Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editor assumes any liability for any injury and/or damage to persons or property arising out or related to any use of the material contained in this book.

meaning, joy, and continuity to our lives.

Foreword to the First Edition

The aim of the editor and contributors to this volume is to establish an effective bridge between the surging progress in biomedical science and the clinical practice of pediatric endocrinology. Half a century ago the biochemical elucidation of the structure and subsequent synthesis of steroid hormones provided the basis for a revolution in the diagnosis and treatment of a number of endocrine and nonendocrine disorders; that era was soon followed by a succession of fundamental discoveries: structure of peptide hormones, identification of releasing hormones from the brain, rapid and precise assay methods, and synthesis of peptide hormones by molecular biological techniques, to name but a few.

In no field has laboratory science been more effectively translated into clinical progress than in pediatric endocrinology. A glance at the roster of contributors to this volume may well provide insight into why; many who are responsible for the dramatic advances in the laboratory also pursue active clinical careers.

This volume includes many new sections that were not presented in previous texts devoted to clinical pediatric endocrinology. It will serve as a valuable reference for family physicians, internists, pediatricians, and other health professionals, covering as it does the gamut of information from basic molecular biology to practical considerations in the diagnosis and treatment of pediatric endocrine disorders.

Solomon A. Kaplan, MD

Preface

This third edition of *Pediatric Endocrinology* bears witness to the ongoing advances in this field, bringing together basic and clinical science and scientists for a deeper understanding of endocrine problems in infants and children, their diagnosis and their evidence-based treatment. No area of inquiry has been more impacted by the contribution of molecular biology, sophisticated imaging, and computer science to discover new knowledge, apply it, and manage it. There is not a single topic in this edition in which discoveries in the past five years have not occurred to provide new insights on old problems. To incorporate these comprehensive discoveries without significantly changing scope, size. and cost, it was necessary to realign some of the chapters. Hence, the chapters on "Organization and Integration of the Endocrine System" and "Imaging in Pediatric Endocrinology" have been reluctantly removed in this edition; the former is addressed in detail in more fundamental texts which approach endocrinology as the science of cell-to-cell communication via chemical messengers. In so doing, they blur previous concepts of hormones as chemical messengers produced in a single organ with specific effects on a limited number of other cell types. Instead, the newer understanding of endocrinology incorporates signal transduction cascades in various cell types in response to circulating messengers as diverse as cytokines into the family of "hormones."

The expanding horizons of sophisticated imaging could not be limited to a single chapter without compromising depth and quality; where relevant, appropriate references are provided in specific chapters, best exemplified by the use of 18-[F] L-DOPA positron emission tomography (PET) scanning to distinguish focal from diffuse hyperinsulinemia.

Taking the place of these realigned chapters is a new chapter on dyslipidemias and an expanded chapter on energy homeostasis and its disorders. These metabolic topics were deemed to be essential inclusions for this book, reflecting the importance of the epidemic of obesity and its consequences in pediatric populations throughout the developing and developed world, and the significant time commitment to management by pediatric endocrinologists. Likewise, management of dyslipidemias in children and adolescents is of increasing importance as data accumulate on the effectiveness and safety of lipid lowering agents in reversing intimal changes and delaying or preventing the consequences of atherosclerosis.

As in previous editions, the book is divided into seamless sections. First, there is an introductory section on molecular endocrinology and endocrine genetics, receptor transduction cascades, and the complexity of normal homeostasis as exemplified by the paradigm of bone mineral metabolism. Three chapters on endocrine disorders in newborns follow cover the topics of ambiguous genitalia, hypoglycemia, and abnormalities of thyroid function. These, together with calcium disorders, form the most common endocrine problems in the newborn nursery for which endocrine consultation is sought. A series of chapters on specific disorders in childhood follows, including thyroid, growth, posterior pituitary, diabetes mellitus, hypoglycemia, the adrenal cortex, pheochromocytoma and multiple endocrine neoplasias, puberty in the female, Turner syndrome, disorders of the testes, disorders of calcium and bone mineral metabolism, autoimmune polyglandular syndromes, disorders of energy balance, and lipid disorders in children and adolescents. Finally, the chapter on laboratory methods in pediatric endocrinology is included because of the importance of understanding the methodologies used in correct and appropriate interpretation of test results. Each chapter has a comprehensive bibliography, which, like all modern hard paper texts, may be somewhat out of date by the time of publication.

From an editor's point of view, it has been a pleasure to welcome new contributors from Europe and Israel to the list of recognized authorities in their respective fields; the text is enriched by their expertise and so too will be its readers.

For any oversight, omissions, or errors, we extend our apologies with request for indulgence and forgiveness from our readers. As always, we welcome your input to improve the value of this book.

Recombinant DNA Technology and Therapy of Pediatric Endocrine Diseases
Concluding Remarks

Introduction

The study of the endocrine system has undergone a dramatic evolution in the last two decades, from the traditional physiologic studies that had dominated the field for many years to the discoveries of molecular endocrinology and endocrine genetics.[1,2] At the current time, the major impact of molecular medicine on the practice of pediatric endocrinology relates to diagnosis and genetic counseling for a wide variety of inherited endocrine disorders.

In contrast, the direct therapeutic application of this new knowledge is still in its infancy. This chapter is an introduction to basic principles of molecular biology, common laboratory techniques, and some examples of the recent advances made in clinical pediatric endocrinologic disorders—with an emphasis on endocrine genetics.

Basic Molecular Tools

ISOLATION AND DIGESTION OF DNA AND SOUTHERN BLOTTING

The human chromosome comprises a long double-stranded helical molecule of DNA associated with different nuclear proteins.[3,4] Because DNA forms the starting

point of the synthesis of all protein molecules in the body, molecular techniques using DNA have proven crucial in the development of diagnostic tools for analyzing endocrine diseases. DNA can be isolated from any human tissue, including circulating white blood cells. About 200 micrograms of DNA can be obtained from 10 to 20 ml of whole blood, with the efficiency of DNA extraction being dependent on the technique used and the method of anticoagulation employed.

The extracted DNA can be stored almost indefinitely at an appropriate temperature. Furthermore, lymphocytes can be transformed with the Epstein-Barr virus to propagate indefinitely in cell culture as "immortal" cell lines—thus providing a renewable source of DNA. For performing molecular genetic studies, lymphoid lines are routinely the tissue of choice because a renewable source of DNA obviates the need to obtain further blood from the family. It should be noted that because the expression of many genes is tissue specific immortalized lymphoid cell lines cannot be used to analyze the abundance or composition of mRNA for a specific gene. Hence, studies involving mRNA necessitate the analysis of the tissue(s) expressing the gene—as outlined in the section on the analysis of RNA.

DNA is present in extremely large molecules. The smallest chromosome (chromosome 21) has about 50 million base pairs, and the entire haploid human genome is estimated to consist of 3 to 4 billion base pairs. This extreme size precludes the analysis of DNA in its native form in routine molecular biology techniques. The techniques for identification and analysis of DNA became feasible and readily accessible with the discovery of enzymes termed *restriction endonucleases*. These enzymes, originally isolated from bacteria, cut DNA into smaller sizes on the basis of specific recognition sites that vary from two to eight base pairs in length.[5,6]

The term *restriction* refers to the function of these enzymes in bacteria. A restriction endonuclease destroys foreign DNA (such as bacteriophage DNA) by cleaving the DNA at specific sites and thereby restricting the entry of foreign DNA in the bacterium. Several hundred restriction enzymes with different recognition sites are now commercially available. Because the recognition site for a given enzyme is fixed, the number and sizes of fragments generated for a particular DNA molecule remain consistent with the number of recognition sites and provide predictable patterns after separation by electrophoresis.

Analysis of the DNA fragments generated after digestion usually employs the technique of electrophoresis.[7] Electrophoresis exploits the property that the phosphate groups in the DNA molecule confer a negative charge to that molecule. Thus, when a mixture of DNA molecules of different sizes is electrophoresed through a sieve (routinely either agarose or acrylamide) the longer DNA molecules migrate more slowly relative to the shorter fragments. Following electrophoresis, the separated DNA molecules can be located by a variety of staining techniques—among which ethidium bromide staining is a commonly used method.

Although staining with ethidium bromide is a versatile technique, analysis of a few hundred base pairs of DNA in the region of interest is difficult when the DNA from all human chromosomes are cut and separated on the same gel. These limitations are circumvented by the technique of Southern blotting (named after its originator, Edward Southern) and the use of labeled radioactive (or, more commonly, nonradioactive) probes. Southern blotting involves digestion of DNA and separation by electrophoresis through agarose.[8] After electrophoresis, the DNA is transferred to a solid support (such as nitrocellulose or nylon membranes) that enables the pattern of separated DNA fragments to be replicated onto the membrane (Figure 1-1).

The DNA is then denatured (i.e., the two strands are physically separated) and fixed to the membrane, and the dried membrane is mixed with a solution containing the DNA probe. A DNA probe is a fragment of DNA that contains a nucleotide sequence specific for the gene or chromosomal region of interest. For purposes of detection, the DNA probe is labeled with an identifiable tag such as radioactive phosphorus (e.g., ^{32}P) or a chemiluminescent moiety. The latter has almost exclusively replaced radioactivity in recent years. The process of mixing the DNA probe with the denatured DNA fixed to the membrane is called hybridization, the principle being that there are only four nucleic acid bases in DNA [adenine (A), thymidine (T), guanine (G), and cytosine (C)] that always remain complementary on the two strands of DNA—A pairing with T, and G pairing with C.

Following hybridization, the membrane is washed to remove the unbound probe and exposed to an x-ray film either in a process called autoradiography to detect radioactive phosphorus or processed to detect the chemiluminescent tag. Only those fragments that are complementary and have bound to the probe containing the DNA of interest will be evident on the x-ray film, enabling analysis of the size and pattern of these fragments. As routinely performed, the technique of Southern analysis can detect a single-copy gene in as little as 5 µg of DNA (the DNA content of about 106 cells).

RESTRICTION FRAGMENT LENGTH POLYMORPHISM AND OTHER POLYMORPHIC DNA STUDIES

The number and size of DNA fragments resulting from the digestion of any particular region of DNA form a recognizable pattern. Small variations in a sequence between unrelated individuals may cause a restriction enzyme recognition site to be present or absent. This results in a variation in the number and size pattern of the DNA fragments produced by digestion with that particular enzyme. Thus, this region is said to be polymorphic for the particular enzyme tested [i.e., a restriction fragment length polymorphism (RFLP)] (Figure 1-2). The usefulness of RFLP is that it can be used as a molecular tag for tracing the inheritance of the maternal and paternal alleles.

Furthermore, the polymorphic region analyzed does not need to encode the genetic variation that is the cause of the disease being studied, but only to be located near the gene of interest. When a particular RFLP pattern can be shown to be associated with a disease, the likelihood of an offspring inheriting the disease can be determined from the offspring's RFLP pattern by comparing it with the RFLP

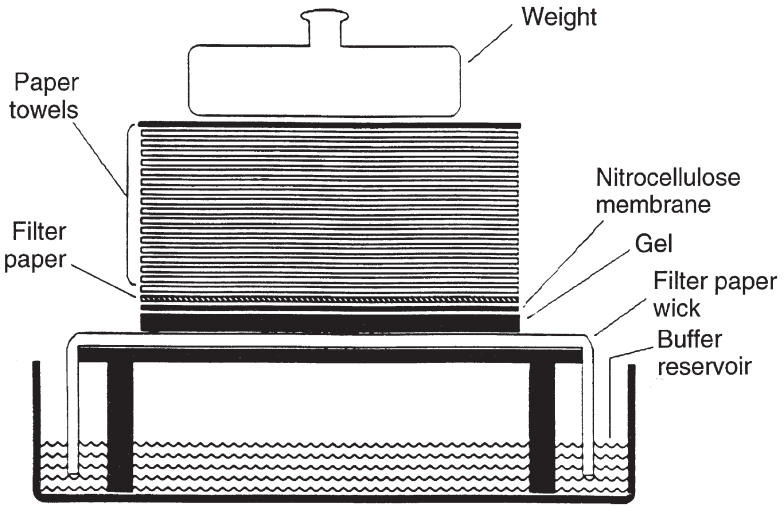

Figure 1-1. Southern blot. Fragments of double-stranded DNA are separated by size by agarose gel electrophoresis. To render the DNA single stranded (denatured), the agarose gel is soaked in an acidic solution. After neutralization of the acid, the gel is placed onto filter paper—the ends of which rest in a reservoir of concentrated salt buffer solution. A sheet of nitrocellulose membrane is placed on top of the gel and absorbent paper is stacked on top of the nitrocellulose membrane. The salt solution is drawn up through the gel by the capillary action of the filter paper wick and the absorbent paper towels. As the salt solution moves through the gel, it carries along with it the DNA fragments. Because nitrocellulose binds single-stranded DNA, the DNA fragments are deposited onto the nitrocellulose in the same pattern in which they existed in the agarose gel. The DNA fragments bound to the nitrocellulose are fixed to the membrane by heat or ultraviolet irradiation. The nitrocellulose membrane with the bound DNA can then be used for procedures such as hybridization to a labeled DNA probe. Techniques for transferring DNA to other bonding matrices, such as nylon, are similar. [Adapted from Turco E, Fritsch R, M. Trucco M (1990). Use of immunologic techniques in gene analysis. In RB Herberman, DW Mercer (eds.), *Immunodiagnosis of cancer*. New York: Marcel Dekker, 205.]

pattern of the affected or carrier parents. The major limitation of the RFLP technique is that its applicability for the analysis of any particular gene is dependent on the prior knowledge of the presence of convenient ("informative") polymorphic restriction sites that flank the gene of interest by at most a few kilobases. Because these criteria may not be fulfilled in any given case, the applicability of RFLP cannot be guaranteed for the analysis of a given gene.

In the early years of the molecular endocrinology era, the RFLP technique was the mainstay of experimental strategies employed for investigating the genetic basis of endocrine diseases. For example, RFLP-based genomic studies were used to identify mutations in the RET oncogene as the etiology of the multiple endocrine neoplasia type-2 syndrome. However, at present for routine disease mapping and whole genome and even gene-specific association studies the RFLP technique has been supplanted by more powerful and facile techniques such as microsatellite and single-nucleotide polymorphism studies (see material following). At present, RFLP analysis is only used within the context of a specific gene investigation.

POLYMERASE CHAIN REACTION

The polymerase chain reaction (PCR) is a technique that was developed in the late 1980s. It has indeed revolutionized molecular biology (Figure 1-3). PCR allows the selective logarithmic amplification of a desired fragment of DNA from a complex mixture of DNA that theoretically contains at least a single copy of the target fragment. In the typical application of this technique, some knowledge of the DNA sequences in the region to be amplified is necessary so that a pair of specific short (approximately 18 to 25 bases in length) oligonucleotides ("primers") can be synthesized. The primers are synthesized in a manner such that they define the limits of the region to be amplified. The DNA template containing the segment to be amplified is heat denatured such that the strands are separated and then cooled to allow the primers to anneal to the respective complementary regions.

The enzyme Taq polymerase, a heat-stable enzyme originally isolated from the bacterium *Thermophilous aquaticus*, is then used to initiate synthesis (extension) of DNA. The DNA is repeatedly *denatured, annealed*, and *extended* in successive cycles in a machine called a thermocycler. This machine permits the process to be automated. In the usual assay, these repeated cycles of denaturing, annealing, and extension result in the synthesis of approximately 1 million copies of the target region in about 2 hours. To establish the veracity of the amplification process, the identity of the amplified DNA can be analyzed by electrophoresis, hybridization to RNA or DNA probes, or digestion with informative restriction enzyme(s) or can be subjected to direct DNA sequencing.

The relative simplicity combined with the power of this technique has resulted in widespread use of this procedure and has spawned a wide variety of variations and modifications that have been developed for specific applications.[9,10] From a practical point of view, the major drawback of PCR is the propensity to obtain cross-contamination of the target DNA. This drawback is the direct result of the extreme sensitivity of the method, which permits amplification from one molecule of the starting DNA template. Thus, unintended transfer of amplified sequences to items used in the

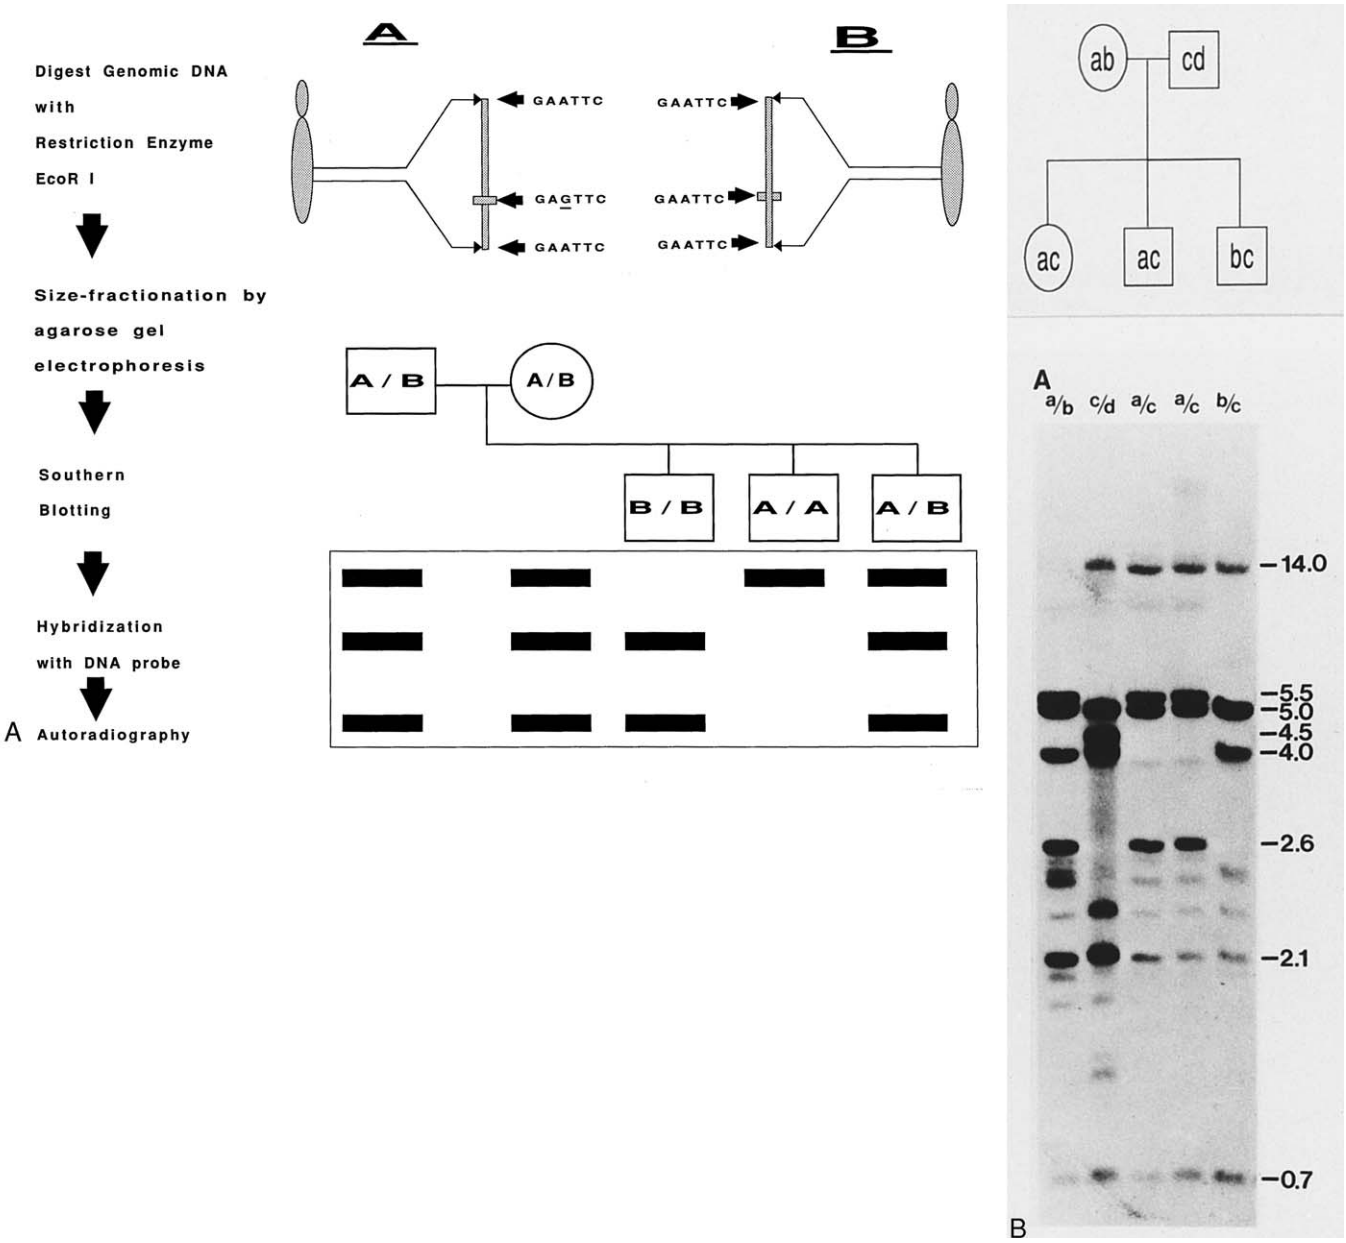

Figure 1-2. Restriction fragment length polymorphism. *(A)* Schematic illustration in which A and B represent two alleles that display a polymorphic site for the restriction enzyme EcoR I. EcoR I will cut DNA with the sequence GAATTC, and hence allele B will be cut by EcoR I at three sites to generate two fragments of DNA—whereas allele A will be cut by EcoR I only twice and not at the site (indicated by horizontal bar) where nucleotide G (underlined) replaces the nucleotide A present in allele B. Following digestion, the DNA is size fractionated by agarose gel electrophoresis and transferred to a membrane by Southern blot technique (see Figure 1-1 for details). The membrane is then hybridized with a labeled DNA probe that contains the entire sequence spanned by the three EcoR I sites. Autoradiography of the membrane will detect the size of the DNA fragments generated by the restriction enzyme digestion. In this particular illustration, both parents are heterozygous and possess both A and B alleles. Matching the pattern of the DNA bands of the offspring with that of the parents will establish the inheritance pattern of the alleles. For example, if allele A represents the abnormal allele for an autosomal recessive disease examination of the Southern blot will establish that (from left to right) the first offspring (B/B) is homozygous for the normal allele, the second offspring (A/A) homozygous for the abnormal allele, and the third offspring (A/B) a carrier. *(B)* RFLP analysis of the DQ-beta gene of the human lymphocyte antigen (HLA) locus. Genomic DNA from the members of the indicated pedigree was digested with restriction enzyme Pst I, size fractionated by agarose gel electrophoresis, and transferred to nitrocellulose membrane by Southern blot technique. The membrane was then hybridized with a cDNA probe specific for the DQ-beta gene, excess probe removed by washing at appropriate stringency, and analyzed by autoradiography. The sizes of the DNA fragments (in kilobases, kb) are indicated on the right. The pedigree chart indicates the polymorphic alleles (a, b, c, d), and the bands on the Southern blot corresponding to these alleles [a (5.5 kb), b (5.0 kb), c (14.0 kb) , d (4.5 kb)] indicate the inheritance pattern of these alleles. [Adapted from Turco E, Fritsch R, Trucco M (1998). First domain encoding sequence mediates human class II beta-chain gene cross-hybridization. Immunogenetics 28:193.]

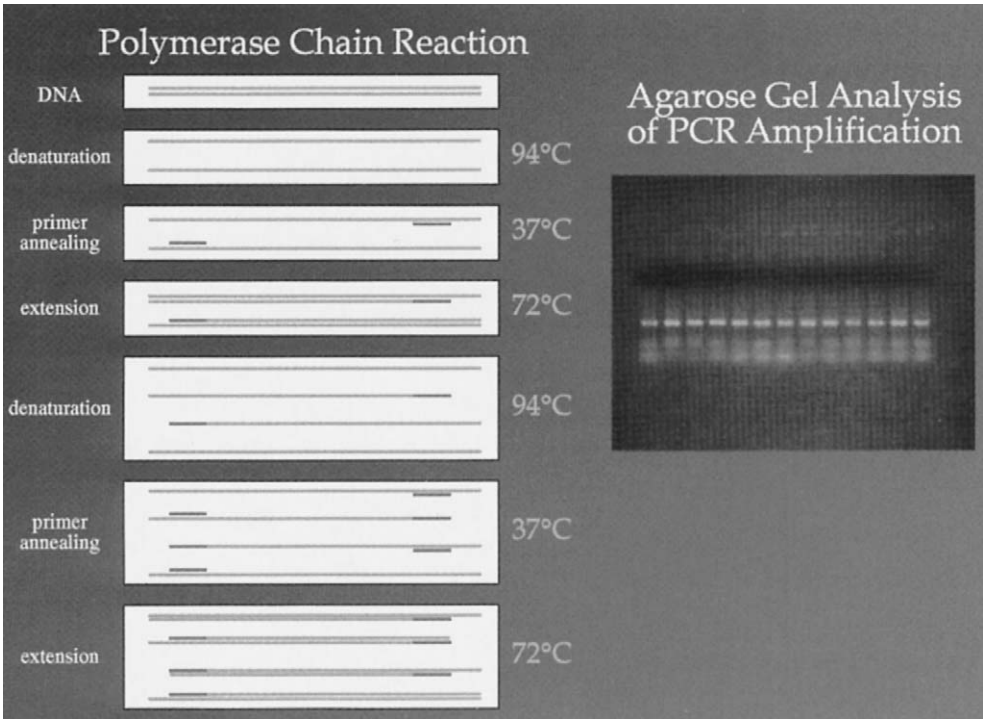

Figure 1-3. Polymerase chain reaction (PCR). A pair of oligonucleotide primers (solid red bars), complementary to sequences flanking a particular region of interest (shaded, stippled red bars), are used to guide DNA synthesis in opposite and overlapping directions. Repeated cycles of DNA denaturation, primer annealing, and DNA synthesis (primer extension) by DNA polymerase enzyme results in an exponential increase in the target DNA (i.e., the DNA sequence located between the two primers) such that this DNA segment can be amplified 1 x 106–107 times after 30 such cycles. The use of a thermostable DNA polymerase (i.e., Taq polymerase) allows for this procedure to be automated. Inset: The amplified DNA can be used for subsequent analysis (i.e., size fractionation by agarose gel electrophoresis). [Adapted from Trucco M (1992). To be or not to be ASP 57, that is the question. Diabetes Care 15:705.]

procedure will result in the amplification of DNA in samples that do not contain the target DNA sequence (i.e., a false positive result).

Cross-contamination should be suspected when amplification occurs in negative controls that did not contain the target template. One of the most common modes of cross-contamination is via aerosolization of the amplified DNA during routine laboratory procedures such as vortexing, pipetting, and manipulation of microcentrifuge tubes. Meticulous care to experimental technique, proper organization of the PCR workplace, and inclusion of appropriate controls are essential for the successful prevention of cross-contamination during PCR experiments.

In general, PCR applications are either directed toward the identification of a specific DNA sequence in a tissue or body fluid sample or are used for the production of relatively large amounts of DNA of a specific sequence—which is then used in further studies. Examples of the first type of application are very common in many fields of medicine; for example, in microbiology, wherein the PCR technique is used to detect the presence DNA sequences specific for viruses or bacteria in a biological sample. Prototypic examples of such an application in pediatric endocrinology include the use of PCR of the *SRY* gene for detection of Y chromosome material in patients with karyotypically defined Turner syndrome and for the rapid identification of chromosomal gender in cases of fetal or neonatal sexual ambiguity (Figure 1-4).[11]

Most PCR applications as research tools and for clinical use are directed toward the production of a target DNA or the complementary DNA of a target RNA sequence. The DNA that is made (amplified) is then analyzed by other techniques, such as RFLP analysis, allele-specific oligonucleotide hybridization, or DNA sequencing.

RNA ANALYSIS

The majority (>95%) of the chromosomal DNA represents non-coding sequences. These sequences harbor regulatory elements, serve as sites for alternate splicing, and are subject to methylation and other epigenetic changes that affect gene function. However, at present most disease-associated mutations in human genes have been identified in coding sequences. An alternative strategy for analyzing mutations in a given gene is to study its messenger RNA (mRNA), which is the product (via transcription) of the remaining 5% of chromosomal DNA that encodes for proteins. In addition, because the mRNA repertoire is cell and tissue specific the analysis of the mRNA sequences provides unique information about tissue-specific proteins produced in a particular organ or other tissue.

There are many techniques used in the analysis of mRNA, but one of the most commonly used methods is called Northern blotting (so named because it is based on the same principle as the Southern blot). In Northern

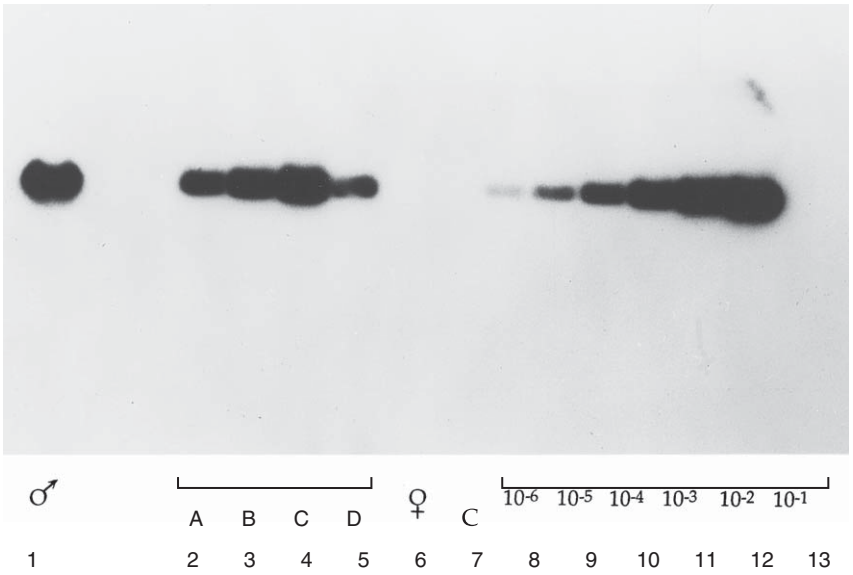

Figure 1-4. Detection of SRY-gene specific sequence in Turner's syndrome by PCR amplification and Southern blot. SRY-specific primers were used in PCR to amplify DNA from patients with 45X karyotype. The amplified DNA was size fractionated by agarose gel electrophoresis and transferred to membrane by Southern blotting. The membrane was then hybridized to labeled SRY-specific DNA and autoradiographed. From left to right: amplified male DNA (lane 1), amplified DNA from patients with 45X karyotype (lanes 2–5), amplified female DNA (lane 6), negative control with no DNA (lane 7), and serial dilution of male DNA (lanes 8–13). [Adapted from Kocova M, Siegel SF, Wenger SL, Lee PA, Trucco M (1993). Detection of Y chromosome sequence in Turner's Syndrome by Southern blot analysis of amplified DNA. Lancet 342:140.]

blotting, RNA is denatured by treating it with an agent such as formaldehyde to ensure that the RNA remains unfolded and in linear form.[12,13] The denatured RNA is then electrophoresed and transferred onto a solid support (such as nitrocellulose membrane) in a manner similar to that described for the Southern blot.[8] The membrane with the RNA molecules separated by size is probed with the gene-specific DNA probe labeled with an identifiable tag. As in the case of Southern blotting, the tag is either a radioactive label (e.g., ^{32}P) or more commonly a chemiluminescent moiety.

The nucleotide sequence of the DNA probe is complementary to the mRNA sequence of the gene and is hence called cDNA (complementary DNA). It is customary to use labeled cDNA (and not labeled mRNA) to probe Northern blots because DNA molecules are much more stable and easier to manipulate and propagate (usually in bacterial plasmids) than mRNA molecules. The Northern blot provides information regarding the amount (estimated by the intensity of the signal on autoradiography) and the size (estimated by the position of the signal on the gel in comparison to concurrently electrophoresed standards) of the specific mRNA.

Although the Northern blot technique represents a very versatile and straightforward method of analyzing mRNA, it has major drawbacks. Northern analysis is a relatively insensitive technique in terms of the concentration of mRNA that can be detected and in terms of the fine structure. Small changes in size or nucleotide composition of the mRNA being analyzed cannot be detected by this technique. Hence, for these types of specialized analyses newer methods [such as solution hybridization and reverse transcriptase-PCR (RT-PCR)] are employed.

Solution hybridization methods are based on the principle of hybridizing RNA in solution with either radioactively labeled DNA or RNA probes specific for the mRNA of interest. The main advantages of these methods are the enhanced sensitivity and the ability to yield information regarding the fine structure of the mRNA species being investigated. The enhanced sensitivity of these methods accrues from the fact that neither the mRNA being measured nor the probe being used are constrained by immobilization to a solid support, and hence do not require the additional steps of electrophoresis and transfer prior to hybridization (as in Northern blot analysis). In addition, the probe can be added in excess to drive the hybridization reaction to completion.

The two main types of solution hybridization use either single-stranded DNA (S1 nuclease protection assay) or RNA (ribonuclease protection assay) as the probe in the hybridization reaction. The greater sensitivity and the recent commercial availability of kits have propelled the popularity of the ribonuclease protection assay (RPA) as the solution hybridization method of choice for analysis of RNA (Figure 1-5). The first step in RPA is the synthesis of a radioactive single-stranded RNA probe. The RNA probe, which is complementary to the mRNA being analyzed, is synthesized by the RNA polymerase-directed transcription of a suitably engineered commercially available RNA expression vector. An excess of this synthesized RNA probe is then mixed with an aliquot of mRNA to be measured such that the RNA probe will hybridize to the complementary mRNA.

Separation of the hybridized from the free probe is achieved by exploiting the property of the enzyme RNase, which will only digest single-stranded RNA molecules.

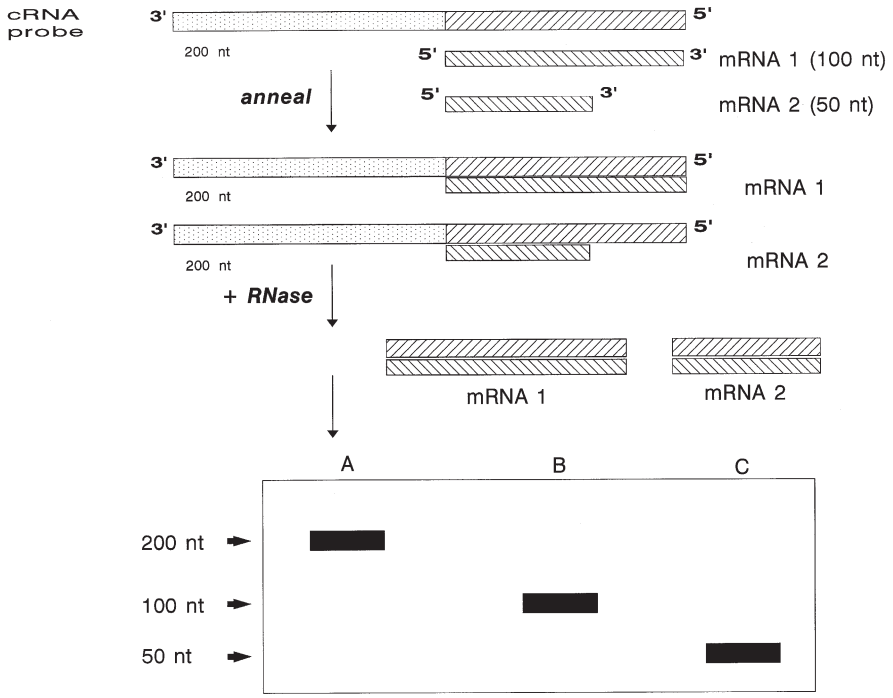

Figure 1-5. Detection of mRNA splice variants by ribonuclease protection assay (RPA). The mRNA species (100 and 50 nucleotides long) to be measured are represented by bars with cross hatches. A cRNA probe is synthesized with a region complementary to the mRNAs to be measured. This cRNA probe, which is internally labeled with ^{32}P is hybridized to the sample containing the target mRNAs. After hybridization, the unhybridized segments of the cRNA probe are digested with RNase enzyme. RNase enzyme will preferentially digest single-stranded RNA molecules and leave double-stranded RNA molecules intact. Hence, following RNase digestion RNase-resistant radioactivity will represent that segment(s) of the cRNA probe that was "protected" from RNase digestion by virtue of forming a double-stranded molecule with the target mRNA containing the complementary sequence. Following acrylamide gel electrophoresis, the RNase-resistant radioactivity is detected by autoradiography. Because the cRNA probe is always added in excess, the amount of the RNase-resistant radioactivity will be proportional to the concentration of the target mRNA. As depicted in the lower portion of the cartoon, the undigested probe (lane A) will electrophorese with a size distinct from the probe hybridized to mRNA 1 (lane B) or mRNA 2 (lane C).

Double-stranded RNA (such as that formed by the hybridization of the probe with the complementary RNA) is relatively resistant to digestion by RNase (such as RNase T1 or A). The RNase-resistant radioactive material is then size fractionated by electrophoresis and the double-stranded RNA molecules detected by autoradiography.

Because RNase is very discriminatory with respect to its ability to digest single-stranded RNA, while permitting double-stranded RNA to remain intact, even a single mismatch in the nucleotide sequence between the probe and the measured RNA will result in the probe RNA being digested at that point of mismatch (because the RNA will be single stranded at that point) and the appearance of additional radioactive bands after RNase digestion. Thus, this method is very useful for the detection and quantitation of internal splice variants wherein significant changes in one splice variant may be masked by the unchanged combined level of all mRNA variants analyzed by techniques such as Northern analysis. The major disadvantage of RPA is that it requires some prior knowledge of the RNA structure for the design of appropriate RNA probes.

One of the most sensitive methods for the detection and quantitation of mRNA currently available is the technique of quantitative RT-PCR (qRT-PCR).[9] This technique combines the unique function of the enzyme reverse transcriptase with the power of PCR. qRT-PCR is exquisitely sensitive, permitting analysis of gene expression from very small amounts of RNA. Furthermore, this technique can be applied to a large number of samples and/or many genes (multiplex) in the same experiment. These two critical features endow this technique with a measure of flexibility unavailable in more traditional methods, such as Northern blot or solution hybridization analysis.

Whereas the detection of a specific mRNA by this technique is relatively straightforward, the precise quantitation of the mRNA in a given sample is more complicated. The first step in qRT-PCR analysis is the production of cDNA to the mRNA of interest. This is done by using the enzymes with RNA-dependent DNA polymerase activity that belong to the reverse transcriptase (RT) group of enzymes [e.g., Moloney murine leukemia virus (MMLV), avian myeloblastosis virus (AMV) reverse transcriptase, or an RNA-dependent DNA polymerase].

The RT enzyme, in the presence of an appropriate primer, will synthesize DNA complementary to RNA. The second step in the qRT-PCR analysis is the amplification of the target DNA, in this case the cDNA synthesized by the reverse transcriptase enzyme. The specificity of the amplification is determined by the specificity of the primer pair used for the PCR amplification. To establish the veracity of the amplification process, the identity of

the amplified DNA can be analyzed by electrophoresis, hybridization to RNA or DNA probes, digestion with informative restriction enzyme(s), or subjection to direct DNA sequencing.

Whereas the detection of a specific mRNA by this technique is relatively straightforward, the precise quantitation of the mRNA in a given sample is more complicated. Because the production of DNA by PCR involves an exponential increase in the amount of DNA synthesized, relatively minor differences in any of the variables controlling the rate of amplification will cause a marked difference in the yield of the amplified DNA. In addition to the amount of template DNA, the variables that can affect the yield of the PCR include the concentration of the polymerase enzyme, magnesium, nucleotides (dNTPs), and primers. The specifics of the amplification procedure (including cycle length, cycle number, annealing, extension, and denaturing temperatures) also affect the yield of DNA.

Because of the multitude of variables involved, routine RT-PCR is unsuitable for performing a quantitative analysis of mRNA. To circumvent these pitfalls, alternative strategies have been developed. One technique for determining the concentration of a particular mRNA in a biological sample is a modification of the basic PCR technique called competitive RT-PCR.[9,14,15] This method is based on the co-amplification of a mutant DNA that can be amplified with the same pair of primers being used for the target DNA. The mutant DNA is engineered in such a way that it can be distinguished from the DNA of interest by size or by the inclusion of a restriction enzyme site unique to the mutant DNA.

The addition of equivalent amounts of this mutant DNA to all PCR reaction tubes serves as an internal control for the efficiency of the PCR process, and the yield of the mutant DNA in the various tubes can be used for the equalization of the yield of the DNA by PCR. It is important to ensure for accurate quantitation of the DNA of interest that the concentrations of the mutant and target template are nearly equivalent. Because the use of mutated DNA for normalization does not account for the variability in the efficiency of the reverse transcriptase enzyme, a variation of the original method has been developed.

In this modification, competitive mutated RNA transcribed from a suitably engineered RNA expression vector is substituted for the mutant DNA in the reaction prior to initiating the synthesis of the cDNA. Competitive RT-PCR can be used to detect changes of the order of two- to threefold of even very rare mRNA species. The major drawback of this method is the propensity to derive inaccurate results due to contamination of samples with the mRNA of interest. In theory, because the technique is based on PCR contamination by even one molecule of mRNA of interest can invalidate the results. Hence, scrupulous attention to laboratory technique and setup is essential for the successful application of this technique.

In general, there are two types of methods used for detection and quantitation of PCR products: the traditional "endpoint" measurements of products and the newer "real-time" techniques. Endpoint determinations (e.g., the competitive RT-PCR technique described previously) analyze the reaction after it is completed, whereas real-time determinations are made during the progression of the amplification process. Overall, the real-time approach is more accurate and is currently the preferred method. Advances in fluorescence detection technologies have made real-time measurement possible for routine use in the laboratory. One of the popular techniques that takes advantage of real-time measurements is the TaqMan (fluorescent 5'-nuclease) assay (Figure 1-6).[16,17]

The unique design of TaqMan probes, combined with the 5'-nuclease activity of the PCR enzyme (Taq polymerase), allows direct detection of PCR product by the release of fluorescent reporter during the PCR amplification by using specially designed machines (ABI Prism 5700/7700). The TaqMan probe consists of an oligonucleotide synthesized with a 5'-reporter dye (e.g., FAM; 6-carboxy-fluorescein) and a downstream 3'-quencher dye (e.g., TAMRA; 6-carboxy-tertamethyl-rhodamine). When the probe is intact, the proximity of the reporter dye to the quencher dye results in suppression of the reporter fluorescence primarily by Forster-type energy transfer. During PCR, forward and reverse primers hybridize to a specific sequence of the target DNA.

The TaqMan probe hybridizes to a target sequence within the PCR product. Because of its 5'- to 3'-nuclease activity, the Taq polymerase enzyme subsequently cleaves the TaqMan probe. The reporter dye and the quencher dye are separated by cleavage, resulting in increased laser-stimulated fluorescence of the reporter dye as a direct consequence of target amplification during PCR. This process occurs in every cycle and does not interfere with the exponential accumulation of product. Both primer and probe must hybridize to the target for amplification and cleavage to occur. The fluorescence signal is generated only if the target sequence for the probe is amplified during PCR.

Because of these stringent requirements, nonspecific amplification is not detected. Fluorescent detection takes place through fiber-optic lines positioned above optically nondistorting tube caps. Quantitative data are derived from a determination of the cycle at which the amplification product signal crosses a preset detection threshold. This cycle number is proportional to the amount of starting material, thus allowing for a measurement of the level of specific mRNA in the sample. An alternative machine (Light Cycler) also uses fluorogenic hydrolysis or fluorogenic hybridization probes for quantification in a manner similar to the ABI system.

Detection of Mutations in Genes

Changes in the structural organization of a gene that impact its function involve deletions, insertions, or transpositions of relatively large stretches of DNA—or more frequently single-base substitutions in functionally critical regions. The deletion or insertion of large stretches of DNA can usually be detected by Southern blotting and RFLP analysis. However, these analytic methods can be used for detecting point mutations only if the mutation

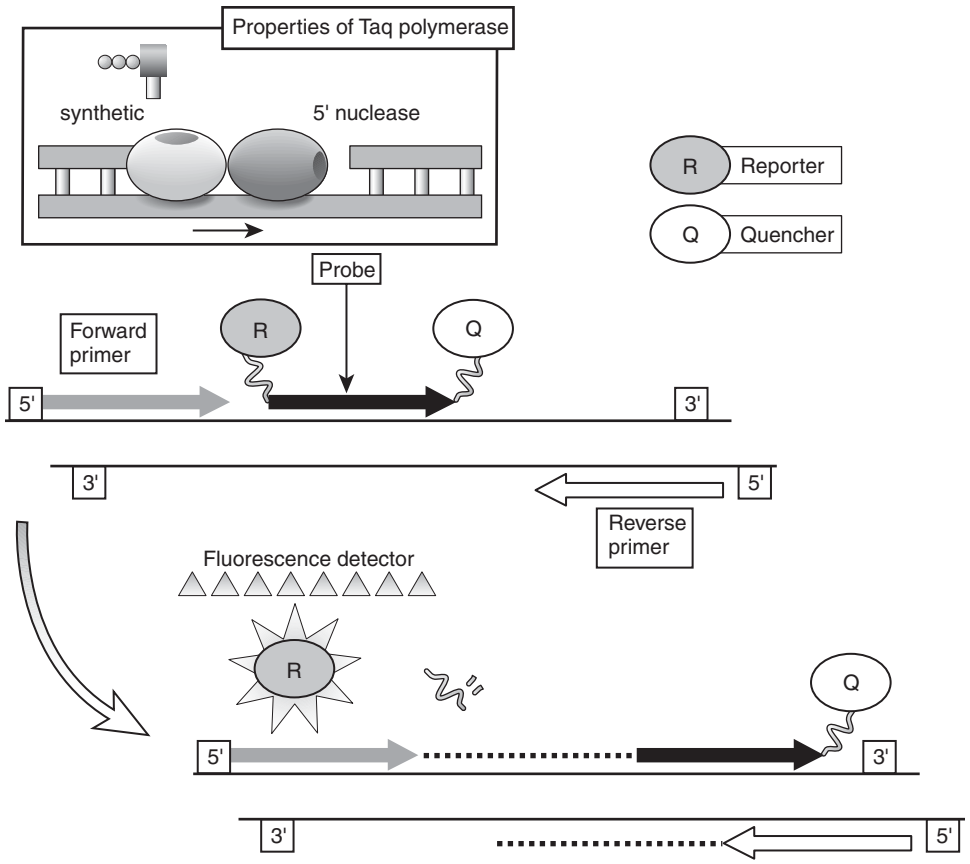

Figure 1-6. Fluorescent 5′-nuclease (TaqMan) assay. Three synthetic oligonucleotides are utilized in a fluorescent 5′-nuclease assay. Two oligonucleotides function as "forward" and "reverse" primers in a conventional PCR amplification protocol. The third oligonucleotide, termed the TaqMan probe, consists of an oligonucleotide synthesized with a 5′-reporter dye (e.g., FAM; 6-carboxy-fluorescein) and a downstream 3′-quencher dye (e.g., TAMRA; 6-carboxy-tertamethyl-rhodamine). When the probe is intact, the proximity of the reporter dye to the quencher dye results in suppression of the reporter fluorescence—primarily by Forster-type energy transfer. During PCR, forward and reverse primers hybridize to a specific sequence of the target DNA. The TaqMan probe hybridizes to a target sequence within the PCR product. Because of its 5′- to 3′-exonuclease activity, the Taq polymerase enzyme subsequently cleaves the TaqMan probe. The reporter dye and the quencher dye are separated by cleavage, resulting in increased fluorescence of the reporter dye as a direct consequence of target amplification during PCR. Both primers and probe must hybridize to the target for amplification and cleavage to occur. Hence, the fluorescence signal is generated only if the target sequence for the probe is amplified during PCR. Fluorescent detection takes place through fiber-optic lines positioned above the caps of the reaction wells. Inset: The two distinct functions of the enzyme Taq polymerase: the 5′-3′ synthetic polymerase activity and the 5′-3′ polymerase-dependent exonuclease activity.

involves the recognition site for a particular restriction enzyme such that the absence of a normally present restriction site or the appearance of a novel site unmasks the presence of the point mutation. More commonly, these techniques cannot be used for such an analysis—necessitating alternative procedures.

DIRECT METHODS

DNA sequencing is the current gold standard for obtaining unequivocal proof of a point mutation. However, DNA sequencing has its limitations and drawbacks. A clinically relevant problem is that current DNA sequencing methods do not reliably and consistently detect all mutations. For example, in many cases where the mutation affects only one allele (heterozygous) the heights of the peaks of the bases on the fluorescent readout corresponding to the wild-type and mutant allele are not always present in the predicted (1:1) ratio. This limits the discerning power of "base-calling" computer protocols and results in inconsistent and/or erroneous assignment of DNA sequence to individual alleles.[18]

Because of this limitation, clinical laboratories routinely determine the DNA sequence of both alleles to provide independent confirmation of the absence/presence of a putative mutation. DNA sequencing can be labor intensive and expensive, although recent advances in pyrosequencing (see material following) have made it technically easier and cheaper.

Although the first DNA sequences were determined with a method that chemically cleaved the DNA at each of the four nucleotides,[19] the enzymatic or dideoxy method developed by Sanger et al. in 1977 is the one most commonly used for routine purposes (Figure 1-7).[20] This method uses the enzyme DNA polymerase to synthesize a complementary copy of the single-stranded DNA ("template") whose sequence is being determined. Single-stranded DNA can be obtained directly from viral

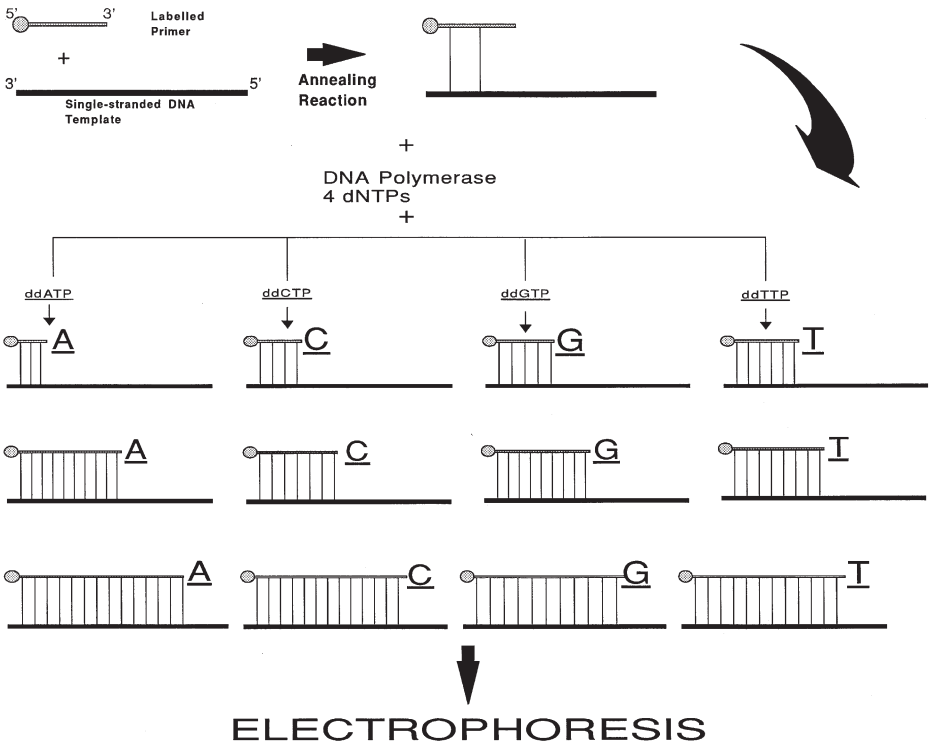

Figure 1-7. DNA sequencing by the dideoxy (Sanger) method. A 5′-end-labeled oligonucleotide primer with sequence complementarity to the DNA to be sequenced (DNA template) is annealed to a single strand of the template DNA. This primer is elongated by DNA synthesis initiated by the addition of the enzyme DNA polymerase in the presence of the four dNTPs (2′-deoxynucleoside triphosphates) and one of the ddNTPs (2′,3′-dideoxynucleoside triphosphates). Four such reaction tubes are assembled to use all four ddNTPs. The DNA polymerase enzyme will elongate the primer using the dNTPs and the individual ddNTP present in that particular tube. Because ddNTPs are devoid of 3′-hydroxyl group, no elongation of the chain is possible when such a residue is added to the chain. Thus, each reaction tube will contain prematurely terminated chains ending at the occurrence of the particular ddNTP present in the reaction tube. The concentrations of the dNTPs and the individual ddNTP present in the reaction tubes are adjusted so that the chain termination occurs at every occurrence of the ddNTP. Following the chain elongation-termination reaction, the DNA strands synthesized are size separated by acrylamide gel electrophoresis and the bands visualized by autoradiography.

or plasmid vectors that support the generation of single-stranded DNA or by partial denaturing of double-stranded DNA by treatment with alkali or heat.[21]

The enzyme DNA polymerase cannot initiate synthesis of a DNA chain de novo but can only extend a fragment of DNA. Hence, the second requirement for the dideoxy method of sequencing is the presence of a primer. A primer is a synthetic oligonucleotide 15 to 30 bases long, whose sequence is complementary to the sequence of the short corresponding segment of the single-stranded DNA template. The dideoxy method exploits the observation that DNA polymerase can use both 2'-deoxynucleoside triphosphate (dNTP) and 2',3'-dideoxynucleoside triphosphates (ddNTPs) as substrates during elongation of the primer. Whereas DNA polymerase can use dNTP for continued synthesis of the complementary strand of DNA, the chain cannot elongate any further after addition of the first ddNTP because ddNTPs lack the crucial 3'-hydroxyl group.

To identify the nucleotide at the end of the chain, four reactions are carried out for each sequence analysis—with only one of the four possible ddNTPs included in any one reaction. The ratio of the ddNTP and dNTP in each reaction is adjusted so that these chain terminations occur at each of the positions in the template where the nucleotide occurs. To enable detection by autoradiography, the newly synthesized DNA is labeled—usually by including in the reaction mixture radioactively labeled dATP (for the older manual methods) or, most commonly, currently fluorescent dye terminators in the reaction mixture (now in use in automated techniques). The separation of the newly synthesized DNA strands manually is done via high resolution denaturing polyacrylamide electrophoresis or with capillary electrophoresis in automatic sequencers.

Fluorescent detection methods have enabled automation and enhanced throughput. In capillary electrophoresis, DNA molecules are driven to migrate through a viscous polymer by a high electric field to be separated on the basis of charge and size. Although this technique is based on the same principle as identical to that used in slab gel electrophoresis, the separation is done in individual glass capillaries rather than gel slabs—facilitating loading of samples and other aspects of automation. Whereas manual methods allow the detection of about 300 nucleotide of sequence information with one set of sequencing reactions, automated methods using florescent dyes and laser technology can analyze 7,500 or more bases per reaction. To sequence larger stretches of DNA, it is necessary to divide the large piece of DNA into

smaller fragments that can be individually sequenced. Alternatively, additional sequencing primers can be chosen near the end of the previous sequencing results—allowing the initiation point of new sequence data to be progressively moved along the larger DNA fragment.

One of the seminal technological advances in recent years has been the introduction of microarray-based methods for detection, and analysis of nucleic acids (see material following). For purposes of detection of mutations, the oligonucleotides fixed to the slide/membrane are complementary to all possible base substitutions or a subset of small deletions and insertions. Fluorescent labeled PCR probes derived from the patient and representing the genes to be tested are then hybridized to the microarrays. Following appropriate washing protocols, the retention of particular probes on the slide provide information regarding the presence/absence of a given mutation, deletion, or insertion.

There are limitations of microarray-based techniques. For example, similar to direct DNA sequencing methods microarray-based methods also suffer from the disadvantage of not being able to reliably or consistently detect heterozygous mutations. In addition, microarrays cannot be used to detect insertions of multiple nucleotides without exponentially increasing the number of oligonucleotides that must be immobilized on the glass slides.

The most exciting new technique in mutation identification is pyrosequencing. This is based on an enzymatic real-time monitoring of DNA synthesis by bioluminescence. This "read as you go" method uses nucleotide incorporation that leads to a detectable light signal from the pyrophosphate released when a nucleotide is introduced in the DNA strand.[22] The rapidity and reliability of this method far exceed other contemporary DNA sequencing techniques. However, the major limitation of this technique is that it can only be used to analyze short stretches of DNA sequence.

INDIRECT METHODS

Screening for mutations of the thousands of the sequence products provided by human genome analysis has proven to be a daunting task. Although the gold standard for identifying sequence alterations is direct sequencing, this method remains labor intensive and the least cost effective. Since the mid 1980s, the need for rapid, high-throughput, accurate, and economical mutation analysis systems has led to the development of several technologies as alternatives to analysis by direct sequencing that have allowed detection of single mutations in long stretches of DNA (200–600 bp). These techniques include restriction endonuclease digestion of PCR products (PCR-RFLP), denaturing gradient gel electrophoresis (DGGE), single-strand conformation polymorphism (SSCP), dideoxy fingerprinting (ddF), and heteroduplex mobility assay (HMA).

Most of these methods utilize PCR to amplify a region of the DNA, a physical or chemical treatment of amplified DNA (by restriction digestion or denaturation), separation of the amplicons by gel electrophoresis (by denaturing or nondenaturing), and visualization of the separated sequence strands (by autoradiography or fluorescence-based detection). Most recent modifications in some of these techniques allow simultaneous separation and detection of DNA fragments with the use of sophisticated equipment such HPLC and capillary electrophoresis.

Originally described in 1989, SSCP analysis has been a widely used method for the detection of mutations because of its simplicity and efficiency. In SSCP, DNA regions with potential mutations are first amplified by PCR in the presence of a radiolabeled dNTP (Figures 1-8 and 1-9). Single-stranded DNA fragments are then generated by denaturation of the PCR products and separated on a native polyacrylamide gel. As the denatured PCR product moves through the gel and away from the denaturant, it will regain a secondary structure that is sequence dependent. The electrophoretic migration of single-stranded DNA is a function of its secondary structure. Therefore, PCR products that contain substitution differences (as well as insertions and deletions) will have different mobility when compared with wild-type DNA.

Although SSCP is simple, rapid, and inexpensive, it also has some disadvantages. The major limitations of the technique are lack of sensitivity and the inability to provide information about the location of a mutation in a DNA fragment. Efficacy studies, in which the technique was evaluated against a known mutation, showed that the sensitivity of SSCP can be highly variable in identifying sequence alterations. This variability is seen not only between amplicons but within the same amplicon if examined under different conditions. Overall, SSCP detects previously identified sequence changes in as many as 90% and as little as 60% of the specimens—depending primarily on the sequence, the amplicon's size, and the location of the mutation.

To circumvent the disadvantages of SSCP, an alternative technique was proposed that became known as dideoxy-fingerprinting (ddF). ddF is essentially a hybrid of SSCP and dideoxy sequencing in which primer extension products are generated in the presence of one dideoxynucleotide and subjected to chemical denaturation and electrophoresis on a nondenaturing polyacrylamide gel to exploit differences in secondary structure of single-stranded conformers. The resulting electrophoretic pattern resembles sequencing gels in which the mobility of extension products is determined by both size and conformation. In ddF, single-base and other sequence changes may result in elimination of a normal band or appearance of an extra band (informative dideoxy component) and altered electrophoretic mobility of one or more sequence termination products (informative SSCP component). The intensity of bands may also be used for dosage analysis because detection of "half loss" would indicate heterozygous mutation.

There are three major advantages of ddF over conventional SSCP: the relative position of a mutation may be revealed due to addition or deletion of a dideoxy termination product; the sensitivity is increased because, unlike SSCP, there are multiple bands that exhibit altered mobility (making it unlikely that a mutation will be missed because the technique is based on the same extension principle as dideoxy sequencing, in which multiple DNA strands are generated that contain the sequence change); and it permits large PCR

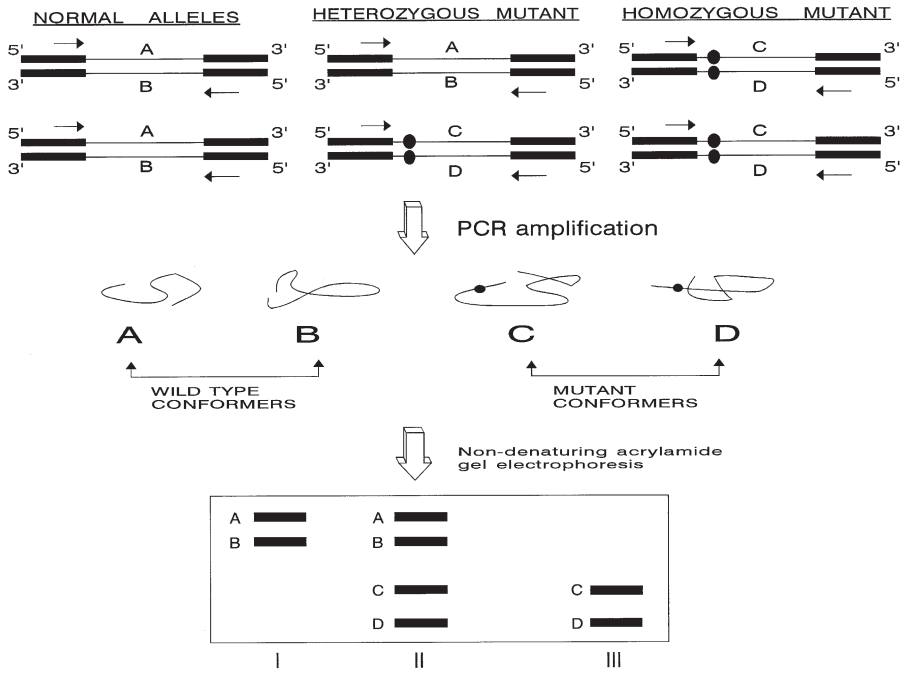

Figure 1-8. Single-stranded conformational polymorphism (SSCP). Schematic representation of an experiment designed to use SSCP to detect the presence of heterozygous and homozygous single–base-pair mutation (represented as a filled circle). The segment of DNA is amplified using PCR with flanking primers (represented by arrows). ^{32}P is incorporated into the newly synthesized DNA by end labeling the primers or by the addition of ^{32}P-dATP to the PCR reaction. Theoretically, four different types of conformers can be formed: A and B from the sense and anti-sense strand of the wild-type (normal) DNA, and C and D from the sense and anti-sense strands containing the single–base-pair mutation. Following PCR, the DNA is denatured and analyzed by nondenaturing gel electrophoresis. Lane I represents the wild-type conformers, lane II represents the wild-type and mutant conformers from an heterozygous patient, and lane III represents the presence of mutant conformers with the absence of wild-type conformers from a homozygous patient.

fragments to be generated only once and analyzed in smaller subfragments using different primers. The originally described ddF could screen the same size of DNA as SSCP (250-350 bp), but with a significantly higher level of detection.

In recent years, modifications of the original procedure have resulted in new and improved variants of ddF. Bidirectional ddF (bi-ddF), in which the dideoxy termination reaction is performed simultaneously with two opposing primers, has allowed larger fragments (~600 bp) to be screened with almost 100% sensitivity. RNA ddF (R-ddF), in which RNA is used as starting material, enables identification of mutations that result in splicing errors and allows screening of genes with large intronic regions. Denaturing fingerprinting (DnF), a modification of bi-ddF in which fingerprints are generated by performing denaturing gel electrophoresis on bidirectional "cycle-sequencing" reactions with each of two dideoxy terminators, has allowed screening of DNA regions with high GC content—avoiding the generation of "smearing" bands and thus increasing the sensitivity of the technique in identifying heterozygous mutations.

Further modifications have streamlined the previously cited procedures by adapting them to either automated fluorescent sequencers or capillary electrophoresis utilizing fluorescent dNTPs or primers (automated bi-ddf, capillary electrophoresis-ddf). Automated fingerprinting technology allows simultaneous analysis of a larger number of samples, higher reproducibility, faster data processing, and the ability to analyze longer sequences from a single reaction.

DGGE is a method used to detect single-base pair substitutions (or small insertions or deletions) in genes.[23-25] Like SSCP, DGGE is also a PCR-based method and exploits the observation that when double-stranded DNA migrates through a polyacrylamide gel incorporating a gradient of chemical denaturing agents the mobility of the partially denatured ("melted") DNA molecule is extremely sensitive to its base composition. Thus, even single-base changes in the nucleotide composition of the DNA will result in altered mobility of the partially denatured DNA. G-C clamp is a modified DGGE procedure wherein the sensitivity of the procedure is enhanced by the incorporation of a G- and C-rich region at one end of the DNA.[24,26-28]

This manipulation is most readily done by modifying one of the primers used for the PCR. The addition of the G-C–rich region increases the melting point of the DNA fragment and makes it easier to detect changes in the nucleotide composition. Depending on the relative orientation of the chemical gradient and the electrical field during electrophoresis, DGGE could be parallel or perpendicular. The relative sensitivity of these two protocols has to be determined empirically for each application of this method. Denaturing high-performance liquid chromatography (DHPLC) is a related technique that detects a variation in the DNA sequence but uses HPLC instead of gel electrophoresis for separation of DNA

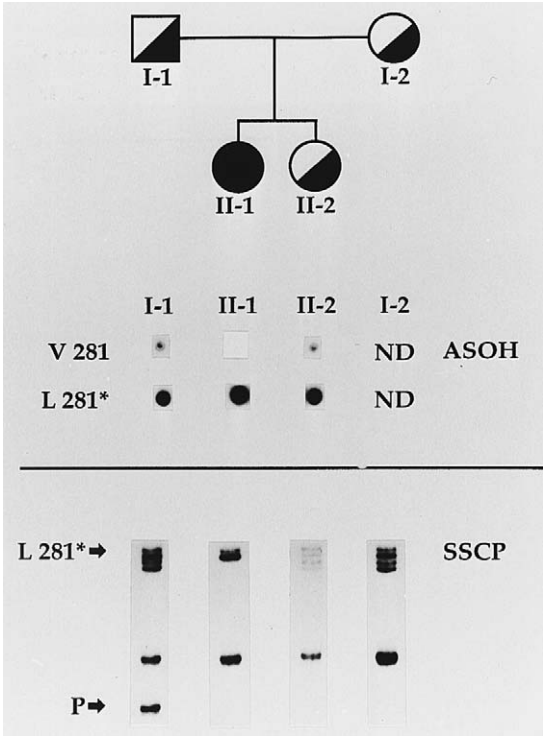

Figure 1-9. Application of SSCP and ASOH to the analysis of the 21-hydroxylase gene in congenital adrenal hyperplasia. Detection of a mutation of codon 281 from valine to leucine (V281L). Upper panel: Pedigree of a family with proband II-1, which was referred for evaluation of hirsutism and secondary amenorrhoea. Middle panel: ASOH results from both mutant and normal alleles at codon 281 show both the father and sister of the proband to be carriers of the V281L mutation, whereas the patient is homozygous. ASOH was not performed on the mother. The asterisk indicated the mutant allele (L281). Lower panel: SSCP analysis revealed that the two additional conformers, representing the L281 conformer, were detected at the top of the gel in this patient and her family. The greater intensity of the conformers in the proband compared to her family members and the disappearance of the normal V281 conformer (adjacent to the L281 conformers) are consistent with her being homozygous for this mutation. L281 indicates the mutant conformer. P indicates normal polymorphism. [Adapted from Siegel SF, Hoffman EP, Trucco M (1994). Molecular diagnosis of 21-hydroxylase deficiency: Detection of four mutations on a single gel. Biochem Med Metab Biol 51:66.]

fragments. The incorporation of HPLC allows for automation of this technique and significantly enhances throughput by this method.

Heteroduplex analysis is a variation of the SSCP method and is used to detect single-pair mismatches in double-stranded DNA.[29-31] When polymorphic PCR products are denatured and allowed to slowly cool to 37° C before being loaded onto a native gel, some of the polymorphic strands will reanneal to the slightly different complementary strand and form a double-stranded DNA molecule with a small number of mismatches (i.e., a heteroduplex). During electrophoresis, heteroduplexes migrate more slowly than homoduplexes and the resulting pattern can be visualized after autoradiography.

Although heteroduplex analysis would not detect abnormal sequences in a homozygous individual, it is possible to combine known DNAs with the DNA being tested to form the heteroduplexes and reveal the presence of the variant allele. Because of the technical similarity of the SSCP and heteroduplex analyses, the choice between the two methods can be dependent on which empirically performs best for each application. However, SSCP has the advantage of greater sensitivity because the definitive bands usually represent a major portion of the particular labeled molecule—whereas heteroduplex analysis must detect the fraction of labeled molecules that actually formed heteroduplexes.

Allele-specific oligonucleotide hybridization (ASOH) and reverse blot technique analyze DNA after amplification by PCR and detect sequence variations by the success or failure of hybridization of short oligonucleotide probes that either exactly match or mismatch the sequence being tested (Figure 1-10). The amplified target DNA is first denatured and applied to a nylon membrane in the form of a small dot. Once this target DNA is anchored to the membrane either by heating or by brief ultraviolet irradiation, the DNA is hybridized with a labeled (usually with ^{32}P) oligonucleotide that encompasses the variable nucleotides of the DNA sequence of interest. The membrane is then washed with a salt solution whereby the salt concentration and the temperature control the specificity ("stringency") of the procedure.

Following the wash, the probe remaining on the membrane is detected by autoradiography. When several nucleotide variations (i.e., alleles) are known to exist in the same target sequence, several identical membranes are prepared and each is hybridized with a different oligonucleotide probe complementary to one of the known sequence variations. Although the net result is similar to having actually sequenced the DNA region, the ASOH method is considerably less labor intensive and relatively less expensive than DNA sequencing. Hence, ASOH is one of the methods of choice for screening a large number of samples for a particular genetic variation.

The major disadvantage of this method is that it requires prior knowledge of the base changes involved in the mutation and the precise stringency parameters for hybridization and washing of the membrane. In effect, these limitations exclude the routine use of this method for the characterization of a new mutation but allow the use of this method for the rapid screening of large number of samples for a previously characterized mutation.

A variation of the original method to perform ASOH is called the reverse blot technique (Figure 1-10).[32] The difference when compared to ASOH is that the amplified target DNA is labeled and then hybridized to an anchored unlabeled probe. Because the length of the DNA molecules is an important factor facilitating binding to the membrane, a key to the design of this method was the development of a relatively simple means of synthesizing (using the PCR) a stretch of DNA that contained multiple copies (i.e., a polymer) of the relatively short allele-specific oligonucleotide probes.[33]

In practice, the amplified DNA is nonradioactively labeled by previously tagging the PCR primers with fluorescein or biotin. After hybridization of the denatured PCR product in the presence of a membrane containing

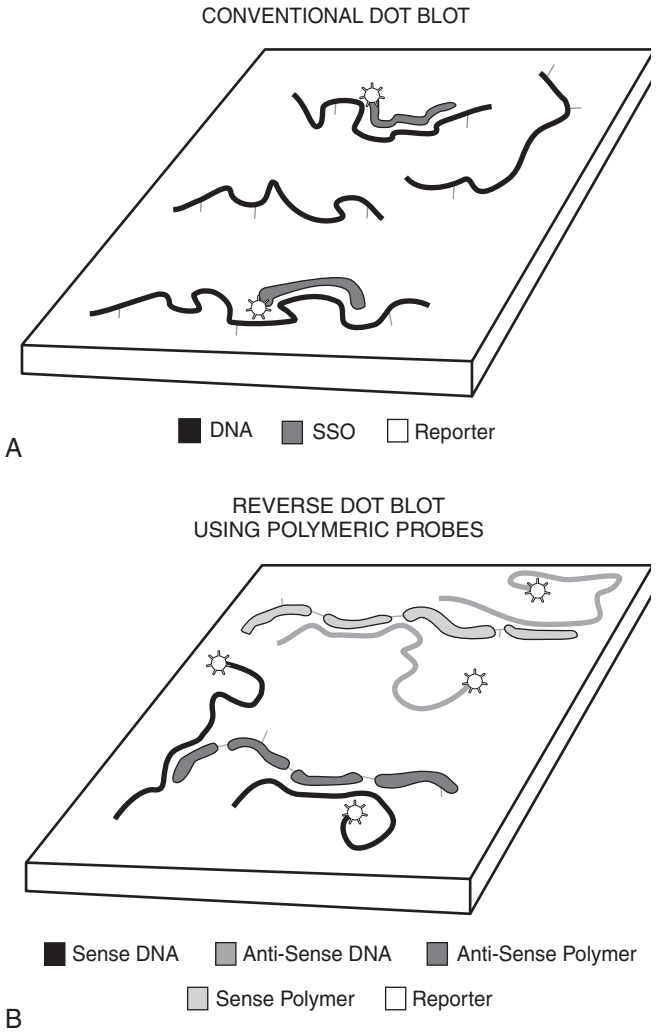

Figure 1-10. *(A)* Allele-specific oligonucleotide hybridization (ASOH). The denatured (single-stranded) target DNA is anchored to a membrane, which is then treated (hybridized) with a solution of a short DNA segment of the gene of interest [sequence-specific oligonucleotide (SSO)]. The SSO is tagged with a reporter molecule, such as ^{32}P. Unbound probe DNA is removed by washing with buffer solutions. Appropriate stringency conditions of hybridization and washes limit the hybridization of the probe specifically to its complementary segment in the target DNA molecule. Depending on the manner in which the DNA is spotted onto the membrane, this procedure is referred to as a dot blot or a slot blot. *(B)* Reverse dot blot. In this variation of the conventional ASOH procedure, the DNA probes (sense and anti-sense polymer) tagged with the reporter molecule are fixed to a membrane and the denatured target DNA (sense and anti-sense DNA) is then hybridized to the immobilized probe. Similar to the ASOH procedure, appropriate stringency conditions of hybridization and washes limit the hybridization of target DNA to those that contain the complementary segment to the immobilized probe. The advantages of this method include the increased sensitivity derived from the ability to fix multiple copies (polymer) of the probe to the membrane and that both complementary strands of the probe sequence are present on the membrane. [Adapted from Trucco M (1992). To be or not to be ASP 57, that is the question. Diabetes Care 15:705.]

all of the relevant polymeric probes, and washing, the retained PCR products are revealed by detection via enzyme activity linked to fluorescein antibodies or to streptavidin. This method is especially useful for testing alleles that are highly polymorphic because a large number of probes and controls are easily tested using a single small membrane. Other advantages include the ability to use nonradioactive tracers, better reproducibility, and the potential for automation.

Certain classes of mutations are inherently difficult to detect using the traditional methods of detection outlined previously.[18] These types of mutations include promoter region, 3' untranslated region (UTR), or intronic region mutations affecting levels of transcript of mRNA or deletions of entire genes or of contiguous exons. Thus, if the genomic region examined is deleted from the mutant allele, PCR-based methods will be unable to detect this mutation because the PCR product obtained from the genomic DNA will be exclusively derived from the wild-type allele and thus appear to be normal. Promoter regions, 3'UTR, and intronic regions usually span genomic segments several orders larger than the coding exons and are thus not easily accessible for analysis with the methods outlined previously.

Different strategies need to be implemented for the analysis and detection of such mutations. Thus, deletions of one or more exons can be detected by quantitative hybridizations, quantitative PCR, Southern blotting, or fluorescence in situ hybridization—with the combined use of such methods enhancing the sensitivity of the testing protocol. A particularly promising and novel technique, termed *conversion*, exploits the principle that the diploid state of the human genome is converted to a haploid state that is then analyzed by one of the traditional methods.[34] The critical advantage of this manipulation is that heterozygous mutations are much easier to detect in the haploid state because of the absence of the normal wild-type sequence.

Positional Genetics in Endocrinology

THE PRINCIPLES OF POSITIONAL GENETICS

For the purpose of disease gene identification, the candidate gene approach relies on partial knowledge of the genetic basis of the disease under investigation. This process was successful in identifying disease genes whose function was obvious. For example, the genetic defects of most of the hereditary enzymatic disorders [including congenital adrenal hyperplasia (CAH) syndromes] became known in the late 1980s when the introduction of PCR made the tools of molecular biology widely available to the medical and genetic research community. However, at about the same time research on diseases without any obvious candidate genes [e.g., the multiple endocrine neoplasia (MEN) syndromes] and on diseases in which the screening of obvious candidate genes failed to reveal mutations was ongoing.

It was in these diseases that the application of "reverse genetics" (or more appropriately termed *positional cloning*)[35,36] yielded information regarding the genetic basis of

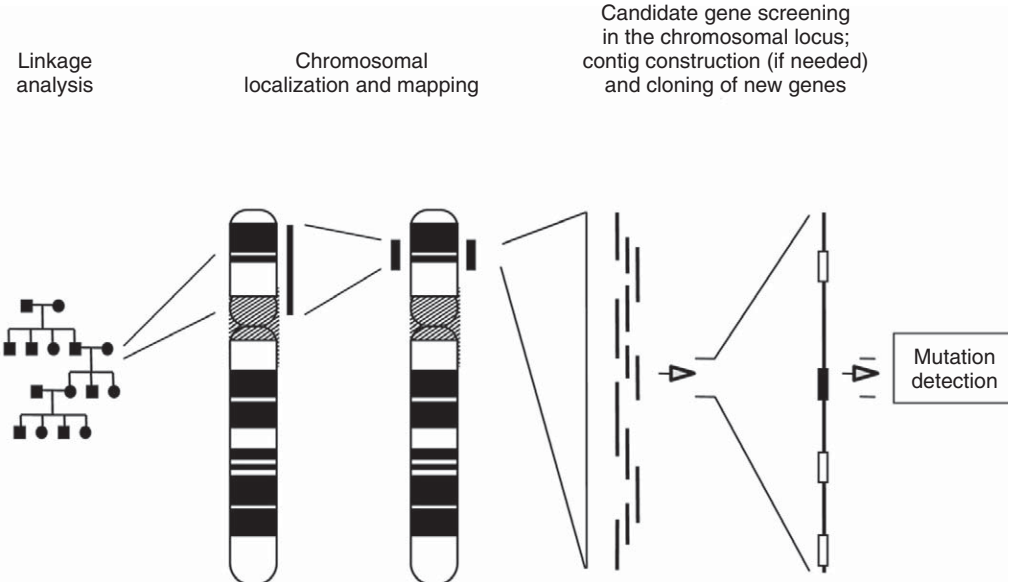

Figure 1-11. The steps of positional cloning (see text).

these disease states. Positional cloning is complemented by the Human Genome Project (HGP) and the Internet in making available in a fast and controlled manner information that would otherwise be inaccessible.[37] The process of positional genetics is outlined in Figure 1-11.

The first step is the collection of clinical information from families with affected members, the determination of the mode of inheritance of the defect (autosomal dominant or recessive, X-linked, complex inheritance), and the phenotyping of subjects (or tissues) following well-established criteria for the diagnosis of the disorder. If inheritance is not known, formal segregation analysis needs to be performed to determine the autosomal or X-linked (and the recessive or dominant) nature of the inheritance.[38] Once this determination is made and the penetrance of the disorder is known, appropriate linkage software may be used.[39] For more information on currently available computer software packages, the reader may check *http://darwin.case.edu* and other related links.

Linkage is examined with polymorphic markers that span the entire human genome.[36] Any marker that shows polymorphism and is known to lie close to or within a putative disease gene may be used. Genetic linkage can be defined as the tendency for alleles close together on the same chromosome to be transmitted together as an intact unit through meiosis. The strength of linkage can then be used as a unit of measurement to find out how close genetically different loci are to each other. This unit of map distance is an approximation of physical distance but is also highly dependent on other factors (e.g., the frequency of recombination is not the same in both genders, differing along the length of chromosomes and through the various chromosomes). The likelihood [logarithm of odds (LOD) score] method is widely used for linkage analysis.

Once a locus on a chromosome has been identified, narrowing of the region (this region is usually several thousands of base pairs in length) is accomplished by analyzing informative recombinations in the cohort of patients and families available for study. The disease region may harbor already mapped genes. Online databases [Gen Bank, ENSEMBL at www.ensembl.org, and others, and especially for clinicians the Online Mendelian Inheritance in Man (OMIM)][40] may provide the necessary information. If a transcript is a reasonable candidate, mutation screening may identify the disease gene. If, however, these steps fail to identify the disease gene cloning of new sequences from the area may be needed.

This is usually done through the construction of a "contig," a contiguous array of human DNA clones covering the disease region. These DNA clones are maintained in large vectors such as bacterial artificial chromosomes (BACs). P1 and cosmid clones may also be used for coverage of the entire region or a subset of it. Contig construction may take a long time, depending on the genetic distance to be covered and the features of the genomic region. The identification of new genes and the construction of the contig are also called "chromosomal walking." The building blocks of this "walk" are the individual clones, which are linked by sequence-tagged sites (STSs) that are present in more than one clone—thus providing critical information that allows for the proper aligning of these clones.

Polymorphic markers (including those that were used for the linkage part of the process) are the most useful STSs because they provide a direct link between the genetic and the physical mapping data. Individual clones can be sequenced. Genes are identified in this process through their unique sequence features or through in vitro translation. The latter usually provides expressed sequence tags (ESTs), which can then be analyzed through software that is available online to determine the full gene structure and to identify redundancies (multiple ESTs or STSs of the same gene) and other errors.

Each of the newly identified genes may be screened for mutations, as long as the expression profile of the identified transcript matches the spectrum of the tissues

affected by the disease under investigation. Although this is helpful for most diseases, for others the expression profile may even be misleading. Thus, the presence of a transcript in an affected tissue is not always necessary. Complete segregation of the disease with an identified mutation, functional proof, and/or mutations in two or more families with the same disease are usually required as supportive evidence that the cloned sequence is the disease gene.[41]

POSITIONAL CLONING OF ENDOCRINE GENES

A number of genes were identified by positional cloning in endocrinology in the 1990s. It is worth noting that endocrine tumor syndromes, despite their rarity and small overall impact on everyday clinical endocrine practice, are seminal examples of diseases whose molecular etiology was elucidated by positional cloning. Positional cloning played an essential role in unraveling the etiology of these syndromes because for most endocrine tumor syndromes there were no obvious candidate genes. Futhermore, positional cloning of genes responsible for familial tumor syndromes was greatly assisted by the use of neoplastic tissue for studies such as loss of heterozygosity (LOH), comparative genomic hybridization (CGH), and other fluoroscent in situ hybridization (FISH) applications.

These techniques narrow the genetically defined chromosomal regions and thus facilitate the identification of the responsible genes. LOH studies were critical to the identification of von-Hippel-Lindau disease (VHL-elongin),[42] MEN 1 (menin),[43] Cowden disease (PTEN),[44] Peutz-Jeghers syndrome (STK11/LKB1),[45,46] and Carney complex (PRKAR1A)[47] genes.

Expression Studies: Microarrays and SAGE

Advances in biotechnology, instrumentation, robotics, computer sciences, and the completion of genome sequencing initiatives for several organisms (including the human) have resulted in the development of novel and powerful techniques. A seminal example of such a technique is the development of the microarray technology. Microarrays contain thousands of oligonucleotides deposited or synthesized in situ on a solid support, typically a coated glass slide or a membrane. In this technique, a robotic device is used to print DNA sequences onto the solid support. The DNA probes immobilized on the microarray slide as spots can be cloned cDNA or gene fragments (ESTs) or oligonucleotides corresponding to known genes or putative open reading frames.

The arrays are hybridized with fluorescent targets prepared from RNA extracted from tissue/cells of interest. The RNA is labeled with fluorescent tags such as Cy3 and Cy5. The prototypic microarray experimental paradigm consists of comparing mRNA abundance in two different samples. One fluorescent target is prepared from control mRNA, and the second target labeled with a different fluorescent label is prepared from mRNA isolated from the treated cells or tissue under investigation. Both targets are mixed and hybridized to the microarray slide, resulting in target gene sequences hybridizing to their complementary sequences on the microarray slide. The microarray is then excited by laser and the fluorescent intensity of each spot is determined with the relative intensities of the two colored signals on individual spots being proportional to the number of specific mRNA transcripts in each sample (Figure 1-12). Analysis of the fluorescent intensity

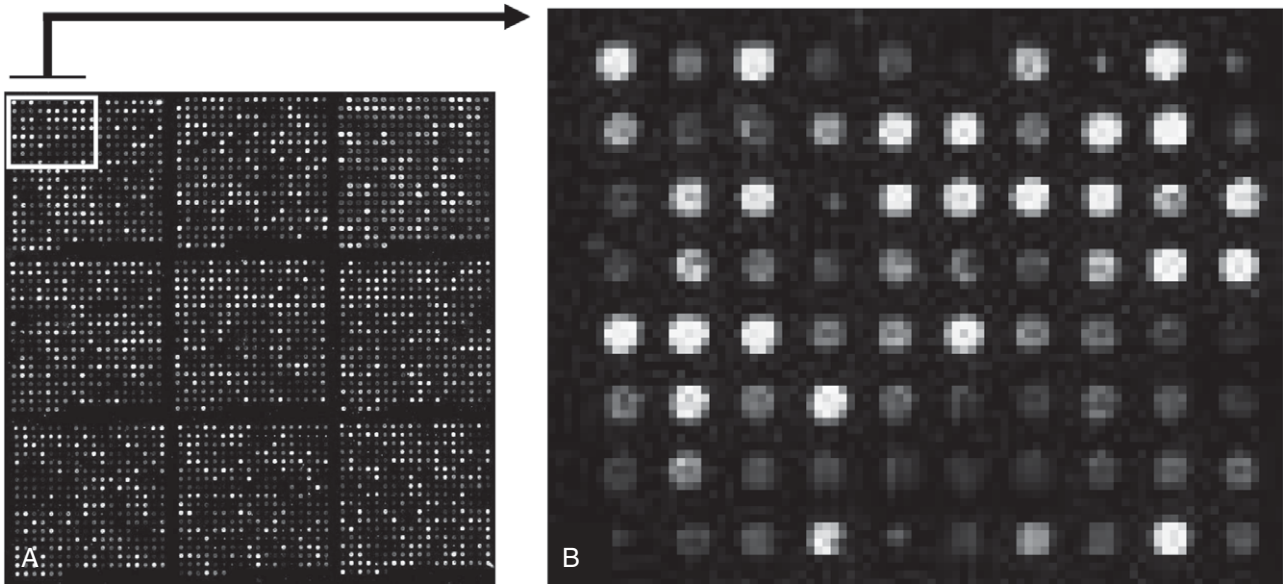

Figure 1-12. *(A)* cDNA microarray. Fluorescent labeled cDNA targets, ACTH-independent bilateral macronodular adrenal hyperplasia (Cy3), and ACTH-dependent hyperplasia (Cy5) were hybridized to glass slides containing genes involved in oncogenesis. Following laser activation of the fluorescent tags, fluorescent signals from each of the DNA "spots" are captured and subjected to analysis. *(B)* Magnified view of the microarray platform displaying the fluorescent signals: green (Cy3) and red (Cy5), with yellow representing overlap of these two colors. (See color plates.)

data yields an estimation of the relative expression levels of the genes in the sample and control sample. Microarrays enable individual investigators to perform large-scale analysis of model organisms and to customize arrays for special genome applications.

Most endocrine human genes participate in complex and highly interactive signaling pathways. They not only directly control a number of genes but modulate the functioning of a larger complement of genes by cross-talking with a multitude of signaling pathways. As noted elsewhere,[48] this is analogous to the Internet—the relevant genes being "nodes" or "hubs" in this Internet-like structure.[49] It was recently stated that "progress in dissecting signaling pathways has begun to lay out a circuitry that will likely mimic electronic integrated circuits in complexity and finesse, where transistors are replaced by proteins (e.g., kinases and phosphatases) and the electrons by phosphates and lipids."[50] Although this statement related to cancer research,[50] translational medicine today identifies these complex interactions to be ubiquitous[51]—making it no surprise that 30,000 to 40,000 genes (rather than the previously predicted 100,000 genes)[52] are sufficient to produce the human phenotype. It is not the number of genes that is critical but the regulation of expression of these genes and the number, quality, and temporospatial organization of interactions among their protein products.

An excellent example of an endocrine transcriptome is that recently presented by Roberts et al.:[53] the description of mitogen-activated protein kinase (MAPK) pathways during yeast pheromone response. Similar analytic strategies are currently being applied to investigations in a wide variety of fields of study, including that of endocrine tumors.[54] In this process (investigations by microarrays), simultaneous collection of information for hundreds of genes at a time (or the entire genome, depending on the type of the array used) have become the standard approach. An example from a recent study[55] is shown in Figure 1-12. Endocrine concepts and the reemergence of signaling as the chief means of understanding the complex interactions of genes may shape the new bioinformatics tools needed for the analysis of these data, and may direct the development of new drugs tailored to insights provided by these initiatives.[56,57]

Currently, in addition to the transcriptional profiling of any tissue performed by applying various types of microarrays there is the alternative technology of generating libraries of ESTs. An advanced expansion of EST libraries, especially in terms of high-throughput and transcript quantitation, is serial analysis of gene expression (SAGE). SAGE is based on generating, cloning, and sequencing concatenated short-sequence tags—each representing a single transcript derived from mRNA from target tissue.[58] Analysis of the transcriptional data gained by both methods is most commonly performed using clustering algorithms that group genes and samples on the basis of expression profiles, and statistical methods scoring the genes on the basis of their relevance to clinical manifestations.

The method of choice for global expression profiling depends on several factors, including technical, labor, price, time and effort involved, and most importantly the type of information sought. When comparing microarrays to EST libraries, an appreciable advantage of the latter is its inherent ability to identify transcripts without prior knowledge of the genes' coding sequences. This is the reason for its important potential for cloning and sequencing novel transcripts and genes. On the other hand, recent technical advances in the development of expression arrays, their abundance and commercial availability, and the relative speed with which analysis can be done are all factors that make arrays more useful in routine applications.

In addition, array content can now be readily customized to cover gene clusters and pathways of interest to the entire genome. Some studies examine series of tissue-specific transcripts and/or genes known to be involved in particular pathology. Others directly use arrays covering the entire genome. Another factor that needs to be considered prior to embarking on any high-throughput approach is whether individual or pooled samples will be investigated. Series of pooled samples reduce the price, the time spent, and the number of the experiments down to the most affordable. Investigating individual samples, however, is important for identifying unique expression ratios in a given type of tissue or cell.

A requirement of all high-throughput screening approaches is confirmation of findings (expression level of a given gene/sequence) by other independent methods. A select group of genes is tested. These genes are selected from the series of sequences that were analyzed either because they were found to have significant changes or due to their particular interest with regard to their expression in the studied tissue or their previously identified relationship to pathology or developmental stage. The confirmation process attempts to support the findings on three different levels: reliability of the high-throughput experiment (for this purpose, the same samples examined by the EST libraries or microarrays are used), trustfulness of the observations in general (to achieve this, larger number of samples are examined—assessment of which by high-throughput approaches is often unaffordable in terms of price and/or labor), and verification of expression changes at the protein level.[59]

A commonly used confirmatory technique is quantitative real-time reverse transcription PCR (qRT-PCR). For verification at the protein level, immunohistochemistry (IHC) and Western blot are the two most commonly chosen techniques. IHC is not quantitative but has the advantage of allowing for the observation of the exact localization of a signal within a cell (cytoplasmic versus nuclear) and the tissue (identifying histologically the tissue that is stained). Modern Western blot methods require a smaller amount of protein lysate than older techniques, and have the advantage of offering high-resolution quantitation of expression without the use of radioactivity.

Chromosome Analysis and Molecular Cytogenetics

Chromosomes represent the most condensed state in metamorphosis of the genome during a cell cycle. Condensation of the genetic material at metaphase stage is a crucial event that provides precise and equal segregation of chromosomes between the two newborn daughter cells during the

next step, anaphase. This is followed by relaxation of the genetic content after cell division. This ability of the genome to transform from a molecular level (DNA) to materialistic submicroscopic stage (chromosome) provides a unique opportunity to visualize the genome of an individual cell of an organism. Different chromosomal abnormalities related to particular diseases or syndromes can be detected at this stage by karyotyping chromosomes.

Chromosomes can be individually recognized and classified by size or shape (ratio of the short/long arm) or by using differential staining techniques. In the past, identification of chromosomes was restricted to chromosome groups only. The introduction of chromosome banding technique revolutionized cytogenetic analysis.[60] The banding patterns are named by the following abbreviations: G (Giemsa), R (reverse), Q (Quinacrine), and DAPI (4'6'-diamino-2-phenylindole). The last two give a pattern similar to G-banding. Further development of high-resolution banding techniques[61] enabled the study of chromosomes at earlier stages of mitosis, prophase, and prometaphase. Chromosomes are longer and have enriched banding pattern at those stages, providing great details for identification of chromosomal aberrations.

OUTLINE OF METHODS

Preparation of quality chromosomes is an art. Many different methods for chromosome isolation have been developed in cytogenetics within the last half century. The main principle behind all methods is to arrest cells at metaphase by disruption of the cell spindle. Metaphase spindle is a structure composed of tubular fibers (formed in the cell) to which the chromosomes are attached by kinetochors (centrosomes). The spindle separates the chromosomes into the two daughter cells. The agent commonly used for spindle disruption is colcemid. The exposure time to colcemid varies depending on the proliferative activity of cells. Cells with a high proliferative index need a shorter time of exposure to a high concentration of colcemid (0.1–0.07 ug/ml for 10 to 20 minutes).

Slow-growing cells require longer exposure (1–4 hours or overnight with a lower concentration of 0.01–0.05 ug/ml). Prolonged exposure to colcemid or the use of high concentrations increases the proportion of chromosomes at late metaphase, resulting in shortening of the chromosomes. Conversely, a short exposure with a high concentration of colcemid reduces the total yield of metaphases. The optimum strikes a balance of these parameters. There are some additional modifications that allow for the enrichment of long (prometaphase) chromosomes by using agents that prevent DNA condensation, such as actinomycin D, ethidium bromide, or BrDU. Cell synchronization techniques can also significantly increase the total yield of metaphase chromosomes.

APPLICATIONS

Chromosomes are invaluable material for the evaluation of genome integrity and its preservation at the microscopic chromosomal level. The areas of application include prenatal diagnostics, genetic testing of multiple familial syndromes (including cancer), positional cloning of the genes, and physical mapping (assignment of the genes to chromosomes and subchromosomal regions). The number and morphology of all 23 chromosome pairs in humans can be examined using G-banding differential staining of chromosomes obtained from a peripheral blood sample.

Abberations in the number of chromosomes or visible chromosomal alterations (such as translocations, deletions, and inversions involving extended regions) can be detected by this method. Recent advances such as spectral karyotyping (SKY) allow for better visualization of aneuploidy and translocations between different chromosomes.[62] Subtle rearrangements, such as submicroscopic deletions or cryptic translocations (an exchange of the small distal telomeric regions between the two nonhomologous chromosomes), can be visualized using specific probes in the fluourescent in situ hybridization (FISH) technique (Figure 1-13).[63]

FUTURE DEVELOPMENTS

Chromosome analysis will remain a powerful analytical tool in clinical and research fields for the foreseeable future. Possible strategies for improving existing methods include automation and linearization of the genetic content by increasing resolution to visualize at the level of the chromosome, chromatin, DNA, and gene. Another possible direction of development is functional analysis of the genome using constitutional chromosomes and labeled expressed sequences from particular tissues mapped directly to their original position on chromosomes (expression profiling).

Molecular Basis of Pediatrc Endocrinopathies

The past two decades haves witnessed the increasing application of recombinant DNA technology to the understanding of the pathogenesis of endocrinopathies. Although this new approach to endocrinologic disorders has resulted in the delineation of new syndromes, its major impact has been in facilitating the diagnosis of these disorders. Genetic counseling that includes anticipatory surveillance, as in multiple endocrine neoplasia (MEN) syndromes (see Chapter 13), is also one of the areas of clinical pediatric endocrinology experiencing major impact from this "new" knowledge. For example, it is becoming increasingly clear that phenotypically homogenous clinical syndromes may result from different genotypic abnormalities and that similar genetic abnormalities may have very different clinical manifestations.

In contrast, therapeutic implications of such knowledge are still limited. Hence, the earlier hopes of spectacular gains from gene therapy have not been realized and significant problems need to be addressed before gene therapy becomes a reality in routine patient care. However, targeted pharmacotherapy exploiting knowledge gained regarding molecular mechanisms and pathogenesis has been successfully employed in the treatment of some diseases (such as androgen insensitivity and thyroid cancer). The following section explores a couple of seminal examples of clinical endocrine disorders whose molecular

basis has been elucidated. Details of the specific disorders are elaborated in the respective chapters of this book.

DEFECTS IN PEPTIDE HORMONES

Genomic Deletions Causing Human Endocrine Disease

One of the early discoveries regarding the molecular basis of endocrinopathies was the absence of the gene coding for a particular peptide hormone. The entire gene could be missing, or only a part of the gene could be deleted. In either case, this resulted in the inability to synthesize a functional peptide so that the patient presents with clinical features indicative of deficiency of the hormone. A classic example of this type of endocrinopathy relevant to pediatric endocrinology is isolated growth hormone deficiency, type 1A (IGHD 1A).[64] In this syndrome the gene for human growth hormone-N (hGH-N) is deleted. Disease results when both alleles of hGH-N are absent (indicative of an autosomal recessive inheritance).

In the human, there are two hGH genes (hGH-N and hGH-V)—and both of them, along with the three placental lactogen (chorionic somatomammotropin) genes, are clustered along a 48-kilobase region of DNA. hGH-N is expressed in the pituitary gland and is the source of circulating growth hormone in the human, whereas hGH-V is expressed only in the placenta and its biologic function is not clear at this time. In autosomal recessive type 1A isolated growth hormone deficiency, although hGH-V is intact the absence of the active gene (hGH-N) results in deficiency of circulating growth hormone and the growth-hormone–deficient phenotype. In the original case description, the infants were of relatively normal size at birth but developed severe growth failure during the first year of life. A distinctive feature of these infants was the propensity to develop antibodies against growth hormone in response to exogenously administered growth hormone. This feature, although common, is not invariably present in patients with IGHD 1A. The state-of-the-art method for screening for a hGH-N deletion is based on PCR amplification of the highly homologous regions of DNA on the long arm of chromosome 17 that flank the hGH-N gene.[65,66]

The presence of convenient restriction enzyme sites, such as SmaI, in the amplified DNA is exploited to ascertain the presence or absence of deletions in this region of the chromosome. Although this PCR-based approach is useful in most cases, it does not identify all cases with abnormalities in the hGH-N gene. In particular, more rigorous methods are required for the identification of the less common causes of IGHD-1A (such as point mutations). The study of the hGH-hPL gene cluster has also shed light on the function of prolactin because several studies have identified subjects with hPL deletions. These deletions do not result in overt clinical abnormalities, and specifically do not cause clinical effects in pregnant patients—suggesting that despite high levels of hPL found during pregnancy hPL serves no essential function in the human.[67]

Point Mutations

Peptide hormones act by binding to a specific receptor, which then results in the biologic actions attributed to that particular hormone. The binding of the peptide hormone to its receptor, classically described as the lock-and-key mechanism, is a very precise mechanism dependent on the complementary structures of the receptor and the site on the hormone involved in binding to the receptor. A change in the nucleotide sequence of the

gene coding for a peptide hormone that results in altering an amino acid residue of the hormone can affect the function of the hormone if this change interferes with the hormone's ability to bind or activate the receptor.

Historically, point mutations resulting in aberrant protein production were well described with hemoglobin. This was possible because hemoglobin is present in abundant quantities in the blood, enabling purification and analysis of hemoglobin from patients suspected of having hemoglobinopathies. On the other hand, peptide hormones are present in infinitesimally lesser amounts in circulation—making their direct purification and analysis from blood a more daunting task. With the advent of recombinant DNA technology, it became feasible to clone and analyze the gene coding for the hormone directly without having to resort to purification of the protein from blood or tissue. This approach resulted in the identification of several clinical syndromes due to mutant hormones. One of the classic examples of this type of molecular pathology is non-insulin diabetes mellitus (NIDDM) due to mutant insulins.[68] A number of patients have been described with point mutations in the insulin gene.

In general, these patients present with hyperglycemia, hyperinsulinemia, and normal insulin sensitivity—a clinical picture that is attributed to the production of an abnormal insulin molecule with reduced biologic activity. Thus, Insulin Chicago is characterized by a single nucleotide change (TTC to TTG) that results in the substitution of a leucine for phenylalanine residue at position 25 of the B chain (Phe-B25-Leu). Similarly, the other two well-characterized point mutations are characterized by the change of a single amino acid residue and result in the formation of Insulin Wakayama (Val-A3-Leu) and Insulin Los Angeles (Phe-B24-Ser). These mutations are located within the putative receptor-binding region of the insulin molecule, and the insulin molecules transcribed from these mutant genes are characterized by low binding potency (<5% compared to normal) for the insulin receptor.

A separate class of mutations in the insulin gene gives rise to the syndrome of hyperproinsulinemia with or without clinically significant carbohydrate intolerance. Thus, two mutations described involve substitution of a histidine for an arginine at position 65 in one case and histidine at position 10 of the B chain changed to aspartic acid in the other. Although the original descriptions of these mutant insulins relied on the purification and analysis of the abnormal insulin molecule per se, the current availability of PCR-based methods to screen for these mutations has greatly simplified the laboratory diagnosis of this syndrome.

Another example of point mutations resulting in a phenotype that is especially relevant to pediatric endocrinologists is hypopituitarism secondary to abnormalities in transcription factors that orchestrate embryologic development of the anterior pituitary gland.[69,70] POU1F1 (also known as PIT1 or GHF-1) was the first transcription factor identified as playing a specific role in pituitary development. The POU1F1/PIT-1 gene encodes a 291–amino-acid Pit Oct Unc (POU) homeodomain DNA binding nuclear protein present in somatotrophs, lactotrophs, and thyrotrophs. POU1F1/PIT-1 is necessary for the normal development of these pituitary cell types. The first indication that abnormalities in POU1F1/PIT-1 may result in a phenotypic change was derived from studies on strains of mice with genetic forms of dwarfism.

The Snell and Jackson strains of dwarf mice are characterized by a deficiency of growth hormone, prolactin, and TSH. In 1990, Li et al. reported that Snell phenotype was caused by a missense mutation and that the Jackson phenotype was caused by a rearrangement in the POU1F1/PIT-1 gene.[71] Since this landmark study, several recessive and dominant types of POU1F1/PIT-1 abnormality have been recognized in sporadic cases and in multiplex families with hypopituitarism.[72-74] POU1F1/PIT-1 activates growth hormone and prolactin gene expression, and can bind to and transactivate the TSH-B promoter. Accordingly, patients with POU1F1/PIT-1 mutations demonstrate growth hormone, prolactin, and variable TSH deficiencies.[72] The syndrome can be inherited in an autosomal dominant or recessive manner, but POU1F1/PIT-1 mutations are not a common cause of combined pituitary hormone deficiencies.

HESX1 is a paired-like homeodomain transcription factor expressed in the developing pituitary gland. Mutations in this gene leading to decreased activity have been found in two siblings with panhypopituitarism, absent septum pellucidum, optic nerve hypoplasia, and agenesis of the corpus callosum—implicating HESX1 in the mediation of forebrain development.[75,76] Another mutation in HESX1 was recently discovered in a patient with septo-optic dysplasia and isolated growth hormone deficiency.[77] Experimental evidence suggests that this particular mutation results in the production of an altered HESX1 protein with enhanced DNA binding activity that abrogates the transcriptional activity of PROP1, another transcription factor necessary for pituitary development.

PROP1 is thought to be involved in the differentiation of somatotropes, thyrotropes, lactotropes, and gonadotropes. Mutations in PROP1 leading to reduced DNA binding and transcriptional activity have been identified in patients with combined pituitary hormone deficiency. These patients have a deficiency of TSH, growth hormone, prolactin, LH, and FSH.[78] Patients with a demonstrated gonadotropin deficiency may present with failure to enter puberty spontaneously, whereas other patients do enter puberty but have subsequent loss of gonadotropin secretion. Although PROP1 is directly implicated in the differentiation of only four of the five anterior pituitary cell types, some patients have been described with ACTH deficiency. PROP1 mutations are believed to be relatively common (32%–50%) genetic causes of combined pituitary hormone deficiency.[79]

Rathke's pouch initially forms but fails to grow in LHX3-knockout mice.[80] Humans have been found to have mutations in the LHX3 gene (a LIM-type homeodomain protein), and demonstrate complete deficits of growth hormone, PRL, TSH, and gonadotropins in addition to a rigid cervical spine leading to limited head rotation. LHX4 is a related protein that (similar to LHX3) regulates proliferation and differentiation of pituitary lineages. A patient has been identified with a dominant mutation in this protein, demonstrating deficiencies of

growth hormone, TSH, and ACTH; a small sella turcica; a hypoplastic anterior hypophysis; an ectopic posterior hypophysis; and a deformation of the cerebellar tonsil into a pointed configuration.[81]

Finally, Rieger syndrome is a condition with abnormal development of the anterior chamber of the eye, dental hypoplasia, and a protuberant umbilicus associated with growth hormone deficiency. All mutations in RIEG (Pitx2) found thus far have been heterozygous, with an autosomal dominant inheritance.[82]

DEFECTS IN PEPTIDE HORMONE RECEPTORS

Molecular defects resulting in phenotypic abnormalities in humans have been described in a variety of peptide hormone receptors, including growth hormone, LH, FSH, TSH, ACTH, and insulin. It is expected that this list will continue to expand in the future. Mutations in receptors for peptide hormone interfere in the actions of the hormone by altering the binding of the hormone, by altering the number of the receptors available for binding to the hormone, by interfering with the synthesis or intracellular processing of the receptor, or by disrupting the activation of the postreceptor signaling pathways.

In general, mutations in the receptor result in decreased actions of the cognate hormone. However, mutations involving G-protein–linked receptors are exceptions to this generalization and can result in a phenotype characterized by "over-activity" of the particular hormone system. Examples of these "gain-of-function" mutations include mutations in the LH receptor responsible for familial testotoxicosis[83] and mutations in the TSH receptor causing thyrotoxicosis[84] (see Chapter 2).

Insulin Receptor

Following the initial reports in 1988, a variety of mutations have been identified in the insulin receptor gene—with the majority of them being in patients with genetic syndromes associated with acanthosis nigricans and insulin resistance.[85] Patients with leprechaunism (a congenital syndrome characterized by extreme insulin resistance, fasting hypoglycemia, and intrauterine growth retardation) have two mutant alleles of the insulin receptor gene. Another syndrome associated with acanthosis nigricans and extreme insulin resistance, the Rabson-Mendenhall syndrome, has been linked to two different mutations within the insulin receptor gene existing in a compound heterozygous state.

The syndrome of type A insulin resistance is a heterogeneous collection of conditions defined by the presence of insulin resistance, acanthosis nigricans, and hyperandrogenism in the absence of lipoatrophy or obesity. Molecular analysis of the insulin receptor gene has revealed that several of these patients have mutations in one or both alleles of the insulin receptor gene. The initial expectation that mutations in the insulin receptor would provide the molecular basis for the common type of type 2 (NIDDM) diabetes mellitus has not been fulfilled. And, no alterations in the insulin receptor gene were identified in a study of Pima Indians—an ethnic group with a greater than 50% incidence of type 2 diabetes mellitus. It is noteworthy, however, that recent studies have advanced the search for genetic variations that influence the propensity to develop type 2 diabetes mellitus.[86,87]

Positional-cloning–based analysis suggests that specific polymorphisms in the CAPN10 gene are associated with type 2 diabetes mellitus in the Finnish and Mexican-American (Pima Indian) populations. Whether these genetic variations in the CAPN10 gene, a chromosome 2 gene that encodes a widely expressed calpain-like cysteine protease, are causal factors for Type 2 diabetes mellitus or are merely co-segregating markers remains to be established. However, current studies have not excluded the possibility that polymorphisms in the insulin receptor gene may confer a genetic predisposition for the precipitation of the development of NIDDM by obesity and/or hypertension.

Growth Hormone Receptor

Genetic abnormalities in the growth hormone receptor result in the primary form of the syndrome of growth hormone insensitivity, also called Laron syndrome.[88] The human growth hormone receptor gene located on the proximal part of the short arm of chromosome 5 spans approximately 90 kilobases and includes nine exons (numbered 2 through 10) that encode the receptor protein and additional exons in the 5'UTR region of the gene. The growth hormone receptor protein contains an open reading frame of 638 amino acids that predicts a 246-amino-acid-long extracellular ligand-binding domain, a single membrane-spanning domain, and a cytoplasmic domain of 350 amino acids. In the human, the extracellular portion of the receptor exists in circulation as the growth-hormone–binding protein (GHBP).

Exon 2 encodes a signal sequence, exons 3 through 7 the extracellular GHB domain, exon 8 the transmembrane domain, and exons 9 and 10 the cytoplasmic domain and the 3'UTR region. The mutations that have been described in the growth hormone receptor gene include large deletions, nonsense mutations, splice mutations, and frameshift mutations.[89] The diagnosis of growth hormone insensitivity due to mutations in the growth hormone receptor gene is considered when patients demonstrate elevated growth hormone levels and low IGF-1 levels.

Because the GHBP is the cleaved extracellular portion of the growth hormone receptor, patients with mutations in the growth hormone receptor that results in decreased synthesis of the receptor protein can demonstrate low GHBP levels in circulation. However, mutations in the growth hormone receptor gene that selectively involve the transmembrane or intracellular domains may demonstrate normal or even enhanced circulating levels of GHBP. For example, a patient with a mutation that inhibits dimerization of the receptor had normal GHBP levels because the receptor had a normal GHB site.[90] Another set of affected individuals had a mutation of the transmembrane domain of the receptor, leading to a truncated growth hormone receptor product postulated to be more easily released from the cell membrane. In addition, elevated GHBP levels were noted.[91]

Recombinant DNA Technology and Therapy for Pediatric Endocrine Diseases

From a therapeutic point of view, recombinant DNA technology can be exploited to tailor pharmacotherapy according to the genotype of a patient (i.e., targeted pharmacotherapy), to manipulate genes within the human body (gene therapy), or to engineer prokaryotic or eukaryotic cells to produce proteins (such as hormones) that can then be administered for therapy or diagnosis. Whereas targeted pharmacotherapy and gene therapy are largely restricted to the research arena, the use of hormones produced by recombinant DNA technology is well established in clinical endocrinology. Historically, insulin was the first hormone synthesized by recombinant DNA technology to be approved for clinical use.[92,93] At present, a variety of recombinant hormones (including growth hormone, LH, FSH, TSH, PTH, and erythropoietin) are being used clinically or are in advanced stages of clinical trials.

On a theoretical basis, it should be possible to synthesize any protein hormone whose gene has been cloned and DNA sequence determined. Thus, recombinant DNA technology makes it possible to insert the gene coding for a particular protein hormone into a host cell such that the protein is produced by the host cell's protein synthesizing machinery. The synthesized protein is then separated from the rest of the host cell proteins to obtain the pure form of the hormone of interest. Both prokaryotic and eukaryotic cells can serve as the host cell for the production of proteins by this technology. Because post-translational modifications such as glycosylation may be essential for the optimal action of a protein hormone, the choice of the specific cell system utilized for the production of a particular protein hormone is critical. Prokaryotic cell systems such as *Escherichia coli* are suitable for the production of protein hormones that do not need post-translational modifications, such as growth hormone.[94]

Eukaryotic cell systems such as CHO (Chinese hamster ovary) cells, which are capable of post-translational modification of the protein, are useful for the production of hormones (such as TSH) that require glycosylation for optimal bioefficacy.[95] In addition, eukaryotic cells are capable of synthesizing proteins that undergo the appropriate folding—a step that is not carried out by prokaryotic cells. The advantages of the use of recombinant DNA for the production of these proteins include the possibility of a limitless supply of a highly pure form of a protein and the absence of the risk of contamination with biologic pathogens associated with extraction of proteins from human or animal tissue. In addition, this technology permits the development of hormone analogues and antagonists with much greater ease than conventional protein synthesis protocols.

The influence of genetic factors on the metabolism of various drugs is a well-established phenomenon, with the effect of various isozymes of cytochrome p450 on the circulating half-life of drugs such as anticonvulsants being a classic example of this interaction. Another example of the role of genotype on the choice of pharmacotherapy is the phenomenon of drug-induced hemolytic anemia in patients with G6PD deficiency. The recent genomic revolution has allowed for the exploitation of computational approaches to identifying polymorphisms of known genes encoding proteins with different functional characteristics. These single-nucleotide variations (also called single-nucleotide polymorphisms or SNPs) occur with varying frequencies in different ethnic populations and are the focus of intense scrutiny at this particular time.

The promise these SNPs hold out is that analysis of these SNPs for a given gene will allow the investigator to predict the response of the particular individual to a class of drugs or chemicals. This pharmacogenomic approach to clinical therapeutics has already been successful in demonstrating an association between specific polymorphisms in the beta-adrenergic receptor and response to beta-agonists in patients with bronchial asthma, and polymorphisms in hydroxytryptamine receptors and response to neuroleptic drugs. The widespread application of the tools of molecular biology to unravel the molecular basis of action of hormones has also yielded benefits by allowing for customization of pharmacotherapy of endocrine diseases and syndromes based on the specific individual genetic defect.

One such example is the report of directed pharmacologic therapy of an infant with ambiguous genitalia due to a mutation in the androgen receptor.[96] In this infant with an M807T mutation in the androgen receptor, in vitro functional studies had indicated that the mutant receptor exhibited loss of binding capacity for testosterone with retention of binding for dihydrotestosterone (DHT). Furthermore, this differential binding was also reflected in the better preservation of the transactivation potential of DHT compared to testosterone. These in vitro findings were exploited to treat the infant with DHT, resulting in restoration of male genital development. This case illustrates that in selected cases in vitro functional assays can help identify subsets of patients with ambiguous genitalia and androgen insensitivity who would respond to targeted androgen therapy. It can be anticipated that in the coming years more examples of such innovative therapeutic strategies and "customized" hormonal treatment protocols will become routinely implemented in the practice of clinical pediatric endocrinology.

Concluding Remarks

The application of recombinant DNA technology has resulted in a tremendous increase in our understanding of physiologic processes and pathologic conditions. The U.S. government sponsored Human Genome Project initiative launched in 1992 has catalyzed this revolution, which is currently being fueled by both public sector efforts and private sector entrepreneurship. The central goal of this initiative, which represents collaborative efforts among scientists in the United States and around the world, is to sequence the entire 3 to 4 billion base pairs of the human genome and to construct a detailed genetic and physical map of the entire human genome (i.e., each of the 24 different human chromosomes).

Such a map, along with advances in communication and computers, will allow a scientist to locate and isolate any human DNA sequence of interest. Recent achievements, such as the draft sequence of the human genome, are major milestones toward the fulfillment of this goal and have resulted in a paradigm shift in the way that novel genes are being discovered and in the analysis of the function of hormones and related proteins.[97] In the traditional paradigm, investigators seeking to discover new genes or to analyze the function of known proteins needed to devote a significant part of their time to conducting "bench research" in "wet laboratories." The new approach in this "post-genomic" era takes advantage of the unprecedented power of computational biology to "mine" nucleotide, protein sequence, and other related databases.

In the future, most researchers will deal with abstract models and data sets stored in computer databases. Hence, initial discoveries of novel genes or novel interactions between known proteins or intracellular signaling pathways could be made using the analytic power of computational software tools (functional genomics). These initial insights can then be verified and expanded upon by traditional benchtop methods. The advantages of this new paradigm are obvious, with computational approaches taking a significantly shorter time and with fewer demands on manpower. The new paradigm can also easily expand the scope of the search to include multiple molecules and organisms (phylogenetic profiling).

One of the key contemporaneous scientific developments that have enabled the efficient and widespread use of this new paradigm is the expansion of the Internet. The Internet has enabled the capture, storage, analysis, and dissemination of the enormous amounts of data generated by the Human Genome Project in a manner that is efficient, protects the privacy of individuals, and is easily accessible for legitimate use. Several public-domain web-accessible databases are currently serving as the major repositories for this information. GenBank is the major repository for sequence information and is currently supported by the National Institutes of Health. One of the main sources of the physical location, clinical features, inheritance patterns, and other related information of specific gene defects is the Online Mendelian Inheritance in Man (OMIM) operated by Johns Hopkins University in Baltimore, Maryland.

Johns Hopkins University also operates the online Genome Database (GDB), which allows scientists to identify polymorphisms and contacts for gene probes and other related research tools. The ever-expanding number of endocrine (and other) disorders that can be attributed to changes in the nucleotide sequence of specific genes has also increased the necessity for the availability of accurate, reliable, and timely genetic tests such as mutation detection. One source for such information is a collaborative website *(www.genetests.org)* that maintains an up-to-date catalog of commercially available and research-based tests for inherited disorders.

With the ubiquitous use of these powerful tools in laboratories around the world, genes are being cloned and genetic diseases being mapped at a very rapid pace. In all of this excitement, one still needs to keep in mind that whereas this "new" science has allowed for hitherto inaccessible areas of human biology to be probed and studied, a lot remains to be understood with respect to individual disease processes. Hence, at the present time we have only a rudimentary understanding of the correlations between phenotype and genotype in many of the common genetic diseases (such as congenital adrenal hyperplasia).

These lacunae in our knowledge dictate that clinicians should be cautious about basing therapeutic decisions solely on the basis of molecular and genetic studies. This is especially true in the area of prenatal diagnosis and termination of pregnancy based on genetic analysis. As we improve our understanding of the molecular and genetic basis of disease and translate this knowledge into gains at the bedside, it behooves us both as individuals and as a society to be cognizant of critical issues relating to privacy of health data and to remain vigilant against misuse by inappropriate disclosure of this powerful knowledge.

Receptor Transduction of Hormone Action

ALAN M. RICE, MD • SCOTT A. RIVKEES, MD

Introduction
G-Protein–Coupled Receptors
Class A Receptors That Transduce Hormone Action
The Peptide Receptor Group
Adrenocorticotropin and Melanocortin-2 Receptors
Other Melanocortin Receptors
Vasopressin Receptors
The Hormone Protein Receptor Group
LH Receptors
FSH Receptors
TSH Receptors
HCG and TSH Receptors During Pregnancy
HCG and FSH Receptors During Pregnancy
The Gonadotropin-Releasing Hormone Receptor Group
Gonadotropin-Releasing Hormone Receptors
The Thyrotropin-Releasing Hormone and Secretagogue Receptor Group
Thyrotropin-Releasing Hormone Receptors
Other Class A Receptors That Transduce Hormone Action
Free Fatty Acid Receptor 1
GPR54
Orexin Receptors
Ghrelin Receptors
Melanin-Concentrating Hormone Receptors
Class B Receptors That Transduce Hormone Action
Growth-Hormone–Releasing Hormone Receptor
Gastric Inhibitory Polypeptide Receptors
Parathyroid Hormone and Parathyroid-Hormone–Related Peptide Receptors
Other Class B Receptors That Transduce Hormone Action
Class C Receptors That Transduce Hormone Action
Calcium-Sensing Receptors
G-Protein Gene Disorders
Inactivating Mutations of the GNAS1 Gene
Activating Mutations of the GNAS1 Gene
Cytokine Receptors
Structure and Function of Type I Cytokine Receptors
Cytokine Receptors That Transduce Hormone Action
Growth Hormone Receptors
Leptin Receptors
Receptor Tyrosine Kinases
Insulin Receptor Tyrosine Kinase Family
The Insulin Receptor
The Insulin-Like Growth Factor-1 Receptor
The Fibroblast Growth Factor Receptor Family
Fibroblast Growth Factor Receptor 1
Fibroblast Growth Factor Receptor 3
Nuclear Receptors
General Structure of the Nuclear Receptors
Subfamily 1 Nuclear Receptors: Thyroid Hormone, Vitamin D3, and Peroxisome Proliferator-Activated Receptors
Thyroid Hormone Receptors
Vitamin D3 Receptor
PPARγ
Subfamily 2 Nuclear Receptors: Hepatocyte Nuclear Factor and Retinoid X Receptors
HNF

Subfamily 3 Nuclear Receptors: The Steroid Receptors and Glucocorticoid, Androgen, Estrogen, and Mineralocorticoid Receptors
Glucocorticoid Receptors
Androgen Receptors
Estrogen Receptors
Mineralocorticoid Receptors
Subfamily 0 Nuclear Receptors: DAX1
DAX1
Summary

Introduction

Hormones exert their actions by activating specific receptors. Activation of these receptors stimulates intracellular responses that influence cellular physiology and, at times, gene expression. The specificity of hormone action is thus determined by the affinity of hormones for different receptors, receptor distribution, and effector and genetic responses to ligand occupancy.

Over the past two decades, our understanding of hormone action has increased greatly—in part due to the cloning of many receptors that transduce hormone action. Four major receptor superfamilies have been identified that share common structural elements and/or effector systems. These families include the G-protein–coupled receptors (GPCRs), cytokine receptors, tyrosine kinase receptors (RTKs), and nuclear receptors (Table 2-1). This chapter reviews major features of these important receptor families. Mutations influencing receptor function leading to endocrine disorders are also highlighted.

G-Protein–Coupled Receptors

More than 1% of the genome of vertebrates encodes GPCRs.[1] Most of these GPCRs are odorant and pheromone receptors.[1] It is also important to note that most of the receptors that transduce the effects of hormones are GPCRs (Table 2-2).

The GPCR superfamily is divided into eight major classes.[1,2] These receptors contain an N-terminal extracellular domain that is frequently called the ectodomain or exodomain.[3] These receptors also contain seven putative transmembrane helixes (TM-I to TM-VII) connected by three intracellular (i1 through i3) and three extracellular (e1 through e3) loops that are often collectively called the serpentine region (Figure 2-1).[3,4] The C-terminal intracellular region is usually referred to as the endodomain.[3]

GPCRs are activated by a wide variety of signals, including proteins, nucleotides, amino acid residues, Ca^{2+}, light, and odorants (Figure 2-1).[1] It is postulated that alteration of the conformation of transmembrane domains by ligand binding changes the conformation of intracellular loops, leading to activation of heterotrimeric guanosine nucleotide binding proteins (G proteins) (Figure 2-1).[5,6] When a GPCR is activated by a ligand, guanosine 5'-diphosphate (GDP) is converted to guanosine 5'-triphosphate (GTP)—which causes the heterotrimeric G protein to dissociate into active Gα-GTP and Gβγ subunits (Figure 2-1).[5-7] GTPase then converts GTP into GDP, which inactivates Gα and increases affinity of Gα for Gβγ leading to reformation of the inactive heterotrimeric G protein.[5-7] Active Gα and Gβγ subunits can alter the activity of transmembrane channels, and the activity of intracellular effector enzymes that include phospholipase C, adenylyl cyclase, and kinases (Figure 2-1).[1,7]

Specificity in ligand binding is conferred by variations in the primary structures of the extracellular and intracellular domains.[1] Specificity of effector responses is conferred by the variations in the primary structure of intracellular domains and isoforms of the Gα subunits of G proteins.[8,9] Some GPCRs couple predominantly with G proteins with $G\alpha_i$ /$G\alpha_o$ subunits that act primarily to decrease adenylyl cyclase activity.[9-12] Other GPCRs couple predominantly with G proteins with $G\alpha_s$ subunits that act to increase adenylyl cyclase activity, or $G\alpha_q$/$G\alpha$[11,14,15,16] subunits that increase phospholipase C activity.[9,13,14]

Interestingly, data show that cytoskeletal proteins may module receptor–G-protein coupling. For example, the erythrocyte membrane cytoskeletal protein 4.1G can

TABLE 2-1

Major Types of Hormone Receptors

Receptor Class	Hormone Receptors
G-protein–coupled receptors	ACTH and other melanocortins, V2 vasopressin, LH, FSH, TSH, GnRH, TRH, GHRH, corticotropin releasing factor, somatostatin, glucagon, oxytocin, gastric inhibitory peptide, type 1 PTH, free fatty acid, GPR54, orexin, ghrelin, melanin-concentrating, calcitonin, glucagon-like peptide-1, and calcium-sensing receptors
Type I cytokine receptors	Growth hormone, prolactin, and leptin receptors
Receptor tyrosine kinases	Insulin, IGF-1, and fibroblast growth factor receptors
Nuclear receptors	Thyroid hormone, vitamin D3, PPARγ, HNF-4α, glucocorticoid, androgen, estrogen, mineralocorticoid, and DAX1 receptors

TABLE 2-2

G-Protein–Coupled Receptors and Clinical Conditions Associated with Receptor Mutations

Receptor	Germ Line Mutation	Endocrine Disorder
ACTH/melanocortin-2 receptor	Inactivating mutations (homozygous, compound heterozygous)	Familial glucocorticoid deficiency type 1
Melanocortin-4 receptor	Inactivating mutations (most heterozygous, some homozygous)	Obesity
V2 vasopressin receptor	Inactivating mutations (most X-linked recessive, rarely X-linked dominant)	X-linked nephrogenic diabetes insipidus
LH receptor	Inactivating mutations (homozygous, compound heterozygous)	Males: types I and II Leydig cell hypoplasia
		Females: asymptomatic or hypergonadotropic hypogonadism with primary amenorrhea
	Activating mutations (heterozygous)	Males: male limited precocious puberty
FSH receptor	Inactivating mutations (homozygous, compound heterozygous)	Females: autosomal recessive hypergonadotropic ovarian dysgenesis or milder hypergonadotropic hypogonadism
		Males: variable impairment of spermatogenesis
TSH receptor	Inactivating mutations (most homozygous or compound heterozygous, rarely heterozygous)	Resistance to TSH
	Activating mutations (heterozygous)	Autosomal-dominant inherited nonautoimmune hyperthyroidism/toxic adenomas
GnRH receptor	Inactivating mutations (homozygous or compound heterozygous)	Isolated hypogonadotropic hypogonadism
TRH receptor	Inactivating mutations (compound heterozygous)	Central hypothyroidism
GPR54	Inactivating mutations (homozygous, compound heterozygous)	Normosmic isolated hypogonadotropic hypogonadism
Ghrelin	Inactivating mutations (homozygous, possible heterozygous)	Short stature due to decreased growth hormone secretion
GHRH receptor	Inactivating mutations (homozygous/compound heterozygous)	Isolated growth hormone deficiency
Type 1 PTH receptor	Inactivating mutations (homozygous, heterozygous)	Blomstrand's chondrodysplasia if homozygous and rarely if heterozygous; enchondromatosis if heterozygous
	Activating mutations (heterozygous)	Jansen's metaphyseal chondrodysplasia
Calcium-sensing receptor	Inactivating mutations (heterozygous, homozygous)	Familial benign hypocalciuric hypercalcemia typical if heterozygous, neonatal severe hyperparathyroidism rarely if heterozygous, typical if homozygous
	Activating mutations (heterozygous)	Autosomal-dominant hypocalcemic hypocalciuria, Bartter syndrome type V

interfere with A1 adenosine receptor signal transduction.[15] 4.1G also influences mGlu1alpha-mediated cAMP accumulation, increases the ligand-binding ability of mGlu1alpha, and alters its cellular distribution.[16] 4.1G may also play a role in receptor-receptor dimerization.

Receptor agonist-independent and agonist-induced homo- and heterodimerization have increasingly been recognized as important determinants of GPCRs function.[17] For example, the GPCR somatostatin receptor 5 (SSTR5) primarily exist as monomers in the absence of an agonist. However, they form homodimers in the presence of an agonist.[18] Furthermore, it has been shown that SSTR5 can form heterodimers with type 2 dopamine receptors (DRD2)—another GPCR—in the presence of hsst2 agonist or dopamine.[19] Agonist-induced activation of SSTR5-DRD2 heterodimers in China hamster ovary (CHO) cells expressing SSTR5 and DRD2 is increased when compared to agonist-induced activation of monomers and homodimers in CHO cells expressing only SSTR5 or DRD2.[19] Heterodimerization of receptors may also lead to inactivation of one of the receptors in the complex. For example, heterodimerization of somatostatin receptor 2A (sst2A) with somatostatin receptor 3 (SSTR3) appears to lead to inactivation of the heterodimerized SSTR3 without inactivating the heterodimerized SSTR2.[20]

GPCRs can form heterodimers with nonreceptor transmembrane proteins. Both the calcitonin receptor (CALCR) and the calcitonin receptor-like protein (CALCRL) can form heterodimers with three different receptor-activity–modifying proteins (RAMPs): RAMP1, RAMP2, and RAMP3.[21-23] Whereas CALCRs can be activated by ligand in the absence of heterodimerization with a RAMP, CALCRLs

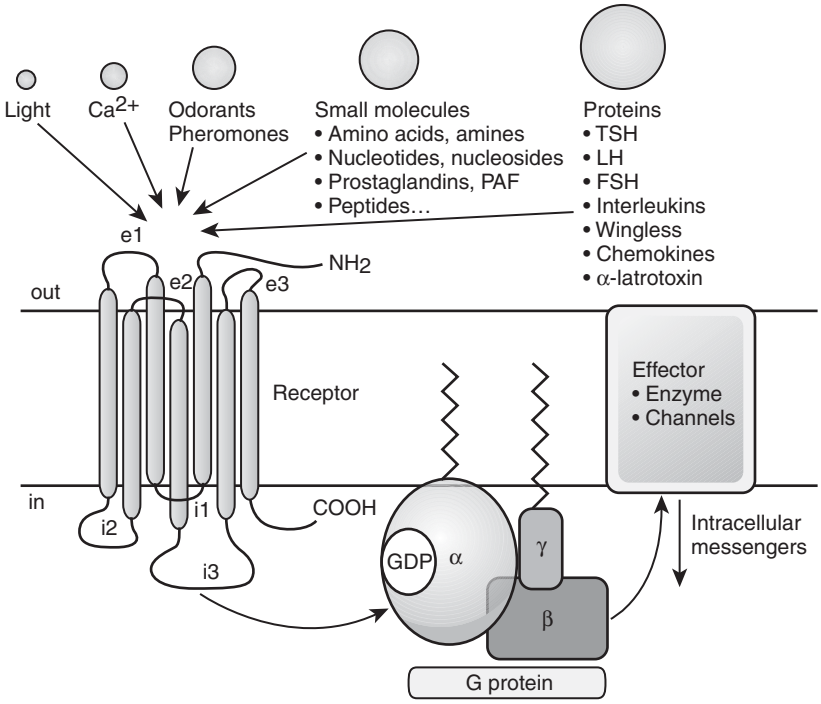

Figure 2-1. GPCR structure and function. GPCRs have an N-terminal extracellular domain, seven putative transmembrane domains separated by three extracellular loops (e1-e3) and three intracellular loops (i1-i3), and a C-terminal intracellular domain. Ligand binding results in the exchange of GTP for GDP, which induces dissociation of the G protein into a GTPα subunit and a βγ subunit. Then these subunits alter the activity of intracellular effector enzymes and transmembrane channels, resulting in the alteration of intracellular levels of second messengers that can include cAMP and calcium. [Adapted with permission from Bockaert J, Pin JP (1999). Molecular tinkering of G-protein–coupled receptors: An evolutionary success. Embo J 18:1724.]

are only activated by ligand if heterodimerized with a RAMP.[21,22] RAMPs alter the ligand specificity of the heterodimerized receptor.

CALCRs that are not in heterodimers with RAMPS are activated by calcitonin and thus constitute the classic CALCR.[21,22] However, CALCRs heterodimerized with RAMP1, RAMP2, and RAMP3 bind amylin and constitute amylin1, amylin2, and amylin3 receptors, respectively.[21,22] CALCRLs dimerized with RAMP1 bind calcitonin gene-related peptide and constitute the calcitonin gene-related peptide receptor.[21,22] CALCRLs dimerized with RAMP2 and RAMP3 bind adrenomedullin, and constitute adrenomedullin1 and adrenomedullin2 receptors, respectively.[21,22] RAMPS alter function of other GPCRs that transduce hormone action. The distribution and function of parathyroid hormone 1 and 2 receptors are altered by binding to RAMP2 and RAMP3, respectively.[24] The distribution and function of the glucagon receptor is altered by binding to RAMP2.[24]

Dimerization/heterodimerization may occur in the endoplasmic reticulum (ER) shortly after protein synthesis occurs.[25] The ER plays a role in determining whether or not a protein will be expressed elsewhere in the cell, thus protecting the cell from misfolded and (likely) mutant proteins.[25] The non-heterodimerized CALCRL is an orphan receptor because the CALCRLs cannot leave the ER for the cell membrane unless heterodimerized with RAMPs.[26]

Failure of the endoplasmic reticulum to export mutant GPCR homodimers and mutant GPCR wild-type GPCR heterodimers to the cell membrane has been unequivocally found to be the cause of two dominant negative endocrine conditions, and to occur without apparent clinical effect in a third endocrine condition. A dominant negative mutation is a heterozygous mutation that results in a phenotype that would only be expected in the presence of a homozygous mutation. Some V2 vasopressin receptor gene mutations that are known to cause nephrogenic diabetes insipidus encode mutant V2 vasopressin receptors that form dimers in the ER that cannot be exported to the cell membrane.[27]

These mutant receptors also interfere with cell surface expression of wild-type receptors by forming heterodimers with the wild-type receptors that cannot be exported from the ER to the cell membrane.[28] This finding explains why females heterozygous for these V2 vasopressin receptor gene mutations do not concentrate their urine with even high doses of desmopressin, a synthetic V2 vasopressin receptor agonist, in spite of being able to produce wild-type V2 vasopressin receptors.[29] A similar phenomenon explains dominant transmission of partial TSH receptor resistance in patients heterozygous for some inactivating TSH receptor mutations.[30] In these patients, mutant TSH receptors form oligomers with wild-type receptors and prevent export of wild-type receptors from the endoplasmic reticulum to the cell membrane.[30]

Similarly, misfolding and misrouting of some mutant gonadotropin-releasing hormone (GnRH) receptors in the endoplasmic reticulum (as well as oligomerization of these mutant GnRH receptors with wild-type GnRH receptors)

decrease cell membrane expression of wild-type GnRH receptors.[31-33] This phenomenon, however, has not been found to have clinical implications in relatives of probands homozygous or compound heterozygous for mutations that cause isolated hypogonadotropic hypogonadism (IHH) because individuals heterozygous for these mutations demonstrate an intact GnRH-gonadotropin axis and do not have clinical signs of IHH. Thus, in these individuals enough wild-type GnRH receptors do not oligimerize with mutant GnRH receptors and are transported to the cell membrane to maintain sufficient normal GnRH-GnRH receptor interactions to avoid development of IHH.[32]

It has been recognized that many GPCRs (including lutenizing hormone, thyroid-stimulating hormone thyrotropin-releasing hormone, glucagon-like peptide-1, melanocortin, and cannabinoid receptors) activate G proteins in the absence of ligand binding.[34,35] Thus, these receptors are constitutively active and cellular G-protein activation increases linearly with increased cell surface expression of the receptors.[36] It has also been recognized that there are ligands (often called inverse agonists) that decrease the activity of these receptors.[37] Receptor ligands that neither increase nor decrease the activity of receptors are now frequently referred to as neutral antagonists.[35]

The term *antagonists* is applied to these ligands because they block activation and inactivation of receptors by agonists and inverse agonists, respectively.[35] The term *agonist* only refers to receptor ligands that increase receptor activity.[35] A scale has been formulated to express the continuity in receptor ligand function—from –1 (representing a full inverse agonist), to 0 (representing a neutral antagonist), to +1 (representing a full agonist).[35,37] It is possible that inverse agonists play a role in treating medical conditions caused by GPCR mutations that lead to increased constitutional activation of the receptor.[35]

Receptor desensitization and resensitization play a role in GPCR activity. During the past decade, mechanisms of GPCR desensitization and resensitization have been elucidated. Three processes for receptor desensitization have been described.[38,39] The first receptor desensitization process is rapid uncoupling of the G protein from GPCRs.[39] This process occurs within seconds to minutes after initiation of the process and occurs as a result of phosphorylation of GPCRs.[39] G-protein–receptor kinases (GRKs) have been increasingly recognized as playing a major role when this process involves homologous desensitization.[38]

Homologous or agonist-dependent desensitization occurs after agonist activation of the receptor that is desensitized.[39] GRK-mediated phosphorylation of serine and threonine residues in the third intracellular loop or the C-terminal intracellular domain leads to activation of β-arrestins, which in turn inactivate adenylyl cyclase (Figure 2-2).[38-41] Second-messenger–dependent protein kinases also contribute to receptor desensitization when

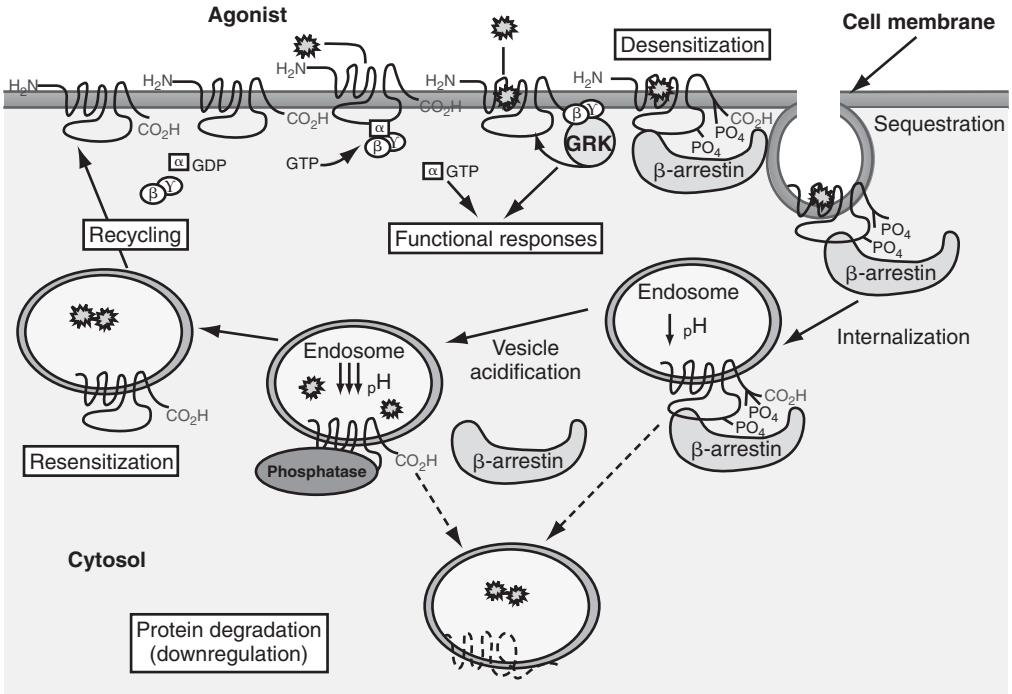

Figure 2-2. Desensitization and recycling of GPCRs. Shortly after an agonist binds a GPCR, G-protein–receptor kinases phosphorylation of serine and threonine residues in the third intracellular loop or the C-terminal intracellular domain leads to activation of β-arrestin. Activation of β-arrestin inactivates adenylyl cyclase and initiates sequestration of the GPCR in clathrin-coated vesicles. Dephosphorylation of the sequestered receptor and subsequent disassociation of the receptor from β-arrestin is followed by recycling of the GPCR to the cell membrane. Alternatively, once sequestered the GPCR can be destroyed in lysosomes. [Adapted with permission from Saunders C, Limbird LE (1999). Localization and trafficking of α2-adrenergic subtypes in cells and tissues. Pharmacol Ther 84:200.]

this process involves homologous desensitization, but also participate in receptor desensitization when desensitization involves heterologous desensitization. Heterologous or agonist-independent desensitization occurs as a result of activation of a different receptor from the one that is desensitized.[39]

The second receptor desensitization process is internalization/sequestration of GPCRs. This process is slower than receptor phosphorylation-induced uncoupling of the G protein from GPCRs and occurs within minutes to hours after initiation of the process. This process is reversible because the receptors can be recycled to the cell surface (Figure 2-2).[39] GRKs and β-arrestins play a role in initiating internalization/sequestration of β2-adrenergic, LH, FSH, TSH, TRH, vasopressin V2, angiotensin II type 1A, and other G-protein–coupled receptors in clathrin-coated vesicles (Figure 2-2).[38,42-49] Dephosphorylation of the sequestered receptor followed by disassociation of the receptor from β-arrestin is necessary for the receptor to be recycled to the cell membrane and resensitized (Figure 2-2).[14]

The third receptor desensitization process is down-regulation. With down-regulation the number of intracellular GPCRs decreases due to increased lysosomal degradation and decreased synthesis of the receptors due to alteration of transcriptional and post-transcriptional regulatory mechanisms (Figure 2-2).[50,51] Down-regulation is a slow process that occurs within several hours to days after initiation of the processes that lead to its development.[52]

One of the ways the Arg137His V2 vasopressin receptor mutation interferes with mutant receptor function and causes X-linked nephrogenic diabetes insipidus is by altering desensitization and recycling of the mutant receptor.[53] In vitro studies have revealed that the mutant receptor is constitutively phosphorylated. Thus, even in the absence of ligand binding the mutant receptor is bound by β-arrestin—which in turn leads to sequestration of the mutant receptor within clathrin-coated vesicles. Recycling of the mutant receptor back to the cell membrane requires the mutant receptor to be dephosphorylated and disassociated from β-arrestin. However, the mutant receptor remains constitutively phosphorylated while sequestered and thus cannot be disassociated from β-arrestin and recycled to the cell membrane—thereby reducing cell membrane expression of the mutant receptor.

Some investigators suggest that most GPCR-inactivating mutations can be classified by the effects of the mutations into one of five classes.[54] Class I inactivating mutations interfere with receptor biosynthesis. Class II inactivating mutations interfere with receptor trafficking to the cell surface. Class III inactivating mutations interfere with ligand binding. Class IV inactivating mutations impede receptor activation. Class V inactivating mutations do not cause discernible defects in receptor biosynthesis, trafficking, ligand binding, or activation but may cause medical disorders. There are also inactivating mutations that interfere with receptor function via multiple mechanisms and thus cannot be placed into one class.

Of the eight classes of GPCRs, only classes A, B, and C contain receptors for mammalian hormones (Figure 2-3).[2] Class A receptors contain the rhodopsin-like receptors

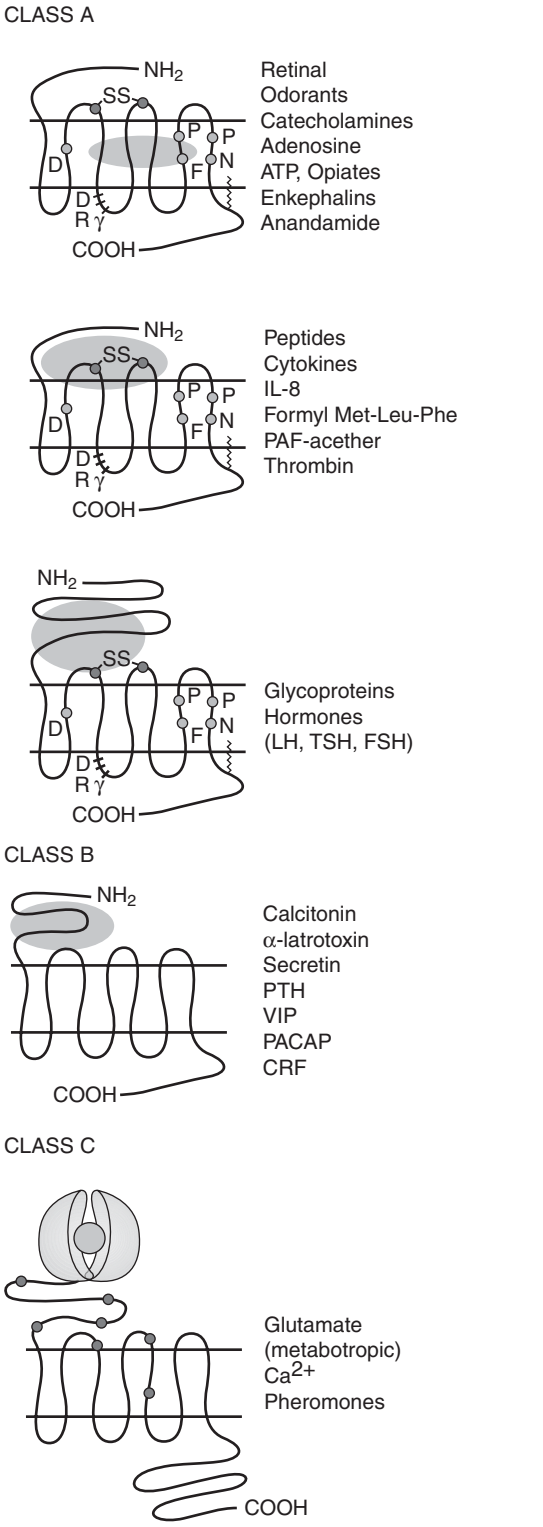

Figure 2-3. Examples of class A, B, and C GPCRs. The orange oval represents the ligand. These receptors can differ in amino acid sequence, in length of the N-terminal extracellular and C-terminal cytoplasmic domains, and in the receptor regions involved with ligand-receptor interactions. [Adapted with permission from Bockaert J, Pin JP (1999). Molecular tinkering of G protein-coupled receptors: An evolutionary success. Embo J 18:1725.]

and are divided into at least 15 groups.[2,55] Four of these groups contain receptors activated by hormones. These are the peptide receptor, hormone protein receptor, gonadotropin-releasing hormone (GnRH) receptor, and the thyrotropin-releasing hormone (TRH) and secretagogue receptor groups.[2]

The peptide receptor group includes the angiotensin, adrenocorticotropin hormone (ACTH)/melanocortin, oxytocin, somatostatin, and vasopressin receptors.[2] The hormone protein receptor group includes the receptors for glycoprotein hormones, including follicle-stimulating hormone (FSH), leutinizing hormone (LH), and thyrotropin (TSH) receptors.[2] These receptors have large extracellular N-terminal domains and ligand-binding sites that include the first and third extracellular loops (Figure 2-3).[1,2] There is also much similarity in amino acid sequence among these receptors (Figure 2-3).[1] The GnRH receptor group only contains the GnRH receptor.[2] The TRH and secretagogue receptor group includes the TRH receptor and the growth hormone secretagogue receptor.[2]

Class B GPCRs are structurally similar to members of the hormone protein receptor group (Figure 2-3).[1] However, unlike the glycoprotein hormone receptors class B GPCRs do not share similar amino acid sequences.[1] This family contains receptors for high-molecular-weight hormones, including calcitonin, glucagon, gastric inhibitory peptide, parathyroid hormone (PTH), and corticotrophin-releasing factor (CRF).[1,2,56]

Class C receptors have a very large extracellular domain with two lobes separated by a hinge region that closes on the ligand (Figure 2-3).[57] This region has also been called the "Venus's-flytrap" domain or module due to the trapping mechanism of the hinge region.[58] This family includes the calcium-sensing receptor (CASR).[1,2]

Class A Receptors That Transduce Hormone Action

THE PEPTIDE RECEPTOR GROUP

Adrenocorticotropin and Melanocortin-2 Receptors

It is important to note that a newly accepted name for the ACTH receptor is melanocortin-2 receptor (MC2R) because the ACTH receptor is one of five members of the melanocortin receptor family of GPCRs.[54] For the purpose of clarity, when discussing interactions between ACTH and its receptor the older name will be used for the remainder of this chapter. The ACTH receptor gene is located on the short arm of chromosome 18.[59] The ACTH receptor has a small extracellular and intracytoplasmic domain. Adrenocorticotropin-induced activation of ACTH receptor in the *zona fasciculata* and *zona reticularis* of the adrenal cortex stimulates $G\alpha_s$, resulting in increased intracellular cAMP levels that stimulate steroidogenesis by activating cAMP-dependent kinases.[60-62]

Hereditary isolated glucocorticoid deficiency, resistance to ACTH, and familial glucocorticoid deficiency (FGD) are the same names for an autosomal recessive syndrome that consists of glucocorticoid deficiency accompanied by normal mineralocorticoid secretion. FGD has been classified further as FGD types 1 and 2 and the triple A syndrome.[63] Patients with FGD type 1 are homozygous or compound heterozygous for point mutations, resulting in ACTH receptors with abnormal function.[63-69] In contrast, patients with FGD type 2 have ACTH resistance that is not caused by ACTH receptor mutations.[62,63,70] Triple A (Allgrove syndrome) is an autosomal recessive syndrome characterized by ACTH-resistant adrenal insufficiency, achalasia, and alacrima—which is also not caused by ACTH receptor gene mutations.[63,67,71]

Patients with FGD type 1 usually present during infancy or early childhood with hypoglycemia.[66,72-76] Less commonly, patients may present with a severe infection, frequent minor infections, or childhood asthma that resolves with treatment with physiologic doses of glucocorticoids.[63,66,72] Hyperpigmentation may be seen as early as the first month of life, but usually becomes apparent after the fourth month of life.[64-66,72-74,77] Neonates may also suffer from jaundice.[66,74,76,78] Tall stature accompanied by an advanced bone age, in spite of normal age of onset of puberty, appears to be common in children with FGD type 1.[63,66,69,72,73,77] Patients with FGD type 2 have normal heights.[63,79]

At presentation, plasma cortisol, androstenedione, and dihydroepiandrosterone levels are low or low normal—and plasma ACTH levels are elevated.[63,66,72-76] When supine, patients with FGD type 1 have renin and aldosterone levels that are near normal.[63,73,75,76] Histologically, the *zona fasciculata* and *zona reticularis* are atrophied with FGD.[72] However, demonstrating the lack of an essential role for ACTH in the embryologic development and maintenance of the *zona glomerulosa,* adrenal cortices in patients with all types of FGD contains *zona glomerulosa* cells.[63,71-73,77,80]

Abnormalities in ACTH receptor expression may be seen in other conditions. Evidence suggests that the ACTH receptor-$G\alpha_s$-adenylyl cyclase-cAMP cascade maintains differentiation of adrenocortical cells, and that impairment of this cascade leads to dedifferentiation and increased proliferation of adrenocortical cells.[81,82] Adrenocortical carcinomas from some patients have been found to have a loss of heterozygosity (LOH) for the ACTH receptor gene, resulting markedly in decreased ACTH receptor mRNA expression.[82] Growth of the tumors with LOH for the ACTH receptor gene also may be more aggressive than the other tumors. An activating mutation of G_{i2} that constitutively suppresses adenylyl cyclase activity has also been found in adrenocortical tumors.[81] Thus, decreased ACTH receptor activity may be associated with tumorigenesis.

Interestingly, many patients with ACTH-independent macronodular adrenal hyperplasia (AIMAH)—a cause of ACTH-independent Cushing's syndrome—exhibit increased glucocorticoid levels in response to non-corticotropin hormones that do not normally induce glucocorticoid release.[83-88] These hormones include gastric inhibitory peptide, exogenous arginine and lysine vasopressin, lutenizing hormone, human chorionic gonadotropin, angiotensin II, catecholamines, leptin, and

serotonin receptor agonists.[83-88] Increased expression of the receptors for these ligands in the abnormal adrenal glands has been implicated as a possible explanation for the abnormal induction of glucocorticoid release by these non-corticotropin ligands.[88] However, receptors for some of these ligands are expressed in normal adrenal glands.[88] Thus, the mechanism for this phenomenon remains to be fully elucidated.

Other Melanocortin Receptors

Murine studies reveal that melanocortin-3 receptor (MC3R), another of the five members of the melanocortin receptor family, regulates fat deposition.[54] The role of the MC3R in humans is less clear. Homozygosity for a pair of single-nucleotide polymorphisms of the MC3R gene that result in production of partially inactive MC3Rs was found to be associated with pediatric-onset obesity in Caucasian American and African American children.[89]

The melanocortin-4 receptor (MC4R) is another member of the melanocortin receptor family and plays a role in controlling appetite and weight.[90] The MC4R has baseline constitutive activity that can be inhibited by the inverse agonist agouti-related peptide (AgRP).[90,91] Activation of the MC4R by its natural agonist α-melanocyte stimulating hormone (α-MSH) produces anorexigenic effects.[90,92,93] Naturally occurring inactivating MC4R mutations have been identified in some individuals with hyperphagia, increased lean body mass, obesity, and hyperinsulinism due to insulin resistance and increased linear growth.[94-96]

Most of these obese individuals were heterozygous for the identified mutations, and an autosomal dominant mode of inheritance was identified in their blood relatives.[95,96] However, five obese children from a consanguineous kindred were found to be homozygous for an N62S missense mutation.[95] Family members heterozygous for the N62S mutation were noted to be nonobese. These MC4R mutations are thought to be the most common monogenic cause of human obesity. In one study, 5.8% of 500 probands with severe childhood obesity were found to be heterozygous or homozygous for MC4R mutations.[96] AgRP gene polymorphisms appear to be associated with anorexia nervosa.[97,98]

Very little is known about melanocortin-5 receptors (MC5Rs) in animals and humans. There is only weak evidence from a single linkage and association study of families in Quebec suggesting that MC5Rs may also play a role in regulating body weight and fat mass.[99]

Another member of the melanocortin receptor family, the melanocortin-1 receptor (MC1R), controls skin and hair pigmentation. Activation of MC1Rs in skin and hair follicle melanocytes with the pro-opiomelanocortin (POMC)-derived peptides α-melanocyte stimulating hormone (α-MSH) and ACTH leads to release of eumelanin, a brown-black pigment, from the melanocytes.[100,101] Inhibition of MC1R baseline constitutive activity by agouti protein leads to release of pheomelanin, a red-yellow pigment, from the melanocytes.[101]

Inactivating homozygous mutations of the POMC gene cause hypoadrenalism, red hair, fair skin, and early-onset obesity due to lack of ACTH production from the POMC precursor, lack of ACTH and α-MSH-induced melanocyte release of eumelanin resulting from activation of MC1Rs, and lack of α-MSH-induced anorectic effects resulting from activation of MC4Rs, respectively.[102] Heterozygosity for Arg236Gly and Tyr221Cys POMC gene mutations are associated with hyperphagia, early-onset obesity, and increased linear growth.[102,103] In one study, 5 out of 538 unrelated probands with severe early-onset obesity were found to be heterozygous for the Tyr221Cys POMC gene mutation.[103]

Vasopressin Receptors

Nephrogenic diabetes insipidus (NDI) occurs when the renal response to arginine vasopressin (AVP) is impaired. NDI is characterized by polydipsia and polyuria that is not responsive to vasopressin and vasopressin analogs.[104] X-linked NDI is caused by inactivating mutations of the V2 vasopressin receptor (AVPR2) gene located at Xq28.[105-108] An autosomal recessive variant of NDI is also caused by loss-of-function mutations in the gene for the aquaporin-2 AVP-sensitive water channel.[109,110]

More than 100 inactivating AVPR2 gene mutations have been identified that cause X-linked NDI.[104] Some of these mutations are complete gene deletions or mutations that cause abnormal mRNA splicing. Other mutations result in receptors with abnormal trafficking to the plasma membrane, ligand binding, or G_s activation.[104,111]

Gain-of-function mutations in the V2 vasopressin receptor have also been reported.[112] DNA sequencing of two patient's V2R gene identified missense mutations in both, with resultant changes in codon 137 from arginine to cysteine or leucine. These mutations resulted in constitutive activation of the receptor and a syndrome of inappropriate antidiuretic hormone secretion (SIADH)-like clinical picture, which was termed *nephrogenic syndrome of inappropriate antidiuresis.*[112]

THE HORMONE PROTEIN RECEPTOR GROUP

The glycoprotein hormones include TSH, FSH, LH, and HCG. These hormones are composed of similar α subunits that dimerize with hormone-specific β subunits. TSH, FSH, and LH bind to the extracellular N-terminal domain of the TSH, FSH, and LH receptors, respectively.[1,2,113,114] The effects of hCG are mediated by the LH receptor.[115]

Glycoprotein hormone receptors have a large (350–400 residues) extracellular N-terminal domain, also known as the ectodomain, that participates in ligand binding (Figure 2-3).[3,115] The ectodomain includes leucine-rich repeats that are highly conserved among the glycoprotein hormone receptors.[3,115] There is 39% to 46% similarity of the ectodomain and 68% to 72% similarity of the transmembrane or serpentine domain among the three glycoprotein hormone receptors.[3]

Activated glycoprotein hormone receptors increase G_s coupling to adenylyl cyclase, leading to increased intracellular cAMP levels and protein kinase A (PKA) activation.[115] Mutations leading to endocrine dysfunction have been reported for each of the glycoprotein hormone receptors.

LH Receptors

Both inactivating and activating mutations of the LH receptor have been found in humans.[115] The LH receptor gene is located in chromosome 2 p21 and consists of 11 exons.[116,117] Exon 1 encodes a peptide that directs the LH receptor to the plasma membrane.[115] Exons 2 through 10 encode the ectodomain.[115] The last exon encodes the transmembrane domains that are also known as the serpentine regions.[3,115,116] Single nonsense mutations, amino acid changes, and partial gene deletions have been found that lead to expression of LH receptors with decreased activity.[115] Single–amino-acid changes have also been found that lead to activation of G_s in the absence of ligand binding.[115]

Inactivating mutations of the LH receptor gene require homozygosity or compound heterozygosity to alter endocrine function because the presence of one normal receptor allele in the heterozygous state can compensate for the decreased function of a mutated allele.[115] In contrast, activating mutations of the LH receptor gene cause endocrine disorders in the heterozygous state.[115]

In the fetus, LH receptors are primarily activated by hCG.[115] Leydig cells begin to express LH receptors shortly after testicular differentiation at 8 weeks of gestation.[115] Thereafter, androgen production due to activation of these receptors by hCG plays an important role in the development of male genitalia and testicular descent.[115] Thus, male infants with inactivating mutations of the LH receptor may present with abnormally developed genitalia—including micropenis, cryptorchidism, and intersex..[115]

Males with mutations that completely inactivate the LH receptor may present with male pseudohermaphroditism accompanied by failure of fetal testicular Leydig cell differentiation. This phenotype, which is known as type I Leydig cell hypoplasia, includes female external genitalia with a blind-ending vagina, absence of Müllerian derivatives, and inguinal testes with absent or immature Leydig cells.[118-125] In addition, patients have elevated serum LH levels, normal serum FSH levels, and decreased serum testosterone levels that do not increase in response to HCG administration.[118-125] Mutations that lead to this phenotype include a nonsense mutation (Arg545Stop) that results in a receptor that is missing TM4-7, an Ala593Pro change, and a TM7 deletion (ΔLeu608, Val609) that decreases cell surface expression of the LH receptor.[123,124,126] These mutant receptors are unable to couple to G_s.[123,124,126]

Males with mutations that do not completely inactivate the LH receptor present with type II Leydig cell hypoplasia, which is characterized by a small phallus and decreased virilization.[122] A mutation that leads to this phenotype includes the insertion of a charged lysine at position 625 of TM7 in place of hydrophobic isoleucine that disrupts signal transduction.[127] Another mutation (Ser616Tyr, found in patients with mild Leydig cell hypoplasia) is associated with decreased cell surface expression of the LH receptor.[124,127] Other deletion and nonsense mutations have also been found to cause mild Leydig cell hypoplasia.[115]

Males with inactivating mutations of the LH receptor may also present with a phenotype intermediate in severity between type I and type II Leydig cell hypoplasia. A compound heterozygote patient with Ser616Tyr on one allele and an inactivating deletion (Δexon 8) on the other allele presented with Leydig cell hypoplasia, hypoplastic phallus, and hypospadias.[128] The Cys131Arg mutation has also been found in patients with Leydig cell hypoplasia, small phallus, and hypospadias.[129] This mutation is located in the leucine-rich repeat segment of the LH receptor extracellular domain and interferes with high-affinity ligand binding.[129]

Deletion of exon 10 of the LH receptor gene results in an LH receptor that binds LH and HCG normally.[130] However, although there is normal intracellular signaling in response to binding of the mutant receptor by HCG there is impaired intracellular signaling in response to binding of the mutant receptor by LH.[130] Because HCG is the main in utero LH receptor-activating hormone, and second-messenger response of the mutant receptors to HCG is not impaired, it is not surprising that a male patient found to be homozygous for the mutation was born with normal male genitalia.[54,130] Pubertal progression and later gonadal function, however, are dependent on LH activation of the LH receptor.[54,130]

Because deletion of exon 10 of the LH receptor gene results in a mutant LH receptor with diminished intracellular signaling in response to LH, it is also not surprising that the patient homozygous for this mutation was found to have delayed pubertal development, small testes, and hypergonadotropic hypogonadism when evaluated at the age of 18 years.[130] Prolonged HCG therapy resulted in normalization of testicular testosterone production, increased testicular size, and the appearance of spermatozoa in semen.[130]

Males with mutations that constitutively activate LH receptors present with male-limited precocious puberty (MLPP), also known as testotoxicosis—which may be familial or sporadic.[125,131,132] Boys with this condition present with GnRH-independent precocious puberty before the age of 4 years when the Asp578Gly is present, and as early as the first year of life when the Asp578Tyr mutation is present.[115,133-135] Patients with this condition may have an enlarged phallus at birth.[133]

During the first five years of life, patients with MLPP have very low LH and FSH levels and testosterone levels in pubertal ranges.[136] During adolescence and adult life, testosterone levels do not increase above age-appropriate concentrations and gonadotropin levels normalize.[115,136-138] Thus, adolescents and adults with MLPP do not usually manifest signs of androgen excess (such as hirsutism or severe acne).[115,136] Most mutations that cause MLPP are located in TM6 and i3, regions that participate in receptor-G protein coupling.[115] Somatic activating mutations cause sporadic Leydig cell adenomas.[90]

In contrast to males, the LH receptor is not known to play an important role in females until puberty. During puberty, activation of LH receptors on ovarian theca cells leads to the production of androgens that are converted to estrogens by aromatase in granulose cells.[115] LH, along with FSH, also plays a role in inducing the differentiation of follicles into Graaffian follicles and triggers ovulation and release of the oocyte.[115]

Females with inactivating mutations of the LH receptor may be asymptomatic or present with primary

amenorrhea.[115] Females with complete inactivating LH receptor mutations may present with primary amenorrhea, inability to ovulate, and decreased estrogen and progesterone levels accompanied by elevated LH and FSH levels.[124,139] Affected individuals may have signs of low estrogen levels, including a hypoplastic uterus, a thin-walled vagina, decreased vaginal secretions, and decreased bone mass.[124,139]

FSH Receptors

Inactivating and activating FSH receptor mutations have also been described.[140] However, FSH receptor mutations are considerably less common than LH receptor mutations.[140] The FSH receptor gene is located in chromosome 2 p21 and contains 10 exons.[141] The last exon of the FSH receptor gene encodes the transmembrane and intracellular domains.[142]

FSH is required in females for normal follicle maturation and the regulation of estrogen production by ovarian granulosa cells.[140,143,144] FSH is required in pubertal males for Sertoli cell proliferation, testicular growth, and the maintenance of spermatogenesis.[140,145]

The first inactivating mutation of the FSH receptor was found in Finnish females with autosomal recessive inherited hypergonadotropic ovarian dysgenesis (ODG). ODG is characterized by primary amenorrhea, infertility, and streak or hypoplastic ovaries in the presence of a 46XX karyotype and elevated gonadotropin levels.[146] Twenty-two out of 75 Finnish patients with ODG were found to be homozygous for a C566T point mutation in exon 7 of the FSH receptor gene.[147] This mutation leads to the production of an FSH receptor with an Ala189Val substitution in an area of the extracellular ligand-binding domain that is thought to play a role in turnover of the receptor or in directing the receptor to the plasma membrane.[147] The mutated receptor demonstrates normal ligand-binding affinity but has decreased binding capacity and impaired signal transduction in transfected MSC-1 cells.[147] Males homozygous for this mutation have variable impairment of spermatogenesis and low to low-normal testicular volume but are not azoospermic and can be fertile.[148] The C556T point mutation is uncommon outside Finland, where the carrier frequency is 0.96%.[149]

Compound heterozygosity for mutations that cause partial loss of FSH receptor function may cause endocrine dysfunction in women.[150,151] Women may present with infertility, secondary amenorrhea, osteoporosis, and a history of delayed onset of puberty accompanied by elevated LH and FSH, low-normal plasma estradiol, low plasma inhibin B levels, slightly enlarged ovaries with immature follicles, and a small uterus.[150] This may be caused by FSH receptor gene mutations that result in an Ile160Thr mutation in the extracellular domain that impairs cell surface expression, and an Arg573Cys mutation in e3 that interferes with signal transduction.[150] Other women present with primary amenorrhea, and very elevated gonadotropin, low plasma estradiol and inhibin B levels, normal-size ovaries with immature follicles, and a normal-size uterus.[151] This condition is associated with an Asp224Val substitution in the extracellular domain leading to impaired cells surface expression, and a Leu601Val substitution in e3 impairing signal transduction.[151]

An activating mutation of the FSH receptor has also been described. Surprisingly, a hypophysectomized male was found to be fertile and to have serum testosterone levels above 4.9 nmol/l and normal testis volume in spite of undetectable gonadotropin levels.[152] This patient was found to be heterozygote for an A1700G mutation in exon 10 of the FSH receptor gene that resulted in an Asp567Gly substitution in an area of the third intracytoplasmatic loop that is highly conserved among FSH, LH, and TSH receptors.[152-154] The same substitution in corresponding areas of the LH and TSH receptors results in constitutively active receptors, and is found in MLPP and thyroid adenomas, respectively.[152-154]

TSH Receptors

The TSH receptor gene is located on chromosome 14 and contains 10 exons, with the first nine exons encoding the large extracellular domain and the tenth exon coding the remainder of the receptor.[155-158] At low extracellular TSH concentrations, TSH receptor activation leads to stimulation of $G\alpha_s$—which activates adenylyl cyclase, resulting in increased intracellular cAMP levels.[159,160] At higher extracellular TSH concentrations, activation of the TSH receptor also stimulates the G_q and G_{11} proteins—activating phospholipase C and resulting in the production of diacylglycerol and inositol phosphate.[160]

TSH receptors differ from the other glycoprotein hormone receptors in that they exist in two equally active forms.[161,162] These are the single-chain and two-subunit forms of the TSH receptor (Figure 2-4). The single-chain form of the TSH receptor is made up of three contiguous subunits: the A subunit, C peptide, and B subunit.[162-164] The A subunit begins at the N-terminal of the extracellular domain and contains most of the extracellular domain.[162-164] The C peptide is connected to the C-terminal of the A subunit and continues the extracellular domain.[162-164] The C peptide contains a 50-amino-acid sequence that is only found in TSH receptors.[162-164] The B subunit is connected to the C-terminal of the C peptide and contains the TMs and the C-terminal cytoplasmic portion of the receptor.[162-164] The two-subunit form of the receptor is missing the C-peptide, which is cleaved from the protein during intracellular processing and consists of the A and B subunits attached by disulfide bonds.[165-168] It is surprising that both receptor forms are activated equally by TSH because the C-peptide and nearby regions of the A and B subunits participate in signal transduction.[161-163,169,170]

Spontaneous single-allele mutations of the TSH receptor gene leading to replacement of Ser-281 (near the C-terminal of the A subunit, with Ile, Thr, or Asn) result in a constitutively active TSH receptor that may cause intrauterine or congenital hyperthyroidism, or toxic adenomas.[164,171-173] Activating somatic mutations that cause toxic adenomas have also been found in different transmembrane domains of the TSH receptor.[174-181] More specifically, clusters of mutations are located in the i3 and TM6 regions—found to be involved with signal transduction in all glycoprotein hormone receptors.[174-176,178-180]

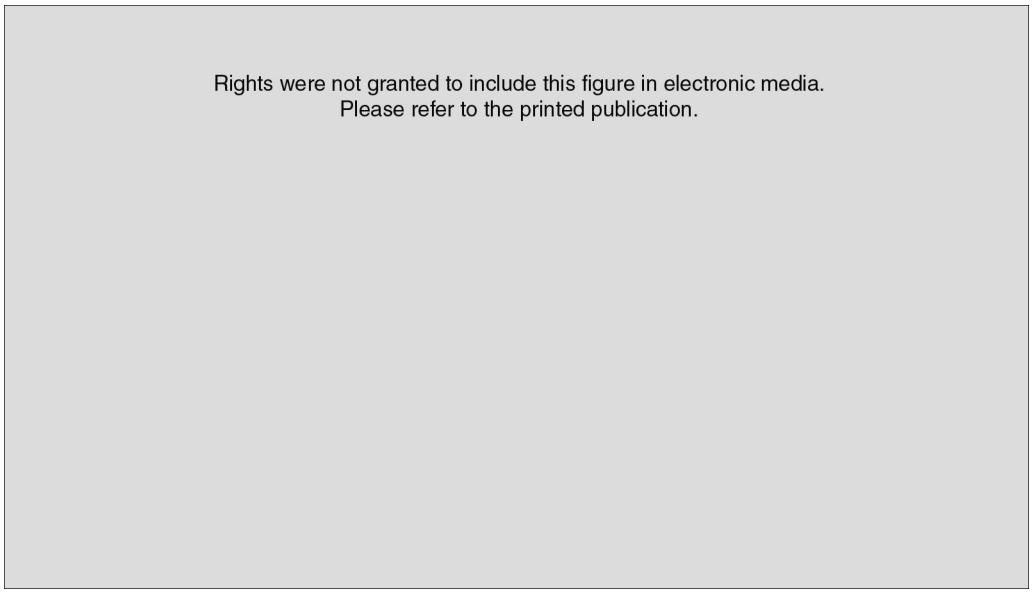

Figure 2-4. The TSH receptor. There are two forms of TSH receptors. The single-chain form is made up of an A subunit, C peptide, and B subunit. Post-translational cleavage of the C peptide from the single chain form results in the two-subunit form. This form consists of the A subunit joined to the B subunit by disulfide bonds between the C-terminal cysteine residues of the A subunit and the N-terminal cysteine residues of the B subunit. Copyright 1998, The Endocrine Society.]

The prevalence of activating mutations of the TSH receptor in toxic adenomas has been estimated to range from 2.5% in Japan to 86% in Brazil.[177,178,180,182-185]

Activating somatic mutations of the TSH receptor have also been found in multinodular goiters.[186] Interestingly, different activating mutations have been found in separate nodules in the same individual.[186] Some well-differentiated thyroid carcinomas have activating mutations of the TSH receptor.[187-189] Activating mutations of the $G\alpha_s$ gene have also been found in toxic adenomas and differentiated thyroid carcinomas.[81,190,191] Activating germ line mutations of the TSH receptor can cause sporadic or autosomal dominant inherited nonautoimmune hyperthyroidism that presents in utero, during infancy, or during childhood.[173,192-200] These mutations have been found in the N-terminal extracellular and transmembrane domains.[173,192-200]

Patients with one allele producing constitutively active TSH receptors and one normal allele may present with hyperthyroidism.[162] In contrast, homozygosity or compound heterozygosity for mutations resulting in TSH receptors with reduced function is required to cause clinically apparent thyroid disease.[162] Most known loss-of-function TSH receptor mutations are located in the N-terminal extracellular domain.[201] A spontaneous Asp410Asn substitution, near the carboxy-terminus of the C peptide, results in a TSH receptor with normal ligand binding affinity and impaired $G\alpha_s$-mediated signal transduction.[202] Patients homozygous for this type of mutation present with compensated hypothyroidism.[202]

Patients homozygous or compound heterozygous for loss-of-function mutations of the TSH receptor present with the syndrome of resistance to TSH (RTSH). Loss-of-function mutations of the TSH receptor that cause RTSH have been identified in the N-terminal extracellular domain, TM4, i2, e1, and e3.[203] Clinical severity of RTSH may range from a euthyroid state accompanied by elevated TSH levels (fully compensated RTSH), to mild hypothyroidism unaccompanied by a goiter (partially compensated hypothyroidism), to congenital thyroid hypoplasia accompanied by profound hypothyroidism (uncompensated RTSH).[62,202,204-208] In patients with uncompensated RTSH, a small bilobar thyroid gland is located at the normal site.[62] Because the sodium-iodide symporter is TSH dependent,[131] iodine and (99m) Pertechnetate uptakes are diminished or absent in patients with RTSH.[62,209] Some families have been found to have an autosomal-dominant form of RTSH that is not caused by a mutation of the TSH receptor.[210,211]

HCG and TSH Receptors During Pregnancy

Due to its structural similarity with TSH, HCG can activate the TSH receptor.[212] During pregnancy, HCG activation of TSH receptors leads to elevation in thyroid hormones seen after the ninth week of gestation—and decreases in TSH levels between the ninth and twelfth weeks of gestation.[213] This phenomenon does not usually result in maternal hyperthyroidism (gestational thyrotoxicosis).[213,214] However, when HCG levels are abnormally elevated due to a molar pregnancy or choriocarcinoma hyperthyroidism may occur.[215-219]

A mother and daughter were identified with recurrent gestational hyperthyroidism and normal serum HCG levels.[220] These individuals were found to be heterozygous for a point mutation in the TSH receptor gene, resulting in a Lys183Arg substitution in the extracellular domain of the receptor. It is believed that this substitution increases activation of the receptor by HCG, causing gestational hyperthyroidism.

HCG and FSH Receptors During Pregnancy

Promiscuous activation of wild-type FSH receptors by excessively elevated HCG and TSH levels during pregnancy, and promiscuous activation of mutated FSH receptors by normal levels of HCG and TSH during pregnancy, have been found to cause spontaneous ovarian hyperstimulation syndrome.[221-224] Ovarian hyperstimulation syndrome may occur spontaneously or iatrogenically as a result of ovarian stimulation treatment. The ovaries enlarge as multiple ovarian cysts form in association with the extravascular fluid shifts thought to result from increased mesothelial capillary permeability.

The extravascular fluid shifts may cause life-threatening pleural and/or pericardial effusions, and/or ascites.[225] Surprisingly, the heterozygous promiscuity-inducing FSH receptor gene mutations alter the serpentine domain rather than the ectodomain.[221-224] This finding reveals that transmembrane domain plays a role in conferring FSH receptor specificity. Interestingly, these mutations also cause the FSH receptor to be constitutively active.[3]

THE GONADOTROPIN-RELEASING HORMONE RECEPTOR GROUP

Gonadotropin-Releasing Hormone Receptors

The GnRH receptor gene is located on 4q13 and includes three exons.[226,227] Unlike glycoprotein hormone receptors, GnRH receptors lack an intracellular C-terminal domain.[228,229] The GnRH receptor also differs from most endocrine GPCRs in that its actions are mediated by G_q/G_{11} stimulation of phospholipase C activity.[230] Phospholipase C cleaves phosphatidylinositol-4,5-diphosphate (PIP2) to inositol 1,4,5-triphosphate (IP3) and diacylglcerol, leading to increased protein kinase C (PKC) activity.[231,232]

Some patients with IHH (idiopathic) have been found to be homozygous or compound heterozygous for loss-of-function mutations in the gene for the GnRH receptor.[233-235] Unlike patients with Kallman's syndrome, they have a normal sense of smell.[233-235] GnRH receptor mutations that cause IHH result in decreased binding of GnRH and/or impaired GnRH receptor signal transduction, or decreased cell GnRH receptor cell membrane expression due to misrouting of GnRH receptor oligomers from the endoplasmic reticulum.[32,33,233-235]

Female patients with mutations that partially compromise GnRH receptor function may present with primary amenorrhea and infertility associated with a normal or small uterus and small ovaries with immature follicles.[233,236] Males with the same mutations may present with incomplete hypogonadotropic hypogonadism (characterized by a delayed and incomplete puberty) or with complete hypogonadotropic hypogonadism, characterized by absent puberty.[233,236]

Some patients with IHH due to mutated GnRH receptors have partial or normal gonadotropin responses to exogenous GnRH.[233,234] However, decreased amplitude in the pulsatile LH secretion can be observed in these patients.[233] Females with a partial or normal gonadotropin response to exogenous GnRH are more likely than nonresponders to become fertile in response to pulsatile exogenous GnRH.[233,237]

THE THYROTROPIN-RELEASING HORMONE AND SECRETAGOGUE RECEPTOR GROUP

Thyrotropin-Releasing Hormone Receptors

Like the GnRH receptor, TRH receptor activation leads to increased phospholipase C activity.[238] To date, only inactivating mutations that cause endocrine dysfunction have been reported for the TRH receptor. One patient has been identified with central hypothyroidism due to mutated TRH receptors.[239] He presented during the ninth year of life with short stature (–2.6 SD) accompanied by a delayed bone age (–4.1 SD), low plasma thyroxine level, and normal plasma TSH level. Exogenous TRH did not induce an increase in plasma TSH and prolactin levels. He was found to be compound heterozygous for TRH receptor gene mutations, resulting in receptors with decreased binding.

OTHER CLASS A RECEPTORS THAT TRANSDUCE HORMONE ACTION

Free Fatty Acid Receptor 1

At the time of discovery of a new GPCR, the ligand for the newly discovered receptor is often unknown. Thus, until a specific ligand is discovered these GPCRs are known as orphan receptors. According to the Human Genome Organization (HUGO) Gene Nomenclature Committee, these G-protein–coupled orphan receptors should be named alphanumerically GPR followed by a number until their ligand is known. Once a specific ligand is identified, a more specific name is given the receptor.

The ligands for GPR40 were unknown when the receptor was first discovered. The HUGO Gene Nomenclature Committee changed the name of the receptor to free fatty acid receptor 1 (FFAR1) when the ligands were identified as medium- and long-chain fatty acids. With rare exceptions that are clearly identified, HUGO Gene Nomenclature Committee recommendations are followed in this chapter (see *http://www.gene.ucl.ac.uk/nomenclature/index.html* for more information on receptor nomenclature).

FFAR1 is one of several GRCRs for lipid mediators. Lipid mediators are intercellular lipid messengers that include sphingosine 1-phosphate, sphingosylphosphorylcholine, dioleoyphosphatidic acid, lysophosphatidic acid, eicosatetraenoic acid, bile acids, and free fatty acids.[55] FFAR1 is activated by medium- and long-chain fatty acids, whereas FFAR2 (formerly known as GPR43) and FFAR3 (formerly known as GPR 41) are activated by shorter-chain fatty acids.[55] There is now evidence that FFAR1 activation by medium- and long-chain fatty acids has endocrine implication. FFAR1 is expressed in human pancreatic β-islet cells.[240]

Fatty-acid–induced stimulation of FFAR1 in β-islet cells leads to activation of the $G\alpha_q$-phospholipase C second-messenger pathway, which in turn leads to release of

calcium from the endoplasmic reticulum that augments insulin-mediated increases in intracellular calcium concentrations due to glucose-induced activation of voltage-gated calcium channels.[241-244] Because an increased intracellular calcium concentration induces insulin release, FFAR1-mediated augmentation of glucose-mediated increases in the intracellular calcium concentration leads to amplification of glucose-stimulated insulin release.[241-244]

Wild-type mice placed on an 8-week high-fat diet develop glucose intolerance, insulin resistance, hypertriglyceridemia, and hepatic steatosis—whereas FFAR1 knockout mice on the same diet do not develop these conditions.[245] The clinical relevance for humans is yet unclear. However, an Arg211His polymorphism in the FFAR1 gene may explain some of the variation in insulin secretory capacity found in Japanese men. Arg/Arg homozygotes had lower serum insulin levels, homeostasis model of insulin resistance, and homeostasis model of beta-cell function than His/His homozygotes.[246]

GPR54

Separate groups of investigators from France and the United States simultaneously found homozygous inactivating GPR54 mutations that cause IHH in consanguineous French and Saudi Arabian kindreds, respectively.[247-249] The United States group also found an African American patient with IHH due to compound heterozygous inactivating GPR54 mutations.[248] Since then, a patient with a Jamaican father and a Turkish-Cypriot mother, and with cryptorchidism and micropenis at birth and undetectable LH and FSH levels at 2 months of age, was found to have compound heterozygous GPR54 mutations.[250]

Unlike patients with Kallmann syndrome, these patients' sense of smell is intact. Furthermore, in contrast to patients with isolated hypogonadotropic hypogonadism due to GnRH mutations patients with IHH due to GPR54 mutations also exhibit increases in gonadotropin levels in response to exogenous GnRH. Thus, inactivating homozygous and compound heterozygous GPR54 mutations are a rare cause of normosmic IHH.[249,250]

Ligands for GPR54 derive from a single precursor protein, kisspeptin-1.[251,252] The longest derivative protein that acts as a ligand for GPR54 is metastin, which is named metastin because metastin is a metastasis suppressor gene in melanoma cells.[251] Metastin consists of kisspeptin-1 69-121.[251,252] However, shorter C-terminal peptides derived from kisspeptin-1 bind and activate GPR54.[251] Administration of metastin to adult male volunteers increases LH, FSH, and testosterone levels.[253] Recent animal research suggests that metasin and GPR54 play a role in the timing of onset of puberty, in modulating sex steroid feedback on GnRH release from the hypothalamus, and in the timing of onset of puberty.[249]

Orexin Receptors

Orexins act on orexin receptors, located predominantly in the hypothalamus, to control food intake and play a role in the regulation of sleep/wakefulness.[254-256] There are two types of orexin receptors, the orexin-1 and the orexin 2 receptors.[256] There are also two types of orexins, orexin A and orexin B, formed from the precursor peptide preproorexin.[256] Orexins are also known as hypocretins, and orexin A is synonymous with hypocretin-1 and orexin B with hypocretin-2.[255,256] Orexin A acts on orexin-1 and orexin-2 receptors, whereas orexin B only acts on orexin-2 receptors.[254,257,258]

Like most class A GPCRs, orexin receptors couple with $G_{q/11}$ and G_i/G_o to activate phospholipase C and inactivate adenylyl cyclase, respectively.[256,259-261] Surprisingly, however, recent evidence suggests that orexin receptors also couple with G_s—which increases adenylyl cyclase activity.[261] Orexins increase food intake and duration of wakefulness.[254,255,262] Orexin A and activation of the orexin-1 receptor have greater orexigenic effects than orexin B and activation of the orexin-2 receptor.[263] The orexin-2 receptor mediates the arousal effect of orexins.[263] Most patients with idiopathic narcolepsy have diminished levels of orexins in cerebral spinal fluid and lack orexin-containing neurons.[255,264-267]

Ghrelin Receptors

Another class A receptor that transduces hormone action is the ghrelin receptor. The receptor is also known as the growth hormone secretagogue receptor type 1a because the receptor is also activated by a family of synthetic growth hormone secretagogues.[90,263] Ghrelin is a product of post-translational modification of the ghrelin gene product proghrelin.[268] Ghrelin is mainly produced in the stomach.[269,270] Ghrelin activation of ghrelin receptors located in the hypothalamus and pituitary somatotrophs results in growth hormone secretion.[271] The ghrelin receptor also has an orexigenic role.

Plasma ghrelin levels are elevated just prior to eating, and decrease rapidly after eating.[272,273] In addition, intravenous administration of ghrelin to humans increases appetite and food intake.[274] Plasma ghrelin levels are elevated in individuals with Prader Willi syndrome.[275] Thus, hyperphagia in patients with Prader Willi syndrome may be due at least in part to overactivation of ghrelin receptors by ghrelin. Screening of 184 extremely obese children and adolescents for mutations of the ghrelin receptor gene failed to identify a single mutation likely to cause obesity.[276]

Short individuals in two unrelated Moroccan kindreds were found to have a C to A transversion at position 611 in the first exon of the ghrelin receptor gene.[277] This transversion results in replacement of the apolar and neutral amino acid alanine at position 204 of the receptor by the polar and charged amino acid glutamate. This mutation interferes with normal constitutive activity of the receptor, and decreases cell membrane expression of the receptor. Receptor activation by ghrelin, however, is preserved. Two-thirds of individuals in the kindreds heterozygous for the mutation had height greater than or equal to 2 standard deviations below the mean. One heterozygous individual's height was 3.7 standard deviations below the mean. Prior to onset of growth hormone therapy, the only individual in the kindreds homozygous for the mutation had a height 3.7 standard deviations below the mean. Whereas the patient homozygous for

the mutation became overweight during puberty, the weight of the patients heterozygous for the mutation varied from underweight to overweight.

Another product of post-translational modification of proghrelin, obestatin, appears to play a role in controlling appetite and weight.[268] Activation of the obestatin receptor, previously known as GPR39, in rats results in decreased food intake and weight.

Melanin-Concentrating Hormone Receptors

Formerly known as SLC-1 or GPR24, the type 1 melanin-concentrating hormone (MCH) receptor (MCHR1)—and the more recently discovered type 2 MCH receptor (MCHR2), formerly known as SLT or GPR145—may play a role in regulating feeding and energy metabolism in humans.[278-281] When activated by MCH, MCHR1 couples with $G_{q/11}$ and $G_{i/o}$ to increase phospholipase C activity and inhibit adenylyl cyclase activity, respectively.[278,279,282] When activated by MCH, MCHR2 couples with $G_{q/11}$ to increase phospholipase C activity.[280,281]

Studies in rodents reveal that MCH is an orexigenic hormone, and treatment of rodents with MCHR1 antagonists decreases food intake, weight, and body fat.[278,283,284] Little is known about the role of MCHR2 in animals, and both receptors in humans. Analysis of the MCHR1 gene in more than 4,000 obese German, Danish, French, and American children and adolescents revealed several single-nucleotide polymorphisms and gene variations in the German children and adolescents that may be associated with obesity.[285] Another study of 106 American subjects with early-onset obesity failed to definitively identify MCHR1 and MCHR2 mutations as a cause of obesity.[286]

Class B Receptors That Transduce Hormone Action

GROWTH-HORMONE–RELEASING HORMONE RECEPTOR

The growth-hormone–releasing (GHRH) receptor gene is located at 7p14.[287] GHRH receptors interact with G_s to stimulate adenylyl cyclase, resulting in increased intracellular cAMP levels that lead to somatotroph proliferation and growth hormone secretion.[288] Thus, it is not surprising that activating mutations in $G\alpha_s$ leading to constitutive activation of adenylyl cyclase have been found in some growth-hormone–secreting pituitary adenomas in humans.[289]

Some patients with isolated growth hormone deficiency have been found to be homozygous or compound heterozygous for inactivating mutations in the GHRH receptor gene.[288] The same mutation was found in three apparently unrelated consanguineous kindreds from India, Pakistan, and Sri Lanka.[287,290,291] A different mutation has been identified in a Brazilian kindred.[288] Both mutations result in the production of markedly truncated proteins with no receptor activity.[288,291] In another family, two sibling with isolated growth hormone deficiency were found to be compound heterozygous for inactivating GHRH receptor gene mutations.[292]

Individuals in these kindreds homozygous or compound heterozygous for inactivating GHRH receptor gene mutations experienced severe postnatal growth failure that resulted in proportionate short stature.[287,288,291,292] Males have high-pitched voices and moderately delayed puberty.[287,288,291] Unlike infants with complete growth hormone deficiency, they do not have frontal bossing, microphallus, or hypoglycemia.[287,291,292] Their bone age was delayed with respect to chronologic age but advanced with respect to height age.[291] Some patients were found to have pituitary hypoplasia.[287,291] Growth velocity increased with exogenous growth hormone therapy.[287,288,291,292]

GASTRIC INHIBITORY POLYPEPTIDE RECEPTORS

The gastric inhibitory peptide receptor (GIPR) gene is located on the long arm of chromosome 19.[293] Two functional isoforms exist in humans due to alternate splicing.[294] GIPR activation induces $G\alpha_s$ activation of adenylyl cyclase.[294-296] Gastric inhibitory polypeptide (GIP) is also known as glucose-dependent insulinotropic polypeptide and is released by K cells in the small intestine in response to food. GIP has numerous physiologic actions, including stimulation of glucagon, somatostatin, and insulin release by pancreatic islet cells.[297,298] GIP does not normally induce cortisol release from adrenocortical cells.[299,300]

Circulating cortisol levels in patients with food-dependent or GIP-dependent Cushing's syndrome rise abnormally in response to food intake.[83,84] These patients may have adrenal adenomas or nodular bilateral adrenal hyperplasia that overexpress GIPRs that abnormally stimulate cortisol secretion when activated.[299,301] Thus, in these patients postprandial GIP release leads to activation of these abnormally expressed and functioning adrenal GIPRs—resulting in excessive adrenal cortisol secretion.[299,300]

PARATHYROID HORMONE AND PARATHYROID-HORMONE–RELATED PEPTIDE RECEPTORS

Two types of PTH receptors have been identified. The type 1 PTH receptor (PTHR1) is activated by PTH and parathyroid-hormone–related peptide (PTHrP) and mediates PTH effects in bone and kidney.[302] In spite of 51% homology to the PTHR1, the type 2 PTH receptor (PTHR2) is only activated by PTH.[302-305] The PTHR2 is expressed in the brain and pancreas and its function is largely unknown.[302,303]

The PTHR1 has a large amino-terminal extracellular domain containing six conserved cysteine residues.[302] Ligand binding induces the PTHR1 to interact with G_s and G_q proteins, leading to activation of the adenylyl cyclase/protein kinase A and phospholipase C/protein kinase C second-messenger pathways, respectively.[306-311] Interestingly, mutations in i2 interfere with coupling of the PTHR1 to G_q without interfering with coupling to G_s—whereas mutations in i3 disrupt coupling of the receptor to both G proteins.[312,313]

Loss-of-function PTHR1 gene mutations cause Blomstrand's chondrodysplasia.[302] This lethal disorder is

characterized by accelerated chondrocyte differentiation, resulting in short-limbed dwarfism, mandibular hypoplasia, lack of breast and nipple development, and severely impacted teeth.[302,314] One patient with this rare condition was found to be homozygous for a point mutation that resulted in a Pro132Leu substitution in the N-terminal domain that interferes with ligand binding.[315,316] Another patient was found to be homozygous for a frame-shift mutation that results in a truncated receptor lacking TM5-7, and contiguous intracellular and extracellular domains.[317]

A third patient was found to have a maternally inherited mutation that altered splicing of maternal mRNA, resulting in a PTHR1 with a deletion of residues 373 through 383 in TM5 (which also interferes with ligand binding).[318] In spite of heterozygosity for the mutation, the patient was unable to produce normal PTHR1s because for unknown reasons the paternal allele, was not expressed.[318] Heterozygosity for an Arg150Cys PTHR1 gene mutation was found in two out of six patients with enchondromatosis.[319] Enchondromatosis is an autosomal-dominant condition characterized by benign cartilage tumors and increased risk for the development of osteosarcomas.[14]

Some cases of Jansen's metaphyseal chondrodysplasia have been found to be caused by constitutively activating mutations of the PTHR1 gene.[320-322] This autosomal-dominant disorder is characterized by short-limbed dwarfism due to impaired terminal chondrocyte differentiation and delayed mineralization accompanied by hypercalcemia.[320,321] Interestingly, constitutive activation appears to result predominantly in excessive $G\alpha_s$ activity because adenylyl cyclase activity is increased and PLC activity is unchanged in COS-7 cells expressing mutated receptors.[320-322]

OTHER CLASS B RECEPTORS THAT TRANSDUCE HORMONE ACTION

Other class B receptors that transduce hormone action include glucagon-like peptide-1, glucagon, calcitonin, and corticotrophin-releasing factor receptors.[323] Class B receptors usually couple with heterotrimeric G_s proteins, leading to activation of adenylyl cyclase—which in turn leads to elevated intracellular cAMP levels.[323,324] (See Chapter 10 for discussion of the role of GLP1 in promoting insulin secretion and the use of GLP1 analogues or inhibitors of GLP1 breakdown in therapy.)

Class C Receptors That Transduce Hormone Action

CALCIUM-SENSING RECEPTORS

The calcium-sensing receptor (CaSR) is located on the long arm of chromosome 3 (3q21.1).[325] The CaSR has a large amino-terminal domain that contains nine potential glycosylation sites.[326] Binding of ionized calcium to the CaSR leads to activation of phospholipase C, presumably via activation of a G_q protein.[326,327]

The CaSR is an integral component of a feedback system that utilizes parathyroid hormone and renal tubular calcium reabsorption to keep the serum concentrations of ionized calcium in a narrow physiologic range.[328] Increased extracellular ionized calcium concentrations activate CaSRs in parathyroid chief and renal tubular epithelial cells, leading to decreased PTH release and renal tubular calcium reabsorption.[326,329] When ionized calcium concentrations fall, CaSR activation decreases—leading to increased PTH release and renal tubular calcium reabsorption.[326,329]

Recent evidence suggests that the CaSR also binds another cation, magnesium, and thus may play a role in magnesium homeostasis by altering reabsorption of magnesium in the thick ascending limb of Henle in the kidneys.[330,331] It is probable that increased peritubular levels of magnesium activate renal CaSRs, leading to inhibition of reabsorption of magnesium from the thick ascending limb of Henle—which in turn leads to increased renal excretion of magnesium.[330,331]

Autosomal-dominant familial benign hypocalciuric hypercalcaemia (FBH) and neonatal severe hyperparathyroidism (NSHPT) are caused by loss-of-function mutations of the CaSR gene.[332,333] Most of these mutations are located in the N-terminal extracellular domain.[334,335] With few exceptions, individuals heterozygous for loss-of-function mutations have FBH—whereas individuals homozygous for such mutations have NSHPT.[336,337] Therefore, children of consanguineous FBH parents are at risk for NSHPT.[334,338,339] Occasionally, infants with NSHPT are heterozygous for CaSR gene mutations.[340]

Decreased CaSR function impedes calcium ion suppression of PTH release and renal tubular calcium reabsorption.[333] Thus, FBH is characterized by mild hypercalcemia that is accompanied by inappropriately normal or elevated serum PTH levels and by relatively low urinary calcium excretion.[336,341,342] Individuals with FBH may also have hypermagnesemia as a result of decreased peritubular inhibition of magnesium reabsorption from the thick ascending loops of the kidneys by the CaSR.[331] There are three type of FBH: FBH type 1 (FBH1), FBH type 2 (FBH2), FBH type 3 (FBH3).[343]

FBH1 is due to heterozygous loss-of-function mutations of the CaSR gene on 3q21.1.[343] Two other chromosome loci have been identified in patients with FBH without CaSR gene mutations. FBH2 has been mapped to 19p13.3 and is biochemically and clinically similar to FBH1.[343,344] FBH3, which is also known as the Oklahoma variant (FBH_{OK}), has been mapped to 19q13.[343,345] Adults with FBH3 have hypophosphatemia, elevated serum PTH levels, and osteomalacia in addition to the clinical and biochemical findings found in individuals with FBH1 and FBH2.[343,346] NSHPT is characterized by severe hypercalcemia accompanied by elevated circulating PTH levels, undermineralization of bone, rib cage deformity, and multiple long-bone and rib fractures.[336]

Activating mutations of the CaSR gene may cause autosomal-dominant hypocalcemic hypercalciuria (ADHH), also known as autosomal dominant hypocalcemia, as increased CaSR function leads to increased calcium ion suppression of PTH release and suppression of renal tubular calcium reabsorption.[327,343,347-351] ADHH is characterized by hypocalcemia and hypomagnesemia accompanied by inappropriately normal or increased urinary

calcium excretion and inappropriately normal or low serum PTH levels.[327,349-351] Patients with ADHH may be asymptomatic or may present with tetany, muscle cramps, or seizures during infancy or childhood.[349-352] Similar to inactivating mutations, most activating mutations are located in the N-terminal extracellular domain.[347,349,350,352] Treatment of patients with ADHH with vitamin D or its metabolites is contraindicated because treatment with these vitamins results in worsening hypercalciuria and nephrolithiasis, in nephrocalcinosis, and in renal impairment.[349,350]

Bartter syndrome type V, like other types of Bartter syndrome, is characterized by hypokalemic metabolic alkalosis and by hyperaldosteronism due to elevated renin levels.[353,354] Patients with Bartter syndrome type V, unlike patients with other types of Bartter syndrome, may also have symptomatic hypocalcemia and are at risk for developing nephrocalcinosis due to hypercalciuria.[353,354] Evidence from in vitro functional expression studies suggests that patients with mild or moderate heterozygous gain-of-function mutations of the CaSR develop ADHH, whereas those with severe heterozygous gain-of-function mutations of the CaSR develop Bartter syndrome type V.[353-355]

Some single–amino-acid polymorphisms of the CaSR gene appear to be predictive of whole-blood ionized and serum total calcium levels, and may increase risk for bone and mineral metabolism disorders in individuals with other genetic and environmental risk factors for these disorders.[356-358] Individuals heterozygous or homozygous for a Gln1011Glu CaSR gene polymorphism tend to have higher calcium levels than individuals with the polymorphism.[358,359] The 15.4% of 387 healthy young Canadian women with at least one CaSR gene allele with an Ala986Ser polymorphism were found to have higher total calcium levels than the remainder of the women without the polymorphism.[357]

Another study of 377 unrelated healthy Italian adult males and females found that 24% of study subjects were heterozygous or homozygous for the Ala986Ser polymorphism, and confirmed the finding that individuals without the polymorphism have lower whole-blood ionized calcium levels than individuals with the polymorphism.[358] The Ala986Ser polymorphism has also been associated with Paget disease and primary hyperparathyroidism.[359-361] Individuals with a less common Arg990Gly polymorphism tend to have lower whole-blood ionized calcium levels than individuals without the polymorphism.[358] The Arg-990Gly polymorphism has been found to be associated with hypercalciuria and nephrolithiasis.[361,362]

Auto-antibodies against the CaSR that interfere with binding of calcium to the receptor may cause autoimmune hypocalciuric hypercalcemia.[363] These patients have the clinical and biochemical features of patients with FBH.[363] Conversely, auto-antibodies that activate the CaSR cause autoimmune-acquired hypoparathyroidism.[364] Both conditions may occur in association with other autoimmune conditions (such as autoimmune thyroiditis), with celiac disease in patients with autoimmune hypocalciuric hypercalcemia, and with autoimmune thyroiditis and autoimmune polyglandular syndrome types 1 and 2 in patients with autoimmune-acquired hypoparathyroidism.[363-365] Auto-antibodies that activate the CaSR were found in approximately one-third of individuals with acquired hypoparathyroidism.[365]

G-Protein Gene Disorders

Inactivating and activating mutations of the GNAS1 gene that encodes $G\alpha_s$ cause endocrine disorders.

INACTIVATING MUTATIONS OF THE GNAS1 GENE

Pseudohypoparathyroidism type Ia (PHP-Ia; Albright hereditary osteodystrophy) and pseudopseudohypoparathyroidism (PPHP) are caused by heterozygous inactivating mutations of the GNAS1 gene that encodes $G\alpha_s$.[366-370] PHP-Ia is characterized by hypocalcemia, hyperphosphatemia, elevated circulating PTH levels, short stature, obesity, mental retardation, brachycephaly, short fingers, and short fourth and fifth metacarpals.[366-369] Some patients may also have a small phallus, reflecting the same defect in LH receptor transduction. FSH and TSH also may be affected. PPHP is characterized by the same somatic features as PHP-Ia in the absence of resistance to PTH.[366,367,370] Interestingly, patients who inherit these mutations from their mothers have PHP-Ia and patients who inherit these mutations from their fathers have PPHP.[366-370]

It is now known that in the renal proximal tubules $G\alpha_s$ can only be encoded from the maternally inherited GNAS1 allele, whereas elsewhere in the body $G\alpha_s$ can be encoded from either the maternally or paternally inherited GNAS1 allele.[371] Thus, patients with maternally inherited inactivating GNAS1 gene mutations are not able to express $G\alpha_s$ in the proximal tubules and have PHP-Ia.[371] Patients with paternally inherited inactivating GNAS1 gene mutations have wild-type maternally inherited GNAS1 alleles and thus have normal $G\alpha_s$ expression in the proximal renal tubules and have PPHP.[371]

Pseudohypoparathyroidism type Ib (PHP-Ib) is characterized by resistance to parathyroid hormone in the absence of the somatic features of PHP-Ia. It was thought that PHP-Ib is caused by inactivating mutations in the PTHR1 gene.[372] However, no deleterious PTHR1 gene mutations have been found in patients with PHP-Ib.[373,374]

Instead of PTHR1 gene mutations, defective imprinting is now thought to play a role in causing PHP-Ib. In most tissues, $G\alpha_s$ is encoded by both GNAS1 alleles.[371] However, in the renal proximal tubules $G\alpha_s$ is only encoded by the maternal GNAS1 allele.[371] The exon 1A region of the GNAS1 gene contains a region that is imprinted in the oocyte by methylation of the DNA.[371,375] This region is not imprinted in most PHP-Ib patients.[375] Thus, failure to maternally imprint the maternally inherited GNAS1 allele is now thought to play a role in causing most cases of PHP-Ib.[368,375] $G\alpha_s$ cannot be expressed in the renal proximal tubules of these patients due to lack of a maternal GNAS1 allele. The PHP-Ib syndrome is also limited to renal resistance to PTH rather than (as in Albright's hereditary osteodystrophy) having other clinical manifestations because $G\alpha_s$ expression in nonrenal tissues does

not require a maternally imprinted GNAS1 allele.[376] One patient with PHP-Ib was found to have paternal uniparental isodisomy for chromosome 20, which contains the GNAS1 gene.[377] Thus, the patient was found to have two paternally inherited GNAS1 alleles. Thus, lack of a maternally imprinted GNAS1 allele also appears to have played a role in causing this patient's PHP-Ib.

ACTIVATING MUTATIONS OF THE GNAS1 GENE

When a GPCR is activated by a ligand, GDP is converted to GTP—which causes the heterotrimeric G protein to dissociate into active Gα-GTP and Gβγ subunits.[5-7] GTPase then converts GTP into GDP, which inactivates Gα and increases affinity of Gα for Gβγ—leading to reformation of the inactive heterotrimeric G protein.[5-7] Arg^{201} and Gln^{227} of $G\alpha_s$ are critical to GTPase activity.[376] GNAS1 mutations that result in substitutions of these amino acid residues by amino acid residues that disrupt GTPase activity prolong the active state of $G\alpha_s$.[376] Somatic mutations of these residues that disrupt GTPase activity are present in approximately 40% of growth-hormone–secreting and some ACTH-secreting and nonsecreting pituitary tumors; in some parathyroid, thyroid, and adrenal tumors; and in some intramuscular myxomas.[81,378,379]

More widespread mosaic Arg^{201} $G\alpha_s$ mutations that decrease GTPase activity cause fibrous dysplasia or (when tissue distribution of the mutation is very widespread) McCune Albright syndrome, which is characterized by the triad of café au lait spots, polyostic fibrous dysplasia, and gonadotropin-independent precocious puberty.[380,381] Patients with McCune Albright syndrome may also have excessive growth hormone production, hyperthyroidism, and Cushing's syndrome—as well as associated nodularity of the pituitary and the thyroid and adrenal glands due to overactive $G\alpha_s$ subunits in GHRH, TSH, and ACTH receptors, respectively.[381,382] Hypophosphatemia, which is not uncommon in patients with McCune Albright syndrome, appears to be due in yet unknown ways to fibrous dysplasia. Patients with McCune Albright syndrome may also have nonendocrine problems such as hepatobiliary abnormalities, cardiomyopathy, and sudden death due to overactive $G\alpha_s$ subunits in nonendocrine GPCRs.[382]

Cytokine Receptors

Cytokines are molecules produced by one cell that act on another cell.[383] Thus, the term can apply not only to molecules with immunologic functions but to hormones. Therefore, growth hormone, prolactin, and leptin are classified as type I cytokines.[384] These and other type I cytokines, (including ILs 2–9, 11–13, and 15; erythropoietin; thrombopoietin; and granulocyte-colony–stimulating factor) are characterized by a four α-helical bundle structure and signaling via type I cytokine receptors.[384] Type II cytokines include the interferons and IL-10 and do not include hormones.[384]

Type I cytokines are divided into long-chain and short-chain cytokines.[384] Prolactin, leptin, and growth hormone belong to the long-chain subclass of type I cytokines because their helixes are 25 amino acids in length.[384] The short-chain type I cytokines, including IL-2 and stem cell factor, have helixes of approximately 15 amino acids in length.[384]

STRUCTURE AND FUNCTION OF TYPE I CYTOKINE RECEPTORS

All type I cytokine receptors have four conserved cysteine residues, fibronectin type II modules, a Trp-Ser-X-Trp-Ser motif in the extracellular domain, and a praline-rich Box 1/Box 2 region in the cytoplasmic domain.[384,385] With the exception of stem cell factor, type I cytokine receptors do not contain catalytic domains such as kinases.[384]

Type I cytokine receptors for long-chain type I cytokines require homodimerization for activation.[384,386] First, the ligand binds a monomeric receptor.[384,386] Then, the ligand interacts with a second receptor to induce receptor dimerization and activation.[384,386] Activated receptors then stimulate members of the Janus family of tyrosine kinases (Jak kinases) to phosphorylate tyrosine residues in itself and the cytoplasmic region of the receptors.[384,387] Signal transducers and activators of transcription (STATs) then dock on the phosphorylated cytoplasmic receptor domains or Jak kinases via an SH2 domain and are tyrosine phophorylated.[384] The phosphorylated STATs then dissociate from the receptors or Jak kinases, form homo- or heterodimers, and translocate to the nucleus.[384,388,389] In the nucleus, the STAT dimers bind and alter the activity of regulatory regions of target DNA.[384,388,390]

There are four Jak kinases.[388,391] Jak3 is only expressed in lymphohematopoietic cells, whereas Jak1, Jak2, and Tyk2 are expressed in every cell.[384,392,393] There are seven STATs (Stat1, Stat2, Stat3, Stat4, Stat5a, Stat5b, and Stat6), which have different SH2 domain sequences that confer different receptor specificities.[384,387-389]

CYTOKINE RECEPTORS THAT TRANSDUCE HORMONE ACTION

The actions of growth hormone, prolactin, and leptin are mediated via specific type I cytokine receptors.[384] Mutations of the growth hormone receptor (GHR) and the leptin receptor have been found that are associated with endocrine disorders (Table 2-3).

Growth Hormone Receptors

The GHR gene is located on the short arm of chromosome 5 (5p13.1-p12), and 9 of the 13 exons of the gene encode the receptor.[394-397] A secretion signal sequence is encoded by exon 2, the N-terminal extracellular ligand binding domain is encoded by exons 3 through 7, the single transmembrane domain is encoded by exon 9, and the C-terminal cytoplasmic domain is encoded by exons 9 and 10.[394-397] Growth hormone binding protein (GHBP) is the product of proteolytic cleavage of the extracellular domain of the GHR from the rest of the receptor.[398] Approximately 50% of circulating growth hormone is bound to GHBP.[398]

TABLE 2-3

Cytokine Receptors and Clinical Conditions Associated with Receptor Mutations

Receptor	Germ Line Mutation	Endocrine Disorder
Growth hormone receptor	Some inactivating (heterozygous)	Partial growth hormone insensitivity with mild to moderate growth failure
	Inactivating (homozygous, compound heterozygous)	Growth hormone insensitivity/ Laron syndrome with moderate to severe postnatal growth failure
Leptin receptor	Inactivating (homozygous)	Obesity and hypogonadotropic hypogonadism

Growth-hormone–induced receptor dimerization stimulates Jak2, resulting in tyrosyl phosphorylation of Stat1, Stat3, and Stat5.[399-403] Then the STATs translocate to the nucleus, where they regulate growth-hormone–responsive genes.[400-403] In particular, growth hormone indirectly controls growth by regulating production of insulin-like growth factor-1 (IGF-1)—which has direct effects on cell proliferation and hypertrophy.[404] Jak2 also activates the mitogen activated protein (MAP) kinase and insulin receptor substrate pathways.[405-407] However, the extent to which these pathways contribute to growth hormone action is as yet unknown.[397]

Patients are considered to have growth hormone insensitivity (GHI) if they do not exhibit appropriate growth and metabolic responses to physiologic levels of growth hormone.[398] The phenotype of GHI is variable and ranges from isolated moderate postnatal growth failure to severe postnatal growth failure accompanied by the classic features of Laron syndrome in Ecuadorean patients with GHR deficiency.[398,408-411] Features of GHR deficiency include frontal temporal hairline recession, prominent forehead, decreased vertical dimension of face, hypoplastic nasal bridge, shallow orbits, blue sclera, small phallus prior to puberty, crowded permanent teeth, absent third molars, small hands and feet, hypoplastic fingernails, hypomuscularity, delayed age of onset for walking, high-pitched voice, increased total and low-density lipoprotein cholesterol, and fasting hypoglycemia.[398,411] All patients with GHI have normal or elevated circulating growth hormone levels, markedly decreased circulating IGF-1 levels, and a delayed bone age.[398]

Patients homozygous or compound heterozygous for deletion of exons 5 and 6—or homozygous or compound heterozygous for numerous nonsense, missense, frame-shift, and splice-point mutations throughout the GHR gene—have been found to have GHI characterized by severe postnatal growth failure and usually low or absent circulating GHBP levels.[398,412,413] Patients homozygous or compound heterozygous for the Arg274Thr or the Gly223Gly splice mutations that result in a truncated receptor that cannot be anchored to the plasma membrane (or that result in the Asp152His missense mutation that interferes with GHR dimerization) have normal circulating GHBP levels.[398]

Patients heterozygous for mutations that alter the GHR have dimerization complexes that consist of two wild-type receptors (a wild-type receptor and a mutant receptor) and two mutant receptors. Thus, heterozygosity for loss-of-function GHR gene mutations may have a dominant negative effect because the wild-type receptor/mutant receptor dimers may not be able to function normally. As expected from this phenomenon, some patients with moderate to severe growth failure have been found to be heterozygous for loss-of-function point or splice mutations of the GHR gene that alter the cytoplasmic or extracellular domains.[398,414-417]

Some patients with severe short stature and GHI do not have GHR mutations. Rather, they have defects in GHR-mediated intracellular signaling—including impaired STAT activation.[418]

Leptin Receptors

The leptin receptor [LEPR (also known as Ob-R)] gene is located at 1p31. There are five isoforms of LEPR due to alternative splicing of the LEPR gene transcript (Figure 2-5).[419] Only the Ob-Rb isoform contains both the Jak kinase binding and STAT motifs necessary to maximally transduce the effects of leptin.[419] The Ob-Ra, Ob-Rc, and Ob-Rd isoforms contain intact extracellular and transmembrane but are missing the STAT motif from their cytoplasmic domains.[419] The Ob-Re isoform is missing the transmembrane and cytoplasmic domains.[419] Thus, the Ob-Rb isoform is thought to be the main isoform involved in mediating the effects of leptin.[419]

Three sisters from a consanguineous kindred were found to be homozygous for a splice mutation in the LEPR gene that resulted in expression of an 831 amino acid protein (Ob-Rhd) that lacks transmembrane and cytoplasmic domains.[420] They had been hyperphagic and morbidly obese since birth.[420] They were found to have elevated circulating leptin levels, decreased TSH and GH secretion, and failure of pubertal development due to hypogonadotropic hypogonadism.[420] Heterozygous carriers of the mutation are not morbidly obese and do not have delayed or absent puberty.[420]

More recently, in studies of 300 obese subjects 3% had nonsense or missense LEPR mutations. Individuals with mutations had hyperphagia, severe obesity, altered immune function, and delayed puberty due to hypogonadotropic hypogonadism. Importantly, circulating leptin levels were within the range predicted by the elevated fat mass, and clinical features were less severe than those of subjects with congenital leptin deficiency.[421]

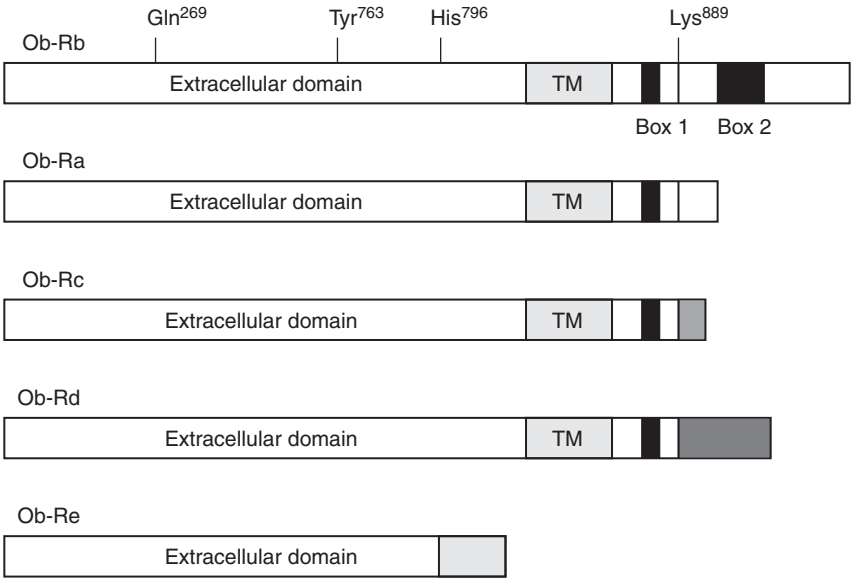

Figure 2-5. Leptin receptor isoforms. There are five leptin receptor isoforms. Box 1 represents the Jak kinase binding motif, and box 2 represents the STAT motif. The Ob-Rb isoform is the only isoform that contains Jak kinase binding and STAT motifs, and is thus thought to be the main isoform involved in mediating the effects of leptin. The Ob-Ra, Ob-Rc, and Ob-Rd isoforms are missing the STAT motif. The Ob-Re isoform is missing the transmembrane (TM) and cytoplasmic domains. [Reproduced with permission from Chen D, Garg A (1999). Monogenic disorders of obesity and body fat distribution. J Lipid Res 40:1737.]

Receptor Tyrosine Kinases

The receptor tyrosine kinase (RTK) superfamily consists of 15 receptor tyrosine kinase families (Figure 2-6).[422] With one exception, these families consist of receptors with one membrane-spanning domain (Figure 2-6).[422] The single-membrane–spanning receptors typically contain an N-terminal extracellular portion, a transmembrane helix, a juxtamembrane region, a tyrosine kinase (TK) domain, and a C-terminal region (Figure 2-6).[422] These receptors require dimerization to be maximally activated.[422-424] Receptors belonging to insulin RTK family differ from other RTKs, as they contain two membrane-spanning polypeptide chains linked by disulfide bonds to two intervening extracellular peptide chains and thus do not dimerize (Figure 2-6).[421]

Activation of RTKs leads to phosphorylation of tyrosine residues in the activation loop (A-loop) in the TK domain(s), resulting in activation of the TK(s).[421,425] Activation of the TK(s), in turn, induces the transfer of phosphate from adenosine triphosphate (ATP) to tyrosine residues in the cytosolic portion of the receptor and in cytosolic proteins that serve as docking sites for second messengers.[421]

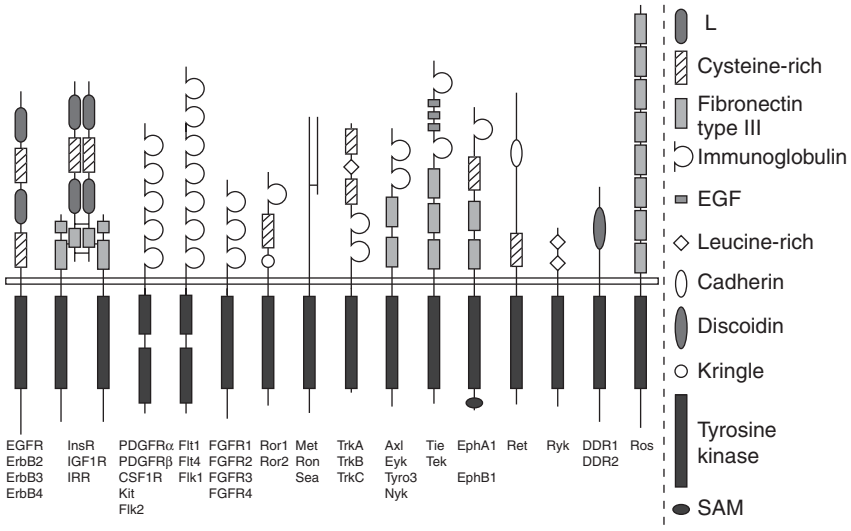

Figure 2-6. The fifteen RTK families. Each family has a characteristic extracellular portion, and a cytoplasmic portion that contains a tyrosine kinase domain. [Reproduced with permission from Hubbard SR (1999). Structural analysis of receptor tyrosine kinases. Prog Biophys Mol Biol 71:344.]

There is a growing body of evidence suggesting that members of the receptor tyrosine kinase superfamily can directly and indirectly interact with heterotrimeric G proteins. The insulin, insulin-like growth factor-1, and insulin-like growth factor-2 receptors appear to directly interact with $G_{i/o}$ and $G_{q/11}$, $G_{i/o,}$ and G_i, respectively.[426] The fibroblast growth factor receptors appear to directly and indirectly interact with G_s.[426] Congenital alteration of function of receptors in the insulin and the fibroblast growth factor RTK families leads to endocrine disorders (Table 2-4).

INSULIN RECEPTOR TYROSINE KINASE FAMILY

The insulin RTK family includes the insulin receptor (INSR) and the insulin-like growth factor-1 receptor (IGF1R).[423] These receptors are heterotetramers consisting of two α and β subunits in a αββα configuration (Figure 2-7).[427-429] The cysteine-rich extracellular α subunits are linked by disulfide bonds, and each α subunit is linked to a plasma membrane-spanning and cytosolic β subunit by disulfide bonds.[429,430] Each β subunit contains a TK domain and a C-terminal region that contain tyrosine residues.[421]

Both insulin and insulin-like growth factor-1 (IGF-1) can bind INSRs and IGF1Rs. However, insulin has greater affinity for the INSR and IGF-1 has greater affinity for the IGF1R. Ligand binding alters the conformation of the receptor, resulting in *trans*-autophosphorylation of the C-terminal tyrosine residues on one β subunit by the TK on the other β subunit.[431,432] The phosphorylated tyrosine residues create motifs that can be bound by Src homology 2 (SH2)-domain-containing proteins, including Shc, Grb-2, SHP2, nck, phosphatidylinositol-3-kinase (PI3K), and Crk.[433-437] The receptor TK also phosphorylate tyrosine residues in insulin receptor substrate proteins (IRS), including IRS-1 and IRS-2, that bind INSRs and IGF1Rs.[437-440] When phosphorylated, these tyrosine residues create motifs that are bound by SH2-domain-containing proteins.[433,434,436,437,440] Thus, insulin receptor substrates can serve as docking proteins—allowing SH2-domain-containing proteins to indirectly interact with INSRs and IGF1Rs when stearic constraints do not permit direct interactions between the proteins and the receptors.[433,434,437] Ultimately, IRSs, SH2-domain-containing proteins, and other proteins (including mSOS) interact to activate the Ras/Raf/MAPKK/MAPK and PI3K/protein kinase B (PKB) cascades (Figure 2-7).[436,437,440]

Activation of the Ras/Raf/ MAPKK/MAPK cascade increases mitogenesis and proliferation, and activation of the PI3K/PKB cascade increases glucose uptake and glycogen synthesis.[429,441-446] Evidence suggests that IGF1 has a greater effect on cell growth than on glucose metabolism because activation of the IGF1R stimulates the Ras/MAPK cascade more than INSR activation.[429,445] Conversely, it appears that insulin has a greater effect on glucose metabolism because INSR activation stimulates the PI3K/PKB cascade more than IGF1R activation.[429,446]

The Insulin Receptor

The INSR gene is located on 19p and contains 22 exons.[447] αβ half-receptor precursors are derived from proteolysis of a single proreceptor comprised of α and β subunits in tandem and disulfide linkage of these subunits.[437,447,448] These αβ half-receptor precursors then join to form a single αββα heterotetrameric insulin receptor.[448] Interestingly, αβ half-receptor precursors encoded by one allele may combine with αβ half-receptor precursors encoded by the other allele to form a single insulin receptor.[449] This phenomenon explains how heterozygote mutations resulting in impaired β subunit tyrosine kinase activity can have a dominant negative effect because activation of the INSR requires trans-autophosphorylation of one β subunit by the other β subunit.[449]

Patients with "type A syndrome" have acanthosis nigricans and severe inherited insulin resistance in the absence of INSR autoantibodies.[450-452] Patients with this syndrome tend to be lean and develop glucose intolerance.[452,453] Females with this syndrome also exhibit signs of ovarian hyperandrogenism, including hirsutism, severe acne, oligomenorrhea, and infertility.[450-452]

Patients with "type B syndrome" present during adulthood with acanthosis nigricans, ovarian hyperandrogenism, and severe insulin resistance in association with signs of autoimmune disease—including alopecia areata, vitiligo, primary biliary cirrhosis, arthritis, and nephritis.[450-452,454] Surprisingly, these patients may present with fasting

TABLE 2-4

Receptor Tyrosine Kinases and Clinical Conditions Associated with Receptor Mutations

Receptor	Germ Line Mutation	Endocrine Disorder
Insulin receptor	Inactivating (heterozygous)	Some cases of type A syndrome
	Inactivating (homozygous, compound heterozygous)	Rabson Mendenhall, Donohue (leprechaunism), and some cases of type A syndromes
IGF-1 receptor	Gene deletion (heterozygous)	Pre- and postnatal growth failure
FGFR1	Inactivating mutation (heterozygous)	Kallmann syndrome, missing teeth, cleft palate
FGFR3	Activating mutations (heterozygous)	Achondroplasia, severe achondroplasia with developmental delay and acanthosis nigricans, thanatophoric dysplasia types I and II, and platyspondylic lethal skeletal dysplasias (San Diego types)

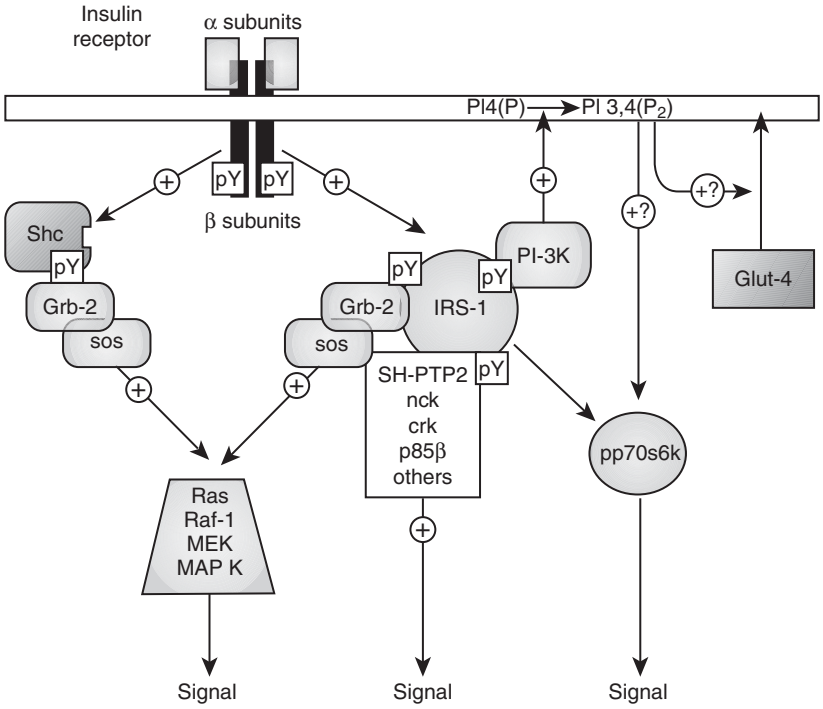

Figure 2-7. Insulin receptor signaling. IRS proteins, SH2-domain–containing proteins (including Grb-2 and Shc), and other proteins (including SOS) interact to activate the Ras/Raf-1/MAP K cascade and PI-3K/PKB cascades, and other enzymes—including SH-PTP2 (SHP2) and p70(s6k). [Adapted with permission from White MF (1997). The insulin signaling system and the IRS proteins. Diabetologia 40:S10.]

hypoglycemia that may or may not be accompanied by postprandial hyperglycemia.[450-452,454] Hodgkin's disease and ataxia-telangiectasia are also associated with this syndrome.[452] Patients with type B syndrome are distinguished from patients with type A syndrome by the presence of anti-INSR antibodies in the plasma that block insulin binding.[450-452,454]

The term *HAIR-AN* (hyperandrogenism, insulin resistance, and acanthosis nigricans) has also been used to describe women with features of types A and B syndromes in association with obesity.[452] However, this term is imprecise because many women who have been labeled as having HAIR-AN may actually have type A or B syndrome or severe polycystic ovary syndrome.[452]

Patients with Rabson-Mendenhall syndrome present during childhood with severe insulin resistance.[455-457] Although patients with this disorder may present initially with fasting hypoglycemia, eventually they develop severe diabetes ketoacidosis that is refractory to insulin therapy.[457] Patients with this condition also have acanthosis nigricans, accelerated linear growth, dystrophic nails, premature and dysplastic dentition, coarse facial features, and pineal hyperplasia.[453,455-457]

Patients with leprechaunism or Donohue syndrome are also severely insulin resistant.[458,459] Patients present during infancy with severe intrauterine and postnatal growth retardation, lipoatrophy, and acanthosis nigricans.[456,458] They also have dysmorphic features that include globular eyes, micrognathia, and large ears.[456,458] Affected male infants commonly have penile enlargement, whereas affected female infants often have clitoromegaly and hirsutism.[456,458] In spite of hyperinsulinemia associated with glucose intolerance or diabetes mellitus, the major glucose metabolism problem for these patients is fasting hypoglycemia.[456,458] Unlike patients with Rabson-Mendenhall syndrome, patients with leprechaunism do not present with diabetic ketoacidosis.[457] Many patients with this condition do not survive past the first year of life.[456,458]

Mutations in the INSR have been found in 10% to 15% of patients with type A syndrome, and in all patients with Rabson-Mendenhall syndrome and leprechaunism.[452,459,460] These mutations are divided into five classes.[452,453,461] Class I mutations are frame-shift or nonsense mutations that prematurely terminate translation and thus interfere with INSR synthesis. Class II mutations interfere with post-translational processing and intracellular trafficking of the INSR. Class III mutations decrease insulin binding to the INSR. Class IV mutations are point mutations usually located on the intracellular region of the β subunit that decrease INSR TK activity. Class V mutations increase INSR degradation by increasing insulin-induced endocytosis and degradation of the receptors.

Patients with Rabson-Mendenhall syndrome and leprechaunism are homozygous or compound heterozygous for these mutations.[452,462-466] Some patients with type A syndrome have been found to be heterozygous for dominant negative β-subunit mutations that reduces TK activity by 75%.[461,466-471] Other patients with type A syndrome have been found to be homozygous or compound heterozygous for α-subunit mutations that interfere with receptor trafficking to the plasma membrane, β-subunit mutations that interfere with TK activity, or mutations that interfere with proreceptor cleavage into α and β subunits. Still other patients have been found to have decreased INSR mRNA levels that may be due to a loss-of-function

mutation in the INSR gene promoter.[453,472-476] Interestingly, one patient with leprechaunism with parents with type A syndrome has been described.[466] The proband was found to be homozygous for an INSR mutation that decreases TK activity, and the parents were found to be heterozygous for the mutation.[466]

The Insulin-Like Growth Factor-1 Receptor

The growth-promoting effects of IGF-1 are mediated by IGR1Rs. IGF1R αβ subunits are encoded by a single gene.[448] Like the insulin receptor, an αβ half-receptor precursor is produced that then joins with a half-receptor precursor that may be encoded from the other allele to form a complete heterotetrameric IGF1R.[448] The IGF1R has 100-fold less affinity for insulin than for IGF1.[477]

Patients who are heterozygous for a ring chromosome 15, resulting in deletion of the IGF1R gene, present with intrauterine growth retardation and postnatal growth failure accompanied by delayed bone age, mental retardation, cardiac abnormalities, cryptorchidism, and dysmorphic features that include microcephaly, triangular face, frontal bossing, hypertelorism, and brachydactyly.[478,479] Similarly, IUGR and postnatal growth failure are commonly found in patients heterozygous for deletion of distal 15q that results in deletion of the IGF1R gene. Patients with deletion of distal 15q often have microcephaly, triangular facies, hypertelorism, high-arched palate, micrognathia, cystic kidneys, and lung hypoplasia or dysplasia.[477,480-482] However, the ring chromosome and deleted area of distal 15q may also be missing other genes—and it is unknown to what extent absence of the IGF1R gene contributes to the phenotype found in these patients.[477,479]

It has been suggested African Efe Pygmies are short due to resistance to IGF1.[477] T-cell lines established from Efe Pygmies have decreased IGF1R gene expression, cell surface expression, receptor autophosphorylation, and intracellular signaling when compared with T-cell lines established from American controls.[477] However, no IGF1R gene mutation has been identified in Efe Pygmies that can account for these findings.[477]

In addition to defective INSR function, some patients with leprechaunism and Rabson-Mendenhall syndrome are resistant to the glucose lowering or growth promotion of IGF1 and have abnormal IGF1R function—resulting in decreased ligand binding or altered intracellular signaling.[477,483-487] No deleterious IGF1R gene mutation has been identified in patients with these syndromes, and many patients with leprechaunism and Rabson-Mendenhall syndrome have normally functioning IGF1Rs and no evidence of IGF1 resistance.[477,488]

The Fibroblast Growth Factor Receptor Family

There are four members of the fibroblast growth factor receptor (FGFR) tyrosine kinase family.[421] These are FGFR1, FGFR2, FGFR3, and FGFR4. These receptors consist of a single polypeptide chain that contains an N-terminal extracellular region, a transmembrane region, and a cytosolic region (Figure 2-6).[421] The extracellular region contains three immunoglobulin-like domains: IgI, IgII, and IgIII (Figure 2-6).[489] The cytosolic region contains a TK domain split into two segments (TK1 and TK2) by an intervening amino acid segment.[489]

At least 13 types of fibroblast growth factors (FGFs) have been identified.[489] As monomers, FGFs can only bind a single FGFR—forming an inactive 1:1 complex.[423] FGFR activation by dimerization occurs when two or more FGF molecules in 1:1 complexes are linked by heparan sulfate proteoglycans.[423]

Activation of FGFRs increases receptor TK activity.[489] Increased TK activity leads to autophosphorylation of a tyrosine residue in the C-terminal region, resulting in a binding site for the SH2 domain of phospholipase Cγ (PLCγ).[490,491] Once PLCγ is bound to this site, it is phosphorylated and activated.[490,491] In chondrocytes, activation of FGFR3 also induces activation of STAT1.[492]

FIBROBLAST GROWTH FACTOR RECEPTOR 1

In 2003, inactivating FGFR1 gene mutations were identified as a cause of autosomal-dominant Kallmann syndrome (KS).[493] Individuals with KS have anosmia and isolated hypogonadotropic hypogonadism.[494,495] The FGFR1, which is located on 8p12, plays a role in olfactory and GnRH neuronal migration from the nasal placode to the olfactory bulb and in the subsequent migration of the GnRH neurons to the hypothalamus.[493] Prior to identification of these FGFR1 gene mutations, X-linked KS was found to be caused by inactivating KAL1 gene mutations.[494,496,497] The KAL1 gene is located on the X chromosome and encodes anosmin-1.[494,496,497] Anosmin-1 is a ligand for the FGFR1 receptor.[498] Like FGFR1s, anosmin-1 plays a role in olfactory and GnRH neuronal migration to the nasal placode, and in the subsequent migration of GnRH neurons to the hypothalamus.[494,498,499]

There is a high penetrance for anosmia and signs of hypogonadotropic hypogonadism, (including lack of puberty, microphallus, and cryptorchidism) in the 10% of KS patients with X-linked KS due to KAL1 gene mutations.[494] Female carriers of KAL1 gene mutations do not have anosmia or isolated hypogonadotropic hypogonadism.[494] In contrast to patients with KS due to KAL1 gene mutations, the approximately 10% of KS patients with FGFR1 gene mutations (even within the same kindred) exhibit variable phenotypes ranging from anosmia and complete hypogonadotropic hypogonadism (characterized by cryptorchidism and microphallus in males and absent pubertal development in both genders) to anosmia and/or delayed puberty.[493,500,501]

It has also been noted that in most kindreds with FGFR1 gene mutations females present with more mild KS phenotypes than males.[493,501] Female carriers may even be asymptomatic.[493,501] Because the KAL1 gene is located on the X chromosome, females may produce more anosmin-1 than males.[493] Thus, a possible explanation for milder KS phenotypes in females with FGFR1 gene mutations may

be that the increased anosmin-1 levels in females may lead to increased anosmin-1–induced activation of the mutant FGFR1s that may partially compensate for the mutation.[493] Interestingly, missing teeth and cleft palate are not an uncommon finding in individuals with KS due to FGFR1 gene mutations, whereas unilateral renal agenesis and bilateral synkinesia are associated with KS due to KAL1 gene mutations.[500]

FIBROBLAST GROWTH FACTOR RECEPTOR 3

In addition to variants of Kallmann syndrome, FGFR mutations cause many conditions—including Pfeiffer syndrome (activating mutations of FGFR1 and FGFR2), Crouzon syndrome (FGFR2 mutations), Crouzon syndrome with acanthosis nigricans (an FGFR3 mutation), Apert syndrome (FGFR2 mutations), and craniosynostosis (FGFR3 mutations).[489] Several autosomal-dominant short-limb dwarfism syndromes—including achondroplasia, severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN), hypochondroplasia, and three types of platyspondylic lethal skeletal dysplasias (PLSD) [thanatophoric dysplasia I (TDI), thanatophoric dysplasia II (TDII), and San Diego types (PLSD-SD)]—are often caused by heterozygous constitutively activating FGFR3 gene mutations.[502-505]

Individuals with achondroplasia have activating mutations in the transmembrane domain of FGFR3, with the Gly380Asn found in >95% of achondroplastic patients.[503,506-508] Forty to 70% of individuals with hypochondroplasia have an activating Asn540Lys mutation in the TK1 domain.[503,509-512] All individuals with TDII have an activating Lys650Glu mutation in the activating loop of the TK2 domain, and >90% of individuals with TDI and PLSD-SD have FGFR3 mutations.[503,505] Patients with SADDAN have an activating mutation in the same codon as patients with TDII.[513] Instead of the Lys650Glu mutation associated with TDII, patients with SADDAN have a Lys650Met mutation.[513] However, unlike patients with TDII patients with SADDAN do not have craniosynostosis and a cloverleaf skull—and often survive past childhood.[513]

The FGFR3 gene is primarily expressed in endochondral growth plates of long bones, brain, and skin pre- and postnatally.[514,515] Constitutional activation of FGFR3s in chondrocytes leads to growth arrest and apoptosis.[492,516,517] In addition, constitutive activation of FGFR3s is also postulated to alter neuronal migration because patients with SADDAN, TDI, and TDII have neurologic abnormalities that may include developmental delay, paucity of white matter, polymicrogyria, dysplastic temporal cortex, dysplasia of nuclei, and neuronal heterotopia.[513,518-520] Furthermore, constitutive activation of FGFRs in skin fibroblasts and keratinocytes is thought to cause the acanthosis nigricans seen in patients with SADDAN and Crouzon syndrome with acanthosis nigricans.[521] However, it is not yet known why some activating FGFR3 mutations effect the skeletal system, central nervous system, and the skin whereas other activating FGFR3 mutations only effect the skeletal system.[513]

Nuclear Receptors

Using a phylogenetic tree based on the evolution of two highly conserved nuclear receptor domains (the DNA-binding C domain and the ligand-binding E domain, V), Laudet divided nuclear receptors into six related subfamilies and a subfamily. Subfamily 0 contains receptors, such as the embryonic gonad (EGON) and DAX1 receptors, that do not have a conserved C or the E domain (Figure 2-8).[522,523] Subfamily 1 includes the peroxisome proliferator-activated retinoic acid, thyroid hormone, and vitamin D3 receptors. Subfamily 2 includes the hepatocyte nuclear factor-4α (HNF-4α) and retinoid X receptors (RXRs). Subfamily 3 contains the steroid receptors.

Subfamilies 4 and 5 contain the NGFIB and the FTZ-F1 orphan receptors, respectively. Subfamily 6 consists of the GCNF1 orphan receptor. Recent evidence suggests that subfamily 3 (which includes the glucocorticoid, androgen, progesterone, and mineralocorticoid receptors) rapidly evolved from a common steroid receptor gene about 500 million years ago.[524]

GENERAL STRUCTURE OF THE NUCLEAR RECEPTORS

Nuclear receptors are made up of four domains: A/B, C, D, and E (Figure 2-9).[522] Supporting the notion that nuclear receptor subfamilies are derived from a common ancestral orphan receptor, the C and E domains are highly conserved among the subfamilies.[522] Mutation of several nuclear receptors are associated with endocrine disorders (Table 2-5).

The A/B domain is located at the N-terminal and contains the activation function 1 (AF-1)/τ 1 domain.[525] The AF-1/τ 1 domain regulates gene transcription by interacting with proteins (such as the Ada and TFIID complexes) that induce transcription.[526,527] This transactivation function of the AF-1/τ 1 domain is not dependent on binding of the nuclear hormone receptor to its ligand and is not specific in its choice of DNA target sequences.[522,528-530] Thus, specificity of action of the nuclear hormone receptor is determined by the function of other nuclear hormone receptor domains.

The C domain has characteristics that help to confer specificity of action on each nuclear hormone receptor. This domain consists of two zinc-finger motifs responsible for the DNA-binding activity of the receptor and the selection of dimerization partners.[531,532] Each zinc-finger module consists of a zinc ion surrounded by the sulfurs of four cysteine residues, resulting in a tertiary structure containing helixes.[531,532] The P-box lies near the cysteines of the first zinc finger and contains the three to four amino acids responsible for specificity of binding to response elements.[532,533] The D-box consists of a loop of five amino acids attached to the first two cysteines of the second zinc finger that provides the interface for nuclear receptor dimerization.[532]

The D "hinge" domain contains nuclear localization signals and contributes to the function of the adjacent C and E domains.[522] Thus, the N-terminal portion of the domain contributes to DNA binding and heterodimerization and

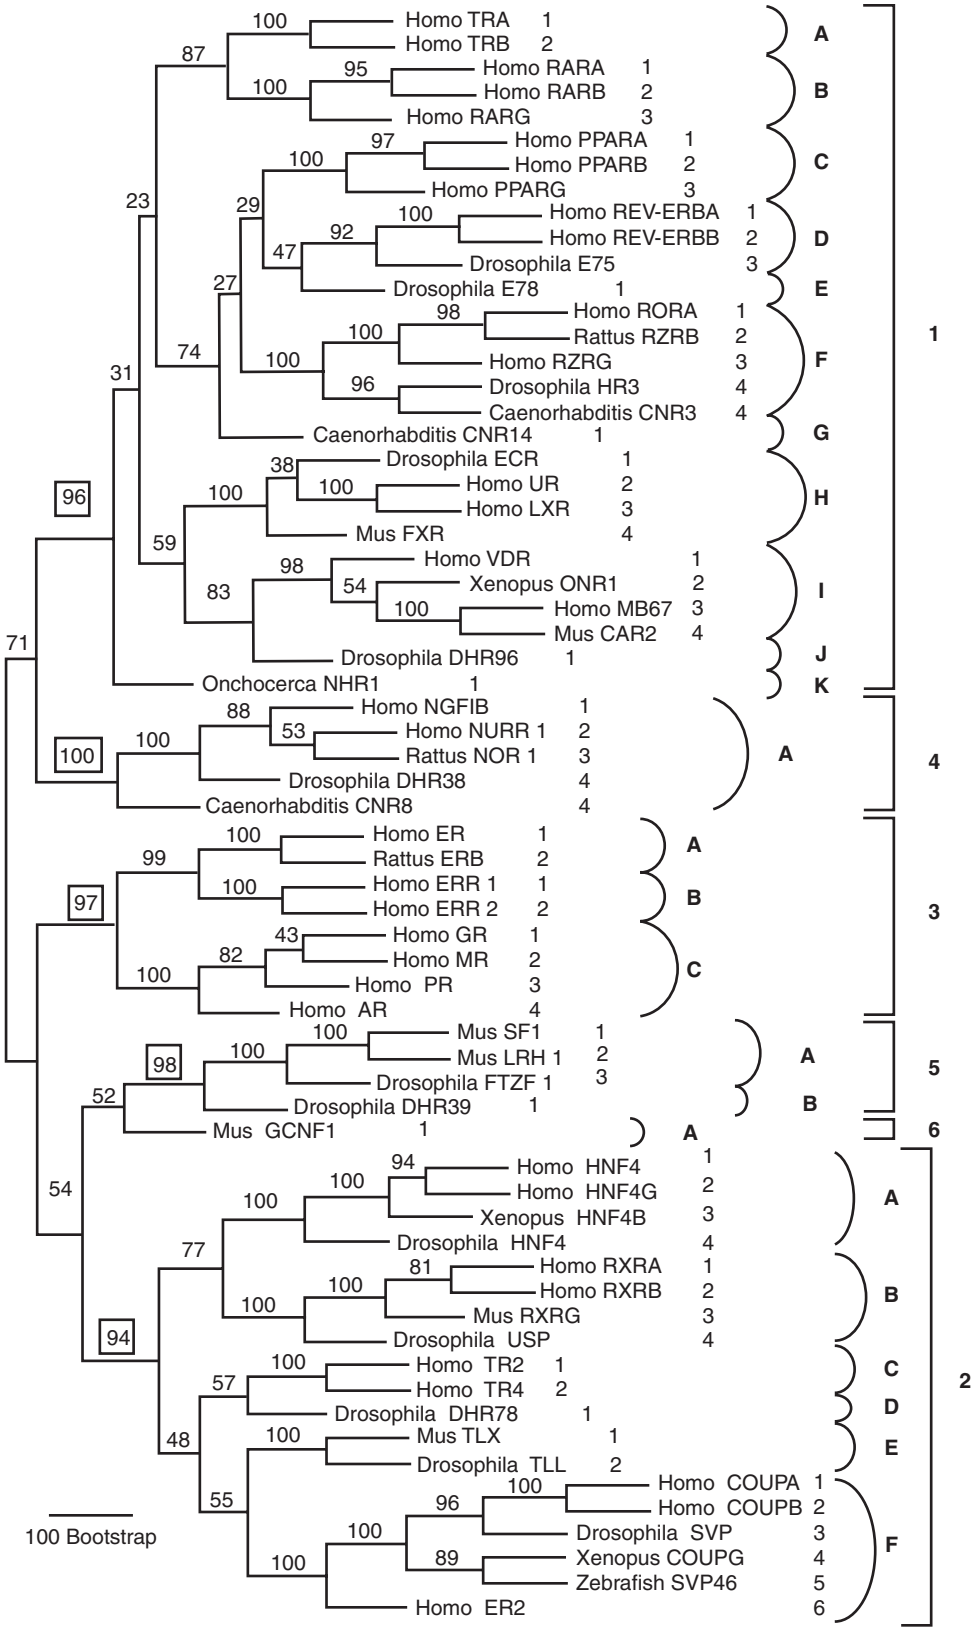

Figure 2-8. Phylogenetic tree of nuclear receptors based on the evolution of the highly conserved C and E domains. Numbers at the right side of the figure represent subfamilies, and capital letters represent groups of more closely related receptors. The small numbers to the right of the receptor names are used in combination with the subfamily letters and group letters in a proposed nuclear receptor nomenclature. This nomenclature proposes that nuclear receptors should be named NR, followed by subfamily number, group letter, and individual receptor number. Thus, the mineralocorticoid receptor is named NR3C2 and the PPARγ receptor is named NR1C3 according to this nomenclature. Numbers to the left of the receptor names represent bootstrap values. Values that define subfamilies with more than one member are boxed. [Reproduced with permission from the Nuclear Receptors Nomenclature Committee (1999). A unified nomenclature system for the nuclear receptor subfamily. Cell 97:161.]

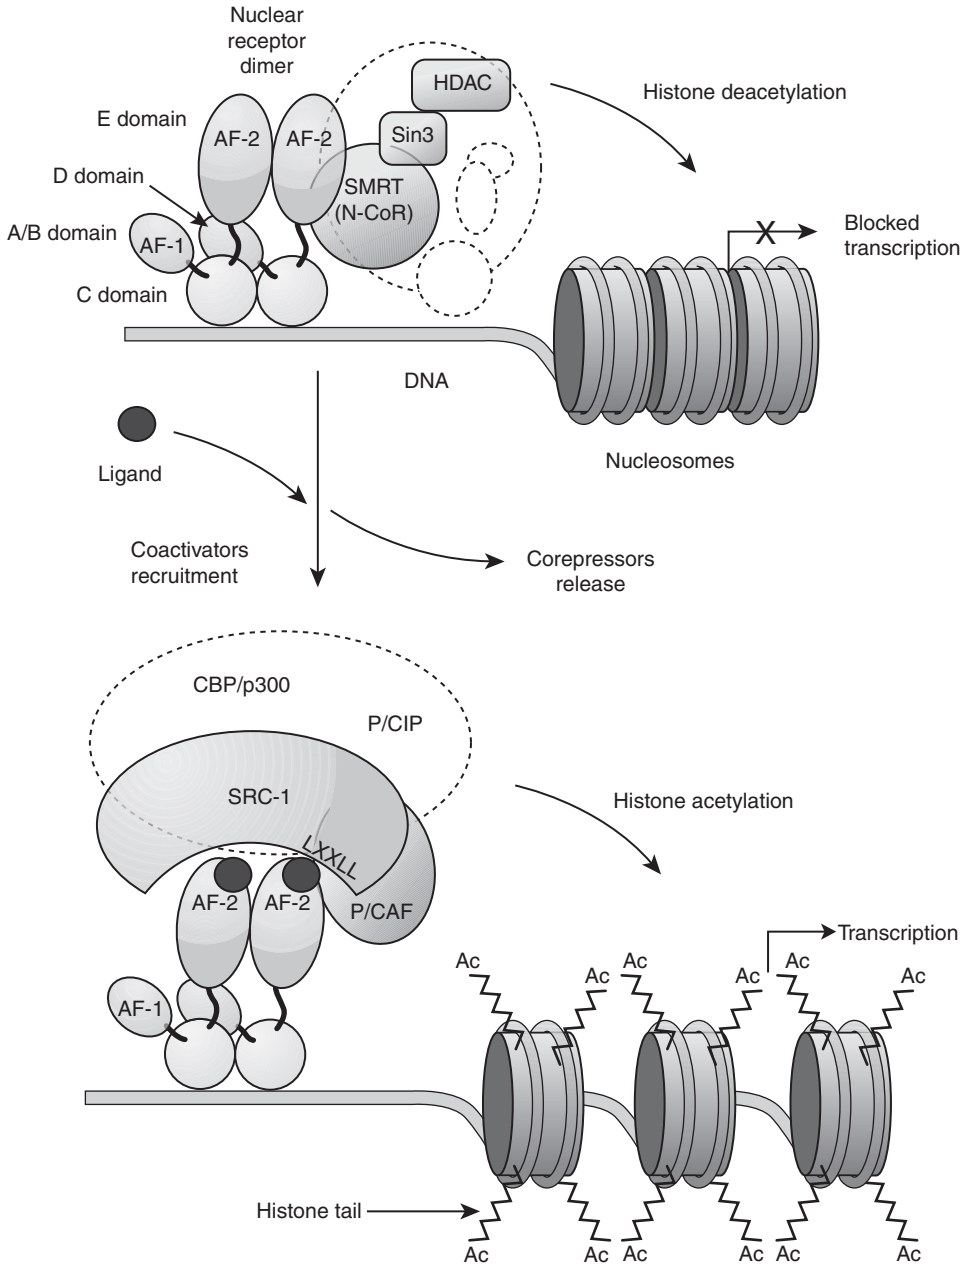

Figure 2-9. Ligand-induced activation of transcription by nuclear receptors. Often, corepressors [including SMRT and nuclear receptor copressor (N-CoR)] bind a nuclear receptor that is not bound by its ligand. These corepressors then associate with Sin3, which in turn associates with a histone deacetylases (HDAC). Then, HDAC represses transcription by deacetylating histone tails—resulting in compaction of the nucleosomes into structures that are inaccessible to transcription factors. Ligand binding induces structural changes in the E domain that result in release of the corepressor/Sin3/HDAC complexes from the receptor, and binding of coactivator complexes that may include steroid receptor coactivator 1 (SRC-1), p300/cAMP responsive element binding protein (CBP), p300/CBP-associated factor (P/CAF), or p300/CBP cointegrator-associated protein (pCIP) to the LXXLL motif of the AF2-AD. Then, the coactivator complexes induce transcription by acetylating (Ac) the histone tails—resulting in decompaction of the nucleosomes into structures that are accessible to transcription factors. Dashed lines are used to represent coactivator and corepressor complexes because their composition in vivo is yet unknown. [Adapted with permission from Robyr D, Wolffe AP, Wahli W (2000). Nuclear hormone receptor coregulators in action: Diversity for shared tasks. Mol Endocrinol 14:339. Copyright 2000, The Endocrine Society.]

the C-terminal portion contributes to ligand binding.[533-536] The nuclear localization signal plays a particularly important role in the function of glucocorticoids and mineralocorticoid receptors because these receptors bind their ligand in the cytoplasm and must then localize to the nucleus to alter gene transcription.[525]

The E domain is known as the ligand-binding domain (LBD) or the hormone-binding domain. In addition to ligand binding, the E domain has effects on dimerization and transactivation.[522] The LBD consists of 11 to 12 α helixes (named H1 through H12) and contains a ligand-binding pocket that is made up of portions of some of

TABLE 2-5

Nuclear Receptors and Clinical Conditions Associated with Receptor Mutations

Receptor	Germ Line Mutation	Endocrine Disorder
Thyroid hormone receptor β (TRβ)	Inactivating mutations (heterozygous and homozygous)	Generalized resistance to thyroid hormones
Vitamin D3 receptor	Inactivating mutations (homozygous)	Vitamin D3 resistance
PPARγ2	Inactivating mutations (heterozygous)	Obesity or early-onset type II diabetes mellitus
HNF-4	Inactivating mutations (heterozygous)	Maturity-onset diabetes of the young (MODY) type I
Glucocorticoid receptor	Inactivating mutations (heterozygous)	Glucocorticoid resistance
Androgen receptor	Inactivating mutations (X-linked recessive)	Androgen insensitivity syndrome, Kennedy's disease
Estrogen receptor α (ERα)	Inactivating mutations (homozygous)	Tall stature and incomplete epiphyseal fusion
Mineralocorticoid receptor	Inactivating mutations (heterozygous, homozygous) Activating mutations (homozygous)	Pseudohypoaldosteronism type I Syndrome of apparent mineralocorticoid excess
DAX1	Inactivating mutations (X-linked recessive)	X-linked adrenal hypoplasia congenita

the different helixes.[537-540] For example, the thyroid receptor (TR) LBD has a ligand-binding cavity that includes components from H2, H7, H8, H11, and H12.[540] The contribution of different parts of LBD to the ligand-binding pocket accounts for the finding that mutation of single–amino-acid molecules in different helixes of the LBD can interfere with ligand binding.[525]

Unlike the AF-1/τ 1 transcriptional activating factor, the E domain activation factor 2 (AF2-AD) requires ligand binding to function (Figure 2-9).[538-545] Often, when the receptor is not bound by its ligand corepressor complexes simultaneously bind the LBD and transcriptional machinery consisting of protein complexes that place transcription factors on nucleosome binding sites (Figure 2-9).[538-545] The corepressor complexes then suppress gene transcription by using histone deacetylases to compact the nucleosomes into inaccessible structures (Figure 2-9).[546-549] Ligand binding induces structural rearrangements in the E-domain that lead to release of these corepressor complexes from the transcriptional machinery and the LBD, and exposure of the transcriptional machinery and the LXXLL motif of the AF2-AD to coactivator complexes (Figure 2-9).[538-545] These coactivator complexes have histone acetyltransferase activity that acts to relax nucleosome structures, enabling transcription factors to access nucleosome binding sites (Figure 2-9).[550]

Most nuclear receptors are capable of binding their hormone response element and repress transcription when they are not bound by their ligand.[551] However, in the absence of ligand steroid receptors are bound to a complex of heat-shock proteins instead of their response element and do not appear to repress transcription.[552]

Agonists and antagonists have different effects upon the interaction between the ligand binding pocket and AF2-AD. For example, when 17β-estradiol binds to the estrogen receptor the position of the AF2-AD containing H12 is altered so that coactivators can access the LBD-binding coactivator binding site.[537] However, when the estrogen antagonist raloxifene binds at the same site the coactivator binding site on H12 remains blocked by other portions of H12.[537]

Although some of the nuclear receptors are fully active when bound as monomers to DNA, the hormone receptors in the nuclear receptor superfamily are most active when bound as homodimers or heterodimers (Figure 2-9).[522] RXRs, hepatocyte nuclear factor 4, and the steroid receptors can bind DNA as homodimers or heterodimers.[522,553,554] The α isoform of the estrogen receptor (ESR1) is particularly promiscuous, and is able heterodimerize with HNF4-α and retinoic acid receptors, the β isoform of the estrogen receptor (ESR2), RXR and the thyroid receptors.[553,554] As a homodimer, RXR binds the dINSRect repeat 1 (DR1).[555] It can also join the thyroid, vitamin D3, and peroxisome proliferator-activated receptors to form heterodimers.[522,556-558]

Interestingly, it has also been suggested that some steroid hormones also act on transmembrane receptors—and these interactions may be responsible for the acute cellular effects of steroids.[559] Progesterone has been shown to interact with the G-protein–coupled uterine oxytocin, nicotinic acetylcholine, $GABA_A$, NMDA, and sperm cell membrane progesterone receptors.[560-565] Cell membrane estrogen and glucocorticoids receptors have also been identified.[566-569]

Subfamily 1 Nuclear Receptors: Thyroid Hormone, Vitamin D3, and Peroxisome Proliferator-Activated Receptors

THYROID HORMONE RECEPTORS

The two thyroid hormone receptor (THR) isoforms—thyroid hormone receptor α (THRA) and thyroid hormone receptor β (THRB)—are encoded by different c-erbA genes on chromosomes 17 and 3, respectively.[536,570] THRs that are not occupied by the thyroid hormone triiodothyronine (T3) exist as homodimers or heterodimers with RXRs that are attached to DNA thyroid hormone response elements in association with corepressor proteins.[571] Thyroid hormone binding induces the release of the corepressors from the THR.[571] A coactivator, steroid receptor coactivator-1 (SRC-1), is then able to attach to the THR—enabling activation of transcription.[571]

Generalized resistance to thyroid hormones (GRTH) is due to mutations in the THRB gene.[570,572,573] Patients with this syndrome have impaired receptor response to triiodothyronine (T3).[570] They have elevated T3 and thyroxine (T4) levels with normal TSH levels.[570,572,573] The clinical manifestations are variable but may include goiter, attention deficit disorder, hearing defects, learning disabilities, poor weight gain, mental retardation, and delayed boned age.[570,572,573]

Mutations have been found in the D and E domains of THRBs of GRTH patients.[570,574,575] Thus, these mutations alter ligand binding or transactivation.[570,575,576] However, most mutant THRBs retain the ability to repress transactivation of target genes through interactions with corepressors.[575,576] Some of the GRTH mutant receptors continue to associate with corepressors and are unable to bind the coactivator SRC-1 even when bound by T3.[576,577] Thus, mutant THRBs have a dominant negative effect in the heterozygote state because they are able to interfere with the function of wild-type receptors by repressing transcription of target DNA.[570,575,576]

Patients who are homozygous for deleterious mutations of THRB demonstrate more severe clinical abnormalities than patients who are heterozygous for the mutations. One such patient with a deletion of both THRB alleles presented with deaf mutism, dysmorphic features, and stippled epiphyses.[578] This condition is inherited in an autosomal recessive mode because the mutant allele is missing the THRB gene and is therefore unable to produce a THRB with corepressor function.[578] Another patient homozygous for a THRB mutant ("kindred S receptor") with an amino acid deletion in the ligand-binding domain presented with mental retardation, very delayed bone age, and very elevated T3 and T4 levels.[574,579] Heterozygous carriers of the kindred S receptor mutation have milder clinical manifestations of GRTH because this mutant THRB retains corepressor activity and thus has dominant negative effects.[574,579,580]

VITAMIN D3 RECEPTOR

Severe rickets, hypocalcemia, secondary hyperparathyroidism, and increased 1,25-dihydroxyvitamin D3 (D3) levels occur in patients with the autosomal recessive syndrome of "vitamin D3 resistance."[581] These patients have defective vitamin D3 receptors (VDRs). Mutations causing this syndrome have been found in the zinc fingers of the DNA-binding domain (C domain), leading to decreased or abolished receptor binding to regulatory elements of target genes.[582] Causative mutations have also been found that lead to the production of receptors that have decreased or abolished ability to bind D3 and heterodimerize with retinoid X receptors (RXRs), which are required for the VDR to maximally transactivate target genes.[582,583]

Less severe mutations in the VDR are associated with decreased gastrointestinal calcium absorption and bone mineral density, even during childhood, and an increased risk for osteoporosis and fractures.[584-589] However, it has not been possible to replicate these findings in some ethnic groups.[590-594] Thus, other factors (such as estrogen receptor genotype, dietary calcium, and age) probably contribute to the effects of VDR polymorphisms on bone mineral metabolism.[587,589,595,596]

VDR polymorphisms have been associated with pre- and postnatal growth failure. Absence of VDR alleles digested by BSMI in the presence of homozygosity for estrogen receptor alleles digested by PVU II estrogen receptor polymorphism is associated with decreased pre- and postnatal linear growth.[597] In addition, girls homozygous for VDR alleles digested by TaqI have been found to be shorter than girls who do not have the polymorphism.[598]

Other important associations have been found with VDR polymorphisms. Homozygous polymorphisms have been reported to be associated with primary hyperparathyroidism.[599] In addition, the presence of VDR alleles digested by TaqI is associated with increased risk for the development of early-onset periodontal disease.[600] Conversely, absence of such alleles has been associated with familial calcium nephrolithiasis.[601] Absence of alleles digested by BSMI may be a risk factor for the development of sarcoidosis.[602] However, the presence of these alleles is associated with hypercalciuria and nephrolithiasis and increased risk in women for the development of metastatic breast cancer.[603,604] Absence of alleles digested by ApaI may be a risk factor for the development of psoriasis.[605] VDR polymorphisms have also been associated with increased susceptibility to tuberculosis, leprosy, and other infections.[606-609]

PPARγ

The orphan nuclear receptor PPARγ2 has a role in regulating adipocyte differentiation and metabolism. This orphan receptor, as the term indicates, does not have a known ligand. Recent evidence suggests that mutations in the gene encoding PPARγ2 may cause obesity. A missense mutation leading to a Pro115Gln substitution near a site of serine phosphorylation at position 114 that suppresses transcriptional activation in PPARγ2 was found in some morbidly obese patients.[610] The Pro115Gln substitution interferes with phosphorylation of the serine at position 114, leading to increased transcriptional activation by PPARγ2—which in turn leads to increased adipocyte differentiation and triglyceride accumulation.[610]

Two other mutations in the PPARγ2 gene have been identified that cause severe insulin resistance, early-onset type 2 diabetes mellitus, and hypertension by the end of the third decade of life.[611] These mutations lead to amino acid substitutions that disturb the orientation of H12 in the E domain leading to decreased ligand-dependent transactivation by AF-2/AD and coactivator recruitment.[611] In addition, these mutant receptors interfere with wild-type receptor function in a dominant-negative manner by continuously suppressing target gene transcription.[611]

Subfamily 2 Nuclear Receptors: Hepatocyte Nuclear Factor and Retinoid X Receptors

This subfamily includes the HNF receptors and the RXR. RXRs form heterodimers with other nuclear receptors (including the estrogen, vitamin D, and thyroid hormone receptors) and with PPARγ (RXRs are discussed elsewhere in this chapter).

HNF

Alteration of another orphan nuclear receptor, HNF-4α, also causes an endocrine disorder. Mutations of the HNF-4α gene on chromosome 20 that alter the ligand-binding domain (E domain) or the DNA-binding domain (C domain) have been found in patients with maturity-onset diabetes of the young type I (MODY1).[612-615] Patients with MODY usually develop diabetes mellitus by the end of the third decade of life. They have a defect in glucose-mediated stimulation of insulin secretion.[613,616]

Carriers of a glycine-to-serine substitution in codon 115 in the DNA-binding domain (C domain) appear to be at increased risk for developing low-insulin diabetes mellitus.[617] Hepatocyte nuclear factors 3 (HNF-3α, -3β, and -3γ) are also regulators of the early-onset type 2 diabetes genes HNF-1 α, HNF-4 α, and IPF-1/PDX-1—which are associated with MODY types 3, 1, and 4, respectively.[618-621]

Subfamily 3 Nuclear Receptors: The Steroid Receptors and Glucocorticoid, Androgen, Estrogen, and Mineralocorticoid Receptors

GLUCOCORTICOID RECEPTORS

Glucocorticoid resistance is clinically characterized by the presence of elevated plasma cortisol and ACTH levels, accompanied by the effects of hyperaldosteronism and hyperandrogenism in the absence of striae and central fat deposition.[536,622,623] Excess adrenal steroids are made in an attempt to make sufficient cortisol to overcome glucocorticoid resistance. Thus, patients with this disorder may also suffer from hypokalemia, hypertension, fatigue, severe acne, hirsutism, irregular menses, and infertility.[622,623] Boys may present with isosexual precocity.[624]

A single Ile 559 to Asp 559 mutation in the DNA-binding domain is responsible for many cases of glucocorticoid resistance.[625] This mutation has a dominant negative effect in that it is able to inhibit the function of the wild-type allele in the heterozygote state.[625] Thus, glucocorticoid resistance is often an autosomal-dominant familial disease. Glucocorticoid resistance can also be caused by a mutation in the nuclear localization signal consensus that interferes with hormone-induced nuclear translocation of the glucocorticoid receptor.[626] According to the HUGO Gene Nomenclature Committee, the glucocorticoid receptor is also known as the nuclear receptor subfamily 3, group C, member 1 (NR3C1). However, the HUGO Gene Nomenclature Committee also acknowledges the alias GR for the glucocorticoid receptor. GR will be used as the abbreviation for glucocorticoid receptor for the remainder of this chapter.

ACTH-secreting pituitary macroadenomas can also be caused by a frame-shift mutation in the GR gene that interferes with signal transduction.[625] Patients with this mutation manifest the symptoms of glucocorticoid resistance. The tumor develops as a result of impaired negative feedback regulation by glucocorticoids of the hypothalamic-pituitary axis.

ANDROGEN RECEPTORS

The human androgen receptor (AR) gene is located on the X chromosome. Known disorders characterized by AR dysfunction due to AR gene mutations are only expressed in patients with a 46 XY karyotype.[627] Thus, these disorders are either transmitted by X-linked recessive inheritance or are due to sporadic mutations.

Numerous mutations of the AR gene have been found to cause androgen insensitivity syndrome (AIS; testicular feminization). The phenotype of this syndrome can vary in severity from partial undervirilization to complete AIS characterized by intraabdominal testes, absence of mullerian structures, absence of androgen-induced body hair such as pubic and axillary hair, and a female appearance.[627-629] Incomplete AIS refers to individuals with ambiguous external genitalia with an enlarged clitoris or microphallus and patients with Reifenstein syndrome.[628] Reifenstein syndrome is characterized by severe hypospadias with scrotal development and severe gynecomastia.[628]

The phenotypic heterogeneity of AIS is due to the wide variety of locations for the mutations causing AIS. Functional consequences of each mutation causing AIS relate to the function of the domain in which the mutation is located. However, the degree of impairment of mutated receptor function in in vitro studies does not always correlate with the phenotypic severity of the syndrome.[630]

Mutations in exons that code for the AR hormone-binding domain decrease hormone-binding affinity.[631] However, these mutations do not abolish the hormone-binding capability of the receptor.[631] Thus, patients with these mutations usually present with the incomplete AIS or occasionally with complete AIS.[631-634] Patients with mutations in the hormone-binding domain do not appear to respond to treatment with high doses of testosterone.[631] Mutations in the DNA-binding domain lead to failure of target gene regulation. Thus, patients with these mutations usually manifest the complete AIS.[635,636]

Complete AIS is also caused by a point mutation that results in a premature termination condition, leading to transcription beginning downstream of the termination signal and the AF1/tau1 domain.[637] Numerous other mutations have been described that cause truncation or deletion of the AR and complete AIS.[638-641] Two patients with ambiguous genitalia and partial virilization were found to be mosaic for mutant ARs.[642,643]

Some patients with Reifenstein syndrome have been found to have a mutation in the DNA-binding domain that abolishes receptor dimerization.[644] Other patients have been found to have a mutation in a different area of the DNA-binding domain that does not effect receptor dimerization, or to have mutations in the hormone-binding domain in the E domain.[645-648] The Ala596Thr mutation in the D-box area of the DNA-binding domain has been associated with an increased risk of breast cancer.[649]

AIS is also a feature of Kennedy's disease, which is an X-linked recessive condition causing spinal and muscular atrophy.[632] This condition is caused by extension of a poly-CAG segment in the AR gene exon that codes for the N-terminus of the AR, leading to an increased number of glutamine residues in the A/B domain.[650,651] ARs with a polyQ region increased to 48 glutamine residues accumulate abnormally in transfected cells due to misfolding and aberrant proteolytic processing.[652] Because polyQ extension does not completely abolish of transactivation, patients with Kennedy's disease exhibit a mild partial AIS phenotype consisting of normal virilization accompanied by testicular atrophy, gynecomastia, and infertility.

ESTROGEN RECEPTORS

Two major full-length estrogen receptor isoforms have been identified in mammals. Estrogen receptor α (ESR1) was discovered first and mediates most of the known actions of estrogens.[536] ESR1 is expressed primarily in the uterus, ovaries, testes, epididymis, adrenal cortices, and kidneys.[653] Estrogen receptor β (ESR2) was discovered in 1996.[654] ESR1 and ESR2 share 95% and 50% homology in the DBD and LBD, respectively.[655] There is little homology in the N-terminal between the two isoforms.[655] ESR2 is expressed primarily in the uterus, ovaries, testes, prostate, bladder, lung, and brain.[653] Although ESR2 has a high affinity for estrogens, it has less transactivating ability than ESR1 and has not yet been found to be involved in any pathologic condition.[536,656,657]

There is evidence supporting the existence of other functional estrogen receptors.[658] Some of these putative estrogen receptors localize to the cell membrane instead of or in addition to the nucleus. A 46-kDa amino terminal truncated product of ESR1, named ER46, localizes to the cell membrane and mediates estrogen actions that are initiated at the cell membrane.[659] Another of these putative estrogen receptors has been named ER-X and is postulated to be a G-protein–coupled receptor that localizes to the cell membrane.[660] Another putative receptor is the aptly named heterodimeric putative estrogen receptor (pER), which has been found on the cell and nuclear membranes.[661] The pER acts as a serine phosphatase.[661] Five other estrogen-binding proteins have also been identified, and at least three of them localize to the cell membrane.[662-665]

It had been thought that androgens are the main hormones responsible for closing the epiphyses during puberty. In 1994, however, it was shown from extensive studies of a 28-year-old man with incomplete epiphyseal closure and continued linear growth (in spite of otherwise normal pubertal development) that the estrogen receptor mediates epiphyseal closure.[666] He was found to have a homozygous C-to-T point mutation of codon 157 of the second exon in the ESR1 gene, introducing a premature termination signal. Expression of this gene leads to the production of a nonfunctional ESR1 lacking both the DNA- and hormone-binding domains. He was also found to have increased estradiol levels, impaired glucose tolerance with hyperinsulinemia, and decreased bone density.

Further strengthening the association between ESR1 and epiphyseal closure is the observation that women with ESR1-positive breast cancer and a mutation in the B domain (B' allele) of ESR1 have an increased incidence of spontaneous abortion and tall stature.[667] These associations were not found in female carriers of the allele without breast cancer or with ESR1-negative breast cancer. Thus, a second (as yet undiscovered) mutation is likely to play a role in the development of tall stature and spontaneous abortions in female carriers with ESR1-positive breast cancer.

MINERALOCORTICOID RECEPTORS

Mineralocorticoid resistance is also known as pseudohypoaldosteronism (PHA). Both sporadic and familial cases with either autosomal-dominant or -recessive cases have been reported.[668-672] Clinical presentation of patients with PHA ranges from asymptomatic salt wasting; to growth failure; to chronic failure to thrive, lethargy, and emesis; to life-threatening dehydration accompanied by severe salt wasting.[669-671,673-675] Patients with the severe forms of PHA typically present within a year of birth and may even present in utero with polyhydramnios due to polyuria.[676] Biochemically, the condition is characterized by urinary salt wasting, hyponatremia, elevated plasma potassium, aldosterone, and renin activity and urinary aldosterone metabolism that are unresponsive to the mineralocorticoid treatment.[677-679]

Two forms of PHA are recognized. PHA type I consists of classical PHA (due to renal tubular mineralocorticoid resistance) and PHA type II with kidney, intestine, salivary and/or sweat gland mineralocorticoid resistance.[680] Unlike PHA type I, PHA type II is not due to defective mineralocorticoid function. Rather, it is due to increased chloride reabsorption by the renal tubule. Patients with these conditions present with hyperkalemia that only responds to treatment with non-chloride ions, such as bicarbonate or sulfate, which increase delivery of sodium to the distal tubule.[681]

A transient form of mineralocorticoid resistance probably due to abnormal maturation of aldosterone receptor function also exists.[682] This variant of PHA is known as the syndrome of early-childhood hyperkalemia. Children with this disorder present with failure to thrive or linear

growth failure accompanied by hyperkalemia and metabolic acidosis. This condition resolves spontaneously by the second half of the first decade of life.

The cause of PHA type I is not well understood. The HUGO Nomenclature Committee refers to the mineralocorticoid receptor as the nuclear receptor subfamily 3, group C, member 2 (NR3C2) but accepts the alias MR for the mineralocorticoid receptor. MR will be used in the remainder of this chapter. MRs from patients with PHA type I exhibit decreased or absent binding to aldosterone.[683] Mutations have been identified in the genes for MR in patients with PHA type I.[684] However, these mutations are not thought to be solely responsible for causing this condition because they have also been found in individuals without PHA.[684] Altered MR transcription does not appear to cause PHA type I because MR mRNA levels are not decreased in patients with this condition.[683] Thus, it has been hypothesized that PHA type I may be due to a defective post-receptor event that may involve cofactors involved in ligand binding.[677,684]

An interesting syndrome involving overactivation of the MRs is the syndrome of apparent mineralocorticioid excess. Patients with this autosomal-recessive condition can exhibit pre- and postnatal growth failure, hypervolemic hypertension, medullary nephrocalcinosis, and hypokalemic metabolic alkalosis accompanied by hyporeninemic hypoaldosteronism.[685-688] Patients with this syndrome may also be asymptomatic and exhibit only biochemical abnormalities.[689] Patients with this syndrome also have increased serum and urinary cortisol-to-cortisone ratios.[688] This syndrome is caused by mutations in the 11 β-hydroxysteroid dehydrogenase type 2 (11 β-HSD2) genes that reduce the activity of the enzyme.[687,688,690-692] 11 β-HSD2 converts the active glucocorticoid cortisol to inactive cortisone. Thus, decreased activity of 11 β-HSD2 increases cortisol levels in MR-containing tissues, leading to increased binding and activation of MRs by cortisol.[687,688]

Subfamily 0 Nuclear Receptors: DAX1

Subfamily 0 nuclear receptors include DAX1.[523] DAX1 plays a role in the regulation of steroid, mullerian-inhibiting substance, and gonadotropin production.

DAX1

The dosage-sensitive sex-reversal adrenal hypoplasia congenital critical region on the X chromosome gene 1 (DAX1) is an orphan nuclear receptor because its ligand has not yet been identified.[693] It has homologies in the E domain to other orphan receptors, including RXRs.[694] However, DAX1 has an unusual DNA-binding C domain that contains a tract of amino acid repeats instead of zinc finger motifs.[694] DAX1 inhibits steroidogenic factor 1 (SF-1)-mediated transcription. SF-1 is another orphan nuclear receptor that regulates transcription of adrenal and gonadal steroid hydroxylases, mullerian-inhibiting substance, and gonadotropin genes.[695,696]

DAX1 gene mutations have been identified that cause X-linked adrenal hypoplasia congenita.[694] Patients with this condition have congenital adrenal insufficiency and are therefore deficient in glucocorticoid, mineralocorticoid, and androgen production.[694,697] Gonadotropin deficiency and azoospermia also occur in these patients.[697,698] Female carriers may have delayed puberty.[698] All mutations that have been found to cause X-linked congenital adrenal hypoplasia are either located in or prevent transcription of the area of the E domain that inhibits SF-1-mediated transcription.[693,699-701] Thus, DAX1 mutations may cause X-linked congenital adrenal hypoplasia by altering SF-1 regulation of gonado- and adrenogenesis.[699] DAX1 deletion may also occur in the setting of the contiguous gene deletion syndrome, resulting in complex glycerol kinase deficiency (cGKD) if individuals have deletions extending from the GK gene into the Duchene muscular dystrophy (DMD) gene and/or involving a significant extension telomeric from DAX1.[702]

Summary

Understanding of receptors that transduce or influence hormone action has increased dramatically during the past decade. As molecular biology techniques improve, it is expected that knowledge of receptor action will continue to increase at a rapid pace. It is likely that subtle defects in receptor function (such as regulatory or promoter region mutations that increase or decrease receptor gene expression, or mutations in second messenger proteins) will be found that cause endocrine disorders. It is also likely that new receptors will be discovered that transduce or influence hormone action and that endocrine roles will be found for receptors that were not previously thought to mediate or alter hormone action.

Skeleton: Cartilage and Bone
  Effects of Hormones and Growth Factors on the Skeleton
  Assessment of Bone Mass and Strength
Concluding Remarks

Introduction

Calcium (Ca), phosphorus [as phosphate (HPO_4^{2-}) because this substance does not exist in the free state in living tissues], and magnesium (Mg) are elements essential to the structural integrity of the body and to the function of each of its cells[1] (Table 3-1). This chapter examines the genetic and physiologic mechanisms that regulate normal mineral homeostasis and bone development, composition, and strength from the prenatal period through adolescence. Table 3-2 lists some of the many genes that direct these processes. Figure 3-1 schematically depicts the factors that regulate serum concentrations of calcium and phosphate.

Calcium

Calcium is an essential component of the mineral portion of bone and is necessary for the function of each of the body's cells. Together, calcium and phosphate form the hydroxyapatite crystal [$Ca_{10}(PO_4)_{10}(OH)_2$] of bone. Hydroxyapatite accounts for 65% of bone weight and provides its mechanical and weight-bearing strength. Hydroxyapatite also serves as a reservoir for calcium that may be quickly needed for homeostatic and functional purposes. Although 99% of total body calcium is present in the slowly exchangeable deeply deposited skeletal crystal, it is the rapidly exchangeable 1% of body calcium in recently accumulated surface bone and in vascular, extracellular, and intracellular (soft tissues) spaces with which it is in equilibrium that modulates intercellular communication and intracellular signal transduction; neural transmission; cell-to-cell adhesion; clotting; striated, smooth, and cardiac muscular contraction; cardiac rhythmicity; enzyme action; synthesis and secretion of endocrine and exocrine factors; and cellular proliferation.[2]

Approximately 50% of total serum calcium is bound to albumin and globulin; 5% is complexed/chelated to citrate, phosphate, lactate, bicarbonate, and sulfate; and 45% is present as biologically active and closely regulated ionized Ca^{2+}_e. Serum total and ionized calcium concentrations are related to levels of albumin, creatinine, parathyroid hormone (PTH), phosphate, and serum pH. Approximately 75% of the variability in total serum calcium concentrations is accounted for by genetic factors.[3] The measured Ca^{2+}_e level is dependent on the serum pH (normal adult range

TABLE 3-1

Abbreviations

$1,25(OH)_2D_3$	1,25-Dihydroxyvitamin D_3 (calcitriol)
$24R,25(OH)_2D_3$	24,25-Dihydroxyvitamin D_3
$25OHD_3$	25-Hydroxyvitamin D_3 (calcidiol)
aa	Amino acid
ADHR	Autosomal-dominant hypophosphatemic rickets
AF	Activating function
AMP	Adenosine monophosphate
ATP	Adenosine triphosphate
ATPase	Adenosine triphosphatase
BMAD	Bone mineral apparent density ~ volumetric BMD
BMC	Bone mineral content
BMD	Bone mineral density
BMP	Bone morphogenetic protein
BRU	Bone remodeling unit
BTT	Bone transmission time
Ca^{2+}_e	Calcium (ionized, extracellular)
Ca^{2+}_i	Calcium (ionized, intracellular)
CaSR	Calcium-sensing receptor
Cl^-	Chloride
DAG	1,2-Diacylglycerol
DBP	Vitamin D binding protein
DEXA	Dual energy x-ray absorptiometry
DNA	Deoxyribonucleic acid
Dpd	Deoxypyridinoline
ECF	Extracellular fluid
ER	Estrogen receptor
FGF	Fibroblast growth factor
FGFR	Fibroblast growth factor receptor
FRP4	Frizzled related protein-4
GABA	Gamma (γ) amino butyric acid
GDNF	Glial cell line-derived neurotrophic factor
$G_{i\alpha}$	Alpha subunit of inhibitory GTP-binding protein
$G_{s\alpha}$	Alpha subunit of stimulatory GTP-binding protein
$G_{q\alpha}$	Alpha subunit of another stimulatory GTP-binding protein
GH	Growth hormone
GPCR	G-protein–coupled receptor
GMP	Guanosine monophosphate
GTP	Guanosine triphosphate
H^+	Hydrogen ion, proton
ICTP	Carboxyl terminal cross-link telopeptide of collagen type I
IGF	Insulin-like growth factor (somatomedin)
Ihh	Indian hedgehog
IL	Interleukin
IP_3	Inositol-1,4,5-trisphosphate
K^+	Potassium
LRP	Low-density lipoprotein receptor-related protein
MAPK	Mitogen activated protein kinase
MARRS	Membrane-associated rapid response steroid binding protein (see TBP-2)
M-CSF	Macrophage colony stimulating factor
MEPE	Matrix extracellular phosphoglycoprotein
Mg^{2+}	Magnesium
MMP	Matrix metalloproteinase
Na^+	Sodium
NFκB	Nuclear factor-κB
NPT2	Sodium/phosphate transporter 2, kidney
NTx	Amino terminal cross-link telopeptide of collagen type I
OMIM	Online Mendelian Inheritance in Man
OPG	Osteoprotegerin
P3H1	Prolyl 3-hydroxylase-1
PHEX	Phosphate-regulating endopeptidase on the X chromosome
PICP	Carboxyl terminal propeptide of collagen type I
PIIINP	Amino terminal propeptide of collagen type III
PKA	Protein kinase A
PLC	Phospholipase C
PO_4	Phosphate (HPO_4^{2-})
PTG	Parathyroid gland
PTH	Parathyroid hormone
PTHrP	PTH-related protein
PTHR1	PTH/PTHrP receptor (PTH/PTHrP-R)
Pyr	Pyridinoline
QCT	Quantitative computed tomography
QUS	Quantitative ultrasonography
RANK	Receptor activator of NFκB
RANKL	RANK ligand
RNA	Ribonucleic acid
RXR	Retinoic acid X receptor
SOS	Speed of sound
SOX	SRY-Box
STAT	Signal transduction and transcription
TALH	Thick ascending loop of Henle
TBP-2	Thioredoxin binding protein-2 (see MARRS)
TGF	Transforming growth factor
TIP	Tuberoinfundibular protein (hypothalamic)
TLIMP	TBP-2-like inducible membrane protein
TNF	Tumor necrosis factor
TNSALP	Tissue nonspecific alkaline phosphatase
TR	Thyroid (hormone) receptor
TRAF	TNF receptor associated factor(s)
TRANCE	TNF-related activation induced cytokine
TRAP	Tartrate-resistant acid phosphatase
TRP	Transient receptor potential (channel)
VDR	Vitamin D receptor
VDRE	Vitamin D response element
VEGF	Vascular endothelial growth factor
XHR	X-linked hypophosphatemic rickets

a. A = adenine, C = cytidine, G = guanine, T = thymidne.

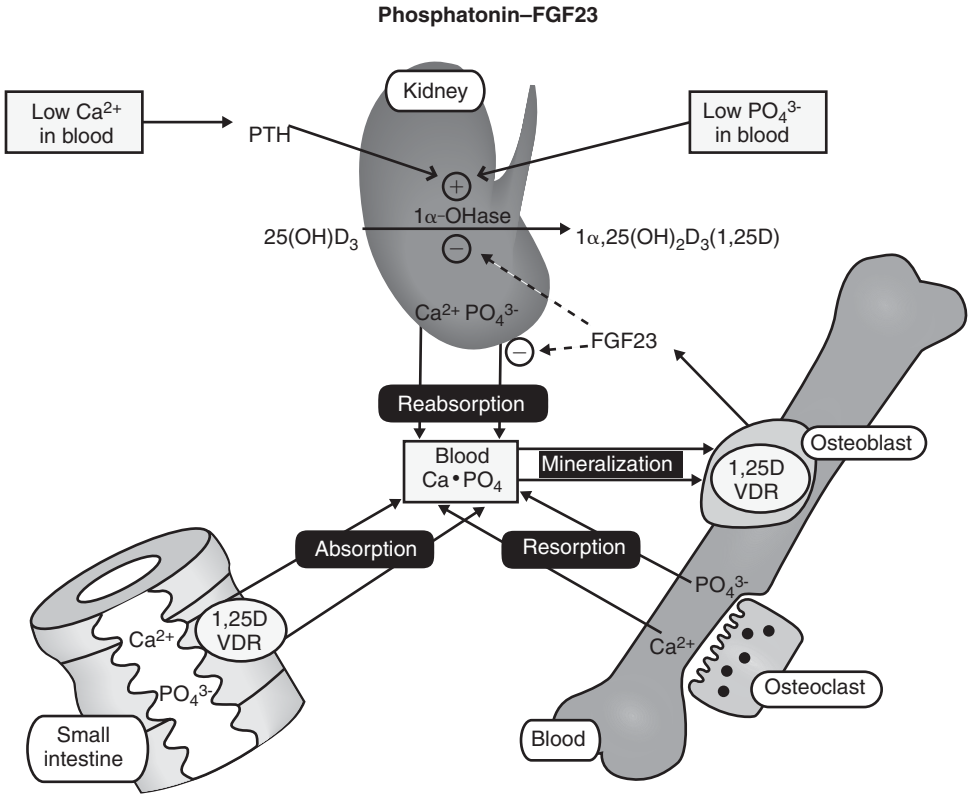

Figure 3-1. Regulation of calcium and phosphate homeostasis. Calcium is absorbed from the intestinal tract, kidney tubule, and bone in response to calcitriol [$1,25(OH)_2D_3$] and parathyroid hormone (PTH). Calcitonin inhibits resorption of calcium from bone. The Ca^{2+}-sensing receptor modulates the activity of the parathyroid glands and the renal tubules. Hypocalcemia and hypophosphatemia enhance renal tubular generation of calcitriol and absorption of intestinal phosphate. PTH inhibits renal tubular reabsorption of phosphate. Fibroblast growth factor-23 (FGF23), a phosphatonin secreted by osteoblasts, inhibits renal tubular reabsorption of phosphate and synthesis of calcitriol. [Reproduced with permission from Kolek OI, et al. 1.15-1.35 mmol/L at pH 7.4). An increase in alkalinity (higher pH) raises calcium binding to albumin, thus decreasing $Ca^{2+}{}_e$—whereas acidic changes (lower pH) decrease binding and thus increase $Ca^{2+}{}_e$. The relationship between pH and $Ca^{2+}{}_e$ is best described by an inversely S-shaped third-degree function.[4]

The serum concentration of $Ca^{2+}{}_e$ is maintained within narrow limits by an integrated system involving the plasma membrane $Ca^{2+}{}_e$ sensing receptor (CaSR), PTH and its receptor [PTH and PTH-related protein (PTHrP)-R], the thyroidal parafollicular C-cell product calcitonin and its receptor, and the vitamin D hormone system acting upon the intestinal tract, bone, and kidney[5] (Figure 3-1). With increase in serum $Ca^{2+}{}_e$ concentration, the CaSR on the chief cell of the parathyroid gland (PTG) is activated, which depresses PTH secretion instantly—whereas the CaSR in the distal renal tubule is activated, decreasing reabsorption of calcium filtered through the glomerulus and increasing urinary calcium excretion. When the serum $Ca^{2+}{}_e$ concentration falls, signaling through the CaSR also declines—thereby increasing PTH secretion and renal tubular reabsorption of filtered calcium, activating osteoclastic bone reabsorption, and somewhat later increasing synthesis of 1,25 dihydroxyvitamin D_3 (calcitriol) and intestinal absorption of ingested calcium.[1]

The intracellular concentration of cytosolic free $Ca^{2+}{}_i$ is 10,000-fold less than that in serum and extracellular fluid, a gradient maintained by extrusion of the cation through energy-dependent sodium-calcium exchangers.[2] Within the cell, $Ca^{2+}{}_i$ is primarily (99%) within mitochondria, associated with the endoplasmic reticulum, or bound to the inner plasma membrane—from which sites it can be released by chemical signals [e.g., inositol-1,4,5-trisphosphate (IP_3)]. IP_3 acts upon IP_3 receptors (encoded by ITPR1; see Table 3-2 for gene locus and OMIM site) located in the membrane of the endoplasmic reticulum to effect rapid egress of Ca^{2+} from storage and thereby quickly increase $Ca^{2+}{}_i$ levels.[6]

$Ca^{2+}{}_i$ serves as a second-messenger signal transducer that controls many cellular activities, including cell movement, secretion of synthesized products, transcription, and cell division and growth. Ca^{2+} enters the cell through transmembrane protein "pores," such as voltage-gated calcium channels that "open" in response to depolarization of the plasma membrane—permitting rapid influx of Ca^{2+} into the cell cytoplasm and leading to further depolarization of the membrane and activation of cell function.[7,8] These channels are widely distributed in the plasma membranes of all cells (e.g., neurons; cardiac, skeletal, and smooth muscle; endocrine glands; gastric mucosa; white

blood cells; and platelets) and in cytoplasmic organelles such as mitochondria and the endoplasmic reticulum. They may be activated by high or low electrical voltage. The skeletal muscle high-voltage–activated calcium channel consists of five subunits: α_1, α_2, β, γ, and δ. The voltage-sensing pore-forming Ca^{2+}-binding α_1 subunit has four repeated domains, each with six transmembrane-spanning regions (or helixes) and intracytoplasmic amino and carboxyl terminals. Transmembrane helix 4 serves as the voltage sensor. The α_1 subunit also has a sequence of amino acids between transmembrane helixes 5 and 6 that is partially inserted into the membrane to serve as a "selectivity filter."[8]

The assembly, intracellular movement, interaction with other proteins, activation, and kinetic properties of the α_1 subunit are modified by the extracellular glycosylated α_2 subunit, the β subunit (a cytoplasmic globular protein), a small membrane-spanning δ subunit that is disulfide linked to form dimeric $\alpha_2\delta$, and a second transmembrane subunit γ.[7-9] (The subunit structure of the low-voltage–activated voltage-gated calcium channels is as yet unknown.) The voltage-gated calcium channels are currently designated in accord with their cloned specific α_1 subunits and have been termed Cav 1.1, Cav 1.2 *(CACNA1C),* and Cav 1.3 to Cav 3.3. Formerly, they were designated in accord with the high- or low-voltage strength required for activation and for their sensitivity to specific inhibitors (e.g., L, N, P, Q, R, and T subtypes).[7,8,10,11]

The high-voltage–dependent L-type calcium channels (Cav 1.1 through Cav 1.4) are present in skeletal, cardiac, and vascular smooth muscle; endocrine cells; neurons; and fibroblasts. L-type calcium channels are activated by the guanine triphosphate (GTP)-binding α_q subunit of G_q proteins through stimulation of phospholipase C (PLC), leading to phosphorylation of the channel protein. L-type calcium channels modulate the growth and proliferation of fibroblasts and smooth muscle cells, the synthesis of extracellular matrix collagen proteins, and the activation of specific transcription factors.[9]

In addition to traversing rapidly across the cell's plasma membrane through voltage-gated channels, Ca^{2+} enters the cytosol but at a markedly slower rate through bifunctional membrane-associated IP_3 receptors that also serve as calcium channels.[6,12] Encoded by *ITPR1,* the tetrameric IP_3 receptor has six transmembrane domains and a pore-forming loop between the fifth and sixth transmembrane segments. Whereas many IP_3 receptors/channels are expressed in the endoplasmic reticulum, only one to two such channels are expressed in the plasma membrane of each cell. A third site of Ca^{2+} entry into the cytosol is through a plasma membrane protein important to "store-operated" Ca^{2+} entry termed CRACM1 [or TMEM142A (transmembrane protein 142A) or *ORAI1*].[6]

Store-operated Ca^{2+} entry is triggered after Ca^{2+} release from storage sites has depleted intracellular stores of $Ca^{2+}{}_i$ and is mediated by CRACM1, a protein with four transmembrane-spanning domains. Multiple copies of CRACM1 are expressed in each cell, permitting large amounts of Ca^{2+} to cross the plasma membrane through this route.[13] Loss-of-function mutations in *ORAI1* have been identified in patients with severe combined immune deficiency.[14] Ca^{2+} is translocated not only through specific Ca^{2+} channels but through paracellular transport channels.[15] $Ca^{2+}{}_i$ is extruded from cell cytoplasm by calcium and energy-dependent adenosine triphosphate (ATP)-driven calcium pumps and in exchange for sodium (Na^+) through H^+-ATPase and Na^+-Ca^{2+} exchangers.[1,2]

There are many intracellular calcium-binding proteins (e.g., calcium-binding proteins 1 and 4, calbindin, sorcin, calmodulin, and so forth). Calmodulin 1 *(CALM1)* is a widely distributed 149-aa protein with an amino terminal "lobe" linked to a carboxyl terminal lobe that can assume more than 30 three-dimensional conformations. It is a member of a large family of calcium-modulated proteins.[8] Each lobe has two calcium-binding motifs. Calcium binding exposes hydrophobic "pockets" that allow calmodulin to bind to and regulate the activity of target proteins. While bound to a target protein, calmodulin can assume any of an exceedingly large number of conformations. This versatility enables calmodulin to act as a calcium sensor for many different proteins subserving distinct processes within a single cell, including the voltage-gated calcium channels and calcium/calmodulin-dependent protein kinases.

Gastrointestinal absorption of calcium is primarily an active and saturable process (stimulated by calcitriol) that regulates the availability of transmembrane calcium "pumps" and channels on the luminal and basolateral surface membranes of duodenal and jejunal enterocytes.[1] The ileum and colon are also able to absorb calcium when dietary intake is low or demand increases. Calcitriol acting through the vitamin D receptor (VDR) increases duodenal expression of calcium transport protein-1 (epithelial calcium channel 2 encoded by *TRPV6*-transient receptor potential-vanilloid 6), a luminal calcium channel with six transmembrane domains and intracytoplasmic amino and carboxyl terminals that form a homotetramer or heterotetramer combined with TRPV5. [There are six subfamilies of the transient receptor potential (TRP) family of ion channels, many of which are permeable to calcium.[16]]

After entering the enterocyte, calcium traverses its interior within the cytosol or within a lysosomal vesical bound to $calbindin_{9kd}$. After fusion of the vesicle with the basolateral plasma membrane, Ca^{2+} is extruded. Ca^{2+} is also released into the circulation through a basolateral Na^+-Ca^{2+} exchanger *(SLC8A1)* or a Ca^{2+}-Mg^{2+}-dependent ATPase calcium channel *(ATPB21).* When present in high amounts, luminal calcium may also be absorbed by diffusion along paracellular channels. PTH indirectly increases intestinal calcium absorption by enhancing renal 25-hydroxyvitamin D-1α hydroxylase activity and calcitriol synthesis. Growth hormone (GH) and estrogens also increase intestinal absorption of calcium. Glucocorticoids and thyroid hormone inhibit this process.

Intestinal calcium absorption is increased during adolescence, pregnancy, and lactation—and is depressed in patients with nutritional or functional vitamin D deficiency, chronic renal disease, and hypoparathyroidism. Calcium is excreted into the intestinal tract in the ileum and in pancreatic and biliary secretions. The amount of calcium ingested influences the net amount of calcium absorbed. The lower the calcium intake the greater the efficiency of its absorption. In the adult, when the dietary

calcium intake is <200 mg/day fecal calcium excretion exceeds intake. Thus, active absorption of calcium cannot compensate for very low intake. As dietary calcium increases from 200 to 1,000 mg/day, active calcium absorption increases but at a progressively decreasing rate.

When dietary calcium exceeds 1,000 mg/day, active calcium absorption remains relatively constant at 300 mg/day but passive absorption of calcium through paracellular channels continues to increase.[1] Thus, hypercalcemia may result from dietary calcium excess (as in the milk-alkali syndrome). The availability of calcium for bone mineralization and cellular function is determined by its intake, absorption, excretion, and turnover. Intestinal calcium absorption is influenced by vitamin D status, its food source (the bioavailability of calcium in cow milk formulas is 38%, that in human breast milk is 58%; leafy green vegetables are also a good source of dietary calcium), the form of the calcium salt in supplements, and the presence in food of inhibitors of calcium absorption such as phytates, oxalates, or phosphates (e.g., cola beverages).[17]

It is currently recommended that infants (including those who are breast fed), children, and adolescents receive a minimum of 200 IU (5.0 μg) of cholecalciferol (vitamin D_3) daily, but this amount may be too low (vide infra).[18,19] Low calcium intake appears to be associated with increased fracture rate in children and adolescents, and therefore adequate dietary intake of calcium during infancy, childhood, and particularly adolescence has been considered necessary to attain a peak bone mass that may lessen the risk of fracture and the later development of osteopenia.[20]

In an effort to ensure optimal mineralization of the developing skeleton, age-related dietary intakes of elemental calcium for infants, children, and adolescents have been recommended (Table 3-3).[20] However, critical review of these recommendations suggests that after basal levels of calcium intake have been achieved (>500 mg/day in children and adolescents) increased calcium intake in dairy foods or supplements has only transient effects on indices of bone mineralization and no documented positive long-term effects on fracture rate or future risk of osteoporosis.[17] Nevertheless, adherence to these guidelines has been strongly advocated by the American Academy of Pediatrics.[20] In addition to dietary intake of calcium and vitamin D status, the most significant modifiable determinant of bone mineralization is weight-bearing physical activity (vide infra).[21]

NAS = National Academy of Science (1997 data), NIH = National Institutes of Health (1994 data).

Calcium is primarily excreted by the kidney. Ultrafiltrable serum calcium (both $Ca^{2+}{}_e$ and that complexed or chelated) crosses the renal glomerular membrane. Ninety-eight percent of filtered calcium is reabsorbed by the renal tubule [70% in the proximal renal tubule primarily by a paracellular mechanism, 20% in the thick ascending loop of Henle (TALH) by the paracellular route through generation of a lumen-positive voltage differential by a sodium-potassium-chloride (Na^+K^+-$2Cl^-$) transporter, and 8% in the distal convoluted tubule by active transcellular transport regulated by PTH and calcitriol].[1,22] In the TALH, calcium and magnesium are reabsorbed through voltage-driven paracellular channels (in part through paracellin-1, a tight-junction protein channel instrumental in renal reabsorption of filtered calcium and magnesium).

Cells of the TALH also express the CaSR on their basolateral membrane. When activated by peritubular Ca^{2+}, this G-protein–coupled receptor (GPCR) decreases renal tubular reabsorption of calcium through the paracellular channels by inhibiting activity of the Na^+-K^+-$2Cl^-$ transporter and lowering lumen-positive voltage. In active transcellular calcium reabsorption, Ca^{2+} crosses the luminal or apical surface of the renal distal convoluted tubular cell from the tubular lumen through calcium transport protein-5 (renal epithelial calcium channel 1 encoded by *TRPV5)*—whose expression is increased by calcitriol, estradiol, and a low-calcium diet. The multifunctional β-glucuronidase transmembrane protein klotho *(KL)* is able to de-glycosylate TRPV5, thereby trapping it in the renal tubular cell membrane and prolonging its activity.[23]

PTH increases calcium reabsorption in the distal tubule by increasing chloride efflux from the basolateral membrane of the distal renal tubular cell, thus increasing the transmembrane voltage gradient.[2] Calcium exits the basolateral serosal surface of the renal tubular cell against a chemical gradient in exchange for Na^+ through the Na^+-Ca^{2+} exchanger with the aid of Mg^{2+}-dependent Ca^{2+}-ATPase. Increased glomerular filtration and/or decreased renal tubular reabsorption increase renal excretion of calcium, phosphate, and magnesium. Urinary excretion of calcium is augmented by increased dietary intake, hypercalcemia of diverse pathophysiology (with the exception of that associated with familial hypocalciuric hypercalcemia), expansion of extracellular volume, metabolic acidosis, and loop diuretics (furosemide) (Table 3-4).[1] PTH and PTHrP increase renal tubular reabsorption of Ca^{2+}, whereas glucocorticoids, mineralocorticoids, and Ca^{2+} itself suppress its reabsorption.

In utero, fetal serum calcium concentrations are quite high (12-13 mg/dL), because calcium is transported across the placenta against a chemical gradient—likely under the influence of placentally synthesized calcitriol. The high calcium levels in umbilical cord blood (12 mg/dL) decline rapidly postnatally to a nadir of 9 mg/dL between 24 and 48 hours of age, increase to approximately 10 mg/dL, stabilize, and then decline marginally

TABLE 3-4

Factors Affecting Renal Excretion of Calcium, Phosphate, and Magnesium in Normal Subjects (Sites of Action)

ECF = extracellular fluid.

over the next 18 months. In children and adolescents, serum calcium levels are slightly higher than in adults (8.5–10.5 mg/dL). In preterm infants or full-term ill infants, hypocalcemia is often present because the PTH secretory response to hypocalcemia is blunted and calcitonin secretion exaggerated and prolonged.

CALCIUM-SENSING RECEPTOR

Plasma Ca^{2+}_e concentrations are detected by the CaSR, a 1,079-aa cell membrane protein with seven transmembrane domains whose extracellular domain binds Ca^{2+}, Mg^{2+}, and specific aromatic amino acids.[24] Through its binding of Ca^{2+}_e, the CaSR finely regulates the concentration of this anion by modulating the secretion of PTH and the renal tubular reabsorption of calcium. The CaSR is encoded by *CASR* and is a member of the C family of GPCRs with extremely long extracellular domains (500- to 600-aa residues) and homologies with receptors that bind glutamate, γ-amino butyric acid, and pheromones.[25,26] The very long extracellular domain is heavily glycosylated, a post-translational modification essential to efficient movement of the receptor to the cell surface. This domain forms "pockets" into which the ligand binds.

Interestingly, this GPCR is biologically active in the dimeric form linked by cysteine residue numbers 129 and 131.[24] Homodimerization of the CaSR takes place in the endoplasmic reticulum after core N-linked glycosylation. Homodimeric CaSR is then packaged within the Golgi apparatus, where it is further glycosylated and then transported to the cell membrane.[27] The CaSR is expressed on the plasma membrane of parathyroid chief cells, at the apical or basolateral membranes of most renal tubular cells (particularly the TALH and the collecting ducts), on the cell membranes of the parafollicular (C) cells of the thyroid, in cartilage, and in bone, lungs, adrenals, breast, intestines, skin, lens, placental cytotrophoblasts, and nervous tissue.[26,28]

The serum Ca^{2+}_e concentration is related to polymorphic variants of the CaSR. Seventy percent of individuals are homozygous for alanine at aa position 986 within the intracellular domain, 3% are homozygous for serine, and the remainder are heterozygous for the two aa. In heterozygous Arg986Ser and homozygous Ser986 subjects, Ca^{2+}_e concentrations are significantly higher than in those homozygous for Ala986.[29,30] In addition, there are cellular Ca^{2+} sensors unrelated structurally to the CaSR or to subtypes of the CaSR itself.[26] The CaSR also serves as a magnesium sensor and perhaps as a moderator of nutrient availability. By binding to the CaSR, aromatic L-amino acids appear to "sensitize" the receptor to a given level of Ca^{2+}_e.[24] The CaSR also modulates renal tubular reabsorption of magnesium, decreasing its reabsorption when serum cation values rise.

Although in the kidney the CaSR is expressed in greatest abundance in the basolateral (plasma) membranes of

the medullary and cortical TALH, it is also found in glomerular cells and other segments of the renal tubule.[26] There too, increasing peritubular concentrations of Ca^{2+}_e and Mg^{2+}_e inhibit renal tubular reabsorption of filtered Ca^{2+}. Acting through the CaSR, rising serum Ca^{2+}_e concentrations stimulate release of calcitonin from thyroid C cells. The CaSR is expressed throughout the (rat) intestinal tract, where it may modulate the changes in intestinal motility that accompany low (increased) and high (depressed) serum Ca^{2+}_e values. Cell membrane CaSRs are present in (mouse, rat, bovine) articular and hypertrophic chondrocytes of the epiphyseal growth plate and to a lesser extent in proliferating and maturing chondrocytes.[31]

Osteoblasts, osteocytes, and osteoclasts also express the CaSR—and agonist (Ca^{2+}, neomycin, gadolinium) activation of the CaSR stimulates intracellular signal transduction.[31] The CaSR may mediate recruitment of osteoblast precursor cells to sites of high Ca^{2+} levels, the residue of local osteoclast activity, thus linking the bone-remodeling processes of resorption and formation.[20] *In vitro* Ca^{2+} inhibits bone reabsorptive activity of (rabbit) osteoclasts by causing the osteoclast to decrease secretion of acid and catabolic enzymes and to withdraw from the site of bone resorption.[32]

Through its intracellular carboxyl terminal, the CaSR is linked to G proteins that couple the ligand-receptor message to intracellular signal transduction pathways.[24,26,33,34] After binding of Ca^{2+} to the extracellular domain of the CaSR, $G_{\alpha q/11}$ dissociates from its $\beta\gamma$ subunit complex and activates membrane-bound PLC-β1. In turn, this enzyme hydrolyzes membrane-bound phosphatidylinositol 4,5-bisphosphate to diacylglycerol and IP_3—the latter leading to increased cytosolic concentrations of Ca^{2+}_i. Activation of the CaSR also stimulates activity of phospholipases A_2 and D and mitogen-activated protein kinases (MAPK) but inhibits that of adenylyl cyclase, the latter through stimulation of adenylate-cyclase–inhibitory $G_{\alpha i}$ activity.[24] Within the PTG, increases in plasma Ca^{2+}_e and consequently cytosolic Ca^{2+}_i concentrations suppress expression, synthesis, and secretion of PTH and inhibit proliferation of chief cells.

Decline in Ca^{2+}_e leads to increased PTH secretion, thus enabling the CaSR to exercise minute-to-minute control over the release of PTH and hence of the Ca^{2+}_e. In the kidney, binding of Ca^{2+}_e to the CaSR decreases not only transcellular transport of filtered Ca^{2+} but its paracellular transport in the TALH.[28] Inactivating mutations in CASR result in familial hypocalciuric hypercalcemia, whereas gain-of-function mutations in this gene are associated with autosomal-dominant hypoparathyroidism ("familial hypercalciuric hypocalcemia").[24]

The Ca^{2+}/CaSR complex inhibits antidiuretic hormone-induced renal tubular permeability to water by decreasing the number of apical water channels in the inner medullary collecting ducts, thus leading to polyuria. The CaSR also binds Mg^{2+} and regulates its urinary excretion in a manner similar to that of Ca^{2+}. The CaSR is widely expressed throughout the gastrointestinal tract, where it may regulate secretion of gastrin and gastric acid, intestinal motility, and nutrient absorption.[35] Expression of the CaSR in the brain suggests a mechanism whereby Ca^{2+} may influence neural function locally by modulating neurotransmitter and neuroreceptor function (such as the metabotropic glutamate receptor, which also recognizes Ca^{2+}).

Calcimimetics are agonistic drugs that activate the CaSR. Calcilytics are antagonists of the CaSR.[35] As noted, the CaSR binds not only Ca^{2+}_e but Mg^{2+}_e, selected L-amino acids, and some antibiotics. The latter are designated type I calcimimetics. Synthetic compounds that bind to the transmembrane domains of the CaSR and increase the sensitivity of the CaSR to ambient Ca^{2+}_e are designated type II calcimimetics. The most widely employed of the calcimimetics is cinacalcet [N-[1-(R)-(-)-(1-naphthyl)ethyl]-3-[3-(trifluoromethyl)phenyl]-1-aminopropane hydrochloride], which has been effective in decreasing secretion of PTH in patients with primary or secondary hyperparathyroidism.[36] Calcilytics decrease the sensitivity of the CaSR to Ca^{2+}_e and thus increase the secretion of PTH and depress renal tubular reabsorption of Ca^{2+}. These compounds remain investigational at present but might in the future be useful for the treatment of some forms of metabolic bone disease.

Phosphate

Eighty-five percent of body phosphate is deposited in bone as hydroxyapatite. The remainder is intracellular (in the cytosol or mitochondria in the form of inorganic phosphate esters or salts, membrane phospholipids, and phosphorylated metabolic intermediate compounds) or in interstitial fluid or serum (0.1%), where it circulates as free orthophosphate anions HPO_4^{2-} and $H_2PO_4^-$ (55%), bound to proteins (10%), or complexed to calcium, magnesium, or sodium (35%).[1,22] At pH 7.4, serum HPO_4^{2-} and $H_2PO_4^-$ are present in a molar ratio of 4:1. In alkalotic states, the ratio increases—and with acidosis it declines. (At pH 7.4, 1 mmol/L of orthophosphate = 1.8 mEq/L = 3.1 mg/dL.) Intracellularly, cytosolic free phosphate concentrations approximate those in serum (i.e., 3–6 mg/dL). Phosphate is an integral and absolutely essential component of cellular and intracellular membrane phospholipids, ribonucleic (RNA) and deoxyribonucleic (DNA) acids, energy-generating ATP, and intracellular signal transduction systems.[2,37]

The serum phosphate concentration is regulated by intake, intestinal absorption, excretion, and renal tubular reabsorptive mechanisms and fluctuates with age, gender, growth rate, diet, and serum calcium levels.[1,38] Inasmuch as phosphate is found in all cells and foods, dietary deficiency is unusual. Dietary phosphate is absorbed across the intestinal brush border as HPO_4^{2-} in direct proportion to its intake, principally in the duodenum and jejunum. It is absorbed by both passive paracellular diffusion related to the luminal concentration of this anion and by an active transcellular mechanism stimulated by calcitriol.

The latter is an energy-requiring transport process with sodium through a Na^+-HPO_4^{2-} cotransporter protein (*SLC34A2*, solute carrier family 34, member 2) maintained by a calcitriol-dependent Na^+, K^+-ATPase. Phosphate is also secreted into the intestinal tract. When dietary

phosphate intake falls below 310 mg/day in the adult, net phosphate absorption is negative. At low phosphate intakes, absorption is active in the duodenum, jejunum, and distal ileum—whereas at high intakes 60% to 80% of ingested phosphate is absorbed primarily by diffusion. Phosphate absorption can be impaired by its intraluminal precipitation as an aluminum or calcium salt and by intestinal malabsorption disorders.

Phosphate is filtered in the renal glomerulus and reabsorbed in the proximal (85%) and distal convoluted tubules. It is actively transported across the luminal membrane against an electrochemical gradient through specific Na^+-HPO_4^{2-} cotransporter proteins with the aid of Na^+, K^+-ATPase.[1,22] Expression of the renal Na^+-HPO_4^{2-} cotransporter protein *(SLC34A1)* is regulated by serum phosphate levels (hypophosphatemia increases expression), PTH, PTHrP, and fibroblast growth factor (FGF)-23. Phosphate exits the renal tubular cell with sodium through cation exchange for potassium. The maximal tubular reabsorption of phosphate approximates the filtered load.

Tubular phosphate reabsorption is increased by low phosphate intake and hypophosphatemia (due to decrease in filtered load), hypercalcemia (by decrease in the glomerular filtration rate), depletion of extracellular fluid volume, and metabolic alkalosis (Table 3-4). Renal tubular reabsorption of phosphate is depressed by high phosphate intake and by PTH- and PTHrP-mediated down-regulation of *SLC34A1.* Calcitriol, glucocorticoids, and thiazide diuretics decrease renal tubular reabsorption of phosphate. Phosphate is deposited in bone as hydroxyapatite dependent on local levels of calcium, phosphate, and alkaline phosphatase activity and is reabsorbed by osteoclasts whose activity is stimulated by PTH, calcitriol, and other osteoclast-activating factors. Serum concentrations of phosphate are highest in infancy and early childhood (4–7 mg/dL) and then decline during mid-childhood and adolescence to adult values (2.5–4.5 mg/dL).

PHOSPHATONINS

Renal tubular reabsorption of phosphate is regulated by several substances collectively termed *phosphatonins* (Figure 3-1). Phosphaturic agents have been identified in the serum of normal subjects and in patients with X-linked hypophosphatemic rickets (XHR), which is due to loss-of-function mutations in the membrane-bound 749-aa endopeptidase encoded by *PHEX* (phosphate-regulating gene with homologies to endopeptidases located on the X chromosome). They have also been identified in patients with autosomal-dominant hypophosphatemic rickets (ADHR-OMIM 193100), due to activating mutations in *FGF23,* and in patients with tumor-induced osteomalacia in which increased production of FGF23 and other phosphaturic agents has been identified.[38,39]

By inhibition of phosphate transport in the kidney, phosphatonins lead to hyperphosphaturia and hypophosphatemia. They also inhibit activity of 25-hydroxyvitamin D-1α hydroxylase, resulting in decreased synthesis and thus inappropriately normal or low serum concentrations of calcitriol and in impaired intestinal absorption of phosphate.[40] Among the best characterized of the phosphatonins is FGF23, generated as a 251-aa with a 24-aa signal sequence that is post-translationally glycosylated. It is expressed primarily by osteoblasts and osteocytes and to a lesser extent by the brain, thyroid, PTG, thymus, cardiac/skeletal muscle, liver, and intestines. In osteoblasts, expression of FGF23 is enhanced by calcitriol acting through the VDR and modified by a chondrocyte-derived secreted factor yet to be characterized.[41,42]

FGF23 induces renal phosphate wasting by down-regulating expression of *SLC34A1,* the Na^+-HPO_4^{2-} cotransporter expressed in the apical or luminal membrane of the proximal renal tubule. It also down-regulates expression of a related renal tubular Na^+-HPO_4^{2-} cotransporter encoded by *SLC34A3,* and of 25-hydroxyvitamin D-1α hydroxylase encoded by *CYP27B1.* FGF23 acts through binding to the c isoform of tyrosine kinase FGF receptors (FGFR) 1, 2, and 3. The genes encoding the FGFRs consist of 19 exons that may be alternatively spliced to include or to exclude exon 8 or exon 9 (encoding the third extracellular immunoglobulin-like domain of the FGF receptor, which helps to specify the ligand bound by the receptor). When exon 8 is included in the mRNA transcript, the b isoform of the FGFR is formed. When exon 9 is included in the transcript, the c isoform is produced. Although it is likely that FGF23 binds to multiple FGFR c isoforms, the multifunctional protein klotho has been reported to convert FGFR1(IIIc) into a specific FGF23 receptor in renal tissue.[38,43] Highly sulfated glycosaminoglycans facilitate ligand-receptor interaction.

FGF23 is measurable in normal adult sera with a mean concentration of 29 pg/mL that does not correlate with age or gender. Its concentration is inversely related to that of phosphate, and values rise when dietary phosphate increases and decline with phosphate restriction.[38] Serum values of FGF23 are increased in patients with XHR, ADHR, tumor-induced osteomalacia, and fibrous dysplasia associated with hypophosphatemia. In patients with ADHR, gain-of-function mutations (e.g., Arg179Trp) in *FGF23* result in resistance to degradation of the protein that is normally cleaved between Arg179 and Ser180. In subjects with tumor-induced osteomalacia, the production of FGF23 is greatly increased.

Serum FGF23 concentrations are also elevated in the Hyp mouse model of XHR. FGF23 may be a substrate for PHEX enzymatic activity, but it is unclear if it is the endogenous substrate for this enzyme.[40,44] In the Hyp mouse, biallelic "knockout" of Fgf23 reverses the hypophosphatemia and relative calcitriol deficiency—suggesting that FGF23 is of fundamental pathogenic importance in XHR. In familial tumoral calcinosis (OMIM 211900), loss-of-function mutations in FGF23 lead to accelerated intracellular degradation of FGF23 that prevents secretion of intact protein—resulting in decreased renal excretion of phosphate, in hyperphosphatemia, in relatively increased calcitriol levels, and in diffuse ectopic calcification.[38,45]

Tumors associated with hypophosphatemic osteomalacia also express *FRP4* (frizzled related protein-4), *MEPE* (matrix extracellular phosphoglycoprotein), and *FGF7*—all of which have phosphaturic properties.[38,46] FRP4 is a secreted 346-aa glycosylated protein that shares the structure of the extracellular domain of transmembrane

frizzled receptors. The natural ligands of frizzled receptors are Wnt proteins, and their coreceptors are the cell surface low-density lipoprotein receptor-related proteins (LRP-5/6). These heterotrimeric complexes stabilize intracellular β-catenin and the attendant signal transduction systems and are essential for bone formation (vide infra).

Secreted FRP4 serves as a "decoy" receptor competing with the frizzled receptor for binding to Wnt, thus inhibiting the function of this receptor. FRP4 is expressed in bone cells and in large amounts by tumors with associated osteomalacia. In normal adults, the mean serum FRP4 concentration is 34 ng/mL. FRP4 inhibits sodium-dependent renal tubular phosphate reabsorption by inhibition of Wnt signaling, leading to hypophosphatemia. It also reduces expression of the gene encoding 25-hydroxyvitamin D_3-1α.hydroxylase.[40] MEPE is primarily expressed by osteoblasts, osteocytes, and odontoblasts—as well as by tumors associated with hypophosphatemic osteomalacia. It encodes a 525-aa 58-kDa protein, a member of the short-integrin-binding ligand-interacting glycoprotein family that also includes osteopontin. MEPE modulates osteoblast and osteoclast function and may both inhibit and support bone mineralization.[38] Although MEPE is able to inhibit sodium-dependent renal tubular phosphate reabsorption, its role in phosphate metabolism may be more complex inasmuch as knockout of MEPE in mice results in increased bone mass without altering serum phosphate or calcitriol values.[47] MEPE is associated with and may serve as a substrate for PHEX on the osteoblast surface.[44]

Magnesium

Magnesium is the fourth most abundant of the body cations. Two-thirds of body Mg is found in bone (primarily on the surface of the hydroxyapatite crystal, where 50% is freely exchangeable), one-third is intracellular, and 1% is in the ECF compartment.[1,2] In blood, magnesium (1.7-2.4 mg/dL = 0.7-1.0 mmol/L) is partially bound to proteins (30%), complexed to phosphate and other anions (15%), and found as free Mg^{2+}_e (55%). As with Ca^{2+}_e, Mg^{2+}_e levels rise as pH falls (increased acidity).[22]

Intracellularly, magnesium (0.5 mmol/L) is bound to ATP and other molecules. Ten percent is in the ionic form, and 50% within mitochondria. Mg^{2+}_e is a cofactor in many enzymatic reactions, including those that consume or produce ATP. Mg^{2+}_e alters free radicals and influences nitric oxide synthase activity, cyclic guanosine monophosphate generation, endothelin production, and immune function. Mg^{2+}_e decreases membrane excitability in nerve and muscle cells and blocks the excitatory *N*-methyl *D*-aspartate receptor. It is a necessary cofactor for the regulation of neuromuscular excitability, nerve conduction, enzyme activity, oxidative metabolism by mitochondria, glycolysis, phosphorylation, transcription, and translation. It is essential to the secretion (but not the synthesis) of PTH by the parathyroid chief cell.

Net intestinal magnesium absorption is directly related to dietary intake and independent of calcitriol.[1] Magnesium is passively absorbed primarily by diffusion through paracellular channels in proportion to the intestinal luminal concentration of this cation. In addition, there is a small component of active transcellular magnesium absorption. Magnesium is also excreted into the intestinal tract, where its absorption may be impaired by high phosphate intake, significant intestinal disease, or chronic laxative abuse.

Seventy percent of serum magnesium is ultrafiltrable and passes through the renal glomerular membrane. Ninety-five percent is reabsorbed: 15% in the proximal convoluted and straight tubules, 70% in the cortical TALH, and 10% in the distal convoluted tubule.[1,22] In the TALH, Mg^{2+} reabsorption occurs through a paracellular pathway that is impermeable to water.[48] Mg^{2+} is conducted from the lumen of the TALH to the interstitial space and vasculature by paracellin-1 (*CLDN16*, also termed claudin 16), a 305-aa tight-junction protein whose encoding gene is expressed only in the renal cortical TALH and distal convoluted tubule. Paracellin-1 has four transmembrane domains with intracellular carboxyl and amino terminals and is a member of the claudin family of proteins that bridge intercellular gaps within the tight junctions.[15,48]

Paracellin-1 is also utilized for Ca^{2+} reabsorption in the TALH. Loss-of-function mutations of *CLDN16* lead to familial autosomal-recessive renal hypomagnesemia because of renal wastage of magnesium in association with hypercalciuria and renal calcification (OMIM 248250).[48,49] In the distal convoluted tubule, Mg^{2+} reabsorption is related to activity of a Na^+-Cl^- cotransporter and perhaps to paracellin-1. PTH increases magnesium reabsorption in the renal TALH and distal convoluted tubule, perhaps by regulating paracellin-1. On the other hand, hypermagnesemia and hypercalcemia (acting through the CaSR) decrease renal tubular magnesium reabsorption—as do expansion of extracellular fluid volume, metabolic alkalosis, phosphate depletion, loop diuretics, aminoglycoside antibiotics, and impaired renal function (Table 3-4).[1]

Alkaline Phosphatase

The gene *(ALPL)* encoding tissue-nonspecific alkaline phosphatase (TNSALP) is expressed in bone (synthesized and secreted by the osteoblast), liver, kidney, and skin fibroblast. ALPL is a 507-aa protein that by alternative processing during transcription and translation permits the osteoblast to synthesize and secrete a reasonably specific bone form. Although TNSALP circulates as a homodimer, in tissue it is a homotetrameric ectoenzyme (ectophosphatase) located on the cell surface anchored through its carboxyl terminal to cell membrane phosphatidylinositol-glycan. In bone, alkaline phosphatase binds to collagen type I and prepares skeletal matrix for mineralization, hydrolyzes organic phosphates (thus increasing the local concentration of phosphate to a value that exceeds the calcium X phosphate product, encouraging deposition of calcium phosphate as hydroxyapatite), transports inorganic phosphate and Ca^{2+} into the cell, and inactivates pyrophosphate and other inhibitors of mineralization by removing their phosphate moieties.

Among the endogenous substrates for TSNALP are phosphoethanolamine and pyridoxal-5'-phosphate. The

hepatic form of TNSALP is formed by alternative splicing of exon 1 of *ALPL*. Hepatic alkaline phosphatase converts pyridoxal-5'-phosphate to pyridoxal, a compound essential for normal synthesis of neural γ-amino butyric acid (GABA)—an inhibitory neurotransmitter. Without pyridoxal-5'-phosphate, central nervous system levels of GABA are low and seizures may occur.[50] Loss-of-function mutations in ALPL lead to infantile, childhood, and adult forms of hypophosphatasia. Three genes encoding tissue-specific intestinal, placental, and germ cell alkaline phosphatase isoenzymes are clustered at chromosome 2q34-q37.

Parathyroid Hormone and Parathyroid-Hormone–Related Protein

PARATHYROID HORMONE

PTH is secreted by the chief cells of four paired PTGs that are derived from the endoderm of the dorsal segments of the third (paired inferior glands) and fourth (paired superior glands) pharyngeal pouches. Occasionally, there may be a fifth PTG embedded within the substance of the thyroid gland or in the mediastinum.[24] The thymus is formed by the endoderm of the third pharyngeal pouch and calcitonin-synthesizing parafollicular (C) cells of the thyroid by that of the fourth pharyngeal pouch. The mRNA of PTH has also been demonstrated in rodent thymus and hypothalamus.[51]

A critical factor for the development of the PTGs is the nuclear DNA binding transcription factor encoded by *Gcm2* (glial cell missing, drosophila, homolog of, 2). Although essential to neural glial cell development in insects, GCM is not expressed in mammalian brain but is expressed primarily in the rodent placenta and thymus *(Gcm1)* and in the PTG *(Gcm2)*. The pharyngeal pouch expression of *Gcm2* is maintained by a number of homeobox and transcription factors, including those encoded by Hoxa3, Pax1, Pax9, and Eya1. The human homolog of *Gcm2 (Gcm2* or *GCMB)* is expressed in the PTG and in intrathymic PTH-secreting adenomas but not by normal human thymus.[52] Intragenic deletion or missense mutations of *Gcm2* have been identified in subjects with familial autosomal-recessive hypoparathyroidism (Table 3-5).

Chief cells synthesize, store, and secrete PTH—a hormone that increases serum concentrations of calcium, lowers phosphate values, and exerts both anabolic and catabolic effects on bone [primarily in response to ambient Ca^{2+}_e concentrations that either enhance (when low) or repress (when high) transcription of *PTH* and secretion of PTH and regulate the rate of chief cell proliferation, responses mediated by the CaSR]. Calcimimetic drugs have inhibitory effects on PTH secretion. Higher phosphate values enhance transcription of *PTH*, secretion of PTH, and chief cell replication. 1α,25-dihydroxyvitamin D_3 (calcitriol) and its synthetic analogues inhibit transcription of *PTH*, secretion of PTH, and proliferation of chief cells.[24] In response to acute hypocalcemia, PTH stored in secretory vesicles is rapidly released. When hypocalcemia is prolonged, the secretion of $PTH^{1\text{-}84}$ is augmented by a decrease in its intracellular degradation and an increase in transcription of *PTH*. When hypocalcemia is extended, it is augmented by an increase in chief cell number.

The three exons of *PTH* encode the prepro-PTH sequence of 115 aa. The amino terminal 25-aa signal sequence (encoded by exon 2) is removed by furin, a prohormone convertase, as it leaves the endoplasmic reticulum [forming pro-PTH (90 aa)]. It is then further processed in the Golgi apparatus by furin to mature human PTH (84 aa). PTH is stored in secretory vesicles and granules. The stability, translation, and intracellular translocation of PTH mRNA are regulated by binding of cytosolic proteins to the 3'-untranslated region of PTH mRNA. These proteins include a member of the dynein complex that also binds to microtubules within the parathyroid chief cell and to HNRPD (heterogeneous nuclear ribnucleoprotein D or AUF1), which directs mRNA into the proteasomal pathway of degradation.[53]

TABLE 3-5

Parathyroid Hormone–Related Protein: Sites of Expression and Proposed Actions

Site	Action
Mesenchyma	
Periarticular cells	PTH-rP depresses the rate of differentiation of late-proliferating chondrocytes to hypertrophic chondrocytes, thus permitting increased proliferation and delay of ossification.
Bone	Enhances or depresses bone resorption.
Smooth muscle Vascular system Myometrium Urinary bladder	Relaxation.
Cardiac muscle	Positive chronotropic and inotropic effects.
Skeletal muscle	
Epithelia	
Skin	Perhaps regulates proliferation of keratinocytes.
Breast	Induces ductal branching, secreted into milk, and drives mobilization of calcium from maternal bone for transfer to nursing infant.
Teeth	Stimulates resorption of overlying bone enabling eruption.
Endocrine system	
Parathyroid glands	Stimulates transport of calcium.
Pancreatic islets	Stored and co-secreted with insulin.
Placenta	Enhances calcium transport.
Central nervous system	Neuroprotective by antagonizing excessive calcium-related excitotoxicity.

Compiled and adapted from Broadus AE, Nissenson RA (2006). Parathyroid hormone-related protein. In Favus MJ (ed.), *Primer on the metabolic bone diseases and disorders of mineral metabolism, Sixth edition.* Washington, D.C.: American Society for Bone and Mineral Research 99-106.

The full biologic activity of PTH^{1-84} is found in its first 34-amino-acid sequence, and all of its renal effects are localized within the segment PTH^{1-31}. Amino acid numbers 1 and 2 (serine-valine) comprise an activation sequence essential to the bioactivity of the amino terminal portion of PTH^{1-84}. The PTGs secrete intact PTH^{1-84}, a phosphorylated form of PTH^{1-84}, and carboxyl terminal PTH fragments of varying length but do not secrete amino terminal fragments of PTH^{1-84}.[54,55] Intraglandular PTH^{1-84} is degraded by cathepsins B and H (proteases colocalized with PTH^{1-84} in secretory granules). PTH degradation represents an important mechanism regulating the release of bioactive PTH^{1-84} and is accelerated when the Ca^{2+}_e concentration is elevated.

The half-life of circulating PTH^{1-84} is approximately 2 minutes. It is rapidly metabolized by the liver and excreted by the kidney. In the hepatic Kupffer cells, PTH^{1-84} is cleaved usually after either aa 33 or aa 36 to carboxyl terminal PTH peptides with half-lives of approximately 15 to 20 minutes. In the kidney, intact and carboxyl terminal fragments of PTH are filtered by the glomerulus, reabsorbed by the renal tubule, and then degraded to small fragments. Megalin (a multifunctional receptor expressed in coated pits on the luminal/apical surface, endocytic vacuoles, and lysosomes of proximal renal tubular cells; in the PTG; and in other epithelial structures) specifically recognizes intact PTH^{1-84} and amino terminal fragments of PTH and mediates the renal tubular endocytosis of intact PTH^{1-84} that has been filtered through the glomerulus.[28]

The classic functions of PTH^{1-84} as well as its shorter peptide derivatives PTH^{1-34} and PTH^{1-31} upon regulation of calcium and phosphate homeostasis are carried out through the seven-transmembrane G-protein–coupled PTH/PTHrP receptor in the renal tubule and osteoblast. Thus, with equal potency PTH^{1-84}, PTH^{1-34}, and PTH^{1-31} increase urinary excretion of phosphate by inhibiting its renal tubular reabsorption, the renal tubular and osteoclastic reabsorption of calcium thereby raising serum calcium concentrations common and the renal synthesis of calcitriol by enhancing expression of *CYP27B1* (encoding 25-hydroxyvitamin D_3-1α hydroxylase), thereby augmenting intestinal absorption of calcium. Mediated by the $G_{s\alpha}$ subunit of the G-protein and adenylyl cyclase, these actions involve generation of cyclic adenosine monophosphate (AMP) and signaling through protein kinase A (PKA). Whereas the first two residues of PTH^{1-84} (serine-valine) are essential to activation of adenylyl cyclase, residues 15 through 34 are needed for high-affinity binding to its receptor. In addition to cyclic AMP, PTH^{1-84} activates other signal transduction pathways in skeletal and kidney cells—including those involving PLC and cytosolic Ca^{2+} flux, PKC, and MAPK.[55]

As noted, multiple species of carboxyl terminal peptides derived from PTH^{1-84} circulate. They are secreted directly by the PTG or returned to the circulation after metabolism of intact PTH^{1-84} by hepatic Kupffer cells.[55] Indeed, carboxyl terminal fragments of PTH^{1-84} are secreted in greater abundance from the PTG than is intact PTH^{1-84}, and the proportion of carboxyl terminal fragments secreted increases as the ambient Ca^{2+} concentration rises. Many of the circulating carboxyl terminal fragments of PTH are generated by hepatic uptake and degradation of PTH^{1-84}.

Amino terminal fragments generated by hepatic degradation of PTH^{1-84} are degraded further within the liver and do not recirculate. PTH^{1-84} and the carboxyl terminal fragments of PTH are filtered by the kidneys, and the carboxyl terminal fragments are reabsorbed by the renal tubules and further degraded intracellularly. The kidneys are not a major source of circulating carboxyl terminal fragments of PTH. Among the carboxyl terminal fragments of PTH found in circulation are PTH^{7-84}, $^{24-84}$, $^{34-84}$, $^{37-84}$, $^{41-84}$, $^{43-84}$. They are extracted by the kidneys, muscle, and bone. The presence of as yet structurally uncharacterized receptors for these carboxyl terminal peptides of PTH^{1-84} has been demonstrated by their biologic actions.

In addition to their classic effects on mineral homeostasis, several nonclassic actions of PTH^{1-84} have been identified—including rapid and direct stimulation of intestinal calcium absorption independent of its effects on vitamin D metabolism, stimulation of hepatic gluconeogenesis, acute natriuresis and calciuresis, and enhancement of neutrophil movement *in vitro*.[55] Inasmuch as many of these nonclassic biologic effects of intact PTH are not replicated by the amino terminal fragment PTH^{1-34}, it has been suggested that they may be related to the carboxyl terminal portion of the protein.

Indeed, specific effects of carboxyl terminal PTH fragments have been observed [e.g., PTH^{7-84} lowers serum calcium levels in parathyroidectomized rats (maintained eucalcemic by diet) and antagonizes PTH^{1-84} -stimulated increase in calcium concentrations, urinary phosphate excretion, and bone turnover.[55] PTH^{7-84} directly lowers the rate of bone resorption and suppresses the bone resorbing effects of PTH^{1-34}, calcitriol, prostaglandin E_2, and interleukin (IL)-11. PTH^{7-84} also antagonizes osteoclastogenesis. On the other hand, PTH^{39-84} and PTH^{53-84} augment the biologic effects of PTH^{1-34}. PTH^{7-84} does not bind to the PTH/PTHrP receptor, nor does it inhibit PTH^{1-84}-mediated increase in cyclic AMP generation—implying that PTH^{7-84} acts through a unique receptor.

Because there are multiple circulating forms of PTH, its immunologic measurement is dependent on the specificity of the antibody or antibodies employed in the assay. When a polyclonal PTH radioimmunoassay is utilized, intact and carboxyl terminal fragments of PTH are usually measured. Use of dual monoclonal antibodies and immunometric assays has improved the specificity of immunologic assays. Nevertheless, most assays detect intact and selected fragments of PTH and are consequently rather poor predictors of bone turnover—particularly in patients with chronic renal insufficiency.[56] The comparability of PTH assays from different commercial sources is limited.[57] Employing a two-site immunochemiluminescent assay, serum PTH concentrations average approximately 11 to 13 pg/mL and range between 2.3 and 24.5 pg/mL in children and adolescents 2 to 16 years of age. Values do not vary with age but are a bit higher in girls than in boys.[58]

The synthesis and secretion of PTH^{1-84} and its various fragments are modulated for the most part by the serum Ca^{2+}_e concentration acting through the CaSR

expressed on the plasma membrane of the parathyroid chief cell. Because a change in serum Ca^{2+}_e concentration sensed by the parathyroid chief cell CaSR is quickly reflected in changes in cytosolic Ca^{2+}_i levels, the release of PTH is regulated on a minute-to-minute basis. Rapidly declining and steady-state low serum concentrations of Ca^{2+}_e increase PTH secretion by accelerating its release from storage sites in secretory granules. Hypocalcemia also raises PTG levels of PTH mRNA by increasing the transcription rate of *PTH* and enhancing the stability of PTH mRNA by its post-transcriptional binding to cytosolic proteins.[2,24] Hypercalcemia slightly deceases PTH transcription and cellular levels of PTH mRNA. The serum Ca^{2+}_e concentration also determines the form of PTH released by the PTG. During hypocalcemia, $PTH^{1\text{-}84}$ is the predominant form secreted. In hypercalcemic states, carboxyl terminal fragments of PTH are released.

Low serum phosphate concentrations exert an independent and direct inhibitory effect on the transcription of *PTH*, post-transcriptional PTH mRNA stability, PTH secretion, and proliferation of parathyroid chief cells. Hyperphosphatemia enhances PTH secretion.[24] Prolonged hyperphosphatemia may contribute to the PTG hyperplasia frequently encountered in patients with chronic renal disease. Calcitriol directly inhibits *PTH* transcription acting through the VDR and a vitamin D response element (VDRE) in the 5'-untranslated region of *PTH*. Calcitriol also controls expression of *CASR* and of *VDR* and decreases proliferation of parathyroid cells. However, chronic hypocalcemia overcomes the suppressive effects of calcitriol on *PTH* transcription by decreasing VDR number in the PTG.[2] Hypomagnesemia and hypermagnesemia inhibit release but not synthesis of PTH. Other agents that increase PTH release include β-adrenergic agonists, dopamine, prostaglandin E, potassium (by decreasing cytosolic Ca^{2+}_i levels within the parathyroid chief cell), prolactin, lithium (by "resetting" the set point for PTH release), glucocorticoids, estrogens, and progestins. Prostaglandin $F_{2\alpha}$, α-adrenergic agonists, and fluoride suppress PTH release by increasing Ca^{2+}_i values.

PTH regulates the serum concentration of Ca^{2+}_e directly by stimulating its reabsorption in the distal renal tubule and from the skeleton, and indirectly by augmenting the intestinal absorption of calcium by increasing the synthesis of calcitriol. In bone, PTH enhances osteoclast activity indirectly by acting on and through the osteoblast.

When administered intermittently, $PTH^{1\text{-}84}$ and amino terminal $PTH^{1\text{-}34}$ exert anabolic effects upon skeletal mass. They augment bone formation by increasing osteoblast number by accelerating their differentiation from progenitor cells and from inactive bone-lining cells and by reducing their rate of death.[24] The anabolic effect of PTH may be mediated further by release of matrix-embedded growth factors and by local generation of insulin-like growth factor I (IGF-I). PTH stimulates calcitriol synthesis by increasing renal tubular expression of *CYP27B1,* the gene encoding 25-hydroxyvitamin D_3-1α-hydroxylase (the enzyme that catalyzes the synthesis of calcitriol from calcidiol). PTH depresses proximal and distal renal tubular reabsorption of phosphate by decreasing expression of *SLC34A1,* a Na^+-HPO_4 cotransporter protein, thus increasing the urinary excretion of this anion.

PARATHYROID HORMONE–RELATED PROTEIN

PTH and PTHrP have evolved from a common ancestor. They share 8 of their first 13 amino acids (the site of the activating domain for PTHR1), but their structures diverge thereafter. Both peptides bind with equal affinity to a common PTH/PTHrP receptor (PTHR1), but their receptor binding domains are distinct. PTHrP was initially identified as a primary mediator of hypercalcemia of malignancy. However, PTHrP is normally synthesized in many fetal and adult tissues (cartilage, bone, smooth, cardiac and skeletal muscle, skin, breast, intestines, PTGs, pancreatic islets, pituitary, placenta, and central nervous system) and plays a crucial role in chondrocyte differentiation and maturation, formation of the mammary gland and eruption of teeth, epidermal and hair follicle growth, and other developmental events.[59,60]

Whereas PTH acts as an endocrine hormone on tissues distant from the PTG, PTHrP is synthesized locally and acts primarily as a paracrine or juxtacrine (and perhaps intracrine) messenger. (A nuclear localization sequence is present in the latter half of the PTHrP molecule.[59]) Although the secretion of PTH is regulated by ambient calcium levels and fluctuates rapidly, the production of PTHrP is constitutive and is controlled at the point of expression of its encoding gene. The six exons of the gene encoding PTHrP *(PTHLH)* are transcribed and translated into 108-, 139-, 141-, and 173-aa isoforms employing coding sequences from exon 4 alone or from exons 4 and 5 or 6.[24] In addition, amino and carboxyl terminal and mid-region products of *PTHLH* are also formed by post-translational processing. The predominant isoform of PTHrP is the 141-aa sequence. In specific tissues, $PTHrP^{1\text{-}139}$ is cleaved by prohormone convertases to smaller peptides ($PTHrP^{1\text{-}36,\ 37\text{-}94,\ 107\text{-}139}$) that may act as paracrine factors or be secreted into the circulation. PTHrP secreted by fetal PTGs and a mid-region fragment of $PTHrP^{37\text{-}94}$ synthesized by the placenta increase placental calcium transport. $PTH^{107\text{-}139}$ inhibits bone resorption (and has been termed osteostatin).[60]

Serum concentrations of PTHrP are low except when it is secreted by tumors, leading to humoral hypercalcemia of cancer. There are high concentrations of PTHrP in breast milk. Although the effects of $PTHrP^{1\text{-}36}$ on calcium, phosphate, and vitamin D metabolism are similar to those of PTH, the major roles of this and other segments of PTHrP in many developmental processes (including those of breast, teeth, cartilage, and endochondral bone) distinguish PTHrP from PTH. In the cartilaginous growth plate, proximal periarticular proliferative chondrocytes synthesize PTHrP in response to Indian hedgehog (Ihh), a protein secreted by chondrocytes in their late proliferative and early prehypertrophic phases (Figure 3-2).

PTHrP then diffuses into and through the growth plate and signals prehypertrophic chondrocytes through PTHR1 to slow their rate of differentiation to hypertrophic

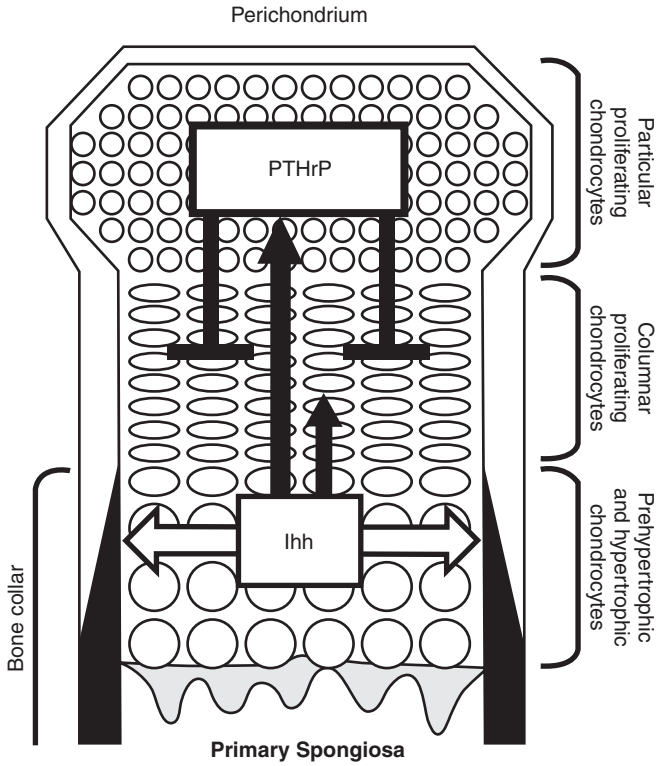

Figure 3-2. The epiphyseal cartilage growth plate consists of zones of proliferating, transitional, and hypertrophic chondrocytes. Indian hedgehog is synthesized by prehypertrophic chondrocytes. Receptors for parathyroid-hormone–related protein are expressed by proliferating and transitional chondrocytes. Indian hedgehog stimulates secretion of parathyroid-hormone–related protein from periarticular cells, and this in turn blocks further differentiation and maturation of late proliferating chondrocytes to hypertrophic chondrocytes—thus prolonging the period of cartilage growth. [Reproduced with permission by the American Society for Bone and Mineral Research from Broadus A (2006). Parathyroid hormone-related protein. In Favus M (ed.), *Primer on the metabolic bone diseases and disorders of mineral metabolism, Sixth edition.* Washington, D.C.: American Society for Bone and Mineral Research 99–106.]

chondrocytes, thus prolonging the stage of proliferation and delaying ossification.[59,60] Biallelic loss of PTHrP in knockout mice is lethal due to bony malformations. In these mice (*Pthlh*$^{-/-}$), there is a decrease in the number of resting and proliferating chondrocytes, disruption of the columnar organization of the growth plate, premature acceleration of chondrocyte maturation and apoptosis, and inappropriate ossification resulting in a dwarfing phenotype (a domed and foreshortened cranium, short limbs, small thorax) similar to that of Blomstrand chondrodysplasia (a disorder associated with loss-of-function mutations of PTHR1).[61] Most of these mice die at birth.

Mice in which expression of Pthlh has been maintained only in chondrocytes survive, but display small stature, cranial chondrodystrophy, and failure of tooth eruption.[60] In the heterozygous state (*Pthlh*$^{+/-}$), mouse fetal development is normal but by 3 months of age the trabeculae of the long bones are osteopenic. A similar bone phenotype is noted when loss of *Pthlh* expression is confined to osteoblasts.[59] For comparison, in mice in which *Pth* has been "knocked out" there is decreased mineralization of cartilage matrix, expression of vascular endothelial growth factor (VEGF) and neovascularization, osteoblast number, and trabecular bone volume.[62] Thus, PTH and PTHrP are necessary to normal fetal endochondral bone development. PTHrP has also been identified in the nucleus of chondrocytes and other cells, where it may regulate cell proliferation and act as a survival factor.[59,63] Cortical thickness of long bones is increased in *Pth*- and *Pthlh*-null mouse models, indicating that the regulation of endochondral and periosteal osteoblast function differs.

The placental transport of calcium is dependent on PTHrP produced by the placenta itself because the maternal-fetal calcium gradient is lost in its absence and may be restored by administration of a mid-molecular fragment.[59] PTH and PTHrP are required for normal mineral homeostasis *in utero*. In mice that lack PTGs, fetal serum calcium and magnesium concentrations are low and phosphate levels are elevated. To a lesser extent, similar changes occur with loss of expression of *Pthlh*.[64] PTH does not regulate placental calcium transfer, whereas PTHrP is essential to this process. During lactation, mammary expression of *PTHLH* and secretion of PTHrP increases—whereas production of estrogens declines, permitting unopposed PTHrP-induced mobilization of maternal skeletal calcium necessary for the breast-fed infant but substantially decreasing maternal bone mineral content (a process reversed when lactation ceases).[65,66]

PARATHYROID HORMONE AND PARATHYROID-HORMONE–RELATED PROTEIN RECEPTORS

PTH and PTHrP utilize a common receptor (PTHR1), through which most of the "classic" physiologic functions of these peptides are exerted. PTHR1 is a 585-aa protein that shares its structure with that of the B family of GPCRs (calcitonin, GH-releasing hormone, secretin, glucagon, vasoactive intestinal polypeptide, corticotropin-releasing hormone) that are characterized by long extracellular amino terminal domains (~100-aa residues) with multiple cysteine residues forming disulfide bridges.[25] As a result of alternative mRNA splicing, there are several isoforms of the PTH/PTHrP receptor. PTHR1 recognizes the amino terminal sequences of PTH$^{1\text{-}84}$ and PTHrP as essential to activation (aa 1–9) and binding (aa 15–34).[2,55]

The amino terminal extracellular domain of PTHR1 contains six conserved cysteine residues that form three disulfide bonds; clustered near the first transmembrane domain are four glycosylated asparagine residues. PTH$^{15\text{-}34}$ binds to the extracellular domain and loops of the transmembrane domains of PTHR1, whereas the amino terminal of PTH$^{1\text{-}84}$ interacts with the transmembrane domains and their connecting extra- and intracellular loops (termed the J or juxtamembrane domain) to activate G_s- and G_q-proteins and their respective signal transduction pathways.[67]

PTHR1 is expressed in renal tubular cells and osteoblasts, skin, breast, heart, and pancreas, among other

tissues—the latter sites reflecting the paracrine targets of PTHrP. It is coupled primarily through G_s-protein to adenylyl cyclase, cyclic AMP, and PKA—the initiating steps in intracellular transduction of the PTH signal. PTHR1 also activates G_q-proteins, thereby stimulating PLC activity and leading to hydrolysis of membrane phosphatidylinositol 1,4,5-trisphosphate to IP_3 and diacylglycerol, activation of PKC, release of Ca^{2+} from intracellular storage sites, and stimulation of the MAPK signal transduction pathway. PTH and calcitriol decrease expression of *PTHR1*.

Targeted loss of *PTHR1* is accompanied by impaired proliferation of chondrocytes and acceleration of chondrocyte maturation and calcification, an outcome mimicked by targeted loss of $G_{s\alpha}$ in chondrocytes.[55,59] Constitutively activating mutations of PTHR1 leads to hypercalcemia and Jansen metaphyseal chondrodysplasia, whereas inactivating mutations results in hypocalcemia and Blomstrand chondrodysplasia. The abnormalities of chondrocyte maturation seen experimentally with inactivating mutations of *Pthr1* are mimicked to an extent by loss of PTHrP function as well. Loss of PTH results in aberrant formation of primary spongiosa of long bone and in defective mineralization.[62]

After activation of the G-protein is complete, PTHR1 is phosphorylated by a GPCR kinase. It then associates with β-arrestin proteins and undergoes endocytosis. By an alternate pathway, carboxyl terminal PTH peptides may also promote endocytosis of PTHR1.[55] Once internalized, PTHR1 may be degraded, recycled to the cell membrane, or directed to the nucleus by importins-α_1 and -β where it is found in the nucleoplasm.[68] The role of nuclear PTHR1 in relaying the many biologic effects of PTH and PTHrP is unknown at present, but one can speculate that it might interact with DNA directly to regulate gene transcription.

A second PTH receptor *(PTHR2)* is selectively activated by PTH but does not recognize PTHrP. PTH specificity is determined by Ile^5 and Trp^{23} in native PTH, sites that affect activation and binding, respectively.[55] *PTHR2* encodes a 539-aa GPCR with 70% homology to PTHR1 that activates adenylyl cyclase. It is expressed predominantly in brain, testis, placenta, and pancreas, but not in bone or kidney. Its physiologic role is uncertain.[69] In response to $PTH^{1\text{-}84}$, PTHR2 enhances both cyclic AMP generation and Ca^{2+} mobilization. However, the naturally occurring endogenous ligand for PTHR2 is not PTH but is likely to be the 39-aa PTH-related hypothalamic tuberoinfundibular peptide (TIP39). This protein is also expressed in the testis and various central nervous system regions. TIP39, PTH, and PTHrP may have evolved from a common ancestral protein. A third PTH receptor that recognizes amino terminal sequences of PTH has been identified in zebra fish and is termed the type-3 zPTH receptor (zPTHR3). Rat PTH binds to this receptor and activates adenylyl cyclase.[55] This species also expresses a PTHR1-like protein. A human homolog for zPTHR3 has not been identified to date. Specific receptors recognizing the amino terminal sequences of PTHrP have been found in brain and skin. PTHrP stimulates release of arginine vasopressin from the supraoptic nucleus *in vitro*.[55]

Although as yet not specifically characterized, receptors for carboxyl terminal fragments of $PTH^{1\text{-}84}$ have been identified as renal and bone cell binding sites for $PTH^{1\text{-}84}$ from which intact hormone can be only partially displaced by $PTH^{1\text{-}34}$ but can be further displaced by $PTH^{53\text{-}84}$ and $PTH^{69\text{-}84}$.[55] In addition, in osteocytes, osteoblasts, and chondrocytes from which the PTH/PTHrP receptor has been knocked out and to which intact $PTH^{1\text{-}84}$ but not $PTH^{1\text{-}34}$ binds, labeled $PTH^{1\text{-}84}$ can be displaced by carboxyl terminal $PTH^{19\text{-}84,\ 28\text{-}84,\ 39\text{-}84}$ fragments. Important determinants for binding of PTH to the carboxyl terminal selective receptor(s) appear to be aa 24 through 27 (Leu-Arg-Lys-Lys) and aa 53 and 54 (Lys-Lys).

Furthermore, carboxyl terminal fragments of PTH exert biologic effects in intact and *PTHR1*-null cells—such as regulation of alkaline phosphatase activity in osteosarcoma cells and osteoblasts (but not generation of collagen type I), stimulation of Ca^{2+} uptake by osteosarcoma cells and chondrocytes, and cell survival *in vitro*. Thus, the physiologic actions of PTH likely reflect the integrated sum of the individual functions of the intact hormone and its carboxyl terminal fragments. Because carboxyl terminal fragments of PTHrP are not recognized by the membrane sites that bind carboxyl terminal fragments of PTH, a means of specifying cellular response to these closely related proteins potentially exists.

Calcitonin

Calcitonin is a 32-aa peptide that in mammals is secreted by the neural-crest–derived parafollicular (C) cells of the thyroid gland. It inhibits osteoclastic bone resorption, thus lowering blood calcium concentrations.[70] It is encoded by a six-exon gene *(CALCA)* that by alternative transcription and translation can form two products: a 141-aa protein from which calcitonin (exons 1-4) and katacalcin (a 21-aa hypocalcemic peptide adjacent to the carboxyl terminus of calcitonin) are derived and a 128-amino-acid protein from which is gleaned the 37-aa calcitonin-gene-related peptide-α (exons 1-3, 5, 6)—a vasodilator and neurotransmitter that also interacts with the calcitonin receptor. Calcitonin is also expressed by cells in the adenohypophysis and brain, and by neuroendocrine cells in the lung and elsewhere.

Calcitonin is produced in abundance by medullary carcinoma of the thyroid, and at times by other neuroendocrine tumors. The calcitonins of multiple species share similar structures, including five of the first seven amino terminal aa, a disulfide bridge between aa 1 and aa 7, glycine at aa residue 28, and a proline amide residue at carboxyl terminal aa 32. In the interior of the peptide, species other than human have several basic amino acids that make them more stable and easily recognized by the human calcitonin receptor and thus more biologically potent (e.g., therapeutically useful salmon calcitonin).

Calcitonin secretion is stimulated primarily by increasing serum concentrations of Ca^{2+}_e transduced by the CaSR expressed on the plasma membrane of the parafollicular cell.[2] Members of the gastrin-cholecystokinin intestinal peptide hormone family (gastrin, glucagon, pancreozymin) are also potent calcitonin secretagogues.[70]

Calcium, pentagastrin, and glucagon are effective stimuli employed to assess calcitonin secretion clinically. Somatostatin, calcitriol, and chromogranin $A^{1\text{-}40}$ inhibit (and chromogranin $A^{403\text{-}428}$ stimulates) calcitonin secretion. Calcitonin secretion falls as the ambient $Ca^{2+}{}_e$ concentration declines.

The half-life of calcitonin is brief. It is metabolized primarily by the kidney but also by liver, bone, and thyroid gland. Serum levels of calcitonin are high in the fetus and newborn, fall rapidly after birth as serum $Ca^{2+}{}_e$ values decline, and then fall more slowly (until three years of age)—remaining relatively constant thereafter (<12 pg/mL). After 10 years of age, serum concentrations of calcitonin are higher in males than in females. The physiologic role of calcitonin is unclear because serum calcium concentrations are normal in patients with both decreased (primary congenital or acquired hypothyroidism) and increased (medullary carcinoma of the thyroid) secretion of this peptide. However, disposal of a calcium load is slower in the calcitonin-deficient subject. Immunoassayable concentrations of calcitonin are increased in patients with medullary carcinoma of the thyroid, chronic renal insufficiency, and pycnodysostosis.[70] Individual commercial immunoassays for calcitonin may detect differing epitopes, have altered intra-assay dynamics, and provide inconsistent measurements.[71]

The biologic effects of calcitonin are mediated through its 490-aa GPCR encoded by *CALCR*, a member of the B family of GPCRs. Intracellular signaling of the CALCR is transduced through the adenylyl cyclase-cyclic AMP-PKA signal transduction pathway. Alternative splicing of *CALCR* results in two isoforms of the calcitonin receptor, one of which has an additional 16-aa inserted into its first intracellular loop between transdomains I and II. Accessory proteins that modulate function of the calcitonin receptor have also been described.[70] The calcitonin receptor is expressed in osteoclasts. When exposed to calcitonin, the osteoclast shrinks and bone resorbing activity declines quickly. Thus, calcitonin lowers serum calcium and phosphate levels—particularly in patients with hypercalcemia.

Polymorphic variants of *CALCR* have been related to variations in bone mineral density (BMD). In subjects heterozygous at aa 463 (Pro/Leu) in the third intracellular domain, BMD is greater than in individuals who are homozygous for either amino acid.[72] However, for the most part there has been little evidence that calcitonin plays a major role in mineral and skeletal homeostasis. In lactating women, serum levels of calcitonin rise and calcitonin is excreted in breast milk. Women who are breastfeeding their infants lose 5% to 10% of their trabecular bone mineral during 6 months of lactation. This is recouped rapidly when lactation ceases—much more quickly than when bone mass is lost because of other problems (e.g., glucocorticoid excess, bed rest).

Experimentally, in the female mouse in which the gene encoding calcitonin has been eliminated loss of calcitonin has no effect on maternal bone mineralization during pregnancy or on the rate of skeletal remineralization after weaning of pups. However, 21 days of lactation are associated with much more marked demineralization of the spine of the nursing mother without calcitonin than in the wt female—a response that is reversible by the administration of exogenous calcitonin during the interval of lactation.[73] Thus, in mammals calcitonin may be essential to the protection of maternal skeletal mass during lactation.

Vitamin D

Cholecalciferol (vitamin D_3) is synthesized in skin from cholesterol through 7-dehydrocholesterol. It is also present in oily fish such as salmon and mackerel. Ergocalciferol (vitamin D_2) is a plant and yeast sterol[74] (Figure 3-3). Vitamin D_2 differs from vitamin D_3 by the presence of a double bond between carbons 22 and 23 and a methyl group on carbon 24 in vitamin D_2. Both forms of vitamin D undergo similar chemical modifications to bioactive metabolites. However, physiologically vitamin D_2 is 3- to 10-fold less biologically effective in man than is vitamin D_3 because its product (25-hydroxyvitamin D_2) is cleared much more rapidly from serum than is 25-hydroxyvitamin D_3.[75] In skin, provitamin D_3 7-dehydrocholesterol is transformed to previtamin D_3 and then isomerized to vitamin D_3 by exposure to ultraviolet B-photon radiation (290–315 nm) and heat (37° C).[74,76]

The latitude, season of the year, and time of day influence the rate of synthesis of vitamin D_3 stimulated by exposure to sunlight. In higher latitudes, the path through which ultraviolet B photons from the sun travel is longer and fewer reach the target. Exposure of the back of a white adult to intense summer sun (mid July) for 10 to 12 minutes in the northeastern United States generates ~10,000 to 20,000 IU of vitamin D_3 over the next 24-hour interval.[19] (For black persons, 30 to 120 minutes of exposure to sunlight may be required for comparable effects.) Sun-screening agents and aging also decrease the cutaneous formation of cholecalciferol in response to sunlight.

Orally ingested vitamin D is packaged into chylomicrons and absorbed into the intestinal lymphatic system. It then enters the circulation and is transported to the liver by vitamin-D–binding protein (DBP), a polymorphic variant of the serum α2-globulin termed Gc (group-specific component) encoded by *GC*. In the liver, vitamin D is hydroxylated to 25-hydroxyvitamin D (25OHD; calcidiol is $25OHD_3$) by vitamin D-25 hydroxylase—a 501-aa class I mitochondrial cytochrome P450 enzyme encoded by *CYP2R1*. In addition, there are other hepatic 25-hydroxylases that carry out this reaction (CYP27A1, CYP2J3).[74] Calcidiol exerts only a minimal inhibitory effect on its production. Thus, serum concentrations of 25OHD reflect body stores of vitamin D.

There are substantial data indicating that because of decreased exposure to sunlight and marginal dietary intake of vitamin D_3 body stores of this vitamin are deficient or insufficient in many North American subjects.[19] In addition, currently established normal values for serum concentrations of 25-hydroxyvitamin D (25OHD, 10–55 ng/mL) have likely been derived from populations that are not completely vitamin D sufficient. In populations

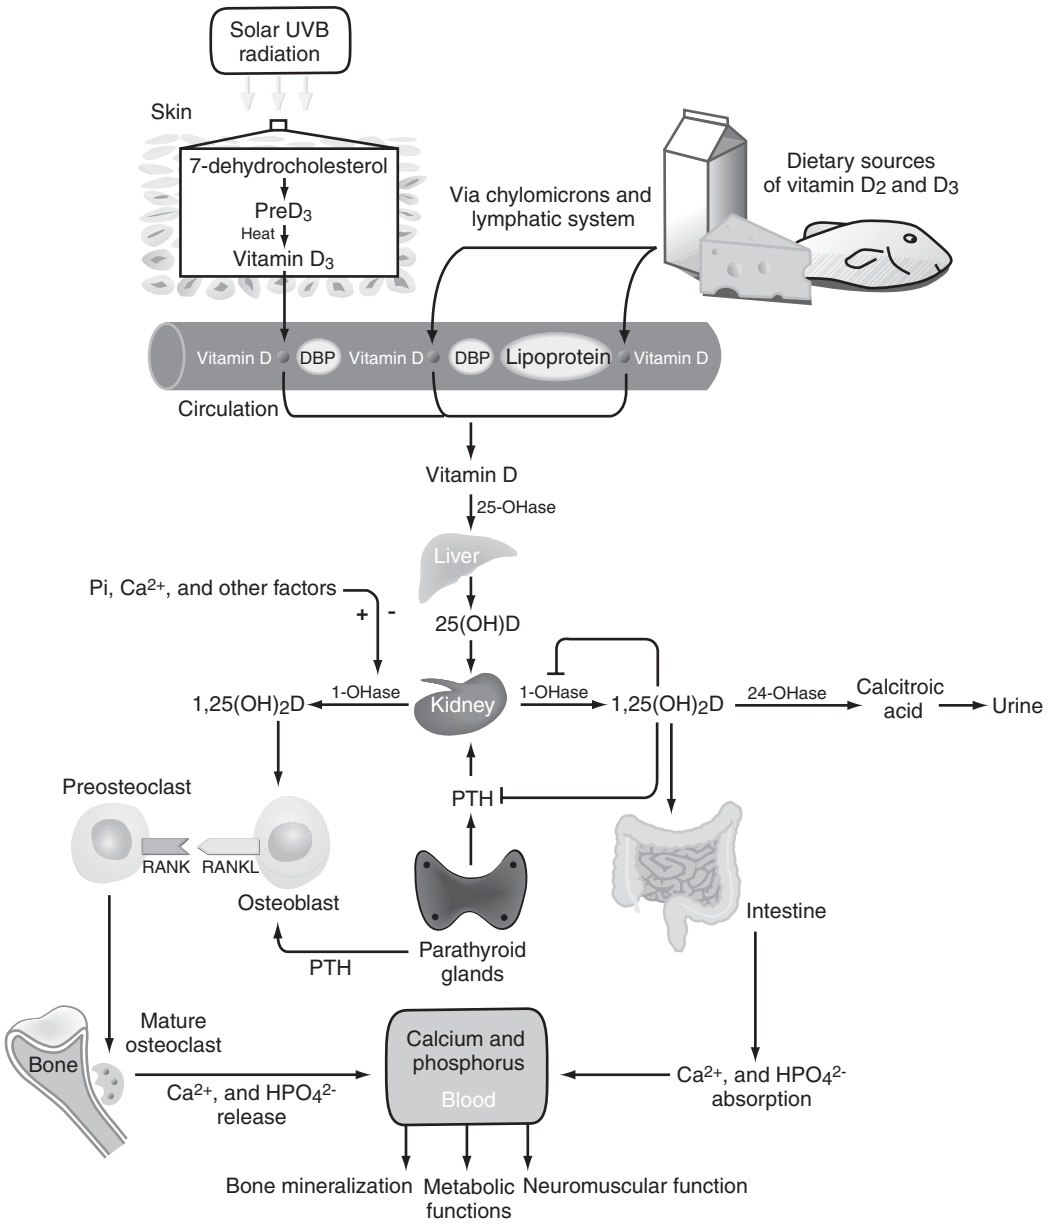

Figure 3-3. Metabolism of vitamin D. Cholesterol is metabolized to cholecalciferol in skin, and hydroxylated in the liver to calcidiol and in the kidney to calcitriol. Factors that regulate these processes are depicted (see text). [Reproduced with permission from Holick MF (2006). Resurrection of vitamin D deficiency and rickets. J Clin Invest 116:2062-2072.]

living in sun-rich environments, the lower normal concentration of serum 25OHD is 32 ng/mL—with a range to 100 ng/mL. Physiologic data such as the relationship between serum concentrations of 25OHD and those of PTH, intestinal absorption of calcium, and optimal bone mineralization support the concept that a serum 25OHD level of 32 ng/mL is the minimum normal value in humans and that 25OHD concentrations between 10 and 30 should be considered insufficient.

Although the current officially recommended minimal supplemental dose of vitamin D for breast and formula-fed infants and older children and adolescents is 200 IU/day, it is likely that 400 IU/day (10 μg) is more appropriate. It has been suggested that children, adolescents, adults, and pregnant and nursing women should receive 400 to 600 IU (10-15 μg) of supplemental vitamin D daily. Some data suggest that the daily required amount of supplemental vitamin D may be closer to 2,000 IU/day (50 μg), and even more in pregnant and lactating women.[19,76,77]

Bound to DBP, calcidiol is transported to cells in the proximal convoluted and straight renal tubules. There it is further hydroxylated to the biologically active metabolite 1,25-dihydroxyvitamin D_3 [$1,25(OH)_2D_3$ or calcitriol] by the cytochrome P450 mitochondrial monooxygenase 25OHD-1α-hydroxylase encoded by *CYP27B1*.[78,79] *CYP27B1* has nine exons that encode a 508-aa protein with a mitochondrial signal sequence at

its amino terminal and ferredoxin- and heme-binding sites within its structure. As a class I mitochondrial cytochrome P450 enzyme, 25OHD-1α-hydroxylase requires for catalytic activity electrons from NADPH that are ferried to the enzyme protein by the electron transport proteins ferredoxin and ferredoxin reductase.[80]

Although *CYP27B1* is expressed primarily in renal proximal convoluted and straight tubular cells, it may also be expressed by keratinocytes and hair follicles, osteoblasts, placental decidual and trophoblastic cells, the gastrointestinal and central nervous systems, testes, breast, and pancreatic islets. In monocytes and macrophages, expression of *CYP27B1* may be induced by inflammatory cytokines such as interferon-γ.[81] In the kidney, expression of *CYP27B1* in the proximal convoluted tubules is stimulated by PTH through cyclic AMP and in the straight tubules by calcitonin by a pathway independent of cyclic AMP. In addition, activity of 25OHD-1α-hydroxylase is increased by hypocalcemia and hypophosphatemia, PTHrP, 24R,25$(OH)_2D_3$, GH, insulin-like growth factor-I (IGF-I), and prolactin.[82]

Increased serum and tissue levels of Ca^{2+} and phosphate directly suppress expression of *CYP27B1* and thus depress 25OHD-1α-hydroxylase activity. Calcitriol exerts an indirect inhibitory effect upon renal *CYP27B1* expression and thus upon its own synthesis by inhibition of PTH synthesis in the PTG.[76] In activated monocytes, calcitriol actually enhances transcription of *CYP27B1*.[81] FGF23 depresses 25OHD-1α-hydroxylase activity, whereas calcitriol up-regulates FGF23 expression—effectively establishing an auto-control system for these compounds.[41] Inactivating mutations of *CYP27B1* result in vitamin-D–dependent rickets type I or 1α-hydroxylase deficiency (OMIM 264700), a disorder associated with hypocalcemia, hypophosphatemia, secondary hyperparathyroidism, severe rickets, and often alopecia.

Calcitriol is inactivated in bone, intestine, liver, and kidney by glucuronidation, sulfation, multisite (carbons 23, 24, and 26) hydroxylation, and lactone formation to water-soluble compounds (such as calcitroic acid) excreted in urine and bile.[76] In the kidney, 25OHD and 1,25$(OH)_2D$ are converted to 24R,25$(OH)_2D$ and 1,24R,25$(OH)_3D$, respectively, by 25OHD-24 hydroxylase encoded by *CYP24A1*—the first in a series of degradative hydroxylations. The expression of this gene is up-regulated by hypercalcemia, hyperphosphatemia, and calcitriol and is suppressed by hypocalcemia and PTH. Cleavage of the side chain between carbons 23 and 24 [which have been hydroxylated by hepatic cytochrome P450-3A *(CYP3A4)*-dependent enzymes] generates water-soluble calcitroic acid.[74]

Many drugs (e.g., phenobarbital, phenytoin, carbamazepine, rifampicin) that are known to impair bone mineralization by inactivating calcitriol do so by increasing its state of hydroxylation by binding to and activating the nuclear pregnane X receptor *(NR112),* which in turn increases expression of *CYP3A4*.[83] Calcitriol may also induce expression of hydroxylases that utilize cytochrome P450-3A, thereby enhancing its own hydroxylation and degradation.[84] Bound to DBP, calcidiol is filtered through the glomerular membrane and reabsorbed by cells in the proximal renal tubule by the multifunctional receptor megalin (gp330)—expressed in coated pits on the luminal/apical surface, endocytic vacuoles, and lysosomes of proximal tubular cells.[28]

After uptake, the megalin-calcidiol complex enters the lysosome—where calcidiol is released, enters the cytosol, and is metabolized to calcitriol in mitochondria. The bulk of circulating calcitriol is bound to DBP, but it is its free fraction that is biologically active. Approximately 0.04% of calcidiol and 0.4% of calcitriol are present in free form in serum. Normal ranges of calcitriol concentrations are 8 to 72 pg/mL for neonates, 15 to 90 pg/mL for infants and children, and 21 to 65 pg/mL for adults.

Once calcitriol is synthesized, its three-dimensional configuration is flexible rather than fixed—enabling it to exert both genomic and nongenomic (rapid-response) actions.[85] The nuclear VDR serves as a transactivating transcription factor after binding to its ligand, calcitriol. The VDR is also associated with caveolae of the cell plasma membrane, flask-shaped invaginations of the membrane composed to a large extent of sphingolipids and cholesterol.[85,86] Through binding to the nuclear VDR, calcitriol regulates the expression of many genes involved in mineral and bone metabolism. These effects take place over hours to days as the processes of transcription, translation, and post-translational modifications to the encoded protein(s) occur in multiple cytosolic compartments.

Calcitriol also generates rapid responses evident within seconds to minutes after its contact with the cell. Examples of rapid cellular responses to calcitriol include immediate intestinal absorption of calcium (transcaltachia), opening of voltage-gated calcium and chloride channels in osteoblasts, endothelial cell migration, and pancreatic β cell secretion of insulin.[85] The three-dimensional flexibility of calcitriol structure is enabled by rotation of side chain carbon pairs 17-20, 20-22, 22-23, 23-24, and 24-25; by rotation of the carbon 6-7 bond around the B ring, and by A-ring chair-chair interconversion with formation of either an α- or β-configuration of the cyclohexane-like A ring (Figure 3-4). Rotation about the carbon 6-7 bond of the B ring allows calcitriol to assume an extended 6-s configuration or a 6-s-*cis* conformation. It is the trans form of calcitriol that is employed by the VDR for its genomic responses and the *cis* form for its rapid actions. For binding to DBP, calcitriol assumes yet another shape.[85]

Calcitriol primarily regulates intestinal and renal absorption of calcium and phosphate by enhancing expression of genes encoding calcium transporters and channels [e.g., calbindin-D_{28K}, calbindin-D_{9K}, TRPV5 (expressed primarily in the kidney) and TRPV6 (expressed predominantly in the intestinal tract)]. Calcitriol also promotes endochondral bone formation and increases length of the long bones by amplifying epiphyseal volume, proliferation, and differentiation of chondrocytes and mineralization of cartilage matrix.[87]

Furthermore, this sterol increases trabecular and cortical bone formation by augmenting osteoblast number and function—including alkaline phosphatase activity, osteocalcin synthesis, and type I collagen formation—and by

Figure 3-4. Cis and trans structures of calcitriol. [Reproduced with permission from Norman AW (2006). Vitamin D receptor: New assignments for an already busy receptor. Endocrinology 147:5542-5548.]

repressing bone resorption by osteoclasts. It does so by a direct cellular effect independent of endogenous PTH, evidenced by its activity in the mouse in which both *CYP27B1* and *Pth* have been knocked out.[87] Calcitriol directly suppresses transcription of *PTH* in the PTG, acting through the VDR. Vitamin D is also important for normal muscle development and is an integral component of the system requisite for achievement of optimal skeletal integrity and strength.[88]

Mediated by the VDR, calcitriol stimulates the absorption or reabsorption of calcium in the intestines, bone, and kidney. In the duodenum and proximal small intestine, calcitriol increases the efficiency of calcium uptake from the intestinal lumen by increasing the number of epithelial calcium transport channels (TRPV6) in enterocytes, its movement through the cytoplasm, and its transfer across the basal lateral membrane into the circulation—in part by the induction of calbindin$_{9k}$ (a calcium-binding protein), alkaline phosphatase, Ca-ATPase, calmodulin, and other proteins.[74] Calcitriol also increases jejunal and ileal absorption of phosphate through a transcellular mechanism utilizing the type II Na^+-HPO_4^{2-} cotransporter protein (NPT2, encoded by *SLC34A1)* expressed on the luminal surface of the enterocyte.

When vitamin D stores are replete, 40% of dietary calcium and 80% of dietary phosphate may be absorbed. Even greater efficiency of mineral absorption is realized during growth spurts, pregnancy, and lactation. A major task of calcitriol is to maintain calcium and phosphate concentrations in blood at levels sufficient to sustain mineralization of osteoid-collagen-containing bone matrix synthesized by osteoblasts. Paradoxically, in states of calcium deficiency calcitriol acts indirectly within bone to stimulate monocytic stem cell differentiation into osteoclasts by stimulating osteoblast/stromal cell synthesis of osteoclast-activating factors such as the ligand for the receptor activator of nuclear factor κB (RANKL).

During periods of calcium deficiency, calcitriol is also able to promote bone resorption through osteoblast production of osteopontin—a bone matrix noncollagenous protein to which osteoclast cell surface integrin receptors bind.[89] Calcitriol stimulates osteoblasts to produce osteocalcin, bone-specific alkaline phosphatase, osteoprotegerin, osteonectin, and various cytokines.[74]

In addition to the classic effects of calcitriol upon mineral and skeletal metabolism, vitamin D and synthetically constructed ligands of the VDR have many non-calcemic actions.[90] Among the several synthetic vitamin D_3 analogues are alfacalcidiol [1α-$(OH)D_3$], calcipotriol [1α,25-$(OH)_2$-24-cyclopropyl-D_3], maxacalcitrol [1α,25-$(OH)_2$-22-oxa-D_3], and talcitol [1α,24R-$(OH)_2D_3$]. These vitamin D analogues have been engineered to retain the non-calcemic actions of the parent compound and reduce calcemic properties. Calcitriol and vitamin D_3 analogues exert many immunomodulatory effects.

In animal models of autoimmune diseases such as systemic lupus erythematosis, multiple sclerosis, type I diabetes mellitus, and inflammatory bowel disease, these agents inhibit T-lymphocyte differentiation into Th1 [IL-2, tumor necrosis factor (TNF)-α, and interferon-γ secreting] cells and thereby modify disease induction, course, and severity. Calcitriol and analogues also exert differentiating and antiproliferative effects on a variety of cells. Thus, calcitriol induces differentiation of promyelocytes into monocytes and macrophages.

These agents enhance differentiation of keratinocytes, and when administered orally or topically to patients with psoriasis vulgaris effectively ameliorate the disease. They are particularly effective when coadministered with a topical glucocorticoid. *In vitro,* calcitriol and its analogues inhibit growth of prostate, breast, and colon cancer cell lines—and clinical trials of these agents in patients with these neoplasms appear promising. Calcitriol

and several of its analogues have been employed successfully in the treatment of osteoporosis, secondary hyperparathyroidism, and arthritis.[90] Calcitriol also enhances secretion of insulin and down-regulates activity of the renin-angiotensin system.[74]

VITAMIN D RECEPTOR

Calcitriol acts primarily by binding to the VDR, a 427-aa protein encoded by 11-exon *VDR*.[91] Because of two potential start site codons for transcription of VDR in exon 2, there is a second isoform of VDR with 424 aa. At its 5' end, the VDR has three noncoding exons (1A, 1B, 1C)—followed by exons 2 through 9, which encode the active protein [enabling transcription of three unique mRNA isoforms, depending on the splicing pattern of exons 1B and 1C (Figure 3-5A)].

As a member of the steroid/thyroid/vitamin-D receptor gene superfamily of nuclear-transcription–activating factors, the VDR has five domains: a short amino terminal segment of 24 aa (domains A/B) that houses a ligand-independent transactivation function termed activation function-*1* (AF-1), a DNA-binding domain (C) with two zinc fingers (exons 2 and 3), a "hinge" region (D), and a long carboxyl terminal ligand-binding domain (E) (exons 7, 8, 9). Structurally, the E domain consists of 12 α-helixes (H1–H12) and has two ligand-dependent transactivating regions (E1 between aa 232 and 272 and AF2 between aa 416 and 424) that recruit transcriptional cofactors when the VDR is activated by binding to calcitriol.[91]

Among the stimulants to the transcription of VDR are calcitonin, retinoic acid, estrogen, the transcription factor SP1, and β-catenin. In part, estrogens increase expression of VDR through binding to estrogen receptors present in the caveolae of the cell membrane and then through activation of the MAPK signal transduction pathway.[92] The *VDR* is expressed in the intestinal tract, distal renal tubule, osteoblast, keratinocyte, hair follicle, fibroblast, smooth and cardiac muscle, lung, bladder, thyroid, parathyroid, pancreas, adrenal cortex and medulla, pituitary, placenta, uterus, ovary, testis, prostate, activated T and B lymphocytes, macrophages, monocytes, spleen, thymus and tonsil, brain, spinal cord, and sensory ganglia.

Allelic polymorphisms (random variations in gene composition not known to affect structure or function) of VDR have been related to bone mineralization and linear growth (Figure 3-5B). These gene variants have been identified by examining restriction fragment length

Figure 3-5. *(A)* Structure of mRNA and protein of the vitamin D receptor (VDR) derived from the 9-exon gene structure of VDR. The five domains of the VDR are depicted. Exons 2 and 3 encode the DNA-binding domain, and exons 7 through 9 encode the ligand-binding domain. Sites E1 and AF2 are subregions within the E domain that serve transactivating functions. Regions of homology shared with other members of the nuclear receptor steroid/thyroid hormone/vitamin-D superfamily are indicated by the gray and black areas. *(B)* Polymorphic variants of VDR. By convention, uppercase letters denote the absence (and lowercase letters the presence) of a polymorphic restriction site. The site of the start codon polymorphism (SCP) is depicted above the gene structure. It generates a FokI polymorphism and generates vitamin D receptor proteins of different lengths. The site of the BAT polymorphism is indicated above intron 10/exon 9. The BsmI, ApaI, and TaqI restriction sites are placed below the VDR gene structure. These polymorphic variants do not change the amino acid structure of the VDR. In exon 9, there is a poly A microsatellite of variable length. [Reproduced with permission from Malloy PJ, et al. (1999). The vitamin D receptor and the syndrome of hereditary 1,25-dihydroxyvitamin D-resistant rickets. Endocrine Reviews 20:156-188.]

polymorphisms (DNA fragments of varying lengths) defined by endonuclease digestion of *VDR* DNA by BsmI (B), TaqI (T), FokI (F), and ApaI (A). For example, in *VDR* there are BsmI cut sites in the 3' region and in exon 10. By convention, BB indicates absence of a BsmI cut site on both alleles, bb the presence of the cut site on both alleles, and Bb the heterozygous state.[91,93]

The BB *VDR* genotype has been variably associated with lower BMD in postmenopausal women and adult men, whereas the aa, bb, and TT genotypes have been linked to higher BMD in prepubertal girls.[94] Polymorphic variants of the *VDR* have also been associated with differences in intestinal calcium absorption (subjects with the bb genotype on a low-calcium diet absorb ingested calcium to a greater extent than do those with the BB pattern), in birth length (BB neonatal males are shorter than Bb and bb male infants), in growth in infancy (at 2 years of age BB girls are longer and heavier than bb girls, BB boys weigh less than bb boys although of similar length, and at 1 year of age tt infant females are heavier than TT or Tt subjects), in pubertal growth (boys with the BB genotype are smaller than their Bb and bb peers through puberty), and in adult stature (the adult stature of subjects with the bT haplotype is on average 1.6 cm greater than that of individuals with other haplotypes).[95,96] Polymorphic variants of *VDR* have also been linked to development of hyperparathyroidism and parathyroid tumors. The mechanism(s) by which polymorphic variants might exert these effects (or even if the associations are meaningful) is unclear. However, it has been suggested that the polymorphisms may influence the expression of the *VDR* or its function.

Whereas most members of the superfamily of nuclear-receptor–transactivating factors pair as homodimers to bind to their specific hormone response elements in the 5'-untranslated region of the target gene, the calcitriol-VDR complex teams through its E (ligand-binding) domain with its obligate partner [unliganded retinoid X receptor α *(RXRA)*] to form a heterodimer that then binds to a VDRE. The endogenous ligand for RXRα is 9-cis-retinoic acid. When unliganded, the bulk of the VDR is cytoplasmic. Binding of calcitriol to the VDR leads to heterodimerization with RXRα and translocation of the tripartite complex to the nucleus. However, the unliganded VDR can also be guided to its target gene within the nucleus by a multi-protein chromatin-remodeling complex termed WINAC (where it remains inactive until bound by calcitriol).[97]

The generic VDRE, located in the 5' upstream promoter region of the target gene, is composed of two directly repeated hexanucleotide sequences (5'-AG-G/T-TCA-3') separated by three base pairs (bp). RXRα binds to the 5' half of the VDRE, and the VDR to its 3' segment. After binding to the VDRE, the calcitriol-VDR-RXR complex recruits coactivating or corepressing comodulating proteins (e.g., SRC/p160 family, TRIP/SUG1, CPB/p300, TIF1, NcooR-1RIP13) into the promoter site and the general transcription apparatus of the target gene (TF-IIA, -B, TAF family).[90,91] Gene activation by the VDR complex is initiated by recruitment of a histone acetyltransferase complex to the promoter segment of the gene that destabilizes the region and leads to unwinding of DNA, thereby granting access to basal transcription factors and RNA polymerase II that bring about RNA modeling of the target gene.

In addition to positive and negative regulation of target gene expression through binding to the VDRE, the VDR complex may also affect transcription by modifying the effect of other transcription factors.[90] Corepressors cause chromatin to compact, thereby silencing gene expression. Genes whose expression is regulated by the VDR are listed in Figure 3-6. Calcitriol acting through the VDR stimulates transcription or genes encoding calcium transport proteins (TRPV5/6), bone matrix proteins (osteopontin, osteocalcin), bone reabsorption factors (RANKL), and 25OHD-24-hydroxylase—and represses those that encode PTH and PTHrP. The calcitriol-VDR complex represses expression of multiple cytokines (IL-2, interferon-γ, granulocyte macrophage-colony stimulating factor) by negatively interacting with transcription factors that enhance their transcription (e.g., NF-κB).

Although the VDR is necessary for the actions of calcitriol in the intestines, kidney, bone, skin, and elsewhere, its loss does not interfere with embryogenesis and fetal development in humans with loss-of-function mutations in *Vdr* and vitamin D resistance or in mice in which *Vdr* has been knocked out. Newborn mice homozygous for targeted deletion of the second zinc finger (exon 3) and resultant truncation of the *Vdr* survive fetal life, appear normal at birth, and grow well for the first 24 days of life.[98] However, after weaning their rates of weight gain and linear growth and serum Ca^{2+}_e and phosphate levels decline and serum PTH concentrations and PTG weights increase.

In $Vdr^{-/-}$ mice as young as 15 days of age, osteoid surface is increased, bone mineralization decreased, and epiphyseal plate cartilage formation disorganized—with irregular columns of chondrocytes, increased matrix, and excessive vascularity relative to wt-type or heterozygous ($Vdr^{+/-}$) mice.[69,99] In mice in which both *Vdr* and *Rxra* have been knocked out, development of the cartilage growth plate is even more disrupted than in $Vdr^{-/-}$ pups.[100] In addition, hair loss begins at 4 weeks of age and is complete by 4 months of age in homozygous $Vdr^{-/-}$ animals and is due to a defect in the growth cycle of hair follicles, a phenocopy of the generalized alopecia associated with loss of hairless *(HR),* a transcriptional corepressor that interacts with the *VDR*.[90] (Vitamin D deficiency alone does not interfere with hair growth.)

At approximately 8 weeks of age, $Vdr^{-/-}$ mice are a bit smaller than their wt counterparts and have lower calcium concentrations and cortical bone density and thickness—although trabecular bone density is similar in $Vdr^{-/-}$ and wt animals.[101] $Vdr^{-/-}$ mice usually succumb between 4 and 6 months of age. However, maintenance of normal serum concentrations of calcium and phosphate by the feeding of high calcium-phosphate diets to $Vdr^{-/-}$ pups beginning at 16 days of age prevents the development of all of the skeletal abnormalities—suggesting that the main physiologic effects of calcitriol and the VDR are upon the intestinal absorption of calcium and phosphate and the maintenance of normal serum concentrations of these ions.[99] In pregnant $Vdr^{-/-}$ 8-week-old mice, fetal ($Vdr^{+/-}$) epiphyseal cartilage is histologically abnormal and skeleton

mineralization subnormal. Both defects can be reversed by increasing maternal dietary calcium and phosphate intake.[101] Thus, absorption of intestinal calcium by non vitamin-D–dependent mechanisms can bypass the absorptive defect caused by loss of the VDR and by inference the deficiency of vitamin D itself.

As previously discussed, in addition to acting through the nuclear VDR to regulate gene expression calcitriol also has rapid nongenomic effects mediated through plasma membrane caveolae-associated VDRs (Figure 3-7).[85] The classic ligand-binding domain of the VDR recognizes the 6-s-*trans* configuration of calcitriol, whereas the 6-s-*cis* shape of the VDR mediates the nongenomic actions of calcitriol. An alternative VDR ligand binding domain that overlaps with the classic domain and accommodates the 6-s-*cis* conformation of calcitriol has been tentatively identified.[85] The mechanism(s) by which the 6-s-*trans* and 6-s-*cis* forms of calcitriol recognize the genomic or nongenomic "pockets" of the VDR has not been established at this writing.

In vitro, calcitriol induces expression of several membrane-associated rapid-response steroid-binding (MARRS) proteins such as the multifunctional thioredoxin-interacting protein-2 (TXNIP) and its homologue TXNIP-like inducible membrane protein, both of which are situated on the interior of the cell plasma membrane.[102-104] After binding of calcitriol to the plasma membrane-associated VDR, its signal is transmitted by several classical intracellular signal transduction systems—including adenylyl cyclase induction of cyclic AMP and PKA; PLC- and PLD-mediated increase in phosphoinositide turnover resulting in generation of 1,2-diacylglycerol and IP_3 that increase the permeability of Ca^{2+} channels and release Ca^{2+} from cytosolic storage sites; G_q protein through PLC-β1 activation and intracellular redistribution of PKC isoforms (α, β, δ); and Jun-activated kinase and the MAPK pathway.[102]

Within minutes after exposure of a vitamin-D–responsive tissue (e.g., intestine, chondrocyte, osteoblast) to calcitriol, there is increase in the intracellular concentration of $Ca^{2+}{}_i$ (transcaltachia) and activation of PLC, PKC, and MAPK.[85] In osteoblasts from *VDR*$^{-/-}$ mice and in fibroblasts from patients with inactivating mutations of *VDR*, the rapid actions of calcitriol are lost—as is the association of the VDR with caveolae (evidence of the importance of the VDR to membrane-initiated responses to calcitriol).[102] The plasma membrane caveolae-associated VDR may link to $G_{s\alpha}$ and thence to a calcium channel, to adenylyl cyclase, to PLC, or to caveolin—a protein that interacts with the nonreceptor tyrosine kinase Src and in turn with PLC or the kinase h-Ras.[102,105]

The physiologic role(s) of the rapid actions of vitamin D are not certain. In chondrocytes, there is MARRS-dependent enhancement of calcium flux, PKC activity, and matrix vesicle mineralization.[106] Vitamin-D3–mediated activation of TLIMP suppresses cell proliferation, perhaps in part by antagonizing the effects of IGF-I by increasing synthesis of IGF-binding protein-3.[104,107] The rapid effects of vitamin D may optimize its genomic effects by phosphorylation of proteins required by the VDR transcriptional complex. As expected, membrane-related phenomena are often better mimicked by analogs of calcitriol that are in the *cis* conformation than by calcitriol itself. A membrane-binding protein for $24,25(OH)_2D_3$ has also been reported.[108]

Skeleton: Cartilage and Bone

The skeleton is the framework of the body. It consists of cartilage and bone—specialized forms of connective tissue that provide mechanical support for muscle/tendon insertion that enables movement, protective shielding for soft-tissue organs, repository for bone marrow, and reserve source of calcium, phosphate, and other metabolically important ions.[109,110] There are two primary bone shapes: flat bones (e.g., cranium, scapula, pelvis) and long bones (e.g., humerus, femur).[111] Flat bones develop by membranous bone formation, whereas long bones develop by endochondral and membranous bone formation.

The external surface of bone is enveloped by periosteum (containing blood vessels, nerve terminals, osteoblasts, and osteoclasts), whereas the interior of bone next to marrow is lined by endosteum. Long bones consist of a hollow shaft (diaphysis), distal to which are the metaphyses, cartilaginous growth plates, and epiphyses. The diaphysis consists of cortical bone and the metaphysis/epiphysis of trabecular bone surrounded by cortical bone. Eighty percent of the adult skeleton is dense cortical bone whose primary function is to provide mechanical strength. Twenty percent is cancellous bone, a network of trabeculae with a large surface area and increased turnover of bone constituents.

Bone matrix or osteoid is the component of bone that is composed of collagenous (collagen types I and III) and noncollagenous proteins (e.g., osteocalcin, osteopontin) secreted by osteoblasts—upon which the mineral phase of bone is deposited. Modeling of bone is the process that takes place during growth in which the shape and size of the bone are determined. Remodeling of bone is a continual process in which formed bone is periodically reabsorbed and replaced by new bone. Remodeling occurs in both the growing child and the adult. Osteoprogenitor pluripotent stromal mesenchymal stem cells provide a continuous supply of bone-forming osteoblasts, the network of osteocytes embedded throughout bone that monitor bone integrity and strength and bone-surface-lining cells. Osteoclasts derived from hematopoietic precursor cells mediate bone resorption.

Chondroblasts, osteoblasts, adipocytes, myoblasts, and fibroblasts are derived from a common mesenchymal cell (Figure 3-8).[112] Bone morphogenetic proteins (BMPs) are members of the transforming growth factor-β (TGFβ) superfamily that direct the transformation of a pluripotent mesenchymal cell into the pathway leading to formation of chondrocytes and osteoblasts. BMP-2, -4, and -7 are among the factors important for this differentiation process, although there is substantial redundancy in the system and other BMPs participate also. The BMPs act through designated cell membrane threonine/serine kinase receptors (e.g., BMPRIA, BMPR2). Depending on the interaction of the BMP receptors involved, intracellular signaling is transduced by the SMAD (mothers against decapentaplegic homolog) and/or MAPK pathways and induces synthesis of specific transcription factors that further the differentiation process.[113,114]

During early embryogenesis, bone is formed by condensation of mesenchymal cells in genetically determined patterns of position, arrangement, size, and shape.[115] Individual mesenchymal cells then differentiate either into chondrocytes that secrete a matrix of collagen

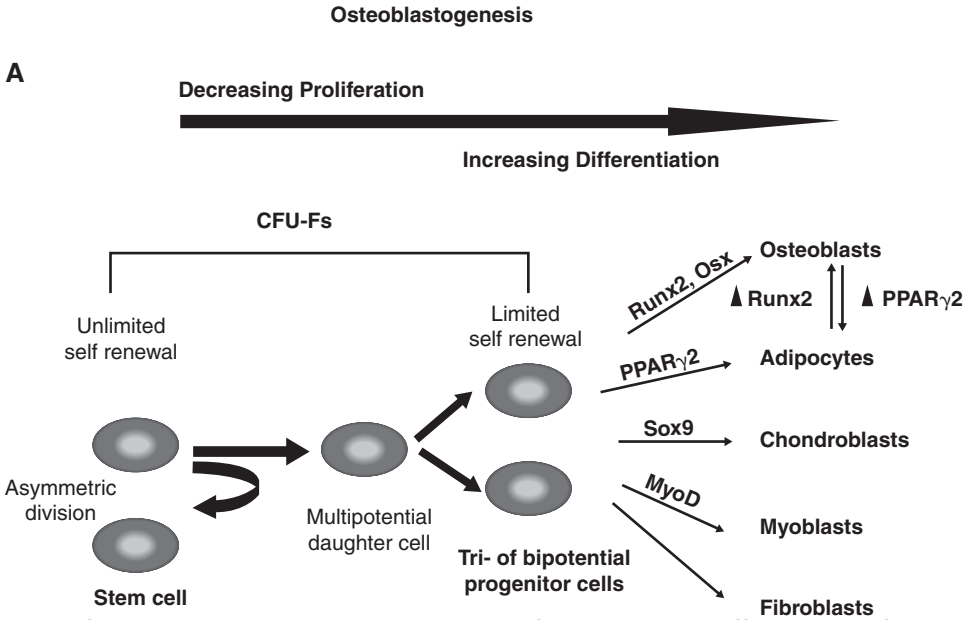

Figure 3-8. Commitment of stem cells to the osteoblast lineage. Many factors guide the differentiation of chondroblasts, osteoblasts, myoblasts, fibroblasts, and adipocytes from a common mesenchymal stem cell (see text). Bone morphogenetic proteins are involved in the earliest steps, leading to the differentiation of the common mesenchymal precursor cell. RUNX2 is necessary for the initial differentiation of the common progenitor cell of chondrocytes and osteoblasts and for further delineation of osteoblasts in association with osterix. PPARγ2 (peroxisome proliferator-activated receptor γ2) stimulates the differentiation of adipocytes. Osteoblasts and adipocytes may be interconverted, depending on the active transcription factor. MyoD is a muscle-specific transcription factor necessary for the development of myoblasts. [Reproduced with permission from Aubin JE, et al. (2006). Bone formation: Maturation and functional activities of osteoblast lineage cells. type II in the anlagen of endochondral bones or directly into osteoblasts in precursor regions of intramembranous bone, where they secrete a matrix rich in collagen type I. Differentiation of the pluripotent mesenchymal cell into an osteoblast is under the guidance of the canonical Wnt signaling pathway.[116] (The name Wnt is derived from combining and contracting the *Drosophila* gene *Wingless* with the corresponding mouse gene *Int.*)

Binding of secreted Wnt cytokines, a family of lipid-modified signaling glycoproteins with 350 to 400 aa and a conserved sequence of 22 cysteine residues (e.g., Wnt1, Wnt9A), to GPCR frizzled receptors (FZD1) and to the LRP 5/6 coreceptors also situated on the mesenchymal stem cell's plasma membrane leads to intracellular accumulation of β-catenin *(CTNNB1)*.[117] Frizzled receptors act through the $G\alpha_q$-protein and PLC signal transduction pathway. LRP 5/6 *(LRP5, LRP6)* are long-chain proteins with a single transmembrane domain whose function is to prevent degradation of cytoplasmic β-catenin through the ubiquitination-proteasomal pathway. When a Wnt ligand binds to its frizzled receptor, the intracellular protein disheveled-1 *(DVL1)* is phosphorylated and inhibits glycogen-synthase-kinase-3-mediated phosphorylation of β-catenin—which slows its rate of degradation and releases it from binding to axin *(AXIN1),* another intracellular protein.

The intracellular domain of LRP5 then binds axin, permitting further increase in cytoplasmic levels of β-catenin.[118] In designated mesenchymal cells, increased levels of β-catenin acting as a transcriptional cofactor with T-cell factor/lymphoid enhancement factor *(LEF1)* stimulates expression of runt-related transcription factor 2 (*RUNX2,* also termed core-binding factor alpha subunit 1 or CBFA1). The product of *RUNX2* is itself a transcription factor that stimulates production of osterix (encoded by *SP7*). RUNX2 and osterix, a 431-aa protein, are essential for differentiation of mesenchymal cells into osteoblasts and for the synthesis of osteocalcin and collagen type I(α1) by osteoblasts.[116]

Osteocalcin *(BGLAP)* plays an important role in normal mineralization of bone matrix. Other gene targets of RUNX2 include those encoding BMP4, FGFR1, Dickkopf, Wnt10a, and Wnt10b.[119] Thus, RUNX2 is not only central to initiation of osteoblastogenesis but to its maintenance. Wnt signaling also increases production of osteoprotegerin, a protein that inhibits osteoclastogenesis—thereby further increasing bone mass vide infra. When intracellular stores of β-catenin are depleted, mesenchymal cells differentiate as chondrocytes rather than osteoblasts.[120] Through changes in its state of phosphorylation, β-catenin also affects cell-to-cell adhesion and cell migration.[117]

The Wnt signaling pathway is opposed by inhibitors of LRP5 function [including secreted frizzled-related proteins, Dickkopf, and sclerostin *(SOST)*] that ensure orderly and normal bone mineralization. The axin-binding function of LRP5 is inhibited by binding of its extracellular domain to Dickkopf. Osteocytes are derived from osteoblasts after they have been embedded within mature bone. They form an interconnected network of long-cell processes within canaliculi that link deep osteocytes with newly formed osteocytes and with surface-lining

cells.[118] Osteocytes detect mechanical strain by movement of fluid within these channels and respond by secreting growth factors and sclerostin. Because sclerostin inhibits Wnt signaling by binding to the extracellular domain of LRP5, when new bone formation is needed the secretion of sclerostin declines.

Cortical or compact bone is present in the cranium, scapula, mandible, ilium, and shafts of the long bones and has periosteal and endosteal surfaces—both of which are lined with layers of osteogenic cells. Cancellous (trabecular or spongy) bone is located in the vertebrae, basal skull, pelvis, and ends of the long bones. Because only 15% to 25% of trabecular bone volume is calcified (compared to 80%-90% of cortical bone volume) and thus has a far greater surface area, trabecular bone is metabolically quite active. It has a high turnover rate, making it more vulnerable to disorders that affect bone mineralization.

In flat bones (skull, ilium, mandible), intramembranous ossification begins with the local condensation of mesenchymal cells that then differentiate directly into preosteoblasts and osteoblasts and initiate the formation of irregularly calcified (woven) bone that is then replaced by mature lamellar bone.[109] Membranous bones grow by apposition, a process supported by development of new blood vessels induced by VEGF (a protein that also enhances bone formation).[121] The periosteum is a fibrous network in which osteoblasts synthesize peripheral compact bone. Cortical bone reinforces bone strength and complements and extends that provided by trabecular and endosteal bone. Tendons and ligaments insert and are fixed into cortical bone.

Chondrocyte differentiation and cartilage formation occur in mesenchymal regions in which activity of the canonical Wnt signaling pathway and the expression of *VEGF* are low but not totally absent. This results in increased expression of *SOX9* and related *SOX* family members, transcription factors that direct differentiation of mesenchymal cells into chondrocytes that are characterized by synthesis and secretion of collagen types II, IX, and XI. The expression of *SOX9* is stimulated by FGF signaling through the MAPK pathway. SOX9 is a 509-aa protein with an SRY homology domain that is also expressed in the testis, where it is responsible for differentiation of Sertoli cells.

Inactivating mutations of *SOX9* lead to campomelic dysplasia and sex reversal in males (OMIM 114290). Target genes of *SOX9* include those that encode collagen type II(α1) and aggrecan, a chondroitin sulfate proteoglycan core protein. A mutation in the gene encoding aggrecan leads to an autosomal-dominant form of spondyloepiphyseal dysplasia associated with premature degenerative arthropathy (OMIM 608361). *SOX9* is expressed not only in chondrocytes in the resting phase but in those in the proliferative phase but not in chondrocytes in the hypertrophic phase of maturation.[114]

The pattern of endochondral bone development is directed by factors that are independent of bone formation (e.g., in transgenic mice in which *Runx2* is inactivated, the cartilage "skeleton" forms normally but is not ossified).[116] [In humans, heterozygous inactivating mutations in *RUNX2* result in cleidocranial dysplasia (OMIM 119600), manifested by growth retardation, hypoplasia of the clavicle and pelvis, delayed closure of cranial sutures, and defective tooth eruption.] Vertebrae evolve from the condensation and segmentation of paraxial mesoderm into somites under the direction and control of multiple genes, including *Notch1, Sonic hedgehog,* and *Pax1* and Notch ligands encoded by *DLL3* and *JAG1*.[116]

The appearance of limb buds, proliferating mesenchymal cells that grow out from the lateral body wall and are capped by an apical ectodermal ridge, heralds development of the cartilage anlagen of the long bones—a process of segmentation directed by homeobox genes *(HOXA13, HOXD13), Sonic hedgehog, WNT7a, GLI3, TGFβ, FGF4, FGFR1, FGFR2, BMP2, BMP4, BMP6, BMP7, LMX1B, PITX1, TBX4, TBX5, TWIST,* and other signaling, receptor, and transcription-regulating factors involved in differentiation, paracellular communication, and cell-to-cell interaction.[116,122,123] Mitochondrial RNA-processing endoribonuclease encoded by *RMRP* is a ribonucleoprotein essential to assembly of ribosomes and cyclin-dependent cell cycle activity as well as chondrocyte proliferation and differentiation.

Inactivating mutations of *RMRP* result in anauxetic dysplasia (OMIM 607095), a spondylometaepiphyseal dysplasia characterized by intrauterine and postnatal growth retardation (with adult stature <85 cm).[124] Histologically, the growth plates of these patients are depleted of chondrocytes. Different mutations of *RMRP* result in varying clinical manifestations [e.g., cartilage hair hypoplasia (OMIM 250250) and metaphyseal dysplasia without hypotrichosis (OMIM 250460)].

In bones of cartilaginous origin (long bones, vertebrae), mesenchymal stem cells differentiate initially into prechondrocytes and chondrocytes that secrete collagen type II into a matrix in which chondrocytes are embedded as the cartilage mold enlarges. In the center of the mold, chondrocyte proliferation ceases. The chondrocytes hypertrophy and begin to synthesize collagen type X and VEGF.[114] Blood vessels from the perichondrium together with cartilage-resorbing cells (chondroclasts) and osteoblasts and osteoclasts invade the hypertrophic region, destroy and reabsorb cartilage matrix and apoptotic chondrocytes, and deposit the primary spongiosa of bone that is later replaced by mature bone—a process dependent on normal function of the VDR.[42]

At the ends of the long bones, the cartilaginous epiphyseal growth plate develops—separating the epiphysis (a secondary ossification center at the end of a long bone) from the central metaphysis and diaphysis. Orderly columnar proliferation of chondrocytes in isogenous groups permits longitudinal growth of the long bone. Differentiation of resting chondrocytes from the reserve (resting, germinal, or stem cell) zone of the cartilage growth plate into the proliferating zone is initiated by BMP-6 and GH. Locally synthesized IGF-I induced by GH increases proliferation of chondrocytes (Figure 3-9).[125,126] The perichondrium contributes chondrocytes to the growth plate and supports its appositional growth. Sequentially, proliferating chondrocytes evolve into prehypertrophic chondrocytes and then into hypertrophic chondrocytes that secrete collagen type X into the matrix in which they are

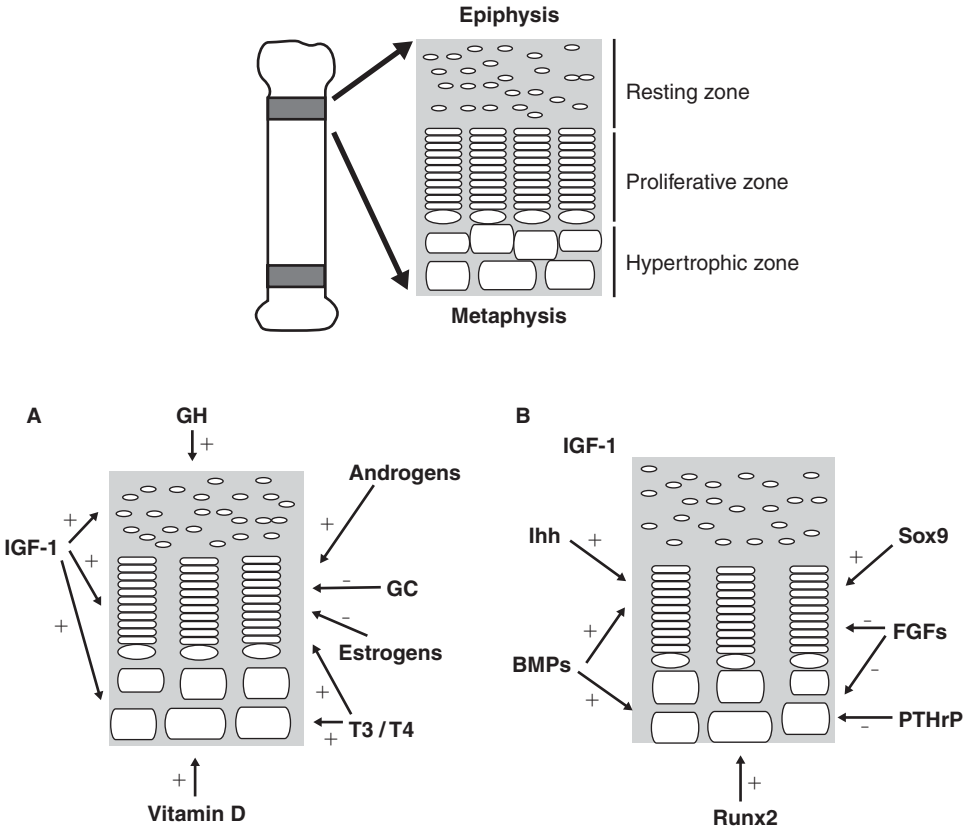

Figure 3-9. Hormones and growth factors affecting differentiation and proliferation of the cartilage growth plate. [Reproduced with permission from De Luca F (2006). Impaired growth plate chondrogenesis in children with chronic illness. Pediatr Res 59:625-629.]

embedded—thus contributing to interstitial growth of cartilage.

Central to the maturational development of chondrocytes are PTHrP and Indian hedgehog (Ihh). The latter is a 45-kDa protein synthesized by prehypertrophic and early hypertrophic chondrocytes whose expression is increased by BMP-6. Ihh acts through its receptor Patched 1 *(PTCH1)* and coreceptor Smoothened *(SMOH)* to stimulate transcription of genes that are essential to chondrocyte proliferation and maturation. Ihh directly stimulates chondrocytes in the reserve zone to differentiate into proliferating chondrocytes, thus increasing the number of proliferative chondrocytes and lengthening the cartilage growth plate.[127] It promotes cell division and growth by increasing expression of cyclins D and E, Wnts, and IGF-I. Ihh also regulates the generation of PTHrP by perichondrial cells on the articular surface, periarticular chondrocytes at the ends of the long bones, and most abundantly by early proliferative chondrocytes.[59,114]

PTHrP (through PTHR1) decreases the rate of differentiation of proliferating chondrocytes to prehypertrophic chondrocytes, thus antagonizing the effect of BMP-6. It prolongs the stage of chondrocyte proliferation by preventing premature hypertrophic differentiation and delays the generation of Ihh in a negative feedback loop.[127] PTHrP also enhances phosphorylation of SOX9 in prehypertrophic chondrocytes in the cartilage growth plate and thereby enhances its transcriptional activity. SOX9 contributes to the decelerating effect of PTHrP on the rate of differentiation of prehypertrophic to hypertrophic chondrocytes while maintaining the rate of chondrocyte proliferation and therefore continued elongation of the growth plate and long bone.[60,128] Thus, Ihh and PTHrP interact to determine the height of the growth plate and the length of the long bone. In mice in which *Ihh, Pthlh* (the gene encoding PTHrP), or *Pthr1* has been eliminated (knocked out), chondrocyte proliferation is decreased and there is accelerated differentiation into terminal hypertrophic chondrocytes and rapid replacement of cartilage by mineralized bone.[129]

In humans, inactivating mutations of *PTHR1* result in rapid chondrocyte maturation and Blomstrand chondrodystrophy (OMIM 215045)—whereas activating mutations in *PTHR1* lead to impaired chondrocyte maturation and Jansen metaphyseal chondrodysplasia (OMIM 156400). FGFs have dual effects upon chondrocyte proliferation and maturation. In part they enhance proliferation by increasing expression of *SOX9* and decreasing that of *Ihh*.[114] On the other hand, FGF18 inhibits chondrocyte proliferation and antagonizes the effects of BMPs acting through its cell surface tyrosine kinase receptor (FGFR3).[114,116]

Furthermore, spontaneous activating mutations of FGFR3 decrease the rate of chondrocyte proliferation and disturb their organization and are associated with achondroplasia and other chondrodysplasias. In hypertrophic chondrocytes, the expression of *Runx2* and *Vegf* is

enhanced—contributing to the invasion from the perichondrium into hypertrophic cartilage of blood vessels, cartilage resorbing cells, and osteoblast precursor cells.[116] Ihh also enhances osteoblast differentiation in perichondrium. Subsequently, a primary ossification center is formed—and cartilage is replaced by trabecular bone and marrow (endochondral bone formation).

Stromal mesenchymal stems cells differentiate not only into osteoblasts [through Wnt signaling of Runx2, Dlx5 (another gene capable of stimulating osteoblastogenesis), and osterix] but into chondroblasts (through Sox9), adipocytes [through peroxisome proliferator-activated receptor γ2 (PPARγ2)], myoblasts, and fibroblasts (Figure 3-8). Committed osteoblasts and adipocytes appear to be able to re-differentiate one into the other cell type, depending on whether the expression of *Runx2* or Pparg is paramount. This process is directed by Wnt10b, which enhances expression of *Runx2*, *Dlx5*, and *Sp7* while suppressing that of *Pparg*.[112]

The nuclear NAD-dependent protein deacetylase encoded by Sirt1 also inhibits the adipocyte-differentiating effects of PPARγ2 by docking corepressors to this transcription factor, thereby diverting mesenchymal stem cells into the osteoblastogenic pathway.[130] BMP-2, -4, and -7 induce osteoblastogenesis acting through their heterodimeric cell surface receptors and transduce their intracellular signals through receptor-regulated SMADs 1, 5, and 8 (which heterodimerize with DNA-binding SMAD 4 to induce expression of *Runx2, Dlx5,* and *Sp7*).[131,132]

Osteoblasts have a life span of 3 months. They secrete type I collagen and many noncollagenous proteins that form osteoid into which calcium and phosphate are deposited as hydroxyapatite. In mature osteoblasts, Runx2, Dlx5, and osterix promote the synthesis of osteoblast-restricted proteins—including collagen type I(α1) and noncollagenous matrix proteins such as bone-specific alkaline phosphatase, osteocalcin, fibronectin, osteonectin, and osteopontin. Several factors (including TGFβ, platelet-derived growth factor, FGF, and IGF) enhance the proliferation and further differentiation of committed osteoblast precursors, but they cannot initiate this process.

Osteoblasts are heterogeneous and express diverse genes independent of the stage of the cell cycle and extent of differentiation. An early marker of the osteoblast is expression of bone alkaline phosphatase.[112] The heterogeneity of osteoblasts may relate to the variety of bone architectures and microenvironments. Actively bone-forming osteoblasts have an enlarged nucleus, plentiful Golgi apparatus, and abundant endoplasmic reticulum. When the rate of bone formation is low, osteoblasts are small and quiescent and incorporated into the endosteum separating bone mineral from marrow or into the undersurface of the periosteum.

Once differentiated, mature osteoblasts secrete collagenous and noncollagenous proteins—including collagen type I, bone-specific alkaline phosphatase, and calcium and phosphate binding proteins (osteocalcin, osteopontin, and osteonectin)—thus making bone matrix competent for mineralization. They also secrete many other proteoglycans and glycoproteins.[133] Osteocalcin, osteonectin, and various phosphoproteins account for approximately 10% of the noncollagenous proteins of bone matrix.[110] Osteoblasts control mineralization of matrix by regulating local concentrations of phosphate through synthesis of cell-membrane–bound alkaline phosphatase and by reducing levels of inhibitors of bone formation such as pyrophosphates.

Calcium and phosphate precipitate in bone matrix as hydroxyapatite crystals. After completing matrix synthesis and local bone formation, mature osteoblasts are embedded in bone as osteocytes (the most abundant cell in bone). Osteocytes are interconnected with each other and with surface osteoblasts by extension of plasma membranes through narrow canaliculi. They function as sensors of bone strength and mechanical integrity and act to identify sites of bone damage requiring repair (i.e., remodeling).[112] Osteocytes synthesize osteocalcin and sclerostin but not alkaline phosphatase. Osteocytes may live for several decades in quiescent bone but ultimately die.

Receptors for $PTH^{1\text{-}84}$ (PTHR1) and calcitriol (VDR) are expressed by osteoblasts.[134] PTH stimulates growth of osteoblast progenitor cells and inhibits apoptosis of osteoblasts and osteocytes, thereby enhancing bone formation and accounting for its therapeutic usefulness in treatment of osteopenic states. However, $PTH^{1\text{-}84}$ also promotes bone resorption via osteoblast production of an osteoclast-activating factor that increases osteoclastogenesis. In osteoblasts, carboxyl terminal fragments of PTH affect generation of alkaline phosphatase, procollagen I, and apoptosis—some of which effects may be opposite those of $PTH^{1\text{-}84}$. There is a high density of binding sites for carboxyl fragments of PTH on osteocyte membranes, suggesting that these sequences may play a role in the mechano-sensory activity of the osteocyte network.[55]

Calcitriol increases synthesis of several noncollagenous matrix proteins, including osteocalcin. Glucocorticoids increase differentiation of osteoprogenitor cells but also accelerate apoptosis of osteoblasts and osteocytes.[112] Estrogens stimulate osteoblast proliferation and synthesis of collagen type I and inhibit apoptosis of osteoblasts and osteocytes. They enhance osteoclast apoptosis. Estrogens stimulate trabecular and endosteal bone growth and are thought to exert a biphasic effect on periosteal bone growth. Thus, in prepubertal boys and girls low amounts of estrogens enhance periosteal bone growth—whereas in pubertal and adult subjects estrogens oppose this process. Estrogens also accelerate growth plate fusion and inhibit bone resorption. Androgens primarily promote mineralization by conversion to estrogens, as evidenced by the osteopenia noted in adult males with aromatase deficiency or loss-of-function mutations in estrogen receptor (ER)α.[135] However, androgens also have a direct effect on bone mineralization because acting through the androgen receptor they increase periosteal bone growth during puberty in both males and females. However, the stronger bones of men compared to women reflect not increased volumetric bone mineral density but rather increased bone size due to greatly expanded periosteal bone width.[136]

Increased periosteal bone width in males is due in part to the androgen-induced effect of increased muscle mass, strain, and mechanical loading on bones. Nevertheless,

estrogens too are necessary for normal periosteal bone growth because despite normal testosterone secretion the aromatase-deficient male has decreased periosteal bone width—a situation that can be reversed by administration of estrogen acting through ERα. A portion of the anabolic effects of estrogens on bone mineralization may be mediated through their stimulation of the GH/IGF-I axis. GH enhances proliferation and differentiation of osteoblast precursors, whereas IGF-I increases osteoblast function and trabecular and cortical bone volume and protects osteoblasts and osteocytes from apoptosis.[112]

IGF-I also mediates (some of) the stimulatory effects of PTH on osteoblast function.[137] The endogenous GH secretagogue ghrelin promotes proliferation and differentiation of osteoblasts and bone mineralization in vivo.[138] Leptin secreted by adipocytes or osteoblasts acting locally in bone exerts anabolic effects and promotes bone formation, whereas centrally active (hypothalamic ventromedial nucleus) leptin both impairs and promotes bone formation.[110]

In addition to their pivotal role in bone formation, osteoblasts and stromal cells regulate bone resorption by controlling the differentiation, maturation, and function of osteoclasts (Figure 3-10). They do so by expressing RANKL (an osteoclast activator) and a decoy acceptor protein for RANKL that inhibits osteoclastogenesis [osteoprotegerin (OPG)] in response to PTH, calcitriol, interleukins, and other cytokines (e.g., TNFα) and in response to prostaglandins. RANKL [also termed osteoprotegerin-ligand (OPGL)] is a member of the TNF ligand superfamily and is encoded by *TNFSF11*. It is expressed on the surface of (and its extracellular domain secreted by) bone marrow stromal cells and osteoblasts. RANKL binds to RANK expressed on the surface of primitive osteoclast progenitor cells, where it induces their further differentiation and activation (Figure 3-11).[139,140] (Transcription factors important in the very early commitment of the mesenchymal stem cell to the osteoclast lineage are those encoded by *PU.1, c-Fos,* and *MI*.[141])

RANKL is a 317-aa protein composed of cytoplasmic (48 aa), transmembrane (21 aa), and extracellular (248 aa) domains—with the binding site for RANK extending between aa 137 and aa 158. In the promoter region of TNFSF11 is a response element for RUNX2, the osteoblast-differentiating transcription factor. TNF-related activation-induced cytokine (TRANCE) is the soluble extracellular domain of RANKL released by a specific metalloprotease.

RANKL is also expressed in skeletal and lymphoid tissue, striated and cardiac muscle, lung, intestines, placenta, thyroid, pre-chondroblast mesenchymal cells, and hypertrophic chondrocytes. In addition to furthering osteoclast differentiation, RANKL enhances function of the mature osteoclast and inhibits its apoptosis. RANKL stimulates transcription of osteoclast-specific proteins such as tartrate-resistant acid phosphatase (TRAP), cathepsin K, β_3-integrin, and the calcitonin receptor. It also stimulates development of calcium resorption lacunae and pits. In

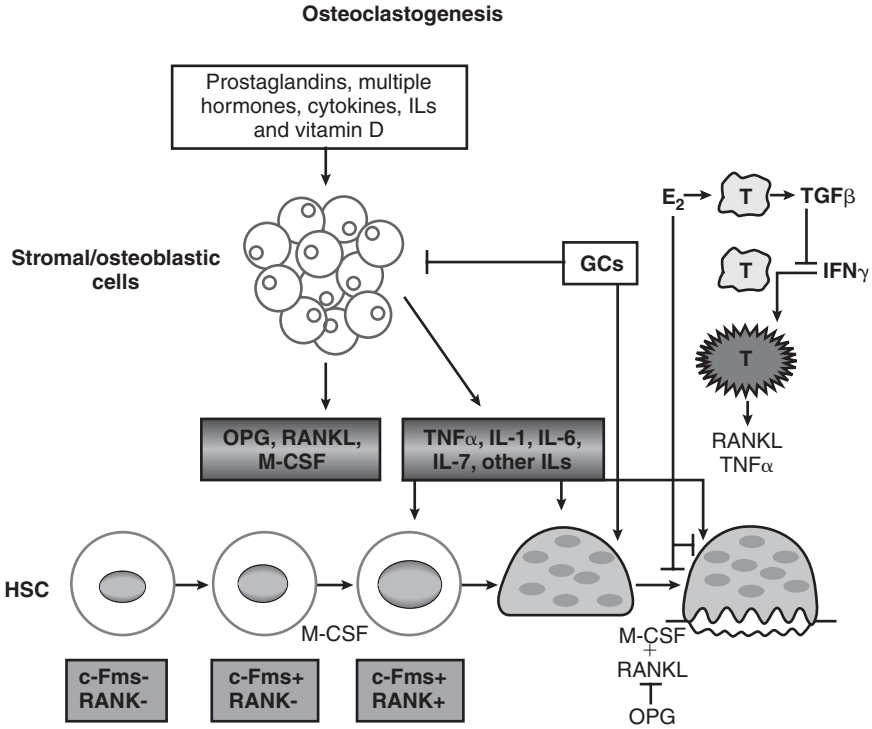

Figure 3-10. Regulation of osteoclast differentiation from the pluripotent mesenchymal stem cell. Osteoclasts differentiate from precursor cells of monocyte/macrophage lineage in response to osteoblast/stromal cell secretion of macrophage-colony–stimulating factor (M-CSF) stimulated by parathyroid hormone (PTH) and other osteoclast-activating cell factors acting through its receptor (c-Fms) and stromal cell/osteoblast derived ligand for the receptor for activation of nuclear factor κB (RANKL). [Reproduced with permission from Ross FP (2006). Osteoclast biology and bone resorption. Effect of RANKL and OPG on osteoclast differentiation

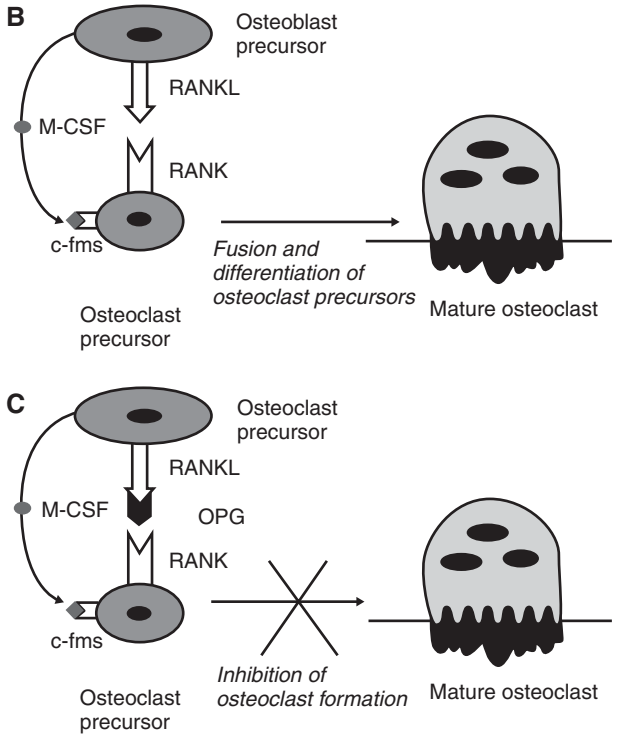

Figure 3-11. Interaction of RANK, RANKL, and osteoprotegerin in osteoclastogenesis. Osteoprotegerin serves as a pseudoreceptor for RANKL, thus preventing its association with RANK and thereby inhibiting osteoclastogenesis. [Reproduced with permission from Rogers A, Eastell R (2005). Circulating osteoprotegerin and receptor activator for nuclear factor kB ligand: Clinical utility in metabolic bone disease assessment. J Clin Endocrinol Metab 90:6323-6331.]

RANKL knockout mice, loss of osteoclasts leads to osteopetrosis. Because RANKL also affects differentiation and function of the immune system, these animals have thymic hypoplasia and lymph node agenesis. BMPs too stimulate osteoclast formation and function.[142]

OPG is a member of the TNF receptor superfamily and is synthesized and secreted by the stromal cell/osteoblast. It acts as a "decoy" receptor by binding to RANKL, thus inhibiting the interaction of RANKL and RANK and thereby osteoclastogenesis.[134,139] The 5 exon gene *(TNFRSF11B)* encoding human OPG is expressed also in the lung, liver, heart, kidney, intestinal cells, brain, thyroid, lymphocytes, and monocytes. Human OPG is synthesized as a 401-aa propeptide. After cleavage of the 21-aa signal peptide, the mature protein of 380 aa contains four cysteine-rich amino terminal domains and two carboxyl terminal "death" domains. It is glycosylated and released into the paracellular space as a disulfide-linked homodimer.

The synthesis of OPG is enhanced by IL-1α and -1β, TNFα, TNFβ, BMP-2, TGFβ, and estrogen—and is antagonized by calcitriol, glucocorticoids, and prostaglandin E_2. Through binding of RANKL, OPG inhibits the osteoclast-activating and bone-absorbing effects of calcitriol, PTH, and the interleukins. Overexpression of OPG in transgenic mice leads to osteopetrosis, whereas its knockout is associated with loss of cortical and trabecular bone and osteoporosis, multiple fractures, and hypercalcemia. The latter model is the experimental counterpart of juvenile Paget disease.[143,144]

In response to macrophage colony-stimulating factor (M-CSF) secreted by both mature osteoblasts and bone marrow stromal cells that acts through its receptor c-Fms expressed on the membrane of preosteoclasts, osteoclast progenitor cells further proliferate and differentiate.[134,140,141] Also expressed on the plasma membrane of the preosteoclast is transmembrane RANK *(TNFRSF11A)*, a member of the TNF receptor superfamily. It is a 616-aa protein with a signal peptide (28 aa), cytoplasmic domain (383 aa), transmembrane domain (21 aa), and extracellular domain (184 aa) that is expressed in osteoclasts, fibroblasts, and B and T lymphocytes (Figure 3-11).

By cell-to-cell interaction, RANK on the surface of the prefusion osteoclast binds to RANKL expressed on the membrane of the osteoblast and/or stromal cell (or secreted by a monocyte) to induce osteoclast fusion and activation, leading to bone resorption. After binding of its ligand, RANK signals [through TNF receptor-associated factors (TRAFs)] a family of intracellular adaptor proteins that bind to the intracellular domain of RANK and activates several intracellular signaling cascades—including the classical pathway of nuclear factor κB (NFκB) activation, JNK-AP1, c-src-PI3K-AKT/PKB, and Ca^{2+}-calmodulin-calcineurin.[140]

In turn, there is enhanced generation of c-Fos, c-Jun, NFAT1c, and NFκB—transcription factors essential for osteoclast formation and function. Synthesis of interferon-β is also increased. This cytokine limits expression of c-Fos and consequently osteoclast differentiation, thus establishing an autoregulatory system for osteoclast production.[145] Osteopetrosis develops in transgenic mice in whom RANK is overexpressed or in whom NF-κB or TRAF-6 has been knocked out. In TRAF-6-depleted mice, osteoclasts develop normally but are not activated and do not form ruffled borders (structures essential to osteolysis).

NFκB subunit 1 *(NFKB1)* is a component of a widely expressed "master" transcription factor complex essential for cell differentiation, growth, and function within the hematopoietic and immune systems and the key regulatory element in osteoclastogenesis. The NFκB complex is composed of five subunits: NKκB1, NFκB2, RELA, RELB, and c-REL.[146] The subunits form homodimers or heterodimers with one another (e.g., NFκB1/RELA and NFκB2/RELB), which are trapped in the cytoplasm bound to specific inhibitors of NFκBs or IκBs (e.g., *NFKB1A*). After cell stimulation, phosphorylation of serine residues on IκB proteins targets them for ubiquitination and proteasomal destruction—thereby freeing the NFκB dimer and allowing it to enter the nucleus and activate target genes.

Within the nucleus there are DNA-binding motifs for NFκB (e.g., 5'-GGGA/GNNC/TC/TCC-3') that control the transcription of several hundred genes involved in cell replication and apoptosis, including the interleukins, TNFs, VEGF, and colony-stimulating factors. The intricate relationship between osteoblasts and osteoclasts provides the pathway(s) through which bone formation and

bone resorption are linked. Thus, BMP and other factors induce osteoblast differentiation and production of RUNX2—leading to synthesis of RANKL that binds to RANK of the osteoclast precursor and enhances further differentiation and function of mature osteoclasts.[132] The effects of modifying agents and of disease processes on bone formation and bone resorption are mediated to a large extent by their influence on the RANKL-RANK-OPG system. Particularly at the level of the osteoblast/stromal cell production of RANKL and OPG may these effects be exerted, with the relative proportion of the two products being synthesized (or their ratio) regulating osteoclastogenesis and bone resorption.[139]

Mature osteoclasts are short-lived (approximately 2 weeks) bone-reabsorbing multi-nucleated giant cells. When attached to bone, the inferior surface of the osteoclast forms the ruffled border—a series of villus projections that bind to underlying bone at the site of bone resorption, creating an isolated microenvironment between the inferior surface of the cell membrane and the outer bone surface (Figure 3-12).[140,141] These villus structures anchor to the bone surface through interaction of dimeric αvβ3 integrins expressed on the osteoclast cell membrane and matrix-embedded osteopontin and other components that contain the amino acid sequence Arg-Gly-Asp (RGD).

Beneath this shield and into the isolated sealed zone the osteoclast pumps acid (H^+ or protons) generated from carbon dioxide by carbonic anhydrase II and transported via an electrogenic proton pump and chloride ions transmitted through a chloride channel to form a highly acidic (pH 4.5) milieu that dissolves hydroxyapatite, the mineral phase of bone. The osteoclast also pumps lysosomal proteolytic enzymes [such as the cysteine proteases cathepsins K, B, and L and matrix metalloproteinases (MMP) such as MMP-9 a collagenase] that digest osteoid, the protein matrix of bone. Mutations in the genes controlling carbonic anhydrase II or the chloride channel result in osteopetrosis, whereas mutations in the gene encoding cathepsin K lead to pycnodysostosis (OMIM 265800).

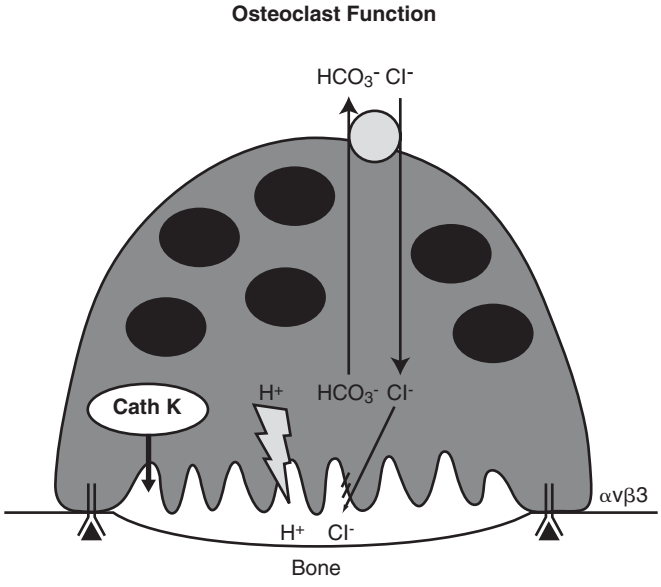

Figure 3-12. Differentiated osteoclasts form a ruffled border by adhering to bone surface through αvβ3 integrin receptors. A sub-osteoclast lacuna is formed by the dissolution of bone mineral and the resorption of organic bone matrix by osteoclast secreted acid and cathepsin K, respectively. Subsequently, osteoblasts are attracted to this pit (perhaps by the high local Ca^{2+} concentration) as new bone is formed in the continuing process of bone remodeling. [Reproduced with permission from Ross FP (2006). Osteoclast biology and bone resorption. In Favus MJ (ed.), *Primer on the metabolic bone diseases and disorders of mineral metabolism, Sixth edition.* Washington, D.C.: American Society for Bone and Mineral Research 30-35.]

The heterodimeric αvβ3 integrin (vitronectin receptor) consists of two transmembrane proteins (αv integrin, β3 integrin) with extra- and intracellular domains that attach the osteoclast to bone surface. They are crucial to normal osteoclast function. The integrins also transmit signals between the interior and exterior of the osteoclast. After the osteoclast contacts bone, it functionally polarizes into two realms. The inferior portion of the osteoclast above the ruffled membrane transports protons, chloride ions, and enzymes from the interior of the cell into the subcellular space and reabsorbs the products degraded by these agents. The superior portion of the osteoclast processes and excretes the reabsorbed materials. The absorptive lacuna is surrounded and isolated by a "sealing zone," whereas the osteoclast is encircled by an actin ring.[140] In the β3 integrin knockout mouse, the ruffled membrane is abnormal and osteoclast function impaired. Osteoclasts withdraw from the sites of bone resorption in response to the high local concentration of Ca^{2+}.[32]

$PTH^{1\text{-}84}$, PTHrP, calcitriol, thyroid hormone, IL-1β, -3,-6, and -11, TNFα, prostaglandin E_2, and glucocorticoids stimulate expression of RANKL and M-CSF and depress that of OPG and hence favor osteoclast development and bone resorption. Calcitonin, estrogen, interferon-γ, IL-4, -10, and -18, TGFβ, glucocorticoids, and bisphosphonates antagonize these processes.[140] Estrogen maintains and augments bone mass by inhibiting its dissolution by suppressing T-cell production of osteoclast-activating cytokines such as IL-1, -6, and TNF and by suppressing expression of RANKL and increasing that of TGFβ.

Glucocorticoids decrease bone mineralization by depressing osteoblast differentiation, function, and life span and by prolonging the life span of osteoclasts. Receptors for calcitonin and to a limited extent for PTH are expressed by osteoclasts. Calcitonin antagonizes formation and activity of osteoclasts and accelerates their death. Interestingly, carboxyl terminal fragments of $PTH^{1\text{-}84}$ can inhibit osteoclast formation and function and antagonize the osteoclast-stimulating effects of $PTH^{1\text{-}84}$, calcitriol, prostaglandins, and interleukins.[55] Thus, they may exert a protective effect upon the skeleton and perhaps work in concert with intact $PTH^{1\text{-}84}$.

Bone modeling is accomplished by the independent action of osteoblasts and osteoclasts and is not dependent on prior bone resorption.[111] On the other hand, during bone remodeling (the process during which the strength, structure, and function of bone are renewed) bone resorption and deposition are sequentially linked. Bone remodeling is accomplished within the bone remodeling unit (BRU) of designated osteoclasts and osteoblasts. It is

a continuous process in which old cancellous and cortical bone is reabsorbed and replaced by new bone and takes place in the growing as well as the mature skeleton. The BRU is 1 to 2 mm in length, 0.2 to 0.4 mm in width, led by osteoclasts, and trailed by osteoblasts. In the adult skeleton, the life span of the BRU is 6 to 9 months—and 10% of the skeleton is turned over each year.

The site selected for remodeling may be random or may be targeted by osteocytes sensing a mechanical or stress defect. Bone remodeling occurs in four stages. Stage 1 is activation, in which osteoclast precursor cells target a resting bone surface, evolve into osteoclasts, convert the area into a BRU composed of a sub-osteocytic bone resorption compartment, and initiate stage 2. Stage 2 is bone resorption, during which the mineral phase of bone is solublized by acid and the protein component degraded by proteases. When complete, the osteoclast dies. This phase is followed by stage 3, reversal—in which monocytes, osteocytes, and osteoblasts perhaps attracted to the BRU through their detection of the high Ca^{2+} concentrations in the resorption lacunae or by growth factors (IGF-I and -II, TGFβ, BMP) released from the matrix or secreted by osteoclasts enter the area of reabsorbed bone and initiate the fourth stage. Stage 4 is renewed bone formation, in which osteoid is secreted, increase local concentrations of calcium and phosphate to levels that exceed their solubility, and are degraded pyrophosphates and proteoglycans that inhibit mineralization. The majority of osteoblasts and osteoclasts in the BRU are eliminated by programmed cell death (apoptosis), whereas some osteoblasts develop into osteocytes.[132]

Organic matrix proteins comprise 35% of bone, and type I collagen makes up 90% of these proteins.[133] Type I collagen is composed of a coiled triple helix of two polypeptide chains of collagen type I(α1) and one of (α2) that are cross-linked intramolecularly by disulfide bonds and intermolecularly at the amino (N) and carboxyl (C) telopeptides by pyridinium compounds that permit bundling of collagen molecules into fibrils and fibers (Figure 3-13).[147,148] Glycine occupies every third aa position in the collagen α peptides and permits the chains to coil. Proline, hydroxyproline, and hydroxylysine are also incorporated in large quantities. Proline is hydroxylated to 4-hydroxyproline and 3-hydroxyproline by prolyl 4-hydroxylase and prolyl 3-hydroxylase-1 (P3H1), respectively. Lysine is hydroxylated by lysyl hydroxylase and some hydroxylysine residues further glycosylated.

P3H1 (also termed leprecan, *LEPRE1*) specifically hydroxylates the proline residue at codon 986 in bone collagen type I(α1), a reaction that requires interaction of P3H1 with cartilage-associated protein *(CRTAP)* and cyclophilin B *(PIPB). CRTAP* is expressed in the proliferative zone of developing cartilage and at the chondro-osseous junction. Cyclophilin B is a peptidyl-prolyl cis-trans isomerase. That post-translational modifications of collagen type I(α1) are essential to normal bone formation is evidenced by the association of inactivating mutations of *CRTAP* with osteogenesis imperfecta types IIB (OMIM 610854) and VII (OMIM 610682) and of *LEPRE1* with osteogenesis imperfecta type VII.[149-151]

Amino and carboxyl terminal extensions of the propeptides of collagen are removed by proteolysis during formation of the mature collagen molecule and are partially secreted into extracellular space and serum. Pyridinoline (Pyr, hydroxylysyl-pyridinoline) and deoxypyridinoline (Dpd, lysyl-pyridinoline) form nonreducible pyridinium cross-links between mature collagen fibers, thus making them insoluble (Figure 3-14). Type I collagen predominates in bone but is also present in ligaments, tendons, fascia, and skin. Type II cartilage is composed of three procollagen type II(α1) chains and is primarily deposited in cartilage. Type III collagen [three procollagen type III(α1) chains] is present in bone, tendons, arteries, and intestine, and type IV [three procollagen type IV(α1)] cartilage is a component of cell basement membranes.

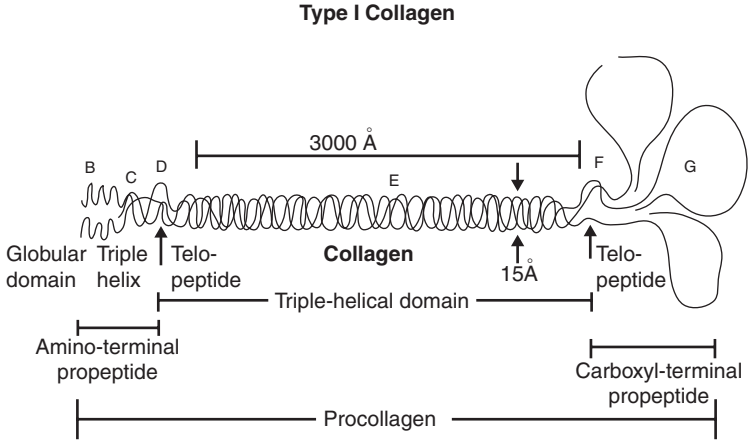

Figure 3-13. Type I collagen is a coiled triple helix of two polypeptide chains of collagen α1(I) and one of α2(I) that are cross-linked intramolecularly by disulfide bonds and intermolecularly at the amino and carboxyl telopeptides by pyridinium compounds. In the process of collagen formation, carboxyl and amino terminal propeptides are removed. [Reproduced with permission from Byers PH (1995). Disorders of collagen biosynthesis and structure. In Scriver CR, Beaudet AL, Sly WS, Vale D (eds.),,*The metabolic and molecular bases of inherited disease, Seventh edition.* New York: McGraw-Hill 4029-4077.]

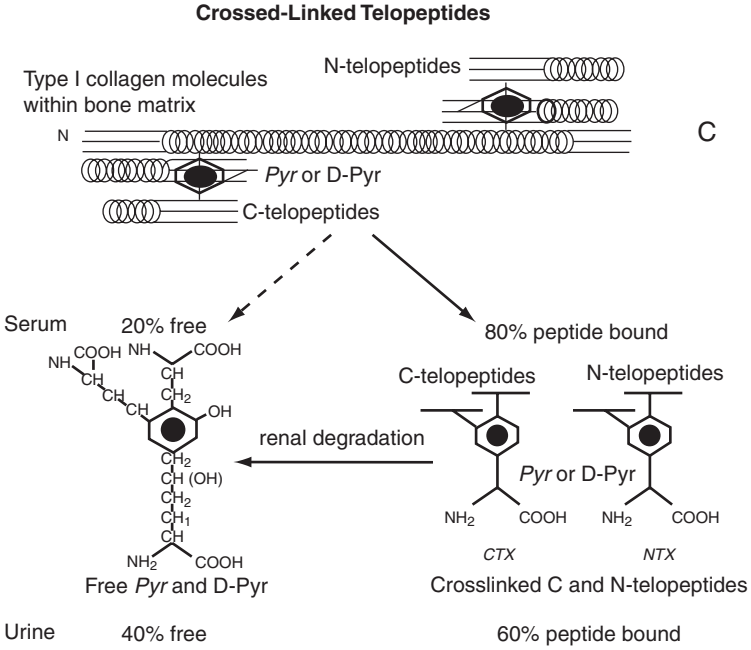

Figure 3-14. Pyridinium and telopeptides of collagen. Pyridinoline (Pyr, hydroxylysyl-pyridinoline) and deoxypyridinoline (D-Pyr or Dpd, lysyl-pyridinoline) form nonreducible pyridinium cross-links between mature collagen fibers, rendering them insoluble. Amino (N-) and carboxyl (C-) terminal extensions (NTx, CTx) of the propeptides of collagen are proteolytically removed during formation of mature collagen and secreted into extracellular space and serum. [Reproduced with permission from Garnero P, Delmas PD (1998). Biochemical markers of bone turnover: Applications for osteoporosis. Endocrinol Metab Clin NA 27:303-323.]

Measurement of serum concentrations of the procollagen I extension peptides such as the C-terminal extension of procollagen type I (PICP) and the N-terminal extension of procollagen type III (PIIINP) provides information about bone and collagen formation (as does determination of the osteoblast products, osteocalcin and bone-specific alkaline phosphatase). Degradation of mature bone matrix by osteoclasts catabolizes type I collagen and releases Pyr, Dpd, and the N- and C-telopeptides [NTx; ICTP (CTx) = amino or carboxyl terminal cross-link telopeptide of type I collagen, respectively]. The urinary excretion of hydroxyproline, hydroxylysine, Pyr, Dpd, and NTx reflects catabolism of collagen type I and bone resorption.

Serum/urine levels of markers of bone formation and resorption are higher in the fetus than mother[152] (Table 3-6). Fetal umbilical cord plasma PICP concentrations are highest in mid-gestation and decline in the last trimester to term values. After birth, PICP values fall in preterm neonates during the first 3 days of life and then increase steadily to peak values at 36 weeks postconceptual age. PICP levels in cord plasma are higher in males than females and correlate with gestational age and birth weight.[153] Urine levels of NTx at 2 days of age are higher in preterm than term neonates. Markers of bone turnover increase during the first 3 weeks of life in preterm infants.[154]

Values of bone formation and resorption markers are highest in infants and decline during childhood and adolescence to adult levels[155-160] (Tables 3-7A and B). In the normally menstruating young adult female, urine Pyr and Dpd levels fall during the first half of the cycle and increase during the second half. Serum concentrations of PICP have the reverse pattern. These data suggest that the fluctuations in estrogen secretion during the menstrual cycle alter the dynamics of bone formation and resorption.[161] Osteoprotegerin and RANKL are also measurable in serum, but their utility in children and adolescents has yet to be assessed.[139]

The adult skeleton is composed of mineral (50%-70%), organic matrix (20%-40%), water (5%-10%), and lipids (<3%). Ten percent to 15% of bone matrix is composed of noncollagenous peptides secreted by the osteoblast, including proteoglycans (chondroitin sulfate, heparan sulfate), glycoproteins, growth-stimulating proteins (BMP, TGFβ, IGF-I, and IGF-II), cell attachment peptides (integrin ligands such as osteopontin, osteonectin, fibronectin), and γ-carboxylated proteins or proteins derived from serum (e.g., albumin).[133] Macromolecular proteoglycans are composed of glycosaminoglycans (acidic polysaccharide side chain) linked to a core protein and are important to normal synthesis of collagen and bone development.

Osteonectin is a phosphorylated 35- for 45-kDa glycoprotein that binds Ca^{2+} and is necessary for growth and survival of osteoblasts and osteoclasts and for normal mineralization of matrix. Alkaline phosphatase is an 80-kDa glycoprotein essential to bone mineralization. Osteopontin (also termed *bone sialoprotein* or *secreted phosphoprotein 1*) is an 85-kDa sulfated and phosphorylated glycoprotein that contains the aa sequence [Arg-Gly-Asp (RGD)] necessary for linkage to integrins and hence for attachment of osteoclasts to bone. It also binds Ca^{2+} and hydroxyapatite and may play a role in the initiation of bone matrix mineralization. Osteopontin is secreted by osteoblasts in response to calcitriol. Osteocalcin is a 49-aa γ-carboxylic acid-containing 6-kDa peptide that likely

regulates osteoclast activity and the interface between bone resorption and formation, whose synthesis is dependent on vitamin K activation of γ-carboxylases.

Calcium and phosphate deposit in extracellular matrix around the osteoblast. Type I collagen and osteopontin are important for the nucleation of hydroxyapatite and the determination of bone structure.[162] In the first phase of bone formation, hypertrophic chondrocytes and/or osteoblasts initiate bone crystal formation by generating 100 nm subsurface matrix vesicles containing among other components calcium, phosphate, alkaline phosphatase, calbindin-D_{9K}, carbonic anhydrase, pyrophosphatases, osteocalcin, and osteopontin. These vesicles are extruded from the osteoblast and attach to adjacent bone matrix—in cartilage to collagen types II and X and in bone to collagen type I. Ca^{2+} and $H_2PO_4^{2-}$ enter the vesicle through ion channels and possibly first form rudimentary crystals of calcium phosphate that enlarge, attain the structure of hydroxyapatite, and penetrate the vesicle wall. In the matrix, these crystals enlarge further and deposit about collagen type I.

Mineralization of bone is partially dependent on the extent of phosphorylation of osteopontin. When 40% of the phosphorylation sites of osteopontin are phosphorylated, bone mineralization is inhibited. When 95% of its sites are phosphorylated, hydroxyapatite formation is promoted—a process further enhanced by a complex of osteopontin and osteocalcin.[133,163] Osteocalcin is also synthesized by osteoblasts in response to calcitriol acting through the VDR/RXR heterodimer. Inhibition of calcification is an active process as well. In addition to osteopontin, matrix GLA protein (an 84-aa vitamin K-dependent peptide containing γ-carboxylated glutamate that is related to but distinct from osteocalcin and encoded by *MGP*) has great affinity for Ca^{2+} and inhibits precipitation of calcium and phosphate. *MGP* is expressed in arteries and chondrocytes but not in osteoblasts. In patients with biallelic loss-of-function nonsense mutations in *MGP* (Keutel syndrome, OMIM 245150), there is extensive calcification of cartilage and its experimental deletion in mice leads to calcification of both cartilage and arteries and early demise.[162]

Bone strength is determined by its size (height, width, depth), mineral mass, macro- and microarchitecture, and material properties (e.g., elasticity) of collagen that in turn are regulated not only by endocrine hormones and paracrine growth factors but by mechanical forces exerted upon the skeleton by the environment (gravity) and by the muscular system.[164,165] Bone mass and strength are determined by the loads placed on bone by biomechanical

forces exerted by muscles (the "mechanostat" model).[166] In this model, bone tissue monitors the stresses and strains (deformations) that are the result of mechanical forces placed upon it.[167]

In part, mechanical forces are recognized by osteocytes, whose rate of apoptosis declines in response to these dynamic changes. In addition, stromal cells modify their expression of RANKL—and thus the process of osteoclastogenesis. Deformation of the osteoblast cell membrane induced by mechanical forces (e.g., stretch, gravity, vibration) generates signals that are transmitted through alterations in configuration of its cytoskeleton that act upon cytoplasmic organelles and within the nucleus itself, increasing expression of transcription factors such *c-Fos* and *c-Myc*.

In response to mechanical stress, multiple growth factors likely generated by the osteoblast itself (FGF, IGF-I, TGFβ) act in an autocrine/paracrine manner upon their tyrosine kinase receptors expressed in the cell membrane of the osteoblast to activate phosphoinositide 3-kinase, PKB, and the MAPK signal transduction system. Prostaglandins activate G-protein–coupled receptors, adenylyl cyclase, PKA, and the cyclic AMP responsive transcription factor. PLC generation leads to increase in cytosolic Ca^{2+}_i and osteoblast function, as does influx of Ca^{2+} through L-type calcium channels in the cell membrane.[168]

One of the target genes affected by mechanical stimulation is *Runx2,* whose product is essential to osteoblast differentiation and expression and synthesis of osteoblast-related proteins such as collagen type I, bone-specific alkaline phosphatase, osteopontin, and collagenase-3.[169] Repetitive bone strain (an applied deforming force that might be compressive, lengthening, or angulating) leads to enhanced quantity and quality of bone (bone strength). It is this property that enables various exercises to increase bone mineralization at all ages and states of mobility.

The mechanisms that lead to increased bone mass are inactivated by decreased weight bearing, such as immobilization or decreased gravity (e.g., space flight), and lead to bone loss ("disuse osteoporosis"). Although bone strength is in part dependent on bone mass, it is the size of the bone that primarily determines its strength.[170] Clinically, this is illustrated by the increased rate of fractures in children with osteopetrosis ("marble bone disease") despite extremely dense bones with thick cortices and trabeculae.

Skeletal accretion of calcium begins early in fetal life and progresses through childhood and puberty. The skeleton accumulates 25 to 30 grams of calcium *in utero* and accrues 1,300 grams by adulthood.[171] The average total body bone mineral content (BMC) of the adult male is 2,800 g, and that of the adult female 2,200 g. Approximately 60% of total adult bone calcium is acquired during adolescence (26% in the two years prior to and after the peak velocity of BMC accrual) (Figure 3-15). Thirty-two percent of the mean BMC of the adult female lumbar spine (60 g) is deposited during this interval.[172]

It is recommended that the adolescent ingest 1,300 to 1,600 mg of elemental calcium daily in order to absorb and retain the 220 mg per day of calcium needed to achieve optimal adult bone mineral mass. Although calcium supplementation has been reported to increase radial and femoral BMC in children, extensive review of the effects of calcium supplementation in approximately 3,000 children and adolescents (3–18 years of age) did not support this conclusion. Nor did supplementation decrease fracture rate.[173,174]

As evidenced by the close concordance of bone mineral status between mothers and daughters, identical and fraternal twins and siblings, 60 to 80% of the peak or maximum adult bone mass is determined by genetic factors.[175] There are numerous candidate genes through which this parental relationship might be exercised, including those encoding the vitamin D, calcium-sensing, estrogen, low-density lipoprotein-related, leptin and β-adrenergic receptors, cytokines (e.g., IL-6, TGFβ) and growth factors (BMPs, IGF-I), and bone matrix proteins such as type I collagen and osteocalcin—emphasizing the fact that the regulation of bone mineralization is genetically complex and heterogeneous.[176]

In addition to intrafamilial factors, race, sex, body size, and composition are important genetic determinants of bone calcium content. In black males and female youths, there is higher whole-body, lumbar spine, total hip, and femoral neck BMD and bone mineral apparent density (BMAD) than in white, Asian, or Hispanic youth.[177] Asian female children and adolescents have lower whole-body and femoral neck BMD than do white and Hispanic subjects. Hispanic males have lower lumbar spine BMD than do white and Asian youth. Radial and femoral neck (peripheral) and vertebral (axial) BMDs correlate with sex, age, height, weight, body mass index, pubertal and postpubertal hormonal status, calcium intake, and exercise in children, adolescents, and adults.[178,179]

In young women, only 16% to 21% of peak vertebral and femoral bone mass can be accounted for by weight, height, physical activity as an adolescent, and the VDR genotype—emphasizing once more the essential role of multiple genetic factors in this process. Adult peak bone mass is inversely related to the risk of osteopenia and osteoporosis in later adulthood. In adults, a 10% increase in BMD reduces the risk of femoral neck fracture by 50%. Thus, it is essential that bone mass be maximized during childhood and adolescence.[180]

The effects of diminished physical activity on bone growth and strength are dramatically illustrated by those children with neurologic insults that prevent normal motion (Erb paresis, hemiplegia, spinal cord insults) and thus restrain limb growth.[166] During prolonged bed rest, the BMC of the peripheral skeleton substantially declines—whereas that of the cranium increases. Thirty minutes of programed exercise thrice weekly increases BMC of the femoral neck and lumbar spine in prepubertal boys and girls.[181,182] High-impact weight-bearing exercises (ballet, tennis, volleyball, gymnastics, soccer, rugby) increase mass of weight-bearing bones, particularly in children and adolescents.[172,183,184]

Exercise does so in part by augmenting periosteal bone acquisition and increasing the cortical thickness of long bones, particularly of the legs at their most distal extremes closest to the ground where weight bearing is maximal. Active boys and girls accrue more bone mineral than do relatively inactive youth at similar intakes of calcium (1,150 mg/day). At peak BMC velocity (Figure 3-15), the annual gain and total accumulation

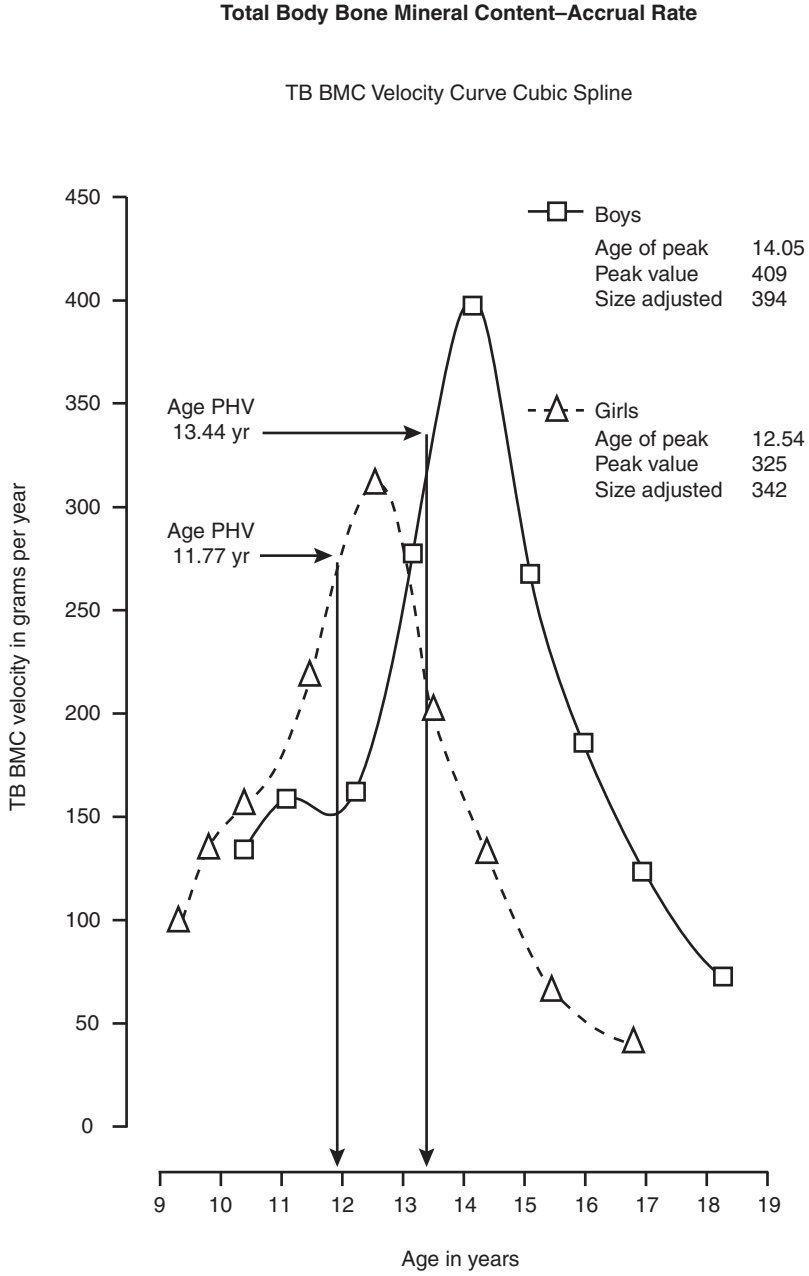

Figure 3-15. During adolescence, the peak rate of accrual of total body bone mineral content (BMC) occurs in boys and girls 0.7 years after attainment of peak height velocity (PHV). [Reproduced with permission from Bailey DA, et al. (1999). A six-year longitudinal study of the relationship of physical activity to bone mineral accrual in growing children: The University of Saskatchewan bone mineral accrual study. J Bone Miner Res 14:1672-1679.]

(over 2 years) of total body bone mineral in active boys and girls are 80 g/year and 120 g/yr (respectively) greater than in inactive adolescents. One year after peak BMC velocity, the total body, femoral neck, and lumbar spine BMCs are 9% to 17% greater in active than in relatively inactive subjects.

EFFECTS OF HORMONES AND GROWTH FACTORS ON THE SKELETON

Systemic hormones and growth factors (GH, IGF-I, PTH, leptin, thyroid and sex hormones, glucocorticoids) have substantial effects on chondrocyte proliferation, maturation, and function.[185] GH increases the synthesis of BMPs, directly enhances differentiation of prechondrocytes, supports proliferation of chondrocytes in the reserve or resting zone, and increases expression of *IGF1*. IGF-I then ensures the clonal expansion of committed chondrocytes.[126] *In utero,* both IGF-I and IGF-II are essential for normal fetal growth as denoted by the *in utero* growth retardation experienced by the fetus with a loss-of-function mutation in *IGF1, IGF2,* or *IGFR1*.[185,186]

GH and IGF-I receptors are expressed in chondrocytes in the reserve, proliferative, and hypertrophic zones—whereas IGF-I and IGF-II are expressed predominantly in proliferating chondrocytes.[187] GH mediates chondrocyte

proliferation and maturation and IGF-I synthesis through the Janus kinase-2 signal transduction and transcription 5b (JAK2-STAT5b) signal transduction system.[188] IGF-I coordinates chondrocyte proliferation and inhibits their apoptosis. It modulates their differentiation and maturation and their synthesis of matrix heparan sulfate proteoglycan, a matrix component necessary for efficient signaling of FGFs and their receptors.[126,186]

IGF-I also influences the interaction of Ihh and PTHrP. IGF-binding proteins (IGFBP) 1 through 6 are synthesized by growth plate chondrocytes, where they regulate levels of bioactive IGF-I as well as exert direct stimulatory/inhibitory effects on chondrocyte proliferation (depending on the stage of chondrocyte differentiation).[126,189] Neither GH nor IGF-I is necessary for patterning of the skeleton, however. Systemic loss of GH secretion or IGF-I production or inactivation of the IGF-I receptor greatly impairs linear growth of long bones postnatally. Selective loss of hepatic IGF-I production lowers total circulating levels of IGF-I to 25% of normal but does not adversely affect growth in transgenic mice, indicating that it is IGF-I synthesized by the cartilage growth plate that affects chondrocyte division by a paracrine mechanism.[190]

In patients with inactivating mutations of the GH receptor or deletion of the gene encoding IGF-I, administration of IGF-I enhances linear growth—indicating that this growth factor is able to stimulate cartilage proliferation without the initial differentiating effect of GH but does so to a lesser extent than does GH in the GH deficient subject. Thus, sufficient numbers of differentiated prechondrocytes are necessary for optimal IGF-I effect.[191] The GH secretagogue ghrelin is also synthesized and secreted by chondrocytes and affects their intracellular metabolism, but its physiologic significance in this region is unknown at present.[192]

Through expression of the GH receptor by osteoblasts, GH stimulates their differentiation, proliferation, and function—enhancing synthesis and secretion of osteocalcin, bone-specific alkaline phosphatase, and type I collagen. GH also increases expression of IGF-I by the osteoblast, as do estrogen, PTH, cortisol, calcitriol, and other factors. IGF-I is essential for GH-induced osteoblast proliferation *in vitro.* It also decreases expression of the GH receptor, whereas estrogen stimulates its expression.[193] In response to GH, IGFBP-3 and IGFBP-5 are synthesized by (rat) osteoblasts. IGFBP-4 expression is decreased by GH in rat and human osteoblasts.

The IGFBPs may augment or restrict activity of IGF-I and IGF-II. Thus, IGFBP-5 binds to bone cells, matrix, and hydroxyapatite and enhances the actions of IGF-I on bone. Expression of the GH receptor by the osteoblast is up-regulated by IGFBP inhibition of IGF-I activity. Acting through the osteoblast, GH increases osteoclast proliferation and activity. Human osteoclasts express receptors for IGF-I, which also enhances osteoclast formation and activation.

In children with GH deficiency and adults with childhood-onset or adult-onset GH deficiency, BMC and areal and volumetric BMDs are decreased—and increase when GH is administered.[193,194] Administration of GH to the GH-deficient subject is followed by increase in serum and urine levels of markers of bone formation and resorption (osteocalcin, bone-specific alkaline phosphatase, PICP, PIIINP, ICTP, Pyr, Dpd, and NTx), with maximal values achieved 3 to 6 months after beginning treatment. There is a biphasic response of bone mass during GH treatment. For approximately the first 6 months of GH administration, BMD declines as bone resorption exceeds formation. Thereafter, BMD increases steadily to positive values over the next 6 to 12 months.[193]

In subjects with GH receptor deficiency or IGF-I gene deletion, BMC and BMD are decreased relative to control subjects but volumetric BMD is not—suggesting that bone size but not bone mineral acquisition is impaired by isolated IGF-I deficiency.[195,196] Nevertheless, administration of IGF-I to subjects with deletion of *IGF1* enhances osteoblast function as documented by increased serum concentrations of osteocalcin and bone-specific alkaline phosphatase, BMC, and areal and volumetric BMDs.[196] In acromegalic patients, there is increased bone turnover—and variably increased lumbar spine and femoral neck BMD and iliac crest cortical and trabecular bone mass.[193]

Thyroid hormone receptors (TRα, TRβ) are expressed in the reserve and proliferative zones of the growth cartilage. Triiodothyronine, acting primarily through TRα, enables the differentiation of resting chondrocytes and their entrance into the proliferative phase. However, there thyroid hormone inhibits further chondrocyte proliferation and promotes differentiation to terminal hypertrophic chondrocytes and secretion of collagen type X.[126] They do so in part by disrupting the reciprocal interaction of Ihh and PTHrP, thereby accelerating chondrocyte maturation (effects mediated by FGFR3 and the STAT signaling pathway), and by down-regulation of IGF-I expression in chondrocytes.[126,197]

Thyroid hormone is essential also for invasion of the growth plate's hypertrophic zone by blood vessels and induction of metaphyseal trabecular bone formation. Thyroid hormones are necessary for fusion of the epiphyseal cartilage plate, although fusion may occur in the absence of thyroid hormone through the action of sex hormones. Through osteoblast-expressed receptors for thyroid hormone, triiodothyronine increases osteoblast production of osteocalcin, bone-specific alkaline phosphatase, and IGF-I. Thyroid hormones increase the rate of bone remodeling by expanding the number of osteoclasts and sites of bone resorption and the amount of bone resorptive surface. Urinary calcium excretion is increased by thyroid hormones. In excess, thyroid hormones can lead to net bone loss.

Estrogen and androgens promote chondrocyte maturation.[185] Although many of the effects of androgens are mediated by their conversion to estrogens, nuclear androgen receptors are expressed by chondrocytes and nonaromatizable androgens stimulate chondrocyte proliferation and long bone growth. Estrogens acting through ERα and ERβ expressed in chondrocytes exert dual effects on long bone growth—stimulatory at low levels and inhibitory at high values. Estrogens decrease chondrocyte proliferation and accelerate differentiation and senescence. Complete maturation and fusion of the growth plate are mediated solely by estrogens, as evidenced by the failure

of growth plate fusion in young adult males with inactivating mutations of the genes encoding aromatase (the enzyme that converts androgens to estrogens) or ERα despite adult levels of testosterone.

Chondrocytes may also be capable of synthesizing estrogens from androgens because aromatase activity has been found in growth plate chondrocytes.[185] This observation suggests that locally produced (as well as systemic) estrogens may contribute to chondrocyte maturation and growth plate fusion. Sex hormones play major roles in the accretion of bone mineral in both females and males because the bulk of adult bone calcium stores are deposited during puberty, when the peak rate of accrual of total body BMC occurs in boys and girls 0.7 years after attainment of peak height velocity (PHV) and 0.4 to 0.5 years after peak accrual of lean body mass (a surrogate measurement of muscle mass)[172,198] (Figure 3-15).

After controlling for size, total body mass, and femoral neck peak, BMC velocity and BMC accrual over 2 years around the PHV are greater in males than in females. There is no gender effect on accrual of BMC of the lumbar spine, however. Both androgens (in part by conversion to estrogen) and estrogens markedly influence rates of bone formation and resorption, although it is the effect of estrogen that predominates—as evidenced by the marked osteopenia of adult males with androgen sufficiency but estrogen deficiency related to loss-of-function mutations in the genes encoding aromatase and ERα, by the beneficial effects of estrogen but not of testosterone on BMD in males with aromatase deficiency, by the very close association of BMD and serum levels of bioavailable estrogen in elderly men, and by the significant correlation in adult men treated with testosterone between changes in BMD and increases in serum concentrations of estradiol but not of testosterone.[132,199]

Nevertheless, the osteopenia of adult (46XY) females with complete androgen insensitivity due to loss-of-function mutations of the X-linked androgen receptor despite elevated serum testosterone and (endogenous or exogenous) estradiol concentrations and the fragile bone structure of the (Tfm) mouse counterpart of this disorder indicates that androgens, too, increase bone mineralization.[200] Furthermore, non-aromatizable dihydrotestosterone has a direct anabolic effect on bone because it stimulates the proliferation and maturation of osteoblasts, increases the production of procollagen I(α1), and prevents bone loss in orchidectomized rats.[201]

Estrogens have a biphasic effect on chondrocyte proliferation—increasing it at low doses and reducing it at higher doses. By accelerating their rate of maturation and apoptosis, estrogens lead to epiphyseal fusion.[199] Both males and females with systemic aromatase deficiency have delayed bone age, absent adolescent growth spurt, and marked osteopenia. Males are tall and eunuchoid, whereas females are short and hyperandrogenic (cliteromegaly, hirsutism). Administration of low doses of estrogens results in bone maturation in both genders. Estrogens increase bone mass primarily by suppressing bone resorption. They do so through inhibition of osteoclastogenesis and down-regulating osteoblast production of osteoclast-activating factors such as IL-6 (and its receptor), TNFα, and M-CSF; increasing production of osteoprotegerin; and accelerating apoptosis of mature osteoclasts.[132]

Estrogens also prolong the life span of osteoblasts and osteocytes. During adolescence, in the female not only does the rate of bone deposition increase but that of bone resorption declines.[202] Serum levels of IGF-I are positively correlated with lumbar spine BMD and metacarpal length and cortical thickness in early and mid-pubertal females. There is maturation-related increase in BMC and areal and volumetric BMD, and in metacarpal length, width, and cortical thickness—due in part to decline in width of the marrow cavity. These data suggest that the pubertal increase in production of GH and IGF-I (attributable specifically to increased estrogen synthesis in females) mediates longitudinal and periosteal skeletal growth and mineral acquisition during puberty. Estrogen may decrease endosteal bone resorption through inhibition of IL-6 generation—both systems contributing to increase in cortical bone mass.

Estrogens likely account for part of the pubertal growth spurt of girls and boys, acting both indirectly (by increasing the secretion of GH and the systemic and local production of IGF-I) and directly on the chondrocyte. Other gonadal hormones also influence bone quality.[203] Experimentally, inhibin A (a member of the TGFβ superfamily) increases total body BMD and bone volume and tibial biomechanical strength in transgenic mice through enhancement of osteoblast differentiation and function.[204]

The nuclear glucocorticoid receptor is expressed in chondrocytes in the proliferative and hypertrophic zones. Cortisol exerts an inhibitory effect on chondrocyte proliferation and maturation and hastens the death of hypertrophic chondrocytes.[126] Glucocorticoids act in part by depressing expression of the genes encoding the GH receptor, IGF-I, and IGF1R in growth plate chondrocytes and by regulating synthesis of IGFBPs and thereby indirectly function of IGF-I. However, glucocorticoids also increase expression of *SOX9* and the earliest phase of chondrocyte differentiation. Glucocorticoids suppress osteoblastogenesis and accelerate the rate of apoptosis of osteoblasts and osteocytes, in part by suppressing expression of *BMP-2* and *RUNX2*.[132] Secondarily, glucocorticoids decrease osteoclastogenesis but delay osteoclast death. In excess, glucocorticoids decrease trabecular bone and osteoid volumes and the rate of bone formation—contributing to bone weakness and collapse.

Transcripts of C-type natriuretic peptide *(NPPC)* and its receptor *(NPR2)* are expressed by chondrocytes. These peptides stimulate the growth of proliferative and hypertrophic chondrocytes, stimulate osteoblast function, and induce endochondral ossification.[205] Plasma concentrations of the amino terminal pro-C-type natriuretic peptide are positively related to growth velocity in normal children and adolescents.[206] Biallelic loss-of-function mutations in *NPR2* have been identified in patients with acromesomelic dysplasia [Maroteaux type (OMIM 602875)].[207] In this disorder, there is shortening and deformation of the forearms, forelegs, and vertebrae—resulting in severely compromised adult stature.

After genetic influences, the factor to which bone mass is most closely related is weight. Although obese children,

adolescents, and adults may have greater BMC and BMD than do slimmer subjects, it is primarily lean body mass (i.e., muscle) to which bone mass is related in these subjects.[208] Because osteoblasts and adipocytes arise from a common mesenchymal stem cell and can be interconverted, it is not surprising that the fat cell synthesizes and secretes a number of adipokines that exert effects on bone accumulation. Among these products is leptin, a 16-kDa protein that enhances osteoblast differentiation and maturation (but not proliferation) and inhibits adipocyte differentiation in human bone marrow stromal cells *in vitro*.[209] However, leptin concentrations are not correlated with whole-body BMD in either obese or nonobese late prepubertal or early pubertal subjects.[210]

Furthermore, in mice with loss-of-function mutations in leptin or its receptor bone mass is increased before onset of obesity due to increased osteoblast activity in the presence of normal osteoclast function. Bone mass can be reduced in these and wt animals by intracerebroventricular infusion of leptin, indicating that leptin can act centrally to inhibit bone formation.[211] Central infusion of leptin also decreases bone formation in sheep.[212] These and other data demonstrate that in addition to peripheral modulating factors there is central (hypothalamic) regulation of bone remodeling that is thought to be exerted through the sympathetic nervous system.[213] Adiponectin, another fat cell product, stimulates osteoclastogenesis by inducing osteoblast expression of RANKL and inhibiting that of osteoprotegerin.[214]

ASSESSMENT OF BONE MASS AND STRENGTH

Bone mass is determined by the three-dimensional size (volume) of the bone, its mineral content, and its material properties such as elasticity. Bone mineralization may be assessed by bone biopsy and histomorphometric analysis of bone formation and resorption.[215-217] Undecalcified transiliac biopsies permit limited assessment of bone modeling (changes in bone size, shape, mass), but detailed analysis of remodeling (bone renewal) as the iliac crest biopsy is primarily composed of trabecular bone with a limited amount of cortical bone. Although in children bone biopsies are usually reserved for research studies or for the evaluation of disorders of bone formation/mineralization not readily understood by noninvasive procedures (e.g., osteogenesis imperfecta, fibrous dysplasia), they have substantial clinical utility when applied appropriately by experienced personnel.[216]

During bone modeling, osteoblasts and osteoclasts are active on opposite bone surfaces across from one another. Thus, the bone surface may change position, size, or mass during the modeling process. Usually, modeling is associated with gain in bone mass because the rate of osteoblastic deposition of bone is more rapid than is that of osteoclastic resorption. During bone remodeling, osteoclastic resorption of bone is followed by osteoblastic replacement of the reabsorbed bone at the same surface with a net change of zero in bone mineral at the remodeling site under normal circumstances.

Histomorphometry enables quantitation of structural parameters of bone size and amount (cortical width, trabecular number, and thickness), static bone formation (thickness and surface of osteoid or unmineralized bone matrix, osteoblast surface), dynamic bone formation after labeling with a fluorochrome such as tetracycline (mineral apposition and bone formation rates), and static resorption (osteoclast number and appearance and extent of eroded surfaces). Iliac trabecular thickness but not trabecular number increases substantially between 2 and 20 years of age, whereas remodeling activity peaks in young children, declines, and then increases again during puberty.[215]

Noninvasive methods of assessment of skeletal mineralization include bone x-rays (of limited value), radiographic absorptiometry or photodensitometry, single-photon or single–x-ray absorptiometry, dual-photon or dual-energy x-ray absorptiometry (DEXA), spinal and peripheral quantitative computed tomography (pQCT), quantitative ultrasonography (QUS), quantitative magnetic resonance, and magnetic resonance microscopy.[170] DEXA has become the most frequently employed method of quantifying axial and peripheral bone mass and bone area (as well as body composition) because of its relatively low radiation dosage (5–10 μSv), ease of use and applicability for infants, rapidity (4 minutes for total body scan), accuracy, precision, and reproducibility under controlled circumstances.[170,218]

The ratios of attenuation of x-rays of two energies (70 kV, 140 kV) traversing the same pathway through the patient reflect the "density" and mass of the tissue through which the x-rays have crossed. Computer analysis of these captured energies then reconstructs the boundaries, density, and mass of the tissue. Two methods of imaging geometry have been employed in DEXA instruments: the earlier pencil beam DEXA instruments utilized a pinhole collimator linked to a single detector, whereas the newer fan beam DEXA units apply a slit collimator coupled with a multidetector array.[219]

Fan beam DEXA has the advantages of more rapid scan acquisition and improved resolution, making it especially useful for small children and infants.[220] Because of variability between instruments and analytical software programs (infant, pediatric, adult) employed for DEXA, the report of the DEXA scan should include not only the recorded data but the type of DEXA instrument and the software version employed for analysis. Because relatively low BMDs in children make it more difficult to distinguish clearly bone edges, specific infant and pediatric software must be used to address this problem.[221]

DEXA is employed to quantify bone mass and bone area in the axial (head, spine) and appendicular (limbs) skeleton. DEXA assesses a two-dimensional image, and therefore does not measure "true" BMD (the mass within a volume of uniform composition). DEXA measures the area(l) or surface mass of mineral within a region of bone of nonuniform composition (cortex, trabeculae, osteoid, marrow). It is expressed as g/cm^2.[222] Because DEXA does not take into account the depth of a bone, it underestimates BMD in small children and overestimates it in large subjects.[223]

In children and adolescents, bone size/volume increases with growth and maturation—and the larger the

three-dimensional structure of bone the greater the recorded areal BMD [even though the actual or volumetric (v) BMD may not change substantially].[222] Therefore, calculated or "apparent" (v) BMDs (BMAD) (g/cm^3) data have been generated in an attempt to correct this problem. Volumetric BMD increases as the cortex thickens, the number and width of trabeculae per unit volume rises, and the amount of hydroxyapatite per unit of trabecular volume accrues. Although during childhood and adolescence areal BMD of the femoral shaft increases with age, its vBMD remains relatively constant.[224]

On the other hand, vBMD of the lumbar spine increases in late puberty and early adulthood because of increasing thickness of trabeculae that is not gender specific but is greater in blacks than in whites after puberty.[222,225] Cross-sectional areas of cortical and trabecular bone increase with age, with males achieving greater increase in periosteal apposition than females during puberty. Cortical cross-sectional area is similar in white and black subjects.[226] Included in measurement of whole-body areal BMD is the head. This structure characteristically has twice the areal BMD of that of the rest of the skeleton and may comprise as much as 20% to 50% of the total BMD in children. Whole-body areal BMD correlates better with body height when the head BMD is excluded.[227,228]

Whole- or total body BMC and BMD, lumbar spine BMC and BMD, and femoral BMD are the most commonly measured indices of bone mass in childhood by DEXA and are reported as gm/cm^2. Data are often reported as a Z score, the number of standard deviations about the mean of peers matched for chronologic age and gender. (In adults, the DEXA T score is commonly reported. The T score is the number of standard deviations about the mean of maximal or peak bone mass recorded in healthy young adults aged 20 to 29 years. The T score should not be utilized in children and adolescents.)

In neonates and infants, it is recommended that whole-body BMC be the primary measurement when assessing bone mineralization.[229] In neonates with appropriate weight for gestational age (AGA), whole-body BMC by pencil-beam DEXA doubles between 32 and 40 weeks and increases 3.5-fold between birth weights of 1,000 and 4,000 grams. Neonates small for gestational age (SGA) have lower whole-body BMC than do AGA neonates of comparable gestational age, but they are similar to those of AGA infants with the same birth weights (Table 3-8).[230,231] In young adults (16-19 years) born prematurely with birth weights <1.5 kg, total body BMC is less than that of subjects born at term with normal birth weights but appropriate for their smaller stature.[232]

Utilizing fan-beam DEXA (QDR 4500A, Hologic Inc, Bedford, MA), whole-body BMC of 73 full-term neonates (birth weights 2,720 to 3,982 g) of both genders and of multiple ethnicities has been reported as 89.3 ± 14.1 (SD) grams with BMD of 0.240 ± 0.022 g/cm^2.[220] Areal BMD of the lumbar spine (L2-L4) is low in prematurely born infants but "catches up" to that of full-term infants by

2 years of age.[233] Particular attention to detail must be exercised when assessing bone mineralization in very small subjects by DEXA because even apparently minor changes (position on the scanning table, prone or supine posture, number of blankets overlaid or wrapped around the subject, administration of a bolus of intravenous fluid prior to scanning, presence of a radiographic contrast agent) may affect measurement of BMC and BMD.[234,235] It is important to reemphasize that infant software be employed for data analysis of DEXA measurements in small subjects because adult and pediatric software underestimate bone area and BMC but overestimate BMD in this group.[234]

Whole-body (or total body) BMC is the more accurate and reliable of the measurements provided by DEXA compared to regional measurements, particularly in growing children and adolescents.[228] Whole-body BMC increases three- to fourfold between 6 and 17 years of age[177,236-238] (Tables 3-9A and B). Whole-body BMC is greater in adult males than in females because of the larger size of male bones. The gender difference in whole-body BMC appears after 15 years of age. Lumbar vertebral BMD approximately doubles between 3 and 15 years of age in boys (0.454 to 0.885 g/cm^2) and girls (0.444 to 0.960 g/cm^2); lumbar spine BMD increases rapidly between birth and 5 years in both sexes (between 13 and 15 years in boys, and between 12 and 14 years in girls)[236,238-240] (Table 3-9B and Table 3-10).

BMD of the femoral neck increases 1.5-fold during puberty. In females, the rate of maximal increase in whole-body BMC occurs in the year of menarche and follows the year of peak height velocity (Figure 3-15).[172,241] Peak BMC and BMD are reached at 18 to 20 years in both sexes, although there may be slight accrual of additional bone mass in the third decade of life. In girls with menarche

before 12 years, there is greater peak BMD (at age 18-19 years) than in females with menarche after 14 years.[242] Similarly, in adult males with a history of delayed puberty there is lower lumbar spine BMD than in those with pubertal onset at 11 to 12 years.[243] A major drawback to the use of DEXA for determination of bone mineralization in children is the reliance of reference data on chronologic age independent of body size. Thus, a short child may appear to have decreased bone mineralization relative to chronologic age but a satisfactory value relative to height age.

Accordingly, assessment of bone mass relative to height is essential (Figure 3-16). DEXA measurements of bone mineralization are also affected by the composition of soft tissues that surround the axial skeleton. Thus, variations in fat about the bone may significantly influence the recorded DEXA measurements—limiting the use of DEXA in extremely thin or obese children.[244] Generally, BMC, areal BMD, and/or BMAD below –2 SDs for age and gender are considered abnormally low. However, DEXA measurements must always be interpreted in relationship to the patient's clinical findings.[223]

QCT measures volumetric BMD of both trabecular and cortical bone at any site but has been commonly applied to the lumbar spine.[225] However, the radiation dose delivered to the spine by this method is high (~30 μSv). During childhood, lumbar spine vBMD measured by QCT is similar in black and white youth. During puberty, black males and females gain twice the vBMD recorded in whites (with no gender difference). In peripheral (p)QCT, bone mineralization is quantified in distal and/or proximal radial, femoral, or tibial sites (regions of cortical and trabecular bone). The delivered radiation dose (10 μSv) is low.

Peripheral QCT may be examined in the radius two-thirds of the distance between its proximal and distal ends and distally at a point that is 4% of forearm length, with a reference line being drawn through the most distal aspect of the cartilage growth plate when it is open or through the middle of the ulnar border of the articular cartilage when the growth plate is closed.[245-247] pQCT permits measurement of total and cortical bone area, cortical thickness, BMC (mg/mm), cortical and trabecular vBMD, periosteal and endosteal circumferences, and marrow area. Proximal and distal radial bone pQCT data between 6 and 40 years of age and pubertal stages I through V are recorded in Table 3-11.

Interestingly, at all ages total cross-sectional and cortical areas, cortical thickness, BMC, and BMD are greater in males than in females. As mirrored by the proximal radius, pQCT documents the prolonged period of periosteal expansion in males that ultimately accounts for their larger bone size. Widespread application of pQCT awaits standardization of protocols for data acquisition and

analysis and larger reference databases. By direct comparison of bone mass data gathered by DEXA and tibial metaphyseal pQCT examinations in the same subjects (6-21 years), it has been observed that DEXA whole-body bone area and BMC for height correlate well with pQCT-derived cross-sectional area for tibial length.[248]

Although BMD values of the lumbar spine acquired by DEXA and QCT are reasonably well related, osteopenia is "identified" in children far more often by DEXA than by QCT because DEXA measurements do not account for body height and bone size.[244] Clearly, pQCT would appear to be the preferred method for quantitation of bone mineralization in children at this time.

Quantitative ultrasonography (QUS) measures the speed of a longitudinal sound (SOS) wave as it is propagated along a bone.[170] The rate of movement of sound through bone is dependent on its microstructural and macrostructural characteristics, mineral density, and elasticity—and is thought to be a measure of bone strength. It is an attractive method for assessment of bone because it does not utilize radiation, is low in cost, and the equipment is portable. Transmitter and receiver ultrasound transducers placed on either side of the examination site (os calcis, patella, tibia, radius, phalange) quantitate transmission velocity or signal attenuation and convert these observations to SOS. In a study of 1,085 children and adolescents, SOS increased steeply at the tibia and radius during the first 5 years of life, more slowly between 6 and 11 years of age, and then again more rapidly during pubertal development.[249]

In 3,044 healthy subjects ages 2 to 21 years, phalangeal QUS SOS and bone transmission time (BTT) increased over time and with advancing adolescent development—and were related to gender, age, height, and weight.[250] However, the overlap of QUS data between various ages makes interpretation of a single SOS measurement problematic. Serial assessment may be useful. Thus, in a cohort of 29 preterm infants tibial SOS values declined over time in neonates whose gestational ages were less than 29 weeks—suggesting progressive loss of bone strength in this population

consistent with the development of osteopenia of prematurity.[251] Although there is marginal correlation between vBMD determined by pQCT and SOS measurements in children and adolescents, QUS may complement but is unlikely to replace assessment of mineralization by radiographic methods at this time.[252,253] Magnetic resonance imaging of the skeleton is being examined as a method of assessment of bone geometry and strength.[254]

Concluding Remarks

Calcium, phosphate, and magnesium are vital to normal moment-to-moment function of all cells, and calcium and phosphate compose the mineral phase of the skeleton. This structure is essential to protection of body organs and to movement, and as a warehouse for these minerals. To an extent, the complex genetic and physiologic mechanisms that require vitamin D, PTH, and PTHrP to regulate calcium, phosphate, magnesium, and skeletal homeostasis have been deciphered—thereby permitting application of this information to the management of patients with derangements in this system (as detailed in an accompanying chapter).

In regard to this chapter, two manuscripts of interest have been published. The physiology and genetic regulation of bone formation and resorption have been reviewed in detail.[258] The most current data on whole-body and regional bone mineral content and density in North American children and adolescents analyzed by age, gender, and race have been presented[259] (Figure 3-17).

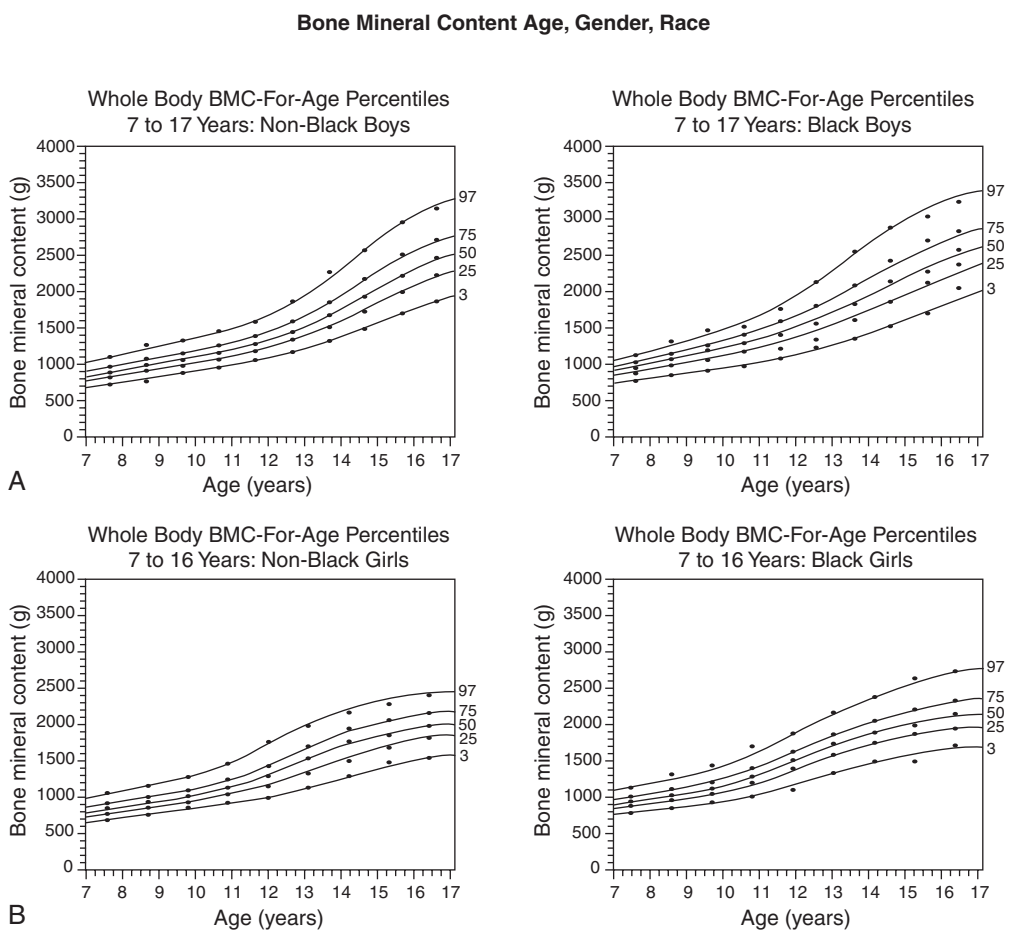

Figure 3-17. Whole-body bone mineral content for non-black and black boys (A) and girls (B) employing fan-beam dual-energy x-ray absorptiometry. Conclusions

Introduction

Under the auspices of the Lawson Wilkins Pediatric Endocrine Society (USA) and the European Society for Pediatric Endocrinology, an international consensus statement was formulated that recommended a revised classification of the medical terminology used for disorders of sex development to avoid confusing and derogatory terms.[1] This descriptive classification attempts to be sensitive to concerns of parents and flexible enough to incorporate novel molecular genetic information. The updated classification system integrates molecular genetic

considerations into the nomenclature for "disorders of sexual differentiation (DSD)."[1]

Terms such as *pseudohermaphrodite*, *intersex*, and *gender labeling* in the diagnosis should be avoided.[2] To accommodate all DSD, the classification system is broad and includes some conditions that do not present with obvious abnormalities of genital development (Table 4-1). The DSD categories are sex chromosome DSDs such as 45,X/46,XY (formerly mixed gonadal dysgenesis) and ovotesticular DSD (formerly true hermaphroditism); 46,XY DSDs such as disorders of testicular development, disorders of androgen synthesis and action (replacing and expanding the former category of male pseudohermaphroditism), and XY sex reversal; and 46,XX DSDs such as masculinization of the XX individual (replacing female pseudohermaphrodite) and XX sex reversal. Because of the complexities of chromosomal and gonadal development, some diagnoses can be included in more than one of the three major categories. Nevertheless, despite many recent advances the specific cause of genital ambiguity cannot always be identified—particularly among those with a 46,XY karyotype.

TABLE 4-1

Summary of Disorders Associated with Ambiguous Genitalia

Sex Chromosome DSD
- 45,X Turner syndrome
- 45,X/46,XY gonadal dysgenesis
- 46,XX/46,XY gonadal dysgenesis

46,XY DSD (Disorders of Testicular Differentiation)
- Denys-Drash syndrome (WT1 mutations)
- Frasier syndrome (WT1 mutations)
- XX gonadal dysgenesis
- XY gonadal dysgenesis
  - SRY positive
  - SRY negative
- Ovotesticular DSD
- Campomelic dwarfism (SOX9 mutations)
- Dosage sensitive sex reversal (duplications of DAX1)
- Desert hedgehog (DHH) mutations
- Monosomy distal chromosome 9p
- Xq28 deletion
- Vanishing testes
- ATR-X syndrome
- ARX
- Persistent Mullerian duct syndrome

46,XY (Disorders of Androgen Synthesis or Action)
- Steroidogenic factor-1 (SF-1 mutations)
- Leydig cell hypoplasia (LHR mutations)
- Smith-Lemli-Opitz syndrome (DHCR7)
- 3β-hydroxysteroid dehydrogenase deficiency (HSD3B2)
- 17α-hydroxylase/17,20-lyase deficiency (CYP17)
- Lipoid adrenal hyperplasia (StAR)
- 17β-hydroxysteroid dehydrogenase deficiency (HSD17B3)
- 5α-reductase deficiency (SRD5A2)
- Androgen insensitivity (AR)
- Hypogonadotropic hypogonadism
- P450 oxidoreductase deficiency (POR)

46XX, DSD
- 21-hydroxylase deficiency (CYP21)
- 11β-hydroxylase deficiency (CYP11B1)
- Placental aromatase deficiency (CYP19)
- Maternal hyperandrogenism
- XX males
- Ovotesticular DSD

Other
- IMAGe syndrome
- Environmental endocrine disrupters
- VACTERL syndrome
- MURCs syndrome
- Cloacal extrophy
- Aphallia

Ambiguous Genitalia: Talking with the Parents

For parents, the birth of a child is a long-anticipated, much desired, and exciting event. However, today the scenario has largely changed. In the past, the typical first question or statement after a child's birth related to the sex of the child: Is it a boy or a girl? Now, with the increased frequency of prenatal ultrasound examinations parents have usually been told the sex of their child and often have selected names for their son or daughter. Thus, when confronted with a newborn with genital ambiguity the issues occur in a different context. This immediately necessitates full disclosure, which allows parents to be actively involved in the medical decision-making process. The parents need to be quickly equipped to deal emotionally with these issues for themselves and to enable them to appropriately interact with their infant, family members, friends, and colleagues.

Initially, the parents need to hear that there has been a problem in the complex system that directs genital development—which makes it impossible to tell the sex of their child simply by examining the external genitalia. It is important to acknowledge that such development is not a consequence of anything that they, as parents, did or did not do. Despite openness and full disclosure, the parents may harbor guilt and negative feelings. Cultural attitudes, preexisting expectations, and family support systems influence the parents' responses to their child. The medical team needs to promote an open and caring network to provide support for the parents.

The initial treatment goal is to determine if there is an underlying or associated life-threatening condition that requires specific urgent treatment. If the child's gender remains unclear, information needs to be obtained to assist the parents in determining the most appropriate sex of rearing. Usually, this can be accomplished within a matter of hours or days. In more complex instances, the diagnostic process may take longer. In situations in which it is impossible to identify the specific etiology, the general DSD category provides a basis for decision making.

These considerations include the extent of external and internal reproductive system development, evidence of gonadal functionality (potential hormone secretion and fertility), and hormone responsiveness. In some instances, these factors are more relevant than the karyotype. When

consensus has been reached regarding a diagnostic category, available outcome information for that diagnosis should be reviewed. Knowledge of the specific etiology, including details of the diagnosis, enables planning therapeutic interventions and genetic counseling for future pregnancies.

The first interview with the parents should set a positive and optimistic tone to promote parental bonding with their infant. Indeed, the emotional tone of this initial interaction is usually more meaningful than the factual information provided and is recalled by parents for many years. Respect for the family and individual perspectives together with a willingness to repeat or defer detailed explanations are crucial. In the midst of the emotional distress associated with the uncertainty of their infant's gender, parents cannot be expected to assimilate the vast amount of information that eventually needs to be shared.

Factual explanations regarding the process of sexual differentiation with a focus on their infant's situation should be initially outlined. Detailed explanations and discussion can be repeated multiple times as the child ages. The use of simple sketches and provision of pictures and diagrams can be helpful to explain the embryology of genital development to the parents. The primary goal at this point is to provide the parents with a basic understanding that the internal and external genital structures for both boys and girls develop from the same primordial tissues. It may be helpful to explain that there are not exclusively male and female hormones, but rather the environments in which male and female fetuses develop are characterized by differing relative amounts of these hormones. Thus, incomplete male or female development represents the consequences of the prenatal hormonal environment. Too much or too little androgen effect is reflected in the degree of prenatal virilization.

During this initial dialogue, showing the parents the specific physical findings of their infant is often beneficial. This can alleviate apprehension, increase their comfort to look at their infant's genitalia, and promote the goal of fostering their perception of their child as a human having the needs of any other infant. This approach allows for information to be presented in a manner that will minimize anxiety and better equip parents to participate in the decision-making process. Before parents can provide the best support for their infant, they must each personally reach a resolution with a commitment to a positive perspective concerning this situation. Discussion of many concerns (particularly those related to gender identity, pubertal development, sexual orientation, sexual function, and fertility) may be helpful. The intent is that honest discussions will engender positive feelings that enhance positive interactions and enable the parents to promote their child's self-esteem.

Unless the gender assignment is clear at this point, delay in naming the infant, announcing the baby's birth, and registering the birth can be recommended until more information becomes available. The message should be clear that there will be an appropriate sex of rearing for their child and that it is the parents' privilege and responsibility to participate in the process leading to a gender assignment. Until sex of rearing is established, it is best to refer to the infant as "your baby" or "your child." Terms such as *he*, *she*, and *it* should be avoided.

Sex Determination

Sex determination is the binary switch that launches the developmental destiny of the embryonic gonads to become testes or ovaries. Sexual differentiation refers to the process through which male or female phenotype develops. The gonads, internal genital ducts, and external genital structures all develop from bipotential embryologic tissues. Each cell in the developing gonad has the potential to differentiate into either a testicular or ovarian cell. However, "the fate decisions in individual cells are highly coordinated such that cells of discordant fate are rarely seen."[3] Thus, differentiation as male or female depends on regulated orchestration of the expression and interaction of specific genes and gene products.

Through Alfred Jost's experiments with fetal rabbits in the 1940s and 1950s, the requirements for a testis and testosterone for male sexual differentiation were established.[4] Chromosomal composition of the embryo, XX or XY, determines gonadal sex. The genetic locus primarily responsible for this binary switch, the sex-determining region on the Y *(SRY)* gene on the Y chromosome, was identified through studies of patients with disorders of sexual differentiation. Analysis of transgenic mice confirmed the essential role of SRY and provided further molecular understanding of testicular differentiation.[5,6]

Whereas the karyotype (46,XY or 46,XX) of the primordial gonad determines whether it differentiates into a testis or ovary, respectively, local factors (such as hormones secreted by the developing gonads or tissue-specific transcription factors) influence the ensuing differentiation of the internal and external genital structures.[7] Divergence from the normal sequence of events leads to disorders of sexual differentiation that can manifest as abnormal gonadal differentiation, inconsistent internal genital differentiation, or ambiguity of the external genitalia. Although genital ambiguity is usually not considered to be a medical emergency, it is highly distressing to the parents and extended family. Hence, prompt referral and evaluation by a team with expertise in disorders of sexual differentiation is beneficial. Information regarding our current knowledge of sexual differentiation is presented, followed by a discussion of the various causes and treatment for ambiguous genital development.

Development of the Reproductive System

UROGENITAL DIFFERENTIATION

In humans, at 4 to 6 weeks of gestation the urogenital ridges develop as an outgrowth of coelomic epithelium (mesothelium).[8] The gonads, adrenal cortex, kidney, and reproductive tract derive from the urogenital ridge (Figure 4-1). Physical contact with the mesonephros appears to be important for

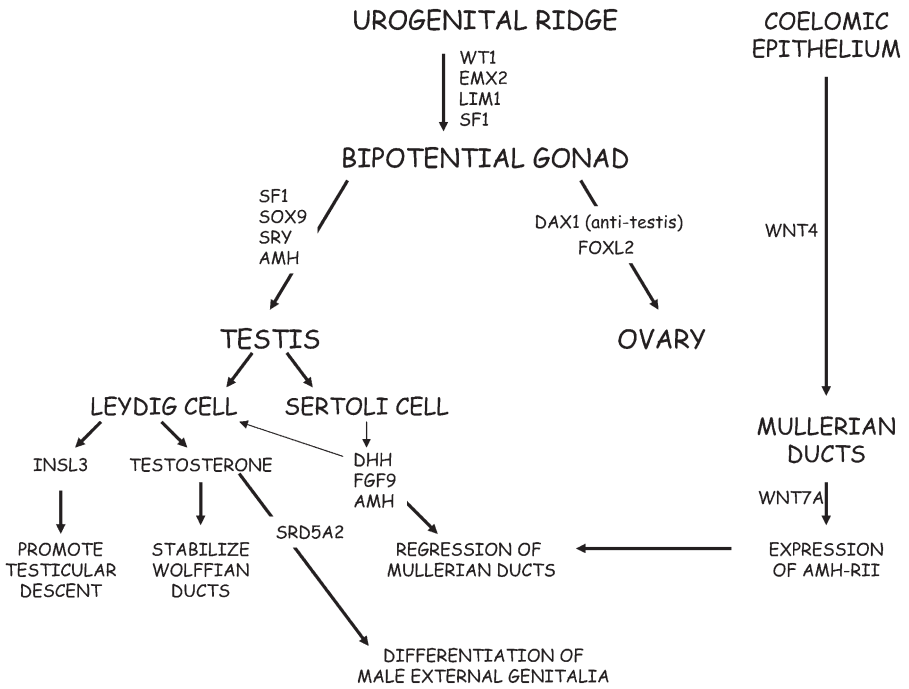

Figure 4-1. Cartoon of the genes involved in the process of sexual differentiation. Wilms' tumor (WT1), EMX2, LIM1, and steroidogenic factor-1 (SF1) play roles in differentiation of gonad from urogenital ridge. Genes involved in testicular differentiation include SF-1, SOX9, sex-determining region on Y (SRY), and anti-Mullerian hormone (AMH). The dosage-sensitive sex-adrenal hypoplasia congenital critical region on X (DAX1) appears to function as an anti-testis factor. Wnt4 promotes development of the Mullerian ducts, whereas Wnt7a promotes expression of the receptor for AMH (AMH-RII). Sertoli cells secrete AMH, which [acting through its cognate receptor (AMH-RII)] promotes regression of the Mullerian ducts. Leydig cells secrete testosterone and insulin-like hormone-3 (INSL3). Testosterone stabilizes the Wolffian ducts and is converted to DHT by 5α-reductase in target tissues to promote differentiation of the prostate and development of male external genitalia. INSL3 is involved in transabdominal testicular descent.

subsequent gonadal differentiation.[9] Due to their origin as part of the developing urogenital system, ovaries and testes are initially located high in the abdomen near the kidneys. One of the earliest morphologic changes is increased proliferation and size of developing 46,XY gonads.

TESTICULAR DIFFERENTIATION

The SRY protein is a nuclear high-mobility group (HMG) domain protein expressed in pre-Sertoli cells, where it triggers a molecular switch to induce Sertoli cell differentiation and initiate the process of male sexual differentiation. The HMG domain of the SRY protein binds to the minor DNA groove, where it functions as a transcription factor by bending DNA to presumably permit other proteins access to regulatory regions and to promote assembly of nucleoprotein transcription complexes.[10] A threshold SRY level must be achieved at a critical time to establish male sexual differentiation. Otherwise, the ovarian differentiation pathway is activated.[11] Yet, the factor(s) upregulating SRY expression remains elusive.

SRY expression is independent of the presence of germ cells. In addition to SRY, sequential expression of several other genes is required for normal male sexual differentiation. These genes include SRY-related HMG box-containing-9 (SOX9), anti-Mullerian hormone (AMH), dosage-sensitive sex reversal adrenal hypoplasia congenita critical region on X (DAX1), steroidogenic factor-1 (SF1), Wilms' tumor 1(WT1), GATA-binding-4 (GATA4), desert hedgehog (DHH), patched (PTC), wingless-related MMTV integration site 4 (WNT4), and WNT7a.

Using immunohistochemistry, SF1 and SOX9 proteins can be detected in human embryonic gonadal tissue at 6 to 7 weeks of gestation. At this time, SOX9 expression becomes limited to nuclei of Sertoli cells in a 46,XY fetus but remains cytosolic in a 46,XX fetus. SF1 and SOX9 protein expression precede that of AMH. Only after AMH protein expression and onset of overt testicular differentiation do Wilms' tumor (WT1) and GATA-4 protein expression increase in the fetal testis.[12] GATA4 belongs to a family of zinc finger transcription factors known as GATA-binding proteins because they bind to a consensus sequence in the promoter and enhancer regions of target genes.

Testicular differentiation occurs earlier than ovarian development. The testis consists of five cell types: supporting or Sertoli cells, endothelial cells, peritubular myoid cells, steroid-secreting Leydig cells, and germ cells. The first evidence of testicular differentiation is the appearance of primitive Sertoli cells at 6 to 7 weeks gestation in the human fetal testis. Cells, mostly endothelial cells, migrate from the mesonephros and interact with the pre-Sertoli cells to promote development of the testicular cords.[13] The testicular cords are precursors of the seminiferous tubules that will contain Sertoli and germ cells. In addition to the migration of mesonephric cells, testes show an increased rate of cell proliferation.[14]

SOX9 induces expression of prostaglandin D synthase (Pgds), an enzyme involved in prostaglandin synthesis.[15] In a positive feedback loop, developing Sertoli cells secrete prostaglandin D2—which binds to its cognate receptor to upregulate SOX9 expression and recruit additional Sertoli cells.[16,17] Phenotype-genotype studies of humans and mice demonstrate that SOX9 expression is a crucial step, downstream of SRY, in testis development. Fibroblast growth factor 9 (FGF9) is another signaling molecule important for testis development. In the mouse, the absence of FGF9 expression is associated with a premature decline in SOX9 expression—leading to arrested Sertoli cell differentiation, upregulation of Wnt4 expression, and male-to-female sex reversal of germ cells.[18]

Vascular development in the gonad is sexually dimorphic with the endothelial cells in the developing testis, forming a characteristic pattern consisting of a prominent coelomic vessel on the antimesonephric surface with branches between the testis cords.[19] This blood vessel is absent in the ovary. The signaling molecule, WNT4 suppresses formation of this coelomic vessel without affecting the development of its side branches.

Peritubular myoid cells are testis-specific smooth-muscle-like cells important to structural integrity and development of the testis cords. Factors relevant to peritubular myoid cell differentiation include desert hedgehog (DHH), which is secreted by Sertoli cells and its receptor Patched (Ptch1)—which is expressed on peritubular myoid cells.[20,21] The peritubular myoid cells surround the Sertoli cells, separating them from the Leydig cells—which are then sequestered in the interstitium.

Leydig cell differentiation depends on paracrine signals, including platelet-derived growth factor receptor-alpha [(PDGFR-α), DHH, PTCH1, and Aristaless-related homeobox (ARX)]. SF1 is expressed in Leydig cells to promote steroidogenic enzyme genes expression. The number of fetal Leydig cells reflects gonadotropin stimulation because the number is decreased in anencephalic male fetuses and increased in 46,XY fetuses, with elevated gonadotropin concentrations secondary to complete androgen insensitivity.[22] Differentiation of adult Leydig cells occurs postnatally.[23]

OVARIAN DIFFERENTIATION

Although ovarian differentiation has been considered the default pathway that occurs in the absence of SRY gene expression, accumulating evidence indicates that specific genes influence ovarian differentiation. Genes involved in cell cycle regulation were found to be overexpressed in developing XX gonads. Persistent DAX1 expression appears to play a role in ovarian differentiation. Other genes identified in developing ovaries include follistatin (Fst), Iroquois-3 (Irx3), Wnt4, and bone morphogenic protein-2 (Bmp2).[24]

The functions of Wnt4 include suppression of the androgen-secreting interstitial cells, inhibition of coelomic vascularization, and support of Mullerian derivatives—suggesting that it plays a major role in ovarian differentiation. Another gene postulated to influence ovarian differentiation is Forkhead L2 (FOXL2), a forkhead transcription factor.[23]

GERM CELL DIFFERENTIATION

Despite the requirement for germ cells in the postnatal ovary to maintain its structure, germ cells are not required for the initial development of ovaries or testes.[3] Primordial germ cells migrate from their origin in the hindgut to the developing gonadal ridges. Factors important for germ cell migration and colonization of the genital ridges include fragilis proteins 1 and 3 (IFITM1 and IFITM3) and stromal-cell–derived factor 1 (SDF1, also known as CXCL12) and its receptor CXCR4.[25,26]

The local environment directs the fate of the primordial germ cells.[3] Germ cell differentiation into a sperm or an egg is closely linked to the cell cycle decision between mitosis and meiosis.[27] In a human XX gonad, the germ cell meiosis begins at 10 to 11 weeks of gestation. This process appears to depend on retinoic acid, which is derived from mesonephric cells. Retinoic acid induces meiosis in an anterior-to-posterior wave and upregulates Stra8 (stimulated by retinoic acid gene 8) expression.[28]

In mice, Stra8 is necessary to premeiotic DNA replication. Thus, premeiotic DNA replication and the ensuing meiotic prophase are sexually dimorphic regulated steps of terminal differentiation characteristic of germ cells resident in the embryonic ovary.[29] After the first meiotic division, the primary oocyte becomes associated with granulosa cell precursors to constitute the primary follicle. In humans, primordial follicles are evident at 20 weeks of gestation. From a peak of 6.8 million oocytes at approximately 5 months of gestation, approximately 2 million are present at birth due to follicular atresia.[30] Accelerated follicular atresia contributes to the degeneration observed in streak gonads in X monosomy.

The developing somatic cells in the testis actively inhibit meiosis through expression of CYP26B1, a cytochrome P450 enzyme that degrades retinoic acid.[28,31] The germ cells in the testis enter a state of mitotic arrest. It has been suggested that fetal germ cells are programmed to enter meiosis and initiate oogenesis unless this process is inhibited.[32]

Maternal and paternal alleles are differentially imprinted such that monoallelic expression of specific genes occurs. During this process of imprinting, mature oocytes and sperm are differentially marked reflecting "parent-of-origin"–specific methylation patterns. In the primordial immature germ cells, inherited imprints are erased shortly after the germ cells enter the gonadal ridge. Sexually dimorphic methylation imprinting is subsequently reestablished in male and female gametes. This process occurs late in fetal development in the male and postnatally in female germ cells.[33,34] The importance of this imprinting process has been elucidated through study of parent-of-origin–dependent gene disorders such as Beckwith-Wiedemann, Prader-Willi, and Angelman syndromes and neonatal diabetes mellitus.

DIFFERENTIATION OF INTERNAL GENITAL STRUCTURES

The Wolffian duct originates as the excretory duct of the mesonephros and develops into the epididymis, vas deferens, ejaculatory duct, and seminal vesicle. The epididymis

consists of four functional portions: initial segment, caput, corpus, and cauda. Sperm mature in the caput and corpus, whereas the cauda is primarily for storage. The Mullerian or paramesonephric duct originates as an invagination of the coelomic epithelium and develops into the Fallopian tubes, uterus, and upper third of the vagina.

In the male fetus, the Sertoli cells secrete anti-Mullerian hormone (AMH), also known as Mullerian inhibitory hormone (MIH). In human 46,XY fetuses, AMH expression can be detected by 7 weeks of gestation, is not dependent on the presence of germ cells within the testis, and promotes regression of the Mullerian ducts.[35] AMH, a member of the transforming growth factor-β (TGF-β) family, undergoes proteolytic cleavage to become biologically active. AMH binds to its receptor, AMH-RII, on the surface of the Mullerian duct mesenchymal cells to induce increased matrix metalloproteinase 2 expression.[36,37] The net result is degeneration and loss of basement membrane integrity of the epithelial and mesenchymal Mullerian cells, leading to regression of the Mullerian ducts.[38]

AMH expression is highly regulated because inappropriate expression in a 46,XX fetus would lead to uterine agenesis. In the 46,XX fetus with absence of both AMH and testosterone, the Mullerian duct derivatives persist and the Wolffian ducts regress. When a female fetus is inappropriately exposed to AMH (as in freemartin cattle), Mullerian duct regression and ovarian masculinization occur.[39,40]

The fetal hypothalamic-pituitary-gonadal (HPG) axis is active by mid-gestation, with peak fetal testosterone concentrations occurring at approximately 15 to 16 weeks of gestation. Prior to this time, placental hCG stimulates testosterone production by the fetal Leydig cells. Secretion of testosterone by the fetal Leydig cells stabilizes the Wolffian ducts in 46,XY fetuses. Region-specific signaling molecules such as bone morphogenic proteins (BMPs), homeobox genes (HOXA10 and HOXA11), growth differentiation factor 7 (GDF7), relaxin, an orphan G-protein–coupled receptor (LGR4), platelet-derived growth factor A (PDGFA), and its cognate receptor (PDGFRA) influence the development of the epididymis and seminal vesicle.[19]

The prostate, a male accessory sex gland, contributes to seminal fluid plasma and develops from the urogenital sinus. After the initial testosterone-dependent induction of prostate differentiation, subsequent development involves epithelial-mesenchymal interactions that lead to cell differentiation and branching morphogenesis. The requisite signaling molecules FGFs, sonic hedgehog (SHH), BMPs, HOXA13, and HOXD13 are similar to those required for external genital differentiation.[41,42]

DIFFERENTIATION OF EXTERNAL GENITAL STRUCTURES

The genital tubercle, urethral folds, and labioscrotal swellings give rise to the external genitalia. Under the influence of circulating androgens that are converted to dihydrotestosterone in the target tissues, the urethral folds fuse to form the corpus spongiosum and penile urethra, the genital tubercle develops into the corpora cavernosa of the penis, and the labioscrotal folds fuse to form the scrotum.

In the normal 46,XY human fetus, a cylindrical 2-mm phallus with genital swellings has developed by 9 weeks of gestation. By 12 to 14 weeks of gestation, the urethral folds have fused to form the cavernous urethra and corpus spongiosum. By 14 weeks, the external genitalia are clearly masculine apart from testicular location. The high incidence of hypospadias in humans suggests that urethral fusion is a delicate and finely regulated process.

In the 46,XX fetus, in the absence of androgens the urethral folds and labioscrotal swellings do not fuse and develop into the labia minora and labia majora, respectively. The genital tubercle forms the clitoris, and canalization of the vaginal plate creates the lower portion of the vagina.[43] By 11 weeks of gestation, the clitoris is prominent and the lateral boundaries of the urogenital sulcus have separated. Minimal clitoral growth, well-defined labia majora, hypoplastic labia minora, and separate vaginal and urethral perineal openings are present by 20 weeks of gestation.

By 33 days postconception, the human fetal adrenal cortex is distinct from the developing gonad. Due to its role as the source of DHEAS for placental estrogen biosynthesis, the fetal adrenal cortex grows rapidly. By 50 to 52 days postconception, expression of several steroidogenic enzymes, steroidogenic acute regulatory protein (StAR), 11β-hydroxylase (CYP11B1), 17α-hydroxylase/17,20-lyase (CYP17), and 21-hydroxylase (CYP21) in the fetal adrenal cortex have been demonstrated immunohistochemically.[44] Recent data indicate that transitory cortisol biosynthesis peaks at 8 to 9 weeks gestation.[44] This early cortisol biosynthesis coincides with transient adrenal expression of both nerve growth factor IB-like (NGFI-B) and 3β-hydroxysteroid dehydrogenase-2 (HSD3B2).[44] Concommitantly, ACTH can be detected in the anterior pituitary—suggesting the presence of negative feedback inhibition during the first trimester.[44] During the time male sexual differentiation begins, this negative feedback inhibition may serve to prevent virilization of female fetuses to ensure normal female sexual differentiation.[44,45]

SEXUAL DIFFERENTIATION OF THE BRAIN

Clinical investigations suggest that the brain is sexually dimorphic and that testosterone is a masculinizing hormone in human. Males with aromatase deficiency manifest male psychosexual behavior and gender identity. Alternatively, 46,XY individuals with complete androgen insensitivity syndrome (CAIS) develop female gender identity.[46,47] Preliminary data implicate genetic differences, independent of sex steroid exposure, as the molecular basis for some aspects of sexual dimorphism of the brain.[48] Postmortem histologic examination demonstrated that women have more synapses in the neocortex, whereas men have more neurons in this region.[49,50]

Lessons Learned from Transgenic Models

Sexual differentiation is a complex process in which precise spatiotemporal coordination and regulation of gene expression are crucial to achieve full reproductive

capability.[51] Despite greater knowledge of the molecular details of sexual differentiation, the precise sequence of biologic events and all component factors remain to be elucidated. Investigation of normal and transgenic mice confirmed the crucial role of the sex-determining region on Y (SRY) gene in male differentiation when XX mice carrying only a 14-kb fragment of the Y chromosome showed a male phenotype.[52] In some instances, sex-reversal phenotypes have been fortuitous observations. Although investigation of transgenic mouse models has provided much information about sexual differentiation (Table 4-2), the mouse and human phenotypes may differ. For example, humans with a 45,X karyotype develop gonadal dysgenesis associated with infertility—whereas XO mice are fertile.

The following brief discussion of the spatiotemporal expression of specific genes and phenotypes of transgenic mice reviews the current understanding of sexual differentiation. Abnormal gonadal development has been described in mice homozygous for targeted deletions of genes involved in urogenital differentiation (such as Wt1, Sf1, Emx2, M33, and Lim1). In mice, these genes are expressed earlier in gestation than Sry, which is expressed transiently at 10.5 to 11 days postcoitum (d.p.c).[53] For example, Wt1 is expressed throughout the intermediate mesoderm at 9 d.p.c. Subsequently, Wt1 is expressed in the developing gonad. The phenotype of Wt1 knockout mice includes embryonic lethality, failure of gonadal and kidney development, and abnormal development of the mesothelium, heart ,and lungs.[54] Unlike humans, as discussed later, heterozygous Wt1 mutations in mice are not associated with kidney tumors or genito-urinary anomalies.

Steroidogenic factor 1 (Sf1), also known as NR5A1, is an orphan nuclear hormone receptor that functions as a transcription factor. In mice, Sf1 is expressed from the earliest stages of gonadogenesis at 9 d.p.c. and regulates expression of steroidogenic enzyme genes in gonads and adrenals. At the onset of testicular differentiation, Sf1 expression becomes sexually dimorphic with increased expression in fetal testis and decreased expression in fetal ovaries.[55] The pathologic findings in mice homozygous for targeted deletion of Sf1 include absence of gonads, adrenal glands, and ventromedial hypothalamus—with decreased number of gonadotropes in the anterior pituitary.[56] Sf1 knockout mice have female internal and external genitalia irrespective of genetic sex and die shortly after birth secondary to adrenal insufficiency.[57] Pituitary-specific Sf1 knockout mice manifest hypogonadotropic hypogonadism, confirming the essential role of Sf1 in pituitary function.[58]

The protein encoded by the Sox9 gene contains a DNA-binding HMG domain and plays a major role in testicular differentiation. Following the onset of testicular differentiation, Sox9 expression increases in the testis and decreases in the ovary by 11.5 d.p.c. Ectopic expression of Sox9 in XX mice leads to testicular differentiation.[59] Mice with homozygous targeted deletion of the Sox9 gene die during mid-gestation.[60] Sox9 also plays a major role in chondrocyte differentiation and cartilage formation.[61]

Homozygous deletion of Emx2, a homeodomain transcription factor, results in an embryonic lethal phenotype associated with absence of kidneys, ureters, gonads—and in Wolffian and Mullerian duct derivatives.[62,63] As Wt1 expression is initially normal in the metanephric blastema of Emx2 knockout mice, Emx2 is likely downstream of Wt1. Interestingly, adrenal gland development is normal in Emx2 knockout mice. Lim1, also known as Lhx1, encodes a homeobox protein—which is important in the differentiation of intermediate mesoderm and the urogenital system.[64] Homozygous deletion of Lim1 is associated with absence of kidneys and gonads and with anterior head structures.[65]

Dax1 is first expressed in the genital ridge at 10.5 to 11 d.p.c. With differentiation of the testicular cords, Dax1 expression becomes sexually dimorphic—with decreased expression in the fetal testis. It continues to be expressed in the fetal ovary, where it appears to inhibit gonadal steroidogenesis.[66] Dax1 may interfere with steroidogenesis by inhibiting StAR expression and/or Sf1-mediated transactivation.[67,68] Dax1 functions as an adaptor molecule to recruit the nuclear receptor corepressor N-CoR to the Sf1 promoter, thus interfering with transactivation.[69,70] Rather than functioning to promote ovarian differentiation, it appears that Dax1 acts as an anti-testis factor. In male mice with targeted disruptions of the Dax1 gene, abnormalities of testicular germinal epithelium and male infertility develop despite normal testicular appearance at birth.[71] Female mice homozygous for targeted Dax1 mutation showed normal adult reproductive function.[72] Testicular development is delayed in XY mice carrying extra copies of mouse Dax1, but sex reversal is not observed unless the mouse also carries weak alleles of the SRY gene.[72]

At 11.5 days, Fgf9 is expressed in gonads of both sexes. By day 12.5, Fgf9 is detected only in testes. Mice homozygous for Fgf9-targeted deletions show male-to-female sex reversal with disruption of testis differentiation.[73] Loss of Fgf9 does not interfere with Sry expression, but prevents persistence of Sox9 expression in the developing testis. As discussed previously, Fgf9 inhibits Wnt4 expression.[18]

At 11.5 to 12.5 d.p.c, in both sexes Mullerian ducts arise from coelomic epithelium in the mesonephric region under the influence of Wnt4.[74] Male mice with homozygous targeted deletions of Wnt4 show normal testicular and Wolffian duct development, but Mullerian ducts never develop. The phenotype of female mice with homozygous deletions of Wnt4 includes absence of Mullerian duct derivatives, retention of Wolffian duct derivatives, and decreased oocyte development. In addition, the large coelomic blood vessel (typical of testicular differentiation) develops in the ovaries of female mice homozygous for targeted deletion of Wnt4.[75] Wnt4 appears to be involved in differentiation of Mullerian ducts, repression of endothelial migration from the mesonephros into the gonad, impeding migration of adrenal cells into the developing gonad, and maintenance of oocyte development.

Persistence of Mullerian duct derivatives and infertility were noted in male mice homozygous for targeted deletion of Wnt7a. One consequence of Wnt7a deletions is absence of Mullerian hormone receptor (AMH-RII) expression by Mullerian ducts. In females, although Mullerian duct derivatives develop they are abnormal—with loss of uterine glands, reduction in uterine stroma, and deficient coiling and elongation of the Mullerian duct. Thus, Wnt7a appears

TABLE 4-2

Consequences of Loss-of-Function Mutations in Genes Associated with DSD

Gene	Human Locus	Human Phenotype	Mouse Phenotype
WT1	11p13	Denys-Drash and Frasier syndrome	Homozygous: embryonic lethal with absence of kidney and gonads.
SRY	Yp11.3	46,XY Gonadal dysgenesis	"Knock-in" female-to-male sex reversal.
SOX9	17q24-25	Campomelic dysplasia and gonadal dysgenesis	Overexpression in XX mice results in female-to-male sex reversal. Heterozygous null associated with perinatal death, cleft palate, and skeletal abnormalities.
DHH	12q13.1	Gonadal dysgenesis	Abnormal peripheral nerves, infertility due to impaired spermatogenesis in males.
ATRX/XH2	Xq13.3	α-thalassemia, mental retardation, genital abnormalities, short stature	Phenotype of null is embryonic lethal. Overexpression associated with growth retardation, neural tube defects, and embryonic death.
ARX	Xp22.13	Lissencephaly, absence of the corpus callosum, microcephaly	Males have abnormal CNS development and abnormal testicular differentiation.
SF1/NR5A1	9q33	46,XY sex reversal with or without adrenal insufficiency	Absent adrenal glands, absent gonads, abnormal pituitary differentiation.
EMX2	10q26.1	Schizencephaly	Absence of kidneys, ureters, gonads, and genital tracts.
FGF9	13q11-q12	??	Male-to-female sex reversal, lung hypoplasia.
WNT4	1p35	46,XX, Uterine agenesis 46,XY, Male-to-female sex reversal	Males are normal. Females manifest female-to-male sex reversal.
WNT7A	3p25	Limb malformation syndromes	Persistent Mullerian duct derivatives in males. Abnormal Mullerian duct differentiation in females.
DAX1/NROB1	Xp21.3	Adrenal hypoplasia congenita; duplication associated with male-to-female sex reversal	Male infertility.
GATA4	8p23.2-p22	Congenital heart disease	Embryonic lethal, heart defects.
FOXL2	3q23	Blepharophimosis/ptosis/epicanthus inversus syndrome	Small, absence of eyelids, craniofacial anomalies, female infertility.
LHGCR	2p21	Leydig cell hypoplasia	NA.
DHCR7	11q12-q13	Smith-Lemli-Opitz syndrome	IUGR, cleft palate, neurologic abnormalities.
StAR	8p11.2	Congenital lipoid adrenal hyperplasia	All with female external genitalia. Neonatal death due to adrenal insufficiency.
CYP11A1	15q23-q24	Male-to-female sex reversal, adrenal insufficiency	Male-to-female sex reversal. Neonatal death due to adrenal insufficiency.
CYP19A1	15q21.1	Aromatase deficiency	Immature infertile female. Males are initially fertile, but develop disrupted spermatogenesis.
POR	7q11.2	Antley-Bixler syndrome	Embryonic lethal.
AMH	19p13.3-p13.2	Persistent Mullerian duct syndrome	Male has persistent Mullerian duct derivatives and infertility.
AMH-RII	12q13	Persistent Mullerian duct syndrome	Male has persistent Mullerian duct derivatives and infertility.
INSL3	19p13.2	Associated with cryptorchidism	Cryptorchidism in males. Overexpression in females associated with development of gubernaculum and aberrant ovarian location.
LGR8	13q13.1	Associated with cryptorchidism	Cryptorchidism.

to function as an epithelial-to-mesenchymal signal important in the sexually dimorphic differentiation of Mullerian duct derivatives. [76]

The phenotype associated with targeted disruption of c-kit ligand, a receptor tyrosine kinase also known as Steel factor, is complete lack of germ cells in the gonads.[77] Affected animals are sterile, but show normal sexual differentiation.[78] Both male and female mice homozygous for targeted deletion of the Stra8 gene show no overt phenotype apart from infertility.[29]

Mullerian inhibitory hormone (Amh) is first expressed at 12 d.p.c. Although direct control of Amh expression by the Sry gene product originally appeared to be an attractive hypothesis,[79] subsequent investigations have refuted this theory.[80] Rather, transcriptional regulation of Amh appears to involve both protein-protein and protein-DNA interactions—with Sf1 and Sox9 being two of the proteins involved.[81-83] Amh action is mediated by a heteromeric-signaling complex consisting of type I and type II serine/threonine kinase receptors. The Amh type II receptor binds Amh and recruits a type I receptor. SF1 appears to regulate expression of the Amh type II receptor (Amh-rIII) gene.[84] The phenotypes of the Amh and Amh-rII knockout mice are identical. In XY mice, both male and female internal genital structures are found. Male mice are infertile because the retained uterus blocks passage of sperm through the vas deferens.

The phenotype of male mice with targeted deletion of desert hedgehog (Dhh) includes infertility and impaired spermatogenesis.[85] These mice also showed abnormal peripheral nerves with extensive minifascicles within the endoneurium.[86] During development, expression of Dhh is limited to Sertoli cells and Schwann cells in peripheral nerves.[87] In mice, other key molecules in the development of male external genital structures include sonic hedgehog (Shh), fibroblast growth factors, Wnts, Bmps, Hoxa13, and Hoxad13. Specifically, Shh increases expression of Bmp4, Hoxa13, Hoxd13, and Ptc expression.[19] Expression of 5α-reductase in the genital tubercle mesenchyme occurs. Male mice homozygous for targeted deletions of the insulin-like hormone-3 (Insl3), Hoxa10, or leucine-rich repeat-containing Lgr8 genes show bilateral cryptorchidism.[88-91]

Investigations involving normal and transgenic mice have provided much information about the genes and gene products involved in sexual differentiation. Nevertheless, differences do exist between rodents and humans. Thoughtful examination of patients with disorders affecting sexual differentiation has elucidated many of the factors involved in human sexual differentiation.

Disorders of Gonadal Differentiation

WILMS' TUMOR GENE

The Wilms' tumor suppressor (WT1) gene, located at chromosome 11p13, plays an important role in both kidney and gonadal differentiation.[92] Although Wilms' tumor and genitourinary abnormalities can be associated with heterozygous WT1 deletions, only 6% to 15% of sporadic Wilms' tumors are associated with WT1 mutations.[93] Heterozygous deletions at chromosome 11p13 can be part of a contiguous gene deletion syndrome known as WAGR syndrome (Wilms' tumor, aniridia, genito-urinary anomalies, gonadoblastoma, and mental retardation).

Denys-Drash syndrome (characterized by genito-urinary anomalies, Wilms' tumor, and nephropathy) is due to mutations in the WT1 gene. Typically, the nephropathy begins during the first few years of life, manifests with proteinuria, and results in end-stage renal failure due to focal or diffuse mesangial sclerosis.[94-97] Among affected 46,XY individuals, the external genitalia can range from ambiguous to normal female. Affected 46,XX individuals show normal female external genital development. Internal genital differentiation varies because persistence of Wolffian and/or Mullerian structures is inconsistent. Typically, the gonads are dysgenetic in 46,XY individuals. The heterozygous missense mutations associated with Denys-Drash syndrome are believed to act in a dominant negative fashion.[98]

The features of Frasier syndrome include gonadal dysgenesis, progressive glomerulopathy, and an increased risk for gonadoblastoma. Wilms' tumor is extremely rare in Frasier syndrome.[99] The typical renal lesion is focal glomerular sclerosis. The majority of cases are associated with a specific point mutation in intron 9 of WT1.

In the fetal kidney, WT1 induces the mesenchymal-epithelial transition—leading to nephron formation.[100] Depending on cellular context, WT1 can function as a transcriptional activator, a transcriptional repressor, or tumor suppressor. The carboxyl terminal domain of the WT1 protein contains four zinc fingers that serve as the nucleic acid binding domain. Downstream target genes include WNT4 and AMHRII.[101] Through alternative splicing, multiple translation start sites, and post-translational RNA editing, multiple isoforms can be derived from this one gene. Distinct isoforms may have unique functions.

Alternative splicing between the third and fourth zinc fingers generates two isoforms differing by the presence or absence of three amino acids [lysine, threonine, and serine (KTS)]. Subnuclear localization studies have shown that the –KTS form colocalizes predominantly with transcription factors, whereas the +KTS form colocalizes mainly with splicing factors.[102] The ratio of the +KTS/–KTS isoforms appears to be tightly regulated. The mutation associated with Frasier syndrome alters splicing patterns, leading to decreased amounts of the +KTS isoform.

WNT4 GENE

WNT4 is a secreted molecule that binds to members of the frizzled family of receptors, resulting in transcriptional regulation of target genes. WNT4 increases follistatin expression, which inhibits formation of the coelomic vessel (anti-testis action) and supports ovarian germ cell survival (pro-ovarian action).[103] Duplication of the WNT4 gene, located at chromosome 1p31-1p35, has been associated with 46,XY male-to-female sex reversal. One such patient presented with ambiguous external genitalia accompanied by severe hypospadias, fibrous gonads, remnants of both Mullerian and Wolffian structures, cleft lip, microcephaly, and intrauterine growth retardation.[104] Loss of function WNT 4 mutations have been detected in two women with primary amenorrhea secondary to Mullerian duct abnormalities and androgen excess.[105,106] The phenotypes of these patients support the hypothesis that WNT4 plays a role in ovarian differentiation.

46,XY DISORDERS OF SEXUAL DIFFERENTIATION (GONADAL DYSGENESIS)

Phenotype/genotype studies of 46,XY sex-reversed patients played a major role in the localization of the Y chromosome gene responsible for the initial signal-promoting

testicular differentiation. Subsequently, this gene was identified to be the sex-determining region on Y (SRY) gene located at Yp11.3 near the pseudoautosomal region on Yp. Identification of mutations in SRY in 46,XY females confirmed the vital role of SRY in testicular differentiation.

SRY is a gene with a single exon that codes for a 204-amino-acid protein and that contains an HMG DNA-binding domain flanked by nuclear localization signals (NLS). The majority of sex-reversing SRY mutations are located in the HMG/NLS domain and affect DNA-binding affinity, DNA bending ability, or nuclear localization.[107] Yet, only 15% to 20% of cases of 46,XY DSD due to gonadal dysgenesis can be attributed to SRY mutations.[108] Paternal mosaicism for SRY mutations in which different cells carry different SRY genes has been described.[109,110] More puzzling are the pedigrees in which fathers and unaffected brothers carry the identical mutant SRY allele as the propositus.[111,112] These paradoxical findings implicate involvement of other genes, gene-gene interactions, and gene-environment interactions in the process of sexual differentiation.

Individuals with sex chromosome DSDs due to partial or mixed gonadal dysgenesis usually present with asymmetric genital ambiguity (Figure 4-2). Somatic features of Turner syndrome such as short stature, webbed neck, cubitus valgus, and gonadal failure may be present. Multiple cell lines, including a monosomic X cell line, may be detected. The most common karyotype is 45,X/46,XY. However, there is much phenotypic heterogeneity associated with 45,X/46,XY karyotype in that internal and external genital differentiation ranges from normal male to ambiguous to female.[113,114] Whereas the typical histologic features consist of poorly developed seminiferous tubules surrounded by wavy ovarian stroma, gonadal differentiation can range from normal testis to streak gonads. At the time of puberty, virilization can occur.

Individuals with sex chromosome DSDs due to gonadal dysgenesis have an increased risk of developing gonadal tumors such as gonadoblastoma or dysgerminoma because a dysgenetic gonad carrying a Y chromosome has an increased risk for neoplastic changes.[115,116] Although gonadal tumors typically do not develop until the second decade of life, they can occur earlier.[117]

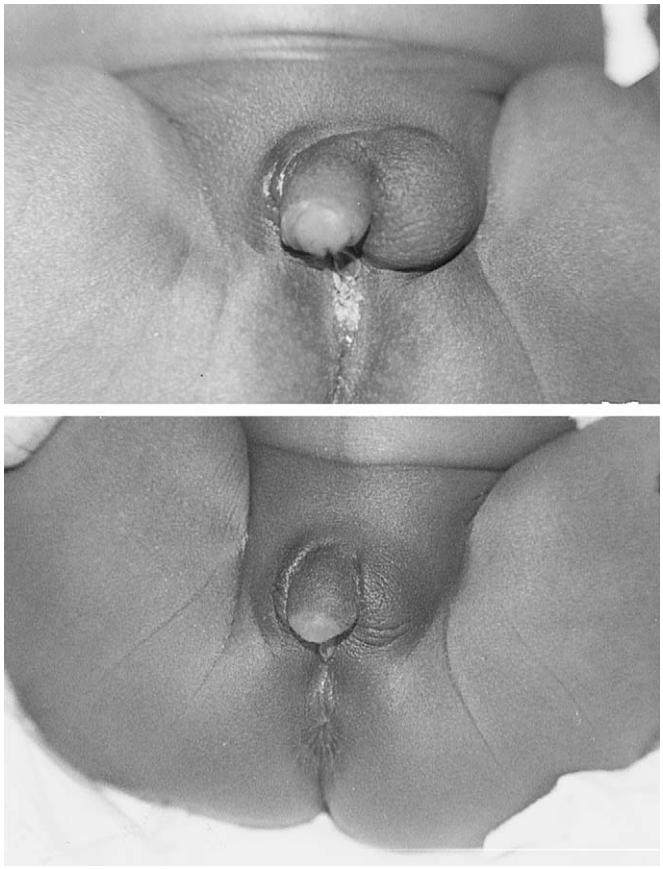

Figure 4-2. Genital ambiguity with asymmetry in patient with 46, XY disorder of sexual differentiation (mixed gonadal dysgenesis).

SOX9

Heterozygous loss of function mutations in the SOX9 gene are associated with autosomal-dominant campomelic dwarfism and male-to-female sex reversal.[118,119] Features of campomelic dwarfism include congenital bowing of long bones, hypoplastic scapulae, 11 pairs of ribs, clubfeet, micrognathia, and cleft palate. SOX9 mutations do not cause sex reversal in the absence of skeletal malformations.[120] Although the severity of the bone malformations varies, most affected individuals die shortly after birth due to respiratory failure. Approximately 75% of affected 46,XY fetuses show sex reversal, with external genital differentiation ranging from ambiguous to female. Gonadal dysgenesis and persistence of Mullerian duct derivatives are typical. Phenotypic heterogeneity with differing phenotypes (ovotesticular DSD or true hermaphroditism and complete sex reversal) in affected siblings has been described.[121]

SOX9 is a member of the SRY-related HMG domain gene family located at chromosome 17q24.3-17q25.1.[122] It is a 508-amino-acid protein containing an 80-amino-acid HMG domain involved in DNA binding and bending; a 41-amino-acid proline, glutamine, and alanine motif; and a C-terminal transactivation domain. Mutations in SOX9 can affect DNA-binding affinity, DNA bending ability, nuclear import, transactivation, and nuclear export.[123] An interstitial deletion of SOX9 in an affected patient provides the strongest evidence to date that haploinsufficiency is the mechanism responsible for the effects of SOX9.[124] Somatic cell mosaicism, de novo germ-line mutations, and mitotic gene conversion events have been described.[125]

DAX1

DAX1 is an orphan nuclear receptor that lacks a typical zinc finger DNA-binding domain. The gene (NROB1) coding for DAX1 is located on the short arm of the X chromosome and consists of two exons. Duplication of the DAX1 locus is associated with male-to-female sex reversal.[126] External genital differentiation ranges from female to ambiguous. Descriptions of internal genitalia

include presence of Mullerian and Wolffian structures. Gonads are typically described as streaks. A submicroscopic interstitial duplication of the DAX1 gene was discovered during thorough evaluation of two sisters. The older sister had presented with primary amenorrhea, female external genitalia, 46,XY karyotype, and gonadal dysgenesis.[127]

Loss-of-function mutations are associated with X-linked adrenal hypoplasia congenita (AHC). In this disorder, development of the fetal adrenal cortex is normal. However, the adult or definitive adrenal cortex fails to develop—leading to postnatal adrenal insufficiency. Although the symptoms of adrenal insufficiency generally manifest in infancy or early childhood, phenotypic heterogeneity in severity and age at presentation occurs.[128] Unilateral or bilateral cryptorchidism can also occur.[129] At the age of expected puberty, hypogonadotropic hypogonadism due to hypothalamic and pituitary dysfunction may occur among affected males.[130] Delayed puberty has been recognized in heterozygous females.[131] One female homozygous for DAX1 mutations has been reported. Her phenotype was hypogonadotropic hypogonadism.[132] As part of a contiguous gene deletion syndrome, X-linked AHC can be associated with glycerol kinase deficiency, Duchenne muscular dystrophy, ornithine transcarbamylase deficiency, and mental retardation.[133]

DAX1/NROB1 is expressed throughout the HPG axis. The DAX1 protein functions as a transcriptional repressor of many genes, including SF1 and some steroidogenic enzyme genes. Nonsense mutations have been identified throughout the gene. Missense mutations account for 20% of mutations associated with AHC. These mutations tend to cluster in the carboxyl terminal of the protein corresponding to the putative ligand-binding domain and impair the transcriptional repression activity of the protein.[134,135] One missense point mutation, located in the hinge region of the protein, was identified in an 8-year-old girl with clinical and laboratory features indicative of adrenal insufficiency. Additional studies showed that this mutation hindered nuclear localization of the protein. Curiously, the hemizygous father and heterozygous younger sister of the proband did not manifest the AHC phenotype.[136]

Recently, an alternatively spliced form of DAX1 (DAX1A) has been identified and found to have a more ubiquitous expression pattern than DAX1. DAX1A is expressed in adrenals, gonads, and pancreas.[137,138] The deduced protein sequence of DAX1A contains 400 amino acids, compared with 470 amino acids for DAX1. Another member of the NROB family is small heterodimer partner (SHP). Among its actions, SHP influences expression of cholesterol, bile acid, and glucose homeostasis.[139] The protein domain structures of DAX1, DAX1A, and SHP lack the canonical DNA-binding domain, AF-1 modulator domain, and the hinge region—which are characteristics of nuclear hormone receptors. All three proteins can form homodimers or heterodimers with one other, as well as with other nuclear receptors. As transcriptional repressors, DAX1 and SHP repress gene transcription by direct protein-protein interactions with target genes and recruit additional corepressor proteins such as nuclear receptor corepressor Alien.[140] DAX1, DAX1A, and SHP may have novel and complex interactions.[141]

DESERT HEDGEHOG

One patient with 46,XY DSD associated with a dysgenetic gonad was found to be homozygous for a single nucleotide substitution at the initiation codon, ATG→ACG, of the DHH gene. This variation was predicted to abolish initiation of translation at the normal start site. This patient's phenotype consisted of female external genitalia, polyneuropathy, a testis on one side, and a streak gonad on the other side. Histologic analysis of the sural nerve revealed extensive formation of minifascicles within the endoneurium.[142] Mutations in the DHH gene have been reported in several additional 46,XY patients with either complete or mixed gonadal dysgenesis.[143,144] The DHH gene is located on chromosome 12q12→q13.1 and encodes a protein consisting of 396 amino acids.[145]

CHROMOSOME 9p MONOSOMY

Monosomy for distal chromosome 9p has been reported in male-to-female sex reversal. External genitalia have been described as ambiguous or female. Differentiation of internal genitalia is highly variable, with the presence of Mullerian and Wolffian remnants being reported.[146] Description of the gonads has ranged from streak gonads to hypoplastic testes. In addition to sex reversal, clinical features include mental retardation, low-set ears, trigonocephaly, wide nasal bridge, and single palmar creases.[147,148] Neither the size of the deletion nor parental origin influences the degree of sex reversal.[149-151] Two genes related to double-sex (dsx) and mab-3 regulators of sexual differentiation in *Drosophila melanogaster* (DMRT1 and DMRT2)[152] have been mapped to 9p24. It has been suggested that these human genes, DMRT1 and DMRT2, play roles in testis differentiation.[153]

Although, to date no, mutations have been detected in either gene,[154] a submicroscopic deletion at 9p24.3 was identified in two 46,XY sex-reversed sisters. This deletion was also present in their fertile mother.[155] This small deletion (less than 700 kilobases) mapped 5' of both DMRT1 and DMRT2, but within 30 kilobases of DMRT1. Thus, the deletion could include a previously unidentified upstream exon or regulatory sequence(s) of DMRT1. Because karyotypes for most 9p deletion patients with sex reversal have been 46,XY, DMRT1 may be involved in testicular differentiation. Investigation of sexual differentiation in other species shows higher DMRT1 expression in testis compared to ovaries, whereas DMRT2 is not expressed in adult testis or in developing gonadal ridges.[156,157] Sexually dimorphic expression of DMRT1 was found in 6- and 7-week-old human fetuses, with expression limited to male fetuses.[158]

Xq28 DELETION

Sex reversal and myotubular myopathy are associated with interstitial deletions at Xq28. One family has been described in which there were two affected 46,XY infants in

whom MTM1 and F18 (now known as CXorf6) genes were deleted.[159,160] Three nonsense mutations in CXorf6 were identified in three Japanese males with hypospadias.[161]

ATR-X SYNDROME

ATR-X (α-thalassemia, mental retardation, X-linked protein) syndrome is an X-linked disorder characterized by mild alpha-thalassemia, severe mental retardation, and genital abnormalities. The urogenital anomalies consist of ambiguous genitalia, cryptorchidism, hypoplastic scrotum, hypospadias, shawl scrotum, and small penis.[162,163] Other typical features include short stature, microcephaly, seizures, talipes equinovarus, and gastrointestinal problems. Facies are described as coarse, with midface hypoplasia, short nose, and widely spaced incisors.

The hemoglobin H inclusions can be demonstrated on brilliant cresyl blue stained peripheral blood smears.[164] The typical presence of Wolffian duct and absence of Mullerian duct structures indicates at least partial Sertoli and Leydig cell function. Histologic studies of testes suggest aberrant Leydig cell development.[165]

The molecular basis of this entity is mutations in the ATRX (also known as XH2 or XHP) gene located at Xq13.3.[166,167] The ATRX gene product is a member of the SWI/SNF DNA helicase family and contains functional domains involved in protein-protein and protein-DNA interactions. Based on in vitro evidence and its functional domains, the protein appears to play a role in chromatin remodeling.[168,169] Phenotype-genotype correlations are inconsistent. Urogenital anomalies are associated with mutations that truncate the protein and with mutations located in the plant homeodomain-like domain.[170] Skewed X-inactivation is typical of carrier females. Greater than 75% of cases are inherited from carrier mothers.[171] Carpenter-Waziri, Juber-Marsidi, and Smith-Fineman-Myers syndromes and X-linked mental retardation with spastic paraplegia are also associated with mutations in the ATRX gene.[172]

VANISHING TESTES

The terms *testicular regression syndrome* and *vanishing testes* are used to describe testicular absence in boys with undescended testes. In some instances, this situation is associated with ambiguous genitalia and under-virilization—which presumably represents regression of testicular tissue occurring between 8 and 14 weeks of gestation. Physical findings reflect duration of testicular function. At operation, a rudimentary spermatic cord and nubbin of testicular tissue may be identified. Histologic examination of the testicular nubbins often reveals hemosiderin-laden macrophages and dystrophic calcification. It has been suggested that an antenatal vascular accident associated with antenatal testicular torsion is a cause of testicular regression.[173] Although usually sporadic, familial testicular regression has been described.[174]

MULTIPLE CONGENITAL ANOMALIES

In affected 46,XY infants, the IMAGe syndrome is characterized by intrauterine growth retardation, metaphyseal dysplasia, adrenal hypoplasia, cryptorchidism, and micropenis in the absence of DAX1 or NR5A1/SF1 mutations.[175] The Pallister-Hall syndrome is associated with micropenis, hypospadias, hypothalamic hamartoma, postaxial polydactyly, and imperforate anus.[176] Features of the autosomal dominant Robinow syndrome include small penis, cryptorchidism, bulging forehead, hypertelorism, depressed nasal bridge, short stature, short limbs, and hemivertebrae.[177] Genital ambiguity in affected 46,XY individuals in association with X-linked lissencephaly, absence of the corpus callosum, and hypothalamic dysfunction (including temperature instability) has been described. This constellation of features has been associated with mutations in the ARX gene.[178-180]

OVOTESTICULAR DISORDER OF SEXUAL DIFFERENTIATION (TRUE HERMAPHRODITISM)

Ovotesticular DSD is defined as presence of ovarian tissue with follicles and testicular tissue with seminiferous tubules in the same individual. Although an ovotestis is the most commonly identified gonad, there can be an ovary on one side and a testis on the other. In most ovotestes, ovarian and testicular tissue show distinct separation in an end-to-end arrangement. Karyotypes are usually 46,XX. Mosaic karyotypes (46,XX/46,XY and 46,XX/47,XXY) have been described.[181] In some instances, Y chromosomal material such as the SRY gene can be detected by PCR amplification. However, ovotesticular DSD in the absence of Y chromosomal material has been reported.[182] In one patient in whom the peripheral blood karyotype was 46,XX, molecular genetic analysis showed a deletion of the promoter region of the SRY gene in the testicular tissue of an ovotestis.[183]

Several pedigrees in which both XX males and XX true hermaphrodites coexist have been described.[184,185] These families likely represent incomplete penetrance of mutations of genes involved in sexual differentiation.[186] Although most patients present in infancy or childhood, two phenotypic males who presented with bilateral gynecomastia have been reported.[187,188] Outcome regarding fertility has been disappointing. In a series of 33 patients followed longitudinally, germ cells identified in the testicular tissue during infancy degenerated—resulting in azoospermia. Although normal menstrual cycles have been reported in a few females, no pregnancies were documented in one series.[182] However, pregnancies have been reported in some females with ovotesticular DSD.[189-191]

46,XX TESTICULAR DISORDER OF SEXUAL DIFFERENTIATION

The frequency of the XX male syndrome is approximately 1 in 25,000 males.[192] The majority of 46,XX males are found to carry the SRY gene, have normal male genitalia, and often present with infertility.[193] In most instances, the SRY gene is located on an X chromosome due to illegitimate recombination between the X and Y chromosomes. An incidental finding was reported for a 61-year-old man with a history of small testes and azoospermia. His karyotype showed 46,XX, with the

insertion of the SRY gene on the terminal end of chromosome 16q.[194] Rare instances of 46,XX males with absence of the SRY gene have been described.[195]

FOXL2

Mutations in the FOXL2 gene have been associated with the autosomal dominant blepharophimosis ptosis epicanthus inversus syndrome (BPES). The phenotype of BPES type 1 involves premature ovarian failure and malformations of the eyelid [which consist of small palpebral fissures (blepharophimosis)], ptosis, epicanthus inversus, and a broad nasal bridge.[196] FOXL2 is a forkhead transcription factor. Curiously, in goats mutations in this locus are responsible for the autosomal dominant phenotype characterized by the absence of horns in male and female goats (polledness). It is also associated with XX female-to-male sex reversal in a recessive manner.[197]

Disorders of Androgen Synthesis

Genital ambiguity can be a manifestation of alterations in sex steroid biosynthesis, which most commonly are secondary to mutations in a steroidogenic enzyme gene. During fetal life, steroidogenic enzymes are expressed in placenta, testis, and adrenal (Figure 4-2). The fetal testis secretes testosterone that is converted to dihydrotestosterone in target tissues such as the prostate and external genitalia. Inborn errors of testosterone biosynthesis can lead to ambiguous genitalia in 46,XY fetuses. Specific proteins necessary to testosterone biosynthesis include SF1, LH receptor, steroidogenic acute regulatory peptide (StAR), 17α-hydroxylase/17,20-lyase, 3β-hydroxysteroid dehydrogenase type 2, 17β-hydroxysteroid dehydrogenase type 3, P450-oxidoreductase, and 5α-reductase type 2 (Figure 4-3). Inborn errors of glucocorticoid biosynthesis are often associated with the virilizing congenital adrenal hyperplasias.

The fetal adrenal cortex is derived from coelomic epithelium and consists of two major zones: the fetal zone and the adult zone. Because the human placenta does not express 17α-hydroxylase/17,20-lyase, it cannot directly convert progesterone to estrogens. The fetal zone is primarily responsible for DHEA synthesis, which is then sulfated to provide substrate for placental estrogen biosynthesis (Figure 4-3). The adult zone, which after birth differentiates into the three zones of the adult adrenal cortex, is primarily responsible for cortisol biosynthesis. By 10 weeks of gestation, the adrenal is secreting DHEAS and the hypothalamic-pituitary-adrenal axis is functional.

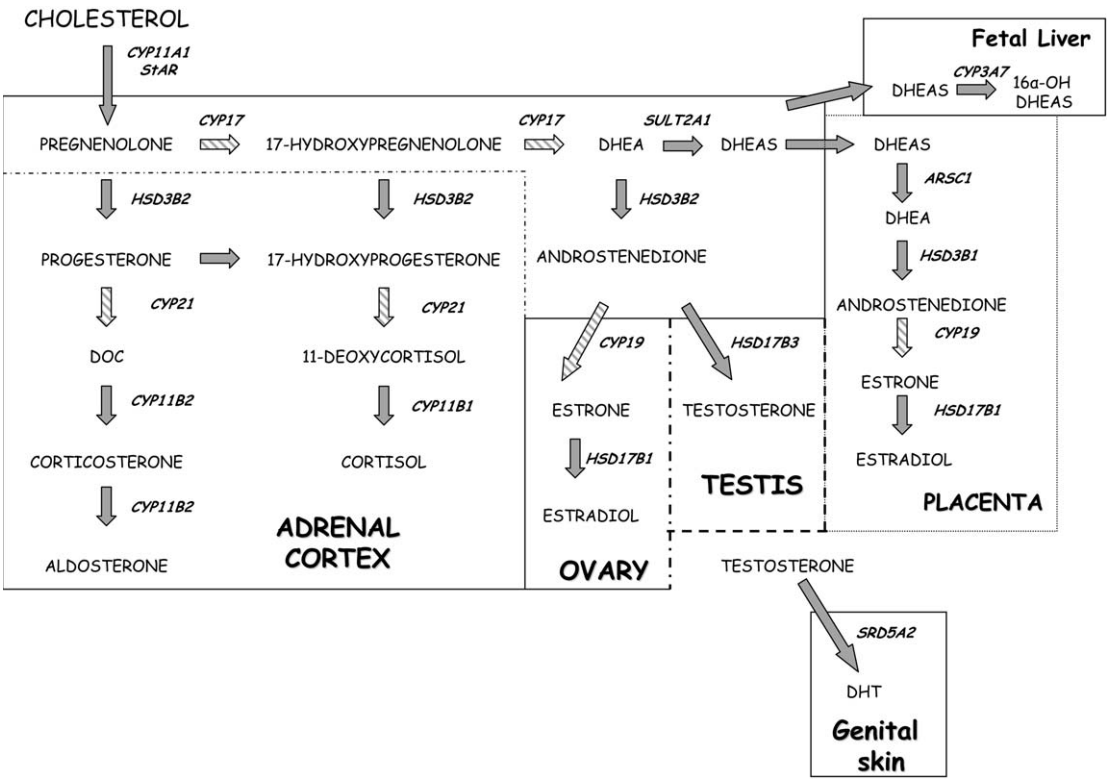

Figure 4-3. Diagram of classical steroidogenic pathways. Substrates, products, and genes involved in adrenal, ovarian, testicular, and placental steroidogenesis are indicated. Genes are 17α-hydroxylase/17,20-lyase (CYP17), 3β-hydroxysteroid dehydrogenase (HSD3B2), 21-hydroxylase (CYP21), 11β-hydroxylase (CYP11B1), aldosterone synthase (CYP11B2), aromatase (CYP19), 17β-hydroxysteroid dehydrogenase type 1 (HSD17B1), 17β-hydroxysteroid dehydrogenase type 3 (HSD17B3), 5α-reductase type 2 (SRD5A2), sulfotransferase (SULT2A1), and steroid sulftase/arylsulfatase C (ARSC1). CYP3A7 is a cytochrome P450 enzyme expressed in fetal liver, where it catalyzes the 16α-hydroxylation of estrone (E1) and DHEA. Its expression decreases postnatally. Steroidogenic enzymes that utilize P450 oxidoreductase, a flavoprotein encoded by POR, to transfer electrons are indicated by hatched arrows.

SF1/NR5A1 GENE

The SF1/NR5A1 gene, located at chromosome 9q33, codes for a 461-amino-acid protein. One 46,XY patient heterozygous for an NR5A1/SF-1 mutation presented in the newborn period with adrenal insufficiency and was initially considered to have lipoid adrenal hyperplasia. The patient had female external genitalia, normal Mullerian structures, and streak gonads. Reevaluation prior to induction of puberty revealed normal gonadotropin response to GnRH stimulation. Functional studies showed that this mutation, G35E, fails to transactivate a known SF1 responsive reporter gene.[198]

A 46,XX female with adrenal insufficiency, adrenal hypoplasia, and an SF1/NR5A1 mutation showed normal ovarian morphology.[199] With identification of more patients heterozygous for missense mutations in the SF1/NR5A1 gene, it has become apparent that haploinsufficiency of SF1 can manifest a predominantly gonadal phenotype characterized by undervirilization of affected 46,XY fetuses without overt adrenal insufficiency.[200] Females heterozygous for missense mutations appear to lack an obvious phenotype.

LUTEINIZING HORMONE CHORIOGONADOTROPIN RECEPTOR GENE

Leydig cell hypoplasia is an autosomal recessive disorder characterized by failure of testicular Leydig cell differentiation secondary to inactivating LHCGR mutations and target cell resistance to LH.[201-203] The inability to respond to hCG or LH results in decreased Leydig cell testosterone biosynthesis. The phenotype of affected 46,XY infants ranges from undervirilization to female external genitalia. Affected individuals raised as females often seek medical attention for delayed breast development. Mullerian duct derivatives are absent because AMH is secreted by the unaffected Sertoli cells. Laboratory studies show elevated LH, low testosterone, and normal FSH concentrations. There is no significant testosterone response to hCG stimulation.

The LHCGR gene is mapped to chromosome 2p21.[204] The 674-amino-acid protein is a seven-transmembrane domain G-protein–coupled receptor. Specific mechanisms through which the loss-of-function mutations induce LH resistance include decreased receptor protein, decreased ligand binding, altered receptor trafficking, and impaired ability to activate G_s. Undervirilization with hypospadias, micropenis, and cryptorchidism has been described with incomplete loss-of-function missense mutations.[205] Genetic females, sisters of affected 46,XY individuals, who carry the identical mutations show normal female genital differentiation and normal pubertal development but have amenorrhea and infertility.[206,207] Genetic analysis may be helpful to distinguish LHCGR mutations from other disorders affecting testosterone biosynthesis (such as isolated 17,20-lyase deficiency).[208]

SMITH-LEMLI-OPITZ SYNDROME

Clinical features of this autosomal recessive disorder include multiple malformations, urogenital anomalies, mental retardation, failure to thrive, facial abnormalities, developmental delay, and behavioral abnormalities. The most common urogenital abnormalities include male-to-female sex reversal, hypospadias, and cryptorchidism. The facial abnormalities consist of a broad nose, upturned nares, micrognathia, short neck, and cleft palate.[209] Typical limb anomalies comprise short thumbs, syndactyly of the second and third toes, and post-axial polydactyly.

Several enzymes catalyze the conversion of lanosterol to cholesterol. Decreased activity of these enzymes leads to cholesterol deficiency. The enzyme, 7-dehydrocholesterol reductase, encoded by the 7-dehydrocholesterol reductase (DHCR7) gene catalyzes the last step in cholesterol biosynthesis. Smith-Lemli-Opitz (SLO) is due to mutations in the 7-dehydrocholesterol reductase (DHCR7) gene located at chromosome 11q12-q13.[210,211] Mutations in the DHCR7 gene are associated with elevated 7-dehydroxycholesterol concentrations. Demonstration of elevated 7-dehydroxycholesterol concentrations is required to confirm the diagnosis. To date, more than 80 mutations have been reported.[212]

As anticipated, mutations in this cholesterol biosynthetic pathway are associated with decreased cholesterol and accumulation of sterol intermediates proximal to the defective enzyme. Decreased cholesterol concentrations lead to decreased steroid concentrations because cholesterol serves as the precursor for glucocorticoid, mineralocorticoid, and sex steroid biosynthesis. In addition to its role as the precursor for steroid biosynthesis, cholesterol modification of sonic hedgehog protein (SHH) is necessary for normal signaling through its cognate receptor, Patched (PTCH), which contains a sterol sensing domain. In fibroblasts from patients with SLO, SHH signaling is impaired. Using transgenic mouse models, available data indicate that accumulation of sterol intermediates rather than cholesterol deficiency interferes with midline fusion of facial structures. These observations shed light on the molecular pathophysiology responsible for the cleft palate associated with SLO.[213,214]

Prenatal diagnosis can be performed by measurement of amniotic fluid DHCR7 concentrations.[215] Low plasma estriol and elevated 16α-hydroxy-estrogens concentrations are found in women pregnant with affected fetuses, presumably due to impaired fetal cholesterol production.[216] The incidence of biochemically confirmed SLO is estimated at 1/20,000 to 1/60,000 live births.[217] With the identification of the molecular basis for this disorder, a surprisingly high heterozygote carrier rate for DHCR7 mutations has been found. Because the prevalence of SLO at 16 weeks of gestation is comparable to the prevalence at birth, early fetal loss and/or reduced fertility of carrier couples may be occurring.[218]

CONGENITAL LIPOID ADRENAL HYPERPLASIA

This autosomal-recessive disorder is characterized by a severe defect in the conversion of cholesterol to pregnenolone, leading to impaired steroidogenesis of all adrenal and gonadal steroid hormones. Impaired testosterone biosynthesis in utero prevents male sexual differentiation. Hence, all affected fetuses (46,XY or 46,XX) have female

external genitalia. Low or undetectable steroid hormone levels are consistent with this diagnosis. The hormone determinations to distinguish congenital lipoid adrenal hyperplasia from 3β-hydroxysteroid dehydrogenase deficiency should include 17-hydroxypregnenolone or pregnenolone. These hormones will be low in the former but elevated in the latter. Milder forms of this disorder with presentation beyond the newborn period have been described.[219]

Following cloning of the gene for steroidogenic acute regulatory protein (StAR), mutations in the StAR gene were identified among patients with congenital lipoid adrenal hyperplasia.[220-224] The StAR protein facilitates cholesterol transport across the mitochondria to P450scc.[225,226] In congenital lipoid adrenal hyperplasia, impaired cholesterol transport into mitochondria leads to accumulation of cholesterol esters and sterol autooxidation products. Ultimately, the lipid accumulation alters the cell cytostructure—provoking cell destruction and complete loss of StAR-dependent steroidogenesis.[227] Yet, the presence of low levels of StAR-independent steroidogenesis allows for preservation of Wolffian duct remnants in affected 46,XY fetuses and spontaneous pubertal mutation in affected 46,XX girls.[228,229]

SIDE CHAIN CLEAVAGE CYTOCHROME P450 ENZYME

The side chain cleavage enzyme (also known as cholesterol desmolase) is a cytochrome P450 enzyme encoded by the CYP11A1 gene mapped to chromosome 15q23-q24. This enzyme converts cholesterol to pregnenolone and is essential to steroidogenesis. Despite the crucial role of this enzyme for placental progesterone synthesis, rare fetuses with loss-of-function mutations on both alleles may be viable. Children affected with this autosomal-recessive disorder have female external genitalia irrespective of the karyotype and adrenal insufficiency. Postnatally, sizes of adrenals and gonads on ultrasound or magnetic resonance imaging have been variable but not enlarged. The absence of adrenal/gonadal tissue has been speculated to result from lipid accumulation similar to the cell destruction observed in patients with StAR mutations.[230-232]

VIRILIZING CONGENITAL ADRENAL HYPERPLASIAS

The virilizing congenital adrenal hyperplasias are a group of disorders due to mutations in the steroidogenic enzyme genes involved in cortisol biosynthesis. These genes are 3β-hydroxysteroid dehydrogenase type 2 (HSD3B2), 21-hydroxylase (CYP21), and 11β-hydroxylase (CYP11B1). The common pathophysiology is decreased negative feedback inhibition due to insufficient cortisol concentrations, but the specific manifestations and laboratory abnormalities vary depending on which enzyme gene is involved. Steroid intermediates proximal to the deficient enzyme accumulate.

Overall, relative cortisol deficiency leads to a diminution of negative feedback inhibition with subsequent increased ACTH secretion. The adrenal cortex responds by proportionally increasing adrenal androgen production. Thus, the clinical signs and symptoms reflect androgen excess in addition to glucocorticoid and mineralocorticoid deficiencies. Indeed, the magnitude of glucocorticoid and mineralocorticoid deficiencies varies—generally in proportion to the severity of the enzyme deficiency.

The most common type of congenital adrenal hyperplasia (accounting for 90% to 95% of cases) is 21-hydroxylase deficiency due to mutations in the 21-hydroxylase (CYP21A2) gene located at chromosome 6p21.3 in the HLA class III region.[233-237] The reported incidence of 21-hydroxylase deficiency ranges from 1 in 5,000 to 1 in 15,000, with variation among ethnic/racial backgrounds.[238,239] Decreased 21-hydroxylase activity impairs conversion of 17-hydroxyprogesterone to 11-deoxycortisol in the zona fasciculata (the primary site of cortisol biosynthesis) and conversion of progesterone to deoxycorticosterone in the zona glomerulosa, the primary site of aldosterone biosynthesis.

In addition to the shunting of 17-OHP to androstenedione, DHEA, and DHEAS resulting in increased androgen concentrations in the affected female fetus, 17-OHP can be converted through an alternate route to DHT. This alternate route (the "backdoor pathway") involves 5α-reduction of 17-OHP to 5α-pregnane-17α-ol-3,20-dione, ultimately generating androstanediol—which is the substrate for 3α-reduction and conversion to DHT[240] (Figure 4-4). During fetal life, accumulation of 17-OHP due to mutations in CYP21A2, CYP11B2, or P450-oxidoreductase (POR) may increase flux through this "backdoor pathway"—leading to elevated DHT concentrations.[241]

Infant girls with classic salt-losing 21-hydroxylase deficiency usually present in the immediate neonatal period due to genital ambiguity (Figure 4-5). When the diagnosis is delayed, affected girls develop dehydration, hyponatremia, and hyperkalemia due to glucocorticoid and mineralocorticoid deficiencies. Among affected female infants, virilization of the external genitalia ranges from clitoromegaly to perineal hypospadias—with chordee to complete fusion of labiourethral and labioscrotal folds. The magnitude of external genital virilization may be so extensive that affected female infants appear to be males with bilateral undescended testes.[242,243] Unless identified by neonatal screening, infant boys typically present at 2 to 3 weeks of age with failure to thrive, poor feeding, lethargy, dehydration, hypotension, hyponatremia, and hyperkalemia. When the diagnosis is delayed or missed, congenital adrenal hyperplasia is potentially fatal. Newborn screening programs decrease the morbidity and mortality associated with acute adrenal insufficiency.

In affected infants, random 17-hydroxyprogesterone concentrations are usually elevated. Concentrations are greater than 5,000 ng/dL, and often much higher.[244] Androstenedione and progesterone concentrations are also typically elevated. In some instances, plasma renin activity (PRA) can be helpful to assess mineralocorticoid status. Measurement of 21-deoxycortisol is extremely helpful, but availability of this hormone assay is limited.[245,246] For female infants, a normal uterus is present and can be identified on ultrasound. Ovaries may be too small to be readily identified on ultrasound. Despite excessive antenatal androgen exposure, ovarian position is normal and internal Wolffian structures are not retained.

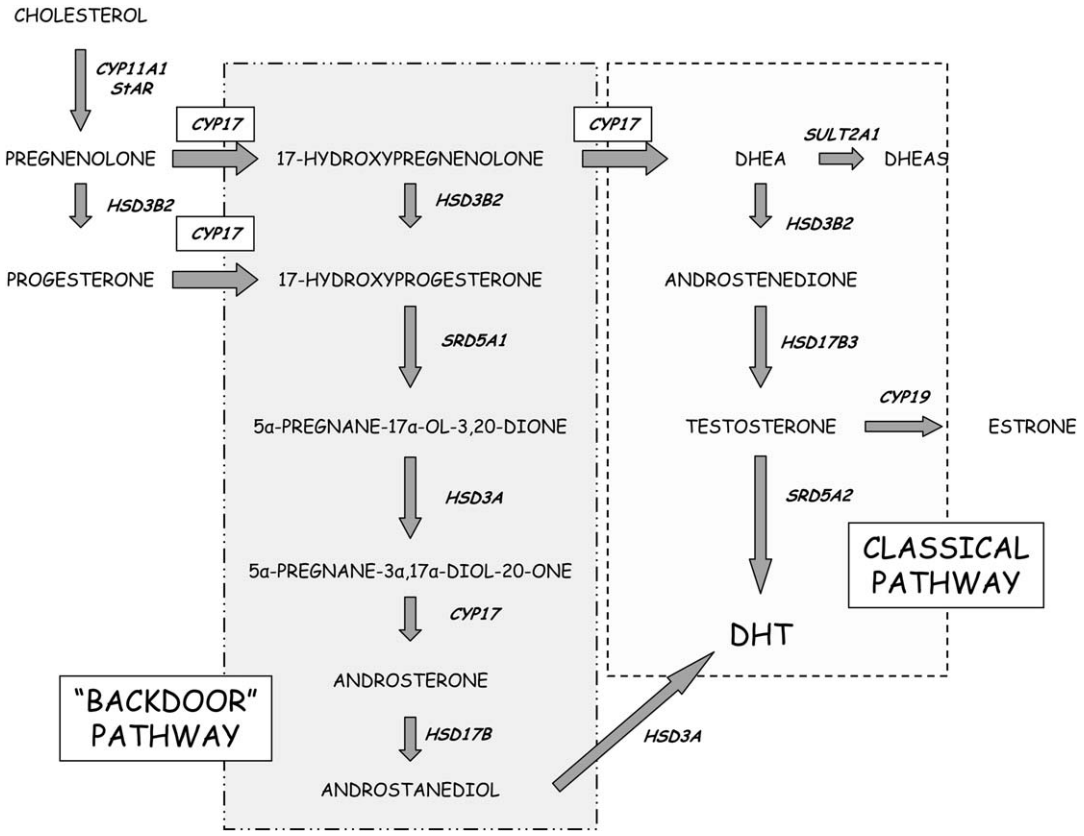

Figure 4-4. Steroidogenic pathways relevant to fetal androgen biosynthesis. The classic steroidogenic pathway relevant to the testis (light background) and the "backdoor pathway" (dark background) are indicated. Both pathways can generate DHT through the actions of target tissue enzymes capable of converting substrates, testosterone, and androstanediol into DHT. In the presence of elevated ACTH and 17-OHP concentrations due to CYP21, CYP11B1, or POR mutations, the backdoor pathway may contribute to the excessive androgen concentrations responsible for virilization of XX fetuses.

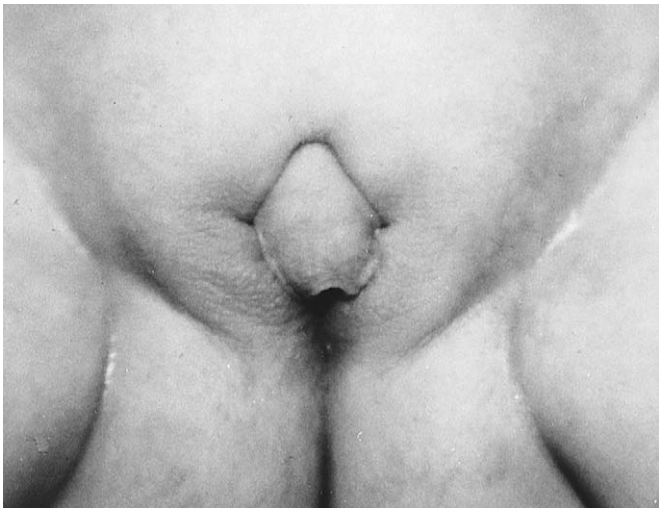

Figure 4-5. Genital ambiguity in virilized female with 21-hydroxylase deficiency. The labioscrotal folds are fused, and the clitoris is enlarged.

The spectrum of impaired 21-hydroxylase activity ranges from complete glucocorticoid and mineralocorticoid deficiencies to mild deficiencies manifested principally by compensatory excessive adrenal androgen secretion. Infants capable of adequate aldosterone synthesis do not usually manifest overt salt loss. Female infants capable of adequate aldosterone synthesis may still have sufficient androgen exposure in utero to virilize their external genitalia. In the absence of newborn screening programs, affected males capable of aldosterone biosynthesis may not be identified until they present with genital overgrowth or premature pubarche. Infants with the milder forms of congenital adrenal hyperplasia are generally not identified by most newborn screening programs.[247]

CYP21A2 is located approximately 30 kilobases from a highly homologous pseudogene, CYP21A1P. The tenascin-XB (TNXB) gene encoding an extracellular matrix protein is located on the DNA strand opposite CYP21A2.[248] At this time, more than 100 CYP21A2 mutations have been reported. However, only a few mutations account for the majority of affected alleles.[249,250] Most of the common mutations represent gene conversion events in which CYP21A2 has acquired deleterious CYP21A1P sequences. The frequency of specific mutations varies among ethnic groups.[251] Molecular genotyping can be a useful adjunct to newborn screening.[252,253] Caveats to bear in mind are that multiple mutations can occur on a single allele and that different CYP21A2 mutations can occur in one family.[254-256]

Congenital adrenal hyperplasia due to 11β-hydroxylase deficiency is characterized by glucocorticoid deficiency, excessive androgen secretion, and hypertension.

This enzyme is expressed in the zona fasciculate, where it converts 11-deoxycortisol to cortisol. This form of congenital adrenal hyperplasia is rare (3%–5% of cases) apart from the high incidence among Moroccan Jews, for whom the incidence approaches 1 in 6,000.[257] Despite the presence of the identical mutation, phenotypic heterogeneity for the magnitude of virilization and hypertension occurs even in a single family. Affected females may present with ambiguous genitalia. Typical laboratory findings are elevated serum concentrations of 11-deoxycortisol. Serum concentrations of 17-hydroxyprogesterone, androstenedione, and testosterone may be mildly elevated. PRA concentrations are low or suppressed. Although ACTH-stimulated hormone responses among heterozygotic carriers are usually normal, elevated 11-deoxycortisol and 11-deoxycorticosterone have been reported.[258,259]

Mutations in the 11β-hydroxylase (CYP11B1) gene have been identified in patients with 11β-hydroxylase deficiency.[260-262] The CYP11B1 gene is located at chromosome 8q22 in close proximity to a highly homologous gene CYP11B2, which codes for aldosterone synthase.[263] CYP11B1 is expressed in the zona fasciculate, whereas CYP11B2 is expressed primarily in the zona glomerulosa.[264]

3β-HYDROXYSTEROID DEHYDROGENASE DEFICIENCY

Congenital adrenal hyperplasia due to 3β-hydroxysteroid dehydrogenase type 2 deficiency leads to virilization of the external genitalia of 46,XX fetuses due to increased DHEA synthesis. Affected 46,XY fetuses have ambiguous genitalia characterized by undervirilization of the external genitalia secondary to testosterone deficiency. Despite decreased testosterone synthesis, affected 46,XY fetuses usually have intact Wolffian duct structures (including vas deferens). The NAD^+-dependent enzyme 3β-hydroxysteroid dehydrogenase/Δ^5-Δ^4-isomerase catalyzes the conversion of the Δ^5 steroid precursors, pregnenolone, 17-hydroxypregnenolone, and DHEA into the respective Δ^4-ketosteroids, progesterone, 17-hydroxyprogesterone, and androstenedione.[265]

Two isozymes encoded by two different highly homologous genes have been identified and mapped to chromosome 1p13.1.[266,267] The type 1 (HSD3B1) gene is expressed primarily in skin, placenta, prostate, and other peripheral tissues. The type 2 (HSD3B2) gene is the predominant form expressed in the adrenal cortex and gonads. Mutations in HSD3B2, but not HSD3B1, have been detected in patients with 3β-hydroxysteroid dehydrogenase deficiency congenital adrenal hyperplasia.[268-270] Acute adrenal insufficiency occurs in the newborn period when complete loss of function mutations impair biosynthesis of mineralocorticoids, glucocorticoids, and sex steroids. Typical presentations for the non–salt-losing forms include premature pubarche and (in 46,XY infants) perineal hypospadias.[271] Confirmatory laboratory findings include elevated pregnenolone, 17-hydroxypregnenolone, and DHEA concentrations with elevated ratios of Δ^5 to Δ^4 steroids. Because enzymatic activity of the type 1 isozyme is unimpaired, elevated 17-hydroxyprogesterone and androstenedione concentrations may be found.

17β-HYDROSTEROID DEHYDROGENASE DEFICIENCY

Saez and colleagues first described ambiguous genitalia in 46,XY fetuses due to 17β-hydroxysteroid dehydrogenase deficiency.[272] In this autosomal recessive disorder, external genitalia range from female with perineal hypospadias and a blind-ending vaginal pouch to ambiguous with labioscrotal fusion to hypospadias. Testes are present and may be palpable in the labio-scrotal folds or incompletely descended. Despite the presence of female external genitalia, Wolffian structures are typically present. In The Netherlands, incidence was estimated to be 1:147,000.[273]

The 17β-hydroxysteroid dehydrogenase type 3 gene (HSD17B3) is located at chromosome 9q22 and is expressed in the testis, where it converts androstenedione to testosterone. Loss-of-function mutations result in testosterone deficiency and subsequent undervirilization of 46,XY fetuses.[274,275] When unrecognized, patients are usually considered to be female at birth. The clinical features are similar to those of 5α-reductase deficiency and androgen insensitivity. Phenotypic heterogeneity occurs.[276] Diagnostic laboratory features include increased basal and hCG-stimulated androstenedione to testosterone ratios.

At puberty, progressive virilization attributed to extratesticular conversion of androstenedione to testosterone occurs.[277] With progressive virilization, affected individuals may choose to change gender identity from female to male. Increased conversion of androstendione to estrogen may cause gynecomastia. Appropriate male gender assignment can be made in infancy when the diagnosis is suspected and confirmed.[278] Affected females show no phenotype.[279,280]

5α-REDUCTASE DEFICIENCY

In this autosomal-recessive disorder, affected males have genital ambiguity characterized by differentiation of Wolffian structures, absence of Mullerian-derived structures, small phallus, urogenital sinus with perineal hypospadias, and blind vaginal pouch. At puberty, progressive virilization occurs with muscular development, voice change, and phallic enlargement. Facial hair tends to be scanty and the prostate is smaller than normal. Despite pronounced virilization at puberty, semen tends to be viscous and with low amount of ejaculate. The ducts to mature and transport sperm are inadequately developed, so that most affected men are unable to father children.

In one case report, intrauterine insemination with sperm from an affected male resulted in two pregnancies.[281] Deletions and mutations of the 5α-reductase type 2 gene (SRD5A2) have been identified in affected individuals.[282] The SRD5A2 gene is located at chromosome 2p23 and is expressed primarily in androgen target tissues. An isozyme (SRD5A1, located at chromosome 5p15) is expressed in skin and scalp. Clusters of individuals with SRD5A2 mutations have been described in regions of the Dominican Republic, Papua New Guinea, Turkey, and the Middle East.[283]

CYTOCHROME P450 OXIDOREDUCTASE DEFICIENCY

In 1985, a disorder with biochemical evidence suggesting decreased 17α-hydroxylase and 21-hydroxylase activity was initially reported.[284] Clinical features include genital ambiguity, craniosynostosis, midface hypoplasia, and radiohumeral synostosis. At birth, genital ambiguity occurs in both males and females. However, there is no progressive postnatal virilization. During pregnancy, some mothers develop signs associated with androgen excess such as acne, hirsutism, and clitoromegaly.[285] Typical laboratory findings include elevated 17-OHP, low sex steroid, and normal mineralocorticoid concentrations. Glucocorticoid deficiency can occur.

However, despite the apparent resemblance to combined steroidogenic enzyme deficiencies mutations were not identified in the CYP17A1 or CYP21A2 genes. Rather, this disorder is associated with mutations in the cytochrome P450 oxidoreductase (POR) gene. The POR gene codes for a protein involved in electron transfer from NADPH, which functions as a cofactor for steroidogenic and hepatic cytochrome P450 enzymes. The POR gene, mapped to chromosome 7q11-12, consists of 15 exons. Loss-of-function mutations appear to be scattered throughout the gene, without an apparent hot spot.

The skeletal malformations resemble those found in the Antley-Bixler syndrome, which is an autosomal dominant disorder associated with mutations in the fibroblast growth factor receptor 2 (FGFR2) gene. The molecular basis of the skeletal anomalies is unclear but may reflect impaired sterol biosynthesis.[286,287] Patients with Antley-Bixler syndrome due to FGFR2 mutations have normal steroidogenesis, whereas patients with POR mutations have abnormal steroidogenesis.[288]

The paradox in this disorder is the virilization of the female fetus and undervirilization of the male fetus. It has been suggested that the alternative backdoor pathway for androgen synthesis (Figure 4-4) occurs with conversion of 17-OHP to 5α-pregnane-3α,17α-diol-20-one through the sequential activity of 5α-reductase type 1 and 3α-hydroxysteroid dehydrogenase. Subsequently, 5α-pregnane-3α,17α-diol-20-one can be converted to androstenedione by the 17,20-lyase activity of CYP17A1.[289,290]

PLACENTAL AROMATOSE DEFICIENCY

Placental aromatase deficiency is a rare autosomal recessive disorder. During pregnancies with affected fetuses, progressive maternal virilization characterized by hirsutism, clitoral hypertrophy, acne, and frontal balding occurs. During pregnancy, testosterone, DHT, and androstenedione concentrations are elevated and estradiol, estrone, and estriol concentrations are low. In the postpartum period, some clinical features of androgen excess regress and the elevated androgen concentrations return to normal levels.

At birth, 46,XX infants are variably virilized with labioscrotal fusion, clitoromegaly, and perineal scrotal hypospadias.[291,292] Affected 46,XX individuals generally manifest delayed puberty characterized by minimal or absent breast development, primary amenorrhea, hypergonadotropic hypogonadism, multi-cystic ovaries, and decreased bone mineral density.[293,294] At birth, affected 46,XY infants have normal internal and external genital development. Affected males have generally presented after puberty with tall stature, skeletal pain, delayed skeletal maturation, and infertility.[295] Investigation of aromatase-deficient men suggests that estrogen deficiency is associated with abdominal obesity, insulin resistance, dyslipidemia, and relative infertility.[296] Patients with less severe phenotypic features have been described.[297]

Aromatase is a cytochrome P450 enzyme that plays an important role in the biosynthesis of estrogens (C18 steroids) from androgens (C19 steroids). The aromatase gene, CYP19A1, maps to chromosome 15q21.2 and codes for a 503-amino-acid protein.[298] Inactivating mutations of CYP19A1 impair conversion of androgens to estrogens, leading to increased androgens.[299,300] In addition to its role in estrogen biosynthesis in adolescents and adults, aromatase located in the human placenta converts fetal adrenal androgens to estrogens and protects the mother from the potential virilizing effects of the fetal androgens. Tissue-specific aromatase expression is governed by several different promoters associated with alternative first exon usage.[301]

Maternal Hyperandrogenism

Maternal hyperandrogenism during gestation can be due to luteomas of pregnancy, androgen secreting tumors, and exposure to exogenous androgen. The excessive maternal androgen concentrations can cause virilization of the external genitalia of 46,XX fetuses. Organochlorinepesticides, polychlorinated biphenyls (PCBs), and alkylpolyethoxylates are considered to be "endocrine disruptors" because of their estrogenic and/or antiandrogenic properties. In addition, some pesticides can inhibit placental aromatase activity.[302] Genital ambiguity, described in three 46,XY infants born in heavily agricultural areas, was attributed to fetal exposure to endocrine disruptors (especially because no mutations were detected in the SRY or SRD5A2 genes).[303]

Prenatal treatment with diethylstilbesterol (DES), a nonsteroidal synthetic estrogen, is also associated with urogenital abnormalities of both male and female fetuses. Cryptorchidism has been noted in 46,XY fetuses.[304] It has been speculated that the frequency of cryptorchidism and poor semen quality is increasing because exposure to endocrine disruptors in the environment has increased.[305-308] One potential mechanism is that environmental hydroxylated PCB metabolites can bind to estrogen sulfotransferase, some with greater affinity than estradiol, leading to increased estrogen levels and cryptorchidism.[309]

Disorders of Androgen Action

During the process of sexual differentiation, androgen action is essential to retention of Wolffian duct derivatives, development of the prostate, and differentiation of male external genitalia. Complete androgen insensitivity

(CAIS) is characterized by female external genitalia, absence of Mullerian duct derivatives, sparse sexual hair, inguinal masses, spontaneous pubertal breast development due to aromatization of androgens to estrogens, and a 46,XY karyotype. Partial androgen insensitivity (PAIS) is characterized by clinical features suggestive of a partial biologic response to androgens.[310] Androgen insensitivity is an X-linked recessive disorder secondary to mutations in the androgen receptor (AR) gene, which is located near the centromere on Xq11-12.[311,312] Approximately 30% of cases represent de novo mutations. Somatic cell mosaicism can occur when the mutation arises in the post-zygotic stage and is associated with a lower recurrence risk.[313,314]

Clinical features of CAIS include inguinal or labial masses in an otherwise normal-appearing female infant or primary amenorrhea in an adolescent girl. Among patients with CAIS, Wolffian duct derivatives (e.g., vas deferens and epididymides) are absent because of deficient androgen action. Although rare exceptions have been described, Mullerian-derived structures are usually absent because Sertoli cell function is normal with in utero AMH secretion. It has been suggested that 1% to 2% of girls with bilateral inguinal herniae may have androgen insensitivity. The finding of a gonad within the hernia sac should prompt cytogenetic studies.[315] The expected LH surge in testosterone concentrations during the first few months of life may be absent in some infants with CAIS.[316]

Phenotypic features associated with PAIS include ambiguous genitalia with perineoscrotal hypospadias, microphallus, and bifid scrotum. Testicular position is variable, ranging from undescended to palpable in the scrotum. Infants with PAIS generally manifest the expected neonatal testosterone surge, suggesting that prenatal androgen responsiveness plays a role in imprinting of the HPG axis.[317] Features of mild androgen insensitivity (MAIS) include gynecomastia and infertility in otherwise normal males. Older chronological age at presentation is typical. In all instances, karyotype is 46,XY.

Typical laboratory findings are elevated LH and testosterone concentrations because testicular testosterone synthesis is unimpeded and there is loss of negative feedback inhibition of gonadotropins. LH is usually higher than FSH because testicular inhibin secretion is not impeded. FSH concentrations may be elevated or normal. Infants with PAIS may require dynamic endocrine tests to assess hCG-stimulated Leydig cell testosterone secretion and, more importantly, end-organ responsiveness to androgens. The risk for gonadal tumors is increased in the presence of a Y chromosome. Tumors associated with AIS include carcinoma-in-situ (CIS) and seminoma. In one series, only 2 of 44 subjects with CAIS had CIS. Both subjects were postpubertal.[318]

Androgen action is mediated by the androgen receptor, a member of the steroid/thyroid hormone family of hormone receptors. In common with other members of this receptor family, the androgen receptor is a ligand-dependent transcription factor with a characteristic modular structure. The major modules of the 110-kD protein include the amino-terminus transactivation (AF1), DNA-binding, and ligand-binding domains. Other features include a nuclear localization signal and another transactivation domain (AF2) in the carboxy terminus ligand-binding domain. Although the androgen receptor is usually described as containing 910 amino acids, the actual number varies because of three polymorphic trinucleotide repeat regions [CAG, GGN (N = any nucleotide), and GCA] located in the amino terminal domain encoding polyglutamine, polyglycine, and polyproline repeat regions, respectively.[319,320]

The normal range for the polyglutamine repeat is 8 to 31, with an average length of 20 repeats. In vitro, AR transcriptional activity varies inversely with the number of repeats. Variation in the length of the CAG repeat, even within the normal range, appears to influence AR function—with long normal repeat lengths associated with infertility secondary to decreased spermatogenesis.[321,322] The role of CAG repeat length in male sexual differentiation is controversial at this time and awaits more data.[323] One possible mechanism is a cell-specific effect on transactivation.[324] The usual range for the polyglycine repeat is 10 to 30. The functional significance of the polyglycine repeat is unclear, but complete deletion reduces transactivation in vitro.[325] Reports regarding the role of CAG repeat length in females influencing ovarian hyperandrogenism, acne, and premature pubarche have been inconsistent.

Phosphorylation, acetylation, ubiquitylation, and sumoylation are post-translational modifications that influence AR transactivational function. The physiologic roles of these modifications remain to be established.[326,327] The DNA-binding domain (DBD) contains two zinc fingers that interact with DNA. X-ray crystallographic studies indicate that the three-dimensional structure of the ligand-binding domain (LBD) consists of 12 α-helixes that form the ligand-binding pocket. Kinetic and biochemical assays with molecular dynamic simulations of mutations identified in patients with CAIS indicate that the position of helix 12 is crucial to AR function.[328]

In the absence of ligand, the receptor is located primarily in the cytoplasm—where it is bound to chaperone proteins. Upon ligand binding, the conformation of the androgen receptor changes. The ligand-receptor complexes dimerize and move to the nucleus.[329] A key feature of androgen receptor dimerization is the intramolecular interaction between the N-terminal and C-terminal domains.[330] Binding of ligand stabilizes the androgen receptor and slows its degradation.[331] In the nucleus, the complex binds to androgen response elements (AREs) and alters target gene transcription. Nucleotide sequences of AREs in conjunction with specific AR amino acids confer greater specificity for transcriptional regulation of specific genes.[332]

Additional proteins (such as coactivators and other transcription factors) are involved in transcription. These other proteins presumably provide a physical bridge linking the basal transcription machinery, the ligand-receptor complex, and chromatin. Once the ligand dissociates from the receptor, the receptor dissociates from the DNA. The most important physiologic ligands are testosterone and dihydrotesterone. The increased potency of dihydrotestosterone is attributed to the greater stability of the dihydrotestosterone-receptor complex compared to the testosterone-receptor complex.

Numerous AR mutations have been described in affected individuals. Complete loss-of-function mutations (such as deletions, insertions, and deletions associated with frame-shifts) and premature termination codons are typically associated with complete androgen insensitivity.[333] Partial loss-of-function mutations are typically missense mutations. Receptors with mutations in the DBD bind ligand normally but fail to transactivate target genes. Mutations in the LBD of the AR gene can be associated with decreased affinity for ligand, increased instability of the hormone-receptor complex, or increased susceptibility of the receptor to thermal denaturation.[334] In addition to hormone determinations, diagnostic evaluation may include DNA sequence analysis of the AR gene *(www.genetests.org and www.androgendb.mcgill.ca)*.

In general, the phenotype correlates with degree of impaired androgen action. However, clinical features can vary despite the presence of the identical mutation (even within the same family). Complete and partial androgen insensitivity associated with the same AR mutation can occur in siblings.[335] Different missense mutations at the same position can also be associated with differing phenotypes.[336,337] Factors potentially responsible for this phenotypic heterogeneity include individual variation in ligand concentration, variations within the AR or in other genes influencing androgen action and metabolism, variations in mRNA concentrations, and epigenetic phenomenon.[338]

In addition to androgen sensitivity, Kennedy's disease (also known as spinal and bulbar muscular dystrophy) is mapped to the androgen receptor locus. Kennedy's disease is a progressive neurodegenerative disorder with onset in the thirties or forties. This disorder is associated with excessive expansion of the CAG polyglutamine trinucleotide repeat region in exon 1 of the androgen receptor.[339] Repeat lengths greater than 35 are associated with spinal and bulbar muscular atrophy. In Kennedy's disease, aberrant degradation of misfolded AR generates insoluble aggregates—leading to cellular toxicity. In a mouse model, castration improved the neurologic phenotype—suggesting that the androgen-AR signaling pathway influences the phenotype of Kennedy's disease.[340] Mild symptoms of androgen insensitivity can be detected with slight decreases in AR mRNA and protein concentrations.[341]

Mullerian Duct Abnormalities

PERSISTENT MULLERIAN DUCT SYNDROME

The typical clinical features of PMDS include cryptorchidism, testicular ectopia associated with inguinal hernia, and hernia uteri inguinalis. Testicular differentiation is usually normal, but the male excretory ducts may be embedded in the Mullerian duct remnants or incompletely developed. Infertility may ensue secondary to cryptorchidism, intertwining of vas deferens and uterine wall, or lack of proper communication between the testes and excretory ducts. Testicular torsion is not uncommon because the testes may not be anchored properly to the bottom of the processus vaginalis.[342]

AMH is a member of the TGF-β family and signals through two different interacting membrane-bound serine/threonine receptors. The ligand, AMH, binds to the type II receptor—which leads to recruitment and phosphorylation of a type I receptor. The type II receptor is specific for AMH, whereas there are multiple subtypes of the type 1 receptors. Inheritance is autosomal recessive and associated with mutations in the AMH gene or in the Mullerian inhibitory hormone receptor (AMH-RII) gene.[343] AMH concentrations are low among patients with mutations in the AMH gene. Among patients with AMH-RII mutations, AMH concentrations are normal or elevated. The phenotypes of patients with AMH or AMH-RII mutations are comparable. Females who carry mutations on both AMH alleles appear to have normal fertility.

MULLERIAN DUCT ABNORMALITIES IN 46,XX INDIVIDUALS

Mayer-Rokitansky-Küster-Hauser syndrome refers to congenital absence of the vagina associated with uterine hypoplasia or aplasia. Primary amenorrhea is the typical presentation. Renal anomalies and skeletal malformations may be present. Unilateral renal agenesis was found in 29.8% of cases of Mullerian duct anomalies on magnetic resonance imaging (MRI).[344] The aggregation of Mullerian duct aplasia, renal aplasia, and cervico-thoracic somite dysplasia has been labeled MURCS syndrome.[345] Mullerian duct hypoplasia has been associated with facio-auriculo-vertebral anomalies such as Goldenhar syndrome.[346]

Transverse vaginal septa can occur sporadically or in association with other features, such as polydactyly in the McKusick-Kaufman syndrome.[347] Because of the high frequency associated anomalies, careful physical examination for skeletal malformations and renal sonography should be included in the diagnostic evaluation of women with abnormal development of the Mullerian duct system.[348]

Hypogonadotropic Hypogonadism

Hypogonadotropic hypogonadism may present with microphallus and/or cryptorchidism in male infants (see chapter 16). Genital ambiguity would not be anticipated because.placental hCG secretion is unaffected. Decreased gonadotropin secretion presumably results in decreased testosterone secretion such that microphallus and cryptorchidism can occur.[349,350]

Kallmann syndrome is the eponym used for the X-linked recessive form of hypogonadotropic hypogonadism associated with anosmia due to failed migration of GnRH neurons from the olfactory placode into the forebrain along branches of the vomeronasal nerve.[351,352] Olfactory tract hypoplasia or aplasia has been found on MRI.[353] The molecular basis of this X-linked form is mutations in the Kallmann (KAL) gene (located at Xp22.3). This gene escapes X-inactivation, codes for a 680-amino-acid protein, and helps target GnRH neurons to the hypothalamus.[354,355]

Mutations in the GnRH receptor (GNRHR), fibroblast growth factor receptor 1 (FGFR1), and GPR54 genes are also associated with hypogonadotropic hypogonadism.[356-359] More recently, mutations in the genes coding for prokineticin receptor-2 (PROKR2) and its ligand [prokineticin-2 (PROK2)] have been associated with hypogonadotropic hypogonadism.[360]

Cryptorchidism

Cryptorchidism (undescended testes) is the most common disorder of sexual differentiation, affecting 3% of male infants. Because spontaneous descent often occurs during infancy, the prevalence decreases to 1% by 6 months of age.[361] Cryptorchidism has been associated with hypothalamic hypogonadism, aberrant testicular differentiation, impaired testosterone biosynthesis, androgen insensitivity, holoprosencephaly, abnormal AMH production or action, and abnormalities affecting INSL3/LGR8 function. Other associations include prune belly syndrome, bladder exotrophy, and renal anomalies. Cryptorchidism is also a feature of many syndromes (Table 4-3). Maternal diabetes mellitus, including gestational diabetes, may be a risk factor.[362]

During sexual differentiation, the gonads are positioned between two structures: the cranial suspensory ligament and the gubernaculum. Testicular descent is divided into two phases: intraabdominal and inguinoscrotal. Factors involved in gubernacular development during the intraabdominal phase include INSL3 and its receptor, LGR8. INSL3 is secreted by Leydig cells. Its receptor, LGR8, is a leucine-rich G-protein–coupled receptor expressed by the gubernaculum. By 13 or 14 weeks of gestation, the gubernaculum anchors the testis to the internal inguinal ring.[363]Androgen action during the intraabdominal phase appears to be limited to regression of the cranial suspensory ligament. In females, the cranial suspensory ligament persists as the suspensory ligament of the ovary. Testicular descent through the inguinal canal is usually accomplished by the end of seventh month of gestation, with completion of the inguinoscrotal phase by the end of week 35.[363]

Heterozygous missense INSL3 mutations have been identified in patients with cryptorchidism.[364] Mutations have also been identified in the LGR8 gene in males with cryptorchidism. Sequence variants have been identified in the HOXA10 gene in boys with cryptorchidism.[365] Typically, the testes of patients with androgen insensitivity have completed the intraabdominal phase but fail to undergo inguineoscrotal descent because this second phase is androgen dependent. However, the more complete the androgen insensitivity the greater likelihood of finding abdominal testes. Exposure of XX fetuses to androgen does not promote significant ovarian descent in humans, as evidenced by normal ovarian position in females with congenital adrenal hyperplasia.[366,367]

Cryptorchidism can be associated with decreased number of germ cells, impaired germ cell maturation, and decreased number of Leydig cells.[368] In some instances of unilateral cryptorchidism, abnormal histology is apparent in the contralateral normally descended testis.[369] However, it is unclear if these features represent consequences or causes of cryptorchidism.

Disorders Associated with Small Penis or Cryptorchidism

- Aarskog syndrome
- Börjeson-Forssman-Lehman syndrome
- Carnevale syndrome
- Cornelia de Lange syndrome
- Deletion 4p, 5p, 9p, 11q, 13q, 18q
- Duplication 3q, 10q, 15q
- Faciogenitopopliteal syndrome
- Goldenhar syndrome
- Holoprosencephaly
- Juberg-Marside syndrome
- Johanson-Blizzard syndrome
- Lenz-Majewski hyperostosis syndrome
- Lowe syndrome
- Malpeuch facial clefting syndrome
- McKusick-Kaufman syndrome
- Meckel-Gruber
- Miller-Dieker syndrome
- Multiple pterygium syndrome, Escobar variant
- Myotonic dystrophy
- Najjar-syndrome
- Noonan syndrome
- Pallister-Hall syndrome
- Pfeiffer
- Prader-Willi syndrome
- Robinow syndrome
- Rubinstein-Taybi syndrome
- Seckel syndrome
- Shprintzen-Goldbert
- Simpson-Golabi-Behmel, type 1
- Townes-Brocks syndrome
- Varadi-Papp syndrome
- VATER syndrome
- Weaver

Diagnosis

HISTORY

A detailed family history should be obtained. The family history should include ascertainment of unexplained infant deaths, consanguinity, and infertility. Infants with congenital adrenal hyperplasia may have died prior to diagnosis. Many DSDs are inherited as autosomal-recessive disorders. Infertility and gynecomastia may represent milder phenotypes for some DSDs. For X-linked disorders such as androgen insensitivity, there may be affected maternal family members (i.e., either amenorrheic or infertile aunts or partially virilized uncles). Pertinent questions include prenatal exposure to exogenous or endogenous androgens, estrogens, or potential endocrine disruptors. Maternal virilization during pregnancy should be queried.

PHYSICAL EXAMINATION

DSDs encompass a spectrum of physical findings. The specific physical findings range from micropenis, hypospadias, undescended testes, minimal clitoromegaly, and scrotalized labia to more extensive forms of genital ambiguity. Severe clitoromegaly with posterior labial fusion in an 46,XX patient may be difficult to distinguish from perineal hypospadias, undescended testes, and a bifid scrotum in an 46,XY individual. During the physical examination, attention should be focused on phallic size, symmetry of the external genitalia, presence and location of palpable gonads, and any additional anomalies.

The extent of virilization should be carefully documented, recording the configuration, stretched dorsal length, and diameter of the phallus (including the glans penis). The location of the urethral opening, degree of labiourethral fold fusion, and extent of labioscrotal fold fusion should also be noted. Labioscrotal folds fuse from posterior to anterior such that the appearance extends from posterior labial fusion, a partially fused hemiscrota, to completely fused scrotum with labiourethral fusion extending to a midline urethral opening. The position of the urethra should be noted, as well as whether one or two perineal openings are present.

Gonadal or adnexal structures may be identified upon careful palpation for content of the labioscrotal structures, scrotum or labia majora, inguinal region, and the lower abdomen. The groin area may be "milked" to maneuver the testis into the scrotum. The absence of palpable testes may indicate a genetic female with virilization, as occurs with adrenal hyperplasia or a genetic male with undescended or absent testes. Although structures palpated within the labioscrotal folds are usually testes, ovaries or even the uterine cervix can be found within the labioscrotal folds. Testes typically have a characteristic ovoid structure.

Symmetry or asymmetry of external genital differentiation may provide clues to the etiology of the genital ambiguity (Figure 4-6). Unilateral structures with asymmetry of other genital structures suggests ovotesticular or 45X/46,XY DSDs and is often associated with unilateral gonadal maldescent. Asymmetry implies differing local influences, which often reflect abnormalities in gonadal differentiation (Figures 4-6 and 4-7). Repeated examinations may be beneficial for diagnostic precision.

Penile length measurements extend from the tip of stretched penis from the pubic ramus. Normal length depends on gestational age, the lower limit (approximately –2.5 SD) at term being 2.0 cm. An isolated micropenis can be a consequence of decreased testosterone exposure in the second half of gestation due to Leydig cell failure, LH deficiency, androgen insensitivity syndrome, LHCGR mutations, or GH deficiency. A micropenis with hypospadias suggests more severe DSDs.

Clitoral length is usually less than 1.0 cm, although rare variations exist. Measurement of the clitoris requires a careful estimate of the proximal end and careful exclusion of overlying skin. The location of the urethral opening should be ascertained by visualization, witnessing the urinary stream, or with careful insertion of a firm catheter. If urination is observed, force, diameter, and direction

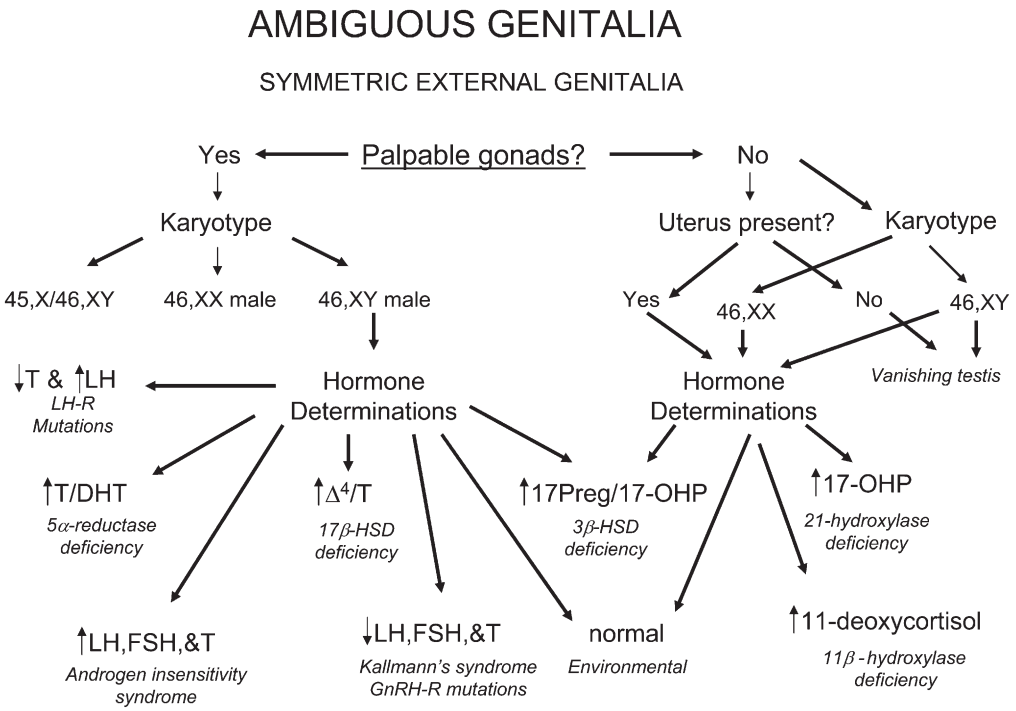

Figure 4-6. Algorithm for the approach to the child with symmetric genital ambiguity. The configuration of the labio-scrotal folds and presence/absence of palpable gonads is comparable on both sides. The presence or absence of palpable gonads directs the initial laboratory evaluation. Ultrasound examination to determine whether a uterus is present is helpful. For example, symmetric fusion of the labioscrotal folds, nonpalpable gonads, and presence of a uterus provide strong circumstantial evidence for the diagnosis of a virilized female with congenital adrenal hyperplasia.

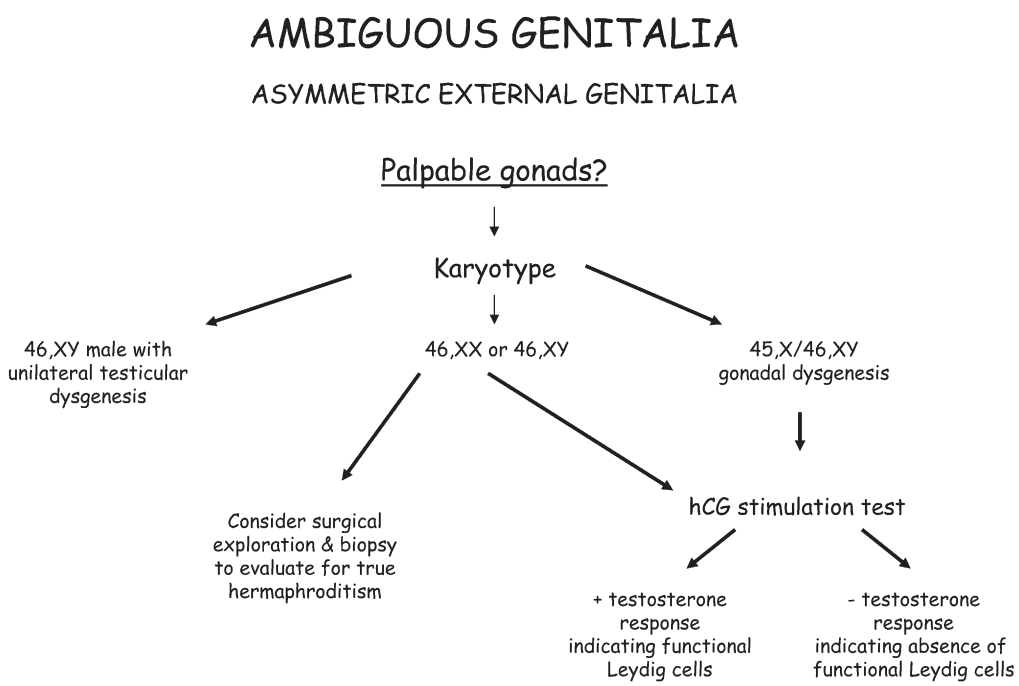

Figure 4-7. Algorithm for the approach to the child with asymmetric genital ambiguity. In this instance, the labio-scrotal folds may appear different or a gonad is palpable only on one side.

of the urinary stream should be noted. The position of the inserted catheter may also provide crucial initial information. If directed toward the anal opening and palpable under the perineal skin, the catheter is likely in a urogenital sinus—as occurs often with virilization of a 46,XX fetus secondary to 21-hydroxylase deficiency. However, a penile urethra is anticipated if the catheter is directed anteriorly and is nonpalpable.

The anogenital ratio is measured as the distance between the anus and the posterior fourchette divided by the distance between the anus and the base of the phallus. If the ratio is >0.5, this suggests a component of female differentiation and hence virilization with posterior labial fusion.[370] Because pelvic ultrasound is part of the initial laboratory assessment, a rectal examination may not be necessary. If present, a midline uterine cervix can often be palpated upon rectal exam.

The Prader scale is often used to classify the appearance of the external genitalia: (1) normal female genitalia with clitoromegaly, (2) partial labial fusion and clitoromegaly, (3) labioscrotal fusion so that there is a single opening from the urogenital sinus and clitoromegaly, (4) fusion of labioscrotal folds so that the single opening is at the base of the phallic structure, and (5) complete male virilization with penis-size phallus, complete labial fusion, and meatus on the glands. A recent description extends this traditional Prader classification to include urogenital sinus characteristics by defining the vaginal confluence in relation to the bladder neck and the meatus.[371]

In addition to the genital examination, the examination should include weight, length, and other features to ascertain whether findings are consistent with gestational age—particularly in the apparent female because the clitoris is more prominent in preterm infants in that there is scant subcutaneous fat and clitoral growth is completed before the last trimester of fetal life.[372] A careful examination includes inspection for additional dysmorphic features because genital ambiguity may occur in association with other anomalies. These include midline facial defects, head size, and ear and digital anomalies. Infants with congenital adrenal hyperplasia may manifest hyperpigmentation of the genitalia and nipples due to adrenal insufficiency and ACTH hypersecretion.

LABORATORY STUDIES

Initial laboratory studies to assess genital ambiguity should include an abdominal/pelvic ultrasound and karyotype. The ultrasound will provide information regarding the presence or absence of a uterus. Information regarding the size and location of the gonads and adrenals may be obtained on ultrasound. When gonads are not palpable, the external genitalia are symmetrically ambiguous, and a uterus and possibly ovaries are present, the most likely diagnosis is a virilized 46,XX fetus with congenital adrenal hyperplasia. However, the possibility of markedly dysgenetic testes cannot be excluded. If the differential diagnosis based on the presentation includes congenital adrenal hyperplasia, the initial laboratory studies should include electrolytes, plasma renin activity, and serum 17-hydroxyprogesterone and cortisol levels.

The karyotype is essential to determine chromosomal sex even if prenatal chromosome testing was performed. In general, peripheral blood karyotypes are sufficient. However, the patient may be a mosaic with one or more additional cell lines restricted to gonadal tissue.[373] Other initial studies depend on the physical findings. If the external genitalia are symmetrically virilized to any degree in the absence of palpable gonads, particularly if a normal

uterus is present, additional studies should be directed toward causes of virilization of a female infant. Because 21-hydroxylase deficiency is the most common cause of virilization and genital ambiguity in 46,XX infants, initial laboratory studies should include determination of 17-hydroxyprogesterone concentrations. If one or both gonads can be palpated, the intent of screening studies is to determine the adequacy of androgen synthesis and androgen action in a male infant. Determination of LH, FSH, and testosterone concentrations in infancy provides information regarding the function of the testes and the HPG axis (Table 4-4).

The pattern of steroid hormone concentrations provides evidence for specific defects in steroidogenesis (Table 4-4). The diagnosis of congenital adrenal hyperplasia due to 21-hydroxylase deficiency is confirmed by finding elevated 17-hydroxyprogesterone concentrations. Typically, 17-hydroxyprogesterone concentrations are greater than 10,000 ng/dL (300 nmol/L) in the affected neonate. For 11β-hydroxylase deficiency, 11-deoxycortisol and 17-hydroxyprogesterone concentrations are elevated. For 3β-hydroxysteroid dehydrogenase deficiency, pregnenolone, 17-hydroxypregnenolone, and DHEA concentrations are typically elevated. When salt-losing forms of congenital adrenal hyperplasia are included in the differential diagnosis, serum electrolytes and plasma renin activity should be monitored. Typically, hyponatremia and hyperkalemia are not present at birth and develop during the first week of life.

Newborn screening programs have been established in many states and countries to identify infants with classic congenital adrenal hyperplasia. Many screening programs measure whole-blood 17-hydroxyprogesterone concentrations eluted from a dried filter paper blood spot.[374] Whereas false negative 17-hydroxyprogesterone results are uncommon, slightly increased whole-blood 17-OHP concentrations are detected often enough (especially in preterm infants) to complicate clinical decision making regarding affected status and need to initiate glucocorticoid therapy. Etiologies of slightly increased 17-OHP concentrations include prematurity, cross-reacting steroids, sampling prior to 36 hours of age, heterozygosity for 21-hydroxylase deficiency, and late-onset congenital adrenal hyperplasia.

To avoid an excessive number of false positive screening results, the cutoff levels are typically selected to identify all infants with classic salt-losing or simple virilizing forms—often missing those infants with late-onset congenital adrenal hyperplasia. Improved specificity can be achieved by use of additional procedures such as organic extraction, chromatography, or GC/MS analysis. Prenatal or neonatal treatment with glucocorticoids can result in a false negative screening result.[375] If the differential diagnosis includes CAH, specific laboratory testing is warranted even if the newborn screen results are reported as negative for 21-hydroxylase deficiency.

For the milder forms of congenital adrenal hyperplasia, ACTH stimulation testing may be necessary to confirm the diagnosis. After a basal blood sample has been drawn, synthetic ACTH (0.25 mg) can be administered by intravenous bolus or intramuscular injection. A second blood sample to measure ACTH-stimulated hormone response can be obtained 30 or 60 minutes later. The milder forms of congenital adrenal hyperplasia generally do not affect external genital differentiation and are therefore not usually associated with genital ambiguity. Infants with late-onset congenital adrenal hyperplasia are generally not detected through newborn screening programs, presumably because the whole-blood 17-OHP concentrations determined from the newborn screening filter paper are lower than the values used as cutoffs.

In addition to the diagnostic evaluation for disorders of steroidogenesis, hormone measurements in the immediate neonatal period provide an index to the function of

TABLE 4-4

Normal Values (Mean and SD) for Full-Term and Preterm Infants from 2 Hours to 7 Days of Postnatal Life.

	2 Hours		24 Hours		4 Days		7 Days

PT = preterm (*n* = 8), FT = full-term (*n* = 12).

Data from Sippel et al. (1980). Plasma levels of aldosterone, corticosterone, 11-deoxycorticosterone, progesterone, 17-hydroxyprogesterone, cortisol, and cortisone during infancy and childhood. Pediatr Res 14:39; and from Doerr et al. (1988). Plasma mineralcorticoids, and progesterins in premature infants: Longitudinal study during the first week of life. Pediatr Res 23:525.

the HPG axis. Low testosterone and elevated gonadotropin concentrations in a 46,XY infant with ambiguous genitalia suggest inadequate testosterone biosynthesis. Elevated testosterone and gonadotropin concentrations in an infant with female external genitalia, bilateral labial masses, and 46,XY karyotype are consistent with the diagnosis of androgen insensitivity (Table 4-5).

Measurement of AMH may provide another assessment of testicular function because AMH concentrations reflect Sertoli cell function. AMH concentrations are sexually dimorphic, with high values in boys (20–80 ng/mL) during the first six years of life and low values in girls.[376] Thus, in the patient with nonpalpable gonads and absence of Mullerian structures AMH concentrations may help distinguish between anorchia and cryptorchidism.[377] In addition, AMH concentrations can be helpful in disorders of testicular dysgenesis or in virilized females to determine the presence of testicular tissue.[378] Inhibin B concentrations, lower in females than in males, provide another marker of Sertoli cell function.[379]

Assessment of the ability of a gonad to secrete testosterone may be helpful, especially for patients with evidence of testicular tissue by palpation or ultrasound and AMH levels indicating testicular tissue. This can be done by administering hCG and measuring hormone responses. To assess hormone responses, doses of 1,000 to 1,500 units can be injected subcutaneously either daily or every other day for one to five days—with blood sampling on the day after the last injection. Hormone determinations should include androstenedione, testosterone, and dihydrotestosterone.[380] Testosterone concentrations should more than double, and the T/DHT ratio should be <10:1. Intermittent injections can be given for up to three weeks to stimulate penile growth to demonstrate both testosterone secretion and target tissue responsiveness. Total dosage should not exceed 15,000 units of hCG.

Normative data for the steroidogenic response of mineralocorticoids and their precursors to adrenocorticotropin in a healthy pediatric population. J Clin Endocrinol Metab 75:1491.

Molecular genetic analyses have become increasingly available to determine and confirm the molecular basis of the genital ambiguity. Knowledge regarding the specific mutation enables more accurate genetic counseling for inherited disorders of sexual differentiation. The genetics laboratory can often perform fluorescent in situ hybridization (FISH), for the SRY gene, or other detailed chromosomal tests. For some DSDs, molecular genetic analysis of specific genes is available through commercial laboratories. Information regarding the particular details can be obtained from an NIH-funded web-based resource, Genetests *(http://www.genetests.com)*. In some instances, genetic testing is available through research laboratories.

Endoscopic studies can be used to locate the vaginal-urethral confluence in relation to the bladder neck and the single opening of the urogenital sinus. Using a cystoscope and catheter placement, these distances can be determined before or in conjunction with retrograde contrast studies performed to outline the urethra and to demonstrate (if present) the vagina, uterus, cervix, and uterine cavity. Such information is needed to plan for reconstructive surgery, to assess the risk of medical complications, and in certain instances to provide information to determine the sex of rearing. If such procedures are unhelpful, laparoscopy may be necessary to visualize and biopsy gonadal and internal genital structures. MRI may be helpful to define anatomic relationships.

Treatment

While awaiting results of the initial laboratory studies, attention is focused on the main decision: the gender of rearing. In the ideal situation, there is a specific DSD team comprised of a pediatric surgeon or pediatric urologist with expertise in urogenital reconstructive surgery, a behavioral science professional (psychologist, social worker, or psychiatrist), a pediatric endocrinologist, and a neonatalogist. Initially, the neonatalogist may facilitate coordination of care and communication with the parents. Long-term management needs to be delineated. In addition to the appointments necessary to the patient's medical, surgical, and psychological needs, additional sessions may benefit the parents to address their questions and concerns about their child.[381] These evaluations should be performed promptly and often necessitate transfer of the infant to a tertiary care facility.

The parents need to participate in discussions and decision making regarding the options for sex of rearing and possible surgical interventions. Honest, sensitive, and candid discussions with the parents can only benefit the child. As the child matures, honest explanations regarding the medical condition are essential. The child should progress from a silent partner to a full participating member in this decision-making process, with the child's wishes taking precedence where appropriate.

Once the diagnosis is confirmed as specifically as possible, therapy is instituted. When a specific diagnosis has been confirmed, decision making and therapy can be guided accordingly. Considerations for medical care

include sex of rearing, possible need for surgery and a timeline for planned surgery, plan for medical treatment, and timely and appropriate psychological counseling and support.

SEX OF REARING

Decisions regarding the appropriate sex of rearing are based on the specific pathophysiology, prognosis for spontaneous pubertal development, capacity for sexual activity and orgasm, and potential for fertility.[382] With the use of assisted techniques, the potential for fertility is more likely than in the past. Although current surgical techniques spare more of the neurovascular bundle of the phallus, surgery should be avoided except in those instances of severe ambiguity or markedly discordant genitalia to preserve sexual responsiveness.

In instances where a decision regarding sex of rearing is necessary, each child evaluated for genital ambiguity warrants careful consideration of the physical findings, laboratory information, and available outcome data. In most instances, children are raised in the gender consistent with the karyotype—acknowledging that there are rare exceptions of sex reversal. Limited longitudinal outcome studies are available regarding adult function and gender identity. Virtually all 46,XY CAIS patients identify themselves as female.

About a quarter of PAIS patients are dissatisfied with the gender assignment, regardless of whether they are raised as male or female. The majority of patients with 5α-reductase deficiency identify as male, whereas about half of those diagnosed with 17β-hydroxysteroid dehydrogenase self-reassign from female to male.[383,384] The majority of virilized 46,XX individuals with CAH identify as female. Of the few estrogen-deficient males identified, all are heterosexual and report normal libido and sexual function.[385] Thus, in spite of the accumulating evidence that androgen exposure to the CNS alters general and cognitive behavior much remains to be learned about the influences of nature and nurture on gender identity.[386]

Because the majority of 46,XX virilized females (primarily those with CAH) identify as female, this sex of rearing is usually recommended if the question arises in infancy. For virilized 46,XX patients with Prader stage 4 or 5 genitalia, the recent consensus conference felt that the outcome data was insufficient to support a sex of rearing as male despite the anecdotal data suggesting good adjustment when this has occurred with late diagnosis of CAH. For virilized females with CAH, the primary issue is not gender assignment but questions regarding genital surgery.

To date, more information and knowledge is available about physical sexual development than about psychosexual cognitive development. The primary factors, critical steps, and sequence of psychosexual development are unclear. Traditionally, psychosexual development has been viewed as having three components: gender identity, gender role, and sexual orientation. The development of gender identity begins as an infant with the self-recognition that one is a boy or girl. Gender role develops during childhood as a result of society's expectations concerning behavior and is influenced by prenatal hormonal exposure.

Gender roles are defined in part by the messages society relays concerning appropriate and inappropriate male and female behavior. Gender role may subsequently shift, depending on the individual's reaction to the expectations of society. How prenatal factors such as hormones and environmental exposures impact gender role has been difficult to ascertain. Sexual orientation may be apparent prior to puberty or not expressed until late in adult life, underlying the unknown influencing factors.

The effects of prenatal androgen exposure on gender identity are uncertain.[387,388] Prenatal androgen levels apparently influence gender-related behavior and cognitive function during childhood.[387] Yet, the impact on degrees of femininity and masculinity and cognitive function (spatial and verbal abilities) and handedness does not appear to persist into adult life.[389,390] Data obtained from some studies of the 46,XX CAH patient suggest that prenatal androgen exposure may be associated with reduced satisfaction with a female sex assignment.[391] Among virilized 46,XX individuals with CAH, an increased rate of homosexual orientation has been reported—primarily based on self-reported sexual imagery and sexual attraction, with reports of actual homosexual involvement being less well documented.[392-394]

Some females with classic CAH are more likely to question their female gender,[395] and the reported incidence of sex reassignment from female to male is greater than in the general population.[396] Among 46,XX CAH patients with gender self-reassignment, it was judged that factors contributing to this change were not genotype or phenotype but gender-atypical behavioral self-image and body image and development of erotic attraction to women.[397] Other studies concluded that psychological adjustment was comparable between females with CAH and their unaffected siblings.[398] In another study, gender identity of girls with CAH was comparable to the control group.[399] In these studies, the impact of environmental influences cannot be separated from the effects of prenatal hormonal exposures.

Female gender of rearing is appropriate for 46,XY individuals with complete androgen insensitivity because virilization and fertility are unattainable. The lack of androgen responsiveness limits androgen effect on the developing CNS of individuals with CAIS. Conversely, the decision regarding gender of rearing for individuals with partial androgen insensitivity may be problematic because the extent of androgen impact on CNS development and the androgen responsiveness of the genital development are uncertain. The clinical response to exogenous testosterone may benefit this decision-making process. Testosterone responsiveness may be ascertained by assessing penile growth following one or more intramuscular injections of 25-mg testosterone depot formulations.

Among individuals with DSD associated with gonadal dysgenesis, hCG-stimulated testosterone secretion and clinical response facilitates the decision regarding gender of rearing. The genital phenotype, ability of the Leydig cell to secrete testosterone, and extent of genital virilization in response to androgen stimulation are indicators regarding the potential for spontaneous pubertal development and need for hormone replacement therapy. Nevertheless, in gonadal dysgenesis the impact of prenatal

androgen exposure on gender development processes is often indeterminate and cannot be reliably predicted from routine diagnostic studies in the newborn period.

Generally, with the exception of CAIS, 46,XY individuals with fetal androgen exposure manifested as partial genital masculinization should be raised as males unless there are extenuating individual circumstances. Caution, reflection, and dialog are appropriate before those with a 46,XY, karyotype are assigned female because fetal androgen exposure appears to impact strongly on self-concept as male despite compromised external genital development.

CONSIDERATIONS WITH REGARD TO SURGERY

For the virilized female patient with female sex of rearing, the extent of ambiguity in combination with the magnitude of clitoromegaly and posterior fusion must be carefully evaluated to determine whether genitoplasty, including clitoral reduction or clitoroplasty, should be considered. Another factor in the decision-making process is the location of the urethral outlet. If located high in the urogenital sinus, early surgery may be indicated to decrease the risk of recurrent urinary tract infections by providing a direct urinary outflow path. The current perspective is that girls with mild to moderate degrees of clitoromegaly do not need surgery because of the potential risk of compromising genital sensitivity.

One important point to share with parents of a virilized girl with CAH is that the stimulated genital tissues will regress after glucocorticoid therapy is begun. On one hand, the parents need to be informed that some (including patient advocacy) groups discourage genital surgery until the child is old enough to make her own decision. On the other hand, they must be empowered to make the choice with which they will be comfortable. This must be done with the understanding that their daughter may criticize them for this decision when she is older. Most parents of daughters with severe ambiguity still choose surgery.[400]

If there is agreement between the interdisciplinary medical team and the parents for surgery, the surgery is generally performed as soon as feasible. If surgery is anticipated, the operation should be described in a manner understandable to the parents. An experienced surgeon should discuss the options, risks, and benefits of surgery—including the innervation of the clitoris or penis and the surgical approach to be used to attempt to spare the neurovascular supply.[401,402] Although opinions vary as to whether surgery should be done in one or more stages and whether vaginal reconstruction should be attempted during infancy, the parents need to be informed that subsequent vaginoplasty is almost always required after puberty. Among patients who underwent vaginal reconstructive surgery during infancy, the frequency of postoperative vaginal stenosis has been reported to range from 0% to 77%.[403] Therapeutic goals for vaginal reconstruction surgery include adequate sexual function with minimal need for continual dilatation or lubrication.[404]

For the under-virilized male, decisions concerning genital surgery and when it occurs belong to the parents until the patient reaches adolescence and adulthood. Most decide for surgery, except in the instances of minimal to moderate hypospadias. When discussing surgery with the parents, pertinent topics include common male concerns about the importance of being able to stand to urinate, adequacy of genital development, and capability of sexual activities. Because correction of hypospadias and chordee is generally performed in stages, this discussion also needs to cover the details of the surgical approach, the proposed schedule for follow-up visits, the likely number of surgical procedures, and the optimal age for each surgical stage. The surgeon should review the options, risks, and anticipated outcomes. If the precise location and differentiation status of the testes are unknown, the parents should be aware that exploration and biopsy may be performed.

Another consideration regarding the need for and timing of surgery is the relative risk for gonadal tumors. The aberrant fetal gonadal environment and subsequent anomalous germ cell differentiation is associated with the development of germ cell tumors. In general, CIS or gonadoblastoma are the most common germ cell tumors and precede the development of the more invasive neoplasms such as dysgerminoma, seminoma, and nonseminoma. The presence of Y chromosome material increases the propensity risk for gonadal tumors.[405] Increased and prolonged expression of immunohistochemical markers, OCT3/4 and testis-specific protein Y-encoded (TSPY), is common in CIS and gonadoblastoma.[406] In one series, TSPY was abundantly expressed in germ cells within dysgenetic testes and undifferentiated gonadal tissue—suggesting up-regulation when germ cells are located in an unfavorable environment.[406] It is hypothesized that the normal germ cell maturation process is interrupted, resulting in prolonged expression of OCT3/4, erased genomic imprinting, and subsequent immortalization of the cell.[407]

The reported prevalence of gonadoblastoma ranges from 15% to 30%, depending on age of the patient, gonadal histology, and diagnostic criteria used for CIS/gonadoblastoma. In one series of patients with Turner syndrome, 14/171 (8%) were positive for Y-chromosomal material. Among these 14 patients, the prevalence of gonadoblastoma was 33%.[408] A meta-analysis of 11 studies, all using PCR methodology, found that 5% of patients with Turner syndrome showed positive results for Y chromosome material.[407]

Frasier syndrome is also associated with gonadoblastoma. The prevalence of germ cell tumors is lower in androgen insensitivity and disorders of androgen biosynthesis. Nevertheless, limited sample size, ascertainment bias, inconsistent diagnostic criteria for malignant cells, and confusing terminology leave many questions to be answered. For example, which patients with DSD benefit from gonadal biopsy to assess risk for neoplasia? Another consideration is how many biopsies are necessary to be representative of the histology of the gonad. Laparoscopy and video-assisted gonadectomy are invaluable techniques when the risk for malignancy is high. Ultimately, the decision regarding gonadectomy involves consideration of the patient's phenotype (internal and external genital anatomy), karyotype, gender of rearing, psychosocial factors, and gonadal histology.

MEDICAL TREATMENT

With the exception of disorders affecting glucocorticoid and mineralocorticoid biosynthesis, most DSD conditions do not require specific medical therapy in infancy. At the time of expected puberty, patients with hypogonadism will need appropriate hormone replacement therapy. In general, hormone replacement therapy is initiated using low doses of the appropriate sex steroid hormone—with incremental increases designed to mirror spontaneous pubertal development. It is helpful to review with families the anticipated frequency of outpatient visits and how the adequacy of replacement therapy will be assessed.

For females, induction of puberty involves low-dose estrogen therapy—usually initiated between 10.5 to 12 years of age to avoid excessive acceleration of skeletal maturation. The initial estrogen dosage is usually the lowest available, such as 0.3 mg of conjugated estrogens every other day, 5 ug of ethinyl estradiol daily, or transdermal estrogen preparations (0.025 mg) weekly. Transdermal patches may be used only at night in an effort to mimic spontaneous puberty.[409] Matrix transdermal patches can also be cut into smaller pieces to provide a lower estrogen dosage. Based on clinical response and the patient's perception, the dose of estrogen can be increased in 6- to 12-month intervals such that complete replacement doses and development are achieved within 3 years.

Therapy involves the addition of a progestational agent after 12 months of estrogen therapy or when withdrawal bleeding occurs, whichever occurs sooner. Thereafter, cyclic estrogen-progesterone therapy should be used. Once full pubertal development has been reached, the estrogen dosage should be the minimum that will maintain normal menstrual flow and prevent calcium bone loss (equivalent to 0.625 conjugated estrogen or 20 ug ethinyl estradiol). Options for cyclic estrogen-progesterone therapy include low-dosage estrogen birth control pills or estrogen-progesten transdermal patches.

Another regimen involves a daily oral estrogen regimen or the transdermal form for 21 days—with the addition of progesterone, 5 to 10 mg of medroxyprogesterone acetate, or 200 to 400 mg of micronized progesterone daily added for 12 days (day 10 to day 21). This is followed by a week of no hormones. At this point, the replacement regimen may be extended so that less frequent withdrawal bleeding occurs. In the absence of a uterus, progesterone therapy becomes optional. Among patients with low circulating androgen levels, sexual hair growth and libido may be improved by administering small doses of DHEA or methyltestosterone. Gonadotropins hCG and/or hMG (human menopausal gonadotropin/recombinant FSH) are only used to stimulate ovulation or during assisted fertility attempts.

For males, testosterone hormone replacement typically begins at 12.5 to 14 years. In instances where the psychological impact is felt to be needed, therapy may be initiated one or two years earlier. If therapy is begun earlier to assure the patient concerning physical changes, the rate of skeletal maturation should be carefully monitored. Conversely, treatment may be delayed to allow for psychological or emotional maturity or catch-up growth. Testosterone therapy may be given by depot intramuscular injections or topically by a patch or gel. Depot testosterone (such as enanthate or cyprionate) is begun at a dosage 50 mg IM every four weeks, followed by increased dosing and frequency over about 3 years to a full replacement dosage of approximately 200 mg every 2 weeks. Availability of the gel in metered-dose pumps allows gradual increases of dosage from 1.25 g daily upward. Among those with differentiated testes and gonadotropin deficiency, assisted fertility techniques may involve intratesticular germ cell retrieval or hFSH/hLH stimulation.

For patients with CAH, carefully monitored hormone replacement therapy is essential. The goal of glucocorticoid therapy is suppression of excessive adrenal androgen secretion while maintaining normal growth and development. Typically, oral cortisol doses range from 8 to 20 mg/m^2/day. This range is based on provision of 1.5 to 2 times the daily cortisol production rate, 7 to 12 mg/m^2/day. Oral fludrocortisone (e.g., Florinef) is commonly used for mineralocorticoid replacement for patients with salt-losing CAH. Patients with simple virilizing CAH may benefit from mineralocorticoid replacement. The typical dose is 0.1 mg administered as a single daily dose. Neonates and infants may require higher fludrocortisone doses as well as salt supplementation because of relative mineralocorticoid resistance, higher aldosterone production rates, and relatively lower sodium intakes. Topics of discussion with parents include how to crush and administer tablets, what to do if doses are accidentally missed, and when to administer "stress" dosages.

For children with CAH, adequacy of replacement therapy is monitored by periodic reassessment of growth velocity, extent of virilization, and salt craving. Laboratory monitoring may include serum androgen and 17-OHP concentrations, skeletal maturation, and 24-hour urinary 17-ketosteroid excretion. Androstenedione concentrations are useful to assess adequacy of glucocorticoid replacement, whereas 17-hydroxyprogesterone concentrations are useful to assess for overtreatment. Determination of testosterone concentrations is helpful in girls and prepubertal boys. In pubertal and postpubertal girls, menstrual cyclicity is a sensitive indicator of hormone replacement therapy. Adequacy of mineralocorticoid replacement can be judged using plasma renin activity.

At times of physiological stress (such as fever greater than 101° F, persistent vomiting, significant trauma, and surgical procedures), the glucocorticoid dose should be increased. In general, two to three times the usual dose is sufficient to prevent adrenal insufficiency. Higher doses may be necessary for surgical procedures. All families should have at home and be able to administer injectable hydrocortisone (e.g., Solu-Cortef) intramuscularly in case of medical emergencies. Recommended intramuscular doses are 25 mg for infants, 50 mg for children less than 4 years of age, and 100 mg for all others.

During surgical procedures, additional hydrocortisone can be administered either as continuous intravenous infusion or intramuscular injection. Intravenous normal saline (0.9% NaCl) can be used if oral mineralocorticoid replacement is not tolerated by the patient. While receiving glucocorticoid replacement therapy (and occasionally in the newborn period), physiologically stressed individuals with

11β-hydroxylase deficiency may develop hyponatremia and hyperkalemia and benefit from mineralocorticoid therapy.

PSYCHOLOGICAL AND GENETIC COUNSELING AND SUPPORT

Longitudinal continuity of care and provision for support systems are essential because of the medical and psychological aspects of DSDs. If an experienced social worker, psychologist, or psychiatrist is available, careful assessment and counseling are valuable throughout childhood and adolescence. Although most such cases of 46,XY DSD do not require medical therapy during childhood, clinical visits with an endocrinologist are helpful intermittently to address the patient's and parents' concerns, update parents concerning new therapy and outcome data, and ensure that appropriate psychological support needs are being addressed. Some parents may find disorder-specific support groups (e.g., AIS, *www.aissg.org*; CAH, *www.caresfoundation.org*; Turner syndrome, *www.turnersyndrome.org*) to be helpful.

Many DSD conditions are inherited. The most common inheritance patterns are autosomal recessive or X-linked traits. Genetic counseling is indicated because parents are often interested to learn about recurrence risks. Because phenotypic heterogeneity occurs in some DSD disorders (i.e., partial androgen insensitivity), hormone determinations and genetic analyses (when available) for other family members may be beneficial.

Conclusions

Identification of genes involved in sexual differentiation has elucidated some of the molecular events responsible for normal and abnormal sexual differentiation. Knowledge of the genetic, hormonal, and environmental factors that influence sexual differentiation benefits the affected children, their parents, and their health care providers. This information enables better parental education regarding the etiology, natural history, and prognosis for their child. With understanding of factors that affect sexual differentiation, recurrence risks can be estimated. Despite the advances in characterizing the molecular basis of ambiguous genitalia, the most important consideration in the management of an infant with genital ambiguity remains the sensitivity and compassion demonstrated by health care professionals in their interactions with the family.

Diagnosis

Treatment

Conclusions

Introduction

One of the most important genetic and metabolic events that marks the transition from fetal to neonatal life is the adaptation from an environment that has a readily available and continuous source of glucose-maternal blood-to an environment in which glucose is provided in a limited and intermittent supply. The complex events involved in the maintenance of plasma glucose concentration must coordinate in their operation to avoid hypoglycemia and resultant damage to the central nervous system. A newborn or infant with hypoglycemia presents an urgent diagnostic and therapeutic challenge. The clinical features must be rapidly assessed and a plan of action developed based on the infant's age, maternal and parturition history, severity and persistence of hypoglycemic state, and all other relevant clinical clues.

PHYSIOLOGY OF PERINATAL GLUCOSE HOMEOSTASIS

A systematic approach to hypoglycemia in the newborn, infant, or child requires an appreciation of the central role of glucose in the body's fuel economy.[1] Glucose metabolism accounts for approximately half of basal daily energy needs. Glucose can be stored for energy in the form of glycogen and fat, and its carbon can be used for synthesis of protein and for structural components (such as cell membranes). The aerobic oxidation of glucose yields high energy by producing 38 mol of adenosine triphosphate (ATP) for each mole of glucose. Glucose is the principal metabolic fuel of the human brain.

All glucose extracted by the brain is oxidized, and thus cerebral glucose utilization parallels cerebral oxygen uptake. In infants of 5 weeks of age, cerebral glucose utilization already represents 71% to 93% of the adult level in most brain regions (ranging from 13 to 25 μmol/100g/min). At that age, the areas with highest metabolic rates for glucose are the sensorimotor cortex, thalamus, midbrain, brain stem, and cerebellar vermis. By 3 months, metabolic rates for glucose increase in the parietal, temporal, and occipital cortices, as well as in basal ganglia.

By 8 months, subsequent increases occur in the frontal cortex and various associative regions, concordant with the appearance of higher cortical and cognitive functions. Adult levels of cerebral glucose utilization (19 to 33 μmol/100g/min) are reached by 2 years of age, and continue to increase until 3 to 4 years of age—when they reach values ranging from 49 to 65 μmol/100g/min that are maintained to approximately 9 years of age. They then begin to decline, reaching adult levels by the end of the second decade.[2] Glucose uptake by the brain occurs by means of a carrier-mediated facilitated diffusion process that is glucose concentration dependent, as well as energy-, Na^+-, and insulin-independent.[3]

This process is mediated by facilitative glucose transporter (GLUT) proteins. The human genome contains 14 members of the GLUT family. Characterization of the different members has provided new insights into the regulation and significance of glucose transport and its disorders in various tissues[3-5] (Table 5-1). Several members of the GLUT family have been detected in the brain. GLUT1 is located at the blood-brain barrier,[6] and although some neurons express GLUT2 and GLUT4 the majority use GLUT3 as their primary transporter.[7]

Of major importance is the confirmation at a molecular level of biochemical evidence that glucose entry into brain cells and its subsequent metabolism are not dependent on insulin but rather are dependent on circulating arterial glucose concentration.[8] Therefore, a decrease in arterial glucose concentration or a defect in the glucose transport mechanism of the brain will result in intracerebral glucopenia and low cerebrospinal fluid glucose concentration (hypoglycorrhachia)—with attendant symptoms and signs of cerebral glucopenia as subsequently described.[8-10]

To prevent circulating arterial blood glucose from decreasing precipitously under normal physiologic conditions, and therefore to prevent impairment of vital function that depends on cerebral glucose metabolism, an elaborate defense mechanism has evolved.[1] This defense against hypoglycemia is integrated by the autonomic nervous system and by hormones that act synergistically to enhance glucose production through enzymatic modulation of glycogenolysis and gluconeogenesis while simultaneously limiting peripheral glucose use.[11,12] Thus, hypoglycemia is the result of a defect in one or several of the complex interactions that maintain a normal range of glucose concentration, preventing its fall to less than 70 mg/dL during fasting and its rise to more than 140 mg/dL during feeding.

These mechanisms are not fully developed in neonates, in whom there is an abrupt transition from intrauterine life (characterized by dependence on transplacental glucose supply) to extrauterine life (characterized ultimately by the autonomous ability to maintain precise glucose balance).[13] A neonate delivered prematurely whose enzymatic machinery mechanisms are not yet fully developed and expressed or one whose placental insufficiency resulted in intrauterine growth retardation with limited tissue nutrient deposits may be particularly vulnerable to hypoglycemia,[14] often with consequences to subsequent cerebral development or function.[15,16] Genetically determined defects in enzyme function or hormones are also relatively common,[17] and therefore hypoglycemia is an important cause of morbidity in the newborn period.[18] The key element in the transition to extrauterine life is separation from the placenta and the adaptations that follow.[13,19]

INTEGRATION OF GLUCOSE HOMEOSTASIS IN THE FETUS: SUBSTRATES, ENZYMES, HORMONES, AND RECEPTORS

Under normal nonstressed conditions, fetal glucose is derived entirely from the mother through placental transfer.[20,21] In humans, the evidence remains indirect in that infusion of stable nonradioactive glucose isotopes to steady-state-specific activity in the mother during labor yields an indistinguishable glucose specific activity in fetal arterial blood at birth.[22] This indicates that maternal and fetal glucose concentrations behave as a single pool, with no endogenous glucose production in the fetus.

TABLE 5-1

Characterization of Glucose Transporters

Subfamily	Name	Tissue Distribution	Glucose Transport Activity	Location of Human Gene	Regulation by Insulin
Class I	GLUT1	Erythrocytes, brain (blood-brain barrier), placenta	Erythrocyte:asymmetric carrier with exchange acceleration; K_m~5-30mmol/L (variable):Vmax (influx) < Vmax (efflux)	1p35-p31.3	Zero to minimal
	GLUT2	Liver, islet cells, kidney, small intestine	Low-affinity. Liver:simple, symmetric carrier; K_m~60mmol/L;intestine: asymmetric carrier: Vmax (efflux) < Vmax (influx)	3q26.1-q26.2	Zero to minimal
	GLUT3	Brain (neuronal), testis, placenta	High-affinity. Exchange K_m~10mmol/L	12p13.3	Zero
	GLUT4	Adipocytes, muscle	High-affinity. Adipocyte:simple, symmetric carrier; K_m~2-5mmol/L	17p13	Dependent on insulin
	GLUT14	Testis	?	12p13.31	?
Class II	GLUT5	Testis, small intestine, kidney	No glucose transport activity, fructose transporter	1p36.2	?
	GLUT7	Small intestine (enterocytes brush border membrane), colon, testis, prostate	High-affinity transport for glucose (K_m=0.3mM)	1p36.2	?
	GLUT9	Liver, kidney. Expressed at preimplantation stage in mouse	Proven glucose transport activity	4p16-p15.3	?
	GLUT11	Pancreas, kidney, placenta, heart, skeletal muscle	Low affinity for glucose (possible fructose transporter)	22q11.2	Mediates insulin-stimulated glucose uptake in embryos
Class III	GLUT6	Brain, spleen, leukocytes	Low affinity for glucose	9q34	?
	GLUT8	Testis, brain (neuronal), adipocytes, preimplantation embryos	High-affinity glucose transporter (possible multifunctional transporter)	9q33.3	?
	GLUT10	Liver, pancreas	Glucose transport activity with K_m~3mmol/L	20q13.1-q12	?
	GLUT12	Heart, prostate, breast cancer	Proven glucose transporter activity	6q23.2	?
	GLUT13 (HMIT)	Brain	No glucose transport activity, myo-inositol and related isomers transporter	12q12	?

There are important clinical consequences implicit in these findings. For example, acute hypoglycemia in a mother with diabetes will result in acute hypoglycemia in the fetus—with no ability to acutely compensate for the abrupt reduction in blood glucose supply.

The transfer of glucose across the placenta to the fetus occurs by facilitated diffusion along a concentration gradient. GLUT1 has been identified as the major isoform in the human placenta,[23] although other members of the family are expressed. Of note is the fact that the placental GLUTs are not regulated by insulin, suggesting that maternal glucose concentration and (more specifically) the maternal-fetal glucose gradient is the major determinant of placental glucose transfer independent of the maternal insulin concentration perfusing the placenta.[24,25]

Observations in infants with mutations of glucokinase, the glucose sensor of pancreatic beta cells, indicate that the physiologic "set point" for plasma glucose in the fetus is identical to that of older children and adults. Fetal glucose metabolism depends directly on simultaneous effects of fetal plasma glucose and insulin concentrations, which in experiments in near-term sheep have been shown to act additively to enhance fetal glucose utilization and oxidation to CO_2 according to saturation kinetics. The relative proportion of glucose oxidized in short-term studies does not change significantly over the physiologic range of fetal glucose utilization rates, indicating little effect of glucose or insulin on intracellular pathways of glucose metabolism.[26]

Although basal plasma concentrations of insulin and glucagon in the fetus are similar to those in the mother, their regulation differs. Acute hypoglycemia or hyperglycemia does not markedly affect fetal insulin or glucagon secretion. Long-term exposure to hyperglycemia is required

to augment insulin secretion and promote glucagon suppression.[27,28] Conversely, chronic starvation of the mother will depress maternal and fetal glucose concentrations and cause diminished insulin but greater glucagon release in the fetus. This sluggishness of intrauterine pancreatic hormone secretion is in part related to immaturity of the cyclic adenosine monophosphate (AMP)-generating system, which occasionally extends into the newborn period.[28]

Studies in animals, principally in fetal sheep, indicate that a proportion of glucose used is oxidized and the remainder is used for tissue accretion.[29] Hyperinsulinemia in the fetus increases total glucose use, whereas the proportions used for oxidation and tissue accretion remain constant.[29] A large proportion of glucose use appears to be relatively independent of insulin and is markedly glucose concentration dependent.[30] Likewise, glucagon in physiologic doses does not increase fetal hepatic glucose output—and pharmacologic doses are required to demonstrate an effect.[31,32] In contrast to glucagon, at relatively physiologic concentrations catecholamines mobilize fetal glucose and free fatty acids by adrenergic mechanisms—reflecting the existence of functionally linked adrenergic receptors in fetal liver and adipose tissues.[33] In addition, in high doses catecholamines can exert appropriate modulation of fetal pancreatic hormone secretion by inhibiting insulin and stimulating glucagon release.[34,35]

CHANGES AT BIRTH

The acute interruption of maternal glucose transfer to the fetus at delivery imposes an immediate need to mobilize endogenous glucose. At least three related events facilitate this transition: changes in hormones, changes in their receptors, and changes in key enzyme activity. In all mammalian species, there is a threefold to fivefold abrupt increase in glucagon concentration within minutes to hours of birth.[19] Insulin, on the other hand, usually falls initially and remains in the basal range for several days without demonstrating the usual brisk response to physiologic stimuli such as glucose.

A dramatic surge in spontaneous catecholamine secretion is also characteristic of several mammalian species.[35] These changes in epinephrine, glucagon, and insulin may be interrelated because epinephrine is capable of stimulating glucagon and suppressing insulin release.[35] In addition, epinephrine can augment growth hormone secretion by α-adrenergic mechanisms—and growth hormone levels are considerably elevated at birth.

Acting synergistically, these hormonal changes at birth (characterized by high epinephrine, high glucagon, high growth hormone, and low insulin levels) would be expected to mobilize glucose through glycogenolysis and gluconeogenesis to activate lipolysis and promote ketogenesis.[1] This appears to be true because after birth in the human newborn the plasma glucose concentration declines, reaching a nadir by 1 hour of age and then rising spontaneously to plateau levels reached between 2 and 4 hours.[36] Liver glycogen stores become rapidly depleted within hours of birth, and gluconeogenesis from alanine (a major gluconeogenic amino acid) can account for approximately 10% of glucose turnover in the human newborn within several hours of age.[37] Free fatty acid concentrations also rise sharply in concert with the surges in glucagon and epinephrine and are followed later by an increase in ketone bodies. In this way, glucose can be spared for brain use—whereas free fatty acids and ketones provide alternative fuel sources for muscle and provide essential gluconeogenic cofactors such as acetyl-CoA and NADH from the hepatic fatty oxidation required to drive gluconeogenesis.[38]

In the early postnatal period, responses of the endocrine pancreas favor glucagon secretion at the relative expense of insulin secretion—perhaps because there is little need for acute insulin responses (AIRs) and so that blood glucose concentration can be protected. In the fetus, the high insulin receptor number tends to facilitate anabolic processes and growth while limiting gluconeogenesis—whereas a low glucagon receptor number (with incomplete functional linkage to cyclic AMP) further limits catabolic events in utero. In contrast, in the newborn there is a fall in insulin receptor number associated with a fall in insulin at a time when glucagon secretion rises abruptly and glucagon receptors become functional.

These coordinate changes serve to mobilize glucose and other fuel stores after the interruption of the maternal supply. The surge in epinephrine secretion and its coupling with appropriate receptors also augment glucose production and lipolysis. Key enzymes involved in glucose production change dramatically in the perinatal period. Thus, there is a rapid fall in glycogen synthase activity—whereas that of phosphorylase rises sharply after delivery.[14,39-41] The rate-limiting enzyme for gluconeogenesis, phosphoenolpyruvate carboxykinase (PEPCK), rises dramatically after birth—activated in part by the surge in glucagon and fall in insulin.[42] This framework is consistent with the insulin and with other hormonal and enzyme responses to acute hypoglycemia in the adult.[1] Failure of these changes to occur may lead to failure of extrauterine autonomy in newborn glucose metabolism.

HORMONAL AND METABOLIC SYSTEMS OF FASTING ADAPTATION

Hypoglycemia in neonates, infants, and children is essentially always a problem with fasting adaptation. Postprandial (reactive) hypoglycemia is exceedingly rare and is limited to a few unusual situations, such as postprandial hypoglycemia after Nissen fundoplication or hereditary fructose intolerance. Therefore, a consideration of the major hormonal and metabolic pathways that maintain fuel homeostasis during fasting provides an important framework for understanding the causes, diagnosis, and treatment of different forms of hypoglycemia.

The physiology of fasting homeostasis in infants is identical to that of adults, although the timing of adaptation is faster owing to the greater metabolic demands of infants and children. Table 5-2 outlines the sources of potential fasting fuels in an adult man with a metabolic rate of 1,800 kcal/day.[43] Note that hepatic glycogenolysis is sufficient to meet energy requirements for only a few hours. Beyond that time, glucose must be produced by hepatic gluconeogenesis from precursors such as amino acids, glycerol, and lactate recycled from glycolysis.

TABLE 5-2

Fuel Composition of Normal Adult

Fuel	Kg	Calories
Tissues		
Fat (adipose triglyceride)	15	141,000
Protein (mainly muscle)	6	24,000
Glycogen (muscle)	0.150	600
Glycogen (liver)	0.075	300
		165,900
Circulating Fuels		
Glucose (extracellular fluid)	0.020	80
Free fatty acids (plasma)	0.0003	3
Triglycerides (plasma)	0.003	30
		113

From Cahill GF (1970). Starvation in man. N Engl J Med 282:668.

The major source of gluconeogenic precursors is muscle protein. Although the pool of muscle protein is large, it is all required for body function and thus in contrast to stores of glycogen and fat there are no "reserves" of protein to draw on during fasting. To spare the use of essential protein during extended fasting, glucose consumption must be suppressed by switching on the mobilization and oxidation of fatty acids from adipose triglyceride stores.

Glucose homeostasis is very limited in children compared with adults, in part because of their smaller reserves of liver glycogen and muscle protein but also because of their relatively larger rates of glucose consumption due to their larger brain-to-body-mass ratio. For example, the fuel stores of a 10-kg infant are only 15% of those of an adult. However, the caloric needs are 60% of those of an adult and glucose turnover rates per kilogram are two- to threefold greater. Major organs (such as skeletal muscle) can readily oxidize free fatty acids, released from adipose tissue lipolysis, in place of glucose and thus limit the need for gluconeogenesis.

Brain cannot directly use free fatty acids, because they do not pass the blood-brain barrier. However, the brain can substitute glucose consumption with the ketones acetoacetate and β-hydroxybutyrate—which are released by the liver as the end product of hepatic fatty acid oxidation. Thus, as shown in Figure 5-1 the essential metabolic pathways of fasting adaptation are hepatic glycogenolysis, hepatic gluconeogenesis, adipose tissue lipolysis, and fatty acid oxidation and ketogenesis.[43] The key enzymatic steps in these pathways are shown in Figure 5-2. A defect in any one of these four pathways impairs fasting adaptation and can lead to fasting hypoglycemia.

The four metabolic systems of fasting adaptation (glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis) are regulated by a fifth system: endocrine control. The most important hormone for control of fasting adaptation is insulin, which acts to inhibit all four of the metabolic systems (Table 5-3). These inhibitory effects of insulin are opposed by several counter-regulatory hormones, which as shown in Table 5-3 have overlapping effects on specific fasting metabolic pathways. Excessive secretion of insulin or deficiency of one or more counter-regulatory hormones can result in fasting hypoglycemia.

The operation of the metabolic and endocrine systems of fasting adaptation is evidenced by the changes in circulating levels of metabolic fuels and hormones during a fast. As shown in Figure 5-3, in young infants a 24-hour fast is accompanied by a gradual fall in glucose levels as hepatic glycogen stores are depleted, a progressive fall in

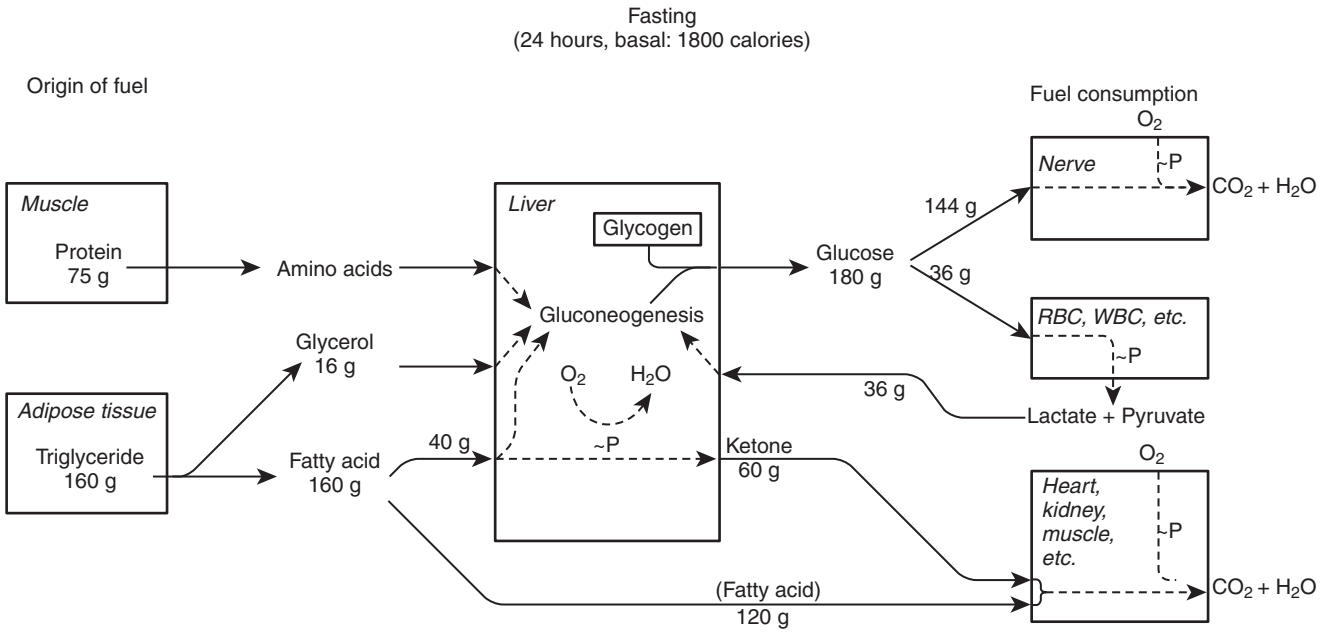

Figure 5-1. General scheme of fuel metabolism in a normal human who has fasted. Shown are the two primary sources of fuel (muscle and adipose tissue) and the three types of fuel consumers that use fatty acids and ketones: nerve, pure glycolyzers [e.g., red blood cells (RBCs) and white blood cells (WBCs), and the remainder of the body (e.g., heart, kidney, and skeletal muscle). ~P represents energy production. concentrations of gluconeogenic substrate (e.g., lactate, alanine) as they are used for hepatic gluconeogenesis, a brisk rise in free fatty acids as lipolysis is activated, and a dramatic rise in β-hydroxybutyrate (the major ketone) as hepatic ketogenesis is turned on.[1,44]

Levels of insulin diminish to less than 2 μU/mL, whereas there is a rise in the four major counter-regulatory hormones (catecholamines, glucagon, cortisol, and growth hormone) as the plasma glucose level falls. These hormonal changes lead to a reversal of metabolic pathways from synthesis to breakdown in order to maintain glucose homeostasis. When insulin concentration is 2 μU/mL or greater at a time when blood glucose concentration is 50 mg/dL or less, there is a hyperinsulinemic state reflecting failure of the mechanisms that normally result in suppression of insulin secretion during fasting or hypoglycemia.[45-47]

Thus, a snapshot of the integrity of the metabolic and endocrine fasting systems can easily be obtained by

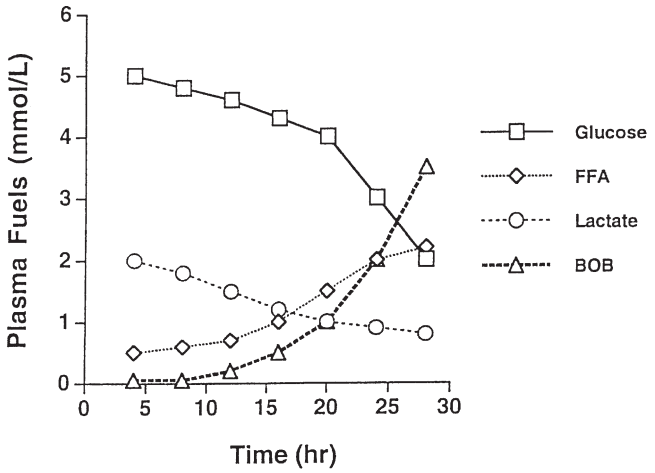

Figure 5-3. Changes in major metabolic fuels during fasting in a normal infant. Note that plasma glucose declines toward hypoglycemic values by 24 hours as hepatic glycogen reserves are depleted. The level of lactate, a representative gluconeogenic substrate, declines gradually during the fast. Late in fasting, levels of plasma free fatty acids (FFA) increase as lipolysis is activated—followed by an increase in β-hydroxybutyrate as rates of hepatic fatty acid oxidation and ketogenesis increase.

measuring the plasma levels of the major fuels and hormones at the end of a fast, when the blood glucose approaches hypoglycemic levels ("critical samples"). The use of these critical samples in diagnosing the cause of hypoglycemia is discussed at the end of the chapter.

The key hormone governing glycogen synthesis during and immediately after meals is insulin. Likewise, glycogen breakdown (and later, gluconeogenesis) depends on a low insulin concentration. The control of insulin secretion, its metabolic effects, and its mechanisms of action are detailed in Chapter 10. In this chapter, the following requires emphasis. The neural, hormonal, and metabolic changes (including the rise in blood glucose associated with feeding) lead to a rise in insulin. This rise in insulin serves to modulate the rise in blood glucose concentration and eventually to lower it through the activation of glycogen synthesis, enhancement of peripheral glucose uptake, and inhibition of gluconeogenesis. In addition, insulin stimulates lipid synthesis—simultaneously curtailing lipolysis and ketogenesis.

Table 5-3 summarizes the synergistic effects of the counter-regulatory hormones on key metabolic pathways and insulin action. There is a hierarchic redundancy in the interaction of these counter-regulatory hormones that provides a margin of safety ("fail-safe mechanism") if only one counter-regulatory hormone is impaired. Epinephrine and glucagon are quick acting, each signaling its effects by activation of cyclic AMP. Deficiencies of glucagon, as occurs in long-standing type I diabetes mellitus, can be largely compensated for by an intact autonomic nervous system with appropriate α- and β-adrenergic effects. Conversely, autonomic failure can be largely compensated for if glucagon secretion remains intact.[1]

Nevertheless, the defense against insulin-induced hypoglycemia is impaired by deficiency of glucagon or catecholamines—with hypoglycemia ensuing quite rapidly. Similarly, growth hormone deficiency can be compensated for in part by intact cortisol secretion (and vice versa). However, deficiency of either impairs the defense against insulin-induced hypoglycemia. Congenital or acquired deficiencies in these hormones may result in hypoglycemia, which will occur when endogenous glucose production cannot be mobilized to meet energy needs in the postabsorptive state (i.e., 8 to 12 hours after meals or during fasting). Combined deficiency of several hormones, as occurs in hypopituitarism, may result in a hypoglycemia that is more severe or appears earlier during fasting than might occur with isolated hormone deficiency.

The intricate physiologic regulation that maintains glucose homeostasis provides a diagnostic framework with which to anticipate the phenotypes of infants with hypoglycemia of varying causes. The deficiency of substrates, an excess of insulin or a deficiency of hormones, and the absence, delay, deficiency, or missed timing of the development of activity of enzymes or transporters will affect the presentation of infantile hypoglycemia. Thus, this detailed presentation of the events leading to, involving, and after parturition allows rapid and specific diagnostic considerations to be entertained and to evolve to an appropriate treatment.

DEFINITION OF HYPOGLYCEMIA IN NEONATES AND INFANTS

The classic definition of symptomatic hypoglycemia is "Whipple's triad" (i.e., symptoms typical of hypoglycemia, a blood glucose value less than 50 mg/dL during symptoms, and relief of symptoms with treatment to raise the blood glucose level into the normal range). These three criteria were originally used for diagnosing insulinomas in adults but apply well to diagnosis of any form of hypoglycemia. In infants, children, and adults, the normal range for plasma glucose in the postabsorptive state equals plasma glucose levels between 70 and 100 mg/dL.

A plasma glucose level of 50 mg/dL is conventionally used for diagnosing hypoglycemia. Note that this value is a very conservative threshold, well below the threshold for hormonal and cognitive deficits to avoid overdiagnosing hypoglycemia. Falling glucose levels elicit a typical

sequence of responses: plasma insulin levels decrease when plasma glucose falls to the range of 80 to 85 mg/dL; glucagon secretion increases when plasma glucose levels are in the range of 65 to 70 mg/dL; epinephrine, cortisol, and growth hormone responses are activated in the range of 65 to 70 mg/dL; acute symptoms may appear in the range of 50 to 55 mg/dL; and cognition is impaired when levels fall below 50 mg/dL.[1]

In some disorders, such as defects in ketogenesis, signs and symptoms may begin to appear during fasting at plasma glucose levels of 60 mg/dL. On the other hand, some patients (those with glucose 6-phosphatase deficiency) may have few symptoms of neuroglycopenia at plasma glucose levels as low as 20 to 30 mg/dL because their high plasma levels of lactate provide an alternative substrate for the brain. Thus, plasma glucose levels between 50 and 70 mg/dL should be regarded as suboptimal and below the goal for therapy for hypoglycemia.

Pediatric endocrinologists should be aware that there continues to be controversy about whether the previously cited standards for normal and abnormal plasma glucose levels should apply in the newborn period.[48,49] Because the risk for low blood glucose levels is high in neonates, especially in the first day after birth, it has been traditional to accept lower standards for hypoglycemia in newborns. The major rationale for this is statistical (i.e., low glucose is so frequent it must be "normal"). However, the authors do not recommend using lower standards for glucose in neonates. Instead, we use the same definition for hypoglycemia and the same targets for treatment of hypoglycemia in neonates as in older children. This is especially true for the diverse groups of neonates who have congenital hyperinsulinism (e.g., birth asphyxia, small for gestational age birth weight, maternal diabetes, genetic defects) because they lack alternative fuels, such as ketones, for brain metabolism when glucose levels are low.

There are a number of potential artifacts that can interfere with measuring glucose levels in neonates and infants (Table 5-4). Whole-blood glucose concentrations are 10% to 15% lower than plasma glucose levels because of lower erythrocyte versus plasma glucose concentrations. Blood samples that are not processed promptly can have erroneously low glucose levels, owing to glycolysis by red and white blood cells. At room temperature, the decline of whole-blood glucose can be 5 to 7 mg/dL/hr. The use of inhibitors, such as fluoride, in collection tubes avoids this problem.

TABLE 5-4

Factors Affecting Measurement of Blood Glucose Concentration

- Whole-blood versus plasma glucose concentration (plasma is ~10%-15% higher)
- Duration between sample collection and sample measurement
- Presence or absence of glycolytic inhibitors in collection tubes
- Sample collection from indwelling lines without adequate flushing

Compiled from Sacks DB (1994). Carbohydrates. In Burtis CA, Ashwood ER (eds.), *Tietz textbook of clinical chemistry, Second edition.* Philadelphia: WB Saunders.

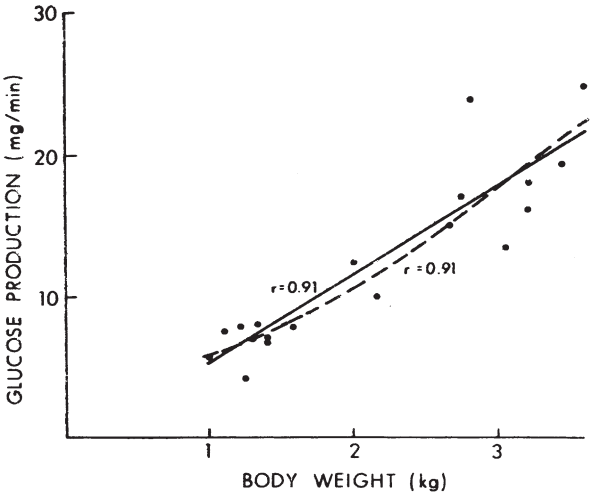

Figure 5-4. Glucose production versus body weight determined in 19 newborns with the use of stable isotopic techniques. These studies provide support for the calculated rates of glucose administration required to correct hypoglycemia. [From Bier DM, Leake RD, Haymond MW, et al. (1977). Measurement of "true" glucose production rates in infancy and childhood with 6,6-dideuteroglucose. Diabetes 26:1016.]

Hospital bedside glucose meters and similar home glucose meters are less precise than clinical laboratory methods and can be expected to have an error range of 10% to 15%. These methods are also prone to errors, such as outdated strips or short-sampling—most of which result in falsely low glucose values. For this reason, bedside monitors can be used for screening purposes—but any glucose value below 60 mg/dL should be verified in the clinical laboratory. Falsely low (or high) glucose values may occur with samples drawn from indwelling lines without adequate flushing of the saline (or glucose) infusate.

If a plasma glucose value below 50 mg/dL is verified, treatment should immediately be provided. Plasma glucose values below 60 mg/dL should be rechecked and treatment considered, if confirmed to be below 60 mg/dL. Symptomatic infants and neonates should be treated with intravenous dextrose (0.2 g/kg bolus, followed by infusion at 5 to 10 mg/kg/min). These rates approximate the normal hepatic glucose production rates in neonates and young infants (Figure 5-4). Asymptomatic neonates with plasma glucose levels below 50 mg/dL may be treated with oral glucose, but only if there is good reason to believe the problem is a transient one that will not recur. This applies essentially only to otherwise normal neonates during the first 12 to 24 hours after birth who have delayed feedings, such as with initiation of breastfeeding. Beyond the first day of life, all neonates with verified plasma glucose below 60 mg/dL should be suspected of having a hypoglycemic disorder.

CLINICAL SYMPTOMS AND SIGNS ASSOCIATED WITH HYPOGLYCEMIA

The clinical features of hypoglycemia in infants may be associated with both adrenergic and neuroglycopenic components (Table 5-5). Symptoms are often quite subtle,

TABLE 5-5

Symptoms of Spontaneous Hypoglycemia and Hypoglycemia in Infancy

Spontaneous Hypoglycemia		Hypoglycemia in Infancy
Symptoms Due in Part to Activation of Autonomic Nervous System Associated Epinephrin Release (Usually Associated with Rapid Decline in Blood Glucose Level)	**Symptoms Due to Decreased Cerebral Glucose and Oxygen Use (Usually with Slow Decline in Blood Glucose Level and/or Severe Prolonged Hypoglycemia)**	
Sweating	Headache	Cyanotic episodes
Shakiness, trembling	Visual disturbances	Apnea
Tachycardia	Lethargy, lassitude	"Respiratory distress"
Anxiety, nervousness	Restlessness, irritability	Refusal to feed
Weakness	Difficulty with speech and thinking, inability to concentrate	Brief myoclonic jerks
Hunger	Mental confusion	Wilting spells
Nausea, vomiting	Somnolence, stupor, prolonged sleep	Nausea, vomiting
	Loss of consciousness, coma	Somnolence
	Hypothermia	Subnormal temperature
	Twitching, convulsions, "epilepsy"	Sweating
	Bizarre neurologic signs	
	Motor	
	Sensory	
	Loss of intellectual ability	
	Personality changes	
	Bizarre behavior	
	Outburst of tempor	
	Psychological disintegration	
	Manic behavior	
	Depression	
	Psychoses	
	Permanent mental of neurologic damage	

and a high index of clinical suspicion must be maintained. Therefore, any alteration in clinical status in a newborn that suggests a change in neurologic behavior, fall in temperature, change in feeding pattern, or presence of tremors must be considered a possible initial presentation of a hypoglycemic episode. Seizures must always be considered a possible manifestation of hypoglycemia.

Classification of Hypoglycemias

A logical approach to diagnosis and treatment must analyze a hypoglycemic event as a maladaptation to fasting. The classification scheme represented in Table 5-6 is based on this approach.

TRANSIENT NEONATAL HYPOGLYCEMIA

Developmental Immaturity of Fasting Adaptation

During the first day of life, normal infants are susceptible to hypoglycemia—especially if fasted after birth for any length of time. As shown in Figure 5-5, 10% of normal appropriate-for-gestational-age term neonates can develop plasma glucose values below 30 mg/dL when the first feeding is delayed for 6 hours after birth.[50] This high risk of hypoglycemia reflects immaturity of several of the fasting systems immediately after birth. As reported by Lubchenco and Bard, whereas plasma glucose levels fell below 50 mg/dL in one-third of term infants in the first 6 hours after delivery by the second day of life the frequency of glucose levels below 50 mg/dL was less than 0.5% and only occurred in small-for-gestational-age infants.[50] As these observations illustrate, the fasting systems mature very quickly after birth.

Studies in normal infants during the first postnatal fast indicate that their high susceptibility to hypoglycemia is associated with developmental lags in the capacity for both hepatic gluconeogenesis and ketogenesis.[51] This is consistent with studies in the guinea pig and rat, which show that hepatic phosphoenolpyruvate carboxykinase (one of the four gluconeogenic enzymes) as well as carnitine palmitoyl-transferase-1 (CPT-1) and β-hydroxy-β-methylglutaryl-CoA (HMG-CoA) synthase (the first and last steps in hepatic ketogenesis) are not expressed for up to 12 hours after birth[52-54] (Figure 5-6). The developmental lags in capacity for ketogenesis mean that during the first day of life, normal neonates lack the protection of generating alternative fuel for the brain during fasting

TABLE 5-6

Classification of Hypoglycemia in Infants and Children

Transient Neonatal Hypoglycemia

Developmental immaturity of fasting adaptation associated with inadequate substrate or immature enzyme function:
- Prematurity
- Normal newborn

Transient hyperinsulinism due to maternal factors:
- Maternal diabetes
- Intravenous glucose administration during labor and delivery
- Medications: oral hypoglycemics, terbutaline, propranolol

Prolonged Neonatal Hypoglycemia

Prolonged neonatal hyperinsulinism:
- Intrauterine growth retardation
- Prematurity
- Birth asphyxia
- Maternal toxemia/preeclampsia

Neonatal, Infantile, or Childhood Persistent Hypoglycemias

Hormonal Disorders

Hyperinsulinism

ATP-sensitive potassium channel congenital hyperinsulinism:
- Diffuse K_{ATP} channel HI
- Focal K_{ATP} channel HI
- Dominant K_{ATP} channel HI

Glutamate dehydrogenase congenital hyperinsulinism (hyperinsulinism/hyperammonemia syndrome):
- Glucokinase congenital hyperinsulinism
- Short-chain L-3-hydroxyacyl-CoA dehydrogenase congenital hyperinsulinism
- Congenital disorders of glycosylation
- Beckwith-Wiedemann syndrome
- Acquired islet adenoma
- Insulin administration (Munchausen by proxy)
- Oral sulfonylurea drugs

Counter-Regulatory Hormone Deficiency
- Panhypopituitarism
- Isolated growth hormone deficiency
- Adrenocorticotropic hormone deficiency
- Primary adrenal insufficiency
- Epinephrine deficiency

Glycogenolysis Disorders
- Amylo-1,6-glucosidase (debranching enzyme) deficiency (GSD 3)
- Liver phosphorylase deficiency (GSD 6)
- Phosphorylase kinase deficiency (GSD 9)
- Glycogen synthetase deficiency (GSD 0)

Gluconeogenesis Disorders
- Glucose 6-phosphatase deficiency (GSD 1a)
- Glucose 6-phosphate translocase deficiency (GSD 1b)
- Fructose 1,6-diphosphatase deficiency
- Pyruvate carboxylase deficiency

Lipolysis Disorders
- Propranolol

Fatty Acid Oxidation Disorders
- Carnitine transporter deficiency (primary carnitine deficiency)
- Carnitine palmitoyl-transferase 1 deficiency
- Carnitine translocase deficiency
- Carnitine palmitoyl-transferase 2 deficiency
- Very long-chain acyl-CoA dehydrogenase deficiency

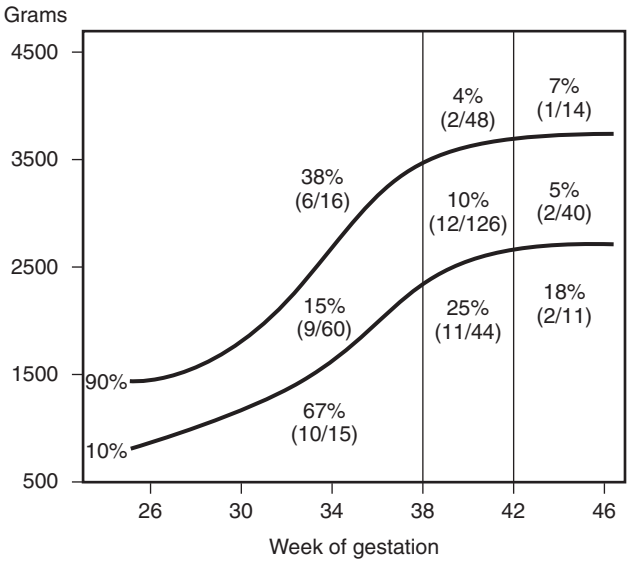

Figure 5-5. Incidence of plasma glucose level being less than 30 mg/dL before first feeding at 3 to 6 hours of age in newborns, classified by birth weight and gestational age. [From Lubchenko LO, Bard H (1971). Incidence of hypoglycemia in newborn infants by birth weight and gestational age. Pediatrics 47:831.]

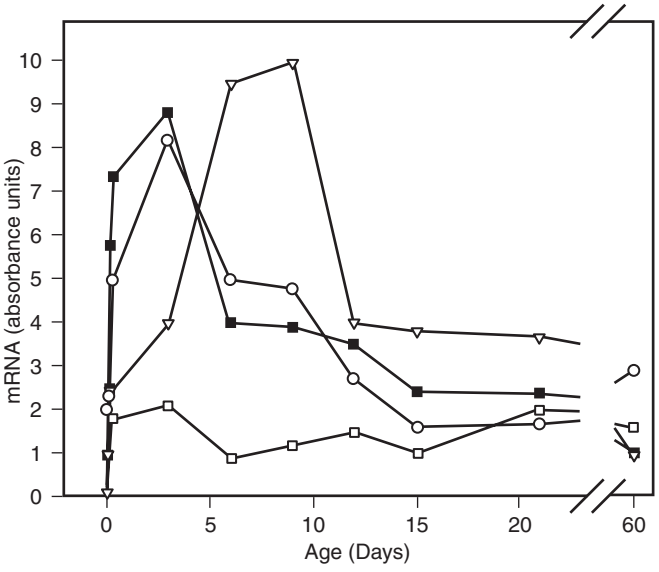

Figure 5-6. Levels of mRNA in newborn, suckling, and adult rat liver for phosphoenolpyruvate carboxykinase (triangles), mitochondrial β-hydroxy-β-methylglutaryl CoA synthase (circles), and carnitine palmitoyltransferase I (solid squares) and II (open squares). [From Hegardt FG (1999). Mitochondrial 3-hydroxy-3-methylglutaryl-CoA synthase: A control enzyme in ketogenesis. Biochem J 338:569.]

hypoglycemia. Fatty acids provided by the first feeding appear to play a key, possibly direct, role in activating transcription of these two important fatty acid oxidation and ketogenesis enzymes.[52,53]

In terms of fasting systems, the normal newborn is highly dependent on hepatic glycogen stores to maintain normoglycemia in the first 12 to 24 hours but rapidly acquires the full complement of fasting systems thereafter.

Normal term infants who are being breast fed unsuccessfully are at highest risk for hypoglycemia because of developmental immaturity of fasting adaptation and may require supplementation until milk production is adequate. Symptomatic hypoglycemia is rare in normal term infants who are fed early and is easily prevented by ensuring that feedings are given.

As shown in Figure 5-5, the risk of fasting hypoglycemia in the immediate postnatal period is considerably higher in preterm appropriate-for-gestational-age infants compared with normal full-term neonates. This increased risk may be explained by the fact that premature infants have the same developmental immaturity of ketogenesis and gluconeogenesis as term infants but lower glycogen reserves. In addition, hormonal responses are initially limited in preterm infants.[55] As discussed later in the chapter, the higher risk of fasting hypoglycemia on day 1 of life in infants who are large or small for gestational age most likely involves additional factors (especially hyperinsulinism).

Hypoglycemia in Normal Infants and Children (Ketotic Hypoglycemia)

The process of fasting adaptation is accelerated in infants and children compared with adults because of their relatively larger ratio of brain weight to body weight. Thus, normal infants may develop fasting hyperketonemia before 24 hours of fasting, whereas adults usually require more than 48 hours of fasting to reach the same point. For this reason, otherwise normal infants and children (as discussed in Chapter 11) are susceptible to fasting hypoglycemia during intercurrent illnesses (such as gastroenteritis)—which interfere with feeding. Beyond acute treatment of the hypoglycemia, these infants need no therapy. However, because of this increased susceptibility to hypoglycemia precautions to avoid prolonged fasting beyond 12 hours should be taken in children with ketotic hypoglycemia.

Early intervention with intravenous dextrose should be considered during intercurrent illnesses that might interrupt normal eating. Ketotic hypoglycemia has often been considered a specific diagnosis, but in most cases may simply represent normal infants who have accelerated fasting adaptation (e.g., smaller infants with less fuel reserve). A diagnosis of ketotic hypoglycemia should only be made after other conditions have been excluded (e.g., glycogen synthase deficiency, pituitary deficiency). Because the timing of hypoglycemia in patients with fatty acid oxidation disorders [such as medium-chain acyl-CoA dehydrogenase (MCAD) deficiency] is similar to that of ketotic hypoglycemia, specific measurements of plasma ketones are essential to diagnosis.

Transient Hyperinsulinism Due to Maternal Factors

Transient hyperinsulinism is a well-recognized complication in infants of diabetic mothers. Gestational diabetes affects approximately 2% of pregnant women, and approximately 1 in 1,000 pregnant women have insulin-dependent diabetes. At birth, infants born to these mothers may be large and plethoric—and their body stores of glycogen, protein, and fat are replete. Thus, in contrast to the transient hypoglycemia of the infant who is small for gestational age (whose body size and tissue nutrient content reflect diminished placental transfer) infants born to diabetic mothers are examples of nutrient surfeit and represent the opposite extreme of the spectrum. The classic clinical description of the effect of hyperinsulinism relates to the infant of the diabetic mother[56]:

> These infants are remarkable not only because like fetal versions of Shadrack, Meshack, and Abednego, they emerge at least alive from within the fiery metabolic furnace of diabetes mellitus, but because they resemble one another so closely they might well be related. They are plump, sleek, liberally coated with vernix caseosa, full-faced, and plethoric. The umbilical cord and placenta share in the gigantism. During their first 24 or more extrauterine hours, they lie on their backs, bloated and flushed, their legs flexed and abducted, their lightly closed hands on either side of the head, the abdomen prominent and their respiration sighing. They convey a distinct impression of having had such a surfeit of both food and fluid pressed upon them by an insistent hostess that they desire only peace so that they may recover from their excesses. On the second day their resentment of the slightest noise improves the analogy when their trembling anxiety seems to speak of intrauterine indiscretions of which we know nothing.

Hypoglycemia in infants of diabetic mothers is related chiefly to hyperinsulinemia and in part to diminished glucagon secretion. Hypertrophy and hyperplasia of their islets have been documented, as has their brisk, biphasic, and typically adult insulin response to glucose. This insulin response is absent in normal infants. Infants born to diabetic mothers also have a subnormal surge in plasma glucagon immediately after birth, subnormal glucagon secretion in response to stimuli, and (initially) excessive sympathetic activity that may lead to adrenomedullary exhaustion because urinary excretion of epinephrine is diminished. Thus, despite their abundance of tissue stores of available substrate the normal plasma hormonal pattern of low insulin, high glucagon, and catecholamines is reversed. Their endogenous glucose production is inhibited and glucose utilization is increased compared with that in normal infants, thus predisposing them to hypoglycemia.

Mothers whose diabetes has been well controlled during pregnancy in general have near-normal-sized infants who are less likely to develop neonatal hypoglycemia and other complications formerly considered typical of maternal diabetes. Nevertheless, treatment of infants born to mothers with diabetes commonly requires provision of intravenous glucose for a few days until the hyperinsulinemia abates. For these infants, glucose should be provided at a rate of 5 to 10 mg/kg/min. However, the appropriate dosage for each patient should be individually adjusted. During labor and delivery, maternal hyperglycemia should be avoided because it may result in fetal hyperglycemia—which predisposes to rebound hypoglycemia when the glucose supply is interrupted at birth. Other maternal factors that can result in transient neonatal hyperinsulinism include oral hypoglycemics (such as

sulfonylureas) or other medications (terbutaline or propranolol).

By definition, transient hyperinsulinism as a cause of neonatal hypoglycemia in an infant of a diabetic mother should abate in 1 or 2 days. If the condition persists, organic hyperinsulinism must become a prominent consideration and the index of suspicion must remain high until it is ruled out. The potential risk of brain damage in an infant suffering from hyperinsulinism is high, placing this diagnosis in a critical position in the diagnostic evaluation of neonatal hypoglycemia.

PROLONGED NEONATAL HYPERINSULINISM: PERINATAL STRESSS-INDUCED HYPERINSULINISM

As shown in Figure 5-5, the risk of postnatal hypoglycemia is increased in neonates who are small for gestational age. Although this may sometimes be caused by poorer stores of glycogen, there is increasing evidence that prolonged hypoglycemia in some neonates exposed to perinatal stress such as birth asphyxia, maternal toxemia, prematurity, or intrauterine growth retardation or other peripartum stress is due to hyperinsulinism.[57-59] The estimated incidence of prolonged neonatal hyperinsulinism is 1:12,000 live births.[59]

The clinical presentation of perinatal stress-induced hyperinsulinism is characterized by high glucose utilization, and the response to fasting hypoglycemia shows an elevated plasma insulin level (although it may be normal in some), low β-hydroxybutyrate and free fatty acid levels, and a glycemic response to glucagon. Unlike the transient hyperinsulinism seen in the infant of the diabetic mother, perinatal stress-induced hyperinsulinism may persist for several days to several weeks. In a series of neonates diagnosed after 1 week of age, the median age of resolution was 6 months.[59] The mechanism responsible for the dysregulated insulin secretion is not known. AIR testing shows that in general the patterns of insulin response to secretagogues (calcium, tolbutamide, glucose, and leucine) in infants with prolonged neonatal hyperinsulinism resembled those of normal controls.[59] This suggests that the defect does not involve the ATP-dependent potassium (K_{ATP}) channel or glutamate dehydrogenase (GDH) sites.

Infants with prolonged neonatal hyperinsulinism usually respond very well to medical therapy with diazoxide.[57-59] Previously, it was common practice to use pharmacologic doses of glucocorticoids to treat such neonates with persistent hypoglycemia. Glucocorticoids are not effective in controlling hyperinsulinism, however. Their use as nonspecific therapy for neonatal hypoglycemia is not recommended.

Endocrine System Disorders

CONGENITAL HYPERINSULINISM

Congenital hyperinsulinism is the most common and most difficult to manage form of persistent hypoglycemia in neonates and infants.[60] Advances in defining the genetic basis of hyperinsulinism during the past decade have been rapid, and improvements in diagnosis and treatment can be expected to occur quickly in the future. As shown in Table 5-6, both recessive and dominantly expressed genetic forms of congenital hyperinsulinism have been described. In addition, a sporadic form of congenital hyperinsulinism associated with focal adenomatosis of the pancreas has been delineated. Unlike adults, insulinomas are not a cause of hyperinsulinism in infancy; these lesions and surreptitious insulin administration are discussed in Chapter 11.

Figure 5-7 outlines the major pathways regulating insulin release by pancreatic beta cells. Glucose-stimulated insulin secretion involves glucose uptake through the GLUT2 glucose transporter and phosphorylation by glucokinase (GK), leading to glucose oxidation and an increased ATP/ADP ratio that results in inhibition of a plasma membrane ATP-dependent potassium (K_{ATP}) channel. The β-cell K_{ATP} channel is a hetero-octameric complex consisting of two subunits: a K^+-selective pore-forming subunit (Kir6.2) and a regulatory subunit (SUR1). Four Kir6.2 subunits form the central pore, coupled to four SUR1 subunits. The K_{ATP} channel is inhibited by sulfonylurea drugs (used therapeutically to stimulate insulin secretion in type 2 diabetes) and activated by diazoxide (the main medical treatment for congenital hyperinsulinism).

In the unstimulated state, the ß-cell ATP-sensitive potassium channels are open—keeping a resting membrane potential of approximately –65 mV. Following the uptake and metabolism of glucose, an increase in the intracellular ATP/ADP ratio results in closure of ATP-sensitive potassium channels, depolarization of the cell membrane, and subsequent opening of voltage-dependent Ca^{2+} channels. The resulting increase in cytosolic Ca^{2+} concentration triggers release of stored insulin granules. Stimulation of insulin secretion by amino acids occurs through an allosteric activation of glutamate dehydrogenase (GDH) by leucine, which results in increased oxidation of glutamate—leading to increased ATP/ADP ratio, inhibition of K_{ATP}-channel activity, and membrane depolarization.

Genetic defects in these pathways associated with congenital hyperinsulinism include loss-of-function mutations of SUR1 (encoded by *ABCC8*) or Kir6.2 (encoded by *KCNJ11*) and gain-of-function mutations of glucokinase (encoded by *GCK*) or glutamate dehydrogenase (GDH; encoded by *GLUD1*).[60,61] Mutations of SUR1 and Kir6.2 are usually recessively expressed, however, a few dominantly expressed mutations of *ABCC8* and *KCNJ11* have been reported.[62-64] Mutations of *GCK* and *GLUD1* are dominantly expressed; sporadic, de novo mutations of the latter have been diagnosed more commonly than familial cases.[65] Loss-of-function mutations of *ABCC8* or *KCNJ1* transmitted from the paternal side have also been demonstrated to be responsible for congenital hyperinsulinism in infants with focal hyperinsulinism.[66] Recently, loss of function mutations in *HADHSC,* the gene encoding the mitochondrial enzyme short-chain L-3-hydroxyacyl-CoA (SCHAD),[67-69] was found to be associated with recessive congenital hyperinsulinism.

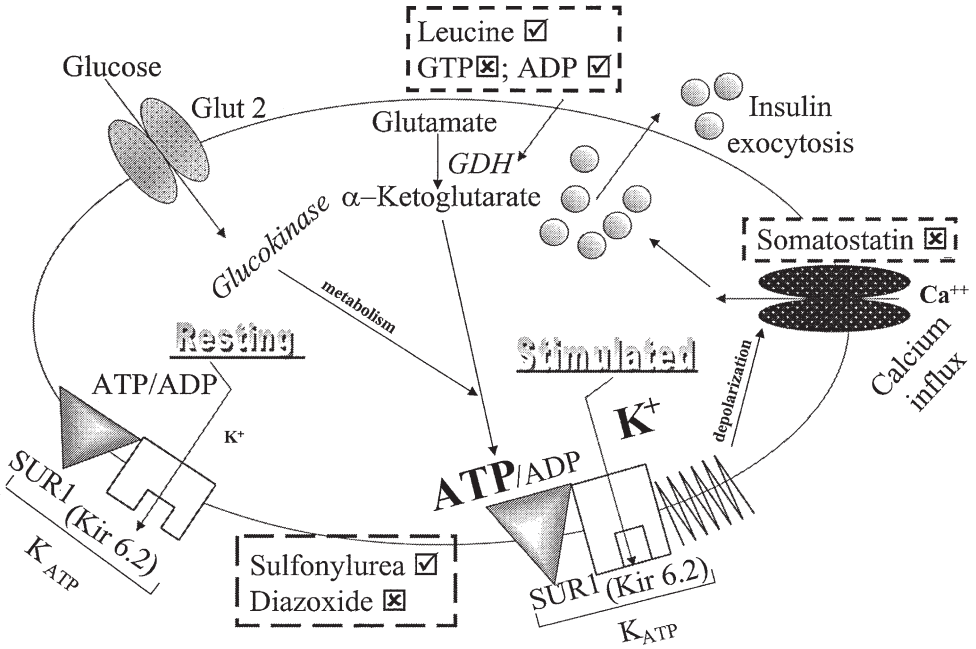

Figure 5-7. Current model of mechanisms of insulin secretion by the beta cell of the pancreas. Glucose transported into the beta cell by the insulin-independent glucose transporter GLUT2 undergoes phosphorylation by glucokinase and is then metabolized, resulting in an increase in the adenosine triphosphate/adenosine diphosphate (ATP/ADP) ratio. The increase in the ATP/ADP ratio closes the KATP channel and initiates the cascade of events characterized by increase in intracellular potassium concentration, membrane depolarization, calcium influx, and release of insulin from storage granules. Leucine stimulates insulin secretion by allosterically activating glutamate dehydrogenase (GDH) and by increasing the oxidation of glutamate, thereby increasing the ATP/ADP ratio and closure of the KATP channel. x = inhibition; (? = stimulation; and GTP = guanosine triphosphate. [From Sperling MA, Menon RK (1999). Hyperinsulinemic hypoglycemia of infancy. Endocrinol Metab Clin North Am 28:695.]

The clinical presentations of congenital hyperinsulinism vary with the severity of the disorder as well as the site of defect. The most severe cases have been associated with recessive or focal K_{ATP} channel defects and are often associated with macrosomia caused by fetal hyperinsulinemia. These infants may be confused with infants of diabetic mothers. They usually present with hypoglycemia in the first hours or days after birth. The hypoglycemia is difficult to control and often requires glucose infusion rates greater than 20 mg/kg/min. Less severe phenotypes of congenital hyperinsulinism are associated with defects of GDH, GK, SCHAD, and dominant K_{ATP} mutations. Episodes of hypoglycemia may not be recognized until 1 to 2 years of age or later.

It is often not easy to diagnose hyperinsulinism based solely on measurements of plasma insulin. This is because standard insulin assays are not sufficiently sensitive in the low range to distinguish a normal from an inadequately suppressed insulin concentration. Plasma insulin levels are rarely dramatically elevated in congenital hyperinsulinism; rather there is inadequate suppression of insulin at low plasma glucose concentrations. Therefore, the diagnosis of hyperinsulinism in infants is most frequently based on evidence of excessive insulin action at the time of hypoglycemia, such as inappropriate suppression of plasma β-hydroxybutyrate and free fatty acid levels and an inappropriate glycemic response to glucagon.

As shown in Table 5-7, at a plasma glucose level below 50 mg/dL, evidence of hyperinsulinism includes plasma insulin greater than 2 μU/mL; plasma β-hydroxybutyrate (BOB) less than 2.0 mmol/L; plasma free fatty acids (FFA) less than 1.5 mmol/L; and glycemic response to glucagon, 1 mg given intravenously, greater than 30 mg/ dL within 15 to 30 minutes.[70,71] Plasma concentrations of insulin-like growth factor binding protein-1 (IGFBP1) may be an additional indicator of insulin action on the liver.[72] Children with hyperinsulinism fail to show a rise in circulating IGFBP1 concentration during fasting, which is in contrast to normal subjects, who show a 10-fold increase during fasting.[72] In neonates, hypoglycemia due to hypopituitarism can mimic hyperinsulinism and may need to be formally excluded. Note that plasma levels of cortisol and growth hormone are frequently not elevated with

TABLE 5-7

Criteria for Diagnosing Hyperinsulinism Based on "Critical" Samples (Drawn at a Time of Fasting Hypoglycemia: Plasma Glucose <50 mg/dL)

1. Hyperinsulinemia (plasma insulin >2 mU/mL)*
2. Hypofattyacidemia (plasma FFA <1.5 mmol/L)
3. Hypoketonemia (plasma BOB <2.0 mmol/L)
4. Inappropriate glycemic response to glucagon, 1 mg IV (delta glucose >30 mg/dL)

*Depends on sensitivity of insulin assay.
BOB, β-hydroxybutyrate; FFA, free fatty acids.

hypoglycemia, hence the need for separate testing to rule out cortisol or growth hormone deficiency.

Additional tests for specific forms of congenital hyperinsulinism include plasma ammonia levels (GDH-HI), plasma acyl-carnitine profile (elevated 3-hydroxybutyryl-carnitine) and urine organic acids (3-hydroxyglutarate) (SCHAD-HI). Genetic testing is available for four of the five genes known to be associated with congenital hyperinsulinism through commercial laboratories *(ABCC8, KCNJ11, GLUD1, GCK)*. For research purposes, AIR tests have been useful in phenotypic characterization. Patients with K_{ATP}-HI display abnormal positive responses to calcium, abnormal negative response to the K_{ATP}-channel antagonist, tolbutamide, as well as impaired responses to glucose[73,74] (Figure 5-8). In contrast, infants with GDH-HI exhibit increased responses to leucine.[75]

K_{ATP}-Channel Hyperinsulinism

Recessive K_{ATP}-HI

Infants with this form of congenital hyperinsulinism frequently present as neonates who are large for gestational age with very severe hypoglycemia immediately after delivery. The genetic defects in these infants are loss of function of either the SUR1 or the Kir6.2 components of the ATP-sensitive potassium channel complex. These two genes are located on chromosome 11p, immediately adjacent to each other. More than 100 mutations of *ABCC8* and 20 mutations of *KCNJ11* have been found. Heterozygous carrier parents are normal. Common SUR1 founder mutations have been reported in Ashkenazi Jews and in Finland. The incidence of the severe hyperinsulinism phenotype seen with recessive K_{ATP}-HI has been estimated at 1 in 40,000 in Northern Europe and Finland, but it is as high as 1 in 2,500 in Saudi Arabia—where the frequency of consanguinity is high.

As shown in Figure 5-7, because the mutations disrupt the K_{ATP} channel these patients are usually unresponsive to diazoxide treatment. Octreotide is helpful in short-term management. However, because of tachyphylaxis, octreotide is often not successful as the sole therapy for long-term management.[76] The use of calcium-channel blockers to decrease voltage-dependent calcium-channel activity has been proposed as an alternative medical therapy. A few reports of successful treatment with nifedipine are published,[77] but most centers have not had success with this drug.

Because of the lack of effective medical therapy, most infants with severe hypoglycemia due to K_{ATP}-HI require treatment with near-total (95% to 98%) pancreatectomy. Near-total pancreatectomy is associated with a high risk of later development of diabetes mellitus.[78] This most likely reflects not only the effects of pancreas resection but the fact that the loss of channel activity renders the beta cells unresponsive to hyperglycemia as well as to hypoglycemia.[73]

Histologically, in diffuse hyperinsulinism beta cells throughout the pancreas are functionally abnormal and have characteristic enlarged nuclei in about 2% to 5% of cells.[79] Previously, this form of hyperinsulinism was termed *nesidioblastosis*, although it is now recognized that islet neogenesis from ductal epithelium is a normal feature of early infancy.[80] The term *nesidioblastosis* should therefore be abandoned as a synonym for hyperinsulinism.

Focal K_{ATP}-HI (Focal Adenomatosis)

From 40% to 60% of the cases of K_{ATP}-HI (which require surgery) have focal disease.[81] Histologically, these lesions are small (usually less than 10 mm in diameter) and are

characterized by the presence of confluent proliferation of endocrine cells (adenomatous hyperplasia). In contrast to true adenomas, the focal adenomatous hyperplasia includes exocrine acinar cells intermixed within the lesion. The morphology of islets away from the focal lesion is normal.[79]

Focal lesions arise by a "two-hit" mechanism of focal loss of heterozygosity for the maternal 11p15 region, leading to a somatic reduction to homozygosity (or hemizygosity) of a paternally inherited mutation of the *ABCC8* or *KCNJ11* gene. The 11p15 region, which carries the *ABCC8* and *KCNJ11* genes, contains several imprinted tumor suppressor genes (*H19* and *CDKN1C,* also known as p57kip2) that are only expressed on the maternal chromosome. Loss of these growth-suppressing genes may play an important permissive role in the clonal expansion of the lesion.[82]

Clinically, infants with focal lesions are indistinguishable from those with diffuse K_{ATP}-HI and nearly always require surgery. The focal lesions are potentially curable by surgery, whereas diffuse K_{ATP}-HI is not. Efforts to diagnose and localize focal lesions in infants with congenital hyperinsulinism are therefore worthwhile. Interventional radiology studies, such as transhepatic portal venous insulin sampling[83] and selective pancreatic arterial calcium stimulation,[84] have only modest success and are technically difficult and highly invasive. Recently, position emission tomography (PET) scans with flurorine-18 L-3, 4-dihydroxyphenylalanine (^{18}F-fluoro-L-DOPA) have been found to accurately discriminate focal from diffuse hyperinsulinism.[85-87] Pancreatic β-cells take up L-DOPA,[88] and DOPA decarboxylase is active in pancreatic islet cells.[89] In children with focal hyperinsulinism, there is local accumulation of ^{18}F-fluoro-L-DOPA. Coregistration of PET and computed tomography (CT) images allows the anatomic localization of the lesion (Figure 5-9).

Dominant K_{ATP}-HI

A few cases of dominantly expressed mutations of *ABCC8* and one of *KCNJ11* have been reported.[62-64,90] The hypoglycemia in these patients is less severe than the recessive K_{ATP}-HI just described. Although birth weight in affected individuals is increased, the onset of

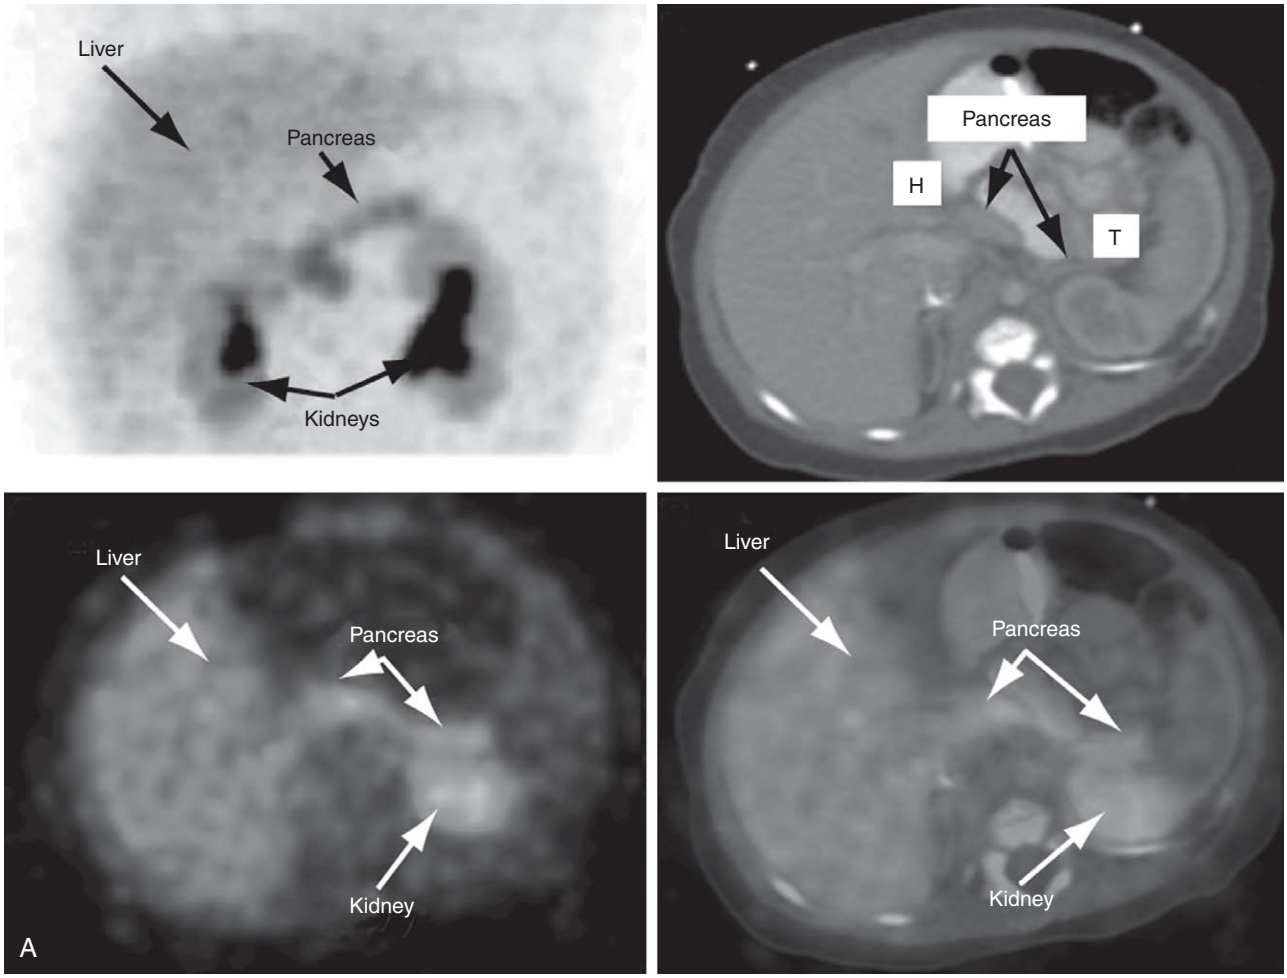

Figure 5-9. Computed tomography and positron emission tomography (CT/PET) using ^{18}Fluoro-L-Dopa. *(A)* Coregistration coronal view of a diffuse lesion and *(B)* focal lesion located in the head of the pancreas. L-DOPA uptake can be appreciated in the liver, in the kidneys, throughout the pancreas in the diffuse form *(A)* and in a focal area corresponding to the head of the pancreas *(B)*. Figure 5-9. cont'd. (See color plates.)

hypoglycemic symptoms is often later in infancy or childhood. The dominant K_{ATP} defects retain responsiveness to diazoxide. These dominant K_{ATP} mutations presumably exert a dominant negative effect in the heteroctameric K_{ATP} channel complexes.

GDH-HI

Hyperinsulinism associated with gain-of-function mutations of *GLUD1* (encoding glutamate dehydrogenase, GDH) is also a dominant disorder.[65,91-94] Affected patients present with symptomatic hypoglycemia together with a characteristically persistent but asymptomatic elevation of plasma ammonia. This unusual hyperinsulinism/hyperammonemia (HI/HA) syndrome represents the second most common form of congenital hyperinsulinism after recessive K_{ATP}-HI. In GDH-HI, size at birth is normal. Episodes of symptomatic hypoglycemia are often not recognized until 1 to 2 years of age, and occasionally may not be detected until adulthood. Most cases are sporadic, owing to de novo mutations.

Familial cases showing autosomal-dominant patterns of inheritance comprise 20% of the identified probands. Plasma ammonia levels in HI/HA patients usually range from 60 to 150 μmol/L. Ammonia levels are quite constant, and in contrast to urea cycle enzyme defects do not increase with protein feeding. The hyperammonemia does not appear to cause symptoms and does not require treatment.

GDH is a mitochondrial matrix enzyme that is a key regulator of amino acid and ammonia metabolism in pancreatic beta cells, liver, and brain. As shown in Figure 5-7, GDH functions in the beta cell pathway of leucine-stimulated insulin secretion. Leucine is an allosteric activator of the enzyme, causing increased oxidation of glutamate to α ketoglutarate and increased ATP production—which results in insulin release. The HI/HA mutations impair allosteric inhibition of GDH by high-energy phosphates (GTP and ATP), thus leading to excessive insulin release. Isolated islets from transgenic mice expressing a mutated human GDH exhibit normal glucose-stimulated insulin secretion but enhanced leucine- and amino-acid-stimulated insulin secretion.[95]

In the liver, increased GDH activity leads to hyperammonemia by overproduction of ammonia owing to increased glutamate oxidation and by depression of ammonia detoxification due to the depletion of tissue

glutamate (because glutamate is the substrate for synthesis of N-acetylglutamate, a required allosteric activator of carbamoyl-phosphate synthetase, the rate-controlling step in ureagenesis). The consequences of increased GDH enzyme activity in the brain are less clear, but might explain the lack of hyperammonemic symptoms in affected individuals. The normal toxic effect of hyperammonemia is thought to be a consequence of increased levels of glutamate and glutamine in brain. Increased GDH activity in HI/HA patients may protect against this effect of hyperammonemia by depleting brain concentrations of glutamate.

Patients with GDH-HI have fasting hypoglycemia, which may be relatively mild. Patients may be able to fast for 8 to 12 hours before becoming hypoglycemic. However, these patients have dramatic protein-sensitive hypoglycemia—becoming severely hypoglycemic within 30 to 90 minutes of ingesting a protein meal[96] (Figure 5-10). Children with GDH-HI may present with an unusual pattern of absence seizure with EEG pattern of generalized epilepsy.[97] Patients with GDH-HI have been shown to have leucine-sensitive insulin secretion.[98] The diagnosis of GDH-HI can be suggested by the persistent mild elevation of plasma ammonia.

Unlike urea cycle enzyme defects, plasma amino acid and urinary amino acid levels are normal in GDH-HI. Plasma ammonia concentrations are not affected by protein feeding, fasting, or plasma glucose levels. GDH enzyme activity can be measured in cultured lymphoblasts to demonstrate impaired responsiveness to allosteric inhibition by GTP. Disease-causing missense mutations have been reported to occur in specific regions of the enzyme involved in GTP inhibition, including exons 6, 7, 10, 11, and 12. Diazoxide therapy, 5 to 10 mg/kg/day, is usually effective in controlling both fasting and protein-induced hypoglycemia in GDH-HI. Carbohydrate preloading may be helpful in avoiding the latter.

GK-HI

A less frequent form of congenital hyperinsulinism is due to activating mutations in *GCK* (encoding glucokinase). Glucokinase is a hexokinase that serves as the glucose sensor in pancreatic beta cells[99] (Figure 5-7). In GK-HI, activating mutations result in increased affinity of glucokinase for glucose, closure of K_{ATP} channels, and inappropriate insulin secretion. The beta cell glucose threshold for glucose-stimulated insulin secretion in children with GK-HI may be less than 2 mmol/L (38 mg/dL), whereas the normal glucose threshold is maintained close to 5 mmol/L (90 mg/dL). Five dominantly inherited mutations have been reported to date.[100] The age of onset and severity of symptoms vary markedly.[101-104] Some mutations seem to have a mild phenotype, with fasting hypoglycemia responsive to diazoxide. Others seem to lower the glucose threshold further and may be more difficult to treat.

SCHAD-HI HYPERINSULINISM

Recently, a mutation in *HADHSC* [the gene encoding the mitochondrial short-chain L-3-hydroxyacyl-CoA dehydrogenase (SCHAD)] was found to be associated with congenital HI.[67-69] SCHAD-HI is an autosomal-recessive disorder characterized by fasting hypoglycemia due to inappropriate insulin regulation. The biochemical hallmark, in addition to markers of increased insulin action, is increased levels of plasma 3-hydroxybutyrylcarnitine and increased levels of 3-hydroxyglutarate in urine.

In contrast to all other defects in fatty acid oxidation, children with SCHAD-HI have no signs of hepatic dysfunction or cardiomyopathy, or of affects on skeletal muscle. The clinical presentation of SCHAD-HI is heterogeneous, ranging from late onset of mild hypoglycemia to severe early onset of hypoglycemia in the neonatal period. Affected patients have been responsive to medical

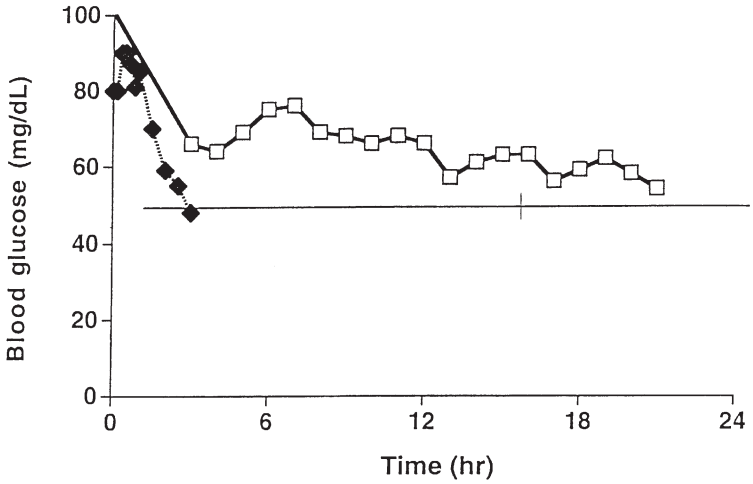

Figure 5-10 Blood glucose responses to fasting (open squares) and protein feeding (solid diamonds) in a 16-year-old girl with the hyperinsulinism/hyperammonemia syndrome caused by a dominantly expressed R269H regulatory mutation of glutamate dehydrogenase. [From Hsu BY, Kelly A, Thornton PS, et al. (2001). Protein-sensitive and fasting hypoglycemia in children with the hyperinsulinism/hyperammonemia syndrome. J Pediatr 138:383.]

therapy with diazoxide. The cause of dysregulated insulin secretion in SCHAD deficiency remains to be elucidated.

OTHER FORMS OF HYPERINSULINISM

Hyperinsulinism can be associated with complex syndromes such as Beckwith-Wiedemann syndrome (BWS) and the congenital disorders of glycosylation (CDG).

BWS is a clinically and genetically heterogenous disorder characterized by fetal overgrowth, hypoglycemia in up to 50% of patients, and a predisposition to childhood tumors. Among cases of BWS, 85% are sporadic and 15% are dominant. Genetic abnormalities in the imprinted region of chromosome 11 have been described in patients with BWS. These often lead to isodisomy for the paternal 11p, a region that is highly imprinted—including some maternally expressed growth-suppressing genes and the paternally expressed fetal growth-promoting *IGF2* gene. The hypoglycemia in BWS may be mild and transient, although in some cases it can be severe and persistent.[105] Some BWS patients respond to diazoxide, whereas others require partial pancreatectomy to control the hypoglycemia. At least two theories have been proposed to explain the hypoglycemia. One involves the insulin-like actions of IGFII. The second involves dysregulated insulin secretion due to loss of K_{ATP} channel genes on 11p.[106]

Hypoglycemia due to hyperinsulinism has been reported in patients with a few of the congenital disorders of glycosylation.[107-109] These inherited metabolic diseases result in hypoglycosylation of different extracellular glycoproteins. They usually affect multiple systems, such as the brain, liver, gastrointestinal system, and the skeleton.[110] Hypoglycosylation of the sulfonylurea receptor has been speculated to be the responsible mechanism for the dysregulated insulin secretion, but the mechanism of hyperinsulinism remains to be proven.

Other forms of hyperinsulinism include islet adenoma or carcinoma (both very rare in childhood), surreptitious insulin administration (Munchausen syndrome by proxy), and ingestion of insulin secretagogues such as sulfonylureas. The latter has occasionally been described in neonates as being caused by drug administration to the mother shortly before delivery. Exogenous insulin produces the usual features of hyperinsulinism (increased glucose use, suppression of lipolysis and ketogenesis, inappropriate glycemic response to glucagon). However, plasma levels of C-peptide are low—indicating suppression of endogenous insulin secretion. Surreptitious insulin administration can be suspected when plasma insulin concentrations at times of hypoglycemia are unusually high (100 μU/mL or greater). Note, however, that biosynthetic forms of insulin such as lispro insulin are not detectable by standard insulin assays.

Counter-Regulatory Hormone Deficiencies

Hypoglycemia associated with endocrine deficiency is usually caused by glucocorticoid or growth hormone deficiency. In patients with panhypopituitarism, isolated growth hormone deficiency, or a combination of ACTH deficiency and growth hormone deficiency the incidence of hypoglycemia is as high as 20%. In the newborn period, hypoglycemia may be the presenting feature of hypopituitarism. In males, a microphallus may provide a clue to a coexistent deficiency of gonadotropin[111,112] (Figure 5-11). Newborns with hypopituitarism may also have liver dysfunction resembling cholestatic liver disease, and some have midline malformations such as the syndrome of septo-optic dysplasia.[113]

Although older infants and children with pituitary deficiency present with ketotic hypoglycemia, in the neonatal period the hypoglycemia may mimic hyperinsulinism. These infants may represent a subset of perinatal stress-induced hyperinsulinism. However, their hypoglycemia is not responsive to diazoxide and only remits with replacement of deficient hormones (including thyroxine, as well as growth hormone and cortisol). When adrenal disease is severe (as in congenital adrenal hyperplasia caused by enzyme defects in cortisol synthesis, adrenal hemorrhage, or congenital absence or hypoplasia of the adrenals,[114,115]), disturbances in serum electrolytes with hyponatremia and hyperkalemia or ambiguous genitalia may provide diagnostic clues.

Abnormalities of the ACTH receptor or adrenal agenesis may also be phenotypically difficult to distinguish from cortisol deficiency of other causes, with the exception of the marked elevations of serum ACTH concentration noted if the ACTH receptor or adrenal gland is malfunctioning.[116] However, all states with ACTH elevations can be clinically suspected by virtue of the associated hyperpigmentation (see Chapter 12). These cases of isolated adrenal insufficiency very rarely cause

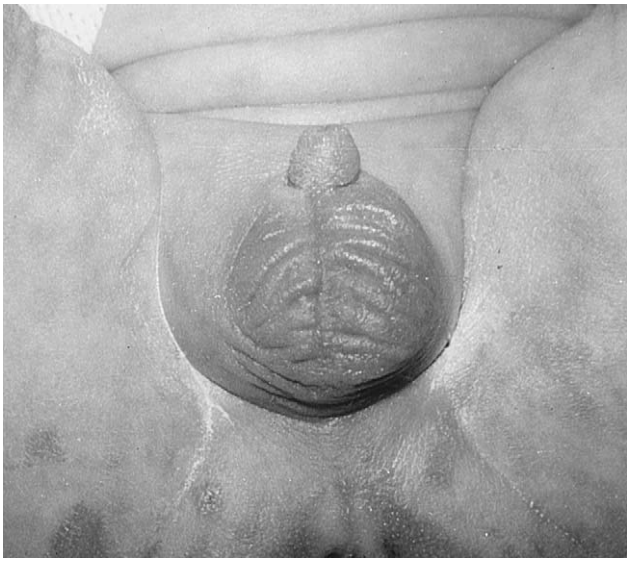

Figure 5-11. Micropenis and undescended testes in an infant with congenital hypopituitarism. The infant was hypoglycemic at 12 hours of age (glucose, 24 mg/dL). At 72 hours of age, he was jaundiced—and a liver biopsy demonstrated neonatal hepatitis. His endocrine evaluation was positive for hypothyroidism, low cortisol level, undetectable growth hormone level, and an elevated prolactin level (confirming hypothalamic hypopituitarism).

hypoglycemia in neonates, whereas in older infants and children treated congenital adrenal hyperplasia and isolated ACTH deficiency can cause profound stress-induced hypoglycemia.

The mechanism of hypoglycemia in growth hormone deficiency may be the result of decreased lipolysis. The mechanism of hypoglycemia with cortisol deficiency may be reduced liver glycogen reserves plus diminished gluconeogenesis, owing to a failure to supply endogenous gluconeogenic substrate in the form of amino acids from muscle proteolysis. Deficiency of either of these hormones can resemble the syndrome of ketotic hypoglycemia. Investigation of a child with hypoglycemia therefore requires exclusion of ACTH, cortisol, or growth hormone deficiency—and if diagnosed appropriate replacement with cortisol or growth hormone. Although glucagon deficiency[117,118] has been described, this disorder is exceedingly rare or nonexistent. Epinephrine deficiency is also rare, but must be a consideration in familial dysautonomia or in children treated with beta blockers.

Glycogen Storage Disorders

The glycogen storage disorders (GSDs) may present primarily as hepatic manifestations or muscular and cardiac manifestations. Hypoglycemia is a consistent feature of certain forms (e.g., glucose 6-phosphatase deficiency). Affected children may display a remarkable tolerance to their chronic hypoglycemia. Blood glucose values in the range of 20 to 50 mg/dL (1.1 to 2.7 mmol/L) are often not associated with the classic symptoms of hypoglycemia, possibly reflecting the use of ketones or lactic acid as alternative fuels by the central nervous system. These disorders are uncommon, but they present with distinct phenotypes and are important to diagnose correctly to avoid long-term sequelae.[119]

Glycogen is a globular structure with a variable molecular weight. It is found primarily in liver and muscle but is present in other cells. The arborized structure consists of straight-chain glucose residues attached through amylo-1,4 linkages, with branch points every 12 to 18 residues attached through a 1,6 linkage. Glycogen is synthesized from incorporation of sequential glucose-1-phosphate residues that have been converted to uridine diphosphoglucose and then incorporated by glycogen synthase. When the elongating glycogen chain consists of at least 11 residues, a branching enzyme transfers a chain of seven molecules to another chain by an α1-6 bound. Thus, glycogen synthase elongates the glycogen chain and the branching enzyme produces new branches—creating a molecule with a helical structure of 12 concentric tiers.

Glycogen degradation is the result of the activities of glycogen phosphorylase and a debranching enzyme. Glycogen phosphorylase catalyzes the rate-limiting step of glycogenolysis. It cleaves α1-4 linkages to remove glucose molecules from the glycogen chain as glucose-l-phosphate. The debranching enzyme has both transferase and glucosidase activity. When four glucose units remain before a branch point, the transferase activity of the debranching enzyme catalizes the transfer of three glucose residues to an adjacent branch of the glycogen chain. Through a second enzymatic glucosidase component, the debranching enzyme next cleaves the α1-6 bond to release a free glucose moiety from the branch point. Glycogen phosphorylase is then able to continue removal of glucose residues from the glycogen chain.[120] This complex system offers many specific points of regulation and many sites for mutation.[121]

GLUCOSE 6-PHOSPHATASE DEFICIENCY (GSD TYPE I)

Glucose 6-phosphatase catalyzes the terminal steps of both hepatic gluconeogenesis and glycogenolysis. The phenotype of infants with type I GSD is characteristic, despite the fact that the glucose 6-phosphatase complex possesses a variety of sites for different mutations and several subtypes of GSD I have been described.[119] The most striking feature is the massive hepatomegaly that may fill the entire abdomen. Affected infants have profound elevations of plasma triglycerides, and their serum may be creamy.

Patients are often tachypneic secondary to respiratory compensation for their metabolic acidemia as a result of dramatic elevation in plasma lactate concentration. Although ketosis is often present, it is minimal compared to the dramatic lactic acidosis seen in untreated patients. Other consistent features are hyperuricemia to plasma concentrations that may precipitate gouty crises, hypophosphatemia, a bleeding diathesis secondary to impairment of platelet adhesiveness, and growth retardation.

Hypoglycemia may occur anytime these children are exposed to even brief periods of fasting. They are completely dependent on the provision of glucose from exogenous sources, with the exception of the small amount of free glucose—which is released as part of the process of debranching glycogen. Because less than 10% of glycogen consists of branch points, this mechanism provides little protection against hypoglycemia during fasting. Affected infants may be diagnosed soon after birth with hepatomegaly, and then hypoglycemia may be documented during the diagnostic evaluation. On the other hand, because lactate and ketones may provide adequate brain substrate to protect central nervous system function (and because in early infancy regular feedings are consistently provided) the diagnosis may be delayed for months until massive hepatomegaly brings the infant to medical attention.

Hepatomegaly, in the absence of splenomegaly or other signs of a generalized storage disorder, should suggest glycogen as the likely storage component causing liver enlargement. After infancy, affected patients may be seen walking with a waddling gait secondary to their prominent abdomen and muscle weakness—with blood glucose levels of less than 40 mg/dL and lactate levels of more than 8 to 10 mmol/L (apparently in total disregard of their hypoglycemia and with deep respirations reflecting their respiratory compensation for metabolic acidosis).

Glucose 6-phophatase is a multicomponent system consisting of a catalytic unit with its active site located on the luminal side of the endoplasmic reticulum, and transmembrane-spanning translocases that allow the entry of

glucose 6-phophate to the catalytic subunit and the exit of Pi and glucose.[122] The gene for the catalytic unit has been cloned and located in a single copy on chromosome 17,[121] whereas the gene for the glucose 6-phosphate translocase is located on chromosome 11.[123] GSD type I is an autosomal-recessive disease. Molecular genetic evidence has unequivocally demonstrated that GSD type Ia[124] is caused by mutations in the catalytic unit, whereas mutations in glucose 6-phosphate translocase cause GSD type Ib.[123]

The clinical hallmark of patients with GSD type 1b is their susceptibility to infection as a consequence of neutropenia, mouth ulcers, and occasionally chronic enteritis (which is similar to Crohn disease).[119] Treatment with granulocyte-macrophage colony-stimulating factor to augment neutrophil production has been shown to ameliorate mouth ulcers and the enteritis.[125] Although two additional types have been reported [GSD type Ic[126] (presumably caused by a mutation in the putative Pi translocase) and GSD type Id[119] (due to a defect in the glucose translocase)], there is insufficient available evidence to sustain the existence of these defects.

Rapid onset of hypoglycemia is the hallmark of GSD type I, which occurs 2 to 3 hours after a meal immediately after intestinal absorption of carbohydrates is complete. Renal disease is a frequent complication of GSD type I (with an estimated prevalence of 30%).[127] Manifestations include proximal renal tubular dysfunction (Fanconi-like syndrome), distal tubular acidification defect, and hypercalciuria. The widespread prevalence and serious prognosis of kidney involvement is manifested by severe glomerular hyperfiltration and microalbuminuria over time, systemic arterial hypertension, and consequently renal failure in a considerable number of patients.[128-130] The early implementation of treatment with angiotensin-converting enzyme inhibitors has been shown to delay the progression of renal damage.[127]

The pathologic findings include focal segmental glomerulosclerosis with interstitial fibrosis. The etiology of this renal involvement is unclear, but it seems to correlate negatively with metabolic control. It has been proposed that the dyslipidemia contributes to the kidney injury.[131] In addition to the characteristic hepatomegaly, the liver undergoes adenomatous changes. Ultrasound of older patients with glucose 6-phosphatase deficiency will frequently show multiple adenomas.[132,133] Reports of malignant degeneration of these lesions are noted.[134] Other complications of GSD I include osteopenia and growth retardation.

The goal of treatment of children with glucose-6-phosphate deficiency is to completely eliminate hypoglycemia and suppress secondary metabolic decompensation. Continuous nasogastric or intragastric feeding during the night or total parenteral nutrition has demonstrated either a reduction or an elimination of the metabolic and clinical findings through complete avoidance of hypoglycemia.[135] Oral uncooked cornstarch supplementation (1.6 g/kg per dose every 4 hours in infants and 1.7 to 2.5 g/kg per dose every 6 hours in older patients) has also been applied in treatment regimens.[136,137]

A typical regimen institutes daytime feedings every 3 to 4 hours that are calculated to provide adequate carbohydrate calories to suppress hepatic glucose output. Most of these calories consist of carbohydrates, primarily providing pure glucose as an energy source and avoiding disaccharides containing fructose or galactose. At night, the regimen consist of an intragastric infusion of glucose with or without protein designed to infuse at rates of about 125% calculated hepatic glucose output[138] for young infants. For older children, a regimen of uncooked cornstarch can be implemented.

Meticulous dietary control of blood glucose levels can lead to a significant clinical and metabolic improvement and prevention of complications. Adjunctive therapies should include careful monitoring of the uric acid level and treatment with allopurinol if the uric acid level remains elevated. With increasing awareness of the renal tubular dysfunction, treatment of the hyperfiltration state with an angiotensin-converting enzyme inhibitor should be initiated promptly.

AMYLO-1,6-GLUCOSIDASE DEFICIENCY (DEBRANCHER DEFICIENCY, GSD TYPE III)

The debraching enzyme, together with phosphorylase, is required for complete degradation of glycogen. The lack of activity of this enzyme results in incomplete breakdown of glycogen and glycogen accumulates. The human debranching enzyme gene is a large single-copy gene located on chromosome 1p21.[139] Debrancher deficiency GSD type III is an autosomal-recessive disease. The phenotype of debrancher deficiency, although similar, can be distinguished clinically from that of glucose 6-phosphatase deficiency (e.g., particularly in regard to lack of lactic academia and renal disease).

During infancy and childhood, hepatomegaly, hypoglycemia, hyperlipidemia, and short stature are the predominant features. The hepatomegaly may be quite marked in GSD type III. Although these individuals also share a propensity for developing hypoglycemia, it usually tends to be less severe. Moreover, these individuals have the capacity to undergo gluconeogenesis—whereas individuals with glucose 6-phosphatase deficiency lack this capacity. The general presentation of debrancher deficiency is hepatomegaly noted with growth retardation. Hypoglycemia is less often the presenting finding than in patients with glucose 6-phosphatase deficiency. The abnormality in liver function is less profound, and these individuals also may have muscle weakness and myotonia.

Approximately half of affected patients may have progressive skeletal muscle weakness and/or cardiomyopathy (type IIIa). In about 15% of patients, GSD III appears to involve only the liver (type IIIb). The patient's serum creatine kinase level can be used to determine muscle involvement. The debranching enzyme is active in leukocytes and erythrocytes, and thus these present easily accessible tissues for biochemical analysis.[140] Because of genetic heterogeneity in enzyme activity, leukocyte or erythrocyte enzyme testing has not been effective in determining the heterozygote state. Frequent feedings with high protein content have been successful in treatment of debrancher deficiency.[141,142]

GLYCOGEN PHOSPHORYLASE DEFICIENCY (GSD TYPE VI) AND PHOSPHORYLASE KINASE DEFICIENCY (GSD TYPE IX)

Glycogen storage disease due to reduction in liver phosphorylase activity is a heterogeneous group of disorders. Deficiency of phosphorylase kinase (GSD type IX) resulting in failure of hepatic phosphorylase activation is the most common of these disorders, whereas deficiency of liver glycogen phosphorylase (GSD type VI) is very rare. Phosphorylase kinase of liver and muscle is a complex enzyme consisting of four subunits (α, β, γ, and δ), of which the γ subunit is catalytically active.

Mutations in three different genes for PHK subunits can result in deficient activity of hepatic phosphorylase. X-linked GSD type IX caused by mutations in the gene encoding the liver isoform of the α subunit is the most common variant. Other less common variants of GSD type IX are autosomal recessive (affecting only liver) or are a form that affects both liver and muscle. GSD type VI is recessive and caused by mutations in liver glycogen phosphorylase.

The clinical phenotype is similar in GSD types VI and IX. Classically, the physical hallmark is hepatomegaly without splenomegaly. Although some patients have been reported with growth retardation and hypoglycemia, this tends to be the exception. The impaired glycogen breakdown in GSD types VI and IX leads to mild hypoglycemia after prolonged fasting. Unlike in GSD type I, blood levels of lactic acid and uric acid are normal. Mild elevation of triglycerides, cholesterol, and serum transaminase may be present. Muscular hypotonia can result in delayed motor development in patients with X-linked GSD type IX. Prolonged fasting should be avoided in these patients. A bedtime snack is usually sufficient to prevent hypoglycemia in the morning. Clinical and biochemical abnormalities gradually improve with age, and most adult patients are asymptomatic.

GLYCOGEN SYNTHASE DEFICIENCY (GSD TYPE 0)

Glycogen storage disease type 0 is caused by deficiency of the hepatic isoform of glycogen syntase.[143] Glycogen synthase catalizes the formation of α-1,4 linkages that elongate chains of glucose molecules to form glycogen. Autosomal-recessive mutations in the *GYS2* gene located on chromosome 12p12.2 cause GSD 0.[144] In contrast to other forms of glycogenoses, in GSD type 0 there is marked decreased in liver glycogen content. GSD type 0 is the only GSD not associated with hepatomegaly. Children with GSD 0 are usually asymptomatic during early infancy, but experience fasting ketotic hypoglycemia when weaned from overnight feedings. They can be relatively asymptomatic because the increased plasma ketones are used as alternative brain fuel.

This condition mimics the syndrome of ketotic hypoglycemia and should be considered in the differential diagnosis. In addition to fasting hypoglycemia, deficiency of glycogen synthase results in postprandial hyperglycemia after ingestion of a carbohydrate-containing meal. After uptake by the liver, glucose is shunted into the glycolytic pathway—leading to postprandial hyperlactatemia and hyperlipidemia. Short stature and osteopenia are common in untreated children, but improve with appropriate metabolic control. The goal of treatment is to prevent hypoglycemia and to minimize metabolic acidosis. Dietary recommendations include a high-protein diet with complex carbohydrates. Uncooked cornstarch is used to prevent fasting ketotic hypoglycemia overnight.

DIAGNOSIS OF GLYCOGEN STORAGE DISORDERS

The diagnosis of glycogen storage disorders is based in grant part on the clinical presentation. The combination of clinical features, biochemical analysis, and mutation analysis allows for the specific types of GSD to be differentiated. Clinically, GSD type I can be easily differentiated by the severity of hypoglycemia (which occurs after a short period of fasting) and the association with lactic academia and hyperuricemia. As previously discussed, hypoglycemia is milder and usually happens after prolonged fasting in patients with other forms of GSD. Hepatomegaly is a common clinical feature in all the types except GSD type 0.

A fed glucagon stimulation testing with simultaneous assessment of blood glucose and lactate is also helpful in the diagnosis. In GSD type I, glucagon cause a rise in lactate levels (whereas blood glucose levels remain unchanged). Biochemical studies of leukocytes provide information on all glycogen storage diseases except glucose 6-phosphatase deficiency. The diagnosis of glucose 6-phosphatase deficiency may be made through enzymatic studies on liver biopsy tissue, but the availability of mutation analysis has made the need for liver biopsy obsolete. Mutation analysis is now available for GSD types Ia and Ib, as well as GSD type 0.

Disorders of Gluconeogenesis

GLUCOSE 6-PHOSPHATASE DEFICIENCY (GSD TYPE I)

Although this disorder is often classified among the glycogen storage diseases, it should be considered primarily a defect of gluconeogenesis.

FRUCTOSE 1,6-DIPHOSPHATASE DEFICIENCY

Fructose 1,6-diphosphatase is a key regulatory enzyme of gluconeogenesis. A deficiency of this enzyme results in a block of gluconeogenesis from all possible precursors below the level of fructose-1,6-diphosphate (i.e., fructose, glycerol, lactate, amino acids) (see Figure 5-2). Infusion of these gluconeogenic precursors results in lactic acidosis without a rise in glucose, and acute hypoglycemia may be provoked by inhibition of glycogenolysis. Normally, however, glycogenolysis remains intact and glucagon elicits a normal glycemic response in the fed but not in the fasted state. Hypoglycemia does not develop until fasted beyond glycogen reserves. In affected

families, there may be a history of siblings with known hepatomegaly who died in infancy with unexplained metabolic acidosis.

Hepatomegaly in individuals with fructose 1,6-diphosphatase deficiency is due to lipid storage. The biochemical hallmark consists of lactic acidosis, ketosis, hyperlipidemia, and hyperuricemia. Their pathogenesis is related to the severity and duration of hypoglycemia and the resultant low levels of insulin and high levels of counter-regulatory hormones. Therapy in these infants consists of avoidance of fasting longer than 8 to 10 hours. A diet high in carbohydrates (56%, excluding fructose, which cannot be used), low in protein (12%), and normal in fat composition (32%) has permitted normal growth and development. Continuous nocturnal provision of calories through the intragastric infusion system described for type I glycogen storage disease is also applicable to children with fructose 1,6-diphosphatase deficiency. During intercurrent illnesses with vomiting, intravenous glucose infusion is necessary to prevent severe hypoglycemia and lactic acidemia.

PYRUVATE CARBOXYLASE DEFICIENCY

Pyruvate carboxylase is a mitochondrial enzyme that catalyzes conversion of pyruvate to oxalacetate, a key metabolite in gluconeogenesis. Clinical manifestations of pyruvate carboxylase deficiency include lactic acidosis and hypoglycemia. Other biochemical markers include elevated pyruvate and alanine.[145] In addition to lactic acidosis and hypoglycemia, a subgroup of patients develops hyperammonemia and elevation of plasma citrulline, lysine, and proline levels.

Mental retardation and seizures may be part of the presentation in some patients.[146] The severity of this condition varies from mild intermittent lactic acidosis without mental disability to severe, rapidly progressive, and often fatal disease. The diagnosis of pyruvate carboxylase deficiency is confirmed by measurement of enzyme activity in fibroblasts. Treatment is primarily symptomatic, with correction of the metabolic acidosis. Replacement of Krebs cycle intermediates (citrate, aspartate, or odd-chain fatty acid compounds) has been used, as well as supplementation with coenzymes of pyruvate dehydrogenase complex (thiamine and lipoic acid).[147,148]

PHOSPHOENOLPYRUVATE CARBOXYKINASE DEFICIENCY

This is a potential gluconeogenic disorder, and a few reported cases have been suggested to have a deficiency of this enzyme. None has been confirmed, however. Therefore, the existence of this defect remains uncertain.

Galactosemia

Galactose metabolism progresses through phosphorylation (galactose-1-P) and then through conjugation with uridine to form uridine diphosphate (UDP) galactose. UDP galactose may undergo epimerization to form UDP glucose (Figure 5-2). The clinical syndrome of galactosemia results from a deficiency of galactose 1-phosphate uridyl transferase. UDP galactose-4-epimerase deficiency may result in a similar syndrome, however.[149] Galactose 1-phosphate uridyl transferase is essential in infants consuming lactose as their primary carbohydrate source.

In infants with classic galactosemia, exposure to dietery galactose results in acute deterioration of multiple organ systems—including liver dysfunction, coagulopathy, poor feeding and weight loss, renal tubular dysfunction, cerebral edema, vitreous hemorrhage, neutropenia, and *Escherichia coli* sepsis.[150] Most state screening programs have included galactosemia in their newborn screening. The important clinical caveat is that hypoglycemia in an infant who has vomiting or diarrhea and jaundice (with or without hepatomegaly) should raise the diagnostic consideration of galactosemia. However, hypoglycemia is not a common feature unless severe hepatic failure has already developed.

A neonate with these findings and concomitant *Escherichia coli* sepsis should also be considered as possibly affected with galactosemia, because neonatal *E. coli* sepsis is increased in this disorder (often leading to death). The toxic accumulation of galactose 1-phosphate is proposed as a mechanism to explain the deleterious effects on certain tissues resulting in intellectual impairment, cataracts, hepatic dysfunction, renal tubular defects with Fanconi syndrome, and ovarian (but not testicular) failure. A galactose-restricted diet will effectively reverse many of the listed abnormalities and almost certainly will eliminate the likelihood of hypoglycemia. Long-term effects on mental function as well as on speech and ovarian function may persist despite appropriate dietary therapy, however.[151]

Hereditary Fructose Intolerance

Hereditary fructose intolerance (HFI) is an autosomal-recessive disorder caused by a deficiency in fructose-1-phosphate aldolase. This aldolase is the primary isoenzyme used during the incorporation of diet-derived fructose into the hepatic glycolytic and gluconeogenic pathways. HFI may be a diagnostic challenge. In the absence of fructose ingestion, patients are entirely normal. Ingestion or infusion of fructose, sucrose, and sorbitol results in the accumulation of fructose 1-phosphate in the liver and a depletion of intracellular phosphate and ATP pools. These metabolic disturbances result in decreased gluconeogenesis and glycogenolysis, which precipitate hypoglycemia.[152]

The severity of the clinical phenotype varies with the quantity of the dietary fructose exposure. Breast-fed or milk-based formula-fed infants are normal until fruits and juices are introduced into the diet. If a fructose- or sucrose-containing formula is fed during the neonatal period to an affected individual, the consequences may be lethal. Because many of the symptoms after fructose ingestion suggest gastrointestinal system disturbances, a soy or elemental formula containing sucrose may be tried—resulting in progressive deterioration of the infant. The worsening of symptoms and hypoglycemia with feedings should raise clinical suspicion. Biochemical confirmation

of the diagnosis may be ascertained by enzyme assay of liver or small intestinal biopsy. Although intravenous fructose tolerance testing was used in the past, the risks to the patient and the availability of molecular diagnosis have made this method obsolete.

Symptoms after acute exposure to fructose include those of hypoglycemia, as well as nausea, abdominal pain, and vomiting. Chronic exposure results in failure to thrive and a clinical spectrum suggestive of chronic liver disease. Hypoglycemia may be missed in patients with HFI because the fall in blood glucose concentration may be transient.[153] Sorbitol ingestion causes biochemical abnormalities similar to fructose ingestion without fructosemia.[154] Treatment of this disorder involves strict dietary avoidance of fructose, sucrose, and sorbitol. This avoidance is often learned and self-imposed by patients if they reach 1 year of age.

Disorders of Fatty Acid Oxidation

At least 25 enzymes and transport proteins are involved in mitochondrial fatty acid metabolism, some of which have been recognized very recently. Defects in 22 of these have been shown to cause disease in humans, and although the first defects were identified 30 years ago most have been identified only in the past 15 years.[155] The inborn errors of metabolism associated with deficiencies of fatty acid oxidation (Figure 5-12) are inherited in autosomal-recessive fashion. All of these disorders may be provoked with fasting and exhibit life-threatening events with varying degrees of hypoglycemia associated with a relative deficiency in the generation of ketone bodies.[156] Disorders of fatty acid oxidation may be divided according to the site of the defect: defects of fatty acid and carnitine transport, β-oxidation defects, electron transport chain defects, and defects of ketone body synthesis and utilization.

The disorders of fatty acid oxidation share many clinical features and tend to be exacerbated with fasting because metabolism of fatty acids is maximal during fasting. Common events (such as immunization or intercurrent infections) will often decrease oral intake and result in symptoms and signs of a defect in fatty acid oxidation. The wide spectrum of clinical presentation includes hepatic, cardiac, and muscle manifestations.[157] The most important of these is the hepatic presentation characterized by acute life-threatening attacks of coma precipitated by fasting. This manifestation occurs in nearly all of the defects, and is more clearly exemplified by medium-chain acyl-coenzyme A dehydrogenase deficiency (MCAD).

Attacks are associated with hypoketotic hypoglycemia with little or no academia; elevation of serum urea, ammonia, and uric acid; liver function abnormalities; and hepatic steatosis. The risk of severe complications and

[From Stanley CA, Hale DE (1994). Genetic disorders of mitochondrial fatty acid oxidation. Curr Opin Pediatr 6:476.]

death is very high unless appropriate treatment to reverse the catabolic state is implemented. The diagnosis of these cases may be confused with Reye's syndrome. Cardiac involvement frequently accompanies acute hepatic presentations, especially in defects affecting long-chain fatty acid oxidation.[158] The cardiac presentation can be acute or chronic, with dilated or hyperthrophic cardiomyopathy. This presentation can evolve to progressive heart failure at 2 to 3 years of age (or later in patients with muscle-kidney plasma membrane carnitine transporter defect).[159] The third manifestation of fatty acid oxidation disorders is acute or chronic muscle presentations.

The least severe cases can be seen in adults with the mild form of carnitine palmitoyl-transferase 2 deficiency who present with acute rhabdomyolysis and renal failure after strenuous exercise.[160] Some manifestations of fatty acid oxidation disorders, such as pigmentary retinopathy and peripheral neuropathy (which occur in long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency), may be explained by toxic effects of fatty acid metabolites. Less common manifestations of fatty acid oxidation disorders involve congenital malformations[161] or the acute fatty liver of pregnancy or the HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome in mothers heterozygous for long-chain 3-hydroxy-acyl-coenzyme A dehydrogenase deficiency (LCHAD) mutations.[162]

Because fatty acid oxidation is reduced with loss-of-function mutations in this pathway, a decreased ability to generate ketones during normal fasting and acute illness is common. Thus, these defects as a class are associated with hypoketotic hypoglycemia. Although hypoglycemia may be a prominent late feature of the severe mutations seen with MCAD, the phenotype of a defect of a fatty acid oxidation disorder may not manifest if a fasting state is avoided. A high index of suspicion for fatty acid oxidation defects is important because appropriate therapy may result in an interruption and prevention of these potentially life-threatening episodes.

The most commonly presenting deficiencies involve the mitochondrial acyl-CoA dehydrogenases with very long-, long-, medium-, and short-chain length specificities (VLCAD, LCAD, MCAD, and SCAD, respectively).[163] MCAD is the most frequent. Neonatal screening in Pennsylvania has shown an incidence of 1 in 9,000 live births.[164] Although there is significant heterogeneity in presentation of MCAD, the most frequent clinical presentation is one of intermittent hypoketotic hypoglycemia. Mild hyperammonemia and coma may be present with a Reye-like syndrome. A distinct association of the symptoms with fasting or substrate deprivation is consistent with this defect.

Affected patients have also been misdiagnosed with idiopathic sudden infant death syndrome.[165,166] Decreased plasma carnitine levels and an increase in the ratio of esterified to free carnitine is a frequently associated laboratory finding. VLCAD deficiency is commonly associated with cardiac and skeletal muscle myophaty, but hypoketotic hypoglycemia, hyperammonemia, and hepatocellular failure can also occur.[167] Although putative LCAD deficiency cases have been reported, all of the patients described before 1992 were subsequently proven to have VLCAD.[168] Hypoglycemia is not usual in SCAD deficiency.

Deficiencies of several steps of carnitine, acylcarnitine, and fatty acid transport into cells and mitochondria have been described.[169,170] A genetic defect of the plasma membrane carnitine transporter represents the only true entity of primary carnitine deficiency. Decreased carnitine accumulation in tissue and renal carnitine losses result in impairment of long-chain fatty acid metabolism, which can lead to severe hypoglycemia and dilated cardiomyophaty in infancy or childhood. This disorder (and no others) responds to carnitine supplementation. Liver carnitine palmitoyl transferase I (CPT I) deficiency is characterized by early-onset episodic hypoketotic hypoglycemia, sometimes with hyperammonemia and multiorgan system failure.

These patients can have elevated levels of plasma carnitine. Deficiency of the carnitine-acylcarnitine translocase presents with severe hypoketotic hypoglycemia, hyperammonemia, and cardiac arrhytmias in the neonatal period. Plasma carnitine levels are extremely low. Cardiomyopathy related to secondary carnitine deficiency may be present. CPT II deficiency is the most common of this group of disorders (with mostly muscle involvement), although a more severe variant similar to CPT I deficiency has also been reported.[171] The carnitine transporter defect may be effectively treated with oral carnitine supplementation, and a rapid reversal of the clinical syndrome (including cardiomyopathy) may be seen over weeks to months.[172,173]

Defects of other mitochondrial matrix enzymes involved in β-oxidation include deficiency of long-chain 3-hydroxy-acyl-coenzyme A dehydrogenase (LCHAD). LCHAD is one of the more severe fatty acid oxidation disorders, with a wide phenotypic spectra and diverse manifestations—including hypoglycemia, cardiomyopathy, skeletal myopathy, hepatocellular disease, pigmentary retinopathy, peripheral neuropathy, and sudden death. In the last decade, many patients with LCHAD deficiency have been reported who were born following pregnancies complicated with severe maternal liver disease (acute fatty liver of pregnancy and HELLP syndrome). Thus, a detailed prenatal history may be key to the diagnosis.[174] The vulnerability to maternal complications of pregnancy can also be seen in other fatty acid oxidation disorders.

Hypoketotic hypoglycemia can be part of the presentation in defects of ketone body production due to deficiency of 3-hydroxy 3-methylglutaryl-coenzyme A (HMG-CoA) lyase and HMG-CoA synthase deficiency. These two disorders can be differentiated by the large urinary excretion of 3-hydroxy-3-methylglutaric acid, which is pathognomonic for HMC-CoA lyase deficiency.

Evaluation of suspected errors in fatty acid oxidation should first include determination of the profile of plasma acyl-carnitines by mass spectrometry and measurement of plasma total, esterified, and free carnitine. Most, but not all, of the fatty acid oxidation disorders are associated with specific abnormalities of plasma acyl-carnitines—such as octanoyl-carnitine, which is diagnostically elevated in MCAD deficiency (Table 5-8). Determinations of urinary organic acids with assessment of the presence or absence of dicarboxylic aciduria are also very useful.

TABLE 5-8

Fatty Acid Oxidation Disorders with Distinguishing Metabolic Markers

Disorder	Plasma Acylcarnitines	Urinary Acylglycines	Urinary Organic Acids
VLCAD	Tetradecenoyl-		
MCAD	Octanoyl	Hexanoyl- Suberyl- Phenylpropionyl-	
SCAD	Butyryl-	Butyryl-	Ethylmalonic

From Stanley CA (1990). Disorders of fatty acid oxidation. In Fernandes J, Bremer E, Saudubray J-M (eds.), *Inborn metabolic diseases: Diagnosis and treatment.* New York: Springer-Verlag 394-410.

Patients whose disorder cannot be identified by these tests may require further evaluations, including assays of fatty acid oxidation and specific enzyme assays in cultured skin fibroblasts or lymphoblasts. Since the early 1990s, the use of tandem mass espectometry has made newborn screening possible for most fatty acid oxidation disorders based on the acyl-carnitine profile in blood spots. Presymptomatic identification of these individuals can prevent catastrophic events such as sudden death. Direct DNA mutational analysis can be performed for many of these defects, which is particularly useful in MCAD and LCHAD deficiencies in which most cases are due to single common mutations.

The primary treatment of disorders of fatty acid oxidation is a devoted avoidance of fasting. For infants younger than 1 year old, 6 to 8 hours of fasting may be sufficient to precipitate an episode. On the other hand, as children become older they appear to be able to withstand periods of fasting of as long as 10 to 12 hours without decompensation. A high index of suspicion and rapid institution of intravenous glucose will often reverse an evolving episode. The presence of hypoglycemia is usually an event that occurs late in the evolution of an episode of metabolic decompensation. High-fat diets should be avoided, although normal amounts of dietary fats do not appear to be toxic. An adjunct approach may involve the use of cornstarch (as used for the treatment of type I glycogen storage disease) in doses of 1.5 to 2 g/kg. This may delay the adaptation from the fed to the fasted state. Riboflavin has been reported to be an adjunct in rare patients.[175] The use of carnitine has been advocated.[176] However, a systematic assessment of various treatment regimens in these defects has not been available.

The expansion of neonatal screening programs based on determination of blood acyl-carnitine profiles by mass spectrometry allows earlier identification of these disorders and allows preventive counseling to parents to significantly decrease the occurrence of life-threatening events in these syndromes. Some chemical agents (such as valproic acid, hypoglycin A, and atractyloside) mimic the fatty acid oxidation disorders outlined in Figure 5-12.[177] Valproic acid can block β-oxidation. Treatment of epilepsy with valproic acid has been associated with Reye-like syndromes, including hypoketotic hypoglycemia.[178] Some investigators have advocated treatment with carnitine for infants receiving valproic acid, but there is not universal agreement on this point.[178]

Jamaican vomiting sickness is caused by the toxin hypoglycin A, a component of the unripened ackee fruit (a Jamaican food staple). This chemical acts as an inhibitor of fatty acid oxidation and can produce a syndrome similar to that of a patient with MCAD deficiency with hypoketotic hypoglycemia.[179] Last, rare ingestions of plant atractyloside (such as found in the Mediterranean species *Atractylis gummifera*) have been associated with a syndrome of vomiting and hypoketotic hypoglycemia.[180] Atractyloside is an inhibitor of mitochondrial oxidative phosphorylation and prevents translocation of adenine nucleotides across the mitochondrial membrane.[181]

Drug-Induced Hypoglycemia

Drug-induced hypoglycemia is rare in neonates and young infants. The administration of medications to infants may represent the Munchausen by proxy syndrome. Rarely, it may represent a pharmaceutical dispensing

error with substitution of an insulin secretogogue (e.g., glyburide) for another medication. Hypoglycemia can also occur as a side effect of therapy (i.e., beta-blockers). Toxic substances such as ethyl alcohol in various beverages or salicylates may be accidentally or deliberately used in detrimental ways in infants. As noted in the discussion of hyperinsulinism, injectable insulin is readily available—as are potent oral hypoglycemic agents. Occasionally, an infant will present with unexplained hypoglycemia and not fit readily into any diagnostic algorithm. In these rare instances, a careful history of drug or alcohol availability in the environment must be undertaken and pharmacy dispensing errors considered.

Defects of Glucose Transporters

GLUT1 DEFICIENCY

GLUT1 deficiency has now been diagnosed in a growing number of patients since the first reports in 1991.[9] The cloning of the human SLC2A1 (encoding *GLUT1*) gene confirmed the initial speculation involving a defect in glucose transport across the blood-brain barrier as the underlying mechanism for the classic presentation of infantile-onset epileptic encephalopathy associated with delayed neurologic development. The genetic inheritance of the condition behaves as an autosomal dominant trait, although spontaneous heterozygous mutation in the SLC2A1 gene can present sporadically in families.[182,183]

The phenotypic presentation is variable, from the classic presentation of developmental encephalopathy with seizures to nonclassic presentations with mental retardation, dysarthric speech, and intermittent ataxia without clinical seizures. It can also manifest as a movement disorder characterized by choreoathetosis and dystonia.[183] The biochemical hallmark is the finding of hypoglycorrhachia (low cerebrospinal fluid glucose concentration) despite normal plasma glucose concentrations. Treatment efforts have been based on providing alternative brain fuel sources by a ketogenic diet.[9,184] The ketogenic diet effectively controls the seizures and other paroxysmal activities, but is has less effect on the cognitive function.

GLUT2 DEFICIENCY

Fanconi-Bickel syndrome (characterized by hepatomegaly, glucose and galactose intolerance, and renal tubular dysfunction) is due to a recessive mutation of the GLUT2 plasma membrane transporter for glucose (encoded by *SLC2A2*).[185] GLUT2 is expressed in liver, renal tubular cells, enterocytes, and pancreatic beta cells. The clinical

For definitions of abbreviations, see Table 7-8 footnote.
GH, growth hormone; GSD, glycogen storage disease.

manifestations reflect impairment of glucose release from liver and of glucose reabsorption from renal tubular cells. Galactose clearance and conversion to glucose is delayed. Patients with GLUT2 deficiency usually present at an age of 3 to 10 months.

The typical clinical signs are hepatomegaly due to glycogen accumulation, a severe Fanconi-type renal tubulopathy with disproportionately severe glucosuria, glucose and galactose intolerance, rickets, and severely stunted growth.[186] These patients may present with a combination of fasting hypoglycemia and postprandial hyperglycemia. The therapeutic goal for patients with GLUT2 deficiency is to ameliorate the consequences of renal tubulopathy by replacing water, electrolytes, and alkali—and by providing phosphate and vitamin D supplementation. In terms of diet, an adequate caloric intake is recommended to compensate for renal and intestinal glucose loss—given as frequent feedings containing slowly absorbed carbohydrates (such as cornstarch) to avoid fasting hypoglycemia.

Systemic Disorders

Hypoglycemia may be a concomitant of severe systemic disease in neonates and infants. Neonatal sepsis is frequently complicated by hypoglycemia.[187] Malnourished infants, either deprived of caloric intake or suffering from malabsorption, may develop hypoglycemia as the malnutrition becomes severe.[188] Unique to newborns, hyperviscosity syndrome may be complicated by hypoglycemia. Up to 14% of infants with a hematocrit of more than 65% were noted to demonstrate hypoglycemia in one study.[189] A high index of suspicion for hypoglycemia should be maintained in any severely compromised neonate or infant.

Diagnosis

Treatment of hypoglycemia in neonates and infants requires making a specific diagnosis of the underlying cause. The diagnosis should be based on the combination of data obtained from the history, physical examination, laboratory findings, and (especially) the hormonal and fuel responses at the time of fasting hypoglycemia. Table 5-9 outlines the major distinguishing features of the various forms of hypoglycemic disorders in neonates and infants. As shown, the most important information required for diagnosis comes from tests on the blood and urine specimens obtained at a time of hypoglycemia (also known as the critical samples).

Important facts from the history include the duration of fasting that provoked hypoglycemia. Based on frequency,

N	N	N	N	Hepatomegaly 1+

hyperinsulinism should always be considered at the top of the list of differential diagnoses. Onset within a few hours of a meal would be consistent with hyperinsulinism or glucose 6-phosphatase deficiency, whereas onset after 10 to 12 hours would be consistent with a defect in fatty acid oxidation. Short stature would be consistent with pituitary deficiency, and this possibility would be supported by the presence of midline facial malformations, microphthalmia, or microphallus. Growth failure is also a prominent feature of glucose 6-phosphatase deficiency or debrancher deficiency glycogen storage disease. Both of these disorders are associated with massive hepatomegaly. Abnormal results of liver function tests (transaminases) and hyperammonemia, with or without elevated creatine kinase level, would suggest a possible fatty acid oxidation disorder.

Figure 5-13 outlines an algorithm for diagnosis of different forms of hypoglycemia based on readily available laboratory tests on the "critical" blood and urine samples. The first discriminant is a measure of acidemia at the time of hypoglycemia using the serum bicarbonate. If the acidemia is caused by elevations of the keto-acids β-hydroxybutyrate and acetoacetate), possibilities include a normal child fasted for too long (ketotic hypoglycemia), a defect in glycogenolysis (type 3 glycogen storage disease), or counter-regulatory hormone deficiency (e.g., hypopituitarism). If the acidemia is caused by an elevation of lactic acid, a block of gluconeogenesis should be suspected (e.g., glucose 6-phosphatase or fructose 1,6-diphosphatase deficiency or ethanol ingestion).

If there is no acidemia (i.e., absence of the normal elevation of ketones) but free fatty acid levels are high, a defect in fatty acid oxidation and ketogenesis can be suspected (e.g., MCAD deficiency). If ketones are not appropriately increased but the free fatty acid concentrations are also suppressed, hyperinsulinism can be suspected. In the neonatal period, the features of hyperinsulinism can be mimicked by congenital pituitary deficiency. Further tests can then be planned using the initial critical specimens to confirm the suspected diagnosis. These may include physiologic tests (such as the glucagon stimulation test at a time of hypoglycemia to confirm hyperinsulinism) or specialized laboratory tests (such as a plasma acyl-carnitine profile) to identify a defect in mitochondrial β-oxidation.

In some cases, a formal fasting test may be necessary to diagnose the cause of hypoglycemia. The goal of this test is to reproduce the setting in which hypoglycemia occurs in order to identify the underlying cause. The fasting test should be considered a method of testing a hypothesis that has already been developed, based on available clinical and laboratory data about the cause of the hypoglycemia. Thus, the test can be modified with additions or deletions to the basic protocol. This is important, because challenging an infant with fasting is not without risk—particularly if a genetic defect in fatty acid oxidation or adrenal insufficiency is present. Therefore, fasting or other diagnostic challenges should be done only in the hospital under carefully controlled settings with experienced physician and nursing staff readily available.

Infants younger than 1 year are usually fasted for up to 24 hours, whereas in older children the maximum fast is 36 hours. The fast is terminated when the plasma glucose

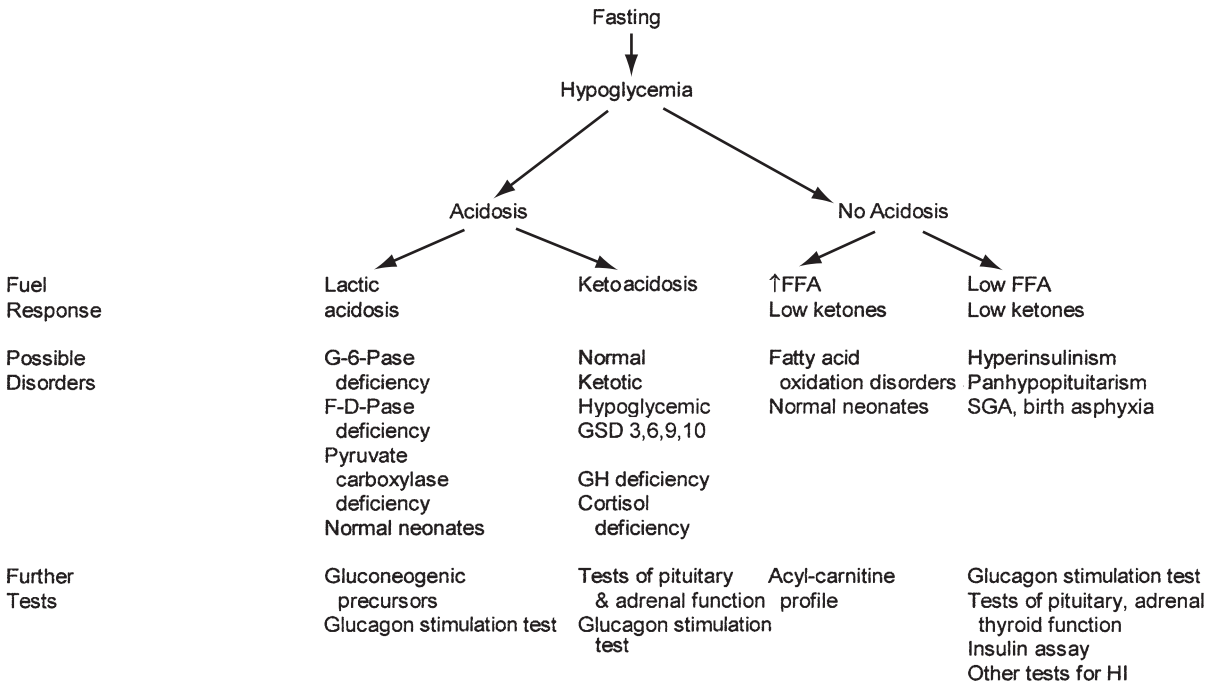

Figure 5-13 Algorithm for diagnosis of hypoglycemia based on "critical" blood tests obtained during a period of hypoglycemia. FFA = free fatty acids, GSD = glycogen storage disorder, HI = hyperinsulinism, and SGA = small for gestational age. [Modified from Stanley CA, Baker L (1978). Hypoglycemia. In Kaye R, Oski FA, Barness LA (eds.), *Core textbook of pediatrics*. Philadelphia: JB Lippincott 280-305.]

falls below 50 mg/dL, but may be ended sooner if plasma β-hydroxybutyrate rises to greater than 2.0 mmol/L or in the case of any adverse signs or symptoms. Periodic blood samples are obtained for analysis of major fuels and hormones and for appropriate ancillary tests (e.g., serum total carnitine, acyl-carnitine profile, liver transaminases, creatine phosphokinase, or urinary organic acids). If hyperinsulinism is suspected, the fasting test may be ended with glucagons (1 mg given intravenously) to evaluate the glycemic response.

Special note should be made that the most frequent cause of hypoglycemia in neonates, infants, and children (hyperinsulinism) often cannot be diagnosed based solely on the plasma insulin concentration. With very sensitive assays, serum insulin concentrations will be less than 1 to 2 μU/mL at times of hypoglycemia (i.e. below the sensitivity of most insulin assays). Therefore, the diagnosis must often be made based on evidence of inappropriate insulin effects: hypoketonemia, hypo-free fatty acidemia, and a positive glycemic response to glucagon.

Treatment

A rational therapeutic approach to the treatment of hypoglycemia relies on a systematic diagnostic evaluation. The key to effective treatment is diagnosis specific. The maintenance of euglycemia is critical to the preservation of central nervous system function. Even in the presence of an uncertain diagnosis, every effort must be used to maintain euglycemia until a diagnosis is made or hypoglycemia resolves. Intravenous glucose infusion remains the mainstay of emergency therapy. Glucose infusion rates may need to be increased as high as 15 to 25 mg/kg/min in infants with hyperinsulinism to maintain euglycemia. Hormones and drugs may be used as insulin antagonists or suppressants. In the case of congenital hyperinsulinism due to KATP mutations, surgery should be considered—especially in children with the focal form of the disease.

Conclusions

Since the early reports of neonatal hypoglycemia in the 1950s by McQuarrie[190] and Cornblath and colleagues,[191] our understanding of the pathogeneses and treatment of hypoglycemia in neonates and infants has progressed rapidly. The recent identification of the molecular causes of congenital hyperinsulinism represents a significant new discovery. The development of noninvasive techniques (such as the ^{18}F-fluoro-L-DOPA PET scan) that can accurately identify patients with focal KATPHI and the potential for cure with surgical removal of the lesion are promising advances in the treatment of these children. These and future discoveries should result in continued improvement in outcome in hypoglycemic patients.

- TBG Excess
- Transthyretin Variants
- Familial Dysalbuminemic Hyperthyroxinemia and Hypertriiodothyroninemia

The Fetus as Patient

Introduction

During the past four decades, understanding of thyroid system ontogenesis and thyroid function and dysfunction in the fetus and newborn have advanced dramatically. Newborn screening for congenital hypothyroidism is now routine throughout most of the industrialized world. Insights regarding fetal and perinatal thyroid function have improved management of complicated pregnancies and thyroid dysfunction in the premature and term infant.

Molecular genetics and technologies now provide differential diagnostic approaches to the inborn defects in thyroid hormone metabolism. This chapter reviews our current understanding of thyroid system ontogenesis and the classification and management of the disorders of thyroid function in the fetus and newborn infant. Gene names are abbreviated throughout the text. Complete names are available according to the Human Gene Nomenclature Committee at *www.gene.ucl.ac.uk/nomenclature/*.

Thyroid System Embryogenesis

Anatomic development of the hypothalamic-pituitary-thyroid system occurs during the first trimester of gestation.[1-4] The human fetal forebrain and hypothalamus begin to differentiate by 3 weeks of gestation. The hypothalamic cell condensations (destined to become the hypothalamic nuclei) and the interconnecting fiber traits are visible histologically by 15 to 18 weeks gestation, and significant concentrations of thyrotropin releasing hormone (TRH) and dopamine are detectable by 10 to 14 weeks.[5] Forebrain and hypothalamic development are dependent on a series of homeodomain proteins or transcription factors.

Mutations of three homeobox genes [sonic hedgehog (SHH), SIX3, and ZIC1] have been identified in infants with holoprosencephaly.[6-8] HESX1 homeobox gene mutations have been described in siblings with septo-optic dysplasia involving midline brain defects and pituitary hypoplasia.[9] Other homeodomain genes involved in hypothalamic development in the rodent include SF-1, SIM1, SIM2, SIX3, SIX6, PAX6, and BRN2.[4,10]

Anatomically, the pituitary gland develops from two anlagen: a neural component from the floor of the primitive forebrain, and Rathke's pouch (an ectodermal component from the primitive oral cavity). The latter is visible by 5 weeks, evolving to a morphologically mature pituitary gland by 14 to 15 weeks.[1,5] The pituitary-portal blood vessels are present by this time, and further mature through 30 to 35 weeks. In rodent models, the Rathke's pouch gene and pituitary homeobox (PTX1) gene are early factors in a cascade of determinants programming pituitary embryogenesis.[11] Later factors in the cascade include TTF1, LHX3, LHX4, Prop1, and Pit1.[4] TTF1 knockout leads to pituitary gland as well as thyroid aplasia. LHX3 and LHX4 are also essential to normal pituitary embryogenesis. Prop-1 and Pit-1 are terminal factors in the cascade, programming development and function of pituitary cells producing growth hormone, prolactin, TSHβ, and the GHRH receptors.[4] Mutations of Prop-1 or Pit-1 have been described in patients with familial hypopituitarism.[12]

The human thyroid gland develops from a median anlage derived from the primitive pharyngeal floor and paired lateral anlagen from the fourth pharyngobronchial pouch. These structures are visible by day 16 to 17 of gestation.[1,2] By 50 days, the median and lateral anlagen have fused, the buccal stalk has ruptured, and the thyroid gland has migrated to its definitive location in the anterior neck. By 70 days gestation, iodide concentration, TSH receptors, thyroglobulin and thyroid peroxidase mRNA, and protein can be demonstrated within the thyroid gland.

Thyroid embryogenesis is dependent on production of a programmed sequence of homeobox and transcription factors, including thyroid transcription factors NKX2.1 (TTF-1), FOXE-1 (TTF2), and PAX8.[13] NKX2.5 appears to play a role in regulation of NKX2.1, and HOX-A3 and HOX-B3 are important in expression of NKX2.1 and PAX8.[2,14] Targeted disruption of NKX2.1 in mice leads to thyroid gland aplasia. PAX8 gene disruption results in a small thyroid gland composed almost exclusively of C cells. FOXE-1 null mice manifest thyroid aplasia or an ectopic sublingual thyroid gland.[13] Mutations in these genes, however, account for only approximately 2% of human thyroid dysgenesis.[13]

Placental Iodine and Thyroid Metabolism

Adequate quantities of iodide are essential to fetal thyroid hormone synthesis, and during pregnancy the fetal thyroid competes with the maternal gland for the available iodine supply. In geographic areas of iodine deficiency, this competition is increased by the increased size and iodine-concentrating activity of the maternal thyroid gland. In lower species, the placenta compensates this maternal advantage to some degree by actively transporting iodide in the maternal-to-fetal direction. Studies in the rabbit have shown that the placental iodide transport is capable of generating a fetal serum/maternal serum iodide concentration ratio of 5–9:1.[15] This is not the case in human pregnancy, and cretinism is likely in the neonates of women with large iodine deficiency goiters.[15,16] The human placenta appears freely permeable to iodide, but whether this transfer is carrier mediated (as is chloride or sulfate transfer) is not clear[17] (Figure 6-1).

The placenta imposes a relative barrier to the thyroid hormones and is impermeable to TSH so that the fetal hypothalamic-pituitary-thyroid system develops largely autonomously of the maternal system.[18,19] There are large maternal-to-fetal gradients of total and free thyroxine (T4) and triiodothyronine (T3) across the placenta during most of gestation.[18,20] Near term, the free T4 gradient

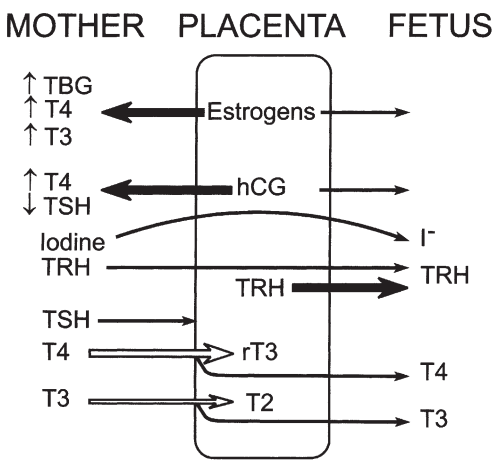

Figure 6-1. The placental role in thyroid metabolism during human pregnancy. The placenta produces estrogens and a human chorionic gonadotropin (hCG), which increase maternal TBG levels and stimulate maternal thyroid hormone production, respectively. Both activities tend to increase maternal T4 and T3 concentrations and inhibit maternal TSH secretion. Iodide and TRH readily cross the placenta. In addition, the placenta synthesizes TRH. The placenta is impermeable to TSH and only partially permeable to T4 and T3. Placental type III iodothyronine monodeiodinase enzymes degrade T4 to reverse T3 and T3 to 3,3′ T2. The placenta is also permeable to the thiourea drugs used to treat maternal Graves' disease.

gradually diminishes as fetal thyroid function matures. However, the marked maternal-to-fetal free T3 gradient persists. The placental barrier is due in part to the presence in placental tissue of an inner ring iodothyronine monodeiodinase (MDI), which converts T4 to inactive reverse T3 and T3 to diiodothyronine (T2).[19] Placental tissue also contains a type II outer ring MDI capable of catalyzing conversion of T4 to active T3.[19]

The net result of the placental metabolism of T4 is that significant maternal T4 does reach the fetus early as well as late in gestation. Significant fetal tissue T4 levels have been documented prior to the advent of fetal thyroid hormone production, and low levels of fetal T4 have been demonstrated in the athyroid human fetus at term.[21,22] Moreover, maternal hypothyroxinemia during the first half of gestation (prior to the activation of fetal thyroid hormone production) is associated with a decreased IQ in the offspring.

The placenta is permeable to the thioureylene antithyroid drugs, and TRH crosses the placenta readily (Figure 6-1). However, little endogenous TRH is normally detected in adult peripheral blood due to the presence of TRH-degrading enzyme systems in the blood.[18,24] Although the sera of pregnant women contain somewhat lower levels of these enzymes than do nonpregnant sera, the nearly immeasurable levels of TRH in the maternal circulation have little effect on fetal thyroid function. The placenta synthesizes a pro-TRH molecule, and fetal gut tissues (particularly pancreas) produce TRH.[18,24] The placental and pancreatic TRH have been isolated and characterized and found to be identical to hypothalamic TRH.

In addition to TRH, the placenta produces thyrotropin-like activity.[15,25] The α-subunit of TSH is identical to that of human chorionic gonadotropin (hCG), and the β-subunit of hCG has structural homology with the β-subunit of TSH. Thus, hCG has some TSH-like bioactivity. However, the biologic potency of hCG is only about 0.01% that of TSH, and hCG normally has little influence on fetal thyroid system development or function. However, the large increase in maternal serum hCG activity that occurs early in pregnancy leads to a transient stimulation of thyroid function with suppression of maternal TSH.

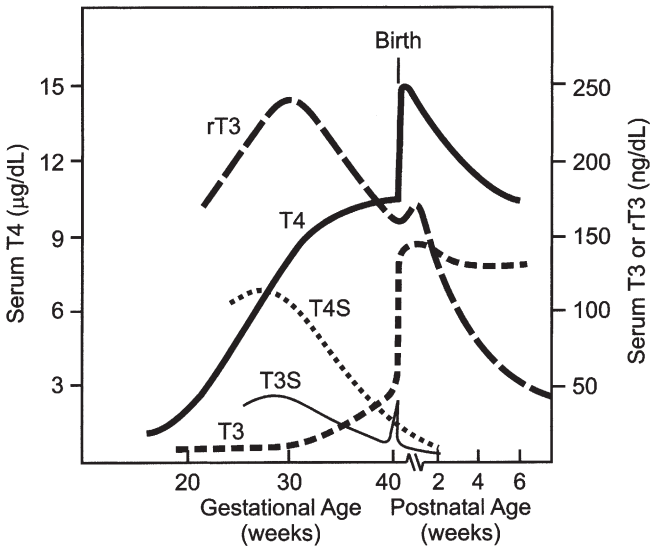

Figure 6-2. The pattern of change in fetal and neonatal thyroid function parameters during pregnancy and extrauterine adaptation. Fetal serum thyroxine (T4) concentrations begin to increase at mid-gestation and increase progressively thereafter to term. This increase is due largely to the increase in thyroxine-binding globulin concentration, but free T4 concentrations (not shown) also increase progressively between 20 and 40 weeks. T4 in the fetus is metabolized predominantly to inactive reverse triiodothyronine (rT3) and sulfated analogues (T4S, T3S). Monodeiodination of T4 to active triiodothyronine (T3) increases at about 30 weeks to levels approximating 50 ng/dL at term. The TSH surge (not shown), which peaks at 25 to 30 minutes after extrauterine exposure, stimulates thyroidal T4 and T3 secretion. Neonatal T4 and T3 peak at 2 to 3 days. Serum T3 concentrations remain at higher postnatal levels due to increased T4-to-T3 conversion mediated by increased type I iodothyronine deiodinase activity in newborn tissues.

Thyroid System Maturation

Maturation of thyroid function in the fetus can be considered to occur in three phases: hypothalamic, pituitary, and thyroidal. Changes in these systems are complex and superimposed on the increasing production and increasing serum concentration of serum thyroid hormone-binding globulin (TBG), as well as the changing pattern of fetal tissue iodothyronine deiodination. As previously mentioned, the fetal thyroid gland is capable of iodide concentration and iodothyronine synthesis as early as 70 days gestation. However, thyroid hormone production is limited until 18 to 20 weeks. At this time, thyroid follicular cell iodine uptake increases and serum T4 levels begin to increase (Figure 6-2).[26-28] Thereafter, TBG and total T4 concentrations increase steadily until the final weeks of pregnancy.

The trend of free T4 concentrations has been variable in several studies, increasing progressively to term in the intrauterine studies of Thorpe-Beeston et al. and seeming to plateau in cord blood studies between 24 weeks and term.[27,28] This variation is due at least in part to underestimation of free T4 concentrations in fetal/neonatal premature blood samples in many commercial free T4 immunoassay systems because of the low TBG concentrations in these samples. The fetal serum T3 concentration remains low (<15 ng/dL) until 30 weeks, and then increases in two distinct phases (a prenatal and a postnatal phase). Prenatally, serum T3 increases slowly after 30 weeks gestation—to reach a level of approximately 50 ng/dL (or 0.77 nmol/L) in term cord serum.

The low fetal T3 concentrations are due to low levels of type I iodothyronine monodeiodinase and relatively low rates of T4 to T3 conversion in fetal tissues and to active type III monodeiodinase in placenta and selected fetal tissues degrading T3 to T2.[18,29] Postnatally, T3 and T4 serum concentrations increase two- to sixfold within the first few hours of life—peaking at 24 to 36 hours after birth. These levels then gradually decline to levels characteristic of infancy over the first 4 to 5 weeks of life. The prenatal increase in serum T3 is due to progressive maturation of hepatic type I (phenolic) outer ring iodothyronine

deiodinase activity increasing hepatic conversion of T4 to T3, and to decreased placental T3 degradation.[18,29]

Fetal serum TSH increases from a low level at 18 to 20 weeks to a peak value of approximately 7 to 10 mU/L at term. At the time of parturition, in response to neonatal (cold) extrauterine exposure there is an acute release of TSH (the TSH surge)—with blood levels peaking at a mean concentration approximating 70 mU/L at 30 minutes. Circulating TSH remains elevated for 3 to 5 days after birth. TSH secretion in the neonatal period increases to a rate approximating 3 mU/L/min, and the increase in serum T4 levels immediately after birth is TSH dependent.[8,30]

Fetal thyroid gland function develops under the influence of an increasing serum TSH level during the last half of gestation. Serum free T4 levels tend to plateau after 24 weeks, and thus the TSH to free T4 ratio tends to increase—suggesting increasing TRH secretion and changes in pituitary thyrotroph sensitivity to the negative feedback effect of thyroid hormones on TSH secretion and changes in thyroid follicular cell sensitivity to TSH[31] (Figure 6-3). A progressive maturation of the thyroidal response to TSH has been shown in the fetal sheep, and seems likely in the human fetus.[32] The events involved in maturation of the negative feedback control system are complex, probably involving changes in pituitary thyrotroph T3 and TRH receptors, in thyrotroph outer ring iodothyronine deiodinase activity, and nuclear-T3-receptor-mediated action on TSH biosynthesis.[31]

The ontogeny of TRH secretion and function in the human fetus remain somewhat obscure. TRH production from the placenta and gut tissues and relatively high serum TRH levels have been demonstrated in fetal sheep.[24] TRH immunoactivity is detectable in the human fetal pancreas early in gestation and in the hypothalamus by midgestation, increasing markedly in the third trimester after the peak in serum TSH activity is noted (Figure 6-3). Serum TRH levels in the human fetus are relatively high at term due to extrahypothalamic production and to low or absent levels of TRH-degrading activity in fetal blood.[24]

Thyroid function in the premature infant (before 30 to 32 weeks) is characterized by low circulating levels of T4 and free T4, a normal or low level of TSH, and a normal or prolonged TSH response to TRH—indicating a state of physiologic TRH deficiency.[33] The full-term human fetus responds to pharmacologic maternal doses of TRH with a somewhat prolonged increase in TSH, suggesting a degree of relative hypothalamic (tertiary) hypothyroidism. Peripheral sources of TRH (placenta and pancreas) contribute to the elevated circulating levels of fetal and cord blood TRH and may be responsible in part for stimulating TSH release in the fetus prior to the increase in hypothalamic TRH concentration.

In summary, the control of fetal thyroid hormone secretion can be characterized as a balance among increasing hypothalamic TRH secretion, increasing thyroid follicular cell sensitivity to TSH, and increasing pituitary sensitivity to thyroid hormone inhibition of TSH release.[24,33] The fetus progresses from a state of primary (thyroidal) and tertiary (hypothalamic) hypothyroidism in mid-gestation through a state of mild tertiary hypothyroidism during the final weeks of pregnancy. There is a progressive decrease in the TSH to free T4 ratio, suggesting a progressive maturation of the negative feedback hypothalamic-pituitary TSH control axis.[31] The marked cold-stimulated TRH-TSH surge at birth is associated with a marked increase in T4 secretion and free T4 concentration with reequilibration by 1 to 2 months. During infancy and childhood, there is a progressive decrease in T4 secretion rate (on a μg/kg/day basis) correlating with a decreasing metabolic rate—probably reflecting decreasing TRH secretion.[31]

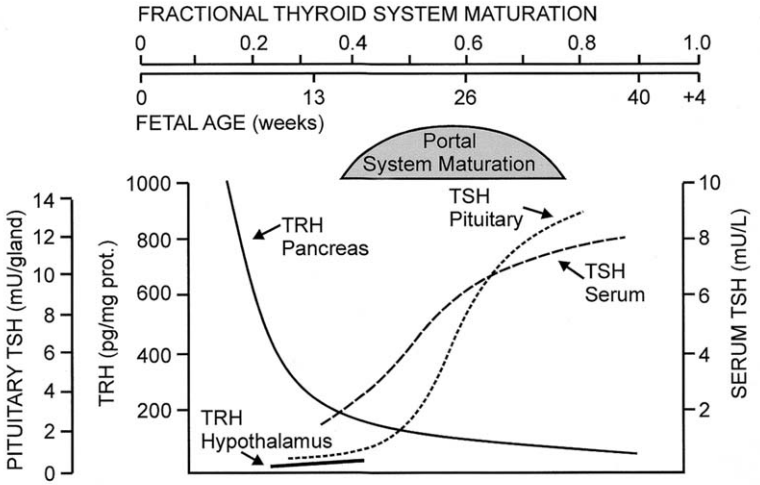

Figure 6-3. Changes in fetal TRH and TSH levels in pancreas, hypothalamus, serum, and pituitary during human gestation. Hypothalamic TRH concentrations increase progressively after mid-gestation, but the pattern of change has not been documented in the human fetus. Oxford, UK: Oxford University Press 359–368.]

Maturation of Thyroid Hormone Metabolism and Transport

The thyroid gland is the sole source of T4. Most of the circulating T3 after birth is derived from conversion of T4 to T3 via monodeiodination in peripheral tissues. Deiodination of the iodothyronines is the major route of metabolism, and monodeiodination may occur either at the outer (phenolic) ring or the inner (tyrosyl) ring of the iodothyronine molecule (Figure 6-4).[18,34] Outer ring monodeiodination of T4 produces T3, the active form of thyroid hormone with greatest affinity for the thyroid nuclear receptor.

Inner ring monodeiodination of T4 produces rT3, an inactive metabolite. In adults, between 70 and 90% of circulating T3 is derived from peripheral conversion of T4—and 10 to 30% is derived from direct glandular secretion. Nearly all circulating rT3 derives from peripheral conversion, with only 2 to 3% coming directly from the thyroid gland. T3 and rT3 are progressively metabolized to diiodo, monoiodo, and noniodinated forms of thyroxine—none of which possesses biologic activity.

Two types of outer ring iodothyronine monodeiodinase have been described.[18,34] Type I MDI (predominantly expressed in liver, kidney, and thyroid) is a high-Km enzyme inhibited by propylthiouracil and stimulated by thyroid hormone. Type I MDI is capable of inner ring monodeiodination, particularly of T4 sulfate (to rT3 sulfate) and T3 sulfate (to T2 sulfate).[34-36] Type II MDI [predominantly located in brain, pituitary, placenta, skeletal muscle, heart, thyroid, and brown adipose tissues (BATs)] is a low-Km enzyme insensitive to propylthiouracil and inhibited by thyroid hormone. Types I and II MDI contribute to circulating T3 production, whereas type II acts as well to increase local tissue levels of T3.[34-36] An inner (tyrosyl) ring iodothyronine monodeiodinase (type III MDI) has been characterized in most fetal tissues, including brain and placenta (and more recently in uterus and fetal skin).[19] This enzyme system catalyzes the conversion of T4 to rT3 and T3 to diiodothyronine.

Types I and II MDI are developmentally and thyroid-state regulated.[34-38] In sheep, a species in which thyroid hormone system maturation closely resembles that in the human, hepatic type I MDI activity increases about 100%—and brain type II MDI activity increases about 50% over the last third of gestation.[39] In the human fetal brain, type II MDI activity in the cortex increases between 13 and 20 weeks gestation and cerebellar activity after mid-gestation.[40] There is a general inverse correlation of type II and type III activities.[38] Both deiodinase species are thyroid hormone responsive.

Hepatic type I MDI activity in the fetal sheep becomes thyroid hormone responsive (i.e., activity decreases with hypothyroidism) only during the final weeks of gestation. Brain type II MDI is responsive (increases with hypothyroidism) throughout the final third of gestation.[39] Thus, in the hypothyroid fetus T4 appears to be shunted from the liver to the brain—where it is preferentially deiodinated to T3 to provide a source of intracellular T3 to those tissues (such as brain and pituitary) dependent on T3 during fetal life. Hepatic type I enzyme activity (to provide increased serum T3 levels) normally increases only during the final weeks of gestation and during postnatal life.

Fetal thyroid hormone metabolism is characterized by a predominance of type III enzyme activity (particularly in liver, kidney, and placenta), accounting for the increased circulating levels of rT3 observed in the fetus.[18,41] However, the persistence of high circulating rT3 levels for several weeks in the newborn indicate that type III MDI activities expressed in nonplacental tissues are important to the maintenance of high circulating rT3 levels. The mixture of type II and type III MDI activities in the

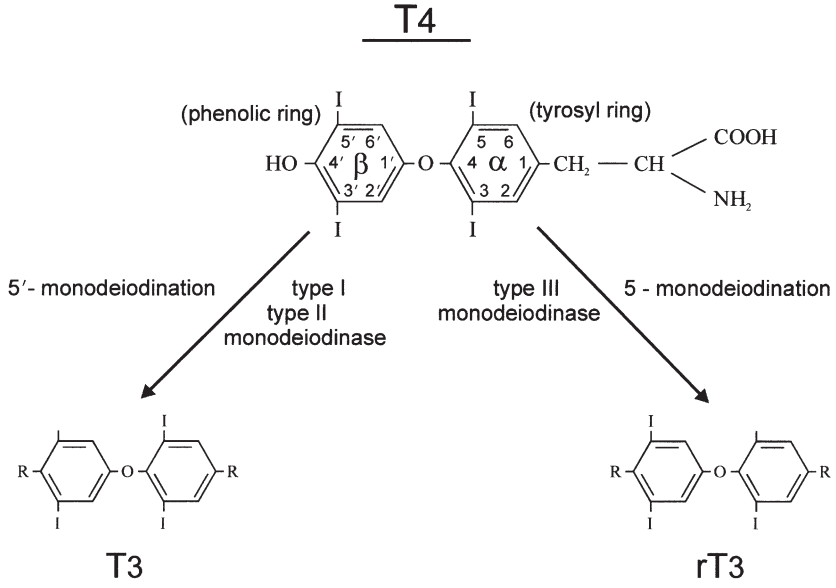

Figure 6-4. The deiodination of thyroxine by types I, II, and III iodothyronine monodeiodinase enzymes. The type I enzyme is also capable of inner ring monodeiodination, particularly of the sulfated conjugates (not shown).

placenta provides for the conversion of T4 to T3 and of T4 and T3 to rT3 and T2, respectively.[18,38]

Sulfated iodothyronines are the major thyroid hormone metabolites circulating in the fetus.[18,36,42-44] Sulfokinase enzymes are present early in fetal life, and sulfation of the phenolic hydroxyl group of the iodothyronine molecule may be a normal prerequisite step for monodeiodination.[36] The sulfated iodothyronines are preferred substrates for the type I MDI, and concentrations are high in fetal serum in part because of low type I MDI activity. However, increased production of sulfated metabolites is also involved. In the fetal sheep during the last third of gestation, the production rate of T4 approximates 40 μg/kg/day.[42] The production rates of rT3, T3, and the sulfated analogues T4S, rT3S, and T3S approximate 5, 2, 10, 12, and 2 ng/kg/day, respectively (Figure 6-5). The sulfate metabolites are biologically inactive, and thus that the sum of biologically inactive T4 analogues produced daily by the fetal sheep (T4S + rT3 + rT3S, + T3S = 10 + 5 + 12 + 2 or 29 ng/kg/day) accounts for the large majority of the T4 metabolized daily in the euthyroid fetus.[39,42] There is evidence that T3S has biologic activity (suppresses TSH) in vivo, suggesting that it can be desulfated by one or more tissue sulfatase enzymes.[36]

The low production rates and low levels of T3 metabolites (T3 + T3S = 2 + 2 or 4 ng/kg/day) and the high ratio of inactive to active metabolites (29/4 ng/kg/day) suggest that fetal thyroid hormone metabolism is largely oriented to inactivating T4, presumably to avoid tissue thermogenesis and to potentiate the anabolic state of the rapidly growing fetus. This is mediated by early activation of type III MDI, inactivation of type I MDI, and augmented iodothyronine sulfation.

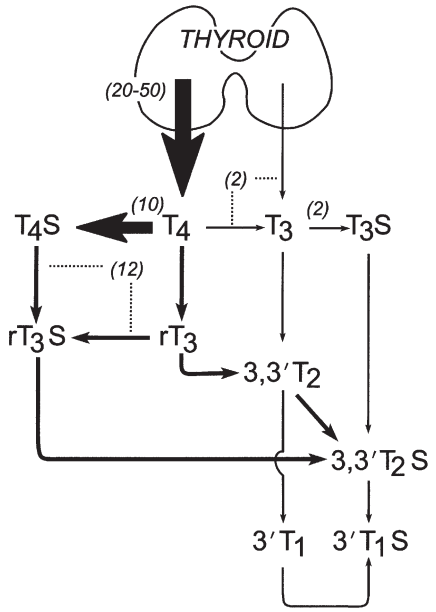

Figure 6-5. The putative pattern of production and metabolism of iodothyronines in the fetal sheep during the last third of gestation. Numbers in parentheses indicate production rates in μg/kg/day. Boca Raton: CRC Press 223–243.]

The developmental expression of type II MDI in brain and other tissues provides for local T3 supply to selective tissues (particularly in the event of T4 deficiency) and helps guarantee provision of T3 during gestation, when brain development is thyroid hormone dependent.[18,45] However, a basal level of thyroid hormone bioactivity in fetal sheep is essential to optimal rates of umbilical O_2 uptake, glucose oxidation, CO_2 production from glucose carbon, and oxygen utilization.[46] The positive correlations between plasma T4 levels and oxygen and glucose utilization and the low metabolism in hypothyroid fetuses suggest that T4 rather than T3 regulates basal fetal metabolism.[46]

T3 and T4 in fetal blood are associated with plasma proteins, including TBG, thyroxine-binding prealbumin (TBPA, or transthyretin), and albumin.[47] TBG serves as the primary transport protein for T3 and T4. About 70% of the total T4 and 40 to 60% of total T3 are bound to TBG. The rest of the thyroid hormones are distributed about equally between TBPA and albumin. The binding affinities of these proteins are such that adult free T4 and T3 concentrations are about 0.03 and 0.3%, respectively, of the total hormone concentrations. TBG, TBPA, and albumin are produced by the liver—and production of these proteins increases progressively during the final half of gestation. Fetal hepatic TBG production is stimulated by estrogen, and hepatic clearance of TBG is reduced secondary to an estrogen-induced increase in sialylation of TBG.[18] The increasing placental estrogen production during pregnancy and the progressive increase in fetal thyroid hormone production result in increasing total and free T4 concentrations during the latter half of gestation.

Extrauterine Thyroid Adaptation

At the time of parturition, the neonate must rapidly convert from the fetal state of predominant thyroid hormone inactivation to a state of relative thyroidal hyperactivity. During the first hours after birth, there is an abrupt two- to sixfold increase in circulating T4 and T3 levels. This is due to the abrupt increase in hypothalamic TRH and pituitary TSH secretion stimulating increased thyroid hormone secretion. The cold-stimulated TRH-TSH surge is short-lived, peaking at 30 minutes. Serum TSH concentrations decrease progressively thereafter to normal infant levels by 3 to 5 days, but the serum free T4 level remains elevated for several weeks[31] (Figure 6-2).

Serum T3 levels increase in response to the TSH surge stimulating an increase in thyroidal secretion and because of a combined cortisol- and T4-stimulated increase in hepatic type I MDI activity increasing T4 deiodination to T3.[36,38] Placental separation decreases T3 deiodination (to inactive diiodothyronine), contributing to the early postnatal increase in serum T3 concentration—which is then maintained by the increased T3 production from T4 mediated by increased hepatic type I MDI activity. The type II MDI activity in BAT increases during the last weeks of gestation to potentiate catecholamine-stimulated

BAT thermogenesis and neonatal homeothermy in the newborn period.[39,47]

Thyroid Hormone Actions

It has been assumed that thyroid hormones diffuse passively into cells, but recent evidence suggests that all thyroid-sensitive cell populations express iodothyronine membrane transporters. These belong to several families of integrin, organic anion, amino acid, and monocarboxylate solute carriers.[48-50] The relative significance of these transporter types is not yet clear. Mutation of the human monocarboxylate transporter 8 (MCT8) localized to developing brain leads to a syndrome of combined thyroid dysfunction and psychomotor retardation.[48] MCT8 expression in neonatal mice is localized to neurons in the olfactory bulb, cerebral cortex, hippocampus, and amygdala—and MCT8 seems to preferentially transport T3 in these developing brain tissues.

αVβ3 integrin binds T4 with high affinity, and this or similar plasma membrane receptors appear to trigger most of the reported nongenomic actions of thyroid hormone.[49] These include rapid changes in solute transport, activation of signal transducing kinases, post-translational modifications of nucleoproteins, actin polymerization, and mitochondrial activity.[49-53] These effects have been triggered by rT3 and T2 and by T4 and T3, indicating that several membrane transporters may be involved.[49-52] The regulation of actin polymerization by thyroid hormone in developing brain provides a nongenomic mechanism to influence neuronal migration.[51]

Thyroid hormone effects are mediated predominantly via nuclear thyroid hormone protein receptors (TR), which act as DNA-binding transcription factors regulating gene transcription. Two mammalian genes code for TR, TRα and TRβ and alternative splicing of expressed mRNA species leads to production of the major thyroid hormone-binding transcripts: TRα1, TRα2, TRβ1, and TRβ2.[54] The TRs exist as monomers, homodimers, and heterodimers with other nuclear receptor family members such as the retinoid X receptors. Other receptor transcripts, including TRδα1 and TRδα2, have been characterized. These do not bind T3 or DNA but can inhibit TR and retinoid receptor activities.[54] The TRα receptors are expressed in most tissues.

TRβ1 is expressed in liver, kidney, heart, lung, brain, cochlea, and pituitary. TRβ2 is expressed in pituitary gland, retina, and cochlea.[53] The receptors function redundantly, as indicated by knockout studies in mice, but predominant effects of one or another TR have been described. In rodent species, hepatic TR-binding activity matures during the first 3 to 5 weeks of extrauterine life. TRα binding in brain and pituitary cells appears during fetal life, whereas TRβ isoforms appear during the early neonatal period.[54] In the fetal/neonatal rat, thyroid hormone effects on thermogenesis, hepatic enzyme activities, skin and brain maturation, and growth hormone metabolism mature during the first 4 postnatal weeks.[2]

Thyroid hormone programmed development of selective fetal tissues requires the interaction of local tissue MDI-I, MDI-II, thyroid receptors (TRs), thyroid coactivators, and thyroid-responsive genes. In most responsive tissues, the timing of maturation events is controlled by the TRs acting as a molecular switch.[54] In the absence of T3, the unliganded receptor recruits corepressors repressing gene transcription. Non-T3-binding receptors also can repress transcription by inhibiting receptor DNA binding. Local tissue maturation events are stimulated by the coincident availability of T3, liganded T3 receptor, T3-mediated receptor exchange of corepressor with coactivators, and activation of responsive gene transcription.

In fetal sheep, maturation of most thyroid hormone actions occurs in utero and during the perinatal period.[39,55] Brain TR are present at mid-gestation and decrease in number during the first 2 to 3 postnatal months. Hepatic TR mature during the last trimester. Thyroid hormone actions on brain maturation, carcass and bone growth, skin maturation, hair growth, and TSH secretion appear near mid-gestation. Effects on cardiac atrial natriuretic hormone and cardiac output, cardiac and lung adrenergic receptors, and hepatic epidermal growth factor receptor muscle, growth hormone receptors, and IGF levels appear near term or during the neonatal period.[39,55,56]

In the human fetus, low levels of TR binding have been detected in brain tissue at 10 weeks gestational age—and hepatic, cardiac, and lung TR binding are observed at 16 to 18 weeks.[57,58] TR levels in human fetal cerebral cortex and cerebellum increase markedly during the second and third trimesters.[59] Information is limited regarding the timing of appearance of thyroid hormone tissue effects in the human fetus. The length, weight, appearance, behavior, biochemical parameters, extrauterine adaptation, and early neonatal course of the athyroid human neonate is usually within normal limits.[60-63] Growth of the human fetus is programmed independently of thyroid hormones by a complex interplay of genetic, nutritional, hormonal, and growth factors. However, 50% to 60% of athyroid newborns manifest delayed epiphyseal maturation in the lower extremities and delayed cerebral fontanelle closure.[61,62] Serum TSH concentrations are elevated in the hypothyroid fetus by 20 to 24 weeks gestation, indicating the presence of a negative feedback effect of T3 on TSH synthesis and secretion.

Congenitally hypothyroid neonates with marked hypothyroxinemia (<30 nmol/L, 2.3 μg/dL) may manifest prolonged physiologic jaundice, feeding difficulty, umbilical hernia, and macroglossia. However, the classic clinical manifestations of congenital hypothyroidism appear progressively during the early months of life. These include soft-tissue myxedema, delayed bone and body growth, metabolic derangements, and retarded central nervous system (CNS) development.[64] The normal or near-normal IQ in most early treated athyroid infants detected by newborn screening seems attributable to the low but significant levels of maternal thyroxine derived from placental transfer and the thyroxine-responsive MDI-II enzyme activity in fetal brain tissue.[21,22] MDI-II is modulated by thyroid hormone. High concentrations suppress (and low concentrations stimulate) MDI-II activity. Thus, in the hypothyroid fetal rat brain MDI-II activity is increased (and T3 concentrations in brain tissue are normal in the face of low fetal serum thyroxine concentrations).[65]

Postnatal thermogenesis is mediated via the BAT prominent in subscapular and perirenal areas in the mammalian fetus and neonate.[66] Heat production in BAT is stimulated by catecholamines via β-adrenergic receptors and is thyroid hormone dependent. The uncoupling protein thermogenin (or UCP-1) unique to BAT is located on the inner mitochondrial membrane and uncouples phosphorylation by dissipating the proton gradient created by the mitochondrial respiratory chain. The type II MDI in BAT mediates local T4 to T3 conversion. Full thermogenin expression in BAT requires both catecholamine and T3 stimulation.[66] BAT matures progressively in the fetus but remains thermoneutral until stimulated by catecholamines in the perinatal period.[39,67]

BAT thermogenesis is immature in small premature infants, and BAT tissue mass decreases in the neonatal period in full-term infants as the capacity for nonshivering thermogenesis develops in other tissues. UCP-2 is found in many tissues, but does not appear to be regulated by β-adrenergic agonists or thyroid hormone.[68] UCP-3 has been cloned and is expressed in muscle and white adipose tissue as well as BAT. Muscle UCP-3 is regulated by β3-adrenergic stimulation and thyroid hormone and probably contributes importantly to nonshivering thermogenesis in adult rats and presumably in humans. UCP-3 mRNA levels are also regulated by dexamethasone, leptin, and starvation, but the regulation differs in BAT and muscle.[68] Starvation increases muscle and decreases BAT UCP-3, suggesting that muscle serves a larger role in thermoregulation during starvation.[68]

The critical role of thyroid hormones is CNS maturation has long been recognized. Nervous system development involves neurogenesis, gliogenesis, neural cell migration, neuronal differentiation, dendritic and axonal growth, synaptogenesis, myelination, and neurotransmitter synthesis.[69] Thyroid hormones have been shown to stimulate a number of developmentally regulated nervous tissue genes, but the role of these factors in the CNS developmental program remains undefined.[69] Available evidence suggests that deficiency or excess of thyroid hormones alters the timing or synchronization of the CNS developmental program, presumably by initiating critical gene actions or other genetic CNS maturation events.

There is increasing evidence for a critical period for thyroid-dependent brain maturation in utero. Early maternal hypothyroxinemia in the rat alters histogenesis and cerebral cortical architecture of the progeny, and maternal hypothyroxinemia in humans is associated with IQ reduction in offspring.[23,70,71] Studies of the timing of iodine supplementation in pregnant women in geographic areas of severe iodine deficiency have suggested a critical period of hormone action on CNS maturation during a narrow interval of time at the beginning of the third trimester of gestation.[72] This period has been likened to the irreversible thyroid-dependent action of thyroid hormone initiating tadpole metamorphosis.[73] Recent studies of the dose and timing of thyroid hormone therapy in infants with congenital hypothyroidism suggest a second critical period of thyroid hormone action during the very early neonatal period, but the period of CNS thyroid hormone dependency extends further (to 3 to 4 years of age).[74]

Thyroid Dysfunction Syndromes in the Premature Infant

Premature infants are defined by gestational age (GA) and weight. By weight, premature infants are classified as low birth weight (LBW, 2,500-1,500 g), very low birth weight (VLBW, 1,500-1,000 g), and extremely low birth weight (ELBW, <1,000 g). They range from 34 to 35 weeks to 23 to 24 weeks GA (the current threshold of viability). Thyroid system control progresses from mid-gestation through early infancy and involves hypothalamic-pituitary-thyroid maturation and tissue responsiveness to thyroid hormones.

VLBW infants (<30 weeks gestation) have relatively immature hypothalamic-pituitary-thyroid systems (Table 6-1) and a high prevalence of neonatal morbidities, including respiratory distress, hypoxia, undernutrition, gastrointestinal and cardiac dysfunction, sepsis, and cerebral pathology.[75-78] As a result, they are predisposed to development of transient primary hypothyroidism and the syndrome of transient hypothyroxinemia of prematurity (THOP)—which probably represents transient hypothalamic-pituitary hypothyroidism and/or nonthyroidal illness (NTI, the low T3 syndrome).[75-78]

TRANSIENT PRIMARY HYPOTHYROIDISM

Transient hypothyroidism in the neonate, characterized by low serum T4 and high TSH concentrations, is more common in Europe than in America—and the prevalence varies geographically relative to iodine intake.[79-81] Transient

hypothyroidism in Belgium, an area of moderate iodine deficiency, occurs in 15 to 20% of premature infants (and prevalence is higher with decreasing gestational age).[79] Cord-blood T4 and TSH values in these infants are usually in the normal range for premature infants. Premature infants require higher iodine intake levels than term infants to maintain a positive iodine balance and adequate T4 production in the extrauterine environment, and in iodine-deficient geographic areas they may develop transient iodine deficiency.[79,81]

The primary hypothyroid state develops during the first 1 to 2 weeks of extrauterine life and is often superimposed on the transient hypothyroxinemia characteristic of prematurity. Urinary iodine and thyroid iodine contents are reduced. The hypothyroidism may persist for several weeks, in which case treatment is recommended. T4 or T3 can be prescribed. The average time to recovery of function and discontinuation of treatment in Belgium was 2 months. Iodine treatment also corrects the primary hypothyroid state in such infants.[79]

Premature infants are also susceptible to iodine overload due to the inhibitory effects of iodide excess on thyroidal iodide organification, referred to as the Wolff-Chaikoff effect.[82,83] The fetal thyroid is inordinately sensitive to the inhibitory effect of iodide on hormone synthesis.[81] Excess iodide exposure has occurred via maternal ingestion of iodide- or iodine-containing drugs or via neonatal exposure from iodide-containing disinfectants used for skin cleansing or iodinated contrast dyes used for radiographic studies.[83]

TRANSIENT HYPOTHYROXINEMIA OF PREMATURITY

Relative to term infants at birth, serum TBG and total T4 concentrations in premature infants are lower, the neonatal TSH surge is obtunded, tissue type I monodeiodinase activity and serum T3 levels are lower, postnatal TSH and free T4 concentrations are lower, bioinactive thyroid hormone analogue levels are higher, BAT thermogenic mechanisms are immature, and tissue thyroid hormone response systems are variably immature[75-78] (Table 6-1). The extent of these immaturities is related inversely to GA. In ELBW and VLBW infants less than 30 weeks GA, the TSH surge and the early thyroidal response are limited and are followed by a progressive decrease in serum total T4—with nadir values at 7 to 10 days of postnatal life.[75-77]

The decrease in serum total T4 concentrations is in part due to a decrease in TBG, which reflects neonatal morbidity.[76,84] Free T4 levels are variable, relative to cord blood concentrations, due to variable suppression of TBG-binding capacity and variable sensitivities of the free T4 immunoassay methods employed.[76,77,85] Serum TSH levels do not usually increase in response to the transient hypothyroxinemia, and serum free T4 levels reequilibrate to cord-blood values by 3 to 4 weeks. These very premature infants manifest a negative iodine balance during the early postnatal weeks, suggesting that they are unable to adapt to the extrauterine environment with augmentation of thyroidal iodine uptake and increased T4 secretion as do the larger infants.[81]

The high prevalence of neonatal morbidities in these infants is associated with characteristics of NTI, including a low serum T3 concentration (secondary to a decreased rate of conversion of T4 to T3) and decreased T4 concentrations. Free T4 levels are variable, but are usually in the range of values for healthy premature infants of matched gestational age and weight. TBG levels tend to be low, and there may be an inhibitor of T4 binding to TBG (as described in adults with the low T3 syndrome).[33,76,84] Serum TSH concentrations are normal or low. It is difficult to differentiate the contribution of NTI versus hypothalamic-pituitary immaturity in the pathogenesis of THOP. van Wassenaer and co-workers have shown that a serum free T4 level, measured by immunoassay, below 10 pmol/L (0.78 ng/dL) will trigger an increase in serum TSH concentration in most VLBW infants—suggesting a major contribution of NTI.[84]

The impact of THOP on brain maturation is not clear. In a placebo-controlled treatment study of VLBW infants, van Wassenaer et al. showed that a subgroup of 13 thyroxine-treated ELBW infants 25 to 26 weeks GA manifested a higher DQ at 24 months than 18 placebo control infants.[86] In a later analysis of IQ and neurologic function data at 5.7 years of age, mean IQ in the treated and control children were statistically similar—although some neurologic dysfunction persisted, especially in infants with free T4 levels in the 10.1- to 12.5-pmol/L range.[87] The infant cohorts were small, however, and the results must be considered preliminary. van Wassenaer administered a thyroxine dose of 8 micrograms/kg/day given parenterally over a 6-week period. Earlier dosage studies suggest that a 4- to 5-microgram/kg parenteral dose or a 5- to 6-microgram/kg oral dose of Na-l-thyroxine provides adequate replacement.[33]

Congenital Hypothyroidism

NEWBORN SCREENING

Newborn screening for congenital hypothyroidism (CH) is now routine in most industrialized societies.[60,64,88,89] CH screening tests are usually carried out in dried blood spot samples collected via skin puncture. Although screening program protocols vary, in effect all are screening for elevated serum TSH concentrations as the most reliable indicator of primary hypothyroidism. The threshold value for a significant TSH elevation in most screening programs is 20 to 25 mU/L (20-25 μU/mL). The preferred time for screening sampling is 3 to 5 days after birth. However, many mother-newborn diads are now discharged from the hospital within 3 days of delivery (and some are discharged within 1 day).

Early measurement increases the prevalence of infants demonstrating elevation of blood spot TSH concentrations due to the physiological neonatal TSH surge. Thus, early screening for CH increases false positive results. In most programs, the false positive to confirmed CH case ratio is 2–3:1. The effect of early hospital discharge of mother and infant in one study increased this ratio from 2.5 to 1 to about 5 to 1. The ratio will vary, however, depending on the threshold value established

for a significant TSH elevation by the individual program. Some programs have a higher threshold value for infants discharged on day 1.

It has been shown that as many as 5% of CH infants are missed in newborn screening programs.[88] Most of these relate to errors in specimen handling, testing and data analysis, or results reporting. In rare instances the increase in serum TSH concentrations in the affected infant is delayed for several days or weeks after delivery, presumably due to immaturity of the hypothalamic-pituitary axis.[60,88] The prevalence of CH approximates 1 in 4,000 births.[64,89] The etiologies include thyroid dysgenesis (aplasia, hypoplasia, ectopy), thyroid dyshormonogenesis, hypothalamic-pituitary (TSH) deficiency, and transient hypothyroidism (usually iodine, drug, or maternal antibody induced). The proportions approximate 75%, 10%, 5% and 10%, respectively, of the total CH cases (Table 6-1). Modifications of CH screening programs have been introduced to improve detection of infants with delayed increase in serum TSH and those with central hypothyroidism.[60,88-91] Repeat testing at 2 to 6 weeks of age has detected an additional 10% of infants with CH, and addition of a T4 has been shown to detect the 12% to 15% of infants with central hypothyroidism. Some 80% of these manifested multiple pituitary hormone deficiency.[90,91]

THYROID DYSGENESIS

The term *thyroid dysgenesis* describes infants with ectopic or hypoplastic thyroid glands (or both), as well as those with total thyroid agenesis. Thyroid dysgenesis is the etiologic factor in most infants with permanent congenital hypothyroidism detected in newborn screening programs.[60,64,89] Some thyroid tissue is probably present in two-thirds of these infants, and thus they represent a spectrum of severity of thyroid deficiency. A normal or near-normal circulating level of T3 in the face of a low T4 value suggests the presence of residual thyroid tissue, and this can be confirmed by a thyroid scan. A measurable level of serum thyroglobulin (TG) indicates the presence of some thyroid tissue. Athyroid infants have no circulating TG.[89]

Thyroid dysgenesis is usually sporadic, and the mechanism(s) for the defective embryogenesis remains obscure. Dysgenesis is more prevalent in female than in male infants. The female-to-male ratio approximates 2:1. The disorder has been reported to be less prevalent in black (1:32,000) than in white infants, and is more frequent (1:2,000) in Hispanic infants.[64,89] Approximately 2% to 3% of thyroid dysgenesis cases are familial and associated with mutations in the homeobox genes TTF1 (NKF2.1), TTF2 (FOXE1), or PAX8.[13,14,92] More recently, mutations of another transcription factor (GL153) have been described as the cause of a rare syndrome of neonatal diabetes: congenital hypothyroidism and congenital glaucoma.[93] The prevalence of thyroid dysgenesis is increased in infants with Down syndrome.[64,89]

An increased prevalence (8%-10%) of nonthyroid anomalies has been reported in infants with congenital hypothyroidism.[64,89,94] The most prevalent are cardiac, but include anomalies of the nervous, musculoskeletal, digestive and urological systems, cleft palate, and eye anomalies.[94] First-degree relatives of children with thyroid dysgenesis have an increased prevalence of thyroglossal duct cysts, a pyramidal thyroid lobe, thyroid hemiagenesis, and ectopic thyroid.[95] These abnormalities are compatible with an autosomal-dominant mode of inheritance with a low penetrance estimated at 21%, supporting the hypothesis of a genetic predisposition for a larger proportion of congenital hypothyroidism than is accounted for by the homeobox gene syndromes.[95] In rare instances, thyroid dysgenesis has occurred in association with maternal autoimmune thyroiditis. However, this appears to be coincidence. There is no correlation between thyroid dysgenesis and the presence of maternal autoimmune thyroiditis or circulating thyroid antimicrosomal or antithyroglobulin autoantibodies.[89]

THYROID DYSHORMONOGENESIS

General Features

The function of the thyroid gland is to concentrate iodide from the blood and return it to peripheral tissues in a hormonally active form.[96-98] The major substrates for thyroid hormone synthesis are iodide and tyrosine. Tyrosine is not rate limiting even in individuals with phenylketonuria, in whom tyrosine becomes an essential amino acid. Iodine, by contrast, is a trace element that can be rate limiting in thyroid hormone synthesis. The process of thyroid hormone biosynthesis is stimulated by TSH binding to the follicular cell TSH receptor and cAMP activation.

Processes stimulated by cAMP include cell membrane iodide transport, thyroglobulin synthesis, oxidation and organification of trapped iodide, activation of colloid endocytosis and intracellular phagolysosome formation, hydrolysis of thyroglobulin to release the iodotyrosines [monoiodotyrosine (MIT) and diiodotyrosine (DIT)] and iodothyronine (T4 and T3) residues, deiodination of MIT and DIT by an iodotyrosine deiodinase, and release of the T4 and T3 into the circulation. Significant amounts of thyroglobulin also escape from the gland, predominantly via the thyroid lymphatic system. These events are summarized in Figure 6-6. Infants with defects in thyroid hormone metabolism comprise some 10% to 15% of newborns with CH. A defect in TSH binding/action and several functional abnormalities have been described.[96-98]

These involve decreased iodide trapping, defective organification of trapped iodide, abnormalities of thyroglobulin structure, or deficiency of iodotyrosine deiodination and recycling. These disorders are usually transmitted as autosomal-recessive traits. Except for the familial incidence and tendency for affected individuals to develop goiter, the clinical manifestations of congenital hypothyroidism due to a biochemical defect are similar to those in infants with thyroid dysgenesis. Thyroid enlargement may be manifest at birth, but in many patients development of the goiter is delayed. Features of these disorders are summarized in Table 6-2.

Resistance to TSH

The thyroid follicular cell response to TSH involves a series of coordinated steps, including TSH binding to a receptor in the plasma membrane, activation of adenyl

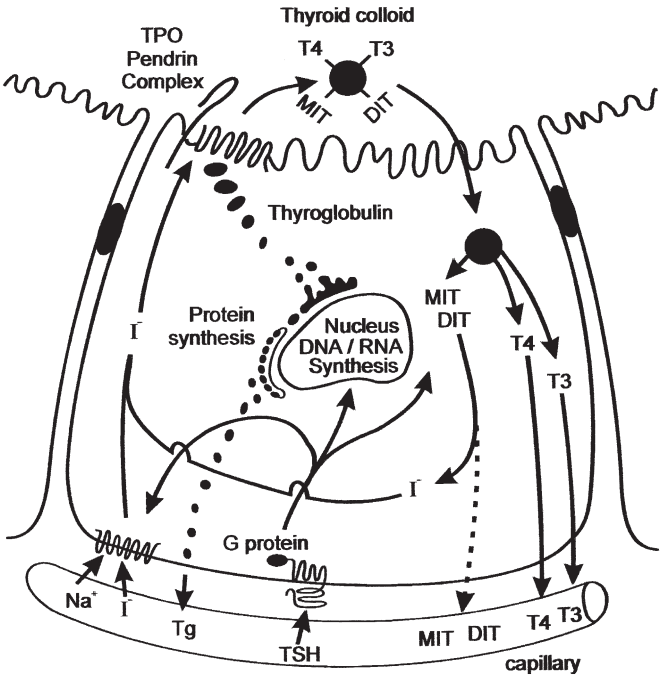

Figure 6-6. The biosynthesis and secretion of thyroid hormones by the thyroid follicular cell. The events of cellular synthesis are shown on the left, and those of secretion on the right. The Pendrin protein is localized with the thyroid peroxidase (TPO) and THOX (not shown) genes at or near the apical cell membrane, facilitating the organification process. With TSH stimulation, thyroid colloid droplets reenter the cell via micropinocytosis. The thyroglobulin-containing vesicles fuse with lysosomes in phagolysosomes, resulting in proteolytic degradation of thyroglobulin and release of T4 and T3, and the iodotyrosines monoiodotyrosine (MIT) and diiodotyrosine (DIT). MIT and DIT are deiodinated via the dehalogenase enzymes (DEHALI) to release and recycle the iodide. Small amounts of MIT and DIT are released into the circulation.

TABLE 6-2

Inborn Abnormalities of Thyroid Hormone Metabolism

			Clinical		
Abnormality	**Prevalence**	**Inheritance**	**CH**	**Goiter**	**T4**
Familial TSH Deficiency	Rare	AR	Yes	No	↓

AR = autosomal recessive; CH = congenital hypothyroidism; Tg = serum thyroglobulin; RAIU = thyroid radioactive iodine uptake; T4 and TSH refer to serum concentrations, V = variable.

cyclase, synthesis of cyclic AMP, activation of protein kinase(s), phosphorylation of receptor protein(s), and stimulation of the several intracellular events of thyroid hormone synthesis and release. A defect at one of several sites could lead to an abnormality in thyroid responsiveness to TSH. Only a few patients with TSH nonresponsiveness have been reported. Characteristically, they present with neonatal CH—including low serum T4 and increased TSH concentrations.[97-99] Thyroid radioiodine uptake is low or low normal and unresponsive to TSH.

The TSH receptor is one of the family of G-protein–coupled receptors. It belongs to the superfamily of seven-transmembrane domain receptors coupled to G proteins. The TSH receptor gene is localized to chromosome 14. A long extracellular hormone-binding domain is encoded by 9 exons. A tenth exon codes the seven-transmembrane and intracellular domains of the receptor.[100] Germ-line mutations of the thyrotropin receptor gene have been described recently in association with congenital or acquired thyroid disease. Both loss-of-function and gain-of-function phenotypes have been described.[97,99,101,102] Sixty to 70% of these map to the aminoterminal hormone-binding domain. Others involve the transmembrane and intracellular domains.[102] Most of these defects lead to asymptomatic hyperthyrotropinemia, and most were compound heterozygotes with normal heterozygote parents. A few cases of severe congenital hypothyroidism with absent iodine uptake and thyroid hypoplasia have been reported. These cases tend to have mutations in exon 10 involving the transmembrane domain.[103,104]

Defects in the Gs subunits have been reported in families with dominantly inherited pseudohypoparathyroidism and in patients with Albright hereditary osteodystrophy, and affected subjects may have reduced TSH responsiveness and compensated or decompensated hypothyroidism.[105] It is difficult to assess the severity of hypothyroidism due to TSH resistance in these cases, because the pituitary TRH receptor also is a G-protein–coupled receptor and therefore circulating TSH levels are low rather than high.

Sodium/Iodide Symporter Defects

The transport of iodide across the thyroid follicular cell membrane from plasma to cytosol is the first step in thyroid hormone biosynthesis. Under normal circumstances, the thyroid cell membrane iodide pump generates a thyroid/serum (T/S ratio) concentration gradient in excess of 20 to 30. This gradient can reach several hundredfold when the thyroid gland is stimulated by a low-iodine diet, by TSH, by a variety of thyroid-stimulating immunoglobulins in Graves' disease, or by drugs that impair the efficiency of hormone synthesis. Other tissues (such as the salivary glands, gastric mucosa, mammary glands, ciliary body, choroid plexus, and placenta) are also capable of concentrating iodide against a gradient. However, these tissues are not capable of organifying inorganic iodide.

Fewer than 50 cases have been reported with defective iodide transport.[106,107] The patients present with congenital hypothyroidism. The diagnosis is based on the presence of goiter, limited or absent radioiodine uptake, and

Features				
TSH	Tg	RAIU	Other	Molecular Abnormality
↓	↓	↓	Absent TSH response to TRH	TSHβ gene mutations
N or ↓	↓	↓	GH and PRL deficiencies	Pit-1 gene mutations
↑	↓	N	No RAIU, T4, or Tg response to TSH	TSH receptor gene mutations
↑	↑	↓	Salivary and gastric tissues also fail to concentrate iodide. Hypothyroid state responds to iodide Rx	Defect not characterized
↑	↑	↑	Positive perchlorate discharge test	TPO or THOX mutations
↑	↑	↑	Deaf mutism; positive perchlorate discharge	Pendrin mutations
↑	↓↑	↑	Usually low Tg with no Tg response to TSH	Tg gene mutations (Abent or defective Tg); hyposialylated Tg due do sialyltransferase defect
↑	↑	↑	High RAIU with early discharge: high serum MIT, DIT; failure to deiodinate IV dose of labeled DIT (excretion intact)	DEHAL1 mutations
N,↑	↑	↑	Generalized resistance, TSH N or ↑; Peripheral resistance. TSH ↑; Pituitary resistance TSH ↑ (patient hyperthyroid)	Thyroid nuclear receptor gene mutations (TR beta; TR alpha?)
N,↑	N	N	Increased T3; psychomotor; retardation	Monocarboxylate Transporter MCT8 Gene mutations
↑	N-↑	N-↑	Decrease T3 and increased rT3	SECISBP2 gene mutation
↓	↑	↑	Absence of thyroid autoimmunity	Activating TSH receptor gene mutations

elevated serum TSH. Other iodine-concentrating tissues (salivary glands, gastric mucosa) also fail to concentrate iodide from the circulation. Lugol's solution ameliorates the hypothyroidism by increasing serum iodide to high levels and increasing intrathyroidal inorganic iodide concentration by diffusion. Partial defects have also been described. Thyroid radioiodine uptake was decreased but not absent in these patients and did not respond to TSH. The salivary-to-plasma ratio of radioiodine also was reduced but not entirely absent. Nonetheless, the patients were hypothyroid with mental retardation.[97,98]

Cloning of the gene for the thyroid hormone sodium/iodide symporter (NIS) was reported in 1996.[108,109] Secondary structure prediction suggests a membrane protein with 12 transmembrane helices. The transporter gene is expressed in thyroid and salivary tissues and in gastric mucosa, where functional protein has been demonstrated. Transporter RNA is present in a variety of other tissues that do not show iodide uptake. The functional significance of the symporter mRNA in these tissues is not clear.[110] Several reports have documented mutations in the NIS gene in patients with congenital hypothyroidism.[106,107] Ten mutations were described through 2003, with affected individuals demonstrating homozygous or compound heterozygous mutation patterns.[107] Heterozygous family members were not clinically affected. The timing of onset of hypothyroidism tends to correlate with the genotype-specific residual NID activity.[107] Neonatal onset is likely with mutations associated with lower radioactive iodine uptake.

Peroxidase System Defects (Organification Defects)

Normally, iodide concentrated by the thyroid follicular cell is rapidly oxidized and bound in organic form. Organification of iodide involves two processes: oxidation of iodide and iodination of thyroglobulin-bound tyrosine.[97-99] Trapped iodide is oxidized to an active intermediate, followed by iodination of thyroglobulin-bound tyrosyl residues to form the iodotyrosines MIT and DIT. Two DIT residues are "coupled" to form T4. MIT and DIT couple to form T3. Tyrosyl iodination and coupling are catalyzed by a thyroid peroxidase enzyme system located at the apical membrane of the thyroid follicular cell in association with thyroid (NADPH) oxidases. Thyroid peroxidase is a membrane-bound heme protein that requires peroxide and an acceptor, which in the normal thyroid gland is thyroglobulin but can be albumin or other proteins or peptides. The hydrogen peroxide may be provided by one or more NADPH oxidases.

Some 200 patients with defective organification of iodide have been reported.[97-99] The defects included a quantitative deficiency of thyroid peroxidase (TPO), an abnormal and functionally defective TPO, or a deficiency of hydrogen peroxide generation. The complete defect can be detected by a perchlorate discharge test. Perchlorate is administered 1 to 2 hours after a dose of radioiodine. If organification is impaired, there is a rapid and profound discharge of the thyroidal radioiodine trapped during the following 1- to 2-hour period. Patients with partial TPO deficiency have a lesser discharge. The test is not specific, however, and more definitive testing is necessary for a precise diagnosis.

Thyroid peroxidase is a glycoprotein located at the apical membrane of the thyroid follicular cell. The gene is located on chromosome 2 and contains 3 kilobases of coding sequence over 17 exons coding for a protein of 933 amino acids. Some 20 different mutations have been described, including homozygous and compound heterozygous missence mutations, frame-shift mutations, base pair duplications, and single-nucleotide substitutions.[111,112] The variable molecular defects account for the clinical and biochemical heterogeneity in patients with defective iodine organification. Premature termination codons prevent translation of the protein. Other mutations affect the structure of the protein and perhaps its cellular location. Mutations in exons 8 through 10, which contain the putative hormone-binding histidine residues, produce a dysfunctional protein. Milder or transient organification defects have been associated with compound heterozygosity.[97,98]

Several patients have been described who were euthyroid or mildly hypothyroid but manifested goiter and partial discharge of radioiodine following perchlorate administration.[97,98,112] In these patients, the thyroid gland was found to contain no peroxidase activity—but such activity could be restored by adding hematin, the noncovalently bound prosthetic group of the peroxidase. This suggested an abnormal peroxidase apoenzyme deficient in binding to its heme moiety. In other patients, the organification defect was found to be associated with defective H_2O_2 generation. Iodination capacity in vitro was restored by the addition of riboflavin, FMN, oxidized cytochrome b2, cytochrome C, NADH, or NADPH. A defect in thyroid H_2O_2 generation was postulated to be due to a defect in biosynthesis of FAD from riboflavin.[98]

The H_2O_2 generation defect is rare. Recently, two genes encoding NADPH oxidases have been cloned and referred to as THOX1 and THOX2.[113] They are closely linked on chromosome 15 and predict proteins of 1,551 and 1,558 amino acids, respectively. The proteins colocalize with TPO at the apical membrane of thyroid follicular cells. Activating mutations in THOX2 associated with transient or severe congenital hypothyroidism have been described in four patients, and inactivating mutations in four other patients.[114]

The Pendred Syndrome

The Pendred syndrome, which includes familial goiter and congenital eighth-nerve deafness, is transmitted as an autosomal-recessive trait.[115,116] Approximately 750 cases were reported in some 400 families by 1992. About 6% of deaf mute children in a survey in England were found to be affected.[97,98] The prevalence is estimated to be 1.5 to 3 cases per 100,000 school children. One in 60 persons has one abnormal Pendred gene and is a carrier. The syndrome includes high tone or complete congenital deafness, goiter of variable degree appearing in middle or late childhood, and euthyroidism or mild hypothyroidism. One-third of patients have the complete syndrome. The remainder

present with hearing loss or mild goiter.[97,98] The degree of impaired iodide organification is mild to moderate.

Infants with the syndrome are usually not detected unless in an iodine-deficient environment. Goitrous children manifest a positive perchlorate discharge with normal TPO activity. Atypical patients without an abnormal perchlorate discharge have been described.[115] The disorder was recently mapped to chromosome 7, and the gene defect localized to a chloride-iodide transport protein referred to as Pendrin.[116,117] The Pendrin gene contains 21 exons and a predicted open reading frame of 2,343 base pairs. The predicted protein consists of 780 amino acids (86 kilodaltons), including 11 putative transmembrane segments. Molecular studies have been conducted in more than 20 affected families from different geographic areas. In most of these there were independent point mutations and no large deletions. The etiology of the deafness remains controversial. The available information suggests that Pendrin gene mutations can give rise to syndromic or nonsyndromic deafness.[97,117,118]

Defects in Thyroglobulin Synthesis

Thyroglobulin is an essential substrate for organification and is the major protein component of thyroid colloid. It is an iodinated glycoprotein with a molecular weight approximating 650,000 daltons and a sedimentation coefficient of 19.7 (19S). It consists of two monomeric chains, 2,767 amino acids in length, each with 67 tyrosine residues and 20 potential glycosylation sites.[97-99] About one-third of the tyrosine residues are spatially oriented such that they are susceptible to iodination. The thyroglobulin gene is located on chromosome 8. It codes for a 300-kilodalton monomer molecule via an 8- to 9-kilodalton mRNA.

Genetic defects can lead to thyroglobulin deficiency or structural/functional abnormalities of the protein. Thyroglobulin synthesis defects occur in about 1 in 80,000 to 1 in 100,000 newborns.[97,98] Goiter and hypothyroidism are usually manifest at birth, but mild defects are likely to be described in association with later onset. To date, the functional defects have included defective thyroglobulin transport with carbohydrate-deficient thyroglobulin sequestered in golgi or cytoplasmic membranes, thyroglobulin with deficient tyrosine residues or tyrosine residues buried within the molecule and not available for iodination, and sialic-acid-deficient thyroglobulin (due to a sialyltransferase deficiency) containing MIT and DIT but manifesting defective coupling.[97,98,119-121]

Iodotyrosine Deiodinase Defect

Deficiency of the iodotyrosine deiodinase can cause congenital hypothyroidism or a less severe form of familial goiter. Failure to deiodinate thyroid MIT and DIT as they are released from thyroglobulin leads to severe iodine wastage because the non-deiodinated MIT and DIT leak out of the thyroid and are excreted in urine. Iodotyrosine deiodinases are present in both thyroid cells and peripheral tissues, and abnormalities involving both systems have been described.

The patients originally described were cretinous and hypothyroid, with goiters presenting at birth or shortly thereafter. They manifested early rapid thyroid radioiodine uptake and rapid spontaneous discharge. By 48 hours, most of the thyroidal radioiodine was discharged.[97,98] The serum in such patients contains high concentrations of iodotyrosines. They excrete essentially all of an intravenous dose of labeled iodotyrosine directly into urine, whereas normal subjects excrete the label almost entirely as free iodide. Partial defects have been described in thyroid and peripheral tissues, in peripheral tissues only, and in thyroid tissue only. In patients with a mild defect, compensation may be possible in a high-iodine environment. A goiter may appear only if iodine intake is limited.

Recently, the gene encoding the iodothyronine dehalogenase (DEHAL1) was cloned.[122] The cDNA encodes a 289-amino-acid protein member of the nitroreductase family. It contains a putative transmembrane segment and a large extracellular N-terminal region. The gene is also expressed in the kidney. DEHAL1 is localized to the apical thyroid membrane close to the thyroglobulin iodination site, closely linking tyrosine deiodination with the organification process. Mutations of the DEHAL1 gene have been identified in patients with congenital hypothyroidism from three different families. The phenotype is variable, including goiter, mental retardation, or normal mental development despite delayed thyroid hormone substitution.[123]

Iodothyronine Monodeiodinase Deficiency

As discussed previously, iodothyronines are metabolized via three iodothyronine monodeiodinases: MDI type I, MDI type II, and MDI type III[18,34] (Figure 6-5). To date, no defects have been identified in the genes encoding the MDI enzymes. All are selenoproteins requiring the incorporation of selenocysteine (sec) during biosynthesis. Incorporation of selenocysteine into the iodothyronine monodeiodinase enzymes requires several components: a selenocysteine insertion sequence (SECIS) element, a SECIS-binding protein (SECISBP2), and a selenoprotein-specific elongation factor (EFSec) and its transfer RNA $tRNA^{sec}$.[124]

Dumitrescu et al. have identified a Bedouin Saudi family with 3 of 7 siblings ages 4, 7, and 14 years with a phenotype of hyperthyroxinemia, decreased T3, increased reverse T3, and mildly increased TSH concentrations. The children were otherwise euthyroid.[124] The parents and four other siblings had normal thyroid function parameters. Patient fibroblasts showed reduced MDI II activity not linked to the MDI II locus, and linkage analysis of the genes involved in MDI synthesis revealed a homozygous missense mutation in SECISBP2. An unrelated Irish child age 6 with a similar phenotype carried compound heterozygous mutations in SECISBP2.[124] The family mutations were in exon 12 (R540Q) of the 17 SECISBP2 exons. The Irish mutations were a paternal K438X and maternal alternative donor splice site in exon 8. In both families, serum selenoprotein levels were low in affected individuals and normal in unaffected individuals.

THYROID HORMONE RESISTANCE

Thyroid Hormone Receptor Defects

Patients with thyroid hormone resistance classically present with increased circulating levels of T4 and T3 with a normal or increased serum TSH concentration.[125,126] Such infants may be detected in newborn screening programs in which TSH in measured directly. TSH levels are mildly to moderately increased, but the increased T4 level would preclude detection in a primary T4, secondary TSH screening program. The prevalence is not yet clear. More than 1,000 cases have been reported.[125] Preliminary data from regional populations suggests a prevalence approximating 1 in 40,000 newborns. They have been classified into three phenotypes: generalized resistance to thyroid hormones (GRTH), pituitary resistance to thyroid hormone (Pit RTH), and peripheral resistance to thyroid hormone (PRTH).

Inheritance has been autosomal dominant in all familial cases except one. Fifteen to 20% of cases appear sporadically. Many patients are asymptomatic or demonstrate nonspecific symptoms. Deafness is observed in 20%, and a syndrome of attention deficit hyperactivity has been documented in half of affected patients.[125-128] Hypothyroid features include growth retardation, delayed bone maturation, and intellectual impairment. Some children exhibit features of thyrotoxicosis, including failure to thrive, accelerated growth, and hyperkinetic behavior.[125,126]

Thyroid hormone action is mediated via nuclear thyroid hormone receptor proteins with zinc-finger DNA-binding regions and thyroid hormone-binding domains. The latter have a 10:1 relative binding affinity for T3/T4. The receptors act as DNA-transactivating factors to stimulate or suppress responsive genes. Two genes coding for the TR proteins have been described: an alpha gene on chromosome 17 and a beta gene on chromosome 3. Each codes for two major transcripts via alternative splicing: TRα1, TRα2, TRβ1, TRβ1. The TRα2 receptors do not bind T3, but have functional DNA-binding domains. The TRβ1 mRNA is distributed in highest concentrations in brain, liver, kidney, and heart.

TRβ2 mRNA is restricted to pituitary, retina, and cochlea. TRα1 and TRα2 mRNA are widely distributed among tissues.[53,54] The molecular defect in all cases studied to date has involved the TRβ1 gene on chromosome 3.[125,126] In most affected subjects, specific TRβ gene mutations have been demonstrated. More than 120 different defects have been described. More than 90% have been single-amino-acid deletions or substitutions involving the hormone-binding domain at the carboxy terminal end of the receptor molecule.[128] A few in-frame deletions and frame-shift insertions have been described.

There has been considerable variation of thyroid effects among tissues within family members with identical TRβ mutations.[125-129] TRs (like other steroid hormone superfamily receptors) bind to DNA response elements as monomers, homodimers, or heterodimers—and heterodimerization can involve another TR, including the TRα2 receptors, or other transactivation factors. The ability of the defective receptor to bind T3, to bind to other TR, or other factors appear to determine the effect of the defective receptor in a given tissue. Affected members of most families studied have one normal and one abnormal TRβ allele. The abnormal TRβ with minimal or reduced T3 binding fails to mediate T3-regulated transcription and may block the action of the normal allele. This has been referred to as a dominant negative effect, presumably mediated by binding of the defective allele with normal TRβ and producing an inactive homodimer.

Recent studies of patients with the PitRTH phenotype have revealed point mutations and decreased T3 binding of TRβ1 receptors similar to defects described in GRTH patients. These observations suggest that the apparent selective pituitary resistance and generalized resistance phenotypes are not qualitatively different syndromes but rather reflect a continuous spectrum of a similar molecular defect with variable tissue resistance.

Thyroid Hormone Membrane Transporter Defects

Carrier-mediated energy-dependent transport of thyroid hormones has recently been demonstrated in many in vitro cell lines involving the Na+/taurochlate co-transporting polypeptide (NTCP), the Na+-independent organic anion transporter (OATP) family, the L-type amino acid transporters, and more recently the monocarboxylate transporter MCT-8.[48] The significance of these several transporter systems in different cell types remains to be clarified. However, mutations in the MCT-8 gene (SLC16A2)—located on the X chromosome and associated with combined thyroid and neurological dysfunction—have been characterized.[48,130-132] The gene encodes a 613-amino-acid protein with 12 predicted transmembrane domains. The N-terminal and 6-terminal domains are located intracellularly.[131]

Nine patients with the MCT-8 thyroid hormone transporter defect have been reported presenting during infancy or childhood with hypotonia, poor head control, involuntary athetoid and dystonic movements, hyperreflexia, nystagmus, and severe mental retardation.[130-132] There were no other signs of hypothyroidism. Serum T3 concentrations were elevated, serum T4 and free T4 were low, and TSH concentrations were normal or slightly elevated. The gene defects have included deletions and missense mutations. Subsequent to these reports, it was recognized that this phenotype resembles that previously characterized as the Allan-Herndon-Dudley syndrome (AHDS)—an X-linked mental retardation syndrome. Recent studies have shown that AHDS is also associated with mutations in the SLC16A2 (MCT-8) gene. By mid 2006, 22 patients from 11 families with AHDS and SLC16A2 mutations had been characterized.[132]

The MCT-8 gene in mice is expressed in brain (choroid plexus, cerebrum, hippocampus, amygdala, striatum, and hypothalamus), liver, kidney, and pituitary and thyroid tissues. In brain tissues, MCT-8 transporters seem localized to neuronal rather than to glial cells.[132] MCT knockout mice have no apparent neurologic phenotype, but hemizygous males have elevated serum T3 and low T4 concentrations with a sevenfold increase in the serum T3/T4 ratio.[132]

Iodothyronine monodeiodinase 2 (MDI-2) activities in the brain and pituitary gland are markedly increased, and brain MDI-3 activity is decreased—supporting the hypothesis that the brain MDI changes in these animals is compensatory to reduced brain T3 levels. MDI-1 activities are increased in liver and kidney, reflecting increased tissue T3 content—suggesting an adequate T3 transport despite the MCT-8 gene inactivation.[132] The thyroid phenotype in human patients is similar to that in the MCT knockout mice and reflects altered T4 monodeiodination patterns due to altered T4 content in various tissues. Much of the brain damage due to decreased neuronal T4 content occurs in utero, and the phenotype resembles that in severe endemic cretinism. There is currently little information regarding effective treatment.

HYPOTHALAMIC-PITUITARY HYPOTHYROIDISM

Infants with central hypothyroidism are relatively uncommon, with a prevalence in the range of 1:20,000 to 1:30,000 newborns.[91,133] These infants are not usually detected in newborn thyroid screening programs because all programs are designed to screen for increased TSH levels. However, some programs also employ initial T4 and/or T4/TBG ratio measurements to detect infants with central hypothyroidism.[91] Hypothalamic-pituitary or central hypothyroidism can result from hypothalamic and/or pituitary dysgenesis or isolated TSH deficiency.

A variety of homeobox (expressed in embryonic stem cells) or transcription factor gene defects have been described in association with hypothalamic-pituitary dysgenesis. SHH, ZIC2, and SIX3 defects have been identified in patients with holoprosencephaly; HESX1 defects in association with septo-optic dysplasia; GL13 mutation in the pallister-hall syndrome; and LHX3, PROP1, PIT1, and POUIFI defects in hypopituitarism.[4-10,97]

Trh Deficiency

The human TRH gene has been mapped to chromosome 3q13.3.-q21, but no human mutations have been described to date. Targeted disruption of the TRH receptor gene in mice led to an unexpected mild phenotype of central hypothyroidism and hyperglycemia.[134,135] To date, only one family with compound heterozygosity for loss-of-function mutations of the TRH receptor gene with central hypothyroidism has been described. The affected patient presented with severe congenital hypothyroidism, short stature, and mental retardation.[136]

Tsh Deficiency

Familial isolated TSH deficiency is a rare disorder best characterized in Japanese patients. Several families have been reported with an autosomal-recessive pattern of inheritance of nongoitrous CH.[137-139] Serum T4 and TSH concentrations are low, whereas other pituitary functions are intact. The thyroid gland responds to TSH. There is no TSH response to TRH. A number of homozygous mutations in the TSHβ subunit gene on chromosome 1 have been described, including single base substitutions in the CAGYC region of the gene.[137,140] The CAGYC-mutated mRNA codes for an altered beta polypeptide that does not associate with TSH alpha subunits to form active TSH. The most prevalent mutation identified in different populations is derived from a common ancestor and results in severe congenital hypothyroidism.[141] It involves a 1-bp deletion from codon 105 of the βTSH gene (C105V).

Recent studies have characterized at least four different Pit-1 gene mutations associated with a subtype of panhypopituitarism manifesting GH, prolactin, and TSH deficiency.[142] All were single base substitutions blocking Pit-1 synthesis or function. Prop-1 gene mutations also lead to multiple pituitary hormone deficiencies. The clinical spectrum resembles that of Pit-1 deficiency but includes gonadotropin deficiency.[143]

All of these disorders are characterized by a low serum free T4 concentration with a low or normal-range TSH level. If TSH deficiency is suspected, measurements of serum cortisol and GH concentrations may indicate panhypopituitarism. Hypoglycemia is a term neonate suggests ACTH and/or GH deficiency. A CAT scan or NMR scan is useful in characterizing hypothalamic-pituitary anomalies. A subnormal serum TSH response (measured at 30 minutes) to 7-μg/kg TRH infusion confirms a diagnosis of pituitary TSH deficiency. Selective studies measuring the TSH and TSH subunits can help characterize a thyrotropin gene defect. Therapy of the hypothyroidism in these infants is similar to therapy of other CH states. In addition, replacement of other pituitary or end-organ hormone deficiencies is necessary.

TRANSIENT CONGENITAL HYPOTHYROIDISM

Transient CH occurs in 5% to 10% of infants detected in newborn thyroid screening programs. These infants manifest low or normal T4 levels with variably elevated serum TSH concentrations. The most common causes in North America are goitrogenic agents and transplacentally derived TSH receptor-blocking maternal autoantibodies. Autoantibody-mediated CH accounts for 1% to 2% of the total.[144] In areas of endemic iodine deficiency, transient CH is more frequent and is due to a relative iodine deficiency associated with the increased thyroid hormone requirements in the neonatal period.[145] Maternal iodine or potentially antithyroid drug ingestion should be considered in all cases of CH. The presence of a goiter in the infant is supportive evidence of a drug- or goitrogen-induced transient hypothyroidism, but transient hypothyroidism is not usually associated with goiter.

The thyroid scan result varies, depending on the cause. Iodine usually inhibits technetium or radioiodine uptake, whereas drug or dietary goitrogens typically increase uptake and produce a positive scan. Maternal TSH receptor-blocking antibody-induced hypothyroidism should be suspected in any case where the mother has a history of autoimmune thyroid disease.[144,146,147] The presence in maternal or neonatal blood of a high level of TSH receptor-blocking antibody (TBA) is strong supportive evidence. The transient CH in these infants is usually of short duration (1-2 weeks) in the case of

drugs, and longer (1-4 months) if related to maternal blocking antibody—the half-life of which approximates 2 weeks. If the CH state persists beyond 1 to 2 weeks, treatment is in order. Feedback control of TSH is normal in these infants, and the serum TSH level is easily suppressed. Measurements of TSH receptor antibody levels can be conducted to determine when to discontinue therapy in TBA-mediated CH.

EUTHYROID HYPERTHYROTROPINEMIA

Asymptomatic hyperthyrotropinemia is a relatively common disorder and may be transient or permanent. The prevalence of transient hyperthyrotropinemia in Europe approximates 1 in 8,000 births, with 50% due to perinatal iodine exposure.[148] Other causes could include defects in TSH or the TSH receptor, a mild intrathyroidal synthetic defect, a hemithyroid, or a resetting of the TSH feedback control system. Germ-line mutations of the thyrotropin receptor gene have been associated with a phenotype of asymptomatic hyperthyrotropinemia. Most were compound heterozygotes with normal heterozygote parents.[101,102]

Transient neonatal hyperthyrotropinemia is a relatively frequent phenomenon in Japan, where it is detected in about 1 in 18,000 newborns.[149] In a recent report of 16 cases followed for 2 to 7 years in Europe, the elevated serum TSH levels at 2 to 7 weeks of age ranged from 17 to 77 mU/L (17-77 μU/mL).[150] Serum T4, T3, and free T4 levels were normal, as were basal metabolic rates and thyroid radioiodine uptake values. All infants had increased TSH responses to exogenous TRH, whereas none had detectable levels of TBA. The elevated TSH values spontaneously normalized in 11 of the 16 infants within 6 months, excluding an abnormal TSH molecule or a TSH receptor defect in these subjects. However, the augmented TSH response to TRH persisted for 3 to 7 years in children.

All infants also had a normal T3 response to TSH, which tends to exclude a hormone synthetic defect. However, small diffuse goiters developed in 3 of 16 cases by 5 to 7 years.[150] The mechanism in these cases remains obscure, but partially inactivating mutations in the TSH receptor gene account for some of the familial cases.[146,147] In Italy, TSH receptor mutations were found in 5 of 42 patients with euthyroid hyperthyrotropinemia.[151] These five were from two families. There were no TSH mutations in the remaining 34 cases. The mutations were in the extracellular portion of the receptor in both families, and TSH levels ranged from 5.2 to 13 mU/L.

Eight families have been studied in Japan.[152] All have the R450H mutation in at least one allele. In four families, the mutation was homozygous—and in four there were compound heterozygotes. With normal serum T4 and free T4 levels, normal thyroid scan results, and absent thyroid antibodies, many such infants are followed expectantly. It is always necessary to rule out primary thyroid disease in such patients. Hyperthyrotropinemia in the newborn is usually treated, but in the presence of free T4 levels in the upper half of the normal range could be managed expectantly. Infants exposed to excess iodine usually recover spontaneously in 3 to 4 weeks.

EVALUATION OF INFANTS WITH PRESUMPTIVE POSITIVE SCREENING RESULTS

A positive screening report for CH in a newborn demands prompt evaluation of the infant, including a history, physical examination, and laboratory testing.[61,64,133] A history of autoimmune thyroid disease in the family suggests the possibility of transient CH, either drug or maternal TSH receptor autoantibody induced. Recurrent CH in the same sibship also suggests maternal autoantibody-mediated disease.[144] A history of familial congenital thyroid disease suggests thyroid dyshormonogenesis, which is usually transmitted as an autosomal-recessive trait.

Physical examination may reveal one of several early and subtle manifestations of hypothyroidism, including a large posterior fontanelle (>1 cm in diameter), prolonged jaundice (hyperbilirubinemia >7 days), macroglossia, hoarse cry, distended abdomen, umbilical hernia, hypotonia, or goiter.[61,133] Less than 5% of infants are diagnosed on clinical grounds before the screening report, but 15% to 20% of CH infants have suggestive signs when carefully examined.

The diagnosis of CH is confirmed by serum measurements of T4 and/or free T4 (FT4) and TSH concentrations. Serum total T4 assays are now quite well standardized but will vary directly with thyroxine-binding globulin concentrations. Automated FT4 immunoassay results vary by method and may underestimate FT4 concentrations in infants with low TBG levels.[153] This is particularly true in premature infants. The gold standard FT4 method is equilibrium dialysis, available in most reference laboratories. Like total T4, FT4 in hypothyroid infants should be maintained in the upper half of the normal range for the assay method employed. In the neonatal period (2-6 weeks), serum T4, FT4, and TSH levels below 84 nmol/L (6.5 μg/dL), 10 pmol/L (0.8 ng/dL), and above 10 mU/L (10 μU/mL), respectively, suggest CH.

In infants with proven CH, 90% have TSH levels above 50 mU/L and 75% have T4 and FT4 concentrations below 84 nmol/L (6.5 μg/dL) and 10 pmol/L (0.8 ng/dL), respectively. Perhaps 20% of CH infants have T4 and FT4 levels in the 84- to 165-nmol/L (6.5-13 μg/dL) and 10- to 25-pmol/L (0.8-1.9 ng/dL) range (respectively)—usually with clearly elevated TSH concentrations (>30 mU/L). A few infants will manifest only modest TSH elevations (7-30 mU/L). Such infants may require repeat examinations in order to establish a diagnosis of CH. Serum T3 or rT3 concentrations have limited practical value in the diagnosis of CH.

Hypothalamic-pituitary hypothyroidism is more difficult to diagnose. Most such infants are missed in screening programs unless a T4/TBG ratio measurement is included as a free T4 surrogate in the testing.[91] The disorder is characterized by a low serum T4 concentration and low T4/TBG ratio, with a normal or low-normal range TSH value. Measurements of serum free T4 concentrations will distinguish these possibilities. An infant or child with a low free T4 concentration and low TSH level should be carefully examined for evidence of hypothyroidism, and other tests of pituitary function should be conducted.[91] A subnormal TSH response to TRH confirms a diagnosis of

pituitary TSH deficiency. If the peak level of TSH is normal and/or prolonged, and there is a good 4-hour T4 (thyroid) response to TSH, hypothalamic TRH deficiency is more likely. The TSH deficiency may be isolated or associated with other pituitary hormone deficiencies. In these infants, treatment with T4 raises the serum T4 and free T4 to normal levels.

All infants with proven CH should undergo radionuclide or ultrasound thyroid scanning if possible, using either technetium or I.[123,133] Radioiodine 123 is preferred, if available. Technetium is trapped by thyroid follicular cells but is not organified. Use of radioiodine provides greater isotope concentration, and allows later scanning (2-24 hours) with lower background radioactivity and improved discrimination. The confirmation of an ectopic thyroid gland provides a definitive diagnosis of thyroid dysgenesis. The absence of uptake of radioisotope suggests thyroid gland agenesis, but some infants may have low radioisotope uptake and a nondetectable gland by scan due to a TSH receptor defect, iodide trapping defect, or TSH receptor blockade by maternal TBA. These infants or the mother should have blood drawn for measurement of TBA if there is a history of maternal autoimmune thyroid disease. Thyroid ultrasound will usually confirm thyroid gland dysgenesis.

A normal radioisotope scan and/or a palpable or ultrasound-positive thyroid gland in the presence of hypothyroidism indicates impaired thyroid hormone synthesis. Infants with mild to moderate TBA-mediated transient CH may have normal thyroid scan results. The maternal and family histories should be carefully reviewed in such cases. A serum thyroglobulin measurement may be helpful in infants with absent uptake or normal scans. A very low or absent serum thyroglobulin level indicates thyroid agenesis in an infant with absent radioisotope uptake, and suggests a defect in thyroglobulin synthesis in infants with a normal imaging study.[154]

Infants with thyroid dysgenesis have elevated serum thyroglobulin levels that relate to the mass of residual thyroid tissue and degree of stimulation. However, levels usually do not exceed 1,000 pmol/L (660 ng/mL). Very high thyroglobulin levels (>1,000 pmol/L) may be observed in infants with CH due to defective thyroxine synthesis not involving the capacity for thyroglobulin production. Serum calcitonin levels are also low in CH infants with thyroid agenesis but offer no advantage over the thyroglobulin measurement in diagnosis. These approaches are summarized in Figure 6-7. Normal thyroid function test results in infants 2 to 6 weeks of age are summarized in Table 6-3. A bone age measurement (x-ray examination of the knee and foot) is also useful as a test for possible intrauterine hypothyroidism.

TREATMENT OF AFFECTED INFANTS

Initial evaluation should be accomplished promptly and should require no more than 2 to 5 days.[64,74,133] In the absence of facilities or funds to conduct scanning, ultrasound, TBA bioassay, or thyroglobulin measurements, treatment should be instituted as soon as the diagnosis is confirmed. The goal of newborn CH screening is the institution of early adequate thyroid hormone replacement therapy. Most of the brain cell thyroid hormone is derived from local T4-to-T3 conversion. Approximately 70% of the T3 in the cerebral cortex is derived via local T4 monodeiodination.[65] Thus, the preferred thyroid hormone preparation for treatment of infants with CH is thyroxine.

Because the focus of screening is early and adequate treatment, the dosage of T4 should normalize the serum T4 level as quickly as possible.[74,133,155,156] To guarantee

TABLE 6-3

Normal Thyroid Function Parameters

Thyroid Parameter	2-6 Weeks of Age Normal Range
T4	84-210 nmol/L (6.5-16.3 ug/dL)
T3	1.5-4.6 nmol/L (100-300 ng/dL)
Free T4	10-30 pmol/L (0.8-2.2 ng/dL)
TSH	1.7-9.1 mU/L (1.9-9.1 mU/ml)
TBG	160-750 nmol/L (1.0-4.5 mg/dL)
Thyroglobulin	15-375 pmol/L (10-250 ng/mL)

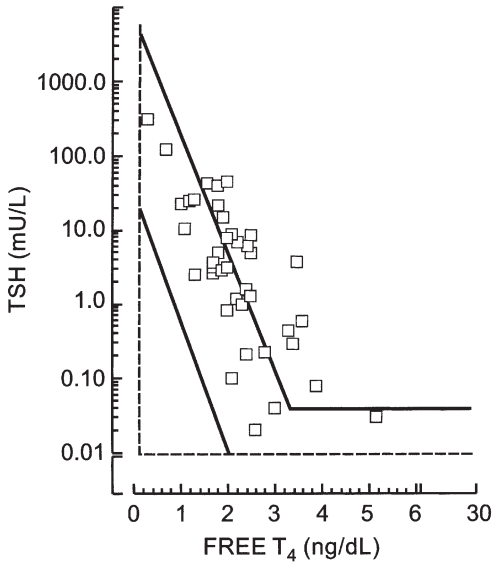

Figure 6-8. Serum third-generation TSH and direct dialysis free T4 measurements in 42 infants 2 to 9 months of age with congenital hypothyroidism on thyroxine replacement therapy. Normal infants plot within the parallel lines demarcating the 99-percentile range characterizing the TSH-free T4 relationship in individuals with a normal hypothalamic-pituitary-thyroid axis. Patients with pituitary resistance to T4 plot to the right of the normal range. Eighteen of the 42 infant values (43%) plot to the right of the 99-percentile range. In treated congenitally hypothyroid children and adolescents 1 year to 20 years of age (data not shown), only 6 of 63 (10%) plot to the right of the normal range. [From Fisher DA, Schoen EJ, LaFranchi S, et al. (2000). The hypothalamic-pituitary-thyroid negative feedback control axis in children with treated congenital hypothyroidism. J Clin Endocrinol Metab 85:2722.]

adequate hormone to all infants, it is desirable to maintain the serum T4 and/or FT4 in the upper half of the normal range during therapy. The 97% upper limit of serum T4 levels in hypothyroid infants may range to 130 nmol/L (10 μg/dL). For these reasons, the initial target range for the total T4 concentration is 130 to 210 nmol/L (10-16.3 μg/dL). This assumes a normal serum TBG concentration. This can be confirmed by measuring a normal-range T3 resin uptake, free thyroxine, or TBG level at the time of the first post-treatment T4 measurement. The initial direct free T4 target concentration should also be in the upper half of the normal infant range and with adequate treatment should transiently range to 40 to 45 pmol/L.[156,157]

To rapidly normalize the serum T4 concentration in the CH infant, an initial dose of Na-L-T4 of 10 to 15 μg/kg/day is recommended.[64,74,133] For the average term infant of 3 to 4.5 kg, an initial dose of 50 μg (0.050 mg) daily is appropriate. Serum TSH concentrations in some treated infants with CH may remain relatively elevated despite normalized levels of T4 or free T4[157] (Figure 6-8). The relative elevation of serum TSH is more marked during the early months of therapy but can persist to some degree in about 10% of patients through the second decade of life.[157] The elevated serum TSH concentration relative to T4 concentration in CH infants is presumably due to a resetting of the feedback threshold for T4 suppression of TSH release in infants with CH.[157] This resetting occurs in utero, but the mechanism remains obscure. Nonetheless, after the first few weeks of treatment serum TSH is the most important marker for therapy management.[74]

Physical growth and development of infants with CH are usually normalized by early adequate therapy, and infants with a delay in bone maturation at the time of diagnosis will normalize their bone by 1 to 2 years of age.[63] IQ values and mental and motor development are also normalized in most infants with CH.[64,158-160] However, low normal or occasionally low IQ values and motor impairments have been reported in treated children with severe CH (very low serum T4 and delayed bone maturation at birth).[161-164] This outcome has been more prevalent in programs employing a relatively low replacement dose of T4 or in infants in whom treatment is delayed.[64,165,166]

This deficit, although variable, amounts to several IQ points for every week of delayed early treatment. Early therapy with 10 to 15 μg/kg/day of levothyroxine reduces the serum TSH level more rapidly and minimizes the early IQ loss.[74,155,156,161,166] Overtreatment resulting in tachycardia, excessive nervousness, or disturbed sleep patterns may occur but can be eliminated by frequent dosage adjustment and carries little or no risk if transient. Excessive dosage over a prolonged period (3-6 months) may produce osteoporosis, premature synostosis of cranial sutures, and undue advancement of bone age.

Infants with presumed transient hypothyroidism caused by maternal goitrogenic drugs need not be treated unless the low serum T4 and elevated TSH levels persist beyond the second week. Therapy can usually be discontinued after 8 to 12 weeks. Hyperthyroid mothers on antithyroid drugs may breast-feed their infants because the concentrations of drug in breast milk are very low. Infants with transient hypothyroidism secondary to maternal (transplacental) TSH receptor-blocking antibody also require treatment if they are hypothyroxinemic. The half-life of the maternal autoantibody approximates 2 weeks, and depending on the initial level may require several months for degradation. Treatment is usually required for 2 to 5 months.

Infants with thyroid resistance are very difficult to manage, and treatment must be individualized. It is important to detect infants with GRTH as early as possible to manage early relative hypothyroidism and to minimize brain dysfunction, including attention deficit hyperactivity disorder. Some patients will be adequately compensated by

the TSH-mediated thyroid hyperplasia and hyperthyroxinemia. Other patients will be poorly compensated, and compensation will vary among tissues.[125,126] The serum TSH level in GRTH patients may be elevated or within the normal range (albeit high in the face of the hyperthyroxinemia).

An elevated TSH level in the absence of clinical evidence for thyrotoxicosis is an indication for treatment. Failure to thrive, delayed developmental milestones, and delayed bone maturation are other indications for treatment. The levothyroxine treatment dose may be three to six times the usual replacement dose. Data from other involved family members may be helpful when available. Patients with predominant PitRTH (and elevated TSH levels) will have variable peripheral tissue responsiveness. TSH-dependent thyrotoxicosis of variable degree usually presents during childhood or adolescence in such patients.

Some infants with GRTH have significant TSH elevation at birth in association with increased serum total and free T4 and T3 concentrations. Figure 6-9 shows pre- and post-treatment serum TSH, thyroglobulin and total T4 and T3, and free T4 index and reverse T3 in a newborn infant with GRTH treated by Weiss et al.[167] Initial TSH approximated 50 mU/L, and total T4 approximated 650 nmol/L (50 μg/dL). The infant manifested an enlarged thyroid gland, and serum thyroglobulin concentrations measured at 1 month approximated 0.5 nmol/L (330 ng/mL). TSH and T4 levels fell during the first month, but TSH remained elevated and treatment was begun at 34 days. On a levothyroxine dosage of 150 to 250 μg daily, serum TSH plateaued in the 5- to 10-mU/L range—with total T4 approximating 500 nmol/L.

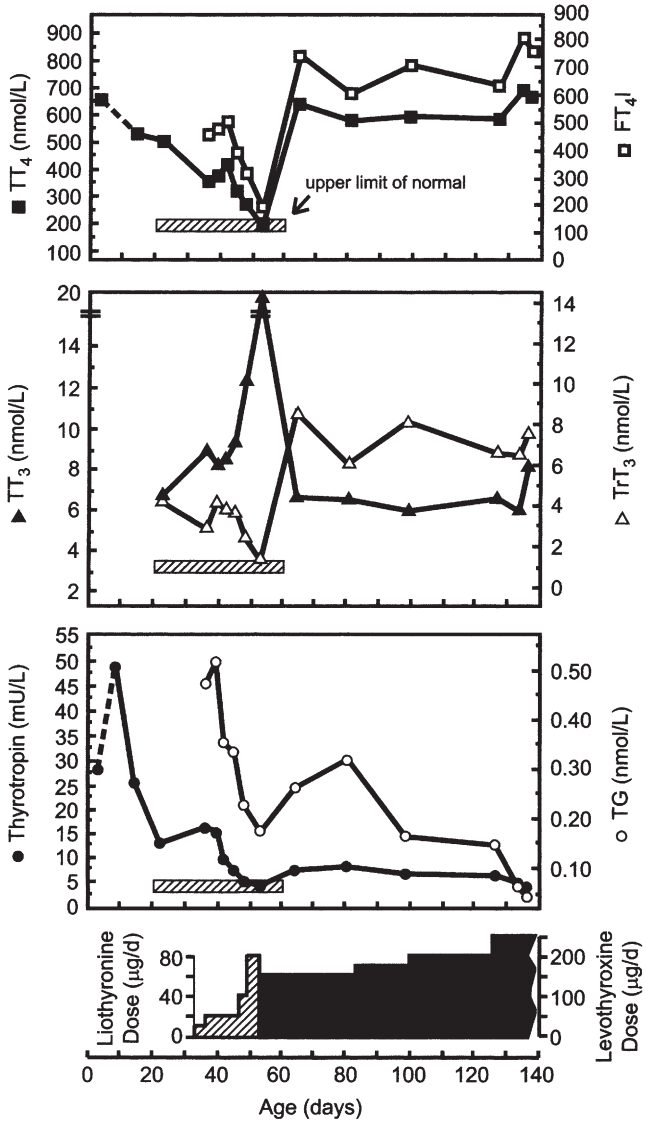

Figure 6-9. Thyroid function parameters in an infant with generalized resistance to thyroid hormone (GRTH). Total T4 (TT4), free T4 index (FT4I), total T3(TT3), total reverse T3(TrT3), thyrotropin (TSH), and thyroglobulin (Tg) levels before and during levothyroxine therapy are shown. Congenital Hyperthyroidism

FETAL-NEONATAL GRAVES' DISEASE

Neonatal Graves' disease is uncommon because of the low incidence of thyrotoxicosis in pregnancy (1 to 2 cases per 1,000 pregnancies) and because the neonatal disease occurs only in about 1 in 70 cases of thyrotoxic pregnancy.[168-170] The disease is usually due to transplacental passage of TSH receptor-stimulating antibody (TSA) from a mother with active or inactive Graves' disease. It is possible to predict neonatal disease in offspring of women with high TSA titers. In general, TSA titers (measured as cAMP response to TSH as a percentage of control in a thyroid cell bioassay) of 300% to 500% are associated with a high prevalence of neonatal Graves' disease.[168] Rarely, an infant may acquire both TSH receptor-stimulating and TSH receptor-blocking antibodies from the mother. The blocking antibodies may block the effect of the stimulating antibodies for several weeks, and the infant develops late-onset neonatal Graves' disease.[168]

In pregnancies associated with autoimmune thyroid disease and high titers of TSH receptor-stimulating and/or TSH receptor-blocking autoantibodies, fetal-neonatal thyroid dysfunction may develop. In a recent study of 230 Graves' disease pregnancies, Mitsuda and colleagues reported a prevalence of neonatal thyroid dysfunction of 16.3%.[171] Overt or chemical hyperthyroidism accounted for 5.6%, and transient hypothyroidism for 10.7% (Table 6-4). These disorders reflect the effects of TSAs, TSH-receptor blocking antibodies, and the effects of fetal hyperthyroxinemia—which can produce fetal growth retardation, tachycardia, and feedback suppression of the fetal hypothalamic-pituitary-thyroid axis, resulting in long-standing hypothalamic-pituitary hypothyroidism.[172]

Antithyroid drugs used to treat maternal disease readily cross the placenta and can compromise fetal-neonatal thyroid hormone production.[168,169] Fetal hyperthyroidism is a significant risk in a pregnancy complicated by Graves'

TABLE 6-4

disease, and surveillance of the fetus with ultrasound allows detection of fetal goiter. Measurement of maternal serum levels of TSA as TSH binding-inhibiting immunoglobulin (TBII, which measures stimulating and blocking antibodies) or TSH receptor stimulating antibody (TSA) provide useful prognostic information. Levels of TBII in excess of 30% or TSA in excess of 300% of control values are predictive of fetal hyperthyroidism.[168,169]

Cordocentesis remains the method of choice for confirmation of fetal thyroid status. Standards for fetal serum thyroid hormone and TSH concentrations versus GA have been developed[28] (Figure 6-10). Fetal Graves' disease is also suspect if the fetus develops tachycardia. Baseline fetal heart rate averages about 140 beats/min between 21 and 30 weeks gestation, and 135 beats/min between 31 and 40 weeks.[169,173] The currently acceptable normal range during the last 15 weeks of gestation is 120 to 160 beats/min. The baseline rate is defined as the average baseline fetal heart rate in a 10-minute period rounded off to the nearest 5 beats/min. In the reported instances of fetal thyrotoxicosis responding to maternal antithyroid drug treatment, fetal tachycardia exceeding 160 beats/min occurred between 25 and 30 weeks gestation.

Maternal antithyroid drug treatment normalized the fetal heart rate within 2 weeks. Treatment of fetal thyrotoxicosis is accomplished by administration of an antithyroid drug to the mother in a dose of 150 to 300 mg daily. The dose is adjusted at 1- to 2-week internals to maintain the fetal heart rate at 140 beats/min. The antithyroid drug dose can usually be decreased progressively, aiming for

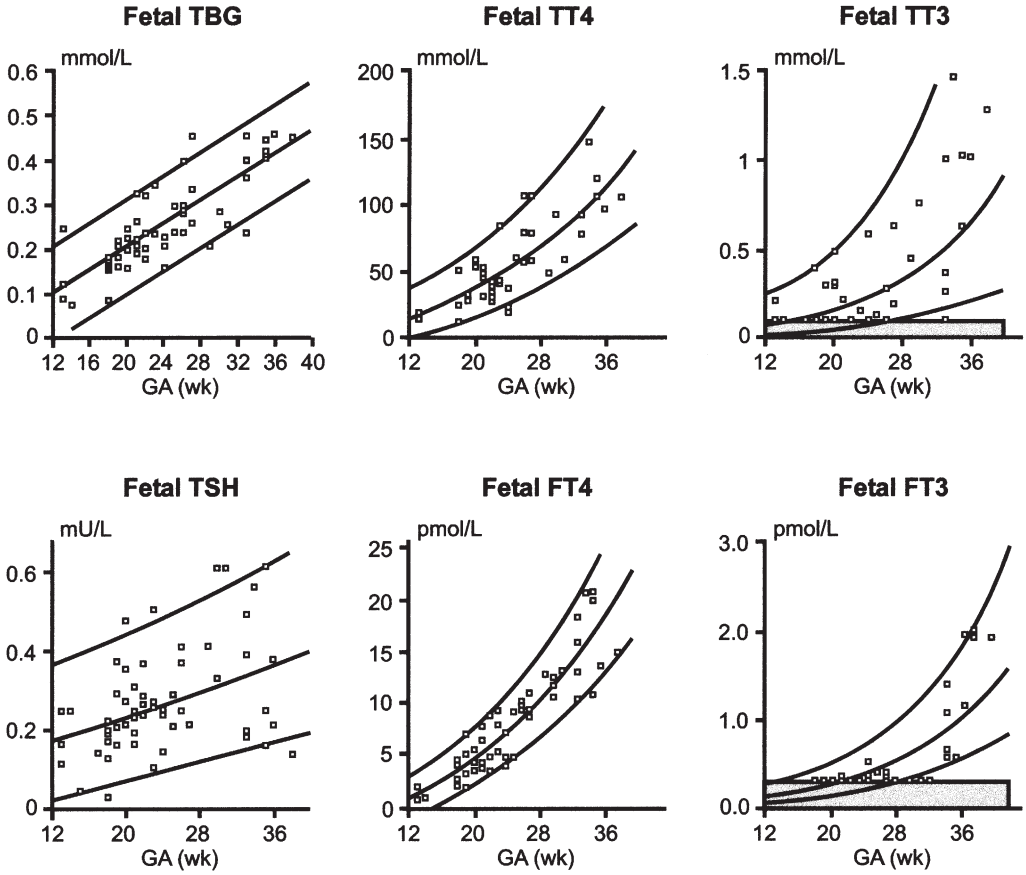

Figure 6-10. Thyroid function test parameters in the normal in utero human fetus. Serum concentrations of TBG, total T4(TT4), total T3(TT3), TSH, free T4(FT4) and free T3(FT3) were measured in blood obtained by cordocentesis or cardiocentesis conducted for prenatal diagnosis of blood disorders, fetal karyotyping, investigation of maternal toxoplasmosis, or fetal blood grouping in red cell isoimmunized pregnancies. These values were derived from fetuses found not to have the disorder or infection in question. The progressive increase in free T4 concentration with increasing gestation age is not in agreement with recent umbilical cord-blood concentrations. [Reproduced with permission from Thorpe-Beeston JG, et al. (1992). Fetal thyroid function. Thyroid 2:207.]

a 75- to 100-mg daily dose near term. In rare circumstances, maternal autoantibodies against thyroxine can produce hyperthyroxinemia in the fetus and neonate and can complicate interpretation of in vitro thyroid function tests.[174] This possibility can be tested if the clinical and laboratory data are incongruent.

Graves' disease in the newborn is manifested by irritability, flushing, tachycardia, hypertension, poor weight gain, thyroid enlargement, and exophthalmos.[169,170] Thrombocytopenia, hepatosplenomegaly, jaundice, and hypoprothrombinemia may occur. Cardiac failure and death may occur if the thyrotoxicity is severe and the treatment inadequate. The suppression of cord-blood TSH to values less than 0.1 mU/L in the presence of normal or elevated levels of T4 and T3 suggests a TSA effect. The diagnosis is confirmed by measuring high levels of T4, free T4, and T3 in postnatal blood.

Cord-blood values may be normal or near normal, but levels at 2 to 5 days may be markedly increased. The serum TSH is low. In some neonates, the onset of symptoms and signs may be delayed as long as 8 to 9 days. This is due both to the postnatal depletion of transplacentally acquired blocking doses of antithyroid drugs, and to the fact that there is an abrupt increase in conversion of T4 to active T3 by liver and other tissues shortly after birth. Neonatal Graves' disease resolves spontaneously as maternal TSA in the newborn is degraded. The half-life approximates 12 days. The usual clinical course of neonatal Graves' disease extends from 3 to 12 weeks.

The treatment of Graves' hyperthyroidism in the newborn includes sedatives and digitalization as necessary.[170] Iodide or antithyroid drugs are administered to decrease thyroid hormone secretion. These drugs have additive effects with regard to inhibition of hormone synthesis. In addition, iodide rapidly inhibits hormone release. Lugol's solution (5% iodine and 10% potassium iodide; 126 mg of iodine per milliliter) is begun in a dose of one drop (about 8 mg) three times daily. Methimazole or propylthiouracil are administered in a dose of 0.5 to 1 mg or 5 to 10 mg, respectively, per kilogram daily in divided doses at 8-hour intervals. A therapeutic response should be observed within 24 to 36 hours. If a satisfactory response is not observed, the dose of antithyroid drug and iodide can be increased by 50%. Adrenal corticosteroids in anti-inflammatory dosage and propranolol (1 to 2 mg per kilogram per day) may also be helpful. Radiographic contrast agents, too, may be useful in treatment (sodium ipodate, 100 mg a day or 0.3 to 0.5 g every 2 to 3 days) either alone or in conjunction with antithyroid drug treatment.[175,176]

AUTOSOMAL-DOMINANT HYPERTHYROIDISM

Several families have been reported with hyperthyroidism segregating as an autosomal-dominant trait in the absence of thyroid autoimmune disease.[101,102,177-181] Some 12 families and 11 children with sporadic occurrence of activating TSH receptor mutations have been reported.[181] The affected individuals present with goiter, increased total and free T4 levels, and suppressed TSH concentrations. In patients treated surgically, the thyroid glands manifest diffuse hyperplasia without lymphocytic infiltration. In two large French cohorts, TSH receptor gene mutations have been characterized involving the third and seventh transmembrane segments of the TSH receptor.[177] Functionally, the transfected mutated receptors demonstrated abnormally increased constitutive cAMP-stimulating activity. Only one constitutively activating mutation (located in the large extracellular domain at position 281) has been identified.[103]

Most of the affected individuals have been detected during childhood or adolescence, but a few infants have been diagnosed before 2 years of age and occasionally at birth.[178,180] Clearly, the abnormality is congenital—and it is possible that some of the earlier reported cases of familial persistent neonatal Graves' disease have been due to unrecognized activating TSH receptor mutations. Treatment of such infants is difficult because the disorder is not transient.[180] Antithyroid drugs and partial or near-total thyroidectomy are the available treatment options.

Disorders of Thyroid Hormone Transport

Several genetic abnormalities of the iodothyronine-binding serum proteins have been described and all are manifest at birth. These include complete TBG deficiency, partial TBG deficiency, TBG excess, transthyretin (TTR) (prealbumin) variants, and familial dysalbuminemic hyperthyroxinemia (FDH).[182-192] Features of these disorders are summarized in Table 6-5. All are associated with a euthyroid state, but the abnormal total thyroxine concentrations can be misleading during neonatal screening and in the assessment of thyroid function.

COMPLETE TBG DEFICIENCY

In 1959, Tanaka and Starr first reported TBG deficiency in a euthyroid male. Since that time, some 14 T4-binding globulin variants have been identified that produce complete deficiency of TBG.[182,183] These include TBG-CD, TBG-CD5, TBG-CD6, TBG-CDJ (Japan), TBG-CDY (Yonago), TBG-CDB (Buffalo), TBG-CDBe (Bedouin), and TBG-CDK (Kankakee). The prevalence of TBG deficiency varies from 1 in 5,000 to 1 in 12,000 newborn infants. This prevalence estimate includes infants with partial TBG deficiency (low TBG). The disorder seems to be transmitted as an X-linked trait. Serum TBG levels measured by immunoassay or T4-binding capacity are very low in affected males and are approximately half-normal in carrier females. Serum T4 levels vary similarly, but affected subjects are euthyroid—with normal serum free T4 concentrations, normal serum TSH levels, and normal serum TSH responses to exogenous TRH.

Male-to-male transmission has not been observed, and there is usually transmission of the trait from affected males to female offspring. Variable phenotypes have been observed in association with selective inactivation of the X chromosome carrying one of the two alleles.[184] The defects have included a single-amino-acid substitution producing abnormal post-translational processing

TABLE 6-5

Thyroid Hormone Binding Protein Abnormalities

Abnormality	Prevalence	Inheritance	Clinical		
			T4	T3	T3RU
Complete TBG Deficiency	1:15,000 Newborns	X-linked	low	↓	↑

*Manifest in heterozygotes.
**Manifest in heterozygotes or homozygotes depending on mutation.

(TBG-CD5). The other five single-nucleotide substitutions or nucleotide deletions produce truncated molecules caused by early termination of translation.[183] The most recently described defect, TBG-CDK (Kankakee), involved an A-to-G transition in the acceptor splice function of intron II—causing a frame-shift and premature stop codon, predicting a truncated TBG protein lacking 201 amino acids.[183]

PARTIAL TBG DEFICIENCY

A partial TBG deficiency has been described, characterized by diminished but not absent TBG. A number of families have been reported.[182,185] Careful studies indicate that in these families, as in those with very low serum TBG levels, serum free T4 and TSH levels are normal. TBG levels are diminished in affected males, and there is a tendency to decreased concentrations in carrier females. However, the carrier state in females is sometimes difficult to identify because of overlap with affected males or normals.

This abnormality also seems to be transmitted as an X-linked trait. Six variant partial TBG defects have been described associated with altered TBG binding of T4. These defects (including TBG-SD, TBG-G, TBG-M, TBG-A, TBG-Q and TBG-PDJ) are characterized by decreased serum TBG concentrations by immunoassay and increased concentrations of denatured TBG identified on the basis of decreased heat stability.[182]

TBG EXCESS

Congenital TBG excess occurs in from 1 in 6,000 newborns in England to 1 in 40,000 in New York.[182] Subjects with increased levels of TBG have increased total serum T4 concentrations with normal free T4 and TSH levels and are hence euthyroid. Studies in these subjects, as in those with low TBG concentrations, have shown correlation between TBG production rates and serum levels—suggesting that the mechanism for the high TBG concentrations is increased production, presumably by the liver.

TBG levels are increased up to 4.5 times normal in affected individuals, and carrier females have serum concentrations intermediate between normal values and the high levels in affected males. Early reports suggested a dominant mode of inheritance, but subsequent studies and review of the earlier data are compatible with an X-linked mode of inheritance.[182] Mori et al., using gene dosage and in situ hybridization studies, showed that the defect in two Japanese families appears to be due to gene amplification secondary to three copies of the TBG gene on the affected X chromosome.[186]

TRANSTHYRETIN VARIANTS

Moses et al. first reported a 52-year-old euthyroid man with an elevated serum T4 (not corrected by the use of a free T4 index) but with normal free T4, normal total serum T3 and TSH concentrations, and normal TSH and T3 responses to TRH.[187] Serum TBG and albumin levels were normal, but the serum TBPA concentration measured by radioimmunoelectrophoresis was 2.5 to 3.0 times greater than the level in a normal human serum pool. Moreover, 70% of the serum T4 was selectively removed by an anti-TBPA immunoglobulin affinity column. One of the subject's three children had a similar abnormality, but the mode of inheritance was not clearly defined. Several similar patients have been reported.[187-189]

The family recently reported by Refetoff et al. demonstrated dominant inheritance, with serum T4 levels in affected family members 50% above the mean of unaffected relatives.[189] Reverse T3 concentrations were increased, but serum T3 and TSH levels were normal. Four transthyretin variants have been reported (Ser6, Thr109, Met119 and Val109). Only two of these, Thr109 and Val109, demonstrated high enough affinity for T4 to produce consistent hyperthyroxinemia in heterozygous individuals.[189]

FAMILIAL DYSALBUMINEMIC HYPERTHYROXINEMIA AND HYPERTRIIODOTHYRONINEMIA

FDH is the most common cause of inherited euthyroid hyperthyroxinemia in Caucasians. The binding protein abnormality was described by several investigators who

Features			
FT4	**Protein Level**	**Other**	**Molecular Abnormality**
N	TBG<0.5 μg/dl	TBG absent or decreased immunoreactivity; decreased binding affinity	TBG gene mutations
N	↓	TBG decreased immunoreactivity or decreased stability; decreased binding affinity	TBG gene mutations
N	TBG ↑ 3.0-4.5 X		Defect not yet clear
N	N	Increased T4-binding affinity*	TTR gene mutations

N	N	Increased T4-binding affinity	Genetic polymorphism?

studied euthyroid subjects with increased serum T4 concentrations not corrected by the use of the free T4 index correction and with normal free T4, total serum T3, and TSH levels.[190] Wada and co-workers described the defect in Japanese subjects. The thyroid function parameters in these subjects resemble those in the patients with high TBPA reported by Moses et al.[187,191]

Serum thyroxine in affected subjects migrates with albumin by conventional polyacrylamide electrophoresis, and TBPA levels are normal on the basis of saturation-binding studies in vitro. The disorder seems to be transmitted as an autosomal-dominant trait. There is male-to-male transmission and an affected-to-unaffected ratio of 1 or greater in first-degree relatives. A missense mutation in codon 218 of the albumin gene has been described in 11 unrelated families (G to A in Caucasians and G to C in the Japanese family), resulting in arginine-to-histidine and arginine-to-proline amino acid substitutions (respectively) in the albumin molecule.[192]

Familial dysalbuminemic hypertriiodothyroninemia has been reported in a Thai family presenting with high serum total T3 and normal T4 concentrations.[192] The affected patients were euthyroid, with normal free T4, free T3, and TSH concentrations. T3-binding studies showed a 40-fold increased association constant (Ka) of serum albumin in affected subjects, whereas the Ka for T4 was increased only 1.5-fold. The molecular defect was a nucleotide substitution at normal codon 66, resulting in substitution of a cytosine for thymine and replacement of the normal leucine by proline.[192]

The Fetus as Patient

Advances in medical science and technology have paved the way for an increasingly direct approach to the fetus as patient.[169,193,194] Improvements in fetal ultrasound imaging, Doppler ultrasound, and the availability and relative safety of intrauterine cordocentesis now provide new windows on fetal development and metabolism. Fetal therapy via maternal transplacental drug therapy or amniotic fluid instillation are now commonplace. Fetal surgery and fetal gene therapy are being pioneered. One of the first fetal disease states directly addressed in the fetus was thyroid dysfunction.

This effort was frustrated by the failure of measurements of amniotic fluid TSH and iodothyronine concentrations to reliably reflect fetal thyroid function. Currently, fetal thyroid size can be reliably assessed by ultrasound—and normative data for thyroid function tests has been provided for cordocentesis samples during the latter half of gestation. Thus, it is now possible to accurately assess and monitor fetal thyroid function and thyroid-directed therapeutic interventions in the in utero fetus during the latter half of human pregnancy (Figure 6-10).

Possible indications for fetal thyroid assessment include a family history of inborn defects in hypothalamic-pituitary function or thyroid hormone metabolism, maternal drug therapy that might affect fetal thyroid function, or maternal autoimmune thyroid disease. It is clear that maternal or fetal hypothyroidism can be associated with reduction in IQ or with psychomotor dysfunction syndromes, and fetal hyperthyroidism is associated with brain damage, reduced fetal growth, and occasional fetal demise.[23,40,69,170,195] Diagnosis and treatment of fetal hypothyroidism using amniotic injection of levothyroxine and the management of fetal hyperthyroidism via maternal antithyroid drug therapy are now accepted procedures.[170,196-198] Refinements will occur with increasing experience.

Future Directions

Introduction

During the last three decades there have been major advances in our understanding of developmental thyroid physiology and important insights and progress in pediatric thyroid disease nosology, diagnosis, and management. Specific etiologic gene mutations have been characterized for pituitary thyroid stimulating hormone (TSH) deficiency, TSH receptor dysfunction, thyroid dysgenesis, the thyroid dyshormonogenesis syndromes, thyroid hormone resistance, and thyroid neoplasia.[1] Our understanding of the pathophysiology and spectrum of thyroid autoimmune disease has expanded significantly.

Ultrasound and fine-needle aspiration (FNA) cytology have become standard approaches to the assessment of thyroid nodules. Major advances in the menu

and efficacy of thyroid function tests have accompanied these advances. Table 7-1 provides a classification of thyroid disorders in children. Thyroid system development, fetal thyroid physiology, thyroid dysfunction in premature infants, and congenital thyroid disorders (including inborn defects in thyroid hormone synthesis, metabolism, and action and thyroid binding protein abnormalities) are discussed in chapter 6.

Metabolism of Iodine

The major thyroid hormone [tetraiodothyronine, or thyroxine (T4)] is approximately 60% iodine by weight, and iodine is the rate-limiting substrate for synthesis of thyroid hormones[2] (Figure 7-1). Iodine is a trace element present in the human body in small amounts (15–20 mg; i.e., 0.02×10^{-3} % of body weight). The recommended dietary allowance of iodine is 100 μg/day for adolescents and adults (150 μg/day in pregnant and lactating women). It is 60 to 100 μg/day for children aged 1 to 10 years, 40 μg/day for infants aged 6 to 12 months, and 30 μg/day for infants 6 months of age or younger. A reevaluation of the iodine requirements in young infants based on iodine balance studies showed that at least in conditions of marginally low iodine intake (as still observed in some parts of Europe) the recommended dietary allowance should be increased to 90 μg for infants aged less than 1 year.[2]

Dietary iodine (I_2) or iodide (I^-) in its ionized form is rapidly absorbed. Iodide is distributed within the extrathyroidal iodide pool, which represents 30% to 40% of body weight. The concentration of iodide in the serum is dependent on iodine intake, and the extrathyroidal pool of iodide is constantly cleared of iodide by two competing mechanisms: active transport into the thyroid cells and excretion by the kidney. The plasma membrane sodium iodide symporter (NIS) confers on the thyroid the ability to concentrate iodide to 20 to 40 times its levels in plasma.[3,4]

TABLE 7-1

Thyroid Disorders in Childhood and Adolescence

Congenital Hypothyroidism

Thyroid Dysgenesis
- Idiopathic (97%-98%)
  - Athyreosis
  - Hypoplasia
  - Ectopia
  - Cryptothyroidism

Genetic (5%)
- Athyreosis
  - TTF-1 mutations
  - TTF-2 mutations
- Hypoplasia
  - PAX-8 mutations
  - TSH receptor mutations

Thyroid Dyshormonogenesis
- Sodium-iodide symporter defect
- Organification defects
- Abnormal thyroglobulin
- Pendrin defect (Pendred syndrome)
- Iodotyrosine deiodinase defect

Hypothalamic-Pituitary Hypothyroidism
- Anencephaly
- Holoprosencephaly
- Septo-optic dysplasia
- Median facial syndromes
- TSHβ mutations
- Pit-1 mutations
- Prop-1 mutations
- LHX3/LHX4 mutations
- Idiopathic

Transient Hypothyroidism
- Maternal TSH receptor-blocking antibody
- Goitrogenic drugs
- Iodine excess or deficiency

Iodine Deficiency Syndromes
- Goiter
- Mental impairment
- Cretinism

Thyroid Hormone Resistance Syndromes
- Thyroid hormone beta receptor (TRβ) mutations
  - Peripheral tissue resistance syndrome
  - Pituitary resistance syndrome
- Thyroid hormone membrane transport defects

TSH Receptor Mutations
- Loss-of-function hypothyroidism
- Gain-of-function hyperthyroidism

Autoimmune Thyroid Disease
- Hashimoto thyroiditis
- TSH receptor autoantibody disease
  - Stimulating antibody, Graves' disease
  - Blocking antibody, hypothyroidism

Infectious Thyroiditis
- Suppurative thyroiditis
- Subacute thyroiditis

Diffuse Nontoxic Goiter

Non-thyroidal Illness

Thyroid Neoplasia
- Adenoma
  - Nonfunctional
  - Functional
  - Cystic
- Papillary-follicular carcinoma
- Medullary carcinoma
  - MEN 2A, 2B, Ret mutations
  - Sporadic
- Undifferentiated
- Metastatic

Binding Protein Abnormalities
- Complete TBG deficiency
- Partial TBG deficiency
- TBG excess
- Transthyretin variants

Miscellaneous
- G protein mutations (non-autoimmune hyperthyroidism)
- Cystinosis
- Chromosomal disorders

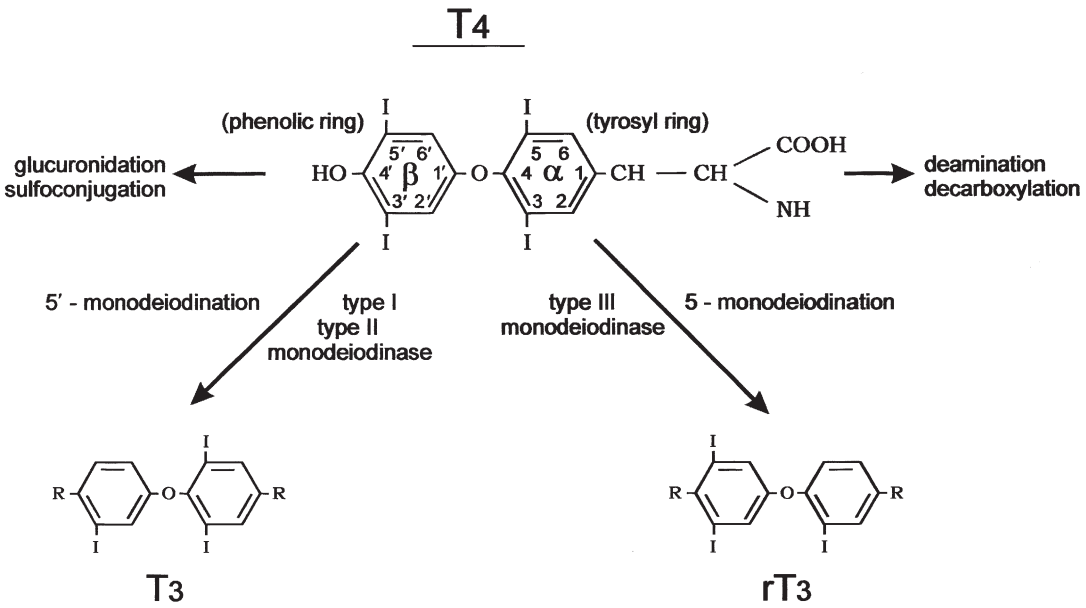

Figure 7-1. The metabolism of thyroxine (tetraiodothyronine). The major metabolic pathway is progressive monodeiodination mediated by the three iodothyronine monodeiodinase enzymes type I, type II, and type III. Outer (phenolic) ring 5′monodeiodination produces active 3,5,3′ triiodothyronine. Inner (tyrosyl) ring 5′monodeiodination produces inactive reverse 3,3′,5′ triiodothyronine. Type I deiodinase is also capable of inner-ring monodeiodination. The alanine side chain of the tyrosyl ring is also subject to degradative reactions, including deamination and decarboxylation. Sulfoconjugation and glucuronide conjugation reactions at the 4′ phenolic ring site occur largely in liver tissue.

Under usual conditions, the thyroid clearance of iodide is 10 to 35 mL/min. However, this varies markedly with the dietary intake—increasing in response to low iodine intake and decreasing with high iodine intake. The renal clearance of iodide is about 35 mL/min in normal adults and is not influenced by the dietary intake of iodine. Fecal excretion of iodine under normal conditions is minimal. A small fraction of iodide (1%-2%) is excreted in sweat under basal conditions, which can increase to 5% to 10% with heavy sweating. In conditions of dietary equilibrium, the excretion of iodide in the urine is equal to iodine intake. Thus, intake can be evaluated by the measurement of the daily urinary excretion of iodine.

Biosynthesis of Thyroid Hormones

Thyroid hormones and analogues are tyrosine derivatives. The steps in the synthesis and release of thyroid hormones are as follows.

1. Iodide trapping by the thyroid gland
2. Synthesis of thyroglobulin
3. Organification of trapped iodide as mono and diiodotyrosines (MIT and DIT)
4. Coupling of the iodotyrosines within thyroglobulin to form the iodothyronines [T4 and triiodothyronine (T3)] and storage in follicular colloid
5. Pinocytosis of colloid droplets and hydrolysis of thyroglobulin within the cytoplasmic phagolysosomes to release MIT, DIT, T4, and T3
6. Deiodination of MIT and DIT with intrathyroidal recycling of the iodine

These steps are shown in Figure 7-2, and are reviewed in Chapter 6.

Metabolism of Thyroglobulin

Until recently, thyroglobulin (Tg) was believed to be present only in thyroid tissue. It is now clear that some Tg escapes during golgi processing and appears in serum in association with secreted iodothyronines. It may be incorporated into classic secretory granules or apical vesicles facilitating secretion.[5] The serum concentration of Tg in adults varies from 1 to 30 ng/mL, with a mean of approximately 5 ng/mL. In normal children, serum Tg varies from undetectable values to 80 ng/mL.

Levels in premature infants are high during the first weeks of life, and decrease with age throughout infancy and childhood.[5-8] The control of thyroglobulin synthesis is complex, involving thyroid-specific transcription factors (TTF-1, TTF-2, and PAX-8), TGF-β1, and TSH. However, the secretion of Tg by the thyroid is at least partly under TSH control.[4,5] Circulating Tg levels may be elevated in patients with a variety of thyroid disorders reflecting thyroidal hyperactivity, including endemic goiter, subacute thyroiditis, Graves' disease, and toxic multinodular goiter.[5] In Hashimoto thyroiditis, serum antithyroglobulin antibody precludes reliable measurement of Tg.

Serum Tg concentrations are also increased, often markedly, in patients with thyroid adenoma and papillary follicular carcinoma—although not in those with anaplastic or medullary carcinoma. In iodine deficiency, elevated serum Tg levels in adults and newborns are not entirely due to increased serum TSH but correlate with the serum T3/T4 ratio—suggesting that iodine availability (which affects the degree of thyroglobulin iodination) also influences Tg secretion.[6-8] The average half-life of circulating 19S Tg varies from 4.3 days to 13.8 days. Clearance presumably occurs

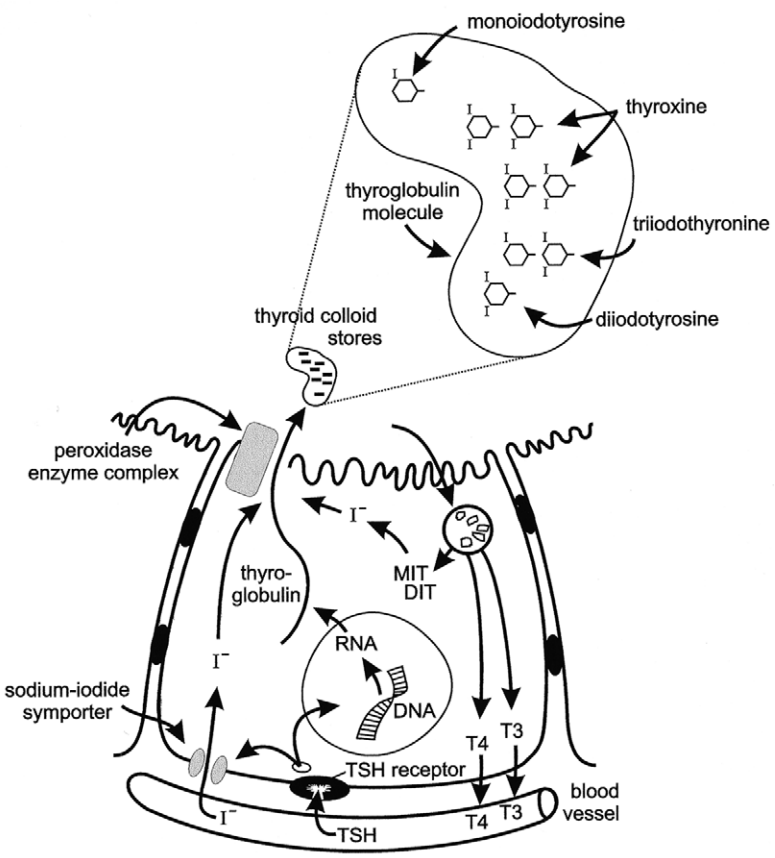

Figure 7-2. Cartoon of the thyroid follicular cell illustrating thyroid hormone synthesis and secretion. TSH regulates the process via the G-protein-linked plasma membrane TSH receptor. TSH binding stimulates thyroglobulin synthesis and sodium-iodide symporter (iodide transporter) uptake of circulating iodide. The iodide diffuses in the cytosol to the apical membrane and is transported to the apical lumen by Pendrin, an anion-bicarconate family exchanger making iodide available to the enzyme organification complex (Pendrin, TPO, THOX). The tyrosine residues of thyroglobulin are iodinated at the apical cell membrane catalyzed by thyroid peroxidase, the organification enzyme. The resulting monoiodotyrosine (MIT) and diiodotyrosine (DIT) residues couple to form the iodothyronines thyroxine (T4) and triiodothyronine (T3) within the stored thyroglobulin molecule. TSH also stimulates micropinocytosis of colloid droplets and progressive thyroglobulin proteolysis within the resulting phagolysosomes. The released T4 and T3 are secreted into the circulation. The uncoupled MIT and DIT are deiodinated by iodotyrosine deiodinase (DEHAL) to release iodide, which is largely recycled within the follicular cell.

within the liver. There is good evidence that Tg reaches the general circulation via thyroidal lymphatics. However, the mechanism of Tg secretion or release remains obscure—and its role in serum or plasma is not known.

Regulation of Thyroid Function

Circulating TSH and iodide levels largely regulate thyroid function. TSH interacts with the thyroid follicular cell at the level of the plasma membrane by binding to TSH receptors, which are coupled to intracellular G proteins.[4,9] TSH activates adenylate cyclase and stimulates the production and accumulation of cyclic adenosine monophosphate (cAMP), which in turn appears to mediate most of the effects of TSH on thyroid metabolism (iodide trapping, iodotyrosine synthesis, Tg synthesis, glucose oxidation, colloid pinocytosis, hormone release, and thyroid growth).

The TSH receptor-stimulating antibodies (TSA) found in the serum of patients with Graves' disease produce the effects of TSH by binding to the TSH receptors. TSH receptor-blocking antibodies (TBA), on the other hand, cause hypothyroidism. A variety of extracellular stimulatory signals have also been implicated in thyroid regulation, including serotonin, epinephrine, histamine, and the prostaglandins.[4,9] However, these agents are much less effective than TSH—and their significance in the control of thyroid function and growth in humans is questionable.

Variations in iodine intake in the physiologic range modulate thyroid membrane iodide trapping, and in pharmacologic doses iodide has been shown to block organification [probably by inhibition of H_2O_2 generation and adenylyl cyclase (the Wolff-Chaikoff effect) followed by decreased Tg synthesis and decreased hormone release].[3] Escape from the Wolff-Chaikoff blockade occurs within days or weeks, mediated by iodide inhibition of NIS mRNA expression and down-regulation of thyroid iodide trapping.[3] Iodide also has an inhibitory effect on the stimulation of cAMP by TSH. TSH functions as a trophic hormone, and removal of the pituitary reduces thyroid cell function to a basal level.

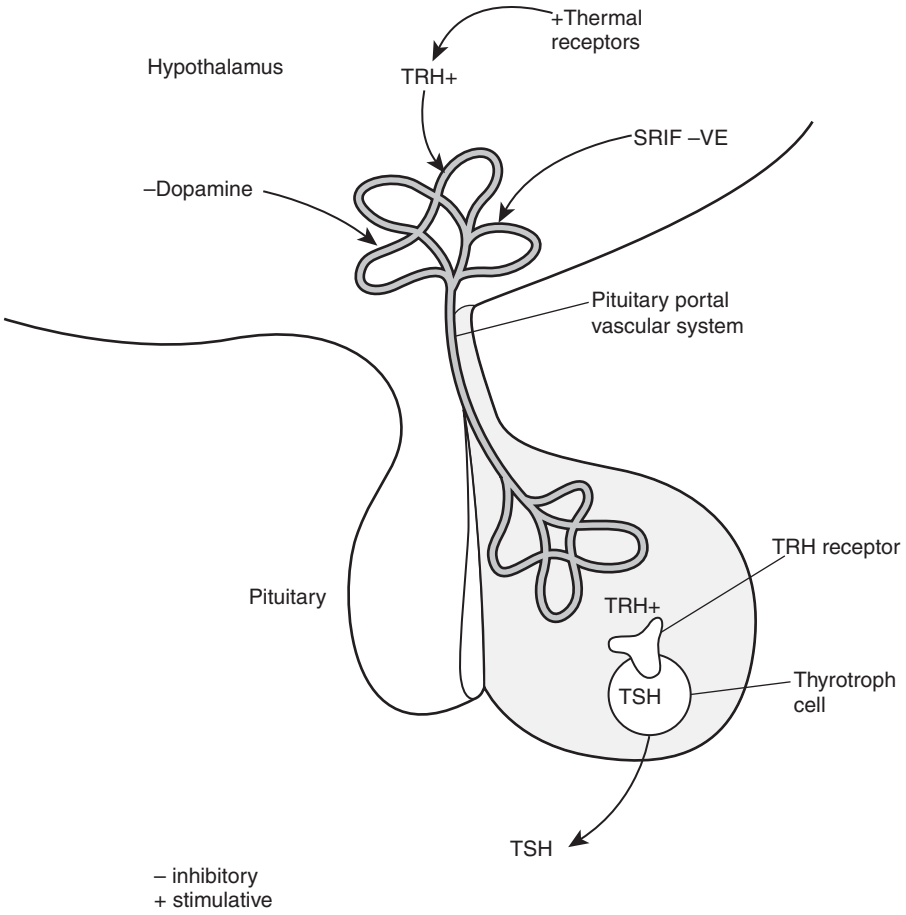

Figure 7-3 Cartoon illustrating the hypothalamic-pituitary TSH axis. Thyrotropin-releasing hormone (TRH) secreted into the pituitary portal vascular system stimulates TSH synthesis and secretion from the pituitary thyrotroph cell. TRH secretion is modulated by central and peripheral thermal sensors. Dopamine or somatostatin (SRIF) can inhibit TSH release.

TSH secretion is modulated by thyrotropin-releasing hormone (TRH), a peptide synthesized in the hypothalamus and secreted into the pituitary portal vascular system for transport to the anterior pituitary thyrotroph cell (Figure 7-3). TRH production is modulated by environmental temperature via peripheral and central (hypothalamic) thermal sensors.[10,11] These sensors modulate neuronal output to the hypothalamic centers regulating TRH secretion. Decreasing environmental and body temperatures increase TRH and increase the tonic level of TSH release. Somatostatin and dopamine can inhibit TSH release, and these transmitters probably contribute to central nervous system modulation of TSH release. Norepinephrine and serotonin may inhibit TSH release, but their significance is not clear. Glucocorticoids inhibit TSH release at the hypothalamic level.

Thyroid Hormone Transport

Thyroid hormones are present in the blood in noncovalent linkage with the carrier proteins: thyroxine-binding globulin (TBG), prealbumin or transthyretin, and albumin. The bound form is in equilibrium with free hormones[12] (Figure 7-4). The major binding protein is TBG, a globulin with an electrophoretic mobility between the α_1- and α_2-globulins. TBG is the most important carrier protein for T4. TBG and albumin seem equally important for T3.

The binding reactions are nearly complete, and thus the euthyroid steady-state concentration of free T4 and T3 approximate 0.03% and 0.30% (respectively) of total hormone concentrations. Absolute mean free T4 and T3 concentrations approximate 10 and 4 pg/mL, respectively. In adolescents and adults, the plasma concentrations of the several binding proteins are 1.0 to 3.0 mg/dL for TBG, 20 to 30 mg/dL for TBPA, and 2 to 5 g/dL for albumin. TBG levels are higher in children than in adults, and decrease progressively to adult levels during adolescence.

Metabolism of Thyroid Hormones

Deiodination is the major pathway of thyroid hormone metabolism.[13] The first step in T4 metabolism is deiodination to T3 or to reverse T3 (rT3) (Figure 7-1). Progressive deiodination of the iodothyronines is mediated via three monodeiodinase enzymes: MDI type I, MDI type II, and MDI type III (Table 7-2). Monodeiodination of the beta or outer ring

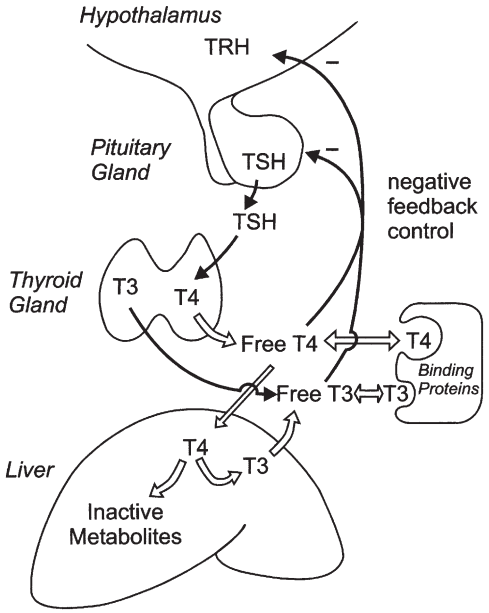

Figure 7-4. Cartoon of the hypothalamic-pituitary-thyroid axis indicating hypothalamic TRH stimulation of pituitary TSH secretion via the pituitary portal vascular system and modulation of hypothalamic-pituitary axis TSH secretion by thyroxine (T4) and triiodothyronine (T3) negative feedback inhibition. The major thyroid gland secretory product is T4, which functions as a prohormone bound to several circulating binding proteins. Only 0.03% of circulating T4 and 0.30% of T3 are free or unbound. Ten to 20% of T3 is secreted by the thyroid gland. The predominant 80% to 90% is derived from monodeiodination of T4 to active T3 in peripheral tissues, here represented by liver. Most of the circulating T3 is produced by liver tissue.

TABLE 7-2

The Iodothyronine Deiodinase Enzymes

Iodothyronine Monodeiodinase Enzymes

Enzyme	Major Tissue	Preferred Substrates	Products
Type I	Liver, kidney, thyroid	rT3, T4, T2S, rT3S	T2, T3, T1S, T2S
Type II	Brain, pituitary, brown adipose tissue Keratinocytes, placenta	T4S, T3S, T4, rT3	rT3S, T2S, T3, T2
Type III	Placenta, brain, epidermis, hemangiomas	T4, T3	rT3, T2

(relative to the alanine side chain) produces T3, which has three to four times the metabolic potency of T4. Monodeiodination of the alpha or inner-ring produces rT3, which is largely inactive metabolically. Under normal circumstances, T3 and rT3 are produced at approximately similar rates.

In most tissues (particularly liver, and excluding brain and brown adipose tissue), T3 and rT3 (generated via T4 monodeiodination) diffuse rapidly from tissue to interstitial fluid to plasma. Significant amounts of T3 and small amounts of rT3 are synthesized and released by the thyroid gland. Thus, the circulating levels of T3 and rT3 reflect both secretion and peripheral production. From 70% to 90% of circulating T3 is derived from peripheral conversion, and 10% to 25% from the thyroid gland. Respective values for rT3 are 96% to 98% and 2% to 4%. Progressive tissue monodeiodination reactions degrade T3 and rT3 to diiodo, monoiodo, and noniodinated thyronine.

The alanine side chain of the inner-ring of the iodothyronines is also subject to degradative reactions, including transmination, deamination, and decarboxylation.[14] Pyruvic acid analogues and small amounts of lactic acid analogues have been observed in urine and bile. These have minimal biologic activity. The acetic acid analogues found in tissue, bile, and urine possess some activity but are rapidly degraded. Thyroid hormones are excreted in urine and stool in both free and conjugated forms. The reactions involve glucuronide conjugation and sulfoconjugation. Glucuronide conjugation occurs mainly in liver via microsomal glycuronyl transferase. Sulfoconjugation is also prominent in liver, and may be an obligatory step for hepatic monodeiodination reactions.[14] Iodothyronine sulfation markedly augments outer-ring deiodination in liver. In the fetus, where outer-ring deiodinase activity is developmentally low, the major thyroid hormone metabolites are sulfate conjugates—which are biologically inactive. (See Chapter 6.)

Actions of Thyroid Hormones

Thyroid hormones influence growth and development, oxygen consumption and heat production, nerve function, and metabolism of lipids, carbohydrates, proteins, nucleic acids, vitamins, and inorganic ions. They also have important effects on other hormone actions.[15-18] The free hormones appear to be transported via plasma membrane iodothyronine transporters belonging to several families of integrin, organic anion, amino acid, and monocarboxylate solute carriers.[19]

T3 is the active hormone, which binds to the nuclear receptors with some 10 times the affinity of T4 (Figure 7-5). T3 also binds to mitochondrial inner-membrane receptors.[20] The major effects of thyroid hormones are mediated via thyroid hormone nuclear receptors (TRs), which are members of the steroid hormone-retinoic acid receptor superfamily and function as DNA transcription factors.[15,16] In humans, there are two genes coding for thyroid hormone nuclear receptors: one on chromosome 17 [designated alpha (TRα)], and one on chromosome 3 [designated beta (TRβ)]. Alternative splicing of expressed mRNA species leads to production of the major thyroid hormone binding transcripts TRα1, TRα2, TRβ1, and TRβ2.[15,16]

The TRs exist as monomers, homodimers, and heterodimers with other nuclear receptor family members (such as the retinoid X receptors). Other receptor transcripts, including TRΔα1 and TRΔα2, have been characterized. These do not bind T3 or DNA but can inhibit TR and retinoid receptor activities. The TRα receptors are expressed in most tissues. TRβ1 is expressed in liver, kidney, heart, lung, brain, cochlea, and pituitary. TRβ2 is

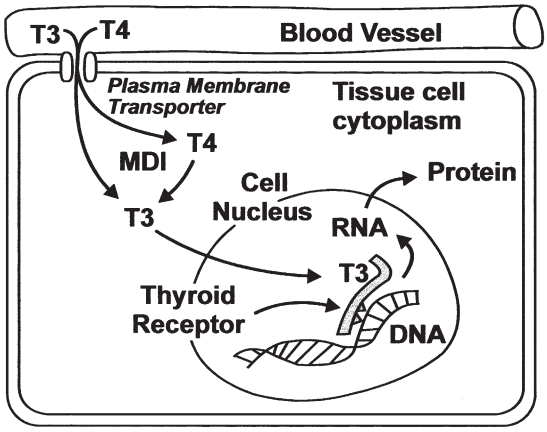

Figure 7-5. Thyroid hormone binding to nuclear receptors. The circulating thyroid hormones appear to be transported into peripheral tissues via iodothyronine plasma membrane transporters. Intracellular T4 is monodeiodinated to triiodothyronine (T3). The cellular cytoplasmic T3 diffuses into the nucleus, where it binds to the thyroid hormone receptors—which in turn bind to DNA and regulate thyroid-hormone-responsive gene transcription.

expressed in pituitary gland, retina, and cochlea. The receptors function redundantly, as indicated by knockout studies in mice. However, predominant effects of one or another TR have been described.[17,18] T3 binding by the TR leads to responsive gene transcription, modulating synthesis of mRNA and proteins—which mediate thyroid hormone effects in various tissues. The effects of thyroid hormones as related to known thyroid actions at the molecular level are summarized in Table 7-3.

TABLE 7-3

Effects of Thyroid Hormones

Central Nervous System Development

General
- Stimulation of cell migration and neuronal cell maturation
- Stimulation of dendritic arborization and synaptic density
- Increases myelinogenesis

Gene Products Regulated by T3
- Myelin basic protein
- Nerve growth factor and its receptors
- Neurotropin 3
- Neural cell adhesion molecules
- Cerebellar PCP-2
- Prostaglandin D2 synthase

Effects on Growth and Development
- Stimulation of pituitary growth hormone (GH) synthesis and secretion
- Potentiation of GH stimulation of insulin-like growth factor (IGF) synthesis and action
- Stimulation of growth factor production
  - Epidermal growth factor
  - Nerve growth factor
  - Erythropoietin
- Stimulation of bone metabolism/growth
  - Cartilage response to IGF-I
  - Osteoblastic/osteoclastic bone remodeling

Thermogenic Effects
- Stimulation of mitochondrial enzyme synthesis
- Stimulation of UCP-1 and UCP-3 in brown adipose tissue and muscle
- Stimulation of membrane Na/K ATPase

Metabolic Effects
- Hepatic protein
  - Induction of hepatic lipogenic enzymes
  - Stimulation of hepatic glutamine synthatase and α amino levulinic acid synthetase
  - Potentiation of prolactin stimulation of lactalbumin synthesis
  - Potentiation of GH stimulation of B2 euglobulin synthesis
- Plasma membrane effects
  - Stimulation of glucose transport

Thyroid Function During Infancy and Childhood

IODINE METABOLISM

During the prepubertal and pubertal periods of growth and development, there is a progressive growth of the thyroid gland, a progressive increase in thyroid thyroglobulin and iodothyronine stores, and a progressive increase in thyroxine production rate measured as μg/day.[2,21,22] The iodide space (on a body weight basis) in infants is relatively larger than in older children, adolescents, or adults—and the thyroid iodide clearance rate is nearly three times that of adults (Figure 7-6). Renal iodide clearance is also high in infants and decreases progressively with age. The progressive decrease in thyroid iodide clearance may be at least in part secondary to the change in renal iodide clearance.

During childhood, the growth of the thyroid gland in residents of iodine-sufficient areas roughly parallels body growth. The gland volume, measured by ultrasound, increases in size from about 1.0 g at birth to a mean of about 5 g at 10 years of age (Table 7-4). Average thyroid iodine content increases from 0.3 mg at birth to 16 mg in adolescents and adults.[21] In areas of severe iodine deficiency, the thyroid weight in newborn infants may be 2 to 3 g (and iodine content may be as low as 40 μg).[21] The iodide space also increases progressively in volume with age. However, the relative size (liters per kilogram, expressed as a percentage of body weight) decreases from about 50% of body weight at birth to 40% in 30-kg children (about age 10 years). These values can be compared with the 33% body weight values in 65-kg adults.

Radioiodine uptake and clearance during childhood and adolescence vary with diet and iodine intake. Values during the first two decades have been reported to decrease progressively or remain relatively stable.[22,23] This discrepancy is presumably due to variations in iodine intake. The data showing a decrease with age were from areas of low iodine intake in Europe and Australia. A relatively high iodine intake could tend to mask differences in uptake with age. Thyroid iodine clearance (per gram of thyroid tissue) decreases progressively with age and is associated with a progressive decrease in thyroxine production rate (or turnover) on a μg/kg/day basis (Figure 7-6). Changes in thyroxine kinetics and production

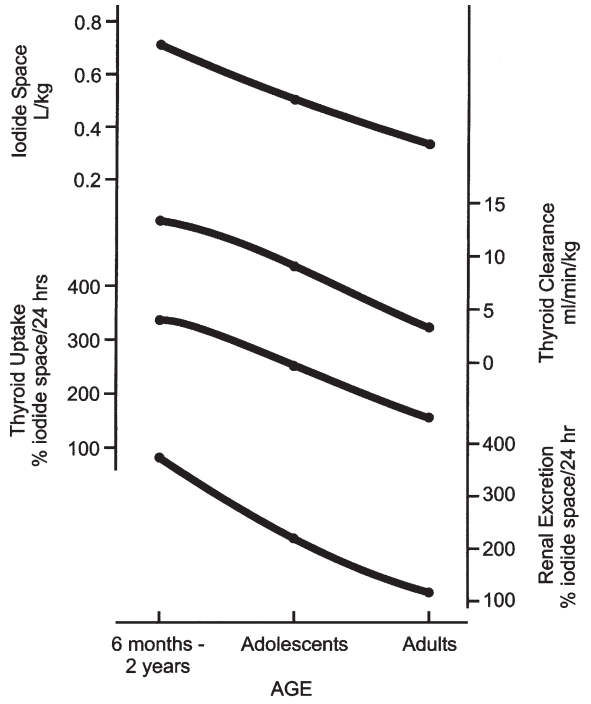

Figure 7-6. Mean iodide distribution space, thyroid and renal iodide clearance rates, and thyroid iodine uptake in infants 6 months to 2 years of age, in adolescents, and in adults. These data were derived from an area of relatively low iodine intake in Belgium. Lower values would be expected in geographic areas with higher mean iodine intake. rate (turnover) during childhood and adolescence are summarized in Table 7-5. A high iodine intake can mask certain defects of thyroid hormone biosynthesis [e.g., partial defects of iodotyrosine deiodinase (dehalogenase) activity, which would result in excessive wastage of iodide]. (See Chapter 6.)

SERUM THYROID HORMONE CONCENTRATIONS AND T4 PRODUCTION

Serum total free T4 and T3 concentrations decrease gradually with age[24-27] (Tables 7-6 and 7-7). The decreases in serum total T4 and T3 result largely from a decrease in serum TBG concentrations that is progressive from early childhood through 15 to 16 years of age, when the mean serum TBG concentration is about the same as in adults. Reciprocal changes occur in serum transthyretin concentrations. These changes presumably reflect the effects of gonadal steroids, but other factors may be involved.

Serum free T4 concentrations decrease slightly during childhood and adolescence[25] (Table 7-7). The percentage of iodine-131 labeled protein-bound iodine appearing in blood (percentage of dose per liter per kilogram of body weight) after labeling of the thyroid gland also decreases with age during the first two decades, as does T4 turnover and production rate on a body weight basis (μg/kg/d)[22] (Table 7-4). Estimated T4 turnover or production rate values are 5 to 6 μg/kg/d in infants, 4 μg/kg/d at 1 to 3 years, 2 to 3 μg/kg/d at 3 to 9 years, and 1 μg/kg/d in adults.

The serum concentration of rT3 remains unchanged or increases slightly during childhood and adolescence (Table 7-7). The serum free rT3 index (total rT3 × fractional T3 resin uptake) remains stable or increases slightly. Because circulating rT3 is derived predominantly from peripheral deiodination of T4, these observations and the fact that the mean calculated ratios of serum rT3/serum T4 and free rT3 index/free T4 index increase progressively with age suggest that the relative rate of T4

In Bertrand J, Rapaport R, Sizonenko PC (eds). *Pediatric Endocrinology.* Baltimore, Williams and Wilkins 242-251; Lucas C, Carayon P, Bellhilehi J, Giraud F (1980). Changes in levels of free thyroid hormones in children from 1 to 16 years. Comparison with other thyroid indices. Pedatric 35:197; and Nelson JC, Clark SJ, Borut DL, Tomei RT, Carlton EI. Age related changes in serum free thyroxine during childhood adolescence. J Pediatr 123:899.

conversion to rT3 increases with age during childhood and adolescence.[24] Direct measurements have not been made. The decreases with age in the ratios of serum T3/serum rT3 and free T3 index/free rT3 index suggests a progressive decrease in the relative conversion of T4 to T3 with age during the first two decades.

The progressive decrease in thyroid T4 production (μg/gm), T4 turnover, serum thyroglobulin, and thyroidal radioiodine uptake indicate a progressive relative decrease in thyroid function with age (Figure 7-7). The decreasing serum TSH concentration with age suggests that these decreases are mediated primarily by reduced TSH secretion. Whether this reflects decreased TRH secretion or non-TRH mechanisms is not clear. A progressive reduction in thyroid gland TSH responsiveness might also be involved.

Acquired Juvenile Hypothyroidism

EXPOSURE TO GOITROGENIC AGENTS

Any food or drug that interferes with thyroid hormone synthesis is a potential cause of goiter and hypothyroidism.[28,29] A partial list of such agents is given in Table 7-8. Dietary goitrogens may be difficult to identify because they

TABLE 7-8

Goitrogenic Agents

Anions
- Iodine (in large amounts)*
- Perchlorate
- Thiocyanate

Cations
- Cobalt (in certain hematinic preparations)
- Arsenic salts
- Lithium salts

Drugs
- Propylthiouracil
- Methimazole
- Carbimazole
- Aminosalicyclic acid
- Aminoglutethimide
- Phenylbutazone
- Amiodarone

Chemicals
- Resorcinol
- 2,4 dinitrophenol
- Polychlorinated biphenyls (PCBs)
- Polybrominated biphenyls (PBBs)

Naturally Occurring Substances
- Cytokines
- Goitrin (1,5-vinyl-2-thiooxazolidone) (present in cabbage and other members of the genus *Brassica*)
- Soybeans (not soybean milk as presently prepared)
- Linamarin (a glycoside in cassava)

* Includes iodinated radiographic contrast agents such as iopanoic acid and ipodate.

may be acquired through devious routes. Epidemiologic evidence suggests that environmental pollutants may be responsible for many goiters. As part of the clinical history, in difficult cases the physician should inquire about intake of known and potential goitrogens and possible environmental or familial occupational contact with PCBs, PBBs, or dinitrophenols. Bacterial contamination of groundwater has been demonstrated, and unidentified goitrogens in groundwater have been postulated. There is also evidence that environmental (region-specific) and immunologic (genetic) factors may be synergistic in goitrogenesis.[29]

THYROID DYSGENESIS

Ectopic thyroid glands in children may first come to attention during childhood because of an enlarging mass at the base of the tongue or along the course of the thyroglossal duct. Generally, thyroid dysgenesis is sporadic and is detected by newborn screening. However, rare familial instances have been reported. An occasional case may be missed by neonatal screening and present during childhood with enlargement of the remnant thyroid and/or hypothyroidism. Remnant enlargement may occur at any age. Commonly, it is accelerated shortly before adolescence. Degrees of hypothyroidism range from barely detectable to severe.

The term *cryptothyroidism,* by analogy with *cryptorchidism,* has been applied for such ectopically located thyroid tissue (Table 7-1). The prevalence of thyroid hemiagenesis approximates 1:2,000 children.[30,31] Such patients are not usually hypothyroid and may be misdiagnosed as having a functioning thyroid nodule as the thyroid lobe enlarges. Complete substitution treatment usually reduces the thyroid tissue enlargement so that surgery can be avoided. Full substitution must be continued for life.

Severe hypothyroidism occasionally follows surgical removal of what has been presumed to be a thyroglossal duct cyst. As with lingual thyroid gland remnants, masses high in the neck may prove to be the only functional thyroid tissue present. In some patients, enlargement of the mass is correlated with failing thyroid function prior to surgery. Some cases of thyroid dysgenesis caused by PAX8 mutations may not have been detected by newborn screening and were diagnosed during childhood as acquired autoimmune hypothyroidism without measurable autoantibodies. (See Chapter 6.)

THYROID DYSHORMONOGENESIS

Most patients whose hypothyroidism is due to defective hormone synthesis are congenitally hypothyroid.[1] (See Chapter 6.) Infants with a compensated defect and normal T4 values may escape detection, however, in a neonatal screening program. Moreover, the appearance of goiter in some of these patients is usually delayed. Hypothyroidism due to the milder Pendred syndrome or other molecular defects producing compensated hypothyroidism may not be detected until later childhood or adolescence.

An increased iodine supply (e.g., by perinatal use of disinfectants or contrast media) can mask milder defects of thyroid hormone biosynthesis, and thus these cases escape diagnosis by newborn screening. In addition, thyroid hormone resistance is usually diagnosed during childhood or adolescence. (See Table 7-1 and Chapter 6.) The goiter in patients with dyshormonogenesis and in those with peripheral resistance to T3 is diffuse, soft, and variable in size. In contrast, Hashimoto glands tend to be firm and bosselated (and only moderately increased in size).

HASHIMOTO (AUTOIMMUNE) THYROIDITIS

Hashimoto thyroiditis (chronic thyroiditis, lymphadenoid goiter, autoimmune thyroiditis) was defined in 1912 when Hashimoto reported four patients with goiter characterized by diffuse infiltration of plasma cells and lymphocytes, fibrosis, parenchymal atrophy, and eosinophilic degeneration in some of the acini. The disease occurs in a genetically predisposed population.[32-34] A family history of thyroid disease is seen in 30% to 40% of patients. The disease also has marked predilection for females. Autoimmune thyroiditis is now the most common cause of nonendemic goiter and of hypothyroidism in children over 6 years of age.[35-40]

The onset of the disorder is usually insidious. Some 5% to 10% of patients (particularly adolescents) may have tachycardia, nervousness, and other signs suggestive of thyrotoxicosis. However, most will have a euthyroid goiter or a goiter with mild hypothyroidism. Only rarely is

marked clinically symptomatic hypothyroidism present at diagnosis. The thyroid gland is usually enlarged and firm, with accentuation of the normal lobular architecture (bosselated). Occasionally, the goiter gives rise to the sensation of local pressure and difficulty in swallowing. If left untreated, the course of Hashimoto thyroiditis is variable. Usually, the gland undergoes progressive atrophy—and the patient has acquired hypothyroidism without any recognized period of compensatory hypertrophy. The yearly incidence of hypothyroidism in adult patients with Hashimoto thyroiditis is 5% to 7%. Spontaneous remission may occur in some 30% of adolescent patients.[36,38-40]

The spectrum of autoimmune thyroid disease in childhood and adolescence includes euthyroid goiter, hypothyroid goiter, Graves' disease, Hashitoxicosis, painless postpartum thyroiditis, painless sporadic thyroiditis, and autoimmune polyglandular syndromes (APS2a, 2b).[32-34,41-44] APS2b is the most common polyglandular syndrome and most commonly involves Hashimoto thyroiditis and type 1 diabetes mellitus. Pernicious anemia and vitiligo are associated in 30% to 40% of cases, with other autoimmune manifestations in 10%.[43] APS2a includes adrenocortical insufficiency with thyroiditis and type 1 diabetes. Again, 10% of patients manifest other autoimmune syndromes. APS1, due to mutation of the AIRE (autoimmune regulator) gene, is more rarely associated with thyroid disease. Hypoparathyroidism, mucocutaneous candidasis, diarrhea, and type 1 diabetes are more common.[43] Other autoimmune disorders accompanying autoimmune thyroid disease include antigen-antibody complex nephritis, thrombocytopenia, and celiac disease.[45-47] Approximately 30% of children with diabetes mellitus have thyroid autoantibodies, and approximately 10% have elevated serum TSH levels.[41-44]

Most patients with Hashimoto thyroiditis have detectable circulating antithyroid autoantibodies.[35-41] Several types of thyroid antibodies have been described: antibodies directed against thyroglobulin, against a colloid component other than thyroglobulin, against the thyroid peroxidase enzyme, against the sodium/iodide symporter protein, against thyroid nuclei, and against the thyroid TSH receptor. Antiperoxidase and antithyroglobulin antibodies are most prevalent, and these are the antibodies that to date are the most useful for diagnosis. The thyroid peroxidase is a microsomal enzyme, and there is a high correlation between antimicrosomal and antiperoxidase antibody levels in affected patients. These antithyroid antibodies are not pathognomonic of Hashimoto thyroiditis because in 15% to 20% of cases without evident thyroiditis significant antibody titers are detected. Most of these individuals are genetically predisposed and may not yet have developed thyroiditis. Moreover, thyroid peroxidase and thyroglobulin antibodies are also present in patients with Graves' disease.

Blood from virtually all patients with Hashimoto thyroiditis and Graves' disease can be shown to contain a population of thymus-dependent (T) autoreactive lymphocytes sensitized against the particulate portion of thyroid cells (microsomes and cell membranes).[42,43] T lymphocytes sensitized against thyroidal components and humoral antibodies directed at various thyroidal components produce the thyroid gland pathology

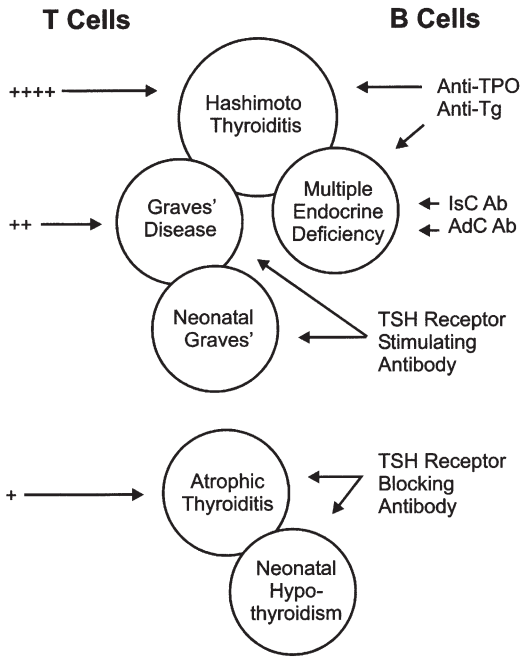

Figure 7-8. Relationship of T-cell infiltrate of thyroid tissue and B-cell antibody production to clinical autoimmune thyroid disease phenotypes. The extent of lymphoid infiltration is shown as + + + + to +. Antibody types are anti-TPO = antiperoxidase antibody and anti-Tg = antithyroglobulin antibody. IsC Ab and AdC Ab are islet cell and adrenal antibodies. The correlations are only approximate.

(Figure 7-8). The latter antibodies are produced by B rather than T lymphocytes, and it is known that the interaction of T and B lymphocytes plays a crucial role in the elaboration of immunoglobulins by B lymphocytes.

Age-specific incidence rates for Graves' disease and Hashimoto thyroiditis show an increasing rate of onset through the fifth decade and a decline thereafter. This has been interpreted as suggesting the existence of a subpopulation of subjects with genetic predisposition who develop thyroid autoimmune disease with increasing exposure to potentiating environmental factors. A genetic predisposition to thyroid autoimmunity is also suggested by observations in twins. There is an approximately 50% concordance for Graves' disease in monozygotic twins, as contrasted with a 5% concordance rate in fraternal twins.[32,48]

There are several reports of monozygotic twins pairs in which one twin manifested Graves' disease and the other Hashimoto thyroiditis. Moreover, thyroid autoantibodies have been reported in some 50% of siblings of patients with Graves' disease. Graves' disease or thyroiditis may occur in the newborn as a result of transplacental passage of maternal thyroid-stimulating immunoglobulins. (See Chapter 6.) In this instance, neonatal Graves' disease is transient—abating as the maternal thyroid stimulator degrades in the newborn.

An increased prevalence of HLA-B8, HLA-DR3, and DQA1-0501 transplantation antigens has been reported in Caucasian patients with Graves' disease. The association has been HLA-DR5 antigen in Japanese patients and HLA-DR9 in Chinese patients with the disorder, but these associations carry a risk ratio of only 3:5.[32,48] Associations

have been observed between HLA DR3, DR4, or DR5 and Hashimoto thyroiditis. Linkage to the HLA genes is weak, however, and linkage with other loci on the X chromosome and on chromosomes 14 and 20 have been reported. Responsible genes have not been identified, and multiple genetic factors may be involved. More recently an association with CTLA-4 has been described.[49]

HYPOTHALAMIC-PITUITARY HYPOTHYROIDISM

Hypothalamic or pituitary disorders (including craniopharyngiomas, granulomatous disease, and and meningitis) may be acquired secondary to head-trauma tumors. However, the most frequent causes are irradiation of the neurocranium and chemotherapy in the treatment of malignant disorders (especially brain tumors). Growth failure due to growth hormone (GH) or TSH deficiency is usually the earliest manifestation of pituitary hypofunction, but other features related to the primary disease, neurologic disorder, or hypothalamic dysfunction may be prominent.

Isolated central hypothyroidism is an uncommon disorder associated with subclinical hypothyroidism and short stature in children.[50,51] In children presenting with these clinical symptoms and low free T4 and normal or low serum TSH concentrations without other evidence of pituitary disease, the diagnosis of central hypothyroidism can be considered straightforward. In those with a serum free T4 level in the lower half of the normal range and a normal TSH concentration, however, the diagnosis is difficult to confirm (even if suspected).[50]

These children manifest an abnormal circadian pattern of serum TSH concentration with absence or blunting of their nocturnal TSH surge.[50,51] Testing is accomplished by measuring serum TSH hourly between 2:00 and 4:00 P.M and between 10:00 P.M and 2:00 A.M. Normally, the serum TSH level increases 50% to 300% during sleep. Blunting of the nocturnal surge should lead to a trial of thyroxine treatment in such children. A prevalence of isolated central hypothyroidism of 16% has been reported in a group of 181 children with idiopathic short stature.[50] Autosomal-recessive inheritance of partial loss-of-function mutations of the β-TSH gene also cause central hypothyroidism of childhood onset, but may already be manifest in the newborn period if no residual TSH activity is present. (See Chapter 6.) The prevalence of central hypothyroidism approximates 1 in 20,000 births.[52]

MISCELLANEOUS CAUSES

Hypothyroidism appears to occur with increased frequency in association with several chromosomal disorders, including Turner syndrome, Down syndrome, and Klinefelter syndrome—with autoimmune thyroiditis being the most prevalent cause.[53-56] In Down syndrome, there also is an increased prevalence of thyroid dysgenesis and what has been called euthyroid hyperthyrotropinemia or subclinical hypothyroidism. Recent studies have suggested that newborns and infants with Trisomy 21 benefit from thyroid hormone administration with regard to their psychomotor development.[57] Compensated hypothyroidism occurs frequently and early in children with nephropathic cystinosis, and some children with the disorder manifest overt hypothyroidism.[58] The thyroid glands show extensive destruction and infiltration of the epithelium with cystine crystals.

MANAGEMENT OF ACQUIRED HYPOTHYROIDISM

The possibility of thyroid deficiency should be considered in any child who is not growing normally. A useful aid in recognizing acquired hypothyroidism in childhood is a serial record of growth.[59] Usually, considerable time elapses between the onset of hypothyroidism and the emergence of classic signs of myxedema. If growth records are available, however, the onset of hypothyroidism can readily be documented by a progressive downward deviation from previously normal growth isobar. Weight tends to increase, and in most patients weight for age is proportionately greater than height for age (Figure 7-9).

The retardation of bone age in hypothyroidism almost always equals or exceeds the retardation in linear growth, but delayed bone age is also present in other forms of dwarfism and is not pathognomonic of hypothyroidism. Tooth eruption may be delayed, and in rare cases stippled epiphyses are evident radiograpically. The thyroid hormone-deficient patient usually exhibits slowing of the deep tendon reflexes, with a delayed relaxation phase. Varying clinical manifestations of myxedema related to organ hypofunction (e.g., cardiac, hepatic, gut, skin, renal) occur with prolonged or severe hypothyroidism. Rarely, encephalopathy can manifest with signs of intracranial pressure, agitation, reduced vigilance, or seizures (Hashimoto encephalopathy).[60]

Sexual development of most hypothyroid children is delayed in approximate proportion to the retardation of skeletal maturation. However, rare children with severe hypothyroidism present with signs of precocious puberty

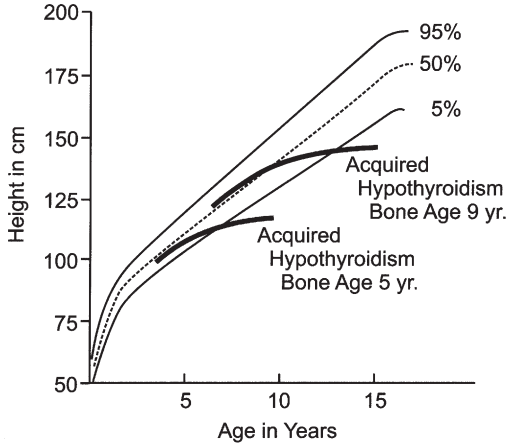

Figure 7-9. Growth failure in acquired hypothyroidism. The evolution of clinical hypothyroidism in childhood and adolescence is usually slow, and the early manifestations are subtle. The earliest sign is a slowing of linear growth, as indicated for two children with thyroid failure at 5 and 9 years, respectively. The rate of bone age maturation also slows markedly, and bone age can be used to estimate the time of onset of the thyroid failure.

(the Van Wyk-Grumbach syndrome).[61-63] Girls manifest precocious menstruation, breast development, and galactorrhea. In boys, this syndrome is associated with excessive enlargement of the penis and testes. Most of these patients lack pubic hair, and bone age is retarded in keeping with the duration of the hypothyroid state. The sella turcica may be enlarged. Serum prolactin and TSH levels are elevated in some children, but the molecular mechanism of precocious puberty is not clear.

The increased serum prolactin levels are probably explained by the fact that TRH stimulates TSH and prolactin release from the pituitary. A paracrine action of the hyperstimulated thyrotropic cells on gonadotrope cells may explain the increased gonadotropin secretion. Because precocious puberty is observed only rarely, it is also possible that these patients have genetic variants of the gonadotropin receptors that can be stimulated by the increased TSH levels.[64] Similar findings have been reported for TSH and FSH receptor variants stimulated by βHCG.[65,66] When the hypothyroid state is alleviated, the manifestations of sexual precocity regress—and normal puberty ensues when the general level of maturity has progressed appropriately.

The diagnosis of Hashimoto thyroiditis is based on a series of characteristic findings. The thyroid gland is moderately enlarged, firm, and bosselated in 80% to 90% of patients. Increased titers of thyroid peroxidase (TPO) or antithyroglobulin antibody occur in 90% to 95% of patients. Serum TSH concentration is elevated in 30% to 40% of patients, who may have an associated low serum T4 concentration, a normal or near normal serum T3 concentration, and an elevated T3/T4 concentration ratio. Minimal documentation should include plasma free T4 and TSH levels. If a goiter exists, antithyroid antibodies should be measured. If antibodies are negative, thyroid ultrasound study or a thyroid scan are useful to exclude thyroid dysgenesis. An elevated TSH level establishes that the disease originates in the thyroid rather than the pituitary gland.

A low T4 (and free T4) with a low serum TSH level indicates hypothalamic or pituitary hypothyroidism. Whenever the latter is suspected, it is mandatory that other pituitary deficiencies be sought by a complete set of pituitary function studies—including provocative tests of ACTH and growth hormone secretion, and the response of TSH to administration of TRH. A CT or MRI scan of the brain and visual field examination should be performed to exclude a pituitary or hypothalamic tumor. Isolated central hypothyroidism should be considered in children with idiopathic short stature if the serum free T4 concentration is low normal.[50,51]

Substitution therapy in older children with hypothyroidism should follow the same guidelines outlined for the treatment of congenital hypothyroidism. Most children respond well to an initial dose of L-thyroxine equivalent to about 100 $\mu g/m^2$ body surface.[59,67-69] If hypothyroidism is longstanding, the dose of Na-L-thyroxine should be increased gradually to prevent cardiac failure. It is also important to exclude Addison disease, and if present to treat it with appropriate glucocorticoid replacement before providing thyroid replacement so as to avoid an Addisonian crisis.

After treatment begins, the hypothyroid child resumes growth at a rate greater than normal (the period of so-called catch-up growth). Indeed, accurate serial height measurements provide assurance that the dosage provided is adequate. If the hypothyroid state is prolonged prior to treatment (>2 years), catch-up growth may be incomplete. Excessive dosage is marked by a disproportionate advancement in skeletal age. This should be avoided because it will hasten the closure of epiphyses and may shorten adult stature. In patients with pituitary TSH deficiency and deficiency of other anterior pituitary hormones, treatment with adrenal glucocorticoids or growth hormone should be provided as necessary.

Non-Thyroidal Illness

Sullivan et al. first described (1973) a selective deficiency of serum and tissue T3 in patients dying with severe prolonged illness. They referred to these patients as the "euthyroid sick." More recently, other terms—including *low T3 syndrome* and *non-thyroidal illness* (NTI)—have been applied. This syndrome of low total and free serum T3; normal, low, or high total serum T4; increased T4 sulfate; normal to high free T4; and normal serum TSH concentrations has now been reported in a variety of situations.[70-72]

These include the premature neonate, patients with protein-calorie malnutrition or anorexia nervosa, fasting subjects, postoperative patients, and patients with a variety of severe acute and chronic illnesses. The latter have included patients with diabetic ketoacidosis, severe trauma, burns, febrile states, cirrhosis, and renal failure. In addition, a number of drugs have been observed to produce a similar syndrome. These drugs include dexamethasone, selected radiographic contrast agents, propylthiouracil, propranolol, and amiodarone.

Three patterns of change in thyroid hormone levels have been described (Table 7-9): low T4, normal T4, and high T4 NTI syndromes. The low serum and tissue T3 levels in this syndrome occur as a result of inhibition of iodothyronine β-ring monodeiodinase-1 activity (MDI-1) and a decreased rate of T3 production from T4 in nonthyroidal tissues.[73,74] In mice, interleukin-1 (IL-1) cytokine inhibition of transcription of iodothyronine monodeiodinase type 1 (MDI-1) results in decreased hepatic T4 to T3 conversion—and this reduction can be reversed by SRC-1 induction of MDI-I.[73] rT3 degradation is decreased because the degradation of rT3 is mediated by the same type I deiodinase enzyme that mediates T4 to T3 conversion. Thus, serum T3 levels fall and rT3 levels tend to remain normal or increase.

TABLE 7-9

Thyroid Function Abnormalities on Non-Thyroidal Illness

Non-Thyroidal Illness Pattern	TSH	T3	rT3	T4
Low T3 syndrome	N	D	N or I	N
Low T4 syndrome				D
High T4 syndrome	N	D	N or I	I

N = normal, D = decreased, I = increased.

In some patients, serum T4 levels also fall (the low T4 syndrome)—and low T4 levels in patients with severe NTI have been associated with increased mortality. TBG levels may be reduced in such patients, and an inhibitor of T4 binding to TBG has been described in the serum and derived from the tissues of such patients. The high T4 NTI syndrome probably involves one or more induced abnormalities in the disposal pathways of T4.

There is no convincing evidence that treatment with thyroid hormones, either T4 or T3, is effective in most patients with NTI. Treatment should be directed to the primary systemic illness. There is also no clear evidence that treatment is disadvantageous, and there is some evidence to suggest that treatment may be beneficial in selected clinical conditions such as postoperative cardiac surgery.[71,75]

Iodine Deficiency Disorders

Iodine deficiency remains the leading cause of hypothyroidism worldwide.[76] During the past 40 years, major efforts to supplement iodine intake in endemic deficiency areas have been highly successful—and the geographic distribution of severe endemic iodine deficiency has been markedly reduced. Residual areas of deficiency include Africa, Southeast Asia, the Western Pacific, and some areas of Europe, the Eastern Mediterranean, and the Americas. It is estimated that some 2 billion individuals remain at risk, with 740 million affected by iodine-deficient goiter and 43 million believed to be mentally handicapped as the result of iodine deficiency.[76] Fifty percent of the world's population are thought to live in countries with iodine deficiency.

Cretinism and severe iodine deficiency are now largely restricted to remote areas of developing countries, but some 40 million individuals in the Americas and 130 million in Europe are exposed to mild to moderate iodine deficiency (largely in more isolated mountainous areas). In Europe in 1989 to 1995, clinically euthyroid school children in iodine-deficient areas were reported to have subtle or overt neuropsychointellectual deficits compared to iodine-sufficient children in the same areas.[76] This is thought to result from transient thyroid failure occurring during fetal or postnatal life during the critical period of brain development.[76] Similar studies have not been conducted in the Americas.

Environmental iodine deficiency leads to a series of thyroid system abnormalities, including increased TSH secretion, increased iodide uptake, reduced thyroglobulin iodination, increased thyroglobulin production and turnover, thyroid colloid depletion, and thyroid gland hypertrophy and hyperplasia.[76] There is an increase in poorly iodinated tyrosine and iodothyronine residues within stored thyroglobulin, resulting in increased MIT/DIT and T3/T4 ratios. As a result, the thyroid T3/T4 secretion ratio is increased and serum T3 levels are increased—whereas serum T4 concentrations fall. T4-to-T3 conversion within the thyroid gland and in peripheral tissues also increases. The result of these changes is a circumstance of compensated euthyroidism manifest by a modest increase in serum TSH, a high normal or increased serum T3 level, a low normal or decreased serum T4 concentration, and thyroidal hyperplasia and hyperactivity.

The increased T3/T4 secretion ratio allows a degree of adaptation to iodine deficiency because T3 possesses four times the metabolic potency of T4 while requiring only 75% as much iodine for synthesis.[76] With severe iodine deficiency, however, such compensation may be inadequate—leading to hypothyroidism of varying degree. In severe endemic goiter areas, goiter and cretinism, decreased fertility, increased perinatal death, increased infant mortality, and varying degrees of mental retardation are observed. In areas of moderate iodine deficiency (<100 μg iodine intake daily) in the absence of overt endemic goiter, thyroid function in adults is normal. However, the prevalence of transient neonatal hypothyroidism is increased, and mental development in euthyroid school children has been shown to be impaired.[77,78]

Consumptive Hypothyroidism

This rare syndrome, first described in 2000, is characterized by excessive ectopic inactivation of thyroid hormone by type III iodothyronine monodeiodinase (MDI III). The syndrome has been associated with massive hemangiomas and hepatic hemangioendotheliomas in children, and by hemangioendothelioma and malignant fibrous tumors in adults.[79-81] The hemangiomata and tumor tissues express high levels of MDI III message and functional activity, which inactivates thyroid hormones at a rate exceeding the production capacity of the thyroid gland. TSH levels are increased, free T4 is decreased, and reverse T3 (rT3) concentrations are increased. The dosage of thyroxine to increase circulating free T4 levels to the normal range is increased severalfold. Treatment includes T4 therapy and management of the causative vascular malformation or tumor.

Diffuse Nontoxic Goiter

A syndrome of euthyroid diffuse goiter has been described during adolescence in nonendemic goiter areas. The prevalence approximates 5% of the population.[82] Many patients with euthyroid goiter have autoimmune thyroiditis, but some have no evidence of thyroid lymphocytic infiltration. A common finding in such patients is a family history of goiter, but detailed tests of thyroid function fail to reveal identifiable defects.[83,84] Recent susceptibility loci have been identified with logarithm of odds (LOD) scores of 1.94 to 2.71.[82] Thyroid volume in affected individuals is positively correlated with age, and older patients are more likely to manifest multinodular goiter.

The genetic pattern in families is suggestive of an autosomal-dominant mode of transmission, with greater expression in the female. Thyroid function tests are normal, and thyroid biopsy in adolescents reveals only "colloid goiter." The thyroid enlargement may regress spontaneously without therapy, but many patients who develop nodular goiters in the third, fourth, and fifth decades of life have a history of mild diffuse thyroid enlargement during childhood or adolescence. There is

some evidence for the presence of modest levels of thyroid autoantibodies in the serum of such patients, and thus simple goiter of adolescence may represent a mild form of autoimmune thyroid disease.[83-87]

Subacute Thyroiditis (de Quervain's Syndrome)

In children, subacute thyroiditis is a relatively rare and self-limited inflammation of the thyroid that usually follows or is associated with an upper respiratory illness.[88,89] Patients have been identified with evidence of associated mumps virus infection or with cat-scratch fever. It is likely that a variety of viral agents may be responsible for this condition. The incidence is similar in males and females. The onset is accompanied by fever and pain that may be local or referred to the angles of the jaws.

The thyroid gland may be exquisitely sensitive to palpation or only mildly tender. Characteristically, there is an increase in serum T4 and T3 levels due to release of stored hormone—and signs and symptoms of hyperthyroidism develop. Thyroidal radioiodine uptake at this time is low or absent, indicating thyroid cell damage. Signs and symptoms of hyperthyroidism usually persist for 1 to 4 weeks. After his time, there is a period of transient hypothyroidism as the thyroid gland recovers. The total course runs 2 to 9 months. A syndrome of painless (subacute) thyroiditis has also been described, with a similar pattern of transient hyperthyroidism associated with a low thyroid radioiodine uptake. The "painless thyroiditis" syndrome, however, resembles Hashimoto thyroiditis histologically—and often occurs in the postpartum period in women with a history of autoimmune thyroid disease.

Treatment of subacute painful (viral) thyroiditis includes large doses of acetylsalicylic acid or other antiinflammatory drugs. In severe cases, corticosteroid medication may be helpful. Most patients do not develop antithyroid antibodies and recover without a residual defect in thyroid function. Subacute thyroiditis may be difficult to distinguish from acute suppurative thyroiditis, but the latter condition is now rare.

Suppurative Thyroiditis

Bacterial infections of the thyroid gland are rare in children and are usually associated with an embryologic remnant and/or a left pyriform sinus tract.[90-92] The left lobe is most often involved. Suppurative thyroiditis may be associated with other head and neck infection. In older children or adolescents, bacterial thyroiditis may be associated with bacteremic spread from distant infection. Children usually present with acute onset of pain (often with dysphagia), and with unilateral or bilateral thyroid enlargement, fever, and local tenderness.

The gland is initially firm and may progress to abscess formation. Leukocytosis is common, and thyroid function tests are usually normal. Early differentiation from subacute thyroiditis may be difficult, but signs and symptoms of hyperthyroidism are uncommon and the course is usually limited to 2 to 4 weeks. The common organisms are *staphylococcus aureus, streptococcus pyogenes*, and *streptococcus pneumoniae*. Rarely, *pastuerella*, *echinococcus*, or *crytococcal* organisms may be causative.[93-95] Thin-needle aspiration and culture are helpful in antimicrobial selection.

Juvenile Hyperthyroidism

GRAVES' DISEASE

Thyrotoxicosis in childhood and adolescence most commonly occurs as a consequence of diffuse thyroid hyperplasia (Graves' disease). Graves' disease is a multisystem autoimmune disease involving hyperthyroidism, eye manifestations, and dermopathy.[96] In children, in contrast to adults the latter manifestations are absent or mild. The disease occurs in preschool children. Rarely, it may begin in infancy. However, the incidence increases sharply as children approach adolescence. Girls are affected six to eight times more often than boys.

Graves' disease, like Hashimoto thyroiditis, has a genetic basis. A high proportion of patients have a family history positive for goiter, hyperthyroidism, or hypothyroidism. It is believed that Graves' disease and Hashimoto thyroiditis arise randomly in a genetically predisposed population. The concordance rate for Graves' disease in monozygotic twins has been reported as 30% to 60%. In dizygotic twins, it is only 3% to 9%. Family studies have disclosed a high percentage of circulating antithyroid antibodies in near relatives. Furthermore, certain HLA haplotypes (such as HLA B8 and Dr3 in Caucasians) and linkage to genetic determinants on the X chromosome and chromosomes 14 and 20 have been reported in affected families.[48,96]

The three principal autoantigens of Graves' disease (the TSH receptor, thyroid peroxidase, and thyroglobulin) have been cloned. The TSH receptor autoantibodies have a major pathogenetic role in Graves' disease. The TSH receptor-stimulating antibodies (TSA) can be identified by bioassay and receptor assay techniques. TSA displaces TSH from membrane TSH receptors and stimulates adenylate cyclase and cAMP production in thyroid follicular cell lines in culture. Current bioassays are available that use TSH receptor-transfected CHO cell lines. These measure cAMP production in response to partially purified serum immunoglobulin moieties. Autoantibodies measured only by displacement of radiolabeled TSH from thyroid cell membrane TSH receptor are referred to as TSH binding-inhibiting immunoglobulin (TBII), or TBIA. The TBII assay measures stimulating and blocking antibodies without differentiation.

The production of TSA by B lymphocytes is probably a secondary response to a cell-mediated immune reaction requiring involvement of T lymphocytes in a manner similar to that postulated for Hashimoto thyroiditis. Cell cultures of lymphocytes from patients with Graves' disease produce immunoglobulins only after stimulation with phytohemagglutinin. Because the latter substance stimulates only T cells (which are incapable of secreting immunoglobulins), it may be inferred that cell-mediated and humoral immune mechanisms are involved in the genesis of the thyrotoxic state. This is supported by recent studies indicating that thyrocytes can

be activated by TSA + IGF-I to express powerful T-cell chemoattractants that stimulate T-cell infiltration independently of the TSH receptor.[97]

Clinical Features

The onset of thyrotoxicosis is usually insidious, with a period of increasing nervousness, palpitation, increased appetite, and muscle weakness.[98-101] Marked weight loss occurs in some patients, usually in association with a voracious appetite. Occasionally, children (and especially adolescents) show a weight increase with the onset of the disease. There is a tendency for thyrotoxic children to be in the upper percentile channels for height. Except for exophthalmos and other eye signs, the symptoms of thyrotoxicosis are nonspecific—and for prolonged periods may be mistaken for some other condition.

Behavioral abnormalities, declining school performance, and emotional instability frequently dominate the clinical picture. In other patients, cardiovascular signs are more prominent—and attention is focused on a cardiac murmur or decreased exercise tolerance. Nocturia is due to the increased glomerular filtration rate. Fatigability and objective muscle weakness are observed in 60% to 70% of patients with juvenile thyrotoxicosis. Myopathy varies in severity from fatigability to periodic paralysis, and as in adults may be the most prominent manifestation of the disease. Rarely, juvenile Graves' disease may occur in association with myastenia gravis or another autoimmune disorder such as lupus erythematosis.

Most of the signs and symptoms of Graves' disease are similar to those produced by a hyperactive sympathetic nervous system and can be simulated by anxiety, fright, or acute illness. Even in patients in whom tachycardia is not impressive, the pulse pressure is widened and the precordium overactive. Underlying heart disease is difficult to exclude in the presence of cardiomegaly, ejection murmurs, precordial thrill, and gallop rhythms. Other signs of sympathetic overactivity are tremor, excessive perspiration, rapid tendon reflex relaxation times, and emotional lability. The size of the thyroid gland is highly variable, and the goiter may escape notice in a patient whose gland is only slightly enlarged. The characteristics of the thyroid to be noted on physical examination are size, uniformity, and consistency. A bruit or thrill provides some indication of the degree of hyperplasia but has no specific diagnostic value. During phases of active hyperplasia, the thyroid typically has a resilient bulging characteristic that is lost as recovery takes place.

Severe Graves' ophthalmyopathy is much less common in children than in adults, and malignant exophthalmos is virtually unknown.[101] The eye findings in this disease may be grouped as those due to sympathetic hyperactivity and those due to specific pathologic changes in the orbit. The latter are rarely seen in childhood and adolescence. Those due to sympathetic hyperactivity give the appearance of stare, owing to retraction of the upper eyelid and a wide palpebral aperture. There is also a lag in the descent of the upper eyelid upon looking downward (lid lag), as well as infrequent blinking and absence of forehead wrinkling upon upward gaze. The eyes frequently present a glazed appearance. To a large extent, these findings parallel the severity of the disease and disappear as the patient is rendered euthyroid.

Rarely, there are changes in the orbit due to infiltration of mucopolysaccharides, lymphocytes, and edema fluid within the ocular muscles, lacrimal glands, and retroorbital fat. These changes can lead to exophthalmos, ophthalmoplegia, chemosis of the conjunctiva, pain, swelling, and irritation. Although the inflammatory changes usually improve with treatment of the hyperthyroid state, the course of the thyroid and eye manifestations may differ. Some degree of exophthalmos tends to remain after recovery from the thyrotoxicosis.

The accumulation of mucopolysaccharides in skin and subcutaneous tissues, referred to as Graves' dermopathy or pretibial myxedema, is also rare in children. Graves' disease and Hashimoto thyroiditis are occasionally encountered in the same patient. These children have clinical and laboratory features of Hashimoto thyroiditis and exhibit thyrotoxicosis and resistance to thyroidal suppression by T3. The somewhat whimsical term *Hashitoxicosis* has been applied to these patients.

Laboratory Diagnosis

The initial laboratory tests should include serum TSH, free T4, and T3 determinations. The serum TSH level is suppressed below the limit of detection of second-generation TSH assays, and is usually below 0.04 mU/L in third-generation ultrasensitive assays. A serum TSH level above 1.0 μU/mL suggests TSH-dependent hyperthyroidism. A measurement of serum levels of TSH receptor autoantibody (TSA and TBII) are confirmatory for the diagnosis.

Treatment

Treatment of thyrotoxicosis must be directed toward reducing the secretory rate of thyroid hormones, and if possible toward blunting the toxic effects produced by high circulating levels. Three principal methods are available for reducing thyroid hormone secretion: subtotal or total ablation of the thyroid gland with radioactive iodine, subtotal surgical thyroidectomy, and blocking thyroid hormone biosynthesis by means of drugs.[102-110]

Treatment with Radioactive Iodine

In terms of ease, cost, efficacy, and short-term safety, treatment with iodine-131 is superior.[102-105] This approach, however, has been used relatively infrequently to date in childhood and adolescence because of the high prevalence of post-treatment hypothyroidism and the potential risks of leukemia, thyroid cancer, and genetic damage. The thyroid glands of young animals are much more susceptible to induction of thyroid carcinoma by ionizing radiation than are those of older animals. Radiation to the neck in infancy has been incriminated as an important cause of thyroid cancer in children, whereas this is infrequent in adults.

Several children treated with radioiodine have been reported to develop thyroid adenomas. This has been attributed to relatively low radioiodine treatment doses in the past. Such low treatment doses (<50 microcuries ^{131}I/gm thyroid tissue) are also associated with the need for additional treatment to achieve euthyroidism and with delayed but eventual hypothyroidism.[103-105] When treating children and adolescents with radioiodine, a dose that will achieve thyroid tissue destruction is recommended. The dosage should be calculated to optimize the thyroid radiation dose while minimizing total body radiation exposure, particularly in young children.[105]

Radioiodine has now been used to treat more than 1,000 reported children and adolescents since 1950, and there have been no recent reports of thyroid neoplasia or other untoward effects.[104,105] Hypothyroidism is expected and requires lifelong management. Most physicians still reserve the use of radioiodine for treatment of thyrotoxicosis in older adolescents who fail to follow a medical regimen and who cannot be adequately prepared for surgical thyroidectomy. However, current evidence suggests that this approach may be safe enough to consider as initial treatment in selected patients—particularly those 10 years of age or older.

Surgical Treatment

With proper preparation of the patient for surgical thyroidectomy, the immediate operative mortality approximates that for other major surgical procedures.[102] With proper surgical management, most patients achieve a rapid and satisfactory remission—and requirements for intensive medical follow-up are less rigorous than in those patients treated exclusively with drugs.

The availability of an experienced thyroid surgeon is an important criterion for successful surgical treatment. The incidences of permanent hypoparathyroidism and recurrent laryngeal nerve damage following subtotal thyroidectomy are still appreciable, and these serious complications will persist and may require lifelong treatment. The surgeon attempts to leave enough thyroid tissue that the patient is euthyroid postoperatively. The patient may, however, have recurrence of the thyrotoxicosis (or, conversely, may develop later hypothyroidism).

Medical Management

Management of Graves' disease patients with antithyroid drugs requires a prolonged period of drug therapy (usually 2 to 5 years), and close supervision by the physician is necessary for years.[98,100,101,110] Even in patients treated successfully, not more than 60% to 70% have permanent remission with drug therapy alone. Combined therapy with an antithyroid drug plus Na-L-thyroxine in replacement dosage has been used to suppress increased serum TSH levels and to minimize the need for frequent adjustment of antithyroid drug dosage. A small percentage of patients are hypersensitive to propylthiouracil (PTU) or methimazole. These reactions are usually mild, and disappear when the drug is withdrawn, but severe drug reactions (including liver failure and agranulocytosis) may occur.[98,103,106]

Approach to Therapy

The choice of therapy in thyrotoxicosis must be individualized, taking into consideration any illnesses, the quality of thyroid surgery available, and the socioeconomic factors that play such a large role in determining the success of a prolonged medical regimen. Patients with weight loss and decreased body mass index (BMI), a large goiter, or a high iodine intake are more resistant to drug therapy.[110] However, in most instances treatment is begun with antithyroid drugs and a decision regarding surgery or radioiodine is made when the patient becomes euthyroid. In severely toxic patients, the β-adrenergic blocking agent propranolol is of value in controlling many of the manifestations of Graves' disease.

The drug is useful in the initial treatment of severely thyrotoxic patients in the interval before specific antithyroid drugs become effective and has proved effective in the preoperative preparation for subtotal thyroidectomy. The antithyroid drugs inhibit oxidation of iodide and thereby block synthesis of thyroid hormone.[106] Neither the release of thyroid hormone nor the effect of TSH on the iodide pump is affected. Of the commonly used drugs, carbimazole and methimazole have a longer half-life of degradation than propylthiouracil—and maintenance therapy with these drugs can sometimes be accomplished with a single daily dose (Table 7-10).

There is always a time lag between institution of drug treatment and achievement of a euthyroid state because the biosynthetic block is not complete and the stores of preformed hormone must first be discharged. The rapidity of response to therapy correlates best with the initial size of the thyroid gland. Those patients with a small gland usually exhibit improvement in a few weeks, whereas those with very large glands may not respond for 2 to 3 months. TSH levels can be suppressed for more than 6 months despite clinical euthyroidism and normal or even low peripheral thyroid hormone levels and are therefore not appropriate in monitoring the success of antithyroid drug treatment.

The initial dose of propylthiouracil varies from 300 to 600 mg daily (175 mg/m^2 or 2-6 mg/kg) in dosages spaced at 6- or 8-hour intervals (Table 7-10). Skin rashes occur in about 2% of patients treated with propylthiouracil or carbimazole, and in 5% of patients treated with methimazole early in the course of therapy. They disappear when the drug is withheld. Often these rashes are

TABLE 7-10

Characteristics of Common Antithyroid Drugs

Drug	Initial Dose (mg/kg /day)	Maintenance Dose (mg/kg /day)	Incidence of Toxic Reactions (%)
Methimazole	0.4-0.6	0.1-0.3	1.4
Carbimazole	0.4-0.6	0.1-0.3	0.5
Propylthiouracil	4-6	1-3	0.9

From Marchant B, Lees JFH, Alexander WD (1979). Antithyroid drugs. In Hershman JM, Bray GA (eds.), *The thyroid: Physiology and treatment of disease.* Oxford: Pergamon Press 209-252.

mild and can be controlled with antihistamines. Severe reactions are rare (0.5%-1.4%). Granulocytopenia, when it occurs, is usually delayed (4-8 weeks of therapy). Protective isolation and antibiotic treatment usually allow recovery. Fatal liver failure has been described in adult patients treated with PTU. Usually, it is necessary to continue drug therapy for 1 to 2 years—and in many instances treatment must be continued for 3 to 6 years before the gland has lost its hyperplastic character.

The best clinical prognostic guide is the size of the thyroid gland. Most patients with continued thyroid enlargement will relapse if antithyroid drugs are discontinued. It is also possible to monitor the levels of circulating TSA. When circulating TSA disappear in a patient in clinical remission on drug treatment, a permanent remission off treatment is more likely. Antithyroid drugs probably have no influence on the fundamental disease process. However, drug treatment does permit the patient to remain euthyroid and in good health until the disease has spontaneously run its course.

Iodide in large doses will block thyroid hormone synthesis, inhibit the release of preformed hormone, and render the gland less vascular. Iodine blockade can be maintained for only a limited period (4-16 weeks) before escape occurs, and a fully euthyroid state may not be achieved. The use of inorganic iodine is reserved for severely toxic patients and for the immediate preoperative preparation of patients who are about to undergo subtotal thyroidectomy. Iodinated radiographic contrast agents (ipodate or iopanoic acid) have been employed successfully in drug treatment of Graves' hyperthyroidism.[107-109] Doses of 0.01 μg/mg/day or 0.04 to 0.05 μg/kg every 3 days have been employed and have maintained remission for 6 to 8 months. There is only limited experience with their use in children. (Neonatal Graves' disease is discussed in Chapter 6.)

TSH-DEPENDENT HYPERTHYROIDISM

Pituitary Tumors

TSH-secreting pituitary tumors associated with clinical hyperthyroidism have been reported in adults and in children.[111,112] In children, the local manifestations of the tumor are prominent. These include visual changes, optic atrophy, hydrocephalus, and amaurosis. Children with hyperthyroidism and measurable serum TSH concentrations (>1 μU/mL or 1 mU/L) should be examined for neurologic dysfunction and visual abnormalities. Skull roentgenograms for careful evaluation of the sella turcica are indicated if this evaluation arouses suspicion or if the serum TSH concentration is normal or elevated.

Selective Pituitary T3 Resistance

Hyperthyroidism with diffuse goiter and elevated serum TSH levels has been reported in several patients without pituitary enlargement.[113-116] These patients manifest resistance to the feedback effect on T3 on TSH release. The TSH response to TRH has been variable. These patients represent selective pituitary resistance to thyroid hormones. Features of thyroid autoimmune disease are absent, and the serum TSH level is inappropriately elevated in relation to the serum T4 and T3 concentrations.

In contrast to patients with pituitary TSH-secreting tumors, the TSH α-subunit level is not elevated and the TSH response to TRH is increased. Treatment of the disorder is difficult. Thyroid ablation controls the hyperthyroidism but aggravates the TSH hypersecretion and increases the risk of development of a pituitary adenoma. Suppression of TSH by exogenous thyroid hormone may aggravate the hyperthyroidism. However, this approach has been successful, and treatment with 3,5,3'-triiodothyroacetic acid (TRIAC) has been proposed.[114,115]

AUTONOMOUS NODULAR HYPERTHYROIDISM

Autonomously functioning thyroid nodules are uncommon in childhood and adolescence. Thyroid function in patients with thyroid nodules is variable. Most patients are euthyroid. Rarely, single or multiple autonomously functioning nodules may be associated with clinical hyperthyroidism.[117-119] Such nodules are true follicular adenomata and nearly always benign. The incidence of thyroid carcinoma in functioning nodules is less than 1%. It is generally felt that function in a thyroid nodule essentially excludes a diagnosis of thyroid carcinoma, but the possibility must be considered.

Small functional nodules usually do not produce clinical thyrotoxicosis. Large nodules (in excess of 3 cm in diameter) are more likely to do so. Somatic gain-of-function mutations of the TSH receptor and gain-of-function mutations of the Gsα-subunit have been found to be a major cause of benign toxic thyroid adenomas.[120] Activating germ-line TSH receptor mutations, by contrast, produce congenital or childhood-onset diffuse thyroid hyperplasia and hyperthyroidism.

Nodular autonomy is usually discerned by thyroid radioiodine scan. A nodule is autonomous if it is the only thyroid tissue showing uptake. If the nodule shows increased radioiodine uptake but the remaining thyroid tissue is still visible on scan, autonomy is likely. Autonomy is confirmed if the serum TSH concentration measured by a highly sensitive method is suppressed. Patients may present euthyroid with normal-range serum T4 and T3 concentrations and suppressed serum TSH. T3-suppression testing has been used to confirm autonomy. Radioiodine uptake in autonomous nodules is not suppressible by exogenous T3. The natural history of functioning thyroid nodules in individual patients is variable.

Most likely, if euthyroid such patients will remain euthyroid. However, there may be a gradual increase in autonomous thyroid hormone production with development of clinical evidence of hyperthyroidism. Nodule enlargement or thyrotoxic symptoms may create the need for ablative therapy. Functioning nodules producing clinical and chemical thyrotoxicosis require surgical removal. Radioiodine treatment now tends to be reserved for older adult patients. Antithyroid drug therapy is considered only for short-term management. Complete lobectomy with preservation of the recurrent laryngeal nerve is the most desirable surgical procedure.

ACTIVATING TSH RECEPTOR MUTATIONS

Several families have been reported with hyperthyroidism segregating as an autosomal-dominant trait in the absence of thyroid autoimmune disease. The affected individuals present with goiter, increased total and free T4 levels, and suppressed TSH concentrations. In patients treated surgically, the thyroid glands manifest diffuse hyperplasia without lymphocytic infiltration. Gain-of-function germline mutations of the TSH receptor have been demonstrated in these patients.[120-123] In vitro studies of cells with transfected mutated receptors demonstrate abnormally increased constitutive cAMP-stimulating activity.

Most of the affected individuals have been detected during childhood or adolescence, but a few infants have been diagnosed before 2 years of age and occasionally in the neonatal period.[122] Clearly, the abnormality is congenital—and it is possible that some of the earlier reported cases of familial persistent neonatal Graves' disease have instead manifested unrecognized activating TSH-receptor mutations. Treatment of such infants is difficult because the disorder is not transient.[122] Antithyroid drugs for short-term management and total or near-total thyroidectomy would seem the therapies of choice at present.

ACTIVATING G-PROTEIN MUTATIONS

The guanine nucleotides (G proteins) are a family of signal-transducing molecules coupling the seven-transmembrane-helix family of cell membrane receptors (including the TSH receptor) to activating cellular effector systems such as adenyl cyclase. Activating mutations of the alpha subunit of the stimulatory G protein, Gs, lead to increased cyclic AMP formation and the associated endocrinopathies of the McCune Albright syndrome.[124] It is postulated that the mutation occurs during embryonic development with a mosaic tissue distribution.

The clinical manifestations relate to the tissues involved and include polyostotic fibrosis, dysplasia of bone, and hyperfunction of one of more endocrine glands. The latter have included ovarian cysts, gonadal hyperfunction and precocious puberty, pituitary adenomas causing adrenal hyperplasia or growth hormone hypersecretion, and hyperthyroidism. The thyroid hyperplasia and hyperthyroidism resemble Graves' disease, but without ophthalmologic features and without autoantibodies. Treatment options for the thyroid disease include antithyroid drugs, surgery, and radioiodine.

Thyroid Neoplasia

CLASSIFICATION

A thyroid neoplasm should be suspected whenever a child is found to have a solitary thyroid mass with a consistency differing from that of the rest of the thyroid gland. A solitary nodule during the first two decades of life has a much greater chance of being malignant than those in older age groups.[125-130] The prevalence of cancer in children with thyroid nodules has been decreasing in North America, presumably due to reduced radiation exposure. Cancer prevalence now approximates 20% of thyroid nodules in children.[127,128] The ratio of girls to boys among children with thyroid cancer varies from 1:6 (F/M) for ages 5 through 9 to 5:2 at ages 15 through 19.[128] Nodular enlargement in boys is somewhat more likely to be cancerous than in girls.

Thyroid cancer accounts for 0.5% of all cancer for all ages and 1% to 1.5% of all childhood cancer. A classification of thyroid neoplasia is shown in Table 7-11. Seventy to 80% of solitary thyroid nodules during childhood prove to be cystic lesions or benign adenomas.[127-130] Hyperfunctioning adenomas are exceedingly uncommon during the first two decades of life. Well-differentiated papillary thyroid carcinoma (PTC) account for more than 60% to 90% of the malignant lesions in this age group. Characterization of the histopathologic type as follicular, papillary, or papillary-follicular carcinoma does not alter therapy.

Other malignant tumors of the thyroid gland during childhood include medullary carcinoma arising in the parafollicular C cells, poorly differentiated thyroid carcinoma, teratomas, lymphoma, and tumors such as metastatic carcinomas arising in other tissues.[125,131,132] The prognosis in these tumors may be worse than in well-differentiated adenocarcinoma of the thyroid. Hence, it is important to establish a tissue diagnosis as early as possible and to design the treatment accordingly. Well-differentiated carcinomas have little tendency to become undifferentiated neoplasms.

RADIATION EXPOSURE

A frequent predisposing cause of the development of differentiated thyroid gland carcinoma during infancy and childhood is radiation exposure involving the neck. In a series of children reported in the 1950s with thyroid cancer, 80% had a history of prior radiotherapy.[133,134] Usually, radiotherapy had been administered during early infancy to the upper mediastinum and neck for control of an "enlarged" thymus gland. Cancer also occurred following irradiation of hypertrophied tonsils and adenoids or acne in older children and adolescents. In those earlier studies, the average time between the irradiation and cancer detection approximated 10 years—and the estimated absolute risk of excess cancers was estimated to be 4.4 per million children per rad of radiation dose (1 rad = 0,01 Gray).

The most recent epidemic of radiation-induced thyroid cancer in children followed the Chernobyl nuclear accident in Russia in 1986.[135,136] The radiation dose ranged from 0.5 to 600 rads (0.006–6 Gray) in a group of 107 exposed Russian children detected by 1992, with a mean of 20 rads (0.2 Gray). The age at exposure ranged from 0 to 11 years, and the age at diagnosis 4 to 16 years. The cancers, predominantly papillary adenocarcinoma, developed in most cases within 3 to 5 years. However, the number of cases has continued to increase.

PAPILLARY-FOLLICULAR CARCINOMA

Most children with papillary follicular thyroid carcinoma present with a midneck or lateral neck mass, and most (60%-80%) have one or more palpable neck lymph nodes containing metastatic thyroid cells by histologic examination. One-third to one-half of patients have extracapsular extension, and 10% distant metastases (usually to the lungs). FNA is a helpful diagnostic approach with analysis by an experienced cytopathologist.[130,137] FNA is omitted if malignancy criteria are present. These include a history or radiation to the head or neck, a rapidly growing nodule that is very firm or hard, satellite lymph nodes, hoarseness or dysphagia, and evidence of distant metastases.

Approximately 80% of differentiated thyroid carcinoma is classified as papillary, and 20% as papillary-follicular.[137] Ras mutations are early events in a complex cascade of somatic mutations contributing to many cases of papillary-follicular thyroid carcinoma, and activation of the tyrosine kinase receptors RET (as RET/PTC) and NTRK (as TRK) may be involved.[138] Cytogenetic abnormalities are associated with the RET/PTC and TRK rearrangements or translocations. RET/PTC gene rearrangements are characteristic of papillary carcinoma in adults and are associated with an aggressive clinical course.

RET/PTC mutations and rearrangements are also common in pediatric papillary thyroid carcinoma, varying from 23% to 67% in reported series and averaging about 50%.[139] RET/PTC-3 rearrangements are more prevalent in radiation-induced thyroid papillary carcinoma, whereas RET/PTC-1 and RET/PTC-2 rearrangements are more common in spontaneous papillary carcinoma.[139-142] The radiation-induced thyroid carcinoma in children after the Chernobyl reactor accident was associated with a high prevalence of RET/PTC in the absence of RAS and p53 mutations.[142,143] Raf kinase is a component of the Ras/Raf-MAPK kinase-ERK/MAPK signaling pathway involved in regulation of cell growth and proliferation. The B-type (BRAF) isoform, when constitutively activated, causes tumorigenesis.[144]

BRAF mutations are found in a variety of human cancers, including 29% to 83% of papillary thyroid cancer in adults, and are associated with poorer clinicopathologic outcomes and independently predict recurrence.[144] BRAF mutations are much less common in childhood papillary cancer.[143] Three gene profiles of thyroid nodules (assessing cyclin D, protein convertase 2, and prostate differentiation factor) have been shown to differentiate follicular thyroid carcinoma and adenoma in 114 adult samples, with 97% accuracy. Gene expression profiling methods for differential diagnosis and prognosis are in development.[146,147]

The prognosis in children with papillary-follicular carcinoma is far better than in most other types of childhood cancer.[131] The course is usually indolent, with long periods without progression. However, local or distant recurrence is observed in as many as 35% of patients and constant surveillance is required. Because spread to the lymph nodes has occurred prior to surgery in some patients, the excellent prognosis may be related more to the biologic nature of this form of cancer than to total removal of all cancerous cells at the initial operation.

Thyroid hormone suppression cannot be overemphasized and should be prescribed in doses adequate to suppress serum TSH (as assessed by a high-sensitivity TSH assay) but avoid evidence of toxicity. Mortality in thyroid carcinoma during childhood and adolescence is primarily accounted for by the relatively uncommon instances of medullary carcinoma and undifferentiated carcinoma. In these lesions, more radical surgery combined with radiation or cancer chemotherapy is fully justified.

MEDULLARY CARCINOMA

Medullary thyroid carcinoma (MTC) arises from the parafollicular or C cells of the thyroid gland and accounts for 3% to 9% of thyroid carcinomas.[148-152] There is a distinctive histologic picture, with large deposits of amyloid situated among sheets of pleomorphic epithelial cells. Most patients with MTC have sporadic disease. Hereditary MTC accounts for 25% to 35% of cases and includes multiple endocrine neoplasia type 2A (MEN2A), MEN2B, and familial MTC (FMTC): 80% to 90%, 5%, and 5% to 15% of cases, respectively.[151]

FMTC is a consistent feature of all clinical subtypes (Table 7-12). MEN prevalence approximates 1:30,000 individuals.[151] MEN syndromes (including pheochromocytoma and parathyroid adenoma or hyperplasia) can be distinguished from MEN I (with parathyroid, pituitary, and pancreatic tumors). MEN 2A (Sipple's syndrome) includes MTC, pheochromocytomas, and hyperparathyroidism. MEN 2B (sometimes termed *MEN 3*) includes MTC, pheochromocytomas, and multiple mucosal neuromata. The common feature of all of these tumors is a neuroectodermal origin. Patients with mucosal neuromas usually have a distinctive appearance, with protruding, thick, often bumpy lips; occasionally prognathism; and a marfanoid habitus[148,149,151,152] (Table 7-12).

TABLE 7-12

Classification of Hereditary Medullary Thyroid Cancer

Phenotype	MTC	MN	PCT	HPT
MEN2A	100%	100%	50%	20%
MEN2B	100%	N	50%	N
FMTC	100%	N	N	N

Modified from Kouvaraki MA, Shapiro SE, Perrier NO, et al. (2005). RET proto-oncogene: A review and update of genotype-phenotype correlations in hereditary medullary thyroid cancer and associated endocrine tumors. Thyroid 15:531.

MTC, medullary thyroid carcinoma; MN, mucosal neuromata; PCT, pheochromocytoma; HPT, hyperparathyroidism; N = not present.

The distinctive feature of MTC is excessive secretion of calcitonin. Other substances (including ACTH, chromogranin A, histaminase, serotonin, prostaglandins, somatostatin, and beta endorphin) may be produced. Serum calcitonin is the most reliable biochemical marker for the presence of MTC. Normal levels usually do not exceed 30 pg/mL. C-cell hyperplasia is associated with increased calcitonin secretion, and baseline and pentagastrin- and/or calcium-stimulated serum calcitonin concentrations have been utilized to distinguish C-cell hyperplasia and MTC. Stimulated calcitonin values in the 30- to 100-pg/mL range are generally associated with C-cell hyperplasia, and levels in the 100- to 1,000-pg/mL range with microscopic MTC confined to the thyroid gland. Stimulated calcitonin levels in excess of 10,000 pg/mL are associated with macroscopic MTC, and 20% of these patients manifest distant metastases.[148-150]

MTC is caused by autosomal-dominant gain-of-function mutations in the RET (rearranged during transfection) proto-oncogene on chromosome 10. RET includes 21 exons and encodes a plasma-membrane-bound tyrosine kinase enzyme. The RET receptor is expressed in neuroendocrine and neural cells, including thyroid C cells, adrenal medullary cells, parathyroid cells, and colonic ganglion cells. Extracellular cadherin-like domains are involved in cell-cell signaling. Cysteine-rich extracellular domains are important to receptor dimerization. There are three isoforms with 9,43 or 51 distinct amino acids in the intracellular C-terminal tail. These have different roles in kidney differentiation, in sympathetic neuronal growth and function, and in neuronal signaling.[151] There are four RET ligands mediating receptor dimerization and tyrosine autophosphorylation, activating various signaling pathways.[151] Inactivating RET mutations are associated with congenital megacolon. Activating gain-of-function germ-line mutations are responsible for FMTC and its variants (Figure 7-10, Table 7-13).

A single point mutation at codon 918 of the intracellular tyrosine kinase domain (exon 16) of the RET oncogene has been described in 95% of patients with MEN2B. A codon 634 mutation has been found in 85% of MEN2A patients, and mutations in codons 609, 611, 618, and 620 in 10% to 15%. In the rare cases of sporadic MEN2A, MEN2B and FMTC RET mutations occur de novo on the paternal allele (or rarely on the maternal allele). Somatic RET mutations are found in sporadic MTC.[153] These most frequently occur in codon 918, but a variety of mutations (including multiple mutations) have been characterized.[151,152] Identical germline mutations have been observed in association with MEN2A and FMTC[150,151] (Table 7-12).

Prior to 1987, the only available test for detecting MTC in at-risk patients was measurement of serum calcitonin with or without stimulation. Since then, DNA diagnosis has become the procedure of choice. The identification of a mutation of the RET protooncogene indicates that the affected individual has a greater than 90% probability of development of MTC. The optimal treatment strategy is to prevent MTC in children with RET gene mutations by performing early thyroidectomy before malignant transformation occurs.[151]

There is now a large experience correlating RET mutations with MTC aggressiveness, and high-risk mutations have been identified (Table 7-14). These are ranked as

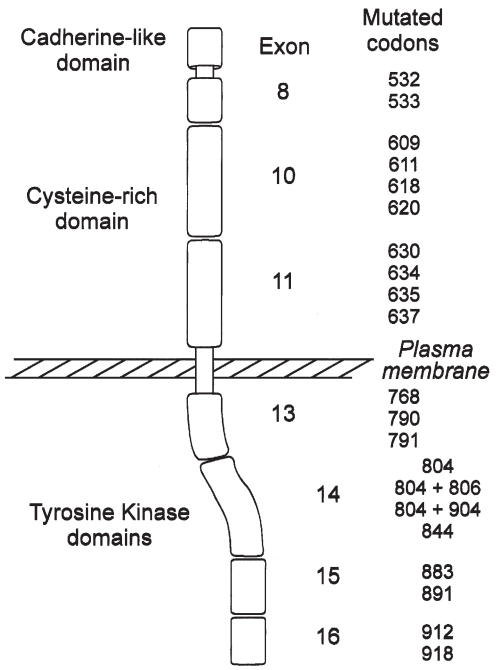

Figure 7-10. The RET proto-oncogene codes for a plasma membrane protein receptor consisting of 21 exons with extracellular, transmembrane, and intracellular tyrosine kinase domains. Activating missense mutations of the indicated codons of exons 8, 10, 11, 13, 14, 15, and 16 predispose to medullary thyroid carcinoma presenting as multiple endocrine neoplasia (MEN) syndromes 2A and 2B or as familial medullary thyroid carcinoma (FMTC). [From Kouvaraki MA, Shapiro SE, Perrier NO, et al. (2005). RET proto-oncogene: A review and update of genotype-phenotype correlations in hereditary medullary thyroid cancer and associated endocrine tumors. Thyroid 15:531.]

TABLE 7-14

Patient MTC Risk Groups and Recommended Management

	Level 1: High Risk	Level 2: High Risk	Level 3: Highest Risk
Mutated codons	609, 768, 790 791, 804, 891	611, 618, 620 634	883, 918
Phenotype	MEN2A	MEN2A	MEN2B
Recommended management	Thyroidectomy 5-10 yr of age	Thyroidectomy <5 yr of age	Thyroidectomy 1-6 mo of age

From Kouvaraki MA, Shapiro SE, Perrier NO, et al. (2005). RET proto-oncogene: A review and update of genotype-phenotype correlations in hereditary medullary thyroid cancer and associated endocrine tumors. Thyroid 15:531.

levels 1 through 3, with 3 being highest risk. For the highest-risk group (mutated exons 883 or 918 in MEN2B patients), thyroidectomy is recommended before age 6 months (or preferably within the first month of life).[151] For level 2 patients, thyroidectomy before age 5 is indicated, and for level 1 mutations thyroidectomy at 5 to 10 years of age is recommended (Table 7-15). An alternative approach in lower-risk patients is to initiate calcium-pentagastrin testing of gene mutation carriers at age 4 or 5 years, with removal of the thyroid gland at the time of a positive test.

Pheochromocytomas in MEN2 patients, in contrast to sporadic forms, are rarely extra-adrenal or malignant and are diagnosed at a younger age. This has led to the practice of cortex-sparing adrenalectomy to avoid the risk of adrenal insufficiency.[151] The tumors are bilateral in 50% of patients. The risk of recurrent pheochromocytoma in the contralateral gland in patients with unilateral disease is 20% to 30%. Patients with unilateral disease can now be managed via laparoscopic unilateral complete adrenalectomy. For bilateral disease, a unilateral cortical-sparing procedure with removal of the entire centralateral gland is recommended.[151]

Long-term follow-up of hereditary MTC patients is essential to detect recurrence of disease in treated patients or the later appearance of pheochromocytoma or hyperparathyroidism. Pheochromocytoma in MEN patients is diagnosed after MTC in 90% of patients. Parathyroid hyperplasia is associated most commonly with codon 634 mutations and less frequently with codon 609, 611, 618, 620, 790, and 791 mutations.[154] Parathyroid hyperplasia or adenoma in MEN2A patients may be associated with symptoms of hypercalcemia or may be subclinical with only mild increase in serum calcium levels.

FMTC is defined as the presence of MTC in kindreds with four or more affected family members, and the onset of MTC is commonly delayed until 20 to 40 years of age. Thus, in many cases it is difficult to distinguish between MEN2A and FMTC because the FMTC kindreds may have few individuals, incomplete histories, or a predominance of young individuals who have not reached an age for full penetrance of pheochromocytoma or hyperparathyroidism.[151,152] Table 7-15 summarizes available laboratory tests. Details may vary among laboratories.

TABLE 7-15

Laboratory Tests for the Management of MEN2 and FMTC

Test Name	Patient Preparation	Specimen Requirements
Calcitonin (ICMA), post calcium-pentagastrin stimulation	NPO after midnight. With the patient supine, give 20 mg/kg calcium gluconate (2 mg elemental calcium) intravenously over 1 minute, followed by pentagastrin 0.5 μg/kg as a bolus over 5 seconds. Draw blood at 0, 1, 2, 5, and 10 minutes.	3 mL frozen serum (red top tube).
Catecholamines	Avoid alcohol, coffee, tea, tobacco and strenuous exercise prior to specimen collection.	—
Plasma		• 4 mL frozen plasma (green top tube).
Random urine		• 10 mL refrigerated aliquot of 24-hour urine preserved in 25 mL of 6N HCl. Record 24-hour urine volume.
Random urine		• 10-mL refrigerated aliquot of random urine specimen.
Calcium, total, serum	Overnight fasting preferred.	1 mL refrigerated serum (red top tube).
PTH, intact (ICMA)	None.	• 2 mL refrigerated serum (red top tube). • Centrifuge and separate immediately.

MISCELLANEOUS NEOPLASIA

Papillary-follicular carcinoma and medullary carcinoma account for 99% of thyroid cancer during childhood and adolescence. Teratomas rarely present as thyroid tumors in children. Anaplastic carcinoma is an adult disease and is extremely rare in children. Primary thyroid lymphoma or neoplasia metastatic to the thyroid gland is uncommon in adults and is extremely rare in childhood.

MANAGEMENT OF THE SOLITARY NODULE

Thyroid nodules in children are uncommon, with a prevalence of 0.2% to 1.8%. Most are asymptomatic and benign, representing follicular adenomas, colloid cysts, thyroglossal duct cysts, or chronic thyroiditis. The prevalence of malignant disease approximates 20% to 25%.[127,130] Features of the history and physical examination suggesting malignancy are summarized in Table 7-16. Thyroid function tests are usually normal. However, a suppressed serum TSH level and/or an increased serum T3 concentration suggests an autonomous functioning nodule. An elevated serum calcitonin concentration and/or clinical features of MENIIb suggests medullary carcinoma. A bosselated gland in a patient with positive antithyroid peroxidase autoantibodies favors benign pseudonodularity in Hashimoto thyroiditis. Pain or local tenderness suggests suppurative thyroiditis with abscess.

Diagnostic modalities available include ultrasound, thyroid isotopic scan, FNA, and excisional biopsy. Ultrasonography is useful to rule out thyroid developmental abnormalities. FNA is recommended in the absence of malignancy features, only if an experienced aspirationist and cytopathologist are available. In experienced hands, false negative results of FNA are infrequent (2%–5%), and clinical follow-up of patients with a negative FNA result is a reasonable management alternative that is now well accepted in adult patients.[130,137] A positive or suspicious FNA result is followed by surgical excision and histopathologic examination. Radioisotope scanning in useful to confirm an autonomous nodule, and to confirm a cold (nonfunctioning) nodule in questionable cases. Surgical biopsy/excision is recommended if there are features suggesting malignancy (Table 7-16), an autonomous nodule, a positive or suspicious FNA, or a cystic lesion.

The initial approach to therapy of a thyroid nodule is surgical, with simple removal of the affected lobe. No further surgery is necessary if the mass proves to be a cystic lesion or benign adenoma. If a frozen section reveals papillary-follicular or medullary carcinoma, total thyroidectomy should be done because well-differentiated papillary-follicular carcinomas are likely to involve multifocal sites in the thyroid gland. Although accessible regional nodes should be removed, a mutilating neck dissection is not warranted.

Routine use of therapeutic dosages of radioiodine following surgery should be discussed in patients with well-differentiated thyroid carcinoma and no evidence of metastases.[128,129] However, in patients with lymph node involvement or other evidence of metastases postoperative radioiodine is mandatory to ablate any residual functioning thyroid tissue. Patients are then followed after surgery and radioiodine treatment by measurement of serum thyroglobulin (Tg) concentrations as a reliable tumor marker. Recombinant TSH-stimulated Tg levels greater than 2 ng/mL have been shown in adults to predict metastases 5 years later.[155]

Serum Tg levels of less than 1 ng/mL (1 μg/L) in the absence of Tg antibody in thyroid-ablated patients on thyroxine suppression therapy indicate remission. Higher values suggest metastases.[155] Supplemental whole-body ^{131}I scanning is also utilized to detect metastases. Metastatic disease is usually treated with high-dose radioiodine. Following surgery or surgery and radioiodine, the patient should be maintained on full substitution dosages of exogenous thyroid hormone to protect from any further stimulation by TSH.[128,129]

The management of medullary carcinoma includes total thyroidectomy and aggressive search for involved lymph nodes. Postoperative management includes serum calcitonin monitoring, imaging or scanning procedures [CT, MR or isotope scanning using thallium, metaiodobenzylguanidine (MIBG), and ^{99}Tc-sesta MIBI], postoperative radiation therapy, and surgery for accessible tumor recurrences. In patients without initial distant metastases and with complete tumor resection, the 20-year survival rate free of metastases approximates 80%. Overall, 10- and 20-year survival rates approximate (respectively) 60% and 40%.[156]

TABLE 7-16

Clinical Features Suggesting Malignancy in Children Presenting with a Thyroid Nodule

- History of neck radiation
- Family history of medullary carcinoma
- Rapid growth of nodule
- Firm nodule
- Fixation to adjacent structures
- Vocal cord paralysis
- Enlarged regional lymph nodes
- Evidence of distant metastases

Future Directions

Before World War II, the focus of endocrine research was the isoloation, purification, and characterization of the major hormones; the study of their effects; and the description of the clinical syndromes resulting from hormone excess or deficiency.[157] Clinical replacement therapy using thyroid extract and synthetic cortisol were introduced. During the past 50 years, the evolution of radioisotope, immunoassay, imaging, molecular genetic, and pharmaceutic science and technologies transformed basic and clinical endocrinology and metabolism and endocrine oncology—allowing endocrinology as a clinical discipline to move progressively from the academic to the physician office environment.

The impact on pediatric endocrinology is evident comparing Williams and Wilkins' 1952 textbook *The*

Diagnosis and Treatment of Endocrine Disorders in Childhood and Adolescence (Charles C. Thomas, Springfield) with this text. The same technologies facilitating our past progress will fuel future advances: molecular genetics, molecular onology, sophisticated imaging modalities, and evolving molecular- and immunologic-based pharmaceuticals.

Likely advances for thyroid and other endocrine disease management include an expanding spectrum of molecular diagnostic testing for heritable endocrine diseases, further advances in endocrine laboratory diagnostics, improved diagnostic and prognostic genetic and proteomic markers for endocrine cancer, advances in efficacy and availability of diagnostic and management imaging for endocrine diseases, and advances in basic insights and diagnostic testing and therapies for autoimmune endocrine diseases.[157,158] Basic endocrine science is increasingly focused on the cascade of endocrine, paracrine, and autocrine pathways of hormones, growth factors, and second-messenger systems involving receptor system cascades amenable to pharmacologic perturbation.[159-162]

The ability to identify and characterize these receptor systems and to design targeted agonist or antagonist small-molecule drugs have already provided effective endocrine therapies. New molecular and proteomic advances will accelerate the progress and availability of more effective agents. Cellular, organ transplant, stem cell, and gene therapies also offer promise for major therapeutic advances.

Diagnosis of GH Excess
Treatment of GH Oversecretion
Conclusions

Normal Growth

The most fundamental characteristic of childhood is that it is a time of growth. As multifactorial and complex as the process of growth is, children normally grow in a remarkably predictable manner. Deviation from a normal pattern of growth can be the first manifestation of a wide variety of disease processes, including endocrine and nonendocrine disorders and involving virtually any organ system of the body. Frequent and accurate assessment of growth is, therefore, of primary importance to physicians and nurses caring for children.

MEASUREMENT

Assessment of statural growth necessitates optimizing accuracy in height determinations.[1-3] When feasible, measurement of supine length is employed in children younger than 2 years of age—and that of erect height is done in older children. The inherent inaccuracies involved in measuring length in infants are often obscured by the rapid skeletal growth normally characteristic of this age. For measurement of supine length, it is best to employ a firm box with an inflexible board (against which the head lies) and a movable footboard on which the feet are placed perpendicular to the plane of the supine infant. Optimally, the child needs to be relaxed—with the legs fully extended and the head positioned in the "Frankfurt plane" (with the line connecting the outer canthus of the eyes and the external auditory meatus perpendicular to the long axis of the trunk).

When children are old enough to stand erect (and physically capable of doing so), it is best to employ a wall-mounted "Harpenden" stadiometer similar to that designed by Tanner and Whitehouse for the British Harpenden Growth Study. Freestanding stadiometers are also available but require frequent recalibration. The traditional measuring device of a flexible arm mounted to a weight balance is notoriously unreliable and cannot be counted on to provide accurate serial measurements.

As with length measurements in infants, positioning of the child is critical. The patient should be fully erect, with the head in the Frankfurt plane. The back of the head, thoracic spine, buttocks, and heels should be touching the vertical axis of the stadiometer and one another. Every effort should be made to correct discrepancies related to lordosis or scoliosis. Ideally, serial measurements should be made at the same time of day because diurnal variation in standing height has been observed.[4]

It is critical that height determinations be performed by an individual with proper training, rather than (as is often the case) by an inexperienced member of the staff. We recommend that lengths and heights be measured in triplicate, that variation be no more than 0.3 cm, and that the mean height be recorded. For determination of height velocity, it is obviously best to have the same individual performing the determinations. Even when every effort is made to maximize the precision of height determinations, a minimum interval of 3 months is necessary for accurate height velocity computation. Six months' data are preferable, although it is of note that seasonal variation in height velocity has been reported.[5]

GROWTH CHARTS

Evaluation of a child's height must be done in the context of normal standards. Such standards can be either cross-sectional or longitudinal. Most American pediatric endocrine clinics continue to use the cross-sectional data provided by the National Center for Health Statistics (NCHS), which were originally introduced in 1977 and recently updated.[6-8] Epidemiologic limitations in these growth charts have been noted, however. The data included in the original infant charts, for example, were derived from a private study of a group of subjects who were primarily white, formula-fed, middle-class infants from southwestern Ohio. Data employed for older children came from national health examination surveys conducted from 1963 to 1974.

The NCHS (now a part of the Centers for Disease Control and Prevention) has provided a set of new growth charts, representing revisions of the previous charts, and has introduced new charts for body mass index[9] (Figures 8-1 through 8-8). Interestingly, the new charts show little change in average height over the past 25 years despite the common perception that today's children are taller than peers from 10 to 25 years ago. This is in contrast to other countries (in particular, Holland), where mean height continues to rise in spite of being the tallest in the world—and many current and formerly developing countries in which the population (which was typically shorter than in the Western world) is becoming taller.

Classic percentile-based growth charts are invaluable for plotting growth of children relative to the 3rd or 5th, 10th, 25th, 50th, 75th, 90th, and 95th or 97th percentiles of normal American children. There are, however, two major limitations of these charts. First, they do not satisfactorily define the growth rates of children below the 3rd or above the 97th percentile—the very children for whom it is most critical to accurately describe the degree to which their growth deviates from the normal growth centiles.

The NCHS data can be used to compute standard deviation (SD) scores (or Z scores), which are more helpful because a short child can be described as having a

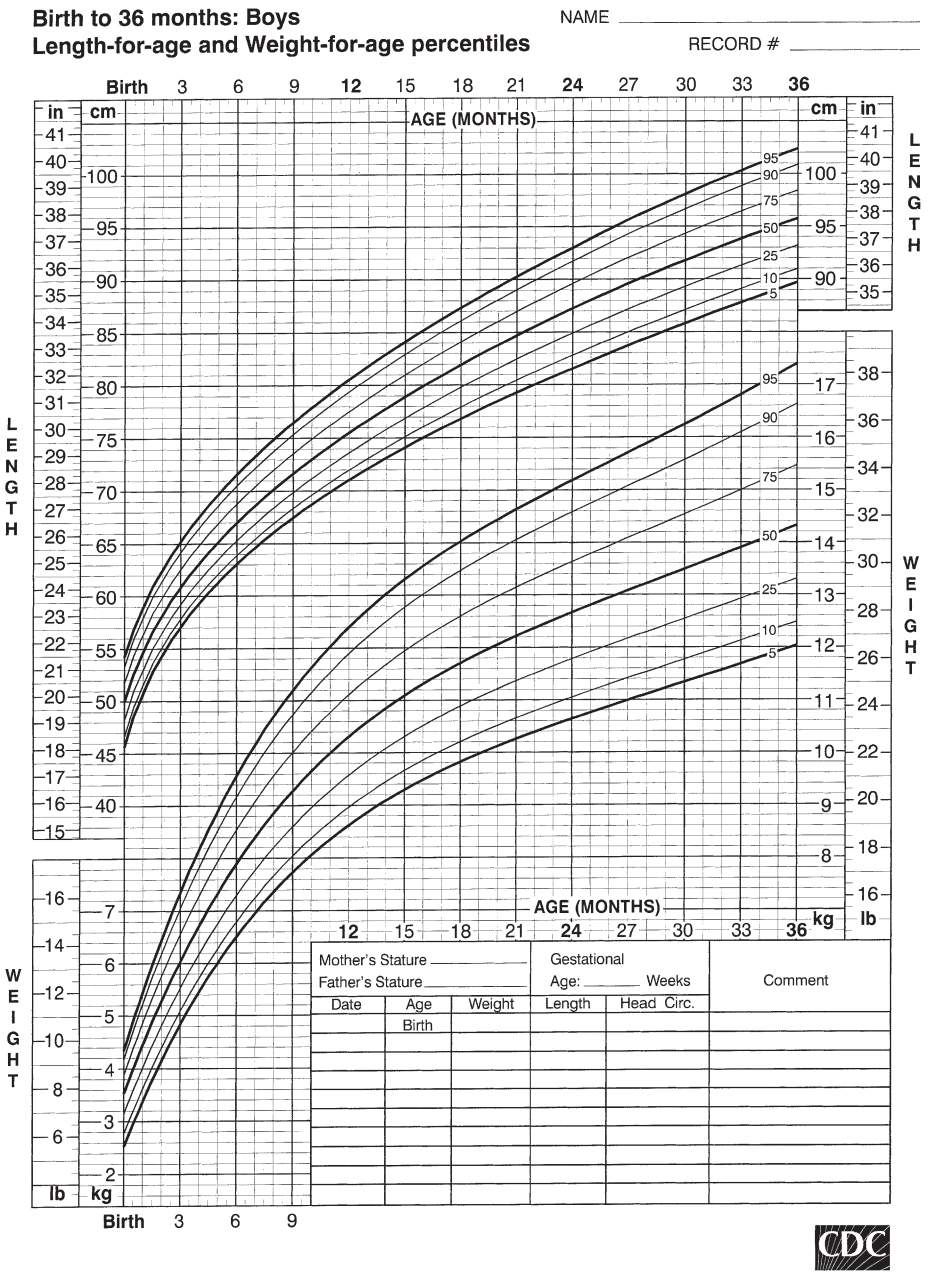

FIGURE 8-1. Length-for-age and weight-for-age percentiles for boys (birth to 36 months). (Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion [2000]. http:www.cdc.gov/growthcharts.)

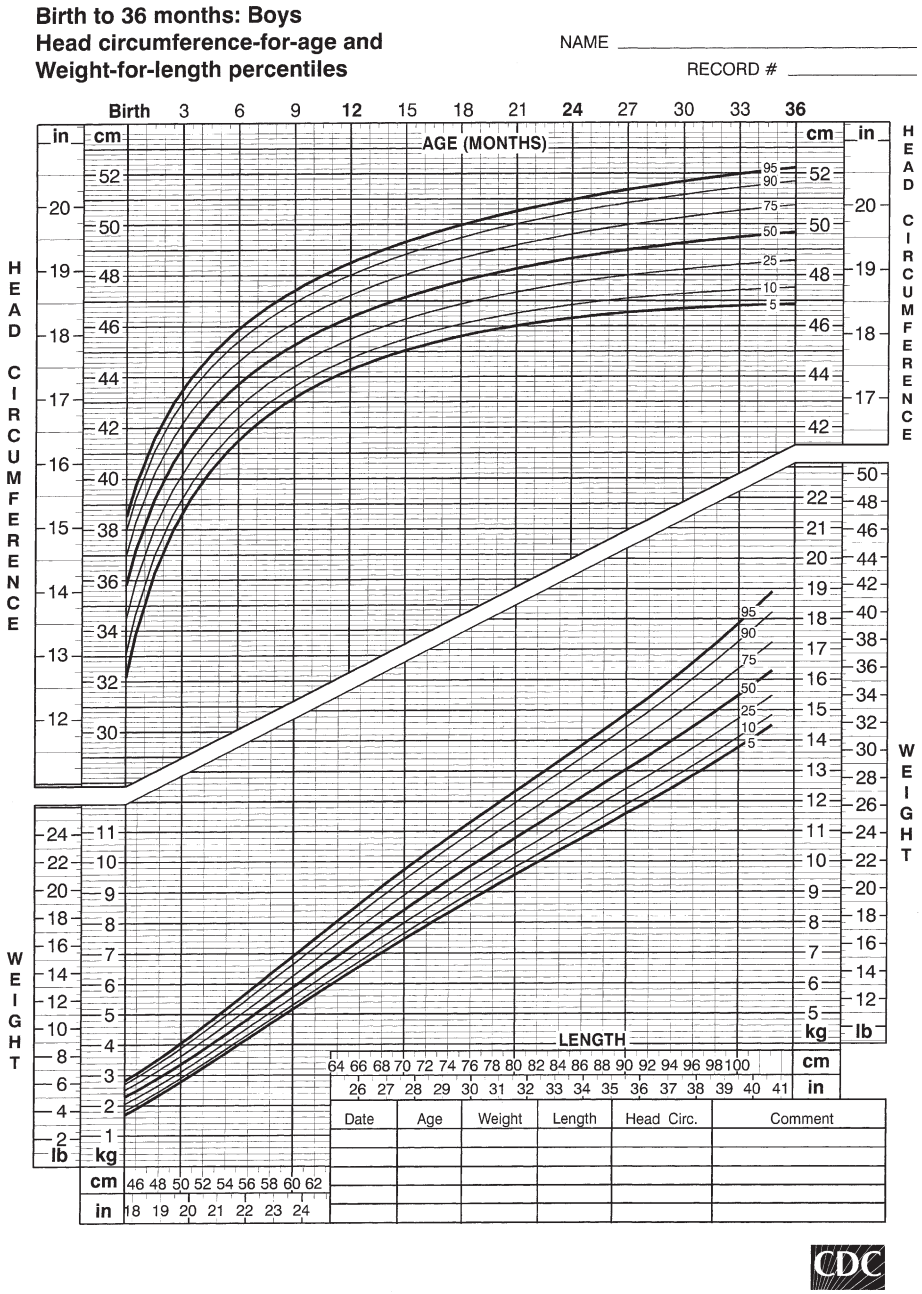

FIGURE 8-2. Head circumference-for-age and weight-for-length percentiles for boys (birth to 36 months). (Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion [2000]. http:www.cdc.gov/growthcharts.)

growth rate of (for example) 2 or 2.5 SD from normal. Because these SDs are defined by cross-sectional data, however, SD scores during childhood are not directly comparable with SD scores during adolescence—when great variation in growth rates can be normally observed. Second, cross-sectional data are of greater value during infancy and childhood than in adolescence—when differences in the timing of puberty can introduce considerable variability into normal growth rates. To address this issue, Tanner and colleagues[10] have developed longitudinal growth charts that accommodate the timing of puberty. These charts are of greatest value in assessing growth during adolescence and puberty, and are probably superior for plotting sequential growth data on any given child.

The data from cross-sectional and longitudinal growth studies have been employed to develop height velocity standards[10] (Figures 8-9 and 8-10). It is important to emphasize that carefully documented height velocity data are invaluable in assessing the child with abnormalities of growth. Although considerable variability exists in the normal height velocity observed in children of different ages, between the age of 2 years and the onset of puberty children normally grow with remarkable fidelity

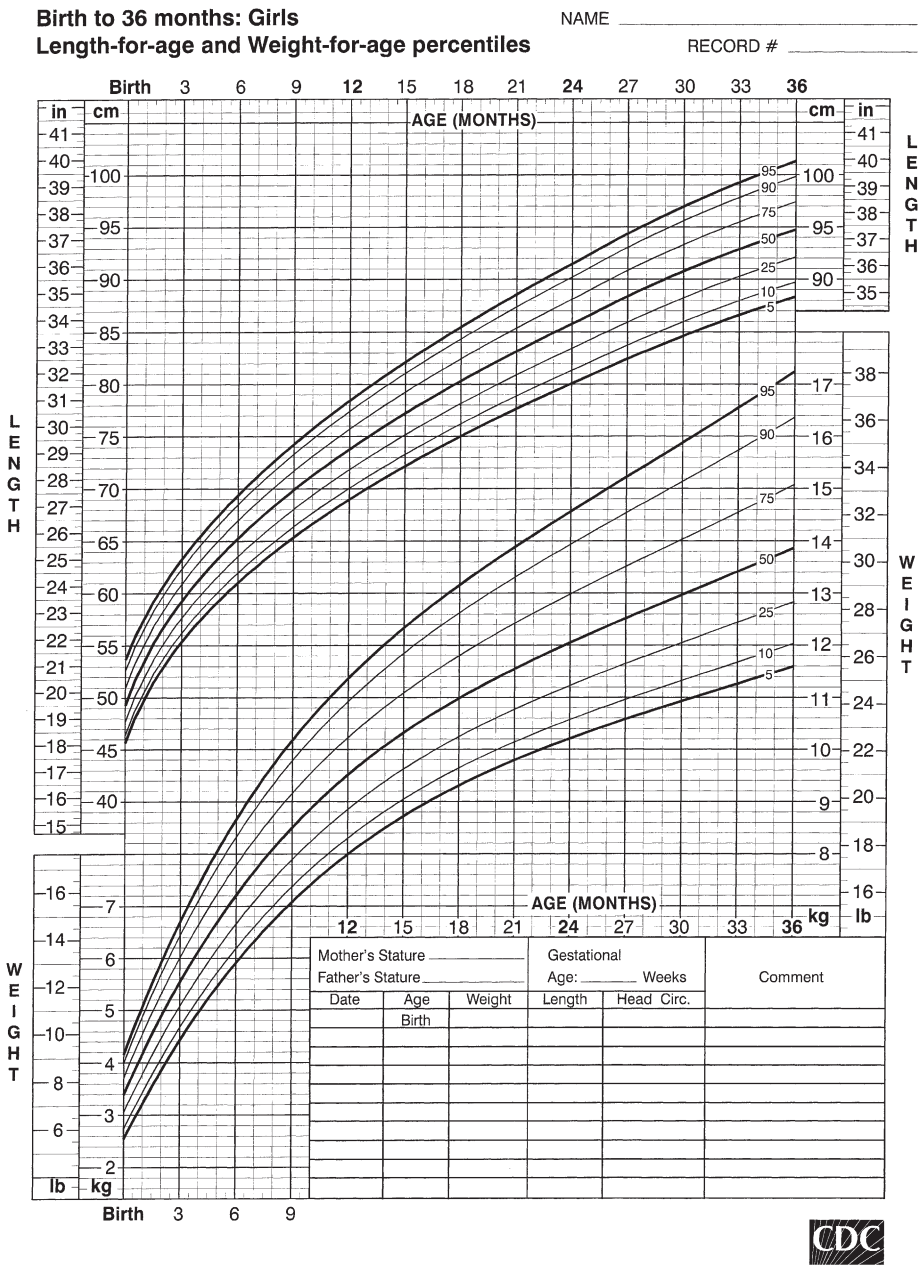

FIGURE 8-3. Length-for-age and weight-for-age percentiles for girls (birth to 36 months). (Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion [2000]. http:www.cdc.gov/growthcharts.)

relative to the normal growth curves. Any "crossing" of height percentiles during this age period should be noted by the physician, and abnormal height velocities always warrant further evaluation.

Disease-related growth curves have been developed for a number of clinical conditions associated with growth failure, such as Turner syndrome,[11] achondroplasia,[12] and Down syndrome. Such growth profiles are invaluable for tracking the growth of children with these clinical conditions. Deviation of growth from the appropriate disease-related growth curve suggests the possibility of a second underlying condition.

BODY PROPORTIONS

Many abnormal growth states, including short stature and excessive stature, are characterized by disproportionate growth. The following determinations should be made as part of the evaluation of short stature.

- Occipitofrontal head circumference
- Lower body segment: distance from top of pubic symphysis to the floor
- Upper body segment: sitting height (height of stool should be subtracted from standing height)
- Arm span

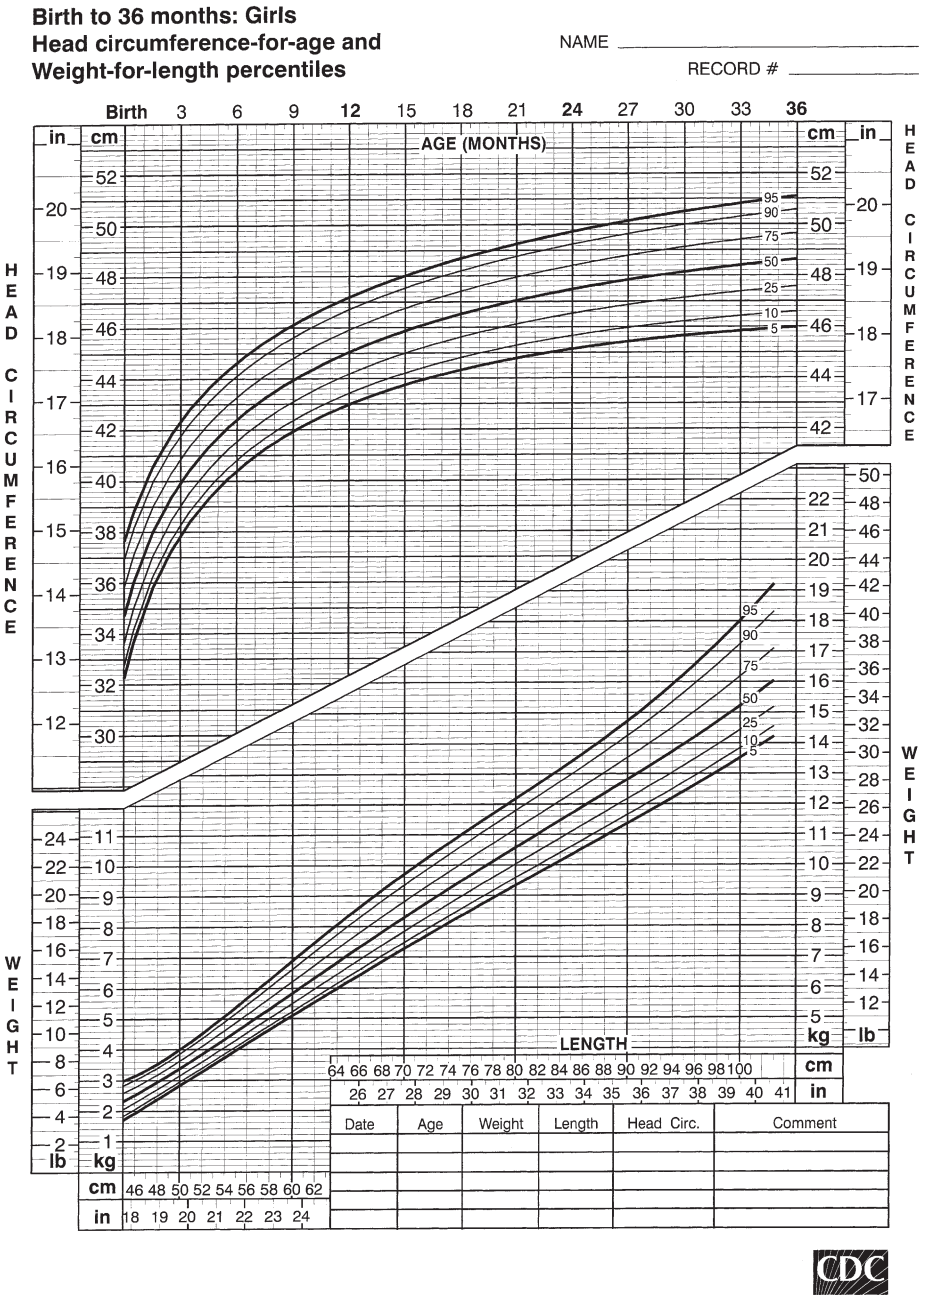

FIGURE 8-4. Head circumference-for-age and weight-for-length percentiles for girls (birth to 36 months). (Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion [2000]. http:www.cdc.gov/growthcharts.)

Published standards exist for these body proportion measurements, which must be evaluated relative to the patient's age.[13] The upper segment to lower segment ratio, for example, ranges from 1.7 in the neonate to slightly below 1.0 in the adult.

SKELETAL MATURATION

The growth potential inherent in the tubular bones of the body can be assessed by evaluation of the progression of ossification within the epiphyses. The ossification centers of the skeleton appear and progress in a predictable sequence in normal children, and skeletal maturation can therefore be compared with normal age-related standards. This forms the basis of "bone age" or "skeletal age." It is not clear what factors determine this normal maturational pattern, but it is certain that genetic factors and multiple hormones [including thyroxine (T4), growth hormone (GH), and sex steroids] are involved in this process.

Studies in patients with mutations of the gene for the estrogen receptor[14] or for aromatase enzyme[15] have demonstrated that it is estrogen that is primarily responsible for ultimate epiphyseal fusion, although it seems unlikely that estrogen is alone responsible for all skeletal maturation.

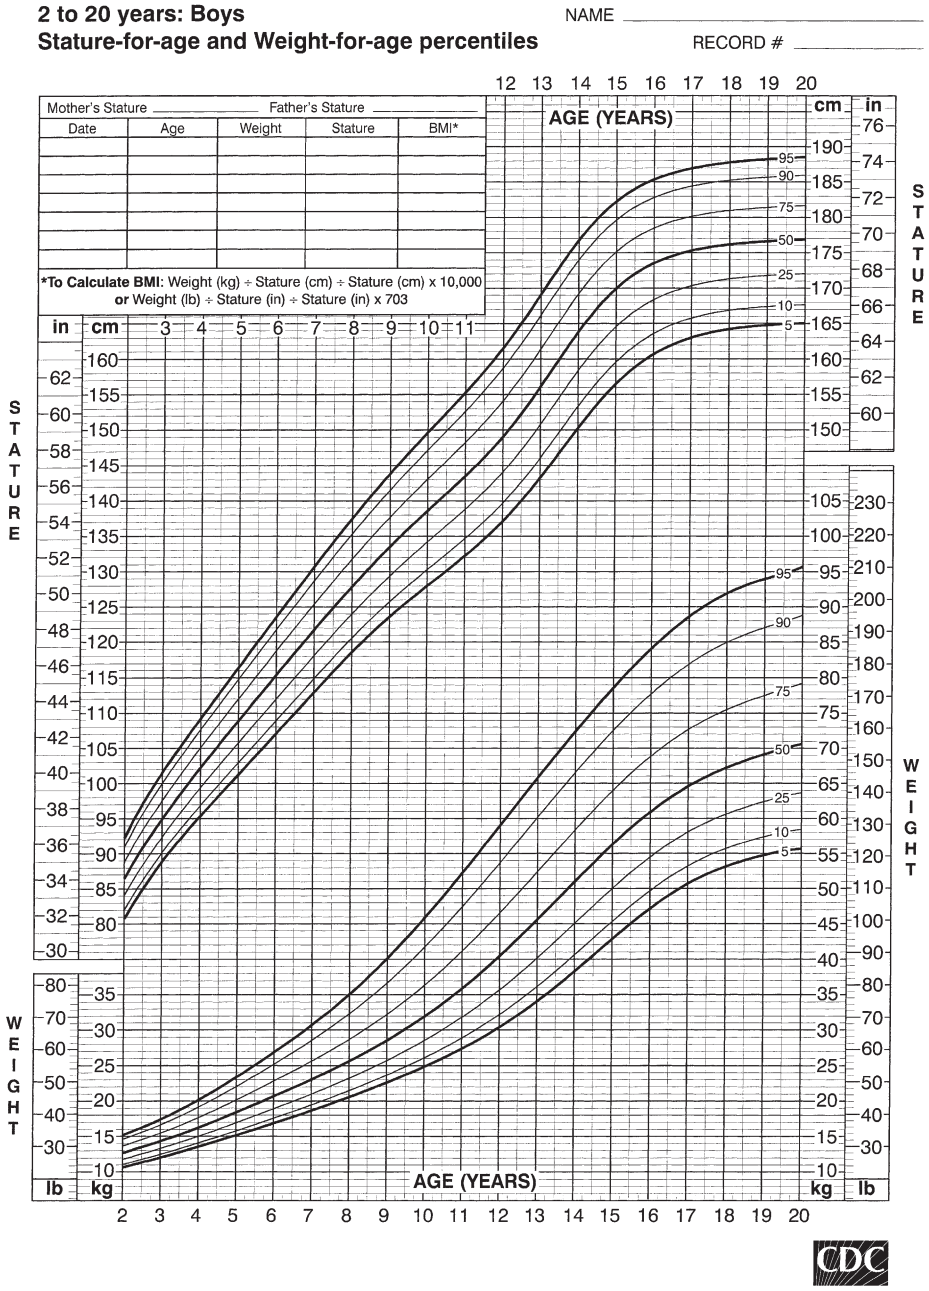

FIGURE 8-5. Stature-for-age and weight-for-age percentiles for boys (2 to 20 years). (Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion [2000]. http:www.cdc.gov/growthcharts.)

Beyond the neonatal period, a radiograph of the left hand and wrist is commonly used for determination of bone age—which can be related to the published standards of Greulich and Pyle.[16] An alternative method for assessment of bone age from radiographs of the left hand, involving a scoring system for each individual bone, has been developed by Tanner and Whitehouse and their colleagues.[17] The left hand obviously represents a compromise, because radiographs of the entire skeleton would be tedious and expensive and necessitate excessive radiation exposure. It is important to note, however, that the hand obviously does not contribute to the height of an individual and that accurate evaluation of growth potential might necessitate radiographs of the legs and spine.

A number of important caveats concerning bone age must be considered. Experience in determination of bone age is essential, and clinical studies involving bone age generally benefit from having a single reader who does all interpretations. Second, the normal rate of skeletal maturation differs between males and females (and ethnic variability exists). The standards of Greulich and Pyle are divided by sex but were developed in American white children. Finally, the Greulich-Pyle and the Tanner-Whitehouse standards were developed using normal children.[18] They are not necessarily applicable to children with skeletal dysplasias, endocrine abnormalities, or a variety of other causes of growth retardation.

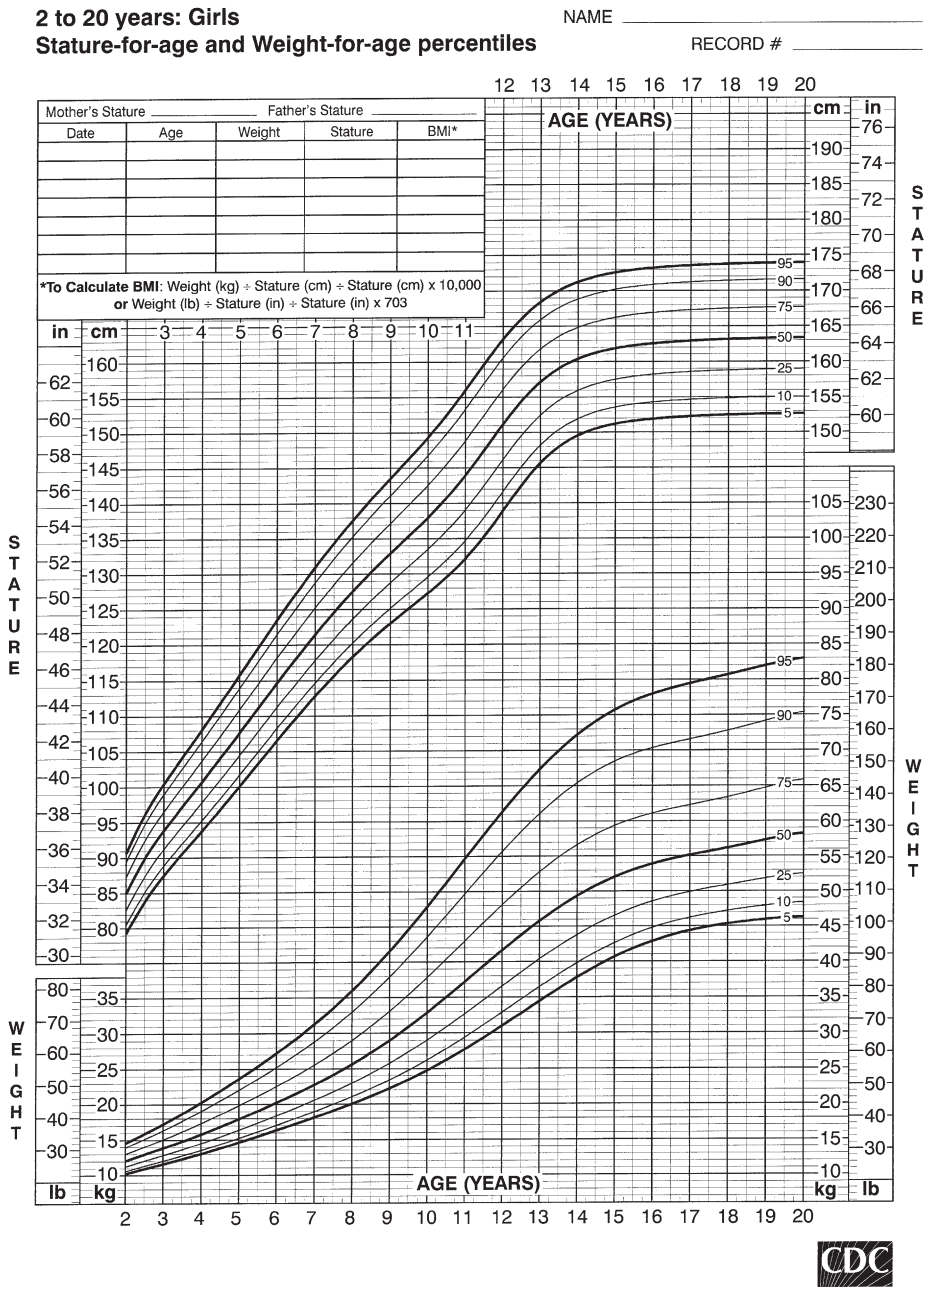

FIGURE 8-6. Stature-for-age and weight-for-age percentiles for girls (2 to 20 years). (Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion [2000]. http:www.cdc.gov/growthcharts.)

PREDICTION OF ADULT HEIGHT

The extent of skeletal maturation observed in a patient can be employed to predict the patient's ultimate height potential. Such predictions are based on the observation that the more delayed the bone age (relative to the chronologic age) the greater the length of time before epiphyseal fusion prevents further growth. The classic method for height prediction, based on Greulich and Pyle's *Radiographic Atlas of Skeletal Development*,[16] was developed by Bayley and Pinneau[19] and relies on the patient's bone age and height (Table 8-1).

Additional refinements were introduced by Tanner and colleagues[17,20] (whose system employs height, bone age, and chronologic age) and by Roche and associates,[21] who employ the combination of height, bone age, chronologic age, mid-parental height, and weight. All of these systems are by nature empirical and should never be used as absolute predictors. The more advanced the bone age the greater the accuracy of the adult height prediction, but this is natural because a more advanced bone age places a patient closer to final height.

All of these methods of predicting adult height are based on data from normal children. None of these systems has

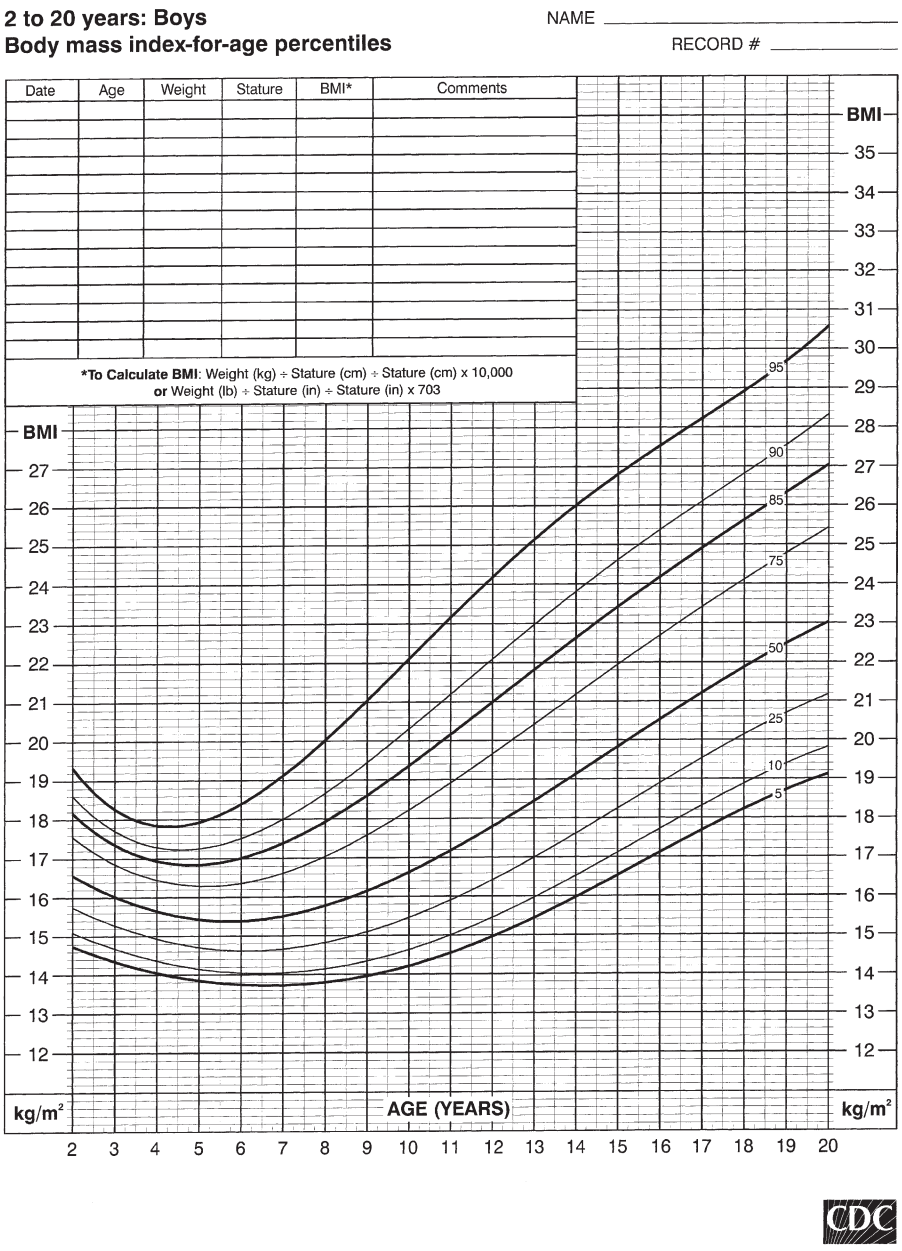

FIGURE 8-7. Body mass index-for-age percentiles for boys (2 to 20 years). (Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion [2000]. http:www.cdc.gov/growthcharts.)

been demonstrated to be accurate in children with growth abnormalities. For this type of precision, it would be necessary to develop disease-specific (e.g., achondroplasia, Turner syndrome) atlases of skeletal maturation. Recent retrospective analyses indicate that bone-age-based adult height prediction slightly under-predict female but often over-predict male children's eventual height. Predictions are also notoriously inaccurate in children born small for gestational age.

PARENTAL TARGET HEIGHT

Because genetic factors are of great importance as determinants of growth and height potential, it is always worthwhile to assess a patient's stature relative to that of siblings and parents. The parental target height can be readily ascertained by calculating the mean parental height and adding or subtracting 6.5 cm for male or female children, respectively. The standard deviation for this calculated parental target height is about 2.5 cm, and the range within which it is likely to occur 95% of the time is approximately 6 to 10 cm. As with predicted adult heights, calculated target heights should be taken as approximations.

Nevertheless, when a child's growth pattern clearly deviates from that of parents or siblings one must seriously consider the possibility of an underlying pathologic process. It is important, when possible, to measure the heights of parents and siblings rather than accepting their own statural claims. In addition, one should recall that it is not always possible to know the heights of the true

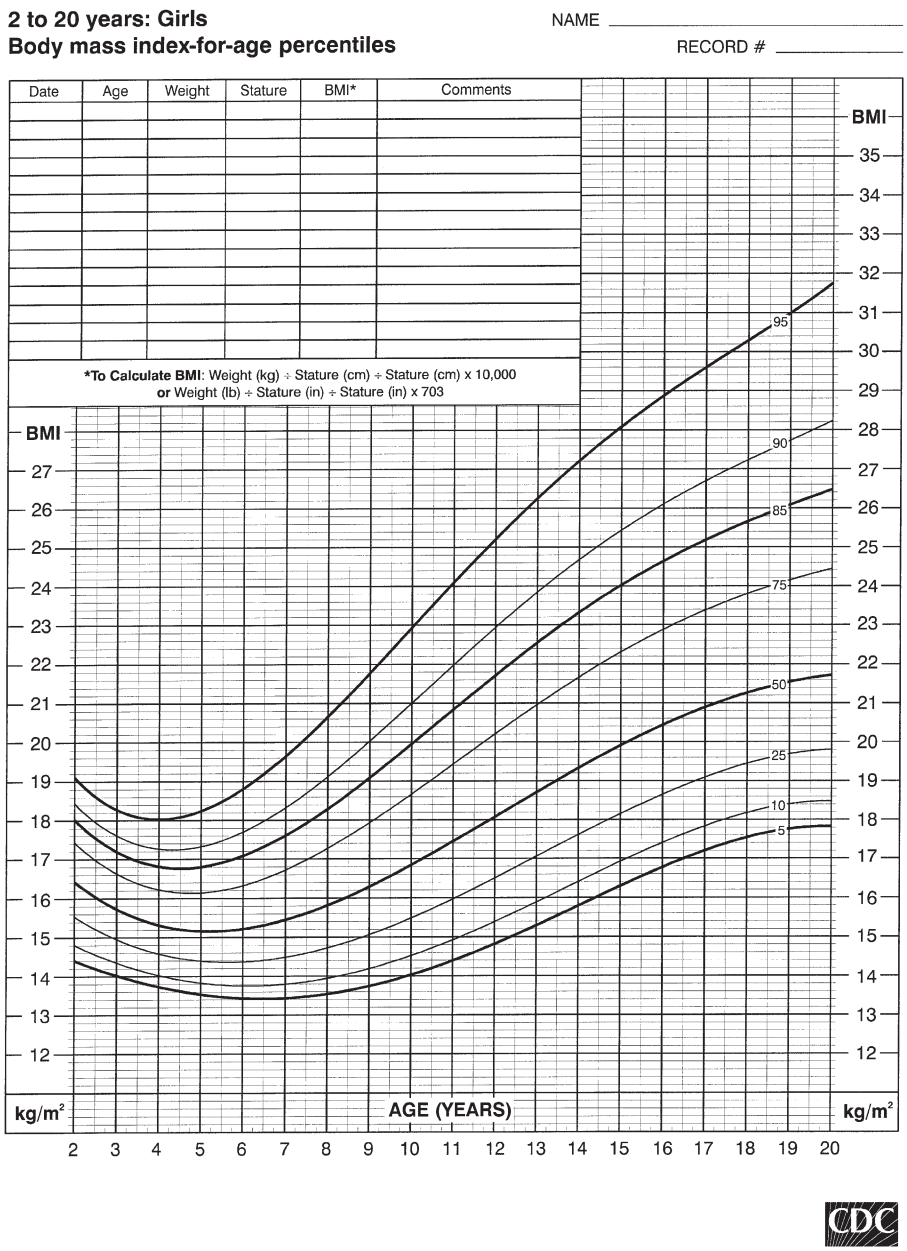

FIGURE 8-8. Body mass index-for-age percentiles for girls (2 to 20 years). Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion [2000]. http:www.cdc.gov/growthcharts.)

biologic parents (or, sometimes, who the real biologic parents actually are). Finally, short parents are not an excuse to avoid working up a child who is clearly short because this may represent a treatable genetic disorder within the growth hormone signaling cascade.

Endocrine Regulation of Growth

THE PITUITARY

The concept of the pituitary as a "master gland" controlling the endocrine activities of the body has become outdated and has been replaced by an appreciation of the importance of the brain, particularly of the hypothalamus in regulating hormonal production and secretion. Nevertheless, the pituitary gland remains central to our understanding of the regulation of growth.

Embryologically, the pituitary gland is formed from two distinct sources.[22,23] Rathke's pouch, a diverticulum of the primitive oral cavity (stomodeal ectoderm), gives rise to the adenohypophysis. The neurohypophysis originates in the neural ectoderm of the floor of the forebrain, which also develops into the third ventricle. The adenohypophysis normally constitutes 80% of the weight of the pituitary and consists of the pars distalis (also known as the pars anterior or anterior lobe), the pars intermedia (also known as the intermediate lobe), and

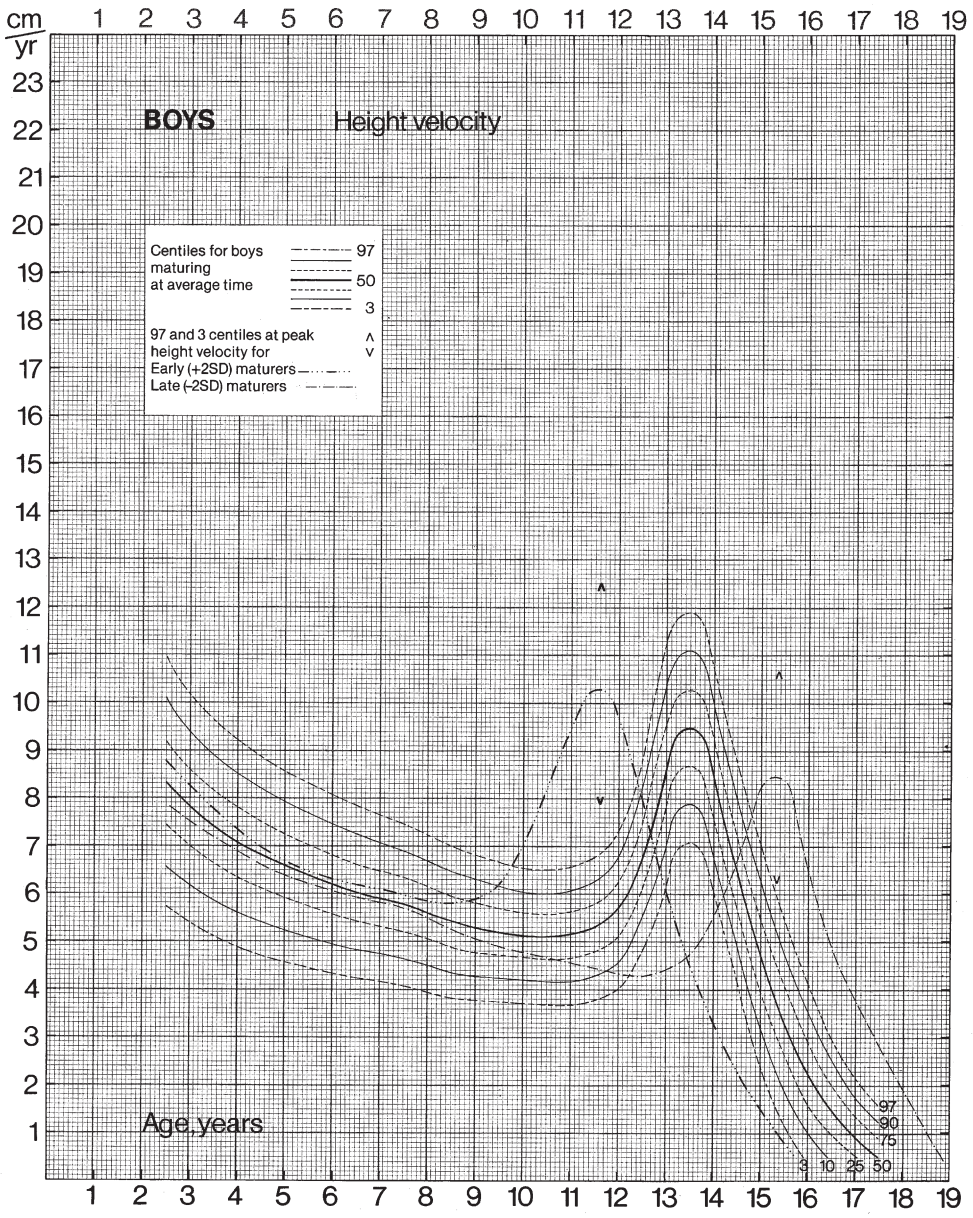

FIGURE 8-9. Height velocity chart for males from 0 to 19 years. (From Tanner JM, Davies SWD: Clinical longitudinal standards for height and height velocity for North American children. J Pediatr 107:312, 1985.)

the pars tuberalis (also known as the pars infundibularis or pars proximalis).

In humans, the pars distalis is the largest portion of the adenohypophysis and houses the great majority of hormone-producing cells. The pars intermedia is, typically, poorly developed and consists of several cystic cavities lined by a single layer of cuboidal epithelium. The pars tuberalis represents an upward extension of the pars distalis onto the pituitary stalk and may contain a limited number of gonadotropin-producing cells. The posterior pituitary (neurohypophysis) consists of the infundibular stem or hypophyseal stalk, the median eminence of the tuber cinereum, and the infundibular process (posterior lobe, neural lobe). It has no known function in the regulation of growth and will not be discussed further in this chapter.

Rathke's pouch, the origin of the adenohypophysis, can be identified in the 3-mm embryo during the third week of pregnancy. GH-producing cells can be identified by 9 weeks of gestation.[24] It is at about this time that the vascular connections between the anterior lobe of the pituitary and the hypothalamus develop,[25,26] although it has been demonstrated that hormonal production by the pituitary can occur in the absence of connections with the hypothalamus. Somatotropic cells in the pituitary are thus frequently demonstrable in the anencephalic newborn. Nevertheless, it appears likely that the initiation of development of the anterior pituitary is dependent on responsiveness of the oral ectoderm to inducing factors from the ventral diencephalon[27-31] (Figure 8-11).

The developing pituitary and hypothalamus are in close anatomic juxtaposition, and their embryonic development

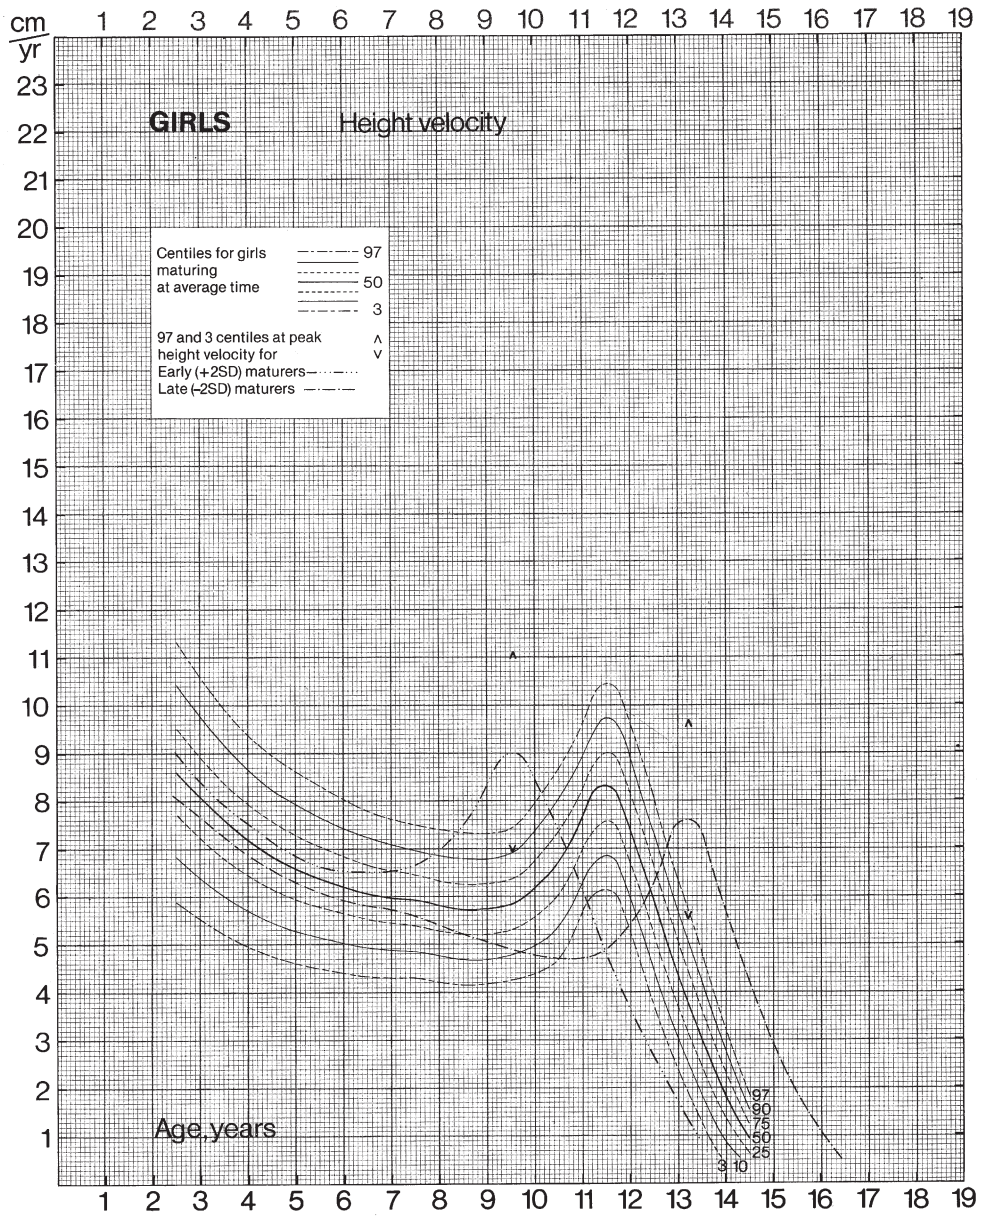

FIGURE 8-10. Height velocity chart for females from 0 to 19 years. (From Tanner JM, Davies SWD: Clinical longitudinal standards for height and height velocity for North American children. J Pediatr 107:312, 1985.)

is likely to be co-dependent.[32] Some of the diencephalic factors identified to be critical in formation and patterning of Rathke's pouch (which in the mouse is initiated on embryonic day 8) are bone morphogenic protein 4 (BMP4), Wnt5a, and fibroblast growth factor 8 (FGF8). Explant studies in the mouse have demonstrated that if Rathke's pouch is removed from the oral ectoderm on embryonic days 12 to 13 and incubated in appropriate culture medium differentiation of each of the pituitary cell types continues, indicating that by that point organogenesis of the anterior pituitary is no longer dependent on hypothalamic signals—although such signals may remain critically involved in pituitary hormone production.

Multiple pituitary-specific transcription factors are involved in the determination of pituitary cell lineages and cell-specific expression of anterior pituitary hormones.[27-31] To date, several homeodomain transcription factors have been shown to be involved in human anterior pituitary development and differentiation. Defects in each have now been associated with various combinations of pituitary hormone deficiencies (Figure 8-11 and Table 8-2). Because additional gene defects have been implicated in abnormal murine pituitary development, it seems likely that the number of human genetic defects will expand.

In the human adult, the mean pituitary size is 13 by 9 by 6 mm.[33] Mean weight is 600 mg, with a range of 400 to 900 mg. Pituitary weight is slightly greater in women than in men, and typically increases during pregnancy.[34] In the newborn, pituitary weight averages about 100 mg. Infrequently, the craniopharyngeal canal (marking the embryonic migration of Rathke's pouch) remains patent and may contain small nests of adenohypophyseal

cells—giving rise to a pharyngeal hypophysis that may be capable of hormone synthesis.[35]

Normally, however, the pituitary resides in the sella turcica immediately above and partially surrounded by the sphenoid bone. The volume of the sella turcica provides a good measure of pituitary size, which may be reduced in the child with pituitary hypoplasia.[36] It is important, however, to recognize that considerable variation in pituitary size occurs normally. The pituitary is covered superiorly by the diaphragma sellae, and the optic chiasm is directly above the diaphragma. The anatomic proximity between the optic chiasm and the pituitary is important because hypoplasia of the optic chiasm may occur together with hypothalamic/pituitary dysfunction, as in the condition of septo-optic dysplasia.[37] The patient with congenital blindness or nystagmus should be monitored carefully for hypopituitarism. In addition, suprasellar growth of a pituitary tumor may initially

manifest with visual complaints or evidence of decreases in peripheral vision.

The existence of a portal circulatory system within the pituitary is critical to normal pituitary function[25,26] (Figure 8-12). The blood supply of the pituitary derives from the superior and inferior hypophyseal arteries, branches of the internal carotid. The anterior and posterior branches of the superior hypophyseal artery may terminate within the infundibulum and the proximal portion of the pituitary stalk. Hypothalamic peptides, produced in neurons that terminate in the infundibulum, enter the primary plexus of the hypophyseal portal circulation and are transported by means of the hypophyseal portal veins to the capillaries of the anterior pituitary. This portal system thus provides a means of communication between the neurons of the hypothalamus and the hormone-producing cells of the anterior pituitary. The blood supply of the neurohypophysis is separate, deriving from the inferior hypophyseal artery. Regulation of the posterior lobe of the pituitary does not involve the hypophyseal portal circulation but, rather, is mediated through direct neural connections.

GROWTH HORMONE

Chemistry

Human GH is produced as a single-chain 191-amino-acid 22-kd protein (Figure 8-13).[38,39] It is nonglycosylated, but in its mature form contains two intramolecular disulfide bonds. GH is homologous with several other proteins produced by the pituitary or placenta, including prolactin, chorionic somatomammotropin (CS, placental lactogen), and a 22-kd GH variant (hGH-V) secreted only by the placenta.[40] The latter differs from pituitary GH by 13 amino acids. The genes for these proteins have probably descended from a common ancestral gene, even though the genes are now located on different chromosomes (chromosome 6 for prolactin and chromosome 17 for GH).[41]

The genes for GH, prolactin, and placental lactogen share a common structural organization—with four introns separating five exons. The HGH subfamily contains five members, whose genes are all located on a 78-kb

section of chromosome 17. The 5-prime to 3-prime order of the genes is GH, a CS pseudogene, CS-A, GH-V, and CS-B.[42] Normally, the vast majority of GH produced by the pituitary is of the mature 22-kd form. Alternative splicing of the second codon results in deletion of amino acids 32 through 46, yielding a 20-kd form that normally accounts for less than 10% of pituitary GH.[41-43] The remainder of pituitary GH includes desamidated and N-acetylated forms, as well as various GH oligomers.

Secretion

The pulsatile pattern characteristic of GH secretion largely reflects the interplay of multiple regulators, including two hypothalamic regulatory peptides: GH-releasing hormone (GHRH)[44,45] and somatostatin [somatotropin release–inhibiting factor (SRIF)].[46] The amino terminus of GHRH is required for stimulation of GH secretion. GHRH activity is species specific, presumably reflecting the specificity of binding to a G-protein–related receptor on the pituitary somatotropes.

Regulation of GH production by GHRH is largely transcriptionally mediated and is dependent on stimulation of adenylate cyclase and increases in intracellular cyclic adenosine monophosphate (AMP) concentrations. The GHRH receptor is a member of the G-protein–coupled receptor family B (also called the secretin family) and has partial sequence identity with receptors for vasoactive intestinal polypeptide, secretin, calcitonin, and parathyroid hormone.[47] Solid tumors secreting GHRH are a rare cause of GH excess. GHRH has previously been approved in the United States for treatment of growth hormone deficiency but has been withdrawn from the market for therapeutic purposes. It is still used as a diagnostic, especially for the identification of adult growth hormone deficiency.

Somatostatin actions appear to be related to the timing and amplitude of pulsatile GH secretion, rather than to GH synthesis. The binding of somatostatin to its specific receptor results in an inhibition of adenylate cyclase activity and a reduction in intracellular calcium concentrations.[46] Treatment of cultured somatotropic cells with GHRH and somatostatin has indicated a dominant effect of somatostatin, with reduction of intracellular calcium concentrations and inhibition of GH secretion. The pulsatile secretion of GH observed in vivo is believed to result from a simultaneous reduction in hypothalamic somatostatin release and increase in GHRH activity.[48] Conversely, a trough of GH secretion occurs when somatostatin release is increased in the presence of diminished GHRH activity. Somatostatin analogues are used therapeutically for the treatment of acromegaly, underscoring its role as a GH secretion inhibitor.

The regulation, on a neuronal basis, of this reciprocal secretion of GHRH and somatostatin is imperfectly understood. Multiple neurotransmitters and neuropeptides are involved in regulation of release of these hypothalamic factors, including serotonin, histamine, norepinephrine, dopamine, acetylcholine, g-aminobutyric acid (GABA), thyroid-releasing hormone, vasoactive intestinal peptide, gastrin, neurotensin, substance P, calcitonin, neuropeptide Y, vasopressin, corticotrophin releasing hormone,[49] and galanin.[50] These factors are clearly implicated in the alterations of GH secretion observed in a wide variety of physiologic states (such as stress, sleep,

hemorrhage, fasting, hypoglycemia, and exercise) and form the basis for a number of GH-stimulatory tests employed in the evaluation of GH secretory capacity/reserve.

GH secretion is also impacted by a variety of nonpeptide hormones, including androgens,[51,52] estrogens,[53] thyroxine,[54] and glucocorticoids.[55,56] The precise mechanisms by which these hormones regulate GH secretion are complex, potentially involving actions at the hypothalamic and pituitary levels. Practically speaking, hypothyroidism and glucocorticoid excess may each blunt spontaneous and provocative GH secretion (and therefore should be corrected prior to GH testing). Sex steroids, at the onset of puberty or administered pharmacologically, appear to be responsible for the rise in GH secretion characteristic of puberty.[57]

Synthetic hexapeptides capable of stimulating GH secretion have been developed[58] and termed *GH-releasing peptides* (GHRPs). These peptides, later recognized as analogues of the gastric hormone ghrelin, are capable of directly stimulating GH release and enhancing the GH response to GHRH.[59] These agents have the potential advantage of oral administration, and in the patient with an intact pituitary may be capable of greatly enhancing GH secretion. When these agents were administered chronically to elderly patients and to some GH-deficient children, the amplitudes of GH pulses were significantly increased. Ghrelin-mimetic ligands were used to characterize a common receptor termed the *GH secretagogue receptor* (GHS-R) for the GH-releasing substances. The GHS-R is distinct from the GHRH receptor.[60]

Subsequently, the GHS-R gene was cloned and shown to encode a unique G-protein–coupled receptor with a deduced protein sequence that was 96% identical in human and rat. Three receptor isotypes were isolated from human genomic libraries. Mutations in this receptor could cause variable degrees of GH insufficiency and short stature. Ghrelin is a 28-amino-acid peptide found in hypothalamus and stomach, and has been identified as the endogenous ligand for the growth hormone secretagogue receptor (GHS-R).[61] Ghrelin is a unique gene product that requires acetylation for normal function. Intravenous, intracerebroventricular, and intraperitoneal administration of ghrelin in animal models stimulates food intake and obesity[62] and raises plasma GH concentrations[63]—and to a lesser extent adrenocorticotropic hormone (ACTH) levels. Mutations in the ghrelin receptor have been identified as a possible cause of idiopathic short stature (ISS).[64]

This suggests that ghrelin is an important stimulus for nutrient allocation for growth and metabolism and that it represents a key component of the GH regulatory system. A second peptide encoded by the same gene as ghrelin has been identified and termed *obestatin*. This gene appears to regulate weight but not GH secretion.[65,66] Abnormalities of pituitary-specific transcription factors have been implicated in genetic forms of short stature. POU1F1 (Pit-1) is involved in the developmental regulation not only of somatotropes but of lactotropes and thyrotropes.[67] Abnormalities of POU1F1 expression are therefore associated with multiple pituitary deficiencies, including GH, thyroid-stimulating hormone (TSH), and prolactin.[68,69] Mutations of the POU1F1 gene have been described in patients with hereditary forms of multiple pituitary hormone deficiencies.

In addition to the complex regulatory processes described previously, the synthesis and secretion of GH are also regulated by feedback by the insulin-like growth factor (IGF) peptides.[70-72] IGF receptors have been identified in the pituitary.[73-75] Inhibition by IGF-1 of GH secretion has been demonstrated in multiple systems.[76] In addition, inhibition of spontaneous GH secretion has been demonstrated in humans treated with subcutaneous injections of recombinant IGF-1.[77,78] GH can be identified in fetal serum by the end of the first trimester. Serum concentrations are lower in term infants than in premature infants, perhaps reflecting feedback by the higher serum levels of IGF peptides characteristic of the later stages of gestation.[79]

Twenty-four hour GH secretion peaks during adolescence,[57] undoubtedly contributing to the very high serum concentrations of IGF-1 characteristic of puberty. GH secretion begins to decline by late adolescence, and continues to fall throughout adult life. Indeed, puberty may be considered with some justification a period of "acromegaly," whereas aging (with its characteristic decrease of GH secretion) has been termed the *somatopause*.[53,80,81]

Twenty-four hour GH production rates for normal men range from 0.25 to 0.52 mg/m^2.[82,83] A wide variety of physiologic conditions, however (in addition to aging) affect GH secretion. These include stage of sleep,[84,85] nutritional status,[86] acute fasting, exercise,[87] stress,[87] and sex steroids.[51,52] Ho and associates[53] have reported that serum estradiol concentrations are the dominant factor affecting GH secretion. Neither age nor sex influenced the integrated serum concentrations of GH when the effects of estradiol were removed from analysis. The effects of testosterone on serum IGF-1 concentrations may be at least in part independent of GH because individuals with mutations of the GH receptor (GHR) still experience a rise in serum IGF-1 during puberty.[88]

The pulsatile nature of GH secretion is readily demonstrable by frequent serum sampling, especially when coupled with sensitive assays for GH.[86] Such assays demonstrate that under normal conditions serum GH concentrations are less than 0.2 ng/mL between bursts of GH secretion. It is consequently impractical to assess GH secretion by random serum sampling. Maximal GH secretion occurs during the night, especially at the onset of the first slow-wave sleep (stages III and IV). Rapid-eye-movement (REM) sleep is, on the other hand, associated with low GH secretion.

Normal young men generally experience 12 GH secretory bursts per 24 hours. Obesity is characterized by decreased GH secretion, reflected by a decreased number of GH secretory bursts.[89] Fasting increases the number and amplitude of GH secretory bursts, presumably reflecting decreased somatostatin secretion. The impact of the pulsatile secretory nature of GH secretion on its biologic actions remains uncertain.

GH Receptor/GH-Binding Protein

The GH receptor is synthesized as a 638-amino-acid peptide, which is later processed into a mature receptor of 620 amino acids and a predicted molecular weight of 70 kDa before glycosylation. The extracellular hormone-binding

domain contains 246 amino acids, followed by a single membrane-spanning domain and a cytoplasmic domain of 350 amino acids. In humans, the circulating GH-binding protein (GHBP) appears to derive from proteolytic cleavage of the extracellular domain of the receptor.

The gene for the human GHR has been localized to chromosome 5p13.1-p12, where it spans more than 87 kb.[90,91] In the mouse[92,93] and rat,[94] on the other hand, multiple transcripts for the GHR have been identified. The larger (3.4 to 4.8 kb) transcript codes for the intact receptor, whereas the 1.2- to 1.9-kb transcript codes for the soluble GHBP. The coding and 3-prime untranslated regions of the human GHR are encoded by the nine exons, numbered 2 through 10.[95] Exon 2 corresponds to the secretion signal peptide, whereas exons 3 through 7 encode the extracellular domain. Exon 8 encodes the transmembrane domain. Exons 9 and 10 encode, respectively, the intracellular domain and the 3-prime untranslated region. Exon 3 of the GHR has been shown to be deleted in a substantial number of normal individuals. This delta-3 GHR polymorphism has been shown by some but not all investigators to determine responsiveness to GH and to be associated with birth size and postnatal growth.[96,97]

The GHR has been found to be highly homologous with the prolactin receptor and to share sequence homology with many of the receptors for interleukins, as well as receptors for erythropoietin, granulocyte-macrophage colony-stimulating factor, and interferon.[95] The GHR is a member of the class 1 hematopoietic cytokine family. Recently, a complex of the GH and the GHBP molecule has been shown to be more effective than GH alone—indicating a physiologic and possible therapeutic role for the GHBP.[98] Examination of the crystal structure of the GH-GHR complex revealed that the complex consisted of one molecule of GH bound to two GHR molecules, indicating a GH-induced receptor dimerization—which is necessary in GH action.[99] Interestingly, a genetically engineered fusion complex of GH and the GHR has been recently shown to have a significantly improved efficacy and a dramatically longer half-life compared to growth hormone alone when tested in rodent models.[100]

After binding to its receptor, and inducing receptor dimerization, GH has been demonstrated to stimulate phosphorylation of a protein with an apparent molecular weight of 120 kd. Janus Kinase 2(JAK2) has been identified as a major GHR-associated tyrosine kinase.[101] The presumed sequence of steps in GH action are binding of GH to the membrane-associated GHR, dimerization of the GHR, interaction of the GHR with JAK2, tyrosine phosphorylation of JAK2 and the GHR, changes in cytoplasmic and nuclear protein phosphorylation and dephosphorylation, and stimulation of target gene transcription. The GHR itself appears to have no intrinsic kinase activity. It is likely that colocalization of two JAK2 molecules by the dimerized GHR results in transphosphorylation of one JAK2 by the other, leading to JAK2 activation.[102]

Activated JAK2 then appears to phosphorylate the GHR on multiple tyrosine sites. GH- and JAK2-dependent phosphorylation and activation have been demonstrated for several signal transducers and activators of transcription (STAT); namely, STAT1, STAT3, and STAT5. These cytoplasmic proteins (after forming homodimers or heterodimers) translocate into the nucleus, bind DNA, and activate transcription.[103] Other GH-activated pathways include mitogen-activated protein kinases (MAPKs), extracellular signal-regulated kinase (ERK)-1 and ERK2, the insulin-signaling pathway [by means of insulin receptor substrate (IRS)-1 and IRS-2], and protein kinase C (PKC). How all of these pathways interact to mediate the various anabolic and metabolic actions of GH remains to be elucidated (Figure 8-14).

The GHBP in human plasma binds GH with high specificity and affinity, but with relatively low capacity.[104-106] The GHBP is in essence the extracellular domain of the GHR and has an apparent molecular weight of approximately 55 kDa. Initial assays for GHBP involved incubation of serum with 125-I-GH and separation of bound from free radioligand by gel filtration, high-pressure liquid chromatography, or dextran-coated charcoal. Carlsson and colleagues[107] developed a ligand-mediated immunofunctional assay (LIFA) that measures GHBP capable of binding GH. Assays of serum concentrations of GHBP have been instrumental in identifying patients with GH insensitivity (GHI) caused by genetic abnormalities of the GHR.[108,109] Patients with GHI from nonreceptor abnormalities, abnormalities of the intracellular portion of the GHR, or inability of the receptor to dimerize may, however, have normal serum concentrations of GHBP.[110]

The inhibition of GH signaling by several members of the GH-inducible suppressors of the cytokine signaling (SOCS) family has been demonstrated.[111] Evidence for the importance of SOCS proteins in controlling growth is derived from SOCS-2 knockout mice, which display gigantism.[112] By contrast, complete inhibition of GH activation of the signal transducer STAT5 and STAT5-dependent transcriptional activity is seen when cellular overexpression of SOCS family members is induced. SOCS also inhibit the GHR-dependent tyrosine phosphorylation of JAK2.[113] Endotoxin and proinflammatory cytokines such as interleukin-1b (IL-1b) and tumor necrosis factor-a (TNFa) induce a state of GH resistance.

All of these agents can also induce SOCS proteins.[114] SOCS-3 induced by IL-1b and TNFa or by endotoxin in vivo may play a role in the GH resistance induced by sepsis.[115] Critically ill patients with septic shock who had been treated with GH were shown to have increased mortality,[116] possibly related to the induction of GH resistance in specific tissues as a consequence of sepsis. Thus, the role of SOCS proteins as intracellular GH signaling antagonists appears to be important in a variety of pathophysiologic states.

GH Actions

According to the somatomedin hypothesis, the anabolic actions of GH are mediated through the IGF peptides.[117,118] Although this hypothesis is at least in part true, it appears that GH is capable of stimulating a variety of effects that are independent of IGF activity. Indeed, the effects of GH and IGF are on occasion contradictory—as evident in the "diabetogenic" actions of GH[119,120] and the glucose-lowering activity of IGFs. Green and colleagues[121] attempted to resolve some of these differences in a "dual-effector" model in which GH stimulates precursor cells, such as prechondrocytes, to differentiate.

When differentiated cells or neighboring cells then secrete IGFs, these peptides act as mitogens and stimulate clonal expansion. This hypothesis is based on the ability of IGF peptides to work not only as classic endocrine factors that are transported through the blood but as paracrine or autocrine growth factors. GH also stimulates a variety of metabolic effects, some of which appear to occur independently of IGF production—such as lipolysis,[122] amino acid transport in diaphragm[123] and heart,[124] and production of specific hepatic proteins. Thus, there are multiple sites of GH action—and frequently it is not entirely clear which of these actions are mediated through the IGF system and which might represent IGF-independent effects of GH.[125] These sites of action include the following.

- *Epiphysis:* Stimulation of epiphyseal growth.
- *Bone:* Stimulation of osteoclast differentiation and activity, stimulation of osteoblast activity, and increase of bone mass by endochondral bone formation. Lupu et al.[126] have shown that mice with a complete knockout of IGF-I (making them substantially smaller than wild-type mice) become even smaller when mated into a GH receptor knockout strain, indicating a direct IGF-independent effect of GH on growth.
- *Adipose tissue:* Acute insulin-like effects, followed by increased lipolysis, inhibition of lipoprotein lipase, stimulation of hormone sensitive lipase, decreased glucose transport, and decreased lipogenesis.[127]
- *Muscle:* Increased amino acid transport, increased nitrogen retention, increased lean tissue, and increased energy expenditure.[127]

The concept of IGF-independent actions of GH is supported by in vivo studies, in which IGF-1 cannot duplicate all of the effects of GH (such as nitrogen retention and insulin resistance). The effects of GH in normal human aging[128] and in catabolic conditions[129] are subjects of active investigation.

INSULIN-LIKE GROWTH FACTORS

Historical Background

The insulin-like growth factors (or somatomedins) constitute a family of peptides that are at least in part GH dependent and that are believed to mediate many of the anabolic and mitogenic actions of GH. Although they were originally identified in 1957 by their ability to stimulate [35S]sulfate incorporation into rat cartilage,[117] it has been established over the ensuing 45 years that they are involved in diverse metabolic activities (Figure 8-15).

In 1957, Salmon and Daughaday[117] first demonstrated that the ability of serum from hypophysectomized rats to stimulate [35S]sulfate incorporation into rat chondrocyte proteoglycans could not be restored by in vitro addition of GH. [35S]sulfate incorporation could be restored by the addition of serum from hypophysectomized rats that had been treated with GH, however, thereby demonstrating the existence of a GH-dependent "sulfation factor."

Concurrent investigations on insulin activity in rat muscle and adipose tissue indicated that only a small component of the insulin-like activity of normal serum could be blocked by the addition of anti-insulin antibodies. The remaining activity was termed *nonsuppressible insulin-like activity* (NSILA) and was subsequently demonstrated to contain two soluble 7-kd forms named *NSILA-I* and *NSILA-II*.[130,131]

A third converging line of investigation arose from studies by Dulak and Temin[132] of the mitogenic nature of bovine serum. Serum-free conditioned media from fetal

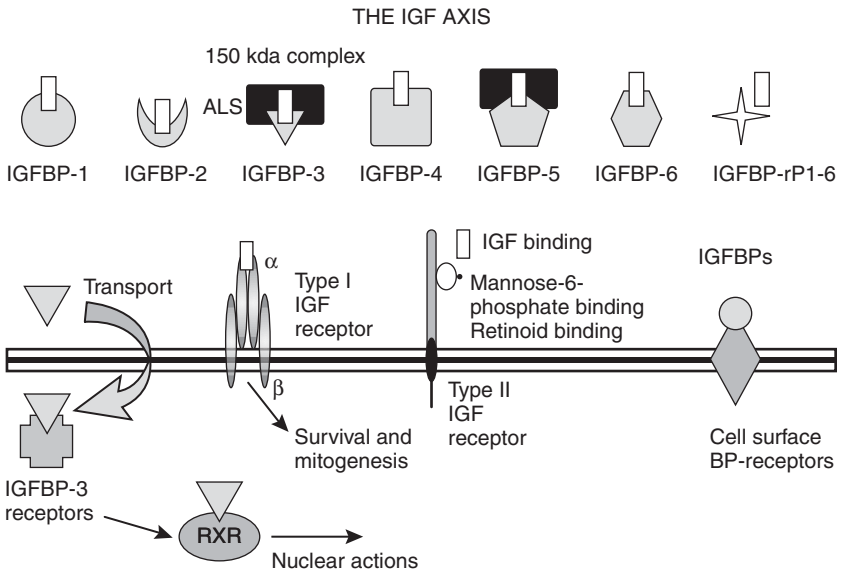

FIGURE 8-15. The insulin-like growth factor (IGF) axis. BP, binding protein; RXR, retinoid X receptor.

Buffalo rat liver cells (BRL-3A) were found to support the growth of cultured cells. The mitogenic factor in the medium was termed *multiplication-stimulating activity* (MSA) and was found to share metabolic and mitogenic activities with sulfation factor and NSILA.

In 1972, the restrictive labels of sulfation factor and NSILA were replaced by the term *somatomedin* (SM).[133] In recognition of the broad metabolic and mitogenic actions of these factors, the following criteria were established: concentration in serum must be GH dependent, must possess insulin-like activity in extraskeletal tissues, must promote the incorporation of sulfate into cartilage, and must stimulate DNA synthesis and cell multiplication.

Purification efforts yielded two legitimate somatomedin peptides: a basic peptide (SM-C) and a neutral peptide (SM-A).[134,135] In 1978, Rinderknecht and Humbel[136,137] isolated two active somatomedins from human plasma that demonstrated a striking structural resemblance to proinsulin. Accordingly, these two peptides were renamed *insulin-like growth factors* (IGFs).

IGF Structure and Molecular Biology

IGF-1, a basic peptide of 70 amino acids, correlates with SM-C—whereas IGF-2 is a slightly acidic peptide of 67 amino acids (Figure 8-16). The two peptides are structurally related, sharing 45 of 73 possible amino acid positions. They have approximately 50% amino acid homology to insulin.[118,136,137] Like insulin, both IGFs have A and B chains connected by disulfide bonds. The connecting

FIGURE 8-16. (C-peptide) region is 12 amino acids long for IGF-1 and 8 amino acids long for IGF-2 and bears no homology with the C-peptide region of proinsulin. IGF-1 and IGF-2 also differ from proinsulin in possessing carboxyl-terminal extensions (D-peptides) of 8 and 6 amino acids, respectively. It is clear that this structural homology explains the ability of both IGFs to bind to the insulin receptor and for insulin to bind to the type 1 IGF receptor. On the other hand, structural differences explain the failure of insulin to bind to the IGF-binding proteins.

Two different forms of IGF-1 precursor molecules have been identified.[118] The first 134 amino acids of each are identical, comprising the signal peptide (48 amino acids), the mature IGF-1 molecule (70 amino acids), and the first 16 amino acids of the E domain of the precursor. IGF-1A has an additional 19 amino acids (total 153 residues), whereas IGF-1B has an additional 61 amino acids (total 195 residues).

Alternative splicing of the IGF-1 gene presumably generates the two alternative messenger RNAs (mRNAs). The primary IGF-2 translation product in human, rat, and mouse contains 180 amino acids—including a 24-residue signal peptide, the 67-amino-acid mature IGF-2 sequence, and a carboxyl-terminal E-peptide of 89 amino acids.

Control of IGF gene expression appears to be complex, perhaps explaining variability in tissue expression as well as differential expression in the embryo, fetus, child, and adult.[118,138-140] IGF-1 and IGF-2 are encoded by single large genes, spanning approximately 95 and 35 kb of genomic DNA, respectively. The human IGF-1 gene contains at least six exons. Exons 1 and 2 encode alternative signal peptides, probably each containing several transcription start sites. Exons 3 and 4 encode the remaining signal peptide, the remainder of the mature IGF-1 molecule, and part of the trailer peptide. Exons 5 and 6 encode alternatively used segments of the trailer peptide (resulting in the IGF-1A and IGF-1B forms), as well as 39 untranslated sequences, with multiple different polyadenylation sites. The human IGF-1 gene is located on the long arm of chromosome 12.[141,142]

The human IGF-2 gene is located on the short arm of chromosome 11,[141-143] adjacent to the insulin gene, and spans 35 kb of genomic DNA—containing nine exons. Exons 1 through 6 encode 59 untranslated RNA, including multiple promoter sites. Exon 7 encodes the signal peptide and most of the mature protein, whereas exon 8 encodes the carboxyl-terminal portion of the protein plus the trailer peptide (whose coding is completed in exon 9). The result is that multiple mRNA species exist for both IGF-1 and IGF-2. This permits remarkable complexity in the regulation of gene expression, allowing for tissue-specific expression of specific transcripts as well as ontogenic and hormonal regulation.

Assay Methodologies for the IGF Peptides

Since their first identification in 1957, the IGF peptides have proven to be remarkably difficult to permit accurate measurement. Bioassay methods were often influenced by a variety of other serum factors capable of mimicking or inhibiting IGF action. More importantly, virtually all assays were influenced by the presence of IGF-binding proteins (IGFBPs)—which have been found in all biologic fluids tested to date.

Bioassay methods included stimulation of [35S]sulfate incorporation, using various modifications of the original method described by Salmon and Daughaday.[117,144,145] A wide variety of several bioassays included stimulation of DNA synthesis,[146] RNA synthesis, protein synthesis,[147] glucose uptake,[148] and others. In general, however, such assays were cumbersome, subject to interference by IGFBPs, and unable to distinguish between IGF-1 and IGF-2. When SM-C (and later, IGF-1 and IGF-2) were purified, it became possible to radiolabel the pure proteins and employ them in a variety of radioreceptor assays[149,150] and competitive protein-binding assays.[151,152] It was not until the development of specific antibodies that it became possible to accurately distinguish between IGF-1 and IGF-2 and measure each peptide accurately.[153-156] Current frequently used assays for IGF-I are primarily "double antibody sandwich assays" such as ELISA and have a reasonable accuracy and reproducibility.[157]

Nevertheless, the issue of IGFBPs must be dealt with in any IGF assay.[158] Powell and co-workers,[159] for example, have demonstrated that the discrepant results found in uremic sera assayed for IGF by bioassay, radioreceptor assay, and radioimmunoassay can be entirely attributed to the interference of IGFBPs. Even antibodies with high affinity and specificity will still exhibit interference by IGFBPs. This is particularly true in conditions in which there is a relatively high IGFBP/IGF peptide ratio, or at the clinical extremes of the assay [i.e., GH deficiency (GHD) or acromegaly].

In general, the most effective and reliable way to deal with IGFBPs is their separation from IGF peptides by sizing chromatography under acidic conditions.[160] IGF-1 and IGF-2, each with a molecular weight of approximately 7 kd, can be readily separated from the IGFBPs—whose molecular weights range from 25 to 45 kd (glycosylated form of IGFBP-3). This is, however, a labor-intensive procedure and has been occasionally replaced by the more rapid acid ethanol extraction.[161] Although this method may be reasonably effective for most serum samples, it is problematic in conditions of high IGFBP/IGF peptide ratios—such as conditioned media from cell lines and sera from newborns, GHD, uremia, and so on.

Alternative methodologies include the use of antibodies generated against synthetic peptides, such as the C-peptide region of IGF-1 or IGF-2. In general, such antibodies have high specificity but relatively low affinity. Nevertheless, the radiolabeled peptide does not bind to endogenous IGFBPs—offering an important advantage. An alternative approach, developed by Blum and colleagues,[162] has been the use of an antibody with high specificity for IGF-2—which permits the addition of excess unlabeled IGF-1 to saturate endogenous IGFBPs. Bang and co-workers[163] have bypassed the interference of IGFBPs by employing truncated IGF-1, which has decreased affinity for IGFBPs, as a radioligand.

At present, the most practical and effective way to perform accurate IGF assays that have minimal interference by IGFBPs is to use methodologies similar to the so-called sandwich assay.[164] These assays, which can be performed in enzyme-linked immunosorbent assay or

immunoradiometric assay, do not employ a radiolabeled IGF molecule—which can bind to IGFBPs (as in the case of conventional radioimmunoassays) and thereby lead to erroneous readings when IGFBPs are elevated.[165]

Serum Levels of IGF Peptides

In human fetal serum, IGF-1 levels are relatively low and are positively correlated with gestational age (Figure 8-17).[166,167] A correlation between fetal cord serum IGF-1 levels with birth weight has been reported by some groups,[166-168] although others have reported no correlation.[169] IGF-1 levels in human newborn serum are generally 30% to 50% of adult levels. There is a slow, gradual rise in serum concentrations during childhood, with attainment of adult levels at the onset of sexual maturation.[170]

During the process of puberty, IGF-1 concentrations rise to be two to three times the concentrations seen in adults.[171] Thus, concentrations during adolescence correlate better with Tanner stage (bone age) than with chronologic age. Girls with gonadal dysgenesis show no adolescent increase in serum IGF-1, clearly establishing the association of the pubertal rise in IGF-1 with the production of sex steroids.[172-174] It has been suggested that the pubertal rise in sex steroids stimulates IGF-1 production indirectly by first leading to a rise in GH secretion. It is of note, however, that patients with GHI from GHR mutations show a pubertal rise in serum IGF-1 despite a decline in GH levels—thereby implicating a direct effect of sex steroids on IGF-1.[178]

After adolescence, or at least after 20 to 30 years of age, serum IGF-1 concentrations demonstrate a gradual and progressive age-associated decline.[128,175] It has been suggested that this decline may be responsible for the negative nitrogen balance, decrease in body musculature, and osteoporosis characteristic of aging.[128] Although this provocative hypothesis remains unproven at this time, it has generated considerable interest in the potential use of GH and/or IGF-1 therapy in normal aging.

Human newborn levels of IGF-2 are generally 50% of adult levels. By 1 year of age, however, adult concentrations are attained with little if any subsequent decline—even out to the seventh or eighth decade of life. It is of interest that this pattern of IGF-2 concentrations is distinctly different from that in the rat or mouse (in which serum IGF-2 levels are highest in the fetus and rapidly decline postnatally to essentially undetectable levels in the adult).[176,177]

Measurement of IGF Levels in Growth Disorders

The GH dependency of the IGFs was established by the initial report from Salmon and Daughaday.[117] Following the development of sensitive and specific radioimmunoassays that could distinguish between IGF-1 and IGF-2, the relationship of serum IGF levels to GH status has been established.[157] Measurement of each IGF peptide offers its own particular advantages. IGF-1 concentrations are far more GH dependent than are IGF-2 concentrations and are useful in identifying changes in GH secretory patterns. Serum IGF-1 concentrations, however, are greatly influenced by chronologic age, degree of sexual maturation, and nutritional status. As a result, construction of age-defined normative values is critical. IGF-1 levels in normal children younger than 5 years of age may be so low that extensive overlap exists between the normal range and values in GH-deficient children.

Ranke and co-workers[178] performed GH stimulation tests in 400 children with heights below the 5th percentile and assessed the value of IGF-I as a surrogate of the diagnosis of GHD. The children subsequently diagnosed as GH deficient on the basis of standard provocative tests had very low levels of IGF-I. However, significant overlap of serum IGF-1 levels existed between GH-deficient patients and children with other forms of short stature and normal provocative GH levels. It was only in children with bone ages greater than 12 years that serum IGF-1 levels permitted complete discrimination between GHD and normal short children.

Similarly, Rose and colleagues[179] found that in children with low provocative GH or overnight GH concentrations serum IGF-1 concentrations were lower but not dramatically lower compared to children with normal GH

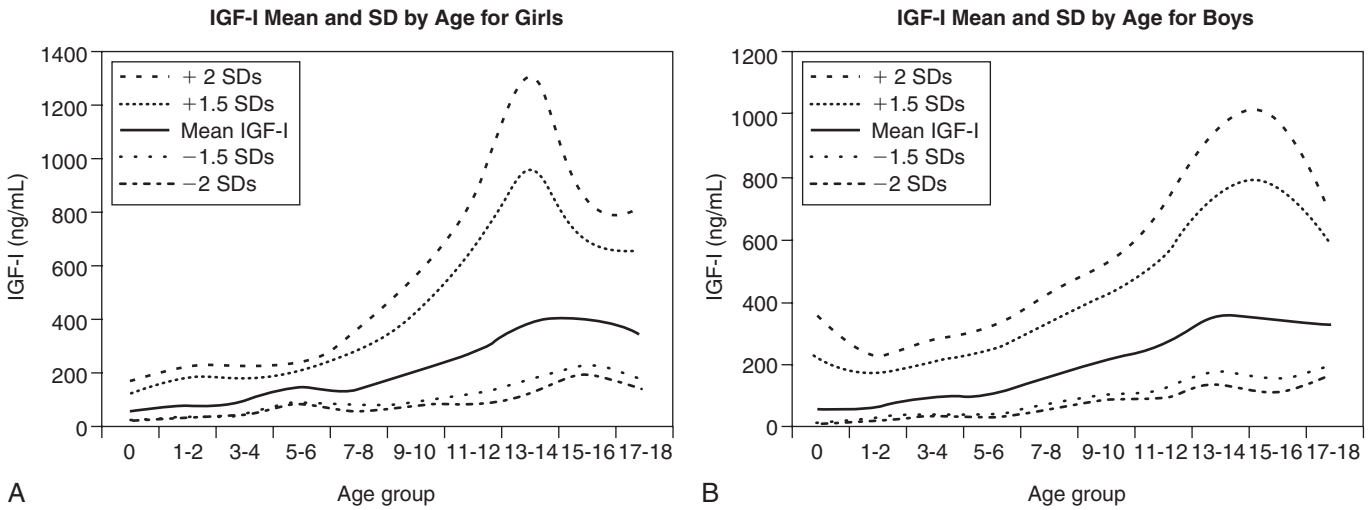

FIGURE 8-17. Serum insulin-like growth factor I (IGF-I) values by age for males *(A)* and females *(B)*. SD, standard deviation.

levels. Rosenfeld and associates[157] evaluated the efficacy of IGF-1 and IGF-2 radioimmunoassays in 68 children with GHD, 197 children of normal stature, and 44 normal short children. Eighteen percent of the GH-deficient children had serum IGF-1 levels within the normal range for age, whereas 32% of normal short children had low IGF-1 concentrations. Low IGF-2 levels were found in 52% of GH-deficient children but also in 35% of normal short children. The use of combined IGF-1/IGF-2 assays provided better discrimination, however, but this is not commonly practiced by pediatric endocrinologists.

The observation that many "normal but short" children have low serum concentrations of IGF-1 or IGF-2 (or both) calls into question the criteria by which the diagnosis of GHD is currently made. Given that provocative GH testing is both arbitrary and nonphysiologic and that inherent variability in GH radioimmunoassays exists, it is not surprising that the correlation between IGF-1 levels and provocative GH levels is imperfect. These points are further supported by observations with radioimmunoassays for IGFBP-3.

IGF Receptors

In the early 1970s, it became apparent that the IGFs could bind (although generally with low affinity) to insulin receptors, thus providing an explanation for their insulin-like activity.[180] Shortly thereafter, Megyesi and associates[181] identified distinct receptors for insulin and IGF in rat hepatic membranes. Specificity studies, employing radiolabeled IGF preparations, demonstrated that at least two classes of IGF receptors existed. Insulin, at high concentrations, could compete for occupancy of one form of IGF receptor but had essentially no affinity for the second form of receptor.

The development of methodologies for structural characterization of these receptors enabled the clear discrimination of two receptor forms[182-185] (Figure 8-15). The type 1 IGF receptor is closely related to the insulin receptor. Both are heterotetramers composed of two membrane-spanning alpha subunits of apparent molecular weight of 130 kd and two intracellular beta subunits of apparent molecular weight of 90 kd. The alpha subunits contain the binding sites for IGF-1 and are linked by disulfide bonds. The beta subunits contain a transmembrane domain, an adenosine triphosphate (ATP)-binding site, and a tyrosine kinase domain, which constitutes the presumed signal transduction mechanism for the receptor. Whereas each alpha-beta heterodimer appears capable of binding one molecule of ligand, it appears that 1 mole of the full heterotetrameric receptor binds only 1 mole of ligand.

Although the type 1 IGF receptor has been commonly referred to as the "IGF-1 receptor," studies indicate that the receptor is capable of binding IGF-1 and IGF-2 with high affinity—and both IGF peptides appear capable of activating tyrosine kinase by binding to this receptor. Affinity of the type 1 receptor for insulin is generally 100-fold less, thereby providing a mechanism for the relatively weak mitogenic effect commonly observed with insulin. Ullrich and co-workers[186] deduced the complete primary structure of the human type 1 IGF receptor from cDNA cloned from a human placental library. The mature peptide constitutes 1,337 amino acids, with a predicted molecular mass of 152 kd.

The translated alpha-beta heterodimer is subsequently cleaved at an Arg-Lys-Arg-Arg sequence at positions 707 to 710. As is the case with the insulin receptor, the beta subunit has the expected hydrophobic transmembrane domain and the intracellular tyrosine kinase domain and ATP binding site. Although it appears reasonable to presume that insulin and IGF-1 receptors have both evolved from a common ancestor protein, they are encoded by genes on separate chromosomes (chromosome 15 for the type 1 IGF receptor and chromosome 19 for the insulin receptor).

The type 1 IGF receptor mediates IGF actions on all cell types, and these actions are diverse and tissue specific. In general, it is believed that all of the effects of IGF receptor activation are mediated by tyrosine kinase activation and phosphorylation of substrates—which activate specific cellular pathways, leading to various biologic actions. Among these effects is induction of cell growth through activation of the cell cycle machinery, maintenance of cell survival (prevention of apoptosis) mediated by effects on the bcl family members, and induction of cellular differentiation, which occurs by as yet incompletely characterized mechanisms.

The substrates, which are phosphorylated by the IGF receptor, include the members of the insulin receptor substrate family (particularly IRS-1 and IRS-2) because both of the knockout mice models for these genes result in poor growth (as well as insulin resistance).[187] Other IRS molecules may have a negative feedback role in regulating IGF action.[188] In addition, several other signaling molecules respond to IGF receptor activation. Blockade of the IGF-I receptor has been proposed as a cancer therapy, and clinical studies are showing promise in early trials.[189]

It is of particular note that a prototypic molecule for the IGF-1/insulin receptor in nematodes (termed Daf2) is related to longevity, such that mutations of this gene extend the life expectancy of these organisms. This extension of life expectancy in nematodes has also been shown for other components of the GH-IGF system, as well as being demonstrated in several other species including flies and mice.[190] It is unclear, however, what relevance the IGF-1/insulin receptor has for human longevity (though this question is under investigation). The type 2 IGF receptor, however, bears no structural homology with either the insulin or the type 1 IGF receptors. On sodium dodecyl sulfate–polyacrylamide gel electrophoresis, the type 2 IGF-R has been demonstrated to migrate at an apparent molecular weight of 220 kd under nonreducing conditions and 250 kd after reduction—indicating that it is a monomeric protein.

The cloned human type 2 receptor has a predicted molecular mass of 271 kd and is characterized by a lengthy extracellular domain containing 15 repeat sequences of 147 residues each,[191] followed by a 23-residue transmembrane domain and a small cytoplasmic domain consisting of only 164 residues. The receptor does not contain an intrinsic tyrosine kinase domain or any other recognizable signal transduction mechanism. Surprisingly, the type 2 IGF receptor has been found to be identical to

the cation-independent mannose-6-phosphate (CIM6P) receptor—a protein involved in the intracellular lysosomal targeting of a variety of acid hydrolases and other mannosylated proteins.[192,193] The majority of these receptors are located on intracellular membranes, where they are in equilibrium with receptors on the plasma membrane.[194]

Why this receptor binds IGF-2 and mannose-6-phosphate–containing lysosomal enzymes remains unresolved. Unlike the type 1 IGF receptor, which binds both IGF peptides with high affinity and insulin with 100-fold lower affinity, the type 2 receptor only binds IGF-2 with high affinity. IGF-1 binds with substantially lower affinity, and insulin not at all.[194] One mole of IGF-2 binds per mole of receptor. The binding sites for IGF-2 and mannose-6-phosphate appear to reside in different portions of the receptor. Nevertheless, the two classes of ligand do show some reciprocal inhibitory effects on receptor binding—suggesting a potential effect of IGF-2 on the sorting of lysosomal enzymes.

Most studies have indicated that the classic mitogenic and metabolic actions of IGF-1 and IGF-2 are mediated through the type 1 IGF receptor, with its tyrosine kinase signal transduction mechanism. Conover and co-workers[195] and Furlanetto and associates[196] have demonstrated that monoclonal antibodies directed against the IGF-1 binding site on the type 1 IGF receptor inhibit the ability of IGF-1 and IGF-2 to stimulate thymidine incorporation and cell replication. Similarly, several groups have shown that polyclonal antibodies capable of blocking IGF-2 binding to the type 2 IGF/mannose-6-phosphate receptor do not block IGF-2 actions.[197-199]

More direct evidence for the role of the type 1 IGF receptor in mediating classic IGF actions of IGF-2 comes from the use of IGF-2 analogues as probes of receptor function. IGF-2 analogues with decreased affinity for the type 1 receptor but preserved affinity for the type 2 receptor were markedly less potent than IGF-2 in stimulating DNA synthesis.[200] In further support of the concept that the type 2 IGF receptor does not mediate the mitogenic actions of IGF-2 it has been shown that the mannose-6-phosphate receptor in hepatic tissues from chicken[201] or frogs[202] does not bind IGF-2. Presumably, IGF-2 mitogenic actions in these species are mediated solely through the type 1 IGF receptor.

Nevertheless, a number of observations are consistent with the possibility of an IGF-2 action mediated via the type 2 IGF receptor. Rogers and Hammerman[203] have suggested that the type 2 receptor is involved in production of inositol triphosphate and diacylglycerol in proximal tubule preparations and canine kidney membranes. Tally and co-workers[204] have reported that IGF-2 stimulates the growth of a subclone of the K562 human erythroleukemia cell line, an action not duplicated by either IGF-2 or insulin. Minniti and co-workers[205] reported that IGF-2 appears capable of acting as an autocrine growth factor and cell motility factor for human rhabdomyosarcoma cells, actions apparently mediated through the type 2 receptor. It has been suggested that IGF-2 can activate a calcium-permeable cation channel by means of the type 2 IGF receptor, perhaps through coupling to a pertussis toxin–sensitive guanine nucleotide–binding protein (Gi protein).[206]

It now appears that the type 2 IGF receptor binds several other molecules in addition to IGF-2. The ability of this receptor to bind mannose-6-phosphate–containing enzymes (such as cathepsin and urokinase) is well recognized and may be important in its ability to remove these enzymes from the cellular environment, thus modulating tissue remodeling.[207] In addition, reports indicate that the type 2 IGF receptor binds retinoic acid and may mediate some of the growth inhibitory effects of retinoids.[208] As discussed later in the chapter, knockout of the type 2 IGF receptor results in excessive growth. It appears that this receptor acts as a growth inhibitory component of the IGF system responding to and mediating multiple antimitogenic systems.[209]

The occasional observation of seemingly anomalous competitive binding results[210] has led to the suggestion that variant or atypical insulin and IGF receptors might exist.[211] One possible explanation for such findings is the existence of hybrid receptors composed of 1 alpha-beta dimer of the insulin receptor and 1 alpha-beta dimer of the type 1 IGF receptor.[212] Ligand-dependent formation of hybrid IGF/insulin receptors has been reported by Treadway and associates,[213] and studies with monoclonal antibodies specific for the insulin or type 1 IGF receptor have suggested that such receptors may develop spontaneously in cells with abundant native receptors.[214] The physiologic significance of such hybrid receptors, however, is entirely speculative.

IGF-Binding Protein Superfamily

Although insulin and the IGFs share significant structural homology, and despite the structural-functional similarity of the insulin and type 1 IGF receptors, the IGFs differ from insulin in one important respect. In contrast to insulin, the IGFs circulate in plasma complexed to a family of binding proteins.[215-217] These carrier proteins extend the serum half-life of the IGF peptides, transport the IGFs to target cells, and modulate the interaction of the IGFs with their surface membrane receptors.

The existence of IGFBPs was initially inferred from chromatographic studies of size distribution of IGF peptides in serum,[218] but it has only been in the decade that the complexity of the interactions among the IGFs, IGFBPs, and IGF receptors has been fully appreciated. The identification and characterization of IGFBPs in body fluids and in conditioned media from cultured cells have been facilitated by the development of a number of biochemical and assay techniques, including gel chromatography, radioreceptor assays, affinity cross-linking, Western ligand blotting,[219] immunoblotting, and recently specific radioimmunoassay and ELISA assays. It has been the study of the molecular biology of the IGFBPs that has provided the most information concerning their structural interrelationship, however.

Six distinct human and rodent IGFBPs have been cloned and sequenced.[216,217,220] Their structural characteristics are summarized in Figure 8-18. The determination of the primary amino acid sequences from the cloned cDNAs of the IGFBPs has revealed important structural relationships among the IGFBPs. Probably the most impressive similarity in structure is the conservation of the

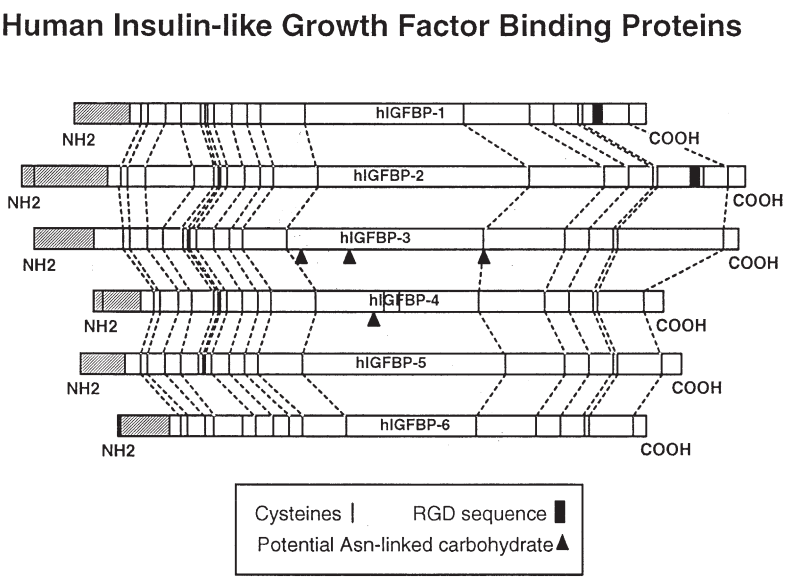

FIGURE 8-18. Schematic representation of the insulin-like growth factor (IGF)–binding proteins. (Adapted from Lamson G, Giudice L, Rosenfeld RG: Insulin-like growth factor binding protein and molecular relationship. Growth Factors 5:19, 1991.)

number and placement of the cysteine residues. The total number of cysteines varies from 16 to 20, and each of the IGFBPs has cysteine-rich regions at the amino and carboxyl termini of the protein. Conservation of the spatial order of the cysteines presumably indicates that the secondary structure of the IGFBPs, which is dependent on disulfide bonding, must also be well maintained. Disulfide bonding establishes the IGF-binding site of each IGFBP. Reduction of the binding proteins results in loss of IGF binding.

Analysis of the amino acid sequences of the IGFBPs also reveals the presence of an arginine-glycine-aspartic acid (RGD) positioned near the carboxyl terminus of IGFBP-1 and IGFBP-2.[221] This sequence has been demonstrated to be the minimum required sequence in many extracellular matrix proteins for their binding by membrane receptors of the integrin protein family. It has been suggested that IGFBPs may associate with the cell surface through such amino acid sequences. On the other hand, IGFBP-3 (which lacks an RGD sequence) also appears capable of specific binding to cell membrane receptors.[222,223] Membrane proteins capable of specifically binding IGFBP-3 have been proposed.[224]

Under most conditions, the IGFBPs appear to inhibit IGF action—presumably by competing with IGF receptors for IGF peptides.[225] This is supported by the observation that IGF analogues with decreased affinity for IGFBPs generally appear to have increased biologic potency.[226-228] In many studies involving transfection of the hIGFBP-3 gene cells, expression of IGFBP-3 resulted in an inhibition of cell growth even in the absence of added IGF—suggesting a direct inhibitory role of the binding protein.[229] Under specific conditions, however, several of the IGFBPs apparently are capable of enhancing IGF action—perhaps by facilitating IGF delivery to target receptors.[230]

Of interest is the recent discovery of several groups of cysteine-rich proteins that contain domains strikingly similar to the amino-terminal domain of the IGFBPs. This has led to the proposal of an IGFBP superfamily,[231] which includes the family of six high-affinity IGFBPs—as well as a number of families of IGFBP-related proteins (IGFBP-rPs). Three of the IGFBP-rPs (Mac25/IGFBP-rP1; connective tissue growth factor, CTGF/IGFBP-rP2; NovH/IGFBP-rP3) have been shown to bind IGFs, although with considerably lower affinity than in the case of IGFBPs. Like the IGFBPs, the IGFBP-rPs are modular proteins—and the highly preserved amino-terminal domain appears to represent the consequence of exon shuffling of an ancestral gene. It is not clear what role, if any, the IGFBP-rPs play in normal IGF physiology. However, it is likely that they can influence cell growth by IGF-independent (and perhaps IGF-dependent) mechanisms.

Evidence indicates that IGFBPs are essentially bioactive molecules that in addition to binding IGF have a variety of IGF-independent functions. These clearly include growth inhibition in some cell types,[232] growth stimulation in other tissues,[233] direct induction of apoptosis,[234] and modulation of the effects of other non-IGF growth factors. These effects of IGFBPs are mediated, undoubtedly, by binding to their own receptors. These IGFBP-signaling pathways are currently being unraveled and involve the interaction of IGFBPs with nuclear retinoid receptors as well as with other molecules on the cell surface and in the cytoplasm.[235] Because IGFBP-3 is regulated by GH, it is intriguing that in vivo IGFBP-3 enhances IGF-I action when given to hypophysectomized rats (rather than inhibiting it).[236] The mechanisms involved in this effect have not been elucidated but may explain the limited effects of IGF-1 therapy on the growth of Laron patients (discussed later in the chapter).

Analysis of IGFBPs is further complicated by the presence of IGFBP proteases, capable of various levels of IGFBP degradation.[237,238] Initially reported in the serum of pregnant women,[237,238] proteases for IGFBP-3, -4, and -5 have already been demonstrated in a variety of biologic fluids—including serum, seminal plasma,[45] cerebrospinal fluid,[239] and urine.[240] Proteolysis of IGFBPs complicates their assay by both Western ligand blotting

and radioimmunoassay methodologies and must be taken into consideration when concentrations of the various IGFBPs in biologic fluids are reported.[241] The physiologic significance of limited proteolysis of IGFBPs remains to be determined, although evidence suggests that protease activity results in decreased affinity of the IGFBP for IGF peptides.

The relative amounts of each of the IGFBPs vary among biologic fluids. IGFBP-1 is the major IGFBP in human amniotic fluid.[242] IGFBP-2 is prominent in cerebrospinal fluid[243] and seminal plasma.[244] IGFBP-3 is the major IGFBP in normal human serum and demonstrates clear GH dependence.[245] Among the IGFBPs, IGFBP-3 and IGFBP-5 are unique in that they normally circulates in adult serum as part of a ternary complex consisting of IGFBP-3 or IGFBP-5, an IGF peptide, and an acid-labile subunit.[246]

Specific immunoassays have been developed for the IGFBPs, including IGFBP-1,[242,247,248] IGFBP-2,[249] and IGFBP-3.[241,250,251] Currently, measurement of IGFBP-3 appears to have the greatest potential clinical value because this IGFBP appears to be directly GH dependent (Figure 8-19). Blum and associates[34] have suggested that radioimmunoassay determination of serum concentrations of IGFBP-3 might be more specific (but less sensitive) than IGF-1 assays in the diagnosis of GHD because normal levels of IGF-1 are so low in young children and many "normal" short children have low levels of IGF-1. Because IGFBP-3 determinations reflect not only IGF-1 levels but IGF-2 concentrations, their age dependency is not nearly as striking as that of IGF-1. Even in young children, normal levels are above 500 ng/mL. The use of IGFBP assays in the evaluation of IGF deficiency and GHD is discussed later in this chapter.

Targeted Disruption of Components of the IGF System

The critical role of the IGF system in fetal and postnatal growth was demonstrated in a series of elegant gene knockout studies in mice.[252] Unlike GH and GHR knockouts,[157] which are near normal size at birth, Igf1 null mice have a birth weight 60% of normal.[88] Postnatal growth is abnormal, and the surviving mice are only 30% of normal size by 2 months of age. A similar prenatal and postnatal growth phenotype has been observed in a reported human case of an IGF-1 gene deletion.[253]

Igf2 null mice (or heterozygous mice carrying a paternally derived mutated Igf2 gene) also have birth weights 60% of normal and remain about 60% of normal size throughout life.[254] When the gene for the IGF-1 receptor is knocked out (Igf1r null mice), the mice are severely growth retarded with a birth weight only 45% of normal and die soon after birth—apparently of respiratory failure.[255] The addition of an Igf1 knockout to the Igf1r knockout does not change the growth characteristics significantly, consistent with the hypothesis that IGF-1 is signaling exclusively (at least from the perspective of growth) through the IGF-1 receptor. On the other hand, the combination of Igf2 and Igf1r knockouts results in further growth retardation (birth weight 30% of normal)—indicating that IGF-2 is signaling through the IGF-1 receptor and a second receptor (probably the insulin receptor).

The relationship between GH and IGF-1 in controlling postnatal growth was analyzed in mouse mutants lacking GHR, IGF-1, or both.[126] This demonstrated that GH and IGF-1 promote postnatal growth by independent and common functions because the growth retardation of double GHR/IGF-1 null mice is more severe than that observed with either class of single mutant. In fact, the body weight of these double-mutant mice is only approximately 17% of normal—indicating IGF-independent GH actions. Thus, the growth control pathway in which the components of the GH/IGF-1 signaling systems participate constitutes the major determinant of body size.

The Igf2 gene has been shown to be maternally imprinted in mice and humans (only the paternal gene is expressed). On the other hand, the gene for the IGF-2 receptor (Igf2r) is paternally imprinted (although only in mice).[256] The phenotypes of Igf2r null mice or of heterozygous mice inheriting a mutated maternal gene are indistinguishable and demonstrate overgrowth, with birth weights 140% of normal. Because this receptor normally degrades IGF-2, increased growth reflects excess IGF-2

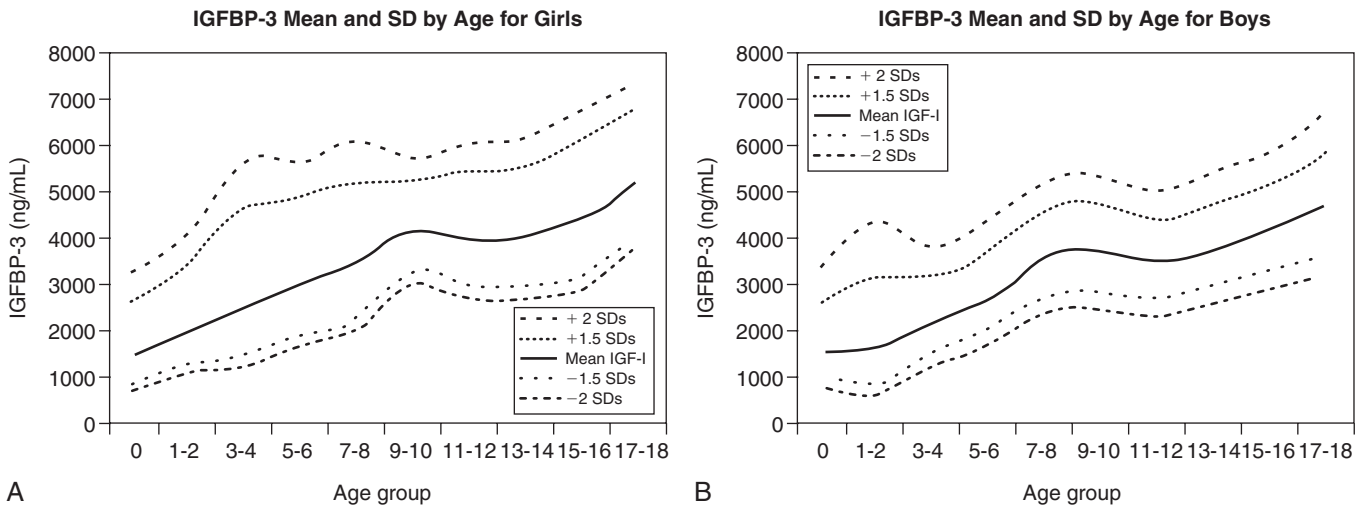

FIGURE 8–19. Insulin-like growth factor–binding protein 3 (IGFBP-3) values by age for males *(A)* and females *(B)*. SD, standard deviation.

acting through the IGF-1 receptor. As mentioned previously, mice with deletions in GH and GH-receptor-related genes (as well as IGF-1R and downstream signaling genes) display increased life span and reduced oxidative stress.

OTHER GROWTH FACTORS

The FGF Family of Peptides and Receptors

Fibroblast growth factors (FGFs) constitute an important and rapidly expanding family of peptide cytokines, which are important in the regulation of many tissues. Initially, it was suggested that these factors may be specific for cells of stromal lineage. However, it appears that many other cells respond to FGFs as well. There are at least seven different FGFs (FGF-1 through FGF-7) that have been identified, including the best characterized acidic FGF (aFGF or FGF-1), basic FGF (bFGF or FGF-2), and keratinocyte growth factor (KGF or FGF-7).

The FGFs mediate their actions by binding to at least three receptors[257] (FGFR1, FGFR2, and FGFR3), which have distinct tissue distributions.[258] For the most part, FGFs appear to be autocrine-paracrine growth factors that participate in organ growth and differentiation (as well as in carcinogenesis) but not in somatic growth. An exception to this rule is the observation that the genetic form of dwarfism known as achondroplasia is caused by a mutation in the FGFR3 gene, suggesting that normal FGFR3 signaling is essential to the normal growth of long bones.[259] A human mutation in the FGFR2 gene causes craniosynostosis, a condition characterized by abnormal closure of the bones in the skull but normal long bone growth.[260] So far, targeted disruptions of several murine FGF and FGFR genes have been reported—and the phenotypes associated with them include various developmental abnormalities.

The EGF System

Epidermal growth factors (EGFs) and their receptors are ubiquitous in many tissues and participate in developmental processes in mice, such as precocious eyelid opening and tooth eruption. The mitogenic actions of EGF have been extensively explored in cell culture systems, and the receptor for EGF was characterized as a prototype model for signal transduction involving tyrosine kinases. The extensive in vitro data indicate multiple cellular functions of EGF. EGF has been identified in most body fluids of several mammalian species. However, neither EGF antibody administration to newborn animals nor gene targeting of EGF has caused major deleterious effects—as might have been expected from the in vitro studies.[261]

The EGF family of growth factors appears to be important in mammalian development and function, although the precise roles and significance are not yet clear. Members of the EGF family may have a role in embryogenesis and fetal growth because receptors have been identified in fetal tissues. It has been proposed that abnormal EGF-EGF receptor interactions may be instrumental in the development of cancer, but it appears that they are not involved in somatic growth.

Other Growth-Promoting Peptides

An ever-growing number of growth factors are being recognized, and multiple hormones and peptides are being characterized as having growth-promoting activities in certain cell types. In general, these molecules appear to lack somatic growth-promoting effects but play important autocrine-paracrine and endocrine roles. Notable among these molecules are groups of growth factors that have tissue-specific effects. Endothelin, platelet-derived growth factor (PDGF), and vascular-epithelial growth factor (VEGF) regulate angiogenesis and other vascular processes in addition to modulating the function of numerous cultured cells. A variety of hematopoietic growth factors [such as the granulocyte and macrophage colony-stimulating factors (GCSF, MCSF), erythropoietin, and thrombopoietin] promote the growth of the different lineages of the hematopoietic cells.

The growth of various cells of the immune system is stimulated by an array of cytokines, including interleukins and interferons. The complex array of cells that comprise the nervous system is under the regulatory influence of specific growth factors, such as nerve growth factor (NGF), the neurotrophins, and brain- and glial-derived neurotrophic factors (BDNF, GDNF). Other growth factors that have been attributed to specific tissues [e.g., hepatocyte growth factor (HGF)] are being recognized as having a general growth-promoting effect in numerous tissues, and additional organ-specific growth regulatory processes have been described in the gastrointestinal tract and kidneys.

Growth Inhibitory Peptides

Of particular interest is a class of cytokines that can negatively modulate cellular growth. Transforming growth factor-beta (TGFb) can act as an agent that mediates cellular growth and malignant transformation and as a growth inhibitory substance that has the potential of arresting the growth of normal and neoplastic cells. Tumor necrosis factors (TNFs) and other compounds have been reported to have similar effects.

These molecules may regulate the entry of cells into programmed cell death (apoptosis). The growth inhibitory processes of TGFb and other cytokines may prove to be of great importance in the development of cancer treatments. A family of genes/proteins, of which the most important is p53, is also critical to growth and tumor suppression.[262] These tumor suppressors may be involved in fetal growth.

SEX STEROIDS

Whereas androgens and estrogens do not contribute substantially to normal growth before the onset of puberty, the adolescent rise in serum sex steroid concentrations is an important part of the pubertal growth spurt. States of androgen or estrogen excess before epiphyseal fusion are invariably characterized by rapid linear growth and skeletal maturation. Thus, just as growth deceleration requires further evaluation growth acceleration can be just as abnormal and may be a sign of increased sex steroids—as

observed in precocious puberty and virilizing congenital adrenal hyperplasia.

A GH-replete state is obligatory for a normal growth response to sex steroids. Children with GHD do not have a normal growth response to either endogenous or exogenous androgens. Although androgens work at least in part by enhancing GH secretion, they must also have a direct effect on IGF-1 production—as observed with the rise in serum IGF-1 concentrations and pubertal growth spurt characteristic of children with mutations of the GHR.[88]

Androgens and estrogens have been shown to increase skeletal maturation. Advancement of skeletal age and epiphyseal fusion appear to be estrogen mediated, as indicated by the report of tall stature with open epiphyses in a patient with a mutation of the estrogen receptor[14] and by similar findings in those with inactivating mutations of the gene regulating aromatase that converts androgens to estrogens.[263] Whatever the mechanism, however, clinical states of androgen or estrogen excess are characterized by disproportionate skeletal maturation and premature epiphyseal fusion. Interestingly, a condition of aromatase excess has been described, resulting from mutations in the propoter region of the gene and leading to early epiphysial closure and gynecomastia.[264]

THYROID HORMONE

Thyroid hormone is a major contributor to postnatal growth, although like GH it is of relatively little importance to growth of the fetus. Hypothyroidism occurring postnatally can, however, result in profound growth failure and virtual arrest of skeletal maturation. In addition to a direct effect on epiphyseal cartilage, thyroid hormone appears to have a permissive effect on GH secretion. Patients with hypothyroidism have decreased spontaneous GH secretion and have a blunted response to GH provocative tests. Treatment with thyroid hormone results in rapid "catch-up" growth, which is typically accompanied by marked skeletal maturation—potentially resulting in overly rapid epiphyseal fusion and compromise of adult height.

Growth Retardation

Systems for classification of growth disorders are problematic because diagnostic categories have not always been sharply defined and frequently overlap. Genetic short stature, for example, may often be associated with constitutional delay of growth and maturation—and both disorders fall under the umbrella of ISS. Because diagnostic criteria for GHD have been problematic, overlap has frequently existed among genetic short stature, constitutional delay, and the vague category of "partial" GHD. In addition, the cause of growth failure in intrauterine growth retardation (IUGR) and various syndromes associated with poor growth has generally remained obscure.

Table 8-3 represents an effort at classification of growth retardation. Growth disorders have been subdivided into primary growth abnormalities, in which the defect(s) appears to be intrinsic to the growth plate; genetic short stature; and secondary growth disorders (i.e., growth failure resulting from chronic disease or endocrine disorders). In recent years, the category of "IGF deficiency (IGFD)" has become accepted as an overall category encompassing disorders that can result from various causes of GH deficiency (sometimes called secondary IGFD) or GH-insensitivity (sometimes referred to as primary IGFD). The category of "IGF deficiency" takes on special meaning in light of recent recommendations for reevaluation of the diagnosis of GHD and primary IGFD.

TABLE 8-3

Classification of Growth Retardation

I. Primary Growth Abnormalities
A. Osteochondrodysplasias
B. Chromosomal abnormalities

II. Secondary Growth Disorders
A. Malnutrition
B. Chronic disease
C. Intrauterine growth retardation
D. Endocrine disorders
  1. Hypothyroidism
  2. Cushing syndrome
  3. Pseudohypoparathyroidism
  4. Vitamin D deficient or resistant rickets

III. IGF Deficiency
A. Secondary IGFD
- GH deficiency due to hypothalamic dysfunction
- GH deficiency due to pituitary GH deficiency

B. Primary IGFD (GH insensitivity)
- Primary GH insensitivity
- Secondary GH insensitivity (Stat-5b)
- Primary defects of IGF synthesis
- Primary defects of IGF transport/clearance (ALS)

C. IGF resistance
- Defects of the IGF-1 receptor
- Post-receptor defects

IV. Idiopathic Short Stature
1. Constitutional delay of growth and puberty with normal height prediction
2. ISS with delayed bone age and tempo of puberty
3. ISS with normal bone age and tempo of puberty
4. ISS with a familial component
5. ISS without a familial component

GH, growth hormone; IGF, insulin-like growth factor.

PRIMARY GROWTH ABNORMALITIES

Osteochondrodysplasias

The osteochondrodysplasias represent a heterogeneous group of disorders characterized by intrinsic abnormalities of cartilage and/or bone.[265] These conditions share the following features: genetic transmission; abnormalities in the size and/or shape of bones of the limbs, spine, and/or skull; and radiologic abnormalities of the bones (generally). More than 100 osteochondrodysplastic conditions have been identified, based on physical features and radiologic characteristics. The ongoing characterization of

biochemical and molecular abnormalities in these conditions will undoubtedly lead to an increase in the number of these disorders.

An international classification for the osteochondrodysplasias was developed.[266] Table 8-4 provides a brief summary of this classification. Of note, the category of dysostoses has been dropped from the classification—which now focuses on developmental disorders of chondro-osseous tissues. Diagnosis of osteochondrodysplasias can be problematic and often relies on careful radiologic evaluation. Although progress has been made in identifying the underlying molecular and biochemical defects in many of these conditions, clinical and radiologic evaluation remains central to the diagnosis at this time. Frequently, the clinical features are obvious—and the diagnosis can then be made at birth (or even prenatally) by ultrasound.

The family history is obviously critical. However, many cases represent fresh mutations—as is generally the case in the classic autosomal-dominant achondroplasia and hypochondroplasia. Careful measurement of body proportions is necessary, including arm span, sitting height, upper/lower body segments, and head circumference. Clinical and radiologic evaluation should be used to determine whether involvement is of the long bones, skull, and/or vertebrae—and whether abnormalities are primarily at the epiphyses, metaphyses, or diaphyses. Two of the more common forms (achondroplasia and hypochondroplasia) of the more than 100 defined osteochondrodysplasias are discussed in the following sections.

TABLE 8-4

Classification of Osteochondrodysplasias

Defects of Tubular (and Flat) Bones and/or Axial Skeleton
Achondroplasia group
Achondrogenesis
Spondylodysplastic group (perinatally lethal)
Metatropic dysplasia group
Short rib dysplasia group (with/without polydactyly)
Atelosteogenesis/diastrophic dysplasia group
Kniest-Stickler dysplasia group
Spondyloepiphyseal dysplasia group
Other spondyloepi(meta)physeal dysplasias
Dysostosis multiplex group
Spondylometaphyseal dysplasias
Epiphyseal dysplasias
Chondrodysplasia punctata (stippled epiphyses) group
Metaphyseal dysplasias
Brachrachia (short spine dysplasia)
Mesomelic dysplasias
Acromelic/acromesomelic dysplasias
Dysplasias with significant (but not exclusive) membranous bone involvement
Bent bone dysplasia group
Multiple dislocations with dysplasias
Osteodysplastic primordial dwarfism group
Dysplasias with increased bone density
Dysplasias with defective mineralization
Dysplasias with increased bone density
Disorganized Development of Cartilaginous and Fibrous Components of the Skeleton
Idiopathic Osteolyses

Achondroplasia. This is the most common of the osteochondrodysplasias, with a frequency of approximately 1:26,000 births. Although transmitted as an autosomal-dominant disorder, 90% of cases apparently represent new mutations. Studies have indicated that achondroplasia is caused by a mutation of the gene for fibroblast growth factor receptor 3 (FGFR3), located on the short arm of chromosome 4.[267] Because the overwhelming majority of cases identified represent mutations at a "hot spot" at nucleotide 1138 of FGFR3, and because these mutations create new recognition sites for restriction enzymes, it is easy to test for the mutation.

Infants homozygous for this condition have severe disease, typically dying in infancy of respiratory insufficiency resulting from the small thorax. Short stature may not be evident until after 2 years of age, although the deviation from the normal growth curve is progressive. Mean adult height in males and females is 131 and 124 cm, respectively. Growth curves for achondroplasia have been developed and are of great value in following patients.[12]

With increasing age, the diagnosis of achondroplasia becomes easier because in addition to short stature these patients have other abnormalities of the skeleton—including megalocephaly, low nasal bridge, lumbar lordosis, short trident hand, and rhizomelia (shortness of the proximal legs and arms). Radiologic abnormalities include small cuboid-shaped vertebral bodies with short pedicles and progressive narrowing of the lumbar interpedicular distance. The iliac wings are small, with narrow sciatic notches. The small foramen magnum may lead to hydrocephalus, and spinal cord and/or root compression may result from kyphosis, stenosis of the spinal canal, or disc lesions.

Hypochondroplasia. Hypochondroplasia has been described as a "milder form" of achondroplasia. However, although the two disorders are both transmitted as autosomal-dominant traits they have not been reported to occur in the same family. Hypochondroplasia, however, has been shown to result from a mutation (Asn540Lys) of the FGFR3 gene—the same gene involved in achondroplasia. The facial features characteristic of achondroplasia are absent, and the short stature and rhizomelia are less pronounced.

Adult heights are typically in the 120- to 150-cm range. As in the case of achondroplasia, short stature may not be evident until after 2 years of age—but stature then deviates progressively from normal. Outward bowing of the legs accompanied by genu varum is frequently observed. Lumbar interpedicular distances diminish between L1 and L5, and as with achondroplasia there may be flaring of the pelvis and narrow sciatic notches.

Chromosomal Abnormalities

Abnormalities of the autosomes and sex chromosomes may be characterized by growth retardation. In general, these disorders are also associated with somatic abnormalities and mental retardation—as in deletion of chromosome 5 or trisomy 18 or 13. Such abnormalities, however, may be subtle—and, for example, the diagnosis of

Turner syndrome must be considered in any girl with unexplained short stature. In many cases, the precise cause of growth failure in these chromosomal abnormalities is unclear because the genetic defects do not appear to affect known components of the GH-IGF system. It is presumed, then, that the chromosomal defect influences normal tissue growth and/or development or indirectly affects the responsiveness to IGF or to other growth factors yet to be identified.

Down Syndrome. Trisomy 21, or Down syndrome, is probably the most common chromosomal disorder associated with growth retardation—affecting approximately 1 in 600 live births. On average, newborns with Down syndrome have birth weights 500 g below normal and are 2 to 3 cm shorter. Growth failure continues postnatally, and is typically associated with delayed skeletal maturation and a poor delayed pubertal growth spurt. Adult heights range from 135 to 170 cm in males and 127 to 158 cm in women.[268] The cause of growth failure in Down syndrome and in other autosomal defects is unknown. Attempts to find underlying hormonal explanations for growth retardation have been unsuccessful, even though hypothyroidism is more common than normal in Down syndrome and should be excluded. It is likely that growth failure in such conditions reflects a generalized biochemical abnormality of the epiphyseal growth plate.

Turner Syndrome. Short stature is the single most common feature of Turner syndrome, occurring more frequently than delayed puberty, cubitus valgus, and webbing of the neck.[269-271] Reviews of large series of Turner syndrome individuals have indicated that short stature occurs in 95% to 100% of girls with a 45,X karyotype. Several distinct phases of growth have been identified in girls with Turner syndrome by Ranke and colleagues:[272] mild IUGR, with mean birth weights and heights of 2,800 g and 48.3 cm, respectively; normal height gain from birth until 3 years of age; progressive decline in height velocity from 3 years of age until approximately 14 years of age, resulting in a gradual and progressive deviation from normal height percentiles; and a prolonged adolescent growth phase characterized by a partial return toward normal height, followed by delayed epiphyseal fusion.

More recent detailed analyses of longitudinal and cross-sectional growth data from several centers have indicated that growth in girls with Turner syndrome is frequently abnormal in infancy and early childhood and that the majority of cases of Turner syndrome diagnosed before adult life have fallen off the normal growth curve by 2 to 3 years of age.[273,274] Investigations of Turner syndrome from the United States and Europe have indicated mean adult heights ranging from 142.0 to 146.8 cm (lower in Asia).

The cause of growth failure in Turner syndrome is multifactorial, although the loss of one copy of the homeobox gene—SHOX (short stature homeobox-containing gene)—is the major contributor.[275] The SHOX gene covers a 40-kb region of the pseudoautosomal region of the X chromosome, escapes X inactivation, and is highly expressed in osteogenic tissue. Haploinsufficiency for SHOX has been implicated in the short stature of Turner syndrome, as well as several other somatic features. In addition, SHOX mutations appear responsible for the mesomelic growth retardation and Madelung deformity characteristic of Leri-Weil dyschondrosteosis—and complete absence of SHOX is associated with Langer mesomelic dysplasia.

The majority of patients have normal GH levels during childhood. Reports of low GH levels in adolescents with Turner syndrome are likely ascribable to low serum levels of sex steroids.[276] Nevertheless, GH therapy is capable of accelerating short-term growth and increasing adult height in both Turner syndrome and SHOX haploinsufficiency.[173,277-279] Indeed, early initiation of GH therapy at appropriate dosages appears to enable most girls with Turner syndrome to attain heights within the normal adult range.[278,279] Turner syndrome is described in greater detail in Chapter 15. The point is worth repeating, however, that the diagnosis of Turner syndrome should be considered in any phenotypic female with unexplained growth failure.

18q Deletions. Deletion of the long arm of chromosome 18 has an estimated prevalence of 1 in 40,000 live births. In one review of 50 cases, 64% of children (mean age 5.8 years) had heights greater than 2 SD below the mean.[280] Fifteen percent had serum IGF-1 concentrations below 2 SD, and 9% had IGFBP-3 concentrations below 2 SD. Seventy-two percent of children had reduced GH responses to provocative testing, although such testing was not always rigorous.

Intrauterine Growth Retardation

Despite the critical importance of the endocrine system in postnatal growth, normal intrauterine growth is largely independent of fetal pituitary hormones.[281,282] Athyreotic and agonadal infants are of normal length and weight at birth. Based on the normal size of anencephalic fetuses, it has been proposed that even the pituitary is unnecessary for fetal growth.[283,284] Careful documentation of birth size of rats with congenital GHD[285] and of human newborns with mutations of the GH or GHR gene[88] has indicated, however, that fetal pituitary-derived GH makes a small but statistically significant contribution to birth size.

These observations should not be interpreted to mean that the IGF axis is irrelevant in fetal growth. Gene knockout studies have shown that elimination of paracrine/autocrine production of IGF-1 has a major impact on fetal and postnatal growth.[286] A human with an IGF-1 gene deletion had the same growth characteristics as observed in the murine IGF-1 knockout. That is, IUGR and postnatal growth failure that was unresponsive to GH administration.[287] Similarly, several reports of IGF-1 receptor defects associated with IUGR and postnatal growth retardation have appeared, and a family with bioinactive IGF-1 has also been reported.[281-282]

Thus, although the fetus may be largely GH independent the production and activity of IGF-1 is clearly critical for normal intrauterine (as well as postnatal) growth. Human cord lymphocytes have been demonstrated to have increased numbers of IGF receptors[288] and mRNAs because IGF-1 and IGF-2 are abundant in fetal tissues.[289,290] Similarly, the IGFBPs are identifiable in serum and other biologic fluids, although it is of note that the relative serum concentrations of various IGFBPs are different in the fetus

and newborn than in the older child or adult.[291] In particular, serum concentrations of IGFBP-3 and acid-labile subunit (ALS)—which together comprise the major serum carriers of IGF peptides in the adult—are much lower in the fetus and newborn.

IUGR is defined on the basis of a birth weight and/or birth length more than 2 SD below the mean for gestational age. Although the majority of such infants show good catch-up growth during the first few years of life, approximately 15% of such children fail to have sufficient catch-up growth to bring them into the normal height range by 4 years of age.[281,282,292] Whereas several studies have demonstrated that infants with IUGR tend to have low serum levels of IGF-1 and IGFBP-3 at birth,[293] it is not entirely clear whether failure of catch-up growth represents the effects of subtle persistent abnormalities of the GH-IGF axis. Barker and colleagues have proposed that in the process of adapting to a limited supply of nutrients in utero IUGR fetuses permanently alter their physiology and metabolism, a reprogramming process that results in physiologic consequences in later life—such as increased risk of coronary artery disease, stroke, hypertension, and diabetes.[294,295]

IUGR can arise from intrinsic abnormalities in the fetus, placental insufficiency, or maternal disorders (Table 8-5). Although it is understandable why uterine constraint or twin pregnancies might result in limited fetal growth, the biochemical and cellular basis for abnormal fetal growth in most cases of IUGR is unclear. It has been proposed that such cases result from reduced cell number or cell size, but the mechanisms for such abnormalities remain to be elucidated. Intrinsic fetal endocrine abnormalities are unlikely explanations for IUGR in most cases.

TABLE 8-5

Etiology of Intrauterine Growth Retardation

- Intrinsic fetal abnormalities
  - Chromosomal disorders
  - Syndromes associated with primary growth failure
    - Russell-Silver syndrome
    - Seckel syndrome
    - Noonan syndrome
    - Progeria
    - Cockayne syndrome
    - Bloom syndrome
    - Prader-Willi syndrome
    - Rubinstein-Taybi syndrome
  - Congenital infections
  - Congenital anomalies
  - Primary abnormalities of insulin-like growth factor axis
- Placental anormalities
  - Abnormal implantation of the placenta
  - Placental vascular insufficiency; infarction
  - Vascular malformations
- Maternal disorders
  - Malnutrition
  - Constraints on uterine growth
  - Vascular disorders
    - Hypertension
    - Toxemia
    - Severe diabetes mellitus
  - Uterine malformations
  - Drug ingestion
    - Tobacco
    - Alcohol
    - Narcotics

From Underwood LE, Van Wyk JJ: Normal and aberrant growth. In Wilson JD, Foster DW (eds): Williams Textbook of Endocrinology, 8th ed. Philadelphia, WB Saunders, 1992; p 1110.

Congenital thyroid and/or GH deficiencies are typically characterized by near-normal birth size. Recently recognized human mutations in IGF-1 and IGF-1 receptors are associated with IUGR, but circulating IGF-1 levels in IUGR children are highly variable—indicating that there is a large clinical diversity in this condition. Infants with IUGR frequently exhibit poor postnatal growth, particularly when the abnormalities are intrinsic to the fetus. Such conditions have frequently been categorized as "primordial growth failure."

Russell-Silver Syndrome. This condition was independently described by Russell,[296] and later by Silver and associates, in the early 1950s. Although this syndrome probably represents a heterogeneous group of patients, the "common" findings include IUGR, postnatal growth failure, congenital hemihypertrophy, and small triangular facies. Because no genetic or biochemical basis for this disorder has been identified, Russell-Silver syndrome is often used improperly as a designation for IUGR of unknown cause. Other common nonspecific findings include clinodactyly, precocious puberty, delayed closure of the fontanelles, and delayed bone age. Recently, it has been demonstrated that hypermethylation (termed *epimutation*) of the IGF2 gene leading to its decreased expression is associated with the majority of cases of this condition.[297]

Seckel Syndrome. Although originally described by Mann and Russell in 1959,[298] this condition is most commonly termed *Seckel syndrome* or *Seckel birdheaded dwarfism.*[299] An autosomal-recessive condition, Seckel syndrome is characterized by IUGR and severe postnatal growth failure combined with microcephaly, prominent nose, and micrognathia. Final height is typically 91.4 to 106.7 cm, with moderate to severe mental retardation.

Noonan Syndrome. Although this condition shares certain phenotypic features with Turner syndrome, the two disorders are clearly distinct.[300] In Noonan syndrome, several genes have been implicated—including KRAS (Kirsten rat sarcoma 2 viral oncogene homolog)—but the majority of cases are caused by PTP11 (protein tyrosine phosphatase nonreceptor type 11) mutations. Both males and females may be affected, explaining the misleading names "Turner-like syndrome" and "male Turner syndrome." As in Turner syndrome, patients typically have webbing of the neck, a low posterior hairline, ptosis, cubitus valgus, and malformed ears.

Cardiac abnormalities are, however, primarily right-sided (pulmonary valve)—rather than the left-sided lesions (aorta, aortic valve) characteristic of Turner syndrome. Microphallus and cryptorchidism are common, and puberty is frequently delayed or incomplete. Mental retardation is observed in approximately 25% to 50% of patients. In a manner similar to Turner syndrome, Noonan syndrome responds to GH therapy—and this

treatment recently resulted in FDA approval in the United States.

Progeria. The senile appearance characteristic of progeria (Hutchinson-Gilford syndrome) typically appears by 2 years of age.[301] There is a progressive loss of subcutaneous fat, accompanied by alopecia, hypoplasia of the nails, joint limitation, and early onset of atherosclerosis—typically followed by angina, myocardial infarction, hypertension, and congestive heart failure. Skeletal hypoplasia results in severe growth retardation, which typically becomes evident by 6 to 18 months of age. The molecular basis of this syndrome, as well as that of the Cockayne syndrome, are described at *http//:www.ncbi.nlm.nih.gov/omim/.*

Cockayne Syndrome. Cockayne syndrome, like progeria, is characterized by a premature senile appearance.[302] Patients also have retinal degeneration, photosensitivity of the skin, and impaired hearing. Growth failure typically appears at 2 to 4 years of age. Transmission is as an autosomal-recessive disorder.

Prader-Willi Syndrome. Growth failure may be evident at birth but is generally more impressive postnatally. The neonatal period is characterized by hypotonia, and in the male by cryptorchidism and microphallus. With advancing age, hyperphagia and obesity become prominent. Hypogonadism may persist into adult life. The cause of growth failure is unclear. Low serum GH concentrations may reflect the impact of obesity and are not necessarily etiologic. On the other hand, low GH secretion and hypogonadism may reflect subtle defects of hypothalamic-pituitary function—and these patients respond well to GH therapy.[303-305] Patients with Prader-Willi syndrome have been found to have deletions of the paternal short arm of chromosome 15, or uniparental disomy of the maternal imprinted region of chromosome 15—a situation equivalent to paternal deletion of that region.

A variety of other syndromes may be associated with moderate-profound growth failure. These include Bloom syndrome, de Lange syndrome, leprechaunism (mutations of the insulin receptor gene), Ellis-van Creveld syndrome, Aarskog syndrome, Rubinstein-Taybi syndrome, mulibrey nanism (Perheentupa syndrome), Dubowitz syndrome, and Johanson-Blizzard syndrome. The syndromes discussed in this section are described in greater detail in Online Mendelian Inheritance in Man (OMIM), a National Institutes of Health–supported regularly updated web site that publishes information on genetic conditions *(http://www.ncbi.nim.nih.gov/omim/).*

Placental insufficiency and maternal factors may also contribute to poor fetal growth. Whereas such infants have a better growth potential than do cases of "primordial growth failure," postnatal growth is not always normal. Maternal nutrition is an important contributor to fetal growth, impacting not only the size of the fetus but growth during the first year of life.[306] Fetal growth retardation may also result from alcohol consumption during pregnancy,[307-309] as well as from use of cocaine,[310,311] marijuana,[311] and tobacco.[312] The mechanisms for such drug-induced fetal growth retardation are unclear but probably include uterine vasoconstriction and vascular insufficiency, as well as placental abruption and premature rupture of membranes. Although maternal tobacco use is statistically a major contributor to reduced fetal size, it is unlikely by itself to result in severe IUGR.

The implications of IUGR may extend beyond decreased fetal size. In a retrospective study of 47 children evaluated before puberty for growth failure secondary to IUGR, 23 boys had an adult height of 162 cm and 24 girls an adult height of only 148 cm[313] in the U.S. and Europe. Being SGA and failing to catch up is in an indication of GH therapy. More recent studies have indicated that small-for-gestational-age infants have an increased risk of hypertension, maturity-onset diabetes, and cardiovascular disease.[314] It remains unclear, however, whether IUGR is causally related to these disorders or is a symptom of an underlying inborn metabolic disorder.

Other Genetic Causes of Short Stature

Regulation of skeletal growth involves multiple factors, including hormones and growth factors, nutrition, general health, and a wide variety of other environmental factors. Even when evaluating hereditary aspects of skeletal growth, it is clear that control of growth in childhood (as well as final height) is polygenic by nature. Nevertheless, a direct impact of familial height on an individual subject's growth is normally evident, and evaluation of a child's growth pattern must be placed in the context of familial growth and stature. As described previously, formulas have been developed for determination of a person's target height based on parental heights—and growth curves that relate a child's height to parental height are available.[315] As a general rule, a child who is growing at a rate that is clearly inconsistent with that of siblings or parents warrants further evaluation.

Many organic diseases characterized by growth retardation are genetically transmitted. This list includes many endocrine causes, such as GHI resulting from mutations of the GHR gene, GH gene deletions, mutations of the POU1F1 gene, pseudohypoparathyroidism, and familial thyroid deficiency. Many other nonendocrine diseases characterized by short stature may be genetically transmitted, such as osteochondrodysplasias, dysmorphic syndromes associated with IUGR, diabetes, metabolic disorders, renal disease, thalassemia, and others. Identifying short stature as genetically transmitted thus does not by itself relieve the physician of responsibility for determining the underlying cause of growth failure.

SECONDARY GROWTH DISORDERS

Malnutrition

Given the worldwide presence of undernutrition, it is not surprising that inadequate caloric and/or protein intake represents by far the most common cause of growth failure.[316] Marasmus refers to cases with a global deficiency of calories, although often accompanied by protein insufficiency. Kwashiorkor, on the other hand, refers to inadequate protein intake—although it may also be characterized by caloric undernutrition. Frequently, the two conditions overlap.

The impaired growth characteristic of protein-energy malnutrition is frequently characterized by elevated basal

and/or stimulated serum GH concentrations.[317] In generalized malnutrition (marasmus), however, GH concentrations may be normal or even low.[318] In both conditions, nevertheless, serum IGF-1 concentrations are typically reduced.[319,320] Malnutrition may, consequently, be considered a form of GHI in cases in which serum IGF-1 concentrations are reduced in the presence of normal or elevated GH levels. It has been suggested that elevated serum GH concentrations represent an adaptive response whereby protein is spared by the lipolytic and anti-insulin actions of GH. Reduced serum IGF-1 concentrations may represent a mechanism by which precious calories are shifted from use in growth to survival requirements of the organism. These adaptive mechanisms may be further enacted by changes in serum IGFBPs during periods of malnutrition.[321]

Inadequate caloric or protein intake may also complicate many chronic diseases characterized by growth failure. Anorexia is a common feature of renal failure and inflammatory bowel disease but may also be associated with cyanotic heart disease, congestive heart failure, central nervous system (CNS) disease, and other illnesses. Some of these conditions may, furthermore, be characterized by deficiencies of specific dietary components—such as zinc, iron, and various vitamins necessary for normal growth and development.

Undernutrition may also be voluntary, as is the case with dieting and food fads.[322] Caloric restriction is especially common in girls (such as among gymnasts and ballet dancers) during adolescence, when it may be associated with anxiety concerning obesity. Anorexia nervosa and bulimia represent extremes of "voluntary" caloric deprivation and are commonly associated with impaired growth if undernutrition occurs before epiphyseal fusion. Even later in adolescence, these conditions may be characterized by delayed puberty and/or menarche and a variety of metabolic alterations.

Chronic Diseases

Malabsorption. Intestinal disorders associated with inadequate absorption of calories or protein are typically associated with growth failure for many of the reasons cited previously.[323-326] It is not uncommon for growth retardation to predate many of the other manifestations of malabsorption and/or chronic inflammatory bowel disease. Accordingly, such conditions [especially gluten-induced enteropathy (celiac disease) and regional enteritis (Crohn disease)] must be in the differential diagnosis of unexplained growth failure. Serum concentrations of IGF-1 may be reduced,[327] reflecting the malnutrition. It is therefore all the more critical to discriminate these conditions from GHD or related disorders.

Documentation of malabsorption requires demonstration of fecal wasting of calories, especially fecal fat. The diagnosis of celiac disease ultimately requires a biopsy of the small intestine and demonstration of the characteristic flattening of the mucosa. Normalization of jejunal mucosa after gluten withdrawal and reappearance of abnormalities on gluten challenge are necessary to confirm the diagnosis. The use of antigliadin autoantibodies has been disappointing in the diagnosis of celiac disease because of its low specificity, but transglutaminase antibodies are useful.

On the other hand, whereas some have recommended jejunal biopsy to rule out celiac disease in all cases of unexplained growth failure during the first 5 years of life this aggressive an approach is not usually necessary.[328] Generally, an alternative would be to reserve biopsies for children with a history of diarrhea and/or steatorrhea in the first 2 years of life, abnormal D-xylose absorption tests, and positive transglutaminase antibodies.[329] The growth failure characteristic of Crohn disease probably represents a combination of malabsorption, anorexia, chronic inflammation, inadequacy of trace minerals, and use of glucocorticoids.[330] As stated previously, growth retardation may precede other clinical manifestations—such as fever, abdominal pain, and diarrhea. An elevated erythrocyte sedimentation rate is a useful clue, although diagnosis ultimately requires endoscopy and biopsy.

Cardiovascular Disease. Cyanotic heart disease and congestive heart failure may be associated with growth failure.[331,332] Because cardiac defects are usually congenital, many infants have syndromes associated with dysmorphic features and IUGR. Postnatal growth failure is usually attributable to hypoxia and the increased energy demands of a failing heart. These conditions are often accompanied by feeding difficulties that exacerbate the poor growth.

Corrective surgery often results in restoration of normal growth, frequently with a phase of "catch-up" growth. Unfortunately, surgery must on occasion be delayed until the infant has reached an appropriate size—resulting in the conundrum that surgery corrects growth failure but cannot be performed because the infant is too small. In these situations, meticulous attention to caloric support and alleviation of hypoxia and heart failure is necessary to maximize growth before surgery.

Renal Disease. A wide variety of clinical conditions that affect renal function can result in significant growth retardation.[333,334] Uremia, Fanconi syndrome, and renal tubular acidosis can all lead to growth failure before other clinical manifestations become evident. It is probable that renal disease leads to growth retardation through multiple mechanisms, including decreased caloric intake, loss of electrolytes necessary for normal growth, metabolic acidosis, protein wasting, inadequate formation of 1,25-dihydroxycholecalciferol, insulin resistance, chronic anemia, and compromised cardiac function.

Although earlier studies suggested a decrease in serum IGF concentrations in uremia, it is now evident that these erroneous determinations reflected inadequate separation of IGF peptides from IGFBPs before assay.[159] Serum IGF-1 and IGF-2 concentrations are in general within normal limits, but increases in serum IGFBPs (especially IGFBP-1) may lead to inhibition of IGF action. The use of chronic glucocorticoid therapy in the treatment of a variety of nephritic and nephrotic conditions can exacerbate the growth retardation characteristic of renal disease.

The age at onset of renal dysfunction is a factor in the resultant growth failure. Impairment of renal function at an early age typically results in a greater degree of growth failure, probably owing at least in part to the cumulative effects of growth retardation over many

years. Subsequent correction of renal failure does not always allow for full catch-up growth. In a study in which renal transplantation was performed before 15 years of age (with a mean age at onset of hemodialysis of 10.6 years and at initial transplantation of 11.8 years), height SD scores did not significantly improve.[335] Approximately 75% of subjects had adult heights below the third percentile.

Although the growth failure of renal disease is not caused by GH or IGF deficiency, GH therapy has proven useful in accelerating skeletal growth. It is likely that such treatment increases the molar ratio of IGF peptides to IGFBPs, potentially overriding the inhibitory actions of IGFBPs.

Hematologic Disorders. Chronic anemias, such as sickle cell disease, are characterized by growth failure.[336-338] The causes of growth retardation probably include impaired oxygen delivery to tissues, increased work of the cardiovascular system, energy demands of increased hematopoiesis, and impaired nutrition. Thalassemia, in addition to the consequences of chronic anemia, can also be characterized by endocrine deficiencies resulting from chronic transfusions and accompanying hemosiderosis.[339,340] Despite vigorous efforts to maintain hemoglobins near normal and to employ chelation therapy, growth failure has remained a common feature of thalassemia—especially in adolescents. It is likely that impaired IGF-1 synthesis,[341,342] hypothyroidism, gonadal failure, and hypogonadotropic hypogonadism—combined with chronic anemia—all contribute to growth failure.

Diabetes Mellitus. Growth failure can be observed in children whose diabetes is under chronically poor control.[71] The so-called Mauriac syndrome[343] describes children with diabetes mellitus, severe growth failure, and hepatomegaly resulting from excess hepatic glycogen deposition. This type of striking growth retardation is unusual in diabetes, and in general growth failure is modest. As with other chronic diseases, growth retardation probably represents a combination of pathophysiologic processes—such as calorie wasting from hyperglycemia or malabsorption secondary to celiac sprue, chronic acidosis, increased glucocorticoid production, and hypothyroidism.

Because IGFBP-1 is normally suppressed by insulin, chronic hypoinsulinemia results in elevated serum IGFBP-1 concentrations—which may inhibit IGF action. In addition, insulin regulates the expression of the GHR—and hypoinsulinemia commonly leads to low IGF-1 levels through this mechanism.[344] Nevertheless, the correlation between glycemic control and skeletal growth is surprisingly unreliable—and many children with apparently marginal control appear to grow well.[345] One can only surmise that such patients are able to attain normal intracellular nutrition despite seeming hypoinsulinemia. It is likely, however, that continued progress in improving glycemic control in diabetes will improve growth in these children.

Inborn Errors of Metabolism. Inborn errors of protein, carbohydrate, and lipid metabolism are often accompanied by growth failure—which can be pronounced. Glycogen storage disease, the mucopolysaccharidoses, glycoproteinoses, and mucolipidoses may all be characterized by poor growth. Many inborn metabolic disorders are also associated with significant skeletal dysplasia.

Pulmonary Disease. Cystic fibrosis is the classic example of growth failure associated with pulmonary disease, although poor growth undoubtedly represents the combined effects of pulmonary and pancreatic dysfunction.[181] The Cystic Fibrosis Foundation reports that 18% of patients with cystic fibrosis fall below the 5th percentile in height, and 23% fall below the 5th percentile in weight. In addition, the appearance of diabetes, the use of steroids, and the presence of frequent infections all contribute to the poor growth cystic fibrosis. Any condition associated with chronic hypoxemia may result in growth retardation. In children with chronic asthma, the long-term use of glucocorticoids undoubtedly contributes significantly to growth failure.

Chronic Infection. In many developing countries, chronic infestation with intestinal and systemic parasites (such as schistosomiasis, hookworm, and roundworm) contributes to nutritional debilitation and growth failure.[346]

Endocrine Disorders

Hypothyroidism. Many of the clinical features characteristic of adult myxedema are lacking in pediatric patients with acquired hypothyroidism. The most common and prominent manifestation of chronic acquired hypothyroidism is growth failure, which may be profound.[347] Postnatal growth retardation may also be observed in the infant with congenital hypothyroidism, but the development of newborn screening programs for hypothyroidism have generally resulted in prompt diagnosis and treatment of such patients. In acquired hypothyroidism, growth retardation may take several years to become clinically evident. However, once present growth failure is typically severe and progressive.

Rivkees and associates[347] have reported a mean 4.2-year delay between documentation of growth deceleration and the diagnosis of hypothyroidism. At diagnosis, girls were 24.04 SD and boys 23.15 SD below heights for age. (This is one of several situations in which the diagnosis of short stature is more delayed in girls than in boys.) Although chronic hypothyroidism is generally characterized by delayed puberty, precocious puberty and even premature menarche can occur in hypothyroid children—an entity called VanWyk-Grumbach syndrome. In some females with severe primary hypothyroidism, large recurrent ovarian cysts may manifest.[348] Skeletal age is usually markedly delayed.

Confirmation of the diagnosis of primary hypothyroidism is usually straightforward. Serum concentrations of T4 are reduced, and TSH concentrations are elevated. The presence of antithyroid antibodies is consistent with a diagnosis of Hashimoto thyroiditis, the most common cause of acquired hypothyroidism in the United States. Isolated secondary and tertiary hypothyroidism, caused by TSH and TRH deficiency (respectively), are very rare causes of acquired hypothyroidism.

Replacement therapy with levothyroxine is associated with a period of rapid catch-up growth. Despite this gratifying response, however, accelerated growth often does not result in restoration of full growth potential—

largely because of the rapid increase in skeletal age during the first 18 months of treatment. In the study of Rivkees and associates,[347] children treated at an initial mean chronologic age of 11 years had adult heights approximately 2 SD below the means for sex. These final heights were significantly lower than mid-parental heights or initial predicted adult heights based on data of Bayley and Pinneau. The deficit in adult stature correlated significantly with the duration of hypothyroidism before initiation of treatment. Accordingly, it may be appropriate to use lower than usual replacement dosages of levothyroxine and/or to consider delaying puberty and epiphyseal fusion pharmacologically.

Cushing Syndrome. Glucocorticoid excess has a profound effect on skeletal growth[348,349] whether the cause of Cushing syndrome is hypersecretion of ACTH, a primary adrenal tumor, or glucocorticoid therapy. It is assumed that the effects of glucocorticoids are directly at the epiphysis because GH secretion is typically normal and serum concentrations of IGF peptides and IGFBPs are not generally affected. This is supported by the observation that treatment with GH cannot completely overcome the growth inhibiting effects of excess glucocorticoids. The "toxic" actions of glucocorticoids on the epiphysis often persist at least in part after termination of chronic glucocorticoid excess, and patients frequently do not attain their target heights.[350]

The longer the duration and the greater the intensity of glucocorticoid excess the less likely the patient will experience complete catch-up growth. It is therefore important to limit exposure to excess glucocorticoids as much as the underlying condition being treated will allow. This may in part be accomplished by the use of alternate-day steroid therapy. The characteristic signs of Cushing syndrome (such as truncal obesity, decreased muscle mass, striae, easy bruising, thin skin, and osteoporosis) are well known. Adrenal tumors secreting large amounts of glucocorticoids frequently also produce excess androgens, which may mask the growth inhibitory effects of glucocorticoids.

It is also important to note that Cushing syndrome in children may be lacking many of the clinical signs and symptoms associated with the disorder in adults and may present exclusively with growth arrest. On the other hand, Cushing syndrome is an unlikely diagnosis in children presenting with obesity because exogenous obesity is associated with normal or even accelerated skeletal growth—whereas in Cushing syndrome growth deceleration is generally evident by the time other signs appear.

Pseudohypoparathyroidism. This condition is discussed in more detail elsewhere, but it is included here because at time of presentation growth failure is a frequent feature.[351] In its classic form, this condition combines growth failure and characteristic dysmorphic features with hypocalcemia and hyperphosphatemia secondary to end-organ resistance to parathyroid hormone (PTH). Children with pseudohypoparathyroidism are short and truncally obese, with short metacarpals, subcutaneous calcifications, round facies, and mental retardation.

Rickets. Hypovitaminosis D is historically a major cause of abnormal skeletal growth and short stature. Often it is associated with other causes of growth failure, such as malnutrition, prematurity, malabsorption, hepatic disease, and chronic renal failure. When vitamin D deficiency occurs by itself, typically when infants have poor exposure to sunlight and are not being nutritionally supplemented with vitamin D, the characteristic skeletal manifestations of rickets are evident: frontal bossing, craniotabes, rachitic rosary, and bowing of the legs.

Vitamin D–Resistant (Hypophosphatemic) Rickets. This X-linked condition results from decreased renal tubular reabsorption of phosphate. Clinical features are generally more severe in males and include short stature and prominent bowing of the legs, but other rachitic signs may be present.[352] The metabolic and skeletal abnormalities cannot be overcome by vitamin D therapy alone, and thus the name "vitamin D–resistant rickets." Treatment requires oral phosphate replacement, but such therapy often results in poor calcium absorption from the intestine. The addition of vitamin D to oral phosphate increases intestinal phosphate absorption and prevents hypocalcemia. Preliminary studies with GH therapy have indicated (at least in the short term) an enhancement of skeletal growth.

IGF Deficiency. Thyroid hormone and IGF-1 appear to be the major mediators of skeletal growth. Studies involving targeted disruption of genes for various components of the IGF system have established the critical role of the IGF axis in prenatal and postnatal growth.[353] Deficiency of IGF-1 can result in severe growth failure and may result from hypothalamic dysfunction, pituitary GHD, or primary or secondary GHI. It is not always possible to completely discriminate between hypothalamic and pituitary dysfunction because both organs may be involved in the same pathologic process. In addition, embryonic development of the hypothalamus and pituitary appears to be co-dependent.[27-31]

A number of factors produced in the developing ventral diencephalon function as molecular signals for initial formation and development of Rathke's pouch. Subsequent differentiation of each of the various anterior pituitary cell types appears to be primarily regulated by a strict temporal and spatial pattern of pituitary transcription factors.

It thus becomes somewhat of a semantic issue as to whether to label some of the molecular defects "hypothalamic" or "pituitary." Nevertheless, some arbitrary classification decisions have been made. Table 8-6 presents our current classification of molecular defects of the GH-IGF axis, and sites of established and hypothetical defects are shown in Figure 8-20. Figure 8-21 provides a "decision tree" for investigation of genetic defects in patients with IGF deficiency. It is to be anticipated that significant developments will be made in our understanding of these defects over the next few years and that this classification will require frequent updating and modification.

Hypothalamic Dysfunction. Hypothalamic dysfunction can arise from congenital malformations of the brain or hypothalamus, trauma, infections, sarcoid, tumors, or cranial irradiation. Anencephaly results in a pituitary gland that is small or abnormally formed and frequently ectopic. Holoprosencephaly, resulting from abnormal midline development of the embryonic brain, is also typically associated with hypothalamic insufficiency.[354,355]

TABLE 8-6

Established Genetic Defects of the GH-IGF Axis Resulting in IGF Deficiency

Mutant Gene	Inheritance	Phenotype
HPA		Developmental abnormalities
HESX1	AR	Septo-optic dysplasia; variable involvement of pituitary hormones
PROP1	AR	GH, PRL, TSH, LH, FSH deficiencies; variable ACTH deficiency
POU1F1 (Pit1)	AR, AD	GH, PRL deficiency; variable degree of TSH deficiency
RIEG	AD	Rieger syndrome
LHX3	AR	GH, TSH, LH, FSH, prolactin deficiencies
LHX4	AD	GH, TSH, ACTH deficiencies
SOX3	XL	GH deficiency, mental retardation
GLI2	AD	Holoprosencephaly, hypopituitarism
GLI3	AD	Pallister-Hall syndrome, hypopituitarism
Isolated GHD		
GHRHR	AR	IGHD, Type IB form of IGHD
GHS-R	AD	GHD and ISS
GH1	AR	Type IA form of IGHD
	AR	Type IB form IGHD
	AD	Type II form of IGHD
	X-linked	Type III form of IGHD; hypogamma-globulinemia
	AD	Bioinactive GH molecule
GHI		
GHR		
Extracellular domain	AR, AD	IGF- I deficiency; decreased or normal GHBP
Transmembrane	AR	IGF-I deficiency; normal or increased GHBP
Intracellular domain	AD	IGF-I deficiency; normal or increased GHBP
IGF		
IGF1	AR	IGF-I deficiency; IUGR and postnatal growth failure
ALS	AR	IGF-I deficiency; variable postnatal growth failure, delayed puberty

HPA, hypothalamic pituitary; ACTH, adrenocorticotropic hormone (corticotropin); AD, autosomal dominant; AR, autosomal recessive; FSH, follicle-stimulating hormone; GH, growth hormone; GHBP, GH-binding protein; GHRHR, GH-releasing hormone receptor; IGF, insulin-like growth factor; IGHD, isolated GHD; IUGR, intrauterine growth retardation; LH, luteinizing hormone; PRL, prolactin; TSH, thyroid-stimulating hormone; and ALS, acid labile subunit.

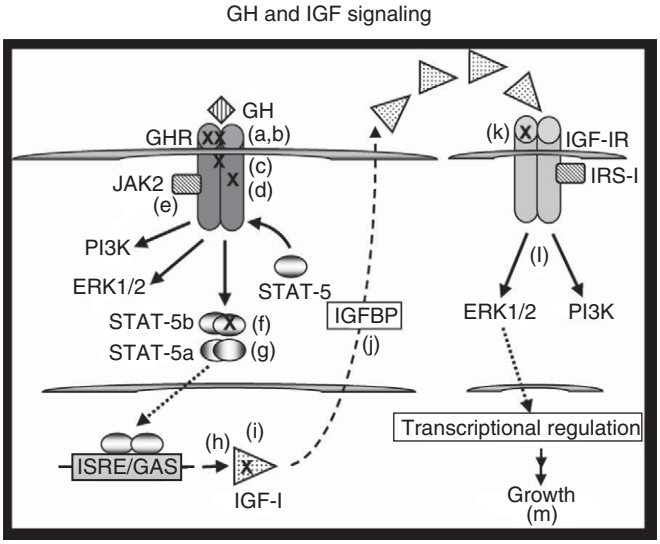

Figure 8-20 Schematic diagram of the GH–IGF axis, showing identified and theoretical defects: (*a*) defects of the extracellular domain of the GHR, affecting binding of GH; (*b*) defects in GHR dimerization; (*c*) defects of the transmembrane domain of the GHR; (*d*) defects of the intracellular domain of the GHR; (*e*) defects of JAK2 (theoretical at this time); (*f*) defects of STAT5b; (*g*) defects of STAT5a (theoretical at this time); (*h*) defects of transcriptional regulation of IGF-I (theoretical at this time); (*i*) defects of the IGF-I gene; (*j*) defects of IGFBPs, affecting IGF availability (theoretical at this time); (*k*) defects of the IGF receptor; (*l*) defects of IGF receptor signal transduction (theoretical at this time); and (*m*) defects at the epiphyseal growth plate, potentially affecting IGF action. GH, growth hormone; GHR, growth hormone receptor; JAK2, janus-family tyrosine kinase 2; PI3K, phosphatidylinositol-3 kinase; ERK, extracellular signal-regulated kinase; STAT, signal transducer and activator of transcription; ISRE, interferon-stimulated response element; GAS, interferon-gamma-activated sequences; IGF, insulin-like growth factor; IGFBP, IGF binding proteins; IGF-IR, IGF-I receptor; and IRS, insulin receptor substrate. [Used with permission from Rosenfeld RG, Hwa V (2004). New molecular mechanisms of GH resistance. Eur J Endocrinol 151(1):S11–S15.]

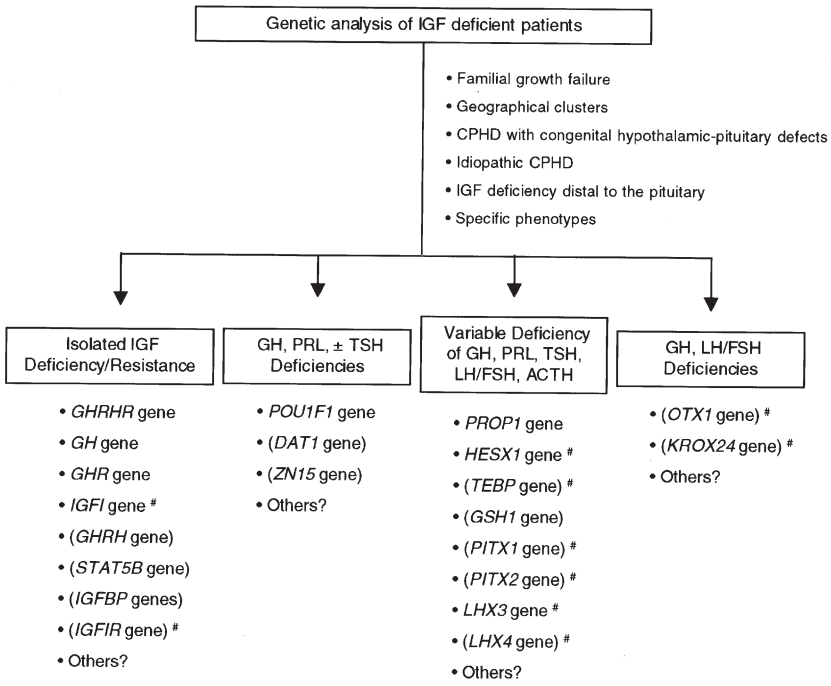

FIGURE 8-21. Decision tree for investigation of genetic defects in patients with insulin-like growth factor (IGF) deficiency. Hypothetical genetic defects are presented in parentheses. Abnormalities in other organs and structures besides the hypothalamus-pituitary-IGF axis are expected to occur as a result of these genetic defects. ACTH, adrenocorticotropic hormone; CPHD, combined pituitary hormone deficiencies; FSH, follicle-stimulating hormone; GH, growth hormone; GHR, growth hormone receptor; GHRHR, GH-releasing hormone receptor; IGFIR,IGF-1 receptor; LH, luteinizing hormone; PRL, prolactin; STAT5, signal transducer and activator of transcription 5; TSH, thyroid-stimulating hormone. (From Lopez-Bermejo A, Buckway CK, Rosenfeld RG: Genetic defects of the growth hormone–insulin-like growth factor axis. Trends Endocrinol 11:43, 2000, with permission from Elsevier Science.)

The clinical spectrum of holoprosencephaly can range from cyclopia to hypertelorism, accompanied by absence of the philtrum or nasal septum and midline clefts of the palate or lip. In these situations, GHD is often accompanied by other pituitary insufficiencies.

Debate continues as to whether the incidence of GHD is increased in cases of simple clefts of the lip and/or palate alone.[356,357] Clearly, children with clefts who are growing abnormally certainly require further evaluation. The syndrome of septo-optic dysplasia in its complete form combines hypoplasia or absence of the optic chiasm and/or optic nerves, agenesis or hypoplasia of the septum pellucidum and/or corpus callosum, and hypothalamic insufficiency.[37,358] The extent of the anatomic abnormalities and hypothalamic/pituitary insufficiency can vary considerably.[359] GHD can occur by itself, or in combination with TSH, ACTH, and/or gonadotropin deficiencies. Accordingly, this diagnosis should be considered in any child with growth failure associated with nystagmus or impaired vision.

Two siblings with septo-optic dysplasia have been reported to have homozygous missense mutations of HESX1, a paired-like homeodomain gene.[360,361] The mutation, which results in an Arg53Cys substitution, appears to totally abrogate DNA binding. Rathke's pouch homeobox (Rpx), the murine homologue, is expressed in the prospective cephalic region earlier during gastrulation. Later, it can be found throughout the prosencephalon—but it is restricted ultimately to Rathke's pouch. Knockout of the Hesx1 gene in the mouse results in phenotypes varying from an embryonic lethal form (with complete absence of Rathke's pouch) to a milder phenotype, with hypoplasia of the anterior lobe of the pituitary.

Molecular Defects of GHRH or the GHRH Receptor. No convincing cases of mutations of the GHRH gene in humans have been identified. This is a somewhat surprising observation, and the GHRH gene must still be considered a candidate gene for familial forms of isolated GHD. Abnormalities of the gene for the GHRH receptor (GHRHR), on the other hand, have been found in at least four kindreds.[362-365] A family from India was found to harbor a nonsense mutation of the GHRHR, resulting from a Glu72 stop mutation in exon 3.[362]

The resulting truncated molecule lacks the transmembrane region and the G-protein–binding sites. An apparently identical mutation has been identified in a family from Sri Lanka,[364] and in 17 members of an inbred kindred in Sindh (Pakistan).[363] The largest kindred with a mutation of GHRHR has been identified in Brazil.[365] A donor splice mutation in position 1 of exon 1 results in a severely truncated GHRHR protein.

Trauma of the Brain and/or Hypothalamus. Trauma to the brain, hypothalamus, pituitary stalk, or anterior pituitary may result in isolated GHD or in multiple deficiencies of the anterior pituitary.[366,367] Many published series of patients with GHD indicate an increased incidence of birth trauma, such as breech deliveries, extensive use of forceps, prolonged labor, or abrupt delivery.[367]

Debate continues as to whether GHD is the consequence of difficult delivery or merely reflects the perinatal consequences of fetal pituitary insufficiency.

Inflammation of the Brain and/or Hypothalamus. Inflammation of the brain (resulting from bacterial, viral, or fungal infections) may result in hypothalamic/pituitary insufficiency.[368,369] The hypothalamus and/or pituitary may also be involved in sarcoidosis.[370]

Tumors of the Brain and/or Hypothalamus. Tumors of the CNS are a major cause of hypothalamic insufficiency.[371] This is especially true for midline brain tumors, such as germinomas, meningiomas, gliomas, colloid cysts of the third ventricle, ependymomas, and gliomas of the optic nerve. Although metastasis from extracranial carcinomas is rarely found in children, hypothalamic insufficiency may result from local extension of craniopharyngeal carcinoma or Hodgkin disease of the nasopharynx. Craniopharyngiomas and histiocytosis may result in hypothalamic dysfunction (discussed under "Pituitary GH Deficiency").

Irradiation of the Brain and/or Hypothalamus. Cranial irradiation continues to emerge as an increasing cause of hypothalamic/pituitary dysfunction.[372-375] Irradiation may directly impair hypothalamic and pituitary function, and it is not always easy to discriminate between damage at each of these levels. In addition, thyroidal and gonadal function may also be directly affected. The degree of pituitary impairment is related to the dose of radiation received. Low doses typically result in isolated GHD. With higher doses, multiple pituitary hormone deficiencies are observed. Two to 5 years after irradiation, 100% of children receiving more than 3000 cGy over 3 weeks to the hypothalamic-pituitary axis showed subnormal GH responses to insulin-provocative tests.[376]

The degree of pituitary deficiency observed is also directly correlated to the length of time since irradiation. Children who test normally at 1 year post-irradiation may still develop pituitary deficiencies at later times. Even when serum GH concentrations after provocative testing are normal, measures of spontaneous GH secretion may indicate an impairment. As little as 1,800 cGy has been shown to affect spontaneous GH secretion in pubertal children.

Decreased GH secretion may be further complicated by the impact of irradiation on spinal growth, which can result in short stature and skeletal disproportion. Surprisingly, cranial irradiation can also result in precocious puberty—with the consequence that epiphyseal fusion occurs at an earlier age than is ideal from the perspective of maximizing growth. Gonadotropin-releasing hormone (GnRH) analogues may be necessary to delay pubertal progression. The endocrinologist observing the child who has received craniospinal irradiation must weigh these three factors: evolving hypopituitarism, decreased spinal growth potential, and early puberty and premature epiphyseal fusion. Care must be taken to maximize the growth potential of the patient without causing skeletal disproportion and without delaying puberty excessively or allowing growth to terminate too early.

Pituitary GH Deficiency. As discussed previously, many of the disease processes that affect hypothalamic regulation of GH secretion also impact pituitary function. Given current diagnostic limitations, it is not in fact always possible to completely discriminate between hypothalamic and pituitary dysfunction. Furthermore, it is likely that many cases of so-called idiopathic GHD will be found to have a molecular basis for the disorder. Indeed, in the past 5 years we have seen an explosion of information concerning genes critically involved in pituitary somatotrope differentiation and function (Tables 8-2 and 8-6).

At this time, however, a clear cause for pituitary GHD is often not identified—hence the term *idiopathic*. An incidence of pituitary GHD in 1:60,000 live births was reported from the United Kingdom.[377] A more recent survey of 48,000 Scottish schoolchildren has indicated an incidence as high as 1:4,000,[378] whereas the best estimate available in the United States population is at least 1:3,480.[379]

It is likely, however, that childhood GHD is an overdiagnosed condition. In particular, the diagnosis of acquired idiopathic isolated GHD should always be suspect. Although one may argue that destructive or inflammatory lesions of the hypothalamus or pituitary may only affect GH secretion, that isolated GHD caused by a mild mutation/deletion of the GHRH receptor gene or GH gene may appear late, or that combined pituitary hormone deficiency (CPHD) may first present with what appears to be isolated GHD, such circumstances appear to be rare. In the absence of anatomic abnormalities evident on imaging studies and/or biochemical evidence of CPHD, the diagnosis of acquired isolated idiopathic GHD demands careful and thorough documentation.

Genetic Abnormalities Resulting in Combined Pituitary Hormone Deficiency. Septo-optic dysplasia and its relationship to HESX1 was discussed previously. The gene PROP1 (standing for prophet of Pit1) is involved in the early determination and differentiation of multiple anterior pituitary cell forms.[380,381] Abnormalities of PROP1 result in CPHD, characterized by variable degrees of deficiency of GH, prolactin, TSH, follicle-stimulating hormone (FSH), luteinizing hormone, and occasionally ACTH.[381-385] In humans, PROP1 abnormalities identified to date include at least three missense and one splicing mutation.

A GA repeat in exon 2 (295-CGA-GAG-AGT-303) has been reported to be a hot spot in PROP1. Any combination of a GA or AG deletion in this repeat region results in a frame-shift in the coding sequence and premature termination at codon 109.[381] Similar abnormalities result from GA or AG deletions at codon 149.[382] Large-scale screening of families with multiple cases of CPHD has suggested that PROP1 mutations may be frequent causes of CPHD (32% of unrelated CPHD-affected patients and 50% of unrelated CPHD-affected families, according to one study).[381]

POU1F1 is the human homologue of the mouse gene pit1 and encodes a transcription factor involved in activation of GH and prolactin genes, regulation of the TSH-b promoter, and specification, proliferation, and survival of the corresponding cell lineages.[69,386] Abnormalities of the POUF1 gene result in deficiency of GH and prolactin and in variable TSH deficiency. CPHD resulting from abnormalities of POU1F1 can be transmitted as an autosomal-recessive or autosomal-dominant trait.[387-389] At least 12 different mutations and a deletion of POU1F1 have been

reported in cases of CPHD. The most common mutation is an R271W substitution, which results in production of a protein that remains capable of binding to DNA but acts as a dominant negative inhibitor of transcription.[388] Screening studies suggest that abnormalities of POU1F1 are less common causes of CPHD than are abnormalities of the PROP1 gene.[381,386]

Haploinsufficiency of the homeobox gene RIEG results in Rieger syndrome, an autosomal-dominant disorder that involves abnormal development of the anterior chamber of the eye, teeth, and umbilicus—with an occasional association with GHD.[390,391] The rieg/pitx2 null mouse has been shown to be characterized by multiple pituitary hormone deficiency (MPHD).

Genetic Abnormalities of GH Production and/or Secretion Resulting in Isolated GHD. It has been reported that up to 30% of patients with isolated GHD have an affected parent or sibling. In addition to the abnormalities of the PROP1 and POU1F1 genes described previously, in which abnormalities of GH secretion are associated with decreased secretion of other anterior pituitary hormones, four mendelian forms of isolated GHD have been reported[392,393] (Table 8-6). GH1 is one member of a cluster of five contiguous structurally related genes located on chromosome 17: GH1, CSHP1 (chorionic somatomammotropin pseudogene), CSH1 (chorionic somatomammotropin gene), GH2, and CSH2.

Isolated GHDIA results from deletions (6.7, 7.0, 7.6, and 45 kb deletions have been reported) or mutations of the GH1 gene that totally block GH synthesis or secretion.[394-396] Transmission of isolated GHDIA is autosomal recessive, and patients have profound congenital GHD. Because GH has never been produced by the patient, even in fetal life, patients are immunologically intolerant of GH and typically develop anti-GH antibodies when treated with pituitary-derived or recombinant DNA–derived GH—although development of growth-attenuating antibodies appears to be less frequent with the newer synthetic GH preparations.

When antibodies prevent a patient from responding to GH, GHDIA can be viewed as a form of GHI and the patient is a candidate for IGF-1 therapy. The less severe form of autosomal-recessive GHD (isolated GHDIB) is likely to also be the result of mutations or rearrangements of the GH1 gene, presumably resulting in a GH molecule that retains some function but is perhaps unstable.[397] To date, however, most patients with presumed isolated GHDIB have not demonstrated an alteration of the GH1 gene and the cause of their GHD remains unclear. These patients generally respond to GH therapy, and development of clinically significant anti-GH antibodies is unusual.

Isolated GHDII is transmitted as an autosomal dominant. If such patients also prove to have abnormalities of the GH1 gene, it is likely they function in a dominant negative manner. Isolated GHDIII is transmitted in an X-linked manner. The most common causes of this disorder appear to be splice site and intronic mutations that inactivate the 59-splice donor site of intron 3, resulting in skipping of exon 3. In addition, a missense mutation (Arg183His) has been identified in this phenotype[80]—presumably causing production of an abnormal GH molecule that acts in a dominant negative manner. Finally, the X-linked hypogammaglobinemia and GHD syndrome (an additional X-linked form of GHD associated with hypogammaglobinemia) has not been found to be associated with mutations of the GH gene.[45]

Congenital Absence or Hypoplasia of the Pituitary. A number of reports have described the association of "idiopathic" GHD with an ectopic neurohypophysis.[398-400] Magnetic resonance imaging (MRI) findings have been described in several series of patients with idiopathic dwarfism. Abrahams and associates[399] studied 35 patients with idiopathic GHD and found that those with MRI findings could be divided into two groups: 43% had an ectopic neurohypophysis (neurohypophysis located near the median eminence), absent infundibulum, and an absence of the normal posterior pituitary bright spot, and 43% had a small anterior pituitary as an isolated finding or combined with an ectopic neurohypophysis.

All in all, an ectopic neurohypophysis was found in 87% of cases with multiple pituitary hormone deficiencies but in only 10% of cases with isolated GHD. Kuroiwa and co-workers[400] suggested that the ectopic neurohypophysis, typically visualized as a bright spot at the median eminence, might be the consequence of perinatal asphyxia.

In other studies, however, high-resolution MRI findings of one or more of the following have been suggested to be sensitive and/or specific indicators of hypopituitarism: a small anterior pituitary, attenuated pituitary stalk, and ectopic posterior pituitary. In one study,[401] pituitary abnormalities were found in 80% with isolated GHD and 93% with MPHD. In patients whose peak growth hormone level was less than 3 ng/mL, 90% had MRI findings—compared with 39% of those with growth hormone levels 3 ng/mL or greater. In another study,[402] the stalk was abnormal in 90% of patients with IGHD and was absent in 96% of patients with MPHD. Thus, MRI abnormalities are common in children with isolated GHD and MPHD and are closely associated with the severity of GHD.

Tumors Involving the Pituitary. Many of the tumors that affect hypothalamic function also directly impact pituitary secretion of GH.[371] In addition, craniopharyngiomas comprise a major cause of pituitary insufficiency.[403,404] These tumors arise from remnants of Rathke's pouch, the diverticulum of the roof of the embryonic oral cavity that normally gives rise to the anterior pituitary. Some consider this tumor a congenital malformation because it is believed to be present at birth, gradually growing over the ensuing years and decades.

The tumor arises from rests of squamous cells at the junction of the adenohypophysis and neurohypophysis. As it enlarges, it forms a cyst that contains degenerated cells and that may calcify but does not undergo malignant degeneration. Clinical signs and symptoms of craniopharyngiomas can arise at any age, from infancy to adulthood, but most typically in mid childhood. The most common presentation is with symptoms of increased intracranial pressure, such as headaches, vomiting, or oculomotor abnormalities. Impaired vision is common. Visual field defects may result from compression of the optic chiasm, and papilledema or optic atrophy may be observed.

Visual and olfactory hallucinations have been reported, as have seizures and dementia. Although short stature is not as common a presenting complaint as are symptoms of increased intracranial pressure, most children with craniopharyngiomas have evidence of growth failure at the time of presentation. GH is the most commonly affected pituitary hormone, but TSH, ACTH, and/or gonadotropin deficiency may also occur—and diabetes insipidus is observed in 25% to 50% of patients.

Lateral skull films often demonstrate enlargement or distortion of the sella turcica, frequently accompanied by suprasellar calcification(s). Nevertheless, some children with craniopharyngiomas will have normal plain films (and alternative radiologic techniques are recommended). Computed tomography is a sensitive technique for identification of small amounts of calcification or cystic abnormalities. MRI is probably the most sensitive technique.

Histiocytosis X consists of three related forms: disseminated (Letterer-Siwe), Hand-Schüller-Christian disease, and the solitary form (eosinophilic granuloma). Although these disorders, (especially Hand-Schüller-Christian disease) are classically associated with diabetes insipidus, approximately 50% of patients have growth failure at the time of presentation.[405] GHD may be isolated, or it may be associated with deficiencies of other pituitary hormones.

Psychosocial Dwarfism. An extreme form of "failure to thrive" is observed in a condition labeled "psychosocial dwarfism" or "emotional deprivation dwarfism."[406,407] Most cases of failure to thrive can be traced back to a poor home environment and inadequate parenting, with improved weight gain and growth observed on removal of the infant from the dysfunctional home. In 1967, Powell and co-workers[406] described a group of children with dramatic behavioral manifestations beyond those observed in the typical infant with failure to thrive. Behavior was characterized by bizarre eating and drinking habits, such as drinking from toilets, social withdrawal, and primitive speech. GH secretion was abnormally low after provocative testing but returned to normal on removal from the home. Concomitantly, when eating and behavioral habits normalized children experienced a period of catch-up growth.

The neuroendocrinologic mechanisms involved in psychosocial dwarfism remain to be elucidated, GH secretion is abnormal, and ACTH and TSH activity may also be reduced—although some patients have been reported to be hypercortisolemic. Even though GH secretion is reduced, treatment with GH is not usually of benefit until the psychosocial situation is improved. It is our experience that whereas failure to thrive is a common cause of poor growth in infancy the constellation of findings described in psychosocial dwarfism is, fortunately, rare.

GH Neurosecretory Dysfunction. Because of concerns that tests of GH secretion after pharmacologic provocation do not accurately reflect normal GH secretion, it has been argued that there exists a group of children with "GH neurosecretory dysfunction"—identified by frequent serum sampling over a 12- to 24-hour period or by continuous serum withdrawal over a similar period of time.[408,409] GH neurosecretory dysfunction is characterized by short stature and poor growth, normal provocative serum GH concentrations, reduced 24-hour serum GH concentrations, and low serum IGF-1 concentrations. There appears to be little doubt that some children should be considered GH deficient, even if they pass provocative GH testing, although whether such patients should be identified by 24-hour GH sampling or by measures of the IGF axis remains controversial. This subject is discussed later in the chapter.

Acquired Idiopathic Isolated GHD. In most pediatric endocrine centers, many children receiving GH carry a diagnosis of acquired idiopathic isolated GHD. As stated previously, this diagnosis should always be considered somewhat suspect—although it is clear that some of these patients may actually have undiagnosed gene defects in GH production/secretion or have first manifestations of combined pituitary hormone deficiencies. Tauber and colleagues[410] performed GH stimulation tests on 131 young adults who carried the diagnosis of childhood-onset GHD. Of 10 subjects with organic GHD, 90% had peak GH levels less than 5 ng/mL. On the other hand, 67% of 121 subjects carrying a diagnosis of idiopathic GHD had peak GH levels greater than 10 ng/mL and only 17% had peak levels less than 5 ng/mL.

This study also compared retesting results when subjects were divided into complete GHD (defined by an initial peak), stimulated GH level less than 5 ng/mL, and partial GHD (defined by a peak GH level after two stimulation tests of between 5 and 10 ng/mL or one test below 10 ng/mL and a 24-hour GH level below 2.5 ng/mL). Subjects with partial GHD were twice as likely to have normal GH responses on retesting than were those with complete GHD (71% versus 36%, respectively).

In a similar study, Maghnie and co-workers[411] reinvestigated 35 young adults with childhood-onset GHD divided into four groups according to their first pituitary MRI: isolated GHD and normal pituitary volume; isolated GHD and small pituitary volume; isolated GHD or MPHD, together with hypothalamic-pituitary abnormalities on MRI such as pituitary hypoplasia, pituitary stalk agenesis, and posterior pituitary ectopia; and MPHDs secondary to craniopharyngioma. On retesting, all subjects in the first and second groups had normal GH responses to provocative testing, regardless of pituitary size. On the other hand, all subjects in the third and fourth groups had peak GH responses less than 3 ng/mL. These findings and those of a number of similar studies[412] have indicated that the likelihood of sustained GHD is much greater in cases of MPHDs and/or structural abnormalities of the hypothalamus/pituitary.

Bio-inactive GH. Serum GH exists in multiple molecular forms, representing alternative post-transcriptional or post-translational processing of the mRNA or protein, respectively. It is conceivable that different molecular forms of GH may have varying potency in stimulating skeletal growth, although this remains to be rigorously demonstrated. It has been suggested that some cases of short stature may be characterized by serum GH forms that have normal immunopotency but reduced biopotency.[413] Until recently, no completely convincing cases of "bio-inactive GH" had been demonstrated. In 1996, Takahashi and colleagues[414,415] reported two cases that were heterozygous for point mutations in GH1. One patient was characterized

by a R77C mutant GH molecule that bound with high affinity to the GHBP but abnormally to the GHR.

The mutant molecule appeared to behave in a dominant negative fashion and could inhibit tyrosine phosphorylation through the GHR. This patient had a partial clinical response to GH, and the father (who was heterozygous for the same mutation) was phenotypically normal—thereby raising some questions about the physiologic significance of this mutation. A second patient, with a D112G mutation, produced a GH molecule that apparently inhibits GHR dimerization. This patient, however, was able to respond to exogenous GH by increasing serum IGF-1 and accelerating growth. Although searches will continue for other examples of GH variants with decreased activity, it seems likely that true "bio-inactive GH" is a rare cause of growth failure.

GH Insensitivity. It is important to consider growth in the context of GH secretion and GH sensitivity, which can operate alone or in combination in a variety of patients—including those with ISS (Figure 8-22). GHI describes patients with the phenotype of GHD but with normal or elevated serum GH concentrations[88,416] (Table 8-7). Primary GHI implies abnormalities of the GHR, including the extracellular GH binding site, the extracellular GHR dimerization site, or the intracellular site; post-receptor abnormalities of GH signal transduction; and primary defects of IGF-1 biosynthesis. Secondary GHI is an acquired condition and includes circulating antibodies to GH, antibodies to the GHR, malnutrition, and hepatic disease.

The initial report, by Laron and colleagues, described ". . . three siblings with hypoglycemia and other clinical and laboratory signs of growth hormone deficiency, but with abnormally high concentrations of immunoreactive serum growth hormone."[416] To date, approximately several hundred cases have been identified worldwide.[88] The majority of reported cases come from the Mediterranean region or from Ecuador (in presumed descendants of Spanish "conversos": that is, Jews who converted to Christianity during the Inquisition).[416] These patients have been demonstrated to be unresponsive to exogenous GH in terms of growth, metabolic changes, and alterations in serum concentrations of IGF-1 and IGFBP-3.[417]

Cellular unresponsiveness to GH was demonstrated in vitro by the failure of GH to stimulate erythroid progenitor cells from the peripheral blood of patients.[418] Direct evidence of receptor failure was provided by the demonstration that hepatic microsomes obtained by liver biopsy failed to bind radiolabeled GH.[419] An absence of detectable GHBP activity in the sera of patients with this familial form of GHI was subsequently demonstrated by the reduced ability of serum to bind radiolabeled GH.[108,109]

This observation was rapidly followed by the purification, cloning, and sequencing of the serum GHBP and the demonstration that it was in essence identical to the extracellular domain of the GHR.[90] Initial studies of the GHR gene in Israeli patients indicated that some contained gene deletions.[420] Subsequently, a wide variety of point mutations (missense, nonsense, and abnormal splicing) were identified.[88,421,422] The majority of reported point mutations are in the extracellular domain of the GHR, although there are some at the extracellular domain that

TABLE 8-7

Proposed Classification of Growth Hormone (GH) Insensitivity

A. Primary GH Insensitivity (Hereditary Defects)

1. GH receptor defect (may be positive or negative for GH-binding protein)
   - Extracellular mutation
   - Cytoplasmic mutation
   - Intracellular mutation
2. GH signal transduction defects (distal to cytoplasmic domain of GH receptor)

Stat-5b mutations

3. Insulin-like growth factor-1 defects
   - IGF-1 gene deletion
   - IGF-1 transport defect (ALS mutation)
   - IGF-1 receptor defect
4. Bioinactive GH molecule (responds to exogenous GH)

B. Secondary GH Insensitivity (Acquired Defects)

- Circulating antibodies to GH that inhibit GH action
- Antibodies to the GH receptor
- GH insensitivity caused by malnutrition, liver disease, catabolic states, diabetes mellitus
- Other conditions that cause GH insensitivity

Definitions:

- *GH insensitivity:* Clinical and biochemical features of IGF-1 deficiency and insensitivity to exogenous GH, associated with GH secretion that would not be considered abnormally low.
- *GH insensitivity syndrome:* GH insensitivity associated with the recognizable dysmorphic features described by Laron.
- *Partial GH insensitivity:* GH insensitivity in the absence of dysmorphic features described by Laron.

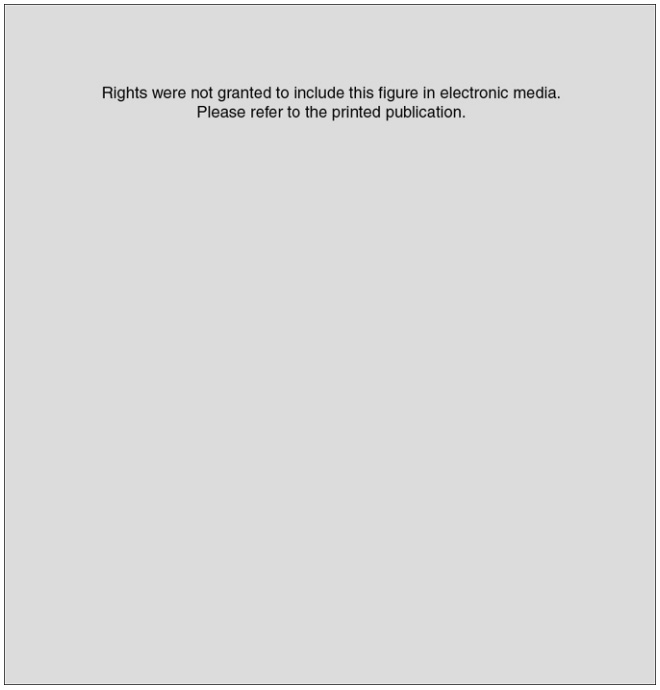

Figure 8-22 Dual contributions of GH secretion and action to growth. [From Cohen P (2006). Controversy in clinical endocrinology: Problems with reclassification of IGF-1 production and action disorders. J Clin Endocrinol Metab 91:4235–4236.]

did not affect GH binding but prevented dimerization of the receptor.[423] Such cases may be characterized by normal or even increased serum concentrations of GHBP because the GHBP binding site is intact. There are reports of patients with two separate amino acid substitutions in the intracellular domain.[424]

Woods and associates[425] reported two cousins with severe GHI resulting from a mutation in the 59-splice donor site of intron 8, resulting in a truncated GHR lacking the transmembrane and intracellular domains and leading to increased concentrations of serum GHBP—presumably owing to accelerated release from the cell membrane. A similar defect has been described in a Druse girl with a mutation of the 39-acceptor site of intron 7.[426] Two defects directly affecting the intracellular domain have been reported to result in dominantly inherited GHI. In one, a white girl and her mother (both with short stature and biochemical evidence of GHI) were found to be heterozygous for a single G-to-C transversion in the 39-splice acceptor site of intron 8—resulting in a truncated GHR 1–277 lacking most of the intracellular domain.[427]

A second report described high serum GHBP concentrations in two Japanese siblings and their mother, who were characterized by partial GHI. The patients and their mother had a point mutation that disrupted the 59-splice donor site of intron 9, causing skipping of exon 9 and the appearance of a premature stop codon in exon 10—resulting in the same GHR 1–277 molecule described by Ayling and associates.[427] Under in vitro conditions, the Japanese mutation has been shown to result in a GHR molecule that behaves in a dominant negative manner—inhibiting GH-induced tyrosine phosphorylation of STAT5.

The clinical features of GHI due to GHR deficiency (GHRD) are identical to those of other forms of severe IGF deficiency, such as congenital GHD.[88] Basal serum GH concentrations are typically elevated in children but may be normal in adults (Figure 8-23). Most patients have decreased serum GHBP concentrations, at least as measured by functional assays. A normal (or even elevated) serum GHBP concentration does not, however, exclude the diagnosis of GHRD because mutations at the GHR dimerization site have been already described, as well as mutations of the intracellular domain of the receptor. Serum IGF-1, IGF-2, and IGFBP-3 concentrations are profoundly reduced in classic GHI (Figure 8-24)—but partial clinical and biochemical phenotypes have been described, typically related to milder mutations of the GHR gene and resulting in only a modest reduction in binding activity and/or receptor action.

GHR Signaling Defects. Although some cases of primary IGFD with normal serum GHBP have proven to have defects of the transmembrane or intracellular domain of the GH receptor, patients have been reported with similar clinical and biochemical phenotypes but with normal sequencing of the GH receptor gene. Until recently, such cases (even when characterized by apparently abnormal activation of the STAT or MAPK pathways) have had no demonstrable molecular basis. Koefed et al.,[428] however, reported a 16-year-old girl with a height of –7.5 SD and markedly low serum concentrations of IGF-I, IGFBP-3 and ALS despite normal serum

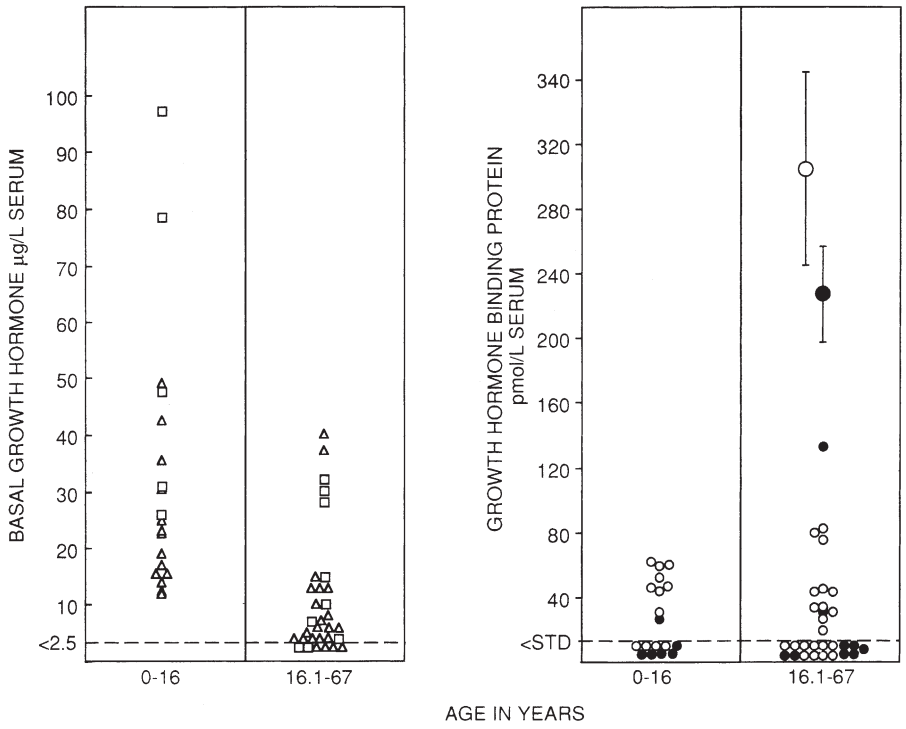

FIGURE 8-23. Growth hormone and growth hormone-binding protein concentrations in sera of patients from Ecuador with GH receptor deficiency. (From Rosenfeld RG, Rosenbloom AL, Guevara-Aguirre J: Growth hormone [GH] insensitivity due to primary GH receptor deficiency. Endocr Rev 15:369, 1994.)

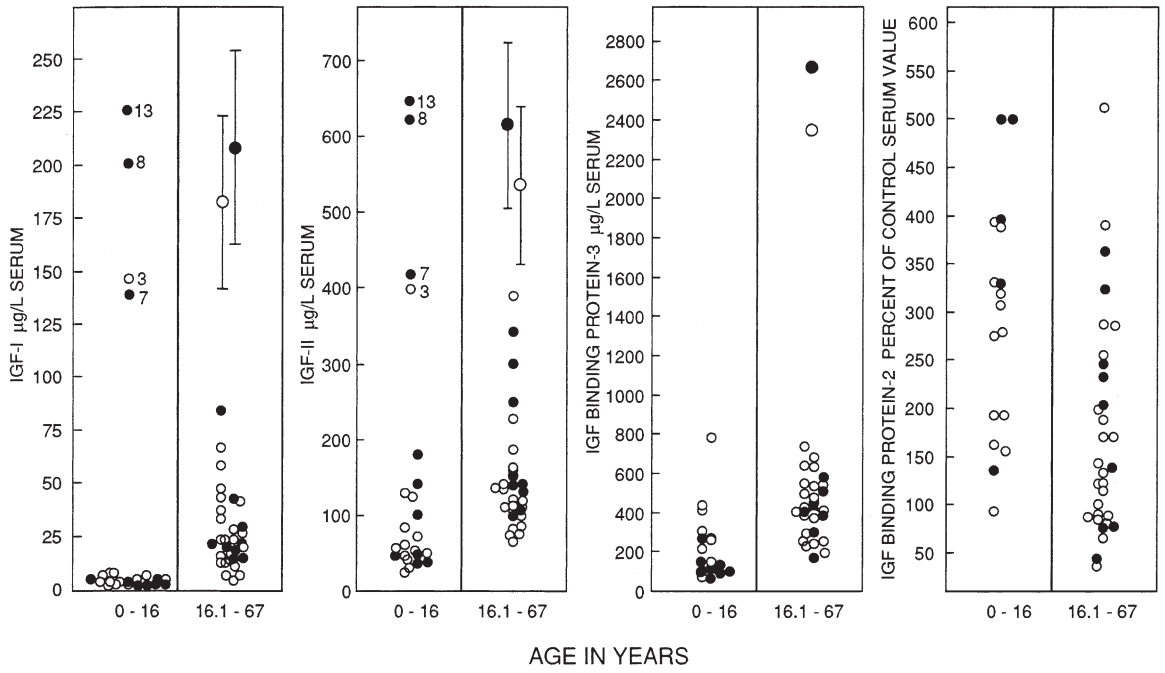

FIGURE 8-24. Serum concentrations of insulin-like growth factor-1 (IGF-1), IGF-binding protein-3, and IGF-binding protein-2 in patients from Ecuador with growth hormone receptor deficiency. (From Rosenfeld RG, Rosenbloom AL, Guevara-Aguirre J: Growth hormone [GH] insensitivity due to primary GH receptor deficiency. Endocr Rev 15:369, 1994.)

concentrations of GHBP and a normal GHR gene sequence.

The patient, born to consanguineous parents, proved to be homozygous for a point mutation resulting in a substitution of proline for alanine at position 630 of the STAT5b gene—with resulting marked decrease in phosphorylation of tyrosine, a critical step in the pathway to STAT activation of IGF-I gene transcription. Subsequent investigations indicated that the mutant STAT5b could not function as a signal transducer or transcription factor, presumably because of an inability to dock with phosophotyrosines on GH-activated receptors as well as an inability to form a stable interaction with DNA. The A630P STAT5b was shown to be characterized by aberrant folding and diminished solubility, resulting in aggregation and formation of cytoplasmic inclusion bodies.

A second case of severe primary IGFD and GH insensitivity resulting from a novel mutation of STAT5b has been reported recently. The patient was shown to be homozygous for a single nucleotide insertion in exon 10 of the STAT5b gene, leading to early protein termination. Because STAT5b is involved in the signaling pathway for multiple cytokines, it is of note that both patients had evidence of immune dysfunction and recurrent pulmonary infections. The growth and clinical characteristics of these two patients strongly support the hypothesis that STAT5b mediates the overwhelming majority, if not all, of GH's effects on IGF-I gene transcription. To date, no convincing mutations of the genes for JAK2 or MAPK have been implicated in primary IGFD and GH insensitivity. It is quite possible that severe mutations of JAK2 (involved in signaling for multiple growth factors and cytokines) are incompatible with life.

ALS Mutations. Markedly reduced serum concentrations of IGF-I and IGFBP-3 have also been observed in two cases involving mutations of the ALS gene.[429] Of note is that in both cases even though serum concentrations of IGF-I and IGFBP-3 were as low as in patients with mutations of the GHR or STAT5b genes growth was only modestly affected. Indeed, the index case actually attained an adult height within the normal range. Whether the relatively normal growth reflects the greater importance of locally produced IGF-I or reflects altered kinetics of serum IGF-I in the face of reduced concentrations of binding proteins remains uncertain.

Growth failure associated with a primary defect of IGF-1 synthesis has also been reported.[287] The first case was a 15-year-old boy who had many of the growth characteristics predicted from mouse knockout models,[286,353,430] including intrauterine and postnatal growth failure. Additional features were mental retardation and sensorineural deafness. The patient was shown to be homozygous for deletions of exons 4 and 5 of the human IGF-1 gene, with both parents being heterozygous carriers and perhaps mildly affected themselves. Although unresponsive to GH therapy, the patient was able to accelerate growth velocity on treatment with IGF-1. Of note is that the patient with IGF-1 gene deletion had in addition to severe growth failure and mental retardation substantial insulin resistance, and that IGF-1 therapy resulted in a marked improvement of insulin sensitivity, reduction of serum insulin, and overall improvement in various aspects of carbohydrate metabolism.[432]

Cases of IGF-1 receptor mutations have also been described.[431] In mouse knockout models, homozygous mutations of the IGF-I receptor result in profound growth

failure and neonatal mortality. Heterozygous mutations are phenotypically similar to wild-type mice. In the African Efe pygmies, a series of studies demonstrated extreme insensitivity to the in vitro growth-enhancing effects of IGF-I. Reduced IGF-I receptor transcripts and sites with resultant diminished tyrosine phosphorylation and post-receptor signaling, though no definable receptor mutation, are suggested explanations.

Patients with IUGR and postnatal growth failure associated with defects of the IGF1R have been reported. Clinical findings have included microcephaly and mild mental retardation. Serum IGF-I concentrations were normal to elevated, but binding of IGF-I was shown to be reduced. Whether such mutations will prove to be a common cause of combined IUGR and postnatal growth failure remains to be determined.

In leprechaunism, a syndrome of growth failure and insulin receptor dysfunction, there is variable IGF-I insensitivity. The profound abnormality of the insulin receptor suggests that heterodimeric insulin- and IGF-I receptor combinations could possible lead to failed activation of the IGF-I signaling cascade. As the IGF-I receptor gene resides at 15q26.3, deletions of the distal long arm of chromosome 15 or ring chromosome 15 may lead to hemizygosity for the IGF-I receptor. Although such patients may have intrauterine growth retardation and striking postnatal growth failure, lack of a biologic response to IGF-I has not been conclusively demonstrated. Whether growth failure in such patients is due to altered levels of IGF-I receptor or represents the net effect of the loss of other genes located on 15q remains to be determined.[431]

Clinical Features. Cases of IGF-1 deficiency resulting from hypothalamic dysfunction, decreased pituitary GH secretion, or GHI share a common phenotype. The striking clinical similarity among patients with GHD caused by a GH gene deletion and patients with GHI secondary to mutations of the GHR gene emphasizes the role of IGF-1 in mediating most, if not all, of the anabolic and growth-promoting actions of GH. This point is further supported by the ability of IGF-1 therapy to partially normalize growth in children with mutations of the GHR gene. Accordingly, the clinical features of severe IGF deficiency are shared by all of these conditions. Children with less severe IGF deficiency will generally have milder clinical characteristics. If GH or IGF deficiency is acquired, clinical signs and symptoms will obviously appear at a later age. (See Table 8-8.)

As stated previously, birth size is remarkably normal even in severe forms of congenital GHD or GHI. Birth length and weight are typically within 10% of normal, and severe IUGR is not part of the classic phenotype. Neonatal signs can exist, however, including hypoglycemia and prolonged jaundice.[433] When GHD is combined with ACTH and TSH deficiency, hypoglycemia may be severe. On the other hand, when GHD is combined with gonadotropin deficiency microphallus, cryptorchidism, and hypoplasia of the scrotum may be observed.[434] GHD (or GHI) should therefore be considered in the differential diagnosis of neonatal hypoglycemia or microphallus/cryptorchidism.

Postnatal growth is strikingly abnormal in severe congenital IGF deficiency (Figure 8-25). Although earlier reports suggested that growth in such cases was relatively normal during the first 6 months of life, more recent surveys of GHD and GHI have indicated that growth failure may be observed during the first months of life. By 6 to 12 months of age, the child is clearly growing at an abnormally slow rate and has usually deviated away from the normal growth curve. It is important to emphasize that the single most important clinical manifestation of IGF deficiency is growth failure, and careful documentation of growth rates is critical to making the correct diagnosis. Deviation away from the normal growth curve should always be a cause of concern, and between the ages of 2 years and the onset of puberty growth deceleration (or acceleration) is always pathologic.

Skeletal proportions tend to be relatively normal, although they often correlate better with bone age than with chronologic age. Skeletal age is delayed, often to less than 60% of the chronologic age. In acquired GHD, as from a tumor of the CNS that presents as symptoms resulting from increased intracranial pressure, the skeletal age may approximate the chronologic age and should therefore not be considered a requirement for the diagnosis of GHD. Weight/height ratios tend to be increased, and fat distribution is often "infantile" in pattern.

Musculature is poor, especially in infancy, which may result in significant delays in gross motor development—leading to the erroneous impression of mental retardation. Facial bone growth is particularly retarded, and the nasal bridge may appear underdeveloped (Figure 8-26). Fontanelle closure is often delayed, but the overall

TABLE 8-8

Clinical Features of Growth Hormone Insensitivity

Growth and Development
Birth weight: near-normal
Birth length: may be slightly decreased
Postnatal growth: severe growth failure
Bone age: delayed, but may be advanced relative to height age
Genitalia: micropenis in childhood; normal for body size in adults
Puberty: delayed 3 to 7 years
Sexual function and fertility: normal

Craniofacies
Hair: sparse before the age of 7 years
Forehead: prominent; frontal bossing
Skull: normal head circumference; craniofacial disproportion due to small facies
Facies: small
Nasal bridge: hypoplastic
Orbits: shallow
Dentition: delayed eruption
Sclerae: blue
Voice: high-pitched

Musculoskeletal/Metabolic/Miscellaneous
Hypoglycemia: in infants and children; fasting symptoms in some adults
Walking and motor milestones: delayed
Hips: dysplasia; avascular necrosis of femoral head
Elbow: limited extensibility
Skin: thin, prematurely aged
Osteopenia

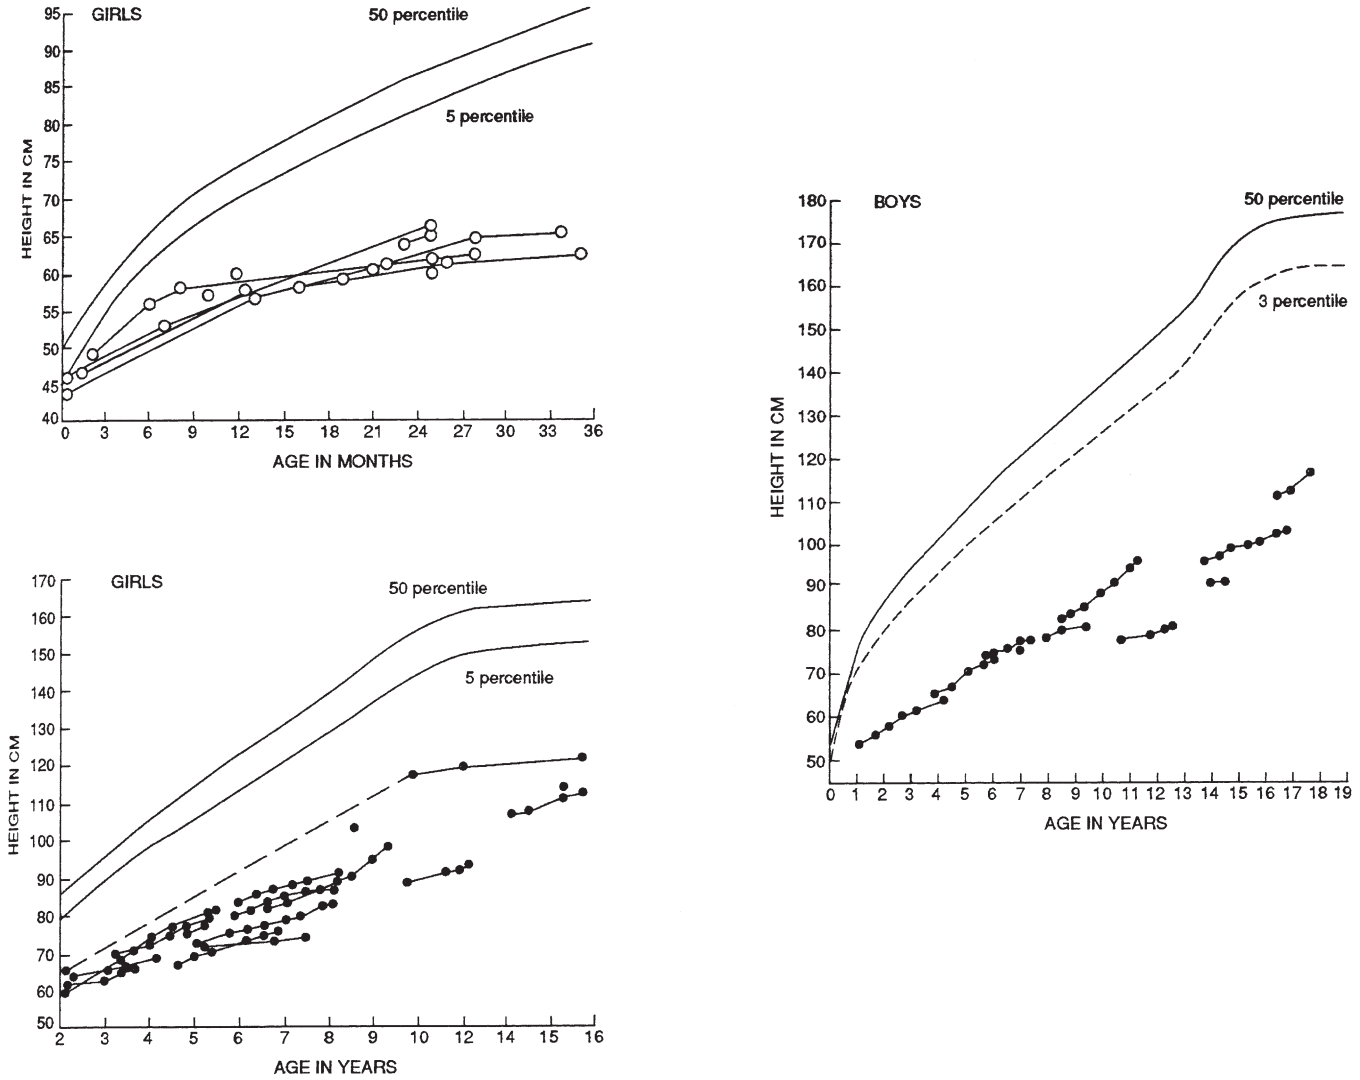

FIGURE 8-25. Height measurements for children from Ecuador with growth hormone receptor deficiency. (From Rosenfeld RG, Rosenbloom AL, Guevara-Aguirre J: Growth hormone [GH] insensitivity due to primary GH receptor deficiency. Endocr Rev 15:369, 1994.)

growth of the skull is normal—leading to cephalofacial disproportion and the appearance of hydrocephalus. The voice remains infantile, owing to hypoplasia of the larynx. Hair growth is sparse and the hair itself is thin, especially during the early years of life. Nail growth is also frequently slow. Even with normal gonadotropin production, the penis is small and puberty is generally delayed.

Diagnosis of IGF Deficiency. The proper means of establishing a diagnosis of GHD continues to be highly controversial.[254] With the availability of highly specific assays for the IGF peptides and binding proteins, and with increasing understanding of the GH-IGF axis, we believe that evaluation of patients with growth failure should rest on a combination of careful auxologic assessment and appropriate measures of the GH-IGF system. Establishment of deficiency of IGF peptides and concomitant alterations in serum concentrations of IGFBPs then necessitates a thorough evaluation of hypothalamic-pituitary-IGF function.

The foundation for the diagnosis of IGF deficiency must be auxology, with careful documentation of serial heights and determination of height velocity. In the absence of other evidence of pituitary dysfunction, it is generally unnecessary to perform tests of GH secretion. Thus, even in children below the 5th percentile in height (which obviously applies to 5% of the population) documentation of a normal height velocity makes the diagnosis of IGF deficiency and GHD highly unlikely.

Assessment of pituitary GH production is problematic because GH secretion is pulsatile throughout the day and night, with the most consistent surges occurring at times of slow-wave electroencephalographic rhythms during phases 3 and 4 of sleep. Regulation of GH secretion is complex, involving two hypothalamic proteins (GHRH and somatostatin) as well as multiple other peptides and neurotransmitters. Spontaneous GH secretion varies significantly with gender, age, and pubertal status—all of which must be factored into any evaluation of GH production.

FIGURE 8-26. Facial appearance of patients from Ecuador with growth hormone receptor deficiency. (From Rosenfeld RG, Rosenbloom AL, Guevara-Aguirre J: Growth hormone [GH] insensitivity due to primary GH receptor deficiency. Endocr Rev 15:369, 1994. Photography by Arlan L. Rosenbloom, MD.)

Between normally occurring pulses of GH secretion, serum GH concentrations are normally low—below the limits of sensitivity of most conventional assays. Accordingly, measurement of random serum GH concentrations is virtually useless in establishing a diagnosis of GHD. Measurement of GH "reserve" has therefore relied on the use of physiologic or pharmacologic stimuli, and these "provocative tests" have been the basis for diagnosing GHD for more than 30 years.[254,435]

"Physiologic" stimuli have included fasting, sleep,[436] and exercise[437,438]—whereas pharmacologic stimuli have included levodopa,[439] clonidine,[440] glucagon,[441] propranolol, arginine,[442] and insulin[443,444] (Table 8-9). Stimulation tests have often been divided into "screening tests" (exercise, fasting, levodopa, clonidine)—characterized by ease of administration, low toxicity, low risk, and low specificity—and "definitive tests" (arginine, insulin, glucagon). To improve specificity, provocative tests are customarily combined or given sequentially.[445-447] It has been generally accepted that a child must "fail" provocative tests with at least two separate stimuli to be considered as having GHD. Standard provocative GH tests are summarized in Table 8-9.

Although provocative GH testing has been the foundation for the diagnosis of GHD since GH radioimmunoassays first became available, its use as a determiner of GH status has come under criticism for a number of reasons.[254,448] These issues, as follows, have been summarized in a consensus report on the diagnosis of childhood GHD.[434]

- Provocative GH testing is nonphysiologic.

None of the standard pharmacologic provocative tests satisfactorily mimics the normal secretory pattern of pituitary GH. Even when naturally occurring regulatory peptides are used for stimulation, their dosage, route of administration, and interactions with other regulatory factors are artificial. In addition, because most endocrine centers use several different stimulation tests there is no validated means of resolving conflicting data from two or more provocative tests.[449] In a report of 6,373 GH stimulation tests performed on 3,233 short French children, 11 different pharmacologic tests were employed, 62 of the possible 66 pairs were employed at least once, and the most frequent combination of tests was used in only 12.7% of the patients.[450]

- Arbitrary definitions of "subnormal" response to provocative tests.

Endocrine centers vary in their definition of a "normal" response to stimulation tests. Whereas early reports generally employed a cutoff level of 5 ng/mL, this was gradually increased to 7 ng/mL. With the availability of recombinant DNA–derived hGH, this level was increased to 10 ng/mL—although no data exist for validating any of these arbitrary cutoff levels. The lack of objective confirmation of any defined normal response can be seen in the use of language such as "lack of adequate endogenous growth hormone secretion"[451] and "inadequate secretion of normal endogenous growth hormone."[452] As indicated by Guyda, many of the newer GH assays measure GH concentrations twofold to threefold lower than older assays and yet there

TABLE 8-9

Growth Hormone Stimulation Tests*

Stimulus	Dosage	Samples (Min)	Comments/side Effects
Levodopa (PO)	< 15 kg: 125mg 15-30 kg: 250 mg >30 kg: 500 mg	0, 60, 90	Nausea
Clonidine (PO)	0.15 mg/m^2	0, 30, 60, 90	Tiredness, postural hypotension
Arginine HCl (IV)	0.5 g/kg (max 30 g) 10% arginine HCl in 0.9% NaCl over 30 min	0, 15, 30, 45, 60	
Insulin (IV)	0.05-0.1 IU/kg	0, 15, 30, 45, 60, 75, 90, 120	Hypoglycemia; requires supervision†
Glucagon (IM)	0.03 mg/kg (max 1 mg)	0, 30, 60, 90, 120, 150, 180	Nausea

* Tests should be performed after an overnight fast. It is generally recommended by some authorities that prepubertal children be "primed" with sex steroids (e.g., premarin, 5 mg PO the night before and the morning of the test, or ethinyl estradiol, 50 to 100 μg/d for 3 consecutive days before testing; or depot testosterone, 100 mg 3 days before testing). Patients should be euthyroid at time of testing.

† Insulin-induced hypoglycemia is a potential risk of this procedure, which is designed to lower the blood glucose by at least 50%. Documentation of appropriate lowering of blood glucose is recommended. If growth hormone deficiency, the lower dosage of insulin may be advisable, especially in infants. $D_{50}W$ solutions and glucagon should be available.

has been no systematic reevaluation of the "normal" GH cutoff level.

• Age dependency and use of sex steroids.

Serum GH concentrations typically rise during puberty, manifested as an increase in pulse-amplitude but not pulse frequency.[57,453] Immediately before puberty and during the earliest phases of puberty, GH secretion may normally be so low as to blur the distinction between GHD and constitutional delay of growth and maturation.[57,453] There are multiple reports of children who "failed" provocative testing before the onset of puberty but proved to have "normal" GH secretion after puberty or after administration of exogenous sex steroids.[454-457] One study of provocative GH testing in children of normal stature has clearly demonstrated the inherent problems with provocative GH testing and the need for standardization of sex steroid administration during stimulation tests.[458]

When exercise and arginine/insulin stimulation tests were administered to these normal children, the lower limit of normal (2 SD) for peak serum GH concentration in prepubertal children was only 1.9 ng/mL—whereas in children of Tanner stage 5 puberty this level was 9.3 ng/mL. When estrogen was administered before provocative testing, the lower 95% confidence limit for the normal serum GH range rose to 7.2 ng/mL. All in all, when estrogen was not administered 61% of the normal prepubertal children failed to raise their serum GH concentration above 7 ng/mL after three provocative tests. These children could have been erroneously labeled as having GHD.

• GH assays of limited accuracy.

Several studies have demonstrated as much as threefold variability in the measurement of serum GH concentrations by established laboratories.[460,461] This is explained at least in part by the existence of several molecular forms of GH in serum and by the use of monoclonal versus polyclonal antibodies. The inevitable result has been that children labeled as having GHD by one assay would be considered normal by another.

A highly sensitive immunofunctional GH assay has been developed that measures concentrations of GH capable of binding to GHBP. It is not clear, however, that such assays necessarily have any advantages over standard radioimmunoassays for routine GH measurements.[462] When arginine/levodopa or arginine/insulin stimulation tests were used, approximately 50% of normal children had peak GH concentrations less than 7 ng/mL and 30% were less than 5 ng/mL whether GH was measured by immunofunctional assay or enzyme-linked immunosorbent assay.

• Expense, discomfort, and risks of provocative GH testing.

Provocative testing typically requires multiple timed blood samples, and frequently necessitates parenteral administration of drugs. The resulting discomfort to the patient and expense are self-evident. In addition, insulin administration carries the risk of hypoglycemia and seizures and should be performed by experienced medical personnel under appropriate supervision. Death has been reported from insulin-induced hypoglycemia and from its overly vigorous correction with parenteral glucose.[463]

• Poor reproducibility of provocative tests.

The reproducibility of provocative GH tests has never been adequately demonstrated, even when GH concentrations

are determined with the same assay.[463] An alternative approach is the measurement of spontaneous GH secretion. This can be done either by multiple sampling (every 5 to 30 minutes) over a 12- to 24-hour period or by continuous blood withdrawal over 12 to 24 hours.[82,408,464,465] The former method allows one to evaluate and characterize GH pulsatility, whereas the latter only permits determination of mean GH concentration. Either approach, however, is subject to many of the same criticisms as provocative GH testing. The potential expense and discomfort of such testing are obvious.

Furthermore, although it has been claimed that this technique is more reproducible than are provocative GH tests variability remains problematic.[343,345,466,467] The ability of such tests to discriminate between GHD and normal short children is also an issue. Rose and colleagues[468] reported that spontaneous GH determinations identified only 57% of children with GHD, defined by provocative testing. In this report, no case of "neurosecretory dysfunction" could be identified in the group of normal short children. Similarly, Lanes and co-workers[469] reported that one-fourth of normally growing children had decreased overnight GH concentrations.

Given the problems with GH testing in general, it is not surprising that provocative tests and 24-hour GH profiles do not correlate perfectly. It is in fact likely that 12- to 24-hour GH profiles can correctly identify the majority of children with GHD and may be superior in sensitivity and specificity to provocative GH testing. With the advent of more routine treatment of ISS with GH, GH testing is no longer the controversial topic it once was—and many experts recognize that a large overlap exists between GHD and ISS as they are commonly defined.

"Neurosecretory dysfunction" probably does exist in children who have had cranial irradiation and likely does describe a subgroup of children with GHD and IGF deficiency. However, the expense and discomfort of frequent overnight or 24-hour sampling combined with many of the problems intrinsic to GH determinations preclude this form of testing for GH deficiency from being the test of choice in establishing the diagnosis of GHD.

The measurement of GH concentrations in urine has provided an alternative means of assessing "integrated" GH secretion (or at least excretion).[470-472] This technique requires anti-GH antibodies of high affinity because urinary GH concentrations are normally low. It also requires timed urine collections. Adequate age- and sex-related standards have not yet been fully developed, and the diagnostic use of urinary GH determinations remains to be adequately evaluated.

Whereas some have interpreted these difficulties in measuring GH as a reason to stop performing GH testing altogether, we strongly recommend continuing use of this testing modality that is nevertheless critical to differentiating GHD from ISS, and secondary from primary IGFD. These conditions are vastly different in a variety of ways. Rather, we believe that the results of the GH testing should not serve as an absolute determinant of the decision to treat with GH (or other drugs, including IGF-I). A complementary approach to the diagnosis of GHD is the use of IGF-related assays.[153,154,157,179] GHD then becomes part of the differential diagnosis of IGF deficiency, which includes hypothalamic dysfunction, pituitary insufficiency, and GHI.

With the development of sensitive and specific assays for IGFs, as well as for the IGFBPs, it has become apparent that these peptides can reflect the GH status of the patient. Furthermore, they have the advantage that they normally circulate in serum at high concentrations—and thus assay sensitivity is less of an issue. Serum levels of these peptides remain relatively constant during the day, and provocative testing or multiple sampling is not necessary. It is important, however, to recognize the following potential limitations of assays for IGF-1.

- The IGFBPs potentially interfere with radioimmunoassays, radioreceptor assays, and bioassays.[159-161] These binding proteins must be completely removed, as with acid gel chromatography (which is labor intensive),[159-161] or blocked by the addition of excess IGF-2 (which requires a high-affinity antibody with a high degree of specificity for IGF-1).[162] An alternative approach is to employ a radiolabeled IGF-1 analogue with reduced affinity for IGFBPs.[163]
- Serum IGF-1 concentrations are highly age dependent.[155,170,171] They are lowest in young children (<5 years of age), the age at which one most wishes to have a simple diagnostic test.
- Serum IGF-1 concentrations may be reduced in a variety of conditions other than GHD. These include primary and secondary forms of GHI. Malnutrition or any cause of diminished insulin concentration (such as poor food intake; dieting; and malabsorption, such as celiac sprue) will result in low circulating IGF-1 levels. Patients whose weights are less than the 25th percentile for age are likely to have low IGF-1 levels in the range of classic GH deficiency, but their primary problem is malnutrition and not GH deficiency.
- Serum concentrations of IGF-1 (and IGFBP-3) are frequently normal in adult-onset GHD and in children with GHD resulting from brain tumors and/or cranial irradiation.

Even when these caveats are considered, the correlation between serum IGF-1 concentrations and provocative or spontaneous GH measurements is imperfect. Juul and co-workers[473] have reported that in children younger than 10 years of age IGF-1 levels were below 2 SD in only 8 of 15 children with a diagnosis of GHD based on provocative testing (53.3% sensitivity) and were normal in 47 of 48 children with a normal GH response (97.9% specificity).

In one study, 18% of patients with abnormally low provocative GH concentrations had IGF-1 concentrations in the normal range but only 4% of "GHD" patients had normal serum concentrations of IGF-1 and IGF-2. Serum levels of IGF-1 and IGF-2 were reduced in only 0.5% of normal children and in 11% of normal short children.[157] The development of specific immunoassays for IGFBP-3, normally the major serum carrier of IGF peptides, has provided a supplementary means of establishing a diagnosis of IGF deficiency and GHD (Figures 8-19 and 8-27).[241,250,251] Because molar concentrations of IGFBP-3 correlate with the sum of the molar concentrations of IGF-1 and IGF-2, IGFBP-3 determinations offer the following advantages over assays of IGF peptides and other IGFBPs.

Step I—Defining the Risk of GH/IGF Deficiency

Auxologic Abnormalities

- Severe short stature (height SDS <-3 SD)
- Severe growth deceleration (height velocity SDS <-2 SD over 12 months)
- Ht <-2 SD and HV<-1 SD over 12 months
- Ht <-1.5 SD and HV<-1.5 SD over 2 years
- Features of GHD or GHI

Risk Factors

- History of a brain tumor, cranial irradiation, or other documented organic pituitary abnormality
- Incidental finding of pituitary abnormality on MRI

If any of the above exists, proceed to step 2; if not, follow clinically and return to step 1 in 6 months

Step 2—Screening for GH/IGF Deficiency and Other Diseases

A. Order a laboratory panel including assessment of bone age, thyroid function, chromosomes (in females), and nonendocrine tests, and, if indicated, treat diagnosed conditions as appropriate.
And
B. Order an IGF-1 and an IGFBP-3 level.

- If IGF-1/IGFBP-3 are above the mean, follow clinically and return to step 1 in 6 months.
- If IGF-1/IGFBP-3 are low, proceed to step 3; but if the MRI is abnormal, GH stimulation is optional.
- If height <-2,25 SDS proceed to step 3 regardless of the screening tests.

Step 3—Testing GH Secretion

This step can be bypassed if a clear GHD risk factor AND a severe IGF deficiency are identified.
Perform two of the following GH stimulation tests (if appropriate, estrogen prime):

- Clonidine
- Arginine
- Insulin
- Glucagon
- Levodopa
- Propranolol

If both are below 10, go to step 4.
If GH>15, obtain GHBP; if GHBP <-2 SD, consider an IGF-generation test, and, if abnormal, IGF treatment.
If GH>10 and height is <-2.25 SDS consider GH treatment for ISS (Step 5)

Step 4—Evaluating the Pituitary

Perform MRI.
Test HPA, if not already done (CRH stimulation or ITT), and teach cortisol supplementation as needed.

Step 5—Treating for Growth Promotion

Initiate GH therapy (or if GHIS is suspected, consider IGF-1).
Regularly evaluate growth parameters, IGF-1, and IGFBP-3, as well as compliance and safety.
GH secretion should be retested at the end of GH treatment if the diagnosis was GHD.

Figure 8-27 Algorithm of biochemical evaluation of growth failure. CRH, corticotropin-releasing hormone; GH, growth hormone; GHBP, GH-binding protein; HPA, hypothalamic-pituitary axis; HV, height velocity; IGF, insulin-like growth factor; IGFBP-3, IGF-binding protein-3; ITT, insulin tolerance test; MRI, magnetic resonance imaging; SD, standard deviation; and SDS, standard deviation score.

- IGFBP-3 immunoassays are technically simple and do not require any separation of the binding protein from IGF peptides.
- Normal serum concentrations of IGFBP-3 are quite high, typically in the 1- to 5-mg/mL range, and thus assay sensitivity is not an issue.
- Although age dependency exists, serum IGFBP-3 concentrations vary with age to a lesser degree than is the case for IGF-1. Even in infants, serum IGFBP-3 concentrations are normally sufficiently high to allow discrimination of pathologically low values from the normal range.
- Serum IGFBP-3 concentrations are less nutritionally dependent than concentrations of IGF-1, reflecting the "stabilizing" effect of IGF-2 concentrations.
- IGFBP-3 concentrations are clearly GH dependent.

The utility of IGFBP-3 assays in the diagnosis of GHD was evaluated by Blum and colleagues,[251] who found that serum IGFBP-3 concentrations were below the 5th percentile for age in 128 of 132 (97%) of children diagnosed

as having GHD by conventional criteria (height <3rd percentile, height velocity <10th percentile, and peak serum GH <10 ng/mL). At the same time, 124 of 130 (95%) of non-GHD short children had normal IGFBP-3 concentrations.

It is likely that Blum's patients largely consisted of children with severe GHD because this degree of correlation between provocative GH testing and serum IGFBP-3 concentrations has not been consistently identified. For example, Hasegawa and associates[474] reported that the sensitivity of the IGFBP-3 radioimmunoassay in complete GHD (peak GH <5 ng/mL) was 93% but was only 43% in cases of partial GHD (peak GH 5 to 10 ng/mL). Smith and co-workers[475] found that 100% of children with severe GHD (peak GH <1 ng/mL) and low serum IGF-1 also had decreased serum IGFBP-3. Four of 8 children with GHD and normal serum IGF-1 levels had reduced IGFBP-3 concentrations, and 10 of 23 (43%) of normal short children had decreased serum IGFBP-3. The addition of a radioimmunoassay for IGFBP-2 further enhanced the ability of IGF axis measures to identify children who had GHD by conventional criteria.

The correlation between IGF-axis determinations and measures of spontaneous GH secretion nevertheless remains imperfect. Even in healthy normal children the correlation between 24-hour GH secretion and serum IGF-1 and IGFBP-3 concentrations is modest ($r = 0.78$ and $r = 0.62$, respectively).[475] In the Smith study,[476] 18% of patients were found to have discordant measures of IGFBP-3 and provocative GH response. It is impossible at this time to resolve conflicts between assays of the IGF axis and measurements of GH secretion because there is no way to definitively diagnose GHD. Recent experience in patients with GHRD, however, has provided further evidence in support of the utility of IGF-related determinations.[88,477,478]

Although such patients may have normal or elevated serum GH concentrations, mutations or deletions of the GHR gene render them unresponsive to GH—and such patients may be considered "functionally GH deficient." In the experience in Ecuador, of approximately 70 documented cases of GHR gene mutations all patients were found to have markedly reduced serum concentrations of both IGF-I and IGFBP-3. Even so, IGF-1 and IGFBP-3 correlated significantly with height. Measures of serum concentrations of IGF-1 and IGFBP-3 have been used in other studies of GHI to establish diagnostic criteria.

Ultimately, the diagnosis of GHD (or IGF deficiency) should be made on the basis of combined clinical and laboratory criteria. Short children who have well-documented normal height velocities do not generally require evaluation of GH secretion, and normal (>25%) serum IGF-1 and IGFBP-3 concentrations can be reassuring. Children with Turner syndrome and short stature that is consistent with the expected growth pattern for this syndrome should not be required to undergo GH testing to qualify for GH therapy because such treatment is not predicated on abnormal GH secretion.

On the other hand, the child with documented growth deceleration requires further evaluation—even if tests of GH secretion appear normal. Documentation of decreased serum IGF-1 or IGFBP-3 concentrations would then constitute a diagnosis of IGF deficiency, and the diagnoses of GHD and GHI would need to be considered. The child with a history of cranial irradiation, decreased height velocity, and reduced serum concentrations of IGF-1 and IGFBP-3 should be considered to have GHD (or GHI)—even in the presence of normal provocative tests.

This approach still requires measurements of GH secretion. Such determinations are critical to distinguishing between GHD and GHI as causes of IGF deficiency. Documentation of abnormal pituitary GH secretion alerts the physician to the possibility of intracranial tumors and to the potential for other pituitary hormone deficiencies. Evaluation for GHD allows for concomitant assessment of ACTH secretion, and TSH and gonadotropin determinations can be added where appropriate. Ultimately, however, one must conclude that the single most important parameter in assessment of children with growth failure is careful clinical evaluation—including accurate serial measurements of height and determinations of height velocity.

The possibility of hypothalamic-pituitary dysfunction should always be considered in children with documented growth deceleration, particularly in the presence of a known intracranial pathologic process (e.g., tumors, irradiation, malformations, infection, trauma, blindness, nystagmus). Similarly, the neonate with hypoglycemia and/or microphallus warrants evaluation of pituitary function—and patients with documented TSH, ACTH, ADH, or gonadotropin deficiency are candidates for GHD. For children with proportional short stature and documented growth deceleration, assessment of serum concentrations of IGF-1 and IGFBP-3 is clearly warranted—and based on those results the possibilities of hypothalamic dysfunction, pituitary insufficiency, and GHI can be investigated.

Recommendations by the Growth Hormone Research Society (GRS)[280] for the diagnosis of GHD recognize that there is no "gold standard" for the diagnosis of GHD and suggest that in a child with slow growth whose history and auxology suggest GHD testing for GH/IGF-1 deficiency requires the measurement of IGF-1 and IGFBP-3 levels as well as GH provocation tests (after hypothyroidism has been excluded). In suspected isolated GHD, two GH provocation tests (sequential or on separate days) are required. In those with a defined CNS pathologic process, history of irradiation, MPHD, or genetic defect, one GH test will suffice. In addition, an evaluation of other pituitary function is required. In patients who have had cranial irradiation or malformations of the hypothalamic-pituitary unit, GHD may evolve over years and its diagnosis may require repeat testing of the GH-IGF axis.

It is recognized, however, that some patients with auxology suggestive of GHD may have IGF-1 and/or IGFBP-3 levels below the normal range on repeated tests but GH responses in provocation tests above the cutoff level. These children are not classically GH deficient but may have an abnormality of the GH/IGF axis, and after the exclusion of systemic disorders affecting the synthesis or action of IGF-I could be considered for GH treatment. An MRI (or computed tomographic scan) of the brain with particular attention to the hypothalamic-pituitary region should be carried out in any child diagnosed as

having GHD. These GRS recommendations underscore the importance of good clinical judgment rather than specific tests as the key to the diagnosis of GHD.

Testing in the Neonate. The diagnosis of GHD in a newborn is particularly challenging and important. The presence of a micropenis in a male newborn should always be addressed by an evaluation of the GH axis. A GH level should always be measured in the presence of neonatal hypoglycemia in the absence of a metabolic disorder. A GH level in a polyclonal radioimmunoassay of less than 20 mg/L would suggest GHD in the newborn. The use of standard GH stimulation tests is not recommended in newborns, with the exception of the glucagon test (which is safe). In the newborn, although normative data are not available for stimulated serum GH a cutoff of 25 ng/mL is probably appropriate and certainly stimulated values under 20 ng/mL should raise suspicion.

An MRI is essential when the diagnosis is suspected, and results may be available sooner than with serum assays. An IGFBP-3 level is of great value to the diagnosis of GHD in infancy, but IGF-1 levels are rarely helpful.[479] In fact, serum IGFBP-3 should be performed as the test of choice in suspected neonatal GHD. Figure 8-27 provides an algorithm for the biochemical evaluation of growth failure. The diagnosis of IGF and/or GHD should be considered in any child who meets one or more of the criteria listed in Table 8-10.

A child should be considered a candidate for GH therapy if he or she meets one of these criteria, supported by biochemical evidence of GHD based on sex-steroid–primed provocative tests and/or evidence of IGF deficiency based on measurement of IGF-1 and IGFBP-3 concentrations. Such cases need to also have MRI of the hypothalamus-pituitary and assessment of other pituitary hormone deficiencies. It is understood that this approach will result in GH treatment of some children with "idiopathic isolated" GHD or IGF deficiency and that such cases require careful monitoring of both pituitary status and responsiveness to GH treatment. The latter can be assessed relative to recently developed predictive models,[480] and the diagnosis of GHD should be reconsidered in the child with idiopathic isolated GHD, a normal MRI, and a subnormal clinical response to GH.

TABLE 8-10

Key History and Physical Examination Findings That May Indicate Growth Hormone Deficiency (The GRS 2000 Criteria)*

- In the neonate; hypoglycemia, prolonged jaundice, microphallus, or traumatic delivery
- Cranial irradiation
- Head trauma or central nervous system infection
- Consanguinity and/or an affected family member
- Craniofacial midline abnormalities
- Severe short stature (< − 3 SD)
- Height (< − 2 SD) and a height velocity below over 1 year (< − 1 SD)
- A decrease in height SD of more than 0.5 over in children older than 2 years of age
- A height velocity Below − 2 SD) over 1 year
- A height velocity more than 1.5 SD below the mean sustained over 2 years
- Signs indicative of an intracranial lesion
- Signs of multiple pituitary hormone deficiency
- Neonatal symptoms and signs of growth hormone deficiency

Diagnosis of GHI. The combination of decreased serum concentrations of IGF-1, IGF-2, and IGFBP-3 plus increased serum concentrations of GH is highly suggestive of a diagnosis of GHI.[88] The possibility of GHRD is supported by a family history consistent with autosomal-recessive transmission. Savage and Rosenfeld[481] devised a scoring system for evaluating short children for the diagnosis of GHRD based on five parameters: basal serum GH greater than 5 ng/mL, serum IGF-1 less than or equal to 50 ng/mL, height SD scores less than –3, serum GHBP less than 10%, and a rise in serum IGF-1 concentrations after a week of GH stimulation of less than twofold the intra-assay variation (approximately 10%).

Blum and colleagues[482] proposed that these criteria could be strengthened by evaluating GH secretory profiles, rather than isolated basal levels; employing an age-dependent range for evaluation of serum IGF-1 concentrations and using the 0.1 centile as the cutoff level; employing highly sensitive IGF-1 radioimmunoassays and defining a failed GH response as the inability to increase serum IGF-1 concentrations by at least 15 ng/mL; and employing basal and GH-stimulated IGFBP-3 concentrations. These criteria fit well with the population of GHRD patients studied in Ecuador, but that is a remarkably homogeneous population of patients who have severe GHI.[88,478] The universal applicability of these criteria remains to be evaluated. An important biochemical marker will be the IGF-1 (and possibly IGFBP-3) response to GH stimulation. Although such tests were first employed in the early 1980s, normal ranges and age-defined responses of serum IGF-1 concentrations have not yet been determined.[483]

Decreased serum concentrations of GHBP are obviously highly suggestive of a diagnosis of GHRD, but it is important to point out that cases of GHRD with normal serum concentrations of GHBP have already been identified.[425,484] Such cases may represent mutations in the site responsible for dimerization of the GHR, or potentially for abnormalities of the intracellular portion of the receptor or of the postreceptor signal transduction mechanism. On the other hand, polymorphisms of the GHR gene without resulting reductions in IGF-1 and IGFBP-3 concentrations should not be considered GHRD. At this point, definitive diagnosis requires the classic phenotype, decreased serum concentrations of IGF-1 and IGFBP-3, and identification of an abnormality of the GHR gene.

Constitutional Delay of Growth and Maturation. The diagnosis of constitutional delay has had different meanings to different clinicians.[485,486] To some, it has consisted of delayed adolescent growth and maturation in the presence of decreased (even if only transiently) GH secretion.[486,487] More commonly, it has been considered a normal variant (characterized by short stature) but with relatively normal growth rates during childhood, delayed puberty, a delayed pubertal growth spurt, and attainment of normal adult height.

Most patients with constitutional delay begin to deviate from the normal growth curve during the early years of life and are typically by age 2 years at or slightly below the 5th percentile for height. Such children would be expected to have normal serum IGF-1 and IGFBP-3 concentrations, a normal result of a GH provocative test (if pretreated with sex steroids), and skeletal ages that were delayed (Table 8-11). By definition, children with pure constitutional delay should have bone ages sufficiently delayed to result in normal predicted adult heights (Table 8-11). When constitutional delay is found in the context of familial short stature, however, children may experience a delayed adolescent growth spurt and a short final height. Such children should be considered to have elements of constitutional delay and familial short stature and should be classified as ISS and considered for GH therapy.

As stated previously, some have attributed constitutional delay to a transient GHD or to a "lazy" pituitary. It is likely that much of this experience can be attributed to the inadequacies of GH testing, especially to the failure to pretreat patients with a brief course of sex steroids.[458] Low serum concentrations of IGF-1 and IGFBP-3 and/or a poor GH response to provocative testing (after priming with sex steroids) should mandate an investigation for an underlying pathologic process, such as intracranial tumors.

Idiopathic Short Stature. ISS can be defined as a condition in which the height of an individual is more than 2 SD below the corresponding mean height for a given age, sex, and population group without evidence of systemic, endocrine, nutritional, or chromosomal abnormalities. Specifically, children with ISS have normal birth weight and are growth hormone sufficient. ISS describes a heterogeneous group of children consisting of many presently unidentified causes of short stature. It is estimated that approximately 60% to 80% of all short children at or below –2 SD fit the definition of ISS.

This definition of ISS includes short children labeled with "constitutional delay of growth and puberty" and "familial short stature." The frequency of referral of these children is dependent on the socioeconomic environment. Furthermore, there is a greater perceived disability of short stature in boys compared to girls irrespective of social class. ISS should be subcategorized, principally based on auxological criteria. The main distinction is between children with a familial history of short stature whose heights are within the expected range for parental target height and those children who are short for their parents. The corrected target height standard deviation score (SDS) is calculated as 0.72 multiplied by the average of the father's and mother's height SD scores and the lower limit of the target height range as corrected target height –1.6 SD.

It is generally accepted that on average adult height achieved in children with ISS is below the parental target height. ISS should also be classified by the presence or absence of bone age delay, indicating the probability of delayed growth and puberty. Subcategorization may help to predict adult height, which would be expected to be greater in a child with delayed maturation. Individuals with no family history of short stature generally have a lower adult height in comparison to target height. In situations in which a specific genetic diagnosis associated with short stature is expected (such as Noonan's syndrome or GH insensitivity), the gene(s) of interest should be examined. On-line resources exist, such as Genetest *(www.genetests.org),* which identify laboratories capable of performing these tests.

Although routine analysis of SHOX should not be undertaken in all patients with ISS, SHOX gene analysis should be considered for any patient with clinical findings compatible with SHOX haploinsufficiency. With currently available data it is difficult to generalize the impact of short stature on psychosocial adaptation. Short stature may be a risk factor for psychosocial problems, such as social immaturity, infantilization, low self-esteem, and being bullied—especially for those referred for evaluation. The large interindividual differences in adaptation to short stature and in the impact of being short may be a function of several risk and protective factors, including parental attitudes and prevailing cultural opinions. Stress experiences may be frequent, but true psychopathology is rare.[459]

TABLE 8-11

Criteria for Presumptive Diagnosis of Constitutional Delay of Growth and Maturation

- No history of systemic illness
- Normal nutrition
- Normal physical examination, including body proportions
- Normal thyroid function test results
- Normal renal function test results
- Normal complete blood cell count, erythrocyte sedimentation rate, electrolytes
- Normal stimulated GH
- Height between −2.5 and −1.5 SDS
- Height velocity >−1 SDS
- Delayed puberty:
  - Males: failure to achieve Tanner G2 stage by age 13.8 years or P2 by 15.6 years
  - Females: failure to achieve Tanner B2 stage by age 13.3 years
- Delayed bone age (more than 1 year delayed)
- Normal predicted adult height:
  - Males: >165 cm (65 inches)
  - Females: >153 cm (60 inches)

Treatment of Growth Disorders

When growth failure is the result of a chronic underlying disease (such as renal failure, cystic fibrosis, or malabsorption), therapy must be directed at treatment of the underlying condition. Although growth acceleration may be observed with GH or IGF-1 therapy, complete catch-up requires correction of the primary medical problem. If treatment of the underlying condition involves glucocorticoids, growth failure may be profound and is unlikely to be correctable until the patient is weaned from steroids.

Correction of growth failure associated with chronic hypothyroidism requires appropriate thyroid replacement. As discussed previously, thyroid therapy results in dramatic catch-up growth but also markedly accelerates skeletal maturation—potentially limiting adult height. More gradual thyroid replacement and/or the use of gonadotropin

inhibitors to delay puberty may be necessary to maximize final height.

TREATMENT OF CONSTITUTIONAL DELAY

Constitutional delay is a normal variant, with (by definition) potential for a normal (although delayed) pubertal maturation and a normal adult height. Most cases can be successfully managed by careful examination and evaluation to rule out other causes of delayed puberty and/or abnormal growth, combined with appropriate explanation and psychological counseling. The skeletal age and Bayley-Pinneau table are often helpful in explaining the potential for normal growth. A family history of constitutional delay is also frequently a source of reassurance. On occasion, however, the stigmas of delayed maturation and short stature may be psychologically disabling for the adolescent.

Studies have demonstrated that some adolescents with constitutional delay have poor self-images and limited social involvement.[488] In such patients, there is a role for the judicious use of short-term sex steroids. In males, therapy should generally be limited to adolescents who meet the following criteria: a minimal age of 14 years; height below the 3rd centile; prepubertal or early Tanner G2 stage, with a serum testosterone level less than 100 ng/dL; evidence of poor self-image that does not respond to reassurance alone; and predicted adult height well within the normal range. Therapy in males consists of depot testosterone enanthate, 50 to 200 mg every 3 weeks for a total of four injections.[488,489]

Patients will typically show early secondary sex characteristics by the fourth injection and grow an average of 10 cm in the ensuing year. This brief course of therapy has been shown to not cause overly rapid skeletal maturation, compromise adult height, or suppress pubertal maturation.[490] It is important to emphasize to the patient that he is normal, that therapy is short term and designed to provide him with some pubertal development earlier than he would experience on his own, and that treatment will not increase adult height. In such situations, the combination of short-term androgen therapy plus reassurance and counseling has been helpful in assisting the patient with constitutional delay cope with a difficult adolescence.

Patients must be reevaluated to ensure that they spontaneously enter "true" puberty. One year after testosterone treatment, patients should demonstrate testicular enlargement and a serum testosterone level in the pubertal or adult range. If this is not the case, the diagnosis of pituitary insufficiency should be considered. Although a second course of testosterone may be warranted at this time, it is our experience that most such patients eventually prove to be gonadotropin deficient.

The recent availability of several new forms of testosterone supplementation, which are approved for adults with hypogonadism, provided pediatricians with an opportunity to offer patients a choice among different androgen replacement therapies. Although these new therapies have not been published as efficacious in children with constitutional delay, we have personal experience with their successful use—with an equivalent response to that obtained with testosterone injections. Testosterone gel is painless and easy to apply, and has proven popular since its release.[491] Testosterone patches also avoid the need for injections but work best when applied to the scrotum and are often accompanied by complaints of itching.[492] The dosing of these alternative forms of therapy in children is not clearly established, and further experience will undoubtedly accumulate on their use in pediatrics in the coming years.

Referrals for constitutional delay are much more common in males than in females, undoubtedly reflecting our cultural values. When constitutional delay is a problem in girls, short-term estrogen therapy can be employed. The use of GH in patients with constitutional delay is discussed later in this chapter.

TREATMENT OF GROWTH HORMONE DEFICIENCY

Patients with proven GHD should be treated with recombinant human GH (rhGH) as soon as possible after the diagnosis is made. The primary objectives of the therapy for GHD are normalization of height during childhood and attainment of normal adult height. Normally growing patients with craniopharyngioma and GHD should be considered for therapy with GH for metabolic and body composition benefits and for enhancement of pubertal growth.

GH exhibits a high degree of species specificity in its actions. Unlike most other hormones, the only GH biologically active in humans is primate GH. For many years, the only practical source of primate GH for treatment of GHD was human cadaver pituitary glands—first employed in the late 1950s. Over the next 25 years, more than 27,000 children with GHD worldwide were treated. In 1985, distribution of pituitary-derived human growth hormone (hGH) in the United States and most of Europe was halted because of concern about a causal relationship with Creutzfeldt-Jakob disease—a rare and fatal spongiform encephalopathy that had been previously reported to be capable of iatrogenic transmission through human tissue.[493,494]

In North America and Europe, this disorder has an incidence of approximately 1 case per million. Noniatrogenic cases are exceedingly rare before the age of 50 years. To date, more than 20 young adults of about 8,000 patients in the United States who had received human cadaver pituitary products have died of Creutzfeldt-Jakob disease. In France, there have been more than 60 cases of Creutzfeldt-Jakob disease among 1,700 human cadaver GH recipients—and in England 32 cases among 1,900 human cadaver GH recipients have been reported.

Fortunately, by the time the risks of pituitary-derived hGH were discovered recombinant DNA–derived hGH had already begun extensive testing for safety and efficacy.[252,495,496] The original form of rhGH included an N-terminal methionine, added for use as a start signal for transcription (met-hGH). This preparation was found to mimic pituitary-derived hGH in its anabolic and metabolic actions. Subsequent rhGH preparations were produced without the additional methionine. Over the next decade, rhGH universally replaced pituitary-derived hGH as the treatment of choice for children with GHD.

Dosing of GH

Despite continued variability and lack of consensus, considerable progress and improvement have been made in the standardization of GH dosage and administration. It is well established that GH administration should be initiated as early as possible in the GH-deficient child to optimize final height outcome.[497] Daily administration of GH is clearly more effective than giving the same total dose three times weekly.[498] GH injections are best administered in the evening, better mimicking natural physiology and achieving higher GH peaks.[499] The hGH should be administered subcutaneously.

The dosage of GH should be expressed in milligrams (or micrograms) per kilogram per day, although consideration should be given to dosing in micrograms per square meter of body surface per day in patients with obesity. GH is routinely used in the range of 25 to 50 mcg/kg/day. A dose-response relationship in terms of height velocity in the first 2 years has been clearly demonstrated within this range (Figure 8-28).[500-502] On this regimen, the typical GH-deficient child accelerates growth from a pretreatment rate of 3 to 4 cm/year to 10 to 12 cm/year in year 1 of therapy and 7 to 9 cm/year in years 2 and 3. This progressive waning of GH efficacy has been observed universally and is still not fully understood. It can, however, be overcome at least in part by increasing the dosage of hGH. In the United States, at a dosage of 50 mcg/kg/day the approximate current cost of hGH therapy for a 20-kg child is $15,000/year. The practice of individualizing treatment according to the specific needs of each GH-deficient child is gaining popularity.

Consensus does not exist as to how to formulate individualized treatment plans. Emerging evidence suggests that mathematical prediction models of growth response may be useful for determination of the optimal individual dose.[480,503,504] Although these models will need further improvement in their predictive power (as well as further validation), their potential utility is considerable. GH dose can be calculated to achieve specific therapeutic aims (i.e., catch-up to target height within 2, 3, or 4 years). They can also enable a comparison between observed and predicted growth, hastening identification of causes of suboptimal growth. Further application of these models to specific diseases and conditions in which GH responsiveness varies will allow disease-specific optimization.

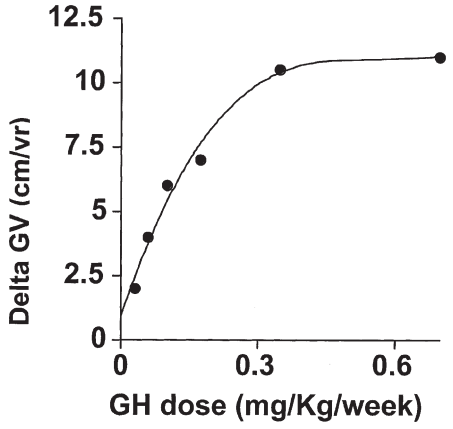

FIGURE 8-28. Meta-analysis of the dose-response relationship between growth hormone (GH) and delta growth velocity (GV) in the first year of treatment of naive GH-deficient children. The lower three doses are from Frasier and colleagues,[501] and the higher three doses are from Cohen and coworkers.[502]

Despite the availability of GH therapy, long-term studies have indicated that many patients fail to achieve normal adult heights—and only a few attain their genetic target heights. Although the development of rhGH has solved the problem of supply experienced in the pituitary GH era, delays in diagnosis and initiation of therapy have still compromised adult height. Data from the National Cooperative Growth Study evaluation of adult heights in 121 patients with childhood GHD indicate a mean adult height in male and female patients of <0.7 SD.[505] By multiple-regression analysis, factors found to correlate with enhanced adult height were baseline height, younger age at onset of treatment, longer treatment duration, and a greater growth velocity during the first year of treatment.

In an effort to increase final height of GHD patients, Mauras and associates[506] have evaluated the use of high-dose GH during puberty—with the rationale that GH secretion normally doubles during the pubertal growth spurt (as indicated by the dramatic rise in serum IGF-1 concentrations during puberty) and that the pubertal growth spurt normally accounts for approximately 17% of adult male height and 12% of adult female height. Earlier studies by Stanhope and associates[507] indicated that little difference in height gain could be observed when adolescent patients were treated with 30 versus 15 IU/m^2/wk of GH (approximately 0.04 versus 0.02 mg/kg/day).

Mauras and associates[506] evaluated higher doses of GH during puberty (100 versus 50 mcg/kg/day) and found that the higher dosage resulted in a 4.6-cm increase in near-final height (defined as height at a bone age of more than 16 years in males and more than 14 years in females). The mean height SD score at near-final height was higher for the 100-mcg/kg/day group. The higher GH dosage did not result in more rapid acceleration of skeletal maturation.

An alternative approach to maximizing height gain during adolescence is to combine GH treatment with suppression of the hypothalamic-pituitary-gonadal axis by GnRH analogues (or recently, but only in boys, the use of aromatase inhibitors). This combined therapy may lead to significant improvement of final height or predicted adult height of patients, as shown in some studies (but long-term results are still lacking). In addition, the effect of suppression of puberty on bone accretion during the critical pubertal phase (as well as on psychosocial function) has not yet been evaluated adequately. Similar concerns may exist for the combination of GH therapy with aromatase inhibitors, which are designed to prevent the effects of estrogen on epiphyseal fusion.

Novel Modalities for Treatment of GHD

Several novel treatment modalities have emerged (Table 8-12). These include oral secretagogues, GHRH, extended-action depot rhGH preparations, and liquid rhGH formulations. A number of GH-releasing peptides and

TABLE 8-12

New and Emerging Modalities for Treatment of Growth Hormone (GH) Deficiency

- Liquid formulations
- Pen-type delivery devices
- Long-acting GH formulations
  - Sustained-release GH formulations
  - Dermal patch delivery of GH
- Oral ghrelin-mimetics

nonpeptidyl GH secretagogues have been formulated since their discovery in the 1980s.[508] Although these oral agents would be an attractive potential treatment option for GHD secondary to hypothalamic GRF deficiency, their evaluation remains incomplete at this time.[509,510] GHRH has been demonstrated to be safe and more effective than placebo at increasing height velocity in some GHD children. However, further long-term studies are needed.[511,512]

The development of sustained-release long-acting depot GH formulations may eventually provide a desirable alternative to daily subcutaneous rhGH injections for some patients. Currently, such formulations remain under study in ongoing clinical trials—and although efficacious they appear less effective than daily rhGH therapy. Further studies will be necessary, however, to ascertain whether such preparations can provide the same level of growth acceleration as is seen with daily GH—and whether side effects will not be increased. Liquid rhGH formulations, which eliminate the need for reconstitution, and new delivery devices such as pen systems have been introduced that appear to improve patient compliance.

Additional novel delivery GH strategies remain under active development, including orally inhaled and intranasally administered rhGH formulations. In time and with further experience, novel treatment approaches may emerge as useful alternatives to conventional rhGH therapy. The combination of GH along with IGF-I therapies may also prove to be a useful treatment of growth disorders.

Management of Multiple Pituitary Hormone Deficiency

In the patient with an initial diagnosis of isolated GHD, particularly those with an ectopic posterior pituitary or other developmental abnormalities, the clinician should be alert to the risk of the development of MPHD. This involves regular repeat biochemical testing and consideration of repeat pituitary imaging. If GHD is part of a multiple pituitary insufficiency, it is necessary to address each endocrine deficiency. TSH deficiency is often "unmasked" during the initial phase of hGH therapy, and thyroid tests should be performed both before the onset of therapy and during the first 3 months of hGH treatment.[513] Even if normal initially, thyroid function should be tested subsequently on at least an annual basis.

The pituitary-adrenal axis is customarily evaluated during the insulin stimulation test for GHD. If ACTH secretion is impaired, patients should be placed on the lowest safe maintenance dose of glucocorticoids—certainly no more than 10 mg/m^2/day of hydrocortisone. Higher doses may impair the growth response to hGH therapy but may be necessary during times of stress. An alternative approach is to avoid maintenance glucocorticoids and treat with steroids only during periods of physiologic stress.

Gonadotropin deficiency may be evident in infancy in the child with microphallus. This can usually be treated with three to four monthly injections of 25 to 50 mg of testosterone enanthate.[514] Management of puberty can be more complicated because the physical and psychological benefits of normalizing sexual maturation must be balanced against the risk of epiphyseal fusion. When hGH therapy is initiated in childhood and the child's growth is normalized before adolescence, it is appropriate to begin sex steroid replacement at a normal age (e.g., 11 to 12 in females and 12 to 13 in males).

In males, this can be done by beginning with monthly injections of 100 mg of testosterone enanthate—gradually increasing to 200 mg/month, and eventually moving to the appropriate adult replacement regimen. In girls, therapy involves use of conjugated estrogens or ethinyl estradiol, and eventual cycling with estrogen and progesterone (as described elsewhere in this book). On the other hand, in patients in whom normal or precocious puberty may limit the statural response to hGH it may be appropriate to delay puberty by the use of the GnRH analogue.

Monitoring GH Therapy

Careful monitoring of pediatric patients with GHD is critical. Important aspects of this process are outlined in Table 8-13. The routine follow-up of GHD children should be performed by a pediatric endocrinologist on a 3- to 6-month basis in partnership with the patient's primary care physician. Assessment of the growth response is perhaps the single most important parameter of monitoring. This consists of accurate determination of height velocity and interval height increase (best expressed in terms of the change in height Z score). Establishment of a target height (typically the mid-parental target height) against which the child's progress can be assessed is important. Careful attention must also be directed toward screening for possible adverse effects and toward assessing compliance.

TABLE 8-13

Elements of Monitoring Growth Hormone Therapy

Close follow-up with a pediatric endocrinologist every 3 to 6 months
Determination of growth response (change in height Z-score)
Monitoring serum IGF-1 and IGFBP-3 levels
Screening for potential adverse effects
Evaluation of compliance
Consideration of dose adjustment based on IGF values, growth response, and comparison to growth prediction models

IGF, insulin-like growth factor; IGFBP-3, insulin-like growth factor-binding protein-3.

Monitoring Serum IGF-1 Levels

The emerging consensus is that annual monitoring of serum IGF-1 and IGFBP-3 levels should be an aspect of routine care of the GHD child receiving rhGH therapy.[515] Titration of rhGH dose to maintain these growth factors within age-dependent normal limits is physiologically sound and is standard practice in the treatment of adults with GHD. It is well recognized that IGF-1 and IGFBP-3 levels are low in children with GHD and increase with rhGH injections.[516]

The relationship between the rise in IGF-1 levels and the growth response during therapy has recently been demonstrated in a study that used a GH-dose titration to achieve target IGF-I levels.[517] In that paper, it was demonstrated that at least over the first two years of treatment there is a substantial correlation between the level of the IGF-I achieved and the height gain—and that this correlation was valid for both GHD and ISS patients. Growth factor monitoring certainly has important utility in assessment of compliance issues as well as in the assurance of safety. Several epidemiologic studies have linked serum IGF-1 levels and lower IGFBP-3 levels to increased risk of prostate, breast, and colorectal cancer in otherwise healthy subjects.[515,518,519] Although a causal relationship between serum IGF-1 levels and cancer is not proven, monitoring lifetime exposure to IGF-1 and ensuring that IGF-1 and IGFBP-3 levels in the GH-deficient patient are within age-defined normal limits certainly seem prudent at this time.

Role of Serial Bone Age Assessment

Although a well-established diagnostic tool in the initial evaluation of a GH-deficient patient, bone age assessment no longer has a role in the ongoing management of childhood GHD. Previously, many clinicians have included serial bone age assessment as part of their monitoring of a GH-deficient child's progress on rhGH therapy by comparing the observed to predicted heights and by following the Bailey-Pinneau predicted height calculations.[520,521]

When the wide SDs applied to such measures and the lack of clinical evidence that management is enhanced by their use are considered, they have no sound role in the monitoring of GH therapy.[522] It also appears that whereas GH therapy accelerates bone maturation there may be an initial delay before this is apparent radiographically and height predictions may be skewed as a result.[522] At this time, the role of bone age assessment during GH therapy lies only in determining remaining growth potential in the patient with GHD approaching final height and in assessing children with concerns about rapid progression of puberty.

Assessment of Treatment Efficacy and Optimizing Growth Response

Clearly defined individual treatment goals need to be established for each patient with GHD. During the initial 2 years of therapy, catch-up growth at a rate twofold to fourfold above pretreatment growth velocity and a gain of 1 to 2 SDs in height should be expected in the majority of patients.[523] This will be influenced by age at diagnosis and severity of GHD. The dose may need to be increased if catch-up growth is inadequate. After the initial catch-up phase, growth velocity should be maintained at a rate at or above the 50th percentile for age.

Mathematical prediction models may be used to not only predict growth response to a specific dose but to guide the pediatric endocrinologist in modifying therapy when the observed growth falls short of predicted growth.[504] Prediction models have considerable promise but need to be improved and studied further in a prospective manner before any recommendations regarding their use can be formulated. In instances in which an inadequate response is encountered, it is also important to consider all possible causes—including poor compliance, technical difficulties, underlying hypothyroidism, incorrect diagnosis, poor nutrition, neutralizing antibodies, and intercurrent illness.

It is critically important to maximize height with GH therapy before the onset of puberty. If this is not achieved, modulation of the GH dose during puberty may be considered. As stated previously, the growth response to hGH typically attenuates after the first year—but it should continue to be equal to or greater than the normal height velocity for age throughout treatment. In situations in which the clinical response to hGH is suboptimal, the following possibilities must be considered: poor compliance; improper preparation of hGH for administration or incorrect injection techniques, subclinical hypothyroidism, chronic disease, glucocorticoid therapy, history of irradiation of the spine, epiphyseal fusion, anti-GH antibodies,[524] and incorrect diagnosis of GHD as explanation for growth retardation. Some recipients of rhGH have developed detectable anti-GH antibodies, but growth failure resulting from such antibodies has been exceedingly rare.

Maximal growth response to hGH can be obtained by early diagnosis and initiation of therapy and by careful attention to compliance and psychological support. Thus, although some studies have indicated that as many as 50% of males and 85% of females with idiopathic GHD do not achieve adult heights above the third centile[505,525] it is our belief that normalization of height (i.e., achieving target height) should be achievable in most cases. Despite the efficacy of hGH in accelerating growth in children with GHD, and the ability of such therapy to normalize adult height if treatment is begun sufficiently early, several studies have indicated that the long-term prognosis for such patients is guarded.[526] The educational, vocational, and social outlook for adults with GHD dating from childhood is frequently suboptimal. Whether this reflects subtle intellectual deficits or the consequences of lower expectations of patients, families, or teachers remains to be determined. In any case, patients with GHD clearly require careful and thorough follow-up throughout childhood and adolescence—and possibly adulthood.

Studies have focused on the clinical consequences of GHD in adults and on the potential benefits of hGH therapy in such patients.[527,528] Signs and symptoms of adult GHD have included reduced lean body mass and musculature, increased body fat, reduced bone mineral density, reduced exercise performance, and increased plasma cholesterol. Adults with GHD have been found to

have a significantly increased risk of death from cardiovascular causes, a finding potentially linked to the increase in adiposity and in serum cholesterol.[529]

Adults with GHD have been found to have "impaired psychological well-being and quality of life" characterized by depression, anxiety, reduced energy and vitality, and social isolation. Several placebo-controlled studies have demonstrated that hGH therapy for adults with GHD results in marked alterations in body composition, fat distribution, bone density, and sense of well-being.[530,531] Whether these effects of hGH therapy will be sustained (and if so, what the optimal hGH regimen will be) remains to be determined.

Because of the potential metabolic benefits of treatment of adult GHD, it is necessary to discuss the need for lifelong GH therapy with patients and families at the time of diagnosis. Given the studies that have demonstrated that many (perhaps the majority) of the children diagnosed with childhood GHD demonstrate normal GH levels on repeat provocative testing, it is recommended that on completion of skeletal growth GH therapy be halted for a period of 1 to 3 months and the patient then retested. Toogood and colleagues[532] have reported that the likelihood of GHD persisting in adult life increases with the number of pituitary hormone deficiencies. Approximately 90% of patients with two or three additional pituitary hormone deficiencies had provocative GH levels less than 5 ng/mL. Similarly, patients with documented structural abnormalities of the hypothalamus-pituitary (such as pituitary hypoplasia, pituitary stalk agenesis, posterior pituitary ectopia, or septo-optic dysplasia) have a very high likelihood of retesting as GHD.

A conservative approach would suggest that all children diagnosed as having GHD should be retested by insulin-provocative tests on completion of skeletal growth, and before a commitment is made for long-term adult treatment. An argument can be made, however, that patients with multiple pituitary hormone deficiencies, documented structural abnormalities, or documented hypothalamic-pituitary molecular defects do not necessarily require retesting—or at most should have IGF-1 and IGFBP-3 concentrations determined. On the other hand, the child who has carried a diagnosis of idiopathic isolated GHD should always be retested.

Transition to Adult Management

A suggested algorithm to guide the transition to adult management is displayed in Figure 8-29. After attainment of final height, retesting of the GH-IGF axis using the adult GHD diagnostic criteria as defined by the Growth Hormone Research Society (GRS) Consensus Workshop on Adult GHD should be undertaken by the pediatric endocrinologist.

Standard GH stimulation tests can be performed after an interval of 1 to 3 months off GH therapy.[533] In places where an insulin tolerance test is mandatory for the patient to qualify for further GH therapy, this test should be performed. At the time of retesting, other pituitary hormones and serum IGF-1 and IGFBP-3 levels should be measured.[473] As recommended by the GRS, the opportunity should be taken to assess body composition, bone mineral density, fasting lipids, insulin, and quality of life before and after discontinuation of GH therapy. Patients with severe long-standing MPHD, those with genetic defects, and those with severe organic GHD can probably be excluded from GH retesting.[411]

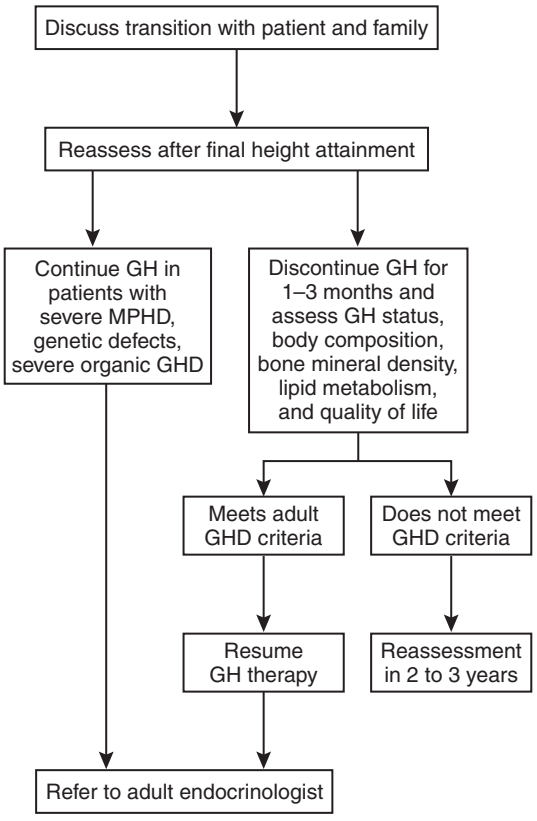

FIGURE 8-29. Algorithm for transition to adult treatment of growth hormone (GH) deficiency. MPHD, multiple pituitary hormone deficiency.

When the diagnosis of adult GHD is established, continuation of GH therapy is strongly recommended. Caution should be exercised when considering the decision of continuing GH therapy in conditions where there is a known risk of diabetes or malignancy. Although large patient registries have not seen an increase in the incidence of malignancy in pediatric GH recipients, patients with certain high-risk states (such as Bloom syndrome) may be at an increased risk as a result of long-term GH therapy and such patients should be monitored carefully. The transition to adult GH replacement should be arranged as a close collaboration between the pediatric and adult endocrinologists, who should discuss the reinitiation of treatment with the patient.

GROWTH HORMONE TREATMENT OF OTHER FORMS OF SHORT STATURE

The development of rhGH has provided the capability for a theoretically unlimited supply of hGH. Although treatment of GHD is the one unequivocal indication for "replacement" therapy, the potential use of hGH for treatment of other forms of short stature has been actively explored. Theoretically, any child with open epiphyses should be

capable of accelerating growth and achieving heights greater than indicated by genetic potential—as indicated by experience with cases of pituitary gigantism. Whether such therapy can be done safely and whether it justifies the cost and potential risks of hGH are more complicated issues. In addition, questions have been raised about the appropriateness of "cosmetic" hormonal therapy.

Chronic Renal Failure

Several studies have now convincingly demonstrated the ability of hGH to accelerate growth over at least several years of therapy.[534,535] These findings have now been confirmed by several double-blind placebo-controlled investigations. Using an hGH dosage of 0.05 mg/kg/day, Fine and co-workers[536] showed a mean first-year growth rate of 10.7 cm in GH recipients and 6.5 cm in the placebo group. In the second year, GH-treated patients had a mean growth rate of 7.8 cm/year versus 5.5 cm/year in placebo recipients. No deleterious effects on renal function were observed. Longer-term studies will be necessary to determine whether these effects on growth will be sustained and whether they will translate into an improved adult height.

Turner Syndrome

Before the availability of rhGH, a number of uncontrolled studies had produced conflicting data concerning the efficacy of GH therapy in Turner syndrome.[537,538] In 1983, a randomized controlled study of rhGH was initiated.[173,277] First-year results indicated a growth rate of 3.8 cm/year in the control group, 6.6 cm/year in hGH recipients, 7.9 cm/year in oxandrolone recipients, and 9.8 cm/year in subjects receiving hGH plus oxandrolone. At the end of 6 years, heights for 30 subjects who had completed therapy were compared with their projected adult heights[539] based on the growth curves of Lyon and colleagues.[11]

Mean height achieved after 2 to 6 years of treatment was 151.9 cm, compared to a mean projected adult height of only 143.8 cm. Near-adult heights in these subjects showed that girls receiving GH alone had a final height 8.4 cm greater than their projected adult heights. Girls receiving GH plus oxandrolone had a 10.3-cm increase.[278] Sixteen of 17 girls receiving GH alone achieved adult heights above the 50th percentile for Turner syndrome, and 10 of 17 attained heights above the 90th percentile. All 45 girls receiving combination treatment attained heights above the 50th percentile for Turner syndrome, and 23 of 45 had heights above the 90th percentile.

In a subsequent study, GH was employed in combination with estrogen replacement at either 12 or 15 years of age.[540] Earlier initiation of estrogen therapy resulted in accelerated epiphyseal fusion and a compromise in final height attained, a not surprising observation given the critical role of estrogen in skeletal maturation. Girls who began GH therapy before 11 years of age and estrogen at age 15 had the greatest increase in adult height.

Even more dramatic results have been observed in Dutch studies, in which the GH dosage was progressively increased to 0.09 mg/kg/day.[279] At the highest GH dosage, increases in adult height over projected heights averaged 16 cm. Estrogen therapy was withheld until subjects had received at least 4 years of GH treatment and reached a minimum age of 12 years. With this regimen, the majority of girls with Turner syndrome attained adult heights within the normal range.

In light of the detailed historical data that exist on natural growth in Turner syndrome, the results to date provide convincing data that hGH can accelerate growth and increase adult height. Furthermore, early initiation of GH treatment should allow for normalization of growth in childhood—as well as the potential to begin estrogen replacement at a physiologically appropriate age. This subject is discussed in detail in Chapter 15.

Down Syndrome

The encouraging results of hGH trials in Turner syndrome have led to studies of hGH in other chromosomal disorders, such as Down syndrome. Several preliminary studies have confirmed the ability of hGH to accelerate growth in such patients, although ethical issues have been raised concerning the appropriateness of such therapy.[541,542] No convincing data exist that hGH improves neurologic or intellectual function in such patients.

Intrauterine Growth Retardation or Small for Gestational Age

A number of studies, employing pituitary-derived or recombinant DNA–derived hGH, have been performed in children with short stature resulting from IUGR/SGA.[543,544] Such studies are hampered by the inherent heterogeneity of this group of patients, whose poor growth may reflect maternal factors, chromosomal disorders, dysmorphic syndromes, toxins, and so on. Interpretation of the results from such studies are frequently complicated by an accompanying diagnosis of GHD, often lacking stringency in diagnostic criteria.

Coutant and colleagues,[545] for example, compared children treated with GH for a diagnosis of IUGR associated with "idiopathic" GHD and children with IUGR not treated with GH and found no significant differences in adult height. Furthermore, almost 80% of the alleged GH-deficient IUGR children proved to have normal GH levels when reevaluated after cessation of growth. Two studies have examined the effects of two doses of continuous GH treatment administered over a 6-year period.[292,546,547] GH at doses of 0.033 and 0.067 mg/kg/day resulted in 2.0- and 2.7-SD increments in height, respectively. Together, most studies have demonstrated taller final height—leading to approval of the therapy in most countries. The doses commonly used in SGA children are between 50 and 70 mcg/kg/day, and treatment is typically started at age 3 years.[546]

Prader-Willi Syndrome

One form of IUGR/short stature in which GH therapy has been studied fairly extensively is Prader-Willi syndrome. Early studies in a limited number of subjects demonstrated promising short-term results.[304] Lindgren and colleagues[548] demonstrated that patients with Prader-Willi syndrome had lower serum IGF-1 concentrations than did

normal obese controls. Prader-Willi subjects treated with GH at a dosage of 0.033 mg/kg/day showed a 1-year increase in height velocity, whereas untreated Prader-Willi subjects experienced a decrease in height velocity.

GH treatment also resulted in a reduction of relative fat mass and an increase in fat-free mass. Carrel and co-workers[125] employed a similar dosage of GH in Prader-Willi patients with reduced clonidine-stimulated GH levels and low serum IGF-1 concentrations and demonstrated an increase in height velocity—whereas untreated controls showed no significant change in height velocity.

Dual-energy x-ray absorptiometry (DEXA) demonstrated a GH-induced reduction in total body fat and increased strength and agility. The Food and Drug Administration has recognized Prader-Willi syndrome to be an accepted diagnosis for GH therapy, even in the absence of demonstrable GHD. This treatment is effective in improving growth and body composition. However, several reports have indicated a possible GH-associated mortality in Prader-Willi patients with massive obesity—perhaps related to tonsillar hypertrophy as a contributory factor.[549]

Osteochondrodysplasias

Therapy with hGH has been studied in several studies of skeletal dysplasias. The largest published study to date in achondroplasia is by Seino and co-workers,[550] who reported on hGH administration to 40 children. During the first year of treatment, the height velocity increased from 3.8 to 6.6 cm/year. In year 2, the height velocity decreased to approximately 5 cm/year. A modest improvement was seen in the ratio of lower limb length to height. Although hGH was well tolerated, it is of note that one patient with atlantoaxial dislocation during hGH therapy has been reported. There has also been limited experience with hGH treatment of other skeletal disorders, such as dyschondrosteosis, hereditary multiple exostoses, osteogenesis imperfecta, and Ellis-van Creveld syndrome.

Idiopathic Short Stature

Several countries, including the United States, have recently approved GH therapy of ISS. It is important to recognize that this is a heterogeneous group of patients, as emphasized by Kelnar and co-workers.[551] Even though they are grouped under the title "normal short children" or as having "idiopathic short stature," this group will include children who have passed provocative GH testing but are nevertheless IGF deficient—reflecting the inadequacies of GH testing.

There is abundant evidence that determination of provocative GH levels does not adequately discriminate between true GHD (IGF deficiency) and ISS. In addition, the group labeled "normal short children" will inevitably contain children with unidentified syndromes and possibly with unidentified chronic illnesses or endocrine disorders. These issues have made it difficult to properly evaluate existing clinical trials. Furthermore, published clinical trials have not contained long-term control groups and have indicated considerable variability in growth response.[552-554]

The majority of normal short children treated with hGH have shown growth acceleration that is generally sustained over the first several years of therapy (although attenuation of the response is seen, just as in all other instances of hGH treatment). Longer-term data are inadequate, however, to address the question of impact of therapy on adult height. Hintz and co-workers[555] treated 80 children with ISS (0.3 mg/kg/wk) for 2 to 10 years and compared results with those in untreated short retrospective control subjects. In children with ISS, GH therapy increased the mean height scores from 2.7 at the start of treatment to 1.4 at final height. The mean increase in final height over the pretreatment predicted adult height was 5.0 cm for boys and 5.9 cm for girls. Concern has been raised that hGH therapy in normal short children may result in an earlier onset of puberty—and as a result, earlier fusion of the epiphyses—and thereby may offset the positive response observed during the early years of hGH treatment.[556]

Other important questions have been raised about the financial, ethical, and psychosocial impact of hGH therapy on normal short children.[557] Given the current cost of hGH, the financial implications of treating normal short children (whether it is the bottom 5, 3, 1, or 0.1%) is considerable and potentially diverts a limited pool of health care dollars away from other needs. The point is well taken that 5% of the population will always be below the 5th percentile whether we treat them with hGH or not. Concern has been raised that focusing on a short child's stature potentially disables an otherwise normal child, handicapping that child psychologically or socially. No convincing data have been presented that hGH treatment of normal short children improves psychological, social, or educational function. Finally, the known and unknown treatment risks of hGH therapy must be considered when treatment of otherwise normal children is an issue.

On the other hand, given the current limitations in our ability to clinically or biochemically discriminate definitively between GHD and normal short stature, our inadequate understanding of neurosecretory defects of GH secretion, our inadequate definition of "partial" GHD, and the need to move to a more global concept of "IGF deficiency" it seems unfair to prevent hGH therapy of short children who do not meet a definition of GHD (i.e., provocative testing) we recognize as inadequate. Many of these children behave clinically and biochemically in a manner identical to those with classic GHD.

The mean improvement in adult height in children with ISS attributable to GH therapy (average duration of 4-7 years) is 3.5 to 7.5 cm compared to initial predicted adult height. Responses are highly variable and are dose dependent. Concern has been raised that in ISS higher GH doses (>50 ug/kg/day) may advance bone age (BA) and the onset of puberty, but this has not been seen in other studies.

Multiple factors affect the growth response to GH in ISS, most of which are unknown. The first-year response is influenced negatively by age at start (and positively by GH dose), weight at start, and difference from target height—and these factors account for approximately 40% of the variance. Adult height outcome is influenced negatively by age at start and positively by mid-parental height, height at start, bone age delay, and the first-year response to growth hormone.[556] The utility of baseline and treatment-related biochemical data including IGF-I has not been validated in

long-term studies, but 2-year studies suggest that the rise in IGF-I correlates with short-term height gain.

Children treated with GH should be monitored for height, weight, pubertal development, and adverse effects at 3- to 6-month intervals. Periodic monitoring for scoliosis, tonsillar hypertrophy, papilledema, and slipped femoral capital epiphyses (SCFE) should be performed as part of the regular physical exam during follow-up visits. We recommend that after 1 year the response to therapy be assessed by calculating height velocity SDS as well as the change in height SDS. Bone age may be obtained periodically to reassess height prediction and for consideration of manipulation of the tempo of puberty. IGF-1 levels may be helpful in guiding GH dose adjustment, but the significance of abnormally elevated IGF-1 levels remains unknown. Thus far, no cases of elevated blood glucose in GH treated patients with ISS have been reported—but there is controversy regarding the need for routine monitoring of glucose metabolism.

Dosage is usually selected and adjusted by weight. If the growth response is considered inadequate, the dose may be increased. There are no definitive data concerning the long-term safety of doses higher than 50 ug/kg/day in ISS. The upper limit of GH dosage used in ISS and other indications is approximately 70 ug/kg/day,[546,555] but the possibility of using such doses varies in terms of national health economics. In the future, growth prediction models may improve GH dosing strategies. IGF-1 levels may be helpful in assessing compliance and GH sensitivity. Levels that are consistently elevated (>2.5 SDS) should prompt consideration of GH dose reduction. Recent studies on IGF-based dose adjustments in ISS demonstrated increased short-term growth when higher IGF targets were selected, but this strategy has not been validated in long-term studies in terms of safety or final height effects.

If height prediction is below –2 SDS at the time of pubertal onset in either sex, the addition of GnRH analogues may be considered. Alternatively, in males aromatase inhibitors may also be an option. However, long-term efficacy and safety data are not available for either of these interventions. In addition, the impact of delayed puberty on somatic and psychological development is not known. We do not recommend aromatase inhibitors in girls.

There are two schools of thought about the duration of treatment. One is that treatment should stop when near-adult height is achieved [Ht velocity <2 cm/year and/or bone age >16 years (in boys) and >14 years (in girls)]. Alternatively, therapy can be discontinued when height is in the "normal" adult range (above –2 SD) or has reached another cutoff for the reference adult population (for example, in Australia the 10th percentile; elsewhere, the 50th percentile). Stopping therapy is influenced by patient/family satisfaction with the result of therapy, on-going cost-benefit analysis, and when the child wants to stop for other reasons.

Miscellaneous Causes of Growth Failure

In addition to the clinical conditions described previously, hGH has been employed in treatment of short stature associated with Noonan syndrome, neurofibromatosis, and a variety of other conditions associated with postnatal growth failure. In general, such trials have been uncontrolled and have not included sufficient numbers of subjects for adequate evaluation of efficacy. A review of a large database, however, indicates that many of these conditions might in fact be responsive to GH therapy.[558]

Although this database is uncontrolled, 4-year results of GH treatment of Prader-Willi syndrome, IUGR, Russell-Silver dwarfism, neural tube defects, neurofibromatosis, and familial hypophosphatemic rickets were indistinguishable from those observed with GH treatment of "idiopathic GHD" using comparable dosages of GH. Furthermore, a variety of other conditions (such as Down syndrome, cystic fibrosis, fetal alcohol syndrome, Crohn disease, sickle cell anemia, hypochondroplasia, and thalassemia) responded in a manner comparable to that observed with Turner syndrome.

Although management of such patients is often complex and the use of GH may be characterized by important ethical issues, one must conclude that at least on auxologic grounds it becomes difficult to discriminate among GHD (as currently diagnosed), Turner syndrome, and many other medical conditions characterized by growth failure. If as proposed by Allen and Fost[559] responsiveness to GH rather than GHD should be the most important criterion for GH treatment, these findings indicate that GH therapy for many of these "other" conditions warrants an open-minded appropriately controlled evaluation.

Normal Aging and Other Catabolic States

A lengthy discussion of the potential use of hGH in normal aging is beyond the scope of this chapter.[128] The rationale for therapy is based on the concept of the "somatopause," referring to the fact that GH secretion normally declines progressively after 30 years of age—reflected in decreasing serum concentrations of IGF-1. Aging can be viewed as a catabolic state, with the potential that hGH therapy will reverse or retard the loss of muscle mass and strength and the decrease in bone density characteristic of the older population.

It is also conceivable, however, that aging individuals may be more sensitive to the metabolic changes produced by hGH—resulting in fluid accumulation, carpal tunnel syndrome, and glucose intolerance. Clinical studies are currently in progress. hGH therapy is also being investigated in a variety of catabolic states,[129] such as burns, tumor cachexia, major abdominal surgery, AIDS, sepsis, and hyperalimentation. Although the frontiers of new indications of GH therapy are being explored in well-controlled trials, we believe that aging, catabolic states, and other unapproved indications for GH therapy should not be routinely treated by clinicians outside appropriate clinical studies.

SIDE EFFECTS OF GROWTH HORMONE

Pituitary-derived hGH, which for a quarter of a century had an enviable safety record, proved to be the agent for transmission of the fatal spongiform encephalopathy Creutzfeldt-Jakob disease.[493,554] Although this risk does

not exist with recombinant DNA-derived hGH, the experience with pituitary hGH serves as a grim reminder of the potential toxicity that can reside in "normal" products and "physiologic replacement." Nevertheless, 15 years of extensive experience with rhGH has been encouraging. Concerns have been raised, however, about a number of potential complications that clearly required continued follow-up and assessment. This evaluation has been greatly facilitated by the extensive databases established by hGH manufacturers.

Development of Leukemia

In 1988, the development of leukemia as a complication of hGH therapy was reported in 5 cases from Japan.[317] Since then, more than 30 cases of leukemia in hGH-treated patients have been reported—a disproportionate number coming from Japan,[318] but with cases also reported in the United States.[319] One of the difficulties in assessing the role of hGH treatment in these cases was that many children with GHD have clinical conditions that may predispose them to the development of leukemia, such as histories of previous malignancies, histories of irradiation, and underlying syndromes known to predispose to the development of leukemia (Bloom syndrome, Down syndrome, Fanconi anemia).

Patients have included recipients of pituitary-derived and recombinant DNA–derived hGH, and leukemia has occurred both during treatment and after termination of therapy. Cases of leukemia have been also reported in GH-deficient individuals without any history of hGH therapy, suggesting that the GHD state by itself might be a predisposing factor. In a comprehensive set of large cohorts of patients from the United States, Europe, and (most recently) Japan, the concern of increased leukemia risk in patients with GHD without predisposing factors has been dispelled.

In a large series describing the entire Japanese experience, the same authors who first reported the increased incidence of leukemia in GHD reanalyzed their data—together with a much larger number of patients treated since the original report—and showed that the risk for leukemia is the same for GH recipients and controls.[560] At this time, most authorities agree that hGH treatment is not a causative agent in the development of leukemia in individuals without a predisposing condition. The authors recommend that this issue be discussed with all potential recipients of hGH.

Recurrence of CNS Tumors and Occurence of Second Malignancies

Because many recipients of hGH have acquired GHD from CNS tumors or their treatment, the possibility of tumor recurrence is of obvious importance. Extensive analysis of the data on 1,300 American children treated for a CNS malignancy before receiving hGH has not indicated any increased risk. A similar conclusion has emerged from analysis of a European database. However, one study suggests that GH recipients who had a brain tumor have a slightly higher risk of a second malignancy.[561]

Pseudotumor Cerebri

Pseudotumor cerebri (idiopathic intracranial hypertension) has been reported in at least 26 hGH-treated patients, approximately half of whom had classic GHD.[562] The mechanism of hGH action is unclear, but it may reflect changes in fluid dynamics within the CNS. Pseudotumor has also been described after thyroid hormone replacement and may represent restoration of a normal physiologic state. In any case, physicians need to be alert to complaints of headache, nausea, dizziness, ataxia, and visual changes.

Slipped Capital Femoral Epiphysis

The potential association of slipped capital femoral epiphysis (SCFE) and GHD was first suggested by studies in rats.[563] It is clear that SCFE can be associated with hypothyroidism and GHD.[564,565] The potential role of hGH therapy has been more difficult to determine. This is in part because the incidence of SCFE in the normal population varies by age, sex, race, and geographic locale—being variously reported as between 2 and 142 cases per 100,000. Accordingly, although SCFE cannot at this time be definitively attributed to hGH therapy per se complaints of hip and knee pain and/or displaying a limp should receive appropriate evaluation.

Miscellaneous Side Effects

A number of other physical concerns have been raised as possible consequences of hGH treatment. Current data are inadequate to ascribe a causal role to hGH treatment. The potential side effects include prepubertal gynecomastia, increased growth of nevi, behavior changes, scoliosis and kyphosis, worsening of neurofibromatosis, hypertrophy of tonsils and adenoids, and sleep apnea. This list is obviously only partial. It is best for the clinician to remember that GH and the peptide growth factors it stimulates are potent mitogens with diverse metabolic and anabolic actions. All patients receiving hGH treatment, even as replacement therapy, must be carefully monitored for side effects.

For the most part, the side effects of GH are minimal and rare. When they occur, careful history and physical examination are adequate to identify their presence. Management of these side effects may include transient reduction of dosage or temporary discontinuation of GH.[566] The association of GH treatment with insulin resistance is well documented,[567] and one report suggested that there is an increased incidence of development of diabetes in pediatric recipients of GH.[568] Most authorities agree, however, that rather than a side effect of GH this relationship probably represents a common susceptibility of patients to develop growth disorders and diabetes owing to a common genetic trait.[569]

In the absence of other risk factors, there is no evidence that the risk of leukemia, brain tumor recurrence, SCFE, and diabetes is increased in recipients of long-term GH treatment. In any case, any patient receiving GH who has a second major medical condition (such as a tumor survivor receiving GH) should be followed in conjunction

with a specialist such as an oncologist or a neurosurgeon when appropriate. Although GH has been shown to increase the mortality of critically ill patients in the intensive care unit,[116] there is no evidence that GH replacement needs to be discontinued during intercurrent illness in children with GHD.

THE QUESTION OF LONG-TERM CANCER RISK

Several epidemiologic studies have been published suggesting an association between high serum IGF-1 levels and the incidence of malignancies.[570,571] In addition, the risk of cancer calculated in those studies was increased for patients with low IGFBP-3 levels. Although additional studies are being conducted to verify or disprove the association between serum IGF-1 and cancer risk, the role of GH in this potential phenomenon should be carefully examined.

In a paper analyzing the risk of colon cancer, it was shown that IGF-1 was not statistically associated with cancer risk. However, the combination of high IGF-1 and low IGFBP-3 was shown to be related to an increased risk (Table 8-14).[572] Notably, GH positively influences both parameters in parallel. This casts doubt on its role as a driving force in the IGF-cancer equation.

Additional epidemiologic data of note involve the risk of malignancy associated with acromegaly. A number of studies have been published that claimed to identify an association between acromegaly and colon cancer risk,[573-575] whereas others did not find significant associations.[576,577] The interpretation of these studies is hampered by their small size, uncontrolled retrospective nature, and multiple possible sources of bias. The largest study to date, reviewing more than a thousand patients, indicated that overall cancer incidence is not increased in acromegaly.[578] The overall incidence of colon cancer was also not shown to be increased in Orme and associates' study, although mortality from colon cancer was higher in this population—suggesting perhaps an effect of GH or IGF-1 on established tumors.[579]

One prospective analysis of colon cancer and colonic polyps in acromegalics using controlled colonoscopies did not observe an association between these two diseases when using autopsy series or prospective colonoscopy screening series for the control population.[580] It is notable that acromegaly is associated with a dramatic increase in the incidence of benign hyperplasia of several organs, including colonic polyps.[581] These findings raise the possibility that the GH-IGF axis may lead to symptomatic benign proliferative disease, which could be associated with symptoms (such as rectal bleeding) that would then lead to a potential detection (or ascertainment) bias.

Children receiving GH have not been shown to have an increased risk of de novo tumors. An earlier concern that leukemia risk was increased has been dispelled by the same authors who first published on this topic, showing in a large cohort that the risk for leukemia is the same for GH recipients and controls.[582] Several studies indicate absolutely no increase in the risk of tumor recurrence in pediatric GH recipients.[583]

In a number of studies, no increased incidence of cancer was found in GH recipients among adults treated for GHD.[584,585] Clearly, these reports represent imperfect uncontrolled studies. However, the experience gained through them demonstrates that even though the IGF-1 levels are normalized GH therapy is not associated with tumor recurrence or with de novo tumors in the absence of other risk factors. The use of IGF-1 and IGFBP-3 in the monitoring of GH recipients, adult and pediatric, has been recommended and endorsed by international bodies such as the GH Research Society.[533]

Until the issue of cancer risk in GH therapy is fully resolved, the most prudent approach appears to be regular monitoring of IGF-1 and IGFBP-3 and modulation of the GH dose to ensure that the theoretical risk profile induced by GH therapy is favorable. This can be done by avoiding the unlikely situation in which a GH-treated patient will have an IGF-1 level at the upper end and IGFBP-3 levels at the lower end. In the twenty-first century, many patients with GHD will receive lifetime GH replacement. In that setting, it is especially important that we monitor serum IGF-1 and IGFBP-3 on a regular basis.

Overall, many controversies still surround the issue of the GH-IGF axis and cancer risk, specifically concerning the safety of GH therapy. In general, the currently approved indications for GH therapy in children and adults do not warrant concern regarding future cancer risk. Although additional research coupled with stringent pharmacovigilance is clearly warranted, the state of the clinical field mandates that patients' physicians be aware of the vast body of evidence regarding the safety of GH in this regard.[586]

TABLE 8-14

Risk of Future Cancer Relative to Serum IGF-I and IGFBP-3 Tertiles

	IGF-I Lowest Tertile	IGF-I Middle Tertile	IGF-I Upper Tertile
IGFBP-3 upper tertile	—	—	—
IGFBP-3 middle tertile	—	—	—
IGFBP-3 lowest tertile	—	—	Fourfold increased risk

IGF, insulin-like growth factor; IGFBF-3, insulin-like growth factor-binding protein-3.

TREATMENT OF PRIMARY SEVERE IGFD: USE OF IGF-1

The production of IGF peptides by recombinant DNA technology has permitted clinical trials of IGF therapy. IGF-I administration to normal adult male volunteers as a single intravenous injection of 100 μg/kg caused hypoglycemia within 15 minutes. On a molar basis, IGF-I has approximately 6% of the hypoglycemic potency of insulin. In contrast, intravenous infusions of IGF-I to normal men at a rate of 20 μg/kg/hour resulted in serum IGF-I levels within the normal range and did not produce hypoglycemia—but did

suppress GH levels, increase creatinine clearance, and decrease plasma urea nitrogen.[77, 587-595]

The most obvious clinical use of IGF-I therapy is in patients with GHI. A number of short-term growth-related studies with IGF-I treatment at varied doses have been reported. Data from 17 patients in a European collaborative trial, treated for at least 4 years, showed an increase in mean height SDS from –6.5 to –4.9—with two adolescents reaching the 3rd percentile. This emphasizes the importance of early diagnosis and initiation of therapy. Side effects included hypoglycemia, headache, convulsions, urolithiasis, and papilledema. The latter, which suggests the possibility of pseudotumor cerebri, resolved spontaneously while receiving IGF-I.

In the longest treatment study, Chernausek and colleagues[589] showed data similar to the European study—with an initial burst of growth followed by slowing to just above baseline by the sixth year of therapy. Height SDS improved from –5.6 to –4.2 by the end of the sixth year (Figure 8-30). A randomized double-blind placebo-controlled trial of IGF-I therapy in GHRD has been performed in Ecuador, probably the only place where the patient population is sufficiently large and homogeneous to permit such investigation.[589] Growth rates in subjects receiving IGF-I increased from 2.9 to 8.6 cm/year over the first year of therapy. The placebo group grew 4.4 cm/year during the same time, and then their growth rate increased to 8.4 cm/year during IGF-I treatment. Incidence of hypoglycemia was equal in the two groups. One recipient of IGF-I developed papilledema, which resolved spontaneously while on treatment.

Although these early studies are promising, little is known about the long-term effects of IGF-I or about the optimal dose or frequency of administration. When all clinical studies are combined, the total number of children treated to date is still only several hundred—and relatively few have been treated for greater than 5 years. Taken together, the IGF-I treatment studies show that although significant the growth response is neither as successful nor as long-lived as that of GHD children treated with exogenous GH. The failure of serum levels of IGFBP-3 to increase with IGF-I administration and the

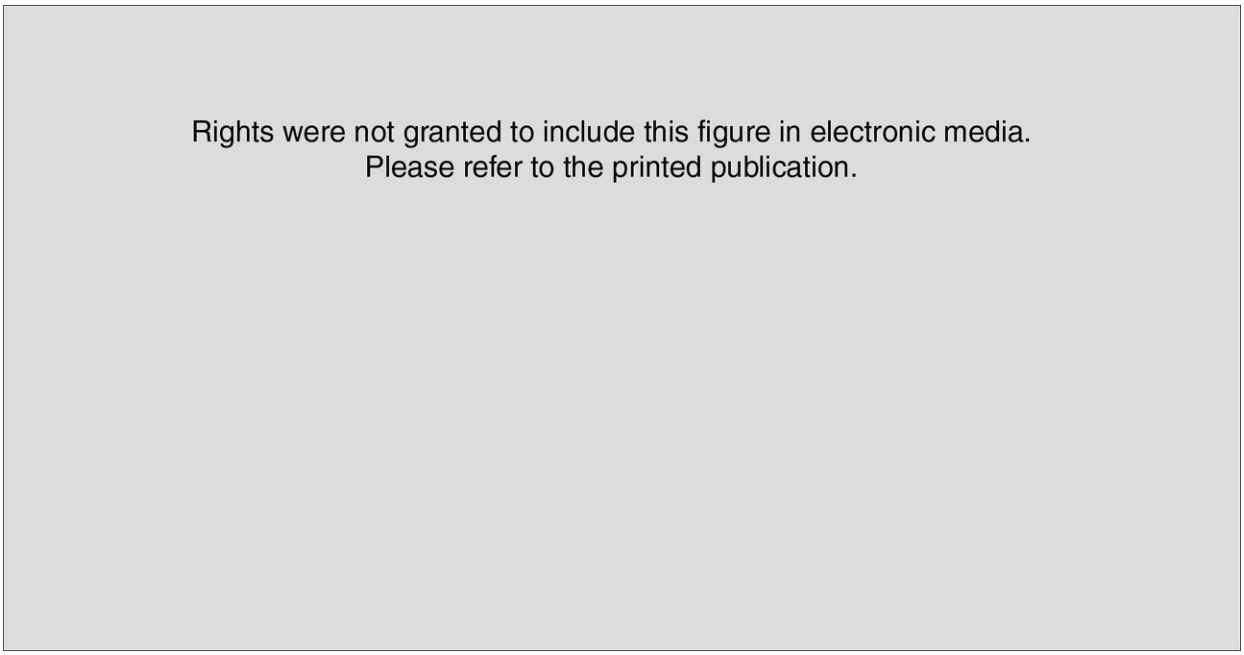

Figure 8-30 Linear growth in response to rhIGF-I treatment. (*A*) Height velocity (centimeters per year) before (open circle) and during first year of therapy (closed circles) for each child is displayed relative to pretreatment height. (*B*) The dose dependency of first-year growth rate is shown. Each point represents a single subject. The equation for the regression line shown is *Height velocity (centimeters per year) = –6.2 + 7.2 log10 rhIGF-I dose (microgram per kilogram, BID).* (*C*) Average growth rates before and during rhIGF-I for first and subsequent years are shown. Error bar shows upper limit of 95% confidence interval. Number of subjects at each year is indicated. [From Chernausek SD, Backeljauw PF, Frane J, Kuntze J, Underwood LE for the GH Insensitivity Syndrome Collaborative Group (2007). Long-term treatment with recombinant insulin-like growth factor (IGF)-I in children with severe IGF-I deficiency due to growth hormone insensitivity. J Clin Endocrinol Metab 92(3):902–910.]

suppression of endogenous GH secretion underscores the complexity of the treatment. The possibility that local production of IGF-I at the growth plate may be critical to optimal growth also requires consideration. Nevertheless, these data indicate that the IGF peptides (long considered to function as autocrine or paracrine growth factors) can act as classic endocrine hormones.

IGF-I has received FDA approval recently. The drug shows promise in treatment of severe primary IGFD. The use of IGF-I in milder forms of primary IGFD is also the subject of current investigations.Vaccarello and co-workers[78] treated six adults with GHRD for 7 days with subcutaneous IGF-1 at a dosage of 40 mg/kg every 12 hours. Normal serum IGF-1 concentrations were achieved 2 to 6 hours post-injection, followed by a rapid decline—reflecting low serum concentrations of IGFBP-3. No symptomatic hypoglycemia was observed, but mean 24-hour GH levels were significantly suppressed and urinary calcium level was increased. In longer-term studies, Laron and co-workers[590] reported significant growth acceleration—to rates of 8.8 to 13.6 cm/year in five children treated for 3 to 10 months with a single daily injection of 150 mg/kg.

Walker and associates[591] reported an increase in growth rate from 6.5 to 11.4 cm/year in a patient with GHRD treated with twice-daily subcutaneous injections of 120 mg/kg. Wilton and co-workers[592] have reported preliminary data in 30 children, aged 3 to 23 years, with GHI from GHRD or GHD-IA with anti-GH antibodies. The dosage of IGF-1 varied from 40 to 120 mg/kg twice daily. With the exception of the two oldest patients, all subjects increased their growth rates by at least 2 cm/year. These results have been updated and indicate a continued good response by most subjects.[593] Observed side effects included hypoglycemia, headache, convulsions, possible urolithiasis, and papilledema—the last indicating the possibility of pseudotumor cerebri, as has been reported with GH therapy.

A randomized double-blind placebo-controlled trial of IGF-1 therapy in GHRD has been performed in Ecuador, probably the only place where the population is sufficiently large and homogeneous to permit such investigation.[594] Subjects receiving IGF-1 showed a significant increase in growth rate (from 2.9 to 8.6 cm/year), which was sustained over the 1-year course of therapy. The placebo group grew 4.4 cm/year during the placebo phase and increased their height velocity to 8.4 cm/year during the IGF-1 phase. Incidents of hypoglycemia were equal in the two experimental groups. One recipient of IGF-1 developed papilledema, which resolved spontaneously while on treatment.

Longer-term studies of IGF-1 treatment of GHI have indicated a persistent, although progressively waning, effect (Figure 8-30).[595] Data from 17 patients treated for at least 4 years showed a total height gain of 1.7 SD score and emphasize the importance of early initiation of therapy.

As promising as these early studies are, IGF-I therapy is still under active investigation and the exact clinical scenarios in which this therapy is appropriate is still evolving. The failure of serum levels of IGFBP-3 to rise with IGF-1 administration underscores the relevance of the IGFBPs to IGF pharmacokinetics.[78,594] Nevertheless, the early results indicate that the IGF peptides (long considered to function primarily as autocrine or paracrine growth factors) are capable of acting as classic endocrine hormones.

Excess Growth and Tall Stature

TALL STATURE AND OVERGROWTH SYNDROMES

Although on a statistical basis as many children have heights more than <2 SD as have heights more than 2 SD, referral for evaluation of tall stature is much less common than that for short stature. This referral pattern speaks eloquently to the psychosocial pressure involved in referral patterns of children with "growth disorders." Nevertheless, it is critical to be able to identify situations in which tall stature or an accelerated growth rate provides a clue to an underlying disorder. Table 8-15 provides a listing of causes of statural overgrowth in infancy and during childhood.

OVERGROWTH IN THE FETUS

Maternal diabetes constitutes the most common cause of overgrowth in infants who are large for gestational age. Even in the absence of clinical symptoms or a family

TABLE 8-15

Differential Diagnosis of Statural Overgrowth

Fetal Overgrowth
Maternal diabetes mellitus
Cerebral gigantism (Sotos syndrome)
Weaver syndrome
Beckwith-Wiedemann syndrome
Other IGF-2 excess syndromes

Postnatal Overgrowth Leading to Childhood Tall Stature
Familial (constitutional) tall stature
Cerebral gigantism
Beckwith-Wiedemann syndrome
Exogenous obesity
Excess GH secretion (pituitary gigantism)
McCune-Albright syndrome or multiple endocrine neoplasia associated with excess GH secretion
Precocious puberty
Marfan syndrome
Klinefelter syndrome (XXY)
Weaver syndrome
Fragile X syndrome
Homocystinuria
XYY
Hyperthyroidism

Postnatal Overgrowth Leading to Adult Tall Stature
Familia (constitutional) tall stature
Androgen or estrogen deficiency/estrogen resistance (in males)
Testicular feminization
Excess GH secretion
Marfan syndrome
Klinefelter syndrome (XXY)
XYY

GH, growth hormone; IGF, insulin-like growth factor.

history, the birth of an excessively large infant should lead to evaluation for maternal (or gestational) diabetes. A group of disorders associated with excessive somatic growth and growth of specific organs has been described and collectively referred to as overgrowth syndromes.[596] These disorders appear to be caused by excess availability of the IGF-2 encoded by the gene Igf2. The best described of these syndromes is the Beckwith-Wiedemann syndrome, which is an overgrowth malformation syndrome that occurs with an incidence of 1:13,700 births.

It is manifested as a fetal overgrowth syndrome in which hypertrophy dominates the clinical picture. Typically, macroglossia, omphalocele, hepatosplenomegaly, nephromegaly, and hypoglycemia secondary to pancreatic beta cell hyperplasia in an infant who is large for gestational age comprise the clinical picture at birth. An additional complication is that these children are predisposed to a specific subset of childhood neoplasms, among which are Wilms' tumor and adrenocortical carcinoma.

Overexpression of IGF-2 in Beckwith-Wiedemann syndrome may be caused by a number of genetic disruptions, including gene duplication, loss of heterozygosity, and relaxation or loss of imprinting of the Igf2 gene. Various lines of investigation have localized "imprinted" genes involved in Beckwith-Wiedemann syndrome and associated childhood tumors to chromosome 11p. These include (in addition to Igf2) the gene H19, which is involved in Igf2 suppression—as well as the gene WT1 (the Wilms' tumor gene). Mutations in GPC3, a glypican gene that codes for an IGF-2 neutralizing membrane receptor, cause the related Simpson-Golabi-Behmel overgrowth syndrome.[597]

Children with cerebral gigantism (also known as Sotos syndrome) are typically above the 90th percentile for both length and weight at birth, and macrocrania may also be noted at that time.[598] Mutations and deletions of the NSD1 gene (located at chromosome 5q35 and coding for a histone methyltransferase implicated in transcriptional regulation) are responsible for more than 75% of cases. FISH analysis, MLPA, or multiplex quantitative PCR allow the detection of total/partial NSD1 deletions—and direct sequencing allows detection of NSD1 mutations. The large majority of NSD1 abnormalities occur de novo, and there are very few familial cases.

Although most cases are sporadic, several reports of autosomal-dominant inheritance have been described.[598] Growth is rapid, and by 1 year of age affected infants are over the 97th percentile in height. Accelerated growth continues for the first 4 to 5 years and then returns to a normal rate. Puberty usually occurs at the normal time, but may occur slightly early. Adult height is usually in the upper normal range. The hands and feet are large, with thickened subcutaneous tissue. The head is large and dolichocephalic, the jaw is prominent, there is hypertelorism, and the eyes have an antimongoloid slant. Clumsiness and awkward gait are characteristic, and affected children have great difficulty in sports, in learning to ride a bicycle, and in other tasks requiring coordination.

Some degree of mental retardation affects most patients. In some children, perceptual deficiencies may predominate. Osseous maturation is compatible with the patient's height. Results of tests of GH and IGF-1 levels and of other endocrine studies are usually normal. There are no distinctive laboratory or radiologic markers for the syndrome. Abnormal electroencephalograms are common. Imaging studies frequently reveal a dilated ventricular system. Most cases are sporadic. Familial cases are usually consistent with autosomal-dominant inheritance and occasionally with autosomal-recessive inheritance. Affected patients may be at increased risk for neoplasia, particularly hepatic carcinoma—and Wilms', ovarian, and parotid tumors have been reported.

TALL STATURE AND POSTNATAL STATURAL OVERGROWTH

The normal distribution of height predicts that 2.5% of the population will be taller than 2 SD above the mean. The social acceptability and even desirability of tallness ("heightism") makes tall stature an uncommon complaint, however. In North America, it is extremely unusual for males to seek help regarding excessive height—although in Europe it is somewhat more common. Even in females, tall stature has become more socially acceptable—although tall girls may still approach their physician with a desire to curb their growth rate.

DIFFERENTIAL DIAGNOSIS OF TALL STATURE

Table 8-15 lists the causes of tall stature in childhood and adolescence. Of these, the normal variant familial or constitutional tall stature is by far the most common cause. Almost invariably, a family history of tallness can be elicited—and no pathologic process is present. The child is often tall throughout childhood and enjoys excellent health. The parent of the constitutionally tall adolescent may reflect unhappily on his or her own adolescence as a tall teenager. There are typically no abnormalities in the physical examination, and the laboratory studies (if obtained) are always negative.

As was described for the child with growth failure, crossing height percentiles between infancy and the onset of puberty always warrants further evaluation. Although such growth patterns frequently are of no concern to parents, an alert pediatrician will recognize that overly rapid statural growth can indicate a serious underlying problem. Furthermore, as with short stature children with tall stature must be evaluated in the context of their familial growth and pubertal patterns.

Klinefelter syndrome (XXY syndrome) is a relatively common (1:500 to 1:1,000 live male births) abnormality associated with tall stature, mild mental retardation, gynecomastia, and decreased upper to lower body segment ratio. The testes are invariably small, although androgen production by Leydig cells is often at the low normal range. Spermatogenesis and Sertoli cell function are defective, resulting in infertility. XYY syndrome is associated with tall stature and possible behavioral and mental problems.

Marfan syndrome is an autosomal-dominant connective tissue disorder consisting of tall stature, increased arm span, and decreased upper to lower body segment

ratio. Additional abnormalities include arachnodactyly, ocular abnormalities, and cardiac anomalies. Homocystinuria is an autosomal-recessive inborn error of amino acid metabolism causing mental retardation when untreated. It has many features resembling Marfan syndrome, particularly ocular manifestations. Hyperthyroidism in adolescence is associated with rapid growth but normal adult height. It is almost always caused by Grave's disease and is much more common in females.

Exogenous obesity is a common condition in childhood and adolescence and may be associated with rapid linear growth and early maturation. This association is so characteristic that the child with obesity and short stature should always be evaluated for an underlying pathologic process such as hypothyroidism, GHD, Cushing syndrome, and various syndromes (such as Prader-Willi). In exogenous obesity, bone age is usually modestly accelerated—and thus puberty and epiphyseal fusion occur early, resulting in normal adult height. As stated, cerebral gigantism and Beckwith-Wiedemann syndrome are associated with rapid perinatal growth but rapid postnatal growth usually ends by early to mid childhood. Nevertheless, these conditions should be considered when tall stature in childhood is accompanied by the characteristic phenotypic features, a history of unexplained fetal overgrowth, or the presence of the childhood tumors mentioned previously.

PRECOCIOUS AND DELAYED PUBERTY

Precocious puberty, whether mediated centrally (increased gonadotropin secretion) or peripherally (increased secretion of androgens, estrogens, or both), results in accelerated linear growth in childhood—mimicking the pubertal growth spurt. Because skeletal maturation is also accelerated, adult height is frequently compromised. The diagnostic evaluation and management of precocious puberty are discussed in Chapters 14 and 16.

Although delayed puberty may be associated with short stature in childhood, as with constitutional delay failure to eventually enter puberty and complete sexual maturation may result in sustained growth during adult life—with ultimate tall stature. The reports of tall stature in men with open epiphyses, resulting from mutations of the estrogen receptor or of the aromatase gene, underscores the fundamental role of estrogen in promoting epiphyseal fusion and termination of normal skeletal growth.[15,263]

DIAGNOSING FAMILIAL TALL STATURE

The purpose of the diagnostic evaluation of tall stature is to distinguish the commonly occurring normal variant constitutional (or familial) variety from the rare pathologic conditions. Often, when the history is suggestive of familial tall stature and the physical examination is entirely normal, no laboratory tests are indicated. It is valuable to obtain a bone age radiograph to be able to predict adult height, which serves as a basis for discussions with the family and for management decisions. If, however, the history is suggestive for any of the previously mentioned disorders or the physical examination reveals abnormalities additional laboratory tests should be obtained to evaluate for brain disorders, GH excess, chromosomal abnormalities, or other rare causes of tallness.

IGF-1 and IGFBP-3 are excellent screening tests for GH excess and can be verified with a glucose suppression test. Laboratory evidence of GH excess mandates MRI evaluation of the pituitary. Chromosome analysis is useful in males, especially when the upper to lower body segment ratio is decreased or when mental retardation is present. If Marfan syndrome or homocystinuria is suspected from the physical examination, referral to a cardiologist and an ophthalmologist should be made. Thyroid function tests are useful to diagnose or rule out hyperthyroidism when this disorder is suspected.

MANAGEMENT OF CONSTITUTIONAL AND SYNDROMIC TALL STATURE

Reassurance of the family and the patients is the key to the management of normal variant tall stature. The use of the bone age evaluation and a careful assessment of pubertal status to predict adult height may provide some comfort for them, as will general supportive discussions on the social acceptability of this condition. Although treatment is available for girls and boys with excessive growth, its use should be restricted to patients with predicted adult height greater than 3 SD above the mean (198 cm in males or 180 cm in females) and evidence of significant psychosocial impairment.

For the child with extreme familial tall stature (or another condition, such as Marfan syndrome) whose parents feel strongly about treatment, a trial of sex steroids is possible. Such therapy is designed to accelerate puberty and epiphyseal fusion, and is therefore of little benefit when given in late puberty. Therapy is initiated ideally prepubertally or in early puberty. Oral estrogens in various doses have successfully reduced the predicted height of females by 5 to 10 cm on the average.[599]

This is a direct result of the known effects of sex steroids on promoting epiphyseal fusion, and therapy must therefore begin before the bone age has reached 12 years. Oral ethinyl estradiol at a dose of 0.15 to 0.5 mg/day until cessation of growth occurs has been used successfully in girls. If necessary, a progestational agent can be added after 1 year of unopposed estrogen. In boys, treatment should begin before the bone age reaches 14 years. Testosterone enanthate is used at a dose of 500 mg intramuscularly every 2 weeks for 6 months. Whereas no long-term complications of sex steroid therapy have been clearly documented, short-term side effects are common. These include lipid abnormalities, thromboembolism, cholelithiasis, hypertension, nausea, menstrual irregularities, and acne fulminans. The lack of extensive experience with this form of therapy and the risks involved should be carefully weighed and discussed with the family before embarking on therapy.

The mechanism of estrogen action affects both GH and IGF production. Perhaps more important, however, is the action of estrogen on the epiphysis. Studies have demonstrated that it is estrogen that mediates epiphyseal fusion in both females and males. In prepubertal girls, adult height is reportedly decreased by as much as 5 to

6 cm relative to pretreatment predictions. When therapy is initiated after the onset of puberty, the decrement in adult height is not likely to be as large. Therapy in boys with tall stature is even more problematic. For the reasons discussed, estrogen is likely to be most efficacious in accelerating epiphyseal fusion but is obviously undesirable in males. Androgens will also accelerate skeletal maturation, presumably through aromatization to estrogen, but at the price of rapid virilization.

EXCESS GH SECRETION AND PITUITARY GIGANTISM

In young persons with open epiphyses, overproduction of GH results in gigantism. In persons with closed epiphyses, the result is acromegaly. Often, some acromegalic features are seen with gigantism—even in children and adolescents. After closure of the epiphyses, the acromegalic features become more prominent. Famous examples of gigantism include Robert Wadlow (the Alton giant), who stood 271.8 cm at the time of his death in his mid 20s. The well-known Andre Rousimoff (Andre the Giant) was 190.5 cm at age 12 and reached a height of 223.5 cm by adulthood.[600] Pituitary gigantism is rare, and its cause is most often a pituitary adenoma—but gigantism has been observed in a 2.5-year-old boy with a hypothalamic tumor that presumably secreted GHRH. Other tumors, particularly in the pancreas, have produced acromegaly by secretion of large amounts of GHRH with resultant hyperplasia of the somatotrophs.[601]

The cardinal clinical feature of gigantism is longitudinal growth acceleration secondary to the GH excess. The usual manifestations consist of coarse facial features and enlarging hands and feet. In young children, rapid growth of the head may precede linear growth. Some patients have behavioral and visual problems. In most of the recorded cases, the abnormal growth became evident at puberty—but the condition has been established as early as the newborn period in 1 child and at 21 months of age in another. Giants may grow to a height of 243.8 cm or more. Acromegalic features consist chiefly of enlargement of the distal parts of the body, but manifestations of abnormal growth involve all portions.

The circumference of the skull increases, the nose becomes broad, and the tongue is often enlarged—with coarsening of the facial features. The mandible grows excessively, and the teeth become separated. Visual field defects and neurologic abnormalities are common. Signs of increased intracranial pressure appear later. The fingers and toes grow chiefly in thickness. There may be dorsal kyphosis. Fatigue and lassitude are early symptoms. GH levels are elevated and may occasionally exceed 100 ng/mL. There is typically no suppression of GH levels by the hyperglycemia of a glucose tolerance test. IGF-1 and IGFBP-3 levels are consistently elevated in gigantism, whereas other growth factors are not. Gigantism is extremely rare, with only several hundred reported cases. The presentation of gigantism is usually dramatic, unlike the insidious onset of acromegaly in adults.

The tumor mass itself may cause headaches, visual changes from optic nerve compression, and hypopituitarism. About half of the patients also have marked hyperprolactinemia as a result of plurihormonal adenomas that secrete GH and prolactin. This is because mammosomatotrophs are the most common type of GH-secreting cells involved in childhood gigantism. GH-secreting tumors of the pituitary are typically eosinophilic or chromophobe adenomas. Adenomas may compromise other anterior pituitary function through growth or cystic degeneration. Secretion of gonadotropins, thyrotropin, or corticotropin may be impaired. Delayed sexual maturation or hypogonadism may occur. When GH hypersecretion is accompanied by gonadotropin deficiency, accelerated linear growth may persist for decades. In some cases, the tumor spreads outside the sella—invading the sphenoid bone, optic nerves, and brain. GH-secreting tumors in pediatric patients are more likely to be locally invasive or aggressive than are those in adult patients.[602]

The cause of these tumors is uncertain, although recent studies of acromegalics have suggested that many cases result from mutations that generate constitutively activated G proteins with reduced GTPase activity. The resultant rise in intracellular cyclic AMP in the pituitary leads to increased GH secretion. McCune-Albright syndrome, which can also be caused by mutations resulting in constitutively activated G proteins, may also include the presence of somatotrophic tumors and excess GH secretion. In fact, approximately 20% of patients with gigantism are those with McCune-Albright syndrome (commonly consisting of a triad of precocious puberty, café-au-lait spots, and fibrous dysplasia). GH-secreting tumors have also been reported in multiple endocrine adenomatosis and in association with neurofibromatosis, tuberous sclerosis, and Carney complex.[603,604]

Activating mutations of the stimulatory Gsa protein have been found in the pituitary lesions in McCune-Albright syndrome and are believed to be responsible for the other glandular adenomas observed in this condition as well. Somatic point mutations of the Gsa protein have also been identified in somatotrophs of up to 40% of sporadic GH-secreting pituitary adenomas.

DIAGNOSIS OF GH EXCESS

The "gold standard" for making the diagnosis of GH excess is a failure to suppress serum GH levels to less than 5 ng/dL after a 1.75-g/kg oral glucose challenge (maximum, 75 g). This test measures the ability of IGF-1 to suppress GH secretion because the glucose load results in insulin secretion, leading to suppression of IGFBP-1, which results in an acute increase in free IGF-1 levels. The increased free IGF-1 suppresses GH secretion within 30 to 90 minutes.[605] This test can be abnormal in diabetic patients. Note that a single measurement of GH is inadequate because GH is secreted in a pulsatile manner. Therefore, the use of a random GH measurement can lead to both false-positive and false-negative results.

Measurement of serum IGF-1 concentration is a sensitive screening test for GH excess. An excellent linear dose-response correlation between serum IGF-1 levels and 24-hour mean GH secretion has been demonstrated. An elevated IGF-1 level in a patient with appropriate

clinical suspicion is almost always indicative of GH excess. Potential confusion may arise when evaluating normal adolescents because significantly higher IGF-1 levels occur during puberty than in adulthood.

For accurate control comparison, the IGF-1 level must be age and gender matched. Serum IGFBP-3 levels may also be useful in the diagnosis of GH excess. In patients with confirmed somatotroph adenomas, increased IGFBP-3 levels have been reported to be a sensitive marker of GH elevations and may be elevated despite normal IGF-1 levels. If laboratory findings suggest GH excess, the presence of a pituitary adenoma should be confirmed using MRI. In rare cases, a pituitary mass may not be identified. This may be an occult pituitary microadenoma or an ectopic tumor. Computed tomography is acceptable when MRI is unavailable.

TREATMENT OF GH OVERSECRETION

The goals of therapy are to remove or shrink the pituitary mass, to restore GH and secretory patterns to normal, to restore IGF-1 and IGFBP-3 levels to normal, to retain the normal pituitary secretion of other hormones, and to prevent recurrence of disease. For well-circumscribed pituitary adenomas, transsphenoidal surgery is the treatment of choice and may be curative.[606] The tumor should be removed completely. The likelihood of surgical cure depends greatly on the surgeon's expertise as well as on the size and extension of the mass. Intraoperative GH measurements can improve the results of tumor resection. Transsphenoidal surgery to resect the tumors has been shown to be as safe in children as in adults. At times, a transcranial approach may be necessary. The primary goal of treatment is to normalize GH levels. GH levels (<1 ng/mL within 2 hours after a glucose load) and serum IGF-1 levels (age-adjusted normal range) are the best tests to define a biochemical cure.

If GH secretion is not normalized by surgery, the options include pituitary radiation and medical therapy. In general, radiation therapy is recommended if GH hypersecretion is not normalized by surgery. Further growth of the tumor is prevented by radiation in more than 99% of the patients. The main disadvantage is the delayed efficacy in decreasing GH levels. GH is reduced approximately 50% from the initial concentration by 2 years and 75% by 5 years, and approaches 90% by 15 years. Hypopituitarism is a predictable outcome, occurring in 40 to 50% of patients 10 years after irradiation.

It is now clear that surgery fails to cure a significant number of patients and therefore medical therapy has taken on a more important role in the management of patients with GH excess. Indeed, the greatest progress in recent years in the treatment of GH excess has been within the realm of medical therapy. Treatment has been improved by the availability of effective and well-tolerated long-acting somatostatin analogues and dopamine agonists, as well as by novel GH antagonists.

The somatostatin analogues have been found to be highly effective in the treatment of patients with GH excess. Octreotide suppresses GH to less than 2.5 ng/mL in 65% of patients with acromegaly, and normalizes IGF-1 levels in 70%. Studies of patients for more than 14 years have shown that the effects of octreotide are well sustained over time. Tumor shrinkage also occurs with octreotide, but it is generally modest. Consistent GH suppression has been obtained with a continuous subcutaneous pump infusion of octreotide in a pubertal boy with pituitary gigantism.[607] New long-acting formulations, including octreotide and lanreotide, have been shown to produce consistent GH and IGF-1 suppression in acromegalics with once-monthly or biweekly intramuscular depot injections. The sustained-release preparations have not been formally tested in children. Octreotide injection in the pediatric population has been used at doses of 1 to 40 mg/kg/day.

Dopamine agonists, such as bromocriptine, bind to pituitary dopamine type 2 (D2) receptors and suppress GH secretion—although the precise mechanism of action remains unclear. Prolactin levels are often adequately suppressed. However, GH levels and IGF-1 levels are rarely normalized with this treatment modality. Less than 20% of patients achieve GH levels less than 5 ng/mL, and less than 10% achieve normalization of IGF-1 levels. Tumor shrinkage occurs in a minority of patients. It is generally used as adjuvant medical treatment for GH excess. Its effectiveness may be additive to that of octreotide.[608]

Long-acting formulations are available. However, data on long-term control of GH and IGF-1 with these agents are not yet available. The dose of bromocriptine needed ranges between 10 and 60 mg orally divided four times a day. Only a minority of patients benefit from doses greater than 20 mg/day. It has been found to be safe when used in children for an extended period of time, but side effects may include nausea, vomiting, abdominal pain, arrhythmias, nasal stuffiness, orthostatic hypotension, sleep disturbances, and fatigue.

A novel GHR antagonist has been approved for use in acromegaly (Pegvisomant). It is an analogue of hGH that functions as a GHR antagonist. It has been shown to effectively suppress GH and IGF-1 levels in patients with acromegaly from pituitary tumors as well as ectopic GHRH hypersecretion.[609] Normalization of IGF-1 levels occurs in up to 90% of patients treated daily with this drug for 3 months or longer.[610] Long-term studies need to be performed. It has not been tested in children. The adult dose is 10 to 30 mg through subcutaneous once-daily injection.

Conclusions

The advancement in our understanding of the molecular mechanisms of growth has resulted in a dramatic enhancement of our ability to diagnose and treat growth disorders. Undoubtedly, in the coming years new and improved methods of identifying specific abnormalities leading to short stature (particularly in the form of genetic tests) will further refine the diagnostic process. In addition, the therapies available to treat growth disorders are also undergoing constant improvements and in the future will surely allow more efficacious, safer, and easier-to-tolerate management of growth abnormalities.

Concluding Remarks

Introduction

Maintenance of the tonicity of extracellular fluids within a very narrow range is crucial to proper cell function.[1,2] Extracellular osmolality regulates cell shape as well as intracellular concentrations of ions and other osmolytes. Furthermore, proper extracellular ionic concentrations are necessary for the correct function of ion channels, action potentials, and other modes of intercellular communication. Extracellular fluid tonicity is regulated almost exclusively by the amount of water intake and excretion, whereas extracellular volume is regulated by the level of sodium chloride intake and excretion. In children and adults, normal blood tonicity is maintained over a tenfold variation in water intake by a coordinated interaction among thirst, vasopressin, and renal systems. Dysfunction in any of these systems can result in abnormal regulation of blood osmolality, which if not properly recognized and treated may cause life-threatening dysfunction in neuronal and other cellular activities.

The posterior pituitary, or the neurohypophysis, secretes the nonapeptide hormones vasopressin and oxytocin. Vasopressin controls water homeostasis, and oxytocin regulates smooth-muscle contraction during parturition and lactation. Disorders of vasopressin secretion and action lead to clinically important derangements in water metabolism. In this chapter, the physiology of water and volume regulation is summarized, a symptom-based approach to the differential diagnosis of the diseases of water homeostasis is presented, and a review of the pathology and treatment of disorders involving these systems is provided. (See Chapter 12 for a discussion of defects in mineralocorticoid regulation that result in disturbances in volume regulation.)

Physiology of Osmotic and Volume Regulation

The control of plasma tonicity and intravascular volume involves a complex integration of endocrine, neural, and paracrine pathways. Osmotic sensor and effector pathways control the regulation of vasopressin release and signal transduction, whereas volume homeostasis is determined largely through the action of the renin-angiotensin-aldosterone system—with contributions from vasopressin and the natriuretic peptide family. An improved understanding of the anatomic structures and molecules involved has developed through detailed molecular biologic and physiologic studies.

Osmotic Sensor and Effector Pathways

VASOPRESSIN AND OXYTOCIN BIOCHEMISTRY

Vasopressin and oxytocin are evolutionarily related peptides (paralogs), having arisen from gene duplication of a phylogenetically common molecule approximately 450 million years ago.[3,4] Both peptides consist of a 6-amino-acid disulfide ring plus a 3-amino-acid tail, with amidation of the carboxy terminus.[5,6] As early as 1895, a potent biologic principle (consisting of vascular pressor activity, "birth quickening," and milk secretory effects) was recognized in neurohypophyseal extracts.[7] The sequences of the individual peptides with pressor and antidiuretic capacity (vasopressin) and oxytocic capacity were determined by Du Vigneaud and colleagues during the mid 1950s,[6] culminating in the synthesis of each hormone in its biologically active form.[8,9]

In most mammals, vasopressin and oxytocin differ in only two amino acids: one substitution within the ring and one within the tail structure (Figure 9-1). Exploration of the structure-function relationship of specific amino acids within vasopressin and oxytocin has allowed characterization of molecules with substantial clinical use. Most notably, by replacement of l-arginine with d-arginine at position 8 of the vasopressin molecule and by amino-terminal deamidation an analogue with enhanced prolonged antidiuretic-to-pressor activity was found [desmopressin (desamino-d-arginine vasopressin; dDAVP); see Figure 9-1].[10] Desmopressin, with an antidiuretic potency

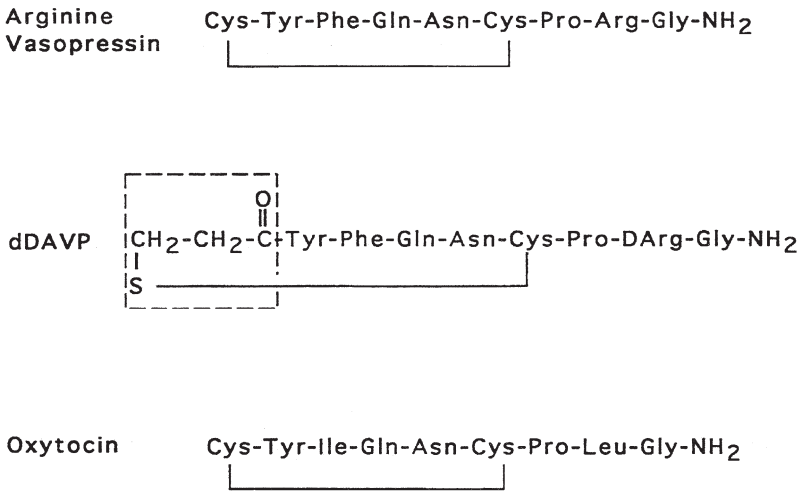

Figure 9-1 Structures of vasopressin, dDAVP, and oxytocin. In dDAVP, the de-amidated cysteine is enclosed in the box.

more than double that of its parent vasopressin, is now routinely used in clinical practice.

The association of vasopressin and oxytocin with specific proteins, the neurophysins, stored in the neurohypophysis was apparent as early as 1900.[11] Subsequent isolation and characterization of the neurophysins revealed two distinct forms: one type exclusively associated with vasopressin and the other exclusively associated with oxytocin.[12,13] Both are single-polypeptide chains of molecular weight 10,000 daltons. Despite extensive biophysical characterization, including crystallography of the oxytocin-neurophysin complex,[14,15] the biologic function of the neurophysins remains unclear. Possible roles for the neurophysins include stabilization against degradation during intracellular storage, more efficient packaging within secretory granules, and enhancement of post-translational processing by the proenzyme convertases.

The common origin of vasopressin and its neurophysin from a single larger precursor was first proposed by Sachs and colleagues,[16,17] who showed increased incorporation of ^{35}S cysteine (infused into canine third ventricle) into vasopressin isolated from the hypothalamus compared with vasopressin isolated from the posterior pituitary. Isolation of the larger precursor from the hypothalamus followed by trypsin-digestion-produced fragments of size similar to those of vasopressin and its neurophysin—with vasopressin immunoreactivity in the 1,000-dalton component.[18,19]

Since 1990, molecular genetic analyses have furthered the understanding of the synthesis, processing, and evolution of the vasopressin and oxytocin preprohormones. Human, mouse, rat, and bovine vasopressin and oxytocin genes consist of three exons (Figure 9-2).[20,21] The first exon encodes the 19-amino-acid signal peptide, followed by vasopressin or oxytocin nonapeptides. This is followed by a 3-amino-acid protease cleavage site leading into the first nine amino acids of neurophysin II (for vasopressin) or neurophysin I (for oxytocin). After interruption of the coding region by an intron, exon 2 continues with neurophysin coding sequences. The third exon completes the sequence of the neurophysin, which for vasopressin only is followed by coding information for an additional 39-amino-acid glycopeptide (copeptin) whose function is unclear. Preprovasopressin contains 16 cysteines, which likely participate in eight disulfide bridges that determine the tertiary structure of the protein (Figure 9-3). One cysteine pair is present in vasopressin peptide, whereas the rest are in neurophysin.

In all mammalian species analyzed thus far, oxytocin and vasopressin genes are adjacent in chromosomal location (chromosome 20 in the human[22]) and linked tail to tail in opposite transcriptional orientation. In the human, they are separated by 12 kb.[22] This likely explains their origin from the ancient duplication of a common ancestral gene.[23] Whether this adjacent linkage is of regulatory significance is under investigation.

Expression of vasopressin and oxytocin genes occurs in the hypothalamic paraventricular and supraoptic nuclei.[18,24] The magnocellular components of each of these nuclei are the primary neuronal populations involved in water balance, with vasopressin synthesized in these areas carried by means of axonal transport to the posterior pituitary, its primary site of storage and release into the systemic circulation (Figure 9-4). The bilaterally paired hypothalamic paraventricular and supraoptic nuclei are separated from one another by relatively large distances

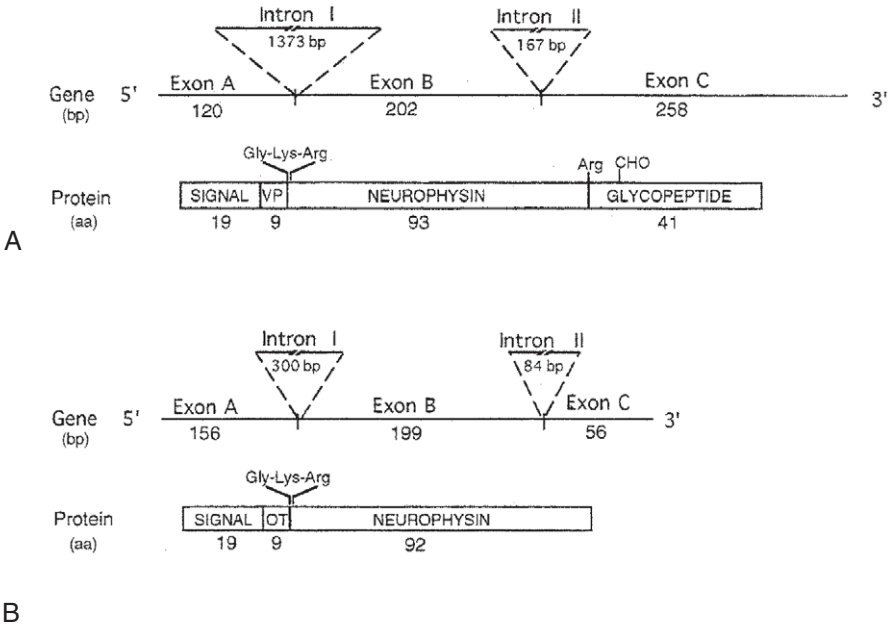

Figure 9-2 Structure of the human genes and peptide products of *(A)* vasopressin (VP) and *(B)* oxytocin (OT). Shown are the sizes of exons and intron in nucleotide base pairs (bp) and peptide products in amino acids (aa). Depicted are the amidation-dibasic cleavage signal (Gly-Lys-Arg) at the carboxy terminus of vasopressin and oxytocin and the monobasic cleavage signal at the end of neurophysin. Signal, signal peptide; VP, vasopressin; OT, oxytocin; and CHO, carbohydrate.

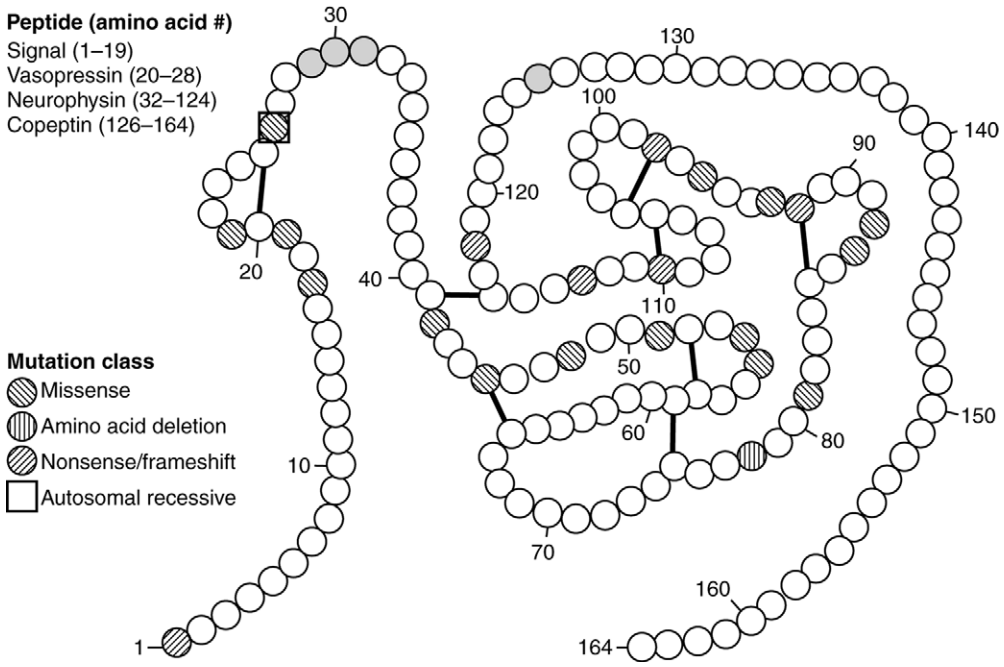

Figure 9-3 Structure of preprovasopressin peptide. The 164-amino-acid preprovasopressin peptide consists of signal peptide, vasopressin, neurophysin, and copeptin. The latter three entities are separated by basic residues (gray), which serve as cleavage sites for proconvertase enzymes. The 16 cysteines are connected by 8 putative disulfide bridges. Amino acid mutations are classified as missense, in-frame deletion, or nonsense/frame-shift mutations. Most mutations are inherited with an autosomal-dominant pattern. The one with an autosomal-recessive pattern is boxed. [Reproduced with permission from Uyeki TM, Barry FL, Rosenthal SM, Mathias RS (1993). Successful treatment with hydrochlorothiazide and amiloride in an infant with congenital nephrogenic diabetes insipidus. Pediatric Nephrology 7:554.

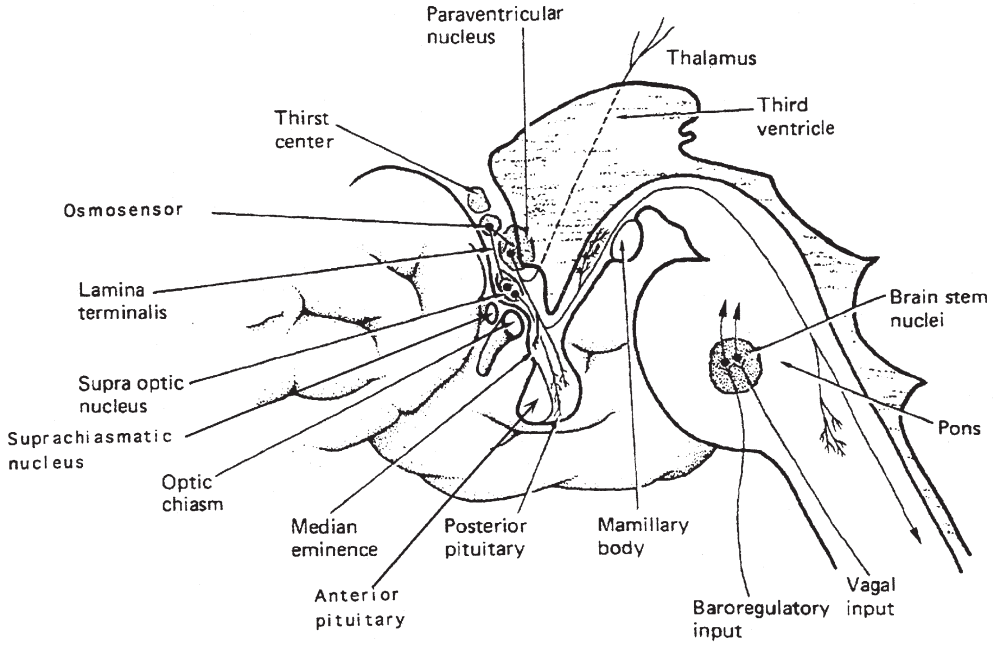

Figure 9-4 Vasopressin cells in the hypothalamus. Diagram of vasopressin cell bodies in the supraoptic, paraventricular, and suprachiasmatic hypothalamic nuclei—and axonal termination in the posterior pituitary and median eminence. Because vasopressin axons terminate at different levels in the pituitary stalk and posterior pituitary, the amount of permanent cell loss following neurosurgical insult is determined by the highest level of damage—which will dictate the degree of vasopressin axon transection and retrograde neuronal degeneration. [Modified with permission from Baylis PH (1989). Vasopressin and its neurophysin. In Degroot LD (ed.), *Endocrinology, Second edition*. Philadelphia: WB Saunders 213.]

(approximately 1 cm). Their axons course caudad, converge at the infundibulum, and terminate at different levels within the pituitary stalk and the posterior pituitary gland (Figure 9-4).

Vasopressin is also synthesized in the parvocellular neurons of the paraventricular nucleus, where it has a role in modulation of hypothalamic-pituitaryadrenal axis activity. In this site, vasopressin is colocalized in cells that synthesize corticotropin-releasing hormone[25,26]—and both are secreted at the median eminence and carried through the portal-hypophyseal capillary system to the anterior pituitary, where together they act as the major regulators of adrenocorticotropic hormone synthesis and release.[27] Vasopressin is also present in the hypothalamic suprachiasmatic nucleus, the circadian pacemaker of the body, where its function is unknown.

REGULATION OF VASOPRESSIN SECRETION AND THIRST

Osmotic Regulation

The rate of secretion of vasopressin from the paraventricular and supraoptic nuclei is influenced by several physiologic variables, including plasma osmolality and intravascular volume—as well as nausea and a number of pharmacologic agents. The major osmotically active constituents of blood are sodium, chloride, and glucose (with insulin deficiency). Normal blood osmolality ranges between 280 and 290 mOsm/kg H_2O.

The work of Verney[28] first demonstrated the relationship of increased vasopressin release in response to increasing plasma osmolality, as altered by infusion of sodium chloride or sucrose. At that time, it was postulated that there existed intracranial sensors sensitive to changes in plasma osmolality. Multiple researchers have subsequently confirmed that plasma vasopressin concentration increases in response to increasing plasma tonicity, although the exact nature of the osmosensor has not been defined.[29,30] Neurons of the supraoptic nucleus can respond directly to hypertonic stimuli with depolarization and vasopressin secretion,[31] but the majority of evidence indicates that osmosensor- and vasopressin-secreting neurons are anatomically distinct.[32,33]

The osmosensor is likely to reside outside the blood-brain barrier, as implicated by differential vasopressin secretory response to similar changes in plasma osmolality depending on whether the change was induced by salt, sucrose, or urea.[28,34] The organ vasculosum of the lamina terminalis (OVLT) and the subfornical organ (SFO), areas of the preoptic hypothalamus outside the blood-brain barrier, are likely sites of osmosensing because lesions of the OVLT result in impaired vasopressin secretion and hypernatremia.[32,33] In addition, the site of action of angiotensin II infused intracerebrally or peripherally to produce vasopressin secretion and antidiuresis resides within the OVLT.[35-37]

The pattern of secretion of vasopressin into blood has been characterized extensively in normal individuals and in those with abnormalities in water homeostasis. Normally, at a serum osmolality of less than 280 mOsm/kg plasma vasopressin concentration is at or below 1 pg/mL (the lower limit of detection of most radioimmunoassays).[29,30] Above 283 mOsm/kg (the normal threshold for vasopressin release), plasma vasopressin concentration increases in proportion to plasma osmolality—up to a maximum concentration of about 20 pg/mL at a blood osmolality of approximately 320 mOsm/kg (Figure 9-5).

The osmosensor can detect as little as a 1% change in blood osmolality. Plasma concentrations in excess of 5 pg/mL are also found with nausea, hypotension, hypovolemia, and insulin-induced hypoglycemia. However, further increments in urine concentration do not occur because peak antidiuretic effect is achieved at 5 pg/mL. The rate of increase of plasma vasopressin concentration, and thus the sensitivity of the osmosensor, exhibits substantial (as much as tenfold) interindividual variation as plasma osmolality increases.[38] The set-point for vasopressin secretion varies in a single individual in relation to changes in volume status and hormonal environment (e.g., pregnancy[39]) or glucocorticoid status.[40,41]

After the seventh week of gestation, osmotic thresholds for both vasopressin release and thirst are reduced by approximately 10 mOsm/kg (Figure 9-5), such that

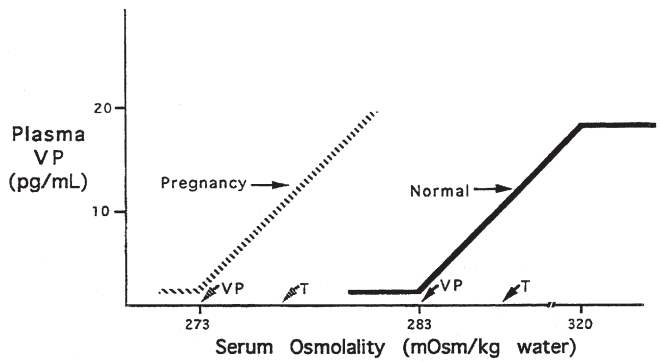

Figure 9-5 Osmotic thresholds for vasopressin and thirst. The threshold for vasopressin release is below that for thirst. In nonpregnant persons, there is linear increase in vasopressin (VP) release up to a serum osmolality of 320 mOsm/kg—after which no further increase occurs. In pregnancy, there is a decreased threshold for vasopressin release and thirst sensation—with no change in the sensitivity (slope) of the vasopressin-osmolality relationship. Vasopressin secretion in pregnancy presumably also plateaus at some level of hyperosmolality, although this has not been studied. Normal nonpregnant persons are indicated with solid line and arrows. Pregnant women are indicated with dashed line and arrows.

normal blood osmolality during pregnancy is approximately 273 mOsm/ kg (serum sodium 135 mEq/L).[39,42] Similarly, thresholds for vasopressin release and thirst during the luteal phase of the menstrual cycle are approximately 5 mOsm/kg lower than those in the follicular phase.[43,44] Human chorionic gonadotropin during pregnancy[45] and luteinizing hormone during the second half of the menstrual cycle may contribute to these changes in osmotic thresholds.

The sensation of thirst, a more integrated cortical activity, is determined by other anatomically distinct hypothalamic neurons—with afferents involving the ventromedial nucleus.[46] The activation of the thirst mechanism is also probably mediated by angiotensin II.[47] Whether the osmosensor for thirst and vasopressin release are the same is not certain, although this is suggested by lesions in the anteroventral region of the third ventricle that abolish thirst sensation and vasopressin release.[48] It makes physiologic sense that the threshold for thirst (293 mOsm/kg) is approximately 10 mOsm/kg higher than that for vasopressin release (Figure 9-5).

Otherwise, during the development of hyperosmolality the initial activation of thirst and water ingestion would result in polyuria without activation of vasopressin release—causing a persistent diuretic state. Immediately after water ingestion, before a change in blood osmolality or volume, vasopressin concentration falls and thirst ceases.[49] The degree of suppression is directly related to the coldness[50] and volume[51] of the ingested fluid. This effect is probably mediated by chemoreceptors present in the oropharynx, which guard against the rapid overdrinking of fluids after intense thirst during the time before the lowering of blood osmolality.

As noted previously, water balance is regulated in two ways: vasopressin secretion stimulates water reabsorption by the kidney (thereby reducing future water loss) and thirst stimulates water ingestion, thereby restoring previous water loss. Ideally, these two systems work in parallel to efficiently regulate extracellular fluid tonicity (Figure 9-6). However, each system by itself can maintain plasma osmolality in the near-normal range. For example, in the absence of vasopressin secretion but with free access to water thirst drives water ingestion up to the 5 to 10 L/m^2 of urine output seen with vasopressin deficiency. Conversely, an intact vasopressin secretory system can compensate for some degree of disordered thirst regulation. When both vasopressin secretion and thirst are compromised, however, by either disease or iatrogenic means there is great risk of the occurrence of life-threatening abnormalities in plasma osmolality.

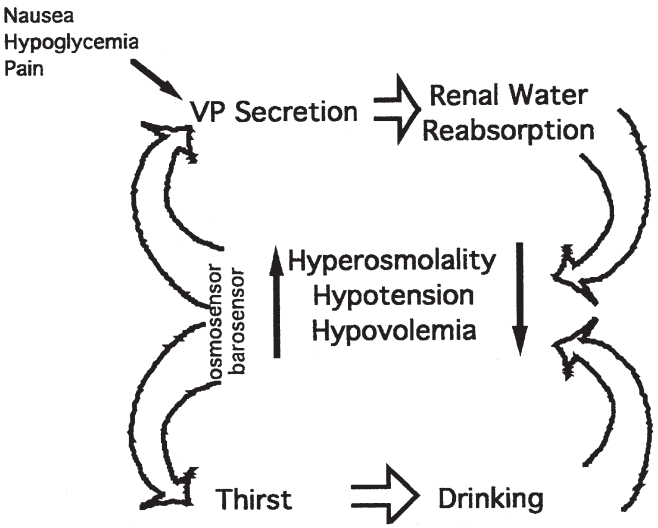

Figure 9-6 Regulation of vasopressin secretion and serum osmolality. Hyperosmolality, hypovolemia, and hypotension are sensed respectively by osmosensors, volume sensors, and barosensors. These stimulate vasopressin (VP) secretion and thirst. Vasopressin, acting on the kidney, causes increased reabsorption of water (antidiuresis). Thirst causes increased water ingestion. The results of these dual negative feedback loops cause a reduction in hyperosmolality or hypotension/hypovolemia. Additional stimuli for vasopressin secretion include nausea, hypoglycemia, and pain.

Nonosmotic Regulation

Separate from osmotic regulation, vasopressin has been shown to be secreted in response to alterations in intravascular volume. Afferent baroreceptor pathways arising from the right and left atria and the aortic arch (carotid sinus) are stimulated by increasing intravascular volume and stretching of vessel walls, and they send signals through the vagus and glossopharyngeal nerves (respectively) to the brain stem nucleus tractus solitarius.[52,53] Upon stimulation, noradrenergic fibers from the nucleus tractus solitarius synapse on the hypothalamic paraventricular nucleus and the supraoptic nucleus inhibit vasopressin secretion.[54,55] Experimental verification of this pathway has included demonstration of increased vasopressin concentration after interruption of baroreceptor output to the brain stem and decreased plasma vasopressin concentration after mechanical stimulation of baroreceptors, an effect diminished by vagotomy.[56,57]

The pattern of vasopressin secretion in response to volume as opposed to osmotic stimuli is markedly different (Figure 9-7). Although minor changes in plasma osmolality above 280 mOsm/kg evoke linear increases in plasma vasopressin, substantial alteration in intravascular volume is required for alteration in vasopressin output.[58-60] No change in vasopressin secretion is seen until blood volume decreases by approximately 8%. With intravascular volume deficits exceeding 8%, vasopressin concentration increases exponentially. Furthermore, osmotic and hemodynamic stimuli can interact in a mutually synergistic fashion such that the response to either stimulus may be enhanced by the concomitant presence of the other (Figure 9-7). When blood volume (or blood pressure[61-63]) decreases by approximately 25%, vasopressin concentrations are evident of 20- to 30-fold above normal and vastly exceeding those required for maximal antidiuresis. Surprisingly, the use of vasopressin antagonists has suggested that the high concentration of vasopressin observed with hypotension does not contribute to the maintenance of blood pressure in humans.[64]

Nausea (as evoked by apomorphine,[65] motion sickness,[66] and vasovagal reactions) is a very potent stimulus for vasopressin secretion. This effect is likely mediated by afferents from the area postrema of the brain stem and

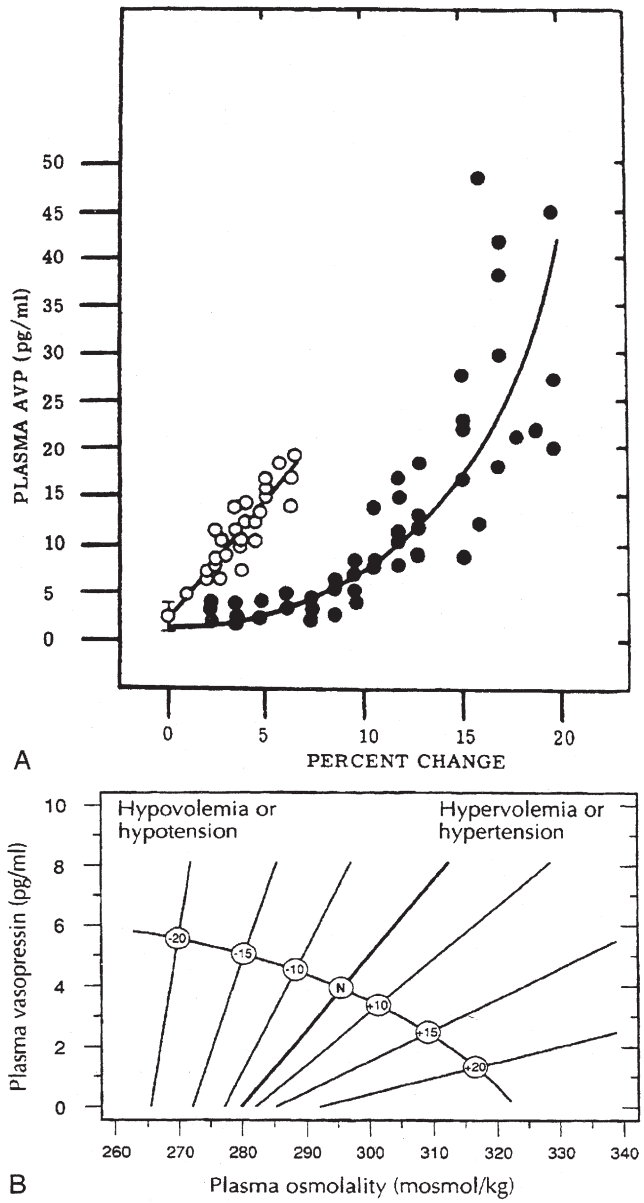

Figure 9-7 Relationships between osmotic and nonosmotic stimuli for vasopressin release. *(A)* Relationship of plasma vasopressin (AVP) concentration to the percent increase in blood osmolality (open circles) or decrease in blood volume (closed circles). *(B)* Alteration of sensitivity of osmotic stimulation of vasopressin secretion by volume or pressure stimuli. [Reproduced with permission from Dunn FL, et al. (1973). The role of blood osmolality and volume regulating vasopressin secretion in the rat. J Clin Invest 52:3212; and from Robertson GL (1985). Regulation of vasopressin secretion. In Seldin DW, Giebisch G (eds.), *The kidney: Physiology and pathophysiology*. New York: Raven Press 869.]

may result in vasopressin concentrations two to three orders of magnitude above basal levels. Nicotine is also a strong stimulus for vasopressin release.[67] These pathways probably do not involve osmotic or hemodynamic sensor systems because blockade of the emetic stimulus with dopamine or opioid antagonists does not alter the vasopressin response to hypernatremia or hypovolemia.

Vasopressin secretion is inhibited by glucocorticoids. Because of this, loss of negative regulation of vasopressin secretion occurs in the setting of primary or secondary glucocorticoid insufficiency.[68,69] The effects of cortisol loss of both enhancing hypothalamic vasopressin production and directly impairing free water excretion[70] are important considerations in the evaluation of the patient with hyponatremia, as is subsequently discussed.

VASOPRESSIN METABOLISM

Once in the circulation, vasopressin has a half-life of only 5 to 10 minutes owing to its rapid degradation by a cysteine amino-terminal peptidase called vasopressinase. A synthetic analogue of vasopressin, desmopressin, is insensitive to amino-terminal degradation and thus has a much longer half-life of 8 to 24 hours. During pregnancy, the placenta secretes increased amounts of this vasopressinase,[71] resulting in a fourfold increase in the metabolic clearance rate of vasopressin.[72]

Normal women compensate with an increase in vasopressin secretion, but women with preexisting deficits in vasopressin secretion or action[73] or those with increased concentrations of placental vasopressinase associated with liver dysfunction[74] or multiple gestations[75] may develop diabetes insipidus in the last trimester—which resolves in the immediate postpartum period.[76] As expected, this form of diabetes insipidus responds to treatment with desmopressin but not with vasopressin.[77,78]

SITES OF VASOPRESSIN ACTION

Vasopressin Receptors

Vasopressin released from the posterior pituitary and the median eminence affects the function of several tissue types by binding to members of a family of G-protein–coupled cell surface receptors, which subsequently transduce ligand binding into alterations of intracellular second messenger pathways.[79] Biochemical and cell biologic studies have defined at least three receptor types, designated V1, V2, and V3 (or V1b). The major sites of V1 receptor expression are on vascular smooth muscle[80] and hepatocytes,[81-84] where receptor activation results in vasoconstriction[85,86] and glycogenolysis,[87] respectively.

The latter activity may be augmented by stimulation of glucagon secretion from the pancreas.[87] The V1 receptor on platelets also stimulates platelet aggregation.[88] V1 receptor activation mobilizes intracellular calcium stores through phosphatidylinositol hydrolysis.[86,89] Despite its initial characterization as a powerful pressor agent, the concentration of vasopressin needed to significantly increase blood pressure is severalfold higher than that required for maximal antidiuresis,[90] although substantial vasoconstriction in renal and splanchnic vasculature can occur at physiologic concentrations.[91]

The cloning of the V1 receptor[80,81,83] has greatly elucidated the relationship of the vasopressin (and oxytocin[92,93]) receptors, and through sensitive in situ hybridization analysis has further localized V1 expression to the liver and the vasculature of the renal medulla—as well as to many sites within the brain, including the hippocampus, the amygdala, the hypothalamus, and the brain stem.[82,84] The V3 (or V1b) receptor is present on corticotrophs in the

anterior pituitary[94] and acts through the phosphatidylinositol pathway[95] to increase adrenocorticotropic hormone secretion. Its binding profile for vasopressin analogues resembles more closely that of the V1 receptor than of the V2 receptor. The structure of this receptor has been determined in humans by cloning of its complementary DNA.[95,96] Its structure is similar to that of the V1 and oxytocin receptors, and it is expressed in the kidney as well as in the pituitary. Recently, mice with deletion of the V1b receptor gene have been created.[97,98] As expected, they have defective activation of the pituitary-adrenal axis following some acute and chronic stressors.

Modulation of water balance occurs through the action of vasopressin on V2 receptors located primarily in the renal collecting tubule, along with other sites in the kidney—including the thick ascending limb of the loop of Henle and periglomerular tubules.[82,84,99] It is also present on vascular endothelial cells in some systemic vascular beds, where vasopressin stimulates vasodilation[100]—possibly through activation of nitric oxide synthase.[101] Vasopressin also stimulates von Willebrand factor, factor VIIIa, and tissue plasminogen activator through V2-mediated actions.

Because of this, desmopressin is used to improve the prolonged bleeding times characteristic of uremia, type I von Willebrand disease, and hemophilia.[102] The V2 receptor consists of 370 amino acids encoding seven transmembrane domains characteristic of the G-protein–coupled receptors.[99,103] These transmembrane domains share approximately 60% sequence identity with the V1 receptor but substantially less with other members of this family (Figure 9-8). Unlike the V1 and V3 receptors, the V2 receptor acts through adenylate cyclase to increase intracellular cyclic adenosine monophosphate (AMP) concentration. The human V2 receptor gene is located on the long arm of the X chromosome (Xq28),[104,105] at the locus associated with congenital X-linked vasopressin-resistant diabetes insipidus. Mice in which V2R has been deleted have a similar phenotype.[106]

Renal Cascade of Vasopressin Function

Vasopressin-induced increases in intracellular cyclic AMP as mediated by the V2 receptor triggers a complex pathway of events, resulting in increased permeability of the collecting duct to water and efficient water transit across an otherwise minimally permeable epithelium (Figure 9-9).[107] Activation of a cyclic AMP-dependent protein kinase imparts remodeling of cytoskeletal microtubules and microfilaments that culminate in the insertion of aggregates of water channels into the apical membrane.[108] These mechanisms may involve a vesicle-associated membrane protein-2-like protein (VAMP-2; which also regulates synaptic vesicle activity in neuronal terminals[109]) and its associated receptor syntaxin-4.[110]

Insertion of the water channels causes an up to 100-fold increase in water permeability of the apical membrane, allowing water movement along its osmotic gradient into the hypertonic inner medullary interstitium from the tubule

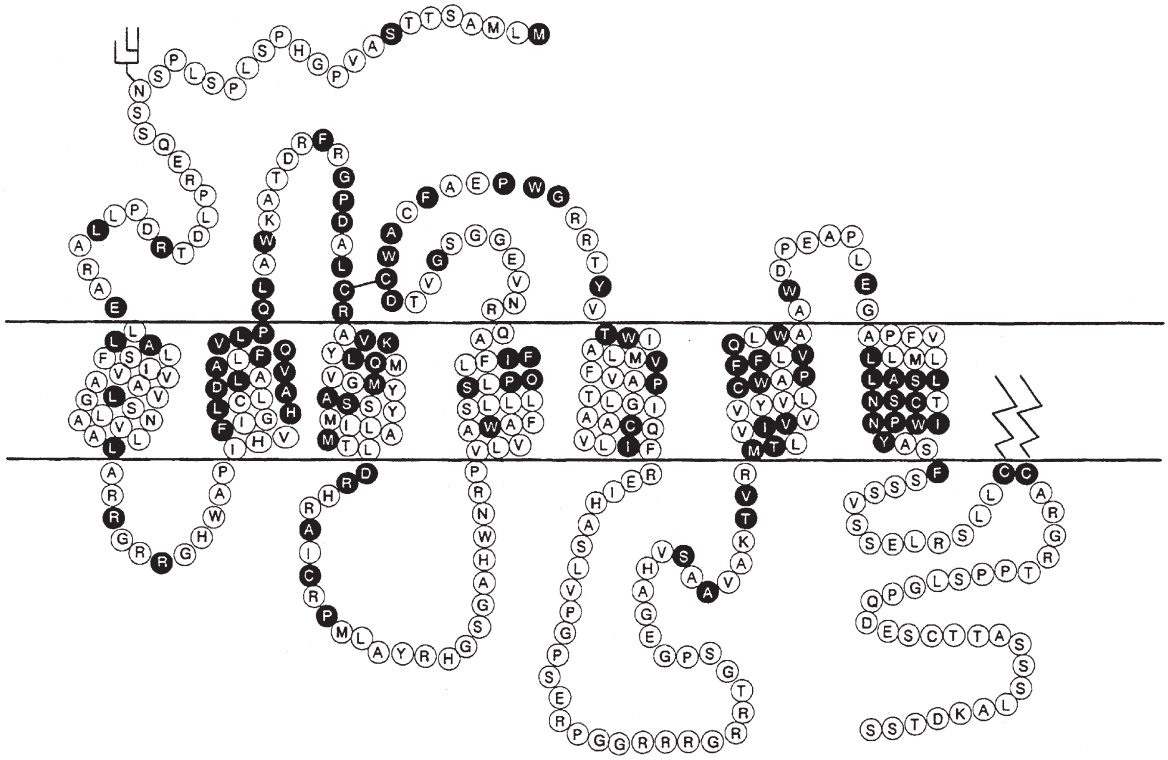

Figure 9-8 Structure of the V1 and V2 vasopressin receptors and the oxytocin receptor. Depicted are predicted membrane topology, with the extracellular domain at the top of the figure and amino acids in the one-letter code. Amino acids in open circles encode the V1 receptor, whereas those in black circles are common to all three receptors. [Reproduced with permission from Bichet DG (1995). The posterior pituitary. In Melmed S (ed.), *The pituitary*. Cambridge: Blackwell Science 277.]

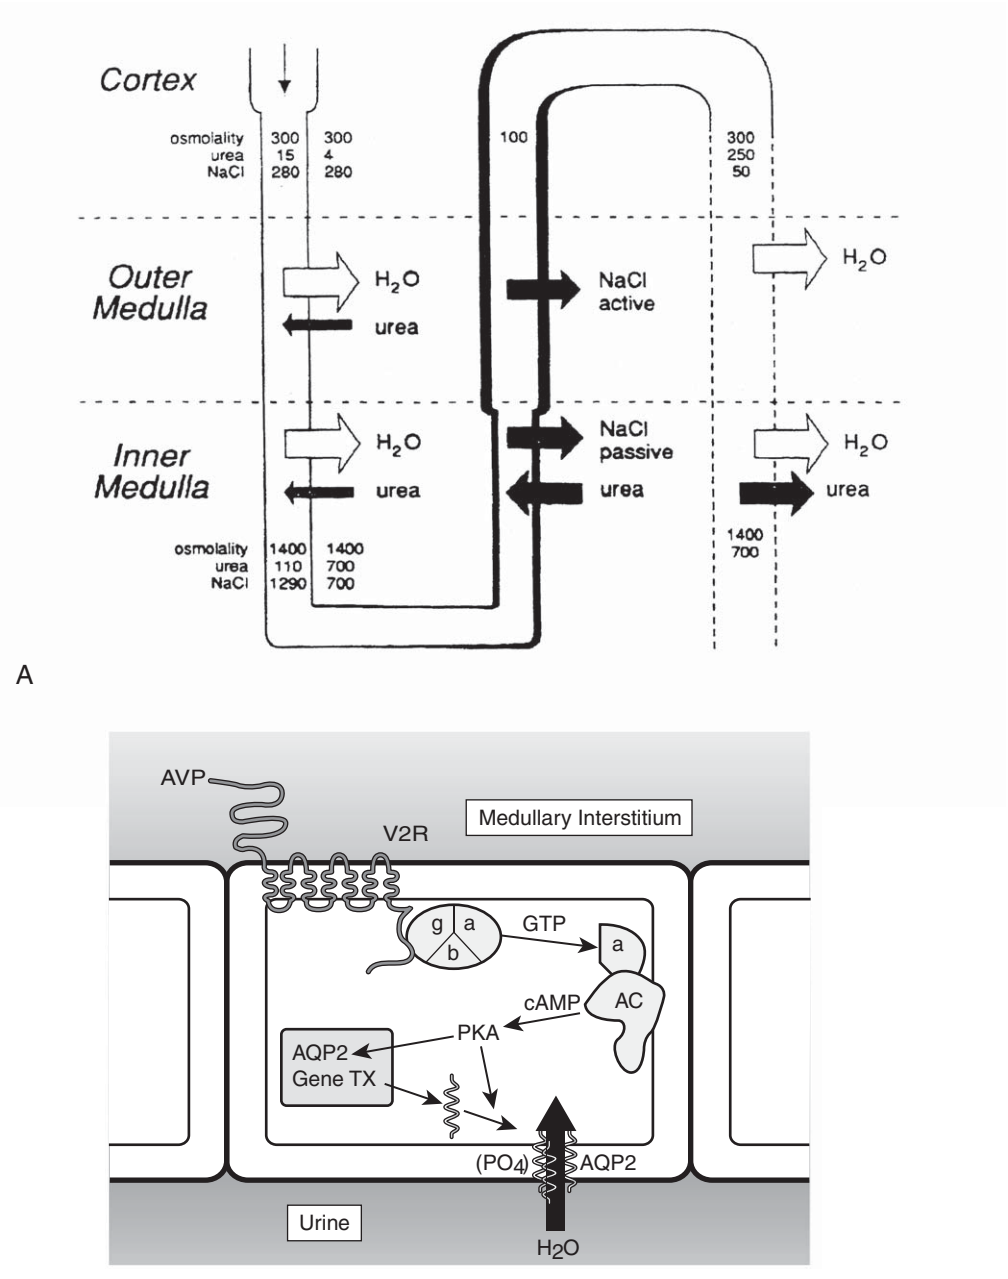

Figure 9-9 Vasopressin action in the kidney. *(A)* Solute and water handling in the kidney. *(B)* Action of vasopressin in the collecting duct cell. Vasopressin (AVP) binds to the V2 receptor (V2R), causing the binding of GTP to the stimulatory alpha G-protein subunit *(α)*. This activates adenylate cyclase (AC), resulting in an increase in cAMP and activation of protein kinase A (PKA). The catalytic subunit of PKA, via phosphorylation of serine 256 of the water channel [aquaporin-2 (AQP2)], causes aggregation of AQP2 homotetramers in membrane vesicles and their fusion with the collecting duct luminal membrane—resulting in an increase in water flow from the urine into the renal medullary interstitium. Demeclocycline, lithium, high calcium, and low potassium interfere with these processes—possibly at the level of cAMP generation and AQP2 synthesis or action. [From Reeves WB, Andreoli TE (1989). Nephrogenic diabetes insipidus. In Scriver CR, Beaudet AL, Sly WS (eds.), *The metabolic basis of inherited disease, Sixth edition*. New York: McGraw-Hill 1985.]

lumen and excretion of a concentrated urine (Figure 9-9). The molecular analysis of the water channels has revealed a family of related proteins (designated aquaporins) that differ in their sites of expression and pattern of regulation.[111] Each protein consists of a single polypeptide chain with six membrane-spanning domains (Figure 9-10). Although functional as monomers, they are believed to form homotetramers in the plasma membrane.[107]

Aquaporin-2 is expressed mostly within the kidney,[112] primarily within the collecting duct.[113] It is also expressed in the vas deferens, at least in the rat, although it is not regulated by vasopressin in this location.[114] Studies with immunoelectron microscopy have demonstrated large amounts of aquaporin-2 in the apical plasma membrane and subapical vesicles of the collecting duct, consistent with the "membrane-shuttling" model of water

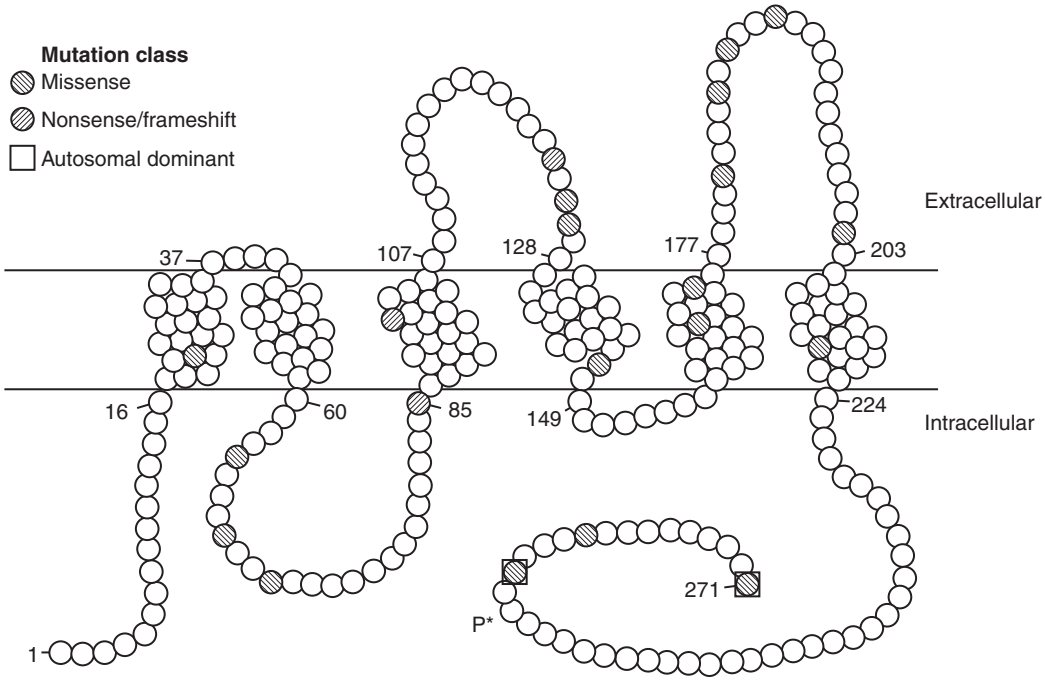

Figure 9-10 Structure of the aquaporin-2 protein inserted into the luminal membrane of the distal tubule. The 271-amino-acid protein consists of five transmembrane domains, four intracellular domains, and three extracellular domains. Amino acid mutations are denoted by filled circles. Most mutations are transmitted with an autosomal-recessive pattern. The two dominant mutations are bounded by squares. Vasopressin-dependent protein-kinase-A-mediated phosphorylation of serine at amino acid 256 (P*) is noted. [Reproduced with permission from Uyeki TM, Barry FL, Rosenthal SM, Mathias RS (1993). Successful treatment with hydrochlorothiazide and amiloride in an infant with congenital nephrogenic diabetes insipidus. Pediatric Nephrology 7:554.]

channel aggregate insertion into the apical membrane after vasopressin stimulation.[114]

Studies analyzing the mechanism by which aquaporin-2 traffics to the apical plasma membrane have demonstrated that vasopressin-induced protein-kinase-A-mediated serine phosphorylation at amino acid 256 is required for its exocytosis,[115] a process also requiring a heterotrimeric G protein of the G_i family.[116] In response to water restriction or desmopressin infusion in humans, the content of urinary aquaporin-2 in both soluble and membrane-bound forms has been found to increase.[117] Mice with targeted deletion of the aquaporin-2 gene have been made.[118] As expected, they have nephrogenic diabetes insipidus that is unresponsive to treatment with vasopressin.

In addition to aquaporin-2, different aquaporins appear to be involved in other aspects of renal water handling. In contrast to the apical localization of aquaporin-2, aquaporin-3 and aquaporin-4 are expressed on the basolateral membrane of the collecting duct epithelium. They appear to be involved in the flow of water and urea from the inside of the collecting duct cell into the extracellular renal medullary space. Mice made genetically deficient in aquaporin-4 demonstrate a mild urinary concentrating defect,[119] whereas those with deficiency of aquaporin-3 alone or together with aquaporin-4 demonstrate more severely impaired urinary concentrating ability.[120] Mice made genetically deficient in aquaporin-1 demonstrate a urinary concentrating defect caused by decreased water permeability in the proximal tubule.[121]

Volume Sensor and Effector Pathways

RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM

In contrast to the vasopressin system, the classic (peripheral) renin-angiotensin system primarily affects maintenance of intravascular volume as opposed to plasma tonicity. In addition to the well-established endocrine regulatory system, several local renin-angiotensin systems have emerged—with both autocrine and paracrine effects in their tissue of synthesis, whose regulation is independent of the classic system. Finally, brain and pituitary angiotensin systems involved in blood pressure, autonomic function, and fluid balance have been characterized with extensive interaction with the vasopressin system.

ENDOCRINE RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM

Anatomy and Biochemistry

Renin (which is synthesized by the renal juxtaglomerular apparatus) is a proteolytic enzyme that catalyzes the cleavage of angiotensinogen, synthesized by hepatocytes, into the decapeptide angiotensin I.[122,123] Angiotensin I possesses no intrinsic vasoreactive or mineralocorticoid secretagogue activity but is efficiently cleaved by angiotensin-converting enzyme in the lungs, as well as

other peripheral sites, to generate the octapeptide angiotensin II. Angiotensin II is further metabolized to the heptapeptide angiotensin III by removal of one amino-terminal amino acid. Angiotensin II possesses greater vasopressor activity and is present in approximately a fourfold greater amount than angiotensin III. Angiotensins II and III possess equivalent mineralocorticoid secretory activity on the adrenal glomerulosa cells.

Angiotensin II and III act through cell surface receptors (AT_1) on the adrenal glomerulosa cells to activate the phospholipase C/protein kinase C pathway.[124-128] This activation results in increased production of pregnenolone from cholesterol by side-chain cleavage enzyme (20, 22-desmolase) and of aldosterone from corticosterone by the glomerulosa-specific corticosterone methyloxidase I and II activities (18-hydroxylation and dehydrogenation, respectively).[129-132] A distinct receptor subtype for angiotensin II, the AT_2 receptor, is not G protein coupled and is of unclear physiologic significance in the periphery.[133-135]

Aldosterone, the primary and most potent endogenous mineralocorticoid released by the zona glomerulosa, acts on target tissues expressing the nuclear mineralocorticoid (or type I glucocorticoid) receptor to promote sodium absorption and potassium excretion. For control of intravascular volume, the primary target of action of aldosterone is the distal nephron. Here, aldosterone increases synthesis of apical membrane sodium channels, mitochondrial enzymes involved in adenosine triphosphate production, and components of Na^+,K^+ adenosine triphosphatase to cause increased sodium reabsorption and potassium excretion.[136]

Regulation of Secretion

Decreased intravascular volume as sensed by the renal juxtaglomerular apparatus results in release of renin.[122,137] Increased plasma renin activity then allows increased conversion of angiotensinogen to angiotensin I, which in turn is converted peripherally to angiotensins II and III. Increased angiotensin II activity causes vasoconstriction and blood pressure elevation, whereas both angiotensins II and III stimulate aldosterone release from the zona glomerulosa and subsequent salt and water retention and potassium excretion by the distal tubule of the kidney. Conversely, expanded intravascular volume causes decreased renin output and less sodium and water resorption in the kidney—serving to decrease intravascular volume and restore homeostasis.

Changes in vascular volume are not the only regulators of the renin-angiotensin-aldosterone system. Serum potassium concentration directly modulates aldosterone release by the adrenal glomerulosa by its effects on plasma membrane potential and activation of voltage-gated calcium channels.[123,138] Membrane depolarization, the result of increased serum potassium, leads to increased aldosterone synthesis—which promotes renal potassium excretion. Low serum potassium reduces aldosterone synthesis and decreases urinary potassium losses. Pituitary adrenocorticotropin hormone and vasopressin act through their respective receptors on the glomerulosa cells to increase acute aldosterone secretion. These effects are of short duration because long-term chronic infusions do not chronically elevate aldosterone concentrations. Direct inhibitors of aldosterone secretion (and thus promoters of natriuresis) include atrial natriuretic peptide (ANP),[139,140] somatostatin,[141-143] and dopamine.[144,145]

LOCAL RENIN-ANGIOTENSIN SYSTEMS

Anatomy and Biochemistry

In addition to the well-defined endocrine circuit, the components of the renin-angiotensin system have been found in a wide variety of tissues—including brain, pituitary, arterial wall, heart, ovary, kidney, and adrenal—where paracrine and autocrine regulatory functions[146-150] have been postulated, undergoing regulation independent of the systemic counterpart. From the standpoint of regulation of water and volume homeostasis, the brain renin-angiotensin system merits further description.[151] It has long been known that peripherally synthesized angiotensin II could increase blood pressure by effects on the brain outside the blood-brain barrier at sites such as the OVLT, SFO, area postrema, and median eminence as revealed by ligand-binding studies.[35,151-153] Over the past decade, it has become clear that the complete system for generation of angiotensin II is present within the brain.

Angiotensinogen has been localized to astrocytes by both immunohistochemical peptide localization and in situ hybridization analysis of messenger RNA.[154] In contrast, renin has been found in high concentration in nerve terminals—with enhanced release on nerve depolarization.[155] Angiotensin-converting enzyme has been found within vascular, choroid plexus, and neuronal components of the central nervous system[156-158]—most notably the SFO and many hypothalamic nuclei, sites of endogenous angiotensin II receptor expression (primarily of the AT_1 subtype), and sites not expressing the angiotensin II receptor such as the basal ganglia. The primary effector molecule, angiotensin II, has been localized specifically to neurons and subcellularly to synaptic vesicles.[159] Two of the most significant sites include the circumventricular organs and the paraventricular nucleus of the hypothalamus. Within the paraventricular nucleus, angiotensin II immunoreactivity colocalizes with magnocellular vasopressin—whereas its receptors are within the parvocellular region of the paraventricular nucleus.[160]

Regulation of Secretion

The forebrain angiotensin II pathway, of which the paraventricular nucleus is one component, and circumventricular organ angiotensin II pathway are important control centers for maintenance of osmotic and volume homeostasis.[161] Increased concentration of peripheral angiotensin II, as would be expected in intravascular volume depletion, stimulates drinking behavior.[35] This action of peripheral angiotensin II can be abolished by destruction of the OVLT or SFO, regions whose destruction has long been recognized as causing adipsia.[36]

Further effects of central angiotensin II action include augmentation of sodium appetite and stimulation of vasopressin release, all serving (as with peripheral angiotensin

II) to restore intravascular volume and maintain blood pressure.[35] The signal of hypovolemia is transduced through the vagal nerve from volume sensors to the brain stem and the region of the nucleus tractus solitarius. Efferents from these brain-stem centers project to the median preoptic nucleus and paraventricular nucleus—as does the forebrain angiotensin II pathway, where drinking and pressor effects as well as vasopressin release are elicited.[162-167]

Separate pathways for vasopressin release mediate the response to peripheral angiotensin II or to purely osmotic stimulation of the osmosensors.[168] The release of vasopressin in response to osmotic stimulation is not increased by peripheral angiotensin II, and pure osmotic stimulation does not increase salt appetite. Central angiotensin II, in contrast, may function as a transmitter in the osmosensing circuit—leading to vasopressin release.[169]

THE NATRIURETIC PEPTIDE SYSTEM

In addition to the classic vasopressin and renin-angiotensin-aldosterone systems, the natriuretic peptide families of ligands and their receptors add further potential for modulation of salt and water balance. The interaction of the natriuretic peptide system occurs in the central nervous system through effects on vasopressin secretion and peripherally through its ability to both directly promote natriuresis in the kidney and indirectly inhibit adrenal aldosterone production.

Anatomy and Biochemistry

Atrial natriuretic peptide was initially discovered as a component of cardiac atrial muscle that was able to induce natriuresis, a decrease in blood pressure, and an increase in hematocrit when injected into rats.[170,171] The biologically active form of ANP consists of a 28-amino-acid peptide that includes a 17-amino-acid ring structure[172] (Figure 9-11). The primary sequence of the peptide has been conserved among mammalian species, and in addition to synthesis in cardiac atrial tissue[173] has been detected in brain, spinal cord, pituitary, and adrenal gland.[174-177]

Within the brain, ANP synthesis occurs at several critical neuroendocrine regulatory sites—including the periventricular, arcuate, anteroventral preoptic, and lateral hypothalamic nuclei.[178,179] ANP is synthesized as a 151-amino-acid preprohormone and is stored as a 126-amino-acid prohormone after removal of the signal peptide sequence.[172,180] Coupled with secretion of pro-ANP is its cleavage between amino acids 98 and 99 to yield the mature 28-amino-acid 99-126 fragment.

Subsequent investigation defined a second peptide from porcine brain with structural homology to ANP.[181] This peptide, designated brain natriuretic peptide (BNP), was later found to be secreted by the heart as well—in this case from ventricular and atrial tissue.[182-184] Human BNP consists of a 32-amino-acid processed from a larger preprohormone[185] sharing a central ring structure with ANP (Figure 9-11), although it is less conserved between species than ANP.

A third member of this family, C-type natriuretic peptide (CNP), was also isolated from porcine brain.[186] In brain, CNP is the most abundant member of the natriuretic peptide family. Within the hypothalamus, specific sites of synthesis largely overlap sites of ANP expression.[179] Little CNP can be detected in plasma, and in marked contrast to ANP and BNP CNP does not increase in plasma in the setting of cardiac failure.[187,188] Outside the brain, CNP is synthesized in endothelial and vascular smooth muscle. In tissues capable of CNP gene expression, two forms of the

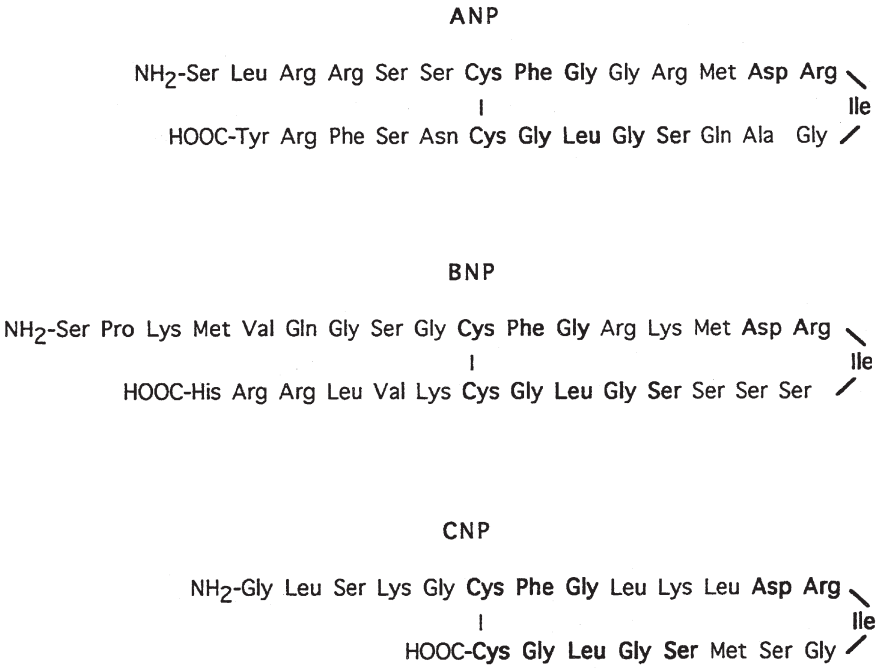

Figure 9-11 Amino acid composition of the human natriuretic peptides. Amino acids identical among the three peptides are indicated by bold letters, and the disulfide bond between Cys residues is shown.

peptide are produced: a 53-amino-acid peptide and a less abundant 22-amino-acid molecule[189] (Figure 9-11).

Three distinct endogenous receptors exist for the natriuretic peptides. The first of these receptors isolated (NPR-A or GC-A) was cloned by virtue of its homology to sea urchin sperm guanylyl cyclase and was later found to have ANP and BNP as its normal ligands.[190-192] A second guanylyl-cyclase-type receptor (NPR-B) has substantial homology to NPR-A. However, it binds CNP with substantially greater affinity than ANP or BNP.[193] A third receptor (NPR-C[194]) does not possess guanylyl cyclase activity and probably functions to clear all three natriuretic peptides from the circulation.[195] In situ hybridization studies using probes capable of distinguishing the different receptor types have revealed some interspecies discrepancy in distribution. The NPR-A receptor has been localized to kidney, adrenal, pituitary, brain, and heart in monkey—with NPR-B limited to adrenal, pituitary, and brain.[196] In rat, broad tissue distribution of both NPR-A and NPR-B has been described.[197] The NPR-C receptor has similarly been found in adrenal, heart, brain, and pituitary.[196]

Regulation of Secretion and Action

Secretion of ANP by cardiac tissue occurs in response to increasing atrial transmural pressure, from both left and right atria.[188,198] Studies employing intravascular volume expansion, exercise, and hypoxia demonstrate increased plasma concentration of ANP after these stimuli in animal and human paradigms.[187,198-200] In addition, increased heart rate (especially increased atrial contractile frequency) results in increased ANP secretion. In the setting of supraventricular tachycardia, high plasma concentration of ANP and suppressed concentration of vasopressin (both probably caused by an increase in atrial volume and pressure) contribute to the polyuria associated with this syndrome.[201-203] Ventricular production of ANP has also been demonstrated. It is increased in states of left-sided overload associated with ventricular hypertrophy.[183] ANP synthesized within the central nervous system varies in a volume-dependent fashion in a manner similar to peripheral ANP, suggesting similar function.[174]

The physiologic ramifications of increased ANP production are several. Infusion of ANP in the setting of normovolemia causes natriuresis, diuresis, and a small increase in divalent cation excretion.[187,188,204] ANP, through the NPR-A receptor, primarily inhibits sodium reabsorption within the renal inner medullary collecting duct but also opposes the salt-retaining effects of angiotensin II at the level of the proximal tubule.[204] ANP similarly inhibits the actions of vasopressin and aldosterone in the renal tubules.[205-207] Direct cardiovascular effects of ANP include arterial smooth-muscle relaxation, both acutely and with chronic administration. In part, this effect may be mediated through opposition of angiotensin II action.[208]

ANP modulates mineralocorticoid production in a manner that results in the reduction of intravascular volume or pressure. Although direct reduction in plasma renin activity has been described with ANP infusion,[209,210] the most dramatic response to ANP occurs at the level of the adrenal glomerulosa cell. ANP inhibits aldosterone production by inhibiting action of most aldosterone secretagogues, with the most pronounced reduction being angiotensin II activity.[98,187,204] The serum concentration of ANP at which the effects on PRA and aldosterone production occur is within the physiologic range, although the importance of this pathway in normal human physiology remains incompletely defined.

Direct injection of ANP into the central nervous system of animals has suggested an important role for ANP (or CNP) in cardiovascular and salt homeostasis. Vasodepression and bradycardia have both been observed,[211] as has inhibition of vasopressin, adrenocorticotropic hormone, and gonadotropin-releasing hormone secretion.[174,212] Thus, antagonistic action of ANP and angiotensin II on intravascular volume and blood pressure remain congruent between central and peripheral systems.

BNP synthesis and secretion from cardiac ventricular tissue are augmented in congestive heart failure, and as for ANP with hypertension, chronic renal, and chronic liver failure.[184,188] BNP binds the NPR-A receptor, where it is capable of stimulating cyclic guanosine monophosphate production.[190] Infusion of BNP inhibits aldosterone production and results in natriuresis similar to that reported for ANP. With infusion rates generating BNP concentrations tenfold greater than baseline, reduction in blood pressure has also been found.

In contrast to ANP and BNP, CNP expression primarily causes activation of the NPR-B receptor.[193] Plasma concentration of CNP does not change significantly with volume overload, and it is believed that the majority of CNP action occurs in a paracrine fashion within the brain and vasculature.[188] CNP synthesized within vascular endothelium acts on receptors in vascular smooth muscle to cause relaxation.[213] CNP infusions in dogs acutely reduce blood pressure and right atrial pressure but do not result in natriuresis, whereas in humans moderately supraphysiologic doses cause neither hypotension nor natriuresis.[214] In contrast to ANP, intracerebroventricular infusion of CNP leads to a reduction in blood pressure—suggesting a role for CNP in central control of arterial pressure.[215] CNP inhibits angiotensin-II-stimulated vasopressin secretion but stimulates thirst.[216] The overall importance of the CNP central pathways in modulation of water balance in humans remains to be defined.

Approach to the Patient: Differential Diagnosis of Disorders of Water Metabolism

HYPONATREMIA

Hyponatremia (serum sodium of 130 mEq/L or less) in children is usually associated with severe systemic disorders. It is most often caused by intravascular volume depletion or excessive salt loss, and is encountered with hypotonic fluid overload (especially in infants). Inappropriate vasopressin excess is one of the least common causes of hyponatremia in children, except for vasopressin administration for treatment of diabetes insipidus.

In evaluating the cause of hyponatremia, one should first determine whether the patient is dehydrated and hypovolemic. This is usually evident from the physical examination (decreased weight, skin turgor, central venous pressure) and laboratory data (high blood urea nitrogen, renin, aldosterone, uric acid). With a decrease in the glomerular filtration rate, proximal tubular reabsorption of sodium and water will be high—leading to a urinary sodium value less than 10 mEq/L.

Patients with decreased "effective" intravascular volume from congestive heart failure, cirrhosis, nephrotic syndrome, or lung disease will present with similar laboratory data but will also have obvious signs of their underlying disease—which often includes peripheral edema. Patients with primary salt loss will also appear volume depleted. If the salt loss is from the kidney (e.g., diuretic therapy or polycystic kidney disease), the urine sodium level will be elevated—as may urine volume. Salt loss from other regions (e.g., the gut in gastroenteritis or the skin in cystic fibrosis) will cause urine sodium to be low, as in other forms of systemic dehydration. Cerebral salt wasting is encountered with central nervous system insults and results in high serum ANP concentrations, leading to high urine sodium and urine excretion.

The syndrome of inappropriate antidiuresis (SIAD) exists when a primary elevation in vasopressin secretion or inappropriate activation of the vasopressin V2 receptor is the cause of hyponatremia. It is characterized by hyponatremia, an inappropriately concentrated urine (>100 mOsm/kg), normal or slightly elevated plasma volume, and a normal-to-high urine sodium (because of volume-induced suppression of aldosterone and elevation of ANP). Serum uric acid is low in patients with SIAD, whereas it is high in those with hyponatremia caused by systemic dehydration or other causes of decreased intravascular volume.[217]

Measurement of plasma vasopressin is often not very useful because it is elevated in nearly all causes of hyponatremia except for primary hypersecretion of ANP[218] or mutations in the vasopressin receptor that lead to inappropriate regulation of its activity. Because cortisol and thyroid deficiency cause hyponatremia by several mechanisms, discussed subsequently, they should be considered in all hyponatremic patients. Drug-induced hyponatremia should be considered in patients on potentially offending medications, as discussed later. In children with SIAD who do not have an obvious cause, a careful search for a tumor (thymoma, glioma, bronchial carcinoid) should be considered.

POLYURIA, POLYDYPSIA, AND HYPERNATREMIA

In children, it must first be determined whether pathologic polyuria or polydipsia (exceeding 2 L/m^2/day) is present. The following questions are asked. Is there a psychosocial reason for either polyuria or polydipsia? Can either be quantitated? Has either polyuria or polydipsia interfered with normal activities? Is nocturia or enuresis present? If so, does the patient also drink after nocturnal awakening? Does the history (including longitudinal growth data) or physical examination suggest other deficient or excessive endocrine secretion or an intracranial neoplasm?

If pathologic polyuria or polydipsia is present, the following should be obtained in the outpatient setting: serum osmolality; serum concentrations of sodium, potassium, glucose, calcium, and blood urea nitrogen; and urinalysis, including measurement of urine osmolality, specific gravity, and glucose concentration. A serum osmolality greater than 300 mOsm/kg, with urine osmolality less than 300 mOsm/kg, establishes the diagnosis of diabetes insipidus. If serum osmolality is less than 270 mOsm/kg, or urine osmolality is greater than 600 mOsm/kg, the diagnosis of diabetes insipidus is unlikely. If upon initial screening the patient has a serum osmolality less than 300 mOsm/kg but the intake/output record at home suggests significant polyuria and polydipsia that cannot be attributed to primary polydipsia (i.e., the serum osmolality is greater than 270 mOsm/kg), the patient should undergo a water deprivation test to establish a diagnosis of diabetes insipidus and to differentiate central from nephrogenic causes.

After a maximally tolerated overnight fast (based on the outpatient history), the child is admitted to the outpatient testing center in the early morning of a day when an 8- to 10-hour test can be carried out with the child deprived of water.[219,220] The physical signs and biochemical parameters shown in the accompanying protocol are measured (Figure 9-12). If at any time during the test the urine osmolality exceeds 1,000 mOsm/kg, or 600 mOsm/kg and is stable over 1 hour, the patient does not have diabetes insipidus. If at any time the serum osmolality exceeds 300 mOsm/kg and the urine osmolality is less than 600 mOsm/kg, the patient has diabetes insipidus. If the serum osmolality is less than 300 mOsm/kg and the urine osmolality is less than 600 mOsm/kg, the test should be continued unless vital signs disclose hypovolemia.

A common error is to stop a test too soon, based on the amount of body weight lost, before either urine osmolality has plateaued above 600 mOsm/kg or a serum osmolality above 300 mOsm/kg has been achieved. Unless the serum osmolality increases above the threshold for vasopressin release, a lack of vasopressin action (as inferred by a nonconcentrated urine) cannot be deemed pathologic. If the diagnosis of diabetes insipidus is made, aqueous vasopressin (Pitressin, 1 U/m^2) should be given subcutaneously. If the patient has central diabetes insipidus, urine volume should fall and osmolality should at least double during the next hour compared with the value before vasopressin therapy. If there is less than a twofold increase in urine osmolality after vasopressin administration, the patient probably has nephrogenic diabetes insipidus.

Desmopressin should not be used for this test because it has been associated with water intoxication in small children in this setting.[221] Patients with long-standing primary polydipsia may have mild nephrogenic diabetes insipidus because of dilution of their renal medullary interstitium. This should not be confused with primary nephrogenic diabetes insipidus because patients with primary polydipsia should have a tendency toward hyponatremia, rather than hypernatremia, in the basal state. Patients with a family history of X-linked nephrogenic diabetes insipidus can be evaluated for the disorder in the prenatal or perinatal period by DNA sequence analysis, thus allowing therapy to be initiated without delay.[222]

Water Deprivation Test

ENDOCRINE FUNCTION TEST | Patient Name

DIAGNOSIS: Suspected Diabetes Insipidus

TEST: Water Deprivation

Present Health _____ Good _____ Fair _____ Poor

COMMENTS: _____

Figure 9-12 Protocol for evaluation of diabetes insipidus using water deprivation. IV, intravenous; OSM, osmolality; S.G., urinary specific gravity; and SQ, subcutaneous.

The water deprivation test should be sufficient in most patients to establish the diagnosis of diabetes insipidus and to differentiate central from nephrogenic causes. Plasma vasopressin concentrations may be obtained during the procedure (Figure 9-12), although they are rarely needed for diagnostic purposes in children.[223] They are particularly helpful in differentiating between partial central diabetes insipidus and nephrogenic diabetes insipidus in that they are low in the former and high in the latter situation.[224] If urine osmolality concentrates normally but only after serum osmolality is well above 300 mOsm/kg, the patient may have an altered threshold for vasopressin release (also termed a *reset osmostat*). This may occur after head trauma, neurosurgery, or brain tumors.[225]

Magnetic resonance imaging (MRI) is not very helpful in distinguishing central diabetes insipidus from nephrogenic

diabetes insipidus.[226] Normally, the posterior pituitary is seen as an area of enhanced brightness in T1-weighted images after administration of gadolinium.[227] The posterior pituitary "bright spot" is diminished or absent in both forms of diabetes insipidus, presumably because of decreased vasopressin synthesis in central (and increased vasopressin release in nephrogenic) disease.[227-229] In primary polydipsia, the bright spot is normal—probably because vasopressin accumulates in the posterior pituitary during chronic water ingestion,[227] whereas it is decreased in SIADH (presumably because of increased vasopressin secretion).[226] Dynamic fast-frame MRI analysis has allowed estimation of blood flow to the posterior pituitary.[230] With this technique, both central and nephrogenic diabetes insipidus are associated with delayed enhancement in the area of the neurohypophysis.[231]

In the inpatient post-neurosurgical setting, central diabetes insipidus is likely if hyperosmolality (serum osmolality >300 mOsm/kg) is associated with urine osmolality less than serum osmolality. One must beware of intraoperative fluid expansion with subsequent hypo-osmolar polyuria masquerading as diabetes insipidus.

Specific Disorders of Water Metabolism

HYPONATREMIA WITH NORMAL REGULATION OF VASOPRESSIN

Hyponatremia with Appropriate Decreased Secretion of Vasopressin

Increased Water Ingestion (Primary Polydipsia). In a hypo-osmolar state with vasopressin secretion normally suppressed, the kidney can excrete urine with an osmolality as low as 50 mOsm/kg. Under these conditions, a daily solute load of 500 mOsm/m^2 could be excreted in 10 L/m^2 of urine per day. Neonates cannot dilute their urine to this degree and are prone to develop water intoxication at levels of water ingestion above 4 L/m^2/day (approximately 60 mL/hr in a newborn). This may happen when concentrated infant formula is diluted with excess water, either by accident or in a misguided attempt to make it last longer.[232]

A primary increase in thirst, without apparent cause, leading to hyponatremia has been reported in infants as young 5 weeks of age.[233] In older children, with a normal kidney and the ability to suppress vasopressin secretion, hyponatremia does not occur unless water intake exceeds 10 L/m^2/day—a feat almost impossible to accomplish. Long-standing ingestion of large volumes of water will decrease the hypertonicity within the renal medullary interstitium, which will impair water reabsorption and guard against water intoxication.[234] Hyponatremia will occur at lower rates of water ingestion when renal water clearance is impaired, because of inappropriately elevated vasopressin secretion or for other reasons.

The rare patient in whom the osmotic thresholds for thirst and vasopressin release are reversed illustrates the importance of the normal relationship between these two responses to osmotic stimulation.[235] If thirst is activated below the threshold for vasopressin release, water intake and hypo-osmolality will occur and suppress vasopressin secretion—leading to persistent polydipsia and polyuria. As long as daily fluid intake is less than 10 L/m^2, hyponatremia will not occur. Despite the presence of polyuria and polydipsia, this entity should not be confused with diabetes insipidus because of the absence of hypernatremia. Desmopressin treatment of such a patient may lower serum osmolality below the threshold for thirst, suppressing water ingestion and the consequent polyuria.

Decreased Renal Free Water Clearance. Adrenal insufficiency, primary or secondary, has long been known to result in compromised free water excretion.[40,70] The mechanisms by which glucocorticoids and mineralocorticoids modulate water diuresis have been the subject of substantial investigation. Some studies have demonstrated increased plasma vasopressin activity in the context of glucocorticoid insufficiency,[236,237] consistent with more recent molecular biologic evidence that glucocorticoids inhibit transcription of the vasopressin gene.[238]

Other investigators, however, have failed to detect vasopressin in plasma of patients with adrenal insufficiency and abnormal water clearance.[239] Consistent with vasopressin-independent actions of adrenal steroids on water metabolism, Brattleboro rats with hypothalamic diabetes insipidus manifest impaired excretion of a water load after adrenalectomy.[70] In adrenalectomized Brattleboro rats, glucocorticoid administration restored urine flow rate but did not restore maximal urinary diluting capacity. Conversely, mineralocorticoid administration restored maximal urinary diluting capacity but not flow rate. Thus, both mineralocorticoids and glucocorticoids are required for normal free water clearance. In part, these vasopressin-independent actions of mineralocorticoids and glucocorticoids have been attributed to the increased glomerular filtration rate arising from reexpansion of extracellular fluid volume (reduced owing to salt wasting) and improved cardiovascular tone, respectively.[41,240,241]

By restoring the glomerular filtration rate, more free water is delivered to the distal tubule for excretion. In addition, volume repletion reduces the nonosmotic stimuli for vasopressin release of volume depletion and hypotension. Recently, nitric oxide has been found to stimulate cyclic-guanosine-monophosphate-dependent membrane insertion of aquaporin-2 into renal epithelial cells.[242] Because glucocorticoid has been shown to inhibit endothelial nitric oxide synthase,[243] it is possible that under conditions of glucocorticoid deficiency high levels of nitric oxide synthase result in elevated levels of endothelial nitric oxide in the renal vasculature—which in the distal renal tubule stimulate increased vasopressin-independent aquaporin-2 activity and decreased free water clearance.

Direct effects of glucocorticoid or mineralocorticoid insufficiency on aquaporin expression and function have not been reported. In addition to impairing maximal renal diluting capacity, adrenal insufficiency compromises maximal urine-concentrating capacity.[244] This effect has been shown to result from reduced tubular response to vasopressin.

Thyroid hormone is also required for normal free water clearance, and its deficiency likewise results in decreased renal water clearance and hyponatremia. Although some studies suggest that vasopressin mediates the hyponatremia of hypothyroidism because ethanol increases free water excretion in hypothyroid patients, this effect has not been found in other reports.[245] In severe hypothyroidism, hypovolemia is not present and hyponatremia is accompanied by appropriate suppression of vasopressin.[246] Similar to the consequences of isolated glucocorticoid deficiency described previously, hypothyroidism impairs free water clearance more than maximal urine diluting capacity.[247] This decrease in free water clearance may result from diminished glomerular filtration rate and delivery of free water to the diluting segment of distal nephron, as suggested by animal[248] and human studies.[249]

Given the often subtle clinical findings associated with adrenal and thyroid deficiency, all patients with hyponatremia should be suspected of having these disease states and have appropriate diagnostic tests performed if indicated. Moreover, patients with coexisting adrenal failure and diabetes insipidus may have no symptoms of the latter until glucocorticoid therapy unmasks the need for vasopressin replacement.[250,251] Similarly, resolution of diabetes insipidus in chronically polyuric and polydipsic patients may suggest inadequate glucocorticoid supplementation or noncompliance with glucocorticoid replacement.

Some drugs may cause hyponatremia by inhibiting renal water excretion without stimulating secretion of vasopressin (Table 9-1), an action that could be called nephrogenic SIAD. In addition to augmenting vasopressin release, carbamazepine[252,253] and chlorpropamide[254,255] increase the cellular response to vasopressin. Acetaminophen also increases the response of the kidney to vasopressin.[254] However, this has not been found to cause hyponatremia. High-dose cyclophosphamide treatment (15 to 20 mg/kg intravenous bolus) is often associated with hyponatremia, particularly when it is followed by a forced water diuresis to prevent hemorrhagic cystitis.[256-258] Plasma vasopressin concentrations are normal, suggesting a direct effect of the drug to increase water resorption.[259] Similarly, vinblastine (independent of augmentation of plasma vasopressin concentration or vasopressin action[260]) and cisplatin[261,262] cause hyponatremia. These drugs may damage the collecting duct tubular cells, which are normally highly impermeable to water, or may enhance aquaporin-2 water channel activity and thereby increase water reabsorption down its osmotic gradient into the hypertonic renal interstitium.

Treatment

Hyponatremia due to cortisol or thyroid hormone deficiency reverses promptly after institution of hormone replacement. Because the hyponatremia is often chronic, too rapid an increase in the serum sodium concentration should be avoided if possible (as will be discussed). When drugs that impair free water excretion must be used, water intake should be limited (as if the patient has SIAD) to 1 L/m^2/24 hr using the regimen recommended later in the chapter.

HYPONATREMIA WITH APPROPRIATE INCREASED SECRETION OF VASOPRESSIN

Increased vasopressin secretion causing hyponatremia may be an appropriate response or an inappropriate response to a pathologic state. Inappropriate secretion of vasopressin or V2 receptor activity (SIAD) is the much less common of the two entities.[263,264] Whatever the cause, hyponatremia is a worrisome sign often associated with increased morbidity and mortality.[265]

Causes

Systemic Dehydration. Systemic dehydration (water in excess of salt depletion) initially results in hypernatremia, hyperosmolality, and activation of vasopressin secretion (as previously discussed). In addition, the associated fall in the renal glomerular filtration rate results in an increase in proximal tubular sodium and water reabsorption—with a concomitant decrease in distal tubular water excretion. This limits the ability to form a dilute urine, and along with the associated stimulation of the renin-angiotensin-aldosterone system and suppression of ANP secretion results in the excretion of urine very low in sodium.

As dehydration progresses, hypovolemia and/or hypotension become major stimuli for vasopressin release—much more potent than hyperosmolality. This effect, by attempting to preserve volume, decreases free water clearance further and may lead to water retention and hyponatremia—especially if water replacement in excess of salt is given. In many cases, hyponatremia caused by intravascular volume depletion is evident from physical and laboratory signs such as decreased skin turgor, low central venous pressure, hemoconcentration, and elevated blood urea nitrogen levels. The diagnosis may be subtle, however. For example, patients with meningitis may present with hyponatremia for which water restriction has been advocated in the belief that it is due to central SIAD.

Several studies have found that volume depletion, rather than SIAD, is often the cause of the hyponatremia[266,267] and that it resolves more readily when supplemental (rather than restricted) fluid and solute are administered.[268] In patients with hyponatremia after head trauma, volume depletion rather than central SIAD is the cause in approximately one half of cases.[269] Similarly, many patients with gastroenteritis who present with mild hyponatremia and elevated plasma vasopressin levels[270] have these on the basis of systemic dehydration rather than SIAD and benefit from volume expansion rather than fluid restriction.[271] More generally, most hospitalized pediatric patients with hyponatremia benefit from isotonic rather than hypotonic fluid replacement, suggesting that the underlying cause of the electrolyte disturbance is dehydration.[272]

Primary Loss of Sodium Chloride. Salt can be lost from the kidney, such as in patients with congenital polycystic kidney disease, acute interstitial nephritis, and chronic renal failure. Mineralocorticoid deficiency, pseudohypoaldosteronism (sometimes seen in children with

urinary tract obstruction or infection), diuretic use, and gastrointestinal disease (usually gastroenteritis with diarrhea and/or vomiting) can also result in excess loss of sodium chloride. Hyponatremia can also result from salt loss in sweat in cystic fibrosis, although obstructive lung disease with elevation of plasma vasopressin probably plays a more prominent role (as has been discussed). With the onset of salt loss, any tendency toward hyponatremia will initially be countered by suppression of vasopressin and increased water excretion.

With continuing salt loss, hypovolemia and/or hypotension ensues—causing nonosmotic stimulation of vasopressin. This plus increased thirst, which leads to ingestion of hypotonic fluids with low solute content, results in hyponatremia. Weight loss is usually evident, as is the source of sodium wasting. If it is the kidney, it is accompanied by a rate of urine output and a urine sodium content greater than those associated with most other causes of hyponatremia except a primary increase in ANP secretion.

Decreased Effective Plasma Volume. Congestive heart failure, cirrhosis, nephrotic syndrome, positive pressure mechanical ventilation,[273] severe burns,[274] lung disease (bronchopulmonary dysplasia[275-277] in neonates), cystic fibrosis with obstruction,[278,279] and severe asthma[280,281] are all characterized by a decrease in effective intravascular volume.[245,282] This occurs because of impaired cardiac output, an inability to keep fluid within the vascular space, or impaired blood flow into the heart, respectively.

As with systemic dehydration, in an attempt to preserve intravascular volume water and salt excretion by the kidney are reduced—and decreased barosensor

stimulation results in an appropriate compensatory increase in vasopressin secretion, leading to an antidiuretic state and hyponatremia.[283] Because of the associated stimulation of the renin-angiotensin-aldosterone system, these patients also have an increase in total body content of sodium chloride and may have peripheral edema—which distinguishes them from those with systemic dehydration. In patients with impaired cardiac output and elevated atrial volume (e.g., congestive heart failure or lung disease), ANP concentrations are elevated—which contributes to hyponatremia by promoting natriuresis.

Treatment

Patients with systemic dehydration and hypovolemia should be rehydrated with salt-containing fluids such as normal saline or lactated Ringer's solution. Because of activation of the renin-angiotensin-aldosterone system, the administered sodium will be avidly conserved and a water diuresis will quickly ensue as volume is restored and vasopressin concentrations fall.[284] Under these conditions, caution must be taken to prevent too rapid a correction of hyponatremia—which may itself result in brain damage.

Hyponatremia caused by a decrease in effective plasma volume from cardiac, hepatic, renal, or pulmonary dysfunction is more difficult to reverse. The most effective therapy is the least easily achieved: treatment of the underlying systemic disorder. Patients weaned from positive-pressure ventilation undergo a prompt water diuresis and resolution of hyponatremia as cardiac output is restored and vasopressin concentrations fall. The only other effective route is to limit water intake to that required for the renal excretion of the obligate daily solute load of approximately 500 mOsm/m^2 and to replenish insensible losses. In a partial antidiuretic state with a urine osmolality of 750 mOsm/kg and insensible losses of 500 mL/m^2, oral intake would have to be limited to approximately 1,200 mL/m^2/day.

Because of concomitant hyperaldosteronism, the dietary restriction of sodium chloride needed to control peripheral edema in patients with heart failure may reduce the daily solute load and further limit the amount of water that can be ingested without exacerbating hyponatremia. Hyponatremia in these settings is often slow to develop, rarely causes symptoms, and usually does not need treatment. If the serum sodium falls below 125 mEq/L, water restriction to 1 L/m^2/day is usually effective in preventing a further decline. Because water retention in these disorders is a compensatory response to decreased intravascular volume, an attempt to reverse it with drugs such as demeclocycline or specific V2 receptor antagonists (which induce nephrogenic diabetes insipidus, as discussed earlier) could result in worsening hypovolemia—with potentially dire consequences.[285]

In general, patients with hyponatremia caused by salt loss require ongoing supplementation with sodium chloride and fluids. Initially, intravenous replacement of urine volume with fluid containing sodium chloride (150 to 450 mEq/L, depending on the degree of salt loss) may be necessary. Oral salt supplementation may be required subsequently.[218] This treatment contrasts with that of SIAD, in which water restriction without sodium supplementation is the mainstay.

Precautions in the Emergency Treatment of Hyponatremia

Most children with hyponatremia develop the disorder gradually and are asymptomatic, and thus should be treated with water restriction alone. The development of acute hyponatremia or a serum sodium concentration below 120 mEq/L may be associated with lethargy, psychosis, coma, or generalized seizures—especially in younger children. Acute hyponatremia causes cell swelling owing to the entry of water into cells (Figure 9-13), which can lead to neuronal dysfunction from alterations in the ionic environment or to cerebral herniation because of the encasement of the brain in the cranium. If present for more than 24 hours, cell swelling triggers a compensatory decrease in intracellular organic osmolytes—resulting in the partial restoration of normal cell volume in chronic hyponatremia.[286]

The proper emergency treatment of cerebral dysfunction depends on whether the hyponatremia is acute or chronic.[1,287] In all cases, water restriction should be instituted. If hyponatremia is acute, and therefore probably not associated with a decrease in intracellular organic osmolyte concentration, rapid correction with hypertonic 3% sodium chloride administered intravenously may be indicated. As a general guide, this solution (given in the amount of 12 mL/kg) will result in an increase in serum sodium concentration of approximately 10 mEq/L. If hyponatremia is chronic, hypertonic saline treatment must be undertaken with caution because it may result in cell shrinkage (Figure 9-13) and the associated syndrome of central pontine myelinolysis.[288]

This syndrome, affecting the central portion of the basal pons as well as other brain regions, is characterized by axonal demyelination—with sparing of neurons. It becomes evident within 24 to 48 hours after too rapid correction of hyponatremia, has a characteristic appearance by computed tomography and MRI, and often causes irreversible brain damage.[288-290] If hypertonic saline treatment is undertaken, the serum sodium concentration should be raised only high enough to cause an improvement in mental status—and in no case faster than 0.5 mEq/L/hr or 12 mEq/L/day.[287-290] In the case of systemic dehydration, the increase in serum sodium level may occur very rapidly using this regimen. The associated hyperaldosteronism will cause avid retention of the administered sodium, leading to rapid restoration of volume and suppression of vasopressin secretion and resulting in a brisk water diuresis and an increase in the serum sodium concentration.[284]

Acute treatment of hyponatremia is more difficult in patients with decreased effective plasma volume. This is because the underlying disorder makes it difficult to maintain the administered fluid within the intravascular space and because an associated increase in ANP promotes natriuresis and loss of the administered salt. Furthermore, patients with cardiac disease who are administered hypertonic saline may require concomitant treatment with a diuretic such as furosemide to prevent worsening of heart failure—which will also increase natriuresis.

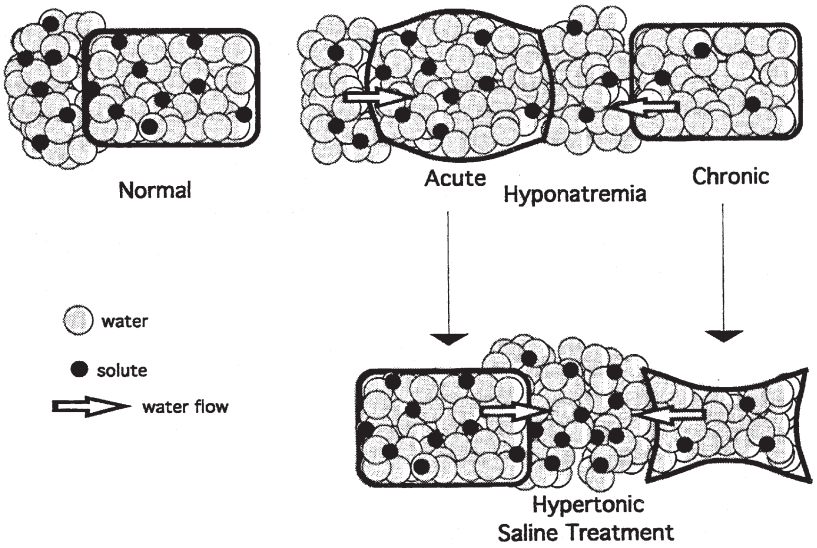

Figure 9-13 Changes in organic osmolytes with hyponatremia and after its correction. Under normal conditions, osmotic balance exists between extracellular and intracellular compartments. With acute hyponatremia, water enters cells—causing cell swelling. After approximately 24 hours of continued hyponatremia, intracellular organic osmolytes decrease—restoring cell volume toward normal. Hypertonic saline treatment of acute hyponatremia results in restoration of normal cell volume, whereas the same treatment of chronic hyponatremia results in cell shrinkage. Large circle, water; closed smaller circle, solute; and arrow, direction of water flow.

Hyponatremia with Abnormal Regulation of Vasopressin

HYPONATREMIA WITH INAPPROPRIATE INCREASED SECRETION OF VASOPRESSIN OR INCREASED VASOPRESSIN V2 RECEPTOR ACTIVITY (SYNDROME OF INAPPROPRIATE ANTIDIURESIS)

Causes of SIAD

SIAD is uncommon in children.[263,264,291] It can occur with encephalitis, brain tumor,[292] head trauma,[269,293] or psychiatric disease[294]; in the postictal period after generalized seizures[295]; and after prolonged nausea,[296,297] pneumonia,[298,299] or AIDS.[300] Many drugs have been associated with impaired free water clearance, as indicated in Table 9-1. Impaired free water clearance can result from alteration in vasopressin release, increased vasopressin effect at the same plasma vasopressin concentration, or vasopressin-independent changes in distal collecting tubule water permeability. Common drugs that have been shown to increase vasopressin secretion and result in hyponatremia include carbamazepine,[253] chlorpropamide,[301] vinblastine,[260] vincristine,[302] and tricyclic antidepressants.[303,304]

Newer sulfonylurea agents, including glyburide, are not associated with SIAD.[305] Other rarer causes of SIAD in children are listed in Table 9-2. Although SIAD has been believed to be the cause of hyponatremia associated with viral meningitis, volume depletion is more commonly the etiology.[266,268] In contrast, the majority of children with tuberculous meningitis have hyponatremia and SIAD—which predict more severe disease and poor outcome.[306-308] SIAD is the cause of the hyponatremic second phase of triple-phase response seen after hypothalamic-pituitary surgery.

Hyponatremia with elevated vasopressin secretion is found in up to 35% of patients 1 week after transsphenoidal pituitary surgery.[309,310] The mechanism is most likely retrograde neuronal degeneration with cell death and vasopressin release. Secondary adrenal insufficiency causing stimulation of vasopressin release[69] may also play a role because hyponatremia most commonly follows the removal of adrenocorticotropin hormone-secreting corticotroph adenomas.[310] In the vast majority of children with SIAD, the cause is the excessive administration of vasopressin—whether to treat central diabetes insipidus,[221,311] or less commonly bleeding disorders[312] (as has been discussed previously), or most uncommonly following dDAVP therapy for enuresis.

Recently, two unrelated infants (with mutations in the vasopressin V2 receptor) who presented with severe hyponatremia in the first months of life have been described.[313] These two infants had missense mutations at codon 137 that converted arginine to cysteine or leucine and led to constitutive activation of the V2 receptor with appropriately suppressed arginine vasopressin plasma concentration. This genetic disorder has been termed *nephrogenic syndrome of antidiuresis*. It remains unclear what portion of isolated early-onset chronic SIAD results from activating mutations of the V2 receptor, although the incidence is likely to be very low. Interestingly, this same codon is also the site of a loss-of-function mutation (R137H) that leads to X-linked nephrogenic diabetes insipidus.[314]

Treatment of SIAD

Chronic SIAD is best treated by chronic oral fluid restriction. Under full vasopressin antidiuretic effect (urine osmolality of 1,000 mOsm/L), a normal daily obligate renal solute load of 500 mOsm/m^2 would be excreted in 500 mL/m^2 of water. This plus a daily nonrenal water

TABLE 9-2

loss of 500 mL/m^2 would require that oral fluid intake be limited to 1,000 mL/m^2/day to avoid hyponatremia, as has been discussed more fully. In young children, this degree of fluid restriction may not provide adequate calories for growth. In this situation, the creation of nephrogenic diabetes insipidus using demeclocycline therapy may be indicated to allow sufficient fluid intake for normal growth.[315]

Demeclocycline is superior to lithium for this purpose.[316] Lithium and demeclocycline, however, are associated with significant toxicities—which may limit their use in pediatric patients. Oral urea has been effectively used to treat adult patients with chronic SIAD by virtue of its ability to induce an effective osmotic diuresis. This therapy was also demonstrated to be safe and effective in four children with chronic SIAD, including two with mutations in the vasopressin V2 receptor.[317] Specific V2 receptor antagonists are also being developed for use in chronic SIAD.[318-320] In a large series of adult patients with euvolemic or hypervolemic hyponatremia, the vasopressin receptor antagonists were effective in sustained elevation of serum sodium concentration.[320] These agents would not be expected to be effective in activating mutations of the V2 receptor unless they interfered with the normal trafficking of the receptor to the cell surface. On that note, some of these V2 receptor antagonists facilitate the proper transport of loss-of-function V2 receptor mutants to the cell surface.[321]

Acute treatment of hyponatremia due to SIAD is only indicated if cerebral dysfunction is present. In that case, treatment is dictated by the duration of hyponatremia and the extent of cerebral dysfunction. Because patients with SIAD have volume expansion, salt administration is not very effective in raising the serum sodium because it is rapidly excreted in the urine due to suppressed aldosterone and elevated atrial natriuretic peptide concentrations.

HYPONATREMIA WITH INAPPROPRIATE DECREASED SECRETION OF VASOPRESSIN DUE TO INCREASED SECRETION OF ATRIAL NATRIURETIC PEPTIDE

Although atrial natriuretic peptide does not usually play a primary role in the pathogenesis of disorders of water metabolism, it may have an important secondary role.[275,322-324] Patients with SIAD have elevated atrial natriuretic peptide concentrations, probably due to hypervolemia, which may contribute to the elevated natriuresis of SIAD and which decrease as water intake is restricted.[322] Likewise, the suppressed atrial natriuretic peptide concentrations found in central diabetes insipidus, probably due to the associated hypovolemia, rise after dDAVP therapy.[322] However, hyponatremia in some patients (primarily those with central nervous system disorders, including brain tumor, head trauma, hydrocephalus, neurosurgery, cerebral vascular accidents, and brain death) may be due to the primary hypersecretion of atrial natriuretic peptide.[218,325-327]

This syndrome, called cerebral salt wasting, is defined by hyponatremia accompanied by elevated urinary sodium excretion (often more than 150 mEq/L), excessive urine output, hypovolemia, suppressed vasopressin, and elevated atrial natriuretic peptide concentrations (>20 pmol/L). Thus, it is distinguished from SIAD—in which normal or decreased urine output, euvolemia, only modestly elevated urine sodium concentration, and elevated vasopressin concentration occur. Direct measurement of intravascular volume status with a central venous line is often helpful. The distinction is important because the therapies of the two disorders are markedly different.

Treatment of Cerebral Salt Wasting

Treatment of patients with cerebral salt wasting consists of restoring intravascular volume with sodium chloride and water, as with the treatment of other causes of systemic dehydration. The underlying cause of the disorder, which is usually due to acute brain injury, should also be treated if possible.

OTHER CAUSES OF TRUE AND FACTITIOUS HYPONATREMIA

True hyponatremia is associated with hyperglycemia, which causes the influx of water into the intravascular space. Serum sodium will decrease by 1.6 mEq/L for every 100 mg/dL increment in blood glucose above 100 mg/dL. Glucose is not ordinarily an osmotically active agent, and does not stimulate vasopressin release—probably because it is able to equilibrate freely across plasma membranes. However, in the presence of insulin deficiency and hyperglycemia glucose acts as an osmotic

agent—presumably because its normal intracellular access to osmosensor sites is prevented.[328]

Under these circumstances, an osmotic gradient exists—and this stimulates vasopressin release. In diabetic ketoacidosis, this (together with the hypovolemia caused by the osmotic diuresis secondary to glycosuria) results in marked stimulation of vasopressin secretion.[329-332] Rapid correction of hyponatremia may follow soon after the institution of fluid and insulin therapy. Whether this contributes to the pathogenesis of cerebral edema occasionally seen following treatment of diabetic ketoacidosis is not known. Elevated concentrations of triglycerides may cause factitious hyponatremia, as can obtaining a blood sample downstream from an intravenous infusion of hypotonic fluid.

Hypernatremia with Inappropriate Decreased Vasopressin Secretion or Action

CENTRAL DIABETES INSIPIDUS

Causes of Central Diabetes Insipidus

Central (hypothalamic, neurogenic, or vasopressin-sensitive) diabetes insipidus can be caused by disorders of vasopressin gene structure; accidental or surgical trauma to vasopressin neurons; congenital anatomical hypothalamic or pituitary defects; neoplasms; infiltrative, autoimmune, and infectious diseases affecting vasopressin neurons or fiber tracts; and increased metabolism of vasopressin. In approximately 10% of children with central diabetes insipidus, the etiology is not apparent.[333,334]

Genetic Causes. Familial autosomal-dominant central diabetes insipidus is manifest within the first half of the first decade of life.[335] Vasopressin secretion, initially normal, gradually declines until diabetes insipidus of variable severity ensues. Patients respond well to vasopressin replacement therapy. The disease has a high degree of penetrance, but may be of variable severity within a family[336] and may spontaneously improve in middle age.[336,337] Vasopressin-containing neurons are absent from the magnocellular paraventricular neurons[338] but present in parvocellular regions.[339] Several different oligonucleotide mutations in the vasopressin structural gene have been found to cause the disease *(www.medcon.mcgill.ca/nephros/avp_npii.html)*.

To date, there have been more than 25 mutations detected in the coding region of the vasopressin gene (Figure 9-3). Most mutations are in the neurophysin portion of the vasopressin precursor, except for five in either the signal peptide or vasopressin peptide regions of the gene. This suggests that neurophysin has a valuable function, possibly in the proper intracellular sorting or packaging of vasopressin into secretory granules. There are no disease-causing mutations in the copeptin region of the vasopressin precursor. This suggests either that this region has a low mutation rate or more likely that it does not serve a critical function in vasopressin biology.

A family with a missense mutation within the vasopressin peptide region (Proline→Leucine at amino acid 7) of the gene, causing markedly reduced biological activity, was reported.[340] The disease in this family is transmitted with an autosomal-recessive pattern. This indicates that haplo-insufficiency is not the basis for the autosomal-dominant nature of the disease in families with the more common mutations in the neurophysin region of the gene. Rather, the abnormal gene product may interfere with the processing and secretion of the product of the normal allele[341] or may cause neuronal degeneration and cell death.[342] In support of this, mutant vasopressin precursors impair the secretion of the normal protein in cell models.[341] In a transgenic mouse model of the disease, a progressive loss of hypothalamic vasopressin-containing neurons occurs as the mice develop diabetes insipidus.[343]

Vasopressin deficiency is also found in the DIDMOAD syndrome, consisting of diabetes insipidus, diabetes mellitus, optic atrophy, and deafness.[344,345] One[346] (but not another[347]) study has suggested that a mitochondrial defect is responsible for the disease. The gene for this syndrome complex, also known as Wolfram syndrome, was localized to human chromosome 4p16 by polymorphic linkage analysis[348] and has recently been isolated.[349] The Wolfram syndrome gene, WFS1, encodes an 890-amino-acid putative transmembrane protein of unknown function.[349] More recent analysis of multiple kindreds with Wolfram syndrome has disclosed a variety of different single-nucleotide mutations in the WFS1 gene, and no mutations in mitochondrial DNA.[350]

Trauma. The axons of vasopressin-containing magnocellular neurons extend uninterrupted to the posterior pituitary over a distance of approximately 10 mm. Trauma to the base of the brain can cause swelling around or severance of these axons, resulting in transient or permanent diabetes insipidus.[351] Permanent diabetes insipidus can occur after seemingly minor trauma. Approximately half of patients with fractures of the sella turcica will develop permanent diabetes insipidus,[352] which may be delayed as long as 1 month following the trauma—during which neurons of severed axons may undergo retrograde degeneration.[353]

Septic shock[354] and postpartum hemorrhage associated with pituitary infarction (Sheehan syndrome)[355,356] may involve the posterior pituitary with varying degrees of diabetes insipidus. Diabetes insipidus is never associated with cranial irradiation of the hypothalamic-pituitary region, although this treatment can cause deficits in all of the hypothalamic-releasing hormones carried by the portal-hypophyseal system to the anterior pituitary (see Chapter 8). Because vasopressin is carried directly to the posterior pituitary via magnocellular axonal transport, radiation may affect hypothalamic-releasing hormone function by interruption of the portal-hypophyseal circulation.

Neurosurgical Intervention. One of the most common causes of central diabetes insipidus is the neurosurgical destruction of vasopressin neurons following pituitary-hypothalamic surgery. It is important to distinguish polyuria associated with the onset of acute postsurgical central diabetes insipidus from polyuria due to the normal diuresis of fluids given during surgery. In both cases, the urine may be very dilute and of high volume, exceeding 200 mL/m^2/h. However, in the former case serum osmolality will

be high—whereas in the latter case it will be normal. A careful examination of the intraoperative record should also help distinguish between these two possibilities.

Vasopressin axons traveling from the hypothalamus to the posterior pituitary terminate at various levels within the stalk and gland (Figure 9-4). Because surgical interruption of these axons can result in retrograde degeneration of hypothalamic neurons, lesions closer to the hypothalamus will affect more neurons and cause greater permanent loss of hormone secretion. Not infrequently, a "triple-phase" response is seen.[357]

Following surgery, an initial phase of transient diabetes insipidus is observed—lasting 0.5 to 2 days and possibly due to edema in the area interfering with normal vasopressin secretion. If significant vasopressin cell destruction has occurred, this is often followed by a second phase of SIAD—which may last up to 10 days and is due to the unregulated release of vasopressin by dying neurons. A third phase of permanent diabetes insipidus may follow if more than 90% of vasopressin cells are destroyed. Usually, a marked degree of SIAD in the second phase portends significant permanent diabetes insipidus in the final phase of this response.

In patients with coexisting vasopressin and cortisol deficits (e.g., in combined anterior and posterior hypopituitarism following neurosurgical treatment of craniopharyngioma), symptoms of diabetes insipidus may be masked because cortisol deficiency impairs renal free water clearance. In such cases, institution of glucocorticoid therapy alone may precipitate polyuria, leading to the diagnosis of diabetes insipidus.

Congenital Anatomic Defects. Midline brain anatomic abnormalities such as septo-optic dysplasia with agenesis of the corpus callosum,[358] the Kabuki syndrome,[359] holoprosencephaly,[360] and familial pituitary hypoplasia with absent stalk[361] may be associated with central diabetes insipidus. These patients need not have external evidence of craniofacial abnormalities.[360] Central diabetes insipidus due to midline brain abnormalities is often accompanied by defects in thirst perception,[358] suggesting that a common osmosensor may control vasopressin release and thirst perception. Some patients with suspected defects in osmosensor function but with intact vasopressin neurons may have recumbent diabetes insipidus, with baroreceptor-mediated release of vasopressin while upright and vasopressin-deficient polyuria while supine.[362]

Neoplasms. Several important clinical implications follow from knowledge of the anatomy of the vasopressin system. Because hypothalamic vasopressin neurons are distributed over a large area within the hypothalamus, tumors that cause diabetes insipidus must either be very large or infiltrative or be strategically located at the point of convergence of the hypothalamo-neurohypophyseal axonal tract in the infundibulum. Germinomas and pinealomas typically arise near the base of the hypothalamus, where vasopressin axons converge before their entry into the posterior pituitary. For this reason, they are among the most common primary brain tumors associated with diabetes insipidus.

Germinomas causing the disease can be very small,[363,364] and can be undetectable by MRI for several years following the onset of polyuria.[365] For this reason, quantitative measurement of the β subunit of human chorionic gonadotropin (often secreted by germinomas and pinealomas) and regularly repeated MRI scans should be performed in children with idiopathic or unexplained diabetes insipidus. Empty sella syndrome, possibly due to unrecognized pituitary infarction, can be associated with diabetes insipidus in children.[366]

Craniopharyngiomas and optic gliomas can also cause central diabetes insipidus when very large, although this is more often a postoperative complication of the treatment for these tumors. Hematologic malignancies can cause diabetes insipidus. In some cases, such as with acute myelocytic leukemia, the cause is infiltration of the pituitary stalk and sella.[367-369] However, more than 30 patients with monosomy or deletion of chromosome 7 associated with acute blast transformation of myelodysplastic syndrome presented with central diabetes insipidus[370-373] without evidence of infiltration of the posterior pituitary by neoplastic cells—leaving the cause of the diabetes insipidus unresolved.

Infiltrative, Autoimmune, and Infectious Diseases. Langerhans cell histiocytosis and lymphocytic hypophysitis are the most common types of infiltrative disorders causing central diabetes insipidus. Approximately 10% of patients with histiocytosis will have diabetes insipidus. These patients tend to have more serious multisystem disease for longer periods of time than those without diabetes insipidus,[374,375] and anterior pituitary deficits often accompany posterior pituitary deficiency.[376] MRI characteristically shows thickening of the pituitary stalk.[377] One report suggests that in patients with Langerhans cell histiocytosis radiation treatment to the pituitary region within 14 days of onset of symptoms of diabetes insipidus may result in return of vasopressin function in more than a third of affected patients.[378]

Lymphocytic infundibuloneurohypophysitis may account for more than half of patients with "idiopathic" central diabetes insipidus.[379] This entity may be associated with other autoimmune diseases.[380] Image analysis discloses an enlarged pituitary and thickened stalk,[379,381] and biopsy of the posterior pituitary reveals lymphocytic infiltration of the gland, stalk, and magnocellular hypothalamic nuclei.[382] A necrotizing form of this entity has been described that also causes anterior pituitary failure and responds to steroid treatment.[383] Diabetes insipidus can also be associated with pulmonary granulomatous diseases,[384] including sarcoidosis.[385]

Whether antibody-mediated destruction of vasopressin cells occurs is controversial. More than half of patients with central diabetes insipidus of a nontraumatic cause have antibodies directed against vasopressin-containing cells,[386] and patients with other autoimmune diseases have such antibodies without evidence of diabetes insipidus.[387] Many patients with central diabetes insipidus also have anti-vasopressin peptide antibodies, although their appearance usually follows institution of vasopressin treatment.[388] It is very possible that antibodies directed against vasopressin-containing cells or vasopressin are not pathogenetic, but are instead markers of prior neuronal cell destruction.

Infections involving the base of the brain (such as meningococcal,[389] cryptococcal, listeria,[390] and toxoplasmosis[391] meningitis; congenital cytomegalovirus infection[392];

and nonspecific inflammatory disease of the brain[393]) can cause central diabetes insipidus. The disease is often transient, suggesting that it is due to inflammation rather than destruction of vasopressin-containing neurons.

Brain Death. Central diabetes insipidus can appear in the setting of hypoxic brain death.[394] Although its presence has been suggested as a marker for brain death in children,[395] in some studies only a minority of patients with brain death manifest the disorder[396] and up to 15% of patients with cerebral insults and diabetes insipidus ultimately recover brain function.[397] Polyuria in the setting of brain death can be accompanied by high concentrations of plasma vasopressin,[398] suggesting that some cases mistaken for diabetes insipidus are actually due to other causes—such as cerebral salt wasting with polyuria.

Increased Metabolism of Vasopressin. The metabolic clearance rate of vasopressin increases fourfold during pregnancy due to the elaboration of a vasopressinase by the placenta.[72] If the mother cannot respond with a concomitant increase in vasopressin action because of preexisting subclinical central or nephrogenic diabetes insipidus,[73] overt transient disease will appear—usually early in the third trimester. This will resolve within 1 week of delivery.[76,399] Even without prior defects in vasopressin function, an extreme elevation in vasopressinase concentrations in primigravidas (with preeclampsia, liver dysfunction, or multiple gestation[74,75,78,400-402]) may result in development of the syndrome.

Drugs. The most common agent associated with inhibition of vasopressin release and impaired urine concentrating ability is ethanol.[403] Because inhibition of vasopressin release by ethanol can be overcome in the setting of concurrent hypovolemia, clinically important diabetes insipidus due to ethanol ingestion is uncommon.[404] Phenytoin, opiate antagonists, halothane, and α-adrenergic agents have also been associated with impaired vasopressin release.[405,406]

Children with Primary Enuresis. Although normal children have a nocturnal rise in plasma vasopressin associated with an increase in urine osmolality and a decrease in urine volume, those with primary enuresis have a blunted or absent rise in vasopressin and excrete a higher urine volume of lower tonicity.[407,408] This has suggested that enuretic children have a primary deficiency in vasopressin secretion, although the same outcome could be caused solely by excessive water intake in these children. The use of the V2 agonist dDAVP is highly effective in abolishing bed wetting episodes, although relapse is high once therapy is stopped.[409-411] Fluid intake must be limited while a child is exposed to the antidiuretic action of dDAVP to guard against water intoxication. Recently, the FDA has issued an alert stating that intranasal forms of dDAVP are no longer indicated for treatment of primary enuresis and all forms should be used with caution.

Treatment of Central Diabetes Insipidus

Fluid Therapy. Patients with otherwise untreated diabetes insipidus crave cold fluids, especially water. With complete central diabetes insipidus, maximum urine-concentrating ability is approximately 100 mOsm/kg. Because 5 L of urine would be required to excrete an average daily solute load of 500 mOsm/m^2, fluid intake must match this to maintain normal plasma tonicity. With an intact thirst mechanism and free access to oral fluids, a person with complete diabetes insipidus can maintain plasma osmolality and sodium in the high normal range—although at great inconvenience. Furthermore, long-standing intake of these volumes of fluid in children can lead to hydroureter[412]—and even in hyperfluorosis in communities that provide fluoridated water.[413]

There are two situations in which central diabetes insipidus may be treated solely with high levels of fluid intake (i.e., without vasopressin). Vasopressin therapy coupled with excessive fluid intake (usually greater than 1 L/m^2/day, as discussed subsequently) can result in unwanted hyponatremia. Because neonates and young infants receive all of their nutrition in liquid form, the obligatory high oral fluid requirements for this age (3 L/m^2/day) combined with vasopressin treatment are likely to lead to this dangerous complication.[311] Oral tablet or intranasal liquid desmopressin is difficult to accurately administer to infants.

Such neonates may be better managed with fluid therapy alone. A reduced solute load diet will aid in this regard. Human milk is best for this purpose (75 mOsm/kg H_2O), whereas cow's milk is worst (230 mOsm/kg H_2O). For example, in an infant with diabetes insipidus with a fixed urine osmolality of 100 mOsm/kg H_2O 300 mL of urine per day is required to excrete the amount of solute consumed in human milk—whereas 900 mL of urine per day is required to excrete the higher amount of solute consumed in cow's milk. Although children managed with such a regimen may be chronically thirsty, parents may have difficulty keeping up with the voluminous fluid intake and urine output, and poor growth may occur if adequate calories are not provided along with water,[233] these problems are more easily addressed than is life-threatening hyponatremia.

Alternatively, thiazide (chlorthiazide, 5-10 mg/kg/dose) twice daily[414] and/or amiloride diuretics may be added to facilitate renal proximal tubular sodium and water reabsorption[415]—and thereby decrease oral fluid requirements. This therapy may be accompanied by a mild degree of dehydration. More recently, parenteral desmopressin (0.02-0.08 μg/dose given once or twice daily) has been administered subcutaneously in infants with good results—although this has not been approved by the FDA.[416]

Parenteral desmopressin was originally formulated at a concentration of 4 μg/mL, to be used at a dose of 0.3 μg/kg/dose to treat bleeding diatheses such as hemophilia A and von Willebrand's disease type 1. Thus, care must be taken if it is used at 1/40 to 1/4 of this dose to treat infants with diabetes insipidus. In older children on more calorie-dense solid diets, the use of short-acting agents such as arginine vasopressin (Pitressin) or lysine vasopressin (Diapid, lypressin) or longer-acting desmopressin will decrease fluid needs while minimizing the possible occurrence of hyponatremia (see "Vasopressin and Vasopressin Analogues").

In the acute postoperative management of central diabetes insipidus occurring after neurosurgery in children, vasopressin therapy may be successfully employed.[417-419] However, extreme caution must be exerted with its use. While under the full antidiuretic effect of vasopressin, a patient will have a urine osmolality of approximately 1,000 mOsm/kg and become hyponatremic if he or she

receives an excessive amount of fluids—depending on the solute load and nonrenal water losses. With a solute excretion of 500 mOsm/m^2/day, normal renal function, and nonrenal fluid losses of 500 ml/m^2/day, fluid intake of greater than 1 L/m^2/day (2/3 of the normal maintenance fluid requirement) will result in hyponatremia. In addition, vasopressin therapy will mask the emergence of the SIAD phase of the triple-phase neurohypophyseal response to neurosurgical injury.

Because of the concerns associated with perioperative vasopressin administration, two different approaches to managing central diabetes insipidus in the surgical patient have been employed. The first approach may be particularly useful in managing acute postoperative diabetes insipidus in young children. It employs fluids alone and avoids the use of vasopressin.[420] This method consists of matching input and output hourly using between 1 and 3 L/m^2/day (40 to 120 mL/m^2/hr). If intravenous therapy is used, a basal 40 mL/m^2/hr should be given as 5% dextrose (D5) in one-fourth normal saline (normal saline = 0.9% sodium chloride)—and the remainder, depending on the urine output, as 5% dextrose in water.

Potassium chloride (40 mEq/L) may be added if oral intake is to be delayed for several days. No additional fluid should be administered for hourly urine volumes under 40 mL/m^2/hr. For hourly urine volumes above 40 mL/m^2/hr, the additional volume should be replaced with 5% dextrose up to a total maximum of 120 mL/m^2/hr. For example, in a child with a surface area of 1 m^2 (approximately 30 kg), the basal infusion rate would be 40 mL/hr of 5% dextrose in one-fourth normal saline. For an hourly urine output of 60 mL, an additional 20 mL/hr 5% dextrose would be given for a total infusion rate of 60 mL/hr.

For urine outputs above 120 mL/hr, the total infusion rate would be 120 mL/hr. In the presence of diabetes insipidus, this will result in a serum sodium in the 150-mEq/L range and a mildly volume contracted state—which will allow one to assess thirst sensation and the return of normal vasopressin function or the emergence of SIAD. Patients may become mildly hyperglycemic with this regimen, particularly if they are also receiving postoperative glucocorticoids. However, because it does not use vasopressin this fluid management protocol prevents any chance of hyponatremia.

Vasopressin and Vasopressin Analogues. Recent evidence suggests that perioperative use of intravenous vasopressin in children with central diabetes insipidus may be the treatment modality of choice in most situations, resulting in excursions of serum sodium of smaller magnitude and few adverse sequelae.[419] Although intravenous therapy with synthetic aqueous vasopressin (Pitressin) had been shown to be useful in the management central diabetes insipidus of acute onset,[417,418] concern existed as to the safety of its administration in the complex and rapidly changing course of the child recovering from hypothalamic/pituitary surgery. If continuous vasopressin is administered, fluid intake must be limited to 1 L/m^2/day or two-thirds maintenance fluid administration (assuming normal solute intake and nonrenal water losses, as described).

The potency of synthetic vasopressin is still measured using a bioassay and is expressed in bioactive units, with one milliunit (mU) equivalent to approximately 2.5 ng of vasopressin. For intravenous vasopressin therapy, 1.5 mU/kg/hr results in a blood vasopressin concentration of approximately 10 pg/mL[421]—twice that needed for full antidiuretic activity.[422] Vasopressin's effect is maximal within 2 hours of the start of infusion,[422] and one must beware of it sticking to intravenous bottles and tubing. Occasionally following hypothalamic (but not trans-sphenoidal) surgery, higher initial concentrations of vasopressin are required to treat acute diabetes insipidus—which may be attributable to the release of a substance related to vasopressin from the damaged hypothalamo-neurohypophyseal system, which acts as an antagonist to normal vasopressin activity.[423] Much higher rates of vasopressin infusion resulting in plasma concentrations above 1,000 pg/mL should be avoided because they may cause cutaneous necrosis,[424] rhabdomyolysis,[424,425] and cardiac rhythm disturbances.[426]

In light of the considerations described in the previous paragraph, an effective and safe algorithm for management of perioperative central diabetes insipidus with central diabetes insipidus has been utilized with encouraging results.[419] This algorithm starts with the child receiving an intravenous infusion of normal saline at two-thirds maintenance or 1 L/m^2/day. A tentative diagnosis of intraoperative or postoperative central diabetes insipidus is made by documenting a serum sodium of greater than 145 mEq/L along with urine output of greater than 4 mL/kg/hr. Additional confirmatory evidence includes plasma osmolarity above 300 mOsm/kg H_2O and a relatively hypotonic urine.

When documentation of parameters consistent with central diabetes insipidus is obtained, an intravenous infusion of aqueous vasopressin begins at 0.5 mU/kg/hr—with no change in intravenous fluid administration. The dose of vasopressin is titrated upward in 0.5-mU/kg/hr increments to establish a urine output rate of less than 2 mL/kg/hr at approximately 10-minute intervals. The vasopressin and intravenous fluid administration then remain stable at these rates, with additional normal saline or equivalent volume expanding solutions given only to replace ongoing blood loss or to maintain hemodynamic stability. Postoperatively, this management paradigm requires intensive care unit monitoring—with frequent assessment of electrolytes (hourly initially), urine output and osmolarity/specific gravity, and vital signs.

This management scheme can also be followed for patients with established central diabetes insipidus requiring general surgery and prolonged restriction of oral intake. In this situation, the usual dose of chronic long-acting vasopressin is withheld or reduced immediately prior to surgery—depending on the timing of surgery in relation to the usual administration times. In preparation for surgery, normal saline is infused at two-thirds maintenance (1 L/m^2/day). When measures consistent with emergence of central diabetes insipidus due to termination of efficacy of the presurgical dose are obtained, the intravenous vasopressin is initiated and titrated as described previously.

Patients treated with vasopressin for post-neurosurgical diabetes insipidus should be switched from intravenous

to oral fluid intake at the earliest opportunity because thirst sensation, if intact, will help regulate blood osmolality. Intravenous dDAVP (Desmopressin) should not be used in the acute management of postoperative central diabetes insipidus because it offers no advantage over vasopressin and because its long half-life (8-12 hr) compared with that of vasopressin (5-10 min) is a distinct disadvantage—as it may increase the chance of causing water intoxication.[221] In fact, the use of intravenous dDAVP (0.3 μg/kg) to shorten the bleeding time in a variety of bleeding disorders has been associated with water intoxication[312]—particularly in young children, who have high obligate oral fluid needs.

A special problem arises when a patient with established central diabetes insipidus must receive a high volume of fluid for therapeutic reasons (e.g., accompanying cancer chemotherapy). Such patients can be managed by discontinuing antidiuretic therapy and increasing fluid intake to 3 to 5 L/m^2/day (rendering the patient moderately hypernatremic). Although 5 L/m^2/day is typically adequate to maintain serum sodium concentration in the range of 150 mEq/L in children with central diabetes insipidus, this rate may not be adequate in the setting of chemotherapy administration when solute excretion increases due to cell death and release of cellular content.

By using a low dose of intravenous vasopressin (0.08-0.1 mU/kg/hr, approximately one-eighth the full antidiuretic dose, titrated upward as needed), a partial antidiuretic effect allows the administration of higher amounts of fluid without causing hyponatremia.[427] Recent data suggests that excretion of a hypotonic urine, as would occur in patients with diabetes insipidus management with fluids alone, increases the risk of developing nephrotoxicity during therapy with platinum-based antineoplastic agents.[428] By allowing administration of 0.45 normal saline at rates of approximately 3 L/m^2/day, the low-dose vasopressin infusion yields a urine osmolarity higher than that achievable with fluids alone[427] and may have the additional benefit of conferring renal protection.

In the outpatient setting, treatment of central diabetes insipidus in older children should begin with oral (see material following) or intranasal dDAVP (10 μg/0.1 mL)—0.025 mL (2.5 μg) given by rhinal tube at bedtime and the dose increased to the lowest amount that gives an antidiuretic effect. If the dose is effective but has too short a duration, it should be increased further—or a second (morning) dose should be added. Patients should escape from the antidiuretic effect for at least 1 hour before the next dose, to ensure that any excessive water will be excreted. Otherwise, water intoxication may occur. dDAVP is also available as a nasal spray in the same concentration, with each spray delivering 10 μg (0.1 mL). This is the standard preparation used for treatment of primary enuresis. Oral dDAVP tablets have recently come into widespread use and have largely replaced intranasal therapy. Although when given orally dDAVP is at least twentyfold less potent than when given via the intranasal route, oral dDAVP in doses of 25 to 300 micrograms every 8 to 12 hours is reported to be highly effective and safe in children.[429-431] Lysine vasopressin (Diapid) nasal spray (50 U/mL) may be used if a duration less than that of dDAVP is desired. One spray delivers 2 U (0.04 mL), with a duration of action between 2 and 8 hours.

As noted previously, cortisol deficiency may cause decreased free water clearance by stimulating a nitric-oxide-mediated pathway that results in the insertion of aquaporin-2 channels into the apical membranes of collecting duct cells in a vasopressin-independent fashion.[242,243] Conversely, it is possible that excessive amounts of cortisol (due to endogenous release during stress, or to treatment with exogenous drug) may inhibit the insertion of water channels. This may explain why patients with central diabetes insipidus treated with desmopressin become "resistant" and require an increased dosage during times of stress or treatment with glucocorticoids.

In addition to polyuria and polydipsia, decreased bone mineral density has been reported in patients with central diabetes insipidus.[432] The decreased bone density was not corrected by vasopressin analog treatment alone, suggesting that institution of bisphosphonate or other therapies designed to prevent bone loss may be of long-term benefit in the treatment of diabetes insipidus.

NEPHROGENIC DIABETES INSIPIDUS

Causes of Nephrogenic Diabetes Insipidus

Nephrogenic (vasopressin-resistant) diabetes insipidus can be due to genetic or acquired causes. Genetic causes are less common but more severe than acquired forms of the disease, although genetic etiologies are more common in children than in adults.

Genetic Causes

Congenital X-linked Diabetes Insipidus: V2 Receptor Mutations. Congenital X-linked nephrogenic diabetes insipidus is caused by inactivating mutations of the vasopressin V2 receptor. Due to its mode of transmission, it is a disease of males—although rarely females may be affected, presumably due to extreme Lyonization during X chromosome inactivation.[433] In keeping with a germ-line (as opposed to somatic) mutation in the V2 receptor, these patients are deficient in all systemic V2-receptor-mediated actions[434,435] and have intact V1-receptor-mediated responses.[436,437] As expected, the V2 receptor defect is proximal to the activation of renal adenylate cyclase.[438,439] Unlike the function of other G-protein–coupled seven-transmembrane receptors such as the PTH and TSH receptors, that of the V2 receptor is unaffected in patients with pseudohypoparathyroidism (who have inactivating mutations in the alpha subunit of G_s[440]).

Because of vasopressin resistance in congenital nephrogenic diabetes insipidus, the kidney elaborates large volumes of hypotonic urine—with osmolality ranging between 50 and 100 mOsm/kg. Manifestations of the disease are usually present within the first several weeks of life,[441] but may only become apparent after weaning from the breast. The predominant symptoms are polyuria and polydypsia. Thirst may be more difficult to satisfy than in central diabetes insipidus. Many infants initially present with fever, vomiting, and dehydration—often leading to an evaluation for infection. Growth failure in the untreated child may be secondary to the ingestion of

large amounts of water, which the child may prefer over milk and other higher-caloric substances.[442]

Mental retardation of variable severity may result from repeated episodes of dehydration.[443] Intracerebral calcification of the frontal lobes and basal ganglia is not uncommon in children with X-linked nephrogenic diabetes insipidus.[444-447] Because this appears early and is not seen in children with central diabetes insipidus of equivalent severity, cerebral calcification is probably unrelated to the level of dehydration or therapeutic intervention. It is possible that elevated vasopressin concentrations, acting via intact V1 or V3 receptors, contribute to some of the unique manifestations of X-linked nephrogenic diabetes insipidus—such as cerebral calcification, intense thirst, vomiting, and growth failure. Older children may present with enuresis or nocturia. They may learn to reduce food intake (and therefore solute load) to decrease polyuria, which may contribute to growth failure. After long-standing ingestion and excretion of large volumes of water, patients may develop nonobstructive hydronephrosis, hydroureter, and megabladder.[412]

Although one founder (arriving in North America from Scotland in 1761 on the ship *Hopewell*) was initially postulated to be the ancestor of most North American subjects with congenital X-linked nephrogenic diabetes insipidus,[448] more than 180 mutations in the V2 receptor have been found—with some appearing to have arisen independently more than once[449-462] (Figure 9-14). These are mostly single base mutations that either result in amino acid substitutions, translational frame shifts, or termination of peptide synthesis and are distributed fairly evenly throughout the receptor protein *(www.medcon.mcgill.ca/nephros/avpr2.html)*. Mutations may affect vasopressin binding, cyclic AMP generation, or possibly transcriptional regulation.[463-467] Patients with different mutations will likely be found to exhibit phenotypic heterogeneity, including in severity of disease and response to treatment. Genetic heterogeneity may underlie the variable response of patients with X-linked diabetes insipidus to dDAVP treatment. In a family with a known mutation, prenatal or early postnatal DNA screening can unambiguously identify affected males—allowing the institution of appropriate therapy.[222]

Congenital Autosomal Nephrogenic Diabetes Insipidus: Aquaporin-2 Mutations. After the initial description of X-linked nephrogenic diabetes insipidus,[468] several patients were reported with similar clinical findings except for autosomal-recessive transmission of the disease[469] or normal V2 receptor function outside the kidney.[470] With the cloning of the complementary DNA for the renal water channel, aquaporin-2, many patients with autosomal-recessive nephrogenic diabetes insipidus have been reported who have a total of 21 mutations different in this gene[464] *(www.medcon.mcgill.ca/nephros/aqp2.html)*. Most are missense mutations, although four are nonsense or frame-shift mutations. They are scattered throughout the molecule, including within four of the five transmembrane domains, two of three extracellular domains, and two of four intracellular domains (Figure 9-10).

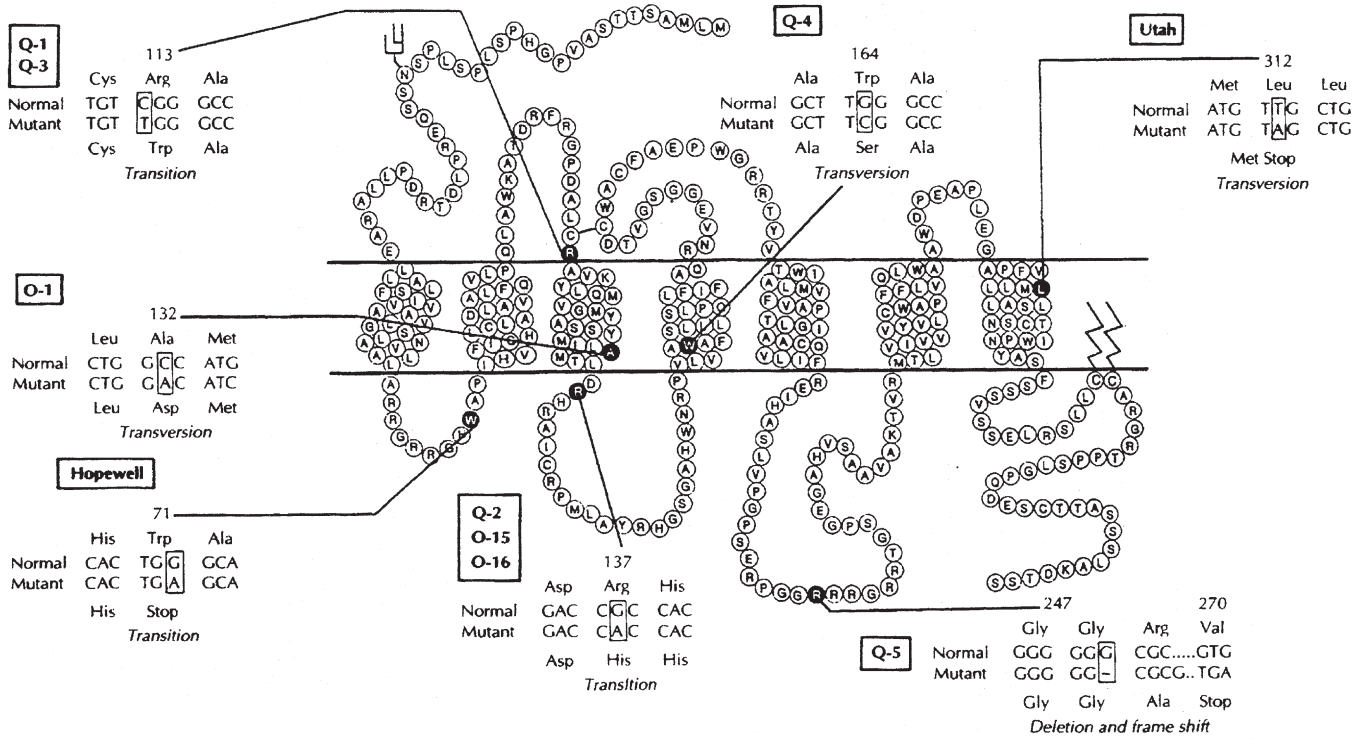

Figure 9-14 Schematic representation of seven of the more than 180 V2 receptor mutations in families with X-linked nephrogenic diabetes insipidus. Q, families from Quebec; F, families from France; and O, other families. [Reproduced with permission from Bichet DG (1995). The posterior pituitary. In Melmed S (ed.), *The pituitary*. Cambridge: Blackwell Science 277.]

Recently, an autosomal-dominant mode of inheritance for nephrogenic diabetes insipidus has been described, associated with mutations in aquaporin-2. One of these dominant mutations results in mixed tetramers of the wild type and mutant alleles being retained in the golgi apparatus.[471] Aquaporin-2 mutations impair the ability of the luminal membrane to undergo an increase in water permeability following signaling through the V2 receptor. They could include patients previously described who had a normal rise in urinary cyclic AMP in response to vasopressin, without a concomitant increase in urine osmolality.[438] Aquaporin-2 protein has recently been shown to be excreted in the urine in both soluble and membrane-bound forms. Aquaporin-2 excretion is low in untreated central and nephrogenic diabetes insipidus, but following dDAVP administration increases markedly in the former (but not the latter) disease.[117] For this reason, its measurement in urine has been suggested as an aid in the differential diagnosis of diabetes insipidus.[117]

Acquired Causes. Acquired causes of nephrogenic diabetes insipidus are more common and less severe than genetic causes. Nephrogenic diabetes insipidus may be caused by drugs such as lithium and demeclocycline, both of which are thought to interfere with vasopressin-stimulated cyclic AMP generation or action. Approximately 50% of patients receiving lithium have impaired urinary concentrating ability, although only 10% to 20% of them develop symptomatic nephrogenic diabetes insipidus—which is almost always accompanied by a reduction in the glomerular filtration rate.[472,473] The risk increases with duration of therapy. Lithium impairs the ability of vasopressin to stimulate adenylate cyclase,[474] resulting in a 90% fall in aquaporin-2 messenger RNA expression in renal collecting duct[475] (which may be the basis for its causing nephrogenic diabetes insipidus).

Demeclocycline treatment causes nephrogenic diabetes insipidus by inhibiting transepithelial water transport.[476] For this reason, it is useful in the treatment of dilutional hyponatremia associated with inappropriate secretion of vasopressin. Other agents that cause nephrogenic diabetes insipidus include hypercalcemia, hyperkalemia, and therapy with foscarnet (used in the treatment of cytomegalovirus infection in immunosuppressed patients),[477,478] clozapine,[478] amphotericin,[479] methicillin,[480] and rifampin.[481] Whether any of these agents causes nephrogenic diabetes insipidus by interfering with the expression or insertion into apical collecting duct membranes of aquaporin-2 water channels is not yet known.

Ureteral obstruction,[482] chronic renal failure, polycystic kidney disease, medullary cystic disease, Sjögren's syndrome,[483] and sickle cell disease can also impair renal concentrating ability. Osmotic diuresis due to glycosuria in diabetes mellitus, or to sodium excretion with diuretic therapy, will interfere with renal water conservation. Primary polydypsia can result in secondary nephrogenic diabetes insipidus because the chronic excretion of a dilute urine lowers the osmolality of the hypertonic renal interstitium, thus decreasing renal concentrating ability. Finally, decreased protein or sodium intake can also lead to diminished tonicity of the renal medullary interstitium and to nephrogenic diabetes insipidus.

Treatment of Nephrogenic Diabetes Insipidus

The treatment of acquired nephrogenic diabetes insipidus focuses on elimination, if possible, of the underlying disorder—such as offending drugs, hypercalcemia, hypokalemia, and ureteral obstruction. Congenital nephrogenic diabetes insipidus is often difficult to treat. The main goals should be to ensure the intake of adequate calories for growth and to avoid severe dehydration. Foods with the highest ratio of caloric content to osmotic load should be ingested, to maximize growth and minimize the urine volume required to excrete urine solute. However, even with the early institution of therapy growth and mental retardation are not uncommon.[484]

Thiazide diuretics in combination with amiloride or indomethacin are the most useful pharmacologic agents in the treatment of nephrogenic diabetes insipidus. Thiazides work by enhancing sodium excretion at the expense of water and by causing a fall in glomerular filtration rate, which results in proximal tubular sodium and water reabsorption.[415,485] Indomethacin (2 mg/kg/day) further enhances proximal tubular sodium and water reabsorption,[415,486,487] although this effect is not mediated by inhibition of cyclo-oxygenase.[488]

The combination of thiazide and amiloride diuretics is the most commonly used regimen for the treatment of congenital X-linked nephrogenic diabetes insipidus because amiloride counteracts thiazide-induced hypokalemia,[441] avoids the nephrotoxicity associated with indomethacin therapy, and is well tolerated (even in infants).[489] In addition, amiloride decreases the uptake of lithium by renal epithelial cells—and for this additional reason has been proposed in combination with thiazide as treatment for lithium-induced nephrogenic diabetes insipidus.[490]

High-dose dDAVP therapy, in combination with indomethacin, has been reported to be helpful in treating some subjects with nephrogenic diabetes insipidus.[491] This treatment may prove to be useful in patients with genetic defects in the V2 receptor that reduce the binding affinity for vasopressin. A therapy that has thus far only been employed in mice and not yet available for humans, in which abnormal stop codons are bypassed,[492] may prove useful in treating patients with nonsense mutations in AVPR2 and AQP2.

Concluding Remarks

Precise regulation of water balance is necessary to the proper function of multiple cellular pathways. Vasopressin released from the posterior pituitary, stimulated by hyperosmolar and nonosmotic factors, acts via the kidney V2 vasopressin receptor to stimulate an increase in aquaporin-2 expression and its insertion into collecting duct luminal membrane—thereby enhancing renal water reabsorption to minimize subsequent water loss. Thirst controls the second major physiologic response to hyperosmolality and results in increased water intake to make up for past water loss. The renin-angiotensin-aldosterone and atrial natriuretic peptide systems also make important contributions to water and volume regulation by modulation of sodium intake and output.

The proper diagnosis of disorders caused by deficient and excessive action of vasopressin requires a thorough understanding of the physiologic regulation of this hormone. Recent advances in molecular medicine have revealed mutations in the vasopressin gene, and in the V2 receptor or aquaporin-2 genes (responsible for familial central and nephrogenic diabetes insipidus, respectively). Molecular methods allow the diagnosis of these disorders in the prenatal or early postnatal periods. Nevertheless, the most frequent cause of central diabetes insipidus remains a destructive lesion of the central nervous system caused by tumor or neurosurgical insult—and pharmacologic toxicity remains the most common cause of nephrogenic diabetes insipidus.

Hyponatremia is a common occurence in childhood, but is rarely due to a primary increase in vasopressin secretion or increase in intrinsic activity of the V2 receptor (SIAD). It is more commonly caused by hypovolemia (primary or secondary to decreased effective vascular volume), salt loss, excessive ingestion of hypotonic fluids, or cortisol deficiency. Hyponatremia due to increased vasopressin action is most commonly caused by excessive vasopressin administration during the treatment of central diabetes insipidus or coagulopathies.

Central diabetes insipidus is best treated in infants with fluid therapy that avoids the administration of vasopressin or its V2 receptor analog, dDAVP—whereas in older children dDAVP is the drug of choice. Nephrogenic diabetes insipidus remains a theraputic challenge. Hyponatremia due to SIAD is best managed by restricting water intake, whereas salt and water replacement are indicated when hyponatremia is due to hypovolemia or excessive secretion of atrial natriuretic peptide (as occurs in cerebral salt wasting). Hyponatremia causing central nervous system dysfunction is a medical emergency. Blood sodium must be raised promptly, but at a rate not greater than 0.5 mEq/L/hr to avoid the occurrence of central pontine myelinolysis.
