), the air to liquid mass flow rate ratio (ALR), gas-droplet relative velocity (U_{rel}), and the agglomerate porosity of suspension droplet (ε_a). In an approximation, the agglomerate porosity of suspension drops (ε_a) can be calculated as a function of the bulk density (ρ_B) and the particle density (ρ_p) as follows (Rajathurai, 1990):

$$\varepsilon_a = 1 - \frac{\rho_B}{\rho_p} \tag{19.138}$$

19.1.9.4 Melts

In Table 19.8, some empirical correlations for particle sizes within molten metal atomization in free-fall and close-coupled atomization are given. In Lubanska's correlation, a liquid Weber number $We_l = \rho_l u_{max}^2 d_l / \sigma_l$ and the inverse of the mass flow rate ratio (1/GMR; GMR = gas to metal mass flow ratio) are used. The empirical constant K_{lub} reflects different atomizer geometries. Lubanska has given its value to be between 40 and 80, but other investigations have found much larger values. A sample evaluation of particle sizes in molten metal sprays for various metals versus the atomizer gas pressure based on Lubanska's correlation is illustrated in Figure 19.59. Several investigations aimed verification of Lubanska's formula for particle size distributions

Table 19.8 Drop Size Correlations for Molten Metal Atomization

Application	Drop Size	Sources
Free-fall atomizer	$d_{50,3} = d_0 K_{\text{lub}} \left[\frac{\nu_l}{\nu_g} \frac{1}{\text{We}_l} \left(1 + \frac{\dot{m}_l}{\dot{m}_g} \right) \right]^{0.5}$	Lubanska (1970)
Close-coupled atomizer	$d_{3,2} = \frac{12\sigma}{\frac{\rho_l u_{rel}^2}{1 + 1/(\varepsilon(\dot{m}_g/\dot{m}_l))} + 4\frac{\sigma}{\tau_f}}$; $\varepsilon = \frac{1.62}{u_g^{1.3}(\dot{m}_g/\dot{m}_l)^{0.63}\mu_l^{0.3}}$	Liu (1997)

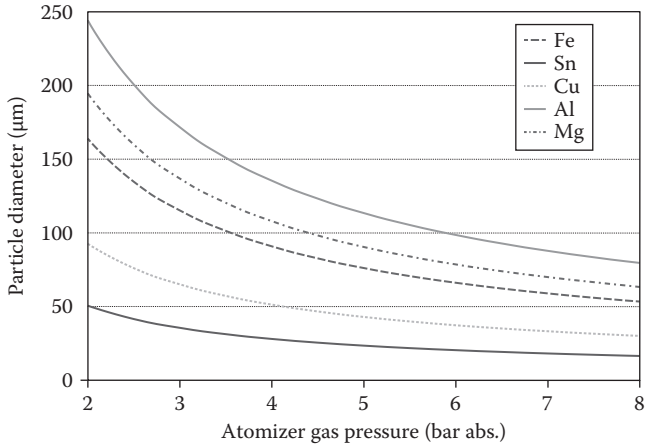

Figure 19.59

Mean particle sizes in molten metal atomization, evaluation of (Lubanska, 1970) correlation.

from melt atomization. The work of Rao and Mehrotra (1980) investigated the influence of nozzle diameter and atomization angle on particle sizes, finding that the mean droplet size decreases with decreasing nozzle diameter and increasing atomization angle. They found a different value of the exponential factor as well as the atomizer constant in Lubanska's correlation. Another modification has been proposed by Rai et al. (1985). These authors studied melt atomization within ultrasonic gas atomizers and also proposed a modification of Lubanska's formula.

A discussion and evaluation of the relevance of Lubanska's formula for the atomization of metal melts in twin-fluid atomization can be found in Bauckhage and Fritsching (2000). A general overview for a number of empirical correlations for mean and median droplet sizes dependent on operational conditions and nozzle types and geometries for melt atomization within different atomizer configurations can be found in Liu (2000b) and Yule and Dunkley (1994).

19.2 Spray Behavior

In terms of a multiphase flow approach to spray analysis, main features of the dispersed spray to be described are

- The overall spray geometry (e.g., spray angle)
- The local fluxes of droplet mass, momentum and enthalpy (where appropriate)
- The equivalent droplet concentrations by number or volume
- The local droplet size and droplet state including velocity and temperature distribution

The analysis of the spray behavior is to be divided into two regions, depending on the relevance of droplet/droplet interactions and the possibility and frequency of droplet/droplet collisions. A rough estimate of the relevance of collisional effects to the overall spray behavior can be done based on the ratio of particle relaxation time τ_p to the time scale between individual particle collisions τ_c. The particle relaxation time is the

time that a droplet takes to be accelerated from velocity u_1 to u_2 that is (in the Stokes flow regime) expressed as (see Chapter 1)

$$\tau_p = \frac{\rho_l d_p^2}{18\mu_g} \tag{19.139}$$

The time constant between collisions for particles is to be derived from the collision frequency as

$$\tau_c = \frac{1}{f_c} \tag{19.140}$$

At low droplet concentrations (dilute flow), the particulate transport mainly is determined by fluid dynamic interactions of the individual particles or droplets with the continuous carrier phase (like drag, lift, etc.). At high particle concentrations (dense flow), the influence of particle collisions affects the movement of the droplets and the droplet size distribution. These two regions may be separated in terms of the ratio of the characteristic time scales as (see also Chapter 1)

$$\text{Dilute: } \frac{\tau_p}{\tau_c} < 1; \quad \text{Dense: } \frac{\tau_p}{\tau_c} > 1 \tag{19.141}$$

In a dense spray, the time between droplet collisions is smaller than the droplet relaxation time. Before reaching another steady slip velocity from the droplet gas interaction, another collision may occur. Therefore, the droplet movement is determined mainly by collisions and fluid dynamic effects are of less importance. In sprays, the area close to the atomizer typically is a dense spray region as here the number concentration of droplets is high, while with increasing distance to the atomizer due to the spreading of the spray cone, droplet collisional effects decrease and transition to dilute flow is achieved.

19.2.1 Dense Spray

19.2.1.1 Collisions and Coalescence

When two liquid droplets are interacting during flight, several events may occur. The colliding droplets may (1) bounce, (2) stably coalesce, (3) temporarily coalesce followed by disruption, or (4) temporarily coalesce followed by fragmentation. The two droplets can be equal or unequal sized from the same liquid, or different miscible liquids, or different immiscible liquids (Brenn, 2011). The merging of the two droplets from different immiscible liquids may result in a complex droplet with core/shell structure. Planchette et al. (2012) describe this phenomenon by use of the term *encapsulation* instead of *coalescence*. Details on binary droplet collision phenomena are discussed in Chapter 14. The following discussion mainly focuses on the collisions of droplets from a same liquid or different miscible liquids.

For relevance in spray processes, experimental works of water/water and hydrocarbon/hydrocarbon droplet collisions have been studied extensively. Orme (1997) reviewed the experimental studies of water and hydrocarbon droplet binary collisions. The basic phenomena of coalescence and separation of droplets during binary collision have been experimentally addressed in some investigations such as by Walzel (1980a), Low and List (1982), Ashgriz and Poo (1990), Rein (1996), Qian and Law (1997) for water and fuel droplets, and Menchaca-Rocha et al. (1997) for mercury droplets.

Brenn et al. (2001b) and Brenn and Kolobaric (2006) have investigated the formation of satellite droplets during unstable binary collisions of equal sized droplets. The satellites are formed by contraction or breakup of a ligament, which is formed from the mass of the two interacting droplets and may eventually pinch off from the remaining portions of the droplets. Stability nomograms of the Weber number (We) and the nondimensional impact parameter (B) have been developed to describe the collision behavior of the droplets by zones with constant numbers of satellite droplets formed only at sufficiently high Weber number due to either reflexive separation (for small impact parameters) or stretching separation (for intermediate and large impact parameters), as illustrated in Figure 19.60. In the reflexive separation regime, the formation of one satellite droplet occurs with highest probability. In the stretching separation regime with moderate values of the impact parameter, the satellite droplets are formed at the ends of the ligament by end-pinching mechanism, and the number of satellite droplets increases with the impact parameter, until a maximum is reached. A further increase of the impact parameter leads to the satellite-droplet formation process dominated by the capillary wave growth and

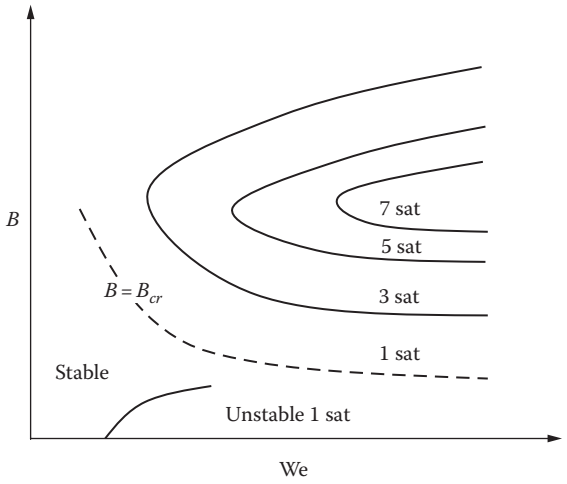

Figure 19.60

Schematic of stability nomogram divided by zones with constant numbers of satellite droplets formed during binary collisions of equal-sized droplets.

thereby a decrease of the number of satellite droplets. An increase of the Weber number generally leads to the formation of more satellite droplets. For example, the collisions of two propanol droplets with a size of 139 μm can produce more than 7 satellites for We > 150. Different satellite-droplet formation mechanisms can be categorized based on the ligament aspect ratio (L_{lig}/d_{lig}, L_{lig} is the ligament length, d_{lig} is the ligament diameter) and the nondimensional ligament diameter (d_{lig}/D, D is the initial droplet diameter): for $L_{lig}/d_{lig} < 10$, the ligament contracts to a single satellite; for $L_{lig}/d_{lig} > 10$ and $d_{lig}/D > 0.17$, the end-pinching mechanism occurs; for $L_{lig}/d_{lig} > 28$ and $d_{lig}/D < 0.17$, the ligament breakup is influenced by capillary waves. Brenn and Kolobaric (2006) have derived the mathematical formulations of the length and volume of the ligaments and the size of the satellite droplets formed after stretching breakup based on the outcomes of binary collisions of propanol droplets.

In most of these experimental studies, only rather low dynamic viscosities, ranging from 1 to 10 mPa s, were considered. Gotaas et al. (2007) investigated different species (i.e., MEG, DEG, and TEG, which is mono-, di-, and triglycol) with viscosities from 21 to 48 mPa s and compared results for the boundary between coalescence and stretching separation as well as reflexive separation. Increasing viscosity results in an upward shift of the boundary between coalescence and stretching separation toward higher impact parameters, and also shifts the onset of reflexive separation to higher Weber numbers.

Binary collisions of solution droplets (i.e., aqueous solutions of saccharose and PVP) have been experimentally investigated by Kuschel and Sommerfeld (2013) and Kuschel (2013), whereby the dynamic viscosities of the aqueous solutions range from 1 up to 73 mPa s by varying the solute contents up to a value, which still allows a production of stable droplet chains. Most of the findings of Gotaas et al. (2007) have also been confirmed by Kuschel and Sommerfeld (2013) and Kuschel (2013). A critical capillary number Ca = 0.577 ($Ca = \mu_l U_{rel}/\sigma$) was suggested by Kuschel and Sommerfeld (2013), below which surface-tension effects govern the collision dynamics, while above which viscous effects govern the collision dynamics. The locations of the triple point (bouncing, coalescence, and stretching separation collapse in one region) and the onset of reflexive separation in a We-B regime map (see Chapter 14) have been formulated by Kuschel (2013), respectively, as

$$\text{Triple point: } \mathrm{Re} = \frac{K^2}{2}\mathrm{Ca}^{-\sqrt{1-(1/e^2)}} \Rightarrow \mathrm{We} \tag{19.142}$$

$$\text{Onset of reflexive separation: } \mathrm{We} = \frac{K^3}{3}\mathrm{Ca} + 2K \tag{19.143}$$

where

Re is the Reynolds number
Ca is the capillary number
We is the Weber number
$K = 6.9451$

The impact parameter (B) corresponding to the triple point can be derived by taking the critical Weber number into the correlations $B = f$ (We) characterizing the onset of stretching separation (as discussed in Chapter 14). As in Brenn et al. (2001b) and Brenn and Kolobaric (2006), the We-B diagram has been employed to describe the formation of satellite droplets. Kuschel and Sommerfeld (2013) found that an increasing of solute content and thereby an increasing of dynamic viscosity lead to a thinner and longer ligament, the breakup of which results in more satellites.

Binary collisions of suspension droplets in off-center collisions (impact parameter $B > 0$) have been experimentally investigated by Kurt et al. (2007, 2008). The formation of satellite droplets during the collisions is correlated by a function based on the basic parameters and dimensionless numbers of the process, for example, the Weber number (We), the particle loading ($\omega = m_{solid}/m_{liquid}$, with m_{solid} the mass of solid particles in a droplet and m_{liquid} the droplet mass), the particle size, and the Reynolds number (Re). The number of satellites produced by stretching separation increases with increasing We and Re values, but decreases with the particle loading.

Binary collisions of equal-sized melt droplets have been experimentally investigated by Gao and Fritsching (2010), where Carnauba wax as a low melting point material has been used. The droplets from two separate droplet-jets are colored differently, one in red and the other in yellow. The results indicate that the molten wax droplet collision shows similar behavior as conventional Newtonian droplets. Figure 19.61 illustrates the process of wax droplet collision in the regime of stretching separation. The right parts of all the figures show the images of the dynamic binary collision process, and the left parts show pictures of the solidified particles collected from that side below the collision zone, in which the yellow droplet is the main droplet color. In the collision regime of the stretching separation, depending on the impact parameter (B), a liquid ligament is formed between the two separating droplets and after

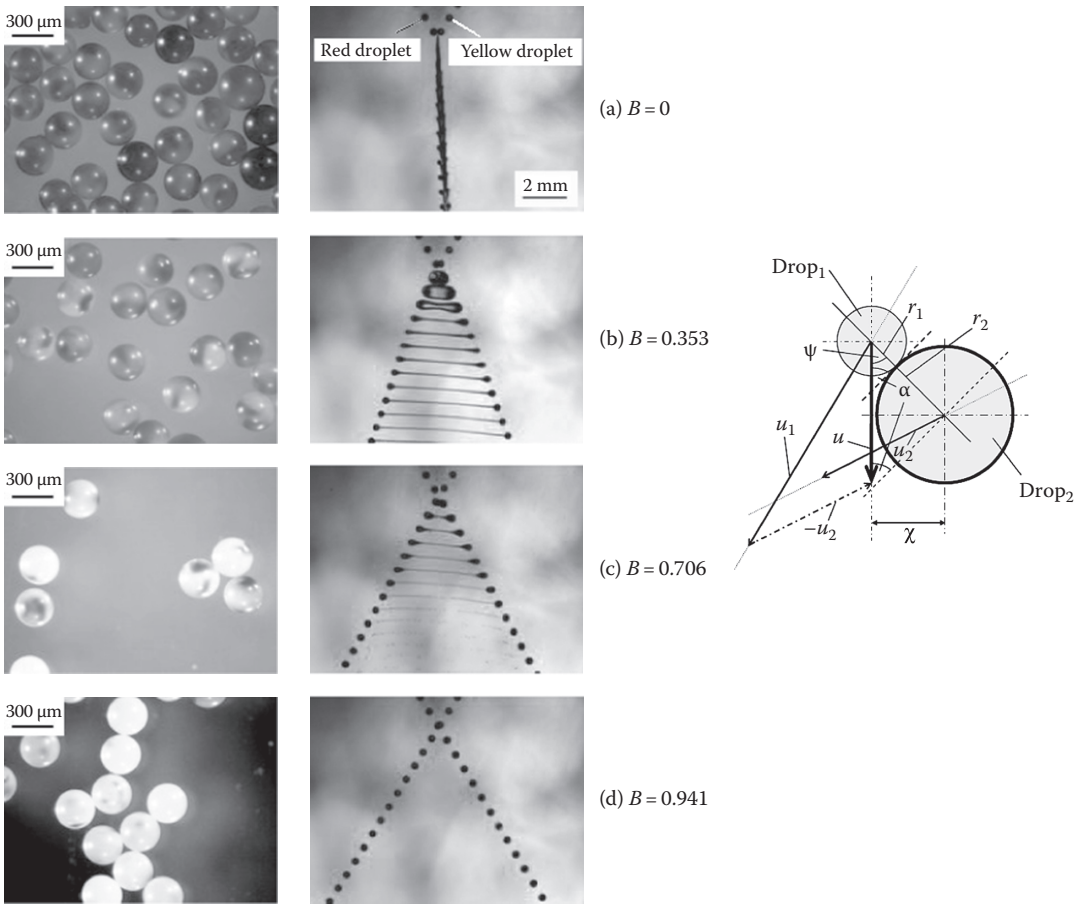

Figure 19.61

Collision process and solidified particles at various impact parameters (We = 570). (Adapted from Gao, S. and Fritsching, U., *Materialwiss. Werkstofftech.*, 41(7), 547, 2010. With permission.)

the ligament breakup, one or more satellite droplets between the two primary drops are formed. The color distribution of the collected particles shows the existence of a certain amount of mass transfer between the two colliding droplets. At smaller values of the impact parameter, this mass transfer is rather large. After the collision, there is a rotation of droplets caused by the angular momentum of the droplets, which plays a role in the process of stretching separation and formation of secondary particles. It should be mentioned that binary droplet collisions in this study have been performed only in the liquid/liquid state of both melt droplets. Fritsching and Gao (2010) have also studied the droplet/droplet and/or droplet/particle collisions in intersecting wax-melt sprays. Thereby, the collisions may lead to coalescence or sticking or aggregation of the particles, depending on the instantaneous solidification states of droplets upon collision.

19.2.1.2 Direct Numerical Simulations of Droplet Collisions

DNSs of the behavior of two droplets during collision have been reported by Nobari and Tryggvason (1996), Nobari et al. (1996), Frohn and Roth (2000), Pan and Suga (2005), Nikolopoulos et al. (2009a,b), Li and Fritsching (2011), Focke and Bothe (2011, 2012), and Kwakkel et al. (2013). Popular methods for DNS are front tracking and front capturing methods. Interface tracking methods are based on the Lagrangian tracking of marker particles that are attached to the interface motion and appear suitable for the interfaces with great regularities and small topological changes. ICMs capture the interface implicitly by a contour of a particular scalar function, for example, the LS function in the LS method and the volume-fraction advection equation in the VOF method. One advantage of the ICMs is its ability to represent topological changes, both in 2D or 3D geometry, quite naturally. Especially, the CLSVOF method combines the sharp interface representation of the LS method with the mass-conserving interface representation of the VOF method. Some principal physical details of drop collisions can be explained by the DNS approach. However, subgrid models are still necessary for an accurate description of the droplet-collision behaviors occurring in different regimes. These subgrid models may not be fully predictive, but nevertheless allow studying more details during the entire collision process.

One example is the modeling of retarded coalescence occurring at low Weber numbers. The reason for this phenomenon is that the air is trapped between the approaching droplets and needs a certain time to leave the gap. This effect is also relevant for the collision result bouncing, where the drops do not merge during the complete time of contact. According to Mackay and Mason (1963) and Bradley and Stow (1978), droplet coalescence may happen when the trapped gas layer thickness reaches a critical value, which is within the range of the molecular interaction, typically in the order of magnitude of 0.01 μm; otherwise, the droplets will bounce. Resolving this scale in a droplet collision simulation would lead to huge computational effort due to a large number of grid cells or levels of adaptive grid refinement, which is currently not feasible in a DNS even with high-performance computing techniques.

To appropriately describe the head-on collision process of retarded coalescence or bouncing during VOF simulation, Li and Fritsching (2011) have introduced an artificial gas layer between the colliding droplets by use of ghost (or dummy) cells adjacent to the symmetry plane. This artificial gas layer prevents the immediate numerical coalescence when two droplets approach each other. At a critical time when the thickness of the gas layer between the droplets reaches a minimum value, the gas layer can be removed, leading to coalescence; otherwise, the two droplets rebound from each other. Figure 19.62 shows collision sequences during retarded coalescence process from the experiment by Qian and Law (1997) and the VOF simulation by Li and Fritsching (2011), respectively.

In Kwakkel et al. (2013), the coalescence is modeled based on a multiple marker CLSVOF method coupled with a computationally efficient film drainage model in Zhang and Law (2011). The film drainage model predicts if and when two colliding droplets will coalesce. If the contact time between the two colliding droplets exceeds the predicted film drainage time, coalescence is numerically accomplished by merging the marker functions of the two separate droplets.

Experiments show that during the extension of the collision complex an extremely thin fluid lamella encircled by the thick rim often appears in case of large Weber numbers. A lamella rupture is not observed in binary collisions at least for Weber numbers up to 2800 in experiments (Focke and Bothe, 2012). In contrast to the physical behavior, simulations often predict the rupture of the lamella because of the unresolved lamella in the vicinity of the rim. If a simulation is continued with the lamella, the restoring forces acting on the rim are significantly reduced, leading to wrong results. According to Focke and Bothe (2011), the droplet collision at a Weber number of 766 can lead to a lamella thickness of 5.5 μm. With a resolution of 4 cells for the lamella thickness to keep the lamella from rupturing, the required resolution

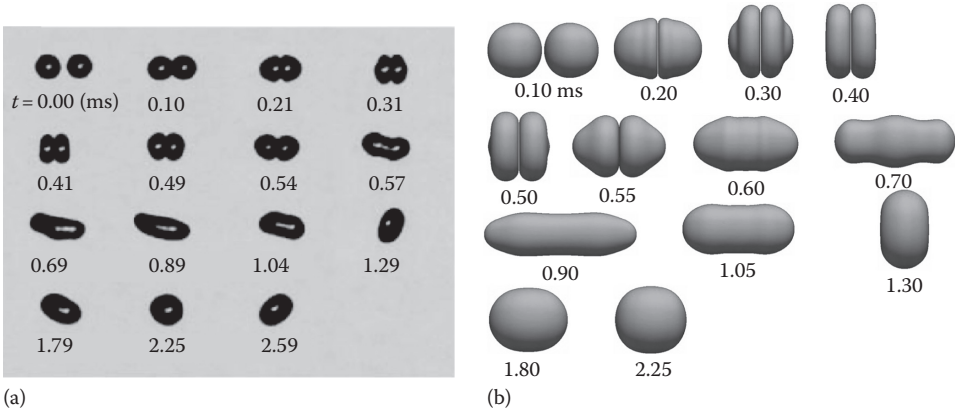

Figure 19.62

Collision sequences during retarded coalescence process: (a) experimental observation, (We, Re, B, D) = (15.2, 139.8, 0.08, 302 μm) (Adapted from Qian, J. and Law, C.K., *J. Fluid Mech.*, 331, 59, 1997.); (b) simulation results, (We, Re, I, D) = (15.2, 139.8, 0, 302 μm). (Adapted from Li, X.G. and Fritsching, U., *J. Comput. Multiphase Flows*, 3(4), 207, 2011.)

is 1.4 μm for the grid cells. Resolving such a lamella thickness in the DNS, even with the AMR technique, will lead to a huge computational cost. To overcome these problems, lamella stabilization schemes have been developed to keep the lamella from rupturing, refer to Focke and Bothe (2011, 2012). The procedure of the stabilization is to guarantee a minimum thickness of the lamella and subsequently compute the surface-tension forces without interactions of the two lamella sides. In the case of a head-on collision of two equal-sized droplets, this can be realized by modifying the volume-fraction (f) field only in the ghost (or dummy) cells adjacent to the symmetry plane. In a general collision, the different sides of a lamella must be firstly distinguished. A minimum thickness of the lamella is guaranteed through the addition of artificial mass. A modified f-field containing interface only on one side of the lamella, which is realized by setting *f*-value to one in all cells which are located on the opposite side of the lamella, is used to compute the surface-tension forces for both lamella sides, respectively. Figure 19.63 shows the shape evolution of the collision complex. The results of the shape using the lamella stabilization show good agreement with the experimental data.

From these droplet collision studies, the outcome of a binary collision can be visualized (see Chapter 14). Typically, droplet collision models are implemented in numerical spray codes such as Sommerfeld (1996), Georjon and Reitz (1999), Aamir and Watkins (1999), and Rüger et al. (2000).

19.2.1.3 Numerical Models of Droplet Collisions in Sprays

The most common used water/water collision model is based on O'Rourke (1981). This model considers only grazing collisions (bounce) and permanent coalescence. The decision criterion, whether grazing or coalescence collisions occur, is the critical collision angle:

$$\sin^2 \phi_{crit} = \min\left[2.4\frac{f(\gamma = d_{p,1}/d_{p,2})}{\mathrm{We}}; 1\right] \tag{19.144}$$

In case of a collision angle less than ϕ_{crit}, the droplets coalesce; otherwise, a grazing collision occurs. The function f has been fitted by Amsden et al. (1989) using experimental results as

$$f(\gamma) = \gamma^3 - 2.4\gamma^2 + 2.7\gamma \tag{19.145}$$

Podvysodsky and Shraiber (1994) proposed an empirical formula for liquid droplet collisions in a wide range of material properties. The mathematical expectation $\phi_{1,2}$ of the ratio between a target droplet's mass change and total mass of "projectile" droplets impacting on the target is

$$E\left[\frac{dm_2/dt}{m_1}\right] = \phi_{1,2} = 1 - 0.246\,\mathrm{Re}_{1,2}^{0.407}\,\mathrm{Lp}_2^{-0.096}\cdot\left(\frac{d_2}{d_1}\right)^{-0.278}; \quad \mathrm{Re}_{1,2} = \frac{u_{1,2}d_1\rho_1}{\mu_1}; \quad \mathrm{Lp}_2 = \frac{d_2\rho_2\sigma_2}{\mu_2^2} \tag{19.146}$$

The mass of the droplet after the collision is predicted from

$$m_{2,ac} = m_{2,bc} + \phi_{1,2}\cdot m_{1,bc} \tag{19.147}$$

The subscripts *ac* and *bc* stand for after and before collision, respectively. This empirical formula was obtained within the parameter range $30 \le \mathrm{Re}_{1,2} \le 6{,}000$; $5 \le \mathrm{Lp}_2 \le 300{,}000$ and $1.9 \le d_2/d_1 \le 12$. The parameter $\phi_{1,2}$ should be in the range $-1 \le \phi_{1,2} \le 1$.

Dubrovsky et al. (1992) studied collisions between liquid drops and solid particles. According to their experimental results, collision outcome between a fast moving small drop and a large solid particle was always accompanied by liquid breakup and certain number of fragments. For small solid particle colliding with a large liquid drop target, they reported four types of collision outcomes: (1) projectile capture by target, (2) shooting through, (3) gas bubble formation, and (4) target destruction.

Lagrangian/Eulerian simulation models are most widely used tools to calculate droplet spray behavior. The gas flow is treated as continuum (Eulerian) and discrete parcels of particles (Lagrangian) are injected into the flow field. Each parcel contains many identical droplets. The Lagrangian step may be performed by simultaneous tracking of all parcels in an integral time step, as developed by Amsden et al. (1989), or tracking of each complete trajectory of the parcel in serial manner, as performed by Crowe et al. (1977). Collision models are incorporated into the main gas-spray flow model. Spray collision models reflect the two approaches: (1) simultaneous tracking of all droplet parcels and search for collision partners, as performed by Amsden et al. (1989), or (2) serial tracking of parcel and sampling individual collision partners from statistical information, as performed by Sommerfeld and Zivkovic (1992), Sommerfeld et al. (1993), Sommerfeld (1995), and Osterle and Petijean (1993). The second approach significantly reduces the calculation task. However, as the collision partner is sampled from a statistical value, the postcollision properties have to be treated carefully if the information of both partners is required.

In both models, the collision partners are the uniform particle cloud contained in each parcel. All parcels presented in a control volume are taken into account for determining the collision probability (all real droplets for O'Rourke model and statistical droplets for Sommerfeld model). Therefore, stochastic collision is treated and kinetic theory of gases is applied. Particle collision is assumed to take place within the collision cylinder, as shown in Figure 19.64. The collision cylinder has a cross-section diameter of $(d_{p1} + d_{p2})$ and length of $(U_{rel}\Delta t)$, where Δt is the time step considered.

The model presented by O'Rourke (1981) and implemented in the KIVA computer program (Amsden et al., 1989) tracks all parcels simultaneously and the possibility of collision between each pair of parcels

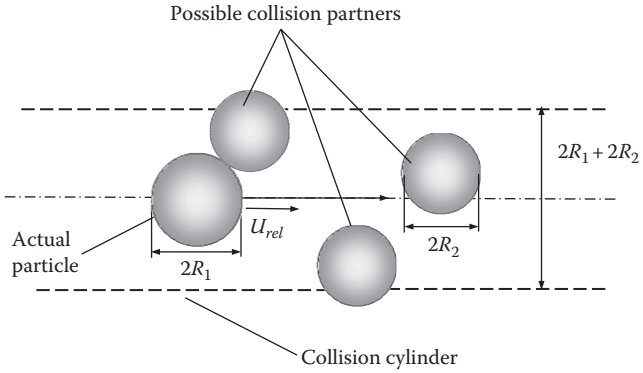

Figure 19.64

Drop collision cylinder from kinetic gas theory.

is evaluated by searching all collisional partners that are present in the computational cell. The criterion whether collision takes place or not is determined by the probability of nil collision:

$$P_{no_collision} = e^{-f\Delta t} \tag{19.148}$$

where f is the collision frequency in a collision cylinder:

$$f = \frac{N_{r_s}}{V}\pi(r_l + r_s)^2\left|\bar{V}_{r_l} + \bar{V}_{r_s}\right| \tag{19.149}$$

N_{r_s} is the number of smaller radius droplets
V is the volume of the computational cell
the subscripts *r_l* and *r_s* describe the properties of larger and smaller droplets, respectively

To decide whether a collision takes place, a random number (RN) is generated from a uniform distribution and compared with $P_{no_collision}$; if RN > $P_{no_collision}$ a collision event is valid. The position of contact point during collision is directly calculated since the collisional partners are both "real" and their trajectories are known. Since the model considers the collision of particles within the same computational cell only, "artifacts" concerning neighboring particles located in an adjacent cell may arise.

Schmidt and Rutland (2000, 2004) developed the no-time-counter (NTC) collision model that predicts how many collisions must occur in a given cell and then randomly samples collision pairs within the cell. In the NTC model, the collision computation is performed on a special collision mesh that is optimized for both sample size and spatial resolution. The mesh is different for every time step to further suppress artifacts.

The proximity collision model has been developed by Bauman (2001) and is designed to improve the previous discrepancy in the KIVA code collision model. To counter the "artifacts" problem, possible collision pairs are chosen based on the proximity of the two particles from each other, irrespective of their placement relative to the computational grid. A user-defined collision radius is introduced to define the maximum distance that two particles can be apart from each other to consider for collision. The equations for determining whether collision occurs, and the outcome of the collision, are nearly identical to the KIVA collision model.

Within the models proposed by Osterle and Petijean (1993) and Sommerfeld and Zivkovic (1992), Sommerfeld et al. (1993), each parcel is tracked in a serial manner and statistical value of particle number density, average and rms velocity size relationship, and other variables are kept and stored in each computational cell. The collision probability assumes a moving droplet while the other droplet (fictitious) is fixed and is calculated within the collision cylinder:

$$P_{collision} = 0.25\frac{N_2}{V}\pi(D_l + D_s)\left|U_r\right|\Delta t \tag{19.150}$$

N_2 is the total particle number density in the computational cell (from the stored particle number in the last Lagrangian step). The particle size of the collision partner (fictitious droplet) is sampled from the local particle size distribution. Rüger et al. (2000) validated this collision model in a spray with experimental results.

The comparison of measurements and predictions showed very good agreement for the profiles of mean properties of both phases and the local droplet size distributions as well as size-velocity correlations. According to the calculation results, the increase of the integral droplet SMD along the spray distance is mainly due to coalescence, while the impact of droplet evaporation on mean diameter decrease is of minor importance.

In a further extension, Sommerfeld (2001) developed an interparticle collision model, taking into account the correlation of the fictitious particle with the velocity of the real particle as a consequence of gas turbulence. The model has been validated with results from LESs in the literature. For all test cases considered, good agreement between model calculations with the results obtained by LES has been found.

Pischke et al. (2012a) developed a hybrid collision algorithm to predict the collision probability: collisions between parcels are described deterministically, that is, by searching for intersecting trajectories between computational parcels, while droplet collisions stochastically. The collision probability formulation eliminates the influence of a gas-phase mesh or a collision mesh by introduction of a parcel diameter, which is a measurement for the volume represented by a specific parcel. Two nonparametric parcel diameter estimators are derived based on the volume-of-influence approach, an isotropic parcel diameter estimator for homogeneous droplet clouds (sphere-of-influence), and an anisotropic parcel diameter estimator for inhomogeneous droplet clouds of reduced dimensionality (ellipsoid-of-influence). During derivation, the exactness for analytical homogeneous dispersions is preserved. The performance of the anisotropic volume-of-influence approach is demonstrated by synthetic validation cases, indicating that the formulation delivers exact predictions in cases where other existing collision algorithms do not even converge. To improve numerical convergence, a velocity decomposition method has been proposed by Pischke et al. (2012b), splitting the relative velocity between the parcels into a velocity gradient (with little influence on collisions, but high numerical sensitivity) and into velocity fluctuations (with high influence on collisions, and little numerical sensitivity). By removing the spurious contribution of the velocity gradient, the convergence of the collision algorithm is increased from first to second order. Based on the anisotropic volume-of-influence approach and the velocity decomposition method, a Lagrangian collision algorithm has been developed by Pischke (2014), which incorporates strategies from Eulerian NTC algorithms. For efficiency reasons, a dedicated collision mesh is introduced, which separates parcels that are improbable to collide. Overlapping control volumes are introduced to avoid mesh artifacts, which typically occur at collision mesh boundaries, while reducing the number of potential collision partners. With the Lagrangian collision algorithm, highly anisotropic sprays with strong velocity gradients appear numerically solvable.

19.2.1.4 Clustering of Droplets

Due to the dynamics of the primary liquid fragmentation process, especially in the dense spray region, a clustering of droplets may occur. Until recently, experimental characterizations of sprays have been limited in most cases to single point statistics of the spray in time or space. Such a description provides as integral information a measure of the mean number density or flux rate of the spray. Progress in measurement techniques like the phase Doppler anemometry (PDA) has made temporal correlated droplet measurements and the particle image velocimetry has made space correlations information available for sprays. Marx et al. (1994) and Edwards and Marx (1995a,b) developed a multipoint statistical description of a spray. Based on this theoretical approach, it is possible to distinguish between steady and unsteady sprays by using the interparticle arrival time τ at a certain position. Steady sprays are defined as those whose interparticle arrival time distribution obeys inhomogeneous Poisson statistics. Unsteady sprays are defined as those whose interparticle arrival time distribution does not obey inhomogeneous Poisson statistics. An example of unsteady spray behavior with droplet clustering is illustrated in Figure 19.65 with a high-speed-video sequence of a disintegrating liquid jet. Areas at higher and lower droplet concentrations in the initial spray have been attributed to the asymmetric instability and primary fragmentation of the liquid jet.

The experimental interparticle time distribution h_{exp} can be determined from a single realization (SR) or multiple short realizations that are ensemble averaged (ER). Edwards and Marx (1995a,b) showed that

$$h_{exp}(\tau_j) = \frac{H(\tau_j)}{N\Delta\tau_j} \tag{19.151}$$

where

τ is the interparticle time gap
$H(\tau_j)$ is the number of events that fall within the jth interparticle time gap
N is the total number of interparticle events
$\Delta\tau_j$ is the width of the jth interparticle time gap

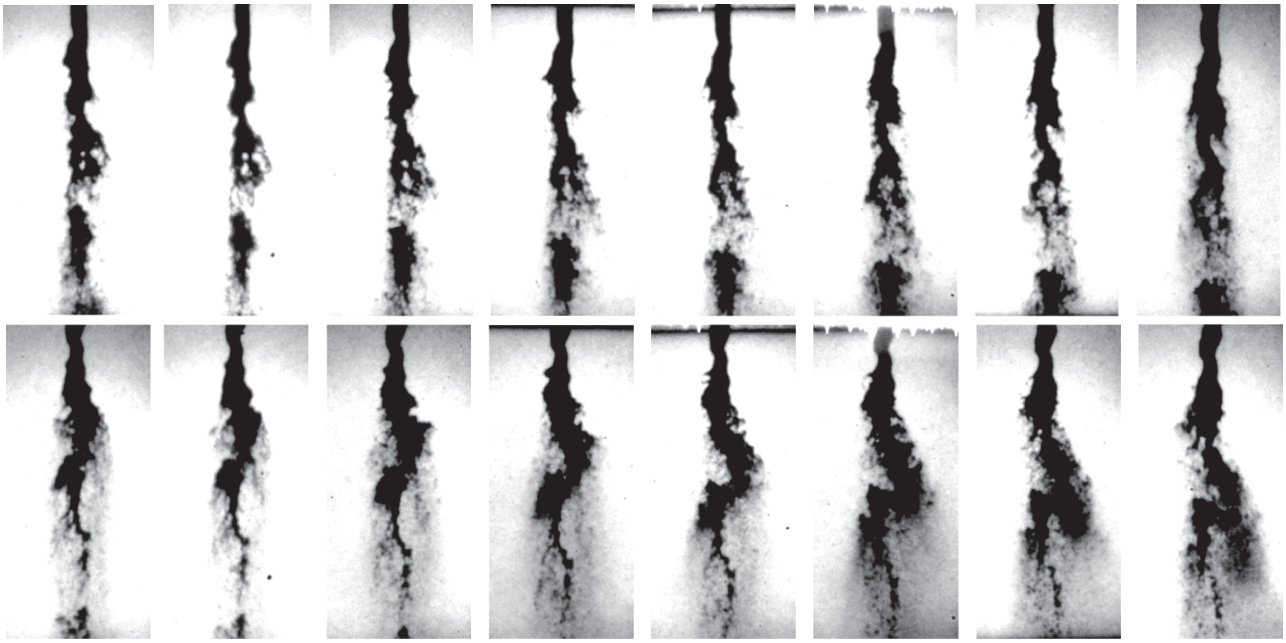

Figure 19.65

Drop clustering in sprays: high-speed photo series of liquid fragmentation process, liquid jet diameter 4 mm, time increment 0.2 ms.

To determine the theoretical interparticle time distribution, the spray is modeled as a marked inhomogeneous Poisson process. The Poisson process is described by the intensity function λ that represents the expected number of particles to be sampled per unit time. The theoretical finite interparticle time distribution is

$$h_{th}(\tau_j) = \frac{\lambda^2 (T-\tau)\exp(-\lambda\tau)}{\lambda T - 1 + \exp(-\lambda T)} \tag{19.152}$$

The theoretical interparticle function is compared with the experimental interparticle distribution function and a decision on spray steadiness or unsteadiness is made based on the statistical analysis using the chi-square tests to get the significance level (Luong and Sojka, 1999).

Figure 19.66 illustrates a sample comparison between experimental data and theoretical steady interparticle time distributions. The data were taken 100 mm downstream of a pressure atomizer (flat sheet cone) on the spray centerline for a liquid mass flow rate of 0.05 kg/min. The bars represent the experimental data in discrete time bins. The solid curve represents the theoretical value, where the error bars show the expected scattering of the theoretical results due to the random nature of a theoretical spray. The experimental interparticle time distribution differs for the first bins from that of the steady theoretical case (e.g. by more than 12 deviations for the first bin). The chi-square value $\chi^2 = 307$ shows the significance and that the two distribution functions are not different due to random fluctuations. For this case, a high probability for having droplets at shorter interparticle arrival times is found, that is, droplet clustering occurs in this spray (unsteady spray). Droplet clustering in spray will lead to significant changes in the main interphase transport mechanisms (momentum, heat and mass, see Chapter 1) because here the local bulk properties vary in between and outside of a droplet cluster.

Heinlein and Fritsching (2006) analyzed the spatial particle distribution in the spray of a pressure and twin-fluid atomizer, respectively, by means of pointwise and time-resolved PDA measurements. Steady and unsteady particle structures are identified by evaluating the interparticle arrival time statistics at a certain position. While for the pressure atomizer clustering takes place mostly within the central area of the spray, this effect is found for the twin-fluid atomizer mostly in the outside spray area. For both atomizers, clustering increases and/or begins only at increasing axial distances. In a droplet cluster, a locally high droplet number density exists, which results in relatively short interarrival times. No significant dependence between the droplet size and the occurrence of droplet clusters has been found; the drop size distribution

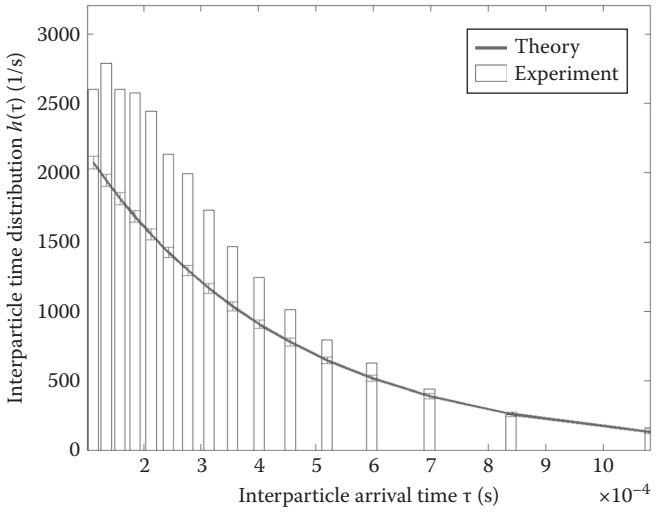

Figure 19.66

Drop clustering: experimental versus theoretical data.

within a cluster corresponds to the drop size distribution of the entire spray. The presence of clusters can be determined, however, primarily in the lower velocity range, which has to be attributed to the fact that collective groups of droplets have different drags than individual droplets.

Lampa and Fritsching (2013) investigated the clustering behavior of droplets in the spray of a twin-fluid atomizer based on different spray chamber geometries. The PIV measurements have captured the large scale vortices located at the edge of the spray cone flow. The LESs indicate that the gas-droplet interaction within the shear layer is the driving force for the formation of droplet clusters.

19.2.2 Dilute Spray

The majority of all spray investigations deal with the dilute spray region where mainly gas/droplet interaction determines the spray behavior. A variety of sophisticated measurement instruments and experimental and numerical techniques are used to investigate details of the gas and droplet behavior in this spray region. These include:

- Nonintrusive laser diagnostic instruments for dispersed multiphase flows, like PDA, diffraction particle sizer, particle image velocimetry and particle-tracking-velocimetry, holography, laser-induced fluorescence, and others (see Hammer et al., 2016)
- Numerical models, based on Euler/Lagrange techniques, Euler/Euler techniques (two-fluid models), direct numerical, or Large–Eddy simulations (Bergström et al., 1999, Bellan, 2000), PDFs, among others (see Chapter 2 on modeling),

These numerical and experimental techniques have contributed to understanding of multiphase transport processes in sprays. Parameters describing the dilute spray structure identify the behavior of the droplets in the spray, the interaction with the gas phase, and the macrostructure of the spray development. These results typically are specific for their spray application under investigation (medium, atomizer type, operational parameters, etc.).

19.2.2.1 Individual Droplet Behavior

The behavior of (individual) droplets in the gaseous atmosphere (Sadhal et al., 1997, Sirignano, 1999) like in a spray is substantially based on aerodynamic and gravitational forces acting on the particles, balanced by the inertia of the droplets (see Chapter 1). Based on a one-dimensional numerical analysis using the droplet trajectory equation (without coupling effects), a principal investigation for the droplet behavior in a spray such as the identification of different atomizer nozzle characteristics is possible:

$$m_p \frac{du_p}{dt} = m_p g - \frac{1}{2}\rho_g (u_p - u_g)\left|u_p - u_g\right| A_p c_d \tag{19.153}$$

Fritsching and Bauckhage (1987) analyzed the interaction of droplets and the surrounding gas phase in a water spray as a function of distance from nozzle for single-fluid (pressure) and twin-fluid (gas) atomizers. Results of measurements of droplet velocities and sizes on the spray centerline measured by PDA have been used for comparison with the one-dimensional model. The two nozzle types and their respective dimensions have been chosen by the criterion of comparable droplet size and velocity spectra in the spray.

For the uncoupled solution of the droplet trajectory, an assumption for a velocity distribution of the gas phase is necessary. This boundary condition has been determined from PDA measurements of droplet velocities of the smallest detected droplets in the spray based on the assumption that these droplets act as tracer particles and the local gas velocity equals the measured droplet velocity (zero slip velocity). The initial droplet (starting) velocity value has been prescribed. For the twin-fluid nozzle, it has been assumed that the starting velocity of the droplets equals the liquid feed velocity from the nozzle. For the pressure atomizer, a constant starting velocity for all droplet size classes has also been assumed. Its value has been obtained by extrapolating the droplet velocities measured for the biggest drop size class detected from the first measurement location in front of the nozzle backward to a common starting location for the droplets in the vicinity of the nozzle.

In Figure 19.67, a comparison between the model results and measurement results (these have been averaged over a certain drop size class) for the pressure atomizer is illustrated. The dash-dotted line in front of the figure indicates the derived distribution of gas velocity as a function of nozzle distance $v_l(z)$. The figure shows that smaller droplets in the spray immediately after fragmentation lose their initial momentum carried from the liquid delivery. This initial momentum is directly transferred to the slow moving (entrained) gas. Further downstream this smaller droplets move at almost the velocity of the gas (the relative velocity between droplet and gas is the constant droplet settling velocity). The bigger droplets are decelerated somewhat more slowly. Therefore, a continuous momentum transfer from the droplets to the slower moving gas occurs. The velocity distribution exhibits strong gradients dependent on droplet size in the nozzle vicinity, while at increased nozzle distances, the velocity distribution for all droplet sizes becomes uniform.

In the spray of the twin-fluid atomizer, a change of the direction of momentum transfer occurs. This can be seen in Figure 19.68. Close to the atomizer, the faster moving atomizer gas accelerates all droplets more or less depending on size. The direction of momentum transfer is always from the gas to the slower particles. Therefore, the gas loses a significant amount of kinetic energy within a small distance from the atomizer. At a certain distance from the atomizer, the direction of momentum transfer is reversed. At greater nozzle distances, all droplets are moving faster than the gas and the direction of momentum transfer is from the droplets to the gas. The droplets in this area accelerate the gas. The point where the

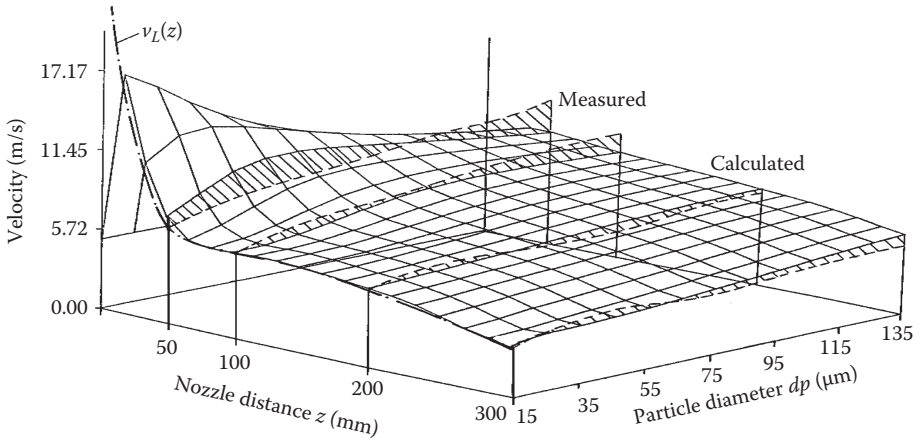

Figure 19.68

Drop velocity on spray centerline: twin-fluid atomization. (From Fritsching, U. and Bauckhage, K., *Chem. Ing. Tech.*, 59(9), 744, 1987. With permission.)

momentum transfer changes direction depends on the droplet size. While the smaller droplets already exhibit this change of momentum transfer closer to the atomizer due to their smaller inertia, the bigger particles change the momentum transfer direction in a somewhat greater nozzle distance.

By comparing the characteristics of these nozzle types, a common characteristic for technical spray processes can be seen. When the aim of the atomizer application is the achievement of almost identical droplet velocities at a specific distance from the atomizer (e.g., for coating application), this behavior is achieved much closer to the atomizer for the twin-fluid atomizer. In addition, the reversal of the momentum transfer direction has to be recognized as an important feature for twin-fluid atomizers.

An important property of a droplet spray is the correlation of drop sizes and velocities. This leads to a two-dimensional distribution of drop properties in sprays. Typical behavior of a drop size/velocity correlation at a single point in the spray of a pressure atomizer is illustrated (from a simultaneous measurement of drop size and velocity by PDA) in Figure 19.69 (Schulte, 1995). In the ground plane of the plot, the measurement result of several ten thousand individual particles is shown (individual droplet size and velocity), while at the two sides of the plot, the integration in terms of number frequencies of drop sizes and velocities respectively is illustrated.

Drop size/velocity correlation in spray. (From Schulte, G., *Zweidimensionale Verteilungen von Partikeleigenschaften*, Shaker Verlag, Aachen, Germany, 1995. With permission.)

19.2.2.2 Spray Cone Spreading

The spray cone angle describes the macrogeometry of a spray. Different atomizers yield different spray characteristics, for example, flat, round, or hollow cone. The spray cone angle initially is determined by the liquid exit condition, the main disintegration mode within primary fragmentation (and here the growth rate of asymmetrical disturbances), later on by gas turbulence effects (particle dispersion), interaction with the ambient air (gas entrainment), and finally by gravity.

Within pressure swirl atomization, as already discussed in Section 19.1.5.1, by assuming an inviscid liquid, the spray cone angle is expressed as a function of the nozzle dimensions only. The half cone angle is (Giffen and Muraszew, 1953)

$$\sin\Theta = \frac{(\pi/2)c_D}{K_1(1+\sqrt{X})} \tag{19.154}$$

For a simplex pressure atomizer with a full spray, the work of Reitz and Bracco (1979, 1982) concluded that the spray angle can be determined by combining the radial velocity of the fastest growing of the unstable waves in the primary fragmentation process with the axial injection velocity. This hypothesis results in an expression for the spray angle that has been later on simplified by Bracco et al. (1985) as follows:

$$\tan\Theta = \frac{2\pi}{\sqrt{3}A}\left(\frac{\rho_g}{\rho_l}\right)^{0.5} \tag{19.155}$$

where A is a function of the orifice length to diameter ratio that must be experimentally determined (Lefebvre, 1989).

The distribution of the sprayed liquid mass in the spray cone is described by the mass flux distribution. Adopting the concept of self-similarity from a single-phase jet, the droplet mass flux distribution in a spray may be described. In full cone sprays, this can be expressed in terms of a general empirical formula as follows (Uhlenwinkel, 1992):

$$\frac{\dot{m}}{\dot{m}_{cl}} = e^{-k_1(r/r_{0.5})^{k_2}} \tag{19.156}$$

where

$\dot{m}_{cl}$ is the maximum value of the mass flux distribution function on the spray centerline

$r_{0.5}$ is the half width of the mass flux distribution (see Figure 19.70)

The proposed empirical constants have been given as $k_1 = \ln(2.0)$ and $1.2 < k_2 < 2.0$. The constant k_2 depends on operational process conditions and liquid properties. The spreading behavior of the spray cone may be described either by a function of the mass flux on the centerline or by the distribution of the half width of the mass flux distribution versus nozzle distance, where for a Gaussian type distribution,

$$r_{0.5} = \sqrt{k_2 \frac{\dot{M}_l}{\dot{m}_{cl}}} \tag{19.157}$$

The behavior of the centerline mass flux has been empirically correlated as follows (Uhlenwinkel 1992, Kramer 1997):

$$\dot{m}_{cl} \approx z^{-k_3} \tag{19.158}$$

For water sprays, Uhlenwinkel (1992) has found $k_3 \cong 2$, while for metal melt atomization, Kramer (1997) found $k_3 < 2$. Spray cone spreading (namely the coefficient k_3) depends on atomization parameters. For water atomization, the spreading of the spray increases with higher gas flow rates, while for metal melt, the reverse trend is observed. In this case, the spray cone width narrows when the gas mass flow rate increases with higher pressure (Uhlenwinkel, 1992).

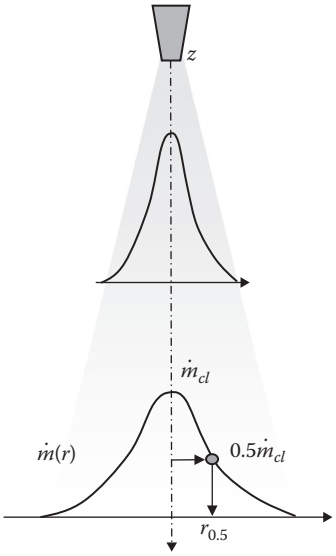

Figure 19.70

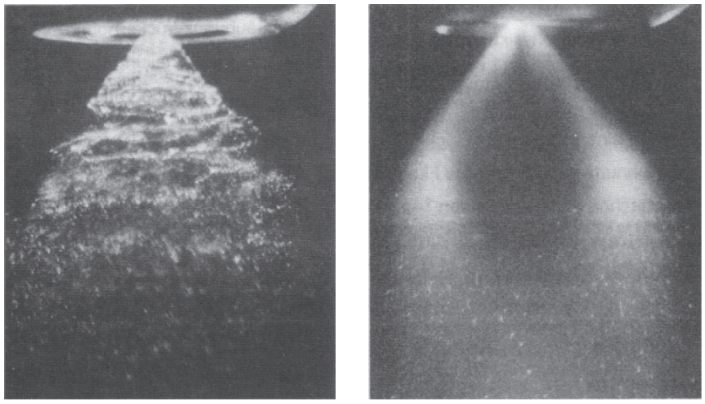
Mass flux distribution in sprays (index: centrenline cl; half width 0.5).

19.2.2.3 Spray/Environment Interaction: Entrainment

The spray system interacts with the environmental gas. Like a single-phase jet, it accelerates ambient gas due to friction (entrainment). Thereby, the plume of the dispersed phase (the droplet spray) maintains a narrower width than the complete flowing gas jet (see Section 19.4.2.1).

The spray/gas interaction and gas entrainment may lead in some cases to a change in the spray structure with increasing distance from the atomizer, namely, a drop size segregation. Generally, this effect is pronounced in pressure atomizers, as in this case, the entrainment effect is strongest, and is typically found in pressure swirl atomization. The primary hollow cone structure is changing toward a solid cone with increasing spray distance. Figure 19.71a illustrates the change as a short exposure view onto the spray (instantaneous structure) from outside in comparison to a light-sheet illumination of the central plane of the spray in Figure 19.71b. Here, due to the entrainment of ambient gas into the initially hollow cone spray, droplets are accelerated and transported into the core region of the spray (see sketch in Figure 19.72b). As an example, in Figure 19.72a, PDA data are presented as radial distributions of the arithmetic number mean value of the measured droplet size distribution at several planes below the atomizer. With increased spray distance, the edge of the spray shows increased drop sizes, while in the spray core, the smaller droplets are more prevalent. Because of their smaller inertia, smaller droplets are more easily transported into the spray core than bigger drops. Here, a size segregation effect follows, where the droplet size distribution in the spray is changed, typically as shown in the sketch in Figure 19.72b.

The total spray/gas entrainment rate depends on the atomizer type. With twin-fluid atomization, entrainment can be estimated based on the overall gas flow rate in circular, turbulent jet, and the distance from the nozzle. The ratio of the total gas flow rate to the initial jet flow rate is a linear function:



$$\frac{\dot{Q}_{total}}{\dot{Q}_0} = \text{const.}\frac{x}{d_0} \tag{19.159}$$

The constant is 0.4565 from the analytical solution for a turbulent jet and varies from 0.30 to 0.45 in experimental and simulation studies of single- and two-phase jets and spray flows.

19.2.3 Heat and Mass Transfer

Fundamentals of heat and mass transfer from droplets in gases have been derived in Chapter 1). Heat transfer mechanisms are important in melt atomization and spray processes (see Section 19.4.2). Simultaneous heat and mass transfer is important in coating applications (e.g., paint sprays) or spray-drying processes (see Section 19.4.3).

As a liquid droplet spray comes in contact with hot atomization gas, three transfer mechanisms (mass, momentum, and energy) become operative simultaneously. Crowe (1980) and Crowe et al. (1998) described these

(a) (b)

transfer mechanisms through spray-drying processes. At the droplet–hot air interface, heat is transmitted into and moisture is transmitted out of the droplet surface. The external transfer of mass or heat can be obtained from

$$\Phi = kA\Delta X \tag{19.160}$$

where

k is the transfer coefficient
A is the particle surface area
ΔX is the driving potential

The transfer is described by the Nusselt number, Nu, for heat transfer and Sherwood number, Sh, for mass transfer that may be obtained from the correlation (Ranz and Marshall, 1952):

$$\mathrm{Nu} = 2 + 0.6\,\mathrm{Re}^{0.5}\,\mathrm{Pr}^{0.33} \tag{19.161}$$

$$\mathrm{Sh} = 2 + 0.6\,\mathrm{Re}^{0.5}\,\mathrm{Sc}^{0.33} \tag{19.162}$$

This correlation has been extended to turbulent effects by Yearling and Gould (1995) (see also Clift et al., 1978). The driving potential ΔX for heat transfer is the temperature difference between droplet and surrounding air, and for mass transfer, the vapor concentration difference between the surrounding air and the vapor film on the droplet surface (Delplanque and Sirignano, 1994).

19.2.3.1 Drying of a Solution/Suspension Droplet

19.2.3.1.1 Drying Mechanism of a Dispersed Droplet Most feed materials in a spray-drying application are dispersed liquids (solution or suspension). Drying of a dispersed liquid droplet may yield a porous-solid shell (or crust) on the droplet skin that significantly changes heat and mass transfer rates compared to those of a pure liquid droplet. When the crust formation begins, the internal mass transfer rate through the porous-solid shell becomes the evaporation-controlling factor for evaporation.

Dolinsky (2001) described the drying mechanism of a dispersed material in high-temperature gas streams ($T_{air} > T_{boil}$). From analysis of experimental data, five successive drying periods have been identified (see Figure 19.73):

1. The period of droplet heating from its initial temperature T_0 up to the temperature of equilibrium evaporation T_{eq}.
2. The period of equilibrium evaporation during which intense removal of moisture from the liquid droplet surface occurs. The period of equilibrium evaporation (t_{cr1}) ends when the solid content on the drop surface is increased to the point that a shell is formed on the surface of the evaporating droplet.
3. The period of crust formation when the droplet temperature increases sharply due to the formation of the dense shell made from dispersed substance.
4. Boiling period: the temperature inside the particle reaches the boiling point and steam is generated.
5. Drying period: the particle temperature sharply increases almost to the temperature of the hot gas. During this period, removal of the bound moisture occurs. Fragmentation may also occur in this period.

Mathematical models permit analysis of the evaporation process at the different stages of a drying droplet. Typically in these models, plug flow of air, no droplet deformation, no droplet–droplet, and droplet–wall

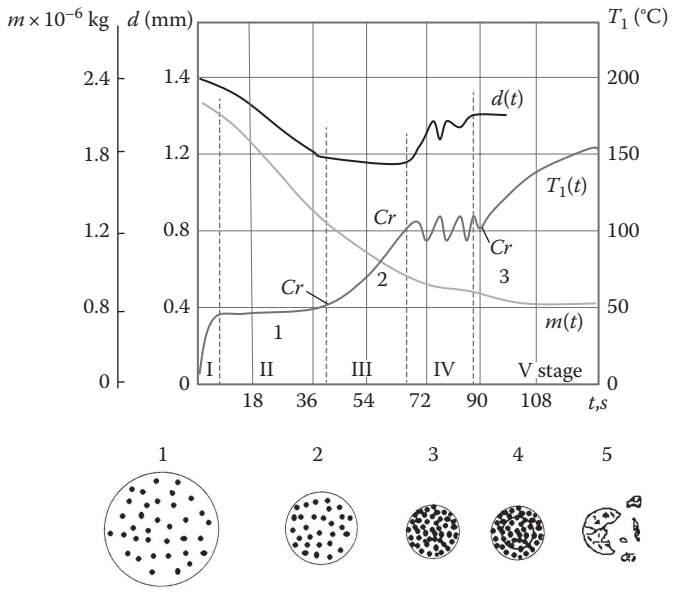

Figure 19.73

Successive drying periods of a suspension droplet, variation of diameter, temperature and mass in a hydration process. (Adapted from Dolinski, 2001.)

collision is assumed. The concentration of average volume at the moment of crust formation, when the equilibrium drying stage ends, is given by

$$C_S = \frac{C_{sat}[C_0 + 3\mathrm{Ki}(C_{sat} - C_0)]}{C_{sat} + 3\mathrm{Ki}(C_{sat} - C_0)} \tag{19.163}$$

where Ki is Kirpichev number

$$\mathrm{Ki} = \frac{D_1 \rho_1}{D_2(\gamma_s - \gamma_\infty)} \tag{19.164}$$

The coefficients C_0 and C_{sat} are the initial and saturation concentration of the solution in an average volume, respectively. D_1 and D_2 are the diffusion coefficients for water in solution and in gas, respectively. This crust concentration is used as a criterion to distinguish constant drying rate period (stage 2) and falling rate period (stage 3). Mass transfer rate during crust formation has to be obtained experimentally.

Elperin and Krasovitov (1995) developed a model that takes into account effects of compressibility and filtration of the gas/vapor mixture within the porous shell. They used the critical volume ratio as crust formation criteria, which could be calculated from a minimum void fraction (ε) attained in packing of spherical particles

$$\delta_c = V_S N_l = \frac{1 - \varepsilon}{\varepsilon} \tag{19.165}$$

The mathematical model—taking into account porosity; permeability; surface tension of solid/gas, solid/liquid, and liquid/gas interface; effective thermal conductivity; and diffusion coefficient—is developed and solved numerically. A pressure balance equation at the liquid interface inside the particle was also included and investigated in this work. Numerical results showed that at the ambient gas temperature above the liquid boiling point, the pressure at the liquid interface increased significantly and thus may cause the fragmentation of the porous shell.

Straatma et al. (1991, 1999) developed numerical drying models for food products, where crust formations are generally found. The drying models take into account both external and internal phenomena. The driving force for mass transfer (from Equation 19.158) is expressed as

$$\Delta X = c_a^\star - c_a \tag{19.166}$$

where $c_a^\star$ is the water vapor concentration that is in equilibrium with the wet surface of droplet. In this work, the GAB equation (Guggenheim, Anderson, and de Boer) was used to calculate $c_a^\star$.

The unstationary diffusion process inside the spherical particles is described by the one-dimensional differential equation

$$\frac{\delta c}{\delta t} = \frac{1}{r^2}\frac{\delta}{\delta r}\left(r^2 D \frac{\delta c}{\delta r}\right) \tag{19.167}$$

The diffusion coefficient (D) depends on the moisture content and the temperature (Ferrari et al., 1989). The differential equation (19.167) is solved numerically in conjunction with external heat and mass transport equations (19.160) through (19.162) using the gas/liquid interface boundary condition and zero gradient boundary condition at the center ($r = 0$). The moisture content at various positions inside droplet can be determined.

A nondimensional differential equation of the concentration field in a solution droplet based on the diffusion equation for mass transfer inside the droplet was proposed by Brenn et al. (2001a). In the nondimensional equation, a characteristic parameter occurs, which is formed from densities and diffusion coefficients in the gaseous and liquid phases and accounts for the Sherwood number of mass transfer and the solvent vapor content in the ambient gaseous medium. The numerical value of this parameter, which separates the regimes leading to the formation of hollow and solid spheres, was calculated using a data set for aqueous sodium chloride solutions from the literature. An experimental verification of the significance of the

threshold value based on measurement results from droplets drying in an acoustic levitator confirmed that drying conditions with values less than the threshold value lead to the formation of hollow spheres, while for larger values, solid spheres are formed.

The solute concentration profiles in a droplet during drying can be obtained by solving the diffusion equation for mass transfer inside the droplet (Brenn, 2005, Eslamian et al., 2006, 2009). The results reveal the formation of large concentration gradients in the droplet at high evaporation rates, and flat concentration profiles for slow drying. If at the onset of the precipitation, which will most likely occur at the droplet surface, the solute concentration everywhere in the droplet is equal to or is above the equilibrium saturation (ES), the solute starts to precipitate everywhere within the droplet. This type of precipitation is called "volumetric precipitation". Therefore, the whole droplet undergoes nucleation, crystallization, and growth of the solute nuclei (Jayanthi et al., 1993). In this case, the final particle is fully filled; otherwise, it is hollow and a crust forms on the surface of the droplet, whose thickness depends on the solute concentration distribution.

19.2.3.1.2 Models of Single-Droplet Drying Kinetics For the prediction of single droplet drying, there are generally four types of approaches to formulate drying models (Mezhericher et al., 2010, Chen and Putranto, 2013):

1. *Empirical models* obtained entirely by regression methods to derive the explicit time-dependent functions.
2. *The concept of characteristic drying curve* (*CDC models*), which recognizes different drying stages, for example, the constant rate period (which may also be called the "unhindered drying period," where the internal transport of the moisture does not affect the surface evaporation) and falling rate ("hindered drying") period (Fyhr and Kemp, 1998, Langrish and Kockel, 2001). In the CDC models, the drying rate can be represented by the following equations:

$$\frac{dX}{dt} = f\frac{Ah}{m_s \Delta H_{evap}}(T_b - T_{wb}) \tag{19.168}$$

$$f = 1, \quad X > X_{cr} \text{ (constant rate period)} \tag{19.169}$$

$$f = \frac{X - X_b}{X_{cr} - X_b}, \quad X \le X_{cr} \text{ (falling rate period)} \tag{19.170}$$

Here

X is the moisture content on a dry basis
A is the droplet surface area
h is the external heat transfer coefficient
m_s is the mass of the solids in one droplet/particle
ΔH_{evap} is the latent heat due to vaporization
T_b and T_{wb} are bulk and wet bulb temperature of the drying air, respectively
X_{cr} is the critical moisture content, which makes the transition from the constant rate period to the falling rate period
X_b is the equilibrium moisture content corresponding to the environmental condition for drying

The constant rate period is identified as the period where the droplet moisture content is above the critical moisture, while the falling rate period below the critical moisture.

Evident in the CDC models, it is assumed that there is a linear drop in drying rate proportional to the moisture in droplet: the constant rate period is simplified analogous to the evaporation of small pure liquid droplet; and the hindering effect of the internal mass transport on the drying rate is simplified by a linear relation relative to the material properties, X_b and X_{cr}. While X_b can be obtained from the isotherms of the material as a function of ambient air humidity and temperature, the X_{cr} is assumed to be constant for the specific material, independent of the drying condition. In reality, this might not be a fair assumption if the droplet experienced extreme contrasting initial

drying rate (Fyhr and Kemp, 1998). In maltodextrin solution, it was observed that a higher initial moisture will result in a higher critical moisture and vice versa (Zbicinski and Li, 2006).

3. *Deterministic drying models*, which describes the comprehensive transport phenomena within a droplet using the continuity, momentum, energy, and species conservation equations (Mezhericher et al., 2007, 2008a,b, Eslamian et al., 2009); deterministic models with distribution of solid component described by population balance are presented by Seydel et al. (2006) and Handscomb et al. (2009a,b).

   The deterministic models take into account and keep track of the detail phenomena within the drying particle (e.g., moisture gradient, diffusion, internal bubble, solid formation) by a set of differential equations with corresponding initial and boundary conditions. Subsequently, the models translate these individual internal phenomena into the internal moisture gradient, which affects the overall drying rate. The solution of this set of equations is complicated by the presence of a moving domain boundary because of the shrinking droplet radius in the constant rate drying stage and the receding interface between the dry crust and wet core regions of the wet particle in the falling rate drying stage. The deterministic models are "physically" realistic, through which the behavior of the main drying characteristics can be predicted for various drying conditions showing a good accuracy and consistency with experimental data. However, solution of the associated partial differential equations in CFD might require high computational effort.

4. *Novel drying models based on reaction engineering approach (REA models)*, which visualizes the drying process as an activation process in which an energy barrier has to be overcome for moisture removal to occur (Chen and Xie, 1997, Chen and Lin, 2005, Patel et al., 2009, Chen and Putranto, 2013). The relation between the drying rate and the apparent activation energy (ΔE_v) can then be expressed as

$$\frac{dm}{dt} = -h_m A\left[\rho_{v,sat}\exp\left(-\frac{\Delta E_v}{RT_d}\right) - \rho_{v,b}\right] \tag{19.171}$$

Here

h_m is the mass transfer coefficient
A is the droplet surface area
$\rho_{v,sat}$ is the saturation vapor concentration
$\rho_{v,b}$ is the bulk vapor concentration
T_d is the droplet temperature
R is the universal gas constant (8.314 J/mol/K)

The first term on the right-hand side of Equation 19.171 is the zero-order drying "reaction," that is, the activation process. The second term on the right is the first-order wetting "reaction." Thus, the rate of moisture removal can be seen as a competitive process between drying and wetting reactions. The apparent activation energy (ΔE_v) reflects the vapor concentration depression or the relative humidity at the droplet surface during drying as

$$\Delta E_v = -RT_d \ln\left(\frac{\rho_{v,s}}{\rho_{v,sat}}\right) \tag{19.172}$$

where $\rho_{v,s}$ is the vapor concentration at the droplet surface.

Based on data sets of different drying temperatures, Chen and coworkers (Chen and Xie, 1997, Chen and Lin, 2005, Patel et al., 2009) suggest that the normalized relation of ΔE_v as a function of average moisture content difference ($X - X_b$) is material specific for each product and is independent of the drying condition. It is assumed that this can be used as the fingerprint of the material to determine ΔE_v at different drying conditions and can be expressed in the following form:

$$\frac{\Delta E_v}{\Delta E_{v,b}} = a\exp(-b(X - X_b)^c) \tag{19.173}$$

where a, b, and c are parameters to be fitted. These parameters can be obtained by back-calculating the ΔE_v value at different moisture contents from experimental data by manipulating Equation 19.171 as

$$\Delta E_v = -RT_d \ln\left(\frac{-(dm/dt)(1/h_m A)+\rho_{v,b}}{\rho_{v,sat}}\right) \tag{19.174}$$

Here, (dm/dt) is obtained from the experimental droplet weight loss curve. At high moisture content, the value of $\Delta E_v/\Delta E_{v,b}$ approaches zero, while at low moisture content, it tends to unity.

Drying models (1), (2), and (4) may be regarded as the "lumped drying models": they do not need solve for the spatially distributed moisture content and temperature within a droplet. These models require solving only algebraic equations, resulting in simpler computational effort, which is desired for CFD modeling. Detailed comparisons between CDC and REA models and their predictions are presented by Chen and Lin (2005), Patel and Chen (2005), and Meng et al. (2008), which indicates that the REA models predict the progressive reduction in drying rate better than the CDC models.

19.2.3.2 Solidification of a Melt Droplet

Solidification of a melt is described by the processes of nucleation and crystal growth. A droplet solidification process model typically is based on equilibrium phase diagrams for slow solidification and time-transfer phase change diagrams and/or experimental solidification investigations for some more realistic (higher) cooling rates. In fact, in spray processes, the cooling rate of droplets especially immediately after atomization might be very high (e.g., max. 10^7 K/s). Therefore, the possibility of undercooling prior to nucleation should be considered. In Figure 19.74b, a typical qualitative temperature/time distribution for a single melt droplet is shown for an equilibrium phase diagram. Here, a low carbon steel droplet (C = 0.3 w%, shown in Figure 19.74a) is considered as an example. Starting with the initial melt temperature (superheat) T_m, the droplet cools down to liquidus temperature T_l. Depending on the actual cooling rate, the droplet may undercool until it reaches the nucleation temperature T_n before solidification starts. Due to the rapid release of latent heat of fusion during recoalescence, the droplet temperature increases until it reaches a local maximum in the cooling curve at T_r. During the following segregated solidification, droplet temperature decreases continuously. At the temperature T_{per} in this specific case, a peritectic transformation takes place at constant droplet temperature. After termination of the peritectic transformation, again segregated solidification occurs until the droplet is completely solidified at T_s. From here on, droplet cooling is in the solid state of the fully solidified particle. The drop cooling behavior in the various stages of solidification is described based on thermal balances (internal and external). For metal droplets, typically no internal temperature gradient is assumed, as the Biot number (Bi) is small for most metal droplets (Bi $\ll$ 1).

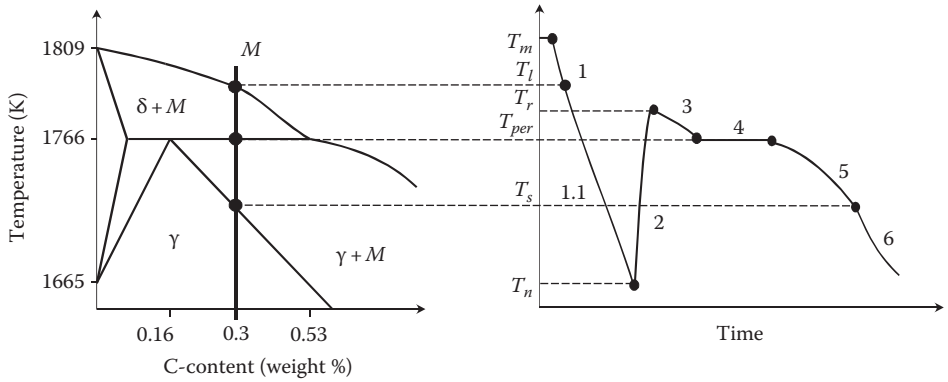

Figure 19.74

Solidification model for melt droplets (here low-carbon steel) (indices: *m* melt; *l* liquidus; *r* recalescence; *per* peritectic; *s* solidus; *n* nucleation).

Depending on cooling rate and droplet size, the temperature T_n where nucleation occurs can be much lower than the liquidus temperature T_l. The nucleation temperature for continuous cooling is defined as the certain temperature, where the number of nuclei N_n in the droplet volume V_d is identical to one:

$$N_n = V_d \int_{T_l}^{T_n} \frac{J(T)}{\dot{T}}\, dT = 1 \approx \frac{0.01 J(T_n) V_d \Delta T_{hom}}{\dot{T}} \tag{19.175}$$

Here

$J(T)$ is the nucleation rate

$\dot{T}$ is the cooling rate (Lavernia, 1996, Lavernia and Wu, 1996, Pryds et al., 1999)

Hirth (1978) has introduced the simplification in the aforementioned equation. ΔT_{hom} is the undercooling temperature difference for homogeneous nucleation. The nucleation rate may be expressed as (Libera et al., 1991)

$$J(T_n) = K \exp\left(-\frac{16\pi\sigma_{sl}^2 V_m^2 T_l^2}{3kT_n \Delta h_{fm}^2 \Delta T_{hom}^2} \right) \tag{19.176}$$

In the work of Turnbull (1950) and Woodruff (1973), a correlation has been given between the solid/liquid interfacial energy σ_{sl}, the latent heat of fusion per atom Δh_{fa}, and the atomic volume V_a. In technical processes, heterogeneous nucleation rather than homogeneous nucleation mechanisms limit the degree of undercooling (Libera et al., 1991). Only in very small droplets does homogeneous nucleation play an important role during solidification. Based on experimental results for different alloys, Mathur et al. (1989b) derived a correlation between the actual undercooling and the amount of undercooling necessary for homogeneous nucleation (Levi and Mehrabian, 1982, Libera et al., 1991). Simulation of molten metal droplet sprays including solidification submodeling has been done by Lee and Ahn (1994), Bergmann (2000), Bergmann et al. (2000, 2001b), Hattel et al. (1999, 2000), and Pedersen et al. (2000) (see also Voller et al., 1991, Wang and Matthys, 1991, 1992, Su and Tsao, 1997).

19.3 Spray Impact

19.3.1 Drop Impingement

Drop impingement is an important process, for example, in coating and surface cooling applications. The different mechanisms for individual drop behavior during wall impact (like deposition, rebounce, or splashing) are introduced in Section 14.2. A main criterion for the different impact regimes is the impact liquid drop Weber number.

19.3.1.1 Spray Deposition

In impact-related spray processes, the deposition rate (or the compaction efficiency) and the deposition mass flux distribution is important. An approach for deposition efficiency is given in Section 19.4.2.2.

19.3.2 Heat Transfer in Impinging Sprays/Spray Quenching

Spray quenching is used extensively in metal casting and welding processes, as well as in heat treatment of metals like aluminum, steel, and other metallic alloys. The combination of large droplet numbers (at small droplet sizes) and large droplet impact momentum is the key attribute to spray cooling, resulting in significant increases in cooling efficiency per flow rate over other cooling techniques. Gas-assisted twin-fluid atomization typically is employed in the cooling of steel, while pressure atomizers are used in aluminum industry (Stewart et al., 1995). Multiphase sprays are more efficient than single-phase sprays because air injected with water increases the droplets momentum and enhances the impaction and heat transfer (Issa, 2009). In gas-atomized spray quenching, heat transfer coefficient of 10,000 W/m^2/K can be achieved within film boiling regime, which is much higher than that of single-phase spray quenching (Alam et al., 2008, Alam, 2011).

During quenching or cooling of a metallic part, the surface experiences successively four different heat transfer regimes (from temperatures above the Leidenfrost temperature to room temperature): film boiling, transition boiling, nucleate boiling, and single-phase liquid cooling. The different heat transfer regimes are identified by the aid of the cooling curve (Nukiyama curve, see Chapter 8). Due to the relatively high initial

temperature, quenching of most metallic surfaces commences in the film boiling regime. Despite the possibility of a momentary contact of the liquid with the surface at the point of drop impact (see Section 14.2), a thermally insulating vapor layer quickly develops on the surface, resulting in a relatively slow cooling process. Better liquid–surface contact is maintained once the surface temperature reaches values below the Leidenfrost temperature (minimum heat flux point). In the transition regime, liquid maintains partial contact with the surface in the region undergoing intense boiling, while other regions remain insulated with vapor. The transition from film to transition boiling occurs not homogeneously across the metal surface, but strongly depends on local surface properties (e.g., geometry, roughness). This significant variation and change in the local heat transfer rate across the specimen causes large stresses on the metallic part that may lead to undesired damage or distortion of the specimen. The intermittent contact in the transitional boiling regime greatly accelerates the cooling. In the nucleate boiling regime, the surface becomes available for liquid–surface contact that accelerates the cooling due to vigorous bubble production and convection. Quenching is concluded in the slow, single-phase liquid cooling regime where the wall superheat becomes too weak to sustain bubble nucleation (Mudawar and Deiters, 1994).

Several investigations have derived correlations for the heat transfer coefficient (HTC, α) in the different boiling regimes, depending on atomizer type, spray conditions, and surface conditions. Among them, for example, Brimacombe et al. (1980), Bolle and Moureau (1982), Mudawar and Valentine (1989), Choi and Yao (1987), Jeschar et al., 1992, Viskanta and Incropera (1992), and Choi and Kang (1993) summarized the results of previous studies for steady-state and transient conditions in liquid and spray jets. Typically, correlations are presented for the heat flux or heat transfer coefficient (HTC, α) in the spray center at different boiling regimes.

In the stable film boiling regime, the heat transfer coefficient of an impinging (dense) spray is independent of the surface temperature. Here, the impinging liquid mass flux (in this context sometimes referred as impingement density or spray density) has the only effect on heat transfer. Other spray parameters such as drop velocities and sizes, as well as spray distance and nozzle type, have only very little effect. Due to the continuous liquid film above the stable vapor film, individual droplets do not impinge directly onto the hot wall. In this region, Müller and Jeschar (1983) derived for the heat transfer coefficient (HTC, α):

$$\alpha = 200 + 109.2\dot{m}_l \tag{19.177}$$

In the transition boiling regime as well as in the single-phase regime, the mean spray droplet size also influences the heat transfer process. In the nucleate boiling regime, the heat transfer coefficient has been found as a function of surface temperature alone, unaffected by variations in any of the spray parameters (Mudawar and Valentine, 1989). As in this contribution, it has been found that the spray boiling curve is insensitive to the type of metallic surface, Müller and Jeschar (1983) found a distinct influence of the metal type on heat transfer at temperatures below the Leidenfrost temperature. This effect has been attributed directly to the coefficient of heat penetration, which is influenced by possible oxide layer formations.

With twin-fluid atomization of water for cooling purposes, when the liquid mass flow rate is decreased by about one order of magnitude to the aforementioned regime, a dilute spray situation results and individual droplets impinge onto the hot liquid surface. Rather than coalescing to a liquid film (with the associated vapor film between liquid and hot solid), the individual droplets either evaporate directly in the liquid/solid contact phase or are blown away by the gas flow field after rebouncing. Therefore, the heat transfer is increased in a range between the conventional spray cooling and a pure evaporative cooling (Choi and Yao, 1987, Puschmann et al., 2001, Puschmann, 2003). The total heat transfer rate in dilute spray cooling is a combined effect of heat transfer during drop contact and heat transfer due to the gas flow field. Also in this dilute spray quenching, the heat transfer is controlled mainly by the liquid mass flux. Drop size and velocity distribution in the spray only play a minor role. Puschmann (2003) correlated his experimental results based on an investigation of liquid/solid contact time for evaporating single droplet impact (Wruck, 1999) by

$$\alpha = \dot{m}_l u^{0.12} d^{-0.29} \tag{19.178}$$

Wendelstorf et al. (2008a) derived an empirical correlation for high surface temperatures and liquid mass fluxes, which correlates the heat transfer coefficient (HTC, α) with spray water mass flux and surface/water temperature difference (ΔT) as

$$\alpha = 190 + \tanh\left(\frac{\dot{m}_l}{8}\right) \times \left(140 \cdot \dot{m}_l \left(1 - \frac{\dot{m}_l \cdot \Delta T}{72{,}000}\right) + 3.26 \cdot \Delta T^2 \left(1 - \tanh\left(\frac{\Delta T}{128}\right)\right)\right) \tag{19.179}$$

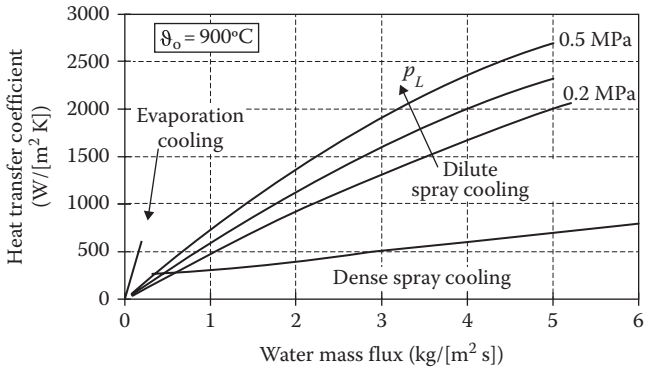

Figure 19.75

Heat transfer coefficient in spray cooling. (From Puschmann, F., Experimentelle Untersuchung der Spraykühlung zur Qualitätsverbesserung durch definierte Einstellung des Wärmeübergangs, Dissertation, University of Magdeburg, Magdeburg, Germany, 2003. With permission.)

Compared to the literature, the correlation is valid for all boiling regimes. The high-temperature values ($\Delta T > 400$ K) are in agreement with the extrapolated data from Equation 19.177.

In Figure 19.75, the result of dilute spray quenching (Puschmann, 2003) is shown. The heat transfer coefficient of dilute spray quenching is higher than for spray quenching but lower than for evaporation quenching. In dilute spray quenching, only single droplets touch the surface, become deformed, and transfer heat. The drops partially evaporate and then move away from the superposed airflow. Thus, the vapor film is avoided as it is the case for other quenching techniques. It is demonstrated that the unintended collapses of the vapor film (Leidenfrost problem) at edges, corners, roughness peaks, etc., are eliminated by this technique (Alam et al., 2008). In this way, mass lumped regions of work pieces can be cooled more intensively than the edges. Consequently, a uniform temperature distribution with reduced thermal stresses can be obtained. For twin-fluid atomization in this dilute spray regime, the heat transfer is also influenced by the atomizer gas flow rate. The dependency of heat transfer on atomizer gas pressure is explained by changing the spray characteristics with respect to drop size and drop velocity (Puschmann, 2003), hence the impact Weber number.

In practical applications, spray cooling is regularly used for the cooling of steel surfaces from high temperatures with an oxide layer. The influence of surface oxidation phenomena on spray water cooling heat transfer has been investigated by Wendelstorf et al. (2008b). Real scale layers on low alloy steels are normally not stable enough to withstand spray cooling. The local (partial) descaling, as well as the formation of vapor gaps at the oxide–metal interface and the movement of scale plates, induces real spatial and temporal fluctuations of the heat transfer, especially in the transition boiling regime, as well as measurement uncertainties. Several general trends have been observed from the measurements: above the Leidenfrost point, the oxide layers normally do not influence the mean HTC but its statistical spatial and temporal fluctuations can reach practically significant values; the oxide layer effect on the HTC decreases with increasing stability and with decreasing thickness of the layer; and the (local) formation of gas gaps between the scale and the hot metal surface can drastically reduce the (local) HTC.

The influences of additives in cooling water on heat transfer in spray quenching process have been investigated by Alam (2011) and Abdalrahman et al. (2014). The addition of salt increases the heat transfer in film boiling, transition boiling, and nucleate boiling regimes. The salt solutions, with increasing cooling ability (or efficiency), are NaCl, $NaHCO_3$, Na_2CO_3, Na_2SO_4, and $MgSO_4$, respectively. With increasing salt concentration (or electrical conductivity (EC) of salt solution in Abdalrahman et al. (2014)), the Leidenfrost point can be shifted to a higher temperature and consequently, the film boiling region is shortened; the total time of quenching is shortened; the critical heat flux is increased; and the wetting front velocity is increased. The cooling ability of a salts mixture is stronger than that of a single salt. Deposition of salts at higher temperature may degrade the surface roughness, which may promote the nucleate boiling heat transfer. Cooling water saturated with CO_2 reduces the cooling rate considerably while that saturated with air causes faster cooling.

19.4 Spray Applications

19.4.1 Energy Conversion/Spray Combustion

Spray combustion is a process to be found in stationary power generation, gas turbines, and internal combustion engines. The combustion of a liquid (or liquid/solid slurry) fuel spray is either a simultaneous or sequential complex process involving fluid dynamics of liquid and gas, heat and mass transfer, and chemical reactions (Williams, 1990, Warnatz et al., 1996). The combustion of individual droplets and groups of droplets is presented in Section 12.7. From atomization, the fuel is present in the form of discrete liquid droplets that have a range of sizes, velocities, and trajectories. This lack of uniformity in the unburnt mixture results in irregularities in the ignition and propagation of the flame through the spray, and thus, the combustion zone is geometrically only poorly defined.

19.4.1.1 Fuel Injection

Direct fuel injection (DI) is applied in diesel and Otto combustion engines (Heywood, 1998). From a first spray analysis, this process is defined as transient high-pressure injection and atomization of a liquid jet. The resulting spray is externally (spark) or self-ignited (Diesel). The principal structure of a *developed* DI diesel flame is depicted in Figure 19.76 as derived by Dec (1997). The sketch shows conceptually how DI diesel combustion develops prior to the end of fuel injection. After the liquid fuel leaves the injector and travels downstream, it atomizes into the droplet spray, entrains hot ambient air, and vaporizes rapidly, forming a sheath-like fuel/air mixture along the sides of the jet. Due to the penetrating nature of the injected liquid jet, macroscopically, a mushroom-like spray structure occurs. The liquid spray penetrates a short distance, during which the vaporized fuel and entrained air form a relatively uniform, rich mixture. The flame fed by the mixture stabilizes at a certain distance from the nozzle as long as the fuel injection continues. Several zones of chemical reaction product formation are found in the spray flame. Soot particles are formed and distributed throughout the cross section of the flame zone and then oxidized in the diffusion flame layer due to the attack of OH and O radicals. NO is formed around the jet periphery on the lean side of the diffusion flame (Tao and Chomiak, 2002). DI diesel combustion is a complex phenomenon in which relevant subprocesses of spray, flow, heat transfer, mass transfer, and chemistry take place over a wide span of time scales. For example, within the sheath near the nozzle at relatively low temperature, the chemical time scale is in the order of 10^0 s, while in the high-temperature zone, chemical reaction time scales span over several orders of magnitude, from about 10^{-6} to 10^0 s.

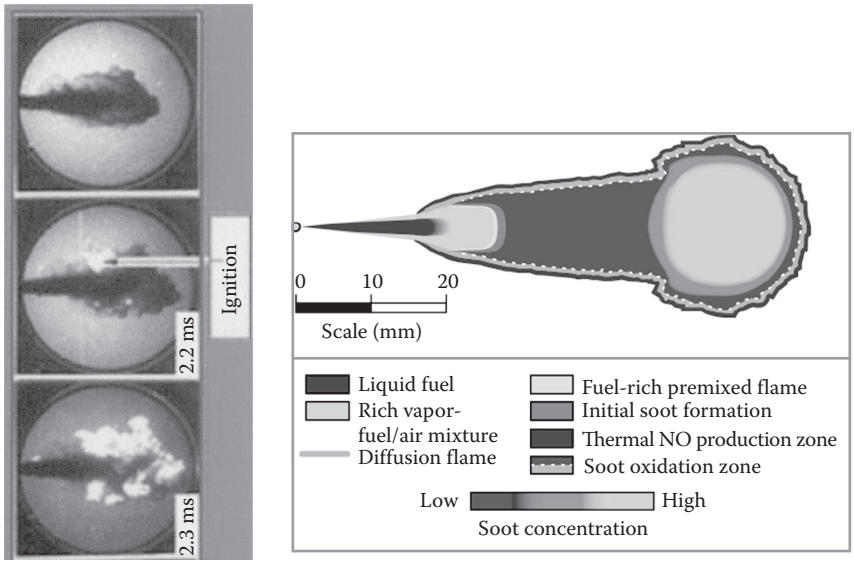

Figure 19.76

Diesel spray flame: photo of injection and ignition, principal stationary flame structure. (From Tao, F., Numerical modeling of soot and NOx formation in non-stationary diesel sprays with complex chemistry, PhD thesis, Chalmers University of Technology, Göteborg, Sweden, 2003. With permission.)

19.4.1.1.1 Diesel Injection (DI) Typical operating parameters of a DI spray in a cylinder are fuel injection pressure up to 200 MPa, injection fuel mass approximately 5–50 mg, injection duration of the order of 1 ms, liquid jet diameter (hole size) about 100 μm, resulting in an SMD droplet sizes of around 10 μm (Spicher, 2001, Tschöke and Leyh, 2003). Two different systems for pressure generation are used: the inline pump system (unit injection system UIS), where each cylinder is connected to and fed by an individual pump, and the common rail system (CRS), where pressure generation and liquid injection are separated as the pressurized fuel is kept at high pressure in a common rail system. An advantage of the CRS is that the injection pressure value, as well as the injection time characteristics (initial time, pre-, main- and postinjection), may be managed electronically depending on the actual engine load. Multihole nozzles are applied at the tip of an injector, as illustrated in Figure 19.77. Two main nozzle configurations are used: valve-covered orifice (VCO) and minisac nozzles. Samples of the injection sprays from these configurations are illustrated in Figure 19.78 (Tsunemoto et al., 2001). These authors deduced that the spray configuration deviations in the VCO nozzle sprays are larger than in the minisac nozzle sprays. Eccentricity of the needle valve as well as slight deviations in hole production deviations may cause asymmetrical spray behavior (from hole to hole and from cylinder to cylinder). The deviation between individual nozzles decreases when the injection pressure increases. These have been identified as sources of emission.

The detailed flame zone structure of a DI diesel spray during combustion may be studied by numerical simulation. It is based on the analysis of transient spray development and drop evaporation (see, e.g., Hohmann (1999)). One key modeling issue in spray combustion is the complex turbulence–chemistry interaction and the formulation of equation closure for mean reaction rates. Typical numerical engine spray combustion studies (Ramos, 1989) use simplified models such as the eddy-breakup model (EBU) (Spalding, 1971), or the eddy-dissipation concept (EDC) (Magnussen and Hjertager, 1977), or models like flamelet models (Kong et al., 1995, Wan et al., 1997, Olguin and Gutheil, 2014) or the "subgrid" partial stirred reactor (PaSR) model (Karlsson, 1995, Tao, 2003). The latter has been used to calculate a diesel flame, as reported by Tao (2003) and Tao and Chomiak (2002). The KIVA-3 code (Amsden et al., 1989, Nordin, 2001) has been modified to include the complex chemical mechanisms based on n-heptane kinetics, where 65 species and 273 elementary chemical reactions are taken into account. Autoignition and lift-off of the flame are calculated in the simulation. The calculated transient diesel spray formation, autoignition, and flame development processes are illustrated in Figure 19.78 as temperature contours in the spray flame between 1 and 4 ms after injection have been started. The fuel jet penetrates deeply into the hot, highly compressed (5 MPa) air before autoignition. The ignition occurs in a fuel-lean premixed region at the side of the jet, downstream from the exit of the nozzle at about 2 ms after injection has started. Following that rapid development of the ignited hot spot leads to a flame propagation toward the axis of the fuel jet, modifying

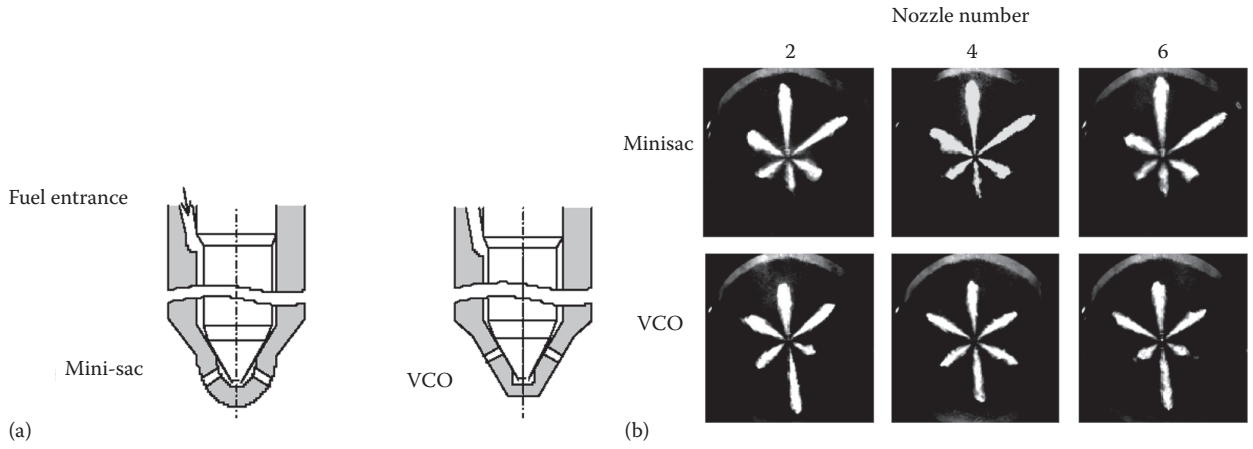

Figure 19.77

Nozzle configurations in high-pressure diesel injection systems: (a) valve-covered-orifice and minisac nozzle; (b) Samples of sprays from high-pressure injection. (Adapted from Tsunemoto, H. et al., Cylinder to cylinder deviations in fuel spray and exhaust emissions at idling in high pressure DI diesel engines, in *Fifth International Symposium Diagnostics and Modeling Internal Combustion Engines*, Nagoja, Japan, 2001.)

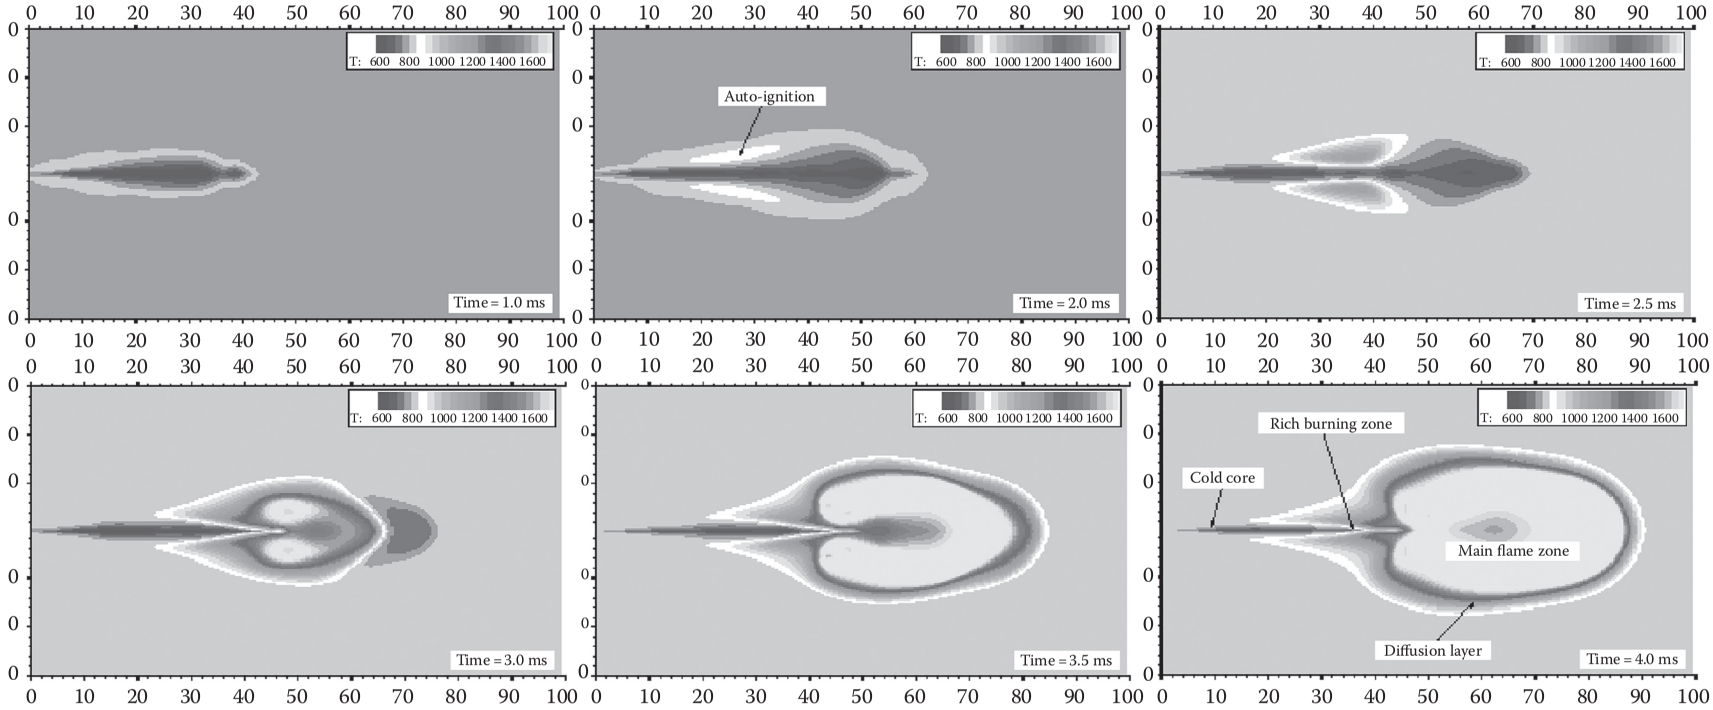

Figure 19.78

With permission.)

the pattern of the jet penetration. Then, the flame propagates upstream and downstream and finally, its development becomes "quasisteady," stabilizing on the top of the jet. This flame feature is retained until the end of the injection. The spray and fuel vapor penetrations are plotted in Figure 19.79a and b. The plot shows that, even after autoignition, the spray penetration does not vary much and its length remains constant until the end of the fuel injection process. The "quasisteady" flame zone structure may be subdivided into: (1) a cold core zone, (2) a fuel-rich burning zone, (3) a main flame zone, and (4) a lean, thin oxygen diffusion layer. In the cold core region, the combined effect of high velocity gradients and evaporation cooling prevents the flame from propagating upstream to the nozzle exit. The leading edge of the flame, located on the lean side of the stoichiometric surface, stabilizes at a considerable distance downstream from the nozzle. This distance is referred to as the "lift-off" length of the diesel flame, distinguishing the cold zone from the fuel rich burning and main combustion zone. From the transient reaction analysis in these zones, emission formations as soot and NOx in the flame are deduced.

In addition to the model combustion flame configuration discussed before, in car engine applications, the three-dimensional interaction of the injected spray with the cylinder/piston geometry, and the interaction of fuel droplets with the hot walls during impingement plays an important role (Lee and Ryan, 2001).

19.4.2 Spray Aerosol Synthesis

Spray pyrolysis (SP) is widely used in industry to produce fine-grained powders because it is relatively inexpensive and quite versatile. In a conventional spray pyrolysis (CSP) process, submicrometer- and micrometer-sized particles are usually formed through droplet-to-particle route (see Figure 19.80). Here, the liquid precursor is first atomized (usually through twin-fluid atomization or ultrasonic atomization) and sprayed into a heated reactor where the aerosol droplets undergo solvent evaporation (shrinkage stage) and the solute is precipitated on and within the droplets. If the temperature in the reactor (or furnace) is high enough, drying and chemical decomposition of the precipitated precursor particles forms early product particles. The CSP process may produce dense or hollow particles, depending on the operating conditions. Hollow particles form if, at the onset of solute precipitation on the droplet surface, the solute concentration at the droplet center is lower than the ES (Eslamian et al., 2006, Eslamian and Ashgriz, 2007). For an impermeable crust, the substantial pressure build-up on the internal wall of the shell may burst the drying particle into particle flakes or break from the weakest part, resulting in a particle with a small hole. As another scenario,

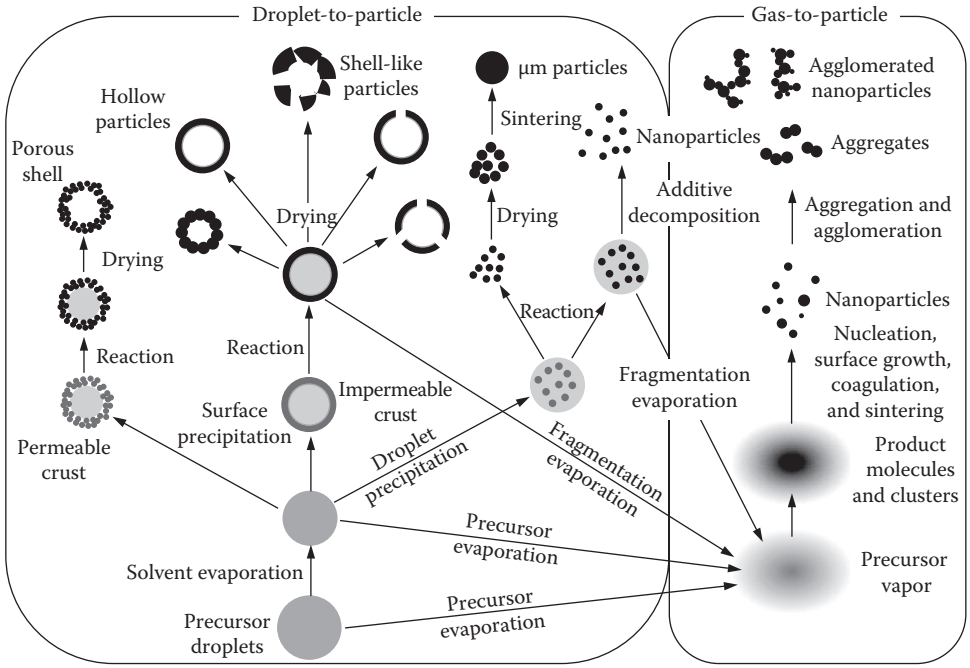

Figure 19.80

Schematic diagram of particle formation mechanisms in spray and flame aerosol synthesis.

if the crust is strong enough to resist the internal pressure, the vapor trapped inside the particle may later condense and the shell may contract due to depression. However, if the shell is fully dried, it is possible that the condensation cannot cause any permanent deformation to the particle, and a hollow smooth-surface particle may form. On the other hand, in the case of a permeable crust, the evaporated solvent leaves the particle, without increasing the internal pressure, and a nondisrupted porous particle forms.

Compared to conventional wet-phase routes with various posttreatment steps, such as filtration, washing, drying, and calcinations, spray aerosol synthesis processes allow one-step preparation of demanding and highly functional products.

Recent advances in combustion engineering, aerosol technology, and materials science now allow scalable spray flame aerosol synthesis (SFAS) of mixed oxides, metal salts, and even pure metals in the form of nanoparticles and films with closely controlled characteristics. In contrast to the CSP processes, spray particle synthesis processes with flames do not require an additional source of energy for precursor convention such as electrically heated walls, making it a rather low capital investment process with proven scalability (Pratsinis, 1998, Maedler, 2004, Teoh et al., 2010, Achelis et al., 2014, Gröhn et al., 2014, Meierhofer et al., 2014). Supplying the energy by a vapor flame allows much higher process temperatures and cooling rates compared to electrically heated hot-wall reactors where temperatures are usually relatively low (<2000°C) and residence time longer (up to a few seconds) (Strobel et al., 2006a). In the SFSA process, the gas-to-particle mechanism (see Figure 19.80) occurs when the metal-organic precursor evaporates soon after it enters the flame, which results in the nanoparticles formation.

Depending on the precursor state (vapor, aqueous-based, solvent-based) fed to the flame and combustion conditions, flame aerosol syntheses are categorized as vapor-fed aerosol flame synthesis (VAFS), flame-assisted spray pyrolysis (FASP), and flame spray pyrolysis (FSP). In the VAFS process, a metal precursor is supplied in the form of vapor into oxygen or air-fuel flames, while both FASP and FSP fall in the regime of liquid-fed aerosol flame synthesis (LAFS) where liquid precursor solution, emulsion, or slurry is atomized into oxygen or air-fuel flames. The core difference between FASP and FSP lies in the origin of majority of combustion enthalpy content of the system. In the FASP process, precursor is supplied in the state of low combustion enthalpy solution (<50% of total combustion energy) usually in aqueous solvent, and an external hydrogen or hydrocarbon flame is thus needed to assist its combustion. In the FSP process, the liquid precursor solution (usually in an organic solvent)

drives the flame process by contributing more than 50% of the combustion energy, and the external flame serves only as an ignition source.

19.4.2.1 VAFS

In the VAFS process, volatile metal precursors (e.g., chlorides) are evaporated and fed into a flame that either supports the process or ignites the process. Metal oxide particles are formed after precursor conversion by nucleation from the gas phase and grow by surface reaction and/or coagulation and subsequent coalescence into larger particles (gas-to-particle route, see Figure 19.80). VAFS is used industrially for synthesis of various ceramic commodities, such as fumed silica, waveguide performs, alumina, and pigmentary titania. However, the need for volatile precursors limits the application of VAFS to products where volatile precursors at reasonable cost are available. The continuous demands for process versatility require the replacement of metal vapor precursor. This prompted the spraying of liquid precursors directly into the flame, that is, LAFS.

19.4.2.2 FASP

In the FASP process, less volatile and economical precursors, especially those of aqueous metal salts (e.g., nitrates and acetates), are used. Many of these precursors, especially aqueous nitrates, have low combustion enthalpy or endothermic in nature and do not form self-sustaining flames. Therefore, an external hydrogen or hydrocarbon flame is employed in the FASP process to support the combustion. The liquid precursor is dispersed into fine droplets (e.g., through ultrasonic or air-assisted nozzle) that are evaporated and pyrolyzed by the external flame. Depending on process conditions, hollow, micron- or nano-sized particles are formed when the precursor reacts in the droplet or gas phase, respectively (see Figure 19.80). In general, complete precursor evaporation leads to solid nanoparticles as in the VAFS process, while incomplete droplet evaporation leads to hollow and shell-like micron-sized particles. The latter usually takes place when operating at low rates of combustion enthalpy (defined as the ratio of combustion rate (kJ/min) to total gas flow (g/min), <4.7 kJ/g), where there is insufficient energy for the formation of metal vapor (Jossen et al., 2005). In such cases, dense particles are formed as a result of drying and solid-state densification, while hollow particles are due to precipitation on surface droplets prior to evaporation of the carrier liquids.

A further step of applying the energy source in closer proximity to the reaction zone is the embedding of the aqueous precursor solution (mainly derived from nitrates) in a combustible droplet environment. This is achieved by preparing an organic solvent–water metal precursor stabilized in an oil (fuel) emulsion phase, which was atomized into micron-sized droplets and subsequently ignited. This self-sustaining spray flame method is called the emulsion combustion method (ECM) (Takatori et al., 1999, Maedler, 2004). This technique has been successfully applied to titania, silica, alumina, zirconia, barium titanate, and zirconia-ceria, as well as electronic, catalytic, and ceramic applications (Tani et al., 1998, 2001, 2003). A major limitation of this method can be the lack of control with respect to product morphology (e.g., hollow particles are often produced) (Maedler, 2004). The presence of incombustible water phase in the ECM precursor not only lowers the combustion enthalpy density, but may also result in poorer gas-phase mixing and reaction as compared to a homogenous solvent-based only precursor, thereby affecting the particles homogeneity (Teoh et al., 2010).

19.4.2.3 FSP

The utilization of the endothermic precursors (mainly metal-nitrates and metal-chlorides dissolved in water) is driven by low cost, availability, and solubility (achievement of high concentration). However, the utilization of these precursors often results in the final product particle formation within the droplet due to insufficient energy, even in the EMC method where very high energy content of the kerosene exists in close proximity to the endothermic-reacting precursor (<1 μm) (Tani et al., 1998). This leads to hollow or fragmented product particles (Maedler, 2004).

The FSP method solves this problem by the use of exothermic liquid precursors. The bulk of flame enthalpy originating from the combustion of liquid precursor maintains a self-sustaining spray flame. This provides direct control over primary particle size by controlling the combustion enthalpy rate and metal concentration of the precursor alone (Maedler et al., 2002). Because of the highly exothermic nature of FSP

liquid precursors, flame temperatures of up to 2600 K (Maedler et al., 2002, Schulz et al., 2005) or 2800 K (Mueller et al., 2004) have been measured. At the same time, the high gas velocities of the FSP induce radial entrainment of surrounding gas. Coupled with the radiation heat loss, this gives rise to extremely short residence times (milliseconds) with high-temperature gradients (170 K/cm) along the flame axis (Schulz et al., 2005). The interplay between high temperature and large temperature gradient is one of the most important features in FSP (Teoh et al., 2010): the high local temperature promotes the formation of homogeneous and highly crystalline materials and also promotes particle growth by sintering and coalescence (Maedler et al., 2002), while the large temperature gradient (and short residence time) preserves the nanoscale feature of the particles. The rapid thermal quenching during FSP may also result in the formation of many metastable materials.

The main particle forming mechanism in the FSP process is through gas-to-particle route (see Figure 19.80), in which particles form in sequential stages: (1) precursor spray evaporation/decomposition forming metal vapor; (2) nucleation as a result of supersaturation; (3) growth by coalescence and sintering; and (4) particles aggregation (forming hard agglomerates by chemical bonds) and agglomeration (forming soft agglomerates by mainly physical bonds).

In the scale-up of nanoparticle production of zirconia by FSP from ~100 to 500 g/h, the product primary particle and agglomerate size as well as the crystallinity are conserved when the precursor and the dispersion flow are increased by keeping the gas-to-liquid mass ratio constant. This is attributed to similar high-temperature particle residence times (PRTs), which is revealed by process simulation with a CFD-based model, employing transport-limited precursor oxidation and monodisperse particle dynamics (Gröhn et al., 2014).

For large-scale nanoparticle production by FSP, a hybrid precursor-atomization concept, as a combination of a liquid pressure swirl nozzle and a swirl dispersion gas nozzle, is presented by Meierhofer et al. (2014). The relevant parameters influencing the atomization process (dispersion gas feed rate, liquid feed rate, nozzle geometry) are investigated (for air, water) in nonburning (cold) spray conditions based on experimental measurements and CFD simulations. Larger gas swirl angles reduce the droplet velocity and furthermore lower the atomization efficiency, leading to larger droplets. Results show that the liquid volume flow rate (and thus the productivity of the process) may be increased significantly while still maintaining an appropriate droplet size compared to the conventional atomization process conditions in FSP reactors.

Within the FSP process for nanoparticle production, the effects of the precursor atomization process and the spray properties on the spray flame structure have been studied by Noriler et al. (2014) using experiments and numerical simulations. The influence of the precursor concentration variations on the spray droplet size distribution was studied for two different FSP nozzles. The resulting spray has been characterized in terms of drop sizes and velocities by means of laser diffraction and particle image velocimetry. A mathematical model was carried out for the spray flame, considering two-way coupling between the gas phase and the droplets. For the combustion model, the eddy dissipation concept model was employed, taking into account the effects of the vaporization of the droplets, chemical reaction mechanisms, and the chemistry–turbulence interaction. Experimental and numerical results are compared to validate the model and to study the potential influence of significant spray parameters on the FSP process. A comparison of the flame height for different nozzle configurations is illustrated in Figure 19.81.

19.4.2.4 Ultrasonic Spray Pyrolysis

In an ultrasonic spray pyrolysis (USP) process, the liquid precursor is atomized through ultrasonic atomization and sprayed into a heated reactor or into a flame under pyrolysis condition, yielding micrometer-, submicrometer-, or nanometer-sized particles through droplet-to-particle or gas-to-particle route. Various principles are applied in ultrasonic atomization (Walzel, 2012, Mwakikunga, 2014), namely,

- Capillary waves (20–100 kHz)
- Cavitation (0.1–5 MHz)
- Stationary ultrasonic waves in a gas
- Exited jet disintegration

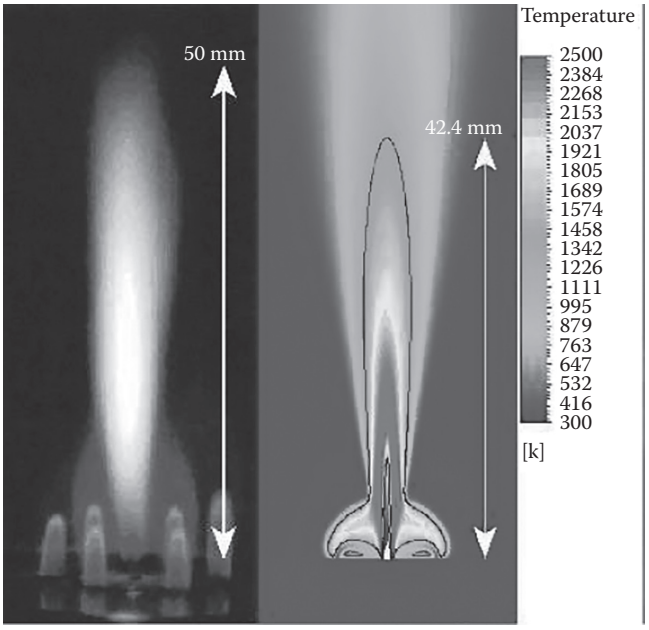

Figure 19.81

Comparison of experimental and numerical simulated spray flame structure (fuel: ethanol) Noriler et al. (2014) in FSP process.

Based on the capillary wave mechanism, Lang (1962) determined the relationship between the wavelength of the capillary waves and the mean size of droplets

$$D = 0.68\left(\frac{\pi\sigma}{\rho f^2}\right)^{1/3} \tag{19.180}$$

without taking into account the dependence of droplet size on liquid viscosity and volumetric flow rate. Here σ is the surface tension, ρ_l the liquid density, and f the frequency of the forcing sound. Since then, the researchers including Davis (1985), Walzel (1993), Rajan and Pandit (2001), and Avvaru et al. (2006) tried to build a universal correlation, which could account for the effects of physical–chemical properties of the liquid (liquid flow rate ($\dot{Q}$), viscosity (μ_l), density, and surface tension) and ultrasonic properties like amplitude (Am), frequency, and the area of vibrating surface. The Avvaru's formula (Avvaru et al., 2006), which suits the so-called Newtonian viscous liquid, is given as

$$D = \left(\frac{\pi\sigma}{\rho f^2}\right)^{1/3} + 0.0013(\mathrm{We})^{0.008}(\mathrm{Oh})^{-0.14/n}(I_N)^{-0.28} \tag{19.181}$$

Here, the symbols We, Oh, and I_N are, respectively, Weber number, Ohnesorge number, and intensity number, defined in the following expressions:

$$\mathrm{We} = \frac{f\dot{Q}\rho}{\sigma};\quad \mathrm{Oh} = \frac{\mu}{fA_m^2\rho};\quad I_N = \frac{f^2A_m^4}{c\dot{Q}} \tag{19.182}$$

Here, the index n in Equation 19.181 can be estimated by fitting the apparent viscosity data to the two-parameter power law model, and c in Equation 19.182 is the speed of sound. Hansmann (1996) also derived a droplet-size expression for USWA (see Table 19.3).

In comparison with twin fluid-atomization (liquid atomization by high-speed gas jets), ultrasonic atomization has the disadvantage of low throughput, but has the advantage of narrow drop size distribution (and therefore narrow particle size distribution) and low momentum associated with ejected droplets (and therefore suitable for coating process).

Besides metal and oxide powders, the USP method can fabricate composite particles with core/shell structure, for example, $Ti_{1-x}Zr_xO_2$ solid solutions (Huang et al., 2006), Ru/Ni nanoparticles (Deng et al., 2008), Cu/Ag submicrometer-sized particles (Jung et al., 2011), and Ru/TiO_2 nanoparticles (Stopic et al., 2010). The core/shell structured particles can be fabricated directly through the gas-to-particle route or the droplet-to-particle route.

In the gas-to-particle route, the kinetic difference of decomposition reaction of the precursor mixture may cause the formation of shell structure on top of a core particle. In the liquid-to-particle route, two hypotheses are proposed to explain the formation of the core-and-shell structure (Deng et al., 2008):

1. The conventional theory believes composite, multicomponent particles are synthesized with precursor solutions consisting of solutes of same or different solubilities (Messing et al., 1993). As the aerosol droplets containing uniform solution of several solutes undergo precipitation, evaporation, drying and coagulation steps, successive precipitation of the solutes occurs; the less soluble components tend to precipitate faster than those with higher solubility and form the core.
2. The second theory is based on melting points of the core and the shell components. The higher melting point element has higher cohesive forces and intermolecular bonding (or lower mobility), leading to the formation of the core (Yang and Kim, 2004, Pingali et al., 2008, Jung et al., 2011).

To achieve phase separation, Stopic et al. (2013) applied multistep USP to synthesize TiO_2 core/RuO_2 shell particles. Here, in contrast to conventional USP, a modified set-up with separated ultrasonic atomizers for each precursor and two horizontal reactors for thermal decomposition was employed. Titania particles are formed in the first pyrolysis zone. The second aerosol stream was then admixed to the stream of solidified titania particles emerging from the first decomposition zone. This mixture was then piped through the second pyrolysis zone, where the desired core/shell particles were formed.

19.4.2.5 Particle Characteristics

The characteristics and the subsequent performance of spray flame-made particles are affected by their synthesis temperature history and concentration that are controlled by burner configuration, precursor composition, and oxidant/fuel flow rates (Pratsinis, 1998). These particles are either aggregates (chemically sinter bonded) of primary particles or agglomerates (physically bonded) of primary single particles and/or aggregates. Short residence times and faster cooling rates decrease primary particle size and extent of aggregation (Strobel and Pratsinis, 2007). Most common flame-made particles are spherically shaped primary particles with different degrees of agglomeration. Other shapes of primary particles depend mainly on crystal structure and related surface energies, as shown in Figure 19.82. Dopants and the related changes in surface energies can be used to alter particle shape.

For synthesis of multicomponent particles, the spatial distribution of individual components is important. Strobel and Pratsinis (2007) and Teoh et al. (2010) summarized five typical configurations of flame-made multicomponent particles, as shown in Figure 19.83: (a) homogeneous mixing between multicomponents; (b) polycrystalline particles with two components forming individual phases within a particle, (c) surface layer of one component coating the other, (d) small clusters supported on the surface of the other component, and (e) an external mixture of separate individual particles of different components.

The distribution of two or more components is strongly affected by their mixing behavior during particle formation in the flame. Similar evaporation, conversion, and nucleation rates favor more homogeneous distribution, whereas a sequential formation of individual particle components favors their segregation. Sequential nucleation/condensation can occur when two materials exhibit large differences in volatility. In some cases, to achieve phase separation, particles can be produced separately by using two flames and mix their plumes downstream by operating two FSP nozzles (Strobel et al., 2006b, Høj et al., 2013, Minnermann et al., 2013, Grossmann et al., 2015), as shown in Figure 19.84. Other factors influencing configuration of multicomponent particles cover composition of precursor and solvent, Strobel and Pratsinis (2011), phase–interface interaction, phase miscibility, oxidant/fuel flow rates, etc. A detailed explanation of formation mechanisms of various particle configurations can be found in Strobel and Pratsinis (2007) and Teoh et al. (2010).

19.4.2.6 Spray Flame Deposition Process

Instead of collecting the flame-made powder by filtration, electrostatic precipitation, or in a cyclone, flame aerosol synthesis methods offer the possibility to directly deposit particles on a substrate, resulting in nanostructured films. The structure of films prepared by deposition of flame products strongly depends on the particle formation stage upon arrival at the substrate and on substrate temperature (Liu et al., 2004, Bahlawane, 2006). Figure 19.85 shows a schematic of spray flame deposition processes. Depending on the particle formation stage upon arrival at the substrate, the resulting deposit can be precursor droplets, precursor/product vapor, or product particles with different degrees of agglomeration. This can be controlled, for example, by placing the substrate at an appropriate distance or by altering the precursor/gas flow rates. If unconverted precursor impacts on the substrate, it results in denser films (Bahlawane, 2006), while airborne product particles lead to very porous particle films (Maedler et al., 2006, Pham et al., 2010). Depending on the substrate temperature, this porous film is either preserved or collapses into more compact structures by sintering (Liu et al., 2004). Substrates such as flat plates (Karthikeyan et al., 1997, Sahle-Demessie et al., 1999), tubes (Miki-Yoshida et al., 2002), or foams (Schimmoeller et al., 2006) are used. Sequential deposition of different aerosol materials gives rise to multilayer films, each of which can be in principle designed with controlled thickness and morphologies (Charojrochkul et al., 1999, Sahm et al., 2007, Kemmler et al., 2013).

19.4.3 Metallurgical Processes

19.4.3.1 Metal Powder Production

Powders of different metals and alloys are produced by melt atomization. The amounts produced in industry vary from a few kilograms to a million tonnes per year (for a single facility), for example, in the production of dental amalgams to steel or iron shot (Yule and Dunkley, 1994). Particle sizes vary from micrometer (e.g., for corrosion protection paints) to millimeter (e.g., for shot blasting). Depending on the application, the desired particle shape may also vary from spheres and aggregates to fibers and flakes. These shapes can be achieved by variation in atomizer type, cooling conditions, and atomization liquid.

Samples of metal particles produced by atomization are illustrated in Figure 19.86. The width of the particle size distribution ranges from single size particles to large values, as shown in Figure 19.87. Rapidly quenched metal powders (at high cooling rates of 10^4 to 10^7 K/s) from spray processes may exhibit specific material compositions and properties due to fine grain sizes or even amorphous metallographic structure, as shown in Figure 19.88.

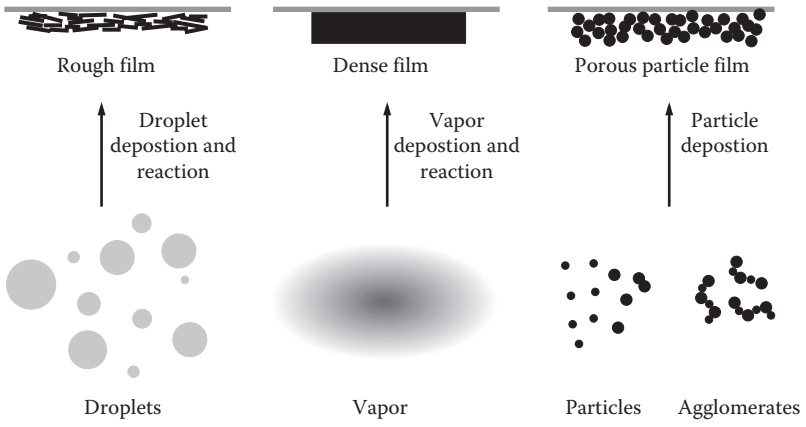

Figure 19.85

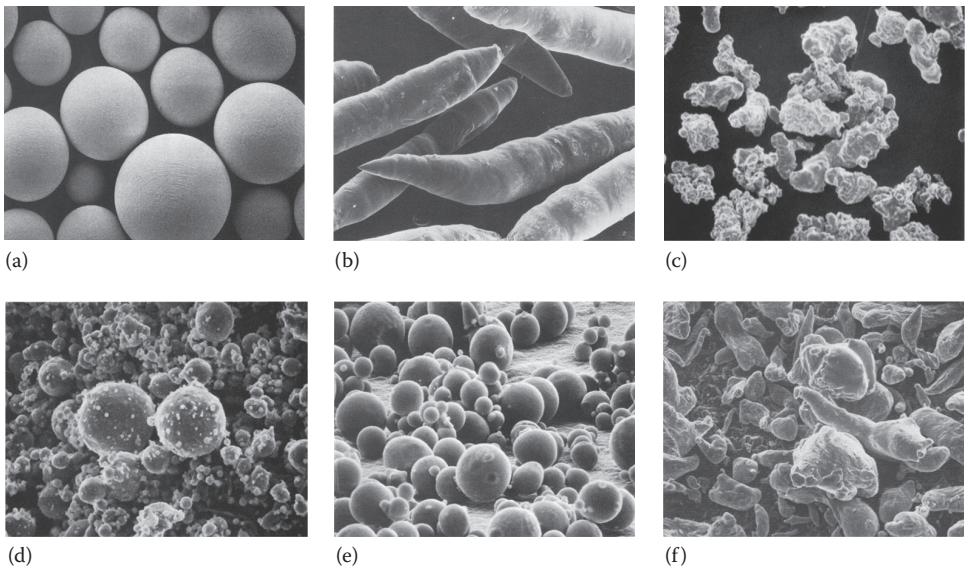

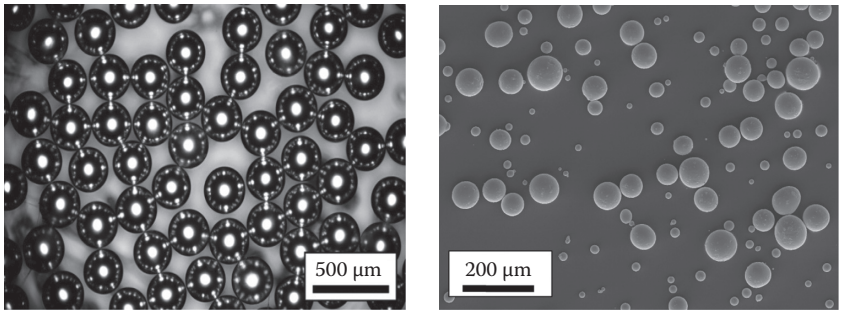

Figure 19.86

Particle shapes in molten metal atomization processes; (a) Rene 95 superalloy powder, produced by the plasma rotating electrode process, (b) aluminum needles produced by rotary atomization with perforated cup, (c) copper particles, produced by twin-fluid atomization with water, (d) aluminum powder, gas atomized with helium, (e) IN-1000 superalloy powder, pressure atomized, and (f) aluminum powder, gas atomized with air. (Adapted from Huppmann, W.J. and Dalal, K., *Metallographic Atlas of Powder Metallurgy*, Schmid, Freiburg, Germany, 1986.)

A major use of metal powders is in manufacturing of complex-shaped mechanical components such as by sintering or (hot or cold) isostatic pressing. In metal injection molding, fine metal powders are blended with a resin or binder to be pressure-injected into a mold, where the resin is removed afterward. Thermal spraying is a coating technique that uses ceramic or metal powders as feed materials. Recently metal powder formulations gained tremendoeus interest due to exploding applications in Additive Manufacturing (AM) techniques where complicated preforms are shaped from powders for instance by selective sintering.

Twin-fluid atomization is by far the most common atomization technique for metal powder production as it gives a high yield. When using oil or water as atomization media, the particle shape is nonspherical, while gas atomized powders show spherical shape. In water atomization, generally higher mass flow rates may be achieved. Gas atomization is typically performed by inert gases for prevention of oxidation

(or sometimes even the other way around, by partial or full oxygen content for controlled oxidation of the material). Twin-fluid atomized powders are in the size range of 10–500 µm at a distribution width (standard variation) of about 2.

For specific applications, metal powder production via atomization also is achieved by rotary or centrifugal atomizers (Halada et al., 1990), metal atomization by means of ultrasound (Bauckhage et al., 1996), in laminar supersonic flows (Gerking, 1993), or by controlled pulses (Henein, 2002) to produce a more narrow width of the size distribution. A general overview on atomization techniques for metal powder production can be found in Klar and Fesko (1984), Yule and Dunkley (1994), Lawley (1992), Bauckhage (1992), Dunkley (1998), Nunez et al. (1999), and Liu (2000b).

In molten metal atomization, the specific atomizer design is typically more complex than that for conventional liquids. Molten metals need to be superheated above liquidus for feeding into the atomizer. Here, these materials become chemically active and chemical reactions and erosions with the containing material in the crucible or tundish may occur. Thermal losses, especially in the combination with cold atomization media like gas, can lower the melt temperature locally below its specific liquidus

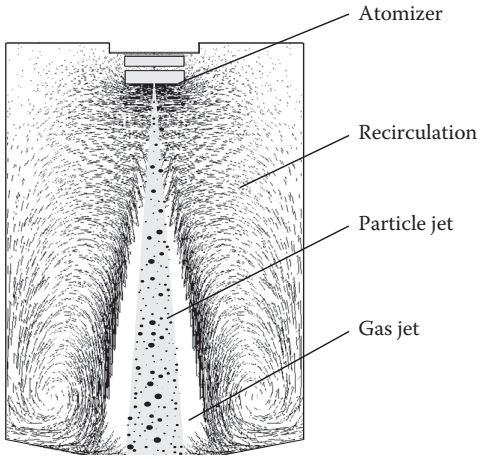

Figure 19.89

Flow field in a spray chamber for powder production, simulation result.

temperature, which may cause solidification and thermal freezing problems of melt atomizer nozzles, influencing the whole process. In this case, local isolation and/or heat sources in combination with suitable materials need to be applied. Molten metals typically have high density, high surface tension, and low viscosity, enabling specific measures to achieve a proper disintegration process. The spray structure in metal atomization is governed by the gas/drop interaction in combination with the high heat transfer between the hot melt and (usually) cold environment.

The principal two-phase flow field in a typical powder production chamber employing gas atomization is illustrated in Figure 19.89 obtained by numerical simulation. The flow is subdivided into three regions (Conelly et al., 1986): (1) the droplet spray in the core, surrounded by (2) the gas jet and (3) a recirculation zone in the outer area of the spray chamber. Typically within the recirculation zone, a large amount of fine particles swirl around in the spray chamber (dust formation). Here, preferably the fine particles can be found due to their small inertia. These particles cool down and solidify in their upward movement and possibly are reentrained into the spray as fine solid particles. As there are a large number of these fines, collisions with spray droplets are likely and result in so-called satellite formation in melt sprayed particles. These satellite formations lower the quality of sprayed powders such as a reduction in free-flow ability. A possibility for satellite formation prevention has been proposed by Dunkley and Telford (2002), Achelis and Uhlenwinkel (2008), and Achelis (2009). Here, part of the exhaust gas (after particle separation) is reinjected from top into the spray chamber (as illustrated in Figure 19.90). The recirculation gas flow rate is controlled by guiding the natural jet entrainment flow (conventionally achieved from recirculating gas inside the chamber) into the spray (see Section 19.2.2.3). As result, dust recirculation and satellite droplet formation is reduced. In Figure 19.91, sprayed particles with and without an antisatellite device are shown, where the number of nonspherical particles is dramatically reduced.

19.4.3.1.1 Metal-Matrix-Composite (MMC) Particles MMC particles can be fabricated through mixing ceramic particles and atomized metallic droplets in a spray atomization and coinjection process (Wu and Lavernia, 1992, Eslamian et al., 2008, Li et al., 2011, Li, 2014). The process is characterized by a three-phase spray flow (gas/droplets/particles). Ceramic particles (usually at least one order of magnitude smaller than atomized droplets), conveyed by the atomization gas or via a separate gas-assisted delivery system, are injected into the metallic droplet spray and likely to be incorporated into the droplets or captured by the droplets surface during frequent impingements, forming MMC droplets that are subsequently solidified as MMC particles. This approach will inherently avoid the extreme thermal excursions, with concomitant degradation in interfacial properties and extensive macrosegregation, normally associated with the MMC production in casting processes. By mixing reinforcements with liquid/semisolid matrix in a spray atomization process, demixing problem associated with the MMC production in powder metallurgy (PM) process can also be eliminated. A maximum incorporation rate (18% vol.%) of ceramic particles in metal matrix was reported by Eslamian et al. (2008), where a prefilming hybrid atomizer was employed for the production of MMC particles.

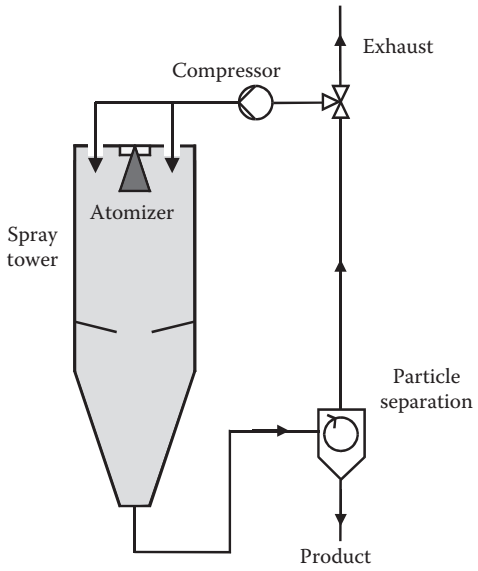

Figure 19.90

Concept for flow configuration in powder production spray process for decreasing of satellite drop formation.

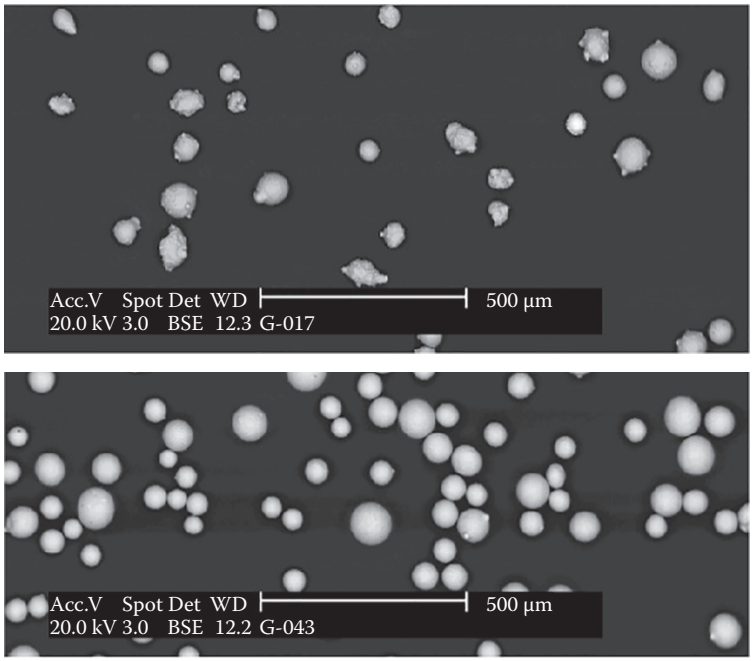

Figure 19.91

Satellite drop formation in melt sprays. (From Dunkley, J.J. and Telford, B., Control of satellite particles in gas atomization, in *Proceedings of World Congress on Powder Metallurgy and Particulate Materials PM²TEC 2002*, Orlando, FL, 2002. With permission.)

For MMC particle production in a spray process, a hybrid gas atomization nozzle configuration ideally fits the requirement of gas/particle/liquid dispersion and mixing in the spray flow field. A typical PGA configuration for MMC particle production is sketched in Figure 19.92a, where solid particles, continuously supplied by a particle pump and conveyed by the atomization gas, are coinjected and impacted by the liquid droplets in the secondary atomization zone. Figure 19.92b shows some spray-processed MMC particles in a PGA process. The fact that the particulate reinforcements are distributed inside or on the surface of the MMC particles

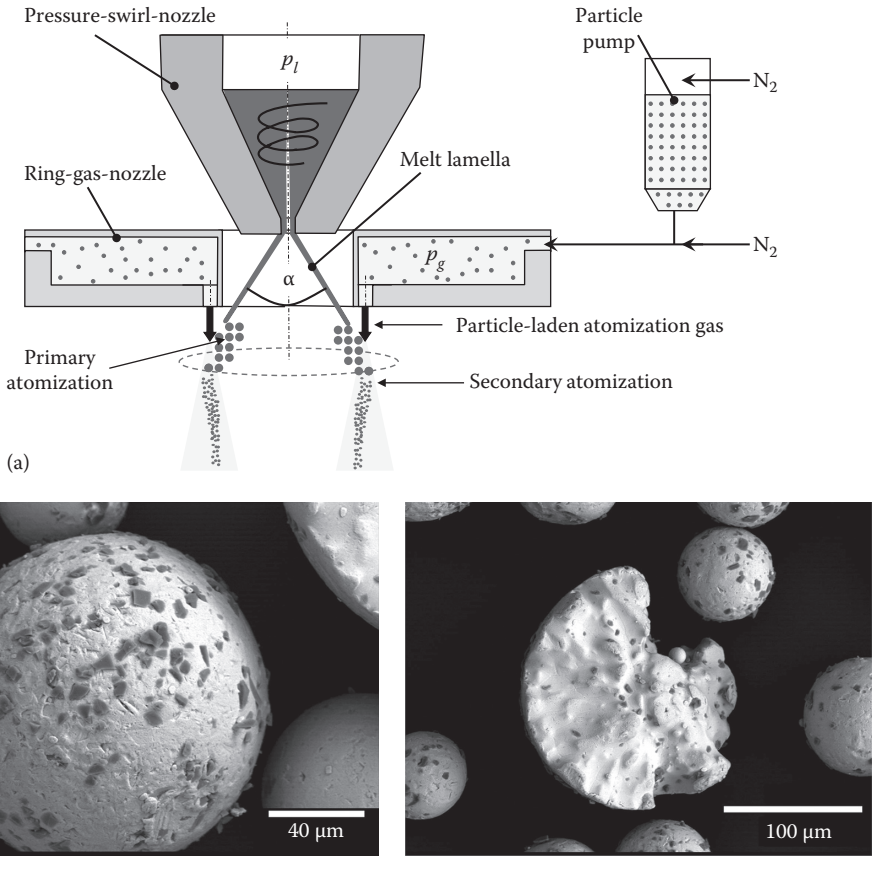

Figure 19.92

(a) Schematic of generation of MMC particles in a PGA process; (b) MMC particles: Sn-matrix + SiC-particulates. (Adapted from Li, X.G. et al., *Atom. Sprays*, 21(11), 933, 2011. With permission.)

proves the concept of MMC particles. MMC particles can be used in powder processes to generate composite parts or for thermal spray coating applications.

Li (2014) and Li and Fritsching (2014b) presented multiscale descriptions of particle–droplet interactions in spray processing of MMC particles based on multiphase computational fluid dynamics (MCFD) models, in which processes such as liquid atomization and particle–droplet mixing spray (macroscale), particle–droplet collision (mesoscale), and particle penetration into droplet (microscale) are taken into account, as shown in Figure 19.93. Thereby, the incorporation efficiency and sticking efficiency of ceramic particles in metal matrix are correlated with the operation conditions and material properties.

On the *macro*scale, the mixing behavior of ceramic particles (SiC) and metallic droplets (Sn) in a PGA configuration is described by an Eulerian–Lagrangian–Lagrangian (ELL) approach. In the PGA process, ceramic particulates conveyed by the atomization gas are coinjected and impacted with the metallic droplets in the secondary atomization zone. The ELL formulation uses Eulerian description for the continuous gas phase; hence, the gas flow through stationary mesh volumes, while the dispersed phases are tracked by the Lagrangian approach. Figure 19.94 shows the particle–droplet mixing configurations at different atomization gas pressures. Here, the TAB model is employed to describe droplet breakup. Increasing atomization gas pressure (i.e., increasing gas-mass-flow rate) causes a spray of tiny droplets, which tend to be involved in the particle-laden gas flow, thus leading to a high particle–droplet mixing degree. However, the fast droplet solidification rate at a high atomization gas flow may reduce the particle–droplet mixing quality. A lower atomization gas pressure results in a more radially expanded droplet spray that tends to intersect the particle-laden gas jets, leading to a poor particle–droplet mixing extent. Therefore, the best particle–droplet mixing configuration is determined at a moderate atomization gas flow.

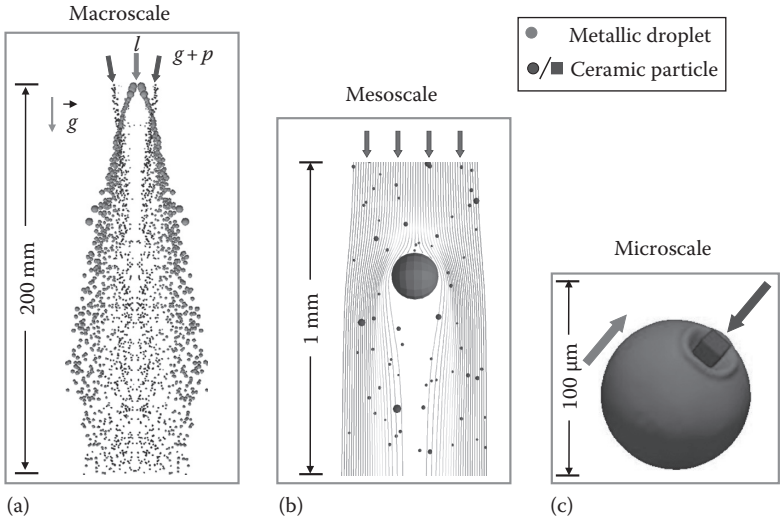

Figure 19.93

Illustration of multiscale modeling of fabrication of MMC particles in spray atomization process: (a) particle–droplet mixing, (b) particle–droplet collision, and (c) particle penetration into droplet. (Adapted from Li, X.G., Modeling and simulation of the gas-atomization process of metal melts for metal-matrix-composite production, Dissertation Universität Bremen, Shaker-Verlag, Aachen, Germany, 2014; Li, X.G. and Fritsching, U., Multiscale modeling and simulation in spray processing of composite particles, in *Proceedings of Second International Symposium on Multiscale Multiphase Process Engineering*, Hamburg, Germany, September 24–27, 2014b. With permission.)

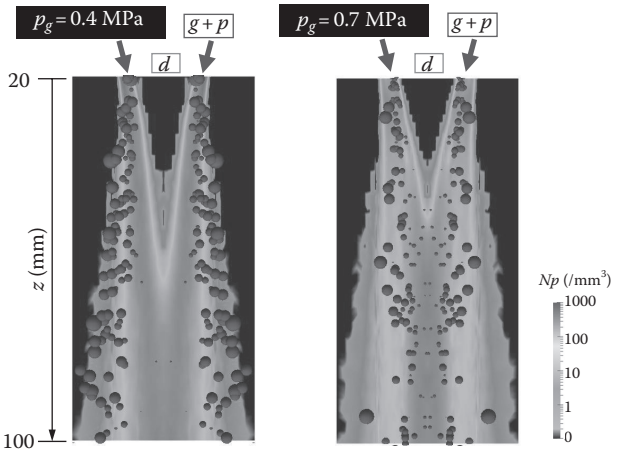

Figure 19.94

(Adapted from Li, X.G., Modeling and simulation of the gas-atomization process of metal melts for metal-matrix-composite production, Dissertation Universität Bremen, Shaker-Verlag, Aachen, Germany, 2014; Li, X.G. and Fritsching, U., Multiscale modeling and simulation in spray processing of composite particles, in *Proceedings of Second International Symposium on Multiscale Multiphase Process Engineering*, Hamburg, Germany, September 24–27, 2014b.)

On the *mesoscale*, the collision behavior between a metallic droplet and solid particles along the droplet trajectory is quantitatively described by

$$Q = \int \frac{\pi(d_p + d_d)^2}{4} \cdot \left|\vec{U}_p - \vec{U}_d\right| N_p \cdot \eta \; dt$$
$$\approx \sum \frac{\pi(d_p + d_d)^2}{4} \cdot \left|\vec{U}_p - \vec{U}_d\right| \cdot N_p \cdot \eta \cdot \Delta t \tag{19.183}$$

Here

Q represents the accumulative droplet-particle collision number along the droplet trajectory
d is the diameter
U is the velocity
N_p is the particle number concentration (m^{-3}) in a control volume ΔV
η is the collision efficiency
Δt is the time step for a droplet to move from one position to another
the subscripts p and d denote the physical quantities relative to particle and droplet, respectively

The particle–droplet relative velocity and the particle number concentration along the droplet-moving path can be obtained based on a Lagrangian tracking. The collision efficiency increases with the relative Stokes number. It tends to 0 if St < 0.1 and is close to unity if St > 10 (Schuch and Löffler, 1978, Li et al., 2011). In the PGA process, the relative Stokes number is usually larger than 10, and the collision efficiency can thus take a value of $\eta = 100\%$.

The droplets have different trajectories in the computational domain because of their different inertias. Along the droplet trajectory, the required information in Equation 19.183 such as the particle–droplet relative velocity and the particle number concentration at the droplet location can be extracted from the macroscale simulation to derive the accumulative particle–droplet collision number. Figure 19.95a shows the accumulative particle–droplet collision numbers along the trajectories of different sized droplets in a gas flow field at p_g = 0.4 MPa. The accumulative particle–droplet collision number achieves a maximum value when the droplet flies into a particle-free region or finishes solidification. The collection efficiency of ceramic particles by a metallic droplet is defined as the volume fraction of ceramic particles colliding with the droplet before it achieves a 50% solidification degree (assuming that when the solidification degree in a droplet is over 50%, the particle–droplet collisions will not lead to particle incorporation or sticking in the droplet). The collection efficiency as a function of droplet size and atomization gas pressure is shown in Figure 19.95b. In general, the collection efficiency first increases with increasing droplet size, reaches a maximum value, and then decreases. The particle–droplet mixing quality at a given operation condition can be described by

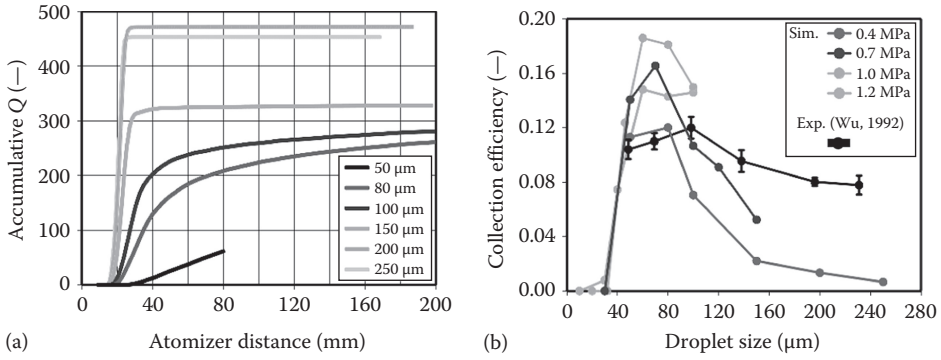

Figure 19.95

(a) Accumulative particle–droplet collision number Q along the droplet flight path vs. droplet size in a gas flow field at p_g = 0.4 MPa. (b) Collection efficiency of SiC-particles by Sn-droplets of different sizes at different atomization-gas pressures. (Adapted from Li, X.G., Modeling and simulation of the gas-atomization process of metal melts for metal-matrix-composite production, Dissertation Universität Bremen, Shaker-Verlag, Aachen, Germany, 2014; Li, X.G. and Fritsching, U., Multiscale modeling and simulation in spray processing of composite particles, in *Proceedings of Second International Symposium on Multiscale Multiphase Process Engineering*, Hamburg, Germany, September 24–27, 2014b.)

a characteristic collection efficiency, for example, the collection efficiency of a droplet with a size of MMD (MMD, $d_{50,3}$) at that operation condition. A maximum characteristic collection efficiency (~16%) is obtained at p_g = 0.7 MPa, which implies a best particle-droplet mixing quality under this operation condition.

On the *microscale*, the numerical simulation of the penetration behavior of a solid particle into a liquid droplet is performed based on a multiphase CFD model, which describes the multiphase flow situation (gas-particle-droplet) by solving incompressible Navier–Stokes (NS) equations coupled with VOF method, six degrees of freedom (6-DoF) method, and dynamic mesh technique (Li and Fritsching, 2014c). Two typical outcomes observed in simulations are (1) the particle partially penetrates into the droplet and (2) the particle completely penetrates into the droplet. The outcomes are categorized with Weber number (We) and Reynolds number (Re) in a regime map, as sketched in Figure 19.96a. The regime boundary is formulated by

$$\ln\left(\frac{\mathrm{We}}{\mathrm{We}_0}\right) = a\left(\ln\left(\frac{\mathrm{Re}}{\mathrm{Re}_0}\right)\right)^b, \quad \text{with } \mathrm{We} = \frac{\rho_l U_{rel,0}^2 d_p}{\sigma}, \mathrm{Re} = \frac{\rho_l U_{rel,0} d_p}{\mu_l} \tag{19.184}$$

Here, We_0, Re_0, a, and b are constants related to solid/liquid contact angle (θ), particle/droplet size ratio (δ), and particle orientation (Li and Fritsching, 2014c). Based on the Re–We regime map, the critical penetration velocity was derived as a function of solid fraction in a droplet by taking into account the variation of viscosity with solid fraction in the solidifying droplet (Li and Fritsching, 2014c). As shown in Figure 19.96b, the critical penetration velocity increases exponentially with increasing solid fraction. An increasing solid/liquid contact angle (θ) leads to an increasing critical penetration velocity, but the increase is not significant when θ ≤ 90°. Based on the discussion, the accumulative collisions derived from the mesoscale modeling and simulation (Figure 19.95) can be thus divided into two groups, as sketched in Figure 19.97:

1. One group of collisions occurring in the penetration regime is the main source for the incorporation of particulate reinforcements in the interior region of MMC particles. The incorporation efficiency can be roughly described by the volume fraction of these particles to the droplet.
2. The other group of collisions will result in particle partial penetration according to the Re-We regime map. Since most of collisions in this regime occur in the downstream spray flow, it is considered reasonable that most of the solid particles are likely to be captured by the droplet surface because of droplet solidification. The sticking efficiency of particulate reinforcements on the surface of MMC particles can be roughly described by the volume fraction of these particles to the droplet.

Suitable process conditions for optimization of the particle sticking/inclusion ratio may be derived from the MCFD simulations. Figure 19.97 shows the calculated characteristic incorporation rate and sticking rate of TiC-particles (θ = 90°) and SiC-particles (θ = 152°) in Tin (Sn)-based MMC particles as a function of atomization gas pressure. It can be found that the incorporation rate as well the sticking rate first increases with increasing atomization gas pressure, reaches a maximum value, and then decreases; a significant portion

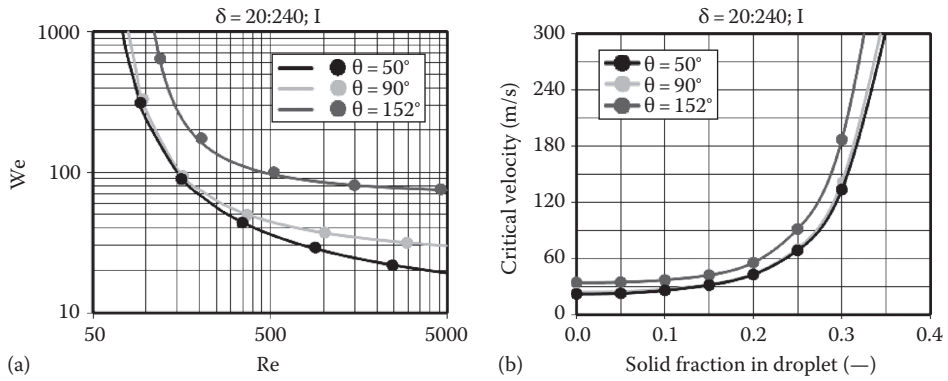

Figure 19.96

Critical penetration condition: (a) shift of regime boundary with variation of solid/liquid contact angle (θ) for head-on particle–droplet collision with particle orientation I; (b) critical penetration velocity vs. solid fraction at different solid/liquid contact angles. Figure 19.97

Characteristic particle incorporation efficiency in droplet and sticking efficiency on droplet surface at different atomization process operation conditions. (Adapted from Li, X.G., Modeling and simulation of the gas-atomization process of metal melts for metal-matrix-composite production, Dissertation Universität Bremen, Shaker-Verlag, Aachen, Germany, 2014; Li, X.G. and Fritsching, U., Multiscale modeling and simulation in spray processing of composite particles, in *Proceedings of Second International Symposium on Multiscale Multiphase Process Engineering*, Hamburg, Germany, September 24–27, 2014b.)

of collisions is squandered by droplet surface. The maximum incorporation rate occurs at p_g = 0.7 MPa, while the maximum sticking rate occurs at p_g = 1.0 MPa. A larger contact angle results in a smaller particle-incorporation rate but a larger particle-sticking rate.

19.4.3.2 Spray Forming

The spray forming process is a metallurgical manufacturing process that combines the main advantages of the classical processes:

- Metal casting: high-volume production, neat-net shape forming
- Powder metallurgy: near-net shape forming (at small volumes) with homogeneous, fine-grained microstructure

The spray forming process combines the atomization and spraying of a metal melt with the consolidation and compaction of the sprayed mass on a substrate. A typical scheme of the spray forming process is illustrated in Figure 19.98. The metallurgically prepared metal melt is distributed from the melting crucible via a tundish into the atomization area. Typically by means of a twin-fluid atomizer with external mixing, inert gas jets with high kinetic energy impinge onto the metal stream and cause the melt disintegration. In the resulting spray, the droplets are accelerated toward the substrate and thereby cool down and partly solidify by intensive heat transfer to the cold atomization gas. The mixture of liquid droplets and semisolid or solidified particles in the spray impinge onto the substrate consolidating to the desired deposited product. This mixture of droplets in different solidification stages on impingement is an essential feature of the spray forming process. The overall amount of the superheat (above the liquidus temperature) and of the latent heat (solidification) is extracted from the sprayed mass in the spray at high cooling rates (approximately 10^5 K/s). The solidification of the remaining melt in the deposit (typically 10%–40% remaining liquid) is started at an already high (finely distributed) solid content (Annavarapu and Doherty, 1995, Doherty et al., 1997), thereby resulting in extreme fine and equiaxed grain structures. After consolidation, the remaining metal finally solidifies and cools down further at cooling rates that are just comparable to casting processes.

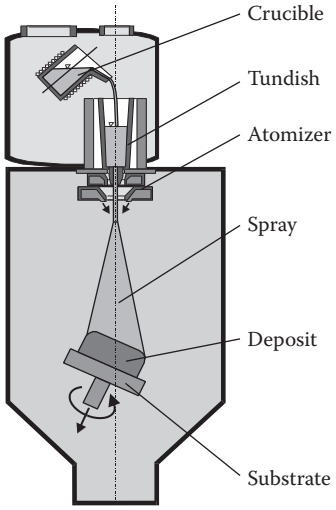

Figure 19.98

Principle of the spray forming process.

An overview of industrial applications and the objectives of spray forming have been given by Lawley et al. (1990), Grant (1995), Lavernia and Wu (1996), Leatham and Lawley (1993), Bauckhage (1997, 2003), Fritsching and Bauckhage (1999), Lawley (2000), Raju et al. (2008), and Antipas (2013). Several materials and alloys are produced with specific advantages via spray forming such as

- Conventional metallic materials and alloys from steel, aluminum, and copper and
- Materials in which alloying components tend to segregate within conventional casting processes, for example, alloys on aluminum, copper and iron bases, super alloys (e.g., on nickel base) for applications in the aircraft and aerospace industries,
- Intermetallic composite materials (IMCs)
- Multilayer composites or gradient materials by cospray forming (Meyer et al., 2009, Cui et al., 2013, Grohmann et al., 2013)
- MMCs, for example, ceramic particle inclusions into a metal matrix (Lavernia, 1996, Schneider, 2005, Raju et al., 2008, Cui et al., 2010)
- Precipitation-controlled alloy composition
- Lightweight materials (e.g., magnesium)
- Metallic glasses (Srivastava et al., 2009, 2013, Cava et al., 2013)

Typical geometries of spray formed preforms in industrial applications are flat products, tubes or rings, and cylindrical billets.

The main advantage of spray formed materials, compared to conventionally produced materials, is related to their outstanding material properties. These are due to the specific cooling and solidification history in the spray process and finally result in

- Absence of macrosegregations
- Homogeneous, globular microstructure
- Increased yield strength
- Decreased oxygen contamination
- Good hot workability and deformability

19.4.3.2.1 Atomization of the Liquid Melt In spray forming, typically twin-fluid atomization with inert gas is used in a free-fall atomizer configuration because

- High mass flow rates of melt can be atomized.
- High heat transfer rates from the droplets can be realized in the spray.
- High momentum transfer rates are achieved to accelerate the droplets.
- Low oxidation rates of the material in the spray process are obtained.

The analysis of the atomization process requires primary knowledge of the gas flowfield of the atomizer gas in the nozzle vicinity. The primary gas flow emerging at low pressure close to the melt exit is responsible for guiding the melt flow into the atomization region below the atomizer, while a secondary gas flow field emerges from the lower gas ring and impinges on the central melt stream, well below the atomizer, and is applied for disintegration of the melt (Uhlenwinkel et al., 1990, Heck et al., 2000, Czisch and Fritsching, 2008).

In Figure 19.99, the results of a numerical simulation of the (subsonic) gas flow in the nozzle vicinity are shown as vector diagrams in comparison to pictures of the atomization of a model fluid (water) in a free-fall atomizer (Fritsching and Bauckhage, 1992). The atomization gas pressure in this case is p_2 = 1.89 bar abs; therefore, the gas exit condition is just critical with an exit velocity equal to the velocity of sound (M = 1). In the first (upper) example, no primary gas flow is applied (p_1 = 0). The secondary atomizer gas flow exits from the gas ring at an inclination angle of 10°, but contracts even more than this angle indicates, and hits the centerline of the atomizer well above the theoretical atomization point, which is the intersection point of the atomizer centerline with the gas jet exit line. By gas entrainment effects, ambient gas is accelerated into the inner flow field. This gas stream flows through the gap between the nozzle main body and the lower atomizer gas ring into the inner area of the flow field. In the middle of the inner area, a recirculating vortex

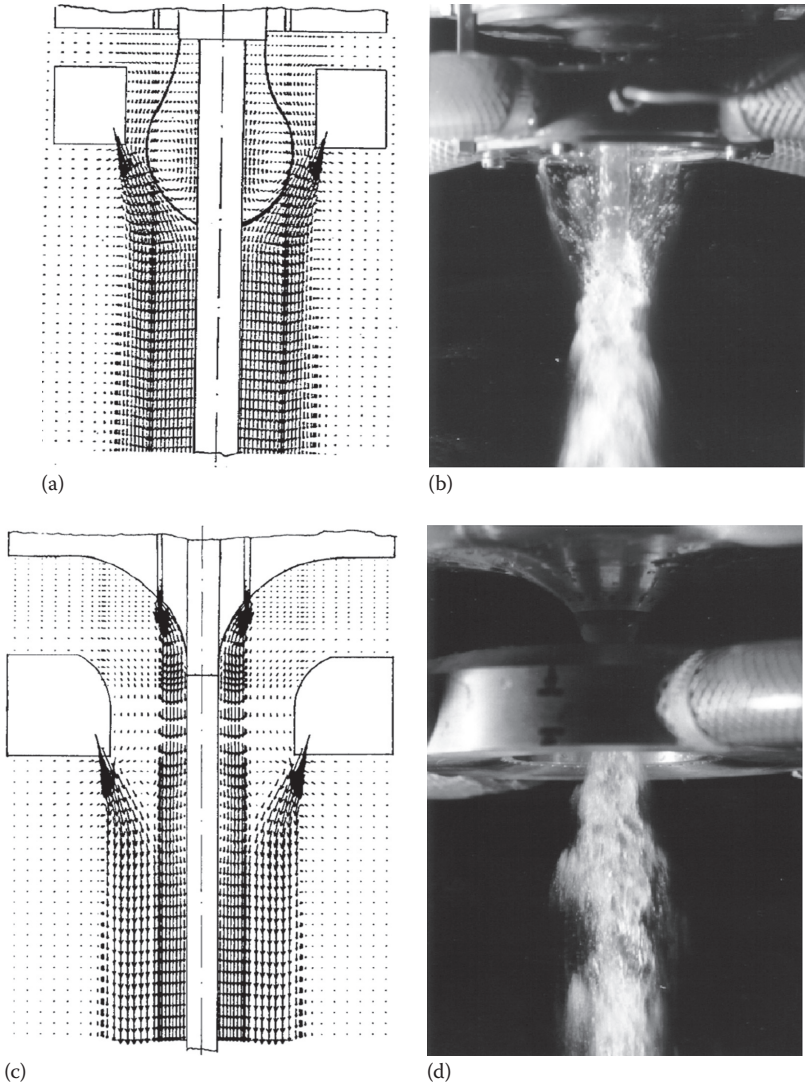

Figure 19.99

Fragmentation process in free-fall atomizer for spray forming application, comparison of gas flow simulation and water atomization; upper: droplet recirculation; p_2 = 0.189 MPa, p_1 = 0; lower: optimized process condition; p_2 = 0.189 MPa, p_1 = 0.14 MPa. (From Fritsching, U. and Bauckhage, K., *PHOENICS J. Comp. Fluid Dyn.*, 5(1), 81, 1992. With permission.)

flow can be seen (indicated by a solid line in the figure). Gas velocities of up to 50 m/s pointing vertically upward are achieved in this area. Individual particles entering this area of upward flowing gas are accelerated toward the nozzle main body and the melt exit. This result can also be observed in some experimental observations of the atomization process, where individual droplets can be seen above the atomization region, which are transported vertically upward. For melt droplets, this effect may cause sticking and even possible blocking of the nozzle. The calculated gas flow field in an optimized free-fall nozzle configuration is shown in the second (lower) example in Figure 19.99 for an atomization gas pressure of p_2 = 1.89 bar abs. and a primary gas pressure of p_1 = 1.4 bar abs (Fritsching and Bauckhage, 1992). Here, a gas flow field without recirculation is seen in the nozzle vicinity. The observation of the atomization model shows the successful prevention of droplet recirculations and illustrates the importance of the primary gas flow for this nozzle.

The interaction of the gas flow and the melt stream has been investigated by Antipas et al. (1993), Markus and Fritsching (2003b, 2006), Liu (1997, 2000a), and Achelis et al. (2010). Here, the primary jet fragmentation and the secondary droplet disintegration have been calculated in a direct way. The principal parameter describing the spray is the droplet size distribution, which in spray forming is typically based on the correlation by Lubanska (1970) (see Table 19.5). In this correlation, a specific liquid Weber number is used as follows:

$$\mathrm{We}_l = \frac{\rho_l u_{g,\max}^2 d_0}{\sigma} \tag{19.185}$$

This needs to be calculated by using the melt properties and the maximum gas velocity of the atomizer gas flow field. The maximum gas velocity in the atomization region has been calculated based on simulations (Fritsching and Bauckhage, 1992) and also measured and correlated for a typical free-fall arrangement (Heck, 1998) as:

$$u_{g,\max} = 645.25 \dot{m}_g^{0.585} \tag{19.186}$$

where the gas mass flowrate is correlated to the absolute atomization gas pressure in the choked flow regime (for nitrogen at pressures above 0.189 MPa) by

$$\dot{m}_g = 0.685 \mathrm{C_d} A_g \frac{p_0}{\sqrt{RT_0}} \tag{19.187}$$

The total gas exit area is A_0 and a typical value for the friction coefficient C_d is 0.84. The result of a sample calculation of the resulting mean droplet sizes for different atomized metals (i.e., aluminum, magnesium, iron, copper, and tin) has been shown in Figure 19.47. The main parameter describing the atomization efficiency (achieving smaller droplets) is the inverse product of dynamic viscosity and surface tension $(\mu\,\sigma)^{-1}$.

19.4.3.2.2 Particle Transport in the Spray In the spray, a complex two-phase flow situation involving gas and particles/droplets occurs. The high-speed gas loses its momentum by accelerating the droplets. Due to the heat transfer from the droplets, the gas undergoes intensive heating in the zone close to the atomizer. The droplets are accelerated and partly solidified during their flight. Modeling the complete dispersed two-phase flow situation including momentum and heat coupling is used to describe and analyze the spray behavior (Grant et al., 1993a,b, Fritsching, 1994c, Fritsching, 1995, Muoio et al., 1995, Bergmann, 2000, Pedersen, 2003, Markus and Fritsching, 2006, Gjesing et al., 2009, Li and Fritsching, 1994c, Fritsching, 2014a). As an example modeling, Figures 19.90 and 19.91 show the behavior of different droplet size classes on the centerline of a spray of molten steel, atomized with nitrogen (Bergmann et al., 1995). The boundary conditions include an atomizer pre-pressure of p_2 = 3 bar abs., a gas to metal flow rate (GMR) of 1.25, and a log-normal droplet size distribution with an MMD of 133 µm. The axial velocity distribution on the spray centerline of gas and particles with different diameters is illustrated in Figure 19.100. The gas velocity upstream of the atomization area is unaffected by the particles. Close to and in the atomization region, the gas velocity decreases due to the momentum transfer associated with acceleration of the droplets. Afterward, the gas velocity further increases because of the heating of the gas and thermal expansion and, also, due to the entrainment of momentum from the edge of the spray cone. The maximum gas velocity is reached at a nozzle distance of ~330 mm. Afterward, the gas velocity decreases due to the spreading of the spray cone. Particles are accelerated in the atomization region and further downstream. In the main region of the spray cone, particle velocities for the bigger particles remain approximately constant.

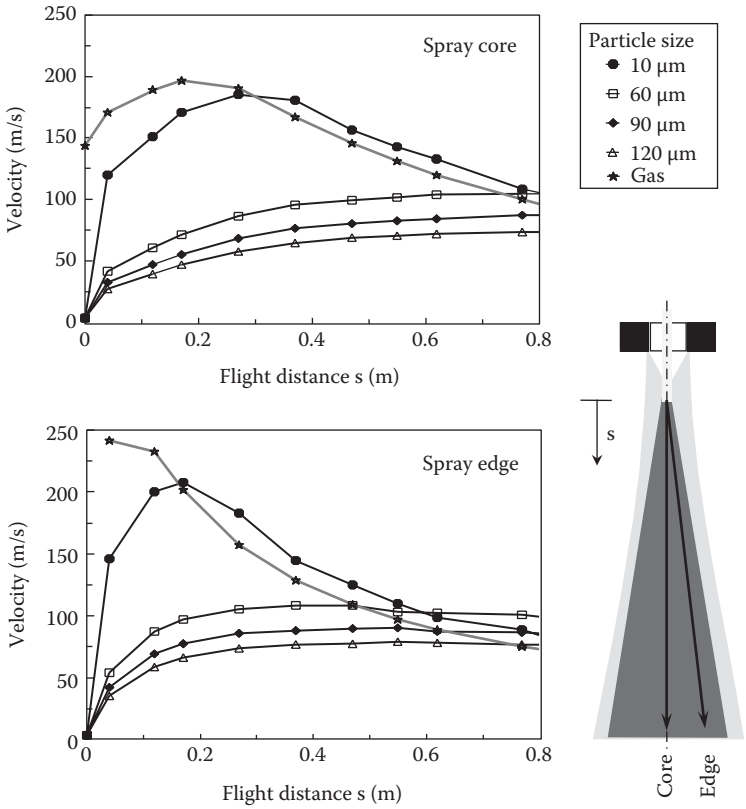

Figure 19.100

Modeling result for gas and particle velocity behavior on spray centerline and edge within spray forming of steel. (From From Bergmann, D. et al., Multiphase flows in the spray forming process, in *Proceedings of the Second International Conference on Multiphase Flow*, Kyoto, Japan, Vol. 1, April 3–7, 1995, pp. SP1–SP8. With permission.)

The gas reaches high temperatures in the atomization region up to 1200 K, as can be seen from Figure 19.101. Further downstream, the local gas temperature on the centerline decreases, but heat transfer from the particles continues, due to the spreading of the spray and mixing with the colder ambient gas. After cooling down to solidification temperature, the phase change occurs inside the particles and the latent heat of the particles is released, whereby the particle temperature remains constant. When the latent heat content of the droplets is removed, the particles further cool down. From these calculations, it can be seen that particles bigger than 210 µm are still in the state of phase change when impacting the substrate/deposit.

Experimental investigations have verified these simulation results. Online measurement techniques have been used to monitor the spray conditions in spray forming. With a modified phase Doppler anemometer (Ziesenis, 2003), local droplet sizes and velocities are measured and used for process control (Bauckhage, 1998). Measurements of individual droplet temperatures (plus droplet sizes and velocities) in metal sprays have been performed by means of a high-speed pyrometer instrument (Krauss et al., 2002, Delshad Khatibi et al., 2011, 2014).

To determine the overall heat and mass fluxes from the spray to the deposit, the droplet data have to be averaged in a suitable manner. Thermal averaging may be performed in two different ways, describing two extreme situations that occur in a molten metal spray (Bergmann et al., 1999). The first averaging method (*the enthalpy method*) describes the thermal status of the particle mass in thermal equilibrium. In this way, the thermal state of a certain particle mass is described after adiabatic equilibration. This means the particle mass has a specific enthalpy, which is directly related to its thermal state (temperature and solid fraction).

In an impinging molten metal spray for forming or coating processes, situations may arise where the particle mass should already be fully solidified depending on its average properties (when calculated by the enthalpy method), although it still contains some liquid. This may occur when the main spray consists of a large proportion of cold, solidified particles, and only a small number of large, fluid, and hot melted particles. These liquid droplets still deliver a certain amount of liquid melt to the mushy layer on the deposit surface, which is not accounted for by the enthalpy method. However, if a *separation averaging method* is used, this difficulty is avoided. Here, the amount of solidified mass or fluid melt mass remaining in the spray is calculated separately.

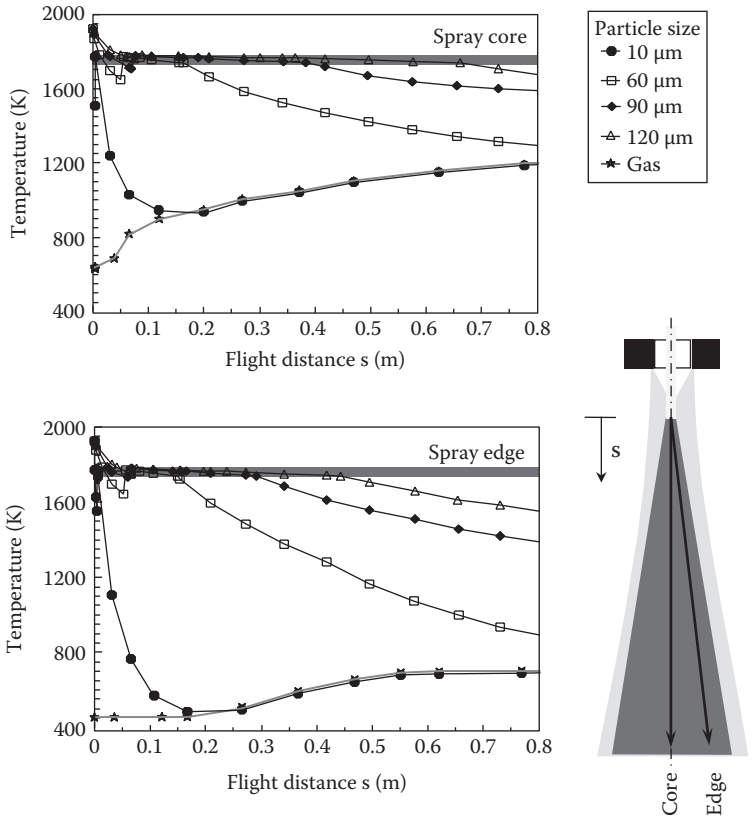

Figure 19.101

Modeling result for gas and particle temperature behavior on spray centerline and edge in spray forming of steel. (From Bergmann, D. et al., Multiphase flows in the spray forming process, in *Proceedings of the Second International Conference on Multiphase Flow*, Kyoto, Japan, Vol. 1, April 3–7, 1995, pp. SP1–SP8. With permission.)

The enthalpy averaging approach yields the thermal equilibrium condition of the total droplet mass (in terms of a discrete number of droplet size classes i):

$$\overline{h_p} = \frac{1}{\sum_i m_{p,i}} \sum_i \{m_{p,i}[(c_{pl}(T_{p,i} - T_s) + \Delta h_f)(1 - f_{s,i}) + c_{ps}((T_{p,i} - T_s)f_{s,i} + T_s)]\} \tag{19.188}$$

Based on the calculated average specific enthalpy $\overline{h_p}$, the mean spray solid fraction $f_{s,h}$ and the mean temperature T_h are calculated according to the solidification state of the droplet mass. In the separation averaging approach, the nonequilibrium situation in the spray process is recognized. The energy exchange within the total particle mass occurs only via the specific heat content and not via the remaining latent heat content of the particles:

$$f_{s,m} = \frac{1}{\sum_i m_{p,i}} \sum_i (m_{p,i} f_{s,i}), \tag{19.189}$$

$$T_m = \frac{1}{(c_{ps} f_{s,m} + c_{pl}(1 - f_{s,m}))\sum_i m_{p,i}} \sum_i (m_{p,i} T_{p,i}(c_{ps} f_{s,m} + c_{pl}(1 - f_{s,m}))). \tag{19.190}$$

Differences in the results obtained using the two averaging methods are shown in Figure 19.102 for the averaged temperatures and solid fractions of the spray along the centerline as a function of the particle flight distance. The results of the enthalpy method represent the thermal equilibrium with respect to the particle mass,

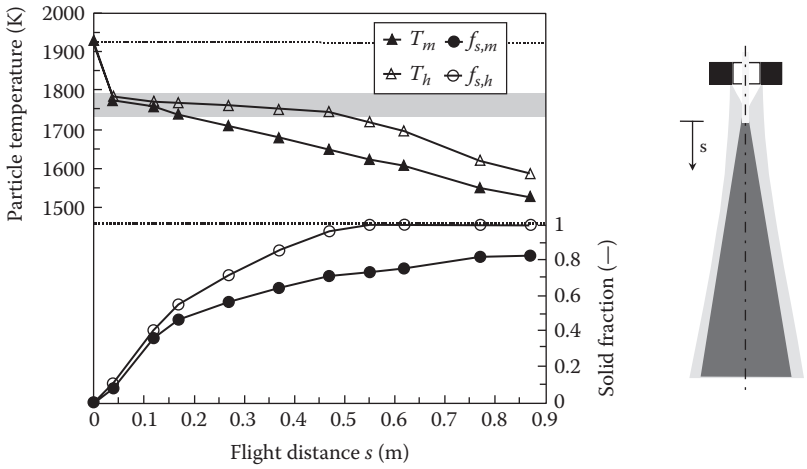

Figure 19.102

Integral temperature and remaining solid fraction in steel melt spray versus the spray distance, two different averaging methods. (From Bergmann, D., Modellierung des Sprühkompaktierprozesses für Kupfer-und Stahlwerkstoffe, Dissertation, Universität Bremen, Bremen, Germany, 2000. With permission.)

considering all particles from a specific location (point of impingement) together and leaving this mass under adiabatic conditions for an inner compensation process (heat conduction and solidification). This compensation process in spray forming immediately occurs when the sprayed particle mass impinges onto the deposit. In the semisolidified mixing layer on top of the deposit, an equilibration process will take place. Therefore, the enthalpy method properly describes the thermal state of the particle mass "in the top mushy layer" after deposition. In contrast, the separation method describes the instantaneous local thermal state (temperature and solid content) of the particle mass *in the spray*. As can be seen in Figure 19.102, the instantaneous mean particle temperatures and mean solidification fractions calculated for the whole particle flight distance by the separation model are lower than the values derived by the equilibrium state (enthalpy) method. With respect to the solidification process after the deposition, this difference means that the overall particle mass is "undercooled" and may be reheated after the deposition (in the mixing layer) by the latent heat released during solidification.

The mass flux distribution in the spray cone is directly connected to the resulting shape of the sprayed deposit. For varying deposit shapes, either the atomizer and/or the substrate can be moved. For a stationary atomizer, the radial profile of the mass flux distribution in the spray cone can be described as an exponential function by Equation 19.154. The maximum mass flux is always found on the spray cone centerline and $r_{0,5}$ is the half width of the mass flux profile (see Figure 19.83). The exponential factor has been correlated as $k_1 = 1.3$ (Uhlenwinkel, 1992) and $k_1 = 1.124$ (Kramer, 1997) for steel atomization. The half width of the mass flux profile is proportional to the maximum mass flux value as

$$\dot{m}(r) = \dot{m}_{\max} e^{(\ln(0.5)|r/r_{0.5}|^{k_2})} \tag{19.191}$$

For calculating the mass flux distribution at each position within the spray cone, a single calibrating measurement on the spray centerline in combination with the mass flux correlations is sufficient.

19.4.3.2.3 Deposition and Consolidation of Droplets The impinging droplets transport mass, momentum, and thermal energy into the top layer of the deposit (Kramer, 1997, Bauckhage et al., 1999, Djuric et al., 1999, Djuric and Grant 2001, Jordan 2003, Markus and Fritsching, 2003a). The compacted mass is not identical to the mass flux in the spray because

- Particles may have a spray trajectory that does not impinge onto the deposition surface.
- Smaller droplets of low inertia will follow the gas streamlines and will be deflected (aerodynamic overspray).
- Droplets may bounce-off or splash (Trapaga et al., 1992, Berg and Ulrich, 1997, Berg, 1999, Bussmann et al., 2000), and secondary droplets may not be incorporated in the deposit.
- Particles with high momentum may tear off parts of the already compacted (soft) mushy top layer.

This particle mass contributes to the overspray. The difference between the mass flux value in the spray cone and the compacted mass is described by the deposition efficiency:

$$k(\vec{x},t)=\frac{\dot{m}_{compac}(\vec{x},t)}{\dot{m}_{spray}(\vec{x})}\leq 1 \tag{19.192}$$

This depends on

- The thermal state of the impingement surface
- The momentum, temperature, and state of solidification of the impinging droplets

The deposition efficiency for spray forming of Gaussian shaped deposits (produced with a stationary atomizer, spraying on a stationary cylindrical substrate) from steel is correlated by (Kramer, 1997)

$$k(T_p,f_l,I_p)=C_4\left[C_1+C_2\left(\frac{T_p}{T_{surf}}\right)^{C_3}\right]f_l^{C_5}I_p^{C_6} \tag{19.193}$$

where the coefficients are: $C_1 = 0.422$; $C_2 = 0.80$; $C_3 = 30.48$; $C_4 = 0.489$; $C_5 = 0.249$ and $C_6 = -0.062$. The main parameter influencing the deposition efficiency is the temperature of the droplets on impact (here, normalized by the liquidus temperature).

During spraying time, the deposit grows continuously and releases its thermal energy by

- Conduction to the substrate
- Convection and radiation to the surrounding gas

To calculate the temperature distribution and history in the deposit and substrate, numerical methods and measurements have been used (Mathur et al., 1989a,b, Fritsching et al., 1993, 1994a,b, Gutierrez-Miravete et al., 1988, Buchholz et al., 2002). The result of a simulation for production of a copper billet is shown in Figure 19.103 (Meyer et al., 2003a,b).

By numerical modeling, a description of the complete material cooling process of metals in the different stages of spray forming, namely, during flight, deposition, and further cooling periods (which are of major importance for the understanding, control, and optimization of the process), can be obtained and analyzed. Integral models

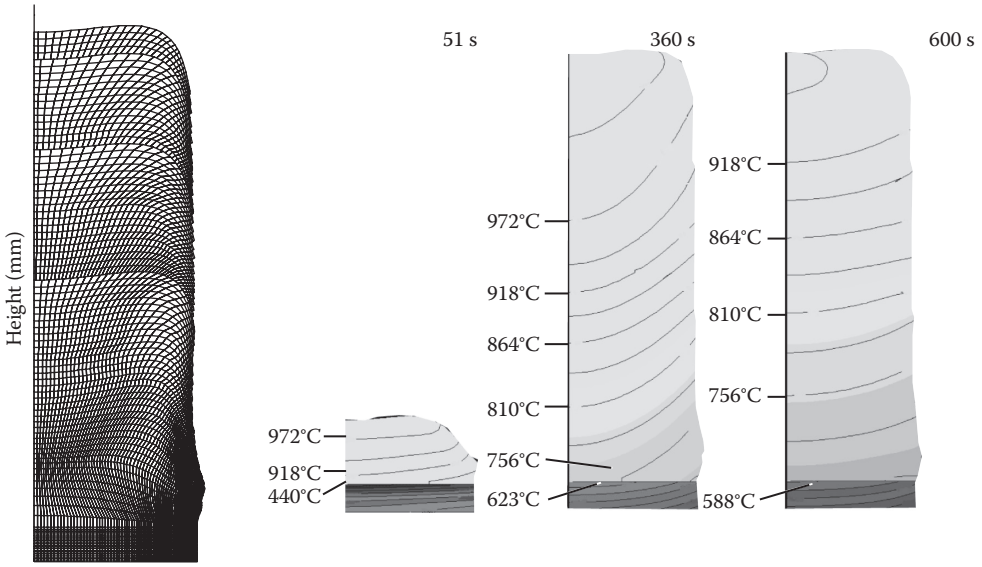

Figure 19.103

Temperature and solid content distribution during spray forming of a copper billet. (From Meyer et al., 2003. With permission.)

of the spray forming process have been dealt with by Lavernia et al. (1988), Mathur et al. (1991), Payne et al. (1993, 1996), Ottosen (1993), Tsao and Grant (1994), Hattel et al. (2000), Pedersen (2003), Pedersen et al. (2000), Bergmann (2000), Markus and Fritsching (2003a), Fritsching (2004), and Gjesing et al. (2009). The quality of spray-formed products in terms of homogeneity and improved material properties is directly controlled by the cooling rate of particles in the spray cone and the further cooling behavior of the resulting preform. The solidification and cooling behavior of the material directly depends on operational parameters. Such temperature simulations based on heat balance in the deposit and substrate show possibilities for thermal homogenization and avoidance of hot spots (Liu et al., 1994, Meyer et al., 2003a).

19.4.4 Spray Drying

In the spray-drying process, the liquid feed material (in form of solution, emulsion or slurry) is atomized into a hot air environment where the moisture is evaporated from the suspended droplets until the dried particles are obtained and collected as a final product. Typical examples are in spray drying of foodstuff (e.g., milk or coffee powders), or in chemical industry (e.g., detergents drying), or in formulation and encapsulation of pharmaceutics. This process is ideal for drying of heat-sensitive feed materials since the droplet–hot air contact time (residence time in the process) is reasonably short. Another advantage of spray drying is the ability to handle highly sticky or corrosive materials (Masters, 1991, 2002, Mujumdar, 2014).

The spray-drying process typically is subdivided into three steps (Crowe, 1980):

1. Atomization: Here, either a (1) rotary, (2) pressure swirl nozzle, or (3) twin-fluid nozzle is used to atomize the liquid and discharge into the spray chamber.
2. Droplets–air contact: the droplet spray is dried by the interaction with hot gases in the spray chamber. The spray-air flow pattern can be categorized into three types: cocurrent flow (Figure 19.104a and b) countercurrent flow (Figure 19.104c) and mixed cocounter current flow (Figure 19.104d). The spray chamber geometry depends on the atomizer used: if a rotary atomizer is used, a "wide-form" (Figure 19.104a) chamber is required. If a pressure nozzle or twin-fluid nozzle is used, "tall-form" dryer (Figure 19.104b through d) is required. The cocurrent flow arrangement is suitable for more heat-sensitive material,

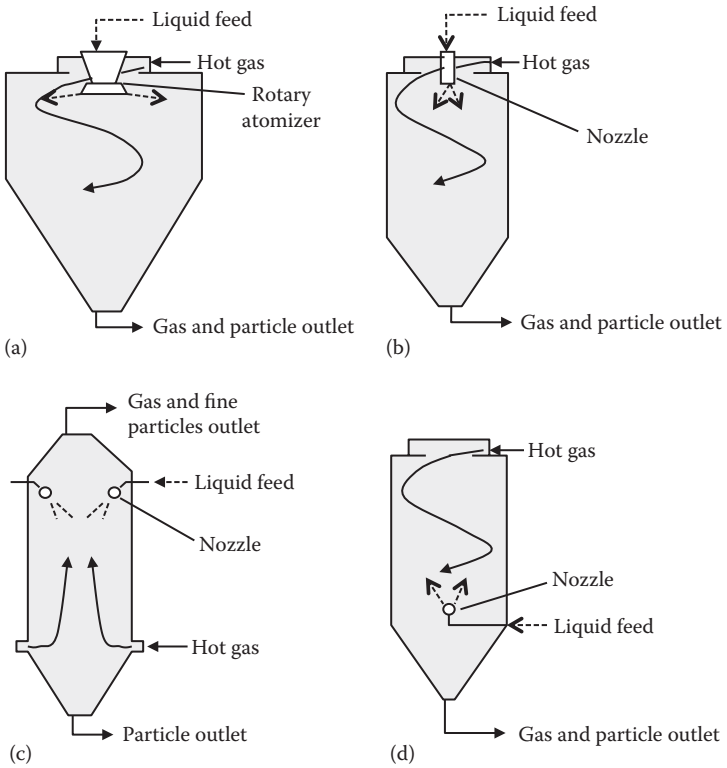

Figure 19.104

Spray dryer configurations: (a) cocurrent with rotary atomizer; (b) cocurrent with pressure nozzle; (c) countercurrent with pressure nozzle; (d) mixed flow with pressure nozzle.

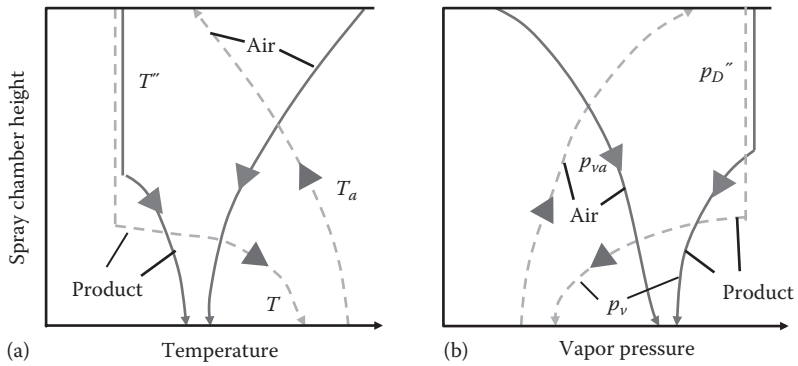

Figure 19.105

(a) Temperature and (b) vapor pressure distribution in cocurrent and countercurrent spray-drying process. (Adapted from Mujumdar, 1987.)

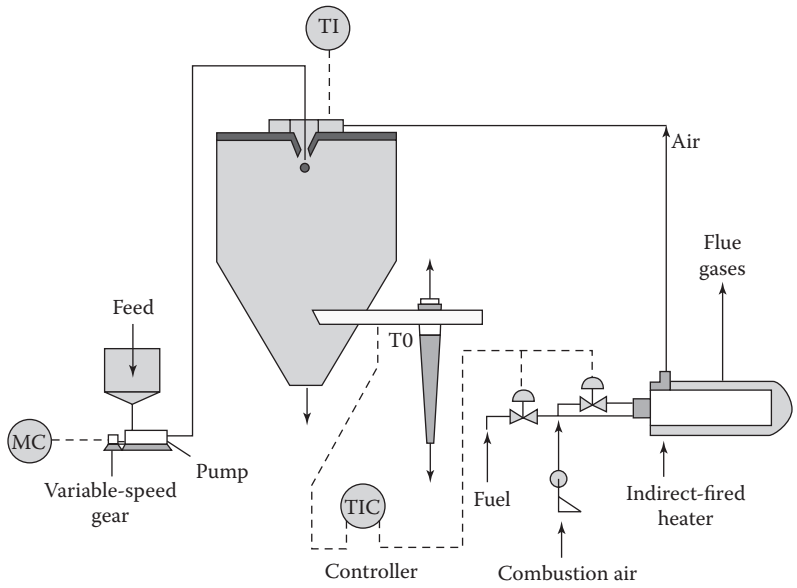

Figure 19.106

Configuration of a spray-drying plant. (Adapted from Oakley, D.E., *Chem. Eng. Progress*, 12, 48, 1997.)

since the air-spray contact time is shorter and the spray is protected from the high inlet air temperature due to evaporative cooling and the dried particles contact with cooler air at the lower section of dryer. Countercurrent flow arrangement is suitable for materials that are not heat sensitive since the dried particles contact with high inlet air temperatures. Although much less common than cocurrent arrangement, the countercurrent arrangement is suitable for some applications. For example, in spray drying of detergent powder, multiple pressure nozzles are used with countercurrent arrangement to attain high bulk density agglomerate form. Typical temperature and vapor pressure profiles (as indicator of moisture content) of cocurrent and countercurrent spray dryers are illustrated in Figure 19.105.

3. Removal of the powder from the drying medium by means of gravity settling and/or cyclone separation.

A typical spray-drying process configuration is illustrated in Figure 19.106.

19.4.4.1 Particle–Gas Interaction

In the droplet spray contact with the drying gas, all three interface transfer mechanisms (mass, momentum and energy) become operative. Crowe (1980) and Crowe et al. (1998) described these transfer mechanisms of spray drying. Momentum transfer consists mainly of the drag force and gravity force. Nikas et al. (2001)

reported the importance of buoyancy force acting on the particles according to their numerical simulation of flow in a spray dryer. At the droplet–hot air interface, heat is transferred into and moisture is removed from the droplet surface. According to the heat and mass transfer analogy, the external transfer of mass or heat is obtained from the transfer relation Equation 19.160 expressed in terms of the Nusselt number (Nu) for heat transfer and the Sherwood number (Sh) for mass transfer (see Chapter 1) together with a suitable droplet drying model (see Section 19.2.3).

19.4.4.2 Air-Spray Flow Pattern

The transient behavior and complex structure of the two-phase flow within a spray dryer has been investigated for many systems. If a swirl vane is mounted at the air inlet, the swirl vane angle affects the air-spray flow pattern, as reported by Oakley (1997), Oakley et al. (1988), Stafford et al. (1997), Kieviet and Kerchof (1995), and Southwell and Langrish (2000, 2001). The common pattern of air flows during spray operation with no swirl induced (or 0° swirl vane angle) exhibits fast flowing central core surrounded by a large recirculation zone (Kröger, 2001). As the inlet swirl increases, the large recirculation zone near the wall becomes less stable. From approximately 25° swirl vane angle and on, a precessing-vortex-core (PVC) begins to form in the core region and at swirl vane angle above 30°, the near-wall recirculation zone is less visible and finally disappears. At the higher swirl vane degree and with atomizer turned off, a central recirculation zone forms, but disappears when the atomizer is turned on. The central recirculation zone is undesirable as the dried particles are pushed back to heat-intensive regions, which may cause thermal degradation of products. Southwell and Langrish (2000, 2001) reported the formation of PVC, disappearance of near-wall large recirculation zone and the tendency that central recirculation might form at the axial distance further from the measurement point at 45° swirl vane angle. Figure 19.107 illustrates the effect on the airflow pattern of swirl by using vane-wheel atomizer.

Southwell and Langrish (2001) reported the spray patterns at various swirl vane angles. The spray cone region could be clearly identified and only small spray fluctuation could be observed at 0° swirl vane angle. As the swirl vane angle increased, the spray cone region was less visible and more transient. The width of the spray cone also increased when increasing the swirl vane angle. At 45°, the spray was torn apart and dispersed toward the wall within 0.2 m of the atomizer. The value of 25° has been found as the optimum swirl vane angle; good spray air mixing without excessive spreading of spray cloud and wall deposition is achieved. At this swirl angle, the spray cone did not spread as widely or interact with the inlet air as violently as at higher swirl vane angles, but adequate mixing was observed in the main body of dryer. Straatma et al. (1999) reported a computational fluid dynamics (CFD) study of two different cases. In the first case, simulation of an existing spray dryer with a rotary-wheel atomizer is performed. At the actual rotary speeds, reversal of the main airflow circulation occurred and a shortcut of hot air from inlet to outlet could be predicted from calculation (also observed in experiments). In the second case study, an industrial spray dryer equipped with one central and several noncentral air inlet channels with nozzle atomizers is simulated. The powder deposition in the conical section was serious, since the particle hit the cone when it was still wet and sticky. Larger, noncentral air inlets at a larger distance from the center solved this problem. This illustrates the importance of airflow pattern in a spray dryer on the drying process.

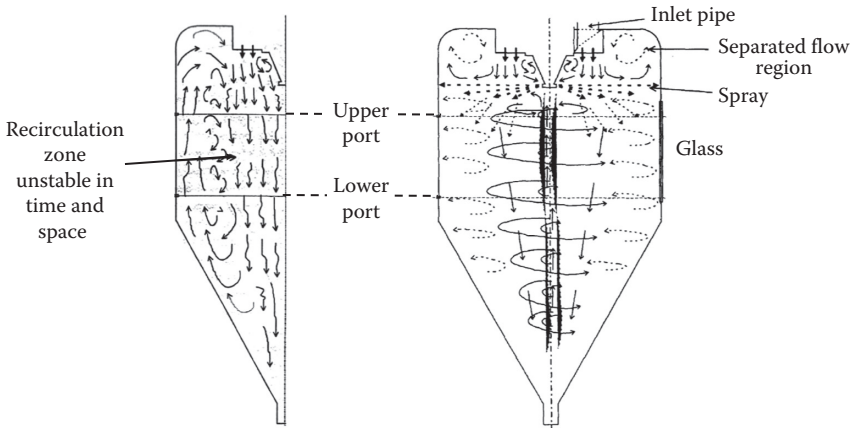

Figure 19.107

Spray dryer flow field. (Adapted from Southwell, D.B. and Langrish, T.A.G., *Dry. Technol.*, 18(3), 661, 2000.)

Mezhericher et al. (2012) argued that a proper formulation of the droplet drying kinetics and realistic 3D flow modeling are crucial for accurate numerical representation of the actual spray dryer performance. Therefore, in their study, a novel 3D CFD model of multiscale multiphase transport phenomena in a steady-state spray-drying process is proposed for predicting more realistic particles paths, residence times, temperatures, and moisture contents. A comprehensive formulation (or deterministic model) of two-stage droplet drying kinetics is employed to describe internal and external transport phenomena, as illustrated in Figure 19.108a. The continuous phase of drying air is treated by an Eulerian approach, and a standard k–ε turbulence model is applied. The trajectories of spray droplets/particles and their essential parameters are calculated using a discrete phase model (DPM) in a Lagrangian moving reference frame by taking into account the drag force, the added mass force, the pressure gradient force, and the gravitational force. The model has been validated on different levels, for example, of drying kinetics of single droplet/wet particle, airflow patterns, and 3D drying of wet particles in a spray dryer. Three-dimensional simulations of silica slurry drying have been carried out based on a cylinder-on-cone short form pilot-scale spray dryer with a cocurrent flow of drying air and spray droplets. The preheated air was supplied without swirling into the drying chamber through a central round inlet of the flat horizontal ceiling at an angle of 35° with respect to the vertical axis. The results of 3D steady-state predictions of particle trajectories colored by moisture contents, particle surface temperatures, and particle morphological states are shown in Figure 19.108b through d, respectively. The 3D calculations predict asymmetric particle flow in the spray chamber: a particle descending motion

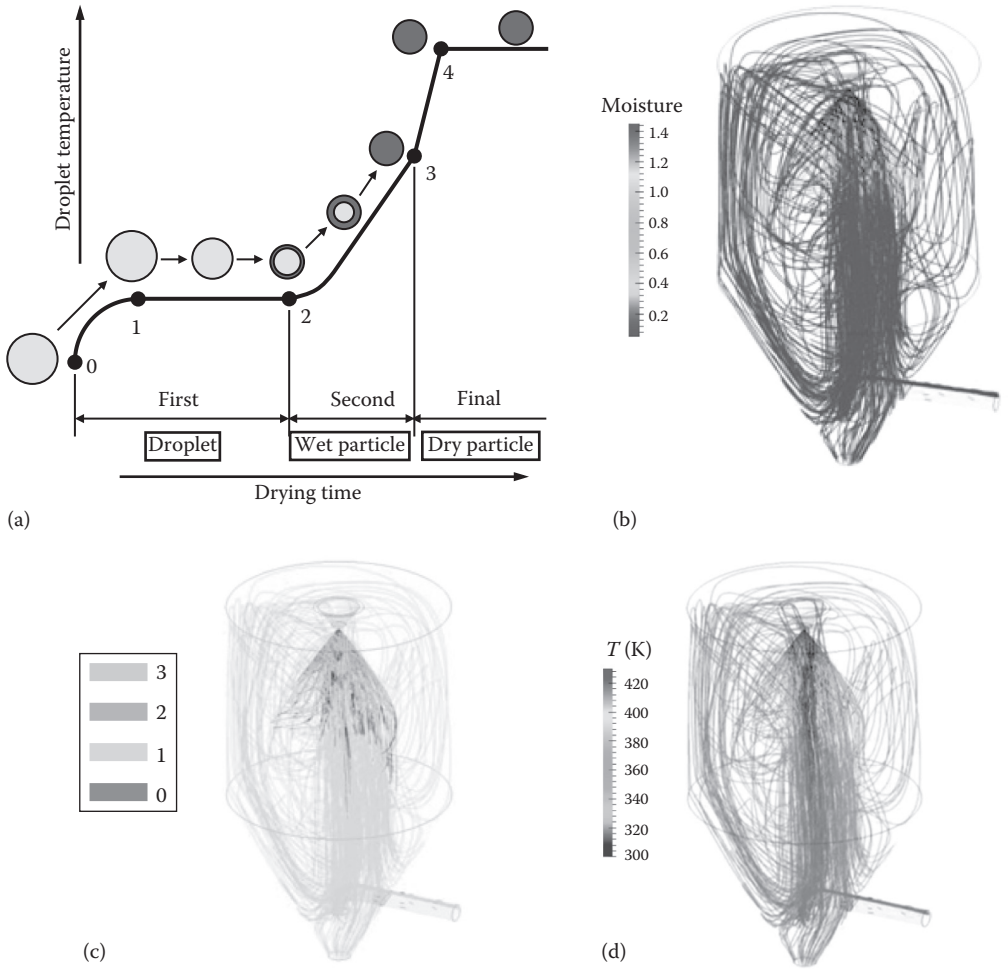

Figure 19.108

in the central core and subsequent upward particle transport with recirculation that occurs mainly in the chamber-half opposite the air outlet pipe, and that all particles that hit the chamber walls are completely dry. For the droplet drying kinetics, Figure 19.109 shows the calculated particle surface temperatures and average moisture contents evolving in time and in the chamber space, which indicates that larger droplets have longer PRTs and correspondingly longer first and second drying stages.

19.4.4.3 Effect of Turbulence Level at Air Inlet on Evaporation Rate

Zbicinski et al. (1996) investigated the effect of turbulence level on heat and mass transfer during atomization in an experimental air tunnel. Turbulence promoters increased turbulence level of the airflow in the tunnel to 17%. A comparative analysis of results obtained for heat and mass transfer for natural turbulence and for enhanced turbulence showed that increasing turbulence of a drying agent can cause 20%–25% increase of drying efficiency. Southwell et al. (1999) studied the experimental results of Zbicinski et al. (1996) using CFD. The simulations consistently predicted an increase in the amount of evaporation resulting from enhanced inlet turbulence. The simulation predicted improvements of 5%–11%, which were significantly less than the measured value. Enhancing inlet turbulence appeared to increase evaporation by improving both spray dispersion and the exchange of air between the spray envelope and the surrounding hot and relatively dry air.

19.4.4.4 Particle Residence Time Distribution

For some heat-sensitive materials, PRT distribution in a spray dryer is an important parameter. The effect of the airflow pattern (at different swirl vane angles) on PRT was discussed by Southwell and Langrish (2001). Kieviet and Kerchof (1995) measured PRT distributions by means of pulse tracer analysis. They showed that the distribution plot contains a very long tail. Wide ranges of residence time

have been reported and suggested that the PRT distribution did not depend on the time consumed as airborne particle but also depended largely on the time a particle may slide down the cylindrical and conical section of the dryer wall.

19.4.4.5 Particle Collision and Agglomeration

Particle–particle collision is a significant phenomenon in spray processes. In the spray-drying process, especially for hygroscopic materials, droplet collision and agglomeration is desirable (e.g., milk, coffee, and detergent) to attain attractive product features (e.g., reduction of fine particles). Droplets collision effects depend on the droplet surface condition, which, depending on the droplet drying stage in spray drying, is not always a homogeneous liquid surface as (1) surface tension dominated, *std* (liquid surface), (2) viscous dominated, *vd* (solid/liquid mixture surface), and (3) dry particle, d_p (solid surface).

19.4.4.6 Agglomeration Model

Details on droplet/droplet collision modeling have been given in Section 19.2.1. Within spray drying, Ho and Sommerfeld (2002) developed a stochastic Lagrangian agglomeration model for dry-dry (d_p) particles. The interparticle collision model of Sommerfeld (2001) has been used. In addition, the collision efficiency due to the geometrical size difference (i.e., small particle hit the larger collector particle), as a function of Stokes number and agglomeration efficiency of dry-dry particle determined by the sticking potential due to van der Waals force, is taken into account. A critical velocity u_{cr} is calculated from energy balance according to the method coined by Hiller (1981). The formation of agglomerate takes place when

$$u_{rel} \cdot \cos\psi \leq u_{cr} \tag{19.194}$$

In the case of solid/liquid dispersion, Blei and Sommerfeld (2003) introduced a stochastic Lagrangian agglomeration model for the spray-drying process. The simulation model developed by Sommerfeld (1995, 2001) is used. Collision of particles with different material properties such as moisture content, density, and surface property (*std*, *vd* or d_p) are taken into account. The mathematical analysis is based on the assumptions of a fully plastic collision, nondeforming spherical droplet during collision and Newtonian fluid. The derivation of the model allows a droplet of higher viscosity to penetrate into a droplet of lower viscosity. Criteria and postcollision properties of different modes of collision pair are derived.

19.4.4.7 Industrial Practice of Agglomeration Processes in Spray Dryer

The processes and unit operations for agglomeration in spray dryer have been described by Louey and Refstrup (2001). According to their classification, the collision-agglomeration process is a forced-primary agglomeration, which is currently operated by using multiple pressure nozzles and fine return particle atomizer (fine particle fractions after separation from the product are mixed into the atomization zone). The relationship between fine return-liquid collision distance from atomizer and agglomerate structure has been discussed. If the collision between fine-return particles and atomized liquid occurs close to the liquid atomizer, the fine-return particle may penetrate into the liquid droplet, producing an "onion" structure of agglomeration, which has high bulk density and low dispersibility. At an optimum distance of collision, the fine return sticks onto the liquid droplet, producing a "compact grape" structure with good dispersibility and sufficient mechanical strength.

A numerical simulation tool of spray dryer flow conditions and process design including agglomeration in industrial scale food spray dryer is being developed as described by Verdurmen et al. (2003, 2004). Here, a computer simulation–based design tool is built, using an Euler–Lagrange approach with appropriate elementary models for drying, collision, coalescence, and agglomeration of the dispersed phase, as outlined in Figure 19.110. This design tool establishes relations among the configuration of the drying installation (geometry, nozzle selection), process conditions, product composition, and final powder properties.

19.4.4.8 Particle-Wall Deposition

Particle-wall deposition can lead to downtime cleaning, spoiled product, and potential fire hazards. The rate of deposition on the wall is thus the interesting parameter. Chen et al. (1993) investigated particle-wall deposition in an industrial spray dryer. Although the effects of operating parameters on wall deposition were not report quantitatively, they suggested the modification of the near-wall airflow and inlet air-temperature distribution could reduce wall deposition significantly. They also suggested that wall insulation could reduce wall deposition. It has been concluded that the effect of insulation was

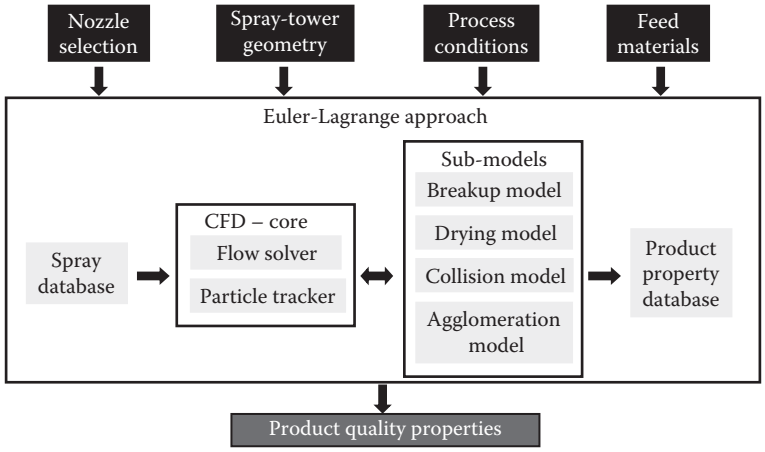

Figure 19.110

General structure of the CFD model for spray-drying process.

to increase the temperature close to the wall, thus preventing both vapor condensation and particles becoming too moist. On the other hand, Brennen et al. (1971) found that when the wall was too hot, more deposition was observed. So, low inlet air temperatures (<180°C) have been used for spray drying of sticky materials to keep the wall cool (Bhandari et al., 1992, 1993).

Ozmen and Langrish (2002) investigated the wall deposition of milk powder in a spray dryer. They measured the wall deposition in terms of wall deposition flux. The effect of inlet air swirl angle, air and chamber temperature and particle moisture content, wall material, and spray duration time on wall deposition flux was investigated. Increasing the angle of swirl from 0° to 30° increased the wall deposition flux by 30% although this increases air-spray mixing and evaporation rate. For temperature effects, if the temperature and moisture plot of a particle is above the sticky-point curve in a sticky point diagram (Hennigs et al., 2001), the wall deposition flux significantly increased (Figure 19.111). They concluded that the sticky point curve appeared to be the better indicator of the tendency for wall deposition flux. With respect to wall insulation, they reported significantly higher deposition flux with insulation compared to noninsulation. The investigation of the adhesion-cohesion process on the measuring plates showed that particle–particle cohesion (which led to agglomerate form) was the controlling process of wall deposition, so the near-wall particle dispersion is important. In this work, particle-wall adhesion had negligible effects on the wall deposition. The measuring surfaces were either nonstick food-grade material, adhesive tape, or stainless steel.

Operating condition and corresponding wall deposition fluxes on the sticky-point diagram for skim milk powder. (Adapted from Ozman et al., 2002.)

19.4.5 Spray Painting and Coating

Application of paints by spray processes provides protection and/or decoration of surfaces. Also, controlling of surface properties like roughness, friction control, fire protection, biological barriers, isolation, and so on are typically achieved by (spray) coating applications. Achieving specific surface quality and process yield (minimization of overspray) are the main aims of spray painting and coating processes. Typical yield of industrial spray painting processes sometimes is only about 70%.

In spray painting and coating applications, either pressure atomizers (here often called airless atomizer), twin-fluid atomizers (pneumatic atomizer), or rotary atomizers are used. Because of flexibility and easy application, pneumatic atomizers are most common in spray painting applications. Their disadvantage is the high overspray loss. Airless atomization is typically operated at 100–200 bar pressure and is used when higher throughput is to be achieved. Typical coating qualities are lower than those of pneumatic atomizers. For painting of large surface areas in combination with high-quality demand on optical coating properties (e.g., in automotive industry), so-called high-rotation atomizers (HR) are used. For increasing yield in paint applications, electrocharging of the droplets is used to decrease the overspray. Electrostatic fields in spray painting are also used to assist coating of back and hidden sides of substrates (Svejda, 2003). The different atomization principles result in different spray characteristics. Drop sizes and drop size/velocity correlations vary. Differences between overspray characteristics of a pneumatic atomizer and an HR atomizer are illustrated in Figure 19.112 (Goldschmidt and Streitberger, 2002). The drop size spectrum in pneumatic atomization typically is broader than in rotary atomization, because in pneumatic atomizer (at high gas velocities) the smaller particles are especially deflected by aerodynamic effects around the specimen to be coated. Here, in the spectrum of deposited particles, the smaller drop size fractions are missing (Figure 19.112a). By application of electrostatic forces, the overspray amount is reduced and the yield is increased. In rotary atomization, the larger particles preferably will not be deposited on the surface (even when assisted by an additional airflow). Therefore, in this case, the deposited drop size spectrum shows some missing larger droplets. When the charge of the particles is increased (higher voltage), the overspray amount is decreased (Figure 19.112b).

19.4.5.1 High-Rotation Atomization

For rotary atomization of paints, either disk- or cone-shaped atomizer-geometries are used. Typically, the disintegration mode of rotary atomization for paint applications is the lamella-mode (Goldschmidt and Streitberger, 2002). For increase of yield, in HR atomization, additional gas flow (called steering air flow) and/or electrostatic charging of the droplets are used (ESTA-HR: electrostatic-assisted high-rotation atomization). An HR atomizer consists of a bell and a drive (air drive). Depending on paint material and mass flow rate, HR atomizers are operated at 15,000–60,000 rpm. The bell diameter is typically about 50 mm with variations in geometry and bell edge surfaces. Charging of the paint material is achieved either by contact charging where the atomizer bell is connected to high voltage (typically 50–120 kV) or by ionization charging, where air ions are deposited on the droplet surface that result from outer free electrodes (see Figure 19.113). Contact charging is used for electrically nonconduction paints (e.g., paints based on organic solvents), while ionization charging is used for electrically conducting materials (e.g., in powder paint applications). The overall yields of ESTA-HR processes are in the order of 85%–90% (Svejda, 2003).

Droplet trajectories in ESTA-HR spray painting process. (From Scholz, T., Experimentelle Untersuchungen zur Mehrphasenströmung im Sprühkegel eines elktrostatisch unterstützten Hochrotationszerstäubers, Dissertation, Universität Bremen, VDI-Verlag, Düsseldorf, Germany, 1998. With permission.)

The spray geometry during ESTA-HR process is characterized by the interaction of aerodynamic, inertia, and electrostatic forces onto the droplets (Böttner et al., 1998, Böttner, 2002), resulting in deflection of the droplets toward the substrate in combination with the fragmentation process of the atomizer. Here, after fragmentation, the droplets are first centrifuged radially outward from the rotary atomizer. Steering air in the direction perpendicular to the substrate plus electrostatic forces onto the droplet deflect the droplets in the direction toward the surface. A model of the resulting droplet trajectories and airflow pattern is shown in Figure 19.114 (Scholz, 1998). A hollow cone spray geometry results, leading to a paint deposition characteristic that has a local minimum in the spray center and an off-center maximum (Svejda, 2003). The complex flow structure in the spray has been investigated experimentally (Scholz, 1998) and by numerical simulation (Domnick et al., 1997, 2003, 2005, 2006, 2009, Olivas and Marty, 2002). The gas flow field as a vector plot of the steering airflow of a rotating bell (45,000 rpm) obtained by simulation (Domnick et al., 2006) is illustrated in Figure 19.115. The velocity close to the bell edge is about 30 m/s. A large vortex can be seen located approximately three bell diameters downstream of the bell edge. In the center of this vortex, a recirculation region can be observed, transporting small paint droplets back to the bell.

In Domnick et al. (2009), the dynamic meshing approach has been chosen to calculate the unsteady grid between moving atomizer and fixed target. The calculation domain has basically been divided into a static zone (fixed target), a moving zone (moving atomizer), and a dynamic zone outside the major spray cone. Regarding the main purpose of these calculations, that is, the local thickness of the paint film on the target, the dynamic calculations are in agreement with experimental results. Local differences even on complex targets are typically less than 2 µm. The resulting dynamic deposition film thickness on a stationary flat target in this painting process is shown in Figure 19.116a comparing simulation and experiment. The hollow cone structure of the spray is reflected in the compaction pattern as a maximum in the radial distribution. The resulting dynamic deposition film thickness on a blended plate in this painting process is shown in Figure 19.116b, comparing simulation and experiment.

Aerosols

Yannis Drossinos and Christos Housiadas

20.1 Introduction
20.2 General Dynamic Equation
20.3 Particle Collision Processes
20.4 Gas-to-Particle Conversion
20.5 Single Particle Motion: Deposition Mechanisms
20.6 Convective Transport and Deposition

20.1 Introduction

An aerosol is a dispersion of small solid or liquid particles suspended in a gas, usually air. The term aerosol refers to both the particles and the suspending gas. Aerosol particle sizes range from 0.001 μm (0.001 μm = 10^{-9} m = 1 nm = 10 Å) to 100 μm (10^{-4} m); hence, the particle sizes of interest span several orders of magnitude, ranging from almost macroscopic dimensions down to near-molecular sizes. An aerosol is a two-phase system with a gas phase and a dispersed phase, called particulate phase, which may be solid or liquid. In aerosols, the particulate phase is very dilute. Particles represent a very small fraction, less than 0.0001%, of the total aerosol mass or volume. The two phases are one-way coupled: the hydrodynamics of the gas phase influences the behavior of the particulate phase, while the particulate phase exerts negligible influence on the hydrodynamics of the gas phase.

The technical term aerosol has a much broader meaning than the popular term aerosol, which refers to the spray of droplets released from a spray can. The technical term applies to a large variety of systems, such as clouds, dust, fog, fume, haze, smog, smoke, and sprays, and it may even include airborne biological material like viruses, pollen, bacteria, fungi, etc. Particle size is the most important parameter characterizing an aerosol. In modern aerosol literature, particle size is specified by the particle diameter, d_p, most commonly expressed in micrometers and occasionally in nanometers. Based on their size, aerosol particles can be classified into a number of categories that, however, are not rigorously defined and are usually application specific. If the aerosol particles are not spherical, a characteristic size may be identified as described in Section 20.3 or Chapter 1. In ambient aerosols, for instance, the classification of Whitby (1978) is often used: particles are divided into two main fractions: the *coarse* fraction ($d_p > 2\,\mu m$) and the *fine* fraction ($d_p < 2\,\mu m$). The fine fraction is further subdivided into the *nucleation* mode ($d_p < 0.1\,\mu m$) and the *accumulation* mode ($0.1 < d_p < 2\,\mu m$). Yet, this classification is not standard. Several aerosol scientists consider the diameter of 1 μm as the division line between coarse and fine fractions. To characterize a generic aerosol particle with $d_p < 0.1\,\mu m$, the term *ultrafine particle* is frequently employed. In the atmospheric aerosol literature, the nucleation mode is restricted to particles of sizes $d_p < 0.01\,\mu m$, whereas particles in the size range $0.01 < d_p < 0.1\,\mu m$ are considered to be in the *Aitken mode*. Nowadays, there is an increasing interest in *nanoparticle* applications. Pui and Chen (1997) recommended the convention $d_p < 50\,nm$ to define "nanometer particles," but occasionally, particles smaller than 100 nm (0.1 μm) are also considered nanoparticles.

The recent interest in studies of aerosols stems from the realization that they can be "desirable" or "undesirable." Undesirable aerosol particles are those that induce adverse effects on human health and contribute to air pollution, whereas desirable aerosols are those used in industrial production of high-technology materials like novel functional nanomaterials, ceramic powders, superconducting materials, and optical fibers. Aerosols, also, influence the earth's climate via their effect on the global energy balance. The aerosol direct effect refers to the scattering of solar radiation back into space by some aerosols and to the absorption of solar radiation by other aerosol types. The first indirect effect, also called cloud albedo effect, refers to the interference of atmospheric aerosols in warm, ice and mixed-phase cloud formation processes by increasing droplet and ice particle concentrations: such processes modify the cloud albedo and thereby radiation reflection and cloud lifetimes.

In this chapter, elements of aerosol dynamics and physics will be summarized and critically reviewed. Space limitations do not allow us to cover a number of important topics in aerosol physics, including experimental techniques, aerosol optical properties, nanoparticle formation, and synthesis (for a review, see, e.g., Kruis et al., 1998); particle resuspension and bouncing (for reviews, see, e.g., Ziskind et al., 1995, Henry and Minier, 2014); and respiratory deposition and modeling of inhalation dosimetry (for a brief summary, see, e.g., Housiadas and Lazaridis, 2010).

20.2 General Dynamic Equation

The primary quantity of interest in aerosol flows is the particle size distribution and its variation in space and time. The size distribution is in general a multivariate distribution function that depends on position $\mathbf{r}$, time t, and on variables that describe the particle morphology and chemical composition. If the particle morphology is neglected and particles are assumed to be spherical, a single-species particle is solely specified by its volume $v = \pi d_p^3/6$. Here, the choice of particle volume as an independent variable is preferred to particle diameter (radius), because particle volume is conserved during coagulation. The single-component, continuous particle size distribution for spherical particles is denoted by $n(v; \mathbf{r}, t)$, where $n(v; \mathbf{r}, t)dv$ is the number of particles per unit volume (number density) for particles with volumes within the range v and $v + dv$ located within a fluid volume centered at $\mathbf{r}$ (between $\mathbf{r}$ and $\mathbf{r} + \delta\mathbf{r}$) and time t. Its discrete version $n_k(\mathbf{r}, t)$ gives the number of particles per unit volume for particles with k-subunits (sometimes referred to as k-molecules or k-mers) at time t and location $\mathbf{r}$. It should be noted that with these definitions the continuous size distribution has dimensions of number of particles per volume squared, whereas the discrete size distribution has dimensions of number of particles per volume.

Particle morphology, and in general the description of nonspherical particles, requires the introduction of additional variables (shape descriptors) to account for particle shape. For example, Koh and Friedlander (1990) introduced surface area as a second independent variable to account for aggregate sintering, whereas Kostoglou and Konstandopoulos (2001) used the fractal dimension of colliding particles as additional variables in their analysis of agglomerate structure and coagulation. If the chemical composition of the aerosol particles is important, then an extended multispecies (multicomponent) size distribution function is required. In this chapter, we will concentrate on aerosol flows of spherical, single-species particles, although we discuss extensively power-law agglomerates in Section 20.3.2: further remarks on particle shape, chemical composition, and agglomerate structure will be made in the appropriate sections. The generalized l-species distribution function is discussed in, for example, Williams and Loyalka (1991).

The size distribution of an aerosol within a volume element may change due to processes that occur within it, processes referred to as *internal* processes, and due to processes that transport particles across the volume boundaries, the *external* processes. Figure 20.1 depicts a schematic diagram of aerosol processes that occur within an elemental volume. Internal processes include coagulation, agglomeration, fragmentation, and gas-to-particle conversion, a term that refers collectively to particle condensation or evaporation and nucleation, homogeneous or heterogeneous. Coagulation and agglomeration modify the size distribution without changing the mass concentration, whereas gas-to-particle conversion modifies the aerosol mass concentration. External processes include transport across the boundaries due to gas flow, diffusion, particle motion induced by temperature, concentration, or other gradients in the gas, gravitational and other external forces. All the processes that modify the size distribution are described by a population balance equation that is known as the *general dynamic equation* (GDE), which will be presented in detail in the following sections. The solution of this nonlinear, integro-differential equation for different initial and boundary conditions provides a complete description of the size distribution for arbitrary geometries and gas flows.

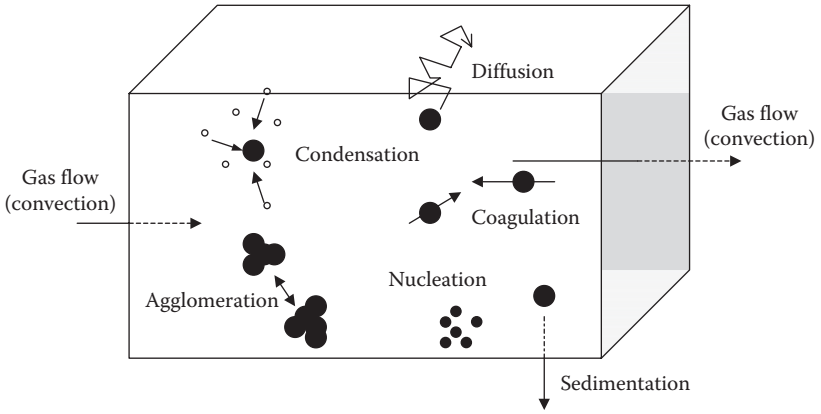

Figure 20.1

Schematic representation of aerosol processes (internal and external) within an elemental volume.

20.2.1 Internal Processes

Smoluchowski (1916) presented the first treatment of the effect of particle coagulation on the discrete particle size distribution. Although his derivation referred to hydrosols (a liquid colloidal suspension), the derivation and the final equation are equally applicable to aerosols. He considered a physical situation without spatial dependencies and without particle gains or losses, where particle coagulation occurred due to Brownian motion and motion induced by a laminar shear. Under the assumption that all particles are spherical, he showed that the dynamic equation for the discrete size spectrum $n_k(t)$ is

$$\frac{dn_k}{dt} = \frac{1}{2}\sum_{i+j=k} K(v_i, v_j) n_i n_j - n_k \sum_{i=1}^{\infty} K(v_i, v_k) n_i \tag{20.1}$$

where $K(v_i,v_j)$, expressed in dimensions of volume per unit time, is the collision frequency function between particles of volume v_i (i-mers) and v_j (j-mers). The first term on the right-hand side (RHS) of Equation 20.1 is the rate (per unit volume) at which k-mers are formed from the collision of i-mers with (k−i)-mers; the factor 1/2 avoids overcounting. The second term is the rate at which k-mers are removed by collisions with other particles that convert them to different size particles. If the collision frequency function is independent of particle size and equal to K, and the aerosol is initially monodisperse with a initial particle volume v_0, the equation for the discrete-size distribution may be solved analytically to give

$$n_k(t) = \frac{N_\infty(0)}{(1+(t/\tau))^{k+1}}\left(\frac{t}{\tau}\right)^{k-1} \tag{20.2}$$

where $N_\infty(0)$ is the total number of particles per unit volume at $t = 0$ and the characteristic time scale is $\tau = 2/[KN_\infty(0)]$. The total number concentration, $N_\infty = \sum_{i=1}^{\infty} n_i$, and the monomer concentration n_1 are found to decrease monotonically in time, whereas the average volume $v_{ave} = N_\infty(0)v_0/N_\infty(t)$ increases linearly with time.

The inclusion of the other internal process, gas-to-particle conversion, by the addition of evaporative fluxes generalizes the Smoluchowski equation. Accordingly, the time-dependent equation for the discrete size distribution within an elemental volume fixed in space and in the absence of sources or sinks becomes (Seinfeld and Pandis, 1998, Friedlander, 2000)

$$\frac{dn_k}{dt} = \frac{1}{2}\sum_{i+j=k} K(v_i, v_j) n_i n_j - n_k \sum_{i=1}^{\infty} K(v_i, v_k) n_i + \alpha_{k+1} s_{k+1} n_{k+1} - \alpha_k s_k n_k \tag{20.3}$$

As before, the first two terms on the RHS are coagulation terms. The last two are the evaporative rates (per unit volume) under the assumption that evaporation occurs via single-molecule events. The evaporative flux from a k-mer is α_k, and the effective area for evaporation is the k-mer surface area s_k. Equation 20.3 includes

condensation and evaporation terms that appear in a kinetic treatment of homogeneous nucleation. This is seen by rewriting the coagulation terms as a group of terms that describe collisions between larger particles ($i, j \neq 1$) and terms that describe single-molecule collision with other particles, for example, terms like $K(v_1,v_{k-1})n_1n_{k-1}$. These single-molecule collision terms added to the evaporative fluxes give the particle current associated to homogeneous nucleation, see Equation 20.84.

For particle volumes much larger than the molecular volume, it is convenient to replace the discrete distribution $n_k(t)$ by the continuous distribution $n(v;t)$. Then, the population balance equation expressed in a compact form becomes

$$\frac{\partial n(v;t)}{\partial t} = \left.\frac{\partial n}{\partial t}\right|_{\text{g-p}} + \left.\frac{\partial n}{\partial t}\right|_{\text{coag}} \tag{20.4}$$

The gas-to-particle conversion term, denoted as the g-p term, is occasionally rewritten in terms of the gradient of a particle current in a form suggestive of motion in particle-volume space. This formulation, according to which the current consists of two terms, renders the incorporation of condensation or evaporation and nucleation in the GDE easier (Friedlander, 2000). One term is proportional to a concentration gradient, and thus, it is interpreted as cluster diffusion with a spatially dependent diffusion coefficient. This diffusion term, which is proportional to $\partial n/\partial v$, and leads to a spread in particle space of an initially monodisperse distribution, is important for homogeneous nucleation. The other term represents cluster transport, or migration, under the influence of an external force. For the growth of large particles, the diffusion term is not significant since the concentration gradient is small, and the migration dominates. Thus, it is customary to model the gas-to-particle conversion term as follows (Seinfeld and Pandis, 1998):

$$\left.\frac{\partial n}{\partial t}\right|_{\text{g-p}} = J_{\text{nuc}}\delta(v - v^\star) - \frac{\partial}{\partial v}\left(n\frac{dv}{dt}\right) \tag{20.5}$$

where the first term J_{nuc} is the particle current due to homogeneously nucleated particles of critical size $v^\star$ (J_{nuc} is the nucleation rate per unit volume, see, e.g., Equation 20.95) and the second term $n\,dv/dt$ is the condensation current with the growth law dv/dt (see, e.g., Equation 20.135). The delta function is the Dirac delta function.

The second term on the RHS of Equation 20.4 is the coagulation term, here written for a continuous size distribution:

$$\left.\frac{\partial n}{\partial t}\right|_{\text{coag}} = \frac{1}{2}\int_0^v d\tilde{v}K(\tilde{v},v-\tilde{v})n(\tilde{v})n(v-\tilde{v}) - n(v)\int_0^\infty d\tilde{v}K(v,\tilde{v})n(\tilde{v}) \tag{20.6}$$

As before, the first term in the RHS of Equation 20.6 denotes the formation of particles of size v from the collision of particles $v-\tilde{v}$ and $\tilde{v}$, and the second the loss of particles of size v through collisions with other particles. Note that the lower limit in the coagulation integrals has been set to 0 instead of the size of the smallest stable (critical) cluster $v^\star$. This approximation renders the evaluation of the integrals easier. It does not cause significant problems, since the initial distribution may be taken to be zero up to the critical size and particles smaller than the critical size are not generated in time. Equation 20.6 is reminiscent of the gain–loss master equation of stochastic theory since $n(v;\mathbf{r},t)$ is a probability distribution function. However, its nonlinearity, which arises from particle collisions, gives it remarkable properties, which do not apply to the linear master equation. In fact, the nonlinearity and gain–loss nature of GDE render it similar to the molecular Boltzmann equation.

20.2.2 External Processes

In the presence of a gas flow, the GDE for a continuous size distribution becomes (Friedlander, 2000)

$$\frac{\partial n}{\partial t} + \nabla\cdot(n\mathbf{v}_p) = \left.\frac{\partial n}{\partial t}\right|_{\text{g-p}} + \left.\frac{\partial n}{\partial t}\right|_{\text{coag}} \tag{20.7}$$

where $\mathbf{v}_p$ is the average particle velocity and $n(v;\mathbf{r},t)dv$ the number density of particles with particle volume in the range v to $v + dv$. The particle flux density $\mathbf{J}_p = n\mathbf{v}_p$ depends on the gas flow velocity and external body forces. The LHS of Equation 20.7 describes changes in the particle size distribution due to external processes, and the RHS changes due to internal processes.

In the aerosol physics literature, it is frequently assumed that transport mechanisms act independently of each other, an assumption that usually leads to fairly good results. The average particle velocity, as obtained from the sum of the various fluxes, becomes

$$\mathbf{v}_p = \mathbf{u} - \mathfrak{D}\nabla \ln n + \mathbf{v}^{\text{ext}} \tag{20.8}$$

where

$\mathbf{u}$ is the carrier gas velocity

$\mathfrak{D}$ is the Brownian diffusion coefficient (see Equation 20.165)

$\mathbf{v}^{\text{ext}}$ is the sum of all other transport velocities, for example, thermophoretic, diffusiophoretic, photophoretic, or other velocities induced by external forces (gravitational, electrostatic)

Each of these terms will be discussed in the appropriate section. The relation of $\mathbf{v}^{\text{ext}}$ to the associated external force is given by Equation 20.167. The GDE, then, takes the form

$$\frac{\partial n(v;\mathbf{r},t)}{\partial t} + \nabla\cdot(n\mathbf{u}) = \nabla\cdot\mathfrak{D}\nabla n + \left.\frac{\partial n}{\partial t}\right|_{\text{g-p}} + \left.\frac{\partial n}{\partial t}\right|_{\text{coag}} - \nabla\cdot(n\mathbf{v}^{\text{ext}}) \tag{20.9}$$

If the coagulation and gas-to-particle conversion terms are neglected, and in the absence of external forces, Equation 20.9 becomes the usual convective diffusion equation

$$\frac{\partial n}{\partial t} + \nabla\cdot(n\mathbf{u}) = \nabla\cdot\mathfrak{D}\nabla n \tag{20.10}$$

whose solutions for different geometries in laminar flow are discussed in Section 20.6.1. Inspection of Equation 20.8 shows that the effect of particle inertia has been neglected. Thus, an assumption inherent in the usual convective diffusion equation is the neglect of inertial particle transport (and, of course, of all internal processes) and the absence of external forces. The effect of particle inertia, and its incorporation in the convective diffusion equation, is described in the following paragraphs, whereas the effect of external forces in Sections 20.5 and 20.6.

Inertial transport is best described in terms of a Lagrangian description, where the particle equations of motions are solved, and not in terms of the Eulerian description implicit in the usual formulation of the population balance equation, Equation 20.7, where processes in a fixed elemental volume are analyzed. However, the determination of important quantities, for example, the local particle concentration field (Slater and Young, 2001) or the mean interphase momentum transfer (Garg et al., 2009), is particularly difficult to obtain. A large number of particle trajectories have to be calculated to minimize statistical error, this renders the Lagrangian approach computationally inefficient. The control of the numerical error associated with Lagrangian simulations becomes more important for highly nonuniform spatial distributions of particles since the number of simulated particles in a grid cell decreases. Accordingly, the statistical error, which is inversely proportional to the square root of the number of particles per cell, increases. Recent advances in numerical implementations of the Lagrangian method have addressed this issue by introducing improved error estimators to obtain numerically convergent simulations (Garg et al., 2009). In addition, if Brownian particle diffusion is of importance, the number of simulated particle trajectories further increases to minimize the noise that arises from the stochastic particle motion. The proper incorporation of inertial transport in the Eulerian description of Equation 20.7 requires an approach similar to that presented in the two-fluid modeling sections of this handbook that are presented in Chapter 2, and the solution of the coupled two-fluid equations for mass, momentum, and energy conservation (Reeks, 1991). The simultaneous description of inertial and diffusional transport is an active area of current research; only a brief summary will be presented herein. In particular, developments to decouple the mass conservation equation from the momentum equation by performing a low Stokes number (the ratio of a particle time scale to a fluid time scale, Equation 20.169) expansion of the (average) particle velocity will be summarized.

In a two-fluid approach to aerosol transport, the average particle velocity $\mathbf{v}_p$ is obtained from the average particle momentum equation, as is common in multifluid modeling approaches to multiphase flows and described elsewhere in this book. If the aerosol particles are considered as a dispersed continuum within another continuous phase, the average momentum equation for the particulate phase may be formally written as (Fernández de la Mora and Rosner, 1982, Konstandopoulos, 1990)

$$\frac{\partial \mathbf{v}_p}{\partial t} + (\mathbf{v}_p \cdot \nabla)\mathbf{v}_p = \beta_V(\mathbf{u} - \mathbf{v}_p) + \frac{1}{mn}\nabla \cdot \ddot{\Pi}_p + \beta_V \sum_i \mathbf{v}_i^{\text{ext}} \tag{20.11}$$

where the Stokes drag has been used, $\ddot{\Pi}_p$ is the particle stress tensor, m is the particle mass within an elemental volume (mn is the local particle concentration), and the external forces per unit particle mass have been expressed in terms of β_V, the inverse particle relaxation time, $\beta_V = 1/\tau_V$ where τ_V is the particle relaxation time, see Equation 20.166 and the discussion following Equation 20.20. In the limit of small particle relaxation times ($\beta_V \to \infty$), a diffusive description of the particle flux becomes appropriate (as discussed in other chapters in this book). Different choices for the particle stress tensor lead to different forms of the GDE and the corresponding convective diffusion equations.

Ramshaw (1979) proposed a phenomenological theory of the motion of Brownian particles in a flowing, nonisothermal, incompressible fluid that leads to a modification of the particle velocity given in Equation 20.8. The derivation clarifies the assumptions and approximations inherent in the usual convective diffusion equation, or, equivalently those related to the linear addition of the various particle currents, as in Equation 20.8. The theory relies on neglecting the particle viscous stresses and assuming that the dispersed (particulate) phase behaves as an ideal gas. The approximation is summarized by $\ddot{\Pi}_p = -\ddot{\mathbf{I}}p_p$, where $\ddot{\mathbf{I}}$ is the identity tensor and p_p is the particle partial pressure (this approximation was examined in Ramshaw (1981)). The approximate expression for the particle stress tensor coupled to the assumption that the particle phase behaves as an ideal gas

$$p_p(\mathbf{r},t) = k_B n(\mathbf{r},t)T(\mathbf{r},t) \tag{20.12}$$

with k_B the Boltzmann constant leads to the following expression for the particle flux:

$$\mathrm{J}_p = n\mathbf{u} - \mathfrak{D}\nabla n - \mathfrak{D}_{\text{th}}\nabla \ln T \tag{20.13}$$

The corresponding transport coefficients are the Brownian diffusion coefficient $\mathfrak{D}$ (see Equation 20.165) and the thermal diffusion coefficient $\mathfrak{D}_{\text{th}}$, which expressed in terms of the Schmidt number Sc_p (see Equation 20.164) and the thermophoretic coefficient K_{th} (see Equations 20.173 and 20.176) becomes

$$\mathfrak{D}_{\text{th}} = n\mathfrak{D}(1 + K_{\text{th}}Sc_p) \tag{20.14}$$

As discussed in Section 20.5.2, and shown in Table 20.1, the particle Schmidt number is much greater than unity. Therefore, for typical aerosol particles (limit of large Sc_p), the thermophoretic term dominates the expression for the thermal diffusion coefficient. Hence, in the limit of large particle Schmidt numbers, the last term of Equation 20.13 becomes $-nK_{\text{th}}\nu_g\nabla \ln T$, and represents the particle mass flux associated with thermophoresis.

Forced diffusion and pressure diffusion are absent in Equation 20.13 because external forces (e.g., gravitational or electromagnetic) and imposed pressure gradients (e.g., centrifugation) were neglected. Their contribution to the total mass flux is discussed in Ramshaw (1979). If these contributions are neglected, the total flux relative to the carrier fluid becomes the sum of concentration and thermal diffusion.

A comparison of Equation 20.13, which was derived in the small particle limit, with Equation 20.11 shows that the inertial acceleration term (LHS of Equation 20.11) has been neglected in the small-particle limit. Fernández de la Mora and Rosner (1982) considered explicitly the effect of inertia on Brownian diffusional transport in isothermal aerosol flows under steady-state conditions. Following arguments similar to those summarized earlier (Ramshaw, 1979), in particular the approximate expression for the particle

Table 20.1 Aerosol Particle Parameters: Spherical Particles of Standard Density (1000 kg/m^3) in Air at 101 kPa (1 atm) and 293 K (20°C)

Particle Diameter d_p (μm)	Slip Correction C_c	Settling Velocity V_s (m/s)	Diffusion Coefficient $\mathfrak{D}$ (m^2/s)	Schmidt Number Sc_p	Relaxation Time τ_V (s)

stress tensor, they obtained a first-order correction to the particle velocity field due to particle inertia. They performed a low Stokes number expansion, Equation 20.169, (a low τ_V expansion) of the average momentum equation to obtain

$$\mathbf{v}_p = \mathbf{u} - \mathfrak{D}\nabla \ln n - \tau_V(\mathbf{u}\cdot\nabla)\mathbf{u} + O(\tau_V^2) \tag{20.15}$$

This relation shows that the particle velocity field of inertial particles is compressible even for an incompressible carrier gas flow and in the absence of diffusion. Equation 20.15 leads to the generalized form of Equation 20.9 (in the absence of external forces)

$$\frac{\partial n}{\partial t} + \nabla\cdot(n\mathbf{u}) - \tau_V\nabla\cdot[n(\mathbf{u}\cdot\nabla)\mathbf{u}] = \nabla\mathfrak{D}\nabla n + \left.\frac{\partial n}{\partial t}\right|_{\text{g-p}} + \left.\frac{\partial n}{\partial t}\right|_{\text{coag}} \tag{20.16}$$

that incorporates effects due to particle inertia to first-order in the particle relaxation time in an Eulerian description. The coupled calculation of diffusion and inertia in an Eulerian description is important, because these two mechanisms act in unison in many aerosol processes, for example, filtration and sampling. This Eulerian approach offers significant advantages over two-fluid models that do not decouple the mass and momentum conservation equations of the dispersed phase. Since the particle momentum equation is solved perturbatively, the particle velocity is expressed solely in terms of the fluid velocity and its spatial derivatives (in steady state, to leading order). It can be used for small particle diameters where the particle equations of motion in a Lagrangian approach become numerically stiff. Finally, it is more accurate than passive tracer models, since it takes into account simultaneously diffusive and inertial particle transport. A detailed examination of the boundary conditions associated with a similar Eulerian description, referred to as the drift flux approach, may be found in Longest and Oldham (2008).

The validity of the particle velocity approximation of Equation 20.15 for various particle relaxation times was tested by Pilou et al. (2011). They examined inertial deposition of aerosol particles in a 90° laminar bend of circular cross section in the absence of internal aerosol processes. Comparison of predictions of the Eulerian model with available experimental data was very good for both low and high Dean-number flows (De = 38 and 419) where the flow Dean number is $De = Re(R_t/R_b)^{1/2}$ where Re is the fluid Reynolds number, R_t is the tube radius, and R_b is the bend radius. Predicted deposition sites, namely, spatial deposition profiles, were also in good agreement with experimental observations. These comparisons suggest that the approximation used for the inertial term, though based on a low-particle relaxation time expansion, provides a reasonable approximation to the particle velocity even at larger τ_V.

The GDE in turbulent flow has not received the attention it deserves although in many cases encountered in practice, for example, in atmospheric dispersion, the underlying flow is turbulent. This case will not be discussed here, but the interested reader is referred to Friedlander (2000), where the full GDE for turbulent flow is presented. It suffices to mention that the starting point of the derivation is the Reynolds assumption. Specifically, if nucleation is neglected, the fluid velocity, the size distribution, and the growth law are each written as the sum of a mean plus a fluctuating component. As a result of time averaging, several new terms appear in the GDE, including a fluctuating growth term and contributions to coagulation from the fluctuating concentrations.

20.2.3 Moment Equations

The GDE may be appropriately integrated to obtain differential equations for moments of the particle size distribution. The moments of the size distribution are defined as

$$M_j(\mathbf{r},t)=\int_0^\infty dv v^j n(v;\mathbf{r},t) \tag{20.17}$$

where we have extended the lower limit to zero, an approximation valid for very small molecular or detection volumes. The zeroth moment of the distribution is of particular interest since it gives the total number concentration $N(\mathbf{r}, t)$,

$$N(\mathbf{r},t)=\int_0^\infty dv n(v;\mathbf{r},t) \tag{20.18}$$

Moment equations may be obtained by performing moment averages of the GDE, for example, of Equation 20.7 or 20.9. For spherical particles, the moments may also be defined in terms of particle diameters

$$M_j(\mathbf{r},t)=\int_0^\infty d(d_p) d_p^j n(d_p;\mathbf{r},t) \tag{20.19}$$

The most important moments are the total number concentration, $N(\mathbf{r}, t) = M_0$, the average particle diameter, $\overline{d}_p = M_1(\mathbf{r}, t)/M_0(\mathbf{r}, t)$, the average surface area per particle, $\overline{S} = \pi M_2(\mathbf{r}, t)/M_0(\mathbf{r}, t)$, and the average volume per particle, $\overline{V} = \pi M_3(\mathbf{r}, t)/[6M_0(\mathbf{r}, t)]$. If the particle density is independent of size, the third moment is proportional to the mass concentration of the particulate phase.

20.2.4 Numerical Methods

Most numerical techniques developed to solve the GDE neglect spatial inhomogeneities by assuming that the aerosol is spatially well mixed. Hence, the numerical methods concentrate on the numerical solution of Equation 20.3 or, more often, its continuous version, Equation 20.4 coupled with Equations 20.5 and 20.6. The numerical solution of the GDE is usually implemented in multidimensional aerosol flow simulations, often in combination with CFD calculations, for a range of applications, for example, in nuclear safety or nanoparticle synthesis applications. Since the evaluation of the particle size distribution is at the core of aerosol-physics calculations, the numerical methods are usually categorized in terms of the functional representation of the size distribution. They may be divided into discrete methods, methods of moments, and sectional (group) methods (Seigneur et al., 1986). These methods may be combined: for example, sectional methods have been combined with discrete methods to optimize the description of the distribution at small particle sizes (Wu and Flagan, 1988).

An early family of the methods of moments are the so-called modal methods (Whitby and McMurry, 1997). The modal methods lead to the numerical solution of moment equations; they are appropriate when the characteristic shape of the size distribution remains unaltered during the simulation period. The GDE is appropriately integrated to obtain integro-differential equations for the moments of the particle size distribution. These coupled, due to the coagulation kernel and the growth law, equations are usually decoupled by postulating a functional form for the unknown distribution function. The usual choices for the distribution

function are lognormal (see, e.g., Pratsinis, 1998), gamma, or multimodal lognormal (see, e.g., Wilck and Stratmann, 1997 and Chapter 1 of this Handbook). In the case of the lognormal distribution, the independent variables reduce to the total particle number, the geometric standard deviation, and the geometric mean. Thus, in modal methods, the solution of the GDE is converted to the numerical solution of a small number of differential equations for these moments, keeping the computational cost at acceptable levels, even for spatially multidimensional problems. Due to their low computational cost, modal methods have been incorporated within CFD calculations for multidimensional aerosol-dynamics simulations (Wilck and Stratmann 1997, Schwade and Roth, 2003, Brown et al., 2006). A significant drawback of modal methods, inherent in the *a priori* assumption for the size distribution shape, is that they do not allow an accurate simulation of the evolution of arbitrary particle size distributions.

The fundamental problem with moment methods is the closure of the evolution-of-moments equations. An important development that avoids the assumption of a distribution function is the quadrature method of moments (QMOM) proposed by McGraw and coworkers (McGraw, 1997, McGraw and Wright, 2003). McGraw (1997) addressed the closure problem by introducing a quadrature-based closure technique, a technique that is applicable to arbitrary growth laws and coagulation kernels. In essence, this method replaces the exact closure by an approximate, but less restrictive, closure. The QMOM method has also been combined and used successfully with CFD calculations (Rosner and Pyykönen, 2002, Marchisio et al., 2003).

In the sectional method (Sugutin and Fuchs, 1970, Gelbard et al., 1980, Raes and Janssens, 1986, Jokiniemi et al., 1994, Hounslow et al., 1988, Park and Rogak, 2004), the particle size spectrum is discretized into a number of size sections (particle-size bins or classes). The GDE is then solved for each section. This method does not require *a priori* assumptions of the functional form of the size distribution: thus, no limitations on the shape of the aerosol size distribution are posed. When a fixed particle-size grid is used, the simulation of nucleation and coagulation is straightforward; however, handling of particle condensational growth is rather troublesome due to numerical diffusion (Zhang et al., 1999). A large number of size sections are needed to cope with condensational growth, which, especially in multidimensional problems, may increase computational costs, rendering the solution impractical (Pyykönen and Jokiniemi, 2000). Alternatively, in the moving grid method (Gelbard, 1990), the bins are allowed to move along the particle-size axis to allow for condensation, thus eliminating numerical diffusion. In the moving grid method, however, the implementation of nucleation and coagulation is not as straightforward as in the fixed grid method because situations may occur where there are no sections at the particle-size of interest, for example, at the size of nucleating particles. The use of a moving particle-size grid raises serious difficulties when simulating particle transport in a multidimensional Eulerian transport framework. To conjoin the advantages of fixed particle-size grid in simulating nucleation, coagulation, and transport with the advantages of a moving grid in solving condensation, methods based on a hybrid (fixed and moving) grid have been developed. In these methods, condensation is accurately solved by allowing particles to grow to their actual size, which is calculated by numerical integration of the growth law. In the moving center method (Jacobson, 1997), particles are then transferred between adjacent sections of the fixed grid, according to their actual size. A new characteristic size is calculated for each section of the fixed grid from the conservation of new and existing particle number and volume. In other hybrid grid methods, the size distribution itself is calculated on the moving grid and then remapped on the fixed grid using high-order polynomial interpolation techniques (e.g., cubic spline) to reduce numerical diffusion (Lurmann et al., 1997, Mitsakou et al., 2005). The latter method was further improved by Mitrakos et al. (2007), who used the cumulative size distribution to ensure conservation of the number of particle during condensation (Yamamoto, 2004). The method was incorporated into a multidimensional transport model through an operator splitting technique. It has been used to simulate aerosol flows involving nucleation, condensation, and coagulation laminar flows (Mitrakos et al., 2008, Kissane et al., 2009).

The Monte Carlo (MC) method, a powerful numerical technique for the evaluation of multidimensional integrals, has been used to solve population balance equations: for example, Kostoglou and Konstandopoulos (2001) used it to study the evolution of fractal aggregates. Coagulation of nonspherical particles has also been studied with a sectional method (Jeong and Choi, 2001).

20.3 Particle Collision Processes

Aerosol particles suspended in a fluid collide with each other due to the following causes: (1) their relative motion, including the motion induced by Brownian diffusion; (2) fluid inhomogeneities (as those generated by turbulence or shear); and (3) motion caused external forces (gravitational, electrostatic, etc.). Concentration

or temperature gradients in the gas phase also induce relative motion, but these effects are considered secondary. Recently, however, thermophoretically dominated coagulation of particles of large thermal conductivity has been shown to modify significantly their size distribution for large local temperature gradients (Rosner and Arias-Zugasti, 2011). When the particles collide, they may agglomerate, namely the colliding primary particles retain their identity and shape, or coagulate, that is, the colliding particles fuse together and lose their identity.

We describe only the most commonly used coagulation kernels, neglecting those less frequently used, for example, the acoustic (or ultrasonic) coagulation kernel. Furthermore, we will not discuss agglomerate fragmentation, a process of significant theoretical and industrial interest; see, for example, Sonntag and Russel (1987), Eggersdorfer et al. (2010), and Vanni and Gastaldi (2010).

The behavior of a moving particle in a gas depends on exchange processes that occur on its surface: particle-to-particle mass-transfer determines their collision behavior, whereas momentum exchange between a particle and the gas determines its friction coefficient. The rates of momentum transfer between gas molecules and a particle are specified by the relative magnitude of the carrier-gas mean free path λ_g to a characteristic particle length scale L. Their ratio, referred to as the gas Knudsen number, $Kn_g = \lambda_g/L$, is the natural parameter to characterize the relative degree of rarefaction of a gas. For spherical particles, the characteristic length scale is the particle radius ($L = a_p$).

In the very small Knudsen number limit, $Kn_g < 0.001$, the fluid behaves as a continuum, characterized by the absence of fluid velocity slip on the particle surface. The drag force may be calculated from (numerical or analytical) solutions of the Navier–Stokes equations with the no-slip velocity boundary condition on the particle surface. In the slip-flow regime, $0.001 < Kn_g < 0.25$, a flow, distinct from the bulk flow, develops around the particle, leading to a velocity slip between the fluid velocity at the surface of the particle and the fluid velocity on the side of the fluid closest to the surface. The flow-velocity field may be calculated from the Navier–Stokes equations with appropriate boundary conditions to simulate the velocity slip. The fluid flow is considered to be transitional when the characteristic particle size is comparable to the gas mean free path, $0.25 < Kn_g < 10$. In the free molecular limit $Kn_g > 10$, gas molecules do not interact with each other close to the particle surface, their velocity distribution being unaffected by the presence of the particle. Exchange processes between gas molecules and the particle may be calculated from kinetic theory. Momentum-transfer processes for colloidal particles dispersed in a liquid are in the continuum regime, $L > \lambda_g$, while for spherical aerosol particles, they may lie in any momentum-transfer regime as the air mean free path is $\lambda_{\text{air}} \sim 66\,\text{nm}$ (under usual atmospheric conditions) and the particle radius may vary from a few nanometers to microns.

The dimensionless number appropriate to describe the relative motion of two colliding particles due to thermal fluctuations (in the absence of an external flow or body forces) may be identified by considering the diffusive motion of a spherical particles colliding with another stationary particle. The Langevin equation that describes the Brownian motion of a spherical particle of radius a_p in the continuum regime is

$$m_p \frac{d\boldsymbol{v}}{dt} = -f\boldsymbol{v} + \boldsymbol{W}(t); \quad \langle \boldsymbol{W}(t) \rangle = 0; \quad \langle \boldsymbol{W}(t)\boldsymbol{W}(t') \rangle = 6fk_BT\delta(t-t'), \tag{20.20}$$

where

$\boldsymbol{W}(t)$ is a noise term that models the effect of collisions between the particle and molecules of the surrounding quiescent gas

$f = \beta_v m_p$ is the friction coefficient with β_v the friction coefficient per unit mass

The random force is assumed to be Gaussian, of zero mean, and white (delta correlated in time). The angular brackets denote an ensemble average over realizations of the random force. Two characteristic time scales may be identified: the inertial particle relaxation time $\tau_V = 1/\beta_v = m_p/(6\pi\mu_g a_p) = 2\rho_p a_p^2/(9\mu_g)$, see, also, Equation 20.166, and the diffusive time scale $\tau_D = a_p^2/\mathfrak{D} = 6\pi\mu_g a_p^3/(k_BT)$, see also Equation 20.165 (Subramanian and Brady, 2004, Lukassen and Oberlack, 2014). By appropriately scaling Equation 20.20, a number of dimensionless numbers may be identified. One is the ratio of the two characteristic time scales. Another is the ratio of the particle velocity mean persistence length, the particle mean free path $\lambda_p = v_{\text{th}}\tau_v = (k_BT/m_p)^{1/2}\tau_V$ herein defined in terms of v_{th} the one-dimensional root mean square particle speed, to the particle radius. Finally, a characteristic temperature may also be defined $T^\star = m_p a_p^2/(k_B\tau_v^2)$ that divided by the system

temperature provides another dimensionless number (Isella and Drossinos, 2010). It is easy to show that these three dimensionless numbers are related. The following particular combination is referred to as the diffusive Knudsen number (Loyalka, 1976, Dahneke, 1983, Rogak and Flagan, 1992, Gopalakrishnan and Hogan, 2011, Thajudeen et al., 2012)

$$Kn_D = \frac{\lambda_p}{a_p} = \left(\frac{\tau_V}{\tau_D}\right)^{1/2} = \left(\frac{T^\star}{T}\right)^{1/2} = \frac{(k_B T m_p)^{1/2}}{6\pi\mu_g a_p^2}. \tag{20.21}$$

The diffusive Knudsen number, which is the ratio of the particle velocity mean persistence length to the particle collision length scale, is the appropriate dimensionless number to describe mass-transfer processes. Therefore, the analysis of collision processes is characterized by the two dimensionless numbers, Kn_g (momentum transfer) and Kn_D (particle–particle mass transfer), each one defining different regimes (continuum, transition, free molecular) for mass or momentum transfer.

For structures more complex than spheres, the identification of the characteristic length scale to be used in the two Knudsen numbers, Kn_g (mobility length) and Kn_D (collision length), is not straightforward. In Section 20.3.1, we consider spherical particles, for which the characteristic scale L is the particle radius and the appropriate momentum-transfer Knudsen number $Kn_g = \lambda_g/a_p$. The increase of L as coagulation progresses with time will not be addressed. In Section 20.3.2, we consider irregularly shaped particles and the associated characteristic length scales. For concreteness, we shall analyze power-law aggregates composed of touching (one-point contact), nonoverlapping (no necking), identical, spherical particles (monomers) that satisfy a scaling law. We shall retain the word coagulation for collision processes that lead to coagulation of colliding spheres, whereas the word agglomeration shall refer to noncoalescing collision processes.

20.3.1 Coagulation: Spherical Particles

For a discrete particle spectrum, the collision frequency function, or collision kernel, $K(i, j)$ which has dimensions of volume per unit time, is defined as follows:

$$N_{ij} = K(i,j) n_i n_j, \tag{20.22}$$

where N_{ij} is the number of particle collision occurring per unit time per unit volume between particles of volumes v_i and v_j, (denoted by the indices i and j) and concentrations n_i, n_j. The collision kernel depends on particle and fluid properties, the mechanisms that force the particles to collide, and the regime of mass/momentum transfer. The particle concentrations in Equation 20.22 are local, instantaneous values: in the aerosol literature, these local values are frequently approximated by average values (well-mixed aerosol assumption), thereby introducing an error that is difficult to quantify. The effect of spatial inhomogeneities on Brownian coagulation kinetics has been addressed by Kasper (1984).

The kernels presented in this section refer to aerosol particles that are perfect, rigid spheres undergoing instantaneous collisions that also yield spheres. The kernels do not include the effect of the modification of the local fluid flow as the particles approach each other (no hydrodynamic interactions). Since these local flows are expected to decrease the collision efficiency, due to increased resistance as the particles move closer, the kernels provide an upper bound to the collision efficiency. Alam (1987) proposed an analytical expression for the effect of the fluid based on the concept that the fluid resists being squeezed out from the region between the approaching particles.

For two colliding entities, the (two-particle) diffusive Knudsen number has to be redefined appropriately. The characteristic length scale associated with the collision cross section (collision radius) becomes the sum of the radii of the colliding spherical particles, the mass is replaced by the reduced mass, $\mu_{ij} = m_i m_j/(m_i + m_j)$, and the length scale associated with the particle relaxation time becomes the "reduced" radius $a_{ij} = a_i a_j/(a_i + a_j)$ (twice the harmonic mean), to obtain

$$Kn_D(i,j) = \frac{(k_B T \mu_{ij})^{1/2}}{6\pi\mu_g a_{ij}} \frac{1}{(a_i + a_j)}. \tag{20.23}$$

20.3.1.1 Brownian Coagulation

The most extensively studied, both experimentally and theoretically, coagulation process is coagulation due to Brownian motion. This process, initially studied by Smoluchowski (1916) and occasionally referred to as thermal coagulation, is important for particles smaller than 1 μm. The collision frequency function in the continuum (mass transfer) regime is

$$K_B^c(i,j) = 4\pi(a_i + a_j)(\mathfrak{D}_i + \mathfrak{D}_j) = \frac{2k_BT}{3\mu_g}\left[\frac{C_c(Kn_g, v_i)}{v_i^{1/3}} + \frac{C_c(Kn_g, v_j)}{v_j^{1/3}}\right]\left(v_i^{1/3} + v_j^{1/3}\right), \tag{20.24}$$

where a_i and a_j are the radii of the colliding particles. The second equality arises from the expression for the Brownian diffusion coefficient, Equation 20.165, that incorporates the slip correction factor $C_c(Kn_g)$, Equations 20.57 and 20.149. The derivation of the Brownian kernel is based on the calculation of the diffusional flux toward a sphere, assuming that the particle diffusion coefficients do not change as the particles approach each other. In the free molecular regime, the collision frequency function is obtained from the kinetic theory of gases, assuming that particle collisions are collision of rigid elastic spheres (Friedlander, 2000)

$$K_B^{FM}(i,j) = \left(\frac{3}{4\pi}\right)^{1/6}\left(\frac{6k_BT}{\rho_p}\right)^{1/2}\left(v_i^{-1} + v_j^{-1}\right)^{1/2}\left(v_i^{1/3} + v_j^{1/3}\right)^2, \tag{20.25}$$

where ρ_p is the particle mass density. The free molecular collision frequency function expressed in terms of the reduced particle mass becomes

$$K_{ij}^{FM}(i,j) = \left(\frac{8\pi k_BT}{\mu_{ij}}\right)^{1/2}(a_i + a_j)^2, \tag{20.26}$$

an expression that manifestly shows the dependence of the collision kernel on the collision cross section. Fuchs (1964) proposed an interpolation formula for the collision frequency function of spherical particles, valid over the entire particle mass-transfer regime:

$$K_B(i,j) = 4\pi(a_i + a_j)(\mathfrak{D}_i + \mathfrak{D}_j)\left[\frac{a_i + a_j}{a_i + a_j + \left(g_i^2 + g_j^2\right)^{1/2}} + \frac{4(\mathfrak{D}_i + \mathfrak{D}_j)}{(a_i + a_j)\left(\bar{c}_i^2 + \bar{c}_j^2\right)^{1/2}}\right]^{-1}, \tag{20.27}$$

where the mean particle velocity is $\bar{c}_i = (8k_BT/\pi m_i)^{1/2}$ with $m_i = \rho_p v_i$ as the particle mass, and g_i is the so-called Fuch's length

$$g_i = \frac{1}{3d_i l_i}\left[(d_i + l_i)^3 - \left(d_i^2 + l_i^2\right)^{3/2}\right] - d_i, \tag{20.28}$$

with $l_i = 8\mathfrak{D}_i/(\pi\bar{c}_i) = (8/\pi)^{1/2}\lambda_p(i)$, a slightly different definition of the particle mean free path. The particle diffusion coefficients in Equation 20.27 are obtained from the Stokes–Einstein expression, but they often include the Cunningham factor to provide an additional correction for the transition from the slip to the continuum regime (see Section 20.3.1.2, Equation 20.165 and subsequent discussion). The interpolation formula was derived under the assumption that every collision results in coagulation. Fuchs (1964) also discusses the effects of relaxing this assumption in terms of the collision efficiency, the fraction of collisions that result in coagulation.

The two limiting cases of the collision kernel, continuum and free molecular with respect to Kn_D, may be expressed compactly in terms of the (two-particle) diffusive Knudsen number. Since it has dimensions of volume per unit time, it may be rendered dimensionless by the scaling

$$\tilde{K}_B(i,j) = K_B(i,j)\frac{\mu_{ij}}{6\pi\mu_g a_{ij}}\frac{1}{(a_i + a_j)^3}, \tag{20.29}$$

where the second factor on the RHS is the characteristic time scale and the third is related to the collision length scale. The limiting forms of the dimensionless collision kernel become

$$\tilde{K}_B^c(i,j) = 4\pi Kn_D^2(i,j) \quad \text{as } Kn_D(i,j) \to 0, \tag{20.30}$$

$$\tilde{K}_B^{FM}(i,j) = (8\pi)^{1/2} Kn_D(i,j) \quad \text{as } Kn_D(i,j) \to \infty. \tag{20.31}$$

Various authors have proposed Brownian collision kernels valid over the entire particle mass-transfer regime; for example, Veshchunov (2010), who, using a careful analysis of the diffusive motion of colliding particles, proposed a kernel obtained via a six-parameter fit. We present the collision kernel proposed by Gopalakrishnan and Hogan (2011)

$$\tilde{K}_B(i,j) = \frac{4\pi Kn_D^2(i,j) + C_1 Kn_D^3(i,j) + \sqrt{8\pi} C_2 Kn_D^4(i,j)}{1 + C_3 Kn_D(i,j) + C_4 Kn_D^2(i,j) + C_2 Kn_D^3(i,j)}, \tag{20.32}$$

where $C_1 = 25.836$, $C_2 = 11.211$, $C_3 = 3.502$, and $C_4 = 7.211$. The constants were determined from a least-squares regression for transition-regime diffusive Knudsen numbers ($0.05 < Kn_D < 2.0$). The transition-regime collision kernel has the expected low and high Kn_D limits, continuum, as in Equation 20.30, and free molecular, as in Equation 20.31. The same reference compares literature expressions for various dimensionless collision kernels, all expressed in terms of the diffusive Knudsen number. Brownian agglomeration is also discussed in Williams and Loyalka (1991) and Friedlander (2000).

20.3.1.2 Brownian Coagulation in an External Force Field

The collision kernel is modified when the colliding particles exert a force on each other. For spherical particles interacting via a conservative force field, $\mathbf{F} = -\nabla\Phi$ where Φ is the interaction potential, the steady-state coagulation flow of particles (number of collisions per unit time per unit volume) is modified by a correction factor W as follows:

$$N_{ij} = \frac{1}{W} K_B(i,j) n_i n_j. \tag{20.33}$$

The correction factor is related to the interaction potential. Analysis of the diffusional flux toward a spherical particle leads to

$$W = \frac{1}{2}(d_i + d_j) \int_{0.5(d_i+d_j)}^{\infty} \frac{dx}{x^2} \exp\left[\frac{\Phi(x)}{k_B T}\right]. \tag{20.34}$$

Thus, for an attractive interaction potential (Φ negative), the collision frequency increases, whereas for a repulsive potential, the collision frequency decreases.

We consider two applications of Equation 20.34: van der Waals forces, which are always present, and Coulomb forces between charged particles. The van der Waals interaction potential between two spheres of different radii is a complicated function of the separation distance and particle radii, and it depends on Hamaker's constant A (see, e.g., Israellachvili, 1992). For two spheres of equal radius a_p separated by a distance r (distance between the centers of the spheres), the interaction potential simplifies to

$$\Phi = -\frac{A}{6}\left[2\left(\frac{a_p}{r}\right)^2 + \frac{2a_p^2}{r^2 - 4a_p^2} + \ln\left(1 - \frac{4a_p^2}{r^2}\right)\right]. \tag{20.35}$$

For electrically charged particles, neglecting induction forces, the Coulomb potential between two particles of radii a_i and a_j leads to a correction factor that may be calculated analytically to give

$$W = \frac{1}{y}(e^y - 1), \tag{20.36}$$

where the dimensionless parameter y is

$$y = \frac{z_i z_j e^2}{\varepsilon k_B T (a_i + a_j)}, \tag{20.37}$$

ε is the dielectric constant of the medium, and z_i is the number of charges on particle i. Thus, for uncharged particles, the correction factor vanishes, whereas for unipolar particles, the correction factor is positive and greater than unity, resulting in collision rates lower than for uncharged particles. The opposite applies to bipolar particles. The introduction of an additional interaction potential requires that an additional term be incorporated in the definition of the diffusive Knudsen number (Gopalakrishnan and Hogan, 2012).

20.3.1.3 Coagulation due to Laminar Shear

Particles in a laminar shear collide due to their relative motion induced by the gas flow spatial inhomogeneity, and thus, they may coagulate. Smoluchowski (1916) showed that in a uniform shear flow with a velocity gradient $\gamma = du/dy$, in the absence of Brownian motion, the collision frequency function becomes

$$K_{LS}(i,j) = \frac{\gamma}{6}(d_i + d_j)^3, \tag{20.38}$$

As argued earlier, this expression is approximate in that the approaching, interacting particles influence the fluid flow and the fluid streamlines about the particle are deflected around it. This effect has not been taken into account in Equation 20.38, but it may be considered by integrating the associated equations of motion in the presence of the shear, or of other inhomogeneities or of external forces, in a Lagrangian description of the particle motion.

20.3.1.4 Gravitational Coagulation

In a polydiperse aerosol in a gravitational field, heavier particles move faster than lighter ones, catching up with them and eventually colliding. This process is significant in the atmosphere where falling raindrops may scavenge aerosol particles. The coagulation kernel becomes the product of the effective target area times the relative particle velocity to give

$$K_G(i,j) = \frac{\pi}{4}(d_i + d_j)^2 \left| V_{s,i} - V_{s,j} \right|, \tag{20.39}$$

where the settling velocities are denoted by $V_{s,i}$, and are given explicitly by Equation 20.155. For spherical particles of the same material density ρ_p, the coagulation kernel may be expressed in terms of particle volume

$$K_G(i,j) = \frac{\rho_p g}{6\mu_g}\left(\frac{3}{4\pi}\right)^{1/3}\left(v_i^{2/3} + v_j^{2/3}\right)\left| v_i^{2/3} C_c(Kn_g, v_i) - v_j^{2/3} C_c(Kn_g, v_j) \right|, \tag{20.40}$$

where $C_c(Kn_g, v_i)$, the Cunningham factor, accounts for corrections in the slip regime (see Equation 20.149). The standard derivation (see, e.g., Williams and Loyalka, 1991) neglects interparticle forces that may lead to particles not colliding even though they would have done so in a purely geometrical calculation. Gravitational coagulation may be neglected for submicrometer particles, but it becomes significant for particle diameters larger than a few micrometers.

20.3.1.5 Turbulent Coagulation

Particles in a turbulent flow may collide due to inertial effects (inertial effects in turbulent flow are described in Section 20.6.3) and due to instantaneous fluid-flow inhomogeneities, that is, local velocity gradients. The first mechanism is due to the large (material) density differences between the fluid and the particle, whereas the second is always present. Saffman and Turner (1956) analyzed both mechanisms. Particles distributed uniformly

in a turbulent fluid collide as a result of small-scale shear flows over distances smaller than the Kolmogorov microscale. Thus, the analysis also requires that particle concentrations be relatively high so that the distance between colliding particles is less than the Kolmogorov microscale. As such, turbulent shear coagulation is similar to coagulation induced by laminar shear. Dimensional analysis arguments lead to the following result for the coagulation kernel due to turbulent shear

$$K_{TS}(i,j) = \frac{1.3}{8}\left(\frac{\varepsilon_d}{\nu}\right)^{1/2}(d_i + d_j)^3, \tag{20.41}$$

where ε_d is the energy dissipation rate per unit mass of the fluid. Note the similar functional dependence of the turbulent coagulation kernel and the laminar shear kernel (Equation 20.38) on particle diameter and on the local shear rate (which in isotropic turbulent flow has been related to the energy dissipation rate and the fluid kinematic viscosity).

Levich (1962) presented an alternative derivation of the turbulent coagulation kernel using concepts of classical diffusion. In the limit of dominant Brownian motion over turbulent motion, the expression he derived reproduces the classic Brownian coagulation kernel (Equation 20.24), whereas in the other limit, it reproduces the Saffman and Turner result except that the numerical prefactor 1.3 (actually the prefactor in Equation 20.41 is $(8\pi/16)^{1/2}$) becomes 5.65.

Saffman and Turner (1956) also considered coagulation due to inertial effects. They used the particle equations of motion to describe the relative particle motion and statistical arguments for isotropic turbulent flow in the high Reynolds number limit to obtain the collision frequency kernel

$$K_{TI}(i,j) = \frac{5.7}{4}(d_i + d_j)^2\left|\frac{1}{\beta_{V,i}} - \frac{1}{\beta_{V,j}}\right|\frac{\varepsilon_d^{3/4}}{\nu^{1/4}}, \tag{20.42}$$

where $\pi(d_i + d_j)^2/4$ is the collision cross section. Williams and Loyalka (1991) summarize results for the coagulation kernels in turbulent flow. They, also, present a generalized theory of turbulent coagulation that incorporates in a single formula the combined effects of Brownian diffusion, turbulent diffusion, and turbulent inertial motion. Their generalized result reproduces the formulae summarized herein (sometimes with slightly different numerical prefactors, e.g., the numerical prefactor 5.7 of Equation 20.42 becomes 6.2), and it provides an approximate expression for the combined effect of Brownian diffusion and gravitational settling. Such derivations are important to estimate inaccuracies inherent in linear (or quadratic) additions of coagulation kernels (see Section 20.3.1.6).

Theoretical developments (Reeks, 2005) suggest that the turbulent agglomeration kernels summarized in Equations 20.41 and 20.42 neglect the effect of coherent turbulent structures. Since these effects have been shown to have a nonnegligible effect on single particle motion in such flows, it has been argued that they might influence significantly coagulation in turbulent flows.

20.3.1.6 Kernel Addition

Some of the mechanisms responsible for coagulation may act simultaneously, for example, Brownian and gravitational coagulation, or gravitational and turbulent. A linear addition of Brownian with turbulent or gravitational kernels is frequently made, since particle coagulation may occur in regimes where one of them is significant and the others are not. This is not the case for the gravitational and turbulent kernels that have similar functional forms, and they may be of the same order of magnitude. An alternative, and more frequently used, approximation based on the work of Saffman and Turner (1956) is to add them quadratically as follows:

$$K_{\text{total}}(i,j) = K_B(i,j) + \left[K_G^2(i,j) + K_{TS}^2(i,j) + K_{TI}^2(i,j)\right]^{1/2}. \tag{20.43}$$

The precise nature of this approximation, or the magnitude of the error introduced in Equation 20.43, is not quantitative at the moment. Williams and Loyalka (1991) discuss a number of cases where two coagulation mechanisms act simultaneously (e.g., Brownian and shear coagulation), and they provide analytical expressions for the combined kernels.

20.3.2 Agglomeration: Power-Law Aggregates

The results presented in the previous section assumed that colliding spherical particles coagulate upon collision. Experiments and numerical simulation show that in some cases the colliding particles form agglomerates composed of smaller, primary particles. Particles that retain their identity upon collision are emitted during combustion in diesel engines, coal combustion in power plants, and commercial production of fine particles, among other processes. The size of the primary particles, the constituents of the agglomerate, ranges from nanometers to approximately 0.1 μm, and the resulting agglomerate structures vary from 0.1 μm to several micrometers. For simplicity, it is frequently assumed that the primary particles are monodisperse even though it is known that primary combustion particles are almost always polydisperse. The importance and influence of a polydispersed primary-particle size distribution on the dynamics of agglomerates is the topic of active current research (Eggersdorfer and Pratsinis, 2012, Eggersdorfer et al., 2012).

We will not distinguish between agglomerates and aggregates, even though the term aggregate (sometimes referred to as cluster) will be preferred. Their usual definitions are as follows (Kulkarni et al., 2011): An agglomerate is a loosely linked group of primary particles often held together by van der Waals forces or surface tension. Agglomerates are usually formed in the gas phase by particle collisions driven by Brownian motion or external forces or flow fields. An aggregate consists of strongly bound primary particles, often generated through coalescence and sintering at high temperatures. Strong necking between the primary particles makes the aggregate difficult to break apart, often rendering the identification of primary particles difficult. Finally, flocculates are also composed of loosely bound primary particles, held together by electrostatic forces. They break up easily in a shear flow.

20.3.2.1 Morphology

Forrest and Witten (1979), in their analysis of agglomeration of ultrafine smoke particles, were the first to suggest that the resulting agglomerates are power-law objects that obey the scaling law (over a finite size range):

$$N = k_f \left(\frac{R_g}{a_1} \right)^{d_f}, \tag{20.44}$$

where

N is the number of primary particles that form the agglomerate
d_f is the fractal (or Hausdorff) dimension
k_f is the fractal prefactor (also referred to as lacunarity (Lapuerta et al., 2010) or structure factor (Gmachowski, 1996))
R_g is the radius of gyration
a_1 is the radius of the primary particles

The fractal dimension provides a quantitative measure of the degree to which a structure fills physical space beyond its topological dimension: a compact three-dimensional structure has $d_f = 3$, whereas a line $d_f = 1$. The fractal prefactor, a parameter whose importance is increasingly being appreciated (Wu and Friedlander, 1993, Gmachowski, 1996, Sorensen and Roberts, 1997), is an essential ingredient of a complete description of power-law aggregates, as suggested by the scaling law. The radius of gyration is a geometric measure of the spatial mass distribution about the aggregate center of mass. For N identical, spherical monomers, it may be calculated via

$$R_g^2 = \frac{1}{N} \sum_{i=1}^{N} (\boldsymbol{r}_i - \boldsymbol{R}_{CM})^2 + c_1^2, \tag{20.45}$$

where $\boldsymbol{r}_i$ is the position of the ith monomer's center, and the aggregate center of mass is $\boldsymbol{R}_{CM} = 1/N \sum_{i=1}^{N} \boldsymbol{r}_i$. The additional term c_1^2 is frequently added to ensure that the scaling law remain valid even as the number of monomers tends to unity: otherwise, Equation 20.45 evaluates to zero for a monomer. It may be chosen to be the monomer radius (Filippov, 2000) or, preferably, the radius of gyration of a single 3d sphere, $c_1 = a_1\sqrt{3/5}$ (Sorensen and Roberts, 1997). Of course, for large N, the choice of the additional additive term is irrelevant.

Equation 20.44 suggests a complex and intricate interdependence of N, d_f, and k_f. Analyses of computer-generated, *in silico* synthetic, aggregates suggest that the prefactor is an indicator of local structure. It is an indicator of an aggregate's small-scale morphology, as determined, for example, from the probability distribution of the angles formed by three adjacent monomers (Melas et al., 2014a). Alternatively, it is a descriptor of packing of the primary particles, as initially proposed by Wu and Friedlander (1993). The fractal dimension is an indicator of the overall aggregate shape (large-scale aggregate morphology). A complementary indicator of large-scale structure is the cluster shape anisotropy, a measure of cluster stinginess (Heinson et al., 2010). For fixed fractal dimension, the mean shape anisotropy provides a good descriptor of aggregate morphology at large scales. The aggregate shape anisotropy is the ratio of two principal radii of gyration, obtained from the diagonalization of the aggregate inertial tensor, $R_g^2 = (R_{g,1}^2 + R_{g,2}^2 + R_{g,3}^2)/2$ with $R_{g,1} \geq R_{g,2} \geq R_{g,3}$. It is defined by $A_{13} = R_{g,1}^2 / R_{g,3}^2$.

Hence, a precise description of an aggregate is provided by the ordered pair (d_f, k_f). The simplest realization of a power-law aggregate is a straight chain, characterized by $(d_f = 1, k_f = \sqrt{3})$.

The fractal-like scaling law Equation 20.44 is valid in a statistical sense, in that aggregate properties become self-similar after an ensemble average over many aggregate realizations. Moreover, since the aggregates have a finite extent, they are never exactly self-similar: they exhibit self-similarity over a finite range of scales. For that reason, these power-law aggregates are referred to as fractal-like or quasi-fractal aggregates, and the scaling law as fractal-like. Note that the scaling law relation is independent of whether the aggregate has a real scale-invariant (self-similar) morphology.

The fractal dimension of an aggregate depends on the agglomeration mechanism: computer simulations have been used extensively to study the fractal dimension of aggregates formed via particle–cluster or cluster–cluster agglomeration in two and three dimensions, the agglomeration mechanisms being diffusive, reaction-limited, or ballistic. For example, three-dimensional simulations of ballistic-limited cluster–cluster growth predict $d_f = 1.80$, and particle–cluster growth gives $d_f = 2.50$ (see, e.g., Table 1.6 in Colbeck, 1998). The most studied aggregates are those generated via diffusion-limited cluster aggregation (DLCA) or reaction-limited cluster aggregation (RLCA). For both groups, the agglomeration mechanism is particle diffusion, the difference arising from the cluster–monomer sticking probability: it is unity for DLCA clusters and approximately 0.001 for RLCA clusters. The most frequently used scaling-law parameters are $(d_f = 1.8, k_f = 1.3)$ for DLCA and (2.05, 0.94) for RLCA clusters.

An alternative, more precise, description of aggregate morphology is provided by the two-point, orientationally averaged monomer–monomer correlation function $g(r)$. It gives the probability (per unit volume) of finding a monomer at distance r from an arbitrarily chosen monomer (Heinson et al., 2012). Note that the pair correlation function, defined with respect to an arbitrarily chosen monomer, is distinct from the radial (mass) distribution function $\rho(r)$, which gives the aggregate (mass) distribution with respect to its center of mass. An analytic expression for $g(r)$ is highly desirable as structural and dynamical aggregate properties may be expressed in terms of it. The expected functional form is

$$g(r) = \frac{A}{a_1^{d_f}} r^{d_f - 3} h\left(\frac{r}{\xi}\right), \tag{20.46}$$

where A is a dimensionless constant. The pair correlation function is normalized to (for large N)

$$N = 4\pi \int_0^\infty dr r^2 g(r), \tag{20.47}$$

and the radius of gyration is $R_g^2 = \langle r^2 \rangle$ where the average is taken with respect to $g(r)$. The algebraic decay arises from the scaling behavior, and the cut-off function $h(r/\xi)$ models the diffuse cluster interface. The correlation length ξ is a measure of interface roughness. The cutoff function is usually taken to be a stretched (or compressed if $\gamma > 1$) exponential,

$$h\left(\frac{r}{\xi}\right) = \exp\left[-\left(\frac{r}{\xi}\right)^\gamma\right], \tag{20.48}$$

the exponent γ at most weakly dependent on the agglomeration mechanism. Values suggested are γ = 2.02 (Heinson et al., 2012) or 2.20 (Lattuada et al., 2003) for DLCA, and 2.16 for RLCA aggregates (Lattuada et al., 2003). The most accurate expression, so far, for $g(r)$ was proposed by Lattuada et al. (2003) who appreciated the importance of small-scale structure by identifying specific functional forms at the first and second shells ($r = 2R_1$ and $2R_1 < r < 4R_1$). The suggested functional form was based on the analysis of synthetic aggregates.

Naumann (2003) considered the morphology of aggregates in the limit of a sharp interface ($\gamma \to \infty$). He introduced the geometric radius R_{geo} to describe the spatial extent of an aggregate: it is defined as the radius of the largest sphere encompassing the aggregate centered at its center of mass (the radius of the smallest convex envelope). For a sharp cluster interface, the radial mass distribution function $\rho(r)$, which gives the probability that a monomer be found at a given distance from the cluster center of mass, decays algebraically with distance $\rho(r) \sim r^{d_f - 3}$ (no exponential cutoff). The geometric radius is related to the radius of gyration by

$$\frac{R_g}{a_1} = \left[\frac{\int_0^{R_{geo}} dr r^4 \rho(r)}{\int_0^{R_{geo}} dr r^2 \rho(r)} \right]^{1/2} = \left(\frac{d_f}{d_f + 2} \right)^{1/2} \frac{R_{geo}}{a_1}, \tag{20.49}$$

and the fractal prefactor becomes

$$k_f = \frac{1}{f} \left(\frac{d_f}{d_f + 2} \right)^{-d_f/2}, \tag{20.50}$$

with f the filling factor, a factor introduced to ensure that monomer packing does not exceed the densest packing arrangement of hard spheres $\eta_{packing} = \pi/(3\sqrt{2}) \approx 0.7405$. An important feature of Equation 20.50 is that it imposes limits on the fractal prefactor as the volume filling factor is constrained by $\eta_{packing}$. The suggested one-to-one correspondence between the fractal dimension and the prefactor, however, is only approximate, as the more accurate analytical work of Heinson et al. (2012) and the morphological analyses of synthetic clusters (Melas et al., 2014a) show. Heinson et al. (2012) suggested that the dimensionless constant A, under the assumption that Equation 20.46 hold at all distances, may be expressed as

$$A = \frac{\phi d_f}{4\pi}, \tag{20.51}$$

with ϕ the packing fraction. The packing fraction was defined by generalizing its three-dimensional definition via $N(r) = \phi (r/a_1)^{d_f}$. Since the radius of gyration is (for large N)

$$R_g^2 = \langle r^2 \rangle = \frac{2\pi}{N} \int_0^{\infty} dr r^4 g(r), \tag{20.52}$$

the prefactor may be expressed as follows:

$$k_f = \left[\frac{2\Gamma(d_f/\gamma)}{2\Gamma((d_f + 2)/\gamma)} \right]^{d_f/2} \frac{\phi d_f \Gamma(d_f/\gamma)}{\gamma}. \tag{20.53}$$

The prefactor, thus, is a complex function of the fractal dimension, the stretching exponent, and monomer packing.

If the aggregate surface is approximately treated as sharp, the scaling law Equation 20.44 may be generalized to

$$N = k_L \left(\frac{L}{a_1} \right)^{d_L}, \tag{20.54}$$

where L is a characteristic length scale and k_L, d_L generalized prefactor and fractal dimension (respectively). The characteristic length scale is an appropriately chosen measure of an aggregate's spatial extent. As is apparent from the generalized scaling law, and already noted by Wu and Friedlander (1993), the generalized prefactor, a measure of average monomer packing, is not well defined because it depends on the choice of L. The arbitrariness in selecting a characteristic length scale arises from the absence of a well-defined interface of orientationally averaged fractal-like aggregates.

Both geometric and dynamic length scales have been chosen for L. A commonly used geometric length scale, in addition to the radius of gyration, is the outer radius, defined as half the maximum distance between any two monomers. It is easily determined from transmission electron microscopy (TEM) images. Its main shortcoming is that a sphere of radius R_{out} centered at the middle of the maximum distance (between monomers) does not necessarily enclose all monomers: only a sphere of radius $2R_{\text{out}}$ centered at an arbitrary monomer ensures that all monomers are enclosed. The geometric radius may also be chosen to be the characteristic length: the corresponding prefactor is related to the volume filling factor $k_{\text{geo}} = 1/f$ (Naumann, 2003). Occasionally, the equivalent volume radius R_{eq}, the radius of a sphere that has the same volume as the aggregate, is used. Simulations suggest that when a geometric length scale is used in the generalized scaling law, the fractal exponent does not change, remaining d_f (Melas et al., 2014a), whereas the prefactor becomes a function of the chosen measure of monomer packing.

20.3.2.2 Dynamics

The continuum-regime Brownian collision kernel suggests that the collision kernel depends on two processes: momentum transfer between particle and gas molecules, specified by Kn_g, which depends on a particle characteristic length scale, and particle-to-particle mass transfer, specified by Kn_D, which depends on the collision radius. We address each process and the associated Knudsen number separately. We remark that there is an important difference between the determination of the collision kernel via the Smoluchowski equation and numerical simulations: in the latter, the fractal dimension of the aggregate is directly obtained from the simulation (see, e.g., Isella and Drossinos, 2010), whereas in the former, the fractal dimension is an input. We also note that Kostoglou and Konstandopoulos (2001) presented an alternative description of the effect of aggregate morphology on the agglomeration rate. They considered a generalized coagulation term in the GDE for the continuous size distribution that depends on two descriptors: aggregate size (as is the case for spherical particles) and fractal dimension.

For concreteness, we concentrate on power-law aggregates composed of N touching (single-point contact), nonoverlapping spherical monomers. The friction coefficient $f_N(Kn_g)$ of an aggregate composed of N monomers over the entire (momentum-transfer) transition regime is usually expressed in terms of the empirical relation:

$$f_N(Kn_g) \equiv \frac{f_N(0)}{C_c(N, Kn_g)}, \tag{20.55}$$

where

$f_N(0)$ is the aggregate friction coefficient in the continuum regime

$C_c(N,Kn_g)$ is the N-monomer slip correction factor, also known as the Cunningham correction factor (Friedlander, 2000)

The slip correction factor $C_c(N,Kn_g)$ is unity in the continuum regime, increasing as the Knudsen increases, leading to a decreasing friction coefficient, see also Equation 20.149.

The slip correction factor of a sphere in the continuum and slip flow regimes may be calculated analytically (Ivchenko et al., 2007):

$$C_c(1, Kn_g) = \frac{f_1(0)}{f_1(Kn_g)} = \frac{1 + 3c_m Kn_g}{1 + 2c_m Kn_g}, \tag{20.56}$$

where c_m is the isothermal slip velocity coefficient. For planar surfaces in the absence of temperature gradients parallel to the surface, an approximate expression is $c_m = 5\pi(2 - \alpha_\tau)/(16\alpha_\tau)$, where α_τ is the momentum accommodation coefficient. It is the fraction of diffusely reflected molecules, or equivalently, the fraction of tangential momentum of incident molecules transmitted to the surface by all molecules. It varies from zero

for specular reflection on the particle's surface to one for perfect accommodation (diffuse reflection). The accommodation coefficient depends on the particle chemical composition, rendering the slip factor material dependent. The slip factor may be calculated across the entire momentum-transfer transition regime via the empirical Knudsen–Weber formula (Friedlander, 2000):

$$C_c(1, Kn_g) = 1 + Kn_g\left[a + b\exp\left(-\frac{c}{Kn_g}\right)\right]. \tag{20.57}$$

The experimentally determined parameters (a, b, c) depend on the material composition of the particle, where a is a function of particle surface roughness (Allen and Raabe, 1985). Their relation to the accommodation coefficient α_τ may be derived by comparing the free molecular limit of the slip correction factor of a sphere to kinetic theory results. Specifically, the friction coefficient of a spherical particle in the continuum regime is given by the (creeping flow, small particle Reynolds number) Stokes expression

$$f_1^c(Kn_g = 0) = 6\pi\mu_g a_1, \tag{20.58}$$

whereas in the free molecular limit it becomes (Friedlander, 2000)

$$f_1^{FM}(Kn_g \to \infty) = \frac{8}{3}a_p^2\rho_g\left(\frac{2\pi k_B T}{m_g}\right)^{1/2}\left(1 + \frac{\pi\alpha_\tau}{8}\right). \tag{20.59}$$

The free molecular limit may be expressed more intuitively via the kinetic theory expression for the molecular viscosity

$$\frac{\mu_g}{\lambda_g} = \phi_{KT}\rho_g\bar{c} = \phi_{KT}\rho_g\left(\frac{8k_B T}{\pi m_g}\right)^{1/2}, \tag{20.60}$$

where

ϕ_{KT} is a dimensionless constant

$\bar{c}$ the mean velocity of gas molecules, see also the discussion following Equation 20.27

Use of Equation 20.60 in the free molecular friction coefficient yields

$$f_1^{FM} = \frac{4}{3\phi_{KT}}\frac{\mu_g}{\lambda_g}\left(1 + \frac{\pi\alpha_\tau}{8}\right)A_p(1), \tag{20.61}$$

where $A_p(1) = \pi a_1^2$ is the collision cross section (projected area) of a sphere. Since in free-molecular limit of the Knudsen–Weber expression, Equation 20.57 gives $C_c(1, Kn_g) \to Kn_g(a + b)$, the friction coefficient may also be expressed as

$$f_1^{FM} = \frac{6}{a+b}\frac{\mu_g}{\lambda_g}A_p(1). \tag{20.62}$$

Comparison of Equations 20.61 and 20.62 leads to

$$\alpha_\tau = \frac{4}{\pi}\left(\frac{9\phi_{KT}}{a+b} - 2\right), \tag{20.63}$$

suggesting that the sum $a + b$ is related to the nature of gas–molecule interactions. Equation 20.63 provides a relationship between the accommodation coefficient and two parameters of the slip factor, parametrized by ϕ_{KT}. A frequently used value for ϕ_{KT} is 0.5, whereas more recent calculations suggest $\phi_{KT} = 5\pi/32 \approx 0.491$

(Ivchenko et al., 2007). The most accurate slip-factor constants are considered to be (a = 1.142, b = 0.558, c = 0.999) (Allen and Raabe, 1985), corresponding to a fraction of diffuse reflections $\alpha_\tau = 0.763$ (Cheng et al., 1988). The fraction of diffuse reflections has also been taken to be $\alpha_\tau = 0.93$, a choice that coupled to $\phi_{KT} = 0.5$ leads to the constants proposed by Millikan, (1.234, 0.414, 0.876), or $\alpha_\tau = 0.84$, which leads to (1.257, 0.4, 0.876). Irrespective of the difference in the slip-flow parameters, the calculated slip correction factors are practically identical.

The analysis of the limiting forms of the friction coefficient of a sphere leads to the important observation that it depends linearly on the particle radius in the continuum regime and quadratically in the free molecular regime (or to the orientationally averaged projected area). These dependencies remain valid even for nonspherical objects under the condition that appropriately length scales are chosen.

The slip correction factor of a N-aggregate $C_c(N,Kn_g)$ is difficult to calculate for nonspherical structures. Instead, their mobility is usually analyzed via *virtual* spherical particles that have desired properties. Two such spheres are commonly used: the equivalent mobility sphere (see, e.g., Rogak and Flagan, 1992), of equivalent mobility radius a_m, and the adjusted sphere (Dahneke, 1973), of radius a_{adj}. In addition, the equivalent hydrodynamic sphere (Filippov, 2000), of radius a_h, is occasionally used to describe aggregate mobility in near-continuum flows. The mapping of the aggregate to a virtual sphere allows the use of the single-sphere slip factor $C_c(1, Kn_g)$ in the corresponding form of Equation 20.55.

In the transition regime, the friction coefficient expressed in terms of the hydrodynamic radius is

$$f_N(Kn_g) \equiv 6\pi\mu_g a_h(Kn_g) = \frac{6\pi\mu_g a_h(0)}{C_c(N,Kn_g)}, \tag{20.64}$$

where the functional dependence of Stokes friction coefficient was used, $f_N(0) = 6\pi\mu_g a_h(0)$, with $a_h(Kn_g)$ as the hydrodynamic radius. Equation 20.64 defines the hydrodynamic radius as the radius of a sphere that has the same average mobility (the same friction and diffusion coefficients) in the *continuum* regime as the aggregate at a given Knudsen number. Its defining equation may be considered a generalization of the Stokes relation over the entire transition regime, or equivalently, a dimensionless friction coefficient.

The mobility radius $a_m(Kn_g)$, the proper hydrodynamic radius of an aggregate, is the radius of a sphere that has the same average mobility under the *same* flow conditions. The friction coefficient becomes

$$f_N(Kn_g) \equiv \frac{6\pi\mu_g a_m(Kn_g)}{C_c(1,Kn_m)}, \tag{20.65}$$

where the mobility Knudsen number is defined with respect to the only particle length scale associated with the fictitious sphere, $Kn_m \equiv \lambda_g/a_m = Kn_g a_1/a_m$. In the continuum regime, the aggregate hydrodynamic and mobility radii are equal, $a_h(0) = a_m(0)$, and for a sphere, they equal the sphere radius.

Dahneke (1973) introduced the adjusted-sphere method to calculate the friction coefficient of nonspherical objects over the entire momentum-transfer regime. The adjusted-sphere radius a_{adj} is defined as the radius of a sphere that has the same *slip* factor as the aggregate over the entire transition regime. This characteristic length is assumed to be constant, independent of the Knudsen number (i.e., independent of the flow regime as specified by the gas mean free path λ_g), in contrast to the mobility radius. The associated adjusted-sphere Knudsen number $Kn_{\text{adj}} \equiv \lambda_g/a_{\text{adj}} = Kn_g a_1/a_{\text{adj}}$ varies with Kn_g. The friction coefficient becomes

$$f_N(Kn_g) \equiv \frac{f_N(0)}{C_c(1,Kn_{\text{adj}})}. \tag{20.66}$$

According to numerous authors (e.g., Dahneke, 1973, Rogak and Flagan, 1992, Zhang et al., 2012), it is the Knudsen number that is appropriate to describe aggregate mobility in the transition regime. There is considerable evidence, both numerical and experimental, of the validity of the adjusted-sphere method in the transition regime, and it has been used in numerical simulations and analyses of experiments (Cheng et al., 1988, Rogak et al., 1991, Thajudeen et al., 2012). More recently, Zhang et al. (2012) using direct simulation MC calculated the friction coefficient of power-law aggregates over the entire momentum-transfer regime. They found excellent agreement of their results with the friction coefficients calculated via the adjusted-sphere method.

The adjusted-sphere method provides a very useful, and successful, computational method to determine the friction coefficient of irregularly shaped particles. Since a_{adj} is posited to be independent of the fluid Knudsen number, it is sufficient to calculate it once and use it for all Knudsen numbers. Nevertheless, the physical interpretation of the adjusted sphere is not transparent (it may be viewed as a constant auxiliary length introduced to calculate an aggregate's drag), nor can it be measured directly, as the equivalent mobility radius.

The adjusted-sphere radius is determined by requiring that the slip factor of the adjusted sphere have the correct continuum and free molecular limits. The free molecular limit (defined as $Kn_m \to \lambda_g/a_m(\infty)$, with $a_m(\infty)$ as the mobility radius in the free molecular regime) of

$$\frac{a_m(0)}{C_c(1, Kn_{\text{adj}})} = \frac{a_m(Kn_g)}{C_c(1, Kn_m)}, \tag{20.67}$$

an expression, which may be derived from the defining equation of the mobility and adjusted-sphere radii, leads to

$$Kn_{\text{adj}} = Kn_g \frac{a_1 a_m(0)}{a_m^2(\infty)} \quad \text{with } \frac{a_{\text{adj}}}{a_1} = \frac{a_m^2(\infty)}{a_1 a_m(0)}. \tag{20.68}$$

Rogak and Flagan (1992), in their study of agglomeration of fractal-like aggregates, were the first (to our knowledge) to present Equation 20.68. They referred to the adjusted-sphere method as an interpolation method between the continuum and transition regimes. Zhang et al. (2012) used dimensional arguments to obtain it.

Equation 20.68 shows that the adjusted-sphere radius may be calculated solely from the continuum $a_m(0)$ and free molecular $a_m(\infty)$ mobility radii. Numerous authors have suggested that in the continuum regime, the momentum-transfer mobility radius $a_m(0)$ may be reliably approximated by the mass-transfer radius. Hubbard and Douglas (1993) argued that the scalar friction coefficient of an arbitrarily shaped Brownian particle may be calculated from the solution of the Laplace equation. They showed that the angular average (corresponding to a physical orientational average due to Brownian motion) of the Oseen tensor leads to the free-space Green's function for the Laplace operator. Similarly, Isella and Drossinos (2011) proposed the collision rate method to calculate the mass-transfer radius in the continuum regime via a heuristic argument based on the calculation of the collision rate of virtual Brownian particles with straight chains. They concluded that the solution of the Laplace equation gives the continuum-regime mass-transfer radius. Comparison of their results with previous calculations confirmed that the mobility (momentum-transfer) radius is approximately equal to the mass-transfer radius. Gopalakrishnan et al. (2011) used the Langevin equation for point mass particles, an alternative way to solve the diffusion equation, to calculate the mass-transfer radius, referring to it as the Smoluchowski radius. Melas et al. (2014b, 2015) extended the collision rate method to slip flow, thus providing additional support that the approximate equality of the momentum and mass-transfer radii is valid in the transition regime. Of course, particle–particle hydrodynamic interactions are neglected in this treatment.

In the continuum regime, Melas et al. (2014a), by studying synthetic aggregates generated by a tunable cluster–cluster agglomeration mechanism (Filippov et al., 2001), proposed an empirical fit that relates aggregate morphological properties to the mass-transfer radius (taken to be equal to the mobility radius):

$$\frac{a_m(0)}{a_1} = 0.248(2 - N^{-1/3})\frac{R_g}{a_1} + 0.69N^{0.415}. \tag{20.69}$$

The empirical fit was based on synthetic-cluster calculations, where the clusters were characterized by ([1.5, 2.1], [1,1.6]). The particularity and usefulness of Equation 20.69 is that the continuum mobility radius may be estimated from the fractal dimension and prefactor in the particular combination that defines the radius of gyration R_g, and from the number of monomers, and the monomer radius a_1. This contrasts to most empirical fits available in the literature (see, e.g., Sorensen, 2011) where the continuum mobility radius is expressed in terms of aggregate statistical properties like d_f and k_f. Equation 20.69 shows that the mobility radius may be estimated for a single cluster if the monomer positions are known (either from measurements or simulations) since the independent variables do not depend on ensemble-averaged properties.

The mobility radius of bead-composed structures in the continuum regime is often estimated via the Kirkwood–Riseman formula (Kirkwood and Riseman, 1948), an expression developed in their pioneering analysis of the translational diffusion coefficient of flexible macromolecules. The Kirkwood–Riseman expression is also a geometric expression, in that it depends only on the position $\boldsymbol{r}_i$ of the monomers in the aggregate:

$$\frac{Na_1}{a_m(0)} = 1 + \frac{1}{N}\sum_{j=1}^{N}\sum_{m=1,m\neq j}^{N}\frac{a_1}{|\mathbf{r}_j - \mathbf{r}_m|}. \tag{20.70}$$

A comparison of predictions of Equation 20.69 with those of Kirkwood–Riseman shows that the latter provides a very good approximation to the mobility radius of both open and compact structures, the difference increasing as the number of monomers decreases (as expected since it is a large N expression). Thajudeen et al. (2012) proposed a slightly different, six-parameter, expression for the Smoluchowski (mass-transfer) radius of limited region of validity.

In the free molecular regime, experiments and gas-molecular scattering calculations suggest that the friction coefficient of power-law aggregates is proportional to their orientationally averaged projected area (Sorensen, 2011, Larriba and Hogan, 2013). The mobility radius of an aggregate was found to be proportional to the square root of its projected area, rendering the mobility radius and the mass-transfer radius in the free molecular regime approximately equal. Therefore, $a_m^2(\infty) = A_p(N)/\pi$ where $A_p(N)$ is the projected area of a N monomer aggregate. The adjusted-sphere radius may be re-expressed as

$$\frac{a_{\text{adj}}}{a_1} = \frac{A_p(N)}{\pi a_1 a_m(0)} = \frac{a_m^2(\infty)}{a_1 a_m(0)}. \tag{20.71}$$

MC sampling has been used to estimate the orientationally averaged projected area it; see, for example, Mackowski (2006). We present the empirical fit proposed by Melas et al. (2014b), an expression derived for aggregates composed of N = [10,60] monomers with ([1.5, 2.1], [1.0, 1.6]),

$$\frac{A_p(N)}{A_p(1)} = \frac{a_m^2(\infty)}{a_1^2} = 1.172N^{0.704}\left(\frac{R_g}{a_1}\right)^{2(-0.146N^{-1/3}+0.192)}, \tag{20.72}$$

where $A_p(1) = \pi a_1^2$ is the projected area of a sphere. The orientationally averaged projected area of a N-monomer straight chain may be approximately calculated via

$$A_p(N) = NA_p(1) - (N-1)A_{\cap}, \tag{20.73}$$

where the monomer–monomer overlap is $A_{\cap} \simeq 0.47a_1^2$.

The expressions for the continuum-regime mobility radius and the orientationally averaged projected area may be combined to obtain an expression for the adjusted-sphere radius of power-law aggregates (accurate to within less than 1%):

$$\frac{a_{\text{adj}}}{a_1} = -0.052(2 + N^{-1/3})\frac{R_g}{a_1} + 1.15N^{0.42}\ \text{(power-law aggregates)}. \tag{20.74}$$

A similar equation for straight chains valid in the entire momentum-transfer regime is

$$\frac{a_{\text{adj}}}{a_1} = -0.14\left(\frac{R_{\text{eq}}}{a_1}\right)^2 + 1.54\frac{R_{\text{eq}}}{a_1} - 0.41\ \text{(straight chains)}, \tag{20.75}$$

where $R_{\text{eq}}/a_1 = N^{1/3}$ is the radius of the equivalent volume sphere.

Equations 20.74 and 20.75 show, as initially postulated by Dahneke (1973) and discussed extensively by Thajudeen et al. (2012), that the adjusted-sphere radius becomes a geometric descriptor of an aggregate: it depends solely on the morphology of the aggregate. For an aggregate, it depends on the radius of gyration, the number of monomers, and the monomer radius, all geometric quantities. For a straight chain, it depends on the number of monomers and the monomer radius.

Given the adjusted-sphere radius, it is easy to calculate the friction coefficient of fractal-like aggregates via the defining equation of the adjusted-sphere radius and the expression for the single-sphere slip correction factor. It is instructive to reconsider the limiting behavior of Equation 20.66. We obtain, in the continuum limit Kn_g, $Kn_{\text{adj}} \to 0$,

$$f_N^c = 6\pi\mu_g a_m(0)\,, \tag{20.76}$$

and in the free molecular limit (Kn_g, $Kn_{\text{adj}} \to \infty$)

$$f_N^{FM} = \frac{6}{a+b}\frac{\mu_g}{\lambda_g}\pi a_m^2(\infty) = \frac{4}{3\phi_{KT}}\frac{\mu_g}{\lambda_g}\left(1+\frac{\pi\alpha_\tau}{8}\right)A_p(N) \approx 2.67\frac{\mu_g}{\lambda_g}\xi A_p(N), \tag{20.77}$$

where the last expression, proposed by Zhang et al. (2012), was evaluated for $\alpha_\tau = 0.91$ (leading to $\xi \approx 1.36$), $\phi_{KT} = 0.5$. The similarities to Equations 20.58 and 20.61 are remarkable.

It has been argued that the scaling law remains valid even when the characteristic length scale is chosen to be the mobility radius. The fractal-like scaling law may be written as

$$N = k_m\left[\frac{R_m(Kn_g)}{a_1}\right]^{d_m}, \tag{20.78}$$

where d_m is the mass-mobility exponent. The scaling law expressed in terms of the mobility equivalent radius is very frequently used in the interpretation of experimental measurements since many instruments, for example, differential mobility analyzer (DMA), measure (electrical) mobility. Even though the fractal dimension does not depend on the choice of the geometric length scale, it changes when the mobility radius is used. Analyses of experimental measurements on some combustion aerosol yielded $d_m \approx 2.1$–2.4, values that correspond to $d_f \approx 1.8$, indicative of DLCA aggregates (Sorensen, 2011). A slight dependence of both (d_m, k_m) on Kn_g has been reported (Melas et al., 2014b).

The previously derived quantities for a single aggregate may be appropriately redefined to obtain a generalized dimensionless collision kernel for nonspherical objects. According to Thajudeen et al. (2012), the dimensionless collision kernel becomes

$$\tilde{K}_B(i,j) = K_B(i,j)\frac{\mu_{ij}}{f(i,j)}\frac{1}{a_{\text{adj}}^2(i,j)}\frac{1}{a_m^{(i,j)}(0)}, \tag{20.79}$$

and the corresponding diffusive Knudsen number

$$Kn_D(i,j) = \frac{(k_B T\mu_{ij})^{1/2}}{f(i,j)}\frac{1}{a_{\text{adj}}(i,j)}, \quad a_{\text{adj}}(i,j) = \frac{A_p(i,j)}{\pi a_m^{(i,j)}(0)}, \tag{20.80}$$

where

$f(i,j) = f_i(Kn_g)f_j(Kn_g)/[f_i(Kn_g) + f_j(Kn_g)]$ is the reduced friction coefficient

$a_{\text{adj}}(i,j)$, $a_m^{(i,j)}(0)$, and $A_p(i,j)$ are determined from combined properties of the two colliding entities.

The functional form of the dimensionless Brownian collision kernel Equation 20.32 remains identical as long as it is appropriately rendered dimensionless and the right diffusive Knudsen number is used. The reader may consult their work for approximate expressions for the necessary two-particle correlations.

It is instructive to compare the expressions for the friction coefficient and the collision radius of power-law aggregates, and the ensuing collision kernel, to a frequently used collision kernel based on a generalization of the Smoluchowski kernel. An expression for the continuum regime kernel for large aggregates $N > 1000$ for which the diffusion coefficient approaches the Stokes–Einstein value, Equation 20.165, is (Friedlander, 2000)

$$K_B^c(i,j) = \frac{2k_BT}{3\mu_g}\left(v_i^{-1/d_f} + v_j^{-1/d_f}\right)\left(v_i^{1/d_f} + v_j^{1/d_f}\right). \tag{20.81}$$

For $d_f = 3$, Equation 20.81 reduces to the Brownian coagulation kernel for spherical particles, Equation 20.24 without the slip correction. The free molecular kernel is taken to be

$$K_B^{FM}(i,j) = \left(\frac{6k_BT}{\rho_p}\right)^{1/2}\left(\frac{3}{4\pi}\right)^{\lambda} a_1^{2-6/d_f}\left(v_i^{-1} + v_j^{-1}\right)^{1/2}\left(v_i^{1/d_f} + v_j^{1/d_f}\right)^2, \tag{20.82}$$

with

$$\lambda = \frac{2}{d_f} - \frac{1}{2}. \tag{20.83}$$

For coalescing spheres ($d_f = 3$), Equation 20.82 reduces to the kernel for Brownian coagulation of spherical particles, Equation 20.25. The region of validity is considered to be $d_f \geq 2$. Both kernels were derived under the assumption that the fractal prefactor is unity, an assumption that if removed would modify the overall constant. More importantly, the collision radius in both regimes was considered to be the radius of gyration. The mobility radius in the continuum regime $a_m(0)$ was also taken to be the radius of gyration, and it was assumed that in the free molecular regime, the two colliding particles behaved as spheres (to calculate the friction coefficient) whose radius is the radius of gyration. Furthermore, it was assumed that the colliding aggregates have the same fractal dimension.

20.4 Gas-to-Particle Conversion

Gas-phase physical or chemical processes may generate a supersaturated ($p_{\text{vap}}(T) > p_{\text{sat}}(T)$, and hence, metastable) vapor state that relaxes to equilibrium either via the generation of new particles (homogeneous nucleation) or via growth of already existing particles (condensation or heterogeneous nucleation). Physical processes that lead to a supersaturated state include cooling at a surface, adiabatic expansion or mixing, turbulent mixing, whereas condensable vapor species may be generated by gas-phase chemical reactions.

20.4.1 Nucleation

A metastable vapor phase state relaxes to equilibrium via homogeneous nucleation in the absence of aerosol particles. Homogeneous nucleation is important in numerous fields: in the atmosphere, for example, ice nucleation in supercooled water droplets is the main mechanism for the formation of cirrus clouds in the upper troposphere, whereas nanoparticle formation in engine emissions occurs via homogeneous nucleation. Herein, we concentrate on the transition from the gas phase (supercooled vapor) to a condensed phase by the formation of liquid droplets: the opposite process, bubble nucleation in superheated liquids. Similarities and differences between these two processes will be briefly mentioned.

Nucleation is a physical process that refers to the appearance of a new phase during a first-order phase transition: it is a thermally activated process that occurs via large-amplitude, localized fluctuations that may be viewed as "droplets" of the new, stable phase. Being an activated process, new particle formation requires the surmounting of a nucleation barrier. At given thermodynamic conditions (e.g., constant temperature), the new condensed phase is stable with respect to the vapor phase (its chemical potential is lower), but there is a free energy cost associated with the creation of the interface between the two phases. The competition between the free energy gain due to the creation of the stable phase and the free energy loss due to the creation of an interface creates the nucleation barrier. Whereas a metastable state decays via nucleation, an unstable state decays via a process that does not involve barrier crossing and which is called spinodal decomposition. Spinodal decomposition, not addressed herein, occurs via the growth of small-amplitude, long-wavelength fluctuations.

Space limitations do not allow us to cover some important nucleation topics including experimental measurements of nucleation rates (see, e.g., the review Heist and He 1994), computer simulations, rigorous definitions of physically consistent clusters, ion-induced nucleation, and Ostwald ripening.

20.4.1.1 Classical Nucleation Theory

The original work of Becker and Döring (1935) on isothermal nucleation and subsequently refined by Zeldovich (1942) forms what is now referred to as classical nucleation theory (CNT). These authors argued that nucleation is an activated process and that the rate should depend exponentially on the reversible work of cluster formation. For an early review of homogeneous nucleation, cf. Feder et al. (1966), whereas for more recent presentations and reviews of CNT, cf. Laaksonen et al. (1995) and Debenedetti (1996).

A complete theory of nucleation considers the dynamics of growth of the stable clusters (also referred to as embryos, droplets, or nuclei) of the new phase. For nonassociated vapors and low cluster concentrations, clusters grow or shrink by the addition or removal of a single molecule. Thus, the rate per unit volume (expressed in number of clusters per unit volume and unit time) at which the number concentration of i-molecule clusters changes is

$$J(i) = f_{i-1}s_{i-1}\beta_{i-1} - f_i s_i \alpha_i \tag{20.84}$$

where

f_i is the nonequilibrium number concentration of i-molecule clusters
s_i is the respective surface area
β_i is the forward (condensation) flux per unit time and area at which an i-cluster gains a molecule
α_i is the backward (evaporation) flux at which the cluster loses a molecule

The following assumptions are usually made:

- The forward and backward fluxes are independent of cluster size, and they do not depend on whether the system is in equilibrium.
- An equilibrium concentration of clusters is established in the bulk metastable state. This assumption converts a kinetic problem into a thermodynamic one by defining an equilibrium cluster distribution that obeys usual Boltzmann statistics. Microscopic reversibility, then, relates n_i, the equilibrium i-cluster concentration, to n_{i-1}

$$\beta s_{i-1} n_{i-1} = \alpha s_i n_i \tag{20.85}$$

  Thus, the assumption of an equilibrium distribution allows the determination of the evaporation flux α, a quantity that is difficult to evaluate, in terms of the condensation flux β, a quantity that may be easily calculated from, for example, kinetic theory of gases. The difficulty to calculate α is thus transformed to the calculation of the equilibrium droplet concentration, or, equivalently, to the study of the energetics of embryo formation. For the equilibrium, unsaturated system the evaporation flux may be calculated from the Kelvin relation (see Equation 20.89).
- A steady-state, i-independent, current (nucleation rate per unit volume) J is established.

Frenkel (1955) argued that the equilibrium cluster distribution takes the form

$$n_i = n_1 \exp\left(-\frac{\Delta G_i}{k_B T}\right) \tag{20.86}$$

where the free energy of an i-cluster is ΔG_i. The proportionality constant is taken to be the total number density of the bulk metastable state n_1 (i.e., the monomer number density, which is frequently denoted as the vapor number density n_{vap}), since it was assumed that there is no free energy change associated with the formation of a single-molecule cluster. The free energy of formation of an i-cluster is calculated by invoking the capillarity approximation, which is the fundamental assumption of CNT. Accordingly, the cluster free energy is determined by treating the cluster as an incompressible macroscopic spherical droplet with

macroscopic (bulk and surface) properties. A perfectly sharp interface is assumed to obtain a droplet free energy that depends on a volume and a surface term

$$\Delta G_i = -\frac{4\pi}{3} a_p^3 n_{\text{liq}} k_B T \ln S + 4\pi a_p^2 \sigma = -i k_B T \ln S + (36\pi)^{1/3} v_{\text{liq}}^{2/3} \sigma i^{2/3} \tag{20.87}$$

where the number of molecules in the droplet is $i = 4\pi a_p^3 n_{\text{liq}}/3$, n_{liq} is the bulk liquid number density, $S = p_{\text{vap}}/p_{\text{sat}}$ is the saturation ratio with p_{vap} the vapor pressure and p_{sat} the saturation pressure (over a flat surface), v_{liq} is the molecular volume in the liquid phase, $v_{\text{liq}} = 1/n_{\text{liq}}$, and σ is the macroscopic surface tension. The liquid number density is related to the liquid material density via $n_{\text{liq}} = \rho_l N_A/\mathfrak{M}$: a similar expression holds for the vapor number density. For a stable vapor phase (saturation ratio less than unity), the droplet free energy is a monotonically increasing function of the droplet radius. For $S > 1$ (metastable vapor phase), the volume term becomes negative. The competition between the negative volume contribution and the positive surface energy term generates a free energy maximum at the critical radius $a_p^\star$

$$a_p^\star = \frac{2\sigma v_{\text{liq}}}{k_B T \ln S} \tag{20.88}$$

Equation 20.88 determines the equilibrium radius of a droplet as a function of the saturation ratio. If rearranged and the saturation ratio is interpreted as the ratio of the vapor pressure at the surface of a spherical droplet p_{drop} to the saturation pressure far from the droplet p_{sat}, then

$$p_{\text{drop}}(a_p) = p_{\text{sat}} \exp\left(\frac{2\sigma v_{\text{liq}}}{k_B T a_p}\right) \tag{20.89}$$

Equation 20.89, known as the Kelvin equation, is a fundamental equation in the thermodynamics of aerosols, because it relates the vapor pressure of a droplet to the (saturation) vapor pressure above a planar interface of the bulk material p_{sat}. It shows that the vapor pressure above a droplet is higher than the vapor pressure above a flat surface, an effect that becomes significant for $d_p < 0.1\,\mu\text{m}$.

The nucleation current is obtained from Equation 20.84 by approximating it according to the previously summarized CNT assumptions. The equilibrium cluster distribution of Equation 20.86 is used. The current, then, is related to the sum of cluster equilibrium distributions times their respective surface areas, summed up to an arbitrarily large cluster size (see, e.g., Debenedetti, 1996). The discrete sum may be replaced by an integral and the clusters free energy of formation is expanded to second-order (an excellent approximation because the integrand is sharply peaked about the critical cluster) to give

$$J = j_{i^*} Z n_{i^*} \tag{20.90}$$

where

the first term j_{i^*} is the rate of arrival of single molecules to the critical droplet
the second factor Z is the so-called Zeldovich nonequilibrium factor
the last term n_{i*} is the equilibrium number concentration of critical nuclei

The rate of arrival of monomers is the product of the forward flux constant β (also known as the impingement rate per unit area), which is the single-molecule growth rate calculated from the kinetic theory of gases (with a unity accommodation coefficient), and the critical droplet surface area:

$$j_{i^*} = 4\pi\left(a_p^\star\right)^2 \beta = 4\pi\left(a_p^\star\right)^2 \frac{p_{\text{vap}}}{(2\pi m_{\text{mol}} k_B T)^{1/2}} \tag{20.91}$$

where $m_{\text{mol}} = \mathfrak{M}/N_A$ is the molecular mass of an impinging molecule. The Zeldovich nonequilibrium factor arises from number fluctuations in the critical cluster

$$Z = \frac{v_{\text{liq}} \sigma^{1/2}}{2\pi\left(a_p^\star\right)^2 (k_B T)^{1/2}} \tag{20.92}$$

The third term $n_{i^\star}$ is the equilibrium number concentration of critical nuclei, which is obtained from Equation 20.86 evaluated at the critical cluster. For completeness, note that the critical droplet-free energy expressed in terms of the critical radius is

$$\Delta G^\star = \frac{4\pi}{3}\left(a_p^\star\right)^2 \sigma \tag{20.93}$$

whereas the number of molecules in the critical cluster is

$$i^\star = \frac{32\pi v_{\text{liq}}^2 \sigma^3}{3(k_B T \ln S)^3} \tag{20.94}$$

Hence, the CNT expression for the nucleation rate per unit volume becomes

$$J_{\text{CNT}} = J_0^{\text{CNT}} \exp\left(-\frac{\Delta G^\star}{k_B T}\right) = \nu_{\text{liq}} n_{\text{vap}}^2 \left(\frac{2\sigma}{\pi m_{\text{mol}}}\right)^{1/2} \exp\left[-\frac{16\pi}{3}\frac{\sigma^3 v_{\text{liq}}^2}{(k_B T)^3 (\ln S)^2}\right] \tag{20.95}$$

where the number density in the vapor phase has been used, $n_{\text{vap}} = p_{\text{vap}}/(k_B T)$. The classical prefactor is often expressed in terms of n_{liq}, the bulk liquid number density,

$$J_0^{\text{CNT}} = \frac{n_{\text{vap}}^2}{n_{\text{liq}}}\left(\frac{2\sigma}{\pi m_{\text{mol}}}\right)^{1/2} \tag{20.96}$$

Note that the CNT expression is occasionally divided by the saturation ratio (Seinfeld and Pandis, 1998), a correction that arises from a different treatment of nucleation kinetics (see the following text for a discussion on consistency issues of CNT).

CNT is one of the most frequently used nucleation theories due to its simplicity and the availability of the required molecular data. Even though its predictions are not very accurate (usually they are accurate to 5–10 orders of magnitude), it provides a qualitative understanding of nucleation. It gives, however, reasonable results for the critical saturation ratio $S_c(T)$, the saturation ratio at which the nucleation rate is $J_{\text{nuc}}[S_c(T)] = 1\,\text{cm}^{-3}\,\text{s}^{-1}$. Two important conclusions can be drawn from comparisons of CNT predictions with experimental data (see Figure 20.2):

1. The isothermal dependence of the nucleation rate on the saturation ratio is well predicted. Theoretical predictions and experimental measurements of the slopes of ln J_{nuc} versus ln S are in reasonable agreement.
2. The temperature dependence of the rate is in considerable disagreement with experimental values: CNT consistently under predicts experimental rates at low temperature, whereas it may overpredict at high temperatures.

The CNT gas-to-liquid nucleation rate differs from the rate frequently used in bubble nucleation, as derived by Blander and Katz (1975), in the preexponential kinetic factor by a factor of $(n_{\text{liq}}/n_{\text{vap}})^2$. This difference stems from the calculation of the concentration of elementary vacancies in the liquid; for the gas-to-liquid transition, this concentration is identified to the monomer concentration, the concentration of the metastable vapor, see Equation 20.86. For bubble nucleation, the calculation of the concentration of elementary vacancies is not as straightforward. Nevertheless, both droplet and bubble nucleation rates are predicted to have an Arrhenius dependence on the critical cluster-free energy, a dependence that dominates the rate calculation.

The main limitation of CNT is the use of macroscopic (bulk and surface) thermodynamic properties to describe the critical droplet. It assumes a sharp interface, thereby neglecting the curvature dependence of the surface tension. The capillarity approximation, moreover, does not distinguish between metastability and instability, that is, it does not predict the existence of a spinodal curve along which the free energy

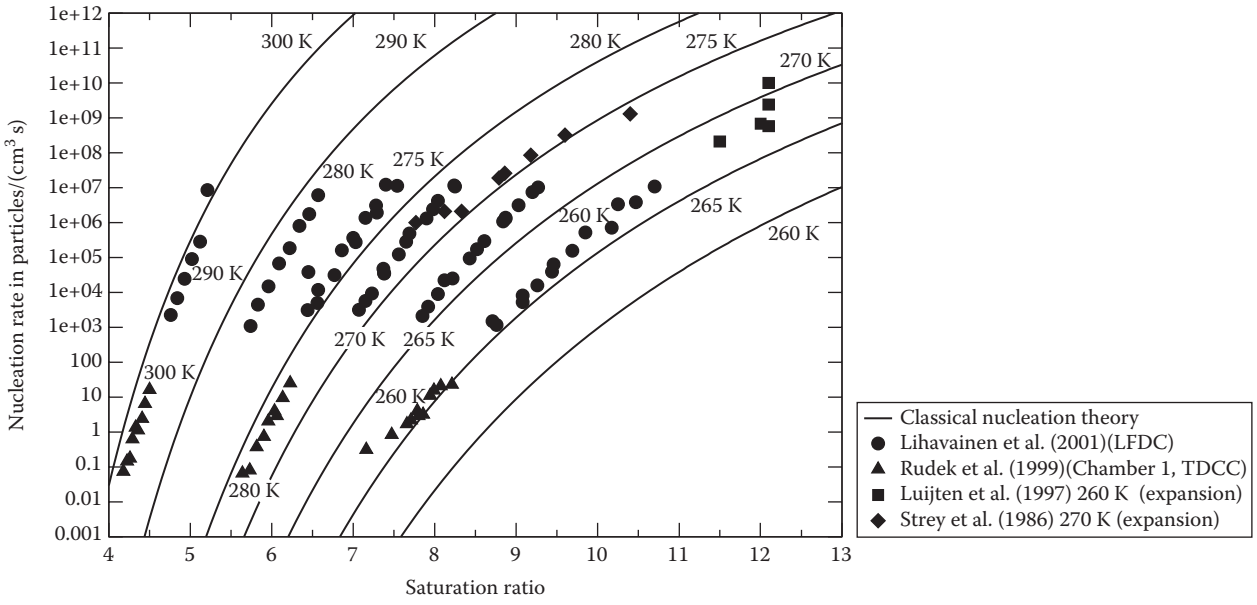

Figure 20.2

Experimental measurements of *n*-pentanol nucleation rates and CNT predictions. LFDC refers to laminar flow diffusion chamber (*n*-pentanol in helium), TDCC to thermal diffusion cloud chamber (*n*-pentanol in helium), and expansion either to pulse-expansion wave tube (Luijten et al. (1997), *n*-pentanol in helium) or to two-piston expansion chamber (Strey et al. (1986), *n*-pentanol in argon).

barrier vanishes and the decay process changes from nucleation to spinodal decomposition. Another important limitation of the classical derivation is the requirement that an equilibrium cluster distribution be established in the metastable state, allowing the use of microscopic reversibility to calculate the evaporative flux α, and thus leading to an equilibrium cluster distribution of the form shown in Equation 20.86.

The preexponential factor in Equation 20.86 is established by requiring that there is no free energy cost for the formation of a single-molecule cluster, $\Delta G_1 = 0$. However, the free energy change in the capillarity approximation does not vanish for $i = 1$, rendering CNT internally inconsistent (limiting inconsistency). The internally consistent classical nucleation theory (ICCT) (Girshick and Chiu, 1990) removes this inconsistency by requiring that $\Delta G_i = 0$ for monomers. As a result, the classical rate is multiplied by c/S, where c is a constant. It should be noted, however, that the physical basis of this correction is questionable, as is the requirement that the capillarity approximation be valid for monomers.

In addition, the CNT cluster distribution Equation 20.86 violates the law of mass action. Courtney (1961) suggested an equilibrium cluster distribution that satisfies the law of mass action, a modification that leads to the previously mentioned division of the CNT rate by the saturation ratio. Numerous other attempts have been made to make the classical theory internally consistent and to satisfy mass action (for a critical review, see Wilemski, 1995). However, all these attempts require consistency in CNT instead of a critical re-evaluation of the underlying assumptions of the theory.

CNT calculates the free energy of formation for a stationary droplet, thereby neglecting the effect of translational fluctuations on the cluster free energy and the nucleation rate. The effect of translational invariance on the rate (i.e., that the droplet may appear anywhere within the system volume) is not taken into consideration by CNT. Lothe and Pound (1962) proposed one of the most intriguing corrections to CNT: they argued that the translational and rotational degrees of freedom of a nucleating droplet are not properly accounted for in CNT. The additional terms they suggested increased theoretical predictions by 10^{18}. The so-called translation-rotation paradox resulted in a long-standing controversy.

Reiss and coworkers (see, e.g., Reiss and Kegel, 1996) emphasized the important relation between a proper counting of translational degrees of freedom and the mixing entropy in mesoscopic, continuum descriptions of nucleation phenomena. Recently, Reiss et al. (1997) suggested that the volume scale required to enumerate states for the calculation of the mixing entropy is the variance of volume fluctuations: a nucleating droplet may be identified as a physical object up to its volume fluctuations. Ford (1997), who used a detailed analysis of the statistical mechanics of molecular clusters, and Barrett (1997) suggested that the scaling

volume in the classical expression should be the molecular volume in the liquid phase. Instead, CNT implicitly assumes that the scaling volume is the molecular volume in the metastable vapor phase. Even though these attempts to resolve the paradox stem from different considerations and they are theoretically sound, they have not managed to improve significantly in comparison with experiments, even though in some cases improved temperature dependence was noted.

Drossinos and Kevrekidis (2003) presented a field-theoretic derivation of a correction to the nucleation rate that arises from the contribution of the translational degrees of freedom of a nucleating droplet (viewed as the translational eigenfunctions of the droplet) to the rate. They argued that the proposed correction is consistent with CNT. Their derivation provides a heuristic justification of the capillarity approximation starting from microscopic, molecular considerations. They concluded that the droplet free energy is modified by an additive mixing-entropy term. The additional contribution, which contains a logarithmic correction to the surface energy term, defines a scaling volume that depends on the range of the coarse-grained, attractive intermolecular interaction potential.

A number of phenomenological modifications of CNT are based on removing the assumption of a sharp interface. Dillman and Meier (1991) extended the work of Tolman on the dependence of the surface tension on the droplet radius through the so-called Tolman length and proposed

$$\sigma = \sigma_\infty \left(1 + c_1 i^{-1/3} + c_2 i^{-2/3}\right) \tag{20.97}$$

where

σ_∞ is the planar surface tension
i is the number of molecules in the i-cluster
c_1, c_2 are constants

Initial predictions greatly improved comparison with experiments, but Laaksonen et al. (1994) pointed out an inconsistency in the Dillman and Meier theory, which when corrected rendered theoretical predictions worse.

Gránásy, in a series of papers (see, e.g., Gránásy, 1997), developed the so-called diffuse interface theory where the finite interface thickness is taken into consideration. A new length scale is introduced to characterize the interface thickness, which can be calculated in terms of measurable quantities, as opposed to the determination of Tolman's length. The resulting model predicts reasonably well nucleation rates for nonane and toluene, but fails for more polar substances.

Ruckenstein and coworkers (see, e.g., Nowakowski and Ruckenstein, 1991) took a different approach by developing a kinetic theory of nucleation, thereby avoiding the equilibrium assumption of CNT. The theory is based on the calculation of the evaporation rate α_i at which a single molecule leaves an i-cluster. Their approach is based on a diffusion equation in energy space. The theory predicts nucleation rates higher than CNT, with more pronounced effects at high supersaturation ratios.

CNT refers to isothermal nucleation where latent heat release is neglected. Barrett (1994) considered nonisothermal nucleation by incorporating energy fluctuations of the critical cluster, but his results did not significantly improve agreement with experiments. Lazaridis and Drossinos (1997) reached a similar conclusion for binary nucleation.

20.4.1.2 Numerical Simulations

In addition to analytical studies of the nucleation process, computer simulations provide additional, difficult to obtain via analytical theories, information. Whereas most analytical theories require various approximations, molecular simulations provide a powerful tool to investigate the nucleation process at the microscopic level. Numerical simulations may be divided into two classes: *Monte Carlo* (MC) and *molecular dynamics* (MD) methods (Kalikmanov, 2013).

In MD simulations, the Newtonian equations of motion for a systems of interacting particles (be they, atoms, ions, molecules, or even spherical nanoparticles (Isella and Drossinos, 2010)) are numerically integrated in time. Time averages of quantities of interest (pressure, velocity, configurational or kinetic energy, etc.) are calculated, and, following the ergodic hypothesis, they are taken to be equal to ensemble averages. In MC methods, physical time is not present: simulations are not performed in physical space but in configurational space. As such, the results of MC simulations are ensemble averaged. MC movements are so constructed that the approach to the equilibrium state is relatively fast, rendering them a powerful tool to simulate systems

with high activation barriers; for such systems, MD simulations would require considerable (often prohibitive) computational times. The two approaches provide complementary information at the molecular level: MD simulations provide insights on the kinetics of the nucleation process, whereas MC methods on the thermodynamics of the process.

A noteworthy contribution to the calculation of the nucleation rate via MC simulations was made by Wedekind et al. (2007). They developed a method to analyze molecular and Brownian dynamics simulations of activated process based on the concept of mean first-passage time (MFPT). The method allows a precise determination of the rate at which an activation barrier is crossed, as well as the location of the transition state (critical cluster for nucleation processes). They analyzed the behavior of the MFPT $\tau(x_0;a,b)$ defined (in one dimension, with x the reaction coordinate) as the average elapsed time until the system, starting at x_0, leaves a prescribed domain $[a, b]$ for the first time. Whereas the MFPT is usually analyzed in terms of the reaction coordinate x_0 Wedekind et al. (2007) considered its behavior as a function of the end point b. This provides information on the average time the system takes to reach b for the first time; in particular, $\tau(b = x^*)$ is the average time needed to reach for the first time the transition state x^*, that is, the top of the activation barrier. They showed, by solving the appropriate Fokker–Planck equation by the steepest descent method, that for high activation barriers, the MFPT in the vicinity of the transition state (critical cluster) may be expressed as

$$\tau(b) = \frac{\tau_J}{2}\{1 + \mathrm{erf}[(b - x^*)c]\}, \tag{20.98}$$

where erf is the error function, $\mathrm{erf}(x) = 2/\sqrt{\pi}\int_0^x dx e^{-x^2}$, c is the local curvature at the top of the barrier and

$$\tau_J = \frac{1}{JV}. \tag{20.99}$$

Thus, the transition rate becomes the inverse of τ_J. For the case of nucleation processes, the (steady-state) nucleation rate (nucleated clusters/s) is $I = VJ = \tau_J^{-1}$ with V the system volume. By evaluating the MFPT from simulations of an activated process, and subsequent fitting of the results to Equation 20.98, many important parameters of the activated process may be obtained: the barrier crossing rate (nucleation rate $I = JV$), the location of the transition state (critical cluster) in the appropriate reaction coordinate, and the curvature at the top of the barrier. The method was applied successfully in a simulation of condensation of Lenard-Jones argon vapor.

20.4.1.3 Density Functional Theory

Density functional theory (DFT) is an alternative approach to phenomenological corrections to CNT. It is intermediate between the capillarity approximation and a purely microscopic theory, as the more rigorous attempts by Reiss and coworkers (Reiss et al., 1990, Senger et al., 1999) or modern computer simulations (Weakliem and Reiss, 1994, ten Wolde et al., 1996). The main idea of DFT as used in nucleation theory is to treat a nucleating droplet within a metastable vapor phase as an inhomogeneous fluid. Then, as is usually done in density functional theories, a free energy functional that depends on the nonuniform average density profile is postulated. The spatially inhomogeneous average density profile $\rho(\mathbf{r})$ is obtained by extremizing the free energy functional. In the grand canonical ensemble, where the number of molecules fluctuates, the critical nucleus is unstable with respect to growth or shrinkage. Equivalently, the matrix of second-order derivatives of the free energy functional with respect to the density has one negative eigenvalue corresponding to droplet growth or decay; the other nonzero eigenvalues are positive. The critical nucleus, thus, is a saddle point of the free energy functional that separates the metastable and stable phases. By introducing a spatially nonuniform density profile, DFT incorporates curvature effects on the surface tension. It can also be shown that it predicts the existence of a spinodal curve.

Cahn and Hilliard (1958, 1959), in their study of spinodal decomposition of a binary fluid, presented the first use of DFT in descriptions of phase transitions. They used a square-gradient approximation of the free energy functional, since during spinodal decomposition, average density changes are small in comparison to atomic dimensions. Oxtoby and coworkers pioneered the use of DFT in vapor-to-liquid nucleation. They extended the van der Waals theory of interfaces, also used by Cahn and Hilliard, by using liquid-state perturbation theory to obtain the Helmholtz free energy of the inhomogeneous fluid.

Oxtoby and Evans (1988) decomposed the Helmoltz free energy into a local, hard-sphere repulsive part and a nonlocal part that depends on the nonlocal attractive part of the interaction potential. The decomposition is based on liquid-state perturbation theory according to which equilibrium fluid properties may be related to a hard-sphere reference fluid with known equilibrium properties; the attractive intermolecular forces are then treated as a perturbation. The highly accurate Carnahan–Starling equation of state was used to determine the properties of the hard-sphere fluid. The grand canonical potential $\Omega[\rho]$ of the inhomogeneous system was accordingly written as

$$\Omega[\rho(\mathbf{r})] = \int d\mathbf{r} f_h[\rho(\mathbf{r})] - \mu \int d\mathbf{r}\rho(\mathbf{r}) + \frac{1}{2}\int\int d\mathbf{r}d\mathbf{r}'\rho(\mathbf{r})\rho(\mathbf{r}')V_{\text{att}}(|\mathbf{r}-\mathbf{r}'|) \tag{20.100}$$

where

$f_h(\rho)$ is the Helmoltz free energy density of a uniform hard sphere fluid of density ρ
μ is the chemical potential of the metastable vapor
$V_{\text{att}}(\mathbf{r})$ is the long-range attractive part of the intermolecular interaction potential

The attractive part has been modeled by, for example, the attractive Yukawa potential or the Lennard–Jones potential decomposed according to the Weeks–Chandler–Andersen perturbation theory. The critical nucleus profile is obtained by extremizing Equation 20.100 with respect to density variations. This procedure amounts to setting the functional derivative of the grand canonical potential to zero, $\delta\Omega(\rho)/\delta\rho(\mathbf{r}) = 0$. The resulting equation, known as the Euler–Lagrange equation, is

$$\mu_h[\rho(\mathbf{r})] = \mu - \int d\mathbf{r}'\rho(\mathbf{r}')V_{\text{att}}(|\mathbf{r}-\mathbf{r}'|) \tag{20.101}$$

with μ_h as the chemical potential of the hard-sphere reference fluid

$$\mu_h = \left.\frac{df_h(\rho)}{d\rho}\right|_T \tag{20.102}$$

Equation 20.101 has to be solved iteratively with the boundary condition that the density far away from the droplet becomes the metastable vapor density. As mentioned earlier, the nonuniform density profile is not a minimum but a saddle point of $\Omega[\rho]$, rendering the iteration process unstable. Oxtoby and Evans (1988) and Zeng and Oxtoby (1991a) suggested an iterative numerical procedure to calculate the saddle point configuration. It consists of an initial guess for the density profile that is substituted on the RHS of Equation 20.101 to obtain the hard-sphere chemical potential at each point, which in turn yields a new density profile and the iterative procedure continues. For a judicious initial guess, the iteration initially converges, allowing the determination of the critical nucleus density profile, but eventually, it diverges away from the saddle point. Once the density profile has been calculated, the nucleation barrier associated with the creation of the critical nucleus is obtained, $\Delta\Omega^*_{\text{DFT}} = \Omega(\rho_{\text{drop}}) - \Omega(\rho_{\text{vap}})$. Most DFT calculations proceed by determining the nucleation rate using $\Delta\Omega^*$ as calculated from DFT, and retaining the classical preexponential factor, $J_{\text{DFT}} = J_0^{\text{CNT}} \exp\left(-\Delta\Omega^*_{\text{DFT}}/k_BT\right)$.

Oxtoby and Evans (1988) noted significant nonclassical effects in that the DFT-calculated liquid density at the center of the droplet was found to differ significantly from either the liquid-state density or the coexistence density at the same chemical potential. Moreover, the nucleation barrier was found to be smaller than the barrier predicted by CNT, and it was found to vanish at the spinodal. A sensitive dependence of the nucleation barrier height (and, thus, of the nucleation rate) on the range of the attractive potential was observed.

DFT is a powerful technique for rigorous calculations of the free energy barrier to nucleation. It has been used extensively in bubble nucleation in superheated liquids, liquid nucleation in dipolar fluids, binary nucleation of liquids and bubbles, phase transitions in micropores, crystallization, and many other systems (for a recent review of the multiple uses of DFT, see Oxtoby, 2002). The studies of bubble nucleation (keeping as previously mentioned the CNT kinetic prefactor) showed that deviations from CNT are more dramatic than those calculated for droplet nucleation. Recently, a time-dependent DFT theory of fluids (Marini Bettolo Marconi and Tarazona, 1999) has been developed.

The calculation of the kinetic prefactor J_0 has received much less attention. Langer and Turski (1973) calculated it for a system close to the critical point using a hydrodynamic model, but their numerical results were not significantly different from those of CNT. Talanquer and Oxtoby (1994) using a dynamical DFT of gas–liquid nucleation concluded that the correction to the preexponential factor due to cluster translation is relatively small. Barrett (1997) used mean-field DFT to calculate the effect of cluster translation on the kinetic prefactor. He showed that the compensation for translational motion leads to a significant increase in the rate, an amount approximately equal to the ratio of liquid to vapor densities. Drossinos et al. (2001) combined DFT with field theoretic methods to calculate the effect of the droplet's translational eigenfunctions on the nucleation-rate prefactor by deriving an expression for their functional form (see, also, the discussion following Equation 20.108).

20.4.1.4 Nucleation Theorems

The derivation of nucleation theorems constitutes a significant recent development in nucleation theory. The first nucleation theorem was proposed by Kashchiev (1982) and later extended by Oxtoby and Kashchiev (1994), Ford (1997), and Bowles et al. (2001). It relates the derivative of the work of formation of the critical droplet with respect to the chemical potential in the metastable phase to the number of molecules in the nucleus

$$\left.\frac{\partial \Delta G^*}{\partial \mu}\right|_{V,T} = -(i^* - \bar{i}) \tag{20.103}$$

where

i^* is the total number of molecules within the volume occupied by the droplet

$\bar{i}$ is the number of molecules that would have occupied the same volume in the uniform metastable phase

Their difference gives the excess number of molecules in the critical droplet over those present in the same volume in the metastable vapor. For most cases of interest, the metastable vapor is dilute, and hence, the term $\bar{i}$ is neglected. The initial derivation required that the cluster surface energy be independent of the chemical potential. Oxtoby and Kashchiev (1994) generalized it to multicomponent nucleation, showing that it is a much more general result. Bowles et al. (2001) extended the nucleation theorem and concluded that it is more valid than the initial derivation had suggested.

The importance of the nucleation theorem becomes apparent when it is rewritten in a form that relates experimental quantities. The Arrhenius form of the nucleation rate

$$J_{\text{nuc}} = J_0 \exp\left(-\frac{\Delta G^*}{k_B T}\right) \tag{20.104}$$

combined with the nucleation theorem yields

$$i^* = \left.\frac{\partial k_B T \ln J_{\text{nuc}}}{\partial \mu}\right|_{V,T} - \left.\frac{\partial k_B T \ln J_0}{\partial \mu}\right|_{V,T} \tag{20.105}$$

Since the kinetic prefactor J_0 is weakly dependent on the chemical potential of the metastable phase, the correction to i^* is expected to be in the range from 0 to 1. Ford (1997) using a combination of statistical mechanics and population cluster dynamics showed that Equation 20.105 becomes

$$\left.\frac{\partial \ln J_{\text{nuc}}}{\partial \ln S}\right|_{V,T} = 1 + i^* \tag{20.106}$$

Typical values for i^* are 30–50 molecules. Thus, $i^* + 1 \approx i^*$, allowing the replacement of the RHS of Equation 20.106 by i^*, a form that is occasionally reported in the literature. Note that since the chemical potential derivative is taken at constant temperature, it has been replaced by a derivative with respect to $k_B T \ln S$. The nucleation theorem in the form of Equation 20.106 is extremely useful in the analysis of experimental results and computer simulations because the number of molecules in a critical cluster may be determined from the slopes of the logarithm of isothermal nucleation rates versus $\ln S$.

It is worth noting that CNT does not satisfy the first nucleation theorem, a violation that according to Ford (1997) stems from the neglect of translational corrections. As mentioned earlier, Section 20.4.1.1, in the capillarity approximation, the droplet-free energy is calculated for a droplet fixed within the system volume, thereby neglecting the mixing entropy associated with translational fluctuations of the cluster. Oxtoby and Kashchiev (1994) as well as Ford (1997), note that ICCT satisfies the nucleation theorem, but the agreement is considered fortuitous, since ICCT does not satisfy the second nucleation theorem.

Ford (1997) presented a second nucleation theorem that concerns the temperature dependence of the nucleation rate at constant supersaturation. In a sense, the second theorem is conjugate to the first. It is usually written as

$$\left.\frac{\partial \ln J_{\text{nuc}}}{\partial T}\right|_{\ln S} = \frac{1}{k_B T^2}\left[L_p - k_B T + E_x(i^*)\right] \tag{20.107}$$

where

L_p is the latent heat per molecule

$E_x(i^*)$ is the excess internal energy of the critical nucleus

Another recent development parallel to the use of nucleation theorems in the study of nucleation phenomena is the use of scaling relations for molecular properties of the critical cluster and the nucleation rate. McGraw and Laaksonen (1996) derived scaling relations for the number of molecules in the critical cluster and the nucleation barrier height. They argued that these scaling relationships constrain functional dependencies of departures from CNT. Thus, they may help in the construction of consistent phenomenological models. These scaling relations were later extended to bubble nucleation (Shen and Debenedetti, 2001).

20.4.1.5 Multicomponent Nucleation

Multicomponent nucleation is an important mechanism for new particle formation since it occurs even in mixtures of unsaturated vapors, as opposed to the unary (single-component) nucleation discussed earlier where supersaturation is required. Multicomponent nucleation is important in the atmosphere where various condensable species, for example, sulfuric acid and water, occur at relatively low concentrations. Langer (1969) proposed a general expression for the decay rate of a metastable state that can be used to calculate multicomponent nucleation rates. Under some general conditions, he showed that the nucleation rate I_{nuc} (not its density J_{nuc}) may be written as

$$I_{\text{nuc}} = \frac{\kappa}{2\pi} V J_{\text{tran}} \Omega' \exp\left(-\frac{\Delta\Omega^*}{k_B T}\right) \tag{20.108}$$

where, as before, $\Delta\Omega^*$ is the nucleation barrier (in the grand canonical ensemble) and κ, the so-called dynamical prefactor, is related to the initial growth rate of a droplet slightly greater than the critical size. The other terms constitute what is called the statistical prefactor: V is the system volume, Ω' is a generalization of the Zeldovich factor that contains contributions of Gaussian fluctuations about the uniform metastable and the spatially nonuniform droplet density profiles (see Equation 20.92 for the Zeldovich factor in unary nucleation, a correction that arises from number fluctuations in the critical cluster). The generalized Zeldovich factor may be viewed as a leading-order fluctuations correction to the droplet free energy. The prime in Ω' denotes that fluctuations corresponding to the translational eigenmodes of the droplet have been excluded. These fluctuations are treated separately to obtain the term VJ_{tran}, where J_{tran} is the Jacobian for the change of variables to the collective co-ordinates associated with the droplet's translational eigenfunctions. The complete expression is reported in Langer and Turski (1973), whereas an alternative formal expression that relates the nucleation rate to the imaginary part of the true system free energy is reported by Langer (1967, 1974). One of the main difficulties in using Equation 20.108 is the evaluation of the statistical prefactor.

The formal procedure introduced by Langer (1969) to solve multidimensional Fokker–Planck equations that arise in nucleation problems, also used to obtain the nucleation rate Equation 20.108, has proven to be useful and versatile. It has been used to calculate the effect of energy fluctuations on the nucleation rate (Barrett, 1994, Lazaridis and Drossinos, 1997), to calculate the contribution of translational fluctuations to the rate (Drossinos et al., 2001), and to calculate nucleation rates in ternary systems (Lazaridis, 2001).

Trinkaus (1983) presented a slightly different expression for the nucleation rate in multicomponent systems. His result, which does not consider the contribution of the droplet translational eigenmodes, is

$$J_{\text{nuc}} = \frac{|\kappa|/\pi}{\sqrt{-\det(\ddot{D}/\pi)}} n_{\text{tot}} \exp\left(-\frac{\Delta G^\star}{k_B T}\right) \tag{20.109}$$

where

$n_{\text{tot}} \exp(-\Delta G^\star/k_B T)$ is the number density of critical clusters

$\ddot{D}$ is the matrix of second-order derivatives of the droplet-free energy with respect to the number of molecules n_i of each species evaluated at the saddle point,

$$D_{ij} = \frac{1}{2k_B T} \frac{\partial \Delta G}{\partial n_i \partial n_j}\bigg|_\star \quad (i,j = 1,\ldots,m) \tag{20.110}$$

m being the number of species. The factor κ is the negative eigenvalue of the product of a growth tensor, a multicomponent generalization of Equation 20.91, times $\ddot{D}$. Note that the determinant of $\ddot{D}$ is negative since the critical nucleus corresponds to a saddle point in number-composition space (see the discussion on DFT in Section 20.4.1.3). This expression has been used to calculate binary nucleation rates in the sulfuric acid–water system (Noppel et al., 2002) and in ternary nucleation of sulfuric acid–ammonia–water (Napari et al., 2002).

For the specific case of two-component nucleation, Reiss (1950) presented the first rigorous binary nucleation theory. He argued that the nucleation rate should be calculated at the saddle point in droplet-composition space by following a steepest descent path. Stauffer (1976) noted that the steepest-descent path resulted in an inconsistent evaluation of the steady-state nucleation rate; instead, he proposed a self-consistent method. Stauffer's result is the most frequently used expression to calculate binary nucleation rates. More recently, Kevrekidis et al. (1999) used the method introduced by Langer (1969) to obtain the rate. Their result is formally identical to Stauffer's result, but much easier to evaluate. Accordingly, the binary nucleation rate for nonassociated vapors is

$$J_{\text{nuc}} = \frac{n_{\text{vap}} \exp\left(-\Delta G^\star/k_B T\right)}{2\left(D_{12}^2 - D_{11}D_{22}\right)^{1/2}} \left[D_{11}R_{11} + D_{22}R_{22} - \sqrt{(D_{11}R_{11} - D_{22}R_{22})^2 + 4D_{12}^2 R_{11}R_{22}}\right] \tag{20.111}$$

where

$n_{\text{vap}} = n_{\text{vap},1} + n_{\text{vap},2}$ is the total number density of condensable vapors

R is the droplet growth tensor

As in unary nucleation, the growth matrix (which is diagonal for nonassociated vapors) is expressed as the product of the droplet surface area and the impingement rate of a molecule of species i, $R_{ij} = \delta_{ij}\beta_i 4\pi(a_p^\star)^2$, with δ_{ij} as the Kronecker symbol (see Equation 20.91 for the corresponding expression for unary nucleation). The impingement rate (per unit area) β_i may be calculated as summarized in the CNT analysis of the condensation flux, Equation 20.91, to give $\beta_i = p_i/(2\pi m_{\text{mol},i} k_B T)^{1/2}$ where p_i is the partial vapor pressure of species i.

Similar to unary nucleation, the free energy barrier in the capillarity approximation (cf. Equation 20.93) is expressed as

$$\Delta G^\star = \frac{4\pi}{3}\left(a_p^\star\right)^2 \sigma \tag{20.112}$$

where

$a_p^\star$, the radius of the (spherical) critical droplet

σ, the droplet surface tension, are functions of the composition of the droplet

According to the revised classical theory, which distinguishes between surface and interior droplet compositions as if the droplet were macroscopic (Wilemski, 1984, 1987), the Gibbs–Thomson equation can be

solved for the critical radius and composition. Accordingly, the bulk composition x of the critical cluster, in particular, the mole fraction of component 2 in the bulk of the droplet ($x = n_2/(n_1 + n_2)$ with n_i as the number of moles of species i in the bulk interior), is found by solving

$$\nu_{\text{sol},1}\Delta\mu_2 = \nu_{\text{sol},2}\Delta\mu_1 \tag{20.113}$$

where

$\nu_{\text{sol},i}$ is the partial molecular volume in the solution droplet of species i (i = 1,2)
$\Delta\mu_i = \mu_i^{\text{liq}} - \mu_i^{\text{vap}} = -k_B T \ln S_i$ the chemical potential difference

The critical radius is

$$a_p^\star = \frac{-2\sigma\bar{\nu}_{\text{sol}}}{(1-x)\Delta\mu_1 + x\Delta\mu_2} \tag{20.114}$$

where the molecular volume of the solution $\bar{\nu}_{\text{sol}} = (1-x)\nu_{\text{sol},1} + x\nu_{\text{sol},2}$ has been expressed in terms of the partial molecular volumes in the liquid–solution droplet.

An alternative approach to binary nucleation was taken by Zeng and Oxtoby (1991b), who developed a DFT for gas–liquid nucleation in binary fluids.

20.4.1.6 Heterogeneous Nucleation

In the presence of a solid substrate, for example, an aerosol particle, the surface provides an interface upon which the new phase may nucleate. The surface limits the extent of penetration in the metastable region; thus, heterogeneous nucleation upon insoluble particles takes place at lower saturation ratios than homogeneous nucleation. The Kelvin equation, Equation 20.89, still governs whether a nucleated cluster will grow or shrink. In the atmosphere, where saturation ratios are low, most nucleation is heterogeneous on already existing particles, for example, on cloud condensation nuclei.

As in the case of homogeneous nucleation, the heterogeneous nucleation rate (nucleated clusters/s) depends on the free energy of formation of the heterogeneously nucleated cluster $\Delta G_{\text{het}}^\star$ through the Arrhenius form

$$I_{\text{het}} = I_{\text{het}}^0 \exp\left(-\frac{\Delta G_{\text{het}}^\star}{k_B T}\right), \tag{20.115}$$

where I_{het}^0 is a kinetic prefactor, and the superscript star refers to quantities evaluated at the critical cluster. Note the difference between the heterogeneous nucleation rate I_{het} discussed in this section and the homogeneous nucleation rate per unit volume (nucleation current) J discussed earlier. The free energy of formation of a heterogeneously nucleated cluster is at most equal to the free energy of formation of a homogeneously nucleated droplet, $\Delta G_{\text{hom}}^\star$. The modification of the free energy of formation due to a preexisting surface is expressed through a multiplicative factor f_g

$$\Delta G_{\text{het}}^\star = f_g(\cos\theta)\Delta G_{\text{hom}}^\star. \tag{20.116}$$

The factor f_g arises from geometric considerations: it is a function of the contact angle θ between the nucleating cluster and the surface. The contact angle varies from 0 (perfect wetting) to 180° (no surface effect), whereas the geometric factor varies from 0 to 1. For water nucleation, the solid is considered hydrophobic or hydrophilic, depending on whether the contact angle is greater or less than 90°. At bulk (mechanical) equilibrium, the contact angle is given by Young's equation (Seinfeld and Pandis, 1998)

$$m \equiv \cos(\theta) = \frac{\sigma_{vl} - \sigma_{sl}}{\sigma_{vl}}, \tag{20.117}$$

where σ_{ij} are the surface tensions between the various phases: vapor (v), liquid (l), and solid (s).

The geometric factor for a nucleated cluster that forms a liquid cap onto the surface of a seed particle of radius R_p is (Fletcher, 1958)

$$f_g(\cos\theta)=\frac{1}{2}\left[1+\left(\frac{1-X\cos\theta}{g}\right)^3+X^3\left(2-3\left(\frac{X-\cos\theta}{g}\right)+\left(\frac{X-\cos\theta}{g}\right)^3\right)+3X^2\cos\theta\left(\frac{X-\cos\theta}{g}-1\right)\right], \quad (20.118)$$

with

$$X=\frac{R_p}{a_p^\star}, \quad g=\sqrt{1+X^2-2X\cos\theta}. \quad (20.119)$$

As before $a_p^\star$ is the critical radius of the nucleated cluster. A contact angle of 180° indicates no affinity of the condensing vapor for the particle, the vapor nucleates homogeneously: $f_g(\theta=\pi)=1$. At smaller contact angles, the seed reduces the free energy activation barrier [$f_g(\theta<\pi)<1$]. The higher the affinity of the vapor for the particle, the smaller the contact angle is (smaller f_g) and the smaller the free energy barrier. In the limit of a zero contact angle (perfect wetting), the cluster forms a film onto the surface of the particle seed. For perfect wetting, there is no activation barrier for particle growth [$f_g(\theta=0)=0$] if the size of the particle is larger than the critical cluster size $a_p^\star$. However, if the particle radius is smaller than the critical cluster size, nucleation becomes again an activated process. Specifically, the geometric prefactor for perfect wetting ($\theta=0$) reduces to (Giechaskiel et al., 2011)

$$f_g=\begin{cases}0, & \text{for } X>1\,(R_p\geq a_p^\star)\\ (1-X)^2(1+2X), & \text{for } X\leq 1\,(R_p\leq a_p^\star)\end{cases} \quad (20.120)$$

In the limit of a flat surface, $R_p\to\infty$ the geometric factor evaluates to

$$f(m)=\frac{1}{4}(2+m)(1-m)^2. \quad (20.121)$$

Inherent in the derivations that lead to the previous equations are the assumptions that the effect of the line tension along the interface between the liquid cap and the seed particle is neglected, and that the surface tension is independent of cluster curvature. These assumptions, in conjunction with the use of macroscopic quantities (as required by CNT), render the contact angle the macroscopic contact angle θ_∞. Their removal leads to additional terms in the activation free energy barrier. We shall consider only the terms that arise from the line tension, neglecting the curvature dependence of the surface tension (in the spirit of CNT).

Fletcher's (1958) initial analysis did not consider the line tension τ formed at the circumference of the cluster cap where the three phases (particle seed, vapor, and cluster) coexist. Inclusion of line-tension effects modifies the critical cluster free energy of formation and contact angle (Lazaridis, 1993)

$$\Delta G_{\text{het}}^\star=f_g(\cos\theta)\Delta G_{\text{hom}}^\star-\frac{2\tau\pi R_p(1-\cos\varphi)}{\tan\varphi}+2\pi R_p\tau\sin\varphi, \quad (20.122)$$

with the associated change of the contact angle

$$\cos\theta=\cos\theta_\infty-\frac{\tau}{\sigma_{gl,\text{planar}}R_p\tan\varphi}, \quad (20.123)$$

where φ is the angle formed between the circumference of the cap and the center of the particle seed. In the limit of negligible line tension, the contact angle does not depend on the particle size, becoming equal to the macroscopic contact angle.

Geometric considerations show that φ is related to the contact angle through (Mamakos et al., 2013)

$$\tan\varphi = \frac{a_p^\star \sqrt{1-\cos^2\theta}}{R_p - a_p^\star \cos\theta}. \tag{20.124}$$

Equations 20.123 and 20.124 allow the calculation of the microscopic contact angle and, therefore, the calculation of the free energy of formation of the critical cluster. The critical radius is independent of the line tension (Lazaridis, 1993). Typical values of the line tension are in the range $[10^{-12}–10^{10}]$ Nt, as determined by studies of the shape of sessile droplets on solid surfaces near the contact line. The line tension can be either positive of negative. Note, however, that measurement of the line tension is notoriously difficult due to its extreme smallness (see also, Hienola et al., 2007).

As in the case of homogeneous nucleation, the nucleation rate is primarily determined by the free energy barrier. It is, thus, sufficient to calculate the kinetic prefactor to an accuracy of one or two orders of magnitude. Following the approach used in homogeneous nucleation, the prefactor may be written as the product of three terms (see also, Equation 20.90):

$$I_{\text{het}}^0 = R_{\text{grow}}^{\text{het}} Z_{\text{het}} \text{F}\,, \tag{20.125}$$

the cluster growth rate $R_{\text{grow}}^{\text{het}}$, the Zeldovich nonequilibrium factor Z_{het}, and a quantity F that, for homogeneous nucleation, is the product of a number concentration and the system volume. The critical cluster growth rate is obtained by considering growth by collisions with single-vapor molecules, neglecting growth by surface diffusion, and assuming that the exposed surface area of the critical cluster is approximately the surface area of the vapor–liquid interface: under these conditions, it equals j_{i^*} defined in Equation 20.91. The Zeldovich nonequilibrium factor Z_{het} arises from number fluctuations in the critical cluster that may cause it to shrink. It is frequently approximated by the homogeneous nucleation factor (Equation 20.92).

The evaluation of F is not as straightforward as in homogeneous nucleation. A frequently used approximation is $F = N_{\text{ads}} A_{\text{ads}}$, where N_{ads} is the total number of molecules adsorbed per unit particle area and A_{ads} is the available surface area for adsorption per particle (Hamill et al., 1982); thus, F becomes the number of adsorbed molecules per particle. The surface concentration of adsorbed molecules is $N_{\text{ads}} = \beta_{\text{ads}} \tau_{\text{ads}}$ where β_{ads} is the collision rate of vapor molecules per unit particle surface and τ is the average time an adsorbed vapor molecule remains on the particle surface (Lazaridis et al., 1991, Wagner et al., 2003, Winkler et al., 2008). A frequently used approximation is $\beta_{\text{ads}} = \beta$, defined in Equation 20.91. The residence time of an adsorbed molecule on the surface is taken to be $\tau_{\text{ads}} = \tau_{\text{ads},0} \exp(E_{\text{lat}}/R_g T)$, where E_{lat} is the heat of adsorption, taken to be the latent heat of condensation. The characteristic time scale $\tau_{\text{ads},0}$ is approximately the inverse vibrational frequency of two harmonically bound molecules $\tau_{\text{ads},0} = 2\pi m_\mu^{1/2} (d^2 V/dr^2)^{-1/2}$, where V is the intermolecular interaction potential and m_μ is the reduced mass. As an example, we present characteristic values for *n*-butanol, the condensing fluid in condensation particle counters, particle counters that detect and count aerosol particles through heterogeneous nucleation on *n*-butanol and subsequent condensational growth. The *n*-butanol Lennard–Jones potential with $\varepsilon/k_B = 593.06$ K and $\sigma_{LJ} = 5.645$ Å leads to $\tau_{\text{ads},0} = 1.29 \times 10^{-12}$ s (Giechaskiel et al., 2011), a value of the same order of magnitude as previously reported for *n*-propanol (Wagner et al., 2003).

Hamill et al. (1982) suggested that the available surface area for adsorption per particle be taken the surface area, a choice that gives the maximum nucleation rate $A_{\text{ads}} = 4\pi R_p^2$. This approximation allows the formation of multiple clusters per particle. Accordingly, the heterogeneous nucleation rate becomes (see, also, Winkler et al., 2008)

$$I_{\text{het}} \equiv I_{\text{het}}^0 \exp\left(-\frac{\Delta G_{\text{het}}^\star}{k_B T}\right) = 4\pi R_p^2 R_{\text{grow}}^{\text{het}} Z N_{\text{ads}} \exp\left(-\frac{\Delta G_{\text{het}}^\star}{k_B T}\right). \tag{20.126}$$

Due to the Arrhenius dependence of the nucleation rate on the free energy of formation of the critical cluster, its accurate determination is more important than a precise calculation of the kinetic prefactor. Fletcher (1958) suggested that the constant value $I_{\text{het}}^0 \approx 4\pi R_p^2 10^{25}$ (particle diameter expressed in cm) would provide a reasonable approximation for most cases.

Heterogeneous nucleation is intimately related to particle activation, a process where by a stable aerosol particle starts to grow rapidly by condensational growth. Particle activation determines the stability of atmospheric aerosol particles and it specifies whether seed particles will grow to become cloud condensation nuclei (Pruppacher and Klett, 1997). Moreover, particle activation determines the counting efficiency of particle instruments like the condensation particle counter, where submicron particles grow to optically measurable supermicron sizes.

The mechanism that determines whether and how a particle activates depends on the relative chemical composition and affinity of the condensing vapor for the pre-existing seed particle. For particles insoluble in the condensing vapor, a heterogeneous nucleated cluster forms on the surface of the seed, with subsequent rapid condensational growth of the condensed phase (determined by the Kelvin equation). The rate of particle activation is specified by the heterogeneous nucleation rate, a process that is usually activated, as discussed. If the seed particle and the condensing vapor are identical, the seed particle grows immediately via condensational growth if the condition for the Kelvin equation is satisfied. If the particle is a solution droplet (or it consists of an insoluble core covered by a soluble coating), or it is soluble in the vapor, then Köhler theory, discussed in Section 20.4.1.7, determines whether seed particle will activate (Seinfeld and Pandis, 1998). These observations become quantitative via the activation probability $P_d(t)$.

Let the number concentration of inactivated particles of diameter d_p be $N_d(t)$. In the presence of a condensable vapor, it changes as (Kalikmanov, 2013, Mamakos et al., 2013)

$$\frac{dN_d(t)}{dt} = -k_{\text{act}} N_d(t), \tag{20.127}$$

where k_{act} is the activation rate constant (nucleated clusters/s) that depends on the chemical composition of the seed particles and on properties of the vapor. The activation probability $P_d(t)$ is the ratio of the concentration of activated particles to their initial concentration $N_{d,in}$,

$$P_d(t) = \frac{N_{d,in} - N_d(t)}{N_{d,in}} = 1 - \exp(-k_{\text{act}} t)\cdot \tag{20.128}$$

The activation probability gives the probability that at least one seed particle would activate to growth during time t. For large number of events, it gives the ratio of activated seed particle to their initial number (at constant volume): for this reason, it is also called nucleation probability, the quantity measured in heterogeneous nucleation experiments (Wagner et al., 2003). The onset condition for heterogeneous nucleation is usually taken to occur at $P_d = 0.5$. Irrespective of the activation mechanism, particles are considered to be activated once their activation probability is greater or equal to 0.5.

The activation rate constant may be calculated by thermodynamic arguments, as in Kelvin and Köhler theories discussed in Section 20.4.1.7, or by kinetic arguments, as in heterogeneous nucleation theories (Giechaskiel et al., 2011). According to thermodynamic theories, that activation rate constant is

$$k_{\text{act}} = \begin{cases} 0 & \text{for } S < S_c \\ \infty & \text{for } S > S_c \end{cases}, \tag{20.129}$$

where the saturation ratio of the ambient vapor S is the ratio of the vapor pressure at the surface of a droplet to its saturation pressure over a planar interface. The critical saturation ratio S_c is given either by Kelvin theory, or Köhler theory and its variants, or multilayer adsorption theory. Thermodynamic theories are not stochastic, since particles are either all activated ($k_{\text{act}} = \infty$, $P_d = 1$) or not activated ($k_{\text{act}} = 0$, $P_d = 0$): the activation probability is independent of the characteristic time.

For kinetic theories, the activation rate constant is the heterogeneous nucleation rate, $k_{\text{act}} = I_{\text{het}}$. Since activation is considered to occur when the activation probability is $P_d \geq 0.5$, the critical activation rate constant is $k_{\text{act},c} = \ln(2)/t = 7\,\text{s}^{-1}$ for $t = 0.1$ s: activation occurs for $k_{\text{act}} \geq k_{\text{act},c}$. Thus, the time t in Equation 20.128 is relevant only for kinetic theories: it is, approximately, the time associated with heterogeneous nucleation of the supersaturated vapor. The nucleation time scale has been chosen from a few milliseconds to 1000 s (Lazaridis et al., 1992, Kulmala et al., 2001, Wagner et al., 2003). An alternative way to determine the activation probability without introducing a characteristic time is to specify a nucleation threshold: Porstendörfer et al. (1985) suggested $k_{\text{act},c} = I_{\text{het}}^{\text{threshold}} = 10^2\,\text{s}^{-1}$.

20.4.1.7 Thermodynamics of Aqueous Droplets

According to the Kelvin relation, Equation 20.89, a pure solvent droplet is in unstable equilibrium: a small perturbation in the form of an infinitesimal droplet radius change would cause the droplet to shrink or grow. However, a solution droplet may be stabilized due to solute vapor-pressure lowering.

For the specific case of an ideal, dilute water solution containing a fixed amount of solute, the vapor pressure of the solution droplet is (Rogers and Yau, 1989)

$$\ln\left[\frac{p_1(d_p)}{p_{\text{sat},1}}\right] = \frac{4\sigma_1\overline{v}_1}{R_u T d_p} - \frac{6n_2\overline{v}_1}{\pi d_p^3} \tag{20.130}$$

where the subscript 1 refers to water (the solvent) and 2 to the solute, and $p_{\text{sat},1}$ is the pure water vapor pressure above a planar, water surface (i.e., a pure-solvent surface). The number of moles of solute is denoted by n_2, and $\overline{v}_1$ is the molar volume of water in the solution. For a dilute solution, the molar volume of water may be taken to be the molar volume of pure water, $\overline{v}_1 \approx \mathfrak{M}_1/\rho_1$. Similarly, to a good approximation, the solution surface tension may be taken to be independent of concentration and equal to the water surface tension.

Equation 20.130, referred to as the Koehler equation or curve, is the fundamental equation of the thermodynamics of aqueous droplets. It combines the two primary effects that determine the vapor pressure above a liquid droplet: the Kelvin effect that increases the pressure and the solute effect that decreases it. Since the two effects have different dependencies on the droplet diameter (and different signs), the curvature (Kelvin) effect behaves as d_p^{-1} and the solute effect as d_p^{-3}, a critical droplet diameter exists. For small droplets, the solute effect dominates, whereas for large droplets, the dominant effect is the Kelvin effect. Stability arguments show that droplets in the ascending part of the Koehler curve (d_p less than the critical droplet diameter) are in stable equilibrium with their environment, whereas those in the descending part (d_p greater that the critical droplet) are in unstable equilibrium. Hence, the Koehler equation gives the wet droplet diameter as a function of saturation ratio. It is frequently used to determine the stability of atmospheric particles.

The saturation ratio S_c of a particle at the critical diameter, obtained by evaluating Equation 20.130 at the critical droplet diameter, is an important particle property. If the ambient saturation ratio S is lower than S_c, droplets of diameter less than the critical droplet diameter are in stable equilibrium, whereas larger droplets are in unstable equilibrium (since the Kelvin effect dominates). If $S > S_c$, no stable equilibrium particle size exists: droplets will grow indefinitely as long as the inequality $S > S_c$ holds. Atmospheric particles for which $S_c < S$ are said to be activated, and they start growing rapidly, becoming cloud or fog droplets (Seinfeld and Pandis, 1998), as discussed in Section 20.4.1.6, Equation 20.129.

20.4.2 Growth

In the presence of supersaturation ($p_{\text{vap}} > p_{\text{sat}}$), preexisting aerosol particles or newly generated particles (via homogeneous nucleation) grow. Condensation or evaporation is driven by the pressure difference between the ambient vapor pressure and the vapor pressure at the surface of the particle: the direction of net vapor flux (evaporation or condensation) depends on their relative magnitude. Since latent heat is released or absorbed at the particle surface during these processes, the treatment of particle growth or shrinkage requires considerations of heat and mass transfer between the particle and the ambient gas mixture. Isothermal conditions prevail when the heat of vaporization may be neglected; otherwise, heat and mass transfer should be considered simultaneously.

Clement (1985) presented a general treatment of heat and mass transfer and their coupling in vapor–gas mixtures. He argued that in addition to the Lewis number, the ratio of the rate of heat transport by conduction to the rate of mass transport by diffusion, another dimensionless number, the surface condensation number, is useful in heat- and mass-transfer processes. The condensation number is defined as the ratio of the conductive heat current to the latent heat carried by the mass current at the surface. The importance of the Lewis number in nucleation experiments has been discussed by, among others, Housiadas et al. (2002).

Chemical reactions may also lead to particle growth. Growth laws, that is, laws that express the rate of change in particle size as a function of particle size and chemicophysical properties of the aerosol system, may be transport or reaction limited. If growth is limited by gas-phase transport, the growth law is transport limited; otherwise, it may be surface-reaction or volume-reaction controlled. Moreover, if growth depends on surface reactions and the reaction rate is fast with respect to transport, the growth law is still determined by gas-phase transport. Surface reactions will lead to growth if the reaction products accumulate at the surface. When the surface reaction is slow, it is frequently assumed that the gas phase concentration of the reacting

species near the surface is the same as the bulk concentration far away from the particle. Volume reaction–controlled growth refers to growth that depends on the conversion of a dissolved species to a condensed phase species. Reaction-controlled growth will be only briefly mentioned herein.

For simplicity, only diffusional growth, primarily in the continuum regime, will be considered in this section: other smaller additional fluxes due to Stefan flow, thermal diffusion, and the Dufour effect are discussed in Kulmala and Vesala (1991).

20.4.2.1 Single-Particle Growth

Isothermal, steady-state growth rates of a single spherical particle in a stagnant gas are presented. Diffusional processes toward a moving particle are discussed in Hindy and Brock (1970). In the continuum regime, the vapor condensation rate (expressed in molecules per second) toward a spherical particle of the same composition is calculated from the steady-state diffusion equation ($\nabla^2 n = 0$ around a sphere) to be

$$J = \frac{2\pi d_p \mathfrak{D}}{k_B T}(p_\infty - p_{\text{sur}}) \tag{20.131}$$

where

$p_\infty = p(T_\infty)$ is the ambient vapor pressure
p_{sur} is the vapor pressure at the surface of the particle

For $p_\infty > p_{\text{sur}}$, the droplet grows, whereas for $p_\infty < p_{\text{sur}}$, the droplet shrinks. The diffusional flow toward a spherical particle and the associated temperature change were first derived by Maxwell (1890) in an article in Encyclopedia Britannica on the theory of the wet-bulb thermometer. The theory of steady-state growth of a spherical particle in the continuum regime is known as Maxwell theory.

In the molecular regime, the net condensation rate (molecules per second) is obtained from kinetic theory to be

$$J = \frac{\alpha\pi d_p^2}{(2\pi m_{\text{mol}} k_B T)^{1/2}}(p_\infty - p_{\text{sur}}) \tag{20.132}$$

where α is the accommodation coefficient or sticking probability ($0 \le \alpha \le 1$). It gives the fraction of incident molecules that are adsorbed. A value of unity means that once a vapor molecule hits the surface, the probability of sticking is unity. The accommodation coefficient may depend on whether evaporation or condensation is considered and its value is determined experimentally.

The calculation of the steady-state flow of vapor molecules toward a spherical droplet in the transition regime requires the solution of the Boltzmann equation. In the absence of a general solution, a number of approximations based on the so-called flux-matching techniques (introduced by Fuchs, 1964) have been proposed. These techniques require matching of the continuum expression with the kinetic at a given distance from the particle surface. For an extensive presentation of the various interpolation formulae, see, for example, Seinfeld and Pandis (1998). The most frequently used interpolation formula was proposed by Fuchs and Sutugin (1971):

$$f_{FS}(\lambda_g, d_p) = \frac{1 + 2\lambda_g/d_p}{1 + 3.42\lambda_g/d_p + 5.33(\lambda_g/d_p)^2} \tag{20.133}$$

where λ_g is the mean free path of the vapor species (see Equation 20.150). Thus, the vapor condensation rate becomes

$$J = \frac{2\pi d_p \mathfrak{D}}{k_B T} f_{FS}(\lambda_g, d_p)(p_\infty - p_{\text{sur}}) \tag{20.134}$$

Equation 20.134 is approximate in that it reproduces the continuum expression, but in the free molecular regime, it gives the kinetic expression multiplied by approximately 1.2 (for $\alpha = 1$).

The previous expressions may be converted into transport-limited growth laws by performing a mass balance on the growing or evaporating particle. Since the rate of change of the number of molecules in a particle equals the total rate of condensing or evaporating molecules,

$$\frac{dv}{dt} = \frac{2\pi \mathfrak{D} d_p v_{\text{liq}}}{k_B T} f_{FS}(\lambda_g, d_p)(p_\infty - p_{\text{sur}}) \tag{20.135}$$

where v_{liq} is the molecular volume of the condensing species ($v_{\text{liq}} = 1/n_{\text{liq}}$ when expressed in terms of the condensed-phase number density). In Equation 20.135, the accommodation coefficient has been set to unity. Growth laws are frequently used for the rate of change of particle radii,

$$\dot{a}_p = \frac{\mathfrak{D} v_{\text{liq}}}{a_p k_B T} f_{FS}(\lambda_g, d_p)\left(p_\infty - p_{\text{sur}}\right) \tag{20.136}$$

For surface reaction growth, if the surface reaction rate is slow compared to transport, the concentration of the reacting species at the particle surface is taken approximately equal to the concentration far away from the particle. The growth law becomes

$$\frac{dv}{dt} = \frac{\alpha \pi d_p^2 v_{\text{liq}}}{(2\pi m_{\text{mol}} k_B T)^{1/2}} p_\infty \tag{20.137}$$

where α, the fraction of effective collisions, is usually much less than unity. A summary of limiting growth laws for gas-to-particle conversion is presented in Friedlander (2000).

Equation 20.135 or 20.136 may be used to calculate the change of mass of a particle if the appropriate expression for the vapor pressure at the particle surface is used. As argued in Section 20.4.1.7, cf. Equation 20.130, the vapor pressure above a droplet depends on the curvature and, for a solution droplet, on the amount of solute present. For small liquid droplets, the exponential terms are usually expanded to obtain (the notation is explained in the discussion following Equation 20.130)

$$\frac{p_{\text{sur}}(T)}{p_{\text{sat}}(T)} = 1 + \frac{4\sigma_1 \bar{v}_1}{R_u T d_p} - \frac{6 n_2 \bar{v}_1}{\pi d_p^3} \tag{20.138}$$

As mass transfer continues, the particle temperature changes due to latent heat release or absorption. The growth rate is then obtained by solving the coupled equations for heat and mass transfer. In the continuum regime, the particle temperature is determined from the steady-state heat conduction equation. Mason (1971) introduced an analytical approximation to the two coupled equations for the rate of growth of a droplet by condensation (see, also, Rogers and Yau, 1989). He proposed

$$\dot{a}_p = \frac{1}{a_p}\left(\frac{S-1}{f_{\text{mass}} + f_{\text{heat}}}\right) \tag{20.139}$$

where $S = p_\infty / p_{\text{sat}}(T_\infty)$ is the ambient saturation ratio. The term f_{mass} represents the contribution associated to vapor diffusion, and thus, it is related to the continuum growth law presented in Equation 20.136

$$f_{\text{mass}} = \frac{k_B T_\infty}{v_{\text{liq}} \mathfrak{D} p_{\text{sat}}(T_\infty)} \tag{20.140}$$

The term f_{heat} is the contribution to the growth rate due to heat conduction

$$f_{\text{heat}} = \left(\frac{L_{\text{mol}}}{k_B T_\infty} - 1\right)\frac{L_{\text{mol}}}{v_{\text{liq}} T_\infty k_g} \tag{20.141}$$

where

L_{mol} is the latent heat per molecule (= $L\mathfrak{M}/N_A$ if expressed in terms of the latent heat per unit mass)

k_g is the thermal conductivity of the gas (e.g., air)

The temperature T_∞ is the temperature far away from the droplet surface. Equation 20.139 is known as Mason's equation. As before, solution and curvature effects may be incorporated into Mason's equation by modifying the droplet's equilibrium surface pressure according to Equation 20.130, namely by replacing the term $S - 1$ in the numerator of Equation 20.139 by

$$S - 1 - \frac{4\sigma_1 \bar{v}_1}{R_u T_\infty d_p} + \frac{6 n_2 \bar{v}_1}{\pi d_p^3} \tag{20.142}$$

Pruppacher and Klett (1997) present modifications of Mason's equation that account for noncontinuum effects in the transition regime. Their results are expressed in terms of a modified diffusion coefficient $\mathfrak{D}'$ and thermal conductivity k_g' that should be used in Equations 20.140 and 20.141. Seinfeld and Pandis (1998) proposed simplified expressions for $\mathfrak{D}'$ and k_g' for the case of air–water vapor system. The modified diffusion coefficient is

$$\mathfrak{D}' = \frac{\mathfrak{D}}{1 + (2\mathfrak{D}/\alpha_c d_p)(2\pi \mathfrak{M}_1 / R_u T)^{1/2}} \tag{20.143}$$

where α_c is the condensation coefficient (mass accommodation coefficient). The modified form of the thermal conductivity is

$$k_g' = \frac{k_g}{1 + (2k_g/\alpha_T d_p \rho_a \hat{c}_p)(2\pi \mathfrak{M}_a / R_u T_a)^{1/2}} \tag{20.144}$$

where

α_T is the thermal accommodation coefficient (frequently assumed equal to the mass accommodation coefficient)

ρ_a, $\hat{c}_p$ are the density and specific heat of humid air, respectively

Barrett and Clement (1988) used the generalized equations for heat and mass transfer in vapor–gas mixtures (Clement, 1985) to study growth rates for liquid droplets. They obtained, in addition to expressions for growth in the molecular regime and the transition regime, an expression for the droplet growth rate in the continuum regime that generalizes Mason's equation. They argued that for water droplets, the most important uncertainty is the choice of the molecular sticking probability.

20.4.2.2 Population of Droplets

A polydisperse aerosol is characterized by its size distribution, whose change in time and space is described by the GDE. Since condensation and evaporation are aerosol processes that occur much faster than coagulation, changes induced by them may be calculated separately without solving the full dynamic equation. In general, the GDE must be solved numerically: inclusion of a growth term in sectional methods leads to numerical diffusion, a problem that has stimulated the development of a number of different numerical schemes (summarized in Section 20.2.4). Alternatively, approximate analytical techniques have been developed. The GDE in the absence of coagulation, homogeneous nucleation, and external processes takes the form (expressed here in terms of the particle radius)

$$\frac{\partial n(a_p;t)}{\partial t} + \frac{\partial}{\partial a_p}[n(a_p;t)\dot{a}_p] = 0 \tag{20.145}$$

In Equation 20.145, the particle current, introduced in Section 20.2.1, see Equation 20.5, has been approximated by the migration term only, $n\dot{a}_p$, because homogeneous nucleation has been neglected. Inclusion of the homogeneous nucleation term would replace the zero on the RHS of Equation 20.145 by the nucleation rate $J_{\text{nuc}}\delta(a_p - a_p^\star)$, where $\delta(a)$ is the Dirac delta function. Equation 20.145 is occasionally referred to as the condensation equation.

The condensation equation can be solved analytically for constant gas-phase supersaturation, unity accommodation coefficient, and in the continuum regime. Under these approximations, the growth law is inversely proportional to the particle radius, $\dot{a}_p = A/a_p$, with A as a constant easily determined from

Equation 20.136. After a suitable transformation, Equation 20.145 may be solved via the method of characteristics. Along the characteristic, the solution is

$$d_p^2(t) = d_{p0}^2 + 2At \tag{20.146}$$

where d_{p0} is the initial ($t = 0$) diameter. Initially, $2At \ll d_{p0}^2$ and, thus, particles do not grow perceptively. In fact, smaller particles grow much faster than larger particles. In the long-time limit, the growth term $2At$ dominates so that condensation tends to shrink the size distribution, and the distribution tends to become more and more monodisperse.

The total condensation rate, defined as the change of aerosol mass due to condensation or evaporation, is related to a single droplet growth rate by considering the third moment of the GDE to obtain (Clement, 1985)

$$\frac{dm}{dt} = 4\pi\rho_l \int da_p n(a_p;t) a_p^2 \dot{a}_p \tag{20.147}$$

The previous equation is obtained by differentiating the third moment of the number distribution, see Section 20.2.3, and substituting Equation 20.145.

20.5 Single Particle Motion: Deposition Mechanisms

In this section, we focus on the mechanisms determining the motion of a single, spherical aerosol particle suspended in a fluid. Aspects of the dynamics of nonspherical, power-law aggregates were covered in Section 20.3.2.2. The fluid itself may be stagnant or in motion. In the latter case, in particular in accelerating fluid motion, the effects associated with the particle's own inertia become manifest. The mechanisms driving particle motion can be collectively called deposition mechanisms because their result is to make particles migrate from the suspending fluid to a surface and deposit there. Clearly, the same mechanisms are also responsible for transferring particles across boundaries within the flow. Therefore, the mechanisms discussed in this section correspond to the external processes in the GDE discussed in Section 20.2.2, with the exception of convection. Convective transport of particles will be addressed separately in Section 20.6.

In most cases, the flow around a moving aerosol particle is in the Stokes regime, $Re_p \ll 1$, where Re_p is the particle Reynolds number, $Re_p = d_p U/\nu_g$. The only point that merits further discussion here is related to noncontinuum flow effects in aerosol systems. In the aerosol literature, the Knudsen number (discussed extensively in Section 20.3, and specifically in 20.3.2 where variants of Equation 20.148 appropriate for nonspherical agglomerates are presented) is defined in terms of particle radius, $Kn_g = \lambda_g/a_p$, rather than particle diameter. For small particles, there is a departure from the continuum flow regime and a corresponding decrease in the Stokes drag force. This effect is taken into account by introducing a correction factor as follows:

$$F_D(Kn_g) = \frac{3\pi\mu U d_p}{C_c(Kn_g)} \tag{20.148}$$

The correction factor C_c, known as Cunningham correction factor or slip correction factor, is given by (Allen and Raabe, 1985)

$$C_c(Kn_g) = 1 + Kn_g\left[1.142 + 0.558\exp\left(-\frac{0.999}{Kn_g}\right)\right] \tag{20.149}$$

This correction factor for spherical particles and other expressions for it are given by Michaelides (2014). For nonspherical, power-law agglomerates, it is discussed in Section 20.3.2, where variants of Equation 20.148 appropriate for nonspherical objects are presented. To evaluate Equation 20.149, knowledge of the gas mean free path λ_g is required. The mean free path according to the kinetic theory of gases is, see, also, Equation 20.60,

$$\lambda_g = \frac{1}{\sqrt{2} n_g \pi d_M^2} \tag{20.150}$$

where
n_g is the number concentration of gas molecules
d_M is the collision diameter of a molecule

For air at 101 kPa (1 atm) and 293 K (20°C), the mean free path is $\lambda_{ref} = 0.0664\,\mu m$, while for air under other conditions, the following formula can be used (Willeke, 1976):

$$\lambda_g = \lambda_{ref}\left(\frac{101}{p}\right)\left(\frac{T}{293}\right)\left(\frac{1+110/293}{1+110/T}\right) \tag{20.151}$$

where
p is in kPa
T in K

For other gases, accurate determination of the mean free path from kinetic theory, Equation 20.150, is difficult. One may resort to the theory that relates the mean free path to gas macroscopic properties, like viscosity. A good approximate formula is (see also Equation 20.60)

$$\lambda_g = \frac{\mu_g}{p}\left(\frac{\pi R_u T}{2\mathfrak{M}}\right)^{1/2} \tag{20.152}$$

Table 20.1 gives values for the slip correction factor at different particle diameters. For a 1 μm particle at standard conditions in air, the slip correction is of the order of 15% and it increases sharply as size decreases. On the other hand, slip effects can be considered negligible for particles with $d_p > 10\,\mu m$.

20.5.1 Gravitational Settling

The terminal velocity of a spherical particle due to gravitational settling can be obtained by equating the drag force (Newton's resistance) on the particle, F_D, which in the general form is written as (Hinds, 1999):

$$F_D = C_D\frac{\pi}{8}\rho_g d_p^2 V_s^2, \tag{20.153}$$

to the force of gravity, $F_G = \pi\rho_p d_p^3 g/6$. Thus,

$$V_s = \left(\frac{4\rho_p d_p g}{3\rho_g C_D}\right)^{1/2}, \tag{20.154}$$

Equation 20.154 holds for any particle size; it gives the terminal settling velocity, if the appropriate drag coefficient, C_D, is used. Buoyancy effects are neglected in Equation 20.154, a largely legitimate assumption, since in most practical cases, $\rho_p \gg \rho_g$.

For Stokes flow, which is the usual case for most aerosols, the drag coefficient is equal to $C_D = 24/Re_p$ as explained in more detail in Chapter 1. Thus, Equation 20.154 becomes

$$V_s = \frac{\rho_p d_p^2 g C_C(Kn_g)}{18\mu_g} \quad \text{for } Re_p < 1. \tag{20.155}$$

Slip correction has been taken into account; hence, the aforementioned expression can be used for any particle size. The Stokes regime strictly holds for $Re_p < 0.1$; however, Equation 20.155 is a good approximation over the extended range $0.1 < Re_p < 1$ (Vincent, 1995, Hinds, 1999). For $10^3 < Re_p < 3 \times 10^5$, the drag coefficient is constant and approximately equal to $C_D = 0.44$; as shown in Chapter 1, the terminal settling velocity becomes

$$V_s = 1.74\left(\frac{\rho_p}{\rho_g} d_p g\right)^{1/2} \quad \text{for } 10^3 < Re_p < 3\times 10^5. \tag{20.156}$$

In the intermediate region, that is, for $1 < Re_p < 10^3$, the drag coefficient depends on the particle Reynolds number, Re_p, thus on V_s itself; therefore, the particle terminal settling velocity has to be calculated iteratively. Methods to calculate V_s at higher particle Reynolds numbers are given by Hinds (1999). In particular, if Equation 20.154 is rearranged and both sides are multiplied by Re_p^2, then

$$C_D Re_p^2 = \frac{4 d_p^3 \rho_p \rho_g g}{3 \mu_g}. \tag{20.157}$$

The RHS of Equation 20.157 does not contain the unknown terminal settling velocity; thus, the quantity $C_D Re_p^2$ can be calculated. If, in addition, the Schiller and Nauman correlation for the drag coefficient in the intermediate region is used, the resulting system of equations gives the particle Reynolds number and, consequently, the terminal settling velocity V_s as a unique function of Re_p.

A quantity related to the terminal settling velocity (not necessarily restricted to gravitational settling) and frequently used in aerosols is the *particle mechanical mobility*, B, in m/N/s. It is defined as the ratio of the terminal velocity to the steady-state force that produces it. In the Stokes regime,

$$B = \frac{C_c(Kn_g)}{3\pi \mu_g d_p} \tag{20.158}$$

Thus, the terminal velocity a particle acquires is the applied force times its mechanical mobility; see also Equation 20.148.

For nonspherical particles, a correction is introduced in Equation 20.154, called the dynamic shape factor χ, when the diameter d_p is replaced by the *equivalent volume diameter*, d_e. The equivalent volume diameter, already mentioned in Section 20.3.2.1, is the diameter of a sphere that has the volume of the particle. With these conventions, Equation 20.154 becomes

$$V_s = \frac{\rho_p d_e^2 g C_c(Kn_g)}{18 \mu_g \chi} \quad \text{for } Re_p < 0.1 \tag{20.159}$$

The slip correction factor for an irregularly shaped particle is difficult to determine with accuracy (see, however, the analysis for power-law aggregates, Section 20.3.1.2). It is occasionally approximated by $a_p = d_e/2$ or by $a_p = R_g$, where the radius of gyration was defined in Equation 20.45, in Equation 20.149. Except for certain streamlined shapes, the dynamic shape factor is greater than 1.0. Colbeck (1998) and Hinds (1999) present tables of the dynamic shape factor for various particle shapes, whereas calculated shape factors for straight chains may be found by Isella and Drossinos (2011) and for fractal-like aggregates by Melas et al. (2014a,b).

A diameter used to characterize nonspherical particles is the *Stokes diameter* d_S. This is the diameter of a sphere of the same density and same settling velocity as the particle. Usually, the Stokes diameter is defined in terms of the bulk material density of the particle, ρ_b, to avoid the problem of specifying the true density that may be affected by porosity or agglomerated structure. From Equation 20.159, it follows

$$d_S = d_e \left(\frac{\rho_p}{\rho_b \chi} \right)^{1/2} \left(\frac{C_c(d_e)}{C_c(d_S)} \right)^{1/2} \tag{20.160}$$

Obviously, for a spherical particle of uniform density $d_S = d_p$. Since the Cunningham slip correction factor depends itself on diameter, an iterative procedure is required to achieve consistency between the Stokes diameter and the respective slip correction factor. For particles with $d_e > 1\,\mu$m, the slip correction is small anyway, and the ratio $C_c(d_e)/C_c(d_S)$ becomes approximately one. On the other hand, for particles with $d_e < 1\,\mu$m and shape factor close to unity, the difference between d_e and d_S is such that the influence of the ratio $C_c(d_e)/C_c(d_S)$ is not very large. Therefore, very often Equation 20.160 simplifies to

$$d_S = d_e \left(\frac{\rho_p}{\rho_b \chi} \right)^{1/2} \tag{20.161}$$

Another characteristic diameter, extensively used in aerosol science and technology, is the *aerodynamic diameter* d_a. This is the diameter of a spherical particle of density $\rho_0 = 1000\,\text{kg/m}^3$ that settles with the same terminal velocity as the particle. The aerodynamic diameter is given by

$$d_a = d_e\left(\frac{\rho_p}{\rho_0\chi}\right)^{1/2}\left(\frac{C_c(d_e)}{C_c(d_a)}\right)^{1/2} = d_S\left(\frac{\rho_b}{\rho_0}\right)^{1/2}\left(\frac{C_c(d_S)}{C_c(d_a)}\right)^{1/2} \tag{20.162}$$

and, in the same way as in Equation 20.160, the calculation requires an iterative procedure. As before, there are many practical cases in which the effect of ratios of slip factors is not very large, (namely, for large particles with $d_e > 1\,\mu\text{m}$, or small particles of smooth shape and density close to ρ_0), and Equation 20.162 is approximately written as

$$d_a = d_e\left(\frac{\rho_p}{\rho_0\chi}\right)^{1/2} = d_S\left(\frac{\rho_b}{\rho_0}\right)^{1/2} \tag{20.163}$$

The aerodynamic diameter and, to a lesser extent, the Stokes diameter are essential parameters; both are used to characterize aerosol behavior irrespective of particle geometry and material. For example, the aerodynamic diameter is used to characterize filtration or respiratory deposition. Several instruments, such as impactors and elutriators, measure aerodynamic diameter.

20.5.2 Diffusion

Aerosol particles exhibit a random motion called Brownian motion as a consequence of their continuous bombardment by the molecules of the surrounding gas. Equation 20.20 is the stochastic Langevin equation that describes the Brownian motion of a particle in a quiescent fluid. The macroscopic effect of Brownian motion is the net transfer of particles from regions of high to low concentration, a process known as diffusion. Diffusion of aerosol particles due to Brownian motion is described by the well-known (macroscopic) Fick's law in terms of number of particles diffused, namely, $\mathbf{J}_p = -\mathfrak{D}\nabla n_p$, where $\mathbf{J}_p$ is the number flux vector (particles/m^2 s), n_p is the number particle concentration (particles/m^3), and $\mathfrak{D}$ is a diffusion coefficient (m^2/s).

The diffusion coefficient depends strongly on particle size, with smaller particles diffusing much more efficiently than larger particles. Table 20.1 gives values of the diffusion coefficient in air for particles of various sizes. The effect of particle size is strong: under the same concentration gradient, the diffusive mass flux of a 0.01 μm particle is about 20,000 times larger than that of a 10 μm particle. A related dimensionless number is the particle Schmidt number defined as in molecular mass transfer

$$Sc_p = \frac{\nu_g}{\mathfrak{D}} \tag{20.164}$$

where ν_g is the kinematic viscosity of the suspending gas. Values of the particle Schmidt number are provided in Table 20.1. Generally, the diffusion coefficient of aerosol particles is orders of magnitude smaller than the diffusion coefficient of molecular diffusion in gases, and comparable in magnitude to diffusion coefficients observed in molecular diffusion in liquids. Accordingly, the particle Schmidt number is generally very large, $Sc_p \gg 1$. Hence, as a rule, the concentration boundary layer of aerosol particles is much thinner than the viscous or thermal boundary layers over a surface.

The particle diffusion coefficient is

$$\mathfrak{D} = \frac{k_B T_g C_c(Kn_g)}{3\pi\mu_g d_p} \tag{20.165}$$

which, without the slip correction factor $C_c(Kn_g)$, cf. Equation 20.149, is known as the Stokes–Einstein equation. Note that the diffusion coefficient depends on particle diameter and gas properties (temperature and viscosity), but not on particle physical properties (e.g., density).

A quantity used to characterize the strength of Brownian diffusion is $x^2_{\text{rms}} = \langle[x(t+\Delta t) - x(t)]^2\rangle$, the root-mean-square net displacement of a diffusing particle over a time interval Δt. This displacement is related

to the diffusion coefficient through the expression $x_{\text{rms}} = \sqrt{2\mathfrak{D}\Delta t}$. The ratio $x_{\text{rms}}/V_s\Delta t$, where $V_s\Delta t$ represents the displacement due to gravitational settling, is an indicator of the importance of diffusion. For spherical particles of standard density in air, this ratio is of order one for $d_p \sim 1\,\mu\text{m}$, whereas it is of order 10^3 for $d_p \approx 0.01\,\mu\text{m}$ and of order 10^{-3} for $d_p \approx 10\,\mu\text{m}$. It follows that Brownian diffusion is an important transport mechanism only for small particles of the submicrometer range. Instead, for particles greater than 1 μm in diameter, gravitational settling and inertial effects outweigh diffusional transport. In turbulent flows, particles diffuse due to eddies, an important mechanism that is extensively discussed in Chapter 2.

20.5.3 Inertial Effects: Impaction

In an accelerating flow field, particles are not able to follow perfectly the fluid motion due to their own mass. In straight-line accelerating (decelerating) motion, aerosol particles lag behind (ahead) the Lagrangian "fluid particles." In curvilinear motion, for example, in a flow around a body surface, particle trajectories deviate from the fluid streamlines and may impinge on the surface. This mechanism, known as *impaction*, is a major deposition mechanism of great practical importance in inertial size classifiers (e.g., cascade impactors), aerosol sampling, filtering, gas-cleaning equipment, respiratory deposition, and generally, in all processes involving particle collection. Such inertial effects become increasingly important with increasing particle size. As a rule of thumb, inertial effects become important for particles with diameter ≥1 μm.

The extent to which the motion of an aerosol particle adjusts to or deviates from the motion of the fluid is described by three interrelated characteristic parameters: the *relaxation time* τ_V, the *stop distance* S_L, and the Stokes number *St*. These parameters are defined for the case of Stokesian particles (strictly for $Re_p < 0.1$, but to a good approximation also for $0.1 < Re_p < 1$).

The particle relaxation time, or velocity response time, is a time scale characterizing the adjustment of particle velocity to a changing fluid velocity. It is calculated by considering the time required by the particle to reach its terminal settling velocity when released with zero initial velocity in a quiescent fluid. The relaxation time is given by, see also the discussion following Equation 20.20, the following equation:

$$\tau_V = \frac{\rho_p d_e^2 C_c(Kn_g)}{18\mu_g \chi} \tag{20.166}$$

Therefore, by Equation 20.159, it can be regarded as the settling velocity of a particle on which a unit gravitational acceleration acts, namely, $V_s = \tau_V g$. This permits one to derive the following useful expression for the calculation of the terminal velocity *U* of an aerosol particle subjected to a constant force *F*:

$$U = \tau_V \frac{F}{m_p} \tag{20.167}$$

Values of particle relaxation times as function of particle size for particles in air at standard conditions are given in Table 20.1. It is important to realize that particle relaxation time, and generally inertial effects and impaction, does not depend on the properties of the particle only, but on the properties of the combined particle–fluid system. The dependence on fluid properties is clearly attested by Equation 20.166, which involves the viscosity of the gas as well as the mean-free path of the gas through the slip correction.

Stop distance is a length scale that characterizes the persistence of a particle to continue its original motion in a changing flow field before it equilibrates again with the fluid motion. The stop distance is simply the initial velocity times the relaxation time

$$S_L = U_0 \tau_V \tag{20.168}$$

This expression is obtained by considering the distance a particle travels in still fluid before it comes to rest, following injection with initial velocity U_0 and in the absence of any external force.

The Stokes number, introduced in Chapter 1, is a dimensionless number defined as the ratio of the stop distance to a characteristic length of the flow, or equivalently, as the product of a characteristic velocity times the relaxation time divided by a characteristic length

$$St = \frac{S_L}{L} = \frac{U_0 \tau_V}{L} = \frac{\rho_p d_e^2 C_c(Kn_g) U_0}{18\mu_g \chi L} \tag{20.169}$$

The Stokes number is an important similarity parameter used to scale particle trajectories, and hence impaction deposition, in particle–flow systems that are geometrically and hydrodynamically similar. Also, it is a widely used practical criterion to determine the responsiveness of aerosol particles to changes of fluid velocity, thereby predicting if impaction will take place. For $St \ll 1$, the particles follow closely the fluid motion and do not impact on surfaces, whereas for $St \gg 1$, the particles escape the flow and may deposit by impaction.

It should be noted that all the definitions assume the validity of Stokes law for the drag force throughout the entire period of motion of the particle. Occasionally, for large particles and high initial velocities, particle motion may be found outside the Stokes regime. Some results on impaction deposition of non-Stokesian particles are given in Section 20.6.2.2.

An important case of inertial transport arises in turbulent flow, originating from the inability of high-inertia particles to follow the fluid turbulent eddies. Inertial deposition due to turbulence is commonly referred to as *turbulent impaction*, *eddy impaction*, or, even, *turbophoresis* (Reeks, 1983), the latter referring to the tendency of inertial particles to acquire a drift velocity in the direction of decreasing turbulence intensity; it is presented in Section 20.6.3.

20.5.4 Motion in an Electric Field

A charged particle placed in an electric field of strength E is subjected to an electrostatic force $F_E = neE$ where n is the number of elementary units of charge on the particle and e the charge of an electron ($e = 1.609 \times 10^{-19}$ C). Large particles frequently acquire multiple charges ($n > 1$), but the probability of charging decreases with decreasing particle size. For small particles, usually $n = 1$. Aerosol particles can readily acquire charge through a variety of processes, such as thermionic emission (e.g., in a flame), diffusion charging (attachment of diffusing ions to particles), field charging (collision of particles with ions in a strong electric field, e.g., a corona discharge), or static electrification (e.g., spray electrification). Radioactive aerosols become self-charged by emitting α or β particles, and they may acquire very high charge during radioactive decay.

Electrostatic forces may give rise to appreciable particle drifts due to the high mobility of aerosol particles. The terminal velocity, referred to as *electrical drift velocity*, can be obtained for the case of a Stokesian spherical particle with the help of Equation 20.167 as follows:

$$V_E = \frac{neEC_c(Kn_g)}{3\pi\mu_g d_p} = neEB \tag{20.170}$$

This expression is the basic formula used to analyze electrical migration of aerosol particles. It is also customary to use the so-called *electrical mobility* of the particle, Z, which is the particle velocity in a field of unit intensity, namely

$$Z = \frac{neC_c(Kn_g)}{3\pi\mu_g d_p} \tag{20.171}$$

The electrical mobility is related to the mechanical mobility by

$$Z = neB = qB \tag{20.172}$$

where q is the charge of the particle. In terms of the electrical mobility, the particle velocity in an electrical field is simply written as $V_E = ZE$.

The electrical properties of aerosols find wide application in air cleaning equipment (electrostatic precipitators), in electrodynamic levitation techniques (electrodynamic balances), and in measurements of particle size distribution (or generally in size classification) with electrical mobility analyzers. For information on electrical measurements techniques, the reader is referred to the reviews by Flagan (1998, 2001) and Davis (2001).

20.5.5 Phoretic Effects

Besides gravitational and electrostatic forces, aerosol particles may be subjected to a variety of forces arising from other external fields. Such forces, negligible for macroscopic objects, may influence significantly the motion of small aerosol particles because of their high mobility. The induced motion is generally coined after the name of the causal agent and the conjunctive "phoresis," which in Greek means "being carried by."

Accordingly, a particle may move by *thermophoresis* (motion induced by a temperature gradient in the carrier gas), *diffusiophoresis* (induced by the concentration gradient of a vapor diffusing through the carrier gas), *photophoresis* (induced by a light beam), *radiation pressure* (induced by an incident electromagnetic radiation), and *sonarphoresis* or *acoustic pressure* (induced by acoustic waves). The following description is limited to the two most common phoretic effects: thermophoresis and diffusiophoresis.

20.5.5.1 Thermophoresis

It has been known for long (since the nineteenth century) that a hot body placed in a dusty gas creates a dust-free zone around it. Indeed, aerosol particles suspended in a nonisothermal gas tend to migrate from the hotter to the colder regions. This movement is called *thermophoresis*: it arises from the asymmetric bombardment exerted on a particle by the gas molecules in the presence of a temperature gradient in the gas. The momentum received on the "hotter side" of the particle is more than that on the "colder side," and the macroscopic result is net transport in the direction of decreasing temperature.

The thermophoretic velocity can, thus, be expressed as a function of the local temperature gradient as follows:

$$\mathbf{v}_{\text{th}} = -K_{\text{th}} \frac{\nu_g}{T} \nabla T \tag{20.173}$$

and, from Equation 20.167, the thermophoretic force is written as $\mathbf{F}_{\text{th}} = \mathbf{v}_{\text{th}} m_p / \tau_v$. In Equation 20.173 K_{th} is a dimensionless parameter, the thermophoretic coefficient, that depends on properties of both the gas and the particle. Theoretical expressions for K_{th} have been rigorously derived only in the limits of continuum flow ($Kn_g = \lambda_g / a_p \ll 1$), the so-called Epstein expression (Fuchs, 1964),

$$K_{\text{th}}^{\text{Epstein}} = \frac{3}{2} \frac{k_g / k_p}{(1 + 2k_g / k_p)} \quad (\text{for } Kn_g \to 0) \tag{20.174}$$

or in the limit of free molecular flow ($Kn_g \gg 1$), the so-called Waldmann expression (Fuchs, 1964),

$$K_{\text{th}}^{\text{Waldmann}} = \frac{3}{4(1 + \pi/8)} \quad (\text{for } Kn_g \to \infty) \tag{20.175}$$

Talbot et al. (1980) proposed a fitting formula over the entire momentum-transfer regime, range $0 \le Kn_g \le \infty$, which agrees to within 20% or better with most of the available experimental data. The fitting formula was obtained by introducing an improved value for the numerical factor in the theoretical expression of Brock (1962), who had suggested an expression for the thermophoretic force valid in the slip-flow regime. The Brock–Talbot expression is

$$K_{\text{th}} = 2C_s \frac{C_c(Kn_g)(k_g / k_p + 2C_t \lambda_g / d_p)}{(1 + 6C_m \lambda_g / d_p)(1 + 2k_g / k_p + 4C_t \lambda_g / d_p)} \tag{20.176}$$

In this equation,

k_g / k_p is the ratio of gas-to-particle thermal conductivity
$C_c(Kn_g)$ is the Cunningham correction factor, cf. Equation 20.149

The order-unity constants C_s, C_t, C_m arise from noncontinuum effects at the particle interface: they are associated with the temperature and velocity boundary conditions (jump conditions) at the particle–gas interface. The recommended values are $C_s = 1.17$ (thermal creep coefficient), $C_t = 2.18$ (temperature jump coefficient), and $C_m = 1.14$ (velocity jump coefficient). Young (2011) revisited theoretical analyses and experimental measurements to suggest an interpolation formula that provides improved comparison with experimental data and is more consonant with theoretical developments than the Brock–Talbot expression. Nevertheless, the Brock–Talbot expression remains the most commonly used formula.

Figure 20.3 shows the thermophoretic coefficient K_{th} as a function of the Knudsen number Kn_g and is parametrized by k_g / k_p. As can be seen, K_{th} typically has values around 0.5 and becomes a constant for very small particles in the free molecular regime. For large particles, it depends both on particle size and on the gas-to-particle thermal conductivity ratio. This dependence is due to the nonnegligible temperature gradient established within a particle of appreciable size, which affects locally the temperature gradient of the gas.

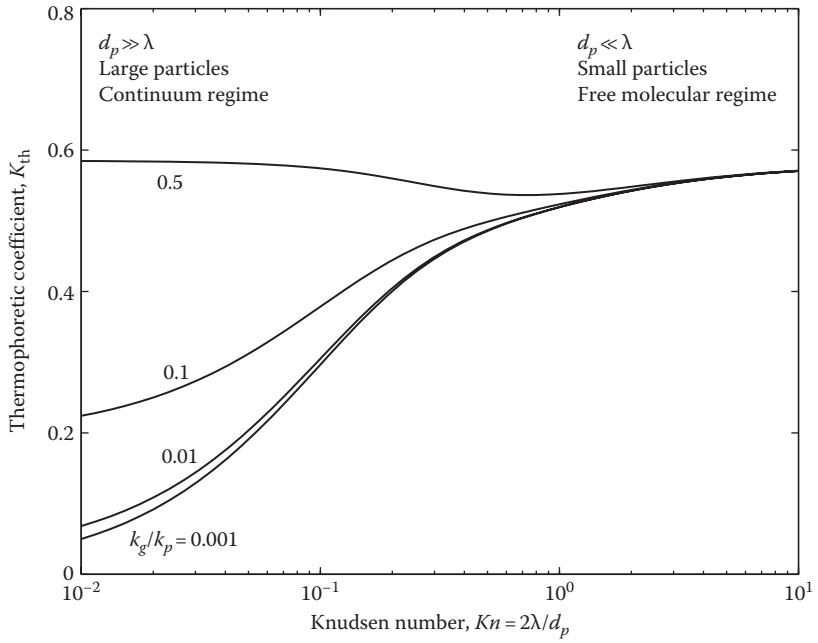

Figure 20.3

Thermophoretic coefficient K_{th} as a function of Knudsen number, $Kn_g = \lambda_g/a_p$, for various gas-to-particle thermal conductivity ratios k_g/k_p.

More details on the thermophoretic motion of particles may be found in Chapter 1 and its relationship to the Brownian motion in Michaelides (2015).

20.5.5.2 Diffusiophoresis and Entrainment by Stefan Flow

Particles suspended in a nonequilibrium binary gas mixture, where two gases interdiffuse, experience unequal momentum transfers by collisions with the molecules of one gas diffusing in one direction and the molecules of the other diffusing in the opposite direction. A net force develops on the particle in the direction of diffusion of the heavier gas molecule. The resulting motion, which is driven by the prevailing concentration gradient, is called *diffusiophoresis*. The diffusiophoretic motion of particles should not be confused with the diffusion of particles: the former is driven by the concentration gradient of a diffusing gas, whereas the latter is driven by the concentration gradient of the particles themselves.

This process, that is, diffusion of two noncondensable gases into each other, is not very usual in aerosol flows. Instead, most practical cases are concerned with diffusion of a condensable vapor through a background gas (e.g., evaporation or condensation of water droplets in air, or wall condensation of steam in nitrogen–steam or air–steam mixtures in nuclear safety experiments). Under such circumstances, a secondary convective flow is established within the gas, known as *Stefan flow*, which arises from a subtle mass balance between the diffusive flows of the gas and the vapor. The direction of Stefan flow is always away from an evaporating surface or toward a condensing surface. Therefore, the motion of the particle is determined by the combined action of Stefan flow and diffusiophoresis. The latter still takes place due, as described earlier, to diffusion of vapor and counterdiffusion of gas. For the combined motion due to diffusiophoresis and Stefan flow, Waldmann and Schmitt (1966) provided the following theoretical expression for the particle drift velocity:

$$V_p = -\frac{\sqrt{\mathfrak{M}_1}}{\psi_1\sqrt{\mathfrak{M}_1} + \psi_2\sqrt{\mathfrak{M}_2}}\frac{\mathfrak{D}_{12}}{\psi_2}\nabla\psi_1 \tag{20.177}$$

where

$\mathfrak{M}_1, \mathfrak{M}_2$ are the molecular weights of the condensable vapor and the background gas
ψ_1, ψ_2 are the molar fraction of the vapor and the gas
$\mathfrak{D}_{12}$ is the binary gas diffusion coefficient

Note that the velocities derived from Equation 20.177 are independent of particle size. The predictions of Equation 20.177 are in very good agreement with the experimental data of Goldsmith and May (1966) that were obtained with small nichrome particles ($0.02 \le d_p \le 0.2\,\mu m$) in diffusing water vapor in air and helium. The use of Equation 20.177 for larger particles requires caution. The measurements of Goldsmith and May (1966) for the case of water vapor in air can be correlated within ±5% as

$$V_p = -1.9\times10^{-4}\,(\mathrm{cm^2/s/mb})\frac{dp_1}{dx} \tag{20.178}$$

where dp_1/dx is the gradient of the partial pressure of the condensable vapor. If Equation 20.177 is evaluated for water vapor diffusing in air at standard conditions, a numerical expression identical to Equation 20.178 is recovered (note that $(1/\psi_2)d\psi_1/dx$ can be written as $(1/p_2)dp_1/dx$ where p_2 is the partial pressure of the gas). Therefore, Equation 20.178 has the appealing property of being both an empirical and a theoretical formula suitable for the calculation of the particle drift velocity due to combined diffusiophoresis and Stefan flow in water vapor–air systems.

20.6 Convective Transport and Deposition

The behavior of aerosol particles as they are transported in a flowing fluid is of fundamental importance in predicting rates of deposition onto surfaces in a great variety of applications, including gas-cleaning equipment, aerosol filtration, aerosol instrumentation and measurements, nuclear safety relevant experiments, respiratory deposition, etc. For submicrometer particles, and in the absence of external force fields, Brownian or turbulent diffusion is the basic mechanism that drives deposition. For particles larger than about 1 μm, deposition is primarily due to inertial impaction and gravitational settling.

A basic quantity characterizing convective transport of an aerosol is the *penetration ratio*, or *penetration fraction*, defined as the fraction of the inflowing particles that exit the flow system. It can be written as

$$f_p = \frac{C_{\mathrm{out}}}{C_0} \tag{20.179}$$

where C_{out} and C_0 are the particle concentrations (either mass or number) at the outlet and inlet, respectively. Alternatively, a *removal efficiency*, or *collection efficiency,* can be defined as the fraction of the inflowing particles that is lost by deposition. The removal efficiency is simply related to penetration fraction by

$$n_R = 1 - f_p \tag{20.180}$$

Another quantity widely employed to characterize deposition in convective aerosol flows is *deposition velocity* is defined as

$$V_d = \frac{G_p}{C_{\mathrm{av}}} \tag{20.181}$$

where

G_p is the particle mass flux to the wall

C_{av} is the average particle concentration above the surface

The latter is taken equal to the average concentration over the cross section of the conduit, or, in external flow systems, equal to the concentration in the undisturbed stream. The usual boundary condition employed at the wall is that deposited particles are totally absorbed there; thus, a zero particle concentration is imposed, $C_w = 0$. Then, Equation 20.181 can be rewritten as $G_p = V_d(C_{\mathrm{av}} - C_w)$. As such, the deposition velocity should be interpreted as a mass-transfer coefficient of the process, and not as the velocity with which particles arrive at the surface (as its name might imply).

In closed ducts, flow can be generally considered hydrodynamically fully developed. The particle Schmidt number is large and as a result, velocity profiles develop much more rapidly than particle concentration profiles. Chen and Comparin (1976) demonstrated that the effects of a developing velocity become negligible when $Sc_p \ge 10$, a condition usually satisfied for particles with $d_p > 0.002\,\mu m$.

Next, the most relevant cases of convective transport/deposition are addressed. First, cases of convection combined with a single additional transport mechanism (e.g., diffusion, inertial transport, gravitational settling, and thermophoresis) are reviewed. The section concludes by addressing one important case in which all deposition mechanisms act in combination: filtration.

20.6.1 Convective Diffusion from Laminar Flow in Ducts

20.6.1.1 Circular Tube

The analytical solution for the fundamental case of convective diffusion of small particles suspended in laminar flow inside a circular tube, cf. Equation 20.10, was derived by Gormley and Kennedy (1949). The Gormley and Kennedy solution is a classic result in the aerosol literature and, as such, it is reproduced here

$$f_p = 1 - 6.46\Delta^{2/3} + 4.8\Delta + 1.124\Delta^{4/3} + \cdots \quad \text{for } \Delta < 0.0312$$

$$f_p = 0.8191\exp(-14.628\Delta) + 0.0975\exp(-89.2\Delta) + 0.0325\exp(-228\Delta) + \cdots \quad \text{for } \Delta > 0.0312 \tag{20.182}$$

where Δ is the dimensionless parameter

$$\Delta = \frac{\mathfrak{D}L}{D^2U} = \frac{\pi}{4}\frac{\mathfrak{D}L}{\dot{V}} \tag{20.183}$$

with L as the length of the tube and U as the mean velocity through the tube. The parameter Δ corresponds to the standard dimensionless length $L/D\,Re\,Sc_p$ commonly used in the mass-transfer literature. However, in the aerosol literature, it has become customary to use the expression of Equation 20.183 that manifestly shows that deposition depends (for a given aerosol) on the flowrate and the length of the tube and not on the tube diameter. Hence, the same deposition result is obtained by passing the same flow through a single long tube or by cutting it into a large number of parallel short tubes. This principle has found wide application in the design of *diffusion batteries*, apparatuses relying on convective diffusional losses in laminar flow to determine the diffusion coefficient and thus particle size. It can also be used to analyze convective diffusion inside a *tube bundle* (Housiadas et al., 1998).

Ingham (1975) derived a single asymptotic expression for the penetration fraction that is valid for both large and small values of Δ:

$$f_p = 0.819\exp(-14.63\Delta) + 0.0976\exp(-89.2\Delta) + 0.0325\exp(-228\Delta) + 0.0509\exp(-125.9\Delta^{2/3}) \tag{20.184}$$

Equation 20.184 is accurate to better than 0.5% for all values of Δ as compared to more accurate solutions.

In the same spirit, Alonso et al. (2010) presented an approximate analytical expression for the two-dimensional fully developed particle concentration profile. In the fully developed region ($\Delta \geq 0.05$), the overall particle concentration profile continues to decay, whereas the radial profile retains a constant shape. They suggested

$$f_p(L,r) = 1.477\exp(-14.636\Delta)\left[1 - \frac{1}{11}(18r^2 - 9r^4 + 2r^6)\right] \quad \text{for } \Delta > 0.05 \tag{20.185}$$

where r was rendered dimensionless by scaling it on the tube radius, $r = 1$ being the wall. The initial condition was uniform particle concentration at the tube entrance.

An expression similar to Equation 20.184 for plug flow (uniform velocity) is (Ingham, 1975)

$$f_p = \frac{4}{\alpha_1^2}\exp(-4\alpha_1^2\Delta) + \frac{4}{\alpha_2^2}\exp(-4\alpha_2^2\Delta) + \frac{4}{\alpha_3^2}\exp(-4\alpha_3^2\Delta) + \left\{1 - 4\left(\frac{1}{\alpha_1^2} + \frac{1}{\alpha_2^2} + \frac{1}{\alpha_3^2}\right)\right\} \exp\left[-\frac{8\Delta^{1/2}}{\sqrt{\pi}\left[1 - 4\left(1/\alpha_1^2 + 1/\alpha_2^2 + 1/\alpha_3^2\right)\right]}\right] \tag{20.186}$$

where α_1, α_2, α_3 are the first three zeros of the Bessel function J_0, which, to an accuracy of four decimal points, are $\alpha_1 = 2.4048$, $\alpha_2 = 5.5201$, $\alpha_3 = 8.6537$. As before, Equation 20.186 is valid for all dimensionless lengths Δ to an accuracy of better than 0.5%. Expression (20.186) in combination with Equation 20.184 permits the calculation of the envelop values of f_p for the case of a hydrodynamically developing flow at the entrance of a tube.

20.6.1.2 Nonuniform Inlet Concentration

In practical situations, the distribution of aerosol mass at the inlet of the tube may deviate from uniformity. Consider, for example, the case of an aerosol flow through a circular tube with nonuniform inlet concentration, whose profile is described as a function of the dimensionless radial co-ordinate $r^\star = r/R$ by a polynomial of degree K

$$C_0 \sim a_0 + a_1 r^\star + a_2 (r^\star)^2 + a_3 (r^\star)^3 + \cdots + a_K (r^\star)^K \tag{20.187}$$

The penetration ratio can be calculated with the help of the series solution of the convective diffusion equation and methods proposed by Housiadas et al. (1999, 2000):

$$f_p = -8 \sum_{n=1}^{\infty} \frac{I_n \exp(-2\lambda_n^2 \Delta)}{\lambda_n \Lambda_n} \tag{20.188}$$

In this expression, the constants I_n are determined by

$$I_n = a_0 (E_1^n - E_3^n) + a_1 (E_2^n - E_4^n) + \cdots + a_K (E_{K+1}^n - E_{K+3}^n) \tag{20.189}$$

whereas the coefficients E_j^n are calculated from the recurrence relation

$$E_j^n = \frac{R_n}{\lambda_n^2} + \frac{(j-3)^2}{\lambda_n^2} E_{j-4}^n + E_{j-2}^n, \quad j = 4,5, \ldots, K+3 \tag{20.190}$$

Table 20.2 gives the eigenvalues λ_n and constants Λ_n, R_n, E_0^n, E_1^n, E_2^n, E_3^n required in the numerical evaluation of the solution up to order $n = 5$. By using five terms, the series solution (20.188) converges to the correct result with an accuracy of better than 1% for all dimensionless lengths $\Delta > 4 \times 10^{-4}$ (better than 2% for all dimensionless lengths $\Delta > 5 \times 10^{-5}$, i.e., for all practical values of Δ).

20.6.1.3 Ducts of Other Geometry

Flat *rectangular geometry* is generally considered the most efficient geometry for the collection of submicrometer particles. Accurate solutions have been derived for particle penetration through a rectangular channel of long side W and short side H with $W \gg H$ (Tan and Thomas, 1972, Bowen et al., 1976):

$$f_p = 1 - 1.526\Delta^{2/3} + 0.15\Delta + 0.0342\Delta^{4/3} \quad \text{for } \Delta \le 0.05 \tag{20.191}$$

Table 20.2 Eigenvalues and Related Constants for the Numerical Evaluation of the Series Solution Equation 20.188

	λ_n	R_n	Λ_n	E_0^n	E_1^n	E_2^n	E_3^n

Table 20.3 First Eigenvalues and Coefficients for Different R_1/R_2 Ratios of a Circular-Tube Annulus

R_1/R_2	0.05	0.1	0.25	0.5	0.75	0.9	0.95
λ_1	3.493	3.6102	3.7641	3.8507	3.8776	3.8828	3.8833
λ_2	7.906	8.0870	8.3141	8.4356	8.4728	8.4798	8.4805
λ_3	12.31	12.557	12.866	13.033	13.083	13.093	13.094
K_1	0.879	0.889	0.9004	0.9076	0.9098	0.9103	0.91034
K_2	0.036	0.026	0.0118	0.0033	0.0006	0.00007	0.00002
K_3	0.044	0.046	0.050	0.052	0.053	0.05312	0.05314

Source: Adapted from Kerouanton, D. et al., *J. Aerosol Sci.*, 27, 345, 1996.

$$f_p = 0.9104\exp(-2.8278\Delta) + 0.0531\exp(-32.147\Delta) + 0.01528\exp(-93.475\Delta) + 0.00681\exp(-186.805\Delta) \quad \text{for } \Delta > 0.05 \tag{20.192}$$

Here, the definition of the dimensionless parameter Δ is $\Delta = 8\mathfrak{D}L/3UH^2 = 8\mathfrak{D}LW/3\dot{V}H$. Hinds (1999) suggests a simplified form of these expressions by neglecting the last term in Equation 20.191 and the two last terms in Equation 20.192. With these simplifications, the calculated penetration fractions agree within 1% with more accurate predictions over the whole range of values of Δ.

The case of a *circular-tube annular* cross section was treated by Kerouanton et al. (1996) who presented the solution as an infinite series:

$$f_p = \sum_{n=1}^{\infty} K_n \exp\left(-2\lambda_n^2 \Delta\right) \tag{20.193}$$

with $\Delta = \mathfrak{D}L/4U(R_2 - R_1)^2 = (\pi/4)(\mathfrak{D}L/\dot{V})$, where R_2 and R_1 are the outer and inner radii of the annulus, respectively. Table 20.3 provides the first three eigenvalues λ_n and coefficients for different R_1/R_2 ratios, as reported in Kerouanton et al. (1996). The use of three terms in the series enables an accurate evaluation of the solution for $\Delta > 0.005$.

20.6.2 External Flows

Here, the collection of particles by objects placed in an unconfined aerosol flow is considered. There are a great variety of practical cases involving external aerosol flow, for example, particle capture by fibers in a filter, build-up of deposits on the outer surfaces of heat exchanger tube bundles, icing of air-plane wings, particle scavenging by falling raindrops, and deposition from the atmosphere on roughness elements of the surface.

In flows around bodies, the particle removal (collection) efficiency n_R is defined as the ratio of the particles collected by the body to the particles geometrically incident on the body, as shown in the schematic diagram of Figure 20.4.

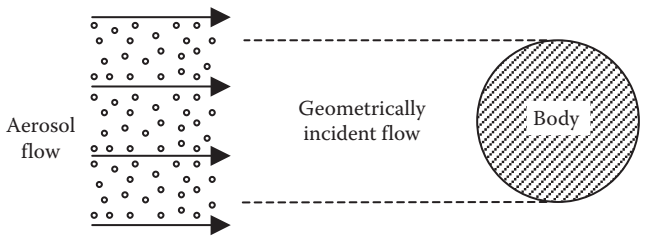

Figure 20.4

Schematic for particle collection efficiency in an external aerosol flow around a body.

20.6.2.1 Deposition at Low Stokes Numbers (St ≪ 1)

This case generally refers to particles with $d_p < 1\,\mu m$ for which the basic deposition mechanism is diffusion and, sometimes, direct *interception*. The latter arises from the finite physical size of the particle, which results in capture when the particle trajectory, although not directed to the surface, passes by within a distance of one particle radius. Interception is characterized by the dimensionless parameter

$$R = \frac{a_p}{L} \tag{20.194}$$

where

a_p is the radius of particle

L is a characteristic dimension of the body

For macroscopic bodies $R \ll 1$ and interception can be ignored, or, equivalently, particles can be taken as point particles. Instead, interception may be important in deposition onto very fine objects like filter fibers, or for particles small in terms of Stokes diameter but of elongated form like asbestos or mineral fibers.

If interception can be ignored, the problem of aerosol deposition becomes formally identical to the problem of convective heat transfer in an external flow, for which extensive amount of information is available in standard books. For combined diffusion and interception, Friedlander (2000) gives a detailed analysis for an aerosol flow around a cylinder placed with its axis normal to the flow.

For $Re < 1$ (e.g., around a filter fiber), the analysis leads to the functional relationship

$$n_R R\, Re\, Sc_p = \frac{\pi V_{d,\text{mean}} d_p}{\mathfrak{D}} = f(\Pi) \quad \text{for } Re < 1 \tag{20.195}$$

where $V_{d,\text{mean}}$ is the mean deposition velocity (taken over the whole circumference of the cylinder). In Equation 20.195, Π is a dimensionless group dependent on the interception parameter, the Reynolds number, and the particle Schmidt number:

$$\Pi = R(A\, Re\, Sc_p)^{1/3} \tag{20.196}$$

where $A = (4 - 2\ln Re)^{-1}$. The function f in Equation 20.195 cannot be analytically determined, but the dependence of n_R on particle size can be shown to exhibit a characteristic U-shape variation, that is, it passes through a minimum. First, n_R decreases with increasing particle size because diffusion decreases with increasing particle size until a size is reached where the interception parameter R becomes nonnegligible, and interception becomes effective, reversing the decreasing trend. An analytical solution can be obtained for the deposition velocity at the forward stagnation point, $V_{d,0}$, which reads

$$V_{d,0} = \frac{(2\mathfrak{D}/d_p)\exp(-AR^3\, Re\, Sc_p/3)}{\displaystyle\int_1^\infty \exp(-AR^3\, Re\, Sc_p\, z/3)dz} \tag{20.197}$$

Although this result applies only at the region of the forward stagnation point, the deposition is greatest there and it reflects the dependence on Re and Sc_p over the entire cylinder.

The case $Re \gg 1$ (e.g., around macroscopic objects) was analyzed by Fernández de la Mora and Friedlander (1982). Based on this analysis, approximate expressions were provided by Parnas and Friedlander (1984) for cylinders and spheres. For cylinders,

$$n_R = 1.88 Re^{-1/2} Sc_p^{-2/3} + 0.8 R^2 Re^{1/2} \quad \text{for } 10^2 < Re < 10^4 \tag{20.198}$$

and for spheres,

$$n_R = 2.40 Re^{-1/2} Sc_P^{-2/3} + 1.10 R^2 Re^{1/2} \quad \text{for } 10^2 < Re < 10^4 \tag{20.199}$$

20.6.2.2 Deposition at High Stokes Numbers ($St \gg 1$)

This case is mainly concerned with particles greater than 1 μm in diameter. Such particles are primarily deposited by inertial impaction. The removal efficiency n_R is usually called *impaction efficiency* in this case. Figure 20.5 shows the removal efficiency by impaction on a single sphere, a single cylinder placed normal to the flow, and an airfoil placed with zero angle of attack. The data are taken from Golovin and Putnam (1962) who surveyed experimental and theoretical results on inertial impaction on single elements for bodies of various shapes. They are presented in terms of removal (impaction) efficiency as a function of Stokes number. In Figure 20.5, the Stokes number does not include the Cunningham correction factor (cf. Equation 20.169), because as such, it was employed in the original data. This exclusion is not a serious limitation, because for supermicrometer particles, slip correction is anyway close to unity (see Table 20.1). The parameter Φ_p shown in Figure 20.5 is $\Phi_p = Re_p^2/St$ and it accounts for deviations from the Stokes regime. For $\Phi_p = 0$, particle motion obeys Stokes law. The results with $\Phi_p = 2000$ correspond to non-Stokesian particle behavior.

20.6.3 Turbulent Pipe Flow

Numerous experimental and theoretical studies have investigated particulate deposition in turbulent flows. Figure 20.6 summarizes the most important experimental measurements on deposition in turbulent pipe flow in terms of the (dimensionless) deposition velocity as a function of (dimensionless) particle relaxation time. The dimensionless particle relaxation time is defined by $\tau_V^\star \equiv \tau_V (u^\star)^2/\nu_g$ where $u^\star$ is the friction velocity, and the dimensionless deposition velocity is $V_d^\star \equiv V_d/u^\star$, with V_d the deposition velocity, see also Equation 20.181. As seen, for $\tau_V^\star < 0.3$, deposition is due almost exclusively to gradient diffusion, whereas for $\tau_V^\star > 0.3$, inertial effects assume importance, resulting in a spectacular increase of deposition rates with particle size. The main principles of inertial deposition were discussed in Section 20.5.3.

The experimental measurements shown in Figure 20.6 may be broadly interpreted as follows. Deposition of low-inertia particles, $\tau_V^\star < 1$, is governed mainly by Brownian and turbulent diffusion. The principal deposition mechanism of moderate-inertia particles, $1 \le \tau_V^\star \le 100$, is turbulent migration (turbophoresis), namely, the mechanism by which particles acquire a drift velocity that moves them from high to low turbulence regions in the fluid. For these particles, and for a range of $\tau_v^\star$, the lift force can exert noticeable influence on their deposition, provided the particle/fluid density ratio is not high. Moreover, for the smaller particles in that size range, preferential accumulation of particles close to the wall occurs: particles are driven close to the wall by turbophoresis, but they do not have enough inertia, to reach the wall. Particle accumulation close to the wall is most prominent at $\tau_v^\star \sim 10$. High-inertia particles ($\tau_V^\star > 100$) are

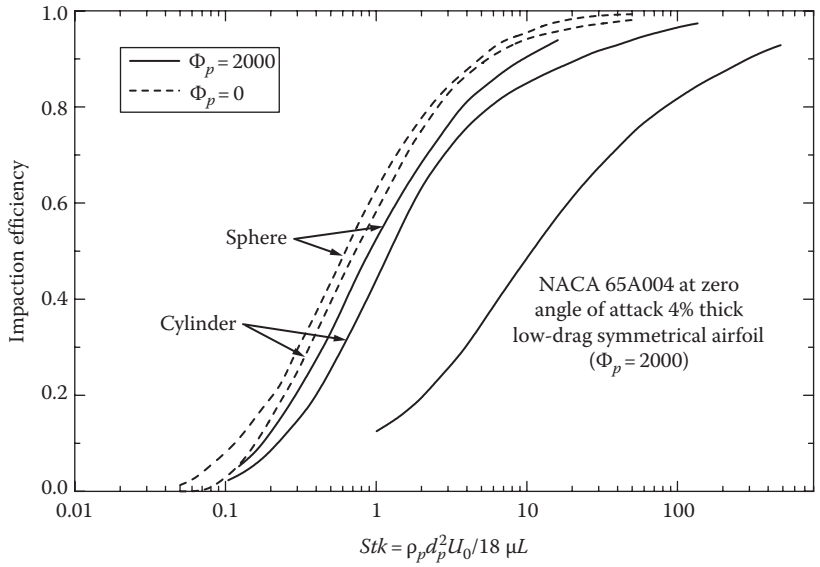

Figure 20.5

Impaction efficiency as a function of Stokes number, for a number of different target shapes. For the cylinder and the sphere L = diameter; for the airfoil L = thickness (maximum distance between upper and lower surfaces of the cross section).

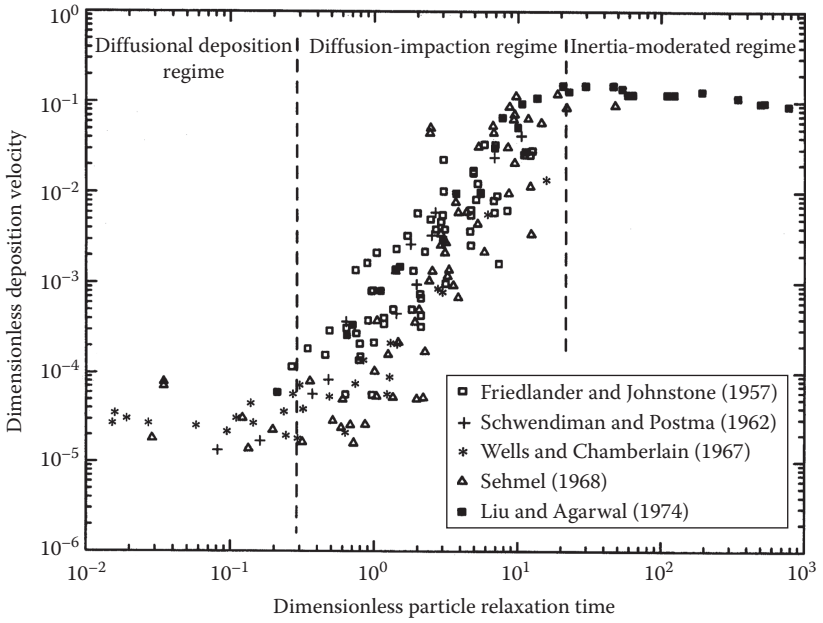

Figure 20.6

Particle deposition from fully developed turbulent pipe flow: a summary of experimental data. (From Young, J. and Leeming, A., *J. Fluid Mech.*, 340, 129, 1997. With permission from Cambridge University Press.)

weakly involved in the turbulent motion of the carrier fluid, their deposition being governed by the characteristics of near-wall turbulence and to a larger extent by the Reynolds number of the fluid. For high-inertia particle, gravity exerts considerable influence on their deposition. The theoretical investigation of particle interactions with turbulence is a vast area of intensive research. The subject is more extensively discussed in Chapter 2. In the following, the discussion is limited to providing practical means for the calculation of particulate deposition in turbulent flow.

For fully developed turbulent flow in a circular pipe of length L, the deposition velocity V_d may be considered as nonvarying along the tube, and the penetration fraction can be expressed as

$$f_p = \exp\left(-\frac{4V_d L}{UD}\right) \tag{20.200}$$

This expression results from a simple mass balance along the tube, and it enables the calculation of penetration through knowledge of the deposition velocity.

For deposition in the diffusional regime, the expression for deposition velocity proposed by Wells and Chamberlain (1967) can be used

$$\frac{V_d}{u^\star} = 0.2 Sc_p^{-2/3} Re^{-1/8} \tag{20.201}$$

This correlation applies for particles with $\tau_V^\star < 0.3$. In most cases, this condition is satisfied for particles with diameter $d_p < 1\,\mu\text{m}$. For deposition in the impaction regime ($\tau_V^\star > 0.3$, or roughly, for sizes $d_p > 1\,\mu\text{m}$), the theory of Friedlander and Johnstone (1957) is frequently used. The theory, known as the "free-flight" model or "stop-distance" model, assumes that particles diffuse with an eddy diffusion coefficient equal to that of the fluid up to one stop-distance of the wall, where they dispose sufficient inertia to escape the flow and reach the wall by flying freely through the quiescent viscous sublayer. The model presents the shortcoming of requiring injection "free-flight" velocities too high in comparison to the fluid radial root mean square velocities encountered close to the surface. Nevertheless, the model finds wide application because it is based

on correct physical arguments and it has proved very successful in reproducing experimental results. The deposition velocity is calculated as follows:

$$\frac{V_d}{U} = \frac{f/2}{1+\sqrt{f/2}\left(\left(1525/S_L^{*2}\right)-50.6\right)} \qquad \text{for } S_L^* < 5$$

$$\frac{V_d}{U} = \frac{f/2}{1+\sqrt{f/2}\left\{5\ln\left[5.04/\left(S_L^*/5-0.959\right)\right]-13.73\right\}} \qquad \text{for } 5 \le S_L^* \le 30 \tag{20.202}$$

$$\frac{V_d}{U} = \frac{f}{2} \qquad \text{for } 30 < S_L^*$$

where S_L^*, the dimensionless stop-distance, is calculated from Equation 20.168 using as injection velocity $0.9u^*$ (which approximates the experimentally determined mean square radial fluctuating velocity) to obtain

$$S_L^* = \frac{\rho_g d_p^2 \rho_p U^2 f/2}{18\mu_g^2} \tag{20.203}$$

It is sometimes useful to express the deposition velocity as a function of particle relaxation time. In the region $\tau_V^* > 0.3$, the experimental results of Figure 20.6 can be simply described by

$$\frac{V_d}{u^*} = \min[6\times10^{-4}\tau_V^{*2}, 0.1] \tag{20.204}$$

This correlation follows very closely the data of Liu and Agarwal (1974), the most frequently quoted experimental results among those summarized in Figure 20.6.

20.6.4 Convective-Gravitational Deposition in Ducts

The case of gravitational deposition from laminar flow in a circular tube is analyzed by Fuchs (1964), Pich (1972), and Heyder and Gebhart (1977). The penetration fraction is

$$f_p = 1-\frac{2}{\pi}\left[2\Phi\sqrt{1-\Phi^{2/3}} - \Phi^{1/3}\sqrt{1-\Phi^{2/3}} + \arcsin(\Phi^{1/3})\right] \tag{20.205}$$

$$\Phi = \frac{3LV_s}{4UD}\cos\theta \tag{20.206}$$

for

$$\frac{V_s \sin\theta}{U} \ll 1 \tag{20.207}$$

with θ as the inclination angle to the horizontal. The criterion expressed by Equation 20.207 requires the streamwise component of the particle settling velocity to be small in comparison to the fluid velocity.

For gravitational deposition from turbulent flow inside a circular tube, Fuchs (1964) provides the following approximation:

$$f_p = \exp\left(-\frac{16\Phi}{3\pi}\right) \tag{20.208}$$

with parameter Φ defined as in Equation 20.206. In general, for the same value of Φ, Equation 20.208 yields higher penetration fractions than Equation 20.205. However, the difference is significant only for $\Phi > 0.3$. Instead, for, $\Phi < 0.3$ the penetration through the tube is essentially the same for both laminar and turbulent flow conditions.

20.6.5 Convective Thermophoretic Deposition in Ducts

Thermophoretic deposition in tube flow has been studied extensively, as it is important in numerous practical applications, such as nuclear safety, gas cleaning, heat exchangers corrosion, microcontamination, and nanoparticle production. Convective deposition of particles in a fluid flow can be calculated in a Lagrangian or Eulerian framework (see relevant discussion in Section 20.2.2). Accurate thermophoretic deposition calculations have been performed by Lagrangian particle tracking in terms of stochastic Langevin equations (Dehbi, 2009). In an Eulerian approach, thermophoretic deposition arises from an additional drift velocity in the average particle velocity, see Equations 20.8 and 20.13; the thermophoretic velocity is calculated by Equation 20.173. In both approaches, the required carrier fluid velocity and temperature fields are provided by multidimensional CFD calculation, except for simple cases, for example, laminar flow in simple geometries, for which analytical solutions exist. In many practical applications, average quantities are needed: for example, in large nuclear safety codes. In such cases, one-dimensional approximations (bulk-averaged over the tube cross section) are used. Recent investigations suggest that the simplified 1D approach provides an accurate description of thermophoretic deposition in laminar flow (Housiadas and Drossinos, 2005, Muñoz-Bueno et al., 2005). In turbulent conditions, the approach appears adequate for small gas-to-wall temperature differences, but for elevated temperature differences, a multidimensional description may provide more accurate predictions (Housiadas and Drossinos, 2005).

An important quantity, of interest in practical applications, is the removal efficiency n_R, Equation 20.180. Several correlations have been proposed for n_R, obtained either from empirical fits or analytically. Housiadas and Drossinos (2005) solved analytically the one-dimensional heat and mass-transfer problem. They derived a universal formula for the convective thermophoretic removal efficiency, valid for laminar and turbulent flow and for any PrK_{th},

$$n_R = 1 - f_p = 1 - \exp\left[-4 Pr\, K_{\text{th}} \int_0^{x^+} d\xi^+ \frac{\theta_m(\xi^+) Nu(\xi^+)}{\theta_m(\xi^+) + \theta^\star} \right]. \tag{20.209}$$

The variables that appear in the previous equation are as follows: K_{th} is the thermophoretic coefficient, see Equation 20.176, x^+ is the dimensionless axial co-ordinate, θ_m is the dimensionless mean fluid temperature, and $\theta^\star$ is a characteristic dimensionless temperature. The dimensionless quantities are

$$x^+ = \frac{x}{2R\, Re\, Pr}; \quad \theta_m = \frac{T_m - T_w}{T_0 - T_w}; \quad \theta^\star = \frac{T_w}{T_0 - T_w}, \tag{20.210}$$

with x the axial coordinate, R the tube radius, T_m and T_0 the mean and inlet fluid temperatures, respectively, and T_w the temperature of wall.

Equation 20.209 was derived for the general case of a Nusselt number (Nu), varying with the distance from the tube inlet due to thermal development effects. If the Nusselt number is taken to be constant, it simplifies to

$$n_R = 1 - \left[\frac{\theta^\star + \exp(-2Nu\, x / R\, Re\, Pr)}{1 + \theta^\star} \right]^{Pr\, K_{th}}. \tag{20.211}$$

In laminar tube flow, the Nusselt number depends on the distance from the tube inlet due to the appreciable size of the thermal entrance zone. In carrying out the numerical evaluation of Equation 20.209, the empirical fits provided by Shah and London are recommended to specify the function $Nu(x^+)$ (Housiadas and Drossinos, 2005). In a turbulent flow, the thermal entrance zone is usually very short and the Nusselt number may be approximated by a constant. For such flows, Equation 20.211 is recommended, along

with the Gnielinski expression for Nu, in conjunction with Churchill's expression for the friction factor (Housiadas and Drossinos, 2005).

In the limit $x \to \infty$, that is, for tubes longer than the thermal entrance length (fully developed regime established), Equation 20.209 becomes

$$n_{R,\infty} = 1 - f_{p,\infty} = 1 - \left(\frac{\theta^*}{1+\theta^*} \right)^{PrK_{th}} = 1 - \left(\frac{T_w}{T_0} \right)^{PrK_{th}}. \tag{20.212}$$

This equation is a practical, universal expression, valid for convective thermophoretic deposition in both laminar and turbulent flows. It shows that in a long tube the total thermophoretic deposition efficiency is a function of only two parameters: the characteristic dimensionless temperature θ^* (or equivalently the ratio of the temperature of the wall to the initial fluid temperature) and the product PrK_{th}. It is valid as long as the one-dimensional description is accurate. This is the case for laminar flow, provided appropriate dimensionless scaling is selected. For turbulent flow, it was found to provide sufficient accuracy in practical applications with moderate gas-to-wall temperature differences (Housiadas and Drossinos, 2005).

20.6.6 Deposition in Filters

Filters are the most commonly used means to collect aerosol particles for sampling or air cleaning purposes. There are several types of filters, but the two most important types are *fibrous filters* and *porous membrane filters*. Fibrous filters consist of mats of individual fibers (e.g., cellulose fibers or glass fibers) that are arranged normal to the flow. Porous membrane filters consist of films (usually a polymeric material) of a porous structure that lets the air to flow through under pressure. The structure of a fibrous filter is characterized by a high void fraction, or porosity, that is, the space between fibers is large relative to their diameter. Typically, porosities in fibrous filters range from 70% to greater than 99%, with fibers having diameters between less than 1 and 100 μm. Porosities in porous membrane filters are typically between 50% and 90%, and the pore sizes are 0.01–10 μm. Despite the differences in structure, both fibrous filtering and porous membrane filtering rely on the same collection mechanisms. The filtering characteristics of a porous membrane filter are equivalent to those of a fibrous filter having fibers with a diameter that is slightly less than the actual pore size. The choice of a given type is mostly based on postsampling criteria rather than collection characteristics.

It is important to realize that an aerosol filter does not work like a sieve, where particles smaller than the holes pass and larger particles are collected, but rather as a trap that collects all sizes. The "holes" in fibrous filters are much larger than particles, but the latter are very efficiently collected by the fibers as they flow through the "holes" by the combined action of various deposition mechanisms, namely, diffusion, interception, inertial impaction, gravitational settling, and, sometimes, electrostatic deposition.

Single fiber efficiency can be analyzed using the same principles discussed in Section 20.6.2. The overall collection efficiency of a filter can be shown to depend on the collection efficiency of a single fiber and the volume fraction of fibers. The collection efficiency of a filter as function of particle size is shown in Figure 20.7. The trend is characteristic in aerosol filtering: large particles deposit very efficiently due to impaction and, eventually, gravitational sedimentation; small particles deposit efficiently as well, as they undergo significant Brownian diffusion due to their high diffusion coefficient. In between, there is a size range where retention drops because particles are too large to diffuse effectively and too small to exhibit significant inertial effects. In this size range, the transition from diffusion to interception takes place and the characteristic U-shaped variation with size is obtained, as discussed in Section 20.6.2.1. As Figure 20.7 shows aerosol filtration exhibits a somehow counterintuitive behavior: the difficulty is not in collecting ultrafine particles from a flow, but particles of intermediate sizes. The particle size corresponding to the minimum efficiency point is called the *most penetrating particle size*. As shown in Figure 20.7, this size also depends on the velocity at the face of the filter. Depending on the filter and velocity, the minimum efficiency is usually in the range 0.05–0.5 μm, but it is generally taken to be approximately at $d_p = 0.3\,\mu m$. This is the basis for the standard DOP test method, where DOP (dioctyl phthalate) particles of 0.3 μm in diameter are used to characterize the collection efficiency of high-efficiency particulate air (HEPA) filters.

Aerosol filtration is a vast domain. Other important issues in aerosol filtration are pressure drop, loading and clogging, selection criteria, etc. For detailed information, the reader may refer to Davies (1973) and Brown (1993).

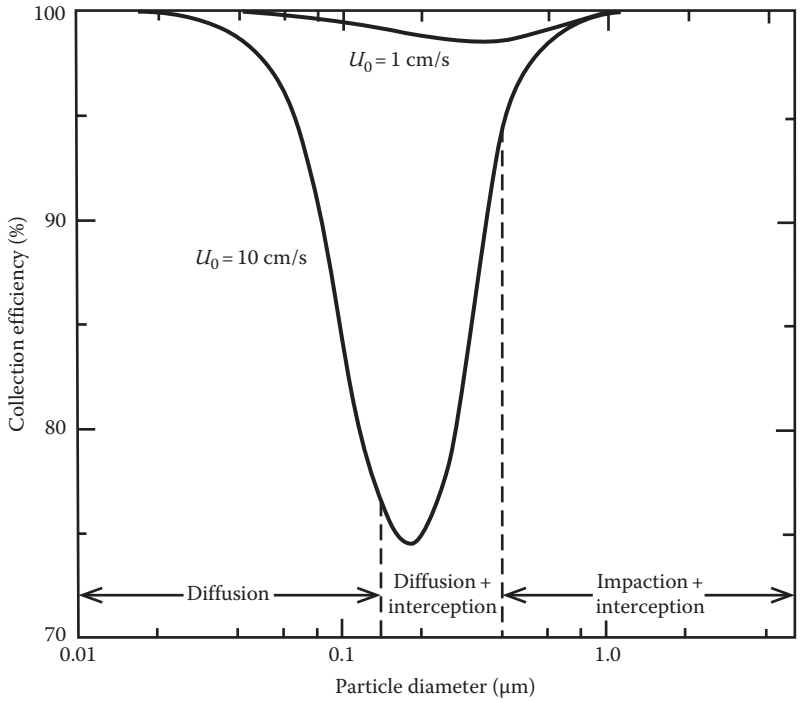

Figure 20.7

Filter collection efficiency versus particle size for face velocities of 0.01 and 0.1 m/s; the filter thickness is 1 mm and the fiber diameter 2 μm. Dispersed Flow in Non-Newtonian Fluids

Raj P. Chhabra

21.1 Introduction
21.2 Newtonian and Non-Newtonian Fluids
21.3 Rigid Nondeformable Particles
21.4 Fluid Spheres
21.5 Other Effects
21.6 Concluding Remarks and Future Directions

21.1 Introduction

The preceding chapters have been concerned with the flow situations when the individual phases on their own are Newtonian fluids and the complexities of the flow stemmed either from the multiphase nature of the fluid (Chapters 3 through 5, 10, 11) or due to phase change (Chapters 8 and 9) or from the turbulent nature of the flow itself (Chapter 12), etc. Undoubtedly, most low-molecular-weight fluids like organic and inorganic liquids, or solutions of inorganic salts, gases, molten metals, and salts, all exhibit what is known as the Newtonian fluid behavior. Their behavior in simple shear is described by a single parameter, namely, the shear or dynamic or simply viscosity of the fluid, which is a function of the temperature and pressure for each substance. For most gases, the viscosity increases with both increasing temperature and pressure, whereas for a liquid, its viscosity decreases with temperature and it increases with pressure. Ever since the development of the Navier–Stokes equations more than 150 years ago, significant advances have occurred in various aspects of the mechanics of Newtonian fluids, as can be gauged from the state-of-the-art chapters included in this book.

In contrast, most structured fluids like solutions of high-molecular-weight (>5000 or so) natural (gums and resins) and synthetic polymers and their melts, slurries, pastes, suspensions, foams, emulsions, and surfactant-laden worm-like micellar solutions, for instance, do not conform to the Newtonian postulate and are accordingly known variously as "non-Newtonian," "rheologically complex," or "nonlinear" fluids. It is difficult to imagine modern life without such materials. Think of the range of processed foodstuffs we consume every day, personal- and health-care products used routinely, cleaning aids and polishing waxes, etc., all of which fill the aisles of modern supermarkets, for instance.

All modern technologies, including modern transportation (in terms of smart materials of construction or advanced fuels), entertainment industry (films, DVDs), medicine, environment, energy generation and conservation, etc., all exploit non-Newtonian characteristics in one form or the other at some stage during the course of their manufacture or application. The extraction of oil from rocks via polymer flooding, the soft gels used to make optical lenses, and the next generation of aviation fuels, all hinge on successfully imparting the desirable rheological characteristics to achieve the satisfactory product quality. Indeed, so widespread is the non-Newtonian fluid behavior that it would be no exaggeration to say that the Newtonian fluid behavior is more of an exception rather than the rule! Consequently, over the past 50–75 years or so, this branch of fluid mechanics has begun to receive systematic attention, albeit it is still in its embryonic stage (Boger and Walters, 1992, Tanner and Walters, 1998, Denn, 2004). Undoubtedly, significant advances

have been made in some simple geometries like flow in ducts of circular and noncircular cross sections (Lawal and Mujumdar, 1987, Chhabra, 1999), porous media flows (Chhabra, 1993, 2006, Chhabra et al., 2001), batch mixing vessels (Chhabra, 2003, Paul et al., 2004, Chhabra and Richardson, 2008), etc. In contrast, the corresponding body of knowledge on external flows such as that over a rigid or fluid (bubble or drop) sphere is rather limited. This chapter is concerned with the momentum and heat transfer characteristics of a single rigid (spherical and nonspherical) particle and a fluid sphere (bubble, drop) in different types of confined and unconfined non-Newtonian fluids. The corresponding behavior in a Newtonian fluid is used as the reference line to draw qualitative inferences regarding the influence of non-Newtonian rheology, and therefore, frequent reference will be made to the pertinent sections of Chapter 1. We begin with the definitions and classification of the different types of non-Newtonian characteristics in the next section.

21.2 Newtonian and Non-Newtonian Fluids

One may classify the behavior of a given fluid in many ways including as being compressible or incompressible, single phase or multiple phase or depending upon its response to the applied stress, as is done here. Thus, for instance, when a shear stress ($\vec{\tau}_{yx}$) is applied to a thin layer of a fluid confined in the narrow gap in between two parallel plates by applying a tangential force to the top plate while keeping the bottom plate stationary, eventually, a linear velocity profile is established (i.e., the constant shear rate, $\dot{\vec{\gamma}}_{yx}$) as shown schematically in Figure 21.1. The response of a Newtonian fluid is characterized by a linear relationship between $\vec{\tau}_{yx}$ and $\dot{\vec{\gamma}}_{yx}$ as

$$\vec{\tau}_{yx} = \mu \dot{\vec{\gamma}}_{yx} \tag{21.1}$$

In Equation 21.1, μ is the viscosity or dynamic viscosity of the fluid, which has a constant value (independent of $\vec{\tau}_{yx}$ and $\dot{\vec{\gamma}}_{yx}$) for a given substance and is a function of temperature and pressure only. Most low-molecular-weight substances like gases, organic liquids, inorganic salts and their solutions, molten metals, and electrolytes exhibit Newtonian fluid behavior and are accordingly known as Newtonian fluids. With further assumption of incompressibility (applicable throughout this chapter), such a fluid will obviously satisfy the familiar Navier–Stokes equations written in their generalized three-dimensional form, for example, see Bird et al. (2002).

In contrast, a substance that, in simple shear, does not conform to Equation 21.1 is called a non-Newtonian fluid. It is customary to further categorize non-Newtonian fluid behavior into three broad types as follows:

21.2.1 Time-Independent Fluid Behavior

In simple one-dimensional shear, such as that shown in Figure 21.1, the current value of the shear stress at a point in such a fluid is determined only by the corresponding value of the rate of shear and vice versa. The steady shear behavior of this type of fluids is thus described by a relation of the form

$$\vec{\tau}_{yx} = f(\dot{\vec{\gamma}}_{yx}) \tag{21.2}$$

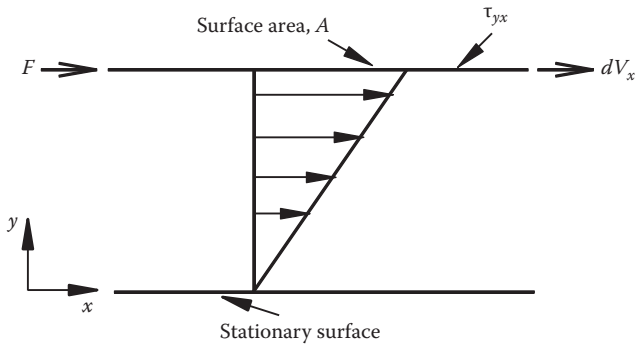

Figure 21.1

Schematic representation of unidirectional shearing flow.

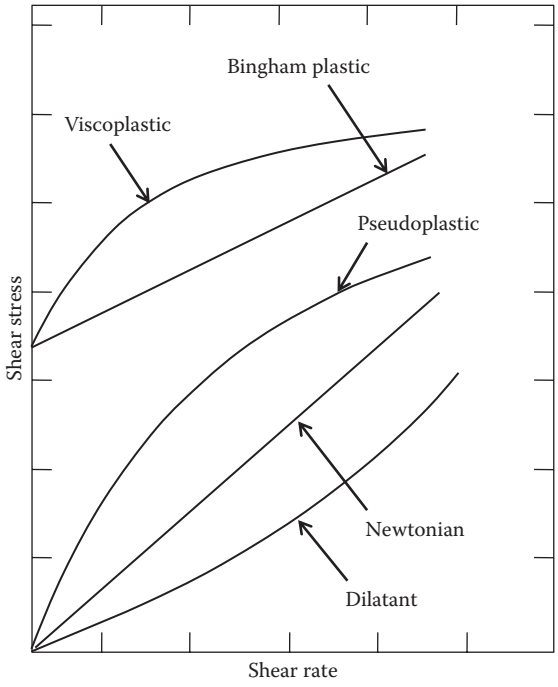

Figure 21.2

Qualitative flow curves for time-independent fluid behavior.

or, its inverse form

$$\vec{\dot{\gamma}}_{yx} = f^{-1}(\vec{\tau}_{yx}) \tag{21.3}$$

Of course, Equation 21.1 is a limiting subset of this family of fluids. Depending upon the nature of the function in Equation 21.2 or 21.3, three distinct types of fluid behaviors can be identified:

1. Shear-thinning or pseudoplastic
2. Shear-thickening or dilatant
3. Viscoplastic with and without shear-thinning

Figure 21.2 shows schematically these three types of fluid characteristics including the limiting case of Newtonian fluid behavior. Each of these will now be treated in some detail.

21.2.1.1 Shear-Thinning (or Pseudoplastic) Fluids

This is possibly the commonest type of time-independent non-Newtonian fluid characteristics encountered in industrial practice. In a simple shear test, it is characterized by an apparent viscosity, μ, defined as $\left|\vec{\tau}_{yx}\right| / \left|\vec{\dot{\gamma}}_{yx}\right|$, which progressively decreases with the increasing shear rate. Most polymeric solutions exhibit Newtonian plateau (constant viscosity) at very high and very low shear rates, that is, the apparent viscosity approaches a constant value of μ_∞ (infinite shear value) and μ_0 (zero shear value), as can be seen in Figure 21.3 for a polymer solution. This figure also illustrates the fact that often several instruments are required to span such a wide range of shear rate or shear stress. Obviously, the infinite shear limiting value, μ_∞, is not observed for polymer melts, or emulsions, or foams, etc. (Bird et al., 1987). While it is difficult to provide generalizations, the onset of shear-thinning behavior is influenced by factors such as concentration, molecular weight, structure (linear, branched, etc.) of the polymer, type of solvent, temperature, etc. Generally, the lower the concentration and/or the molecular weight of the polymer, the higher is the shear rate required to induce shear-thinning behavior in a system (Larson, 1998).

Over the years, many mathematical forms of the functional relationship depicted by Equation 21.2 or 21.3 have been proposed in the literature, for example, see Chhabra and Richardson (2008), Ibarz-Ribas and Barbosa-Canovas (2003). A representative selection of the widely used viscosity models is included here.

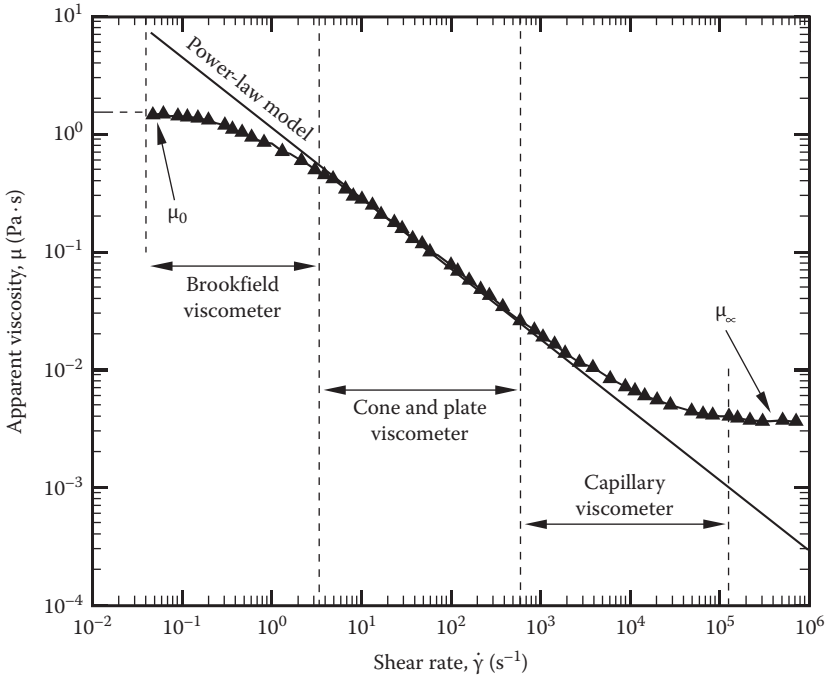

Figure 21.3

Demonstration of zero shear and infinite shear viscosities for a shear-thinning polymer solution. (From Boger, D.V., *Nature*, 265, 126, 1977.)

21.2.1.1.1 Power-Law Model Generally, the relationship between the shear stress ($\vec{\tau}_{yx}$) and shear rate ($\vec{\dot{\gamma}}_{yx}$) for a shear-thinning material can be approximated by a linear dependence on log-log scales, which follows the power law:

$$\left|\vec{\tau}_{yx}\right| = m\left(\left|\vec{\dot{\gamma}}_{yx}\right|\right)^{n} \tag{21.4}$$

Or alternately, it can be written in terms of the apparent viscosity, μ, as

$$\mu = \frac{\left|\vec{\tau}_{yx}\right|}{\left|\vec{\dot{\gamma}}_{yx}\right|} = m\left(\left|\vec{\dot{\gamma}}_{yx}\right|\right)^{n-1} \tag{21.5}$$

For, $n < 1$, Equation 21.5 predicts $\left(\left|d\mu / d\dot{\gamma}_{yx}\right|\right) < 0$, that is, decreasing viscosity with the increasing shear rate. Therefore, the values of the power-law index, n, smaller than unity correspond to shear-thinning behavior. Many polymeric solutions and melts exhibit the value of power-law index, n, in the range of ~0.3 to ~0.7. Still smaller values of power-law index (n = ~ 0.1–0.2) are obtained with fine particle aqueous slurries like china clay, bentonite, coal, etc. (Chhabra and Richardson, 2008). Thus, in contrast to the Newtonian fluids whose flow behavior is characterized by the value of a single parameter, namely, viscosity, a power-law fluid necessitates at least two parameters, m and n for defining its viscosity behavior. However, while Equation 21.4 or 21.5 affords the simplest mathematical representation of the shear-thinning fluid behavior, it predicts unrealistically $\mu_0 = \infty$ and $\mu_\infty = 0$ in the limits of $\left|\vec{\dot{\gamma}}_{yx}\right| \to 0$ and $\left|\vec{\dot{\gamma}}_{yx}\right| \to \infty$ respectively, as can be seen in Figure 21.3. Also, the constant values of m and n are valid generally only over a narrow range of shear stress or shear rate values (e.g., see, Figure 21.4) and, hence, one needs to know *a priori* the expected range of shear rate in a given application (Barnes et al., 1989, Chhabra and Richardson, 2008, Schramm, 2014). In spite of these limitations, this is possibly the most widely (and also most maligned!) used viscosity model in the realm of non-Newtonian engineering fluid mechanics.

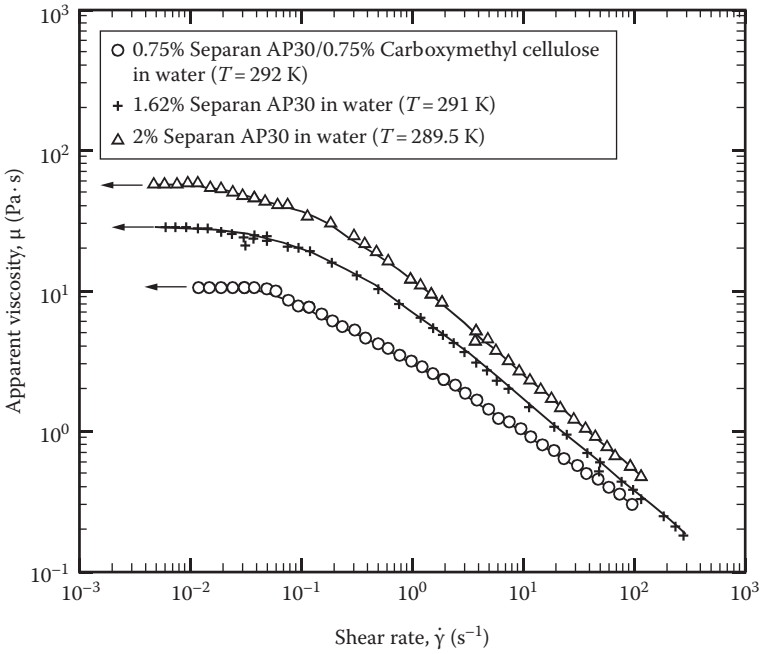

Figure 21.4

Representative apparent viscosity plots for three pseudoplastic (shear-thinning) polymer solutions. (From Chhabra, R.P. and Richardson, J.F., *Non-Newtonian Flow and Applied Rheology*, 2nd edn., Butterworth-Heinemann, Oxford, U.K., 2008.)

21.2.1.1.2 Cross Model Most of the aforementioned deficiencies of the power-law model are rectified by another popular empirical model known as the Cross model (Cross, 1965), written in simple shear as

$$\frac{\mu-\mu_\infty}{\mu_0-\mu_\infty}=\left[1+m\left(\left|\dot{\vec{\gamma}}_{yx}\right|\right)^n\right]^{-1} \tag{21.6}$$

This model also predicts shear-thinning behavior for $n < 1$. Unlike Equation 21.4 or 21.5, it includes the limiting values of μ_0 and μ_∞ under appropriate conditions. However, this improvement has been achieved at the expense of four disposable parameters, namely, μ_0, μ_∞, m, and n as opposed to only two parameters (m, n) present in the simple power-law model, Equation 21.5.

21.2.1.1.3 Carreau Viscosity Equation Based on molecular ideas, Carreau (1972) independently put forward the following viscosity equation, which is similar to Equation 21.6:

$$\frac{\mu-\mu_\infty}{\mu_0-\mu_\infty}=\left[1+\left(t_0\left|\dot{\vec{\gamma}}\right|\right)^2\right]^{-1/2(n-1)/2} \tag{21.7}$$

This is also a four constant viscosity model and it does span the entire range of shear rates including the zero-shear and infinite-shear viscosities.

21.2.1.2 Shear-Thickening (or Dilatant) Fluids

These materials are similar to shear-thinning fluids except for the fact that their apparent viscosity increases with the increasing shear rate. Initially, Reynolds (e.g., see Barnes, 1989, Goddard and Bashir, 1990) observed this behavior in concentrated suspensions and explained it by the dilation or expansion of such a suspension under shear. At low shear rates, the voidage of such a system remains fixed and the volume of liquid available is sufficient to completely fill the interparticle volume. Under such conditions, the motion of particles past each other is lubricated by the fluid present in the system. However, at high shear rates, the system dilates, resulting in an increase in the void volume. In turn, the available liquid is no longer sufficient to fill the

interstitial void volume to lubricate the particle motion. Naturally, due to solid–solid friction, the resulting shear stress shows a stronger dependence on the shear rate than that in Newtonian fluids ($n = 1$). This type of behavior is frequently seen in sand dunes, titanium-di-oxide in water suspensions, aqueous start and corn flour dispersions, etc. This subclass of time-independent fluids has evoked very little interest (Barnes, 1989, Mewis and Wagner, 2012), though now it is receiving increasing attention in the context of pasty materials encountered in a broad spectrum of processing applications. From an engineering perspective, it is customary to approximate the simple shear data for such fluids also using the power-law model, Equation 21.4, with the flow behavior index taking on values greater than unity, that is, $n > 1$. Some of the polymer solutions used as thickening agents in food and pharmaceutical products exhibit values of the power-law index, n, in the range 1.2–1.6 (Barnes, 1989). It is not uncommon for such a substance to exhibit shear-thinning behavior at low shear rates and shear-thickening characteristics at high shear rates.

21.2.1.3 Viscoplastic Fluids

This type of fluid behavior is characterized by the existence of a threshold stress (also known as the yield stress or the apparent yield stress, $\vec{\tau}_0$), which must be overcome for such a substance to shear like a fluid (see Figure 21.2). For stress levels below the fluid yield stress $\left(|\vec{\tau}_0|\right)$, it deforms like an elastic solid. Furthermore, for $|\vec{\tau}_{yx}| > |\vec{\tau}_0|$, such a material may exhibit a constant shear viscosity (Bingham fluid) or shear-thinning behavior (Herschel–Bulkley fluid). This type of dual behavior is generally explained by postulating the presence of three-dimensional structures of sufficient rigidity, which can resist deformation for $|\vec{\tau}_{yx}| < |\vec{\tau}_0|$ by offering very high values of the apparent viscosity, that is, yield stress. On the other hand, for $|\vec{\tau}_{yx}| > |\vec{\tau}_0|$, the structure breaks down, at least partially, and the substance behaves like a viscous fluid. There are three widely used viscosity models for viscoplastic behavior and these are presented here (Bird et al., 1983).

21.2.1.3.1 Bingham Model

$$\vec{\tau}_{yx} - \vec{\tau}_0^B = \mu_B \vec{\dot{\gamma}}_{yx} \quad \text{for } |\vec{\tau}_{yx}| > |\vec{\tau}_0^B| \tag{21.8}$$

$$\vec{\dot{\gamma}}_{yx} = 0 \quad \text{for } |\vec{\tau}_{yx}| < |\vec{\tau}_0^B| \tag{21.9}$$

Once the applied stress exceeds the magnitude of the fluid yield stress, a Bingham fluid exhibits Newtonian flow behavior with a constant shear viscosity, μ_B. However, strictly speaking, this model also predicts shear-thinning behavior because the apparent viscosity of the fluid, $\mu = \mu_B + \left(\vec{\tau}_0^B / |\vec{\dot{\gamma}}_{yx}|\right)$, decreases with the increasing shear rate.

21.2.1.3.2 Herschel–Bulkley Model

This replaces the constant μ_B by a power-law viscosity as

$$\vec{\tau}_{yx} - \vec{\tau}_0^H = m\left(|\vec{\dot{\gamma}}_{yx}|\right)^n \quad \text{for } |\vec{\tau}_{yx}| > |\vec{\tau}_0^H| \tag{21.10}$$

$$\vec{\dot{\gamma}}_{yx} = 0 \quad \text{for } |\vec{\tau}_{yx}| < |\vec{\tau}_0^H| \tag{21.11}$$

This model is used when the flow curve is nonlinear above the fluid yield stress (see Figure 21.2).

21.2.1.3.3 Casson Model

This model has its origins in modeling the rheological behavior of blood, but subsequently, it has been successfully employed for other dispersed systems also. In simple shear, it is written as follows:

$$\left(|\vec{\tau}_{yx}|\right)^{0.5} - \left(|\vec{\tau}_0^C|\right)^{0.5} = \left(\mu_C |\vec{\dot{\gamma}}_{yx}|\right)^{0.5} \quad \text{for } |\vec{\tau}_{yx}| > |\vec{\tau}_0^C| \tag{21.12}$$

$$\vec{\dot{\gamma}}_{yx} = 0 \quad \text{for } |\vec{\tau}_{yx}| < |\vec{\tau}_0^c| \tag{21.13}$$

Typical examples of the structured fluids displaying yield stress include blood, fire fighting and shaving foams, tomato sauce, cosmetics, cleaning waxes, drilling muds, etc. (Barnes, 1999, Mewis and Wagner, 2012).

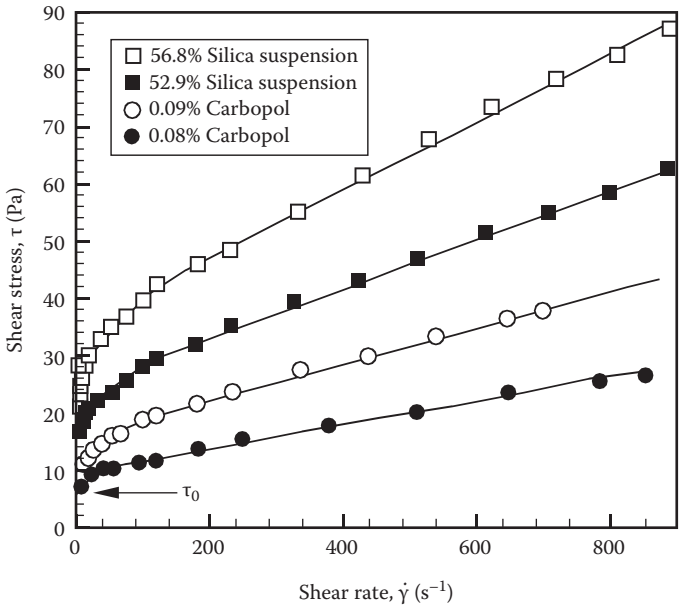

Figure 21.5

Typical experimental data for two polymer solutions and two silica suspensions exhibiting viscoplastic behavior.

Figure 21.5 shows steady shear data for two concentrated silica suspensions and two polymer solutions exhibiting viscoplastic behavior.

Before leaving this subsection, it is appropriate to mention here that it has long been (and continues to be) a matter of debate whether a true yield stress in liquid-like systems exists or not (Barnes and Walters, 1985, Barnes, 1999). Many researchers view the yield stress in terms of a transition from solid-like to fluid-like behavior, the so-called biviscous fluid approach (O' Donovan and Tanner, 1984, Glowinski and Wachs, 2011). Naturally, whether a true yield stress exists or not seems to be closely related to the time scale of observation. Notwithstanding these difficulties, the notion of an apparent yield stress is of practical utility in the context of engineering applications, especially in the formulation and manufacture of food-, pharmaceuticals, and health-care–related products (Laba, 1993).

21.2.2 Time-Dependent Fluid Behavior

Many substances encountered in health-care, food-, and personal-care product sectors (Laba, 1993, Ibarz-Ribas and Barbosa-Canovas, 2003) exhibit rheological characteristics, which cannot be adequately approximated by simple mathematical expressions presented in Section 21.2.1. This difficulty stems primarily from the fact that, in simple shear, their apparent viscosity is not only a function of the shear stress $\left(\vec{\tau}_{yx}\right)$ or shear rate $\left(\vec{\dot{\gamma}}_{yx}\right)$, but it shows additional dependence on the kinematic history, duration of shearing, etc. For instance, when materials such as cement paste, waxy crude oils, hand lotions and creams, etc. are sheared at a constant shear rate following a long period of rest, their viscosities may decrease as the internal structures present in such a substance are progressively broken down. As the number of linkages available for breaking down decreases, the rate of change of viscosity with time approaches zero. Conversely, as the structure breaks down, the rate at which these linkages can re-form increases; thereby, a state of dynamic equilibrium is reached when the rates of building-up and of breakdown are balanced. This can directly be compared with the dynamics of a first-order reversible chemical reaction. Such behavior is known as thixotropy, and these systems are accordingly known as thixotropic materials. On the other hand, the opposite type of behavior has been observed in a few systems in which the application of shear promotes building-up of internal structures and, hence, the apparent viscosity of such a substance increases with the duration of shearing. This behavior is called antithixotropy or rheopexy and such fluids are known as rheopectic (Barnes et al., 1989, Barnes, 1997).

It stands to reason that when the shear rate is steadily increased from a zero value to a maximum value and then decreased at the same rate, this class of materials will exhibit hysteresis phenomenon, as shown schematically in Figure 21.6. Note that the arrows indicating the increasing and decreasing shear rates are opposite to each other for a thixotropic and for a rheopectic material. The area enclosed by these loops is a

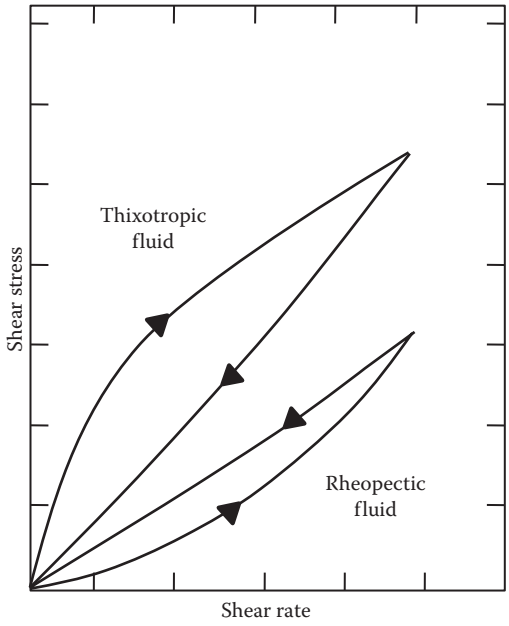

Figure 21.6

Qualitative shear stress–shear rate behavior for thixotropic and rheopectic materials.

crude measure of the severity of time-dependent behavior. This will be zero for a time-independent material described in Section 21.2.1. On the other hand, larger is the area enclosed by the loop, stronger is the time-dependent behavior. Figure 21.7 shows the experimental data for a cement paste exhibiting thixotropic behavior.

The mathematical equations required to describe the rheological behavior of time-dependent materials tend to be far more complex than that presented in the preceding section. While this chapter is not concerned with thixotropic and rheopectic fluids, interested readers are referred to the excellent review article

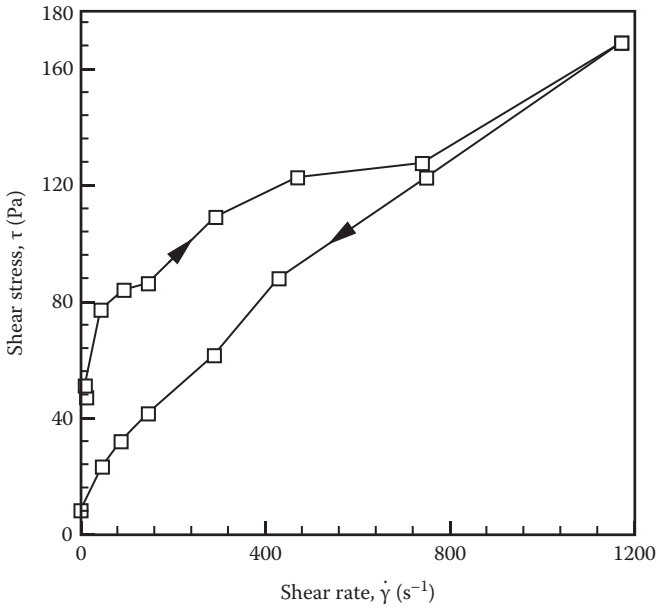

Figure 21.7

Thixotropic behavior of a cement paste. (Data from Struble, L.J. and Ji, X., Rheology, in Ramachandran, V.S. and Beaudoin, J.J., Eds., *Handbook of Analytical Techniques in Concrete Science and Technology*, William Andrew Inc., New York, 2001, Chapter 9.)

of Barnes (1997) and a recent book on this subject (Mewis and Wagner, 2012) for a detailed treatment of time-dependent behavior.

21.2.3 Viscoelastic Fluid Behavior

It is customary to categorize a given substance either as an elastic solid or as a viscous fluid. At one extreme is the Newtonian fluid behavior characterized by a constant shear viscosity, Equation 21.1; the other extreme is the so-called Hookean elastic behavior, which is characterized by the linear relationship between the applied stress and strain, the constant of proportionality being the familiar Young's modulus. From another vantage point, the energy expended in deforming a fluid element at a constant rate is completely lost when the stress is removed. Such a substance thus shows no recovery or has no memory of its virgin state. On the other hand, an ideal elastic solid will exhibit complete recovery and it has a perfect memory. Many materials of industrial relevance show a blend of both viscous and elastic effects under appropriate conditions. In the absence of thixotropic and rheopectic effects, such a material is called elasticoviscous (more solid-like) or viscoelastic (more fluid-like). Therefore, perfectly elastic deformation and viscous flow represent the two limiting cases of viscoelastic behavior. In some materials, only these limits are easily observed. For instance, the viscosity of ice and the elasticity of water may generally go unnoticed! Most polymeric systems exhibit viscoelastic characteristics. In simple shear, a viscoelastic substance exhibits normal stress difference effects, which are in stark contrast to the case of equal normal stresses in Newtonian fluids. Thus, in addition to the shear stress, one also requires the normal stress difference as functions of the applied shear rate to characterize viscoelasticity. Similarly, viscoelastic fluids deviate from Newtonian fluids and time-independent fluids even more dramatically when subject to small amplitude oscillatory shear and extensional deformation (Bird et al., 1987, Macosko, 1994, Larson, 1998). For instance, it is common for a viscoelastic fluid to exhibit shear-thinning viscosity in simple shear and strain hardening in extensional flow.

The corresponding constitutive relations connecting the stress tensor to the rate of strain tensor for a viscoelastic material are invariably in the form of integral and differential equations and a detailed discussion is neither required here nor is possible. Excellent treatises are, however, available on this subject (Bird et al., 1987, Carreau et al., 1997, Larson, 1998). Suffice it to add here that the so-called Deborah number, *De*, is often introduced to ascertain the importance of elastic effects in a given flow situation. In its general form, it is defined as

$$De = \frac{\lambda_f}{\lambda_p} \tag{21.14}$$

where

λ_f is a characteristic time of the fluid
λ_p is the representative process time

In a crude sense, λ_f is a measure of the fluid's memory span. Thus, if $\lambda_p \gg \lambda_f$, the stresses developed in the fluid due to the flow have sufficient time to relax and, hence, no elastic effects are expected. On the other hand, for the case of $\lambda_p \ll \lambda_f$, a fluid element is subjected to rapidly changing kinematic environment such that the fluid element does not have sufficient time to respond to it. Clearly, in this case, viscoelastic effects will manifest. Broadly, vanishingly small values of $De \to 0$ correspond to a viscous response (no memory and recovery) and large values $De \to \infty$ relate to an elastic response (perfect memory and recovery). It is thus not uncommon for the same substance to behave like a viscous fluid in one setting and like an elastic solid in another situation (Bird et al., 1987, Carreau et al., 1997, Tanner, 2000). A great deal of confusion exists, however, in the literature regarding the definitions and evaluation of λ_f and λ_p (Bird et al., 1987). Notwithstanding the gross oversimplification entailed in assigning a single (constant) value to the fluid characteristic time, λ_f, it is sometimes extracted purely from viscosity data (Bird, 1965) or first normal stress difference or small amplitude oscillatory shear results. All of these are probably some measures of the fluid viscoelasticity, but such varied approaches make cross-comparisons impossible. Similarly, the characteristic process time, λ_p, is a "crude" measure of the residence time of the fluid. The following illustrative example further elucidates these ideas. Let us consider a polymer solution with a characteristic time of 10 ms, that is, $\lambda_f = 10$ ms. A small and light sphere of 1 mm diameter settles in it at a terminal velocity of 1 mm/s. Thus, the characteristic process time can be taken as the time required to fall through a distance equal to one diameter, that is, λ_p = diameter/velocity = 1 s. The resulting value of the Deborah number, *De*, is thus, $De = 10 \times 10^{-3}/1 = 0.01$. In contrast, a sphere made of heavy metal but of the same diameter (1 mm) will settle

faster, say, with a velocity of 20 mm/s. In this case, the value of the Deborah number is $De = (10 \times 10^{-3})/(1/20)$, that is, $De = 0.2$, which is much larger than the previous value of 0.01. This thought experiment suggests that the viscoelastic effects are likely to be stronger for the second (heavy) sphere than that for the first (light) sphere. Naturally, the estimated values of De are dependent on the methods of evaluation of λ_f and λ_p; the qualitative inference will, however, not be influenced by such rescaling of the Deborah number.

Before concluding this section, it is worthwhile to reiterate here that in order to solve a transport phenomena problem, one must combine the constitutive relationship with the momentum and energy equations. Therefore, considerable intuition is required in choosing an appropriate fluid model to keep the level of complexity of the resulting partial differential equations at a tractable level. This section is concluded by reiterating that the primary focus in this chapter is on the momentum and heat transfer characteristics of an isolated rigid and fluid sphere in power-law, and Bingham and Herschel–Bulkley fluid models with and without wall effects. This is followed by the prediction of drag and Nusselt number behavior of axisymmetric spheroidal and hemispherical particles and nonspherical particles in power-law and viscoplastic fluids. In view of the limited and inconclusive nature of the corresponding body of knowledge concerning the role of fluid viscoelasticity in these systems, this aspect is discussed only briefly and qualitatively. However, we begin with the case of a single rigid sphere undergoing steady translation in different types of non-Newtonian fluids.

21.3 Rigid Nondeformable Particles

While a detailed discussion of the interactions between particles and moving fluids in a range of settings is presented in Section 1.4, Chapter 1, when the continuous phase exhibits the standard Newtonian fluid behavior, the corresponding information for non-Newtonian fluids is presented in this section. Current interest in such problems stems from both fundamental and pragmatic considerations. From a theoretical standpoint, the flow over a sphere has been used as a model configuration to understand the nature of underlying physical processes to characterize their momentum and convective heat/mass transport aspects. In addition, this simple configuration, which is free from geometric singularities, has also been used to benchmark the efficacy of numerical solution methodologies as well as to test the applicability of the rheological equations of state whose parameters (like $m, n,$ or τ_o^B, μ_B, etc.) are evaluated in well-defined viscometric flows, whereas the flow over a sphere is nonviscometric. In view of the long history of this flow configuration, significant research effort has been expended in obtaining the non-Newtonian equivalent of the Stokes solution. Unfortunately, the answer to this seemingly simple question depends upon the choice of the rheological model (or simply the viscosity model). In view of the nonlinear nature of the viscosity models (such as those discussed in Section 21.2), this aspect adds enormously to the level of difficulty in obtaining solutions to the momentum equations even when the nonlinear inertial effects are neglected altogether (Chhabra, 2006). In addition to its fundamental significance, there are numerous industrial settings where the settling velocity of a sphere in such fluids is frequently needed in process design calculations. For instance, depending upon the application, sometimes, it is necessary to keep particles from settling under the influence of gravity to meet the product specifications (such as in fruit yogurts, health and personal care products and cleaning aids). Similarly, there are occasions when it is desired to effect liquid–solid separation using gravity settling ponds or hydrocyclones or in the dewatering of slurries, etc. In either event, reliable values of the settling velocity of a sphere of the known size and density in a liquid of given density and rheology (values of $m, n,$ or τ_o^B, μ_B, etc.) are thus required. This information is conveniently expressed using the common dimensionless parameters like drag coefficient, Reynolds number, Nusselt number, and the additional dimensionless groups, depending upon the choice of a specific viscosity model. Consequently, over the past 50–60 years, significant advances have occurred in developing reliable expressions for predicting the settling velocity and the rate of heat transfer from a sphere in different types of non-Newtonian fluids. We begin with the case of a rigid sphere undergoing steady translation in unconfined power-law fluids.

21.3.1 Sphere in Power-Law Fluids

Naturally, any attempt to parallel the Stokes analysis must begin with the continuity and Cauchy's momentum equations, which can be written in their compact forms for incompressible flow as follows:
Continuity equation

$$\vec{\nabla} \cdot \vec{u} = 0 \tag{21.15}$$

Momentum equation

$$\rho_f \frac{D\vec{u}}{Dt} = -\vec{\nabla} p + \vec{\nabla} \cdot \vec{\vec{\tau}} + \rho_f \vec{g} \tag{21.16}$$

When the constitutive relation for a Newtonian fluid is substituted in Equation 21.16, it reduces to Equation 1.87 in Chapter 1.

One must, therefore, substitute for the extra stress tensor term $\vec{\vec{\tau}}$ using the tensorial form of the power-law constitutive equation (similar to Equation 21.4). Detailed equations are available, for example, in Adachi et al. (1973); our main focus here is on the presentation and discussion of the results, which have accrued during the past 50–60 years.

Dimensional considerations of the case of a steady flow of power-law fluid with a uniform velocity of u_0 past a sphere of radius a suggest that the drag force on the sphere in the creeping (Stokes) regime is given as follows:

$$F_D = 6\pi a u_0 m \left(\frac{u_0}{a}\right)^{n-1} \cdot X(n) \tag{21.17}$$

In Equation 21.17, $X(n)$ is called the drag correction factor, which accounts for the influence of power-law viscosity on the Stokes drag. Clearly, in the limit of the Newtonian fluid behavior, that is, $n = 1$, no correction is required, that is, $X(n) = 1$ and as expected Equation 21.17 reduces to the familiar Stokes drag formula. It is customary to introduce a dimensionless drag coefficient C_D, defined by Equation 1.96, to rewrite Equation 21.17 as follows:

$$C_D = \frac{24}{Re_{PL}} X(n) \tag{21.18}$$

where the modified definition of the Reynolds number for power-law fluids is given by

$$Re_{PL} = \frac{\rho_f (2a)^n (u_0)^{2-n}}{m} \tag{21.19}$$

In the creeping flow limit ($Re_{PL} \to 0$), the earliest estimates of the drag correction factor $X(n)$ are due to Tomita (1959), who employed the velocity variational principle to get an approximate upper bound on the drag correction factor $X(n)$. Indeed, the first full numerical solution of the momentum equations for power-law fluids was attempted by Crochet et al. (1984), which showed the approximate nature of Tomita's results. Table 21.1 presents the currently available best estimates of the value of $X(n)$ (Song et al., 2009).

Table 21.1 Values of $X(n)$ for a Rigid Sphere

n	$X(n)$
0.1	1.343
0.2	1.434
0.3	1.485
0.4	1.497
0.5	1.42
0.6	1.381
0.7	1.316
0.8	1.258
0.9	1.141
1	1.00

The numerical values of $X(n)$ summarized in Table 21.1 are reasonably well approximated by the following expression:

$$X(n) = \left(\sqrt{6}\right)^{n-1} \left(\frac{3}{n^2 + n + 1}\right)^{n+1} \tag{21.20}$$

The values of $X(n) > 1$ endorse the fact that the drag on a sphere in shear-thinning power-law fluids in the creeping flow regime is augmented over and above the Stokes value in Newtonian fluids. However, the value of $X(n)$ is seen to go through a maximum at about $n \sim 0.4–0.5$. The creeping flow regime generally persists up to about $Re_{PL} \simeq 0.1$ or so.

The next generation of studies in this field have elucidated the role of inertial effects by considering the Reynolds number up to about $Re_{PL} = 500$ (Graham and Jones, 1994, Tripathi et al., 1994, Dhole et al., 2006a, Song et al., 2009). Most of these studies have focused on the prediction of drag coefficient, albeit scant results are also available on the wake characteristics (e.g., angle of separation and wake length). The available information is so sparse that it is not yet possible to develop a predictive expression for drag in the finite Reynolds number range. Table 21.2 tabulates the currently available results for the steady translation of a sphere in power-law fluids beyond the creeping flow regime.

It is worthwhile to make a few observations here about the results summarized in Table 21.2. Firstly, the currently available numerical predictions are restricted to the maximum value of the Reynolds number, $Re_{PL} = 500$. Such predictions become progressively less precise with the decreasing value of the power-law index and/or with the increasing value of the Reynolds number (Chhabra, 2006, Song et al., 2009) owing to the numerical difficulties. On the other hand, reasonable experimental results are available for the drag on a sphere up to about $Re_{PL} \sim 1000–1200$ (Shah et al., 2007) and these are consistent (within ±25% or so)

Table 21.2 Drag on a Sphere in Power-Law Fluids at Finite Reynolds Numbers

with the numerical predictions. These results are thus nowhere near as extensive or coherent as the standard Newtonian drag curve for the estimation of drag on a sphere in unconfined Newtonian fluids. Secondly, the inertial effects rapidly increase with the increasing Reynolds number and therefore, the power-law index (n) exerts only a weak influence on the value of drag at high Reynolds numbers. Therefore, many authors have argued that for $Re_{PL} > \sim 50$ or so, one can use the standard Newtonian drag curve for estimating the hydrodynamic drag (or the free falling velocity) of a sphere in power-law fluids with an error band of $\pm 25\%$ (Chhabra, 2006).

At the next level, no results are available on the delineation of flow regimes like transition from the axisymmetric to unsteady nonaxisymmetric, or even regarding the onset of flow separation from the surface of the sphere. The available results seem to suggest faster spatial decay of the velocity field in shear-thinning fluids ($n < 1$) than that in Newtonian fluids under otherwise identical conditions. This implies that one can employ shorter flow domains (both in experimental and numerical studies) to approach the unconfined flow approximation (Missirlis et al., 2001, Chhabra, 2006, Song et al., 2009). The angle of separation (θ_s) is only weakly dependent on the power-law index and, similar to Newtonian fluids, it shows a rather strong dependence on the Reynolds number. Thus, for instance, $\theta_s \simeq 139°–140°$ at $Re_{PL} = 50$ over the range $1 \geq n \geq 0.5$, which drops to $\theta_s \simeq 123°–126°$ at $Re_{PL} = 100$, that is, it moves forward on the surface of the sphere toward the front stagnation point. On the other hand, the wake length shows a positive dependence on the Reynolds number, which is modulated by the value of the power-law index. For instance, in Newtonian fluids ($n = 1$), the wake length more than doubles as the Reynolds number is increased from $Re_{PL} = 50$ to $Re_{PL} = 100$. In contrast, the corresponding change is three-fold in a highly shear-thinning fluid, $n = 0.5$ over the identical interval of Reynolds number values (Dhole et al., 2006a, Song et al., 2009). Unfortunately, in view of the paucity of the available data, it is not yet possible to put forward definitive predictive expressions for drag, θ_s, wake length, etc. which can rival the well-established state-of-the-art equations for Newtonian fluids, for example, see Clift et al. (1978) and Michaelides (2006).

21.3.1.1 Heat Transfer

Whenever there exists a temperature gradient between a sphere and the ambient fluid, heat transfer occurs from the regions of high temperature to that of low temperature. Depending upon the kinematic (fluid flow) conditions, heat transfer can occur in three possible regimes. In the absence of the externally imposed fluid flow and buoyancy effects, heat transfer occurs solely by conduction. In this extreme case, the viscosity characteristics of the ambient medium are irrelevant and the Nusselt number, $Nu = hd/k$, has a constant value given as $Nu = 2$, which applies for both Newtonian and non-Newtonian fluids. On the other hand, when fluid motion occurs, it is customary to discern three distinct heat transfer regimes: forced convection, free convection, and mixed convection. Dimensional considerations as applied to the thermal energy equation and the boundary conditions suggest that the Nusselt number is expected to be a function of the Reynolds number and Prandtl number or combinations thereof (such as Peclet number) for a given geometrical configuration and type of boundary conditions in the forced convection regime. In the free or natural convection regime, the fluid motion is caused solely by the temperature-dependent density and in this case, the overall heat transfer between a quiescent fluid medium and the submerged sphere is determined by the Grashof number (Gr) and the Prandtl number (Pr) or the combinations thereof, the most common being Rayleigh number ($Ra = Gr \cdot Pr$). In the mixed-convection regime, that is, when both forced- and free-convection effects are present, it is customary to use the familiar Richardson number, $Ri = Gr/Re^2$, to ascertain the relative importance of the two contributions. Naturally, the two limiting conditions of $Ri \to 0$ and $Ri \to \infty$ correspond to the pure forced- and free-convection regimes, respectively. On the other hand, the value of the Richardson number of order one denotes the condition when both the forced- and buoyancy-induced effects are comparable. Furthermore, depending upon the direction of the imposed flow with respect to that of the gravity vector, three distinct mixed flow regimes are identified, namely, aiding-, opposing-, and cross-buoyancy. As the name suggests, both flows are "additive" in a sense (both being in the same direction) in the case of the aiding-buoyancy regime. In the opposing-buoyancy case, the two are oriented in the opposite directions, and finally, the two flows are perpendicular to each other in the cross-buoyancy mixed-convection regime, as shown schematically in Figure 21.8. Broadly, the aiding-buoyancy configuration stabilizes the flow and augments heat transfer by strengthening the flow, and the opposing- and cross-buoyancy configurations destabilize the flow by inducing asymmetry in the flow and/or by accelerating the onset of vortex shedding regime, which directly impinges on the scaling of the Nusselt number with the pertinent variables. In the ensuing sections, heat transfer from a sphere in power-law fluids in the three regimes is discussed in some detail.

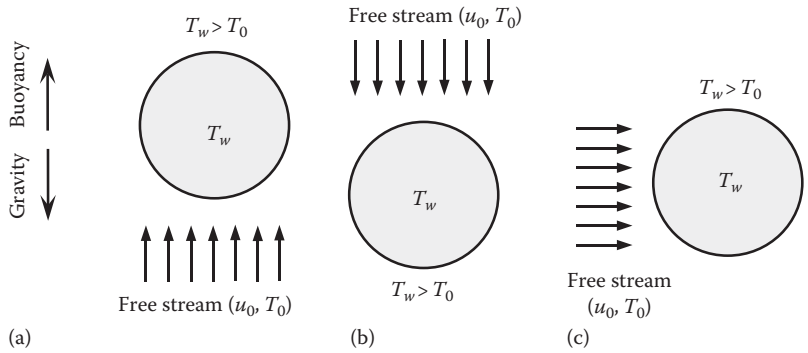

Figure 21.8

Schematics of different mixed-convection regimes: (a) aiding-buoyancy, (b) opposing-buoyancy, and (c) cross-buoyancy.

21.3.1.2 Forced Convection Regime

In the creeping flow limit, many authors (Acharya et al., 1976, Kawase and Ulbrecht, 1981) have employed the high Prandtl (or Schmidt for mass transfer) number thin boundary layer approximation initially introduced by Lochiel and Calderbank (1964) to delineate the role of power-law index (n) on heat/mass transfer. This approach yields a correction factor, $X_m(n)$, in the creeping flow limit for heat/mass transfer akin to $X(n)$ in Equation 21.18 for drag as follows:

$$X_m(n) = 0.866\left[\frac{3}{2} - \frac{9n(n-1)}{2n+1}\right]^{1/3} \tag{21.21}$$

Equation 21.21 predicts varying levels of enhancement in heat/mass transfer on account of shear-thinning behavior ($n < 1$), which is consistent with the available scant experimental results (Chhabra, 2006). The assumption of high Peclet number was relaxed by Westerberg and Finlayson (1990), who solved the field equations in the creeping flow regime from an isothermal sphere in Nylon-6 melt. However, their results are restricted to a specific material and it is thus not possible to develop generalized expressions based on their results.

In the other limit of high Reynolds number ($Re_{PL} \to \infty$), the early studies in this field are invariably based on the boundary layer flow approximation, pioneered by Acrivos et al. (1960) and subsequently by many others including Bizzell and Slattery (1962). Naturally, this analysis yields the general scaling of the Nusselt number as follows:

$$Nu = A(n)Re_{PL}^{(n+2)/3(n+1)}Pr^{1/3} \tag{21.22}$$

where $A(n)$ is a function of the power-law flow behavior index (n). Its value depends on the shape of the particles. Suffice it to add here that the available experimental results are not inconsistent with the functional dependence represented by Equation 21.22. Naturally, such boundary layer results are valid in the limit of $Re_{PL} \to \infty$ and/or $Pr \to \infty$ wherein the boundary layers are really very thin, one can also neglect the curvature effects in the case of a sphere or a cylinder. This approach, however, does not take into account the wake phenomenon encountered at finite Reynolds numbers. In this case, the boundary layer predictions do a good job up to the point of flow detachment from the surface of the sphere.

It is not known *a priori* up to what values of the Reynolds and/or Prandtl numbers the boundary layer approximation is correct. These critical values are expected to be functions of the power-law index. Under otherwise identical conditions, the boundary layer thickness is smaller in shear-thinning fluids ($n < 1$) than that in Newtonian fluids and of course, the reverse is true for shear-thickening fluids ($n > 1$). Finally, for Newtonian fluids, that is, $n = 1$, Equation 21.22 reduces to the well-known scaling of $Nu \sim Re^{1/2}Pr^{1/3}$. In contrast, the dependence of the Nusselt number on the Reynolds number in shear-thinning fluids is seen to be stronger than $Nu \sim Re^{1/2}$.

One must resort to the numerical solution of the complete momentum and energy equations to patch up the intermediate region in between the creeping flow and boundary layer approximation regions. As noted in Section 1.4.4, for Newtonian fluids, the heat transfer from a sphere in power-law fluids is influenced by a

large number of parameters. In the limiting case of an unconfined sphere and for a specific thermal boundary conditions (constant temperature or constant heat flux on the surface of the sphere), with constant thermophysical properties (thermal conductivity, thermal heat capacity, density, rheological constants) and in the absence of viscous dissipation effects (small Brinkman number), the scaling arguments suggest the average Nusselt number (Nu) to be a function of the Reynolds number, Prandtl number, and power-law index, that is,

$$Nu = f\left(Re_{PL}, Pr, n\right) \tag{21.23}$$

This functional dependence has been established by Dhole et al. (2006b) over the following ranges of conditions: $5 \leq Re_{PL} \leq 200$; $1 \leq Pr \leq 400$ (maximum Peclet number ≤ 2000) and $0.5 \leq n \leq 2$. For an isothermal sphere, Equation 21.23 is of the form:

$$Nu = 0.922 + Re_{PL}^{1/n+2} Pr^{1/3} + 0.1 Re_{PL}^{2/3} Pr^{1/3} \tag{21.24}$$

The corresponding expression for an isoheat flux (dissipating heat at a constant flux) sphere is given by

$$Nu = 1 + Re_{PL}^{1/n+2} Pr^{1/3} + 0.158 Re_{PL}^{2/3} Pr^{1/3} \tag{21.25}$$

Both of these equations predict the value of the average Nusselt number with an uncertainty of about ~10%. Subsequently, some of these results have been corroborated independently by Song et al. (2010) and others (Nirmalkar et al., 2013b). These numerical predictions are in line with the limited experimental heat and mass transfer data for spheres in power-law media (Chhabra, 2006).

21.3.1.2.1 Free Convection Regime In this case, the momentum and energy equations are coupled via the buoyancy force even in the case of Newtonian fluids even if all the thermophysical properties other than the fluid density are constant and viscous dissipation effects are neglected. This coupling is accentuated in the case of power-law fluids by the nonlinearity of the power-law constitutive equation. Early analyses pioneered by Acrivos (1960) and subsequently by Stewart (1971) are based on the approximate boundary layer equations, which are valid in the limit of $Gr \to \infty$ and/or $Pr \to \infty$. Undoubtedly, such attempts have led to the correct scaling relationship between the Nusselt number, on one hand, and the Grashof number, Prandtl number, and power-law index, on the other. In essence, the Nusselt number is given by

$$Nu \simeq c(n) \cdot \Omega \tag{21.26}$$

where $\Omega = Gr^{1/2(n+1)} Pr^{n/3n+1}$.

In Equation 21.26, the value of $c(n)$ ranges from 0.9 for $n = 0.1$ to 1.4 for $n = 1.5$ and Acrivos (1960) himself advocated the use of a single value of $c(n) = 1.1$, which compares rather favorably with the experimental value of 1.122 (Liew and Adelman, 1975). However, subsequent experimental data by Amato and Tien (1976) and Lee and Donatelli (1989), which span wider ranges of experimental conditions, correlate much better with the following equation rather than with Equation 21.26:

$$Nu = \Omega \quad \text{for } \Omega > 10 \tag{21.27}$$

$$Nu = 2\Omega^{0.68} \quad \text{for } \Omega < 10 \tag{21.28}$$

In Equation 21.27, the value of $c = 1$ is remarkably close to the value of 1.1 proposed by Acrivos (1960). This seems to suggest that the boundary layer approximation is good for $\Omega > 10$. One must, however, solve the complete field equations for the intermediate values of the Grashof and Prandtl numbers corresponding to the regime characterized by $\Omega < 10$, as has been done in a recent numerical study (Prhashanna and Chhabra, 2010). Indeed, while their numerical results for $\Omega > 10$ are in perfect agreement with Equation 21.27, these deviate only slightly from Equation 21.28, in so far that the exponent of Ω is found to be 0.72 as opposed to 0.68. Such a close correspondence between experiments (represented by Equations 21.27 and 21.28) and the numerical results (Prhashanna and Chhabra, 2010) lends credibility to both the experiments

of Amato and Tien (1976) as well as to the approximate boundary layer flow predictions of Acrivos (1960) under appropriate conditions. Lastly, an examination of the definition of Ω reveals that while for $n = 1$, it coincides with the familiar scaling of $Nu \sim Ra^{1/4}$; the dependence of the Nusselt number on Grashof and Prandtl numbers is modulated by the value of the power-law index, n. For instance, for $n = 0.5$, the composite parameter Ω is given by $Gr^{1/3}Pr^{1/5}$, that is, stronger dependence on Gr and weaker dependence on Pr with reference to that in Newtonian fluids.

21.3.1.2.2 Mixed-Convection Regime Only limited results are available on the laminar mixed-convection heat transfer from a sphere even in Newtonian fluids (mainly air): for example, see Acrivos (1966), Chen and Mucoglu (1977, 1978), who extended the boundary layer flow approximation in both aiding- and opposing-buoyancy configurations for both an isothermal and isoflux sphere. A good review of these as well as of the other pertinent theoretical and numerical studies can be found in Kotouč et al. (2008, 2009). Also Nirmalkar and Chhabra (2013) have thoroughly reviewed the corresponding studies in both Newtonian and power-law media. Only three studies are available on mixed convection from a sphere in power-law fluids. Both Wang and Kleinstreuer (1988) and Meissner et al. (1994) have exploited the boundary-layer flow equations for the aiding-buoyancy configuration and highlighted the positive influence of the Richardson number on skin friction and Nusselt number. As noted earlier, naturally these predictions are applicable in the limit of large values of the Grashof and Prandtl numbers and do not account for wake effects. These results have been complemented by a recent numerical study (Nirmalkar and Chhabra, 2013). Over the range of conditions as $0 \le Ri \le 2$, $0.2 \le n \le 2$, $1 \le Re_{PL} \le 100$ and $1 \le Pr \le 100$ in the aiding-buoyancy configuration, the average Nusselt number values for an isothermal sphere are well correlated by the following equation:

$$Nu = 0.88 Pe^{\star 1/3}\, \Delta^{0.74} \tag{21.29}$$

where the modified Peclet number, $Pe^{\star}$, is defined as

$$Pe^{\star} = Re^{\star} \cdot Pr^{\star} \tag{21.30}$$

with,

$$Re^{\star} = Re_{PL}\left(1 + \sqrt{Ri}\right)^{2-n} \tag{21.31}$$

$$Pr^{\star} = Pr\left(1 + \sqrt{Ri}\right)^{n-1} \tag{21.32}$$

and

$$\Delta = \left(\frac{3n+1}{4n}\right) \tag{21.33}$$

The preceding definitions of $Pe^{\star}$, $Re^{\star}$, and $Pr^{\star}$ include the forced convection limit ($Ri = 0$) as well as the Newtonian fluid limit ($n = 1$). Also, since $\Delta > 1$ for shear-thinning fluids ($n < 1$), its inclusion in Equation 21.29 implies that the shear-thinning fluid behavior enhances the rate of heat transfer over and above that in Newtonian fluids at fixed values of the Reynolds, Prandtl, and Richardson numbers.

No such results are available for a sphere in power-law fluids for the other mixed-convection regimes, that is, opposing- or cross-buoyancy configurations. Nor is there any information available about the conditions for transition from one flow regime to another, that is, laminar/turbulent, steady/time-dependent, etc.

This section is concluded by noting that irrespective of the mode of convection, free, forced, or mixed, it is possible to augment the rate of heat transfer in shear-thinning fluids ($n < 1$) with reference to that in Newtonian fluids at fixed values of the influencing parameters. However, the degree of enhancement is strongly dependent on the value of the Reynolds and Prandtl numbers in the forced-convection; of the Grashof and Prandtl numbers in the free-convection; and of Reynolds, Richardson, and Prandtl numbers in the mixed-convection regimes. This can lead to significant energy savings in chemical and allied process engineering applications.

21.3.1.3 Wall Effects

The confining walls are known to exert an extra retardation force on a freely falling sphere, thereby slowing down its descent in a quiescent fluid. This retardation effect stems from the upward flow of the fluid displaced by a falling sphere. The narrower the annular gap between the particle and the wall, the stronger is the upward flow, thereby augmenting the relative velocity between the fluid and the particle. Even at the detailed level, velocity and pressure (and hence the temperature) fields are altered with reference to that for an unconfined sphere. Such changes, in turn, manifest at the macroscopic level by enhancing the values of the corresponding drag, and Nusselt and Sherwood numbers for a sphere. The most common configuration studied for this purpose is to understand the wall effects on a sphere situated at the axis of a tube, though some studies are also available for eccentric positioning of a particle in a tube filled with Newtonian fluids (Suresh and Kannan, 2013) and/or in vessels of noncircular cross section (Chhabra, 2002, 2006). The available literature on this topic in Newtonian fluids has been reviewed in Section 1.4.3.10 in this book and in other sources, for example, see Chhabra (2002, 2006).

The practical motivation for such studies really comes from the use of falling ball viscometer, chromatographic columns, electrophoresis in slurries, blood flow in arteries, etc. In this section, consideration is given to the analogous studies in power-law fluids. Firstly, owing to the nonlinearity of the power-law and other non-Newtonian viscosity models, analytical results, which can rival the celebrated results of Faxen (1923) or of Haberman and Sayre (1958) in the creeping regime of Newtonian media, are theoretically not possible for power-law fluids. Therefore, one must seek numerical solutions to the governing equations. It is customary to introduce a wall factor, f_w, to quantify the extent of wall effects. From an experimental view point, the wall factor, f_w, is defined simply as the ratio of the terminal falling velocity (u_m) in a confined medium to that in an unconfined medium (u_∞), for a given sphere–liquid–tube combination as

$$f_w = \frac{u_m}{u_\infty} \tag{21.34}$$

Naturally, the wall factor, f_w, ranges from zero (sphere diameter equal to tube diameter) to unity (when tube diameter $\to \infty$). The experimental determination of the wall correction factor thus necessitates measuring the settling velocity of a sphere in tubes of different (at least three) diameters (D) and extrapolating these results to $1/D \to 0$ and the intercept on the ordinate corresponds to the unconfined settling velocity u_∞ for a given sphere–fluid combination. Dimensional considerations of the case of a sphere settling at the axis of a cylindrical tube filled with a power-law fluid suggest the wall correction factor to be governed by three dimensionless parameters, namely, Reynolds number (Re_{PLm}), power-law index (n), and sphere-to-tube diameter ratio, $\Xi (= d/D)$, that is,

$$f_w = f\left(Re_{PLm}, \Xi, n\right) \tag{21.35}$$

In the creeping flow regime for Newtonian fluids, k_{wall} defined by Equation 1.160 is equal to the reciprocal of the wall factor introduced here, that is, $k_{wall} = f_w^{-1}$. However, this relationship is more involved than this for non-Newtonian fluids and/or beyond the creeping flow regime (Clift et al., 1978, Chhabra, 2002, Michaelides, 2006). By analogy with the trends seen in Newtonian fluids (Uhlherr and Chhabra, 1995, Chhabra, 2002), the wall factor, f_w, is independent of the Reynolds number (Re_{PLm}) in the both creeping ($Re_{PLm} \to 0$) and fully inertial ($Re_{PLm} \to \infty$) regimes in power-law fluids (Chhabra, 2006), that is, these two limiting values can be written as

$$Re_{PLm} \to 0; \quad f_{wo} = f_1\left(\Xi\right) \tag{21.36}$$

$$Re_{PLm} \to \infty; \quad f_{w\infty} = f_2\left(\Xi\right) \tag{21.37}$$

Between these two limits, the wall factor is a function of both Ξ and Re_{PLm}. It is, however, somewhat surprising that the presently available experimental results do not point to any influence of the power-law index, n, at least over the range $n \geq 0.5$ on the value of f_w. On the other hand, irrespective of the value of the power-law index, the wall effects are less severe in power-law fluids than that in Newtonian fluids, as can be

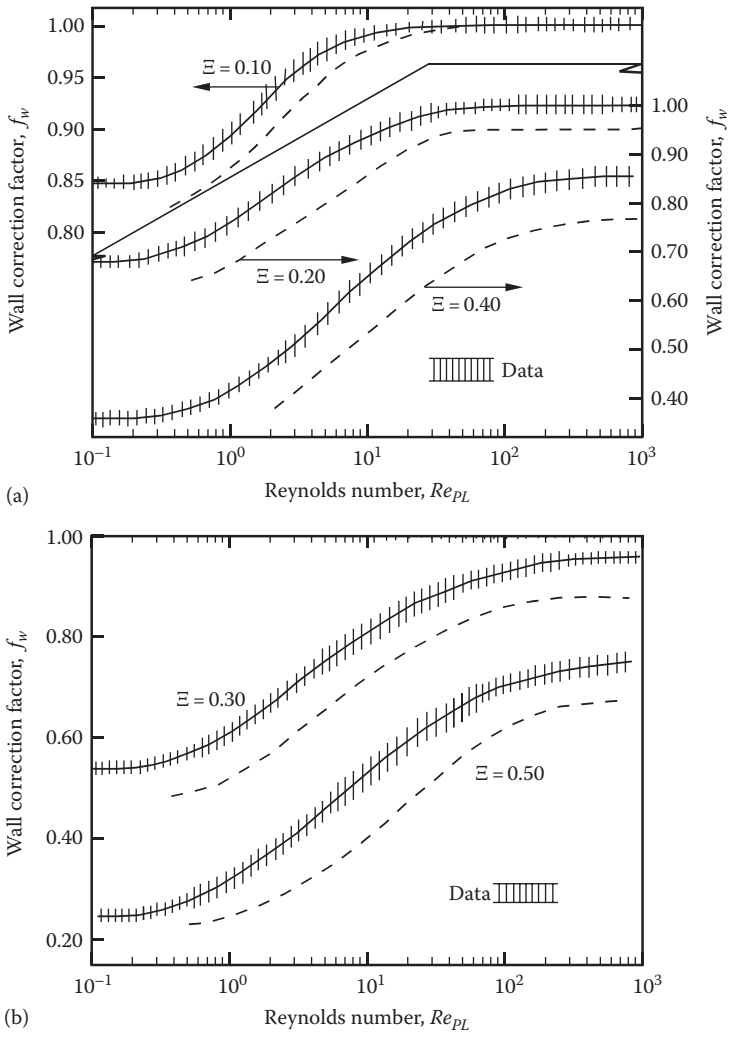

Figure 21.9

Wall correction factor as a function of the Reynolds number and diameter ratio for spheres falling in power-law liquids. The prediction of Equation 21.40 is shown as solid line; the corresponding Newtonian results are shown as broken lines. (Data from Chhabra, R.P. et al., Wall effect for sphere motion in inelastic non-Newtonian fluids, in *Proceedings of the Sixth Australasian Hydraulics Fluid Mechanical Conference*, Adelaide, South Australia, Australia, 1977, pp. 435–438.)

seen in Figure 21.9. Most of the literature results ($\Xi \leq 0.5$; $n \geq 0.5$ and $Re_{PLm} \leq 1000-1200$) are reasonably well approximated by the following set of equations:

$$f_{wo} = 1 - 1.6\Xi \tag{21.38}$$

$$f_{w\infty} = 1 - 3\Xi^{3.5} \tag{21.39}$$

$$\frac{(1/f_w) - (1/f_{w\infty})}{(1/f_{wo}) - (1/f_{w\infty})} = \left(1 + 1.3Re_{PLm}^2\right)^{-0.33} \tag{21.40}$$

Equations 21.38 through 21.40 are based on experimental data spanning $10^{-2} \leq Re_{PLm} \leq 10^3$; $\Xi \leq 0.5$ and $0.53 \leq n \leq 0.95$ (Chhabra et al., 1977, Chhabra and Uhlherr, 1980, Chhabra, 2002, 2006). Subsequently, these equations have been shown to correlate the other literature data also within about ±8% (Chhabra, 2006).

Numerical predictions of wall effects in the creeping flow regime (Missirlis et al., 2001) and up to $Re_{PLm} \simeq 100$ and $\Xi \leq 0.5$ (Song et al., 2009) are not inconsistent with the predictions of Equations 21.38 through 21.40 in overall terms. However, the experimental results and numerical simulations do differ in a significant manner. Both numerical studies (Missirlis et al., 2001, Song et al., 2009) predict a reasonably strong influence of the power-law index on wall effects, especially in the creeping flow regime, but the available experimental results do not reveal such a dependence.

The effect of eccentric positioning of the sphere in a tube has been studied by Suresh and Kannan (2013) and that of a fully developed profile in a tube has been investigated by Song et al. (2011, 2012). The eccentricity further augments the drag force of a sphere by varying amounts depending upon the value of Ξ and the degree of eccentricity, though the effect is less dramatic in power-law fluids than that in Newtonian fluids. Similarly, scant experimental results are also available on wall effects for the steady translation of a sphere at the axis of a duct of square cross section (Balaramakrishna and Chhabra, 1992) and for scores of shapes of nonspherical particles (including cylinders, cones, needles, prisms, rectangles, etc.) in circular tubes (Chhabra, 1995, 1996). In this case, the wall effect is strongly influenced by the orientation of the settling particle. The wall correction factor shows a linear dependence on Ξ, though the slope of such a dependence is seen to vary strongly with the shape of the particle. Also, in this case, d is replaced by the equal volume sphere diameter, d_V.

So far, the consideration has been given to the role of confinement in the settling velocity (or drag force) of a sphere in power-law fluids. Owing to the intimate connection between the velocity and temperature fields prevailing in the close proximity of a heated sphere, the confining walls also influence the resulting values of the Nusselt (or for mass transfer the Sherwood) number for a sphere. This effect is explained by the sharpening of the temperature gradient on the surface of the sphere, which directly influences the value of the Nusselt number for an isothermal sphere. There has not been much activity on this aspect even in Newtonian fluids (Clift et al., 1978, Michaelides, 2006). This is because the wall effects do not influence the rates of heat and mass transfer to the same extent as the hydrodynamic drag force. Owing to the large values of the Prandtl and Schmidt numbers, the temperature and concentration boundary layers are thin and the confining walls seldom influence their thickness. Thus, Song et al. (2010, 2012) studied the wall effects on forced convection heat transfer in power-law fluids from an isothermal sphere mounted on the axis of a cylindrical tube with adiabatic walls. They considered two situations. In the first instance, the configuration was equivalent to a sphere falling in quiescent fluid medium at the axis of the tube. Their numerical study encompassed the range of conditions as follows: $0.2 \leq n \leq 1$; $\Xi \leq 0.5$; $5 \leq Re_{PL} \leq 100$ and $1 \leq Pr \leq 100$. In this case, the enhancement in heat transfer on account of the fluid shear-thinning behavior is found to be maximum for an unconfined sphere and the relative enhancement decreases with the increasing blockage, that is, the value of Ξ. This counterintuitive trend stems from two factors: the boundary layers are known to be thinner in shear-thinning fluids than that in Newtonian fluids under otherwise identical conditions. Conversely, it stands to reason that the confining walls modify the boundary layers in Newtonian fluids much more strongly than that in power-law fluids. The second factor, which contributes to this trend, is the fact that the shear rate varies from one point to another on the surface of the sphere. This is of no consequence for a Newtonian fluid whose viscosity is independent of shear rate. In the case of power-law fluids, however, this can lead to wide ranging values of the fluid viscosity depending upon the value of the power-law index (n) and hence, the increase in heat transfer is reduced for a confined sphere. These trends were further corroborated by their follow-up study (Song et al., 2012), which explored the effect of the fully developed profile in a tube on the forced convection heat transfer from a sphere. These predictions are in line with the few experimental results available in the literature; for example, see Song et al. (2009, 2010, 2011, 2012) for limited comparisons between numerical predictions and experimental data.

In summary, one may conclude that the wall effects influence the drag significantly more than the corresponding heat and mass transfer of a sphere, at least in the axisymmetric flow regime.

21.3.2 Sphere in Viscoplastic Fluids

As noted in Section 21.2.1.3, a viscoplastic fluid exhibits dual characteristics. Such a substance in unsheared state has the capacity to support the weight of an embedded particle for a long time. Conversely, a sphere of given size and density may or may not settle in a quiescent viscoplastic fluid depending upon its weight *vis-a-vis* the fluid yield stress. Indeed, this property is routinely exploited in the formulation and manufacture of a range of food-, health-care, and personal-care products of multiphase nature that keep particles from settling under the influence of gravity. Owing to the nonviscometric nature of the flow field produced around a sphere, it is obvious that flow domain is spanned by the simultaneous coexistence of yielded or fluid-like and unyielded

or solid-like regions. This complexity not only adds to the difficulty of numerical solutions, but it also directly impinges on the resulting values of the drag and Nusselt number. It must be noted that the sole mechanism for heat transfer is conduction in unyielded solid-like subdomains and convection is limited to yielded fluid-like regions. In steady-state situations, conduction may be the overall rate-determining step for heat transfer. Therefore, the mixing/homogenization, heating/cooling of such substances is rather difficult. In this section, the current state of the art is reviewed. In particular, consideration is given to the following aspects: static equilibrium (whether a sphere will settle or not), yield surfaces delineating the fluid-like and solid-like domains, drag behavior, heat transfer, and wall effects for a sphere undergoing steady translation in viscoplastic media.

21.3.2.1 Static Equilibrium

Most of the relevant experimental results in this field have been summarized by Chhabra (2006) and are based on the instances where the motive force is the buoyant weight of the sphere. It is customary to introduce a new dimensionless group indicative of the ratio of the fluid yield stress and the motive force for pushing the sphere as follows:

$$Y = \frac{\tau_0}{gd(\rho_s - \rho_f)} \tag{21.41}$$

Thus, large values of Y (yield stress force > buoyant weight) would correspond to the particle not settling and small values of Y would favor sphere motion. It is obvious that the delineation of this transition in experiments is far from being objective and straightforward. For instance, many researchers (e.g., see Uhlherr, 1986, Schurz, 1990) have simply equated the vertical component of the force due to the yield stress to the buoyant weight of the sphere, thereby arriving at a value of $Y = 0.212$. This argument is open to criticism that the stress (tangential and normal) distribution over the surface of the sphere is not known *a priori* and the shear stress everywhere may not be the fluid yield stress. Notwithstanding this intrinsic difficulty, it is still convenient to explain the available results in terms of the dimensionless parameter, Y. Currently available experimental and numerical values of Y range from about 0.04 to 0.212, that is, a fivefold variation. The numerical predictions (Beris et al., 1985, Beaulne and Mitsoulis, 1997, Blackery and Mitsoulis, 1997) as well as the experimental observations (Jossic and Magnin, 2001, Merkak et al., 2006, Tabuteau et al., 2007a,b) result in the critical value of Y in the range 0.04–0.08. These are considered to be more reliable than the oft-quoted higher value of $Y \sim 0.2$ or so. However, such diverse values of the parameter, Y, seem to suggest inherently different response of such a material whether the motion/no motion condition is approached from above or below. Sometime this effect is also explained in terms of the "static" and "dynamic" yield stress.

21.3.2.2 Yield Surfaces

As noted earlier, depending upon the magnitude of the local stress tensor at a point in the fluid *vis-a-vis* the value of the fluid yield stress, the material may or may not yield. These regions are separated by the so-called yield surfaces. There has not been much experimental activity in this field except the flow visualization studies reported by Atapattu et al. (1990, 1995); representative results are shown in Figure 21.10 in the limit of the creeping flow regime. It is not feasible to achieve truly unconfined flow conditions in experiments, corresponding numerical predictions for a range of values of Ξ and Bn are shown for Herschel–Bulkley model fluids (Beaulne and Mitsoulis, 1997). Broadly, the fluid-like cavity encapsulating the sphere is seen to extend up to about 1.5–2 times the sphere diameter in lateral and axial directions under most conditions. Figure 21.11 shows the effect of Reynolds number on yielded surfaces based on the numerical studies of Nirmalkar et al. (2013a,b). At this juncture, one can remark that the fluid inertia (increasing Reynolds number) tends to expand the yielded regions, whereas this tendency is countered by the increasing Bingham number. For a given Reynolds number, there must exist a limiting Bingham number wherein the yield surfaces attain a limiting morphology corresponding to the fully plastic flow limit. Also, the small blobs of unyielded material adhering at the front and rear stagnation points predicted by the numerical studies have not been observed in the visualization studies of Atapattu et al. (1990, 1995) very likely because of the rather crude resolution scale of the photographic technique employed in this study.

21.3.2.3 Drag Behavior

From a theoretical standpoint, the main difficulty stems from the fact that the yield surfaces are not known *a priori* and therefore, one does not know the flow domain completely. Also, the inherently discontinuous form of the viscosity models, Equations 21.8 through 21.13, does not allow them to be incorporated

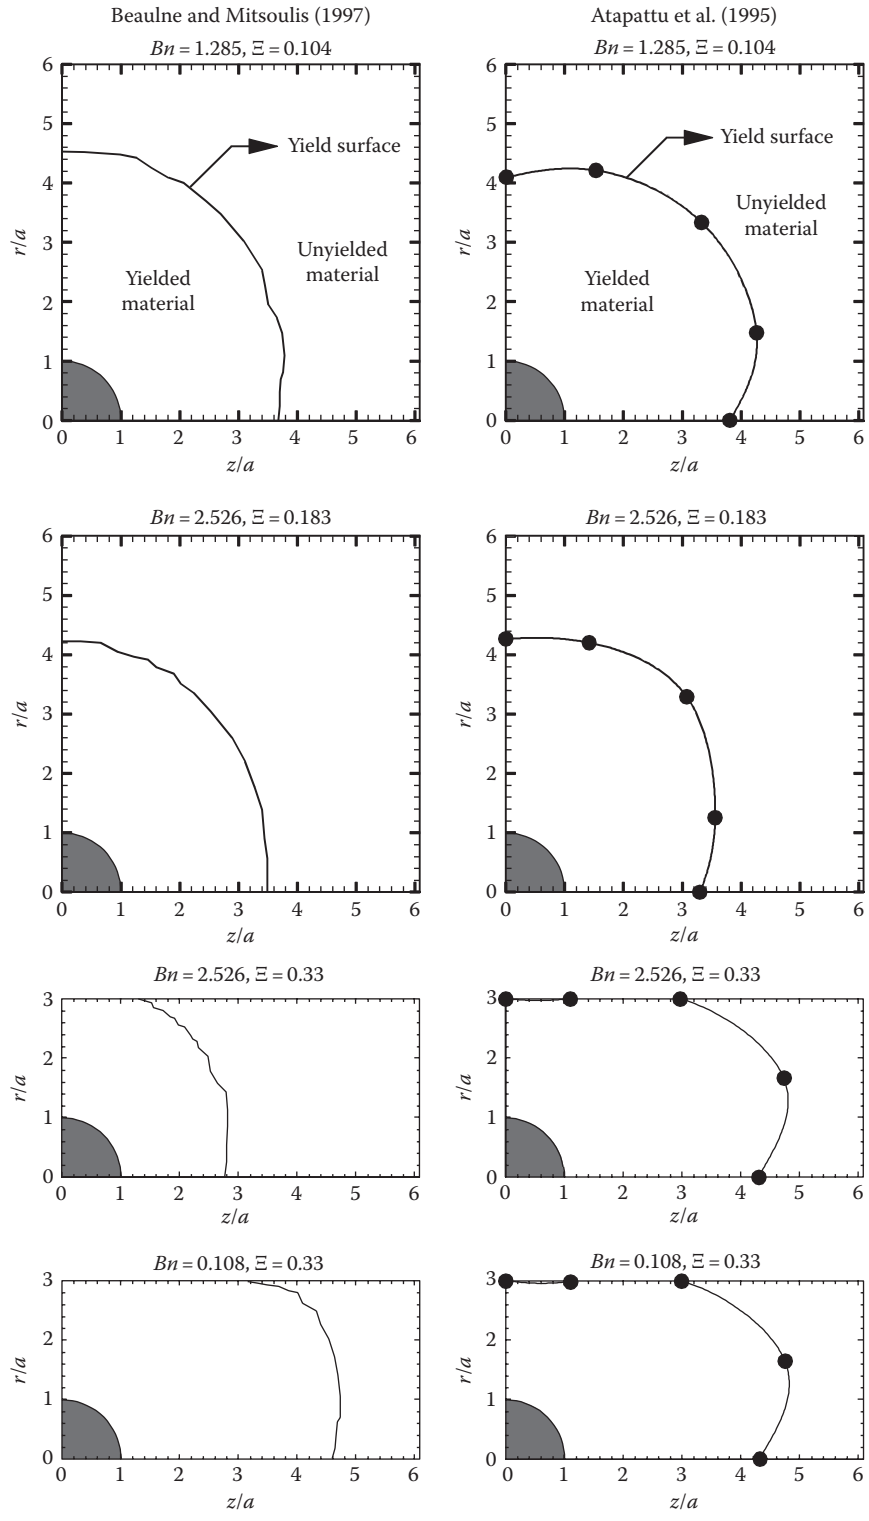

Figure 21.10

Yield surfaces predicted by the numerical results of Beaulne and Mitsoulis (1997) and experimental results of Atapattu et al. (1995) for the creeping motion of a sphere in confined Herschel–Bulkley fluids. Flow is in upward direction.

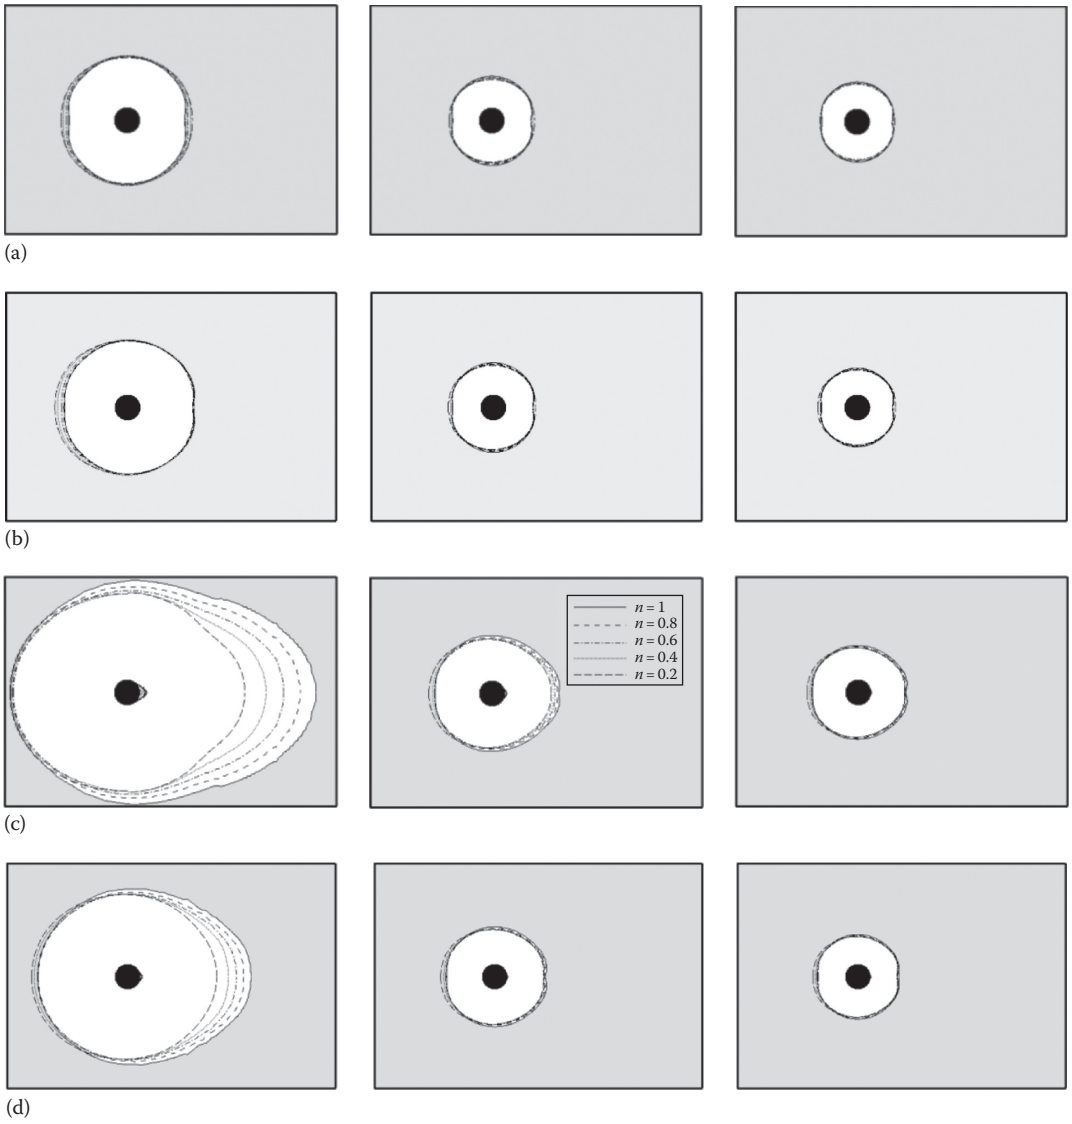

Figure 21.11

Effect of Reynolds number, Bingham number, and power-law index on the structure of yield surfaces for a sphere (Nirmalkar and Chhabra, 2013a,b). Flow is from left to right. Shaded parts denote the unyielded regions.

directly into any numerical solution scheme. One way is to solve for the appropriate momentum equations in both the solid and fluid regions in a trial and error fashion, because the yield surfaces are not known *a priori*. This is very cumbersome. A few regularization schemes have evolved, which convert the abrupt transition from the solid-like to fluid-like behavior into a gradual one (Glowinski and Wachs, 2011). Three such schemes due to Bercovier and Engleman (1980), O' Donovan and Tanner (1984), and Papanastasiou (1987) have gained wide acceptance in the literature and are introduced briefly here.

It is useful to rewrite Equations 21.8 and 21.9 in terms of the apparent viscosity, which brings out the inherent difficulty in its direct implementation in a numerical scheme. In terms of a dimensionless viscosity, Equations 21.8 and 21.9 becomes

$$\mu^{\star} = 1 + \frac{Bn}{\left|\vec{\vec{\dot{\gamma}}}\right|} \quad \text{for } \left|\vec{\vec{\tau}}\right| > Bn \tag{21.42}$$

$$\mu^{\star} = \infty \quad \text{for } \left|\vec{\vec{\tau}}\right| \leq Bn \tag{21.43}$$

Equation 21.43 shows the fluid viscosity to be unbounded for the stress levels below the fluid yield stress. Thus, Papanastasiou (1987) regularized this discontinuity using an exponential function as

$$\mu^{\star} = 1 + Bn\left(\frac{1-\exp\left(-M\left|\dot{\overline{\overline{\gamma}}}\right|\right)}{\left|\dot{\overline{\overline{\gamma}}}\right|}\right) \tag{21.44}$$

where M is the sole regularization parameter. In the limit of $M \to 0$, Equation 21.44 reduces to the Newtonian fluid behavior and for large values of $M \to \infty$, Equation 21.44 reproduces the true Bingham plastic model, that is, Equations 21.8 and 21.9. Thus, large values of M are required to adequately approximate the Bingham behavior, as shown schematically in Figure 21.12. The second regularization scheme, the so-called biviscous model, simply replaces the unbounded viscosity, Equation 21.43, by the so-called yielding viscosity (μ_y) which is several orders of magnitudes larger than the Bingham plastic viscosity (μ_B). This scheme is shown schematically in Figure 21.13, where the increasing values of (μ_y/μ_B) approach the true Bingham behavior. In this framework, Equations 21.42 and 21.43 are written as

$$\mu^{\star} = 1 + Bn\left[1-\left(\frac{1}{\mu_y/\mu_B}\right)\right]\frac{1}{\left|\dot{\overline{\overline{\gamma}}}\right|} \quad \text{for } \left|\overline{\overline{\tau}}\right| > Bn \tag{21.45}$$

$$\mu^{\star} = \frac{\mu_y}{\mu_B} \quad \text{for } \left|\overline{\overline{\tau}}\right| \le Bn \tag{21.46}$$

Clearly, at the limit of $\mu_y \to \infty$, Equations 21.45 and 21.46 coincide with Equations 21.42 and 21.43, respectively. Hence, as large values of μ_y as possible must be used in numerical simulations to obtain reliable results.

In the third approach (Bercovier and Engleman, 1980), the discontinuity is tamed by introducing a small magnitude of the rate of strain tensor into Equation 21.42 as

$$\mu^{\star} = 1 + \frac{Bn}{\left|\dot{\overline{\overline{\gamma}}}\right| + \delta} \tag{21.47}$$

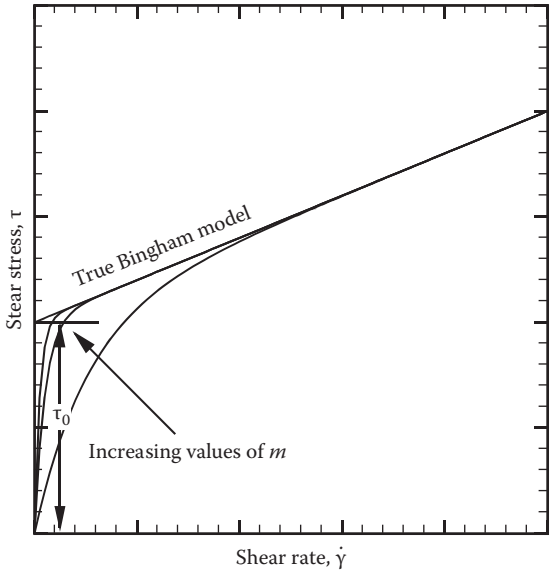

Figure 21.12

Typical shear stress versus shear rate plot for Papanastasiou's regularization approximation, Equation 21.44.

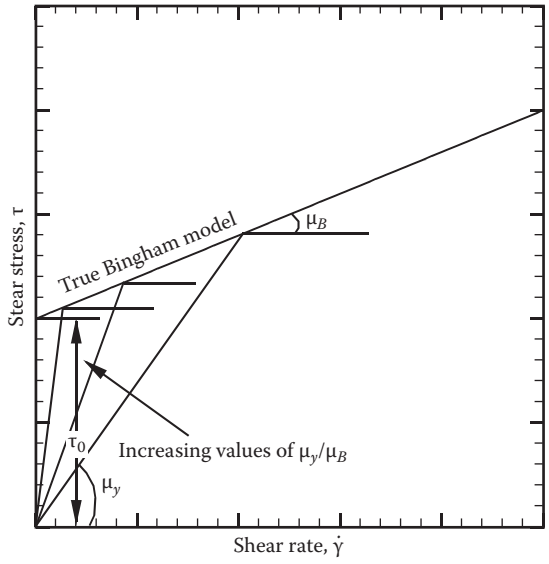

Figure 21.13

Typical shear stress versus shear rate plot for biviscous regularization approximation, Equations 21.45 and 21.46.

In this case, δ denotes the relatively small values of the strain rate in unyielded subdomains when $\left|\dot{\dot{\gamma}}\right| = 0$ and in this case, δ = 0 corresponds to the true Bingham fluid behavior and hence, δ is assigned values as small as 10^{-8} in numerical studies to minimize the numerical artifacts.

Detailed descriptions concerning the relative merits and demerits of the preceding three schemes as well as the other procedures available in the literature can be found in numerous references (Liu et al., 2002, Frigaard and Nouar, 2005, Glowinski and Wachs, 2011, Balmforth et al., 2014, for instance). All these approaches have been successfully employed within the context of the calculation of drag on a sphere and a cylinder in yield stress fluids with and without shear-thinning behavior.

Early attempts at the prediction of drag on a sphere are based on the application of the velocity and stress variational principles (Yoshioka et al., 1971). These results are valid only in the creeping (zero Reynolds number) regime and are based on *a priori* assumption concerning the shape and location of the yield surfaces; that is, an approximate solution to the momentum equations is sought in the yielded region only. Beris et al. (1985) were seemingly the first to seek the numerical solution of the complete momentum equations for the creeping flow of Bingham plastic fluids over an unconfined sphere. Subsequently, the drag values have also been reported by Blackery and Mitsoulis (1997) and Deglo de Besses et al. (2004) with wall effects. For an unconfined sphere in the creeping flow regime, the numerical results of Blackery and Mitsoulis (1997) and of Beris et al. (1985) can be consolidated via the relationship:

$$C_D = \frac{24}{Re_B}\left(1 + 2.93Bn^{0.83}\right) \tag{21.48}$$

In the limit of the fully plastic flow ($Bn \to \infty$), Blackery and Mitsoulis (1997) reported the limiting value of drag coefficient as

$$C_{D\infty} = \frac{28.08Bn}{Re_B} \tag{21.49}$$

This limit was observed for $Bn \to 1000$ and this is in line with the early experiments of Valentik and Whitmore (1965) and Pazwash and Robertson (1975), as detailed in Chhabra (2006).

While the limited analogous results of Beaulne and Mitsoulis (1997) for Herschel–Bulkley fluid model, Equations 21.10 and 21.11, were found to be in fair agreement with the experimental drag data of Atapattu et al. (1995), the effect of fluid slippage on the sphere surface was examined by Deglo de Besses et al. (2004). They concluded that, as expected, the wall slip lowers the drag on the sphere. The effect of inertia up to

Reynolds number values of 100 on the drag of an isolated sphere has been studied numerically only recently (Nirmalkar et al., 2013a,b). These results can be reasonably well approximated by the following expressions:

$$C_D = \frac{28.63}{Re^+}\left(1 + 0.19\left(Re^+\right)^{0.33}\right) \tag{21.50}$$

$$C_{DP} = \frac{21.84}{Re^+}\left(1 + 0.04\left(Re^+\right)^{0.77}\right) \tag{21.51}$$

The modified Reynolds number Re^+ incorporates the influence of the Bingham number, Bn, as follows:

$$Re^+ = \frac{Re_B}{1 + Bn} \tag{21.52}$$

From another vantage point, Equation 21.52 is equivalent to using $(\mu_B + \tau_0 d/u_0)$ as the characteristic viscosity scale as opposed to the Bingham plastic viscosity μ_B, which does not account for the fluid yield stress. This idea was initially postulated by Ansley and Smith (1965) and has since been used extensively by numerous workers including Atapattu et al. (1995) for a sphere, Nirmalkar and Chhabra (2014) for a cylinder, etc.

It must be noted that the numerical predictions of drag, given by Equation 21.50, are within 10% or so of the available limited experimental results (Nirmalkar et al., 2013a,b). Also, the pressure forces seem to make up almost 75% of the total drag even at small values of Re^+, which is in stark contrast to the 1/3 contribution in Newtonian fluids. Finally, similar results for Herschel–Bulkley model fluids are also available, but these are very limited in terms of the range of parameters (Nirmalkar et al., 2013b).

21.3.2.4 Heat Transfer

In this section, we follow the same structure as that used in Section 21.3.1.2 in the context of heat transfer from a sphere in power-law fluids. At the outset, it needs to be recognized that additional complexities arise in the case of heat transfer from a sphere in viscoplastic fluids due to their dual nature, that is, blend of fluid-like and solid-like characteristics. Notwithstanding the fact that difficulties are encountered in numerical solutions of the momentum and energy equations, it stands to reason that heat transfer in such systems tends to be problematic in view of the role of conduction, howsoever small it may be in a given situation. This problem becomes even more acute in the free convection regime wherein the buoyancy-induced flow is generally very weak and, in an extreme case, it is unable to overcome the yield stress effects (Vikhansky, 2009, 2010). This section presents an overview of the limited body of knowledge available in this field and begins with the case of forced convection, followed by the free- and mixed-convection regimes.

21.3.2.4.1 Forced Convection Regime There have been essentially only three numerical studies dealing with the forced convection heat transfer from an isothermal sphere (at a higher temperature than the ambient fluid medium) in unconfined Bingham plastic and Herschel–Bulkley model fluids (Nirmalkar et al., 2013a,b) and from an isothermal sphere confined in a cylindrical tube filled with a Bingham plastic medium (Das et al., 2015). In each case, the fluid properties have been assumed to be temperature independent and viscous dissipation effects in the energy equation have been neglected.

For an unconfined isothermal sphere, scaling arguments suggest the average Nusselt number, Nu, to be a function of the Reynolds number (Re_B), Bingham number (Bn), and Prandtl number (Pr) for Bingham plastic fluids, whereas it shows additional dependence on the power-law index (n) in the case of Herschel–Bulkley model fluids together with the modified definitions of the Reynolds number (Re_{HB}), Prandtl number (Pr_{HB}), and Bingham number (Bn_{HB}) or also known as the Oldroyd number (Od). Broadly, for fixed values of the Bingham number and/or of n, the average Nusselt number bears a positive relationship with the Reynolds and Prandtl numbers. This is attributed to the progressive thinning of the thermal boundary layer within the framework of the classical boundary layer theory for simple fluids. On the other hand, for fixed values of the Reynolds and Prandtl numbers, the fluid yielding is limited to a very thin layer close to the submerged sphere. This may increase or decrease the temperature gradient on the surface of the sphere, because the temperature within the unyielded part adjusts itself to maintain the steady-state rate of heat transfer. Under the same conditions and since the boundary layers are known to be thinner in shear-thinning fluids ($n < 1$) than

Table 21.3 Values of $A_o(n)$ in Equation 21.54

		% Error	
n	$A_o(n)$	Average	Maximum
0.2	13.35	11.50	26.03
0.3	10.22	12.27	28.01
0.4	7.870	12.55	28.45
0.5	6.070	12.95	27.50
0.6	4.701	12.97	28.98
0.7	3.977	12.88	28.94
0.8	3.122	13.50	26.92
0.9	2.452	13.97	35.60
1	2.290	15.76	40.54

that in Newtonian fluids, the Nusselt number is correlated positively with the increasing degree of shear-thinning, that is, with decreasing values of power-law index (n). With these considerations, Nirmalkar et al. (2013a) were able to consolidate their numerical values of the average Nusselt number for an unconfined isothermal sphere in Bingham plastic fluids as follows:

$$Nu \simeq 2.29\left(Re^{+} \cdot Pr^{+}\right)^{1/3} \quad \text{for } 10^{-4} \le Re^{+} \le 100 \tag{21.53}$$

where Re^{+} is defined by Equation 21.52 and $Pr^{+} = Pr(1 + Bn)$. Equation 21.53 spans the range: $1 \le Re_B \le 100$; $1 \le Pr \le 100$ and $Bn \le 10^4$. The resulting average and maximum errors are of the order of 15% and 30%, respectively; most of the large error data points relate to $Pr \sim 1$, which is of no great interest in the context of Bingham plastic fluids. Subsequently, this work was extended to Herschel–Bulkley model fluids (Nirmalkar et al., 2013b) over the range $1 \le Re_{HB} \le 100$; $1 \le Pr_{HB} \le 100$; $0.2 \le n \le 1$ and $10^{-3} \le Bn_{HB} \le 10$ and the resulting correlation is of the form

$$Nu \sim A_o(n)\left(Re^{+} \cdot Pr^{+}\right)^{1/3} \tag{21.54}$$

The values of $A_o(n)$ are summarized in Table 21.3, where the increasing values of $A_o(n)$ with the decreasing values of n elucidate varying levels of enhancement in heat transfer in shear-thinning fluids. The modified definitions of Re_{HB}, Pr_{HB} and Bn_{HB} are given as follows:

$$Re_{HB} = Re_{PL}; \quad Pr_{HB} = \frac{Cm}{k}\left(\frac{u_0}{d}\right)^{n-1}$$

$$Bn_{HB} = \frac{\tau_0}{m(V_0/d)^n}; \quad Re^{+} = \frac{Re_{HB}}{1 + Bn_{HB}}$$

$$Pr^{+} = Pr_{HB}\left(1 + Bn_{HB}\right) \tag{21.55}$$

The uncertainty associated with Equation 21.54 is comparable to that of Equation 21.53. The scaling of $Nu \sim Pe^{1/3}$ observed at low Reynolds numbers/high Prandtl numbers in Newtonian fluids is seen to apply here up to as high Reynolds numbers as 100. This is simply due to the creeping flow-like character imparted by the fluid yield stress.

21.3.2.4.2 Free Convection Regime There has not been much research activity on free convection heat transfer in yield stress fluids from a sphere. In a recent numerical study, Nirmalkar et al. (2014b) presented extensive results on the detailed kinematics of laminar free convection from an isothermal sphere submerged in a Bingham plastic medium in the range: $10^2 \le Ra \le 10^6$; $10 \le Pr \le 100$ and $0 \le Bn \le 10^4$. They employed the exponential and biviscous regularization forms of the Bingham constitutive equation to solve the coupled momentum and energy equations. Figure 21.14 elucidates the combined effects of the Bingham number,

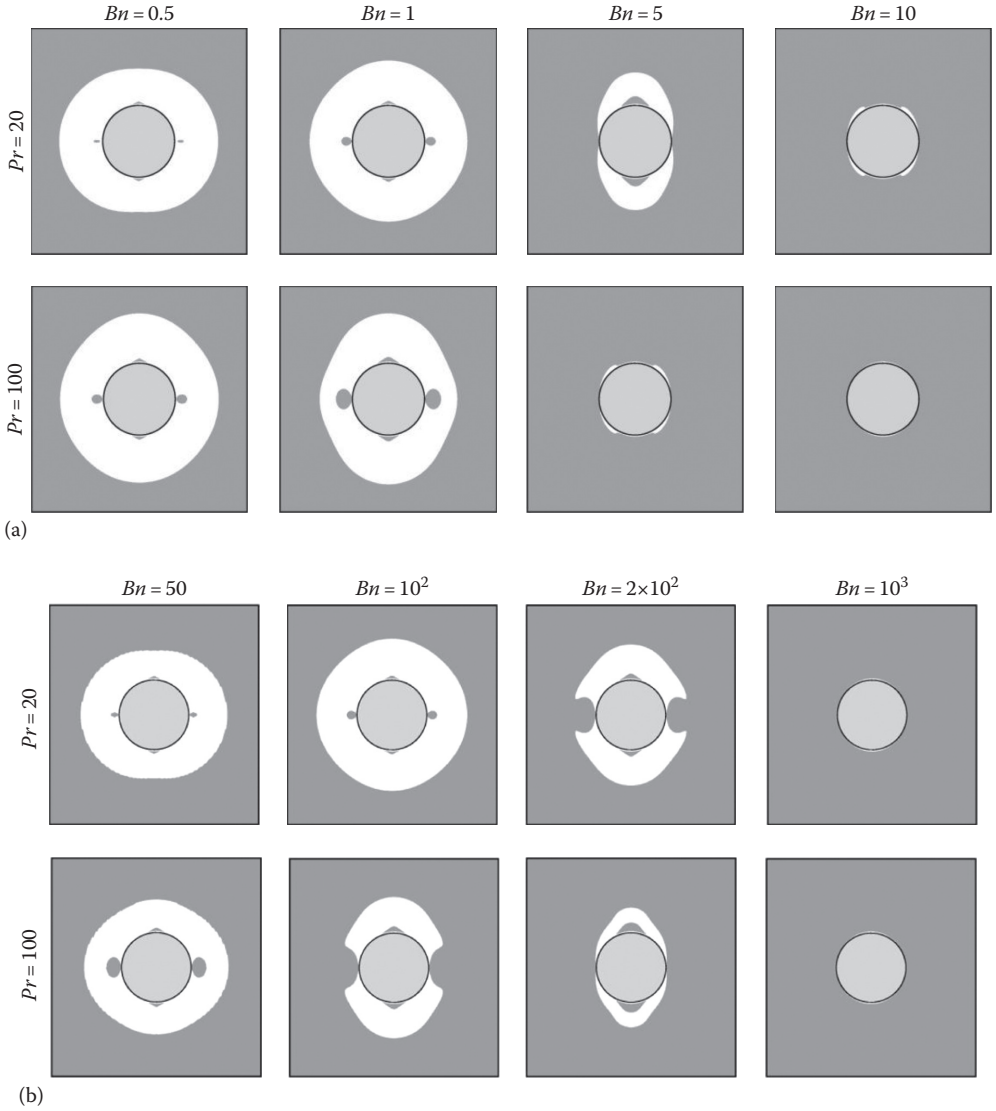

Figure 21.14

Effect of the Bingham number and Prandtl number on the structure of yielded surfaces for a sphere in free-convection regime at (a) $Ra = 10^2$ and (b) $Ra = 10^6$. Shaded parts denote the unyielded regions. (Results are taken from Nirmalkar, N. et al., *Ind. Eng. Chem. Res.*, 53, 17818, 2014b.)

Prandtl number, and Rayleigh number on the morphology of the yielded and unyielded regions around the sphere. The limiting condition of fully plastic limit is seen to approach in all cases. Indeed, for a given value of the Rayleigh number, there exists a limiting Bingham number, Bn_{max}, beyond which no fluid yielding occurs. Naturally, higher the Rayleigh number, the larger is the limiting value of the Bingham number is, that is, Bn_{max}. For instance, for $Ra \leq \sim 1000$, the limiting Bingham number is almost equal to zero. Based on their numerical results, Nirmalkar et al. (2014b) put forward the following expression linking the limiting Bingham number, Bn_{max}, with the other relevant parameters:

$$Bn_{max} = 0.215 + 0.06Ra^{0.65}Pr^{-0.47} \quad \text{for } 10^2 \leq Ra \leq 10^4 \tag{21.56}$$

$$Bn_{max} = 1.04\left(\frac{Ra}{Pr}\right)^{0.35} \quad \text{for } 10^4 < Ra \leq 10^6 \tag{21.57}$$

Conversely, for given values of Ra and Pr, for Bingham number values exceeding the value of Bn_{max}, given by Equations 21.56 and 21.57, the heat transfer occurs solely by conduction and the corresponding Nusselt number is given by the familiar limit: $Nu = 2$. At the other extreme of $Bn \to 0$, the Nusselt number should

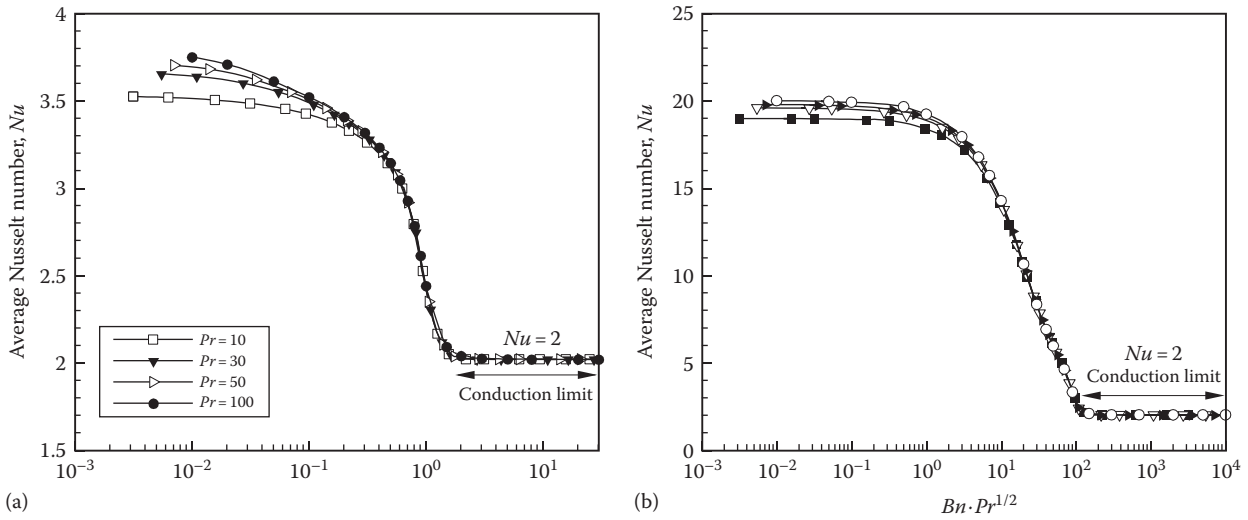

Figure 21.15

Dependence of the average Nusselt number on composite parameter $Bn \cdot Pr^{1/2}$ for: (a) $Ra = 10^2$ and (b) $Ra = 10^6$.

approach the well-known Newtonian limit. Thus, the Nusselt number for a sphere in Bingham plastic fluids progressively decreases from its maximum value in Newtonian fluids ($Bn = 0$) to the conduction limit of $Nu = 2$ with the increasing value of the Bingham number. This behavior is clearly seen in Figure 21.15, wherein the average Nusselt number is plotted against the mixed dimensionless group of $Bn \cdot \sqrt{Pr}$. This group denotes the ratio of the yield stress forces to the buoyancy effects. Except for a minor Prandtl number effect seen at small Bingham numbers (~ close to the Newtonian fluid behavior), the composite parameter $Bn \cdot \sqrt{Pr}$ does collapse the results for different Prandtl numbers to a single curve. Bearing in mind the foregoing factors, Nirmalkar et al. (2014b) have developed the following expressions for the *a priori* estimation of the value of the average Nusselt number in a new application:

$$Nu = 2 \quad \text{for } Bn \geq Bn_{\max} \tag{21.58}$$

$$Nu = 2 + \frac{0.55 Ra^{1/4} \left(1 - \dfrac{Bn}{Bn_{\max}}\right)^{4.66}}{\left(1 + Bn\right)^{0.178}} \quad \text{for } Bn < Bn_{\max} \tag{21.59}$$

The corresponding value of $Bn_{\max}$ is obtained from Equations 21.56 and 21.57 in a new application.

21.3.2.4.3 Mixed-Convection Regime Only Nirmalkar et al. (2014a) have studied the case of buoyancy-assisted mixed-convection heat transfer in Bingham plastic media from an isothermal sphere. Within the framework of the exponential and biviscous regularization schemes, they sought numerical solutions to the coupled momentum and energy equations over the range of conditions as: $0 \leq Ri \leq 2$; $0.1 \leq Re_B \leq 100$, $10 \leq Pr \leq 100$, and, $Bn \leq 10$. As expected, the morphology of the yielded and unyielded regions is found to be a sum of those in the forced and free convection regimes, as can be seen in Figure 21.16, with the limiting behavior being reached at $Bn = 10$ for the strongest flow corresponding to $Re = 100$ and/or $Ri = 2$. A detailed examination of the results suggests the contribution of the free convection to be maximum in Newtonian fluids, that is, $Bn = 0$ and it progressively diminishes with the increasing Bingham number. Following the method of redefining the Reynolds and Prandtl numbers in Section 21.3.1.2 to incorporate the effect of Richardson number, we renormalize the Reynolds and Prandtl numbers to account for the buoyancy induced flow as

$$Re^{\star} = Re_B \left(1 + \sqrt{Ri}\right) \tag{21.60}$$

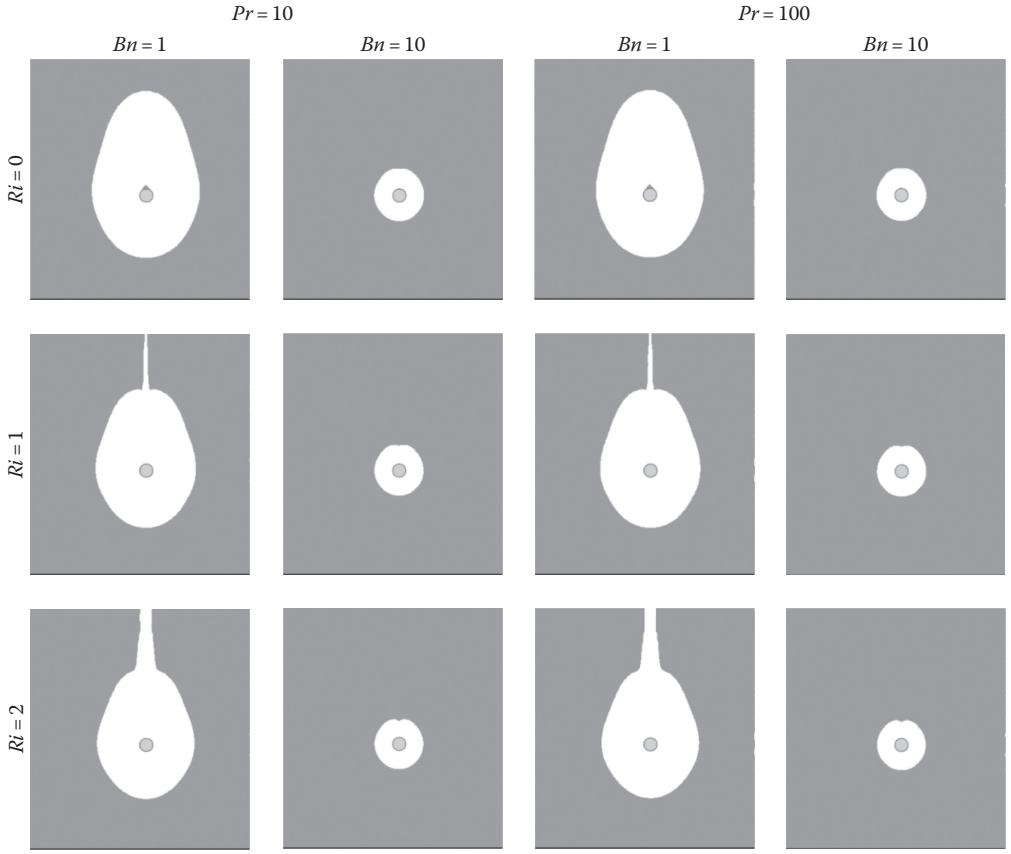

Figure 21.16

Combined effects of the Richardson number, Prandtl number, and Bingham number on the structure of yielded/unyielded regions for aiding-buoyancy, mixed-convection heat transfer from a sphere at Re = 100 (Nirmalkar et al., 2014a). Forced flow is in upward direction. Shaded parts denote the unyielded regions.

$$Bn^{\star} = \frac{Bn}{\left(1+\sqrt{Ri}\right)} \tag{21.61}$$

Naturally, this is tantamount to simply adding the forced convection and buoyancy-induced flow currents. These definitions can be further modified to incorporate the effect of Bingham number as

$$Re_{\text{mod}} = \frac{Re^{\star}}{\left(1+Bn^{\star}\right)} \tag{21.62}$$

$$Pr^{+} = Pr\left(1+Bn^{\star}\right) \tag{21.63}$$

One can, thus, postulate the average Nusselt number for a sphere in the mixed convection to be a function of Re_{mod} and Pr^{+}. Based on their numerical results, Nirmalkar et al. (2014a) developed the following predictive expression:

$$Nu = 1.25\left(Re_{mod}\cdot Pr^{+}\right)^{1/3} \tag{21.64}$$

Equation 21.64 incorporates the known limiting cases of Newtonian fluids (Bn = 0) or pure forced convection (Ri = 0). It predicts the average Nusselt number with an average error of 10%.

21.3.2.5 Wall Effects

In addition to the complications described in Section 21.3.1.3 due to the confinement, the situation gets accentuated further in the context of the translation of a sphere in viscoplastic fluids. This stems from the fact that the fluid yielding is restricted to a region, which at most extends up to three-to-four times the sphere radius, especially in the lateral direction. Thus, if such a yielded region does not reach the physical wall, the sphere does not see the confining boundary and there should be no extra retardation experienced by the settling sphere. This conjecture is borne out by the preliminary experimental results of Atapattu et al. (1986, 1990).

The first detailed systematic numerical study on wall effects on a sphere undergoing steady translation axially in a tube filled with Bingham plastic media is due to Blackery and Mitsoulis (1997). This is, however, restricted to the creeping regime only, as is their subsequent and less extensive study of wall effects in Herschel–Bulkley model fluids (Beaulne and Mitsoulis, 1997). In particular, Blackery and Mitsoulis (1997) outlined expressions for the hydrodynamic drag force of a sphere as the function of blockage ratio, Ξ, ($\Xi \leq 0.5$) and Bingham number ($Bn \leq 1000$) of the following form:

$$X = X_N + a_1(Bn)^{a_2} \tag{21.65}$$

where

X is defined as $(C_D Re_B/24)$

X_N is its value in Newtonian fluids

Thus, the factor X accounts for both effects, that is, blockage and Bingham number and accordingly, X_N is the value of X at $Bn = 0$ (i.e., in a Newtonian fluid). One can also show that $X_N = (1/f_w) = k_{wall}$ where k_{wall} is given by Equation 1.160. These values, along with that of a_1 and a_2, are summarized in Table 21.4.

In a recent work, Das et al. (2015) extended these results to finite Reynolds numbers ($Re_B \leq 100$) to elucidate the effect of blockage on the drag and heat transfer of a sphere. Using the definitions of the modified Reynolds number, Re^+ (Equation 21.52), they put forward the following expressions for calculating the drag coefficient:

$$C_D = \frac{24}{Re^+}\left(1 + 0.32\left(Re^+\right)^{0.31}\right)(1+\Xi)^{2.8} \quad \text{for } Bn \leq 1 \tag{21.66}$$

$$C_D = \frac{24}{Re^+}\left(1 + 0.75\left(Re^+\right)^{0.19}\right)(1+\Xi)^{0.05} \quad \text{for } 1 < Bn \leq 100 \tag{21.67}$$

The smaller exponent of the $(1 + \Xi)$ term in the second equation testifies to the diminishing importance of blockage with the increasing Bingham number. This is very likely due to the fact that fluid-like yielded region shrinks with the increasing Bingham number and these regions terminate well before reaching the physical wall, as can be seen in Figure 21.17. The limited results of Yu and Wachs (2007) for $\Xi = 0.25$ are in line with these equations. Similarly, Das et al. (2015) collapsed their heat transfer data ($1 \leq Pr \leq 100$) using the modified definitions of the Reynolds and Prandtl numbers as

$$Nu = 1.76\left(Re^+ \cdot Pr^+\right)^{1/3} \quad \text{for } Bn \leq 1 \tag{21.68}$$

Table 21.4 Values of Constants in Equation 21.65

Ξ	X_N	a_1	a_2
0	1	2.93	0.83
0.02	1.05	2.59	0.86
0.1	1.26	2.33	0.88
0.125	1.35	2.28	0.89
0.25	1.98	1.92	0.92
0.5	5.94	1.63	0.95

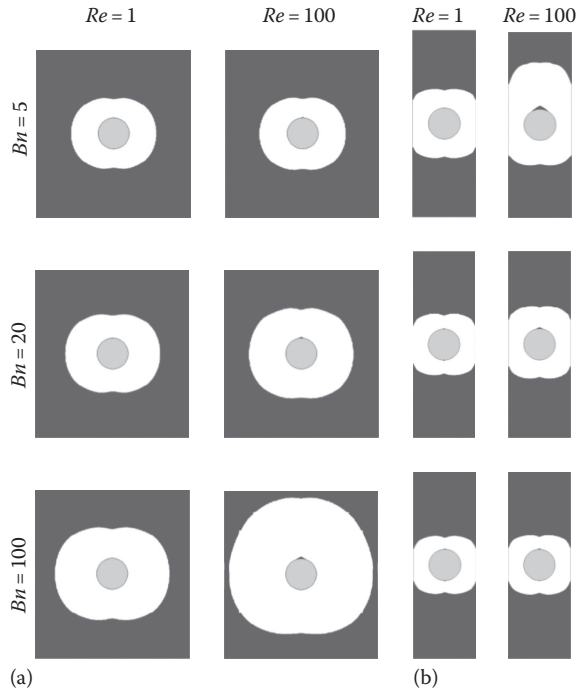

Figure 21.17

Morphology of yielded/unyielded regions for a sphere confined in Bingham plastic fluids from Das et al. (2015): (a) Ξ = 0.2 and (b) Ξ = 0.5. Flow is in upward direction. Shaded parts denote the unyielded regions.

and

$$Nu = 2.11\left(Re^{+} \cdot Pr^{+}\right)^{1/3} \quad \text{for } 1 < Bn \leq 100 \tag{21.69}$$

Though these global correlations incorporate the effect of Ξ implicitly, the resulting deviations can be as high as 40%. Equations 21.68 and 21.69 can be written in terms of a constant a_0 as

$$Nu = a_0\left(Re^{+} \cdot Pr^{+}\right)^{1/3} \tag{21.70}$$

Now a_0 becomes a function of Ξ, as summarized in Table 21.5. Though the maximum error is still of the order of 30%, Equation 21.70 does offer some improvement over the global correlations given by Equations 21.68 and 21.69.

Before concluding this subsection, and notwithstanding the scarcity of results in this field, it appears that the Nusselt number scales as $Pe^{1/3}$ with a suitably modified definition of the Peclet number and the effect of the blockage on drag only shows up if the yielded regions intersect with the physical boundary. Also, the heat transfer is influenced less by wall effects compared to the corresponding hydrodynamic drag on a sphere.

21.3.3 Nonspherical Particles

It is known that most solid particles encountered in real life process engineering applications are nonspherical, regular- and/or irregular-shaped particles. In view of the fact that each nonspherical particle is unique, the developments in this field have not only been rather slow, but these also lack universal appeal, as noted in Section 1.4.3.7. Also, it needs to be recognized here that the shape of a particle exerts much more influence on the drag of a single particle than that in the case of an assemblage of particles such as that encountered in concentrated suspensions and slurries, fixed- and fluidized bed systems, porous media, etc. In the latter case, the interparticle interactions far outweigh the effect of particle shape (Chhabra, 2006). In contrast to the unique case of a sphere, at least three attributes are required to account for the effect of shape

Table 21.5 Value of a_0 in Equation 21.70

		% Error		
Ξ	a_0	Mean	Maximum	Range of *Bn*
0	1.73	12.3	29.3	$Bn \leq 1$
0.1	1.74	12.6	29.4	
0.2	1.73	11.4	28.2	
0.3	1.72	7.6	21.4	
0.4	1.73	4.5	11.6	
0.5	1.89	3.6	9.6	
0	2.17	9.1	22.2	$1<Bn \leq 100$
0.1	2.16	9.1	21.2	
0.2	2.14	8.1	22.9

0.4	2.00	6.5	25.6	
0.5	2.13	6.5	22	

on the drag of a *regular*-shaped object. Firstly, a measure of its size is needed. The most common approach is to employ the so-called equal volume sphere diameter, d_V, defined by Equation 1.146. Second, some measure of the particle shape is needed. Several possible measures of this aspect are available in the literature; for example, see the extensive reviews by Kasper (1982), Hoerner (1965), Clift et al. (1978), Michaelides (2006), and Loth (2008), among others. The simplest and possibly also the most widely used parameter is the so-called sphericity, ψ, defined by Equation 1.147. It is simply the ratio of the surface area of the equal volume sphere to that of the actual particle and therefore, the sphericity is always smaller than unity for nonspherical particles. The fact that the surface area of irregular particles cannot be readily calculated or measured immediately reveals the deficiency of this approach. Besides, both these measures are static in nature and do not account for the actual orientation of the particle during its settling. For instance, for a cylinder of given diameter and length, both d_V and ψ have fixed values, yet it is a common experience that the terminal settling velocity (or hydrodynamic drag) of such a cylinder is strongly influenced by its orientation. Therefore, a parameter, which adequately quantifies this aspect, is also required. There is no simple scheme available to account for the orientation in the calculation of the drag of a nonspherical particle. One approach, which has gained some acceptance in the literature, is by characterizing the orientation of a settling particle by defining a circle of diameter, d_N, whose area is equal to the projected area of the particle (Ganser, 1993, Rajitha et al., 2006). It is worthwhile to add here that even the use of these three measures, namely, d_V, ψ, and d_N, is not entirely foolproof because a cone settling with its apex pointing upward or downward will exhibit different drag characteristics, whereas the values of d_V, ψ, and d_N are identical in these two configurations! A thorough review of the corresponding body of knowledge for Newtonian fluids can be found in Chhabra et al. (1999) and Concha (2014).

21.3.3.1 Power-Law Fluids

Currently available methodologies for treating the drag behavior of nonspherical particles in both Newtonian and power-law fluids fall into two distinct categories. The first approach is aimed at developing drag expressions for a fixed shape and orientation via the numerical solutions of the field equations and/or tow tank experiments, as reviewed by Chhabra (2006). Within the context of power-law fluids, numerical drag values are available only for prolates and oblates (Tripathi et al., 1994, Tripathi and Chhabra, 1995), hemispheres (Sasmal et al., 2013), and long cylinders of circular, elliptical, square, triangular, and semicircular cross sections (e.g., see, Chhabra, 2011). We limit our discussion only to spheroids and hemispheres. Sasmal et al. (2013) solved the momentum equations describing the steady axisymmetric flow over a hemisphere (with its curved surface oriented upstream) and put forward the following expression for the drag coefficient:

$$C_D = \frac{28}{Re_{PL}}\left(1 + 0.064nRe_{PL}^{-0.205n+1.02}\right) \tag{21.71}$$

Over the range of conditions as $1 \leq Re_{PL} \leq 150$ and $0.1 \leq n \leq 1$, Equation 21.71 approximates their numerical data with an average error of ~10%. The diameter of the hemisphere is used as the linear dimension in the definition of Re_{PL}. Sasmal et al. (2013) validated their numerics by using the experimental drag data for hemispheres falling in Newtonian media (Wang et al., 2009). In contrast, the analogous results of Tripathi et al. (1994) and Tripathi and Chhabra (1995) for spheroids are available only in tabular form over the range of conditions of $0.01 \leq Re_{PL} \leq 100$; $0.4 \leq n \leq 1.8$ and aspect ratios of 0.2, 0.5, 1, 2, 5. Broadly, for a given shape, the drag was enhanced over and above its Newtonian value on account of the shear-thinning behavior ($n < 1$). This effect diminishes with the increasing Reynolds number, due to the growing importance of inertial effects. However, the shape of the spheroid exerted significant influence on the drag force. Some of these predictions have been corroborated by the independent numerical studies of Reddy and Kishore (2014) who also reported scant results on wall effects ($0.2 \leq \Xi \leq 0.5$) for particle aspect ratio in the range 0.5–2.5.

It is worthwhile to add here that this family of studies and expressions developed therefrom work well for a specific shape and/or orientation, but extrapolations to other shapes and orientations are clearly not justified. Also, it is unlikely that the numerical results will ever become available for all possible shapes or orientations or flow conditions (laminar, turbulent flow, etc.). Therefore, such numerical studies must be supplemented by experimental results, which are required not only for the purpose of validation of the numerical predictions but also to encompass the range of Reynolds numbers, which is beyond the reach of the numerical solutions, at least as of now.

The second approach to the prediction of drag on nonspherical particles in power-law fluids hinges on the use of the conventional Reynolds number – drag coefficient coordinates together with a set of parameters capturing the deviation from spherical shape, that is, ψ and d_N, etc. to account for the shape and orientation of the particle. The scant results on the drag of scores of shapes including cylinders, cones, prisms, cubes, thin disks and plates, rectangles, oblates, and prolates in power-law fluids have been reviewed by Rajitha et al. (2006) and Chhabra (2006). Based on the available experimental and numerical results, Rajitha et al. (2006) developed the following drag expression for both spherical and nonspherical rigid particles:

$$C_D = C_{Do} + \chi C_{D_\infty} C_{Do}^{2A_o} B_o \left\{ \frac{6X(n)b_o}{6X(n)b_o + C_{Do}} \right\}^{A_o} + C_{D_\infty} \left\{ \frac{6X(n)b_o}{6X(n)b_o + 128C_{Do}} \right\}^{11/12} \tag{21.72}$$

In Equation 21.72, C_{Do} and C_{D_∞} are the values of the drag coefficient in the Stokesian and Newtonian regimes, respectively. The effects of shape and orientation are embodied in the single parameter χ, which is defined as

$$\chi = \frac{4}{\psi}\left(\frac{d_V}{d_N}\right)^2 \tag{21.73}$$

In physical terms, it denotes the ratio of the surface area of the particle to its projected area. Clearly, for a sphere, $\chi = 4$, and this is the minimum value of this parameter. The function $X(n)$ is given by Equation 21.20; the other constants appearing in Equation 21.72 are given as follows:

$$b_o = \exp\{3(C - \ln 6)\} \tag{21.74}$$

$$B_o = \left(\frac{3-C}{6C}\right)\exp\left[3\left\{\frac{3-C}{6C}\right\}\ln 3\right] \tag{21.75}$$

$$A_o = \frac{11\sqrt{6}}{48}\left[1 - \exp\left\{\left(\frac{3-C}{2C}\right)^2 \ln\frac{\sqrt{6}-1}{\sqrt{6}}\right\}\right] \tag{21.76}$$

$$C = \left[6^{(1-n)/2} \cdot X(n)\right]^{1/n+1} \tag{21.77}$$

Regarding the value of C_{D_∞} in Newtonian fluids, the widely accepted values of the limiting drag coefficient C_{D_∞} are 0.44 for a sphere and very close to 1 for an infinitely long cylinder oriented transverse to the flow. However, neither experimental nor numerical results are available to extract the corresponding values for power-law fluids for either of these shapes. On the other hand, it is readily acknowledged that the role of non-Newtonian viscosity weakens with the increasing Reynolds number. Thus, in the absence of any definitive information, Rajitha et al. (2006) suggested the use of the same value of C_{D_∞} as that in Newtonian fluids, that is, $C_{D_\infty} = 0.44$ for a sphere in power-law fluids, at least as a first approximation. The efficacy of Equation 21.72 was tested against an extensive data set spanning wide ranges of conditions as $0.33 \leq \psi \leq 1$ and $10^{-6} \leq Re_{PL} \leq 400$ by Rajitha et al. (2006) and subsequently by Agarwal and Chhabra (2007) for scores of particles of regular shape.

21.3.3.1.1 Heat Transfer Numerical results for forced convection heat transfer in power-law fluids from isothermal spheroids have been reported by Reddy and Kishore (2014), Srinivas and Ramesh (2014) and Sreenivasulu et al. (2014). Though both Sreenivasulu et al. (2014) and Reddy and Kishore (2014) have put forward correlations for the average Nusselt number, these are considered too tentative to be included here. Sasmal et al. (2013) analyzed the forced convection heat transfer from a hemisphere in power-law fluids and they correlated their heat transfer data as follows:

For an isothermal hemisphere:

$$Nu = 1.80\left(Re_{PL} \cdot Pr_{PL}\right)^{1/3}\left(\frac{3n+1}{4n}\right)^{0.21} \tag{21.78}$$

For an isoflux hemisphere:

$$Nu = 1.85\left(Re_{PL} \cdot Pr_{PL}\right)^{1/3}\left(\frac{3n+1}{4n}\right)^{0.24} \tag{21.79}$$

The mean uncertainty in using these equations is in the range 13%–14% over the following ranges of conditions as follows: $1 \leq Re_{PL} \leq 150$; $0.1 \leq n \leq 1$ and $0.72 \leq Pr_{PL} \leq 100$. Given the complexities of the system, this is considered accurate.

21.3.3.2 Bingham Plastic Fluids

Limited information is available about the drag and heat transfer aspects for spheroids and hemispheres in viscoplastic fluids. As noted earlier, the key distinguishing feature of the external flows of such fluids is the simultaneous coexistence of fluid-like and solid-like regions in the flow domain, as noted in Section 21.3.2.2 in the context of the steady translation of a sphere. The forced flow over a spheroid has been studied numerically by Gupta and Chhabra (2014). Using the axis perpendicular to the flow as the characteristic linear dimension in the definitions for the definitions of the Reynolds number, Bingham number, and Nusselt number, they put forward the following expression for drag coefficient:

$$C_D = \frac{24}{Re^+}\left(1 + b_o\left(Re^+\right)^{c_o}\right) \tag{21.80}$$

where the modified Re^+ is still given by Equation 21.48. The resulting values of b_o and c_o are summarized in Table 21.6.

Equation 21.80 consolidates the numerical values of drag coefficient with a mean deviation of about 12% over the range of conditions as: $1 \leq Re_B \leq 100$, $0 \leq Bn \leq 100$, and $0.2 \leq e \leq 5$. They also studied the corresponding forced convection heat transfer problem for an isothermal spheroid for Prandtl number values ranging from 1 to 100 and developed the following expression for the surface average Nusselt number:

$$Nu = a_o\left(Re^+ \cdot Pr^+\right)^{1/3} \tag{21.81}$$

Table 21.6 Values of b_o and c_o in Equation 21.80

Aspect Ratio, e	b_o	c_o
0.2	0.34	0.26
0.5	0.42	0.19
1	0.60	0.13
2	1.04	0.09
5	2.4	0.06

Table 21.7 Value of a_o in Equation 21.81

e	$Re^+ < 0.5$	$Re^+ \geq 0.5$
0.2	2.55	2.20
0.5	2.47	2.25
1	2.18	2.02
2	1.75	1.66
5	1.27	1.20

where

$$Pr^+ = Pr\left(1 + Bn\right).$$

Because of the large number of dimensionless parameters, a single value of the fitted constant a_o could not be obtained to fit the entire data set with acceptable levels of accuracy. Therefore, Gupta and Chhabra (2014) divided the data into two regions as $Re^+ < 0.5$ and $Re^+ \geq 0.5$. The resulting values of a_o are reported in Table 21.7.

The mean deviation associated with Equation 21.81 is ~7% at low Reynolds numbers and/or large Bingham numbers ($Re^+ < 0.5$) and ~14% at high Reynolds numbers and/or low Bingham numbers ($Re^+ \geq 0.5$).

The case of buoyancy assisted mixed convection from a hemisphere in Bingham plastic fluids in the steady axisymmetric regime with the curved surface of the hemisphere oriented in the upstream direction has been studied recently by Nalluri et al. (2015). They have discussed in detail the interplay between the forced- and buoyancy-induced flow and the corresponding kinematics of the flow in terms of the yielded and unyielded regions, and temperature profiles. Their values of the mean Nusselt number shows the following dependence on the pertinent dimensionless groups:

$$Nu = 2.255 + 0.91\left(Re_{mod}\right)^{0.32}\left(Pr^+\right)^{0.42} \tag{21.82}$$

The constant term of 2.255 denotes the conduction limit for this configuration, which is reached for large values of the Bingham number ($\rightarrow \infty$). This is equivalent to $Re_{mod} \rightarrow 0$. The modified Prandtl number is given as $Pr^+ = Pr(1 + Bn^*)$, whereas the modified Reynolds number, Re_{mod}, incorporates the effects of both the fluid yield stress and of the buoyancy-induced flow as

$$Re_{mod} = \frac{Re_B\left(1 + \sqrt{Ri}\right)}{\left(1 + Bn^*\right)} \tag{21.83}$$

where

$$Bn^* = \frac{Bn}{1 + \sqrt{Ri}} \tag{21.84}$$

Equation 21.82 is applicable in the range: $1 \leq Re_B \leq 100$; $1 \leq Pr \leq 100$; $0 \leq Bn \leq 100$ and $0 \leq Ri \leq 10$. The analogous case of forced convection heat transfer from a hemisphere (constant wall temperature and constant heat flux condition) with its curved surface facing upward or downward in Bingham plastic fluids has recently been investigated (Patel et al., 2015). In addition, similar results are also available for two-dimensional cylinders of circular (Bose et al., 2015) and elliptical (Patel and Chhabra, 2016) cross sections.

This section is concluded by noting that scant experimental results are available on the drag behavior of thin plates and disks, cones, cylinders, etc. in viscoplastic fluids and these have been reviewed extensively by Chhabra (2006) and more recently by Ahonguio et al. (2015). Earlier works (Valentik and Whitmore, 1965, Pazwash and Robertson, 1975, etc.) are based on inadequate rheological characterization of the test media used, whereas the major thrust of some of the recent studies is on extracting the value of the fluid yield stress from the velocity-force data in the limit of diminishing velocities. Overall, this field remains relatively less explored as compared to its Newtonian and power-law fluids counterparts.

21.3.4 Effect of Viscoelasticity

Ever since the seminal paper of Leslie and Tanner (1961) dealing with the slow translation of a sphere in Oldroyd model fluids, much has been written about the effect of fluid viscoelasticity on the detailed kinematics and macroscopic parameters like drag and Nusselt number for a sphere, albeit the bulk of the information deals with the fluid mechanical aspects. This problem occupied the center stage for both the experimentalists as well as numerical researchers for well over 10 years; for example, see Walters and Tanner (1992), McKinley (2002) and Chhabra (2006) for state-of-the-art reviews. On the other hand, under appropriate kinematic and rheological conditions, viscoelasticity gives rise to a myriad of intriguing phenomena including: "negative wake"; bouncing and oscillations of sphere; "velocity overshoot"; "stress-induced migration"; "drag reduction or enhancement", etc. Some of these effects have been explained by the currently available numerical and phenomenological considerations, albeit the emerging picture is neither as cohesive nor as conclusive as that available for Newtonian fluids (Chapter 1), or in time-independent viscous fluids (earlier sections in this chapter). Much of the literature (numerical) examines the influence of fluid elasticity on the drag of a sphere in the absence of shear-thinning viscosity, which predicts no or little reduction (~5%–10%) from the Stokes value at low Weissenberg numbers and beyond a critical value of the Weissenberg number, drag augmentation may occur. In contrast, experimental results in model elastic fluids exhibit drag reduction of the order of 25% or drag enhancement of up to 200% with reference to the Stokes value. Similarly, many workers have performed terminal velocity measurements in test fluids exhibiting both viscoelasticity as well as shear-dependent viscosity. Overall, one may say that the drag on a sphere is determined primarily by the viscosity behavior of the fluid, though fluid elasticity seems to modify the detailed flow field, especially in the rear of the sphere. Similarly, limited available studies seem to suggest that both the blockage effects on drag and the rate of heat transfer are suppressed in viscoelastic fluids (Chhabra, 2006). Interested readers should refer to the state-of-the-art reviews and the references therein for further details (Walters and Tanner, 1992, Mckinley, 2002, Chhabra, 2006).

21.4 Fluid Spheres

Additional difficulties arise while studying the rise or fall of bubbles and drops (fluid particles) due to their deformability even in Newtonian fluids, as noted in Section 1.4.3.8, both from experimental and theoretical standpoints, especially in the case of drops made up of a liquid of finite viscosity. In this case, the momentum equations for both inner (dispersed) and outer (continuous) phase must be solved simultaneously. These equations are coupled via the boundary conditions at the interface, that is, continuity of velocity vector and stress tensor. Thus, the momentum is transmitted across the interface, thereby setting up circulation inside the drop also. The case of a bubble can be seen as the limiting behavior of a fluid sphere when the ratio of the viscosity of the dispersed phase to that of the continuous phase, λ, is vanishingly small, that is, $\lambda \to 0$. At the other extreme is the case of a rigid sphere, which is characterized by large values of $\lambda \to \infty$, as seen in Section 1.4.3.8. While it is not possible to provide generalizations, but typically $\lambda \leq 0.01$ offers a good approximation for bubbles and $\lambda \geq 100-500$ corresponds to the case of a rigid sphere in many situations as far as the calculation of the hydrodynamic drag (terminal rise or fall velocity) is concerned. When the motion occurs under the influence of gravity, depending upon the relative magnitudes of viscous, inertial, and interfacial tension forces, fluid spheres (particularly bubbles) exhibit a variety of axisymmetric shapes up to moderate Reynolds numbers, which transit to three-dimensional shapes at still higher Reynolds numbers, as described in detail by Clift et al. (1978), Crowe et al. (1998), and Michaelides (2006) in the context of Newtonian fluids. Therefore, in a given situation, the shape of a fluid particle is continuously evolving and must be calculated at each stage by employing the normal stress balance at the interface to infer the local radius of curvature. Finally, depending upon the nature and concentration of the surface-active contaminants, a part or the whole of the interface may be immobilized. Under such conditions, a part of the surface of the fluid particle exhibits a mobile interface, while the remaining portion behaves like a rigid particle.

The role of the aforementioned factors gets accentuated when either the dispersed or continuous or both phases exhibit non-Newtonian characteristics. It is, therefore, not at all surprising that not only the progress in the field of bubble and drop phenomena in non-Newtonian fluids has been rather slow, but the current body of information is also nowhere near as extensive or definitive as that in Newtonian media; for example, see Chapter 1 or the excellent treaties of Clift et al. (1978), Sirignano (1999), Zapryanov and Tabakova (1999), and Michaelides (2006). We begin our discussion with the case of a bubble in power-law and yield stress fluids in the next section.

21.4.1 Bubbles ($\lambda \to 0$)

Much of the developments in this field are based on *a priori* assumption of the spherical shape of the bubble. In the creeping region, the early developments are based either on the application of a regular perturbation approach (Hirose and Moo-Young, 1969, Bhavaraju et al., 1978, Kawase and Ulbrecht, 1981) or on the application of stress and velocity variational principles (Nakano and Tien, 1968, Mohan, 1974, Gummalam and Chhabra, 1987). All these predictions pertain to a clean (free from impurities) and spherical bubble in an infinite sea of power-law or Bingham plastic fluid in the Stokes regime. By analogy with the case of a rigid sphere, Equation 21.18, the most celebrated result of Hirose and Moo-Young (1969) for a bubble is given by

$$X(n) = (2)^n (3)^{\frac{n-3}{2}} \left\{ \frac{13 + 4n - 8n^2}{(2n+1)(n+2)} \right\} \tag{21.85}$$

Naturally, in the limit of Newtonian fluid behavior, that is, $n = 1$, Equation 21.85 predicts the value of the drag correction factor $X(n) = 2/3$, which when combined with Equation 21.18 yields the expected result of $C_D = 16/Re$ for a spherical bubble in a clean Newtonian fluid in the creeping regime. In view of the approximations inherent in the analysis leading to Equation 21.85, it is expected to hold only for mildly non-Newtonian fluid behavior, that is, the value of power-law index (n) not too far away from its value of $n = 1$ corresponding to the Newtonian fluid behavior.

There has not been much numerical activity at finite Reynolds numbers for the predictions of drag on a rising bubble in power-law fluids except for the work of Dhole et al. (2007a). However, many investigators (Nakano and Tien, 1967, 1970, Ohta et al., 2003, 2005 2006, Kishore et al., 2007a) have solved the governing equations for a drop from which one can recover the case of a spherical bubble by setting $\lambda = 0$. These predictions are found to be broadly in agreement with the available scant experimental results. Thus, for instance, Dhole et al. (2007a) correlated their numerical drag data for spherical bubbles in clean power-law fluids as

$$C_D = \frac{16}{Re_{PL}} \left(1 + 0.27 Re_{PL}^{\frac{1.41n}{0.335n+3.76}} \right) \tag{21.86}$$

Equation 21.86 encompasses the range of conditions as follows: $0.5 \leq n \leq 2$ and $5 \leq Re_{PL} \leq 500$. These results are also in line with the other numerical predictions. The most severe weakness of such results is the assumption of the fixed spherical shape of the bubbles even at as high Reynolds number as 500, which is at odds with the variety of bubble shapes observed experimentally (Chhabra, 2006).

Even less is known about the rising bubbles in viscoplastic fluids. An early and very approximate perturbation result due to Bhavaraju et al. (1978) predicts an increase in drag coefficient in the creeping flow regime for a spherical bubble as

$$X = \frac{C_D \cdot Re_B}{24} = 1 + 1.61 Bn \tag{21.87}$$

Naturally, this analysis assumes *a priori* that the motive force exceeds the value of the force due to the yield stress of the fluid. Equation 21.87 strictly applies in the limit of $Bn \to 0$.

The issue of the critical conditions, whether a bubble of certain size in a yield-stress fluid will ascend or not, has been investigated by Stein and Buggisch (2000), Dubash and Frigaard (2004, 2007), Singh and Denn (2008), and Tsamopoulos et al. (2008). Stein and Buggisch (2000) studied the effect of pulsation in order to mobilize the entrapped bubbles in a Bingham fluid. Both their analysis and experimental results

revealed that the larger bubbles ascended faster than the smaller ones at similar pressure amplitudes. The other studies listed have attempted to obtain the limiting value of Y, defined by Equation 21.41, thereby denoting the motion/no motion transition under the effect of gravity and in the limit of creeping flow regime. Unlike in the case of a solid sphere, the shape of a freely rising bubble is influenced in an interactive fashion by a large number of variables (density, viscosity, surface tension, size), which, in turn, determines the rise velocity that influences the drag and hence the shape (Terasaka and Tsuge, 2001). For highly deformed bubbles with long tails or bullet shaped (Sikorski et al., 2009), further confusion results as some workers use an equal volume bubble diameter, while others have advocated the use of the maximum diameter normal to the direction of flow, etc. Naturally, the conversion from one to another form is not possible without making additional assumptions regarding the shape of the bubble. In the limit of small Bond number (large surface tension), the most reliable estimate of Y appears to be ~0.0715, above which the bubble will remain suspended (Tsamopoulos et al., 2008). On the other hand, using the notion of strain minimization and stress maximization, Dubash and Frigaard (2004) obtained a value of $Y \geq$ ~0.29, which turns out to be a sufficient but not necessary condition for a bubble to move or not in a Bingham plastic fluid. For a two-dimensional circular bubble, Singh and Denn (2008) reported a value of $Y \sim 0.0835$, which is slightly larger than the corresponding value for a solid cylinder of $Y_G \sim 0.06$. Using a slightly different definition of $Y_m (\equiv \pi\tau_0 d_{\max}^2 / 2\rho_f g V_b)$, Sikorski et al. (2009) reported that the bubble motion is possible only for $Y_m \leq 0.53$. While limited results are available on the shape and drag of a bubble as functions of the Bond number, Archimedes number for Bingham fluids (Tsamopoulos et al., 2008) and for Herschel–Bulkley fluids (Dimakopoulos et al., 2013), no predictive correlations have yet been developed, which can be used in a new application.

In contrast to the preceding numerical/analytical studies on bubble motion in power-law and yield stress fluids, there exists an equally extensive experimental body of knowledge, which has been reviewed in Chhabra (2006). Indeed, a great variety of intriguing effects including velocity jump, first reported by Astarita and Apuzzo (1965), negative wake (Hassager, 1979, Bisgaard and Hassager, 1982, Bisgaard, 1983) and a wide variety of shapes (Dekee and Chhabra, 1988, Dekee et al., 1990), etc. have been documented in the literature associated with the motion of bubbles in non-Newtonian fluids. Still diverse shapes of bubbles are encountered in yield-stress fluids (Vasil'chenko and Potapov, 1996, Sikorski et al., 2009). Naturally, all of these effects influence in varying proportions of measure the rise velocity, shape, and drag of a bubble, but some of these phenomena have not yet been explained completely. This coupled with the poor reproducibility of experimental results in this field have led to numerous inconsistencies and conflicting trends in the literature.

Based on the use of the so-called horizontal bubble diameter, $d_{\max}$, (in the calculation of the projected area normal to the flow), Dewsbury et al. (1999) put forward the following correlation for drag on bubbles in inelastic power-law fluids:

$$C_D = \frac{16}{Re_{PL}}\left(1 + 0.173 Re_{PL}^{0.66}\right) + \frac{0.413}{1 + 16300 Re_{PL}^{-1.09}} \tag{21.88}$$

Equation 21.88 encompasses the range of power-law index, $0.16 \leq n \leq 1$ and of the bubble Reynolds number, $Re_{PL} \leq$ ~1000.

21.4.1.1 Mass Transfer

The corresponding problem of mass transfer from a spherical bubble rising in power-law fluids has been studied for the simplest case of a fixed size spherical bubble with negligible mass transfer resistance inside the bubble. In the limiting case of the creeping flow and high Schmidt number (thin boundary layer approximation), the shear-thinning fluid behavior enhances the rate of gas–liquid mass transfer that is consistent with the limited experimental results on single bubbles available in the literature (Barnett et al., 1966, Moo-Young et al., 1970). In the large Peclet number limit, the Sherwood number for a bubble is given by the following expression (Hirose and Moo-Young, 1969):

$$Sh = 0.65 Pe^{1/2} \left\{ \frac{-4n^2 + 6n + 1}{2n + 1} \right\}^{1/2} \tag{21.89}$$

The corresponding expression for mass transfer from a bubble in Bingham plastic fluids is given as follows (Bhavaraju et al., 1978):

$$Sh = 0.65 Pe^{1/2} \left(1 + 0.25 Bn\right)^{1/2} \tag{21.90}$$

Equation 21.90 is valid in the limit of $Bn \to 0$.

At finite Reynolds numbers, over the range of narrow conditions $5 \leq Re_{PL} \leq 100$, $1 \leq Sc \leq 1000$, and $0.7 \leq n \leq 2$, Dhole et al. (2007b) reported only a weak influence of the power-law behavior and one could safely use the corresponding correlations available for Newtonian continuous phase without incurring errors greater than 10%.

21.4.2 Drops

Unlike in the case of a gas bubble ($\lambda = 0$) and a rigid sphere ($\lambda \to \infty$), the internal and external flow fields are coupled via the interfacial conditions for a fluid sphere (of a liquid of finite viscosity) undergoing steady translation in another immiscible liquid medium. Two situations are possible in this case: liquid sphere settling in a liquid continuous medium and a liquid sphere falling in air. The former is relevant to the production of emulsions and polymer blends, the latter is pertinent to the production of aerial sprays. In either event, reliable knowledge of the hydrodynamic force experienced by the fluid sphere is required in numerous process engineering applications. In the absence of surface-active agents and for spherical particles, the drag force gradually increases as the value of λ is progressively increased from $\lambda = 0$ (bubble) to $\lambda \to \infty$ (solid sphere) at the same value of the Reynolds number, as seen in Chapter 1. This trend is also seen for a Newtonian fluid sphere undergoing a steady translation in a quiescent power-law medium. The early approximate results based on the velocity and stress variational principles for a variety of ambient media including power-law (Mohan, 1974), Ellis model (Mohan and Venkateswarlu, 1974), and Carreau viscosity model (Chhabra and Dhingra, 1986, Jarzebski and Malinowski, 1987) confirm this expectation in the creeping flow regime. In this case, the so-called drag correction factor, $X(n)$, is not only a function of the power-law index for power-law fluids and of the additional non-Newtonian parameters depending upon the choice of a specific viscosity model (Chhabra, 2006) but also of the viscosity ratio, λ, which itself needs to be modified to account for the shear-dependent viscosity of the continuous or the dispersed or of both phases. It is thus not possible to develop an analytical expression for drag force even in the limit $Re \to 0$, which can rival the celebrated result of Hadamard and Rybczynski, Equation 1.96 in Section 1.3.4.1 for a Newtonian ambient fluid. For a fixed value of λ, the hydrodynamic drag is augmented with the decreasing value of the power-law index, that is, the increasing extent of shear-thinning behavior. However, the degree of augmentation itself increases with the increasing value of λ, that is, as one transits from a gaseous sphere to a solid sphere.

The effect of finite Reynolds numbers on a Newtonian droplet settling in quiescent power-law media has been studied less extensively (Nakano and Tien, 1970, Kishore et al., 2007a). Kishore et al. (2007a) numerically solved the inner and outer flow field equations for a fluid sphere ($0.1 \leq \lambda \leq 50$) undergoing steady translation in a power-law fluid ($0.6 \leq n \leq 1.6$) over a wide range of Reynolds number (of the continuous phase) as $5 \leq Re_{PL} \leq 500$ with the implicit assumption of small values of the Bond number, that is, large surface tension effects, which ensure the shape to be spherical over the range of Reynolds number of interest. While they reported a variety of results on surface viscosity and vorticity, their drag results can be consolidated by the following expression over the aforementioned ranges of conditions of λ, Re_{PL} and n:

$$C_D = \left(\frac{2^{n+1}}{\lambda + 1.85}\right)\left[1.55\lambda\left\{\frac{6.063}{Re_{PL}^{1.36}} + \frac{1}{Re_{PL}^{0.38}}\right\} + \frac{6.2}{Re_{PL}^{0.78}}\right] \tag{21.91}$$

The average error associated with the use of Equation 21.91 is of the order of 13%, which, in view of the large number of influencing parameters (λ, Re_{PL}, n), is considered to be acceptable. In a subsequent study (Kishore et al., 2007b), they also studied convective mass transfer from a Newtonian fluid sphere (with negligible internal resistance) in power-law fluids and put forward the following expression for the average Sherwood number, Sh:

$$Sh = \left\{\frac{1.19(n+1)}{1.7n + 1.5}\right\} Re_{PL}^{0.53} Sc^{0.42} \lambda^{-0.14} + \left(\frac{n+1}{1.5n}\right)\left(Re_{PL} \cdot Sc\right)^{-0.15} \lambda^{0.25} \tag{21.92}$$

This equation extends over the same range of conditions as Equation 21.91 together with $1 \leq Sc \leq 1000$. With the increasing value of λ, the value of Sherwood number progressively decreases as one transits from a shear free bubble ($\lambda = 0$) to a rigid sphere ($\lambda \to \infty$). In the limit of $n \to 1$, the predictions of Equations 21.91 and 21.92 are consistent with the corresponding results in Newtonian fluids; for example, see Feng and Michaelides (2001a,b) and Juncu (1999).

In contrast, there has been very little activity in seeking solutions of the fluid equations describing the steady translation of a Newtonian fluid sphere in fluids with yield stress (Bingham plastics or Herschel-Bulkley fluids). Thus, for instance, Potapov et al. (2006) have examined shapes of single droplets and interactions between a pair of drops settling at the axis of a cylindrical tube filled with Herschel–Bulkley fluids. They found that, depending upon the values of the Capillary number and Bingham number, a single fluid sphere exhibits a long transient region before reaching a quasisteady settling velocity. There exists a critical Bingham number up to which a fluid sphere remains suspended (without moving) in the medium due to the overwhelming yield stress effects. On the other hand, two drops arranged in series seem to undergo shape changes, depending upon the value of the Capillary number, and the two may merge and/or retain their identity, depending upon the initial separation between the two and/or the extent of the yielded region created by the leading drop in its rear, as also confirmed by subsequent experiments (Holenberg et al., 2011). Subsequently, Lavrenteva et al. (2009) have experimentally examined the wall effects on a single fluid sphere falling in a tube. Consistent with the previous observations for the solid sphere, a falling drop "sees" the wall only when the fluid-like yielded region extends up to the solid boundary. Interactions between two and three droplets in various geometric configurations falling simultaneous in Bingham plastic fluids have also been studied numerically by Singh and Denn (2008).

21.4.3 Effect of Viscoelasticity

While it is known that the viscoelasticity of the continuous phase influences the shapes and deformation of both bubbles and drops in a significant way and their coalescence behavior at detailed and gross levels (Chhabra, 2006), little definitive information is available on the prediction of engineering parameters, like drag coefficient and Sherwood number in viscoelastic fluids. It is widely believed that mass transfer deteriorates in viscoelastic liquids with reference to that in Newtonian and purely inelastic liquids. The currently available information is really too scant and/or tentative that it is not yet possible to develop reliable prediction methods for these engineering parameters in a new application.

21.4.4 Wall Effects

It is useful to recall that in the case of a rigid sphere, the effect of confining walls on drag and heat transfer can be assessed in an unambiguous fashion because the particle shape remains fixed. The corresponding situation with bubbles and drops is more complex due to their tendency for deformation, which may be accentuated with the increasing extent of blockage. Thus, the confining boundaries exert varying levels of influence both on the settling (or rising) velocity of a fluid particle as well as on the shape that itself determines the velocity. Most studies in this field pertain to the conditions when the walls have very little influence on the shape *per se*. In Newtonian liquids, this is the case when $\Xi \leq \sim 0.6$ or so (Clift et al., 1978). While there is a reasonable body of numerical results available on wall effects on fluid spheres in Newtonian liquids filled in cylindrical tubes (Hartholt et al., 1994, Higdon and Muldowney, 1995, Wham et al., 1997, Krishna et al., 1999, etc.) spanning up to moderate Reynolds numbers, only Chhabra and Bangun (1997) have reported some experimental results on Newtonian droplets settling in power-law solutions ($0.52 \leq n \leq 0.87$) and up to about $\Xi \leq \sim 0.45$ but limited to the Stokes regime only. However, as the maximum value of λ in their experiments was only about ~0.07, their fluid spheres behaved more like gas bubbles rather than droplets. Under these conditions, the terminal settling velocity has a linear dependence on Ξ, and this is slightly weaker than that predicted by the available numerical results. A subsequent experimental study concerning wall effects on rising bubbles in power-law fluids suggests the wall effects to be less severe in these systems than that in Newtonian liquids (Dziubinski et al., 2001).

21.5 Other Effects

The discussion so far has been confined to the simplest class of the problems, namely, the steady translation of an isolated rigid or fluid sphere in confined and unconfined media mainly in power-law and Bingham plastic fluids. Analogous results based on the use of other viscosity models like Carreau, Ellis,

and Sutterby, etc. are qualitatively similar and have been compiled by Chhabra (2006). Undoubtedly, this body of knowledge provides a solid foundation to build upon and explore more complex and realistic flows, including interactions between multiple rigid and fluid particles. The former are relevant to the development of constitutive equations for suspensions and/or to model the flow in porous structures. A rational understanding of similar interactions in swarms of bubbles/drops is germane to develop models for coalescence in chemical reactors, multiphase flow in pipes, such as that covered here in Chapter 4 when the liquid phase is Newtonian. The corresponding discussion for the simultaneous flow of a gas and non-Newtonian liquid in pipes can be found in Chhabra and Richardson (2008). Additional effects have been observed depending upon the flow field a sphere is subjected to, for example, shearing and elongational. This gives rise to the migration of rigid particles away or toward the solid wall, depending upon whether the fluid is viscoelastic or not and/or the fluid inertia. This body of literature has been reviewed by Leal (1980) and more recently (but tersely) by Chhabra (2006). Scant results are also available on the transient settling of a sphere in power-law fluids, which enable the estimation of the time/distance required to reach the terminal fall condition (Bagchi and Chhabra, 1991). The influence of dispersed phase rheology on the hydrodynamic behavior of a single drop and their swarms undergoing steady translation in another immiscible non-Newtonian phase has been studied by Tripathi and Chhabra (1992) and Kishore et al. (2008).

21.6 Concluding Remarks and Future Directions

Based on the foregoing detailed discussion, the state of the art of non-Newtonian multiphase flow systems can be summarized as:

1. For the case of steady translation of a rigid sphere in power-law model fluids, adequate information is now available on the hydrodynamic drag exerted on the sphere. Based on a combination of numerical predictions and experimental results, the drag curve akin to the standard drag curve for Newtonian fluids is now available up to about the Reynolds number values of 1,000. As expected, the role of power-law index progressively diminishes with the increasing Reynolds number. In the Stokes regime, the drag is augmented by up to ~40% in power-law fluids under appropriate conditions.

   The effect of confining walls is seen to be qualitatively similar to that for Newtonian fluids except that the wall effects are less severe in shear-thinning fluids due to the rapid spatial decay of the velocity field. This suggests that one can employ shorter domains (both in computations and experiments) than that required for Newtonian fluids otherwise under identical conditions. However, very little is known about the wake phenomena (length and volume, angle of separation, etc.), flow regimes, and transition from one regime to another. Limited results available on heat transfer from a sphere in power-law fluids encompassing forced-, free-, and aiding-buoyancy mixed-convection regimes suggest varying levels of enhancement in Nusselt number over and above that in Newtonian fluids. Suffice it to add here that the numerical predictions and experimental results are mutually consistent, at least qualitatively.
2. The analogous body of knowledge for the steady translation of a sphere in yield stress fluids is less extensive than that in power-law fluids. While it is possible to make reasonable estimates of the hydrodynamic drag on a sphere, much confusion exists concerning the conditions under which a sphere will move or not in such fluids.

   Heat transfer results show a positive influence of the both Reynolds and Prandtl numbers but that of the Bingham (yield stress) number is modulated by the regime of heat transfer, that is, forced, free, or mixed convection. For instance, the Nusselt number gradually decreases from its maximum value in Newtonian fluids to the conduction limit with the increasing Bingham number in the free-convection regime. This is in stark contrast to the positive influence of the Bingham number on the average Nusselt number in the forced-convection regime.
3. Only a few numerical results for axisymmetric nonspherical shapes like hemisphere, spheroids, and circular disks are available for power-law and Bingham plastic fluids. An extensive database has accrued over the years based on experimental drag results for cylinders, cones, prisms, disks, and cubes in power-law fluids. This has led to the development of a predictive empirical correlation for drag on nonspherical rigid particles in power-law fluids, which permits *a priori*

estimation of drag on a regular shaped nonspherical particle settling in power-law fluids with a precision of ±25%.

4. For the case of fluid spheres, the available literature deals only with the most elementary situation of a spherical fluid particle and that too mainly in the absence of surface tension effects. It is accurate to say that the currently available information is more of exploratory nature. The predictive formulae lack universal applicability and these certainly must not be extrapolated beyond the range of their validity.

This chapter is concluded by making two pertinent observations: firstly, the current body of information for the types of model flows considered here is nowhere near as extensive or coherent as that described in this book in the context of Newtonian media. Secondly, considerable scope exists for both numerics and experiments in this little-known branch of non-Newtonian fluid mechanics to explore, discover, and model various aspects of the dispersed flows encountered in a range of industrial applications.

Nomenclature

$A(n)$	function of power-law index, n, Equation 21.22 (dimensionless)
$A_o(n)$	function of power-law index, n, Equation 21.54 (dimensionless)
a	sphere radius (m)
Bn	Bingham number ($\tau_0^B d/\mu_B u_0$) (dimensionless)
Bn_{HB}	Bingham or Oldroyd number $\left[=\left(\tau_0^H/m\right)\left(d/u_0\right)^n\right]$ (dimensionless)
$Bn_{\max}$	maximum value of Bingham number (dimensionless)
C_D	drag coefficient = ($8F_D/\pi d^2\rho_f u_0^2$) (dimensionless)
C_p	thermal heat capacity of fluid (J/kg K)
$c(n)$	function of power-law index, n, Equation 21.26 (dimensionless)
D	tube diameter (m)
De	Deborah number (dimensionless), Equation 21.14
D_m	molecular diffusivity (m^2/s)
d	sphere diameter (m)
d_N	diameter of a circle with equivalent projected area (m)
d_V	equal volume sphere diameter (m)
e	aspect ratio of a spheroid (dimensionless)
F_D	hydrodynamic drag (N)
f_w	wall correction factor (dimensionless), Equation 21.34
f_{wo}	value of f_w in the Stokes regime (dimensionless)
$f_{w\infty}$	value of f_w in the limit of infinite Reynolds number (dimensionless)
Gr	Grashof number (dimensionless)
$\vec{g}$	acceleration due to gravity (m/s^2)
h	convective heat transfer coefficient ($W/m^2 \cdot K$)
h_m	convective mass transfer coefficient (m/s)
k	thermal conductivity of fluid (W/m K)
M	regularization parameter, Equation 21.44 (dimensionless)
m	power-law consistency coefficient ($Pa \cdot s^n$)
n	power-law index (dimensionless)
Nu	Nusselt number = (hd/k) (dimensionless)
Pe	Peclet number ($=Re \cdot Pr$) (dimensionless)
$Pe^\star$	modified Peclet number ($=Re^\star \cdot Pr^\star$) (dimensionless)
Pr	Prandtl number ($=C_p\mu/k$) (dimensionless)
$Pr^\star$	modified Prandtl number, Equation 21.32 (dimensionless)
Pr^+	modified Prandtl number, Equation 21.55 (dimensionless)
Pr_{PL}	Prandtl number for a power-law fluid $\left[=\left(C_p/mk\right)\left(d/u_0\right)^{n-1}\right]$ (dimensionless)
p	pressure (Pa)
Ra	Rayleigh number ($=Gr \cdot Pr$) (dimensionless)
Re_B	Bingham Reynolds number ($=\rho_f u_0 d/\mu_B$) (dimensionless)
Re_{PL}	power-law Reynolds number for ($\rho_f u_0^{2-n} d^n/m$) (dimensionless)
$Re^\star$	modified Reynolds number, Equation 21.31 (dimensionless)

Re^+ modified Reynolds number, Equation 21.52 (dimensionless)
Re_{mod} modified Reynolds number, Equation 21.62 (dimensionless)
Sc Schmidt number (dimensionless)
Sh Sherwood number ($=h_m d/D_m$) (dimensionless)
t_0 rheological constant, Equation 21.7 (s)
$\vec{u}$ velocity vector (m/s)
u_0 free stream or terminal settling velocity (m/s)
u_m measured velocity of a sphere in a confined fluid (m/s)
u_∞ terminal settling velocity in an unconfined fluid (m/s)
X drag correction factor, Equation 21.65 (dimensionless)
X_N drag correction due to wall effects in Newtonian fluids, Equation 21.65 (dimensionless)
$X(n)$ drag correction factor in power-law fluids, Equation 21.17 (dimensionless)
$X_m(n)$ mass transfer correction factor in power-law fluids (dimensionless)
Y dimensionless parameter, Equation 21.41 (dimensionless)

Greek Alphabets

$\vec{\vec{\dot{\gamma}}}$ rate of strain tensor (s^{-1})
$\dot{\vec{\gamma}}_{yx}$ xy component of $\vec{\vec{\dot{\gamma}}}$ (s^{-1})
δ regularization parameter, Equation 21.47 (s^{-1})
θ_s angle of separation (degree)
Δ function, Equation 21.33 (dimensionless)
λ ratio of viscosity of dispersed phase to continuous phase (dimensionless)
λ_f fluid characteristic time (s)
λ_p process characteristic time (s)
μ Newtonian or apparent viscosity (Pa · s)
μ_B Bingham plastic viscosity (Pa · s)
μ_C Casson fluid viscosity (Pa · s)
μ_y yielding viscosity (Pa · s)
μ_0 zero-shear viscosity (Pa · s)
μ_∞ infinite-shear viscosity (Pa · s)
Ξ diameter ratio (d/D) (dimensionless)
ρ_f fluid density (kg/m^3)
ρ_s density of sphere (kg/m^3)
$\vec{\vec{\tau}}$ extra stress tensor (Pa)
$\vec{\tau}_{yx}$ xy component of $\vec{\vec{\tau}}$ (Pa)
$\vec{\tau}_0$ yield stress (Pa)
$\vec{\tau}_0^B$ Bingham yield stress (Pa)
$\vec{\tau}_0^C$ Casson yield stress (Pa)
$\vec{\tau}_0^H$ Herschel–Bulkley yield stress (Pa)
ψ sphericity (dimensionless)

single-phase turbulent flows, 103
two-fluid model, 96
two-phase turbulent combustion, 531–533
VOF method, 1134
Discontinuous dense phase conveying, 376
Discrepancy function,280– 281
Discrete element method (DEM), particle-based simulations
bulk properties estimation, 646
contact model effect, 646–647
parameters, 644–646
Discrete random walk (DRW) model
dispersion of microparticles, 925–926
stochastic fluctuation velocity models, 902–903
turbulence effects, 895–896
Discrete size distribution, 10–12
Dispersed phase
continuum equations
Boltzmann collision integral, 180
collision models, 181–183
gas-solid turbulent flows, 178–179
inelastic collision, 179
Eulerian approach
continuum assumption, 85–87
equations of motion, 84
Lagrangian approach
numerical interpolation, 82–84
particle equation of motion, 79–81
Dispersed phase equations of motion
back-coupling effect, 485
governing equations, 484
inviscid-unsteady force, 485–487
pressure-gradient force, 485
quasi-steady force, 485
viscous-unsteady force, 487
Dispersed phase flows
compressible dense particle flows, 492–493
compressible dilute particle flows
carrier phase equations of motion, 481–484
dispersed phase equations of motion, 484–487
drag coefficient, 477–480
gas-particle interaction, 492
Mach and Reynolds number effects, 476–477
nonspherical effects, 480–481
response times, 473–475
shock-particle interaction, 487–491
dilute and dense flows, 473
dusty gas flows, jump relations, 493–495
Eulerian frame, 471
Lagrangian tracking, 471
phase coupling, 473
volume averaging method, 472
Distributed-force technique, 92–93
d^2-law, 517
Double circle model, 331–332, 335–336
Drift flux model (DFM)
correction factors, 311
distribution parameter, 307–308
general form, 307
graphical representation, 308
ID model, 308
Laplace number, 311
slug flow regime, 309
two-phase friction factor, 310
for vertical upward bubbly flow, 308–309
void fraction correlation, 309–310
Drift velocity, 54
Droplet breakup
aerodynamic breakup, 811–815
capillary effects, 811
causes, 810
deformation, 810–811
relative rim velocity, 810
Reynolds number, 810
in viscous flow, 815–816
Drop-wall impact
influencing parameters, 818
onto dry substrate
average threshold Weber number, 822
corona splash, 821–822
partial/complete rebound, 822
prompt splash, 821
receding breakup, 822
splashing threshold, 822
onto partially wettable substrate, 821
onto wetted wall
bubble entrainment, 823
corona splash, 822
critical *K*-number, 823
prompt splash, 822
splash threshold, 823
stick regime, 822
theoretical modeling, 823–824
wetting, dry surface
dynamic contact angle, 819–820
Hoffman–Voinov–Tanner law, 819
static advancing, 819
static contact angle, 819, 821
static receding, 819
Young's relation, 819
Dropwise condensation
on flat surfaces, 608–609
nanostructured surfaces, 628–629
surface promoters, 628
Drug delivery devices, 891
Durand's correlation, 426–427
Dust collection
of high-resistivity particles
applied voltage and corona current, 855–856
collection efficiency of various kinds of coal, 855, 857
collection efficiency *vs.* moisture content, 859, 861
collection efficiency *vs.* 2Na + K, 859–860
corona current density influence, 855
corona power and collection efficiency, 855, 857
gas temperature influence, 858
low-temperature operation influence, 859
Na, K, Ca and S content influence, 859–860
temperature influence, 855–856
of low-resistivity particles, 854–855

Dust removal equipment
barrier-type dust collectors, 832
classification, 832–833
collection efficiency, 833
flow-through-type dust collectors, 832
gas velocity *vs.* initial capital cost, 833
general features, 832
obstacle-through-type dust collectors, 832
Dynasen piezoelectric probes, 497, 499

E

Eddy impaction, 1298–1299
Effective permeability, 707–708
Effective pore space, 686
Effective porosity, 686–687
Electrical drift velocity, 1299
Electrical mobility, 1299
Electric field-enhanced condensation, 630
Electrostatic precipitator (ESP)
collection conditions
dust collection of high-resistivity particles, 855–861
dust collection of low-resistivity particles, 854–855
dust resistivity, 852–853
space between collection electrodes, 853
collection efficiency, 851–852
electric mobility, 850–851
general features, 832
particle charging
AC charging, 850
charged ions and particle diameter, 849–850
DC charging, 850
diffusion, 849
field, 849
pulse charging, 850
principles, 848–850
Ellipsoidal fibers, equations of motion, 904–907
Emulator function, 281
End pinching, 815–816
Enhanced condensation
dropwise condensation, 628–629
electric field-enhanced condensation, 630
fin spacing, 626
heat transfer enhancements, 626
of tube
bundle effect, 628
3D complex surfaces, 627
2D low fin surfaces, 626–627
Enhanced convection, 567
Eulerian approach
basic equations, 460
continuous phase
dispersed-phase reference frame, 88–89
mixed-fluid volume, 87
momentum, 87–88
dispersed phase
continuum assumption, 85–87
equations of motion, 84
mechanical and thermal equilibrium
five-equation model, 461
four-equation model, 461
response times, 460
resultant equations, 460–461
turbulence, 461–465
mechanical and thermal nonequilibrium
acoustic impedance, 468
characteristic length scale, 468
compaction equation, 467
conservation equations, 466–467
density, 468–469
material velocity, 468–469
pressure, 467–469
seven-equation model, 465
shock velocity, 468–469
timescale, 468
velocity relaxation coefficient, 467
volume fraction gradients, 467
Eulerian–Lagrangian spray atomization (ELSA) model, 1141–1142
Euler–Lagrange methods
angular velocity, 204
conveying pipe configuration, 206–208
drag coefficient, 204
elementary processes, 205
flow structure
air velocity streamlines, 221, 2221
gas-phase fluctuation velocity, 225–226
normalized fluctuating velocities, 225
particle-induced vortices, 220
secondary flow intensity, 219, 221–222
slip velocity, 226
interparticle collisions, 213–214
mass loading, 218–219
particle phase, 201
particle response time, 208
particle size
mean flow deflection, 217
nondimensional segregation parameter, 215–216
normalized particle concentration, 214–215
particle concentration, 214–217
pipe diameter, 214
radial displacement, 216
pipe bend, erosion
CFD-based erosion models, 231
configuration, 235
cutting and deformation, 231
erosion ratio, 231
experimental pipe configuration, 231–232
friction coefficient, 232
gradual refinement, 232
interparticle collisions, 235–237
mechanisms, 230
Oka model, 230–231
parameters, 233
particle mass loading, 239
particle-wall impact angle, 237
penetration rate map, 232–233
penetration ratio, 231, 239
predictive equation, 230
restitution model, 232, 235
shielding effect, 238
trigonometric functions, 230

validation, 231
wall collisions, 237
wall material and wall surface structure, 230
pneumatic conveying systems, 200–201
pressure drop analysis
calculations, 226
interparticle collisions, 228
particle-wall collisions, 225–226
pipe elements, 228
ripple structure, 229
RANS, 201
slip-rotation lift force, 204–205
slip-shear force, 204
Stokes number, 208
two-way coupling procedure, 205–206
validation, 209
wall roughness effects, 209–213
Evaporation, definition, 559
External boundary force (EBF) method, 112–114
External flow boiling, 559
External group combustion, 527

F

Face cleats, 687–688, 696
Falling-film evaporation, 559
Fanning's friction factors, 365
Favre averaging, 457–458
Faxén theorem, 485
Fibrous filters, 1311–1312
Film condensation, 609–612
laminar film, 609–611
turbulent film, 611–612
Fischer–Tropsch (F-T) process, 1035–1036, 1044
Flame-assisted spray pyrolysis (FASP), 1194
Flame spray pyrolysis (FSP), 1194–1196
Flat surface model, *see* Taitel and Dukler (1976) model
Flow boiling
applications, 559, 577
augmentation, 594
of binary mixtures, 586–588
CHF, 589–593
in circular tube, 577–578
in compact heat exchangers, 593–594
convective flow boiling, 559
definition, 559
external flow boiling, 559
flow boiling map, 586
flow patterns, 579–580
fully developed boiling, 578
heat flux, 578
NVG, 578
ONB, 578–579
partial boiling region, 578
saturated flow boiling heat transfer
asymptotic model, 583
convective boiling-dominant region, 583
correlation, 583
fluid-surface parameter, 583–585
friction factor, 584
Froude number multiplier, 584
Kandlikar (1990) correlation, 584–585
nucleate boiling-dominant region, 583
single-phase all-liquid heat transfer coefficient, 584
subcooled flow boiling heat transfer, 580–583
Flow regimes
dilute pneumatic conveying, 963
DSU, 962–963
minimum fluidization, 957–961
minimum slugging velocity, 961–962
superficial gas velocity, 957–958, 961
transport velocity, 962
turbulent fluidization, 962
upward gas flow, 957, 959
Flow-through-type dust collectors, 832
Flow-through-type separators, 834–836
Fluid catalytic cracking (FCC)
advantages, 1033
crude oil cracking, 1031
disadvantages, 1033
fixed/moving-bed operation, 1031–1032
hot catalys, 1032–1033
in North America, 1034
petroleum refining, 1031
QC reactor, 1034–1035
RFCC, 1034
solid catalyst, 1031
Fluidized bed combustion (FBC)
advantages, 1040–1041
CFBC, 1041–1043
coal particles, 1040
nitrogen monoxide, 1041
PFBC, 1043
SFBC, 1041–1043
volatiles and properties, 1040–1041
Fluidized bed reactor
bubble-free fluidization, 964
bubbling fluidization
entrainment, 970–972
freely bubbling bed without tubes, 965–966
gas mixing, 968–969
gas-solid contacting, 969–970
solids mixing and motion, 960, 966–969
throughflow, 964
tubes and baffles, 966
classification, 1030–1031
coking, 1038–1040
equipment design and operation, 956, 983–984
fast fluidization
axisymmetric flow, 976
configuration, 975
DSU, 978
saturation carrying capacity, 977
solids holdup profiles, 976
solids velocity, 977–978
time-mean voidage, 977
FCC
advantages, 1033
crude oil cracking, 1031
disadvantages, 1033
fixed/moving-bed operation, 1031–1032

hot catalys, 1032–1033
in North America, 1034
petroleum refining, 1031
QC reactor, 1034–1035
RFCC, 1034
solid catalyst, 1031
features, 1036
flow regimes
dilute pneumatic conveying, 963
DSU, 962–963
minimum fluidization, 957–961
minimum slugging velocity, 961–962
superficial gas velocity, 957–958, 961
transport velocity, 962
turbulent fluidization, 962
upward gas flow, 957, 959
F-T process, 1035–1036
gas/liquid velocity, 1029
gas-solid reactions
biomass, 1045–1047
calcination, 1047–1048
coal gasification, 1043–1044
coal utilization, 1039
drying, 1048–1050
FBC, 1040–1043
heat exchangers, 1049–1051
incineration of wastes, 1044–1045
particle coating, 1051–1052
powder coating, 1052–1053
roasting, 1047
gas-solid systems, 1030
GLSFB, 1054
grain particles, 1029
heat and mass transfer
active fuel particles, 1016–1019
CFB, 1004–1013
correlations, 995, 999–1000
dense bed, 1019–1020
heat-transfer coefficient, 994–995

properties, 955–957, 1030
slugging, 972–973
spouted bed, 1053
geometry, 978–979
maximum spouting, 980
minimum spouting velocity, 980–981
particle weight-minus-buoyancy, 979–980
thermal cracking, 1037–1038
three-phase fluidization, 981–983
turbulent fluidization
axial and radial voidage variation, 973–974
chemical reaction, 974
entrainment, 975
gas and solids mixing, 974
mass transfer, 974
types, 1029
Fluid-solid flow
pneumatic conveying systems, 357–407
slurry flows, 407–449
Fluid spheres
bubbles, 1357–1359
drops, 1359–1360
momentum, 1356
viscoelasticity, 1360
wall effects, 1360
Fokker–Planck differential equation, 536
Forced boiling, 1077–1078
Formation resistivity factor, 691
Fractal dimension
conditions, 10
Koch curve, 8–9
particle aggregates, 9
porosity, 10
self-similar patterns, 9
Fractional efficiency, 830–831
Fractional flow, immiscible fluids, 715–719
Free energy model, 123
Free shear flows, 746
Frictional stress model, 639–640
Furutsu–Novikov (FN) method, 149

G

Gaseous combustion, 516–517
Gas expansion method, porosity, 687
Gas-liquid-solid fluidized beds (GLSFB), 1054
Gas–liquid two-phase flow
actual phase velocity, 288
flow maps
for downward inclined two-phase flow, 293–294
facts and limitations, 295
for horizontal flow, 290–292
pressure drop variation, 293–294
transition boundaries, 295
for upward pipe inclinations, 292–293
for vertical upward flow, 292
flow patterns
annular flow, 290, 337–345
bubbly flow, 289
intermittent flow, 290
slug flow, 289
stratified flow, 290, 328–337
flow quality, 288
gas volumetric flow fraction, 288
nonboiling two-phase heat transfer
Reynolds analogy, 347, 349–350
two-phase heat transfer model, 346–349
one-component flow, 287
phase superficial velocity, 288
pressure drop
accelerational pressure drop, 312
fluid properties effect, 316–317
frictional component, 312

hydrostatic/gravitational component, 312
phase flow rates effect, 312, 314–316
pipe diameter effect, 315–316
pipe orientation effect, 312–314
pressure gradient minimum phenomenon, 318–320
surface roughness effect, 317
two-phase pressure drop modeling, 320–328
slip ratio, 288
superficial Reynolds number, 288
transitions
between annular and nonannular flows, 299–300
between bubbly and slug flows, 295–296
between stratified and nonstratified flows, 297–299
two-component flow, 287
two-phase mixture velocity, 288
void fraction
definition, 288
DFM, 307–311
phase flow rate effect, 302–304
pipe diameter effect, 304–305
pipe orientation effect, 301–303
separated flow model, 305–307
Gas-solid reactions
biomass, 1045–1047
calcination, 1047–1048
coal gasification, 1043–1044
coal utilization, 1039
drying, 1048–1050
FBC, 1040–1043
heat exchangers, 1049–1051
incineration of wastes, 1044–1045
particle coating, 1051–1052
powder coating, 1052–1053
roasting, 1047
Gas-to-particle conversion
chemical reaction, 1290–1291
condensation/evaporation, 1290
nucleation, 1275–1290
population of droplets, 1293–1294
single-particle growth, 1291–1293
Gaussian vortex, 784
Generalized Bingham model, 413
Generalized Langevin method (GLM)
constitutive relations
algebraic model, 163–164
eddy viscosity model, 164
fluid-particle velocity correlation, 162–163
LHS, 162
transport equations, 162
simple shear and rotational flows, 155–157
Geostatistics, 698–699
Gillies–Shook correlation, 429
Global reaction mechanism, 517
Godunov scheme, 465
Grade efficiency, 830–831
Grad's theory, 181–183
Granular flow, *see* Powder and granular flow
Granular leidenfrost effect, 671–673
Gravitational collectors, 836
Gravitational effects, 736
Green field workflow, 725
Gridded interface method (GIM), 93–94
Group of drops
interactive combustion, 527–530
interactive evaporation, 524–526

H

Hadamard–Rybczynski analysis, 26
Haider and Levenspiel (HL) model, 907–908
Heat transfer
blowing effects, 61–62
creeping/Stokes flow, 54–56
flow turbulence, 60
IBM, 134–135
nonspherical particles, 1354
Peclet number, 54
Prandtl number, 54
radiation effects, 64–65
Reynolds number effects
interfacial velocity slip, 58–59
solid spheres, 56–57
temperature difference, 58–59
viscous spheres, 57–58
rotational motion, 59–60
transient effects, 62–64
viscoplastic fluids
forced convection regime, 1345–1346
free convection regime, 1346–1348
mixed-convection regime, 1348–1349
Herschel–Bulkley model, 413, 416, 1326
Heterogeneous nucleation, 607–608, 775
Heterogeneous slurry flows
with moving bed, 409–410
settling slurries, 424–439
solids' concentration profiles, 409
with stationary bed, 409–410
Hoffman–Voinov–Tanner law, 819
Homogeneous gas-solid flows, 742–744
Homogeneous nucleation, 605–607, 775
Homogeneous slurry flows
of nonsettling slurries
Newtonian slurries, 411
non-Newtonian slurries, 412–413
pressure loss, pipe fittings, 424
pressure loss, straight circular pipe, 414–423
rheological property, 411
particle distributions, 409
principle of continuum mechanics, 409
solids' concentration profiles, 409
Hopper flow, 643
Hydraulic conductivity, 694
Hydraulic conveying, 358
Hydraulic radius, 690
Hydrodynamic bubble cavitation, 781
Hysteresis, 706, 819–820

I

Imbibition method, porosity, 687
Immersed boundary method (IBM), 939
bilinear interpolation, 129

body force density, 127
drag and heat transfer rate
drag coefficient, 138–139
Nusselt Number, 140
Prandtl number, 138
temperature contours, 141
vortex structures, 139–140
elastic fibers and fluid, 128
fluid-particle interface, 128
fluid velocity, 129
fractional step method, 129
heat transfer, 134–135
implementation, 128
Newtonian framework, 126
particle-particle and particle-wall interactions, 130
hybrid lubrication force scheme, 138
repulsive force scheme, 137–138
soft-sphere scheme, 136–137
particle surface, 130
Proteus code, 127
RDPM, 141–142
rigid body motion, 129
3D isothermal flows
Boltzmann equation, 131
boundary nodes, 130
Cauchy theorem and Gauss integral, 132
differential equations, 133
Eulerian grid spacing, 131
force density, 132
LBM, 132
linear momentum, 133
rigid body motion, 134
rotation matrix, 133
spherical particle, 130, 133–134
spreading function, 131
surface force, 131
torque, 133
translational and rotational velocities, 133
two-relaxation-times, 134
Immersed interface method (IIM), 94–95
Immiscible displacement
Buckley–Leverett theory, 718–719
frontal advance in fracture, 720–721
nonwetting phase and wetting phase, 717
Welge's method, 719–720
Immiscible fluids
fractional flow, 715–717
interface in cylindrical capillary, 703
Inception Thoma number, 787
Inclined flow, 643
Inertial dust collectors, 863–864
Interface capturing method (ICM)
coupling procedure, 1138–1139
droplet size, 1139
Eulerian–Lagrangian approach, 1140
swirling conical liquid sheet, 1140–1141
turbulent liquid jet, 1139
Interfacial tension (IFT), 700–701, 711–714
Internal group combustion, 529
Internal mixing twin-fluid atomizer, 1105–1108
Interstitial velocity, 693
IP model, 909
Isolated drop
combustion
convective flow, 522
empirical relations, 523–524
heptane drop, temporal variations, 523
Lewis number, 521
one-state envelope flame, 523
one-state vaporization, 523
quasi-steadiness assumption, 522
saturated drop surface, 522
Sherwood number, 522
spherical drop, species profiles, 521–522
two-state envelope flame vaporization, 523
two-state wake flame vaporization, 523
evaporation
computational domain, 519–520
coordinate system, 519–520
of deformed drop, 520
dimensionless mass flux, 520
energy balance, 519
finite element simulations, 519
gas-phase energy conservation, 518
gas-phase mass conservation, 518
Lewis number, 518
mass flow rate, 519
normalized mass flux variations, 520
saturation temperature, 518
spherical harmonics, 519
steep temperature gradient, 518–519
Isolated pore space, 686

K

Kapila's model, 465–466
Kelvin–Helmholtz (KH) breakup model, 1148–1149
Kinetic method (KM)
constitutive relations
advection–diffusion equation, 158–159
coefficients, 158
identities, 158
kinetic stresses, 161
particle-carrier velocity covariances, 159–161
MFIX, 264
nonreactive gas-particle flows, 148–151
simple shear and rotational flows, 154–155
Klinkenberg effect, 695–696
Koch curve, 8–9
Kolmogorov timescale, 729
k–ω-based turbulence model, 895–896

L

Lagrangian approach, 457
numerical interpolation, 82–84
particle equation of motion, 79–81
Lagrangian history direct interaction (LHDI) method, 148, 150
Lagrangian particle tracking (LPT) approach
coupling procedure, 1138–1139
droplet size, 1139
Eulerian–Lagrangian approach, 1140

swirling conical liquid sheet, 1140–1141
turbulent liquid jet, 1139
Lagrangian velocity autocorrelation, 732
Laminar film condensation
coordinate system, 616
liquid layer, 616–617
vapor system, 617–620
Laminar flows
Newtonian slurries, 415
non-Newtonian slurries
Bingham plastics model, 415–416
Casson model, 417
Herschel–Bulkley model/generalized Bingham model, 416
numerical integration method, 417
power-law model, 415
pipeline pressure loss, 414
shear stress, 414
volume flow rate, 414
Large eddy simulation/filtered mass density function (LES/FMDF) model
atomization, 1137–1138
block diagram, 534
chemical kinetics model, 536
drop response time, 537
filtered gas dynamics equations, 534
FMDF equations, 534–535
Fokker–Planck differential equation, 537
high-speed turbulent spray, 538
Lagrangian equations, 536
Spalding mass transfer number, 538
symmetric heat and mass transfer equations, 537
turbulence, compressible flows, 463
Laser Doppler velocimetry (LDV), 499–500
Lattice Boltzmann method (LBM), 66–67
Boltzmann equation, 108
conservation of momentum, 108
deformable fibers
flexible fiber model, 119–120
linear shear flow, 120
relative shear viscosity, 121
deformable particles and capsules
finite element method, 116–117
spectrin-link method, 117–119
equilibrium density distribution, 109
fluid-solid interaction
EBF, 112–114
linear shear flow, 114–116
SBB, 109–112
liquid-gas flow
free energy model, 123
front tracking, 124–125
mean field theory model, 124
R-K model, 122
S-C model, 122–123
particle velocity, 108
Level set (LS) method, 1134
Lewis number, 521
Limiting particle trajectory, 835
Liquid flow blockage model, 590
Liquid-fuel spray group combustion, 527–528
Liquid instability sheet atomization (LISA) model, 1129–1130
Liquid-phase particle separation
cut size control
classification performance, 880–881
cross section of cyclone with guide plate, 880–881
experimental apparatus, 879–880
hydrocyclones
characteristics, 877
fractional separation efficiency and corrected one, 877, 879
normal operating conditions, 877
standard cyclone and flow pattern, 877–878
tangential liquid velocity distribution, 877–878
tangential velocity, 877
inlet slurry temperature effect, 880–882
wet separation, 877
Liquid-solid flows, 746–747
Liquid-solid fluidized beds (LSFBs), 1053–1054
Liquid sublayer dryout model, 590
Lithium niobate (LN) probe
cloud pressure, 501
current, time history, 500
engineering diagram, 499
height, 501–502
quasi-static failure stress, 499
sensitivity, 499
voltage, 501–502
vs. x-ray measurements, 501–502
Log-normal distribution, 15
Louver-type dust collector, 863–864

M

Mach and Reynolds number effects, 476–477
Mainwaring and Reed classification, bulk solids
deaeration factor, 361–364
permeability factor, 360–361
Marker-and-cell (MAC) method, 96–97
Mass transfer
chemical reactions, 23–24
fluid spheres, 1357–1359
thermodynamic equilibrium
Clausius–Clapeyron equation, 20
diffusion coefficient, 22
droplet diameter, 22
Fick's law, 22
internal pressure, 20
Kelvin number, 21
mass conservation equation, 21
mole fraction, 21
partial pressure, 19–20
phase transition, 20
pressure and temperature fields, 19
Ranz–Marshall relation, 22
saturation relation, 20
Sherwood number, 22
sublimation and evaporation, 21
vapor pressure, 19
velocity, 21
Maxey–Riley–Gatignol (MRG) equation, 487
Maximum entropy formalism (MEF), 1160–1161

Mean depth of penetration rate (MDPR), 778
Mean field theory model, 124
Mercury injection method, porosity, 687
Mesoscopic Eulerian formalism (MEF), 189
Mesoscopic Eulerian particle velocity fields (MEPVF), 186–189
Metal-matrix-composite (MMC) particles
  ceramic particles, 1202
  generation of, 1203–1204
  macroscale, 1204–1205
  mesoscale, 1206–1207
  microscale, 1206–1207
  particle incorporation efficiency, 1207–1208
Metzner–Reed method, 423
MFIX
  accessing, 262–263
  Cartesian grid cut-cell technique, 260–262
  conductive heat flux, 253

upward convection roll
acoustic streaming model, 658–664
negative slip model, 664–665
Vibrating bed flow, 643
Vibratory cavitation, 780–781
Viscoelastic fluid behavior, 1329–1330
Viscoelasticity effect, 1356
Viscoplastic fluids
drag behavior
Bingham plastic model, 1343
biviscous regularization, 1343–1344
dimensionless viscosity, 1342
drag coefficient, 1344
exponential function, 1343
Herschel–Bulkley fluid model, 1344
a priori assumption, 1344
Reynolds number, 1345
solid and fluid regions, 1340, 1342
strain tensor, 1343
heat transfer
forced convection regime, 1345–1346
free convection regime, 1346–1348
mixed-convection regime, 1348–1349
static equilibrium, 1340
wall effects, 1350–1351
yield surfaces, 1340–1342
Viscosity ratio effect, 713–714
Viscous spheres
Bond number, 32
correction functions, 32
drag coefficients, 29, 31
heat transfer, 57–58
streamlines and vorticity, 29–30
Volume-of-fluid (VOF) method, 97, 99, 1134
Vortex cavitation, 784–786

W

Wall-bounded gas-solid flows, 744–746
Wave breakup model, 1148–1149
Weakly separated approach, 90–91
Welge's method, 719–720
Wettability, 702, 711
Wilson's nomogram, 427–428
Wood gasification, 266–267
Wood model, 458

Y

Yield power-law, 413
Young–Laplace equation, 701, 703

Z

Zaichik's model, 197–198
Zandi–Govatos correlation, 428–429
Zenz plot, 363–364
