Conclusions

Introduction

Diabetes mellitus is best defined as a syndrome characterized by inappropriate fasting or postprandial hyperglycemia, and its metabolic consequences which include disturbed metabolism of protein and fat. This syndrome results from a deficiency of insulin secretion or its action. Diabetes mellitus occurs when the normal constant of the product of insulin secretion times insulin sensitivity, a parabolic function (Figure 10-1), is inadequate to prevent hyperglycemia and its clinical consequences of polyuria, polydipsia, and weight loss.

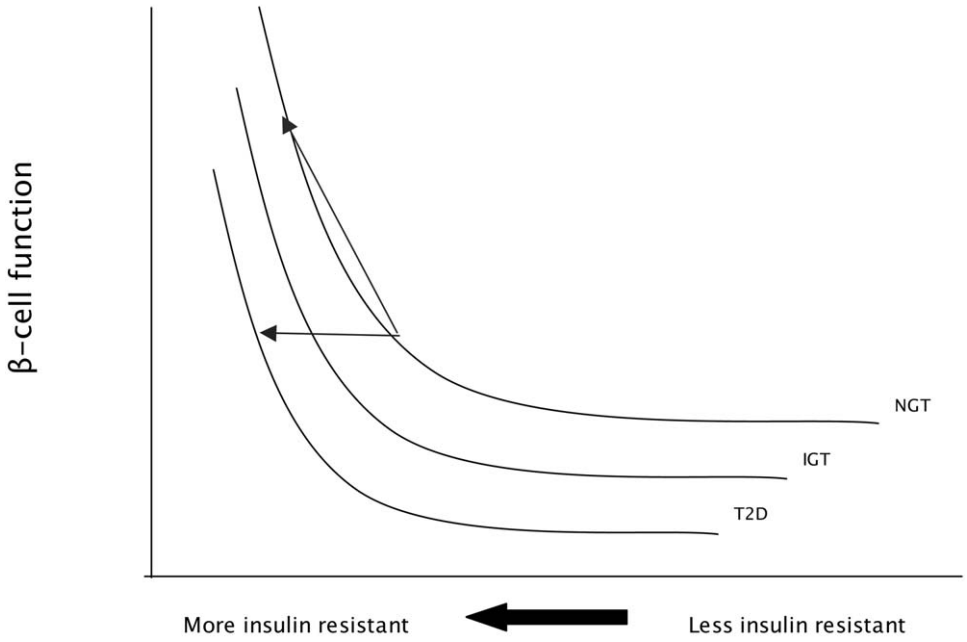

Figure 10-1. The hyperbolic relationship of insulin resistance and β-cell function. In a subject with normal β-cell reserve, an increase in insulin results in increased insulin release and normal glucose tolerance (top arrow). In an individual for whom the capacity to increase insulin release is compromised, increased insulin resistance with no β-cell compensation results in progression from normal glucose tolerance to impaired glucose tolerance to diabetes (bottom arrow). The product of insulin sensitivity (the reciprocal of insulin resistance) and acute insulin response (a measurement β-cell function) has been called "disposition index." This index remains constant in an individual with normal β-cell compensation in response to changes in insulin resistance. IGT, impaired glucose tolerance; NGT, normal glucose tolerance; and T2D, type 2 diabetes. [From Ize-Ludlow D, Sperling MA (2005). The classification of diabetes mellitus: A conceptual framework. Pediatric Clinics of North America 52:1533-1552.]

By simultaneously considering insulin secretion and insulin action in any given individual, it becomes possible to account for the natural history of diabetes in that person (e.g., remission in a patient with T1 diabetes or ketoacidosis in a person with T2DM). Thus, diabetes mellitus may be the result of absolute insulin deficiency, or of absolute insulin resistance, or a combination of milder defects in both insulin secretion and insulin action.[1] Collectively, the syndromes of diabetes mellitus are the most common endocrine/metabolic disorders of childhood and adolescence. The application of molecular biologic tools continues to provide remarkable insights into the etiology, pathophysiology, and genetics of the various forms of diabetes mellitus that result from deficient secretion of insulin or its action at the cellular level.

Morbidity and mortality stem from metabolic derangements and from the long-term complications that affect small and large vessels, resulting in retinopathy, nephropathy, neuropathy, ischemic heart disease, and arterial obstruction with gangrene of extremities.[2] The acute clinical manifestations can be fully understood in the context of current knowledge of the secretion and action of insulin.[3] Genetic and other etiologic considerations implicate autoimmune mechanisms in the evolution of the most common form of childhood diabetes, known as type 1 diabetes.[4,5] Genetic defects in insulin secretion are increasingly recognized and understood as defining the causes of monogenic forms of diabetes such as maturity-onset diabetes of youth (MODY) and neonatal DM and contributing to the spectrum of T2DM.[6]

There is evidence that the long-term complications are related to the degree and duration of metabolic disturbances.[2] These considerations form the basis of standard and innovative therapeutic approaches to this disease that include newer pharmacologic formulations of insulin, delivery by traditional and more physiologic means, and evolving methods to monitor blood glucose to maintain it within desired limits.

Classification

Diabetes mellitus is not a single entity but a heterogeneous group of disorders in which there are distinct genetic patterns as well as other etiologic and pathophysiologic mechanisms that lead to impairment of glucose tolerance.[1,7] Table 10-1 outlines an etiologic classification of diabetes mellitus in children, modified from "Report of the Expert Committee on the Classification and Diagnosis of Diabetes Mellitus," published by the American Diabetes Association in January of 2007.[7]

Our classification is modified to reflect more accurately the major categories in childhood, including the emergence of type 2 diabetes mellitus, cystic fibrosis–related diabetes, and drug-induced diabetes [largely from the antirejection agents cyclosporine and tacrolimus (formerly FK-506)]. Table 10-2 presents a summary of the classification originally proposed in 1979 but incorporates the newer criteria for blood glucose values used to diagnose diabetes, impaired glucose tolerance, and gestational diabetes.

TABLE 10-1

Etiologic Classification of Diabetes Mellitus

I. Type 1 Diabetes (Beta Cell Destruction Ultimately Leading to Complete Insulin Deficiency)
A. Immune mediated
B. Idiopathic

II. Type 2 Diabetes (Variable Combinations of Insulin Resistance and Insulin Deficiency)
A. Typical
B. Atypical

III. Genetic Defects of β-Cell Function
A. MODY syndromes
1. MODY 1 chromosome 20, HNF-4α
2. MODY 2 chromosome 7, glucokinase
3. MODY 3 chromosome 12, HNF-1α, TCF-1
4. MODY 4 chromosome 13, IPF-1
5. MODY 5 chromosome 17, HNF-1β, TCF-2
6. MODY 6 chromosome 2q32, neuro-D1/beta-2
B. Mitochondrial DNA mutations (includes one form of Wolfram syndrome; Pearson syndrome; Kearns-Sayre, diabetes mellitus, deafness)
C. Wolfram syndrome—DIDMOAD (diabetes insipidus, diabetes mellitus, optic atrophy, deafness): WFS1-Wolframin—chromosome 4p
1. Wolfram locus 2—chromosome 4q22-24
2. Wolfram mitochondrial
D. Thiamine responsive

IV. Drug or Chemical Induced
A. Antirejection—cyclosporine
B. Glucocorticoids (with impaired insulin secretion; e.g., cystic fibrosis)
C. L-Asparaginase
D. β-Adrenergic blockers
E. Vacor (rodenticide)
F. Phenytoin (Dilantin)
G. Alfa-Interferon
H. Diazoxide
I. Nicotinic acid
J. Others

V. Diseases of Exocrine Pancreas
A. Cystic fibrosis–related diabetes
B. Trauma—pancreatectomy
C. Pancreatitis—ionizing radiation
D. Others

VI. Infections
A. Congenital rubella
B. Cytomegalovirus
C. Hemolytic-uremic syndrome

VII. Variants of Type 2 Diabetes
A. Genetic defects of insulin action
1. Rabson-Mendenhall syndrome
2. Leprechaunism
3. Lipoatrophic diabetes syndromes
4. Type A insulin resistance—acanthosis
B. Acquired defects of insulin action
1. Endocrine tumors—rare in childhood
A. Pheochromocytoma
B. Cushing
C. Others
2. Anti-insulin receptor antibodies

VIII. Genetic Syndromes with Diabetes and Insulin Resistance/Insulin Deficiency
A. Prader-Willi syndrome, chromosome 15
B. Down syndrome, chromosome 21
C. Turner syndrome
D. Klinefelter syndrome
E. Others
1. Bardet-Biedel
2. Alstrom
3. Werner

IX. Gestational Diabetes
X. Neonatal Diabetes
A. Transient—chromosome 6q24, KCNJ11, ABCC8
B. Permanent—agenesis of pancreas—glucokinase deficiency, homozygous and KCNJ11, ABCC8

Among the insulin-dependent forms, severe lack of insulin secretion results from presumed autoimmune destruction of islets in genetically predisposed hosts. This form is synonymous with type 1a diabetes, formerly called juvenile-onset diabetes.[5,8,9] Severe insulin-dependent diabetes mellitus, however (clinically indistinguishable from the autoimmune form), may not have any evidence of autoimmunity and can result from mitochondrial or other gene defects that interfere with the generation of intraislet energy required for insulin secretion[10-12] or rarely from pancreatic agenesis.[13]

The more severe forms of the MODY syndromes, subsequently detailed, also may require insulin.[14] Clinically similar forms of diabetes may occur secondary to cystic fibrosis[15] from toxic drugs such as the immunosuppressive agents cyclosporine and tacrolimus,[16,17] the rodenticide Vacor,[18] or streptozotocin as used for certain pancreatic islet cell tumors;[19] with the hemolytic uremic syndrome;[20] or after pancreatectomy, such as for persistent hyperinsulinemic hypoglycemia in infancy.[21] Childhood insulin-dependent diabetes is generally type 1 diabetes mellitus.

TYPE 1 DIABETES MELLITUS

This condition is characterized by severe insulinopenia and dependence on exogenous insulin to prevent ketosis and to preserve life. Thus, it was called insulin-dependent diabetes mellitus (IDDM). The natural history of this disease indicates that there are preketotic non–insulin-dependent phases before and after the initial diagnosis. Although the onset is predominantly in childhood, the disease may occur at any age.[1] Therefore, such names as "juvenile diabetes," "ketosis-prone diabetes," and "brittle

TABLE 10-2

Summary of Classification of Diabetes Mellitus in Children and Adolescents

Category	Criteria
Diabetes Mellitus	
Type 1	Typical symptoms: glucosuria, ketonuria; random plasma glucose >200 mg/dL
Type 2	Fasting plasma glucose >126 mg/dL with 2-hour intervening value >200 mg/dL on OGTT more than once and in the absence of precipitating factors
Other types	Type 1 or 2 criteria with genetic syndrome, drug therapy; pancreatic disease or other known causes or associations
Impaired fasting glucose	Glucose >110 mg/dL but <126 mg/dL
Impaired glucose tolerance	Fasting plasma glucose <126 mg/dL with 2-hour >140 mg/dL but <200 mg/dL on OGTT
Gestational diabetes	Two or more abnormal fasting plasma glucose levels >105 mg/dL, 1-hour >180 mg/dL, 2-hour >155 mg/dL, 3-hour >140 mg/dL on OGTT
Statistical Risk Classes	
Previous abnormality of glucose tolerance	Normal OGTT with previously abnormal OGTT, spontaneous hyperglycemia, or gestational diabetes
Potential abnormality of glucose tolerance	Genetic propensity (e.g., identical twin with diabetes mellitus); islet cell antibodies

diabetes" have been abandoned in favor of the term *type 1 diabetes*.

Type 1 diabetes is generally distinct by virtue of its association with certain histocompatibility locus antigens (HLAs) and other genetic markers; by the presence of circulating antibodies to cytoplasmic and cell-surface components of islet cells; of antibodies to insulin in the absence of previous exposure to exogenous injection of insulin, of antibodies to glutamic acid decarboxylase (GAD, the enzyme that converts glutamic acid to γ-aminobutyric acid found abundantly in the innervation of pancreatic islets), and of antibodies to IA-2 (an islet cell–associated phosphatase); by lymphocytic infiltration of islets early in the disease; and by coexistence with other autoimmune diseases. Occasionally, markers of autoimmunity are not found and yet there is profound insulinopenia and dependence on insulin without evidence of a mitochondrial or other genetic defect. In these cases, type 1 diabetes is considered idiopathic (type 1b). With the exceptions noted, diabetes in children is usually insulin dependent and fits the type 1 category.[1]

TYPE 2 DIABETES

Persons with this subclass of diabetes [formerly known as "adult-onset diabetes," "maturity-onset diabetes" (MOD), or "stable diabetes"] may not be permanently insulin dependent and only occasionally develop ketosis. Some may, however, need insulin to correct symptomatic hyperglycemia—and ketosis may develop in some during severe infections or other stress. Therefore, this was previously called non–insulin-dependent diabetes mellitus (NIDDM).[1] It is becoming an increasing problem in overweight adolescents, especially those from vulnerable groups such as Africans, Mexicans, Native Indians, and other susceptible ethnic groups.[22,23]

Type 2 diabetes is not a single entity.[1] It may be a primary disorder, with inadequate insulin secretion caused by mutations in one of several genes encoding enzymes or transcription factors important to islet cell development and insulin secretion. These defects are now part of the spectrum of the syndromes commonly associated with MODY, which has a dominant mode of inheritance.[13,24] However, some patients with MODY defects, which some term *monogenic diabetes of youth*, may require insulin from the outset or as they grow older. A defect in the gene regulating glucose transport into the pancreatic beta cell, the GLUT2 transporter, may be responsible for another form of type 2 diabetes.[25]

Defects in glycogen synthase have also been implicated.[26,27] A primary defect in insulin receptors—often associated with acanthosis nigricans,[28] postreceptor defects [including Rad (Ras associated with diabetes)[29]], and milder mitochondrial gene defects[10]—also may result in type 2 diabetes. Secondary causes of type 2 diabetes mellitus include excessive counterregulatory hormones, especially pharmacologic doses of glucocorticoids, antibodies to the insulin receptor, and obesity with impaired insulin secretion.[30-41]

In type 2 diabetes mellitus, the serum concentration of insulin may be increased, normal, or moderately depressed depending on whether the defect is one of insulin action or secretion.[27-41] The onset of type 2 diabetes mellitus occurs in children generally around the time of puberty or shortly thereafter, but we increasingly recognize that it may occur at any age. It is becoming increasingly frequent in childhood and adolescence.[22,23] In some instances, there appears to be adequate secretion of insulin but with resistance to it—and in some individuals it may represent slowly evolving type 1 diabetes mellitus.[6,42,43] As an initial approach, weight reduction is indicated in children who are obese. In type 2 diabetes, there is no association with specific HLA antigens, autoimmunity, or various islet cell antibodies (ICAs).[42] However, several genetic abnormalities regulating insulin secretion are increasingly implicated in T2DM

Type 1 Diabetes Mellitus

EPIDEMIOLOGY

The prevalence of diabetes mellitus is highly correlated with increasing age. Available data indicate a range of 1 case per 1,430 children at 5 years of age to 1 case in

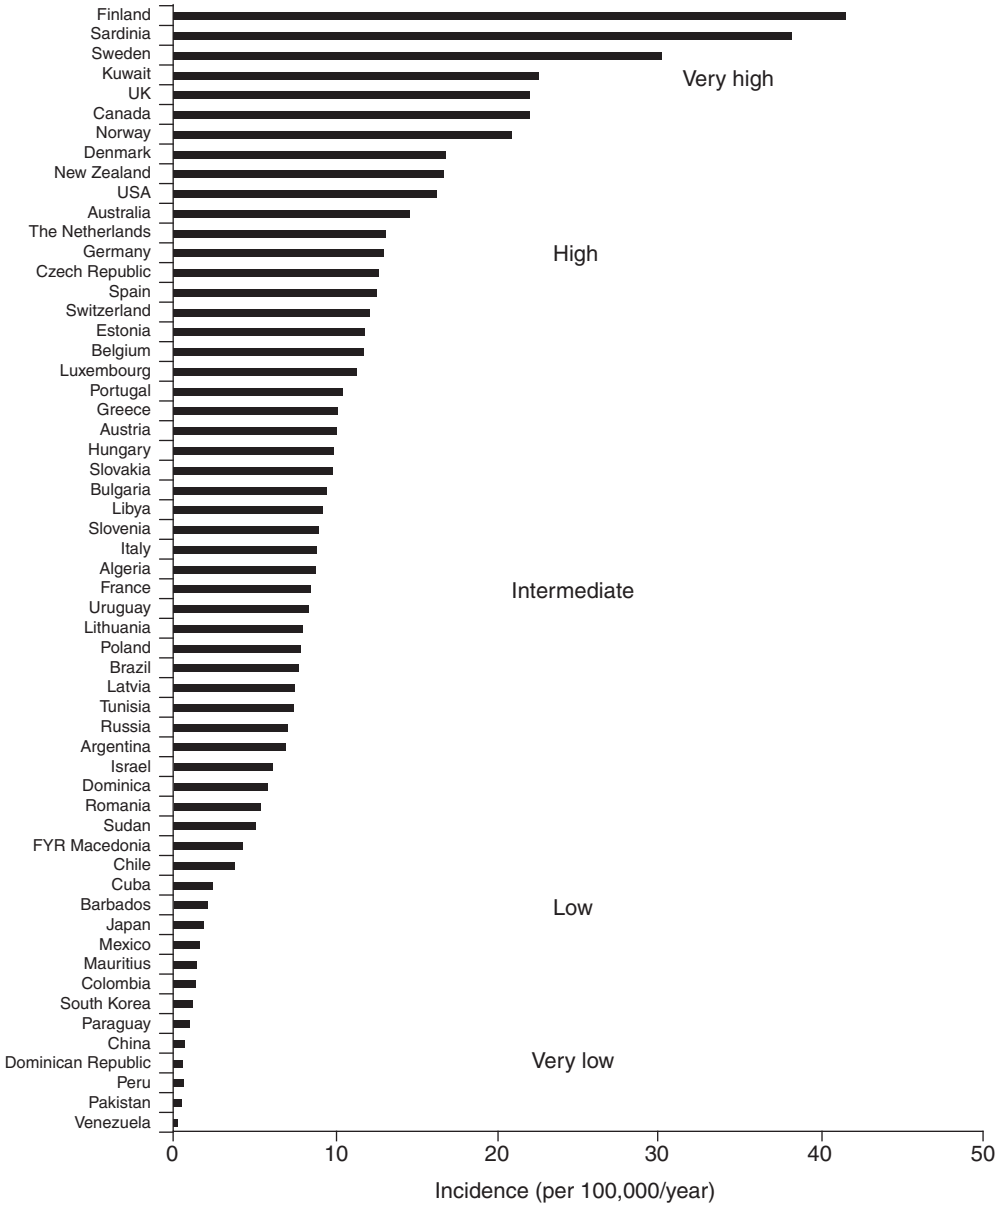

Figure 10-2. Age-standardized incidence (per 100,000/year) of type 1 diabetes in children younger than 14 years of age in 100 populations. Data for boys and girls have been pooled. Countries are arranged in descending order according to the incidence. (Puerto Rico and the Virgin Islands are presented separately from other populations in the United States.) [From Diamond Project Group (2006). Incidence of trends of childhood type 1 diabetes worldwide 1990-1999. Diabetic Medicine 23:857-866.]

360 children at 16 years.[44] Data on incidence in relation to racial or ethnic backgrounds indicate a range of more than 35 new cases annually per 100,000 population in Finland and Sardinia to about 1 per 100,000 in China and parts of South America[45-47] (Figure 10-2). In all examined areas there appears to be an increasing incidence of T1DM of about 2% to 3% per year.

In the United States, the occurrence of type 1 in blacks had previously been reported to be only between one-third and two-thirds of that in whites.[44,47] More recent data suggest that the incidence of diabetes mellitus in African Americans may be as high as in white Americans.[48,49] It is not clear, however, whether this new increase in incidence among African Americans is exclusively type 1 or includes cases of type 2 presenting in ketoacidosis and thus misclassified.[50] The annual incidence in the United States is 15 to 18 cases per 100,000 of the childhood population[45] (Figure 10-2).

Males and females appear to be almost equally affected. There is no apparent correlation with socioeconomic status. Peaks of presentation occur in two age groups: at 5 to 7 years of age and at the time of puberty. The first peak corresponds to the time of increased exposure to infectious agents coincident with the beginning of school. The latter corresponds to the pubertal growth spurt induced by increased pubertal growth hormone secretion and gonadal steroids that antagonize insulin action. Emotional stresses accompanying puberty have also been implicated.

These possible cause-and-effect relationships remain to be proved but are strongly supported for the role of increased growth hormone secretion at the time of puberty. The incidence of type 1 diabetes is increasing worldwide, most prominently in certain populations (e.g., Finland) and in certain age groups (especially those younger than age 5 years).[45,46] In these younger patients, onset appears to be more abrupt and the extent of immune markers is less apparent than in older children.[51] Type 1 diabetes with abrupt onset, less evidence of autoimmunity, and indicators of viral infection (including evidence of pancreatitis) has been described in Japan.[52,53]

Seasonal and long-term cyclical variations have been noted in the incidence of type 1 diabetes. Newly recognized cases appear to occur with greater frequency in the autumn and winter in the northern and southern hemispheres.[54] Seasonal variations are most apparent in the adolescent years.[54] There is no consistent pattern linking long-term cyclicity with the incidence of viral infections. There is a definite increased incidence of diabetes in children with congenital rubella.[55,56] These changing patterns in incidence and associations with viral infections suggest a potential role for viruses or other microbial agents or their products as direct or indirect triggering mechanisms for inducing T1DM in a susceptible host.[57-60]

ETIOLOGY, PATHOGENESIS, AND GENETICS

The cause of the initial clinical findings in this predominant form of diabetes in childhood is the sharply diminished secretion of insulin. Although basal insulin concentrations in plasma may be normal in newly diagnosed patients, insulin production in response to a variety of potent secretagogues is blunted and usually disappears over a period of months to years (rarely exceeding 5 years). In certain individuals considered at high risk for the development of type 1 diabetes, such as the nonaffected identical twin of a diabetic, a progressive decline in insulin-secreting capacity has been noted for months to years before the clinical appearance of symptomatic diabetes that usually manifests when insulin-secreting reserve is 20% or less of normal for that individual (Figure 10-3).[7]

The mechanisms that lead to failure of pancreatic beta-cell function point to autoimmune destruction of pancreatic islets in predisposed individuals. Type 1 diabetes has long been known to have an increased prevalence among persons with such disorders as Addison disease and Hashimoto thyroiditis, in whom autoimmune mechanisms are known to be pathogenic.[6] These conditions, as well as type 1 diabetes mellitus, are known to be associated with an increased frequency of certain histocompatibility loci antigens (HLAs)—in particular, DR3 and DR4. Located on chromosome 6, the HLA system is the major histocompatibility complex—consisting of a cluster of genes that code transplantation antigens and play a central role in immune responses.[61-74]

Increased susceptibility to a number of diseases has been related to one or more of the identified HLA antigens. The inheritance of HLA DR3 or DR4 confers a twofold to threefold increased risk for developing type 1 diabetes. When both DR3 and DR4 are inherited, the relative risk for developing diabetes is increased sevenfold to tenfold. Application of newer molecular genetic techniques has revealed further heterogeneity in the HLA D region among individuals with and without diabetes despite possessing the DR3 or DR4 markers, suggesting the participation of other susceptibility loci within these markers.

Among these loci may be the LMP2 and LMP7 genes that occur within the major histocompatibility complex.[61-72] Extensive genome-wide scans of markers associated with type 1 diabetes mellitus have uncovered more than a

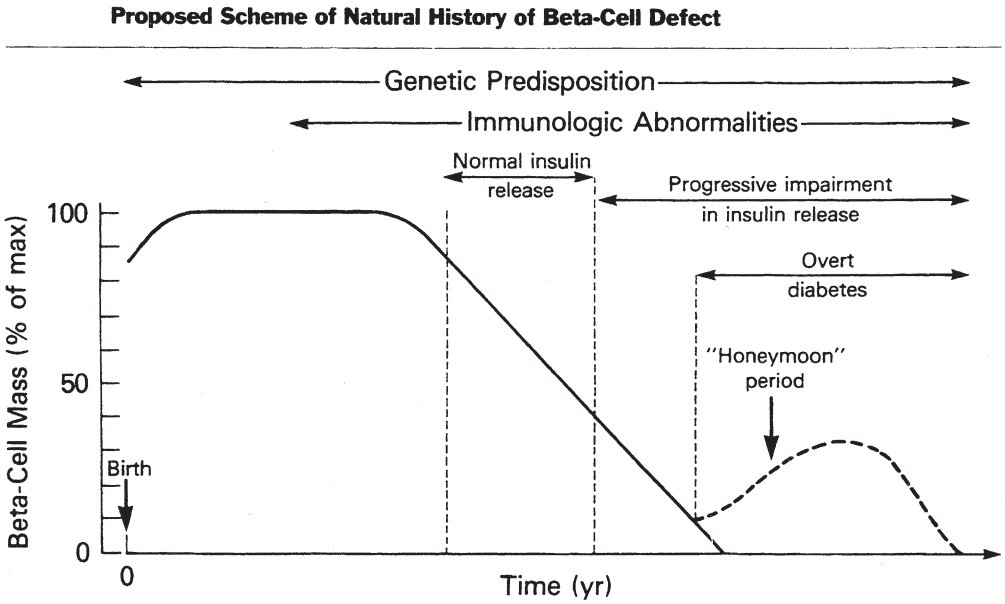

Figure 10-3. Proposed scheme of natural history of the evolution of insulin-dependent diabetes mellitus with progressive beta cell failure. [From Sperling MA (ed.) (1988). *Physician's guide to insulin-dependent (type 1) diabetes mellitus: Diagnosis and treatment.* Alexandria, VA: American Diabetes Association.]

dozen loci considered to confer susceptibility (Table 10-3). Some of these loci are confirmed and replicated by at least three different data sets. Others are suggestive but as yet not definitively linked. The strongest markers are those on chromosomes 6 and 11 (IDDM1 and IDDM2), respectively linked to the HLA DQ β chain and the insulin gene itself.

TABLE 10-3

Summary of Human Susceptibility Loci for Type 1 Diabetes Mellitus

Chromosome	Locus	Linkage Status
6p21	IDDM1; HLA-DQB	Confirmed
11p15.5	IDDM2; INS 59 VNTR	Confirmed
15q26	IDDM3; IGF1R	Suggestive (P,.001, MLS.2.2)
11q13	IDDM4; FGF3	Confirmed (P,2.2310^{25}, MLS.3.6)
6q25	IDDM5; ESR1	Confirmed (P,2.2310^{25}, MLS.3.6)
18q21	IDDM6	
2q31	IDDM7; IL1, HOXD8	Suggestive (P,.001, MLS.2.2)
6q27	IDDM8; IGF2R	Confirmed (P,2.2310^{25}, MLS.3.6)
3q21-q25	IDDM9	
10p11.2-q11.2	IDDM10	
14q24.3	IDDM11	Significant (P,2.2310^{25}, MLS.3.6)
2q33	IDDM12; CTLA-4	
2q34	IDDM13; IGFBP2, IGFBP5	
6p21	IDDM15 (distinct from HLA)	
10q25†	IDDM17	Significant (NPL: P,.002)
7p	Not assigned: GCK, IGFBP1, IGFBP3	
Xq	Not assigned	
Xp‡	Not assigned	Significant (P52.7310^{24}; MLS.3.6)
1q§	Not assigned	Suggestive (MLS53.31)

The IDDM nomenclature is assigned to a locus after linkage has been formally demonstrated, replicated, and confirmed in at least three different data sets. Where functional candidate genes are flanked by or very close to susceptibility markers, they are indicated.
P According to Lander and Kruglyak.
† The evidence for linkage increased substantially (P5.00004) with the higher density of markers and the inclusion of data for additional affected relatives and all unaffected siblings; NPL, nonparametric linkage.
‡ In HLA-DR3–positive patients.
§ This locus colocalizes with loci for systemic lupus enythematosus and ankylosing spondylitis.
MLS, maximum LOD score.
Adapted from Friday RP, Trucco M, Pietropaolo M (1999). Genetics of type 1 diabetes mellitus. Diabetes Nutr Metab 12:3.

TABLE 10-4

HLA DR and DQ Phenotype Frequencies in Patients with Type 1 Diabetes Mellitus and Healthy Control Subjects

Phenotype	Diabetic (%)	Nondiabetic	Odds Ratio (%)
DR (Serology)			
DR3/DR4	33	6	8.3
DR3/DR3	7	1	9.8
DR3/DRX	7	14	0.05
DR4/DR4	26	0	—
DR4/DRX	22	16	1.5
DRX/DRX	4	63	0.02
DQ (Molecular Probes)			
Non-Asp/non-Asp	96	19	107.2
Non-Asp/Asp	4	46	0.04
Asp/Asp	0	34	0

Based on Morel PA, Dorman JS, Todd JA, et al. (1988). Aspartic acid at position 57 of the HLA-DQ beta chain protects against type 1 diabetes: A family study. Proc Natl Acad Sci USA 85:8111.

In IDDM1, the homozygous absence of aspartic acid at position 57 of the HLA DQ *b* chain (non-Asp/non-Asp) confers an approximately 100-fold relative risk for developing type 1 diabetes. Those who are heterozygous with a single aspartic acid at position 57 (non-Asp/Asp) are less likely to develop diabetes and are no more susceptible than individuals who contain aspartic acid on both DQ *b* chains [i.e., homozygous Asp/Asp (Table 10-4)]. Some studies suggest that type 1 diabetes mellitus is proportional to the gene frequency of non-Asp alleles in that population.[65,74] In addition, arginine at position 52 of the DQ *a* chain confers marked susceptibility to type 1.[61] Position 57 of the DQ *b* and position 52 of the DQ *a* chains are at critical locations of the HLA molecule that permit or prevent antigen presentation to T-cell receptors and activate the autoimmune cascade (Figure 10-4).[65]

IDDM2 is a polymorphic marker near the transcription start site of the insulin gene, giving rise to variable numbers of tandem repeats (VNTR) at the promoter end of the insulin gene on chromosome 11. Each tandem repeat element consists of an approximately 14-bp DNA segment with a consensus nucleotide sequence. The number of repeats ranges from about 25 to about 200, and the three classes of alleles are based on overall size. Class I insulin VNTR consists of 26 to 63 repeats and confers susceptibility, whereas class III consists of 140 to 200 or more repeats and is protective of diabetes. Together, the gene markers on chromosomes 6 and 11 (i.e., IDDM1 and IDDM2) account for 50% to 60% of the heritability of type 1 diabetes. However, combinations of certain DQ alleles in association with certain DR alleles may confer susceptibility or protection to the development of type 1 diabetes (Table 10-5).

In addition, other as yet undefined genetic factors play a role because the same high-risk genotypes are about sixfold more likely to develop diabetes in an individual with a

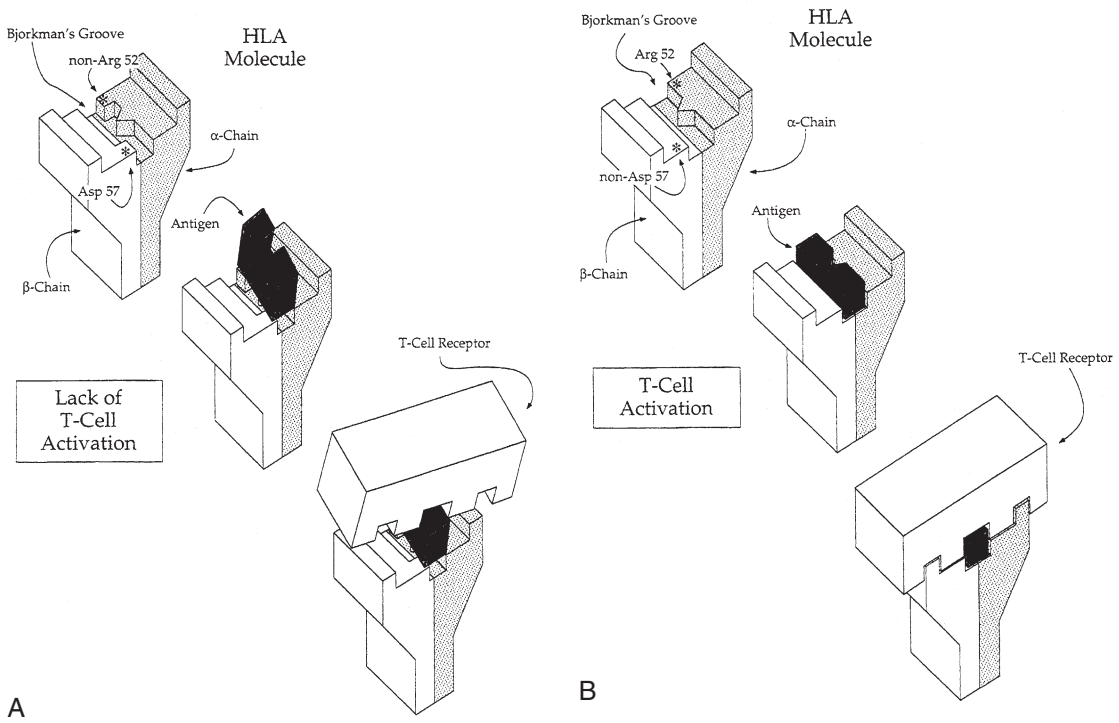

Figure 10-4. Representation of the interaction between antigen presentation in the context of specific HLA-DQ subtypes and the T-cell receptor. *(A)* Presence of aspartic acid at position 57 of the DQ *b* chain and an amino acid other than arginine at position 52 of the *a* chain prevents antigen lodging in the Bjorkman groove. Therefore, antigen presentation to the T-cell receptor is impaired—and in the absence of this "fit" T-cell activation is prevented. *(B)* Lack of aspartic acid at position 57 of the DQ *b* chain and arginine at position 52 of the DQ *a* chain permits antigen to fit and be recognized by the T-cell receptor that is now activated. [From Trucco M (1995). To be or not to be Asp 57, that is the question. Diabetes Care 15:705; and from Faas S, Trucco M (1995). The genes influencing the susceptibility to IDDM in humans. positive family history than in one without a family history without type 1 diabetes (Table 10-6). It was anticipated that as the human genome map and its proteins are increasingly defined more precise knowledge of genetics of type 1 diabetes would become available. Investigation of four genome-wide linkage scans in close to 1,500 families with more than one affected member having T1DM identified several susceptibility loci. Of these, about 40% can still be attributed to allelic variation of HLA loci, and the influence of the VNTR in the insulin gene was confirmed.

In addition, the cytotoxic T-lymphocyte antigen 4 (CTLA4) gene on chromosome 2 and the protein tyrosine phosphatase nonreceptor 22 (PTPN22) gene on chromosome 1p13 were found to contribute significantly to predisposition to T1DM. However, the genome scan identified other potential loci conferring susceptibility on chromosomes 2q31-q33, 10p14-q11, and 16q220q24 and a locus on the long arm of chromosome 6 (6q21) distinct from the HLA region on 6p21. The precise genes in these regions that may predispose to T1DM have not been identified as yet, although some have been excluded[69] and newer candidate genes [such as CBLB interacting with CTLA4,[70] the decay-accelerating factor gene (DAF, a complement inhibitor),[71] and the interleukin 2A receptor IL2RA] are under scrutiny.[63]

These considerations provide a rational framework for the long-recognized association of type 1 diabetes with genetic factors on the bases of the increased incidence in some families, of the concordance rates in monozygotic twins, and of ethnic and racial differences in prevalence.[64-67] From multiple family pedigrees and HLA typing data, it has been estimated that if a sibling shares both HLA D haplotypes with an index case the risk for that individual is 12% to 20%; for a sibling sharing only one haplotype, the risk for IDDM is 5% to 7%; and with no haplotypes in common, the risk is only 1% to 2%.[75] HLA typing is not recommended for routine practice, but for purposes of genetic counseling it can be safely assumed that in whites the overall recurrence risks to siblings is approximately 6% if the proband is younger than 10 years of age and 3% if older at the time of diagnosis. The risk to offspring is 2% to 5%, with the higher risk in the offspring of a diabetic father.[65,74]

Factors other than pure inheritance must also be involved in evoking clinical diabetes. For example, DR3 or DR4 is found in approximately 50% of the general population and (non-Asp/non-Asp) is found in approximately 20% of white nondiabetics in the United States. However, the risk for type 1 diabetes in these subjects is only one-tenth that in an HLA-identical sibling of an index case with type 1 diabetes possessing these markers.[76] Even siblings sharing only one haplotype have a sixfold to tenfold greater risk of developing type 1 compared with the normal population (Table 10-6).

Importantly, approximately 10% of patients with type 1 do not have HLA DR3 or DR4, although almost all white diabetics lack at least one aspartic acid at position 57 of the DQ β chain (Table 10-4).[73] Most compelling is the fact that the concordance rate among identical twins of whom one has insulin-dependent diabetes is only 30% to 50%, suggesting the participation of environmental triggering factors or other genetic factor such as the postnatal selection of certain autoreactive T-cell clones that bear receptors recognizing "self." This postnatal process occurs within the thymus and implies that identical twins are not identical with respect to the T-cell receptor repertoire they possess.

Triggering factors might include viral infections.[48,58,76] In animals, a number of viruses can cause a diabetic syndrome—the appearance and severity of which depend on the genetic strain and immune competence of the species of animal tested. In humans, epidemics of mumps, rubella, and coxsackievirus infections have been associated with subsequent increases in the incidence of type 1 diabetes. The acute onset of diabetes mellitus, presumably induced by coxsackievirus B4, has been described.[57,76] The viruses may act by directly destroying beta cells, by persisting in pancreatic beta cells as slow viral infections, or by triggering a widespread immune response to several endocrine tissues.

A superantigen response may be involved in triggering T cells, bypassing the classic presentation by antigen-presenting cells (APCs) of the processed antigen in the context of restricted HLA molecules to T-cell receptors.[72,77,78] Viruses and certain endotoxins or exotoxins are capable of inducing a superantigen response. In addition, the virus may induce initial beta cell damage—which results in the presentation of previously masked or altered antigenic determinants. It is also possible that the virus shares some antigenic determinants with those present on or in beta cells, including GAD, such that antibodies formed in response to the virus may interact with these shared determinants of beta cells—resulting in their destruction, an example of molecular mimicry.[78]

Early exposure to cow's milk may be a factor in triggering diabetes, thus explaining the reported lower incidence of diabetes among exclusively breast-fed infants. This is the basis for one ongoing primary prevention study: TRIGR (the Trial to Reduce Insulin-dependent Diabetes in Those Genetically at Risk).[79-84] Antecedent stress and exposure to certain chemical toxins have been implicated in the development of type 1 diabetes. Although the rodenticide Vacor has been a cause of diabetes in individuals deliberately or inadvertently poisoned by this agent, some of these patients had islet cell antibodies (ICAs), suggesting that such antibodies are secondary to islet damage or that evolving type 1 disease preceded the drug ingestion. Nitrosamines in cured meat have also been implicated in type 1 diabetes, as have other environmental toxins.[85,86]

Evidence supports an autoimmune basis for the development of type 1 diabetes.[5-8,78] Histologic examination of pancreas from patients with type 1 who die of incidental causes has revealed lymphocytic infiltration around the islets of Langerhans. Later the islets become progressively hyalinized and scarred, a process suggesting an ongoing inflammatory response that is possibly autoimmune. Eighty to 90% of newly diagnosed patients with type 1 diabetes have ICA directed at cell surface or cytoplasmic determinants in their islet cells. The prevalence of these antibodies decreases with the duration of established disease.[87-89] In contrast, after pancreatic transplantation ICA may reappear in patients whose sera had become negative for ICA before transplantation. Taken together, these findings suggest that ICA disappears as the antigens intrinsic to pancreatic islets are destroyed and reappear when fresh antigen (transplanted islets) is presented.[90]

Studies in identical twins and in family pedigrees demonstrate that the existence of ICA may precede by months to years the appearance of symptomatic type 1 diabetes.[6] In vitro, ICA may impair insulin secretion in response to secretagogues and can be shown to be cytotoxic to islet cells—especially in the presence of complement or T cells from patients with type 1 diabetes. As

many as 80% of patients may have antibodies to GAD, and 30% to 40% of newly diagnosed patients have spontaneous anti-insulin antibodies at initial diagnosis. These antibodies may be detected months to years before clinical diabetes becomes apparent.[91-94] There is also some evidence of abnormal T-cell function with an alteration in the ratio of suppressor to killer T cells at the onset of the disease.[5-8]

These findings suggest that type 1 diabetes (akin to other autoimmune diseases such as Hashimoto thyroiditis) is a disease of "autoaggression" in which autoantibodies in cooperation with complement, T cells, cytokines, FAS, and FAS's ligand (or other factors) induce apoptosis or destruction of the insulin-producing islet cells.[5-8] Thus, the inheritance of certain genes (such as those associated with the HLA system on chromosome 6 or other immunoregulatory or immunomodulatory genes) appears to confer a predisposition for autoimmune disease—including diabetes—when triggered by an appropriate stimulus such as a virus.[5-8] Evidence of superantigen-triggered T-cell receptor activation was discussed previously.[72,77,95]

Although it is understood that some insulin-dependent diabetic patients have none of the frequently associated HLA antigens, the evidence for an immune basis of islet cell destruction is sufficiently compelling to have fostered several studies of different immunosuppressive agents in the treatment of newly diagnosed diabetics (Table 10-7). None of these immunosuppressive agents has had long-term positive outcome, and some (e.g., cyclosporine) have proven toxic to beta cells. Although newer approaches are being attempted, all must be considered as experimental and not be viewed as established or recommended therapy.[91-94] The Diabetes Prevention Trial for T1DM (DPT1) was a multicenter randomized but nonblinded study using daily subcutaneous insulin and an annual admission for intravenous insulin infusion in first-degree relatives with proven risk factors for developing T1DM. Whereas prediction was highly accurate in identifying those most likely to develop T1DM within 5 years of entering the study, insulin injections had no protective effect to prevent the appearance of T1DM.[95,97,98]

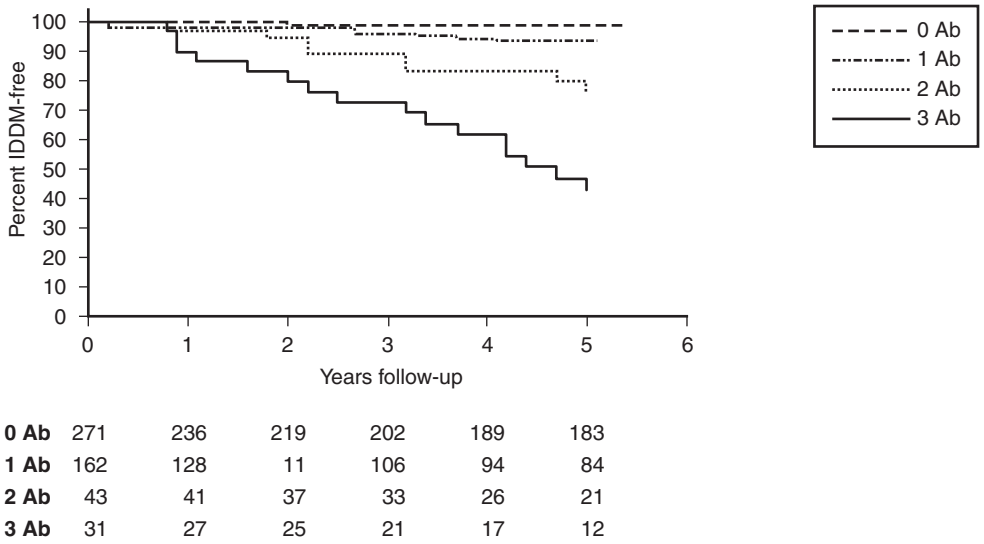
Oral Insulin for the Prevention of Diabetes in Relatives at Risk for Type 1 Diabetes

TRIGR - Trial to Prevent T1DM in Those Genetically at Risk via Cow's Milk Avoidance
Vitamin D supplementation

Figure 10-3 is a summary of current concepts of the cause of type 1 diabetes as an autoimmune disease, the tendency for which is inherited and in which autoimmune destruction of beta cells is triggered by an as yet unidentified agent (possibly a virus). The slope of decline in insulin varies, and there may be periods of partial recovery such that the course of decline in insulin secretion is bumpy rather than smooth. The point at which clinical features appear corresponds to approximately 80% destruction of insulin secretory reserve. This process may take months to years in adolescent and older patients, and weeks in the very young patient in whom acute destruction by nonautoimmune mechanisms may play a significant role. Higher titers of spontaneous anti-insulin antibodies and ICA are characteristic of more active islet cell destruction, typically in the younger patient, and may prove useful in predicting evolving diabetes.[88,93]



PREDICTION AND PREVENTION

Although no presently available single marker or test can accurately predict type 1 diabetes mellitus, evidence suggests that a combination of immune and genetic markers for type 1 diabetes may provide predictability.[89-94] Whereas some authorities suggest that type 1 diabetes is a predictable disease, other authorities have raised objections because predictability is not as robust in their studies. Definitive preventive therapy is not available, thereby raising ethical dilemmas, and the majority of new cases occur sporadically in the absence of a positive family history in a first-degree relative.[92]

Most predictive studies have been performed in first-degree relatives of patients with new-onset type 1 diabetes.[89-94] Nevertheless, there is increasing evidence that the presence of high titers of islet cell, GAD, IA2, and insulin autoantibodies combined with a consistently diminished first-phase response of insulin to a pulse of intravenous glucose (corresponding to the fifth percentile or less for age in insulin response) can be used to reliably predict the onset of type 1 disease.[89-94]

Figure 10-5 demonstrates that in a set of first-degree relatives conversion to type 1 diabetes was highly dependent on the number of antibodies detected in their sera. Of those with three antibodies, about half developed clinical diabetes within 5 years of follow-up. First-phase insulin response and genetic (HLA) markers may be used to augment the predictability. For example, Table 10-8 demonstrates that the relative risk of developing clinical diabetes within 4 years of detecting ICA is almost 230 among those who possess all four heterodimers in HLA DQ β that predispose to diabetes (i.e., Asp572/2 and Arg521/1).

As technologic improvements continue, it is likely that population-wide screening for antibody markers (alone or combined with specific genetic markers) will be available to identify those at risk for developing type 1 diabetes. Such population-wide screening would be ethically justified if prevention could be proven effective. Presently, the

data are sufficiently persuasive to have fostered national trials in Europe and the United States to predict and possibly prevent the clinical onset of type 1 diabetes through immune intervention strategies.[91-94,96-102]

The European Nicotinamide Diabetes Intervention Trial (ENDIT) was a multicenter trial that screened approximately 22,000 first-degree relatives of patients with type 1 diabetes to identify 500 considered to be at high risk for developing this disease.[99,100] These at-risk individuals were treated with nicotinamide or a placebo in a double-blind fashion. The purported advantage of nicotinamide is that it is not known to be toxic or harmful in humans at the recommended doses. Its major disadvantage is that its proposed protective effects in delaying diabetes were based on a small sample cohort. A smaller trial in Germany was abandoned as ineffective, and the results of ENDIT were equally disappointing.

The U.S. Diabetes Prevention Trial for T1DM (DPT-I) was based on promising pilot data that suggested preservation of insulin secretion and prevention of progression to diabetes mellitus in at-risk individuals treated with insulin.[97] Daily subcutaneous insulin, coupled with intensive intravenous insulin every 9 months, prevented diabetes for at least 3 years in five subjects considered to be at risk because of genetic markers, islet cell and insulin autoantibodies, and diminished first-phase insulin response. Among seven similar at-risk subjects who chose not to be treated, six developed insulin-dependent diabetes within 3 years.[97] DPT-1 was concluded in 2001, and there was no difference in the rates of developing diabetes among the placebo and insulin-treated groups. However, the ENDIT and DPT1 studies proved that large-scale multicenter studies could be successfully undertaken and that the prediction of progression to clinical diabetes was remarkably accurate. Thus, in those at highest risk (such as first-degree relatives of patients with T1DM) predicition is feasible and the discovery of a successful means of arresting or reversing progression to clinical diabetes is the subject of intense research.

Another study (TRIGR) involves 3,000 families in whom half will avoid cow's milk for the first 9 months of life to test the hypothesis that the ingestion of breast milk and avoidance of cow's milk formula (with its bovine syrum albumin [BSA]) may protect participants from the appearance of diabetes.[88,102] Several other studies are examining the utility of antibodies to the IL2 receptor, CD3 antibodies, immune suppressors such as mycophenolate mofetil, and immune modulators in preventing diabetes, including oral insulin. These studies are conducted by worldwide consortia of participating institutions (see *http://www2.diabetestrialnet.org*).

In animal models, oral insulin or oral GAD has been successfully used to prevent diabetes.[101] It is postulated

that ingestion of T-lymphocyte–dependent antigens can establish immunologic tolerance. Such oral strategies have been proposed and oral insulin is being tested in humans.[94] The subjects of primary prevention trials and secondary intervention trials to preserve residual insulin secretion at initial diagnosis are of major interest to investigators and clinicians alike. Progress is likely, but at present all of these strategies must be viewed as experimental and not currently in the domain of daily clinical practice.

INSULIN BIOSYNTHESIS

Insulin is synthesized on the ribosomes of pancreatic islet beta cells and released into the circulation as a molecule composed of two separate straight polypeptide chains linked by disulfide bridges between and within these chains.[103-114] The two chains are not synthesized separately but are derived from a larger precursor, proinsulin, a single coiled chain in which the NH_2 terminus of the A chain is linked to the COOH terminus of the B chain by a connecting peptide [C-peptide (Figure 10-6)]. An even larger precursor (preproinsulin, containing an additional peptide chain on the NH_2 terminus of the A chain) is first synthesized, but this additional piece (important to the initiation of synthesis) is rapidly excised. Further processing of proinsulin within the beta cell cleaves the C-peptide, consisting of 31 amino acids, from the insulin molecule at the sites indicated in the figure.

Defects in these cleavage sites are inherited in an autosomal-dominant manner and result in insulin molecules with less-than-normal biologic activity that can give rise to two types of familial hyperproinsulinemia. One defect yields B-C proinsulin, cleaved at site 1 but not at site 2 (Figure 10-6). This intermediate has 50% of the biologic activity of insulin, which is sufficient to prevent any abnormality in carbohydrate metabolism. The defect at site 1 yields A-C proinsulin, cleaved at site 2 but not at site 1, which has inadequate biologic activity to prevent carbohydrate intolerance. A structural mutation in the proinsulin molecule, between the C-peptide and insulin, has been confirmed.[107,110] In addition, a defect also occurs in the enzymatic conversion of a normal proinsulin molecule to insulin—yielding hyperproinsulinemia and mild carbohydrate intolerance.[103]

The proconvertases responsible for correct conversion of proinsulin to insulin are also involved in the processing of other hormones. Thus, impaired prohormone processing may lead to obesity and secondary hypocortisolism owing to defective processing of pro-opiomelanocortin (POMC) and to hypogonadotropic hypogonadism.[106,111-113] Native proinsulin has less than 5%, whereas C-peptide has none, of the biologic activity of insulin. During synthesis, the role of C-peptide appears to be the provision of the spatial arrangement necessary in the formation of the disulfide bonds. Other defects have been described in insulin biosynthesis involving substitution of amino acids in the B chain that lead to impaired glucose tolerance in the presence of hyperinsulinemia.[106,108]

The insulin gene has been cloned and localized to chromosome 11, and genetic defects in insulin synthesis may be associated with diabetes—especially the syndromes MODY1, -3, -5, and -6 with candidate genes for MODY7.[104,105,114] By some estimates, MODY syndromes may constitute 2% to 5% of all lean persons developing clinical diabetes between the ages of 10 and 30 years. The association of VNTRs in the insulin gene and genetic predisposition for diabetes have been described previously.

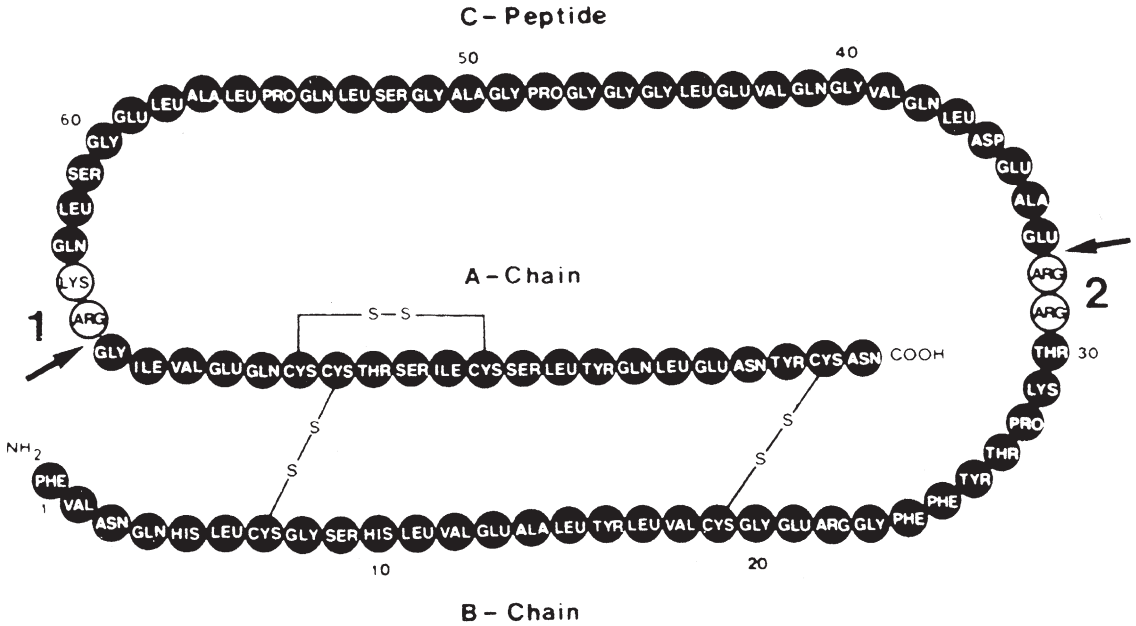

Figure 10-6. Structure of proinsulin. Arrows 1 and 2 indicate the two sites of normal cleavage that yield insulin and C-peptide when the amino acid residues indicated in the open circles are removed. These cleavage points are known mutation sites, are inherited in an autosomal-dominant manner, and can yield two types of familial hyperproinsulinemia. During insulin secretion, equimolar amounts of insulin and C-peptide are released.

Under normal circumstances, only small quantities of proinsulin are released into the circulation—amounting to less than 15% of total insulin as measured by radioimmunoassay (RIA). Even smaller quantities of proinsulin intermediates are also released. However, during insulin secretion induced by all stimuli one molecule of C-peptide is released with each molecule of insulin. Thus, the plasma of normal individuals contains small amounts of proinsulin, proinsulin intermediates, and almost equimolar amounts of insulin and C-peptide. The plasma metabolic half-life of C-peptide is, however, longer than that of insulin. Therefore, the molar ratio of C-peptide to insulin in peripheral plasma is always greater than 1 and the peak of C-peptide secretion or the nadir after suppression of release appears to occur later than that of insulin. Although standard RIA of insulin will also measure proinsulin, C-peptide will not be measured because it is immunologically distinct.

Separation of proinsulin from insulin can be achieved by chromatography to separate the larger proinsulin before assay. This is done with the use of an enzyme that degrades insulin but not proinsulin, or with the use of a C-peptide assay that will also measure proinsulin but not insulin. Because C-peptide is immunologically distinct, RIAs for this substance can be used to assess beta cell secretory reserve even in the presence of insulin antibodies formed in response to injections of bovine-porcine or human insulin.

Endogenous insulin secretion is accompanied by C-peptide release, whereas exogenous insulin administration suppresses endogenous insulin (and therefore C-peptide) secretion in all circumstances except insulinoma. Results of standard RIA with double-antibody precipitation are high in both circumstances. These attributes are important in distinguishing abuse of individuals by injection of exogenous insulin (high insulin, low C-peptide) from insulinomas or dysregulated insulin secretion (high insulin, high C-peptide) in casess of hypoglycemia. Measurements of C-peptide kinetics or of urinary excretion of C-peptide can be used as an index of endogenous insulin secretion.[115]

INSULIN SECRETION

Insulin secretion is governed by the interaction of nutrients, hormones, and the autonomic nervous system. Glucose, as well as certain other sugars metabolized by islets, stimulates insulin release. Basal and peak insulin levels are closely related to the glucose concentration, and prolonged fasting will further reduce glucose and insulin levels—which, however, remain in the measurable range at 2 to 5 mU/mL. There is evidence that a product or products of glucose metabolism may be involved in maintaining insulin secretion and that sugars not metabolized by islet cells do not promote insulin release.

The initial steps of glucose-stimulated insulin release are depicted in Chapter 5 in connection with mutations in the SUR(sulfonylurea receptor)-Kir6 (inward-rectifying potassium channel) complex of the adenosine triphosphate–regulated potassium channel K_{ATP} with the subsequent steps that may cause activation of glucose or amino acid–stimulated insulin secretion. This schema involves glucose transport into the beta cell through the GLUT2 glucose transporter and phosphorylation of glucose by means of glucokinase. Defects in the former are associated with type 2 diabetes, whereas heterozygous mutations in the latter are associated with MODY. Homozygous mutations in glucokinase result in permanent neonatal diabetes mellitus (as described in detail later in the chapter). Glucokinase defects are generally associated with normal insulin release at higher glucose concentrations, and therefore with a milder type of diabetes.[29] During glucose infusion in normal persons, insulin secretion is biphasic—with an initial spike followed by a sustained plateau. It is proposed that the initial spike represents preformed insulin, whereas the sustained plateau represents newly synthesized insulin.

Cyclic adenosine monophosphate (AMP) is involved in stimulating insulin release. Therefore, agents that inhibit phosphodiesterase and reduce cyclic AMP destruction (such as theophylline) augment insulin release. Translocation of calcium ions into the cytoplasm from the exterior as well as from the intracellular organelles plays a key role in the contractile forces that propel insulin to the cell surface.[116] There, the membrane of the insulin vesicle fuses with the cell membrane—allowing extrusion of insulin granules into the surrounding vascular space, a process known as emiocytosis. Other ions, including potassium and magnesium, are involved in the insulin secretion.[117-123] The sulfonylurea receptor is closely linked to potassium channels in the beta cell.[124-128] Amino acids also stimulate insulin release, although the potency of individual amino acids varies. A group of amino acids is more potent than any single one, and the insulin-secretory response is potentiated in the presence of glucose.[129] Free fatty acids and ketone bodies may also stimulate insulin release.[117-121,127]

Insulin responses to oral glucose administration are always greater than responses to intravenous administration of glucose that result in the same blood glucose profile.[128] This has led to the concept that gut factors modulate and increment insulin secretion. Although a variety of gut hormones participate in promoting insulin release,[128] gastrointestinal polypeptide (GIP) pancreatic glucagon and the glucagon-like peptides play a major role in stimulating insulin release. These properties have found application as agents, collectively named incretins, in augmenting insulin secretion in persons with T2DM and in some persons with T1DM. Somatotropin release-inhibiting factor (somatostatin), produced in the delta cells of islets, inhibits insulin and glucagon release and reduces splanchnic blood flow. These properties have found application to reduce insulin secretion in neonates with hyperinsulinemic hypoglycemia of infancy. Together, these factors may finely regulate nutrient intake and its disposition and form an enteroinsular axis for metabolic homeostasis.[117,118]

In addition to these gut hormones, several other hormones modulate insulin secretion. Growth hormone is involved in insulin synthesis and storage. Persons with congenital growth hormone deficiency have subnormal basal and stimulated insulin responses, whereas in acromegaly basal and stimulated insulin levels are increased.[129,130] Human chorionic somatomammotropin (also known as human placental lactogen), structurally

related to growth hormone, likewise affects insulin release. The stimulatory effect of each hormone on insulin secretion is antagonized by the anti-insulin effect at the peripheral level, however. Similarly, glucocorticoids and estrogens evoke greater insulin secretion while inducing peripheral insulin resistance—in part by decreasing insulin receptors on target cells.[129]

Insulin secretion is constantly modulated by the autonomic nervous system.[119] The parasympathetic arm, through the vagus, directly stimulates insulin release. Modulation of insulin secretion by the sympathetic arm depends on whether α- or β-adrenergic receptors are activated. Activation of β_2 receptors by agents such as isoproterenol stimulates insulin secretion by a process that involves cyclic AMP generation. Blockade of β-adrenergic receptors by propranolol blunts basal and stimulated insulin release. Conversely, activation of α-adrenergic receptors blunts insulin secretion, and blockade of these receptors by agents such as phentolamine augments basal and glucose-stimulated insulin release. Epinephrine and norepinephrine stimulate predominantly α-adrenergic receptors in islets, resulting in impaired insulin secretion—as observed during stress or in patients with pheochromocytoma.[119]

In summary, in normal humans insulin secretion is constantly modulated by the quantity, quality, and frequency of nutrient intake; by the hormonal milieu; and by autonomic impulses. The ingestion of nutrients, principally carbohydrate and protein, produces intestinal hormonal signals that prime and initiate insulin release. The entry of glucose into the beta cell, the phosphorylation of glucose, and the generation of adenosine triphosphate (ATP) by this or other nutrients result in insulin release. This sequence involves cyclic AMP, β-adrenergic receptors, and ions—principally calcium and potassium. Glucose metabolism within the beta cell provides energy for further synthesis and release of insulin.

INSULIN ACTION

Insulin action on target cells in tissues such as liver, adipocytes, and muscle begins by binding to specific insulin receptors located on the cell membrane. Binding to these receptors is saturable, occurs with a high energy of association (affinity), and is pH and temperature dependent.[27,131-136] The insulin receptor is a heterodimeric glycoprotein consisting of two α and two β subunits linked by disulfide bonds (Figure 10-7). The α subunit, with a molecular mass of approximately 125,000 kd, acts as the binding site—whereas the β subunit, with a molecular mass of approximately 90,000 kd, possesses tyrosine kinase activity for endogenous and exogenous substrates (Figures 10-7 and 10-8).

This ability to phosphorylate proteins may underlie some of the manifold actions of insulin. Among the classes of proteins phosphorylated are insulin receptor substrates 1 through 3 (considered an important insulin-signaling effector molecule) and pp 185, another substrate of the insulin receptor (Figure 10-8).[27,131-136] Other insulin mediators may be involved in insulin action. This action may also be mediated in part by hydrolysis of

glycan phosphoinositides in the cell plasma membrane.[137,138] The insulin receptor gene has been cloned and localized to chromosome 19, whereas the structurally related insulin-like growth factor-1 (IGF-1) receptor has been localized to chromosome 15.[131]

Under normal conditions, only a small proportion of the total available cell receptors need be occupied to achieve maximal biologic response. Thus, ordinarily there are spare receptors. Insulin receptors display two phenomena: down-regulation (in which high ambient insulin concentrations reduce the number of available receptors) and negative cooperativity, in which the occupancy of a receptor reduces the affinity of adjoining receptor sites. Scatchard analysis of insulin-binding data in in vitro systems reveals curvilinear plots compatible with negative cooperativity or with two classes of receptors: high-affinity/low-capacity and low-affinity/high-capacity. Total receptor number and the affinities of both classes of receptor sites can be calculated with use of these Scatchard plots.

After binding to the cell surface, the receptor-insulin complex is internalized within the cell and processed by lysosomal enzymes, with release of free insulin and potential recycling of the receptor back to the cell membrane. Binding of insulin to the cell surface receptor, perhaps with the participation of internalization that permits insulin action at the level of the nucleus, leads to the complex biochemical processes characteristic of insulin action in a given tissue. The ultimate mechanism or mechanisms by which insulin exerts its effects beyond receptor binding and phosphorylation remain unknown.

With postreceptor events assumed to be normal, however, the biologic response to insulin in a tissue is a function of the number of receptor/insulin complexes formed—which in turn is directly related to the circulating insulin concentration and to the receptor concentration. Thus, a reduction in receptor number could be compensated for by an increase in insulin concentration as long as the critical number of receptors necessary to produce maximal biologic response remains. Conversely, reduced insulin concentration could be compensated for by an increase in receptor number, provided the minimum amount of insulin necessary to produce a maximal biologic response is present.

Insulin receptors and their signaling proteins (Figures 10-7 and 10-8) are widely distributed in various tissues. Using targeted deletions of individual components or various combinations of components of the insulin receptor pathway has provided remarkable insight into the contribution of liver, muscle, fat, the beta cell, and brain to overall glucose homeostasis.[133-136] Key concepts that have emerged are that the insulin receptor signal cascade on beta cells is critically important in maintaining normal insulin secretion. Thus, mutations causing insulin resistance at the beta cell eventually lead to relative hypoinsulinemia that can interact with the insulin resistance in peripheral tissues to produce the hallmark of type 2 diabetes (i.e., peripheral insulin resistance plus relative insulinopenia).

In addition, studies with targeted deletion of the insulin receptor in the brain—the so-called NIRKO mouse (neuron-specific insulin receptor knockout)—demonstrate that these animals developed obesity, increased body fat, insulin resistance with modest hyperinsulinemia, and elevated levels of triglycerides. Reproductive function in both males and females is impaired as a result of abnormal regulation of luteinizing hormone secretion, and serum leptin levels are elevated.[136] Thus, insulin signaling in the brain joins the emerging list of factors important in regulating energy homeostasis and reproduction.

Clearly, primary defects in insulin receptor number or affinity may produce the same profound derangements

TABLE 10-9

Influence of Feeding (High Insulin) or Fasting (Low Insulin) on Some Metabolic Processes in Liver, Muscle, and Adipose Tissue*

	High Plasma Insulin (Postprandial State)	Low Plasma Insulin (Fasted State)
Liver	Glucose uptake	Glucose production
	Glycogen synthesis	Glycogenolysis
	Absence of gluconeogenesis	Gluconeogenesis
	Lipogenesis	Absence of lipogenesis
	Absence of ketogenesis	Ketogenesis
Muscle	Glucose uptake	Absence of glucose uptake
	Glucose oxidation	Fatty acid and ketone oxidation
	Glycogen synthesis	Glycogenolysis
	Protein synthesis	Proteolysis and amino acid release
Adipose tissue	Glucose uptake	Absence of glucose uptake
	Lipid synthesis	Lipolysis and fatty acid release
	Triglyceride uptake	Absence of triglyceride uptake

*Insulin is considered the major factor governing these metabolic processes. Diabetes mellitus may be viewed as a permanent low-insulin state that if untreated results in exaggerated fasting.

in intermediary metabolism as deficient insulin secretion, and similar disturbances may result despite normal insulin concentration and normal receptor characteristics if postreceptor steps are defective.[29,133-138] Insulin signaling for the regulation of metabolism has been the subject of considerable research and is extensively reviewed.[136,138] Examples of each type of defect in the individual components of this integrated system that comprises insulin biosynthesis, secretion, and action exist and can account for the metabolic abnormalities that characterize diabetes mellitus. An approach based on the principles of insulin biosynthesis secretion and action also permits a rational classification of diabetes mellitus.

PATHOPHYSIOLOGY

Normal insulin secretion in response to feeding is exquisitely modulated by the interplay of neural, hormonal, and substrate-related mechanisms to permit controlled disposition of ingested foodstuff as energy for immediate or future use. Mobilization of energy during the fasted state depends on low plasma levels of insulin. Thus, in normal metabolism there are regular swings between the postprandial high-insulin anabolic state and the fasted low-insulin catabolic state that affect three major tissues: liver, muscle, and adipose tissue (Table 10-9).

Insulin is the key anabolic hormone that promotes the synthesis and storage of carbohydrates, lipids, and proteins while simulataneously restraining their degradation. The uptake of glucose, fatty acids, and amino acids is stimulated—as is the activity or expression of enzymes that promote glycogen, fat, and protein synthesis. Conversely, the activity or expression of enzymes that break down these metabolites is restrained. All of these anabolic actions of insulin are reversed during the low-insulin state of starvation. Type 1 diabetes mellitus, as it evolves, becomes a permanent low-insulin catabolic (starvation) state in which feeding cannot reverse but rather exaggerates these catabolic processes.

It is important to emphasize that liver is more sensitive than muscle or fat to a given concentration of insulin. That is, endogenous glucose production from the liver by means of glycogenolysis and gluconeogenesis can be restrained at insulin concentrations that do not fully augment glucose utilization by peripheral tissues. Consequently, with progressive failure of insulin secretion the initial manifestation is postprandial hyperglycemia. Fasting hyperglycemia is a late manifestation that reflects severe insulin deficiency and indicates excessive endogenous glucose production.[139] Although insulin deficiency is the primary defect, several secondary changes that involve the stress hormones (i.e., epinephrine, cortisol, growth hormone, and glucagon) accelerate and exaggerate the rate and magnitude of metabolic decompensation.

Increased plasma concentrations of these counterregulatory hormones magnify metabolic derangements by further impairing insulin secretion (e.g., epinephrine), by antagonizing its action (e.g., epinephrine, cortisol, and growth hormone), and by promoting glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis (e.g., glucagon, epinephrine, growth hormone, and cortisol) while decreasing glucose utilization and glucose clearance (e.g., epinephrine, growth hormone, and cortisol).[140] With progressive insulin deficiency, especially with concurrently elevated stress hormones, excessive glucose production and impairment of its utilization result in hyperglycemia with glucosuria when the renal threshold of approximately 180 mg/dL is exceeded.

The resultant osmotic diuresis produces polyuria, urinary losses of electrolytes, dehydration, and compensatory polydipsia. These evolving manifestations, especially dehydration, represent physiologic stress—resulting in hypersecretion of epinephrine, glucagon, cortisol, and growth hormone that amplifies and perpetuates metabolic derangements and accelerates metabolic decompensation. The acute stress of trauma or infection may likewise accelerate metabolic decompensation to ketoacidosis in evolving or established diabetes.[140-142] Hyperosmolality,

commonly encountered as a result of progressive hyperglycemia, contributes to the symptomatology—especially to cerebral obtundation in diabetic ketoacidosis. Serum osmolality can be estimated with the following formula.

$$\text{Serum osmolality (mOsm/kg)} = (\text{serum Na [mEq/L]} + \text{K [mEq/L]}) \times 2 + \text{Glucose mmol/L} = \left(\frac{\text{mg/dl}}{18}\right)$$

Consideration of serum osmolality has important implications in the treatment of diabetic ketoacidosis. The combination of insulin deficiency and elevated plasma values of the counterregulatory hormones is also responsible for accelerated lipolysis and impaired lipid synthesis, with resulting increased plasma concentrations of total lipids, cholesterol, triglycerides, and free fatty acids. The hormonal interplay of insulin deficiency and glucagon excess shunts the free fatty acids into ketone body formation. The rate of formation of these ketone bodies, principally β-hydroxybutyrate and acetoacetate, exceeds the capacity for peripheral utilization and for their renal excretion. Accumulation of these ketoacids results in metabolic acidosis and in compensatory rapid deep breathing in an attempt to excrete excess carbon dioxide (Kussmaul respiration).

Acetone, formed by nonenzymatic conversion of acetoacetate, is responsible for the characteristic fruity odor of the breath. Ketones are excreted in the urine in association with cations and thus further increase losses of water and electrolytes (Figure 10-9, Tables 10-10 and 11-11). With progressive dehydration, acidosis, and hyperosmolality and diminished cerebral oxygen utilization, consciousness becomes impaired—with the patient ultimately becoming comatose. Thus, insulin deficiency produces a profound catabolic state—an exaggerated starvation in which all of the initial clinical features can be explained on the basis of known alterations in intermediary metabolism mediated by insulin deficiency in combination with counterregulatory hormone excess. Because the counterregulatory hormonal

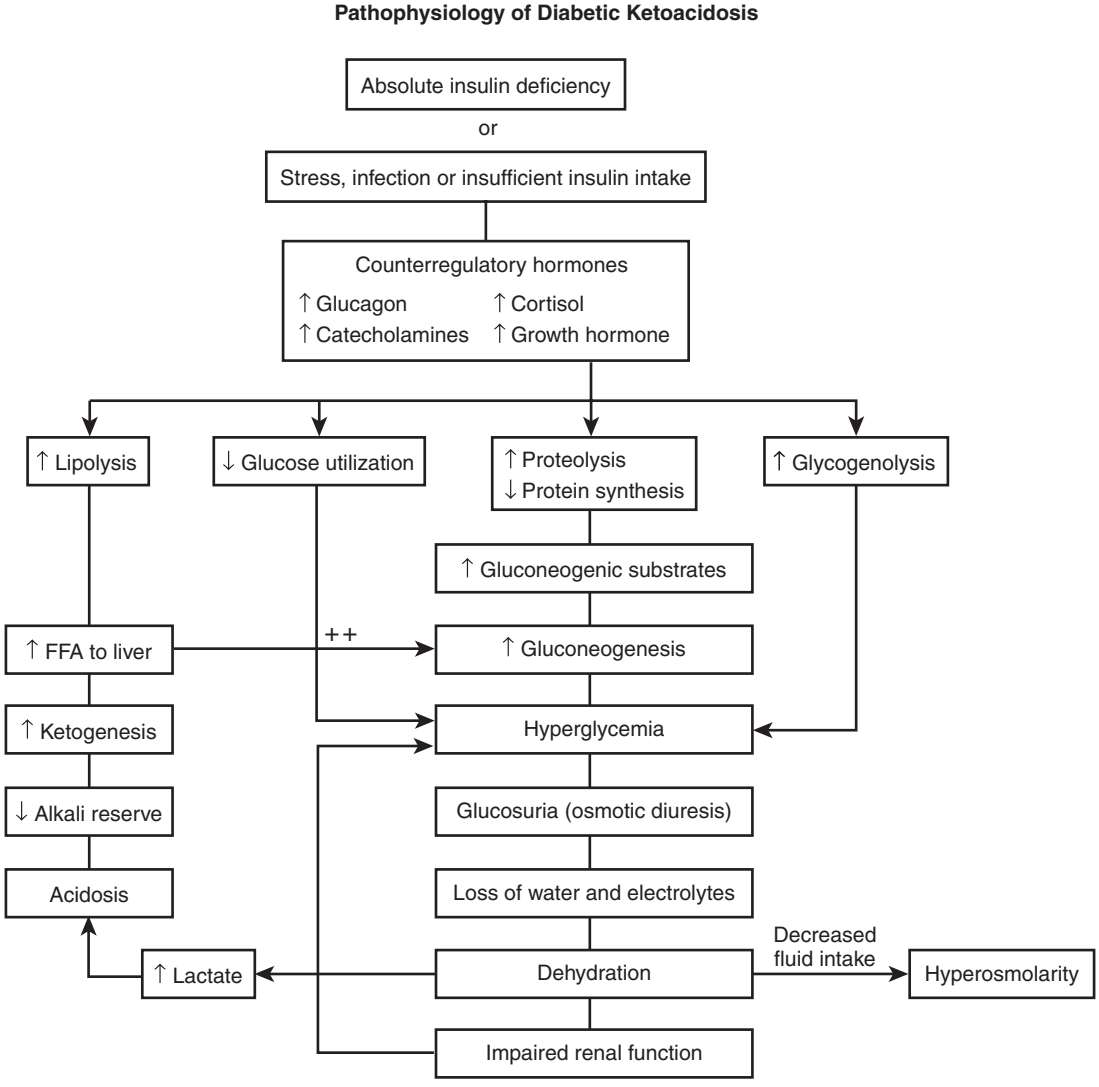

Figure 10-9. The pathophysiology of diabetic ketoacidosis is illustrated as a function of absolute insulin deficiency or insufficient insulin in the presence of major stress such as an infection, which leads to increases in the four major counter-regulatory hormones. Together, these changes increase glucose production via glycogenolysis and gluconeogenesis which together result in hyperglycemia, osmotic diuresis and dehydration. Simultaneously increase lipolysis leads to ketone body production and acidosis in combination with increased lactic acid from dehydration. See text for greater detail.

TABLE 10-10

Fluid and Electrolyte Maintenance Requirements and Estimated Losses in Diabetic Ketoacidosis

Approximate Daily Maintenance Requirements*		Approximate Accumulated Losses†
Water	1,500 mL/m^2	100 mL/kg (range, 60–100 mL/kg)
Sodium	45 mEq/m^2	6 mEq/kg (range, 5–13 mEq/kg)
Potassium	35 mEq/m^2	5 mEq/kg (range, 4–6 mEq/kg)
Chloride	30 mEq/m^2	4 mEq/kg (range, 3–9 mEq/kg)
Phosphate	10 mEq/m^2	3 mEq/kg (range, 2–5 mEq/kg)

* Maintenance is expressed in surface area to permit uniformity because fluid requirements change as weight increases.
† Losses are expressed per unit of body weight because the losses remain relatively constant in relation to total body weight.

changes are usually secondary, the severity and duration of the symptoms are a reflection of the extent of primary insulinopenia.[139-143]

CLINICAL MANIFESTATIONS OF DIABETES MELLITUS

The classic presentation of diabetes in children is a history of polyuria, polydipsia, polyphagia, and weight loss. Polyuria may be heralded by the recurrence of bedwetting in a previously toilet trained child and polydipsia by a child constantly requesting fluids to drink. Unexplained weight loss should raise suspicion of the existence of diabetes that should be confirmed or excluded by measurement of blood glucose concentration first in the postprandial and later in the fasting state. The urine should also be checked for the presence of glucosuria. The duration of these symptoms varies but is often less than 1 month.

An insidious onset with lethargy, weakness, and weight loss is also quite common. The loss of weight despite increased dietary intake is readily explicable by the following example. The average healthy 10-year-old child has a daily caloric intake of 2,000 or more calories, of which approximately 50% are derived from carbohydrates. With the development of diabetes, daily losses of water and glucose may be as much as 5 L and 250 g, respectively. This represents 1,000 calories lost in the urine, or 50% of average daily caloric intake. Therefore, despite the child's compensatory increased intake of food and water the calories cannot be utilized, excessive caloric losses continue, and increasing catabolism and weight loss ensue.

Pyogenic skin infections and candidal vaginitis in girls or candidal balanitis in uncircumsized boys are occasionally present at the time of diagnosis of diabetes. They are rarely the sole clinical manifestations of diabetes in children, and a careful history will invariably reveal the coexistence of polyuria, polydipsia, and perhaps weight loss. Ketoacidosis is responsible for the initial presentation of many (about 25 to 40%) diabetic children. Ketoacidosis is likely to be present more often in children younger than 5 years of age because the diagnosis may not be suspected and a history of polyuria and polydipsia may be difficult to elicit.[144,145] The early manifestations may be relatively mild and consist of vomiting, polyuria, and dehydration.

In more prolonged and severe cases, Kussmaul respiration is present—and there is an odor of acetone on the breath. Kussmaul respiration may be confused with bronchiolitis or asthma and be treated with steroids or adrenergic agents that worsen diabetes. Abdominal pain and/or rigidity may be present and may mimic appendicitis or pancreatitis. Cerebral obtundation and (ultimately) coma ensue and are related to the degree of hyperosmolarity. Laboratory findings include glucosuria, ketonuria, hyperglycemia, ketonemia, and metabolic acidosis. Leukocytosis is common, and nonspecific serum amylase levels may be elevated. The serum lipase level is usually not elevated. In those with abdominal pain, it should not be assumed that these findings are evidence of a surgical emergency before a period of appropriate fluid, electrolyte, and insulin therapy to correct dehydration and acidosis. The abdominal manifestations frequently disappear after several hours of such treatment.

DIAGNOSIS

Children in whom the diagnosis of diabetes mellitus must be considered may, for practical purposes, be divided into three general categories: those who have a history suggestive of diabetes, especially polyuria with polydipsia and failure to gain weight or a weight loss despite a voracious appetite; those who have a transient or persistent glucosuria; and those who have clinical manifestations of metabolic acidosis with or without stupor or coma. In all instances, the diagnosis of diabetes mellitus is dependent on the demonstration of hyperglycemia in association with glucosuria with or without ketonuria. When classic symptoms of polyuria and polydipsia are associated with hyperglycemia and glucosuria, the glucose tolerance test is contraindicated.

Renal glucosuria may be an isolated congenital disorder or a manifestation of the Fanconi syndrome and other renal tubular disorders owing to severe heavy metal intoxication, ingestion of certain drugs (e.g., outdated tetracycline), or inborn errors of metabolism (e.g., cystinosis). When vomiting, diarrhea, and/or inadequate intake of food are complicating factors in any of these conditions, starvation ketosis may ensue and simulate diabetic ketoacidosis. The absence of hyperglycemia eliminates the possibility of diabetes. It is also important to recognize that not all urinary sugar is glucose, and infrequently galactosemia, pentosuria, and the fructosurias will require consideration as diagnostic possibilities.

The discovery of glucosuria, with or without a mild degree of hyperglycemia, during a hospital admission for trauma or infection (or even during the associated emotional upheaval) may herald the existence of diabetes. In most of these instances, the glucosuria remits during recovery.[134] Because this circumstance may indicate a limited capacity for insulin secretion, which is unmasked by

elevated plasma concentrations of stress hormones, these patients should be rechecked at a later date for the possibility of hyperglycemia, clinical features of diabetes mellitus, and family history of diabetes.

A strong family history of diabetes mellitus in two preceding generations suggests the possibility of a MODY syndrome. Under these circumstances, a glucose tolerance test may be useful to establish a diagnosis. Glucose tolerance testing should be performed several weeks after recovery from the acute illness, with a glucose loading dose adjusted for weight. Evidence indicates that the test is most likely to be abnormal in those with HLA DR3 and DR4, in whom ICA or insulin autoantibodies are detected, or who have MODY.[147]

Transient hyperglycemia is common in patients with asthma treated with epinephrine and steroids. Further testing in such patients is not indicated. Screening procedures, such as postprandial determinations of blood glucose or oral glucose tolerance tests, have yielded low detection rates in children—even among those considered at risk, such as siblings of diabetic children. Accordingly, such screening procedures are not recommended in children.

DIABETIC KETOACIDOSIS

Diabetic ketoacidosis is a medical emergency and represents a life-threatening decompensation of metabolism that requires prompt recognition and appropriate treatment, with careful monitoring of clinical and biochemical indices. DKA must be differentiated from acidosis and coma from other causes. These include hypoglycemia, uremia, gastroenteritis with metabolic acidosis, lactic acidosis, salicylate intoxication, encephalitis, and other intracranial lesions. Diabetic ketoacidosis exists when there is hyperglycemia (glucose 300 mg/dL), ketonemia (ketones strongly positive at greater than 1:2 dilution of serum), acidosis (pH 7.30 or less and bicarbonate 15 mEq/L or less), glucosuria, and ketonuria in addition to the clinical features of tachypnea (Kussmaul respiration) and cerebral obtundation.

Precipitating factors, even for the initial presentation, include stress (e.g., trauma), infections, vomiting, and major psychological disturbances. Recurrent episodes of ketoacidosis in established diabetics often represent deliberate errors in recommended insulin dosage, unusual stress responses that indicate psychological disturbances, and at times pleas to be removed from a home environment perceived to be stressful or intolerable.[141] Diabetic ketoacidosis should also be distinguished from nonketotic hyperosmolar coma.[142,148,149]

Nonketotic hyperosmolar coma is a syndrome characterized by severe hyperglycemia (blood glucose concentration of more than 600 mg/dL), absence of or only very slight ketosis, nonketotic acidosis, severe dehydration, depressed sensorium or frank coma, and various neurologic signs that may include grand mal seizures, hyperthermia, hemiparesis, and positive Babinski signs. Respiration is usually shallow, but coexistent metabolic (lactic) acidosis may be manifested by Kussmaul breathing. Serum osmolarity is commonly 350 mOsm/kg or higher. This condition usually occurs in middle-aged or elderly individuals who have "mild" diabetes. Among them, mortality rates have been as high as 40% to 70%, possibly in part owing to delays in recognition and institution of appropriate therapy.

In children, this condition is infrequent. Among reported cases, there has been a high incidence of preexisting neurologic damage. The profound hyperglycemia may develop over a period of days, and initially the obligatory osmotic polyuria and dehydration may be partially compensated for by increased fluid intake. With progression, thirst becomes impaired—possibly because of alteration of the hypothalamic thirst center by hyperosmolarity and possibly in some instances because of a preexisting defect in the hypothalamic osmo-regulating mechanism.[142,148-150] More recently, nonketotic hyperglycemia with coma has been a feature of presentation in youth with T2DM and often associated with morbid obesity. Some of these obese patients may present with ketoacidosis as the initial clinical presentation.

The low production of ketones is attributed mainly to the hyperosmolarity, which in vitro blunts the lipolytic effect of epinephrine, and to the concomitant antilipolytic effect of residual insulin. Blunting of lipolysis by the therapeutic use of β-adrenergic blockers may also contribute to the syndrome. The key difference between diabetic ketoacidosis and hyperglycemic hyperosmolar nonketotic coma appears to be the degree of insulinopenia, which is nearly absolute in ketoacidosis but with sufficient residual activity in hyperglycemic hyperosmolar nonketotic coma to limit lipolysis in adipose tissue but inadequate to permit normal peripheral glucose utilization at a time of increased glucose production induced by the stress hormones. As indicated, prerenal azotemia and decreased thirst contribute to this syndrome in adults and in children. Depression of consciousness is closely correlated with the degree of hyperosmolarity in this condition, as well as in diabetic ketoacidosis. Hemoconcentration may also predispose to cerebral arterial and venous thromboses.[142,148-150]

Treatment of nonketotic hyperosmolar coma is directed at repletion of the vascular volume deficit and correction of the hyperosmolar state (see "Diabetic Ketoacidosis" for management). Patients who are hypotensive should be started on isotonic saline (0.9% NaCl) until the condition is stable. Then, treatment should proceed as for DKA—extending the period of repair to 36 to 48 hours. Insulin may be infused as for DKA or at half the amount used in DKA (i.e., 0.05 U/kg/hour. When the blood glucose concentration approaches 300 mg/dL, the hydrating fluid should be changed to 5% dextrose in 0.2N saline. Approximately 20 mEq/L of potassium chloride, or more if indicated, should be added to each of these fluids to prevent hypokalemia. Serum potassium and plasma glucose concentrations should be monitored at 2-hour intervals for the first 12 hours and at 4-hour intervals for the next 24 hours to permit appropriate adjustments of administered potassium and insulin.[142,148-150]

Insulin can be given by continuous intravenous infusion, beginning with the second hour of fluid therapy. Because blood glucose may decrease dramatically with fluid therapy alone, the intravenous loading dose should be 0.05 U/kg of fast-acting insulin followed

TABLE 10-11

Fluid Electrolyte Therapy for Diabetic Ketoacidosis: Recommendations for Replacement of Fluid

Replacement Fluids	Approximate Accumulated Losses with 10% Dehydration	Approximate Requirements for Maintenance (36 Hr)	Approximate Totals for Replacement and Maintenance (36 Hr)
Water (mL)	3,000	2,250	5,500
Sodium (mEq)	180	65	250
Potassium (mEq)	150	50	200
Chloride (mEq)	120	45	165
Phosphate (mEq)	90	15	100

Replacement Schedule (Continuous Intravenous Infusion)

Approximate Duration	Fluid (Composition)	Sodium (mEq)	Potassium (mEq)	Chloride (mEq)	Phosophate (mEq)
Hour 1	500 mL of 0.9% NaCl (isotonic saline)	75	—	75	—
Hour 2p	500 mL of 0.45% NaCl (0.5 isotonic saline) plus 20 mEq of KCl	35	20	55	—
Hour 3–12 (200 mL/hr for 10 hr)	2,000 mL of 0.45% NaCl with 30 mEq/L of potassium phosphate	150	60	150	40
Subtotal initial 12 hr	3,000 mL	260	80	280	40
Next 24 hr 100 mL/hr	2,400 mL of 5% glucose in 0.2% NaCl with 40 mEq/L of potassium phosphate	75	100	75	60
Total over 36 hours	5,400 mL	335	180	355	100

Note: Maintenance requirements remain the same. Losses and for maintenance of a 30-kg (surface area, 1.0 m^2) child with assumed 10% dehydration (duration of treatment, 36 hours). All replacement values should be halved if dehydration is estimated to be 5%.

Additional guidelines:

- A diabetic flowsheet with laboratory data appropriately recorded must be maintained in the patient's chart.
- Insulin therapy by continuous low-dose intravenous method: priming dose—bolus injection of 0.1 U/kg of regular insulin IV followed immediately by continuous IV infusion of 0.1 U/kg/hr of regular insulin beginning with second hour.
- Directions for making insulin infusion: Add 50 units of regular insulin to 500 mL of isotonic saline. Flush 50 mL through the tubing to saturate insulin-binding sites. For 30-kg patient, infuse at rate of 30 mL/hr. When the blood glucose concentration approaches 300 mg/dL, continue the insulin infusion at a reduced rate or add glucose to the infusate until acidosis is resolved and then start insulin therapy by subcutaneous injections of 0.2 to 0.4 U/kg of insulin at intervals of 6 hours.
- Bicarbonate therapy: For pH $\geq$ 7.10, no therapy is necessary. For pH 7.00 to 7.10, 40 mEq/m^2 of bicarbonate over 2 hours; then reevaluate. For pH $\leq$ 7.00, 80 mEq/m^2 of bicarbonate over 2 hours; then reevaluate. For new diabetics younger than 2 years of age with diabetic ketoacidosis and 10% dehydration or any diabetic with pH $\leq$7.00, coma or blood glucose $\geq$ 1,000 mg/dL should be managed in an intensive care unit or equivalent setting.

by 0.05 U/kg/hour of the same insulin—rather than 0.1 U/kg/hour as advocated for diabetic ketoacidosis. Some advocate that the initial insulin loading dose be omitted. During the recovery period, therapy with insulin and diet and monitoring of the patient are as described for patients recovering from diabetic ketoacidosis (Table 10-11).

TREATMENT OF DIABETES MELLITUS

The management of type 1 diabetes may be divided into three phases, depending on the initial presentation: ketoacidosis, the postacidotic transition period for establishment of metabolic control, and the continuing phase of guidance of the diabetic child and his or her family for daily living with diabetes integrating insulin regimens, nutritional intake, exercise, and glucose monitoring to achieve as near normal glucose control as is feasible. Each of these phases has separate goals, although in practice they merge into a continuum. For purposes of management, the transition period corresponds to presentations with polyuria, polydipsia, and weight loss but without biochemical decompensation to ketoacidosis.

Treatment of Diabetic Ketoacidosis

The pathophysiology and treatment of diabetic ketoacidosis was extensively reviewed and published as a consensus conference. The views and recommendations are endorsed by the Lawson Wilkins Pediatric Endocrine Society, the European Society for Pediatric Endocrinology, the International Society of Pediatric and Adolescent Diabetes, and others. Similar guidelines for management have now also been recommended by the American Diabetes Association.

The immediate aims of therapy are expansion of intravascular volume; correction of deficits in fluid, electrolyte, and acid-base status; initiation of insulin therapy to correct intermediary metabolism; and the exclusion of a treatable precipitating event such as infection or trauma. Treatment should be instituted as soon as the clinical diagnosis is confirmed by the presence of hyperglycemia and ketonemia. Determinations of blood pH and electrolytes should also be obtained. An electrocardiogram is useful to provide a rapid reference for the existence of hyperkalemia.

If sepsis is suspected as a possible precipitating factor, a blood culture should be obtained and the urine should be examined for the presence of bacteria and leukocytes. A flow sheet is essential to record chronologically the rate and composition of fluid input and urine output, the amount of insulin administered, and the acid-base and electrolyte values of the blood. Catheterization of the bladder is not routinely recommended in children. Bag collection or condom drainage permits an assessment of urinary output, but catheterization may be indicated in comatose patients.[141-154]

Fluid and Electrolyte Therapy. The expansion of reduced intravascular volume and correction of depleted fluid and electrolyte stores are important in the treatment of diabetic ketoacidosis (Tables 10-10 and 10-11). It must be stressed, however, that exogenous insulin is essential to arrest further metabolic decompensation and restore intermediary metabolism.[141-145,154] Dehydration is commonly approximately 10%. Initial fluid therapy can be based on this estimate, with subsequent adjustments to be related to clinical and laboratory data. The initial hydrating fluid should be isotonic saline (0.9%). Because of the hyperglycemia, hyperosmolarity is universal in diabetic ketoacidosis. Thus, even 0.9% saline is hypotonic relative to the patient's serum osmolality.

A gradual decline in osmolality is desirable because too rapid a decline has been implicated in the development of cerebral edema, one of the major complications of therapy in children. For the same reason, the rate of fluid replacement is adjusted to provide the total calculated deficit plus maintenance requirement over 48 hours after the initial rehydration with normal isotonic salinel. In addition, administration of glucose (5% solution in 0.2-0.5 N saline) is initiated when blood glucose concentration approaches 300 mg/dL to limit the decline of serum osmolality in an attempt to reduce the risk of developing cerebral edema (Table 10-11). Insulin should be continued until ketoacidosis is resolved and the pH is equal to or greater than 7.3 or the bicarbonate concentration in plasma equal to or greater than 18 mEq/L because blood glucose corrects more rapidly than ketoacidosis. As long as acidosis persists, insulin infusion should be maintained at the same rate (and, if necessary, with 5% to 10% glucose added to the infusate) to maintain blood glucose at approximately 300 mg/dL.

Cerebral Edema. Cerebral edema is an unusual but potentially devastating complication of diabetic ketoacidosis and its management in childhood. There is considerable debate and several hypotheses have been proposed, but there is presently no consensus as to the precise cause of this syndrome. It remains unproved whether cerebral edema during treatment of diabetic ketoacidosis can be predicted on the basis of clinical and biochemical indices and whether physicians contribute to it by their mode of management through the choice and composition of the hydrating fluid, its rate of administration, and the controlled rate of decline of blood glucose.[144,145,155-160]

The incidence of cerebral edema is reported to occur in 0.5% to 1.5% of all episodes of diabetic ketoacidosis. It is more common in younger children, especially at initial presentation.[144] Duration and severity of symptoms and signs before initiating treatment are the major identifiable factors.[144] If cerebral edema develops during treatment for diabetic ketoacidosis, mortality and morbidity are high. Although mortality has declined from previously reported rates of 40% to 90% to a more recently reported rate of 20%, cerebral edema remains the cause of about one-half of all deaths in children with diabetes mellitus. Morbidity from cerebral edema also remains high. About one-fourth of the survivors may have permanent neurologic sequelae.[144,145,160] Prompt recognition and intervention with mannitol or other hyperosmolar agents, respiratory support by means of endotracheal intubation, and hyperventilation may be lifesaving. Awareness, early recognition, and treatment are responsible for the reported decline in mortality cited previously.[141] Subclinical cerebral edema may be more common than hitherto appreciated.[146]

Randomized prospective trials of management of diabetic ketoacidosis are not ethically feasible, but in the most rigorous and extensive retrospective analysis involving some 6,000 episodes of diabetic ketoacidosis the following risk factors were identified: young age, duration and severity of symptoms before starting treatment, low PCO_2, high serum urea nitrogen, lack of an increase in serum sodium during therapy, and treatment with bicarbonate.[144,145] All of the biochemical risk factors in this study may reflect the initial severity of biochemical derangement. Thus, avoidance of diabetic ketoacidosis (especially in young children) by early recognition of the signs and symptoms of diabetes mellitus is the best way to prevent cerebral edema.

The duration and severity of symptoms before therapy may predispose to cerebral ischemia, to which younger children would be more prone because of the higher metabolic rate and hence higher oxygen requirement of a child's brain relative to an adult's. In addition, there may be a longer time to accumulate so-called idiogenic osmoles in the brain. Many children may have evidence of raised intracranial pressure on imaging studies (e.g., computed tomography), but only a minority develop clinical cerebral edema.[161]

Moreover, early studies in dogs and in adult men demonstrated that intracranial pressure rose in all during fluid replacement therapy for diabetic ketoacidosis.[162,163] Thus, given the hyperbolic pressure/volume relationship of the intracranial space and the likely shift of water into the intracellular compartment during therapy it is considered prudent to advocate the use of normal saline (or equivalent volume expanders) during initial therapy to limit the rate of infusion to no more than twice-daily maintenance requirement and not to exceed 4.0 L/m^2/day, to carefully monitor the decline in blood glucose not to exceed about

100 mg/dL/hour, and to carefully monitor the clinical status of the patient. The managing team must be prepared to intervene at the bedside with mannitol or other volume expanders.

Finally, it should be noted that abnormalities in the clotting-fibrinolytic pathway (e.g., protein S and C deficiency, factor V Leiden) are not uncommon in the general population and may contribute to cerebral thrombosis/ischemia in the setting of dehydration, hyperviscosity, and increased platelet adhesiveness that exists in diabetic ketoacidosis.[145,160] There is also evidence that the osmotic mechanisms described previously, the so-called cytotoxic mechanism, may not be the only operative theory. Vasogenic mechanisms with disruption of vascular permeability in the cerebral blood-brain barrier may also be operative. The latter comes from studies via perfusion and diffusion MRI that show a decrease in the apparent diffusion coefficient after recovery (i.e., more pericellular and not intracellular water during DKA treatment). Moreover, in that study one in five episodes of cerebral edema was evident at initial presentation before any fluid or insulin therapy could have contributed to water accumulation in the brain. The two proposed mechanisms are not mutually exclusive and may allow more treatment options in time.

Cerebral edema may be present at initial presentation or early in the course of treatment, but it usually becomes apparent several hours after therapy has begun and when there is improvement in blood glucose level, acid-base status, and clinical state of hydration. Both early and late appearance of cerebral edema have been reported.[144,145] A previously alert patient may become drowsy, complain of headache, have abnormal neurologic findings (including papilledema), progress to coma, and have respiratory arrest with herniation of the brain stem. Recovery may occur with prompt recognition and treatment with intravenous mannitol. Survival and neurologic outcome are markedly improved with prompt recognition and intervention as outlined (Table 10-12).[144,145,157–160] Although clinically apparent cerebral edema is often fatal, subclinical cerebral edema is present in many patients during therapy for ketoacidosis.[161] A series of bedside clinical observations may facilitate the recognition and prediction of those developing cerebral edema during therapy for DKA. The series of major and minor criteria proposed by Muir et al. remains uncorroborated.

Electrolytes. Administration of potassium should be started early. Total body potassium may be considerably depleted during acidosis, even when the serum potassium concentration is normal or elevated. Although potassium moves from intracellular to extracellular sites during acidosis, the reverse occurs during correction of acidosis—particularly when exogenous insulin and glucose are available in the circulation. This shift of potassium back to the intracellular compartment may result in life-threatening hypokalemia. Therefore, after the initial fluid replacement of approximately 20 mL/kg of isotonic saline (0.9%) has been provided potassium should be added to subsequent infusates if urinary output is adequate. Serum potassium concentration should then be monitored periodically.

An electrocardiogram provides a rapid assessment of serum potassium concentration. T waves are peaked in hyperkalemia and are low and associated with U waves in hypokalemia. Because the total potassium deficit cannot be replaced within the initial 24 hours of treatment, potassium supplementation should be continued as long as fluids are administered intravenously (Table 10-7).

It is almost inevitable that the patient will receive an excess of chloride, which may aggravate acidosis. The extent of acidosis, however, can be reduced by substitution of phosphate—which is also significantly depleted in

TABLE 10-12

Steps in Management of Diabetic Ketoacidosis

1. Confirm diagnosis.
   Obtain:
   - Blood glucose
   - Serum electrolytes
   - Acid-base status: pH, HCO_3^2

   Consider:
   - Urine microscopy/culture
   - Chest radiograph
   - Blood culture
   - Throat culture
   - Electrocardiogram

   Intensive care–like setting:
   - pH≤7.00
   - Age 2 years
   - Unconscious
   - Blood glucose≥ 1,000 mg/dL
2. Begin intravenous fluids.
   - 20 mL/kg of 0.9% (normal), saline (NaCl) over 1 hour
3. Reassess the patient: What precipitated this episode?
   - Delayed diagnosis
   - Infection
   - Noncompliance
   - Trauma
4. Follow protocol guidelines in Table 10-11. Begin insulin 0.1 U/kg/hr with hour 2 of IV therapy as outlined in Table 10-11.
5. Measure glucose every 2 hours; electrolytes/acid-base every 2 to 4 hours for the first 24 hours.
6. Continue treatment with insulin even if glucose approaches 300 mg/dL (17 mM) as long as acidosis persists. Consider adding 5 to 10% glucose in IV line or occasionally reducing insulin to 0.05 U/kg/hr.
7. If acidosis is not resolving (or improving) despite fluids and insulin of 0.1 U/kg/hr, consider:
   - Severe sepsis causing lactic acidosis and/or insulin degradation
   - Error in insulin dose
8. In children younger than 10 years (especially, 5 years), anticipate possible clinical cerebral edema after 4 to 6 hours of treatment. The following herald evolving edema:
   - Headache
   - Change in consciousness level/response
   - Unequal dilated pupils
   - Delirium
   - Incontinence
   - Vomiting
   - Bradycardia
9. If cerebral edema is clinically apparent:
   - Reduce IV rate.
   - Give mannitol 1 g/kg IV (10-20 g/m^2).
   - Repeat in 2 to 4 hours if indicated.

diabetic ketoacidosis. Moreover, phosphate in conjunction with glycolysis is essential to the formation of 2,3-diphosphoglycerate (2,3-DPG)—which governs the oxygen dissociation curve. During deficiency of 2,3-DPG, the oxygen dissociation curve is shifted to the left (i.e., more oxygen is retained by hemoglobin and less is available to tissues, a situation that predisposes to lactic acidosis).

Acidosis per se tends to shift the oxygen dissociation curve toward the right (Bohr effect) and thus partially "compensates" for 2,3-DPG deficiency. As acidosis resulting from the accumulation of ketones is corrected by the provision of insulin, with or without administration of bicarbonate, the effects of 2,3-DPG deficiency may no longer be compensated for and the release of oxygen to tissues may again be impaired. Exogenous phosphate, by contributing to the formation of 2,3-DPG, permits the oxygen dissociation curve to shift to the right and thus facilitates release of oxygen to tissues and aids in the correction of acidosis. Furthermore, resistance to insulin action is associated with hypophosphatemia.[141] Therefore, the use of phosphate is recommended (the administration of potassium phosphate is outlined in Table 10-11). Because excessive use of phosphate may result in hypocalcemia, serum calcium should be measured periodically. Symptomatic hypocalcemia should be corrected with calcium gluconate, and potassium chloride should be temporarily substituted for potassium phosphate.[164,165]

Alkali Therapy. With provision of fluids, electrolytes, glucose, and insulin, metabolic acidosis is usually corrected through the interruption of ketogenesis, the metabolism of ketones to bicarbonate, and the generation of bicarbonate by the distal renal tubule. Concern regarding the therapeutic administration of bicarbonate centers on four issues: alkalosis, by shifting the oxygen dissociation curve to the left, may diminish the release of oxygen to tissues and therefore predispose to lactic acidosis; alkalosis accelerates the entry of potassium into cells and therefore may produce hypokalemia; the provision of bicarbonate according to the calculated base deficit overcorrects and may result in alkalosis; and perhaps most important, bicarbonate may lead to worsening of cerebral acidosis during the time when the plasma pH is being restored to normal because HCO_3^- combines with H^+ and dissociates to CO_2 and H_2O to form H_2CO_3.

Although bicarbonate passes the blood-brain barrier slowly, CO_2 diffuses freely, thereby potentially exacerbating cerebral acidosis and possibly cerebral depression. On the other hand, severe acidosis (with blood pH of about 7.1) diminishes respiratory minute volume, may produce hypotension by peripheral vasodilation, impairs myocardial function, and may be a factor in insulin resistance. For these reasons, administration of bicarbonate is recommended only at pH of about 7.1 or less (Table 10-11). At pH of 7.0 to 7.1, we recommend that 40 mEq of HCO_3^-/m^2 (at pH of less than 7.0, 80 mEq of HCO_3^-/m^2) should be infused over a period of 2 hours. Acid-base status should then be reevaluated before further alkali therapy. Bicarbonate should not be given by bolus infusion because it may precipitate cardiac arrhythmias.[144,154,166]

Insulin Therapy. The continuous low-dose intravenous infusion method, in which a priming dose of 0.1 U/kg of regular insulin is followed by a constant infusion of 0.1 U/kg/hour, is outlined in Table 10-11. This method is effective, simple, and physiologically sound—and has gained acceptance as the recommended method for administering insulin during diabetic ketoacidosis. It provides a constant steady concentration of insulin in plasma that approximates the peak attained in normal individuals during an oral glucose tolerance test.

Presumably, the same steady concentration is attained at the cellular level and permits a steady metabolic response without the fluctuations that must occur with intermittent injections of insulin. Concern that the insulin may adhere to glass and tubing has proved to be unfounded, and effective delivery of insulin can be provided without the addition of albumin or gelatin to the infusate. Although insulin infusion can be provided by gravity drip without the use of a special pump, such a pump is helpful. A separate infusion set for insulin connected to the infusion line used for fluid and electrolyte therapy is recommended so that adjustments in the dosage of each can be made independently. After the amount of insulin has been calculated, for the initial 6 to 8 hours this quantity is diluted in a 50-mL syringe containing 0.9% saline infused via a separate pump but connected to the fluid infusate (see Table 10-11 for specific instructions).

When the blood glucose concentration approaches 300 mg/dL, the ongoing potassium requirement is added to 5% glucose in 0.2 to 0.5 N saline (Table 10-11) and the rate of insulin infusion may be reduced from 0.1 to 0.05 U/kg/hour, provided acidosis is correcting. The rate of insulin infusion should, however, be periodically adjusted based on recovery of acidosis and the blood glucose response of each individual.[141,142,165]

In treating diabetic ketoacidosis, it is regularly observed that blood glucose concentration corrects more quickly than pH or plasma bicarbonate.[165-167] Insulin must be provided by infusion or subcutaneous injection as long as acidosis persists, even if glucose approaches 300 mg/dL. It may be necessary to add glucose to the infusate while continuing insulin infusion at a rate of 0.05 to 0.1 U/kg/hour until acidosis is corrected. If acidosis persists despite these measures, a cause such as gram-negative sepsis should be considered.

The essential steps in managing diabetic ketoacidosis are summarized in Tables 10-11 and 10-12. When acidosis is corrected, the continuous infusion may be discontinued and insulin immediately given by subcutaneous injection at a dosage of 0.2 to 0.4 U/kg every 6 to 8 hours while the glucose infusion is maintained until the child can fully tolerate food. Subcutaneous injections of regular insulin at dosages of 0.2 to 0.4 U/kg every 6 to 8 hours before meals should be continued for a full 24-hour day after the child is eating. The blood glucose level should be monitored before and 2 hours after each meal, with the insulin dose adjusted to maintain blood glucose concentration in the range of 80 to 180 mg/dL. The total dose of regular or fast-acting insulin used in this representative day serves as a guide for subsequent insulin treatment with a combination of intermediate- and short-acting insulin, as described later in the chapter.

Ketonemia and ketonuria may persist despite clinical improvement. The nitroprusside reaction routinely used to measure ketones reacts with acetoacetate and weakly with acetone but not with β-hydroxybutyrate. The usual ratio of β-hydroxybutyrate to acetoacetate is approximately 3:1, but is commonly 8:1 or more in diabetic ketoacidosis. With correction of acidosis, β-hydroxybutyrate dissociates to acetoacetate—which is identified by the nitroprusside reaction. Therefore, persistence of ketonuria for 1 or more days may not reliably reflect the clinical improvement and should not be interpreted as an index of poor therapeutic response.

Living with Diabetes

GENERAL PRINCIPLES

Optimal management of the child with diabetes requires an integrated approach, taking into account the overall level of functioning of the child and family, the nutritional and lifestyle patterns specific to that child, and attention to the overall developmental stages of childhood and adolescence. There is no one appropriate insulin regimen or meal plan. The overriding principle should be that the diabetes care plan should fit wherever possible into the surrounding home and school environments, and that the primary childhood tasks of education, socialization, growth, and maturity continue unhindered by the extra responsibilities diabetes care entails.

This potentially daunting task requires a multidisciplinary team, consisting of physicians, nurses, dietitians, and mental health professionals all trained and experienced in the nuances of diabetes care. Children with diabetes should be seen by the team at frequent intervals for assessment of glycemic control, growth and development; evaluation for related disorders and complications, education, troubleshooting, problem solving, and screening for adjustment problems that may affect diabetes and/or the overall health of the child.

GOALS OF THERAPY

As a result of the Diabetes Control and Complications Trial (DCCT) and its follow-up Epidemiology of Diabetes Interventions and Complications (EDIC) study,[168-170] current recommendations mandate that youth with T1DM should aim to achieve plasma glucose and HbA1c levels as close to normal as possible—as early in the course of the disease as possible and with as few severe hypoglycemic events as possible. A particular challenge in the care of children with T1DM is to make the treatment regimens that are employed to achieve these goals of treatment consistent with the general principles of care summarized previously.

Remarkably, a much greater proportion of young patients are able to meet these strict standards of care than imagined possible only a few years ago.[171] Moreover, recent data suggest that an intensive approach to diabetes education and aggressive self-management by patients and families may reduce rather than increase the adverse psychosocial effects of this chronic illness.[172]

TYPES OF INSULIN

Currently available insulins and their duration of action are listed in Table 10-13. They are classified as rapid-, short-, intermediate-, and long-acting and each is available in a concentration of 100 U/mL (U-100). Higher concentrations are available for the unusual patient who has high resistance to insulin. Appropriate dilutions can be prepared for younger patients requiring low doses. The development of recombinant DNA technology to synthesize human insulin and human insulin analogs has changed the face of insulin treatment over the past several years.

The traditional "short-acting" regular insulin has now been supplanted by new insulin analogs with more rapid time-action profiles.[173-176] Lispro (Eli Lilly), aspart (Novo Nordisk) and glulisine (Sanofi Aventis) insulins are produced by amino acid substitutions in the C-terminal region of the B-chain that reduce the affinity for insulin molecules to self-aggregate into hexamers. Consequently, these modifications allow more rapid absorption of the analog into the bloodstream after subcutaneous injection. The advantages of rapid-acting analogs in comparison to regular insulin include more rapid onset, sharper and higher peak concentrations, and shorter duration of action.[177] Thus, insulin is available immediately to cover meal-related glucose excursions and does not persistent as long after the complete absorption of the carbohydrates in the meal. Clinical trials of these analogs have demonstrated improvements in postprandial hyperglycemia and lower rates of hypoglycemia compared to regular insulin.[178] Regular human insulin has been relegated to use in the hospital for intravenous administration.

The pharmaceutical industry has terminated the manufacture of lente insulins, leaving NPH as the only remaining intermediate-acting insulin suspension. Although still employed in some "split-mix" regimens to avoid the need for insulin injections at lunch time or mid-afternoon, the dose-to-dose variability and peaking action of NPH make it less than satisfactory for basal insulin replacement—especially during the overnight period.[179]

TABLE 10-13

Pharmacodynamic Properties of Common Insulin Formulations

Category	Onset (Hr)	Peak (Hr)	Duration (Hr)
Rapid acting insulin lispro, aspart, and glulisine	0.25-0.5	0.5-1	3-5
Short-acting regular	0.5-1	2-4	4-8
Intermediate-acting NPH	2-4	4-10	12-18
Long-acting insulin glargine and detemir	2-4	n/a	18>24
Premixed			
Mix 25 (75% NPH/25% lispro)	0.25-0.5	1-2	12-18
Novolog mix (70% NPH/30% aspart) from living with diabetes	0.25-0.5	1-2	12-18

Glargine (Sanofi Aventis) insulin is a new analog of human insulin with C-terminal elongation of the β-chain by two arginine residues and replacement of asparagine in position A21 by glycine. This molecule is soluble in the acidic solution in which it is packaged but relatively insoluble in the physiologic pH of the extracellular fluid. Consequently, microprecipitates of glargine insulin are formed following subcutaneous injection, which markedly delays its absorption into the systemic circulation.

Pharmacokinetic and pharmacodynamic studies have demonstrated that the insulin analog has a very flat and prolonged time-action profile.[180] Results of preliminary studies of the efficacy and safety of glargine in children and adolescents with diabetes showed modestly lower fasting blood glucose levels and reduced risk of nocturnal hypoglycemia with glargine compared to human NPH insulin, although no differences in HbA1c were noted.[181,182] Because glargine cannot be mixed with other insulins, it has to be given by separate injection—which might affect its acceptability by some youngsters. Detemir (Novo Nordisk) insulin is the second soluble long-acting insulin approved by the FDA.

A prolonged and flat time-action profile was produced with this insulin analog by an amino acid deletion and fatty acid addition that result in extensive binding to albumin in the interstitium and circulation. Compared to glargine, detemir insulin appears to have less day-to-day variability in its pharmacodynamics effects[179] but may have a shorter duration of action.[183] Current experience with this insulin in pediatrics is limited. Because glargine and detemir are not approved for mixing with other insulins, they should be given by separate injection—which might affect their acceptability by some youngsters.

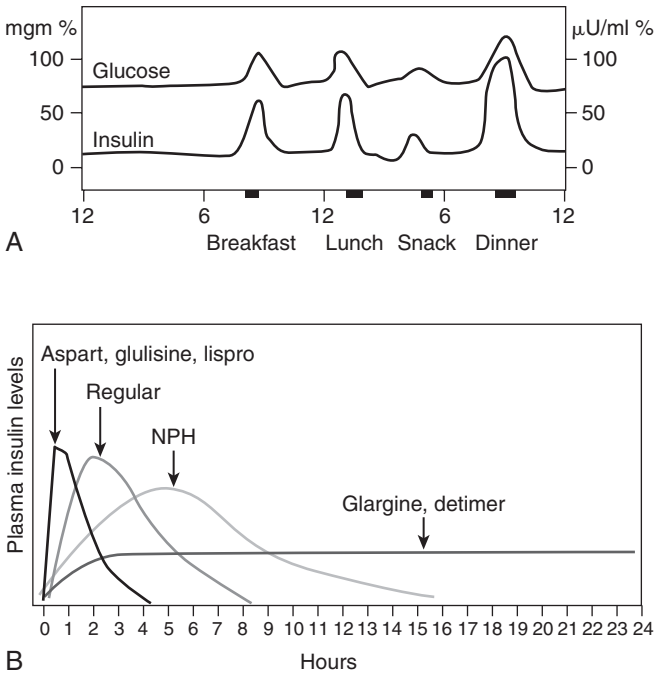

Figure 10-10. *(A)* and *(B)* Representation of the normal relationship between food intake, blood glucose, and serum insulin concentration. Note that glucose concentration is maintained between 80 and 140 mg/dl. Note also the precise release of insulin that has passed through the portal circulation synchronous with and proportional to the food-induced glycemic excursions. Compare and contrast these patterns with the time pattern of insulin action after subcutaneous injection of Aspart/glulisine/lispro, Regular, NPH and glargine/detimer insulins.

INSULIN REGIMENS

Plasma insulin levels in nondiabetic individuals are characterized by basal levels on which are superimposed meal-related spikes in insulin concentrations (Figure 10-10A). Current intensive treatment regimens attempt to simulate this diurnal pattern of plasma insulin by employing a basal-bolus approach to insulin replacement. Because exogenous insulins are injected or infused subcutaneously rather than directly into the portal vein, their rates of absorption may be variable—and because the dose injected is determined empirically it lacks the precision of endogenously secreted insulin. Therefore, it should be apparent that no insulin replacement regimen will precisely duplicate the pattern of normal insulin secretion—and there will be periods of excessive plasma insulin that may produce hypoglycemia and periods of inadequate insulin that permit hyperglycemia (Figure 10-10B).

Analog-Based Basal-Bolus Regimens

Perhaps the most physiologic approach to insulin replace involves the continuous infusion of rapid-acting insulin via an insulin pump. Originally introduced in the late 1970s,[184,185] this approach to basal bolus therapy only began to be used extensively in pediatrics over the past 7 to 8 years. The pumps are battery powered and about the size of a beeper. Most pumps employ a reservoir (modified syringe) to hold the insulin and the infusion set, which consists of tubing with a small plastic catheter at the end.

The insertion site can be the abdomen or hip area, except in the young child in whom there may not be sufficient subcutaneous tissue in the abdomen. Infusion site catheters should be changed every 2 to 3 days. Initially used with regular insulin, insulin pumps are most often used with the rapid-acting insulin analogs—which are associated with improved meal coverage and less hypoglycemia.[175] The newest "smart pumps" have advanced functions that include bolus dose calculators, record and summarize bolus and blood glucose history, and receive sensor inputs from continuous glucose monitoring systems.[186]

With insulin pump treatment, small amounts of rapid-acting insulin (down to 0.05-0.025 U increments) are infused as a basal rate—and bolus doses are given at each meal or snack.[187] The basal rate can be programmed to change every half hour. Varying the basal rate can be particularly helpful in regulating overnight blood glucose levels because it can be lowered for the early part of the night to prevent hypoglycemia and increased in the hours before dawn to keep glucose from rising. However, younger children may need a higher basal rate during the earlier part of the night—perhaps due to earlier nocturnal peaks of growth hormone in this age group.

Bolus doses are given before meals based on glucose level, carbohydrate content of the meal, and anticipated

exercise after the meal. Pump therapy also enhances flexibility in children with variable exercise and meal routines, and temporary basal rates for the evening following vigorous physical activity is a simple means of preventing exercise-related nocturnal hypoglycemia. Most children and parents are encouraged to use carbohydrate counting as a means of adjusting pre-meal bolus doses.

When used correctly, insulin pump therapy has been shown to improve glycemic control in children, reduce severe hypoglycemia, and improve quality of life.[188,189] This is especially true for infants and toddlers, in whom we recently demonstrated durable improvements in HbA1c and risk of hypoglycemia for more than 2 years of treatment.[190] In this group, in whom unpredictable eating and activity patterns make multiple daily injection regimens problematic, part of the usual pre-meal bolus can be given prior to the meal and the rest given at the end of the meal—depending on the actual amount of carbohydrate intake. However, children using insulin pumps and their families must be reminded that because only rapid acting insulin is used in the pump discontinuation of the insulin infusion for more than 4 hours at a time may lead to significant ketoacidosis and preventable hospitalization.[191]

Basal bolus therapy can also be accomplished with multiple daily insulin injections. In this method, once- or twice-daily injections of glargine or detemir provide basal insulin coverage—and meal-related insulin requirements are covered with rapid-acting insulin bolus doses, which may easily be administered with an insulin pen. Multiple daily injection regimens with glargine in children have been associated with lower rates of nocturnal hypoglycemia compared to regimens with NPH.[181,182] Such regimens have become increasingly popular, but the inability to "fine-tune" basal insulin over the course of the day may be a problem.

In addition, the flat time-action profiles of glargine and detemir put a premium on compliance with pre-meal bolus dosing. Indeed, the difficulty of administering 4 to 5 insulin injections daily accounted for the recent finding that adolescents randomized to glargine-based basal-bolus therapy had higher HbA1c levels than those randomized to insulin pumps.[192] Even the added convenience of insulin pumps fails to prevent some adolescents from omitting many of their prescribed pre-meal bolus doses. However, the bolus history function allows clinicians and parents to easily identify such problems with compliance.[187]

NPH-Based Conventional Treatment Regimens

The "split-mixed" regimen consisting of two daily doses of NPH and regular insulin that were mixed together in the same syringe was a standard approach to insulin replacement in pediatrics for many years (Figure 10-11). More recently, the regular insulin component was replaced by rapid-acting insulin analogs. Patients started on this approach generally receive two-thirds of the total daily dose before breakfast and one-third before dinner.[193] Each injection starts with approximately two-thirds NPH and one-third rapid-acting analog. Individual components of the regimen are subsequently adjusted based on blood glucose testing results.

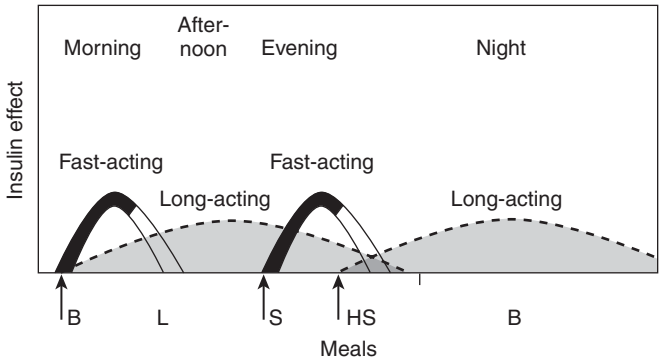

Figure 10-11. Three-dose insulin regimen. The morning dose is composed of a combination short- and intermediate-acting insulin of one-half to two-thirds of the total daily dose. The short-acting dose before supper covers the anticipated glycemic elevation with dinner. The long-acting insulin is not given until bedtime so that the peak effect is delayed. [Redrawn from Schade DS, et al. (1983). *Intensive insulin therapy.* Belle Mead, NJ: Excerptal Medica.]

Although this conventional treatment regimen is almost always inadequate for the patient with T1DM who has no residual endogenous insulin secretion, it may still play a role in the newly diagnosed patient—who frequently goes through a "honeymoon" or partial remission period of diabetes. During the "honeymoon" insulin requirements rapidly decrease and the doses of rapid-acting insulin may even be discontinued due to low pre-lunch and bedtime glucose levels. A major reason the two daily injections regimen is effective during the honeymoon period is that endogenous insulin secretion provides much of the overnight basal insulin requirements, leading to normal fasting blood glucose values. Conversely, increased and more labile pre-breakfast glucose levels often herald the loss of the relatively small amount of residual endogenous insulin secretion required for overnight glucose control.

When residual β-cell function wanes, problems with the two-injection regimen become apparent. One problem is that the peak of the pre-dinner intermediate-acting insulin may coincide with the time of minimal insulin requirements (i.e., midnight to 4:00 a.m.). Subsequently, insulin levels fall off when basal requirements may be increasing (i.e., 4:00 to 8:00 a.m.)—also known as the "dawn phenomenon."[194] Increasing the pre-dinner dose of intermediate-acting insulin to lower fasting glucose values often leads to hypoglycemia in the middle of the night without correcting hyperglycemia before breakfast. Another problem with the conventional two-injection regimen is high pre-dinner glucose levels despite normal or low pre-lunch and mid-afternoon values. This is due in part to eating an afternoon snack when the effects of the pre-breakfast dose of intermediate-acting insulin are waning.

One of the first true multiple daily injection regimens attempted to solve the problem of the dawn phenomenon by moving the pre-dinner NPH to bedtime. A current alternative to this method shown to be effective in children is to retain the pre-breakfast mixture of NPH and rapid-acting insulin, cover dinner with rapid-acting analog, and use glargine or detemir (given before supper or bedtime) for overnight basal replacement.[195] Indeed, some pediatric diabetologists have come full circle back

to two shots a day by mixing the rapid and long-acting insulins together in the same syringe at dinner[196]—even though such mixing is not approved by the FDA.

Self-Monitoring of Blood Glucose

The safety and success of any insulin regimen is dependent on frequent monitoring of blood glucose. Intensive diabetes control would have been impossible without the development of inexpensive, accurate, easy-to-use home glucose meters. There are many brands of glucose meters commercially available, most of which are accurate to within about 5% to 10% of laboratory measurements.[197] Current models utilize glucose-oxidase-based electrochemical methods. The meters are fast (results in 5 seconds) and require very small volumes of blood (0.1 mL). The smaller blood volume requirement has allowed alternate site testing (forearm, thigh, calf), which may minimize discomfort and improve adherence to self-monitoring regimens. Alternate site testing has been associated with a time lag under conditions of rapidly changing blood glucose, and thus it should be used for routine testing before instead of after meals or exercise.[198]

Children with diabetes should routinely test the blood glucose four times daily (pre-meal and pre-bedtime) and record the results in a log (written or electronic) for later review by the family and diabetes care team. A target range is established, typically of 80 to 120 mg/dL before meals and <180 mg/dL 2 hours after meals. However, this may be altered based on the age of the child and the ability of the family. Ideally, 80% of the blood glucose values should fall within the target range—but this is rarely the case in current clinical practice. Information gained from frequent testing is used to titrate insulin dosages according to need. Because daily insulin requirements continually increase in growing children over time and may acutely change with the start of a new sports season, it is important that the families be taught to look for trends that indicate a need to alter insulin doses.

Due to the physiologic insulin resistance normally observed during puberty,[199] the adolescent growth spurt is regularly associated with a sharp increase in insulin requirements—which is usually lower when puberty is completed. Virtually all of the meters are equipped with memory functions that record and store the date and time and results of blood glucose test. Although these data are extremely useful with respect to checking the compliance with and accurate reporting of glucose testing, all too often the patient and parents fail to retrieve and review these data for trend analysis.

Dose-to-dose adjustments should also be made based on blood glucose measurements that are outside the target range. In particular, supplemental correction doses of rapid-acting insulin should be given when blood glucose values above the target range are discovered according to a predetermined formula. For example, a younger child with pre-meal blood glucose values outside the goal range may be given an extra 0.5 unit of rapid-acting insulin analog to reduce the blood glucose by 100 mg/dL (in addition to the usual insulin dose at that mealtime)—whereas an adolescent may use 2 to 3 units to "correct" the glucose by 100 mg/dL.[200] Supplemental blood glucose testing should be performed after correction doses are given, before exercise, or during intercurrent illness.

Even when performed correctly, four (or even six) blood tests daily gives only a limited glimpse into the wide fluctuations in blood glucose that occur during a 24-hour period in children with diabetes. Consequently, the recent introduction of continuous glucose monitoring systems has the potential to be the most important advance in assessing diabetes control in the past 20 years. Nevertheless, the original devices were used for short-term retrospective analysis (the Medtronic MiniMed CGMS) or were too difficult and uncomfortable to use (the GlucoWatch Biographer).[201]

More recently, several new real-time continuous glucose monitoring (RT-CGM) systems have been introduced that have improved accuracy, functionality, and tolerability. Each of these devices employs a glucose-oxidase-based electrochemical probe inserted into the subcutaneous space. Glucose in the interstitial fluid is oxidized by the electrode, and the resultant electric signal is relayed to a monitor (which displays the glucose level). Current sensors require calibration against meter glucose values.[202]

In intensively treated children and adolescents with type 1 diabetes, preliminary results in a relatively small number of children suggest that continuous glucose monitoring will provide a wealth of data regarding postprandial glycemic excursions and asymptomatic nocturnal hypoglycemia that were unavailable from capillary blood glucose measurements.[203] A recent small outcome study in insulin pump-treated children demonstrated improvements in glycemic control and a high level of patient and parent satisfaction with the use of such a device.[204]

Because the error of current devices is considerably higher than conventional glucose meters,[197,205] frequent SMBG is still required for making treatment decisions. Nevertheless, it is likely that these technologic breakthroughs will have a great impact on diabetes management over the next few years as accuracy and performance of these systems improve. Continuous monitoring may be particularly useful in reducing postprandial hyperglycemia, reducing hypoglycemia (particularly at night), and programming overnight basal rates in pump-treated patients.[206]

Ultimately, continuous glucose sensors may be employed as part of a closed-loop system, in which sensor data drives an insulin pump—thus creating an artificial β cell. Urine tests still have a role in management of diabetes. However, these are now restricted to measurements of urine ketone levels when the child is ill, nauseous, or vomiting. Home meters for blood β-hydroxybutyrate levels are also available.[207]

Medical Nutrition Therapy

Proper nutritional management is critical to the short- and long-term health of children with diabetes. Generally, terms such as *diet* should be avoided in favor of *meal plan*—both for the negative connotation associated with the former and for the simple fact that nutritional

requirements for normal growth and development are the same in diabetic and nondiabetic children. However, reasonably accurate estimations of the carbohydrate content of meals are important to optimal glycemic control. The increasing popularity of basal-bolus therapies and the use of carbohydrate counting to adjust the dose of rapid-acting insulin taken with each meal have fundamentally changed the treatment paradigm.

The traditional approach of adjusting the patient's lifestyle around fixed insulin doses and fixed amounts of carbohydrate intake with each meal has been replaced by a much more flexible approach that attempts to adjust the insulin regimen to the patient's lifestyle. The day-to-day variations in appetite in children and adolescents make the latter approach much more likely to be successful. It is important to note that in some patients and some families the traditional approach maybe more successful because it fits their personalities and lifestyle better.

The currently favored model of nutritional therapy is carbohydrate counting, based on the conceptual model of matching carbohydrate "doses" to insulin doses.[208,209] As the total carbohydrate content of foods (rather than the type of carbohydrate) has the greatest impact on blood glucose, the amount of carbohydrates ingested per meal or snack needs to be estimated as accurately as possible. Protein and fat intake, although important in the larger context of a healthy meal plan, are not counted (to simplify the procedure). Food labeling requirements have simplified the process, as most foods are clearly labeled with the amount of carbohydrate grams per serving and the serving size. Foods less easily quantified may be weighed or estimated, and eating out may be a particular problem. Although the prohibition of "sweets" has been done away with, we still recommend that patients drink diet rather than regular sodas.

In the flexible approach to nutrition counseling, there is no set intake. Rather, the child and parents decide the meal content. The carbohydrates are counted and an insulin dose is calculated based on a ratio of the number of insulin units per grams of carbohydrate determined by the empirical trial-and-error method. In younger children, a typical insulin-to-carbohydrate ratio is 1 unit to 20 to 30 g—whereas an older child may require 1:15 g, and an insulin-resistant adolescent 1:5-10g. Actual insulin-carbohydrate ratios vary from child to child and even in the same child from meal to meal. Breakfast often requires relatively more insulin than lunch or dinner. Carbohydrate counting can also be used in the traditional approach to dietary treatment to provide consistent carbohydrate servings per meal/snack. Indeed, a very simple approach that stresses consistency in the timing and size of meals may be very effective at the time of diagnosis of diabetes—when parents and patients are too overwhelmed to be able to learn more advanced nutritional concepts.

The American Diabetes Association's recommendations regarding general nutritional principles in diabetes also take into consideration the long-term goal of prevention of macrovascular and microvascular complications of diabetes.[210] Consequently, heart-healthy diets low in cholesterol and saturated fats are encouraged. Long-term goals of nutritional management of diabetes include maintenance of nutrient intake balance of about 50% carbohydrate, 20% protein, and 30% fat (of which no more than 10% should be saturated). Most importantly, growth and weight gain should be monitored—and regular follow-up with a dietitian trained in diabetes management should be encouraged to individualize a meal plan for each child based on his/her needs and food preferences. We face an epidemic of childhood obesity in developed countries, and one of the adverse consequences of intensive insulin treatment in the DCCT was a twofold increase in the risk of becoming overweight. Thus, any tendency for BMI Z scores to increase excessively needs to be dealt with promptly.

Exercise

Establishment and maintenance of an active lifestyle should be a goal for all children, but are especially important for children with diabetes. Exercise and increased physical fitness are associated with improved insulin sensitivity and glucose utilization, the clinical correlates of which are lower insulin requirements in general and frequently less pronounced blood glucose excursions after meals. Improvements in physical fitness are also frequently associated with greater self-esteem and motivation to participate in diabetes care.

Despite its benefits, acute bouts of exercise in children with T1DM actually make regulation of blood glucose levels more difficult. Hypoglycemia is a common complication during exercise, and excessive snacking to prevent hypoglycemia can result in hyperglycemia and negate some of the metabolic and cardiovascular benefits of exercise. These difficulties are compounded by the irregular pattern of physical activity that characterizes most youth (who are not participating in organized sports or regimented training programs) and by conventional methods of diabetes management that feature fixed basal insulin replacement doses. Moreover, antecedent exercise may reduce the counterregulatory hormone responses to subsequent hypoglycemia.[211]

The effects of exercise must be carefully considered in the context of the entire diabetes care plan. Children participating in school sports or other programs should be counseled to monitor blood glucose before, during, and after exercise because the hypoglycemic effects of exercise may be delayed for 7 to 11 hours—markedly increasing the risk of nocturnal hypoglycemia.[212] The delayed fall in glucose levels on nights following exercise appears to be due to an increase in nonoxidative glucose disposal during sleep, which may serve to support repletion of muscle glycogen stores.[213]

In pump patients, simply suspending the basal infusion rate can markedly reduce the risk of hypoglycemia during exercise—and similar benefits may accrue from reducing the overnight basal rates after very active days. Recent studies that have examined methods of managing glycemia during exercise illustrate that there is an almost infinite number of combinations of conditions that need to be considered.[214] Because of this complexity, trial and error remains the principal method of managing glucose levels during and after exercise in children and adolescents with T1DM.

TABLE 10-14

Levels of Treatment: Biochemical and Clinical Characteristics

Minimal
- HbA1c 11.0%-13.0%, GHb 13.0%-15.0%
- Many SMBG values of 300 mg/dL
- Almost constantly positive urine glucose tests
- Intermittent spontaneous ketonuria

Average
- HbA1c 8.0%-9.0%, GHb 10.0%-11.0%
- Premeal SMBG 160-200 mg/dL
- Intermittent positive urine glucose
- Rare ketonuria

Intensive
- HbA1c 6.0%-7.0%, GHb 7.0%-9.0%
- Premeal SMBG 70-120 mg/dL; post-meal SMBG,180 mg/dL
- Essentially no positive urine glucose or ketones

GHb, glycosylated hemoglobin; HbA1c, glycohemoglobin; and SMBG, self-monitored blood glucose.

Residual β-Cell Function (The Honeymoon Period)

After the initiation of insulin treatment in newly diagnosed patients, secretory function of residual β-cells improves and the insulin resistance and glucotoxicity of decompensated diabetes are reversed in most newly diagnosed diabetic children—heralding the onset of the partial remission (honeymoon period) of T1DM. Patients require a progressive reduction in their daily dose of insulin from >1.0 to <0.5 U/kg. Recurrent hypoglycemia is the manifestation that prompts a reduction in the insulin dose. A minority of children (fewer than 5% of patients) can even maintain normoglycemia for a time without any administered insulin. Although opinion varies, we do not discontinue insulin treatment unless a daily dose of 0.1 U/kg still causes hypoglycemia.

The duration of this honeymoon phase is variable. It commonly lasts several months, but may last as long as 1 to 2 years. Residual insulin secretion, measured as C-peptide, is present during this remission period and to some extent in virtually all diabetic children in the initial year of their disease. In less than 20% there will be some measurable C-peptide even up to 3 years.[215] In comparison to patients who are C-peptide negative, patients with residual b-cell function have lower HbA1c levels and total daily insulin doses—as well as a reduced risk of hypoglycemia.[216] These clinical and metabolic benefits serve as a strong rationale for current research involving immune interventions directed at preserving b-cell function in newly diagnosed patients.[217] The levels of treatment intensity with anticipated glucose and HbA1c values are shown in Table 10-14.

HYPOGLYCEMIA

The dark side of intensive treatment regimens effective in lowering HbA1c levels is that they also increase the risk of hypoglycemia. In the DCCT, intensive therapy was associated with an approximate threefold increased risk for severe hypoglycemia versus conventional treatment—and irrespective of treatment group the rate of severe hypoglycemia was >50% higher for adolescents than for adults.[168,169] Hypoglycemia has become the most significant barrier to the pursuit and maintenance of tight glycemic control among people with DM, and effectively managing the risk for hypoglycemia is especially important in the treatment of children and adolescents with this disease.

Biochemical hypoglycemia (with or without symptoms) is defined by the American Diabetes Association as any plasma glucose level ≤70 mg/dL.[218] In nondiabetic adults, this is the plasma glucose level at which counterregulatory hormone responses engage and at which awareness of symptoms normally occurs. It should be noted, however, that such responses may be triggered at higher glucose levels in healthy 8- to 16-year-olds and in children and adolescents with T1DM who have poor glycemic control.[219] Differentiation of hypoglycemic events, based on symptoms and treatment characteristics, is important clinically.

The two main mechanisms that cause symptoms and signs are an outpouring of catecholamines (which results in pallor, sweating, apprehension, trembling, and tachycardia) and the effects of cerebral glucopenia, which include hunger, drowsiness, mental confusion, seizures, and coma. Mood and personality changes plus some abnormal physical patterns may be other more subtle cerebral glucopenic effects that provide an early clue that plasma glucose has fallen to a dangerous level. Symptomatic episodes in which patients are able to treat themselves without the assistance of others are considered minor or mild hypoglycaemia, whereas episodes in which there is sufficient cognitive impairment that treatment requires the assistance of another person are considered major or severe hypoglycemic events. In severe hypoglycemia, ingestion of carbohydrates may be precluded due to loss of consciousness, seizures, or coma—and treatment may require administration of glucagon injection or IV glucose infusion.

In nondiabetic children, the initial response to falling plasma glucose levels is a prompt suppression of insulin secretion. If plasma glucose continues to fall and threshold values for release of anti-insulin counterregulatory hormones are reached, there are abrupt increases in circulating concentrations of glucagon and epinephrine. Plasma growth hormone and cortisol levels also increase, but these hormones are less important in acutely counteracting the effects of insulin. Defective counterregulation occurs in patients with T1DM because exogenously supplied insulin levels do not decrease in response to low blood glucose levels and the ability to secrete glucagon in response to hypoglycemia is lost early in the course of the disease.[220,221] Consequently, patients with T1DM depend on sympathetic nervous system responses—especially increases in plasma epinephrine levels—to prevent hypoglycemia.

Nevertheless, it has been demonstrated that the repeated episodes of mild hypoglycemia that frequently accompany intensive treatment blunt catecholamine responses and symptom awareness to subsequent hypoglycemic challenges. This phenomenon has been called hypoglycemia-associated autonomic failure (HAAF)[221,222]—a

major contributing factor to the risk of hypoglycemia in patients whose DM is well controlled. Catecholamine responses to hypoglycemia are also impaired during sleep, which is an important reason most of the severe hypoglycemia events occur during the night.[223] Children and adolescents are also prone to erratic eating behaviors and patterns of bolus dosing. Bouts of exercise in the afternoon sharply increase the risk of hypoglycemia on the following night.[212]

The use of basal-bolus therapy with insulin analogs has reduced frequency of severe hypoglycemia somewhat but has by no means eliminated this problem. It is important that the patient and family recognize early symptoms and signs of hypoglycemia and known precipitating factors. Mild episodes should be immediately treated with 10 to 15 g of carbohydrate (e.g., glucose tablets, juice, or glucose gel). Parents and school nurses also need to be instructed on how to perform injections of glucagon (0.5 to 1.0 mg) when the patient is losing consciousness and unable to swallow exogenous carbohydrate. If exercise has been the precipitating factor, the patient should be instructed about preventive measures.

To avoid more severe events, insulin doses need to be adjusted if there are repetitive patterns of mild hypoglycemia. Physicians caring for patients with type 1 diabetes should be aware of a syndrome of cerebral glucopenia with hypoglycemic encephalopathy. In these patients, prolonged severe hypoglycemia that is not recognized or treated may result in seizures and a coma that lasts for hours despite correction of blood glucose concentration. Such patients are often combative and use profane language. Several hours of glucose therapy may be necessary for recovery in such patients.

SICK DAY MANAGEMENT

Children with intercurrent illnesses, such as infections or vomiting, should be closely monitored for elevations in blood glucose levels and ketonuria. On sick days, blood glucose levels should be checked every 2 hours—and the urine should be checked for ketones with every void. Supplemental doses of rapid-acting insulin (0.1 to 0.3 U per kilogram) should be given every 2 to 4 hours for elevations in glucose and/or ketones. Even in the absence of marked hyperglycemia, the presence of ketones indicates insulin deficiency and therefore the need for supplemental insulin.

Adequate fluid intake is essential to prevent dehydration and hasten the excretion of ketones. Fluids such as flat soda, clear soups, popsicles, and gelatin water are recommended to provide some electrolyte and carbohydrate replacement. In the child tolerating oral rehydration, a fluid "dose" of 1 ounce per year of age per hour serves as a rough guideline—the sugar content of which depends on the serum glucose. For blood glucose values >200 mg/dL, sugar-free fluids should be given. For those levels between 140 and 200 mg/dL, a mixture of sugar-free and sugar-containing fluids should be given. For blood sugar <140 mg/dL, only sugar-containing fluids should be given.

If emesis precludes normal oral intake, the intermediate or long-acting insulin should be discontinued and small frequent doses of short- or rapid-acting insulin should be given. Once the ketones have cleared and the child is tolerating an oral diet, the family may resume the normal routine. If vomiting is persistent and ketones remain moderate or large after several supplemental insulin doses, arrangements should be made for potential hydration and evaluation in the emergency department.

ASSOCIATED AUTOIMMUNE DISEASES

Various autoimmune diseases are frequently associated in patients with type 1 diabetes mellitus. These are detailed in Chapter 18 (Heller-Schatz), in the discussion of multiple endocrine deficiency syndromes. Chronic lymphocytic thyroiditis is frequently associated with type 1 diabetes in children, and as many as one in five may have thyroid antibodies in their serum.[224] Only a small proportion of these patients develop clinical hypothyroidism, however. The interval between the diagnosis of diabetes and that of thyroid disease averages about 5 years. Physicians should anticipate the possibility of hypothyroidism in patients with type 1 diabetes mellitus by periodic examination of the thyroid gland and measurement of serum thyroid-stimulating hormone (TSH) concentration.

When diabetes and thyroid disease coexist, the possibility of adrenal insufficiency should be considered. This may be heralded by decreased insulin requirements, increased pigmentation of the skin and buccal mucosa, salt craving, weakness, and postural hypotension. Rarely, frank Addisonian crisis is the first evidence of adrenal failure. This syndrome generally occurs in the second decade of life or later.

Celiac disease affects from 1.5% to 4.5% of children with T1DM and most of them are not aware of any gastrointestinal symptoms.[225] Early diagnosis requires screening of tissue transglutaminase antibodies, which have high degrees of reproducibility, specificity, and sensitivity if total circulating IgA concentrations are not abnormally low. Antibody-positive children should be referred to a pediatric gastroenterologist for confirmation by small bowel biopsy, as well as for counseling and disease management.

When typical signs and symptoms of malabsorption are present or the patient has frequent hypoglycemia or unexplained behavioral mood swings, dietary intervention is indicated. When symptoms are minimal or absent, the decision to introduce gluten-free diets with their additional restrictive and inconvenient burdens on the patient and family are less clear-cut. To guide their decision, the parents and older children need to be made aware of the risk of bowel malignancies in untreated celiac disease in later life and of other long-term complications of this disease.

ASSOCIATED PSYCHOSOCIAL PROBLEMS

Diabetes in a child affects the lifestyle and interpersonal relationships of the entire family. Guidelines for psychosocial management and support of families with childhood diabetes have recently been published.[226] Feelings of anxiety and guilt are common in parents. Similar feelings, coupled with denial and rejection, are equally common in children—particularly during the rebellious teenage years. These issues are not unique to T1DM but are

observed in families with children who have other chronic disorders difficult to treat. Such stresses are often exaggerated in single-parent low-income families and impair their ability to effectively carry out needed self-management tasks, resulting in poor metabolic control.[171]

Language and cultural barriers are additional obstacles in immigrant families. Psychosocial difficulties and conflict between patients and parents may result in nonadherence to instructions regarding nutritional and insulin therapy and in noncompliance with self-monitoring.[227] Deliberate over dosage with insulin resulting in hypoglycemia or omission of insulin, often in association with excesses in nutritional intake resulting in ketoacidosis, may be pleas for psychological help or manipulative events to escape an environment perceived as undesirable or intolerable. Occasionally, they may be manifestations of suicidal intent. Frequent admissions to the hospital for ketoacidosis or hypoglycemia should arouse suspicion of underlying emotional conflict. Overprotection on the part of parents is common and is often not in the best interest of the patient. Feelings of being different and/or of being alone are common and may be justified in view of the restrictive schedules imposed by testing of urine and blood, administration of insulin, and nutritional limitations.

The physician managing a child or adolescent with diabetes should be aware of his or her pivotal role as counselor and advisor and should anticipate the common emotional problems of the patient. When emotional problems are clearly responsible for poor compliance with the medical regimen, referral for psychological help is indicated. In pediatric centers, psychologists form part of the management team for children with diabetes.

OUTPATIENT CARE

The importance of frequent follow-up by the diabetes health care team cannot be overemphasized. Children and adolescents with T1DM should be routinely cared for by a diabetes center that uses a multidisciplinary team knowledgeable about and experienced in the management of young patients. This team should ideally consist of pediatric diabetologists, diabetes nurse specialists, nutritionists, and social workers or psychologists.

The American Diabetes Association has recently published guidelines for care of the child and adolescent with diabetes.[228] Regular follow-up visits with the physician or diabetes nurse specialist/practitioner every 2 to 3 months are recommended for most patients. The main purpose of these visits is to ensure that the patient is achieving primary treatment goals. Routine outpatient visits provide an opportunity to review glucose monitoring, to adjust the treatment regimen, and to assess child and family adjustment. At each visit, the blood glucose records should be reviewed and appropriate dosage or schedule changes should be instituted as needed. Follow-up advice and support are given by the nutritionist and psychologist or social worker.

A detailed interim history should include questions relating to general health, energy, fatigue, polyuria or nocturia, intercurrent illnesses, hypoglycemic episodes, and the presence of symptoms such as abdominal pain, bloating, or diarrhea. It is important to remember the comorbidities of other autoimmune disorders that occur with an increased frequency in children with T1DM: thyroiditis, adrenal insufficiency, and celiac disease. The child should be weighed and measured at each visit, and blood pressure documented. Physical examination of the child should focus not only on the general organ systems but on examination of the skin and insulin injection/pump insertion sites for signs of lipohypertrophy or pigmentary changes, palpation of the thyroid, and determination of the sexual development stage.

Lipoatrophy was commonly observed in the past but is now a rare complication of insulin therapy.[229] A deceleration in growth, delay in sexual development, or finding of goiter may herald hypothyroidism—which occurs in approximately 5% of children with T1DM. The astute clinician should also consider that frequent unexplained hypoglycemia or reduction in insulin requirements in the absence of exercise or activity may be a subtle indicator of hypothyroidism or adrenal insufficiency. Similarly, although the history of frequent foul-smelling greasy stools are more obvious indicators of celiac disease (which occurs in about 2% to 5% of children with T1DM), the presence of abdominal pain, poor weight gain, and unexplained hypoglycemia may be the first and only signs. Indeed, many patients are asymptomatic and are diagnosed by screening for celiac-related autoantibodies.

There are currently no formal recommendations for screening for thyroid/adrenal autoimmunity and celiac disease for pediatric patients with T1DM. However, because the prevalence of thyroid autoantibodies in children with diabetes may be as high as 21% (and of celiac disease in children with T1DM about 4%), we routinely screen with T4, TSH, and tissue tranglutaminase IgA every 1 to 2 years.

Measurement of glycosylated hemoglobin (HbA_{1c}) provides the gold standard by which to judge the adequacy of the insulin regimen. A variety of methods are available for assaying glycosylated hemoglobin. A simple point-of-service method that can be performed in the office in 6 minutes (i.e., DCA 2000 instrument) offers the opportunity to make immediate changes in the insulin regimen while the patient is being seen.[230] Even more important, the results of this test delivered during face-to-face encounters with the clinician serve as the quarterly "report cards" for the child and the parents.

Teenagers may not be able to identify with the concept of working hard on their diabetes to be healthier many years in the future, but most are able to understand good grades. Thus, the HbA1c level provides a tangible outcome with which they can identify. The goal of treatment is to achieve HbA_{1c} levels as close to normal as possible. Based on DCCT results, our general goal of therapy is to try to keep all patients under 7.5%. HbA_{1c} levels are determined at least every 3 months.

Monitoring of the diabetic child for potential complications is an important function of the clinic visit. Urinary albumin excretion may be measured in a spot sample by comparison to urinary creatinine. Urinary albumin/creatinine ratio should be <30 mg albumin to gm creatinine. Elevated spot samples should be confirmed by collections of first morning void or a timed overnight period to eliminate the confounding variable of benign orthostatic proteinuria. If the

first morning void or timed overnight collection demonstrates microalbuminuria (>30 mg albumin to gm creatinine or >30 mg albumin excretion per 24 hours), treatment with angiotensin-converting enzyme inhibitor or angiotensin receptor blocker therapy or referral to pediatric nephrologist may be indicated. All diabetic children with hypertension, regardless of albumin excretion status, should be considered candidates for these medications. Although there are no specific guidelines for diabetic children,[231] current recommendations for nondiabetic children are that blood pressures above the 90th percentile for age warrant lifestyle intervention and those about the 95th merit the use of pharmacologic agents.

Other screening studies for complications of diabetes include measurement of serum lipid concentrations. The current standards of care for adults with diabetes indicate that low-density lipoprotein (LDL) concentrations should be maintained below 100 mg/dL, whereas pharmacologic therapy for dyslipidemia in children with diabetes is not recommended unless dietary interventions fail to lower LDL concentrations below 130 mg/dL. The American Diabetes Association recommends that annual dilated retinal examinations be obtained in patients who are over 10 years or age and have had T1DM for 3 or more years. On the other hand, a recent study from our clinic population indicated that the yield from such examinations is very low in children and adolescents who have normal blood pressure and HbA1c levels that meet current targets and who are without microalbuminuria.[232]

MANAGEMENT DURING SURGERY

Management objectives during surgery are the prevention of hypoglycemia, excessive loss of fluids, and ketosis during anesthesia. The regimens described here are generally applicable, but vigilance and individual adjustments for each patient are necessary to achieve these goals. Evidence-based controlled studies of perioperative care have not been carried out in children, but detailed expert reviews of management have recently been published in the anesthesia and pediatric diabetes literature.[233,234]

The most reliable and straightforward approach to achieving management objectives during major elective or emergency surgeries is to use intravenous infusions of glucose and insulin during the perioperative period. For surgical emergencies that can be briefly delayed, such as acute appendicitis, rehydration and metabolic balance should be restored before the operation. Elective major operations should be performed first thing in the morning, and the glucose and insulin infusions should be started ~2 hours prior to proceeding to the operating room. For elective surgeries, an infusion of 5% glucose in 0.45% or 0.9% saline solution is begun on the morning of surgery—and 1 unit of regular insulin is infused intravenously for each 4 to 6 g of administered glucose. One unit of regular insulin for every 2 to 4 g of exogenous glucose may be required in surgical emergencies due to elevated circulating concentrations of stress hormones or in insulin-resistant obese diabetic patients.

The rate of infusion should provide maintenance fluid requirements plus estimated losses during surgery. The blood glucose concentration should be monitored at periodic intervals before, during, and after surgery. Concentrations of 120 to 150 mg/dL should be the goal. This can be achieved by varying the rate of infusion of the glucose and electrolyte mixture or the rate of insulin administration. The intravenous insulin and glucose infusions can be continued until the patient is awake and capable of taking regular meals, at which time their usual injection or insulin pump regimen can be reinstituted. Most centers do not routinely add potassium to the intravenous fluids until after completion of the surgical procedure.

In patients who receive NHP insulin in the morning and are undergoing surgery of short duration, a standard and effective approach is as follows: on the morning of surgery, one-half of the usual morning dose of NPH insulin is administered subcutaneously, the usual dose of rapid-acting insulin is omitted unless needed to correct hyperglycemia, and a maintenance intravenous infusion of the electrolyte and glucose solution is initiated if needed. Similarly, in patients on insulin pump therapy who are undergoing short procedures the continuous subcutaneous infusion of insulin (CSII) can be continued at the usual or slightly reduced overnight basal rate. Insulin pump-treated patients can also be maintained on CSII for major procedures as long as the integrity of the infusion and infusion site is ensured.

The nighttime dose of glargine or detemir insulin may provide sufficient basal insulin coverage for surgery in patients who receive these long-acting insulins before dinner or bedtime. A reduction in the glargine or detemir dose by 20% to 30% on the night prior to surgery should be considered in patients who have had a tendency to low pre-breakfast plasma glucose levels. With all three regimens, a correction dose of rapid-acting insulin can be given subcutaneously immediately after the procedure if needed for hyperglycemia—and repeated as needed to balance initial oral intake (e.g., carbohydrate-containing clear liquids). When the intravenous infusion is discontinued and the patient is ready to resume regular meals, the usual treatment regimen is reinstituted.

Nonautoimmune Type 1 Diabetes

Not all forms of apparently classic type 1 diabetes mellitus have associated markers of autoimmunity.[235] In one report, among children presenting with newly diagnosed diabetes mellitus fewer of those younger than 5 years of age at diagnosis had positive titers of islet cell and GAD antibodies—and fewer had a honeymoon phase within 6 months—compared with a group with onset at a mean age of 10 years.[51] Similarly, Japanese investigators have reported that some patients with idiopathic type 1 diabetes mellitus have a nonautoimmune fulminant disorder with abrupt onset characterized by absence of circulating antibodies, evidence of insulinitis in pancreatic biopsies, and high concentrations of pancreatic enzymes—suggesting an acute inflammatory process in the pancreas.[52]

MODY syndromes, as discussed in material following, may also be initially considered to be T1DM.[236] However, the strong family history of vertically transmitted DM in

three generations, the relatively milder degree of hyperglycemia, and the absence of autoimmune markers should alert the physician to the possibility of a monogenic form of DM.

Type 2 Diabetes Mellitus

TYPICAL

Type 2 diabetes mellitus, formerly known as NIDDM, is a heterogeneous disorder characterized by defective insulin secretion that progressively fails to compensate for insulin resistance.[235] The cause of insulin resistance is usually obesity,[237-242] although agents such as growth hormone and cortisol also antagonize insulin action and may unmask inadequately compensated insulin secretion. The high concentrations of placental growth hormones during mid to late gestation likewise may unmask inadequate insulin secretion, resulting in gestational diabetes—a harbinger of permanent diabetes later in life.

The mechanism of insulin resistance caused by obesity may in part relate to changes in fatty acid metabolism that interfere with normal glucose metabolism, and in part to factors synthesized within fat cells that antagonize insulin action.[35,37,242] Most notable are the recently described hormones adiponectin, leptin, and resistin,[243] which are produced by fat cells and are a likely major link between obesity and diabetes. Thus, in addition to the genetic component(s) responsible for impaired insulin secretion (which are being investigated, progressively identified, and presently cannot be changed[244-247]) the key modifiable factor responsible for the epidemic of type 2 diabetes in children is the epidemic of obesity increasingly recognized throughout the world.[237-242]

Type 2 diabetes mellitus is being recognized in children, particularly obese adolescents and especially but not exclusively in certain ethnic groups such as Native American Indians, African Americans, Mexican Americans, and Southeast Asians in the developing world.[237-242] Here, too, an epidemic of obesity is responsible for a rapid increase in the proportion of patients with type 2 diabetes—representing up to one-third of newly presenting cases in one major medical center in the United States.[248] These patients often have a family history of type 2 diabetes, may have acanthosis nigricans, are more commonly girls, and often have poor metabolic control that predisposes them to the earlier appearance of microvascular and macrovascular complications.[248] They may present initially in diabetic ketoacidosis suggesting type 1 diabetes, but after recovery they may manifest a prolonged "honeymoon phase"—the so-called atypical diabetes mellitus (ADM), or type 2 diabetes, as documented by significant insulin or C-peptide levels not consistent with type 1 diabetes. They also lack markers of islet autoimmunity and the classic HLA associations.[238]

In those with a family history of type 2 diabetes mellitus, insulin resistance (as shown by impaired insulin-stimulated glucose disposal and higher insulin values during oral glucose tolerance or so-called hyperglycemic clamps) is demonstrable in the first decade of life before clinically demonstrable changes in glucose tolerance.[237-244] The site(s) of this presumably genetic impairment in insulin sensitivity is not yet identified but clearly precedes clinical diabetes mellitus brought about by obesity-induced insulin resistance.[237-244] There may be other factors that induce insulin resistance.

There also are an emerging number of newly identified genetic factors associated with impaired insulin secretion and action. Genome-wide scans have consistently identified three major genetic linkages: the ATP-regulated potassium channel KATP, especially the Kir 6.2 subunit encoded by the KCNJ11 gene; the peroxisome proliferator activator receptor γ (PPARG); and transcription factor 7 like 2 (TCF7L2). The development of sophisticated arrays that permit genotyping of literally hundreds of thousands of polymorpisms has revealed additional loci of genetic markers in T2DM, including a polymorphism in the zinc transporter SLC30A8 (expressed only on pancreatic β cells) and genes potentially involved in pancreatic development (IDE, KIF11, HHEX) or function (EXT2-ALX4).[244-247,250-252]

These sophisticated genetic screening approaches are likely to identify more of the complex genetic traits that underlie T2DM. From a practical point of view, type 2 diabetes mellitus in children and adolescents should be viewed as a major public health issue—and without effective lifestyle interventions (such as weight reduction combined with regular exercise) treatment options are limited and only modestly successful.[237,238] Exogenous insulin may be necessary to control blood glucose initially, but its appetite-stimulating effects challenge attempts at weight reduction. Sulfonylureas may be temporarily helpful, as may meglitinide—which acutely increase insulin secretion.

Metformin, which sensitizes tissue to insulin action and diminishes hepatic glucose production, is the most frequently used agent for treating type 2 diabetes in children. It has been approved for use by the U.S. Food and Drug Administration for those over 10 years of age. The thiozolidinediones (glitazones) that sensitize tissue to insulin are not approved for use in children by the U.S. Food and Drug Administration but nevertheless have reportedly been used.[237,238] These agents are potentially hepatotoxic, and the original product was withdrawn for this reason. Newer glitazones (such as Rosiglitazone) are under investigation in adolescents with T2DM, although Rosiglitazone itself is under scrutiny for potential harmful effects on cardiac function.[253] Alpha-glucosidase inhibitors that slow carbohydrate absorption and lipase inhibitors to diminish fat absorption are available, but none has undergone clinical trials in children/adolescents for efficacy and compliance. This represents a major deficiency in our ability to treat type 2 diabetes mellitus in children.[237]

GENETIC DEFECTS OF BETA CELL FUNCTION

MODY Syndromes

Although MODY was originally conceptualized as a form of maturity-onset (i.e., type 2) diabetes, the MODY syndromes are best considered a group of disorders of monogenic defect in beta cell function. Affected patients may have modest elevation of glucose, may remain

asymptomatic for many years, and may become clinically apparent during intercurrent illness or pregnancy that unmasks the limited insulin secretion.[13] Clinical criteria used to establish the diagnosis include the following.

- Dominant inheritance with at least two (and preferably three) consecutive affected generations
- Onset before age 25 to 30 years
- Evidence of significant but impaired residual insulin secretion reflected in C-peptide levels whether or not the patient is being treated with insulin

As of this time, six specific genetic defects have been identified. (see Table 10-15) Of these genetic defects that together account for no more than 2 to 5% of type 2 diabetes, about two-thirds (65%) are MODY 3 (HNF1α), 10% are MODY 2 (glucokinase defect), and the remainder constitute the other defects. Mild stable hyperglycemia may be present from birth and not require treatment except during stress, such as infections in an infant or child or pregnancy in a young adult.

With glucokinase deficiency, microvascular complications of diabetes are rare. In the other forms of MODY, however, onset is usually in the early teens to 20s, glucose intolerance may become progressively worse and hence require treatment, and microvascular complications may develop. Renal cysts or other reno-pelvic anomalies may occur in MODY 5 (HNF1βb). Notably, if the genetic defect in IPF1 (insulin promoter factor-1, MODY 4) is homozygous pancreatic agenesis results and this is a cause for permanent neonatal diabetes associated with exocrine as well as endocrine insufficiency. Likewise, homozygous mutations in glucokinase have been associated with congenital diabetes. By contrast, gain-of-function mutations in glucokinase cause persistent hyperinsulinemic hypoglycemia of infancy (see Chapter 5). Thus, the MODY syndromes are monogenic defects of islet cell formation (MODY 4) or of transcription factors (MODY 1, 3, 5, and 6)—or a defect in the functional glucose sensor glucokinase (MODY 2).[13,236,254]

Table 10-16 compares and contrasts the four most common types of diabetes found in adolescents: type 1, type 2, atypical diabetes mellitus, and MODY. The monogenic MODY syndromes have been extensively reviewed in terms of chemical, biochemical, and molecular analyses.[13,254] Other monogenic defects reportedly associated with a type 2 clinical picture include mutation in GLUT2 and the glycogen synthase genes.[255,256]

Other Forms of Monogenic Diabetes

Mitochondrial Diabetes. Mitochondrial genetic defects that cause diabetes are commonly but not invariably associated with neuromuscular disorders, including deafness, migraine, seizures, and mental retardation. For example, the MELAS (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes) syndrome may initially present in childhood with short stature, go on to deafness in teen years, and develop diabetes and encephalopathy in midlife. Diabetes mellitus maybe the only manifestation of a mitochondrial disorder encoded by a gene defect within the mitochondria (all of which are maternally inherited) or a nuclear DNA-encoded gene necessary to the oxidative phosphorylation sequence within mitochondria.

This defective energy pathway leads to progressive impairment of insulin secretion, and thus an initially mild hyperglycemia may progressively worsen. This is the case with the most common form of diabetes caused by a mitochondrial gene mutation at nucleotide pair 3243 of the mitochondrial genome, often associated with deafness. Remarkably, this same genetic defect may be associated with the MELAS syndrome. Initially, patients with np 3243 mutations can be controlled by diet alone but later may require insulin. Diabetes mellitus presenting in infancy and severe from the outset and requiring insulin may be associated with mitochondrial DNA deletions, as seen in the Kearns-Sayre syndrome and Pearson syndrome.[257] Figure 10-12 identifies the critical role of energy production by the mitochondrial oxidative phosphorylation pathway for normal insulin secretion.

Defects in this pathway may be responsible for transient or permanent neonatal diabetes mellitus, especially those that involve activating mutations in the KATP channel subunits Kir 6.2 and its regulatory subunit sulfonylurea receptor SUR1. Inactivating mutations in the KATP

TABLE 10-15

Protein/Gene Mutations Causing Maturity-Onset Diabetes of the Young

MODY Type	Protein Mutated	Gene/Gene Location	Gene Function with Respect to the Beta Cell
MODY 1	Hepatocyte nuclear factor-4α	HNF4α; 20q12-q13.1	Binds to HNF1α and IPF1 promoter; regulates HNF1α and IPF1 gene transcription
MODY 2	Glucokinase	GCK; 7p15-p13	Catalyzes conversion of glucose to glucose 6-phosphate
MODY 3	Hepatocyte nuclear factor-1α	HNF1α; 12q24.2	Binds to A3/A4 box of insulin gene promoter; regulates insulin gene transcription
MODY 4	Insulin promoter factor-1	IPF1; 13q12.1	Binds to A5, A3/A4, A2, and A1 boxes of insulin gene promoter; regulates insulin gene transcription
MODY 5	Hepatocyte nuclear factor-1β	HNF1β, TCF2; 17cen-q21.3	Regulates HNF4α gene transcription
MODY 6	Neuro-D1/beta-2	Neuro-D1; 2q32; beta-2	Transcription factor for normal insulin secretion and normal development of pancreatic islets

TCF2, Transcription factor-2, hepatic; also known as LF-B3, variant hepatic nuclear factor.

TABLE 10-16

Comparison of the Common Forms of Youth-Onset Diabetes

Characteristic	Type 1 Diabetes	Type 2 Diabetes	Classic MODY	Atypical Diabetes Mellitus
Age at onset	Peaks at 5 and 15 years old	Teenage years, young adults	<25 years old	>40 years old
Predominant ethnic groups affected	White	Hispanic, African American, Native American	White	African American
Male to female ratio	1.1:1	1:1.5	1:1	1:3
Severity at onset	Acute, severe, insulin required	Subtle, insulin not required	Subtle, insulin not required	Acute, severe, insulin required
Islet autoimmunity	Present	Absent	Absent	Absent
HLA-DR3, -DR4	Very common	No increased frequency	No increased frequency	No increased frequency
Ketosis, DKA	Common	Uncommon	Rare	Common at onset
Long-term course	Insulin-dependent	Non insulin-dependent	Non insulin-dependent	Non-insulin-dependent
Prevalence of obesity	Uncommon	≥90%	Uncommon	40%
Proportion of cases of 100% youth-onset diabetes	Most common form of youth-onset diabetes	Rising in frequency; ± as common as type 1 diabetes in specific populations	≤5% of youth-onset diabetes in whites	≤10% of cases of youth-onset diabetes in African-Americans
Percentage of probands with an affected first-degree relative	≤15%	Variable but common	100%	>75%
Mode of inheritance	Nonmendelian, generally sporadic	Nonmendelian but strongly familial	Autosomal dominant	Autosomal dominant
Number of genes controlling inheritance	Polygenic	Polygenic	Monogenic	Monogenic
Pathogenesis	Autoimmune beta cell destruction: insulinopenia	Insulin resistance plus relative insulinopenia	Insulinopenia	Insulinopenia

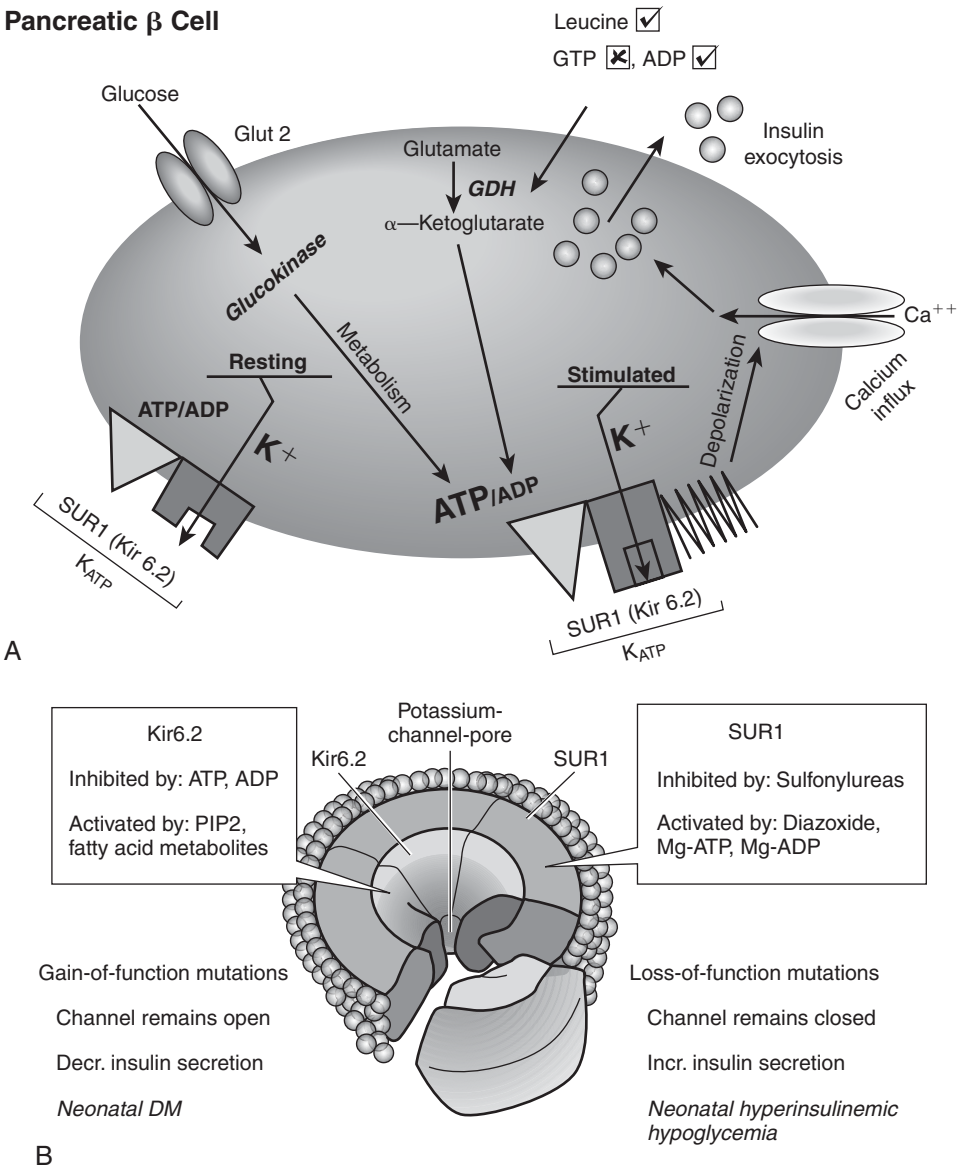

Figure 10-12. *(A)* Model of insulin secretion by pancreatic β cell. Glucose transported into the β cell by the insulin-independent glucose transporter (Glut 2) undergoes phosphorylation by glucokinase and is metabolized. This results in an increase in the ATP/ADP ratio with subsequent closure of the KATP channel and initiation of a cascade of events that is characterized by decreased flux of potassium across the membrane, membrane depolarization, calcium influx, and release of insulin from storage granules. Leucine stimulates insulin secretion by allosterically activating glutamate dehydrogenase (GDH) and by increasing the oxidation of glutamate; this increases the ATP/ADP ratio and closure of the KATP channel. Check mark sign (√) indicates stimulation of insulin secretion; cross sign (x) indicates inhibition of insulin secretion. Diazoxide inhibits insulin secretion by interacting with the sulfonylurea receptor; somatostatin and calcium channel blockers interfere with calcium signaling. *(B)* Regulation of Insulin Secretion. The Kir6.2–SUR1 complex and its regulation and genetic variability. The panel shows the detailed subunit structure of the KATP channel, which is composed of four small subunits, Kir6.2, that surround a central pore and four larger regulatory subunits constituting SUR1. In the normal resting state, the potassium channel is open, modulated by the ratio of ATP to ADP. PIP2 denotes phosphatidylinositol-4,5-bisphosphate. Kir6.2 denotes the inward rectifying potassium channel 6.2; SUR1 denotes the sulfonylurea receptor 1. ADP is adenosine diphosphate; ATP is adenosine triphosphate. As noted, in gain of function mutations, the channel remains open leading to decreased insulin secretion so that neonatal diabetes may result. With loss of function mutations the channel remains closed, leading to persistent insulin secretion and hence is a cause of neonatal hyperinsulinemic hypoglycemia. Redrawn from Sperling MA, New Engl J Med 2006; 355:507-510.

subunits cause neonatal hyperinsulinemic hypoglycemia of variable severity, as described in detail in Chapter 5. Diabetes in the mitochondrial syndromes is generally well controlled by exogenous insulin.[257]

Wolfram Syndrome. Wolfram syndrome is characterized by diabetes insipidus, diabetes mellitus, optic atrophy, and deafness (DIDMOAD).[258] There is a selective loss of beta cells, which is responsible for the diabetes mellitus. Genetic linkage studies in consanguineous families with autosomal-recessive inheritance led to the positional cloning of a gene on the short arm of chromosome 4 (termed *WFS1*, and now identified as Wolframin).

Although the function of this gene is not entirely understood, it is expressed in many tissues (most abundantly in beta cells, compared with the exocrine pancreas). Mutations in Wolframin have been identified in many families with Wolfram syndrome. Affected individuals are usually compound heterozygotes. The Wolframin gene may have a role in beta cell and neural tissue survival, and there does not appear to be a correlation between the observed mutation and severity of disease. Defects in Wolframin have been implicated in the idiopathic common nonimmune form of type 1 diabetes mellitus.[257] A second locus of Wolfram syndrome has been mapped to the long arm of chromosome 4 in several consanguineous Jordanian families.[258] In these patients, diabetes insipidus was not a feature—but upper gastrointestinal bleeding and ulceration were prominent.

Although a mitochondrial form of Wolfram syndrome has been proposed, a defect in mitochondrial DNA could not be confirmed in one large cohort.[260] It has been suggested that diabetes mellitus (before age 15) and progressive optic atrophy are highly predictive of Wolfram syndrome. The sequence of appearance of the stigmata is nonautoimmune type 1 diabetes in the first decade of life, central diabetes insipidus and sensorineural deafness in two-thirds to three-fourths of the patients in the second decade, renal tract anomalies in approximately one-half in the third decade, and neurologic complications such as cerebellar ataxia and myoclonus in one-half to two-thirds in the fourth decade. Other features include primary gonadal atrophy in the majority of males and a progressive neurodegenerative course with neurorespiratory death at a median age of 30 years. Depression has been reported as a frequent feature of relatives of patients with Wolfram syndrome.[236,258-260]

Thiamine-Responsive Diabetes Mellitus (Roger Syndrome). This syndrome is characterized by megaloblastic anemia, diabetes mellitus, and sensorineural deafness—all of which may respond to vitamin B_1 (thiamine). Diabetes mellitus is mild to moderate, insulin secretion may improve with thiamine therapy, and there are no associated autoimmune markers. It may be caused by a defect in the thiamine transporter,[261,262] which has now been identified as being caused by mutations in the SLC19A gene. This gene encodes the membrane-bound thiamine transporter THTR-1.

Uptake of thiamine by the combined pathways of an active high-affinity carrier and a passive low-affinity carrier leads to accumulation of intracellular thiamine, which is then converted to its active form thiamine pyrophosphate. This cofactor enables proper function of transketolase which is important in the pentose phosphate shunt which is key to ribose synthesis and hence nucleic acid production and of pyruvate dehydrogenase, α ketoglutarate dehydrogenase, and branched chain acid dehydrogenase—all of which are key to oxidative decarboxylation. Mutations in the high-affinity transporter THTR-1 lead to cell death in those cells that have a high rate of nucleic acid turnover (such as bone marrow cells) and activity (such as pancreatic β cells), thereby explaining the association of thiamine-responsive anemia with diabetes in those affected by this mutation.

Drug or Chemical Induced. A number of drugs and chemical agents may be toxic to the beta cell. Best known for the diabetogenic effects are the immunosuppressive agents cyclosporine and tacrolimus, which are toxic to beta cells—causing insulin-dependent diabetes in a significant proportion of patients treated with these agents for organ transplantation. Their toxicity to pancreatic beta cells is compounded by the use of immunosuppressive glucocorticoids, which antagonize insulin action to unmask diabetes.

Streptozotocin and the rodenticide Vacor are also beta cell toxic, causing diabetes. Table 10-1 lists other agents that may induce diabetes. Among these, L-asparaginase (used in chemotherapy for leukemia) and diazoxide (used to treat persistent hyperinsulinemic hypoglycemia in infancy) may cause diabetes. All of these agents, especially glucocorticoids, may combine to unmask clinical diabetes mellitus.[262]

Diseases of the Exocrine Pancreas. Cystic fibrosis (CF) is one of the most common inborn errors of metabolism, involving the chloride channel encoded on chromosome 7 and affecting approximately 1 in 2,500 live-born white infants. The increasing survival of patients with CF and the increased use of glucocorticoids to suppress bronchopulmonary inflammation have brought to the fore an entity termed *cystic fibrosis–related diabetes* (CFRD), characterized by variable impairment of carbohydrate intolerance.

Some have mild diabetes mellitus clinically apparent only while receiving steroids, whereas others require insulin for a nonimmune form of insulinopenic diabetes mellitus. Up to 75% of adults with CF have CFRD. Islet amyloid is prominent, both insulin secretion and insulin sensitivity may be impaired, and diabetic ketoacidosis may occur—as may microvascular complications. When fasting hyperglycemia (7 mM = 126 mg/dL or higher) is documented, therapy with insulin is indicated. Insulin also facilitates optimal nutrition and growth and hence promotes a sense of well-being. The diagnostic and management criteria for CFRD have been extensively reviewed.[15,266]

Ionizing Radiation to the Abdomen. Ionizing radiation to the abdomen in childhood for a condition such as nephroblastoma has been associated with the development of diabetes mellitus some 20 years later in 5% to 10% of children so treated.[264]

Pancreatectomy. Extensive pancreatectomy performed for the management of severe hyperinsulinemic hypoglycemia of infancy is associated with diabetes in approximately 50% or more of long-term survivors.[21]

Virus Infections. Several viruses have been implicated in the cause of type 1 diabetes mellitus in children. Coxsackievirus B_4 has been shown in one case report as likely fulfilling Koch's postulates for a direct beta cell

toxic effect in causing acute fulminant diabetes mellitus. In other cases of coxsackievirus infections (as well as with the established association among rubella, cytomegaloviruses, and enteroviruses), molecular mimicry between antigenic determinants in the virus and certain islet cell antigens has been implicated as the mechanism leading to an autoimmune form of type 1 diabetes mellitus. Finally, a superantigen-triggered immune response has been suggested for some viral infections and may be the mechanism related to the acute onset of diabetes mellitus with the hemolytic-uremic syndrome.[20,58,268,269]

Variants of Type 2 Diabetes

GENETIC DEFECTS IN INSULIN ACTION

Type A Insulin Resistance with Acanthosis Nigricans

This syndrome is characterized by severe insulin resistance, acanthosis nigricans in the absence of obesity, or lipoatrophy. Affected females also have hyperandrogenism, possibly as a secondary manifestation of the hyperinsulinemia with stimulation of androgen synthesis by ovarian theca cells. Glucose intolerance is variable and includes symptomatic diabetes. The hyperandrogenism presents as clinical and biochemical findings suggestive of polycystic ovary syndrome.

Some patients (predominantly black females with obesity, acanthosis nigricans, and accelerated growth suggestive of gigantism) may represent insulin resistance owing to obesity, with down-regulation of the insulin receptor. The gigantism may represent a "spillover" effect of insulin acting through the insulin-like growth factor-1 receptor rather than the insulin receptor.[270,271]

Type B Insulin Resistance

Type B insulin resistance is a rare syndrome associated with evidence of immune dysfunction (such as the defined autoimmune disease rheumatoid arthritis) or of nonspecific features of autoimmunity (such as elevated sedimentation rate or high levels of antinuclear antibodies). As with other autoimmune disorders, females are predominantly affected. An insulin-resistant diabetes develops together with acanthosis nigricans and features of PCOS (such as hirsutism).

The syndrome is due to serum autoantibodies against the insulin receptor whose function becomes impaired. However, the receptor may be activated by the presumed conformational changes induced by the antibody and cause severe hypoglycemia rather than diabetes. Treatment may require high doses of insulin to try to control the hyperglycemia, along with immunosuppressive drugs to suppress antibody production.

Leprechaunism (Donohue's Syndrome). Leprechaunism is a syndrome characterized by intrauterine growth retardation, fasting hypoglycemia, and postprandial hyperglycemia in association with profound resistance to insulin in a patient whose serum concentrations of insulin may be 100-fold that of comparable age-matched infants during an oral glucose tolerance test. Various defects of the insulin receptor have been described, thereby attesting to the important role of insulin and its receptor in fetal growth and possibly in morphogenesis. Even a probable complete absence of functional insulin receptors caused by homozygous inheritance of missense mutation in the insulin receptor, however, resulted in normal organogenesis and a live-born infant who had a severe form of leprechaunism. Most of these patients die during the first year of life.[272]

Rabson-Mendenhall Syndrome. The Rabson-Mendenhall syndrome is defined by clinical features that appear to be intermediate between those of acanthosis nigricans with insulin resistance type A and leprechaunism. Features include extreme insulin resistance, acanthosis nigricans, abnormalities of the teeth and nails, and pineal hyperplasia. It is not clear whether this syndrome is entirely distinct from leprechaunism. However, patients with Rabson-Mendenhall syndrome tend to live beyond the first year of life. Defects in the insulin receptor gene have been described in this syndrome.[273]

Lipoatrophic Diabetes. Lipoatrophic diabetes presents an interesting paradox. Whereas classic type 2 diabetes mellitus is generally associated with an excess of fat and its metabolic consequences (as described previously), a paucity of fat also causes severe insulin resistance and marked metabolic disturbances. Table 10-17 lists the genetic syndromes associated with lipoatrophic diabetes. A primary cause has been identified in the form called familial partial lipoatrophy (also known as Dunnigan syndrome). This is a gene defect localized to chromosome 1q21-22 and its product lamin A/C.

This autosomal disease usually manifests peripubertally as subcutaneous fat in the extremities and trunk but with progressively more fat in the face and neck as puberty progresses. Visceral and interfascicular fat also increases. Females seem to develop diabetes mellitus and dyslipidemia earlier and more severely than males. Why and how the lamin A/C mutations cause this lipoatrophy syndrome is unclear, especially as mutations in this gene also are associated with a progressive form of muscular dystrophy (Emery-Dreifuss syndrome), cardiomyopathy, and cardiac conduction defects.[274,275] Recently, the gene altered in Berardinelli-Seip congenital lipodystrophy has been localized to chromosome 11q13.274.[275] In addition, defects in genes encoding the enzyme AGPAT2, the endoprotease ZMPSTE24, the kinase AKT2, the nuclear receptor PPARγ, and the protein BSCL 2 have been found in patients with lipodystrophies.[274,275]

ACQUIRED DEFECTS IN INSULIN ACTION

These defects range from hormonal disorders such as pheochromocytoma and Cushing syndrome that antagonize insulin action to disease to drug-acquired forms of lipodystrophy. Anti-insulin receptor antibodies may be found in some collagen vascular disorders and can cause a type 2 diabetes mellitus syndrome characterized by acanthosis nigricans and severe insulin resistance. This is generally referred to as acanthosis nigricans with insulin resistance type B. The type A syndrome consists of a variety of insulin receptor mutations, some of which were described above. The type B syndrome is rarely described in childhood.[276]

Genetic Syndromes with Diabetes and Insulin Resistance and/or Insulin Deficiency

A number of genetic syndromes are associated with diabetes mellitus. In children, four relatively common genetic syndromes may be associated with diabetes. In trisomy 21 (Down syndrome) and Turner syndrome (a single normal X chromosome) there is an increased incidence of autoimmune disorders, especially of the thyroid. Type 1 diabetes mellitus also has a higher prevalence in patients with Down syndrome than in the general population.

In Turner syndrome, insulin secretory reserve may be limited such that treatment with growth hormone (now common) can result in impaired glucose tolerance or a type 2 diabetes. In Klinefelter syndrome (XXY), insulin resistance is a major feature—but autoimmune associations have been described. In Prader-Willi syndrome, the reported high frequency of diabetes mellitus may not be caused simply by the insulin resistance as part of the obesity of this syndrome but possibly by a primary defect in insulin secretion.[277-280]

Alstrom syndrome consists of retinal dystrophy, sensorineural deafness, obesity and associated diabetes, cardiomyopathy, hypertriglyceridemia, liver disease, and urological abnormalities. Severe insulin resistance may lead to acanthosis and diabetes. Mutations in the gene ALMS1 have been identified in these patients.[281] Bardet-Biedel syndrome also has atypical retinitis pigmentosa as a key feature, along with central obesity, polydactyly, mental retardation, hypogonadism, and renal dysfunction. Eleven loci have been linked to this syndrome, with abnormalities in celia-like structures a central theme.[281,282] The association of these and other syndromes with diabetes (listed in Table 10-1) can be ascertained by searching the Online Mendelian Inheritance in Man database (OMIM, available at *www.ncbi.nlm.nih.gov/omim/*).

Gestational Diabetes

Gestational diabetes is a disease of the second and third trimesters of pregnancy that is due to congenital or acquired defects in insulin secretion that result in the inability to compensate for the increased demands of insulin as a result of the counter-insulin effects of placental growth hormones.[283]

Neonatal Diabetes

Recent discoveries in the molecular basis for pancreas formation and regulation of insulin secretion have propelled the syndromes of neoanatal diabetes from the backwater of rarity to the forefront of research. These syndromes probably occur more frequently than previously

TABLE 10-18

Classification of Neonatal Diabetes Mellitus

Permanent	Transient
• PDX-1/IPF-1 *1 • Glucokinase-GCK *2 • HNF-1β*3 • FOX P3 (IPEX syndrome) • EIF_2AK_3 (Wolcott-Rallison syndrome) • K_{ATP} KIR 6.2 or Sur1 • Others (PTF1)	• ZAC/PLAGL1-HYMA1 mutations • Human • Transgenic mouse • KCNJ11 or ABCC8, mild activating

*Homozygous mutations cause permanent neonatal diabetes heterozygous mutations cause maturity-onset diabetes of youth (MODY). 1 = MODY 2; 3 = MODY 5.

considered, and may have an overall incidence of about 1:100,000 births.[284-291] Moreover, some of those with activating mutations in KATP channel subunits Kir 6.2 or SUR1 lend themselves to treatment with oral sulfonylurea hypoglycemic drugs such as glibenclamide—which results in endogenous insulin secretion with near-normal glycemic control and at least partial reversal of neuromuscular manifestations.[285-288]

Mutations in these genes also may contribute to T2DM in adults by impairing the ability to secrete adequate amounts of insulin to overcome insulin resistance.[289] Table 10-18 outlines the common entities responsible for neonatal diabetes, which clinically present as a transient form in the neonate (followed by remission and then recurrence in the second to fourth decade) or permanent diabetes mellitus from the outset. Both forms share the following clinical features. Most affected infants are intrauterine growth retarded (IUGR), reflecting the critical role of insulin as an in utero growth factor. Clinical features include polyuria with glucosuria, dehydration, failure to thrive, and occasionally diabetic ketoacidsis. When measured, insulin and IGF-1 levels are low.

Dysmorphic features in some include mental retardation, muscle weakness, and epilepsy. These features are found only in the permanent severe forms.[284-289] Treatment with insulin results in dramatic catch-up growth, and after several weeks to months insulin may be withdrawn in about one-half of cases. These constitute cases of transient neonatal diabetes, of whom about one-half or more have recurrence of DM several years later. About 50% of cases of neonatal DM have the permanent form from the outset.[284]

TRANSIENT

Onset of persistent insulin-dependent diabetes before the age of 6 months is very unusual and had previously been estimated to occur in only 1:500,000 births.[292] The syndrome of diabetes mellitus in a newborn has its onset in the first 6 weeks to months of life. The transient form may spontaneously recover within 3 to 6 months, at which time the insulin response to stimuli are brisk.[293] This syndrome should be distinguished from severe hyperglycemia, which sometimes occurs in hypertonic dehydration in infants beyond the newborn period. Such infants promptly respond to rehydration, with minimal requirement for insulin.

During the active phase of transient diabetes of the newborn, administration of insulin is mandatory. From 1 to 2 U/kg/24 hours of an intermediate-acting insulin in two divided doses usually results in dramatic improvement, accelerated growth, and weight gain. Pump therapy has also proven to be highly successful in neonatal diabetes and is likely superior in providing flexibility and precision in managing such patients.[292] As the syndrome resolves beyond 2 to 3 months of age, the recurrent hypoglycemia permits a gradual reduction and discontinuation in exogenous insulin.[292]

A gene for transient neonatal diabetes mellitus has been localized to the long arm of chromosome 6 at 6q24.[285,293] Transient neonatal diabetes mellitus is associated with paternal uniparental disomy of chromosome 6 or paternal duplications in this region. Differential methylation of a subportion of this region has been demonstrated in patients with transient neonatal diabetes whether they do or do not have uniparental disomy or paternal duplications of chromosome 6.[294] These findings suggest that transient neonatal diabetes mellitus may be associated with a specific methylation imprint on chromosome 6 that must be paternally expressed. In one extensive investigation of 30 patients with neonatal transient diabetes, only 6 had no methylation rearrangement in chromosome 6. The role of this imprinted region on 6q24 is not fully understood, but it has been suggested that this gene may have an important function in normal pancreatic development.

To date, defects of this gene have not been found in permanent neonatal diabetes. The imprinted gene in this region is most likely ZAC (Zfinger protein regulating Apoptosis and Cell cycle arrest). A transgenic mouse model expressing the human region of 6q24 has been generated.[295] This mouse model recapitulates many of the human findings and has provided insights into the sequence of events that characterize the human condition (i.e., neonatal diabetes, followed by remission and then recurrence in later life).[295] In addition to the locus on 6q24, some activating mutations in KCNJ11 (which codes for the potassium channel pore) and in ABCC8 (which codes for the sulfonylurea receptor regulatory subunit of the K_{ATP} channel on beta cells) (Figure 10-12) can result in a transient neonatal DM followed by remission and recurrence. However, mutations in the K_{ATP} units are the most common cause of permanent neonatal DM.[284-290]

PERMANENT

The permanent forms of neonatal DM are outlined in Table 10-18. Diabetes mellitus in the newborn period will be permanent if associated with the rare syndrome of pancreatic agenesis. In one such case, there was homozygous mutation of the gene for insulin promoter factor-1 (IPF1)[296]—also known as PDX-1 because it is a pancreas duodenum homeobox gene involved in the formation of the exocrine plus endocrine pancreas and the duodenum. Hence, patients with this cause of

neonatal DM have exocrine manifestations (such as malabsorption) and the endocrine manifestations of severely diminished insulin secretion.

Heterozygous mutations of PDX-1/IPF1 are the cause of MODY 4 and have been implicated as a cause of some forms of late-onset type 2 diabetes mellitus.[297] Likewise, homozygous mutations in the glucokinase gene are associated with permanent neonatal diabetes—whereas the heterozygous forms are the cause of MODY 2.[285,298] Severe mutation in hepatic nuclear factor 1β (HNF-1β) can cause permanent or transient neoanatal DM and is associated with renal cysts.[285] FoxP3 is a human gene that is the ortholog of the mouse scurfy gene and responsible for the IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) syndrome. Autoimmunity may not be the sole factor in causing DM.[285,291]

The Wolcott-Rallison syndrome is a disorder characterized by the appearance of permanent insulin-requiring diabetes mellitus within 3 months of life. It is associated with multiple epiphyseal or spondyloepiphyseal dysplasia, renal and hepatic impairment, ectodermal dysplasia, cardiac anomalies, and poor prognosis. Inheritance is consistent with an autosomal-recessive pattern. The eukaryotic translation-initiation factor-2-alpha kinase-3 (E1F2AK3) was mutated in two consanguineous families with this syndrome. This factor, highly expressed in islets, has a role in protein translation that may account for the multiple manifestations of this syndrome.[43,44,300]

The most common forms of permanent neoantal DM are caused by mutations in the Kir6.2 (KCNJ11) and SUR1 (ABCC8) subunits of the KATP channel.[284-291] Severe mutations, especially of KCNJ11, may be associated with the DEND (developmental delay, epilepsy, and neonatal diabetes) syndrome. The pathophysiology of these syndromes has been elucidated, and the relationship of the severity of mutation in terms of channel activity has been correlated with the clinical manifestations. Remarkably, the KCNJ11 and ABCC8 mutations may be responsive to pharmacologic doses of the oral sulfonylurea glibenclamide—with restoration of endogenous insulin secretion, ability to discontinue insulin injections, and marked improvement in overall metabolic control. In addition, some improvement in neuromuscular activity has been reported.[284-289] Some of the mutations in KCNJ11 have been reported to occur in T2DM, and hence these mutations might be selectively targeted for treatment with sulfonylurea drugs.[289]

Impaired Glucose Tolerance

The term *impaired glucose tolerance* is used to characterize individuals who have a plasma glucose concentration in excess of 140 mg/dL at 2 hours after initiation of the standard oral glucose tolerance test but do not have symptoms of diabetes or fasting hyperglycemia. Such a constellation may represent the earliest phase of a gene defect in insulin secretion or action or be a step in evolving diabetes mellitus type 1. The hyperglycemia may be a chance discovery during an intercurrent illness, during therapy with corticosteroids, or as part of a screening of close relatives of patients with defined genetic syndromes.

In those who have impaired glucose tolerance but do not have fasting hyperglycemia, repeated oral glucose tolerance tests are not recommended. Investigations in such children indicate that the degree of impaired glucose tolerance tends to remain stable except in those who have markedly subnormal insulin response.[3] The arbitrarily designated response that identifies impaired glucose tolerance is defined as a fasting plasma glucose value of less than 110 mg/dL and a value at 2 hours of more than 140 mg/dL. The determination of serum insulin responses during the glucose tolerance test is not a prerequisite for reaching a diagnosis. Because the magnitude of the insulin response may have prognostic value, however, insulin determination is performed by some investigators.[237]

Pancreas and Islet Transplantation

In an attempt to cure insulin-dependent diabetes, transplantation of a segment of the pancreas or of isolated islets has been increasingly performed in humans.[302,303] These procedures are technically demanding and associated with the risks and complications of rejection and its treatment by immunosuppression. Therefore, segmental pancreas transplantation is generally performed in association with transplantation of a kidney for a patient with end-stage renal disease owing to diabetic nephropathy in whom the immunosuppressive regimen is indicated for the renal transplant.

Several thousand such transplants have been performed worldwide during the past 25 years. With experience and newer immunosuppressive agents, functional survival of the pancreatic graft may be achieved for as long as several years—during which patients may be in metabolic control with no or minimal exogenous insulin and reversal of some of the microvascular complications. Because children and adolescents with diabetes mellitus are not likely to have end-stage renal disease as a result of diabetes, however, pancreas transplantation as a primary treatment cannot be recommended (nor its risks justified) in children.

Attempts to transplant isolated islets have been equally challenging because of techniques to harvest sufficient islets and the issue of rejection.[303] Some of the newer antirejection drugs, notably cyclosporine and tacrolimus, are toxic to the islets of Langerhans—impairing insulin secretion and even causing diabetes.[304] The Edmonton protocol for islet transplantation avoids steroid and uses an anti-IL-2 receptor antibody and tacrolimus instead of other immunosuppressants.[303] Initial success had been promising, but long-term survival of the graft beyond 3 to 5 years is most unusual—and there have been serious side effects of the procedure as well as failure to restore hypoglycemia unawareness.[303] Hence, this islet transplantation protocol cannot be recommended in children.

Research continues to improve techniques for the yield, viability, and loss of immunogenicity of islets of Langerhans for transplantation. Transplantation has been investigated of islets coated or microencapsulated with a

film of protective chemicals that permit diffusion of insulin and nutrients but prevent T-cell contact and therefore avoid rejection.[305] These novel approaches have been frustrated in the long term by overgrowth of fibroblasts that progressively impair glucose sensing by the islets and insulin diffusion from them. Should these technical problems be overcome, or methods to avoid rejection become established, transplantation of pancreas or islets as primary treatment for diabetes may be entertained after their risks are carefully compared with and weighed against potential benefits—especially in children. Islet regeneration by modulating the immune response is also under scrutiny.[306,307]

Conclusions

Progress continues to be spectacular in understanding and treating diabetes mellitus. We have moved from a glimmer of understanding that diabetes is a syndrome of broad categories (insulin dependent and non–insulin dependent) to an understanding of disease susceptibility and disease causality at a molecular level. Type 1 diabetes is acknowledged to be an autoimmune disease with major susceptibility loci in the HLA complex. Positional cloning techniques have identified other gene markers, and we now recognize the importance of mitochondrial gene defects in some types of insulin-dependent diabetes that may not be autoimmune.

More spectacular has been the unraveling of the molecular basis of neonatal diabetes and its treatment, including the use of sulfonylureas. Not surprisingly, this knowledge is being rapidly applied to predict the likelihood of disease appearance in individuals whose susceptibility can be quantified by the presence of certain antibodies and by limitations in first-phase insulin response. Population surveys in individuals not known to be at risk for diabetes have just begun. We are in the early stages of attempts to prevent the disease, reminiscent of the early trials examining the relationship between control and microvascular complications.

The monumental DCCT and European studies have irrefutably established the link, requiring new standards of care. Progress and understanding of insulin secretion and insulin action have been equally spectacular for the insights provided in defining non–insulin-dependent forms of diabetes at physiologic, biochemical, and molecular levels. Therapy with human insulin is now standard. Trials with improved insulin-delivery systems, including computerized artificial pancreas as well as pancreas and islet transplantation, are in progress. The beneficiaries of these advances are our patients, whose interests will continue to be best served by bidirectional scientific inquiry from bench to bedside.

Emergency Treatment of Hypoglycemia
Conclusions

Introduction

Hypoglycemia in later infancy and childhood is less common than hyperglycemia. However, the evaluation is more complex—and the consequences of delayed diagnosis or inadequate management may be more harmful to a developing brain.[1] This chapter describes a diagnostic approach grounded in the physiology of glucose homeostasis, in which the key to diagnosis is identification of which system(s) of metabolism is failing to maintain a normal fuel supply.

The transition from continual intrauterine glucose supply to an extrauterine life of alternating periods of postprandial glucose influx and fasting glucose production requires a series of adaptations (see Chapter 5). Once this transition is complete, the mechanisms of glucose homeostasis remain the same throughout life—although higher rates of glucose utilization in infants and children compared to adults impose a greater dependence on glycogenolysis, gluconeogenesis, and fatty acid oxidation for maintenance of an adequate fuel supply during fasting.[2] As feeding intervals increase in late infancy, disorders of these processes can produce hypoglycemia. The developing brain is susceptible to hypoglycemic damage.[1,3,4]

In infants and children, hypoglycemia is a medical emergency demanding immediate investigation and treatment. When the cause of hypoglycemia is obvious, such as intercurrent illness in a child with known adrenal insufficiency, management may immediately focus on rapid reversal. However, when the cause is not readily apparent discovery of hypoglycemia should prompt immediate taking of "critical samples" of blood and urine to enable diagnosis[3] (Table 11-1).

The principal mechanisms of defense against hypoglycemia are outlined in Chapter 5. The focus of this chapter is on disorders of glucose metabolism in postneonatal infants and older children. Many hypoglycemic disorders may present during or after 1 month of age, and those conditions discussed in Chapter 5 in detail are briefly described.

Definition of Hypoglycemia

There has been controversy over the definition of *hypoglycemia*, especially in infancy, for five decades.[4-7] For the purposes of this chapter, two different definitions of hypoglycemia are used: a diagnostic level and a therapeutic level. For diagnostic purposes, hypoglycemia is a plasma glucose value of less than 50 mg/dL (<2.8 mmol/L). Whole-blood glucose levels tend to be 10% to 15% less than plasma.[8] This level differs from the level of 70 mg/dL, which is the lowest level acceptable during therapy for hypoglycemia. That is, the goal of therapy is to maintain plasma glucose levels in the normal range of 70 to 100 mg/dL most of the time. Failure to do so warrants modification of therapy.

Methods of measuring glucose levels in hospitals include bedside glucose meters originally designed for diabetes management. These monitors are adequate for management of hyperglycemia, but are not accurate for measurement of hypoglycemia. Recent developments in bedside monitoring have improved the technology, but none is sufficiently accurate to establish a diagnosis of hypoglycemia. These meters are most useful as screening tests, and any meter blood glucose level less than 60 mg/dL should be confirmed by a more accurate laboratory determination of blood or plasma glucose concentration.[9,10]

TABLE 11-1

The Critical Sample: Acute Blood and Urine Tests at Time of Hypoglycemia

Blood
- Chemistry panel with bicarbonate
- Insulin, C-peptide
- Cortisol, growth hormone
- Free fatty acids, b-hydroxybutyrate, acetoacetate
- Lactate, ammonia
- Total and free carnitine
- Acyl carnitine profile
- Save serum tube

Urine
- Dip for ketones
- Organic acids

Symptoms and Signs of Hypoglycemia

Most clinical features of hypoglycemia fall into one of two categories (Table 11-2). Adrenergic manifestations (sweating, tachycardia, anxiety) include symptoms

TABLE 11-2

Symptoms of Spontaneous Hypoglycemia

Symptoms Caused in Part by Activation of Autonomic Nervous System and Epinephrine Release (Usually Associated with Rapid Decline in Blood Glucose Level)
- Sweating
- Shakiness, trembling
- Tachycardia
- Anxiety, nervousness
- Weakness
- Hunger
- Nausea, vomiting

Symptoms Caused by Decreased Cerebral Glucose Use (Usually Associated with Slow Decline in Blood Glucose Level and/or Severe or Prolonged Hypoglycemia)
- Headache
- Visual disturbances
- Lethargy, lassitude
- Restlessness, irritability
- Difficulty with speech and thinking, inability to concentrate
- Mental confusion
- Somnolence, stupor, prolonged sleep
- Loss of consciousness, coma
- Hypothermia
- Twitching, convulsions, "epilepsy"
- Bizarre neurologic signs
- Motor disturbances
- Sensory disturbances
- Loss of intellectual ability
  - Personality changes
  - Bizarre behavior
  - Outburst of temper
- Psychological disintegration
  - Manic behavior
  - Depression
  - Psychoses
- Permanent mental or neurologic damage

associated with the activation of epinephrine release that occur as the blood glucose concentration declines below 60 to 70 mg/dL.[11] Neuroglycopenic manifestations (lethargy, confusion, seizures) result from decreased cerebral glucose utilization, and are usually associated with glucose levels below the adrenergic activation threshold. Epinephrine release may become blunted or absent in patients with recurrent hypoglycemia, such that neuroglycopenic effects may be the sole clinical presentation. In some children, signs and symptoms are minimal despite prolonged hypoglycemia. However, it cannot be assumed that asymptomatic hypoglycemia carries no risk of harm.

Physiologic Adaptation of Glucose Metabolism During Infancy and Childhood

CHANGES IN GLUCOSE PRODUCTION

Glucose utilization rates per kilogram of body weight are markedly higher in infants than in adults because of their larger brain size relative to body weight. As a result, normal infants and children may develop hypoglycemia after 24 to 36 hours of fasting, whereas normal adults can fast for 48 to 72 hours without hypoglycemia. Stable isotope measurements of glucose turnover rates indicate that the brains of infants and children use glucose at rates of 4 to 6 mg/kg/min, equivalent to almost all of endogenous glucose production during fasting.[2]

The rate of glucose production by the liver is remarkably correlated with estimated brain weight at all ages. Because brain growth is nearly complete as the body weight reaches 40 kg (at 11-12 years of age), little additional glucose production is needed as an adult body mass is achieved (Figure 11-1).[12] Because the greater proportion of brain growth occurs in the first 2 years of life, hypoglycemia occurring during this time may cause significant and permanent neurologic damage. Although hypoglycemia occurring after the first 2 years of life has less likelihood of causing brain damage, its investigation and treatment continue to be crucial.

From the studies of Bier and co-workers it is clear that the glucose requirement per unit of body mass in infants is greater than that of adults, yet the muscle bulk of young children is substantially smaller relative to body mass than that of adults.[2] Because gluconeogenic precursors are derived primarily from muscle, the ability of children to maintain glucose levels through gluconeogenesis while fasting is limited by their smaller muscle mass.

The ability of the infant and child to maintain glucose above 70 mg/dL during a prolonged fast gradually improves with age. Infants from 1 week to 1 year of age should be able to tolerate 15 to 18 hours of fasting. By 1 year of age, a normal child should be able to fast up to 24 hours.[13,14] By 5 years of age, a fast of up to 36 hours may be tolerated. Hypoglycemia induced by fasting of shorter duration should alert the clinician to the possibility of an underlying disorder.

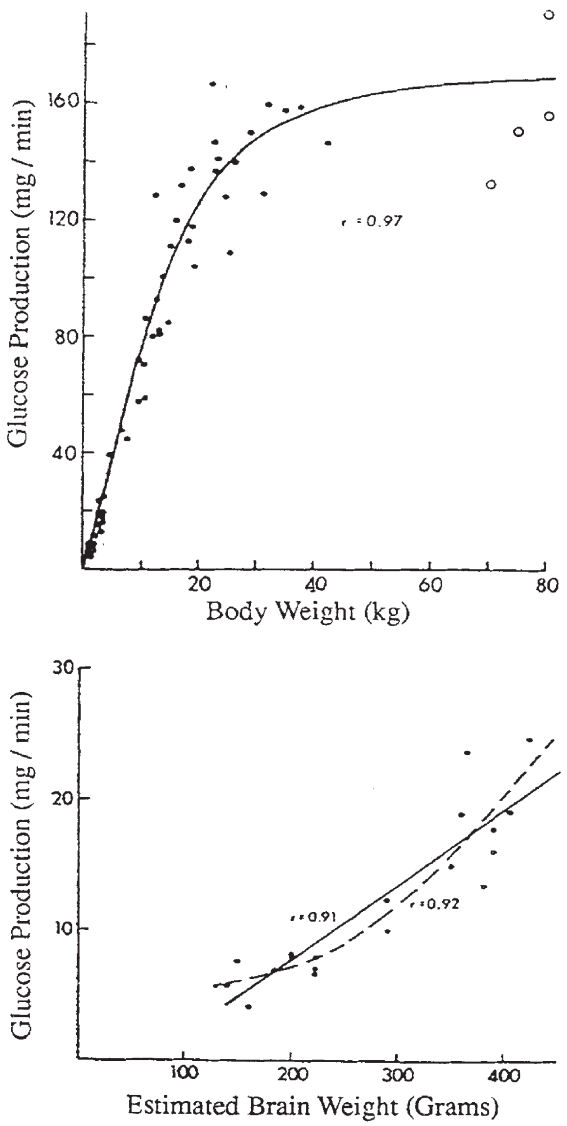

Figure 11-1 Glucose production as a function of body weight (top) and estimated brain weight (bottom). Note the change in slope at approximately 40 kg of body weight when brain growth is complete. [From Bier DM, Leake RD, Haymond MW, et al. (1977). Measurement of "true" glucose production rates in infancy and childhood, with 6,6-dideuteroglucose. Diabetes 20:1016.]

FASTING ADAPTATION

With feeding, serum insulin concentrations rise from fasting values of 3 to 10 μU/mL to peaks of 20 to 50 μU/mL that serve to activate glycogen synthesis, inhibit gluconeogenesis, and enhance peripheral (muscle) glucose uptake. Simultaneously, lipid synthesis is activated and lipolysis and ketogenesis are curtailed. In the postabsorptive state, glucose levels decline and insulin secretion is reduced. Coupled with a rise in counterregulatory hormones during fasting, the fall in insulin levels serves to reverse the anabolic pathways to ensure adequate supplies of glucose, fatty acids, and ketones (Table 11-3). The mobilized fatty acids and the generated ketones serve as alternative fuels for muscle, including cardiac muscle, thereby sparing glucose for brain metabolism.[13]

TABLE 11-3

Hormonal Regulation of Fasting Metabolic Systems

	Hepatic	Hepatic	Adipose Tissue	Hepatic
Hormone	**Glycogenolysis**	**Gluconeogenesis**	**Lipolysis**	**Ketogenesis**
Insulin	Inhibits	Inhibits	Inhibits	Inhibits
Glucagon	Stimulates			Stimulates
Cortisol		Stimulates		
Growth hormone		Stimulates	Stimulates	
Epinephrine	Stimulates	Stimulates	Stimulates	Stimulates

The first stage in the defense against hypoglycemia is glycogenolysis. In infants, glycogen stores may provide glucose for up to 4 hours. As the child grows older, glycogen stores are greater and may provide glucose for up to 8 hours of fasting. Glucagon and epinephrine in the presence of lowered insulin levels trigger glycogenolysis. Deficiency of these hormones is very unusual, other than in children on β-blocker drugs. Therefore, hypoglycemia occurring early in fasting suggests either excess insulin secretion or a primary disorder in glycogenolysis.

As glycogen stores become depleted, there is a greater reliance on gluconeogenesis to maintain plasma glucose levels. The main gluconeogenic precursors are amino acids, especially alanine, most of which is generated from skeletal muscle. To prevent excessive breakdown of muscle protein, adipose tissue provides an additional fuel source in the form of triglycerides hydrolyzed to free fatty acids. Mitochondrial fatty acid oxidation (FAO) in the liver produces ketone bodies (β-hydroxybutyrate and acetoacetate) that can be used by the brain and muscle, including cardiac muscle, for energy production. This decreases glucose utilization by these organs and helps ensure an adequate supply of glucose to tissues (e.g., red blood cells) that use only glucose as fuel. Breakdown of adipose tissue triglycerides (lipolysis) is triggered by secretion of the counterregulatory hormones [epinephrine and growth hormone (GH)] and by declining levels of insulin. In infants, ketones appear in the urine 12 to 18 hours into fasting. In older children, ketonuria may not appear until 18 to 24 hours of fasting have been completed. Cortisol, produced during stress, can further accelerate gluconeogenesis.

Defects in gluconeogenesis will usually become manifest only after glycogen stores have been depleted and will thus not occur in the recently fed state. FAO disorders can be triggered by more prolonged fasting. In the first months of life, feeding intervals gradually increase from the typical 2- to 3-hour interval of the on-demand breast-fed infant to 4 hours, and eventually to 8 to 12 hours as nighttime feedings are omitted. For this reason, disorders of gluconeogenesis and FAO rarely present as hypoglycemia in the newborn period when feeding is frequent, but rather later in infancy as fasting is prolonged. Congenital or acquired deficiencies of the counterregulatory hormones that facilitate these processes may also result in hypoglycemia—in the newborn period if congenital and severe or later in infancy as longer fasting occurs. Combined deficiency of cortisol [adrenocorticotropic hormone (ACTH)] and GH in hypopituitarism may produce earlier or more severe hypoglycemia than occurs with isolated hormone deficiencies (Figure 11-2).

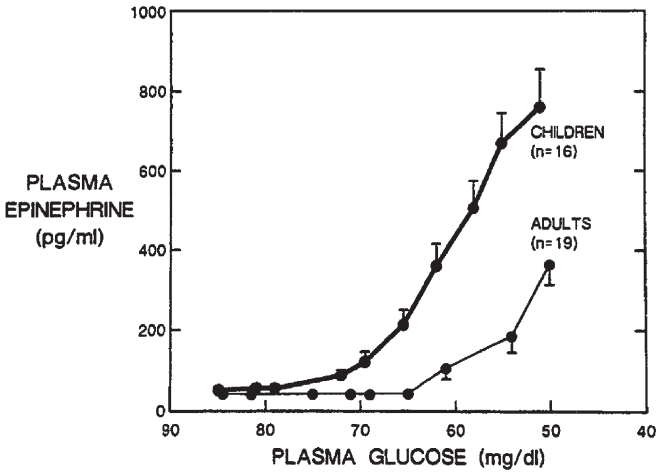

Figure 11-2 Plasma epinephrine response of children and adults to step decreases in blood glucose concentration during a hyperinsulinemic clamp procedure. Note that the increase in epinephrine concentration occurs at a significantly higher glucose concentration in children than in adults. In addition, at comparable glycemia of less than 60 mg/dL epinephrine responses in children are approximately threefold higher than in adults. [From Jones TW, Borg WP, Boulware SD, et al. (1995). Enhanced adrenomedullary response and increased susceptibility to neuroglycopenia: Mechanisms underlying the adverse effects of sugar ingestion in healthy children. J Pediatr 126:171.]

Major Causes of Hypoglycemia in the Infant and Child

HYPERINSULINISM

Hyperinsulinism is the most common and the most severe form of hypoglycemia in early infancy.[16] Although less common in later infancy and childhood, it continues to be a significant cause of newly diagnosed hypoglycemia. The hypoglycemia of hyperinsulinism is particularly dangerous because it is associated with inadequate amounts of all brain fuels (low plasma ketones and glucose), thus amplifying the risk of brain damage.[1] As noted in Chapter 5, 60% of patients with hyperinsulinism present in the first

week of life. Those infants with the most severe forms tend to present earliest.

Milder forms of hyperinsulinism may become evident beyond the first months of life, when the feeding intervals lengthen and night feedings are omitted. Such infants may present with seizures or early-morning lethargy. Many will have a history of hypoglycemia in the newborn period that was not fully appreciated or will have a history of previous seizures. Some of these children may have unexplained developmental delay. In dominant forms of hyperinsulinism, a parent or other relative may report a more subtle history of hypoglycemia.[14] Defects of the KATP channel are the most common form of congenital hyperinsulinism, but a growing number of other defects in insulin secretion are being identified. As outlined in Chapter 5, all of the genetic causes of hyperinsulinism may initially present in the older infant and child.[15-18]

Hypoglycemia due to hyperinsulinism after the neonatal period is likely to present as recurrent episodes of neuroglycopenic symptoms in an otherwise well child. The hypoglycemia may be mild or severe, occurring after overnight fasting or in a "reactive" pattern 2 to 3 hours after a meal. Obvious adrenergic signs (pallor, perspiration) are common but not invariably present. The diagnosis of hyperinsulinism is suggested when hypoglycemia is accompanied by absence of ketosis. A critical specimen obtained during hypoglycemia that demonstrates measurable amounts of insulin, C-peptide, and/or proinsulin (Table 11-4) can be conclusive. However, it is not always easy to demonstrate elevated insulin levels.

Note also that standard insulin assays may not detect exogenous insulin analogs such as lispro, aspart, glargine, glulisine, and detemir. Plasma free fatty acids and beta-hydroxybutyrate are inappropriately low during hypoglycemia due to hyperinsulinism, as is insulin-like growth-factor-binding protein-1 (IGFBP1).[21] A glycemic response to glucagon at the time of hypoglycemia is strong evidence of hyperinsulinism as well.[3,21,22] Because of the increased glucose utilization of hyperinsulinism, a glucose infusion rate above 8 mg/kg/min may be needed to maintain glucose above 70 mg/dL in young infants. However, this is usually more difficult to demonstrate or is inconsistently present in older children.

TABLE 11-4

Criteria for Diagnosing Hyperinsulinism Based on Critical Samples

Critical sample must be drawn at time fasting hypoglycemia (plasma glucose <50 mg/dL
- Detectable insulin (>2 mIU/mL)
- Low free fatty facids (<1.5 mmol/L)
- Low ketones (plasma β-hyrdoxybutyrate, (<2.0 mmol/mL)

Inappropriate glycemic response to 1 mg intravenous glucogen at time of fasting hypoglycemia (glucose rise >30 mg/dL in 20 minutes)

Katp Channel Hyperinsulinism

Two genes, SUR1 and Kir6.2, encode the two proteins of the adenosine triphosphate (ATP)-sensitive potassium channel (KATP channel) in the plasma membrane of the beta cell. Potassium flow through this channel is a key regulator of insulin secretion (Figure 11-3), and defects that impede flow cause excessive insulin secretion. As described in Chapter 5, three distinct defects of these genes are known to cause hyperinsulinism.

- Autosomal-recessive inheritance of two KATP mutations produces a severe neonatal onset of disease that is unresponsive to diazoxide. These mutations are associated with diffuse histologic changes in the pancreatic islets.[19]

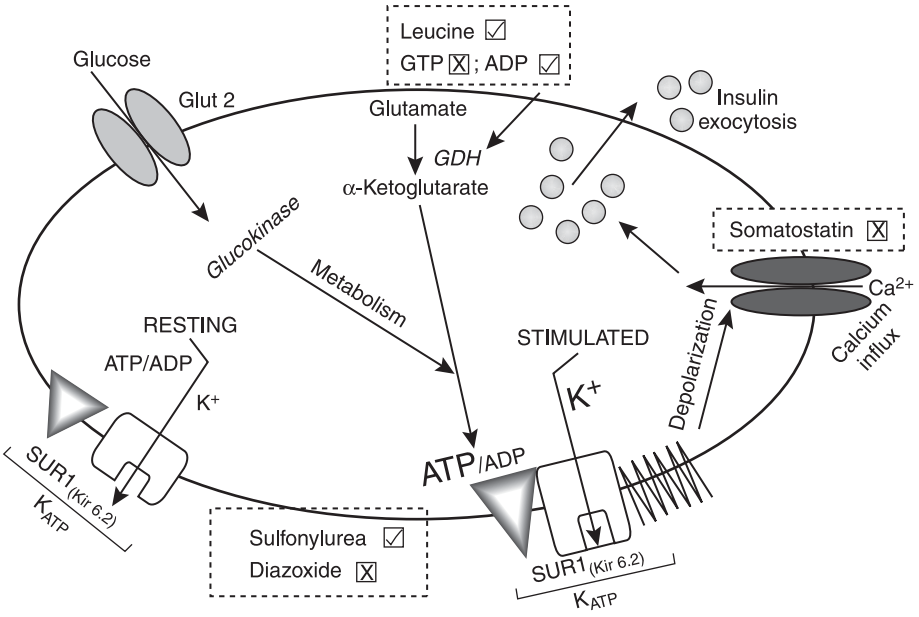

Figure 11-3 Diagram of the pancreatic beta cell, glucose-stimulated insulin secretion, and sites affected by the potassium-channel, SUR1(Kir6.2), glucokinase, and glucose dehydrogenase (GDH) mutations. ADP, adenosine diphosphate; ATP, adenosine triphosphate; and GTP, guanosine triphosphate.

- A clone of beta cells possessing a single recessive mutation on the paternal chromosome may lose the normal maternal allele, resulting in homozygosity for a recessive KATP channel mutation.[17] This "two-hit defect" produces a focal area of adenomatosis in the pancreas.
- A rarer dominantly inherited autosomal mutation causes a milder form of KATP hyperinsulinism, which usually presents after infancy and often responds to diazoxide.[16,24]

The first two forms of KATP hyperinsulinism account for more than 90% of cases of postneonatal endogenous hyperinsulinism in infancy and are clinically similar in their clinical manifestations. Both may require surgery to maintain safe glucose levels. After confirmation of hyperinsulinemic hypoglycemia by the criteria of Table 11-4 and exclusion of the rarer forms described in material following, a KATP channel defect can be presumed the most likely diagnosis. While blood is being tested for specific mutations (e.g., to Athena Diagnostics, *www.athenadiagnostics.com*), management may proceed without molecular confirmation. Treatment measures able to maintain blood glucose levels above 70 mg/dL without surgery are referred to as "medical management" (Table 11-5).

Diazoxide is the first-line drug, but is often ineffective for KATP hyperinsulinism. Octreotide may be given by subcutaneous injection or infusion at up to 20 ug/kg/day.[20] Calcium channel blockers have occasionally been tried.[22] If this approach does not maintain the plasma glucose concentration greater than 60 mg/dL with a normal feeding schedule, surgery may be necessary. Surgical treatment for focal KATP hyperinsulinism is curative, whereas for diffuse disease even a 95% to 99% pancreatectomy may not cure the hypoglycemia (and diabetes is a frequent sequela).[21] PET scanning may distinguish the two types of disease preoperatively, but definitive differentiation of focal and diffuse disease is made intraoperatively by repeated examination of frozen sections.[22] This difficult procedure requires a patient surgeon and a dedicated team of histopathologists.[23-25]

TABLE 11-5

Selective Drugs for Hypoglycemic Disorders

Intravenous Glucose Rescue Doses
- Dextrose emergency bolus: IV push 0.2 g/kg bolus (2 mL/kg of dextrose 10%), followed by D10 continuous infusion of 5 mL/kg/hr
- If plasma glucose not corrected after 15 minutes, bolus 2 mL/kg dextrose 10% and increase continuous infusion by 25% to 50%

Glucagon (Emergency Treatment Only in Case of Insulin-Induced Hypoglycemia)
- 1 mg intramuscularly or intravenously
- Side effects: vomiting and rebound hypoglycemia

Diazoxide (Use in Hyperinsulinism or Sulfonylurea Overdose)
- 5-15 mg/kg/day divided into two or three doses (if given by IV route, must be given over 15 minutes to avoid hypotension)
- Start with maximum dose (15 mg/kg to test), then lower as possible (responders usually require 10 mg/kg or less)
- Side effects: fluid and sodium retention, hypertrichosis

Octreotide
- Start at 2 to 5 mg/kg/day and increase to 20 mg/kg/day SC divided q6-8h
- Continuous IV infusion, 510 mg/kg/24 hr
- Side effects: transient diarrhea, abdominal discomfort, gallstones, transient growth impairment

Cornstarch
- 1-2 g/kg/dose (freshly prepare each dose by suspending in cold sugar-containing liquid)
- Effect lasts 4 to 6 hr
- Not well absorbed in infancy
- Side effect: diarrhea

Carnitine (For Plasma Membrane Carnitine Transporter Defect)
- 100 mg/kg/day divided into three or four doses
- Side effects: diarrhea and fishy body odor

IV, intravenous; and SC, subcutaneous.

Glutamate Dehydrogenase Hyperinsulinism

Hyperinsulinism can also be caused by activating mutations in the gene (GLUD1 on 10q) for glutamate dehydrogenase (GDH).[18] This disorder, also known as the hyperinsulinism-hyperammonemia syndrome, is a milder form of hyperinsulinism than KATP hyperinsulinism and is more likely to present in late infancy and early childhood than in the newborn period.[26,27] Mutations in GDH cause disease in an autosomal-dominant fashion, but up to 80% cases may be de novo mutations. Severity may vary within a family from seizures in infancy to mild postprandial hypoglycemia in adults. Ingestion of protein without carbohydrate may be especially likely to depress the blood glucose.

Activating mutations of GDH in the beta cell amplify leucine-triggered production of ATP, independent of glucose levels, which then causes closure of KATP channels and insulin release. In the liver, the same mutation increases oxidation of glutamate to a-ketoglutarate with the production of ammonia (Figure 11-4). In addition to increased ammonia production, the low levels of glutamate impair the production of N-acetylglutamate, an important allosteric activator of the urea cycle. Thus, the same mutation causes excessive insulin production in the pancreas and excessive ammonia production (with impaired urea synthesis) in the liver.

The diagnosis of GDH hyperinsulinism is similar to that of KATP hyperinsulinism. In addition to the usual laboratory findings of hyperinsulinism, however, persistently elevated ammonia levels (typically 50 to 200 μmol/L, median 135) are diagnostic of this disorder.[28] Most patients respond to diazoxide, and surgery is unnecessary.[26,29] High ammonia levels do not appear to cause problems in GDH hyperinsulinism because the hyperammonemia is not associated with elevated glutamine, the substance thought to be principally responsible for the central nervous system (CNS) toxicity evident with other forms of hyperammonemia.[30]

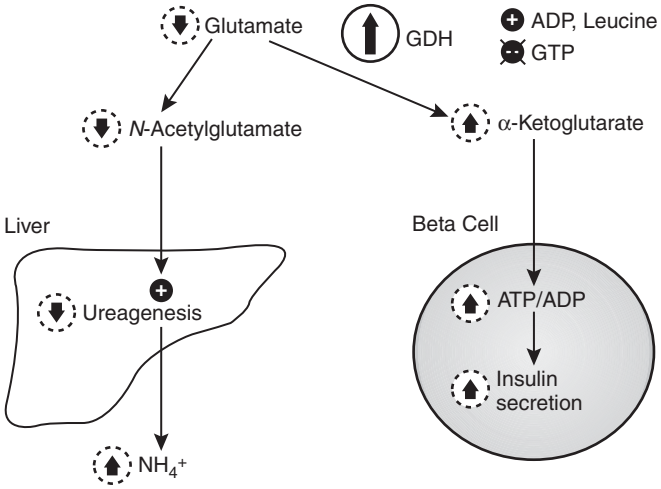

Figure 11-4 The mechanism of hyperinsulinism and hyperammonemia in glucose dehydrogenase (GDH) hyperinsulinism. GDH enzyme activity is increased as a result of mutations that interfere with the inhibitory allosteric effector, guanosine triphosphate (GTP) pancreatic beta cells. This leads to increased oxidation of glutamate to α-ketoglutarate and excessive release of insulin. Simultaneously, in the liver the increase in GDH activity lowers the pool of glutamate—leading to reduced synthesis of N-acetylglutamate. This results in less stimulation of carbamoyl phosphate synthetase (the first step in ureagenesis), and thus in hyperammonemia (NH41). ADP, adenosine diphosphate; and ATP, adenosine triphosphate.

Glucokinase Hyperinsulinism

Glucokinase is the enzyme that serves as the glucose sensor in the beta cells of the pancreas. Gain-of-function mutations can result in a lower glucose threshold for insulin secretion, leading to persistent hypoglycemia. At least six different dominantly expressed mutations have been reported. Enzyme activities, glucose thresholds, and clinical severity of these mutations can vary widely. The most severe mutations have produced neonatal hypoglycemia eventually requiring pancreatic surgery to stabilize glucose levels. Milder mutations have presented as hypoglycemic seizures in childhood, or even reactive hypoglycemia in older relatives.[31] Like the KATP forms of hyperinsulinism, glucokinase mutations can cause apparently transient neonatal hypoglycemia that recurs later in life.

Glucokinase hyperinsulinism resembles KATP hyperinsulinism in the laboratory. In the two GCK-HI patients in whom it was tested, the insulin response to intravenous glucose was greater than is usually seen with KATP hyperinsuinism. Ammonia levels are normal. Mild and moderate mutations have responded to diazoxide treatment, but pancreatectomy was required in two of the more severe cases.[32]

Schad Hyperinsulinism

Short-chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD) is an enzyme of mitochondrial fatty acid oxidation. Recessive loss-of-function SCHAD mutations have been associated with a few cases of familial congenital hyperinsulinism. Some cases have displayed severe hypoglycemia as newborn infants, but at least one showed no signs of hypoglycemia until several months of age.[33] SCHAD hyperinsulinism resembles other forms of hyperinsulinism more than it resembles other fatty acid oxidation disorders. Elevated levels of 3-hydroxybutyryl-carnitine in blood and 3-hydroxyglutarate in urine led to the diagnosis in the patients described. Treatment with diazoxide was effective.[34,35]

Exercise-associated Hyperinsulinemic Hypoglycemia

A small number of children (infants to adolescents) have been found to suffer hypoglycemic seizures or syncope due to hyperinsulinism occurring with anaerobic exercise.[36] The condition has been inherited in an autosomal-dominant pattern, but the specific molecular defect has not been established. Intravenous pyruvate infusion stimulated excessive insulin release in these cases, suggesting that the defect may involve inappropriate expression of a plasma membrane pyruvate transporter on the beta cells.

Carbohydrate-deficient Glycoprotein Hyperinsulinism

Hypoglycemia due to hyperinsulinism has also been reported in children with the carbohydrate-deficient glycoprotein syndrome (also known as congenital disorders of glycosylation). The hyperinsulinism typically causes hypoglycemia in the newborn period, but in some cases hypoglycemia was not apparent until later infancy. Unlike other forms of hyperinsulinism, CDG usually causes major impairment of other organ systems—especially the brain, liver, gut, and skeleton.[37] The diagnosis is usually confirmed by identification of hyposialylated serum transferrin by isoelectric focusing.[38]

Factitious Hyperinsulinism

Rare instances of factitious hyperinsulinism have been reported in infants or children, typically the result of a caregiver administering the medication to gain attention. This is a form of child abuse often referred to as Munchausen by proxy or Meadow syndrome. In most reported cases, the parent was a nurse or other medical professional—or family members used insulin or sulfonylureas for diabetes.[39-41] This syndrome of child abuse may be lethal. The diagnosis is difficult to make unless suspected.

Insulin administration may be difficult to detect, particularly because the more recent insulin analogs (lispro, aspart, glargine, glulisine, detemir) may not be detected by conventional insulin assay. Typically, classic symptoms of hyperinsulinism are present on an irregular basis. Fasting studies in the absence of the caregivers will be normal. As in other forms of excessive insulin, hypoglycemia will be accompanied by suppression of free fatty acids, ketones, and a positive response to glucagon—indicating that glycogen deposits are abundant and their release inhibited by insulin.

In cases in which regular or NPH insulin have been given, insulin levels may be remarkably high at the

times of hypoglycemia. The most conclusive evidence of exogenous insulin is the suppression of C-peptide to undetectable levels at the time other evidence indicates insulin excess, indicating that endogenous insulin production has been suppressed.[42] Insulinomas may secrete high insulin levels, but proinsulin levels will also be persistently elevated.

Oral hypoglycemic agents that induce insulin secretion, especially sulfonylureas, will cause elevation of both insulin and C-peptide.[43] Because they induce endogenous insulin secretion, their use will be difficult to detect unless suspected. Routine toxicology screens on blood and urine may not detect sulfonylureas, but if a sample of the suspected drug can be supplied specific testing can be arranged.

Insulinoma

Insulin-secreting adenomas of the pancreas are rare in young children but become a more common cause of hyperinsulinism by adolescence. They present in a similar manner to the genetic causes of hyperinsulinism but at a later age. One peculiarity of adenomas is that they may cause exercise-induced hypoglycemia. An insulinoma should be suspected when insulin-induced hypoglycemia occurs in older children. Fasting usually produces inappropriate elevation of insulin and proinsulin, but even basal levels of both may be elevated.[44] Routine imaging of the pancreas often fails to reveal the tumor, especially when it is less than 1 to 2 cm in size. Spiral computed tomography, magnetic resonance imaging, and abdominal ultrasound are most often negative. Endoscopic ultrasonography may be most useful before surgery.

Portal venous sampling is invasive and technically challenging in children. In adults, Doppman has demonstrated that pancreatic arterial stimulation with calcium and venous sampling (PASVS) of insulin levels may localize the tumor to a region of the pancreas. This technique has been refined to identify focal KATP hyperinsulinism and equally well to localize insulinomas in infants and children.[45] However, the procedure is invasive and localization is imprecise. Intraoperative ultrasonography is most useful in diagnosing pancreatic insulinomas, with a sensitivity of more than 90%. Islet-cell adenomas are treated by surgical excision. Rarely, isolated insulinomas in childhood may be malignant and metastatic.

Most childhood insulinomas are sporadic, but familial forms should be considered—especially in families with multiple endocrine neoplasia type 1 (MEN 1, Werner syndrome).[46] This disorder is characterized by functioning or nonfunctioning adenomas of the parathyroids, pituitary, and pancreas and is inherited in an autosomal-dominant fashion. MEN 1 is caused by mutation of the gene, localized on chromosome 11, that codes for a protein named menin.

Autoimmune Hypoglycemia

Autoimmune hypoglycemia can result from antibodies directed against insulin or against the insulin receptors. Early cases of hypoglycemia due to anti-insulin antibodies mainly described Japanese women, but cases have been reported in both sexes, all ages, and from all geographic areas.[47,48] The hypoglycemia is most often reactive, but may be fasting. The metabolic features resemble those of hyperinsulinism in most adult cases, with low ketone and fatty acid levels, but intermittent ketosis accompanying severe hypoglycemia was reported in two of the affected children.

Measured levels of insulin can be high, but C-peptide levels are usually low—such that the findings can suggest exogenous hyperinsulinism. Most older patients with this condition have other autoimmune diseases. Among treatments reported to improve the hypoglycemia have been courses of glucocorticoids, plasma exchange, and intravenous immunoglobulin infusions.

Autoimmune hypoglycemia due to antibodies that bind insulin receptors rather than insulin have occurred almost exclusively in adults, usually in association with a malignancy or severe inflammatory disorder, but at least one case in an infant has been described.[49] C-peptide and insulin levels (with some exceptions) are typically undetectable. An even rarer form of autoimmune hypoglycemia has been postulated to involve antibodies directed against surface antigens on beta cells, resulting in stimulation of inappropriate insulin release.[50]

KETOTIC HYPOGLYCEMIA

Ketotic hypoglycemia is a common clinical category of childhood hypoglycemia, with a well-characterized presentation and course but an incompletely understood etiology.[12,51,52] Usually, this condition begins as recurrent episodes of morning hypoglycemia in the second or third year of life—but onset as early as 6 months has been reported. The condition usually remits spontaneously by the age of 8 to 9 years. The classic history is of a child who eats poorly or completely avoids an evening meal, is difficult to rouse from sleep the next morning, and displays neuroglycopenic symptoms that may range from lethargy to seizure or unconsciousness by mid morning. Hypoglycemic episodes are especially likely to occur during periods of intercurrent illness, when food intake is limited.

At the time of documented hypoglycemia, high levels of ketones are found in blood and urine—and plasma insulin concentrations are low (typically under 2 mIU/mL using a high-sensitivity assay). Although ketotic hypoglycemia was described as a clinical entity more than 40 years ago, it remains unsettled whether these children display an accelerated or exaggerated but qualitatively normal metabolic response to fasting (i.e., one tail of the normal distribution) or whether ketotic hypoglycemia is a heterogeneous group of metabolic disorders of substrate availability awaiting further delineation.[53]

Several studies have shown that the hypoglycemia reflects underproduction rather than overutilization of glucose.[54] Children with ketotic hypoglycemia have plasma alanine concentrations that are markedly reduced in the basal state after an overnight fast and that fall still farther with prolonged fasting.[13] Alanine is the only amino acid significantly at lower levels in children with ketotic hypoglycemia. Infusions of alanine produce a rapid rise in plasma glucose concentration without significant changes in blood lactate or pyruvate levels, indicating that the

entire gluconeogenic pathway from the level of pyruvate is intact. This suggests that a deficiency of substrate rather than a defect in gluconeogenesis is involved.

The intact nature of the gluconeogenic pathways in affected children is further supported by the normal glycemic response to infusion of fructose and glycerol. Plasma glycerol levels are normal in these children, in both the fed and fasted states. Glycogenolytic pathways are also intact because glucagon induces a normal glycemic response in affected children during the fed state but not at the time of hypoglycemia. The metabolic response to infusion of β-hydroxybutyrate does not differ from that of normal children. Finally, the levels of hormones that counter hypoglycemia are appropriately elevated—whereas insulin levels are appropriately low.[51]

Quantitatively, alanine is the major gluconeogenic amino acid precursor whose formation and release from muscle during periods of caloric restriction are enhanced by the presence of a glucose-alanine cycle, as well as by de novo formation from other substrates within the muscle (principally branched-chain amino acid catabolism). Glutamine may also contribute significantly to these gluconeogenic events. Thus, defects in any of the complex steps involved in protein catabolism, oxidative deamination of amino acids, transamination, alanine synthesis, or alanine or glutamine efflux from muscle could contribute to ketotic hypoglycemia.

Nevertheless, in the majority of children with ketotic hypoglycemia no specific defects can be demonstrated. It was pointed out in the original description of this syndrome that children with ketotic hypoglycemia are frequently smaller than age-matched controls and often have a history of transient neonatal hypoglycemia. Thus, a compromised supply of gluconeogenic substrate may simply reflect the reduced reserve of a small muscle mass at a time when glucose demands per unit of body weight are relatively high.

Ketosis represents the attempt at switching to an alternate fuel supply. Those with ketotic hypoglycemia may represent the low end of the spectrum of capacity to tolerate fasting. Similar relative intolerance to fasting is present in normal children, who cannot maintain blood glucose levels after 30 to 36 hours of fasting (compared with the capacity of adults for prolonged fasting). Spontaneous remission by age 8 to 9 years might be explained by the increase in muscle bulk, with a resultant increase in the supply of endogenous substrate and the relative decrease in glucose requirement per unit of body mass with increasing age.

The diagnosis of ketotic hypoglycemia is one of exclusion, as episodic hypoglycemia with ketosis can occur with deficiencies of several hormones or a variety of defects of gluconeogenesis or glycogen metabolism. The diagnosis of ketotic hypoglycemia is confirmed by a supervised fast. Hypoglycemia with elevated plasma free fatty acids, β-hydroxybutyrate, and acetoacetate associated with ketonuria develops within 14 to 24 hours in most of these children—whereas normal children of similar age can withstand fasting without developing hypoglycemia for at least 24 hours. A ketogenic-provocative diet was formerly recommended but is no longer considered necessary.[55,56]

Treatment of ketotic hypoglycemia consists of frequent feedings of a high-carbohydrate diet. The overnight fast should be shortened, with a carbohydrate bedtime snack and breakfast. During intercurrent illnesses, parents should test the child's urine for the presence of ketones—the appearance of which precedes the hypoglycemia by several hours. In the presence of ketonuria, high-carbohydrate liquids should be offered to the child. If these cannot be tolerated, the child should be admitted to the hospital for intravenous glucose administration. A letter of explanation and treatment recommendation may help ensure an appropriate emergency department response.

HORMONE DEFICIENCY

Although several hormones (including cortisol, GH, glucagon, and epinephrine) are involved in maintaining blood glucose levels or can produce hyperglycemia in excess, deficiencies of only cortisol and GH are common causes of clinically significant hypoglycemia in childhood. Deficiency of both GH and ACTH can occur in congenital hypopituitarism. In the newborn period, hypopituitarism can produce hypoglycemia requiring a glucose infusion rate high enough to resemble congenital hyperinsulinism. In males, a microphallus may provide a clue to coexistent pituitary gonadotropin deficiency. Neonatal jaundice is a common accompaniment of congenital hypopituitarism and may result from either indirect or combined hyperbilirubinemia. Cholestatic jaundice with liver enzyme elevation is especially suggestive of septo-optic dysplasia.

Although fasting hypoglycemia can occur in all forms of glucocorticoid deficiency, ACTH deficiency or unresponsiveness is more likely to produce hypoglycemia than primary adrenal failure—in which the mineralocorticoid deficiency is typically the presenting problem. An increasing number of conditions resulting in ACTH deficiency have been identified in the last decade. Congenital ACTH deficiency presenting with early hypoglycemia has been reported with several rare mutations in genes involved in pituitary development (POU1F1, PROP1, TPIT).[68-70] Some of the patients have had other pituitary deficiencies. In some of them, ACTH insufficiency was not clinically apparent in early infancy. Red hair and early-onset obesity are better known than ACTH deficiency in POMC mutations, but at least one death has been described.[57] Hypoglycemia in an infant due to ACTH deficiency has been attributed to a defect of prohormone cleavage.[58]

Idiopathic ACTH deficiency can be acquired in childhood, adolescence, or later adult life. Circumstantial evidence such as an association with autoimmune thyroiditis suggests autoimmune hypophysitis as a common cause. In some instances, antipituitary antibodies have been demonstrated. ACTH deficiency has been reported in many other conditions of pituitary damage, such as cranial radiation, head trauma, and pituitary infarction.

Iatrogenic suppression of adrenal function is one of the most common causes of glucocorticoid insufficiency, but may be overlooked because the obvious electrolyte abnormalities of mineralocorticoid deficiency are absent. An adrenal crisis with prostration, vomiting, hypotension, and

hypoglycemia can be triggered by a stressful event in a child recently weaned from high-dose glucocorticoid therapy. More subtle manifestations may be caused by inhaled and nasal glucocorticoid preparations, which have become the mainstay of allergy treatment for millions of otherwise healthy children. Although most tolerate it well, ongoing combined use of topical and inhaled glucocorticoid preparations can cause enough adrenal suppression to produce episodic hypoglycemia and interference with growth in older children.[59] Absence of the 0800 cortisol peak in a child receiving topical or inhaled glucocorticoids suggests this possibility.

Although hypoglycemia is common in adrenal insufficiency secondary to CRH or ACTH deficiency, it is an infrequent manifestation of primary diseases of the adrenal glands themselves (congenital adrenal hyperplasia or hypoplasia, Addison disease). Nevertheless, a number of clues warrant consideration of primary adrenal insufficiency. Hyperpigmentation may be subtle, but commonly accompanies Addison disease—with increased ACTH and its inherent melanocyte-stimulating hormone activity and adrenal unresponsiveness to ACTH due to a defect in the adrenal receptor for ACTH.[60,61] Childhood Addison disease often occurs in combination with other disorders of immunity or autoimmunity.

In polyglandular autoimmunity type 1 (PGA1), adrenal insufficiency is usually preceded by chronic mucocutaneous candidiasis and/or hypoparathyroidism. PGA1 is now known to be caused by defects in the autoimmune regulator gene (AIRE) and is inherited in an autosomal-recessive fashion. In PGA2 (Schmidt syndrome), Addison disease is associated with diabetes and hypothyroidism: frequent hypoglycemia and an unexplained reduction of insulin requirement is the expected manifestation of adrenal failure in a person with type 1 diabetes. Adrenoleukodystrophy should also be considered in the differential diagnosis of primary Addison disease in children. Neurologic abnormalities may precede or follow the adrenal failure. It is an X-linked disease, and although females may be affected few develop adrenal insufficiency.

Morning hypoglycemia with ketosis is a potential presenting indicator of isolated idiopathic GH deficiency without ACTH deficiency in young children. Low GH levels at the time of hypoglycemia are suggestive, although low levels are occasionally found in normal infants or in children with other causes of hypoglycemia. Insulin levels are quite low, and glycemic response to glucagon during spontaneous hypoglycemia is poor. Poor growth and low IGF-1 levels may be the principal clues after recovery from hypoglycemia. Acquired GH deficiency severe enough to cause hypoglycemia in older children is uncommon. Even though many actions of insulin-like growth factor 1 (IGF-1) on carbohydrate metabolism are opposite those of GH, hypoglycemia is described as common in infants with IGF-1 deficiency (also known as Laron dwarfism).[62]

Hypoglycemia may occur in cortisol and GH deficiency as a result of several factors. Decreased gluconeogenic enzymes are associated with cortisol deficiency. Increased glucose utilization occurs from lack of the antagonistic effects of GH on insulin action and from failure to supply endogenous gluconeogenic substrate in the form of alanine and lactate. Finally, loss of the compensatory breakdown of fat and generation of ketones result in ongoing hypoglycemia during prolonged fasting.

The prominence of epinephrine and glucagon in the counterregulatory responses to hypoglycemia suggests that isolated deficiency of either hormone would be likely to cause hypoglycemia,[63] but few well-demonstrated cases of hypoglycemia caused by isolated chronic deficiency of either hormone have been described in children. Although there have been case reports of reduced epinephrine excretion in patients with hypoglycemia, evidence from patients with diabetes suggests that repeated hypoglycemia is more likely to cause diminished epinephrine excretion than vice versa. A reduction in insulin-induced hypoglycemia restores normal catecholamine responses.

Hypoglycemia is rare in patients after bilateral adrenalectomy, provided they receive adequate glucocorticoid replacement. Consequently, the role of disordered sympathetic activity in childhood ketotic hypoglycemia remains unresolved. Theoretically, epinephrine deficiency may contribute to the hypoglycemia of adrenal insufficiency because cortisol is essential to the stimulation of phenylethanolamine N-methyl transferase (PNMT)—the enzyme that converts norepinephrine to epinephrine in the adrenal medulla. Diminished epinephrine secretion has been documented in patients with congenital adrenal hyperplasia, who have decreased endogenous cortisol secretion.[64]

Perhaps the best candidate for an example of hypoglycemia caused by epinephrine deficiency in childhood is the occasional episode of severe hypoglycemia, usually fasting, occurring in a young child taking propranolol or another beta blocker (either therapeutically or accidentally).[65] Impaired glucagon secretion also increases the vulnerability to hypoglycemia of people with type 1 diabetes, but no well-documented case of childhood hypoglycemia due to isolated glucagon deficiency has been reported. Even the case traditionally cited has since been recognized as having been due to familial SCHAD hyperinsulinism. The major clinical setting in which inadequate glucagon secretion contributes to hypoglycemia remains the combined deficiency of catecholamines and glucagon that occurs in long-standing insulin-dependent diabetes.

GLYCOGEN STORAGE DISEASES

Although glycogen storage diseases (GSDs)—along with hyperinsulinism, hypopituitarism, and fatty acid oxidation defects—are among the main causes of persistent hypoglycemia in the newborn period, most cases of GSD present in later infancy and childhood.[66] Despite the severity of the hypoglycemia in the GSDs, they usually present with failure to thrive and hepatomegaly. There are four main types of GSDs that cause hypoglycemia: GSD 1, GSD 3, GSD 6, and GSD 9. In addition, defects in glycogen synthesis from glycogen synthetase deficiency may be an under-recognized cause of hypoglycemia (GSD 0).

Glucose 6-phosphatase Deficiency (Types 1a And 1b Gsd)

Deficiency of the enzyme that hydrolyzes glucose 6-phosphate to free glucose, the final step in the glycogenolytic and gluconeogenic pathways (Figure 11-5),

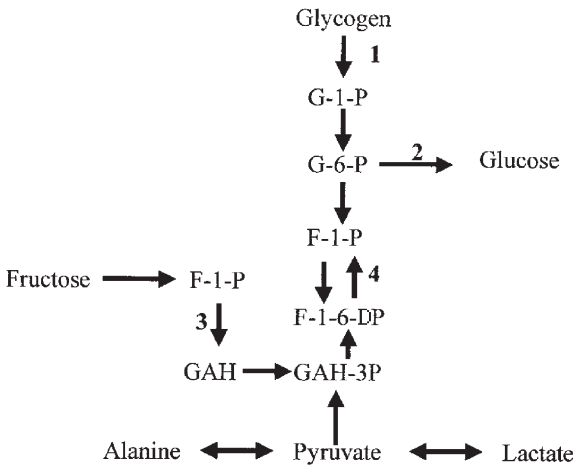

Figure 11-5 The important steps in glycogenolysis, gluconeogenesis, and the metabolism of fructose are shown. (1) Debrancher enzyme (GSD III), (2) glucose 6-phosphatase (GSD I), (3) fructoaldolase (HFI), and (4) FDPase. DP, diphosphate; F, fructose; G, glucose; GAH, glyceraldehyde; and P, phosphate.

results in severe hypoglycemia from early infancy. In its classic form (type 1A, with an estimated incidence of 1:100,000), affected children present with marked hepatomegaly—resulting in a protuberant abdomen that produces an appearance of exaggerated lordosis. Eruptive xanthomas reflect hypertriglyceridemia and hypercholesterolemia in serum, which may be grossly lipemic. Metabolic acidosis is common and is caused by marked lactic acidosis and mild ketosis. Serum triglycerides are markedly elevated and may cause grossly lipemic serum. Hyperuricemia, hypophosphatemia, anomalies in platelet adhesiveness, and severe growth failure are also characteristic features of this form of GSD.

Affected children display a remarkable tolerance to their chronic hypoglycemia. Blood glucose values in the range of 20 to 50 mg/dL are not associated with typical symptoms of hypoglycemia, reflecting the adaptation of the CNS to alternative sources of fuel (lactate). However, the hypoglycemia provokes the appropriate increased secretion of counterregulatory hormones—including GH, glucagon, cortisol, and catecholamines—as well as the suppression of insulin secretion. Thus, glucagon and GH are elevated threefold to fourfold above their normal fasting concentrations—whereas insulin concentrations are suppressed.

These hormonal changes cause increased glycogenolysis and gluconeogenesis to the point of glucose 6-phosphate, with lactic acidosis representing increased formation and decreased utilization of lactate. The hormonal changes also promote exaggerated lipolysis, resulting in fatty liver and hypertriglyceridemia hyperlipidemia and in both the substrate and hormonal settings for accelerated hepatic ketogenesis. Depletion of hepatic ATP and inorganic phosphate as a consequence of glucose phosphorylation ATP consumption during glycogenolysis and resulting excess glycolysis increases the rate of uric acid production by stimulating the degradation of preformed nucleotides.

Endogenous hyperglucagonemia probably contributes substantially to this evolution of hyperuricemia because infusion of exogenous glucagon to patients with type-1 GSD exaggerates the decrease in hepatic ATP and glycogen content while increasing hepatic phosphorylase enzyme activity. Hyperuricemia also reflects decreased renal clearance of urate, which competes with the elevated lactate and ketone concentrations for a common shared renal tubular secretory site. The defect in platelet adhesiveness and resulting clotting abnormalities are consequences of the hypertriglyceridemia and may be the consequence of ATP depletion. Although the liver is laden with glycogen and triglycerides, results of liver function tests remain essentially normal other than mild elevations of serum aspartate aminotransferase levels.

The kidney renal tubules and intestinal mucosa also express the enzyme glucose 6-phosphatase. Renal biopsy reveals excessive glycogen deposition. Long-term renal dysfunction can occur with histologic findings remarkably similar to those found in diabetes (focal glomerular sclerosis). Renal manifestations include kidney enlargement, glomerular hyperfiltration, hypercalciuria, and a mild tubular acidosis.[67] Late renal complications may include Fanconi syndrome, nephrocalcinosis, and progressive proteinuria—leading to end-stage renal failure.[78-80] There are no characteristic gastrointestinal symptoms, but diarrhea has occasionally been reported. Nodular liver enlargement and hepatoma formation have also been reported.

Hepatic glucose 6-phosphatase is now known to be a multicomponent system whose enzyme activity is tightly linked to the inner aspect of the endoplasmic reticular membrane.[68] In addition to glucose-6-phosphatase itself, three translocase systems that allow entry of glucose 6-phosphate (T1), exit of phosphate (T2), and exit of glucose (T3) from the lumen of the endoplasmic reticulum complete the pathway of glycogenolysis. Classic deficiency of enzyme activity is termed *type 1A1a*, whereas deficiency of translocase T1 is termed *type 1B1b*. Both types typically present in infants and children, and have been implicated in sudden infant death syndrome. However, they may present in adults with hepatomegaly and hypoglycemia. Deficiencies of the T2 and T3 transporters as the cause of GSD (types 1c and 1d) have been postulated but not definitively documented.

The genes for human glucose-6-phosphatase and glucose-6-phosphate transporter have been identified on 17q21 and 11q23, respectively. Complementary DNA, its gene, and its expressed protein have been characterized and reported.[69-71] This development has already allowed identification of mutations that inactivate enzyme activity and has demonstrated that the mutations are responsible for type 1A but not types 1B and 1C variants. Mutation analysis for the most common variants is now available commercially.

Type 1b occurs in children with biochemical features that are similar to those of type 1a, but with the addition of neutrophil deficiency, oral lesions, perianal abscesses attributed to the neutropenia, and chronic enteritis indistinguishable from Crohn disease. Treatment with granulocyte-macrophage colony-stimulating factor to increase the neutrophil count ameliorates the enteritis.[72,73]

Diagnosis of GSD 1 is suspected in children with growth failure, protuberant abdomen due to massive hepatomegaly, or hypoglycemia with lactic acidosis. A finding of elevated lactate levels with hypoglycemia combined with an abnormal fed glucagon stimulation test clinches the diagnosis. In the normal child, a 2-hour postprandial (fed) glucagon stimulation test will cause a rise in glucose and no change in lactate. In a patient with GSD 1, lactate rises (but not glucose). Fructose 1,6-diphosphatase deficiency resembles GSD 1, but the fed glucagon stimulation test will be normal.

The previously cited clinical physiologic tests are usually sufficient for a presumptive diagnosis of GSD 1. Liver biopsy with estimation of glucose-6-phosphatase activity has previously been the classic means of definitive diagnosis, but this can often be avoided because of the discovery of the genetic defect—which, as noted, permits genetic testing for the GSD1a and 1b1 genes.

Treatment regimens have transformed the prognostic outlook for duration and quality of life and have resulted in reversal of most of the metabolic disturbances in GSD1. Acceptance of these regimens, including passage of a nasogastric tube for nocturnal provision of glucose, is excellent—and the long-term outcome of this innovative approach is promising. Patients are fed every 2 hours during the day, and have a continuous supply of glucose through a nasogastric tube overnight. The rate of glucose infusion is tailored to the individual but is usually 6 to 8 mg/kg/min (slightly greater than normal hepatic glucose production). Cornstarch therapy has been successfully used in patients older than 1 year of age. Uncooked cornstarch is given in doses of 1 to 2 g/kg every 4 hours, and in some children every 6 hours overnight.

Long-term therapy with uncooked cornstarch and overnight tube feedings has led to improved linear growth and diminution of osteoporosis. Most patients require treatment with allopurinol for hyperuricemia. Although there are no controlled trials of the effect of good metabolic control of GSD on renal disease, some evidence supports the hypothesis that good control lessens the degree of renal impairment. This is assumed from an apparent trend toward later onset of renal disease since the adoption of more effective current treatments.[74] Liver transplantation is not routinely recommended but offers promise of long-term cure for patients who develop liver nodules that become malignant.[66,75,76]

Amylo-1,6-glucosidase Deficiency (Debrancher Deficiency, Gsd Type 3)

Deficiency of this enzyme results in the inability to degrade glycogen beyond the 1:4/1:6 branch point, with the result that only the outer 5% to 10% of glucose residues can be released and the remaining glycogen accumulates as a limit dextrin accumulates. The capacity to generate free glucose from glycogen is therefore markedly impaired, although some free glucose results from the action of liver phosphorylase. However, the gluconeogenic pathways for glucose production from lactate, amino acids, and glycerol are intact. Thus, spontaneous symptomatic hypoglycemia is much less common and less severe than in GSD type 1.[66]

During prolonged fasting, hypoglycemia and a marked compensatory ketonemia and ketonuria appear. Because gluconeogenic pathways are intact, infusions of fructose, galactose, or alanine produce a normal glycemic response. Unlike GSD 1, lactic acidemia at times of hypoglycemia is not a feature of GSD3. Similarly, there is no hyperuricemia in GSD3. Lack of persistent hypoglycemia (and therefore the lack of a rise in counterregulatory hormones) prevents the lipemia, ketonemia, and hyperuricemia. In the fed state, glucagon evokes a normal glycemic response in GSD3 through its activation of phosphorylase enzyme.

When liver glycogen reaches the limit dextrin stage after moderate fasting, glucagon no longer elicits a glycemic response because phosphorylase cannot work on a limit dextrin. Thus, GSD3 (and the related disorders, GSD0, GSD6, and GSD9) can be suspected clinically by features of abbreviated fasting tolerance, hyperketonemia, and absence of fasting lactic acidemia. These defects are also associated with an abnormal rise in blood lactate following oral glucose loading.

Children with this disease usually present with hepatomegaly and growth retardation. Liver function tests (especially transaminases) may be markedly increased, possibly due to cellular responses to accumulated limit dextrin. In addition to the liver, debrancher enzyme is normally present in muscle, kidney, and leukocytes. Consequently, progressive muscle weakness, myotonias, and cardiomyopathy have occasionally been described and may be associated with more severe forms of enzyme deficiency. Cardiomyopathy may be fatal, and severe muscle weakness may appear after the first decade of life.

Creatinine phosphokinase is elevated in these children. Assay of the debrancher enzyme activity in leukocytes has been used to identify affected individuals and presumed heterozygote carriers. Considerable genetic heterogeneity in this enzyme's activity in liver, muscle, or leukocytes among affected individuals and their families precludes the use of leukocytes for the identification of the heterozygous state. The gene locus is on 1p21, and mutation analysis (at least for common mutations) is available from commercial labs. Immunoblot analysis of this enzyme with the use of a monoclonal antibody has been reported.

Two dietary regimens have been advocated for GSD type 3.[77] For those with liver involvement alone, frequent feedings and uncooked cornstarch have been recommended in the expectation that avoidance of prolonged fasting will be sufficient to prevent hypoglycemia and improve growth.[78] However, in patients with liver and muscle involvement the use of a low-carbohydrate high-protein diet has been advocated—with the argument that providing glucose by gluconeogenesis from protein precursors reduces the need to deplete muscle alanine stores. There are no large controlled trials comparing the efficacies of the two approaches. Nasogastric or intravenous glucose infusions may occasionally be indicated if caloric intake cannot be maintained during intercurrent illness.

Liver Phosphorylase Deficiency (Gsd Types 6 And 9)

Normal liver glycogen phosphorylase activity involves a complex cascade of events that activates the enzyme capacity to degrade liver glycogen before and after the debranching step.[66] Consequently, low hepatic phosphorylase activity may result from a defect in any of the steps of activation. Not surprisingly, a variety of defects have been described. In its "classic" form, hepatomegaly, excessive deposition of glycogen in liver, some growth retardation, and occasional symptomatic hypoglycemia occur.

A frequent feeding program with cornstarch overnight is usually adequate therapy, but some authorities also recommend a high-protein diet. Variants of this condition include a presumed defect in the hormonal activating system for phosphorylase, deficiency of the cyclic adenosine monophosphate-dependent protein kinase that activates phosphorylase, and deficiency of the phosphorylase-b kinase that activates phosphorylase-a activity.[79] Patients with GSD 6 and 9 generally do very well, but there has been a report of liver cirrhosis in a patient with GSD type 9.[80]

Glycogen Synthetase Deficiency

An inability to synthesize glycogen appears to be a rare occurrence, but hepatic glycogen synthetase deficiency (GSD 0) has been confirmed through metabolic studies, enzyme assay of liver biopsy material in vivo, and most recently genetic studies identifying mutations in the glycogen synthetase locus (12p12.2.84-86). Infants and children with GSD 0 may have symptoms of fasting-induced hypoglycemia and hyperketonemia from infancy, but may also demonstrate hyperglycemia with glucosuria after meals.[81]

During fasting hypoglycemia, levels of the counterregulatory hormones, including catecholamines, are appropriately elevated or normal—whereas insulin levels are appropriately low. Exogenously administered glucagon produces a glycemic response soon after meals but no response after a 12-hour fast. Gluconeogenic capacity is intact. There is often no hepatomegaly. Glycogen synthetase activity is markedly reduced in liver but normal in muscle. In the index case, protein-rich feedings at frequent intervals resulted in dramatic clinical improvement, including improved growth. Since the initial case reports, more patients have been described. Treatment with uncooked cornstarch has been helpful. Although the majority of cases are recessive mutations, one pedigree has been reported in whom the mother of two affected children had some hypoglycemia. This condition mimics the syndrome of ketotic hypoglycemia and should be considered in the differential diagnosis of that syndrome.[82]

DISORDERS OF GLUCONEOGENESIS

Disorders of gluconeogenesis causing hypoglycemia include a variety of enzyme defects and inborn errors of metabolism, but also some exogenous agents and infections.

Genetic Defects

Hypoglycemia may occur with several inborn errors of organic acid metabolism. In a few of these conditions, the hypoglycemia is a common manifestation (SCHAD deficiency, fatty acid oxidation defects)—whereas in most of the others it is atypical, infrequent, or mild. In the disorders described in the material following, hypoglycemia is attributed mainly to impaired gluconeogenesis—whereas in others the precise mechanism of hypoglycemia is not apparent even though some clinical features are common to most of them.

Hypoglycemia usually occurs during episodes of encephalopathic metabolic decompensation, sometimes spontaneous and sometimes triggered by a stressful illness or starvation. Vomiting and sometimes tachypnea may be prominent symptoms. Many of the conditions result in impairment of physical growth or neuromuscular development even when severe episodes are infrequent. The major clue to diagnosis is usually a pattern of characteristically abnormal organic acids in the urine. In most cases, management (or at least hypoglycemia prevention) consists of providing intravenous glucose at the onset of illness or decompensation.

The major enzymatic defects in gluconeogenesis that are responsible for hypoglycemia include deficiencies in fructose 1-phosphate aldolase (hereditary fructose intolerance), fructose 1,6-diphosphatase, phosphoenol pyruvate carboxykinase (PEPCK), and pyruvate carboxylase. Gluconeongenesis can also be transiently impaired by exogenous agents such as alcohol and salicylates.

In the past, much has been made of the possibility that galactosemia causes significant hypoglycemia. In theory, this is possible because of the role of galactose-1-phosphate and the phosphate pool. Hypoglycemia will occur in galactosemia only when the patient is in extremis with liver failure. Hypoglycemia also occurs in association with advanced liver disease in neonatal hemochromatosis, tyrosinosis type 1, S-adenosylhomocysteine hydrolase deficiency, type 3 glycogenosis, and some of the disorders of mitochondrial function.

Pyruvate carboxylase, despite its pivotal role in gluconeogenesis, will also theoretically cause severe hypoglycemia (but rarely does). Severe lactic acidosis, ketosis, and even hyperammonemia are the primary biochemical disturbances. Hypoglycemia accompanied by ketosis and lactic acidosis has also been reported in late-onset maple syrup urine disease, glycerol kinase deficiency, and phosphenopyruvate carboxykinase (PEPCK) deficiency. In disorders of ketolysis (deficiencies of succinyl CoA transferase and 3-ketothiolase), ketone levels may be quite high but lactic acidosis may not be present.

Fanconi-bickel Syndrome (Glut-2 Deficiency). Mutations of GLUT2 (the gene for the glucose transporter protein 2) can result in hypoglycemia, hepatorenal glycogen accumulation, and a combination of features described as the Fanconi-Bickel syndrome. GLUT2 is a monosaccharide transporter occurring in the plasma membranes of beta cells, renal tubule cells, and hepatocytes, among other tissues. Defective function leads to

glycogen accumulation, enlargement of liver and kidneys, and impairment of gluconeogenesis and renal tubular function. Fasting hypoglycemia, hyperuricemia, hypertriglyceridemia, and postprandial hyperglycemia suggest impairment of gluconeogenesis—whereas reduced glucose sensing by beta cells may contribute to postprandial hyperglycemia. Glucosuria, phosphaturia, aminoaciduria, metabolic acidosis, and hypophosphatemic rickets result from the renal tubular effects. Growth failure can be severe.[83,84]

Hereditary Fructose Intolerance. Hereditary fructose intolerance (HFI) was first described as an idiosyncrasy to fructose[85] and later determined to be caused by an inability to split fructose 1-phosphate.[86] It may present in infancy and children with the onset of fructose exposure in the diet, which often occurs from 3 to 4 months onward. After a fructose ingestion (the greater the amount the worse the symptoms) there is an acute onset of vomiting, abdominal pain, and diarrhea that may progress to hypoglycemia, shock, and acute liver failure.

Chronic low-level ingestion causes failure to thrive and liver and kidney failure. Acute treatment of hypoglycemia by intravenous glucose infusions may reverse all symptoms if fructose exposure is discontinued. Aversion to fructose-containing feeds is the hallmark of infants who survive the first episode. Chronic treatment is the avoidance of all fructose-containing food. Classically, older children and adults who survive infancy have no dental caries owing to their avoidance of sweet foods.[87]

Fructose 1,6-diphosphatase Deficiency. Fructose 1, 6-diphosphatase (FDPase) is a rare cause of hypoglycemia first described in 1970 by Baker and Winegrad.[88] The enzyme catalyzes the irreversible splitting of fructose 1,6-diphosphate to fructose-6-phosphate. It is a key enzyme in the process of gluconeogenesis from lactate, alanine, and glycerol and plays an important role in the utilization of ingested fructose by gluconeogenesis.

FDPase presents typically in the first days of life, but up to 50% of cases present later than this. Typical manifestations include hyperventilation from lactic acidosis and ketoacidosis, seizures and coma from hypoglycemia, and hepatomegaly. Attacks are precipitated in infancy and childhood by prolonged fasting and intercurrent illness. Unlike in hereditary fructose intolerance, liver dysfunction and renal tubular dysfunction are rare. Uric acid is elevated. The diagnosis is suspected in children with fasting-induced hypoglycemia and lactic acidosis, and is confirmed by enzyme studies from liver biopsy material. It may be differentiated from GSD type 1 by the fed glucagon stimulation test. Acute treatment is by intravenous glucose and bicarbonate infusion. Chronic treatment is avoidance of prolonged fasting and a reduction but not total elimination of fructose from the diet.

Diarrhea

Hypoglycemia may occur in infants and children with severe diarrhea. It is uncommon in previously healthy children with acute gastroenteritis (e.g., rotavirus) unless there has been a period of starvation (as occurs after prolonged use of water or sugar-free fluids).[89] Hypoglycemia in this setting is usually ketotic and has a good outcome. However, it is important that the history of prolonged starvation be confirmed and disorders of FAO ruled out, as hypoglycemia is uncommon in healthy children. In one survey of sequential emergency department patients, 28% had a significant unsuspected metabolic or hormonal disorder.[90]

In cases of diarrhea in patients with malnutrition, such as occurs during cholera outbreaks in the Third World or in areas of severe poverty, hypoglycemia is a grave and dangerous problem. During severe malnutrition, gluconeogenic substrates such as alanine and lactate are significantly reduced, the capacity to generate glucose by gluconeogenesis is markedly diminished, and alternative fuels such as ketones and lactate are also reduced. In this situation, almost one-half of patients with hypoglycemia plus diarrhea died with an encephalopathic picture—indicating that hypoglycemia in the malnourished child is a poor prognostic sign.[91,92]

Malaria

Hypoglycemia has been described as occurring in approximately one-third of children with severe malaria. As in those with diarrhea and hypoglycemia, there is increased mortality in children with malaria associated with hypoglycemia. Insulin levels in such children were reported to be appropriately low, whereas ketones, lactate, and alanine levels were high—suggesting impaired gluconeogenesis. Provision of glucose is therefore indicated for such patients.[93] In addition, the therapy for malaria (in particular, quinine) may cause hypoglycemia because of its ability to stimulate insulin release.

DEFECTS IN FATTY ACID OXIDATION

The key steps in carnitine uptake, mitochondrial transport, and oxidation of fatty acids are outlined in Figure 11-5. The spectrum of these disorders is remarkably wide, and improved diagnostic methods and population screening are proving them more common than previously suspected. For example, medium-chain acyl CoA dehydrogenase (MCAD) deficiency has been reported to be as common as 1:9,000 births—a frequency comparable to that of phenylketonuria and half as common as that of primary hypothyroidism, justifying the trend toward inclusion in neonatal screening programs.[94] Although the salient features of this group of disorders were discussed in Chapter 5, their importance merits emphasis of key points.

FAO provides a significant proportion of energy required for sustained gluconeogenesis. Therefore, defects in FAO are especially likely to become clinically apparent during prolonged fasting or the accelerated starvation of catabolic illness associated with vomiting. Because FAO and ketone body generation is impaired, hypoglycemia associated with FAO disorders is usually hypoketotic.

Many affected individuals first manifest the illness at age 6 months to 2 years. The hypoglycemia may be accompanied by an encephalopathy that has mimicked

Reye syndrome and does not always immediately respond to glucose.[95,96] Unrecognized, such episodes may be fatal and may resemble sudden infant death syndrome. Diagnosis requires a high index of suspicion and can be established by analysis of plasma acyl carnitine profiles; by urine analysis for pattern of organic acids (especially dicarboxylic aciduria); by complex metabolic studies of liver tissue or cultured fibroblasts; and in certain cases (such as medium-chain acyl CoA dehydrogenase) by molecular analysis or genotyping.[97]

Cardiac and skeletal muscle weakness is a prominent feature with certain defects, principally long-chain acyl CoA dehydrogenase, carnitine transport deficiency, and carnitine transferase deficiency. In patients with carnitine transport deficiency, supplementation with carnitine may improve the clinical features—including improvement in the cardiomyopathy over a period of weeks to months.[98] The biochemical and clinical indicators of disorders of fatty acid metabolism are summarized in Table 11-6.

The primary treatment of these disorders of FAO is avoidance of fasting. In older children, fasting of as long as 10 to 12 hours may be possible without the manifestations. Once an index case has been identified, acute illness with fasting should be treated by rapid institution of intravenous glucose to reverse an evolving episode or to prevent its occurrence.

Several drugs or chemicals that interfere with FAO may mimic the features of inherited defects in FAO, including hypoglycemia. Principal among these is the use of valproic acid, which has been associated with unusual episodes of hypoglycemia with a Reye-like syndrome and hypoketosis. Elevation of ammonia levels and secondary carnitine deficiency may make this side effect appear similar to an FAO defect, leading some to recommend carnitine as a supplement for infants receiving valproic acid.[99] Urine organic acids and acyl carnitine profile will easily distinguish these conditions.

Plant toxins can occasionally produce hypoglycemia by impairing fatty acid oxidation as well. Hypoglycine, a component of unripe ackee fruit found in the Caribbean and Africa, causes hypoglycemia by interfering with FAO.[100] Atractyloside, found in certain Mediterranean plants, uncouples oxidative phosphorylation in the mitochondria.[101]

NONPANCREATIC TUMOR HYPOGLYCEMIA

Certain non insulin-secreting tumors are sometimes associated with hypoglycemia, usually in adults. Initial reports described large retroperitoneal tumors, often of mesodermal origin, in association with hypoglycemia. It has been postulated that extraction of glucose across the tumor vascular bed was responsible for the hypoglycemia. Subsequently, it became apparent that an insulin-like factor was likely involved because the hypoglycemia was associated with fasting, diminished lipolysis and decreased circulating fatty acids, increased glucose utilization, and impaired glucose production. Insulin-like growth factor (IGF)-2 has been demonstrated in the sera of affected patients.

TABLE 11-6

Clinical Manifestations of Inherited Disorders of Fatty Acid Oxidation

Enzyme/Transporter Deficiency	Hepatic	Cardiac	Acute	Chronic
Carnitine Cycle				
• Carnitine transporter (CTD)	+	+		+
• Carnitine palmityl transferase-1 (CPT-1)	+			
• Carnitine/acylcarnitine translocase (TRANS)	+	+		+
• Carnitine palmityl transferase-2 (CPT-2)	+	+	(+)	+
b-Oxidation Cycle				
• Acyl-CoA dehydrogenases				
• Very long-chain (VLCAD)	+	+		+
• Medium-chain (MCAD)	+			
• Short-chain (SCAD)				+
• 3-Hydroxyacyl-CoA dehydrogenases				
• Long-chain (LCHAD)	+	+	+	
• Short-chain (SCHAD)				+
• Medium-chain ketoacyl-CoA thiolase			+	+
• 2,4-Dienoyl-CoA reductase (DER)				+
Electron Transfer				
• Electron transfer flavoprotein (ETF)	+	+	+	+
• ETF dehydrogenase (ETF-DH)	+	+	+	+
Ketone Synthesis				
• HMG-CoA synthase		+		
• HMG-CoA lyase		+		

HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A.

Interestingly, one form of IGF-2 is "big"—and serum and tumor contain a large proportion of the "big" form of IGF-2. Big IGF-2 stimulates the IGF-1 receptor and cross activates the insulin receptor, causing hypoglycemia. Stimulation of the IGF-1 receptor causes down-regulation of GH secretion. This reduces IGFBP3 secretion, which in turn lessens the binding capacity of free IGFs and thus increases the potential of the abnormal and dysregulated production of big IGF-2 to cause hypoglycemia. Treatment with GH causes increased IGFBP3, which reduces the free IGF pool and thereby decreases hypoglycemia on a temporary basis until definitive treatment is completed.[102] Removal of the tumor by surgical resection or by chemotherapy/radiotherapy may be required to resolve the hypoglycemia completely. A trial of diazoxide therapy was not successful.

Hypoglycemia caused by hepatoblastoma and Wilms' tumor has been described in children and adolescents. A nonendocrine tumor that causes hypoglycemia is Hodgkin disease, with antibodies to the insulin receptor that bind and stimulate the receptor (mimicking the effects of insulin).[103,104]

LATE DUMPING (ALIMENTARY HYPOGLYCEMIA)

Hypoglycemia occurring in infants and children with a combination of Nissen fundoplication and gastrostomy tube placement is common.[105] Feeding glucose-containing fluid results in a rapid rise of glucose levels, followed by a rapid rise of insulin. The combination of rapid completion of glucose absorption and high insulin levels causes the glucose level to plummet to hypoglycemic levels 1 to 2 hours later. There are usually none of the classic gastrointestinal symptoms of dumping. A critical sample obtained at the time of hypoglycemia may suggest hyperinsulinism, but the tolerance for fasting is usually normal and the patient does not develop hypoglycemia after slow weaning from a continuous infusion.[106]

This condition, known as late dumping or glucose dumping, may occur in up to 33% of patients with fundoplication and gastric tubes. Unfortunately, it is often not recognized and seizures are attributed to the neurologic condition that necessitated the surgery. Treatment is not always completely effective, and various remedies have been suggested—including calcium channel blockers[107] and octreotide. A combination of acarbose in doses of 12 to 75 mg per feeding and a complex carbohydrate formula may be successful.[106,108]

REACTIVE HYPOGLYCEMIA

Reactive hypoglycemia is the term used by endocrinologists for any form of symptomatic hypoglycemia occurring 2 to 4 hours after a meal.[109] Other doctors and many other people use the term to refer to autonomic symptoms of any cause occurring a few hours after a meal, with or without demonstrably low blood glucose. The gap between these usages has turned many an endocrine clinic consultation into an exercise in bilateral frustration.

The latter form of "hypoglycemia" is the most common form of hypoglycemia known to most parents and is covered extravagantly on a myriad of Internet sites. The fundamental concept is simple, but the nature of the condition has been a source of controversy for more than 80 years. Within a decade of the first successful diagnosis and surgical cure of an insulinoma in 1929,[110] it became clear that not all patients with symptoms of hypoglycemia had demonstrable insulinomas curable with surgery.

Seale Harris (who began to compile cases) postulated that in some people an exaggerated insulin response to meals could cause transient hypoglycemia 2 to 4 hours after a meal.[111] In such patients, low glucose levels could be demonstrated several hours after a meal or after a standard oral glucose tolerance test (OGTT), and symptoms could be alleviated by frequent eating. The condition, and the use of the OGTT to diagnose it, became embedded in American culture.[112] A wide array of treatment regimens, ranging from benign (frequent snacks, avoiding sugar) to pernicious (elaborate dietary restrictions, expensive supplements or "adrenal extracts" of uncontrolled composition), have been offered to the public. Self-diagnosed patients describing such symptoms present regularly to pediatric and internist endocrinologists.

Much research has demonstrated that few of the self-diagnosed patients have demonstrable abnormalities of glucose metabolism, either when glucose is measured during symptoms or in response to the most rigorous test of metabolic competency (an extended diagnostic fast).[109,113] The OGTT is of little value in this condition, as many healthy children and adults will have glucose levels below 60 mg/dL several hours after a glucose load (with little or no relation to either symptoms or glucose levels after meals).[114] In fact, the diagnostic test with the strongest demonstrated association with hypoglycemic symptoms has been the Minnesota Multiphasic Personality Test.[115]

These problems have led some endocrinologists to reject the entire concept of reactive or "functional hypoglycemia" as illusory or at least completely unrelated to glucose metabolism, preferring the term *idiopathic postprandial syndrome* as a more accurate descriptor. The American Diabetes Association and the Endocrine Society formulated a position statement in 1973 supporting the need to demonstrate low glucose values at the time of symptoms, as well as improvement after glucose ingestion, in order to validate a diagnosis of hypoglycemia (the Whipple criteria).[116]

Management of children and families arriving at the endocrine clinic with this diagnosis is a challenge in tact and communication. Most of the patients are adolescent or preadolescent girls, and mothers often share the complaint. The oral glucose tolerance test should be avoided as of no value (akin to "using a hammer to slice bread"), and other testing will likely produce normal results. Although the idea of sending the patient home with a glucose meter is intuitively appealing, the physician must be prepared to deal with the inevitable low numbers that will be reported.

The endocrinologist will rarely be able to "take away" a reactive hypoglycemia diagnosis without offering another way to understand and deal with the nonimaginary symptoms. Many parents will accept an explanation that the symptoms may not be due to a

measurable low blood sugar (and thus will never be dangerous) but patterns of eating may affect our mood and energy[117] and the best approach may be continued family experimentation with snacks and/or sugar avoidance within healthy boundaries.

Several other conditions are far more common than hypoglycemia as causes of spells in adolescents.[118] Orthostatic hypotension, vasovagal syncope, hyperventilation, and panic attacks all have characteristic histories and features. Management measures are simple, and just identifying the cause of the spells as real but not dangerous often provides considerable relief. Spells occurring with exercise, however, warrant a cardiology evaluation for dangerous arrhythmias.

Reactive hypoglycemia with measurably low glucose levels does occur in several circumstances in both young childen and adolescents. Many forms of hyperinsulinism, from channel defects to insulinomas, may cause hypoglycemia in the postprandial period. When one of these latter types of hypoglycemia is suspected, the correct tool is a fasting study in experienced hands.[119]

HYPOGLYCEMIA IN ORGAN FAILURE AND CRITICAL ILLNESS

Hypoglycemia is common in critically ill patients of all ages,[120] and can occur in failure or severe disease of nearly every major organ system: sepsis,[121] head injury,[122] cyanotic congenital heart disease, congestive heart failure,[123] chronic renal failure,[124,125] acute hepatic necrosis and failure,[126] pancreatitis,[127] severe enteritis, and multiple-organ failure. Hypoglycemia in these patients is often multifactorial, involving substrate depletion, accelerated glucose consumption, undernutrition, impaired gluconeongenesis, cytokine effects, adrenal insufficiency, misplaced infusion lines, and/or drug effects—as well as processes specific to certain diseases. The treating physician should not forget the possibility that an acute illness is unmasking a previously compensated disorder of glucose metabolism, especially in a young child.[90]

HYPOGLYCEMIA INDUCED BY EXOGENOUS AGENTS

In addition to diabetes medications, many less obvious drugs and other exogenous agents have been reported to cause hypoglycemia in individual patients.[53] In children these may represent accidental ingestions or overdoses. Ethanol, salicylates, quinine, and beta-blockers such as propranolol are the most frequent single agents implicated in childhood hypoglycemia. Hypoglycemia has also been reported with sulfonamide and cotrimoxazole use in children, as well as in acetaminophen overdose. Pentamidine is one of the most common nondiabetes medications reported to cause hypoglycemia in adults in therapeutic doses.

Alcohol-induced Hypoglycemia

The liver oxidizes ethanol as a preferred fuel, consuming nicotinamide adenine dinucleotide (NAD^+) in the process. Depletion of NAD^+ slow oxidation of lactate to pyruvate, thereby impairing gluconeogenesis. Hypoglycemia may ensue if glycogen stores are depleted by starvation or by preexisting abnormalities in glycogen metabolism. In children who have been fasting for some time, even the consumption of small quantities of alcohol can precipitate these events.

In addition, the use of rubbing alcohol in infants or swallowing mouthwash in children has been associated with hypoglycemia.[128] Three to 5% of children with alcohol intoxication will also have hypoglycemia.[129] The hypoglycemia responds promptly to intravenous glucose, which should always be given to a child at initial presentation of coma or seizure after taking a blood sample for glucose determination. A careful history allows the diagnosis to be made and may avoid needless and expensive hospitalization and investigation.[126]

Salicylate Intoxication

Hyperglycemia and hypoglycemia have been reported to occur in children with salicylate intoxication. Accelerated utilization of glucose due to augmentation of insulin secretion by salicylates and possible interference with gluconeogenesis may contribute to hypoglycemia.[130] Infants appear to be more susceptible than older children. Monitoring of blood glucose levels with appropriate glucose infusion in the event of hypoglycemia should form part of the therapeutic approach to salicylate intoxication in childhood.

Artifactual Hypoglycemia

When a low glucose level is unexpectedly reported in a "well" child who has an outpatient chemistry profile drawn for reasons unrelated to carbohydrate metabolism, it is easy to suspect it is a misleading result. The most common cause of post-phlebotomy artifactual hypoglycemia is glucose consumption during a long delay before measurement.[131] This can be reduced but not eliminated by chilling the specimen, and by newer tubes designed to sequester cells from serum. Fluoride tubes also reduce but do not eliminate glucose consumption. However, they may not be practical for small specimens when other tests are needed.

Even with fluoride, glucose levels may decline by 20% or more when processing is delayed for even a few hours.[132] Unfortunately, post-phlebotomy glycolysis consumes a higher proportion of glucose when the specimen contains a low level when drawn. Blood glucose meters are also prone to higher proportional errors when used to measure blood glucose levels at the low end of normal. The physician must also remember the possibility that a "fluke" lab test has revealed a chronic but asymptomatic hypoglycemic condition such as a glucokinase mutation.

Fasting System Approach to Diagnosis

Understanding the pathophysiology of fasting and the intricate balance of hormonal changes and their effects on intermediary metabolites is the key to discovering the

cause of hypoglycemia. From the outline of normal fasting physiology given previously, it is clear that normal infants, children, and adults may develop hypoglycemia if fasted long enough. At the time of hypoglycemia, a blood and urine sample (the critical sample) should demonstrate the normal adaptive changes that occur with time. In an infant or child who presents with unexplained hypoglycemia, the testing of this hypoglycemic sample may be pivotal in making the diagnosis and may avoid prolonged dangerous and expensive testing.

HISTORY

The first element in the diagnostic approach to a patient with hypoglycemia is the history. The timing of hypoglycemia in relation to fasting is an important feature. Hypoglycemia occurring in the immediate postprandial period suggests a defect in glycogenolysis or excess insulin secretion. Hypoglycemia occurring later into fasting suggests disorders of FAO, of gluconeogenesis, or of the hormones that control these processes. The presence of sulfonylureas or alcohol in the household suggests an effect of exogenous substances.

CLINICAL EXAMINATION

The second diagnostic step is physical examination. Hepatomegaly may be suggestive of a GSD or an FAO disorder. Short stature and failure to thrive often occur in a GSD, Fanconi-Bickel syndrome, and hypopituitarism. Neuromuscular signs may occur in association with FAO disorders and adrenoleukodystrophy. Midline defects such as central cleft lip and palate, single central incisor, or optic nerve atrophy are associated with pituitary hormonal deficiencies (as is micropenis).

CRITICAL SAMPLE

Finally, the third stage revolves around the critical sample (Table 1-1). The key feature to assess is the presence or absence of acidosis (Figure 11-6). This can be determined from basic studies before the results of the intermediary metabolites. A chemistry panel with measurement of bicarbonate levels and a urine dip for ketones will be immediately available in most centers. In addition, a lactate level should be easily available.

Acidosis with elevated lactate and absent ketones suggests disorders of glycogenolysis or gluconeogenesis. GSD type 1 and fructose 1,6-diphosphatase (FDPase) deficiency may be difficult to differentiate, and a fed glucagon stimulation test may help. There will be a rise in lactate and no rise in glucose in GSD type 1, with a rise in glucose in FDPase deficiency. An intravenous fructose tolerance test may be required. In the older child, lactic acidosis and hypoglycemia may suggest alcohol ingestion. Normal newborns in the first days of life may present with similar features of lactic acidosis and hypoglycemia.

Acidosis with ketones occurs in normal fasting children, idiopathic ketotic hypoglycemia, and GSD types 3, 6, 9, and glycogen synthetase deficiency. Ketones also may be present in deficiencies of GH and cortisol. Disorders of FAO may sometimes present as small to moderate ketones in the urine, particularly when the patient is dehydrated. Some forms (such as the short-chain length disorders, the disorders of electron transport, and HMG-CoA lyase deficiency) may also have mild ketosis.

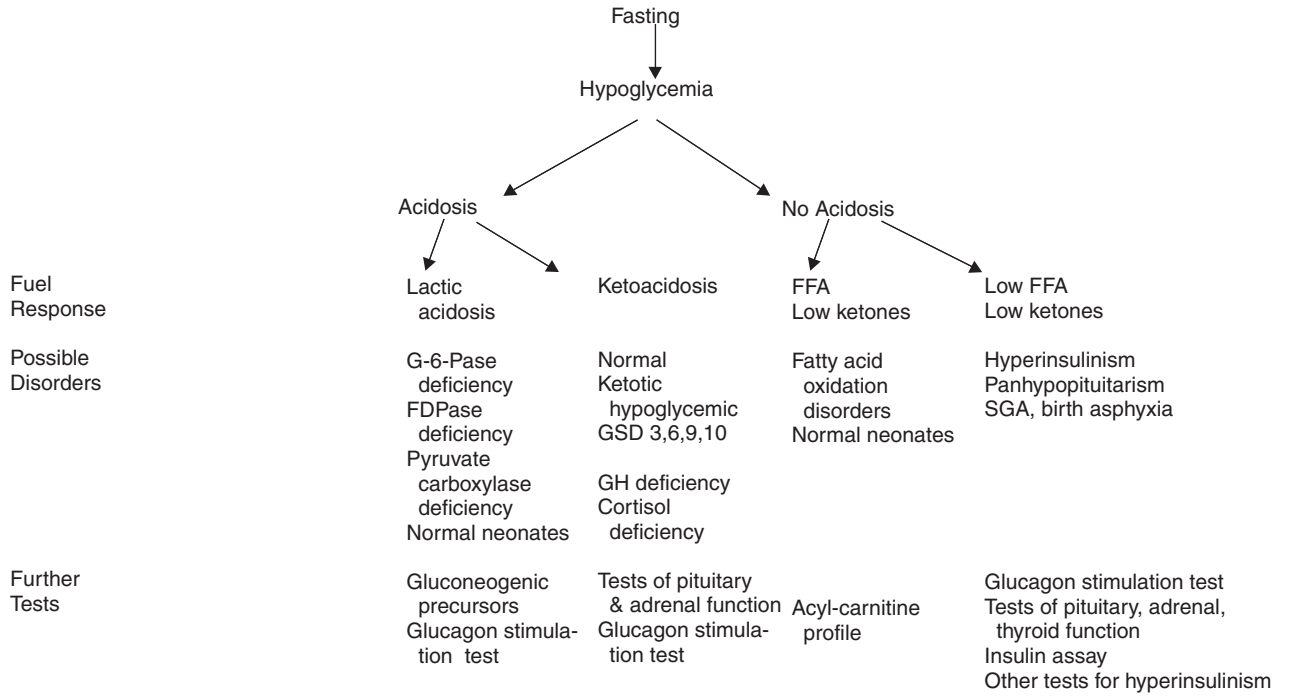

Figure 11-6 An algorithmic approach to hypoglycemia. FDPase, fructose 1,6-diphosphatase; FFA, free fatty acids; G-6-Pase, glucose 6-phosphatase; GH, growth hormone; GSD, glycogen storage disorder; and SGA, small for gestational age.

No acidosis or ketones in the urine is strongly suggestive of hyperinsulinism caused by genetic defects, insulinoma, accidentally administered excess insulin, deliberately administered insulin with intent to harm, or oral hypoglycemic agents. FAO defects will often be hypoketotic, but some forms may have trace or small ketones in the urine. Hyperinsulinism will have neither elevated free fatty acids nor elevated ketones, whereas FAO will have elevated free fatty acids and low ketones. FAO may be diagnosed by acyl-carnitine profile or by urine organic acid measurement. Hyperinsulinism owing to genetic defects and insulinoma can be differentiated from insulin administration by the presence of C-peptide in the plasma at the time of hypoglycemia. Oral hypoglycemic agents will have elevated insulin and C-peptide, and the diagnosis will be missed unless suspected and unless urine toxicology with a request for the specific drug to be sought is performed.

Emergency Treatment of Hypoglycemia

Once the critical sample has been obtained, a mini-bolus of 0.2 g/kg of dextrose should be administered by intravenous infusion over 1 minute (2 mL/kg of 10% dextrose; Table 11-5). This should be followed by a continuous intravenous infusion of 8 mg/kg/min using dextrose 10% solution. This rate of glucose administration may be rapidly and conveniently calculated by using the simple formula that 5 mL/kg/hr of a 10% dextrose solution provides approximately 8 mg/kg/min of glucose. Glucose levels should be determined 15 minutes after the bolus has been given and while the maintenance glucose infusion is running. If hypoglycemia recurs, a bolus of 0.5 g/kg may be given (5 mL/kg of dextrose 10%) and the glucose infusion increased by 25 to 50%. For details of specific treatments of individual disorders, see the sections on each condition.

Conclusions

Since the first edition of this textbook, there have been remarkable changes in one particular area of hypoglycemia-hyperinsulinism. Formerly, it was sufficient to diagnose hyperinsulinism as the cause of hypoglycemia. It is now clear that defects of at least five genes can produce hyperinsulinism. However, it is also known that defects in one of these genes [the sulfonylurea receptor (SUR1)] may be inherited in three different mechanisms (dominant, recessive, and loss of heterozygosity). The association of recessive mutations in SUR1 with diffuse disease and loss of heterozygosity with focal disease is clear. Innovative approaches to identifying focal from diffuse disease have led to the use of partial pancreatectomy with cure in focal disease. New forms of hyperinsulinism continue to be discovered.

Advances in molecular biology allow us to diagnose many conditions without invasive biopsies or prolonged cell cultures. As gene testing expands, even conditions in which there are not common mutations will be easily diagnosed by a simple blood test. Despite all of these advances, one thing is clear: hypoglycemia is a sign and not a diagnosis. No neonate, infant, or child should ever be labeled as having hypoglycemia as a conclusive diagnosis. Rather, the discovery of hypoglycemia should be the first step in the investigative pathway that ends with a diagnosis and a child no longer at risk of brain damage.

Concluding Remarks

History, Embryology, and Anatomy

The adrenal cortex produces three principal categories of steroid hormones that regulate a wide variety of physiologic processes from fetal to adult life. Mineralocorticoids (principally aldosterone) regulate renal retention of sodium and thus profoundly influence electrolyte balance, intravascular volume, and blood pressure. Glucocorticoids (principally cortisol) are named for their carbohydrate-mobilizing activity, but are ubiquitous physiologic regulators influencing a wide variety of bodily functions.

Adrenal androgens serve no known physiologic role but do mediate some secondary sexual characteristics in women (e.g., pubic and axillary hair), and their overproduction may result in virilism. Thus, the adrenal cortex is of considerable interest because of the widespread effects of its secretions and because derivatives of these secreted steroids are widely used as pharmacologic agents.[1] Disorders of the adrenal cortex, once thought to be rare, are being recognized with increasing frequency. The severe congenital adrenal hyperplasias affect nearly 1 in 10,000 persons, and the very mild forms may affect as many as 1 in 100 in some populations. Cushing disease, once regarded as a true rarity in pediatrics, may affect as many children as adults.

HISTORY

The adrenal glands apparently were first described in 1563 by the Italian anatomist Bartolomeo Eustaccio, better known for his description of the eustacian tube of the ear. Medical interest in the adrenals as something other than an anatomic curiosity began in the mid-nineteenth century with Addison's classic description of adrenal insufficiency and Brown-Séquard's experimental creation of similar disorders in animals subjected to adrenalectomy. The signs and symptoms of glucocorticoid excess due to adrenal tumors were well known by 1932, when Cushing described the pituitary tumors that cause what is now known as Cushing disease.[2] Effects of adrenalectomy on salt and water metabolism were reported in 1927, and by the late 1930s Selye had proposed the terms *glucocorticoid* and *mineralocorticoid* to distinguish the two broad categories of actions of adrenal extracts.[3]

Numerous adrenal steroids were painstakingly isolated and their structures determined during the 1930s in the laboratories of Reichstein[4] and Kendall,[5] leading to their sharing the 1950 Nobel Prize in Medicine. Many of these steroids were synthesized chemically, providing pure material for experimental purposes. The observation in 1949 that glucocorticoids ameliorated the symptoms of rheumatoid arthritis[6] greatly stimulated

interest in synthesizing new pharmacologically active analogues of naturally occurring steroids. The structures of the various adrenal steroids suggested precursor/product relationships, leading in 1950 to the first treatment of congenital adrenal hyperplasia with cortisone by Wilkins[7] and by Bartter.[8] This opened a vigorous era of clinical investigation of the pathways of steroidogenesis in a variety of inherited adrenal and gonadal disorders.

The association of cytochrome P450 with 21-hydroxylation was made in 1965,[9] and some of the steroidogenic enzymes were then isolated in the 1970s. However, it was not until the genes for most of these enzymes were cloned in the 1980s that it became clear which proteins participated in which steroidal transformations.[10] The identification of these genes (Table 12-1) then led to an understanding of the genetic lesions causing heritable disorders of steroidogenesis. At the same time, studies of steroid hormone action led to the discovery of steroid hormone receptors in the 1960s. However, it was not until they were cloned in the 1980s that their biology had begun to be understood.[11]

EMBRYOLOGY

The cells of the adrenal cortex are of mesodermal origin, in contrast to cells of the adrenal medulla, which are derived from the neuroectoderm. In human embryos, adreno-gonadal progenitor cells first appear at around the fourth week of gestation as a thickening of the coelomic epithelium, or intermediate mesoderm, between the urogenital ridge and dorsal mesentery (Figure 12-1).

TABLE 12-1

Physical Characteristics of Human Genes Encoding Steroidogenic Enzymes

Enzyme	No. of Genes	Gene Size (kb)	Chromosomal Location	Exons (n)	mRNA Size (kb)
P450scc	1	>20	15q23-q24	9	2.0
P450c11	2	9.5	8q21-22	9	4.2
P450c17	1	6.6	10q24.3	8	1.9
P450c21	2	3.4	6p21.1	10	2.0
P450aro	1	>52	15q21.2	10	3.5, 2.9
3β-HSD-I and -II	2	8	1p13	4	1.7
11β-HSD-I	1	7	1	6	1.6
11β-HSD-II	1	6.2	16p22	5	1.6
17β-HSD-I	2	3.3	17q21	6	1.4, 2.4
17β-HSD-II	1	>40	16q24	5	1.5
17β-HSD-III	1	>60	9q22	11	1.4
Adrenodoxin	1	>30	11q22	5	1.0, 1.4, 1.7
Adrenodoxin Reductase	1	11	17q24-q25	12	2.0
P450 Oxidoreductase	1	69	7q11.2	16	2.5
5α-Reductase - Type 1	1	>35	5p15	5	2.4
5α-Reductase - Type 2	1	>35	2p23	5	2.4

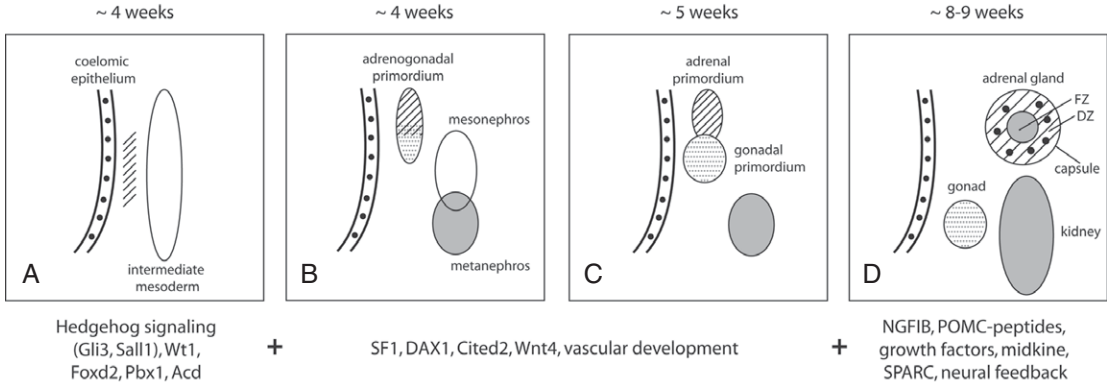

Figure 12-1 Overview of human adrenal development. (*A-C*) The adrenogonadal primordium develops at about 4 weeks gestation, after which the adrenal primordium becomes a distinct structure that then migrates retroperitoneally to the cranial pole of the mesonephros. (*D*) By 8 to 9 weeks gestation, the adrenal gland is encapsulated, contains chromaffin cells (black), and has distinct fetal (FZ) and definitive zones (DZ). Some of the signaling molecules, transcription factors, and growth factors implicated in adrenal development are shown below, although the exact timing and interaction of many of these factors remains poorly understood at present. [Adapted with permission from 14. Else T, Hammer GD (2005). Analysis of absence: Adrenal agenesis, aplasia and atrophy. Trends Endocrinol Metab 16:458-468.]

These progenitor cells give rise to the steroidogenic cells of the gonads and to the adrenal cortex.

The adrenal and gonadal cells then separate, with the adrenal cells migrating retroperitoneally to the cranial pole of the mesonephros and the gonadal cells migrating caudally. Between the seventh and eighth week of development, the adrenal primordium is invaded by sympathetic cells derived from the neural crest that give rise to the adrenal medulla. By the end of the eighth week, the rudimentary adrenal has become encapsulated and is clearly associated with the upper pole of the kidney, which at this time is much smaller than the adrenal.[12]

The fetal adrenal cortex consists of an outer "definitive" zone (the principal site of glucocorticoid and mineralocorticoid synthesis) and a much larger "fetal" zone, which makes androgenic precursors (DHEA, DHEAS) for the placental synthesis of estriol throughout pregnancy. A putative "transitional" zone exists between these regions toward the end of fetal development, but its functional role (if any) is unclear. The fetal adrenal glands are huge in proportion to other structures, and continue to grow well into the third trimester (Figure 12-2). At birth, the adrenals weigh 8 to 9 g (about the same size of adult adrenals) and represent approximately 0.4% of total body weight. However, the fetal adrenal zone rapidly involutes following birth and has virtually disappeared by 6 to 12 months of postnatal life. Thereafter, adrenal growth is comparatively slow and thus the adrenal glands represent only 0.01% of body weight in the adult.

The complex mechanisms regulating adrenal development are still relatively poorly understood. However, important insight into key factors has been obtained from studies of transgenic mice and from patients with disorders of adrenal development.[13] For example, the early stages of adrenal differentiation and development involve a number of signaling pathways (hedgehog/GLI3, WNT3/WNT4/WNT11, midkine), transcription factors [SALL1, FOXD2, PBX1, WT1, SF1 (NR5A1), DAX1 (NR0B1)], coregulators (CITED2), matrix proteins (SPARC), and regulators of telomerase activity (ACD).[14] Subsequent fetal adrenal growth is highly dependent on the tropic effects of adrenocorticotropin (ACTH), its receptor (MC2R), and its downstream signaling pathways, as well as on growth-factor-signaling pathways such as insulin-like growth factor II (IGFII), basic fibroblast growth factor (bFGF), and epidermal growth factor (EGF).

ANATOMY

The adrenals, once termed *suprarenal glands,* derive their name from their anatomical location of sitting on top of the upper pole of each kidney. Unlike most other organs, the arteries and veins serving the adrenal do not run in parallel. Arterial blood is provided by several small arteries arising from the renal and phrenic arteries, the aorta, and sometimes the ovarian and left spermatic arteries. The veins are more conventional, with the left adrenal vein draining into the left renal vein and the right adrenal vein draining directly into the vena cava.

Arterial blood enters the sinusoidal circulation of the cortex and drains toward the medulla, so that medullary chromaffin cells are bathed in very high concentrations of steroid hormones. High concentrations of cortisol are required for expression of medullary phenylethanolamine-N-methyltransferase, which converts norepinephrine to epinephrine, linking the adrenal cortical and medullary responses to stress.[15]

The adrenal cortex consists of three histologically recognizable zones: the glomerulosa is immediately below the capsule, the fasciculata is in the middle, and the reticularis lies next to the medulla. The glomerulosa, fasciculata, and reticularis constitute respectively about 15%, 75%, and 10% of the adrenal cortex of the older child and adult. These zones appear to be distinct functionally as well as histologically, but considerable overlap exists and

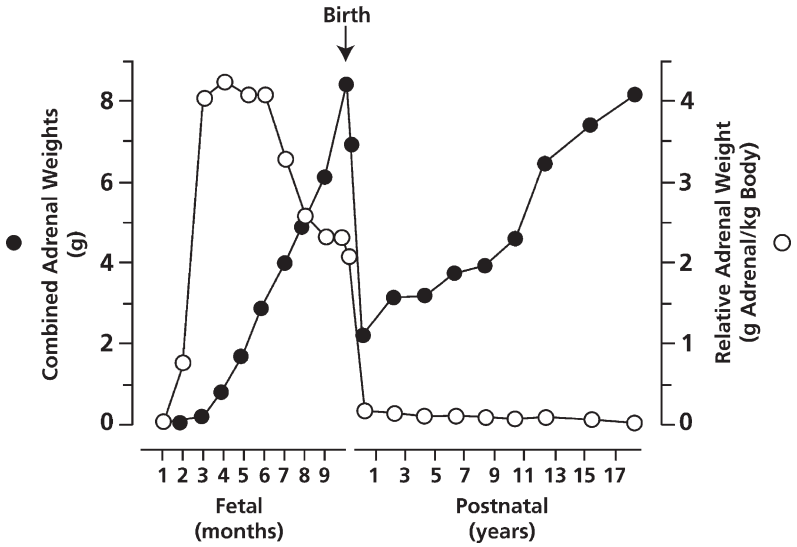

Figure 12-2 Combined adrenal weight (filled circles) and relative adrenal weight (open circles) from the first trimester through early adulthood. [Reprinted with permission from 170. Mesiano S, Jaffe RB (1997). Role of growth factors in the developmental regulation of the human fetal adrenal cortex. Steroids 62:62-72.]

immunocytochemical data show that the zones physically interdigitate. After birth, the large fetal zone begins to involute and disappears by about 6 months of age.

The definitive zone simultaneously enlarges, but two of the adult zones, glomerulosa and fasciculate, are not fully differentiated until about 3 years of age, and the reticularis may not be fully differentiated until about 15 years of age. The origin of the distinct adrenocortical zones and the mechanisms that regulate their proliferation are still poorly understood. One model suggests that a population of undifferentiated stem cells exists between the zona glomerulosa and zona fasciculata, which represents a pool of common precursor cells that can contribute to the inner or outer zones. In contrast, the "cell migration" theory proposes that a subcapsular population of stem cells exists. In this model, precursor cells first differentiate within the zona glomerulosa but change their characteristics as they migrate centripetally into the zona fasciculata then zona reticularis.

Steroid Hormone Synthesis

EARLY STEPS: CHOLESTEROL UPTAKE, STORAGE, AND TRANSPORT

Much is now known about steroid biosynthesis.[16] The human adrenal can synthesize cholesterol de novo from acetate, but most of its supply of cholesterol comes from plasma low-density lipoproteins (LDLs) derived from dietary cholesterol.[17] Rodent adrenals derive most of their cholesterol from high-density lipoproteins via a receptor termed SR-B1, but this pathway appears to play a minor role in human steroidogenesis.[18] Adequate concentrations of LDL will suppress 3-hydroxy-3-methylglutaryl co-enzyme A (HMGCoA) reductase, the rate-limiting enzyme in cholesterol synthesis.

ACTH, which stimulates adrenal steroidogenesis, also stimulates the activity of HMG CoA reductase, LDL receptors, and uptake of LDL cholesterol. LDL cholesterol esters are taken up by receptor-mediated endocytosis and then stored directly or converted to free cholesterol and used for steroid hormone synthesis.[19] Cholesterol can be esterified by acyl-CoA:cholesterol transferase (ACAT), stored in lipid droplets, and accessed by activation of hormone-sensitive lipase (HSL). ACTH stimulates HSL and inhibits ACAT, thus increasing the availability of free cholesterol for steroid hormone synthesis.

STEROIDOGENIC ENZYMES

Cytochrome P450

Most steroidogenic enzymes are members of the cytochrome P450 group of oxidases. *Cytochrome P450* is a generic term for a group of oxidative enzymes, all of which have about 500 amino acids and contain a single heme group.[20] They are termed *P450* (pigment 450) because all absorb light at 450 nm in their reduced states. It is sometimes stated that certain steroidogenic enzymes are "P450-dependent" enzymes. This is a misnomer, as it implies a generic P450 cofactor to a substrate-specific enzyme. However, the P450 binds the steroidal substrate and achieves its catalysis on an active site associated with the heme group.

Human beings have genes for 57 cytochrome P450 enzymes,[21,22] of which 7 are targeted to mitochondria and 50 are targeted to the endoplasmic reticulum—especially in the liver, where they metabolize countless endogenous and exogenous toxins, drugs, xenobiotics, and environmental pollutants. Each P450 enzyme can metabolize multiple substrates, catalyzing a broad array of oxidations. This theme recurs with each adrenal P450 enzyme.

Five distinct P450 enzymes are involved in adrenal steroidogenesis (Figure 12-3). Mitochondrial P450scc is the cholesterol side-chain cleavage enzyme catalyzing the series of reactions formerly termed *20,22 desmolase*. Two distinct isozymes of P450c11, P450c11β and P450c11AS; also found in mitochondria, catalyze 11β-hydroxylase, 18-hydroxylase, and 18-methyl oxidase activities. P450c17, found in the endoplasmic reticulum, catalyzes 17α-hydroxylase and 17,20 lyase activities, and P450c21 catalyzes the 21-hydroxylation of glucocorticoids and mineralocorticoids. In the gonads and elsewhere, P450aro in the endoplasmic reticulum catalyzes aromatization of androgens to estrogens.

Hydroxysteroid Dehydrogenases

The hydroxysteroid dehydrogenases have molecular masses of about 35 to 45 kDa, do not have heme groups, and require NAD^+ or $NADP^+$ as cofactors. Whereas most steroidogenic reactions catalyzed by P450 enzymes are due to the action of a single form of P450, each of the reactions catalyzed by hydroxysteroid dehydrogenases can be catalyzed by at least two, often very different, isozymes. Members of this family include the 3α- and 3β-hydroxysteroid dehydrogenases, the two 11β-hydroxysteroid dehydrogenases, and a series of 17β-hydroxysteroid dehydrogenases. The 5α-reductases are unrelated to this family.

Based on their structures, these enzymes fall into two groups: the short-chain dehydrogenase reductase (SDR) family, characterized by a Rossman fold, and the aldo-keto reductase (AKR) family, characterized by a triosephosphate isomerase (TIM) barrel motif.[23] The SDR enzymes include 11β-HSDs 1 and 2 and 17β-HSDs 1, 2, 3, and 4. The AKR enzymes include 17β-HSD5, which is important in extraglandular activation of androgenic precursors. Based on their activities, it is physiologically more useful to classify them as dehydrogenases or reductases. The dehydrogenases use NAD^+ as their cofactor to oxidize hydroxysteroids to ketosteroids, and the reductases mainly use NADPH to reduce ketosteroids to hydroxysteroids. Although these enzymes are typically bidirectional in vitro, they tend to function in only one direction in intact cells, with the direction determined by the cofactor(s) available.[23]

P450scc

Conversion of cholesterol to pregnenolone in mitochondria is the first rate-limiting and hormonally regulated step in the synthesis of all steroid hormones. This involves three distinct chemical reactions: 20α-hydroxylation,

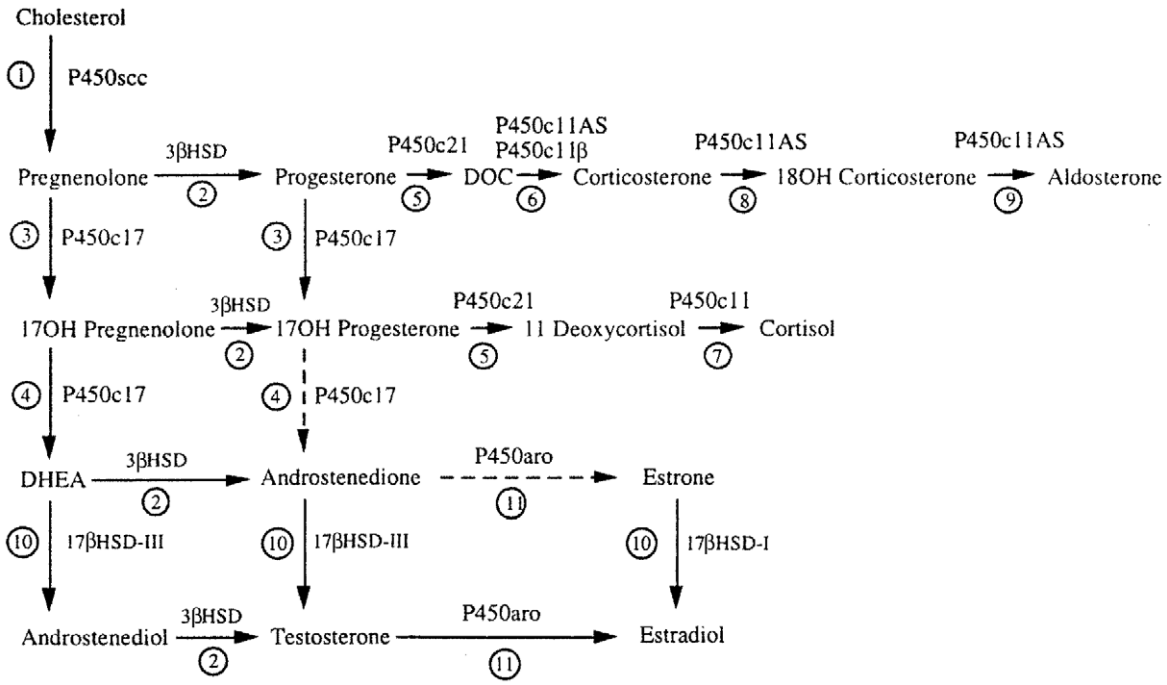

Figure 12-3 Principal pathways of human adrenal steroid hormone synthesis. Other quantitatively and physiologically minor steroids are also produced. The names of the enzymes are shown by each reaction, and the traditional names of the enzymatic activities correspond to the circled numbers. Reaction 1: Mitochondrial cytochrome P450scc mediates 20α-hydroxylation, 22-hydroxylation, and scission of the C20-22 carbon bond. Reaction 2: 3βHSD mediates 3β-hydroxysteroid dehydrogenase and isomerase activities, converting Δ^5 steroids to Δ^4 steroids. Reaction 3: P450c17 catalyzes the 17α-hydroxylation of pregnenolone to 17OH-pregnenolone and of progesterone to 17OH-progesterone. Reaction 4: The 17,20 lyase activity of P450c17 converts 17OH-pregnenolone to DHEA (only insignificant amounts of 17OH-progesterone are converted to Δ^4 androstenedione by human P450c17, although this reaction occurs in other species). Reaction 5: P450c21 catalyzes the 21-hydroxylation of progesterone to DOC and of 17OH-progesterone to 11-deoxycortisol. Reaction 6: DOC is converted to corticosterone by the 11-hydroxylase activity of P450c11AS in the zona glomerulosa and by P450c11β in the zona fasciculata. Reaction 7: 11-deoxycortisol undergoes 11β-hydroxylation by P450c11β to produce cortisol in the zona fasciculata. Reactions 8 and 9: The 18-hydroxylase and 18-methyl oxidase activities of P450c11AS convert corticosterone to 18OH-corticosterone and aldosterone, respectively, in the zona glomerulosa. Reactions 10 and 11 are found principally in the testes and ovaries. Reaction 10: 17βHSD-III converts DHEA to androstenediol and androstenedione to testosterone, whereas 17βHSD-I converts estrone to estradiol. Reaction 11: Testosterone may be converted to estradiol and androstenedione may be converted to estrone by P450aro.

22-hydroxylation, and scission of the cholesterol side chain to yield pregnenolone and isocaproic acid. Because 20-hydroxycholesterol, 22-hydroxycholesterol, and 20, 22-dihydroxycholesterol could all be isolated from bovine adrenals in significant quantities, it was previously thought that three separate enzymes were involved.

However, a single protein, termed *P450scc*, where SCC refers to the side-chain cleavage of cholesterol, encoded by a single gene on chromosome 15[24] catalyzes all steps between cholesterol and pregnenolone.[10,25] These three reactions occur on a single active site that is in contact with the hydrophobic bilayer membrane. Deletion of the gene for P450scc in the rabbit[26] or mouse[27] eliminates all steroidogenesis, indicating that all steroidogenesis is initiated by this one enzyme.

Transport of Electrons to P450scc: Adrenodoxin Reductase and Adrenodoxin

P450scc functions as the terminal oxidase in a mitochondrial electron transport system.[28] Electrons from NADPH are accepted by a flavoprotein, termed *adrenodoxin reductase,* that is loosely associated with the inner mitochondrial membrane. Adrenodoxin reductase transfers the electrons to an iron/sulfur protein termed *adrenodoxin,* which is found in the mitochondrial matrix or loosely adherent to the inner mitochondrial membrane. Adrenodoxin then transfers the electrons to P450scc (Figure 12-4).

Adrenodoxin reductase and adrenodoxin serve as generic electron transfer proteins for all mitochondrial P450s, and not just for those involved in steroidogenesis. Hence, these proteins are also termed *ferredoxin reductase* and *ferredoxin.* Adrenodoxin forms a 1:1 complex with adrenodoxin reductase and then dissociates, subsequently reforming an analogous 1:1 complex with a mitochondrial P450 such as P450scc or P450c11, thus functioning as an indiscriminate diffusable electron shuttle mechanism. Adrenodoxin reductase is a membrane-bound mitochondrial flavoprotein that receives electrons from NADPH. The human genes for adrenodoxin reductase[29,30] and adrenodoxin[31] are expressed in all tissues,[32,33] indicating they may have other roles. Human mutations in these genes have not been described.

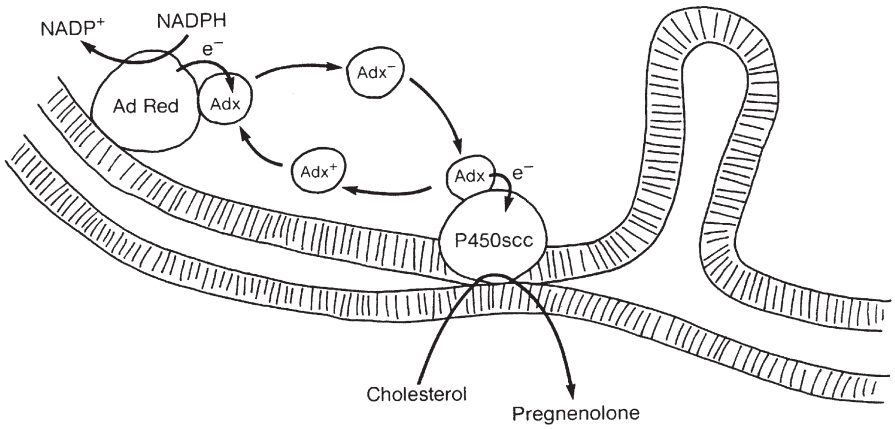

Figure 12-4 Electron transport to mitochondrial forms of cytochrome P450. Adrenodoxin reductase (AdRed), a flavoprotein loosely bound to the inner mitochondrial membrane, accepts electrons (e^-) from NADPH, converting it to $NADP^+$. These electrons are passed to adrenodoxin (Adx), an iron-sulfur protein in solution in the mitochondrial matrix that functions as a freely diffusable electron shuttle mechanism. Electrons from charged adrenodoxin (Adx^-) are accepted by any available cytochrome P450 such as P450c11 (or P450scc, shown here). The uncharged adrenodoxin (Adx^+) may then be again bound to adrenodoxin reductase to receive another pair of electrons. For P450scc, three pairs of electrons must be transported to the P450 to convert cholesterol to pregnenolone. The flow of cholesterol into the mitochondria is facilitated by StAR, which is not shown in this diagram.

Mitochondrial Cholesterol Uptake: The Steroidogenic Acute Regulatory Protein (StAR)

ACTH regulates steroidogenic capacity (chronic regulation) by inducing the transcription of genes for steroidogenic enzymes,[34] but acute regulation (wherein steroids are released within minutes of a stimulus) is at the level of cholesterol access to P450scc.[35,36] When steroidogenic cells or intact rats are treated with inhibitors of protein synthesis such as cycloheximide, the acute steroidogenic response is eliminated, suggesting that a short-lived cycloheximide-sensitive protein acts at the level of the mitochondrion[25] as the specific trigger to the acute steroidogenic response.

This factor was first identified as short-lived 30- and 37-kDa phosphoproteins that were rapidly synthesized when steroidogenic cells were stimulated with tropic hormones[37-39] and then cloned from mouse Leydig MA-10 cells, and named the steroidogenic acute regulatory protein, StAR.[40] The central role of StAR in steroidogenesis was proven by finding that mutations of StAR caused congenital lipoid adrenal hyperplasia.[41,42] Thus, StAR is the acute trigger required for the rapid flux of cholesterol from the outer to the inner mitochondrial membrane that is needed for the acute response of aldosterone to angiotensin II, of cortisol to ACTH, and of sex steroids to an LH pulse.

Some adrenal steroidogenesis is independent of StAR. When nonsteroidogenic cells are transfected with StAR and the P450scc system, they convert cholesterol to pregnenolone at about 14% of the StAR-induced rate.[41,42] Furthermore, the placenta utilizes mitochondrial P450scc to initiate steroidogenesis[43] but does not express StAR.[44] The mechanism of StAR-independent steroidogenesis is unclear. It may occur without a triggering protein, or some other protein may exert StAR-like activity to promote cholesterol flux but without StAR's rapid kinetics.

Substantial data indicate that the action of StAR also requires the peripheral benzodiazepine receptor on the outer mitochondrial membrane.[45-47] The mechanism of StAR's action is unknown, but it is clear that StAR acts on the outer mitochondrial membrane and does not need to enter the mitochondria to be active.[36,48] The interaction with the outer mitochondrial membrane induces structural changes required for StAR's activity, probably permitting it to take up and discharge cholesterol.[36,49,50]

3β-Hydroxysteroid Dehydrogenase/$\Delta^5 \rightarrow \Delta^4$ Isomerase

Once pregnenolone is produced from cholesterol, it may undergo 17α-hydroxylation by P450c17 to yield 17-hydroxypregnenolone, or it may be converted to progesterone—the first biologically important steroid in the pathway. A single 42-kDa microsomal enzyme, 3β-hydroxysteroid dehydrogenase (3βHSD), catalyzes both conversion of the hydroxyl group to a keto group on carbon 3 and the isomerization of the double bond from the B ring (Δ^5 steroids) to the A ring (Δ^4 steroids).[51-53] Thus, a single enzyme (3βHSD) converts pregnenolone to progesterone, 17α-hydroxypregnenolone to 17α-hydroxyprogesterone, dehydroepiandrosterone (DHEA) to androstenedione, and androstenediol to testosterone, all with the same enzymologic efficiency (Km and Vmax).[54]

As is typical of hydroxysteroid dehydrogenases, there are two isozymes of 3βHSD, encoded by separate genes. These isozymes have 93.5% amino acid sequence identity and are enzymatically very similar. The enzyme-catalyzing 3βHSD activity in the adrenals and gonads is the type 2 enzyme,[55,56] whereas the type 1 enzyme, encoded by a closely linked gene with identical intron/exon organization, catalyzes 3βHSD activity in placenta, breast, and "extraglandular" tissues.[55,57] Ultrastructural data surprisingly show that bovine 3βHSD can be found in the endoplasmic reticulum and in mitochondria.[58] It is not clear if this is also true for human 3βHSD, or if this subcellular distribution

differs in various types of steroidogenic cells. However, this could be a novel point regulating the direction of steroidogenesis.[59]

P450c17

Pregnenolone and progesterone may undergo 17α-hydroxylation to 17α-hydroxypregnenolone and 17α-hydroxyprogesterone (17OHP), respectively. 17α-hydroxyprogesterone may also undergo scission of the C17,20 carbon bond to yield DHEA. However, very little 17OHP is converted to androstenedione because the human P450c17 enzyme catalyzes this reaction at only 3% of the rate for conversion of 17α-hydroxypregnenolone to DHEA.[60,61] These reactions are all mediated by a single enzyme, P450c17. This P450 is bound to smooth endoplasmic reticulum, where it accepts electrons from P450 oxidoreductase.

As P450c17 has both 17α-hydroxylase activity and 17,20 lyase activity, it is the key branch point in steroid hormone synthesis. Neither activity of P450c17 is present in the adrenal zona glomerulosa, and hence pregnenolone is converted to mineralocorticoids. In the zona fasciculata, the 17α-hydroxylase activity is present but 17,20 lyase activity is not. Hence, pregnenolone is converted to the glucocorticoid cortisol. In the zona reticularis, both activities are present and thus pregnenolone is converted to sex steroids (Figure 12-3).

17α-hydroxylase and 17,20 lyase were once thought to be separate enzymes. The adrenals of prepubertal children synthesize ample cortisol but virtually no sex steroids (i.e., have 17α-hydroxylase activity but not 17,20 lyase activity), until adrenarche initiates production of adrenal androgens (i.e., turns on 17,20 lyase activity).[62] Furthermore, patients had been described lacking 17,20 lyase activity but retaining normal 17α-hydroxylase activity.[63] However, studies of pig P450c17 showed that 17α-hydroxylase and 17,20 lyase activities reside in a single protein[64,65] and that cells transfected with a vector expressing P450c17 cDNA acquire 17α-hydroxylase and 17,20 lyase activities.[66,67] P450c17 is encoded by a single gene on chromosome 10q24.3[68,69] that is structurally related to the genes for P450c21 (21-hydroxylase).[70]

Thus, the distinction between 17α-hydroxylase and 17,20 lyase is functional and not genetic or structural. Human P450c17 catalyzes 17α-hydroxylation of pregnenolone and progesterone equally well, but the 17,20 lyase activity of human P450c17 strongly prefers 17OH pregnenolone and not 17OH progesterone, consistent with the large amounts of DHEA secreted by the fetal and adult adrenal. Furthermore, the 17α-hydroxylase reaction occurs more readily than the 17,20 lyase reaction. The principal factor regulating the 17,20 lyase reaction is electron transport from NADPH.

Electron Transport to P450c17: P450 Oxidoreductase and Cytochrome b_5

P450c17 and P450c21 receive electrons from a membrane-bound flavoprotein, termed *P450 oxidoreductase,* which is a different protein from the mitochondrial flavoprotein adrenodoxin reductase.[28] P450 oxidoreductase receives two electrons from NADPH and transfers them one at a time to the P450.[71,72] Electron transfer for the lyase reaction is promoted by the action of cytochrome b_5 as an allosteric factor rather than as an alternative electron donor.[61] 17,20 lyase activity also requires the phosphorylation of serine residues on P450c17 by a cAMP-dependent protein kinase[73-75] (Figure 12-5).

The availability of electrons determines whether P450c17 performs only 17α-hydroxylation or also performs 17,20 bond scission. Increasing the ratio of P450 oxidoreductase or cytochrome b_5 to P450c17 in vitro or in vivo increases the ratio of 17,20 lyase activity to 17α-hydroxylase activity. Competition between P450c17 and P450c21 for available 17-hydroxyprogesterone (17OHP) does not appear to be important in determining whether 17OHP undergoes 21-hydroxylation or 17,20 bond scission.[76] Thus, the regulation of 17,20 lyase activity, and consequently of DHEA production, depends on factors that facilitate the flow of

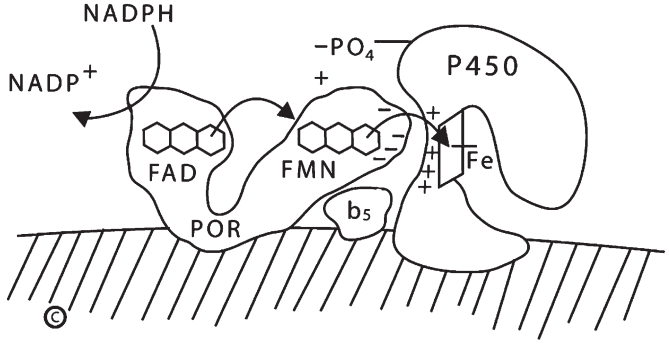

Figure 12-5 Electron transport to microsomal forms of cytochrome P450. NADPH interacts with P450 oxidoreductase (POR), bound to the endoplasmic reticulum, and gives up a pair of electrons (e^-)—which are received by the FAD moiety. Electron receipt elicits a conformational change, permitting the isoalloxazine rings of the FAD and FMN moieties to come close together so that the electrons pass from the FAD to the FMN. Following another conformational change that returns the protein to its original orientation, the FMN domain of POR interacts with the redox partner binding site of the P450. Electrons from the FMN domain of POR reach the heme group to mediate catalysis. The interaction of POR and the P450 is coordinated by negatively charged acidic residues on the surface of the FMN domain of POR and by positively charged basic residues in the concave redox-partner binding site of the P450. The active site containing the steroid lies on the side of heme ring (Fe) opposite the redox partner binding site. In the case of human P450c17, this interaction is facilitated by the allosteric action of cytochrome b_5 and by the serine phosphorylation of P450c17. [Copyright W L Miller.]

electrons to P450c17: high concentrations of P450 oxidoreductase, the presence of cytochrome b_5, and serine phosphorylation of P450c17.[77]

P450c21

After the synthesis of progesterone and 17OHP, these steroids are hydroxylated at the 21 position to yield respectively deoxycorticosterone (DOC) and 11-deoxycortisol (Figure 12-3). The nature of the 21-hydroxylating step has been of great clinical interest because disordered 21-hydroxylation causes more than 90% of all cases of congenital adrenal hyperplasia. The clinical symptoms associated with this common genetic disease are complex and devastating. Decreased cortisol and aldosterone synthesis often lead to sodium loss, potassium retention, and hypotension, which will lead to cardiovascular collapse and death usually within a month after birth if not treated appropriately. Decreased synthesis of cortisol in utero leads to overproduction of ACTH and consequent overstimulation of adrenal steroid synthesis. As the 21-hydroxylase step is impaired, 17OHP accumulates because P450c17 converts only miniscule amounts of 17OHP to androstenedione.

However, 17-hydroxypregnenolone also accumulates and is converted to DHEA, and subsequently to androstenedione and testosterone, resulting in severe prenatal virilization of female fetuses.[78-81] Congenital adrenal hyperplasia (CAH) has been extensively studied clinically. Variations in the manifestations of the disease, and especially the identification of patients without apparent defects in mineralocorticoid activity, suggested that there were two separate 21-hydroxylating enzymes differentially expressed in the zones of the adrenal specifically synthesizing aldosterone or cortisol. However, characterization of the P450c21 protein[82] and gene cloning show that there is only one 21-hydroxylase encoded by a single functional gene on chromosome 6p21.[83-85] As this gene lies in the middle of the major histocompatibility locus, disorders of adrenal 21-hydroxylation are closely linked to specific HLA types.[86]

Adrenal 21-hydroxylation is mediated by P450c21 found in smooth endoplasmic reticulum. P450c21 employs the same P450 oxidoreductase used by P450c17 to transport electrons from NADPH. 21-hydroxylase activity has also been described in a broad range of adult and fetal extra-adrenal tissues.[87] However, extra-adrenal 21-hydroxylation is not mediated by the P450c21 enzyme found in the adrenal.[88] At least three hepatic P450 enzymes can catalyze 21-hydroxylation in vitro,[89] but the significance of this activity in clinical situations is unclear. As a result, patients having absent adrenal 21-hydroxylase activity may still have appreciable concentrations of 21-hydroxylated steroids in their plasma.

P450c11β and P450c11AS

Two closely related enzymes, P450c11β and P450c11AS, catalyze the final steps in the synthesis of glucocorticoids and mineralocorticoids.[90,91] These two isozymes have 93% amino acid sequence identity[92] and are encoded by tandemly duplicated genes on chromosome 8q21-22. Like P450scc, the two forms of P450c11 are found on the inner mitochondrial membrane and use adrenodoxin and adrenodoxin reductase to receive electrons from NADPH.[93] By far the more abundant of the two isozymes is P450c11β, which is the classic 11β-hydroxylase that converts 11-deoxycortisol to cortisol and 11-deoxycorticosterone to corticosterone. The less abundant isozyme, P450c11AS, is found only in the zona glomerulosa, where it has 11β-hydroxylase, 18-hydroxylase, and 18-methyl oxidase aldosterone synthase activities. Thus, P450c11AS is able to catalyze all reactions needed to convert DOC to aldosterone.[94,95]

P450c11β, which is principally involved in synthesis of cortisol, is encoded by a gene (CYP11B1) that is primarily induced by ACTH via cAMP and is suppressed by glucocorticoids. The existence of two distinct functional genes is confirmed by the identification of mutations in each that cause distinct genetic disorders of steroidogenesis. Thus, patients with disorders in P450c11β have classic 11β-hydroxylase deficiency but can still produce aldosterone[96], whereas patients with disorders in P450c11AS have rare forms of aldosterone deficiency, so-called corticosterone methyl oxidase deficiency, while retaining the ability to produce cortisol.[97-99]

17β-Hydroxysteroid Dehydrogenase

Androstenedione is converted to testosterone, DHEA is converted to androstenediol, and estrone is converted to estradiol by the 17β-hydroxysteroid dehydrogenases (17βHSDs), sometimes also termed *17-oxioreductase* or *17-ketosteroid reductase.*[100,101] The terminologies for these enzymes vary, depending on the direction of the reaction being considered. There is confusion in the literature about the 17βHSDs because: (i) there are several different 17βHSDs; (ii) some are preferential oxidases whereas others are preferential reductases; (iii) they differ in their substrate preference and sites of expression; (iv) there is inconsistent nomenclature, especially with the rodent enzymes; / (v) and some proteins termed *17βHSD* actually have very little 17βHSD activity and are principally involved in other reactions.[102]

Type 1 17βHSD (17βHSD1), also known as estrogenic 17βHSD, is a 34-kDa cytosolic reductive SDR enzyme, first isolated and cloned from the placenta, where it produces estriol, and is also expressed in ovarian granulosa cells, where it produces estradiol.[52,103-105] 17βHSD1 uses NADPH as its cofactor to catalyze reductase activity. It acts as a dimer and only accepts steroid substrates with an aromatic A ring, and thus its activity is confined to activating estrogens. The three-dimensional structure of human 17βHSD1 has been determined by x-ray crystallography.[106,107] No genetic deficiency syndrome for 17βHSD1 has been described.

17βHSD2 is a microsomal oxidase that uses NAD^+ to inactivate estradiol to estrone and testosterone to Δ^4 androstenedione. 17βHSD2 is found in the placenta, liver, small intestine, prostate, secretory endometrium, and ovary. In contrast to 17βHSD1, which is found in placental synctiotrophoblast cells, 17βHSD2 is expressed in endothelial cells of placental intravillous vessels, consistent with its apparent role in defending the fetal circulation

from transplacental passage of maternal estradiol or testosterone.[108] No deficiency state for 17βHSD2 has been reported.

17βHSD3, the androgenic form of 17βHSD, is a microsomal enzyme apparently expressed only in the testis.[109] This is the enzyme that is disordered in the classic syndrome of male pseudohermaphroditism that is often termed *17-ketosteroid reductase deficiency*.[109,110]

An enzyme termed *17βHSD4* was initially identified as an NAD^+-dependent oxidase with activities similar to 17βHSD2,[111] but this peroxisomal protein is primarily an enoyl-CoA hydratase and 3-hydroxyacyl-CoA dehydrogenase.[112,113] Deficiency of 17βHSD4 causes a form of Zellweger syndrome, in which bile acid biosynthesis is disturbed but steroidogenesis is not.[113]

17βHSD5, originally cloned as a 3α-hydroxysteroid dehydrogenase,[114] is an AKR enzyme that catalyzes the reduction of Δ^4 androstenedione to testosterone.[115] The 17βHSD activity of 17βHSD5 is quite labile in vitro,[115] and hence its activity in androgen biosynthesis has been less clear. However, it appears to be responsible for low levels of testosterone synthesis in the adrenal and adipose tissue and may convert androstenedione to testosterone in muscle.

Steroid Sulfotransferase and Sulfatase

Steroid sulfates may be synthesized directly from cholesterol sulfate or may be formed by sulfation of steroids by cytosolic sulfotransferase (SULT) enzymes.[116,117] At least 44 distinct isoforms of these enzymes have been identified belonging to five families of SULT genes. Many of these genes yield alternately spliced products, accounting for the large number of enzymes. The SULT enzymes that sulfonate steroids include SULT1E estrogens, SULT2A1 nonaromatic steroids, and SULT2B1 sterols. SULT2A1 is the principal sulfotransferase expressed in the adrenal, where it sulfates the 3βhydroxyl group of Δ5 steroids, pregnenolone, 17OH-pregnenolone, DHEA, androsterone, but not of cholesterol. SULT2B1a will also sulfonate pregnenolone but not cholesterol, whereas cholesterol is the principal substrate for SULT2B1b in the skin, liver, and elsewhere.

It is not clear whether most steroid sulfates are simply inactivated forms of steroid or if they serve specific hormonal roles. Knockout of the mouse SULT1E1 gene is associated with elevated estrogen levels, increased expression of tissue factor in the placenta, and increased platelet activation, leading to placental thrombi and fetal loss that could be ameliorated by anticoagulant therapy.[118] Mutations ablating the function of human SULT enzymes have not been described, but single-nucleotide polymorphisms that alter the amino acid sequences and catalytic activity affecting drug activity are well described. African Americans have a high rate of polymorphisms in SULT2A1, apparently influencing plasma ratios of DHEA and DHEAS, which may correlate with risk of prostatic and other cancers.[119]

Steroid sulfates may also be hydrolyzed to the native steroid by steroid sulfatase. Deletions in the steroid sulfatase gene on chromosome Xp22.3 cause X-linked ichthyosis.[120,121] In the fetal adrenal and placenta, diminished or absent sulfatase deficiency reduces the pool of free DHEA available for placental conversion to estrogen, resulting in low concentrations of estriol in the maternal blood and urine. The accumulation of steroid sulfates in the stratum corneum of the skin causes the ichthyosis. Steroid sulfatase is also expressed in the fetal rodent brain, possibly converting peripheral DHEAS to active DHEA.[122,123]

Aromatase: P450aro

Estrogens are produced by the aromatization of androgens, including adrenal androgens, by a complex series of reactions catalyzed by a single microsomal aromatase (P450aro).[124,125] This typical cytochrome P450 is encoded by a single gene on chromosome 15q21.1. This gene uses several different promoter sequences, transcriptional start sites, and alternatively chosen first exons to encode aromatase mRNA in different tissues under different hormonal regulation. Aromatase expression in the extraglandular tissues, especially adipose tissue, can convert adrenal androgens to estrogens.

Aromatase in the epiphyses of growing bone converts testosterone to estradiol. The tall stature, delayed epiphyseal maturation, and osteopenia of males with aromatase deficiency and the rapid reversal of these conditions with estrogen replacement indicate that estrogen (not androgen) is responsible for epiphyseal maturation in males.[125] Although it has traditionally been thought that aromatase activity is needed for embryonic and fetal development, infants and adults with genetic disorders in this enzyme have been described recently, demonstrating that feto-placental estrogen is not needed for normal fetal development.[126,127]

5α-Reductase

Testosterone is converted to the more potent androgen dihydrotestosterone by 5α-reductase, an enzyme found in testosterone's target tissues. There are two distinct forms of 5α-reductase. The type 1 enzyme, found in the scalp and other peripheral tissues, is encoded by a gene on chromosome 5. The type 2 enzyme, the predominant form found in male reproductive tissues, is encoded by a structurally related gene on chromosome 2p23.[128] The syndrome of 5α-reductase deficiency, a disorder of male sexual differentiation, is due to a wide variety of mutations in the gene encoding the type 2 enzyme.[129]

The types 1 and 2 genes show an unusual pattern of developmental regulation of expression. The type 1 gene is not expressed in the fetus, is then expressed briefly in the skin of the newborn, and then remains unexpressed until its activity and protein are again found after puberty. The type 2 gene is expressed in fetal genital skin, in the normal prostate, and in prostatic hyperplasia and adenocarcinoma. Thus, the type 1 enzyme may be responsible for the pubertal virilization seen in patients with classic 5α-reductase deficiency, and the type 2 enzyme may be involved in male-pattern baldness.[128]

11β-Hydroxysteroid Dehydrogenase

Although certain steroids are categorized as glucocorticoids or mineralocorticoids, cloning and expression of the "mineralocorticoid" glucocorticoid type 2 receptor shows it has equal affinity for aldosterone and cortisol.[130] However, cortisol does not act as a mineralocorticoid in vivo, even though cortisol concentrations can exceed aldosterone concentrations by 100- to 1,000-fold. In mineralocorticoid-responsive tissues such as the kidney, cortisol is enzymatically converted to cortisone, a metabolically inactive steroid.[131]

The interconversion of cortisol and cortisone is mediated by two isozymes of 11β-hydroxysteroid dehydrogenase 11βHSD, each of which has oxidase and reductase activity, depending on the cofactor available, $NADP^+$ or NADPH.[132] The type 1 enzyme 11βHSD1 is expressed mainly in glucocorticoid-responsive tissues such as the liver, testis, lung, and proximal convoluted tubule. 11βHSD1 can catalyze the oxidation of cortisol to cortisone using $NADP^+$ as its cofactor K_m 1.6 μM and can catalyze the reduction of cortisone to cortisol using NADPH as its cofactor K_m 0.14 μM. The reaction catalyzed depends on which cofactor is available, but the enzyme can only function with high micromolar concentrations of steroid.[133,134]

11βHSD2 catalyzes only the oxidation of cortisol to cortisone using NADH, and can function with low nanomolar-concentrations of steroid (K_m 10-100 nM).[135,136] 11βHSD2 is expressed in mineralocorticoid-responsive tissues and thus serves to "defend" the mineralocorticoid receptor by inactivating cortisol to cortisone so that only "true" mineralocorticoids, such as aldosterone or deoxycorticosterone, can exert a mineralocorticoid effect. Thus, 11βHSD2 prevents cortisol from overwhelming renal mineralocorticoid receptors.[131] In the placenta and other fetal tissues, 11βHSD2[137,138] also inactivates cortisol.

The placenta also has abundant $NADP^+$ favoring the oxidative action of 11βHSD1, and thus in placenta both enzymes protect the fetus from high maternal concentrations of cortisol.[132] 11βHSD1 is located on the luminal side of the endoplasmic reticulum, and hence is not in contact with the cytoplasm. In this unusual cellular location, 11βHSD1 receives NADPH provided by the action of hexose-6-phosphate dehydrogenase.[139] This links 11βHSD1 to the pentose monophosphate shunt, providing a direct paracrine link between local glucocorticoid production and energy storage as fat.[140]

FETAL ADRENAL STEROIDOGENESIS

Adrenocortical steroidogenesis begins early in embryonic life, about week 7 of gestation. Steroidogenic enzymes are immunocytochemically detected, principally in the fetal zone, at 50 to 52 days postconception; by 8 weeks postconception the adrenal contains cortisol and responds to ACTH in primary culture systems.[141] This cortisol synthesis is under the regulation of pituitary ACTH and involves transient expression of adrenal 3βHSD2. Following the ninth week postconception, expression of 3βHSD2 and synthesis of cortisol wane. 3βHSD2 is barely detectable at 10 to 11 weeks and is absent at 14 weeks.[141]

At the same time, the fetal adrenal also produces 17βHSD5[141], which can convert androstenedione to testosterone. Thus, the fetal adrenal makes cortisol at the same time during gestation that fetal testicular testosterone is virilizing the genitalia of the normal male fetus. This fetal adrenal cortisol apparently suppresses ACTH, which otherwise would drive adrenal testosterone synthesis via 17βHSD5.

Fetuses affected with genetic lesions in adrenal steroidogenesis can produce sufficient adrenal androgen to virilize a female fetus to a nearly male appearance, and this masculinization of the genitalia is complete by week 12 of gestation.[142] The definitive zone of the fetal adrenal produces steroid hormones according to the pathways shown in Figure 12-3. By contrast, the large fetal zone of the adrenal is relatively deficient in 3βHSD2 activity after 12 weeks.[143] The fetal adrenal has relatively abundant 17,20 lyase activity of P450c17. Low 3βHSD and high 17,20 lyase activity account for the abundant production of DHEA and its sulfate DHEAS by the fetal adrenal, which are converted to estrogens by the placenta.

The fetal adrenal also has considerable sulfotransferase activity but little steroid sulfatase activity, also favoring conversion of DHEA to DHEAS. The resulting DHEAS cannot be a substrate for adrenal 3βHSD2. Instead, it is secreted, 16α-hydroxylated in the fetal liver, and then acted on by placental 3βHSD1, 17βHSD1, and P450aro to produce estriol. Alternatively, the substrates can bypass the liver to yield estrone and estradiol. Placental estrogens inhibit adrenal 3βHSD activity, providing a feedback system to promote production of DHEAS.[144] Fetal adrenal steroids account for 50% of the estrone and estradiol and 90% of the estriol in the maternal circulation.

Although the feto-placental unit produces huge amounts of DHEA, DHEAS, and estriol (as well as other steroids), they do not appear to serve an essential role. Successful pregnancy is wholly dependent on placental synthesis of progesterone, which suppresses uterine contractility and prevents spontaneous abortion. However, fetuses with genetic disorders of adrenal and gonadal steroidogenesis develop normally, reach term gestation, and undergo normal parturition and delivery. Mineralocorticoid production is only required postnatally. Estrogens are not required, and androgens are only needed for male sexual differentiation.[145] It appears that human fetal glucocorticoids are needed at about 8 to 12 weeks,[141] but it is not clear that they are needed thereafter. If they are, the small amount of maternal cortisol that escapes placental inactivation suffices.[145-147]

The regulation of steroidogenesis and growth of the fetal adrenal are not fully understood, but both are related to ACTH. ACTH effectively stimulates steroidogenesis by fetal adrenal cells in vitro,[148,149] and excess ACTH is clearly involved in the adrenal growth and overproduction of androgens in fetuses affected with congenital adrenal hyperplasia. Prenatal treatment of such fetuses by administering pharmacologic doses of dexamethasone to the mother at 6 to 10 weeks gestation can significantly reduce fetal adrenal androgen production and thus reduce the virilization of female fetuses. Thus, the hypothalamic-pituitary-adrenal

axis functions very early in fetal life.[150] By contrast, however, anencephalic fetuses lacking pituitary ACTH have adrenals that contain a fairly normal complement of steroidogenic enzymes and retain their capacity for steroidogenesis. Thus, fetal adrenal steroidogenesis may be regulated by ACTH-dependent and ACTH-independent mechanisms.

Regulation of Steroidogenesis

THE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

Hypothalamus: CRF and AVP

The principal steroidal product of the human adrenal is cortisol, which is mainly secreted in response to adrenocorticotropic hormone (ACTH, corticotropin) produced in the pituitary. Secretion of ACTH is stimulated primarily by corticotropin-releasing factor (CRF) from the hypothalamus. Hypothalamic CRF is a 41-amino-acid peptide synthesized mainly by neurons in the paraventricular nucleus. These same hypothalamic neurons also produce the decapeptide arginine vasopressin AVP, also known as antidiuretic hormone or ADH.[151] CRF and AVP are proteolytically derived from larger precursors, with the AVP precursor containing the sequence for neurophysin, which is the AVP-binding protein.

CRF and AVP travel through axons to the median eminence, which releases them into the pituitary portal circulation, although most AVP axons terminate in the posterior pituitary.[152] AVP is co-secreted with CRF in response to stress, and CRF and AVP stimulate the synthesis and release of ACTH but appear to do so by different mechanisms.[153] CRF binds to a G-protein–coupled receptor on the membranes of pituitary corticotropes and activates adenylyl cyclase, increasing cAMP, which activates the PKA signaling pathway.

PKA triggers ACTH secretion by concerted regulation of cellular potassium and calcium fluxes, and enhances pro-opiomelanocortin (POMC) gene transcription. AVP binds to its G-protein–coupled receptor and activates phospholipase C, which leads to the release of intracellular Ca^{++} and to the activation of protein kinase C (PKC). AVP seems to amplify the effects of CRF on ACTH secretion without affecting synthesis. However, CRF is the more important physiologic stimulator of ACTH release, although maximal doses of AVP can elicit a maximal ACTH response. When given together, CRF and AVP act synergistically, as would be expected from their independent mechanisms of action.

Pituitary: ACTH and POMC

Pituitary ACTH is a 39-amino-acid peptide derived from POMC, a 241-amino-acid protein. POMC undergoes a series of proteolytic cleavages, yielding several biologically active peptides[154,155] (Figure 12-6). The N-terminal glycopeptide (POMC 1-75) can stimulate steroidogenesis and may function as an adrenal mitogen.[156] POMC 112-150 is ACTH 1-39, POMC 112-126 and POMC 191-207 constitute respectively α- and β-MSH melanocyte-stimulating hormone, and POMC 210-241 is β-endorphin. POMC is also produced in small amounts by the brain, testis, liver, kidney, and placenta. However, this extrapituitary POMC does not contribute significantly to circulating ACTH.

Malignant tumors will commonly produce ectopic ACTH in adults and rarely in children. This ACTH derives from ectopic biosynthesis of the same POMC precursor.[154] Only the first 20 to 24 amino acids of ACTH are needed for its full biological activity, and synthetic ACTH 1-24 is widely used in diagnostic tests of adrenal function. However, these shorter forms of ACTH have a shorter half-life than does native ACTH 1-39. POMC gene transcription is stimulated by CRF and inhibited by glucocorticoids.[157]

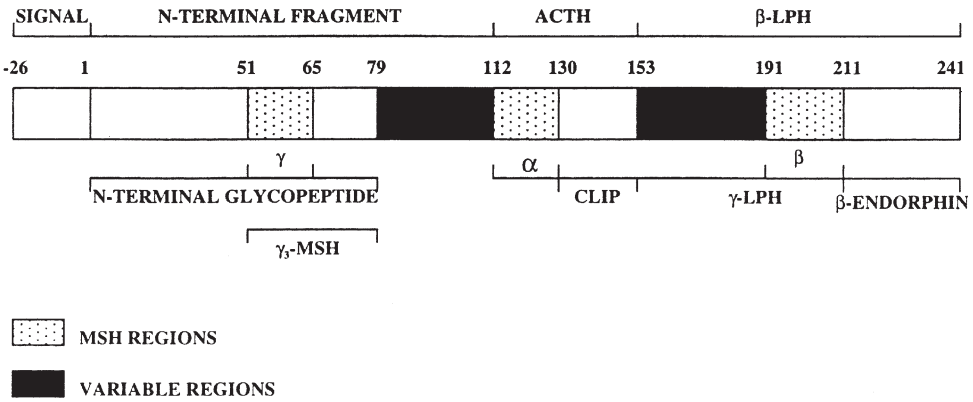

Figure 12-6 Structure of human pre-proopiomelanocortin. The numbers refer to amino acid positions, with no. 1 assigned to the first amino acid of POMC after the 26-amino-acid signal peptide. The α-, β-, and γ- MSH regions (which characterize the three "constant" regions) are indicated by diagonal lines. The "variable" regions are solid. The amino acid numbers shown refer to the N-terminal amino acid of each cleavage site. Because these amino acids are removed, the numbers do not correspond exactly with the amino acid numbers of the peptides as used in the text. ACTH, adrenocorticotropic hormone; CLIP, corticotropin-like intermediate lobe peptide; LPH, lipotropic hormone; and MSH, melanocyte-stimulating hormone.

Actions of ACTH

ACTH stimulates the G-protein–coupled melanocortin 2 receptor (MCR2), which is located almost exclusively in the adrenal cortex. Activation of MCR2 triggers the production of cAMP, activating PKA that catalyzes the phosphorylation of many proteins involved in steroidogenesis, thereby modifying their activity. ACTH elicits acute and long-term effects. ACTH stimulates the biosynthesis of LDL receptors and the uptake of LDL, which provides most of the cholesterol used for steroidogenesis[17], and stimulates transcription of the gene for HMGCoA reductase, the rate-limiting step in cholesterol biosynthesis. However, adrenal biosynthesis of cholesterol is quantitatively much less important than the uptake of LDL cholesterol.[19]

Cholesterol is stored in steroidogenic tissues as cholesterol esters in lipid droplets. ACTH stimulates the activity of cholesterol esterase while inhibiting cholesterol ester synthetase, thus increasing the intracellular pool of free cholesterol, the substrate for P450scc.[158,159] The esterase is similar to gastric and lingual lipases.[160] Finally, ACTH facilitates transport of cholesterol into mitochondria by stimulating the synthesis and phosphorylation of StAR, thus increasing the flow of free cholesterol into the mitochondria. All of these actions are mediated by cAMP and occur within minutes, constituting the "acute" effect of ACTH on steroidogenesis. The adrenal contains relatively modest amounts of steroid hormones. Thus, release of preformed cortisol does not contribute significantly to the acute response to ACTH. Acute responses occur by the rapid provision of large supplies of cholesterol to mitochondrial P450scc.[35,161]

The long-term "chronic" effects of ACTH are mediated directly at the level of the steroidogenic enzymes. ACTH via cAMP stimulates the accumulation of the steroidogenic enzymes and their mRNAs by stimulating the transcription of their genes.[34] ACTH also increases adrenal blood flow, increasing the influx of oxygen and metabolic fuel and the delivery of newly secreted hormones to the circulation.[162] Thus, ACTH increases the uptake of the cholesterol substrate and its conversion to steroidal products. The stimulation of this steroidogenesis occurs at each step in the pathway, not just at the rate-limiting step (P450scc).

The role of ACTH and other peptides derived from POMC in stimulating growth of the adult adrenal remains uncertain.[163,164] However, lack of pituitary POMC causes severe adrenal hypoplasia[165,166] and chronic ACTH excess causes adrenal hyperplasia. In the fetal adrenal, ACTH stimulates the local production of insulin-like growth factor II,[149,167] basic fibroblast growth factor,[168] and epidermal growth factor.[169] These, and possibly other factors, work together to mediate ACTH-induced growth of the fetal adrenal.[170]

Diurnal Rhythms of ACTH and Cortisol

Plasma concentrations of ACTH and cortisol tend to be high in the morning and low in the evening. Peak ACTH levels are usually seen at 4:00 to 6:00 AM, and peak cortisol levels follow at about 8:00 AM ACTH and cortisol are released episodically in pulses every 30 to 120 minutes throughout the day, but the frequency and amplitude of these is much greater in the morning. The basis of this diurnal rhythm is complex and poorly understood. The hypothalamic content of CRF itself shows a diurnal rhythm with peak content at about 4:00 AM.

At least four factors appear to play a role in the rhythm of ACTH and cortisol: intrinsic rhythmicity of synthesis and secretion of CRF by the hypothalamus, light/dark cycles, feeding cycles, and inherent rhythmicity in the adrenal, possibly mediated by adrenal innervation.[171] These factors are clearly interdependent and related. Dietary rhythms may play as large a role as light/dark cycles.[172,173] Animal experiments show that altering the time of feeding can overcome the ACTH/cortisol periodicity established by a light/dark cycle. In normal human subjects, cortisol is released before lunch and supper. However, it is not release at these times in persons eating continuously during the day. Thus, glucocorticoids, which increase blood sugar, appear to be released at times of fasting and are inhibited by feeding.[174,175]

As all parents know, infants do not have a diurnal rhythm of sleep or feeding. Infants acquire such behavioral rhythms in response to their environment long before they acquire a rhythm of ACTH and cortisol. The diurnal rhythms of ACTH and cortisol begin to be established at 6 to 12 months and are often not well established until after 3 years of age.[176] Once the rhythm is well established in the older child or adult, it is changed only with difficulty. When people move to different parts of the world, their ACTH/cortisol rhythms generally take 15 to 20 days to adjust appropriately.

Physical stress (such as major surgery, severe trauma, blood loss, high fever, or serious illness) can increase the secretion of both ACTH and cortisol, but minor surgery and minor illnesses (such as upper respiratory infections) have little effect on ACTH and cortisol secretion.[177,178] Infection, fever, and pyrogens can stimulate the release of cytokines (such as IL-1 and IL-6), which stimulate secretion of CRH and stimulate IL-2 and TNF, which stimulate release of ACTH, providing further stimulus to cortisol secretion during inflammation.[179] Conversely, glucocorticoids inhibit cytokine production in the immune system, providing a negative feedback loop. Most psychoactive drugs, such as anticonvulsants, neurotransmitters, and antidepressants, do not affect the diurnal rhythm of ACTH and cortisol, although cyproheptidine, a serotonin antagonist, effectively suppresses ACTH release.

Adrenal: Glucocorticoid Feedback

The hypothalamic-pituitary-adrenal axis is a classic example of an endocrine feedback system. ACTH increases production of cortisol, and cortisol decreases production of ACTH.[157,180] Cortisol and other glucocorticoids exert feedback inhibition of CRF, ACTH, and AVP principally through the glucocorticoid receptor. Like the acute and chronic phases of the action of ACTH on the adrenal, there are acute and chronic phases of the feedback inhibition of ACTH and presumably CRF.[180]

The acute phase, which occurs within minutes, inhibits release of ACTH and CRF from secretory granules. With prolonged exposure, glucocorticoids inhibit ACTH synthesis by directly inhibiting the transcription of the gene for POMC and AVP. Some evidence also suggests that glucocorticoids can directly inhibit steroidogenesis at the level of the adrenal fasciculata cell itself, but this appears to be a physiologically minor component of the regulation of cortisol secretion.

MINERALOCORTICOID SECRETION: THE RENIN-ANGIOTENSIN SYSTEM

Renin is a serine protease enzyme synthesized primarily by the juxtaglomerular cells of the kidney, but it is also produced in a variety of other tissues, including the glomerulosa cells of the adrenal cortex.[181] The role of adrenally produced renin is not well established. It appears to maintain basal levels of P450c11AS, but it is not known if angiotensin II is involved in this action.[182] Renin is synthesized as a precursor of 406 amino acids that is cleaved to pro-renin, 386 amino acids, and finally to the 340-amino-acid protein found in plasma.[183] Decreased blood pressure, upright posture, sodium depletion, vasodilatory drugs, kallikrein, opiates, and β-adrenergic stimulation all promote release of renin.

Renin enzymatically attacks angiotensinogen, the renin substrate, in the circulation. Angiotensinogen is a highly glycosolated protein and therefore has a highly variable molecular weight, from 50,000 to 100,000 da. Renin proteolytically releases the amino-terminal 10 amino acids of angiotensinogen, referred to as angiotensin I. This decapeptide is biologically inactive until converting enzyme, an enzyme found primarily in the lungs and blood vessels, cleaves off its two carboxy-terminal amino acids to produce an octapeptide termed *angiotensin II.* Angiotensin II binds to specific membrane receptors located in the zona glomerulosa of the adrenal cortex to stimulate aldosterone production. Angiotensin-converting enzyme can be inhibited by captopril and related agents. Alternatively, angiotensin II receptors may be blocked by pharmacologic agents such as irbesartan for the diagnosis and treatment of hyperreninemic hypertension.

Angiotensin II has two principal actions, both of which increase blood pressure. It directly stimulates arteriolar vasoconstriction within a few seconds and it stimulates synthesis and secretion of aldosterone within minutes.[184] Increased plasma potassium is also a powerful and direct stimulator of aldosterone synthesis and release.[185,186] Aldosterone, secreted by the glomerulosa cells of the adrenal cortex, has the greatest mineralocorticoid activity of all naturally occurring steroids. Aldosterone causes renal sodium retention and potassium loss, with a consequent increase in intravascular volume and blood pressure.

Expansion of the blood volume provides the negative feedback signal for regulation of renin and aldosterone secretion. Angiotensin II functions through receptors that stimulate production of phosphatidylinositol, mobilize intracellular and extracellular Ca^{++}, and activate PKC.[187] These intracellular second messengers then stimulate transcription of the P450scc gene by means independent of those employed by ACTH and cAMP.[188] Potassium ion increases uptake of Ca^{++}, with consequent hydrolysis of phosphoinositides to increase phosphotidylinositol. Thus, angiotensin II and potassium work at different levels of the same intracellular second-messenger pathway. However, these differ fundamentally from the action of ACTH.

Although the renin-angiotensin system is clearly the major regulator of mineralocorticoid secretion, ACTH and possibly other POMC-derived peptides such as γ_3-MSH can also promote secretion of aldosterone when used in high concentrations in animal systems.[189,190] Relevance of physiological concentrations in human beings has not been established. Ammonium ion, hyponatremia, dopamine antagonists, and some other agents can also stimulate secretion of aldosterone, and atrial natriuretic factor is a potent physiologic inhibitor of aldosterone secretion.[191]

ADRENAL ANDROGEN SECRETION AND THE REGULATION OF ADRENARCHE

DHEA, DHEAS, and androstenedione which are almost exclusively secreted by the adrenal zona reticularis are generally referred to as adrenal androgens because they can be peripherally converted to testosterone. However, these steroids have little if any capacity to bind to and activate androgen receptors and are hence only androgen precursors and not true androgens. The fetal adrenal secretes large amounts of DHEA and DHEAS, and these steroids are abundant in the newborn. However, their concentrations fall rapidly as the fetal zone of the adrenal involutes following birth. After the first year of life, the adrenals of young children secrete very small amounts of DHEA, DHEAS, and androstenedione until the onset of adrenarche, usually about age 7-8, preceding the onset of puberty by about 2 years.

Adrenarche is independent of puberty, the gonads, or gonadotropins, and the mechanism by which the onset of adrenarche is triggered remains unknown.[62] The secretion of DHEA and DHEAS continue to increase during and after puberty and reach maximal values in young adulthood, following which there is a slow and gradual decrease in the secretion ("adrenopause") of these steroids in the elderly (Figure 12-7).[192]

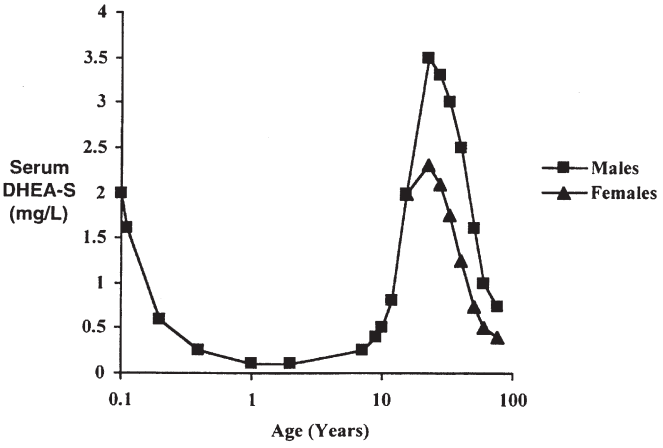

Figure 12-7 Concentrations of DHEAS as a function of age. Note that the X axis is on a log scale.

Throughout much of adult life, adrenal secretion of DHEAS exceeds that of cortisol. In adult women, adrenal secretion of androgen precursors and androgens is equal to their secretion from the ovary. Despite the huge increases in the adrenal secretion of DHEA and DHEAS during adrenarche, circulating concentrations of ACTH and cortisol do not change with age. Thus, ACTH plays a permissive role in adrenarche but does not trigger it. Searches for hypothetical polypeptide hormones that might specifically stimulate the zona reticularis have been unsuccessful.[193,194] Adrenarche is a unique phenomenon confined to a few higher primates such as chimpanzees and orangutans, but the significance of adrenarche remains unknown.[195]

Recent studies of adrenarche have focused on the roles of 3βHSD and P450c17. The abundance of 3βHSD protein in the zona reticularis appears to decrease with the onset of adrenarche,[196-198] and the adrenal expression of cytochrome b_5 (which fosters the 17,20 lyase activity of P450c17) is almost exclusively confined to the zona reticularis.[199,200] Both of these factors would strongly favor the production of DHEA.[201] The phosphorylation of P450c17 also increases 17,20 lyase activity,[73-75] but the kinase has not been identified and hence its role in adrenarche remains uncertain.

Premature and exaggerated adrenarche may be associated with insulin resistance, and girls with premature exaggerated adrenarche appear to be at much higher risk of developing the polycystic ovary syndrome as adults, characterized by hyperandrogenism, fewer ovulatory cycles, insulin resistance, and hypertriglyceridemia.[202-204] Recent evidence suggests that infants born small for gestational age may be at increased risk for this syndrome.[205] Some evidence is accumulating to suggest that replacing the DHEA lost during adrenopause may improve memory and a sense of well-being in the elderly,[206] but this remains controversial.[207] Thus, studies of physiology, biochemistry, and clinical correlates of adrenarche are pointing to premature adrenarche as an early sign of a metabolic disorder.

Plasma Steroids and Their Disposal

STRUCTURE AND NOMENCLATURE

All steroid hormones are derivatives of pregnenolone, whose structure is shown in Figure 12-8. Pregnenolone and its derivatives, which contain 21 carbon atoms, are often termed *C21 steroids*. Each carbon atom is numbered, indicating the location at which the various steroidogenic reactions occur (e.g., 21-hydroxylation, 11-hydroxylation). The 17,20 lyase activity of P450c17 cleaves the bond between carbon atoms 17 and 20, yielding C19 steroids, which include all the androgens. P450aro converts C19 androgens to C18 estrogens. With the exception of estrogens, all steroid hormones have a single unsaturated carbon-carbon double bond. Steroids having this double bond between carbon atoms 4 and 5, including all principal biologically active steroids, are termed *Δ^4 steroids*. Their precursors (having a double bond between carbon atoms 5 and 6) are termed *Δ^5 steroids*. The two isozymes of 3βHSD convert Δ^5 to Δ^4 steroids.

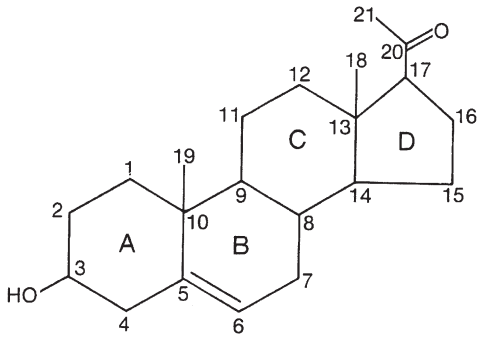

Figure 12-8 Structure of pregnenolone. The carbon atoms are indicated by numbers and the rings are designated by letters according to standard convention. Pregnenolone is derived from cholesterol, which has a 6-carbon side chain attached to carbon 21. Pregnenolone is a "Δ^5 compound" having a double bond between carbons 5 and 6. The action of 3β-hydroxysteroid dehydrogenase/isomerase moves this double bond from the B ring to carbons 4 and 5 in the A ring, forming Δ^4 compounds. All of the major biologically active steroid hormones are Δ^4 compounds.

A rigorous logically systematic and unambiguous chemical terminology has been formulated to describe accurately the structure of all steroid hormones and their conceivable derivatives. However, this terminology is unbelievably cumbersome (e.g., cortisol is 11β,17α,21-trihydroxy-pregn-4-ene-3,20-dione, and dexamethasone is 9α-fluoro-11β,17α,21-trihydroxyprena-1,4-diene-3,20-dione). Therefore, we use only the standard "trivial names." Before the structures of the steroid hormones were determined in the 1930s, Reichstein, Kendall, and others identified them as spots on paper chromatograms and designated them A, B, C, and so on. Unfortunately, some persist in using this outmoded terminology more than 60 years later. Thus, corticosterone is sometimes termed *compound B,* cortisol *compound F,* and 11-deoxycortisol *compound S.* This archaic terminology obfuscates the precursor-product relationships of the steroids and confuses students, and should be discarded.

CIRCULATING STEROIDS

Although more than 50 different steroids have been isolated from adrenocortical tissue, the main pathways of adrenal steroidogenesis include only a dozen or so steroids, of which only a few are secreted in sizable quantities. The adult secretion of DHEA and cortisol are each about 20 mg/24 hr, and the secretion of corticosterone, a weak glucocorticoid, is about 2 mg/24 hr.[208] Although glucocorticoids, such as cortisol, and mineralocorticoids, such as aldosterone, are both needed for life and hence are of equivalent physiologic importance, diagrams such as Figure 12-3 fail to indicate that these steroids are not secreted in molar equivalents.

The adult secretion rate of aldosterone is only about 0.1 mg/24 hr. This 100- to 1,000-fold molar difference in the secretory rates of cortisol and aldosterone must be borne in mind when considering the effects of steroid-binding proteins in plasma and when conceptualizing

the physiologic manifestations of incomplete defects in steroidogenesis due to single amino acid changes causing the partial loss of activity of a steroidogenic enzyme.

Most circulating steroids are bound to plasma proteins, including corticosteroid-binding globulin (CBG, also termed *transcortin*), albumin, and α_1 acid glycoprotein.[209,210] CBG has a very high affinity for cortisol but a relatively low binding capacity. Albumin has a low affinity and high capacity, and α_1 acid glycoprotein is intermediate for both variables. The result is that about 90% of circulating cortisol is bound to CBG and a little more is bound to other proteins. These steroid-binding proteins are not transport proteins because the biologically important steroids are water soluble in physiologically effective concentrations and because absence of CBG does not cause a detectable physiological disorder. However, these plasma proteins do act as a reservoir for steroids.

This ensures that all peripheral tissues will be bathed in approximately equal concentrations of cortisol, which greatly diminishes the physiologic effect of the great diurnal variation in cortisol secretion. Most synthetic glucocorticoids used in therapy do not bind significantly to CBG and bind poorly to albumin, partially accounting for their increased potencies, which are also associated with increased receptor-binding affinities. Aldosterone is not bound well by any plasma protein. Hence, changes in plasma protein concentration do not affect plasma aldosterone concentrations but greatly influence plasma cortisol concentrations. Estradiol and testosterone bind strongly to a different plasma protein, termed *sex-steroid-binding globulin,* and bind weakly to albumin.

Because steroids are hormones, it is often thought that the concentration of "free" (i.e., unbound) circulating steroids determines biologic activity. However, the target tissues for many steroid hormones contain enzymes that modify those steroids. Thus, many actions of testosterone are actually due to dihydrotestosterone produced by local 5α-reductase. Cortisol will have differential actions on various tissues due to the presence or absence of the two isozymes of 11βHSD, which can inactivate cortisol to cortisone or reactivate cortisone back to cortisol. Similar peripheral metabolism occurs via "extraglandular" 21-hydroxylase, P450aro, 3βHSD, and 17βHSD. Thus, circulating steroids are both classic hormones and precursors of locally acting autocrine or paracrine factors.

STEROID CATABOLISM

Only about 1% of circulating plasma cortisol and aldosterone are excreted unchanged in the urine. The remainder is metabolized by the liver. A large number of hepatic metabolites of each steroid are produced. Most contain additional hydroxyl groups and are linked to a sulfate or glucuronide moiety, rendering them more soluble and readily excretable by the kidney. A great deal is known about the various urinary metabolites of the circulating steroids because their measurement in pooled 24-hour urine samples has been an important means of studying adrenal steroids. Although the measurement of urinary steroid metabolites by modern mass spectrometric techniques remains an important research tool,[211-213] the development of separation techniques and of specific and highly sensitive radioimmunassays for each of the plasma steroids has greatly reduced the need to measure their excreted metabolites in clinical practice.

Clinical and Laboratory Evaluation of Adrenal Function

CLINICAL EVALUATION

Astute clinical evaluation can generally reveal the presence of primary adrenal deficiency or hypersecretion before performing laboratory tests. Thomas Addison described adrenal insufficiency in 1849, long before immunoassays became available. Virtually all patients with chronic adrenal insufficiency will have weakness, fatigue, anorexia, weight loss, hypotension, and hyperpigmentation. Patients with acute adrenal insufficiency may have hypotension, shock, weakness, apathy, confusion, anorexia, nausea, vomiting, dehydration, abdominal or flank pain, hyperthermia, and/or hypoglycemia.

Deficient adrenal androgen secretion will compromise the acquisition of virilizing secondary sexual characteristics, pubic and axillary hair, acne, axillary odor, in female adolescents. Early signs of glucocorticoid excess include increased appetite, weight gain, and growth arrest without a concomitant delay in bone age. Chronic glucocorticoid excess in children results in typical Cushingoid facies, but the "buffalo hump" and centripetal distribution of body fat characteristic of adult Cushing disease are seen only in long-standing undiagnosed disease. Mineralocorticoid excess is mainly characterized by hypertension, but patients receiving very low sodium diets (e.g., the newborn) will not be hypertensive because mineralocorticoids increase blood pressure primarily by retaining sodium and thus increasing intravascular volume.

Moderate hypersecretion of adrenal androgens is characterized by mild signs of virilization, whereas substantial hypersecretion of adrenal androgens is characterized by accelerated growth with a disproportionate increase in bone age, increased muscle mass, acne, hirsutism, deepening of the voice, and more profound degrees of virilism. A key feature of any physical examination of a virilized male is careful examination and measurement of the testes. Bilaterally enlarged testes suggest true (central) precocious puberty. Unilateral testicular enlargement suggests testicular tumor. Prepubertal testes in a virilized male indicate an extratesticular source of androgen, such as the adrenal.

Imaging studies are of limited utility in adrenal cortical disease. Computed tomography (CT) will only rarely detect pituitary tumors hypersecreting ACTH, and magnetic resonance imaging (MRI) will detect less than half of these, even with gadolinium enhancement. The small size, odd shape, and location near other structures also compromise the use of imaging techniques for the adrenals. Patients with Cushing disease or congenital adrenal hyperplasia will have modestly enlarged adrenals, but such enlargement is not detectable by imaging techniques with any useful degree of certainty. The gross enlargement

of the adrenals in congenital lipoid adrenal hyperplasia, their hypoplasia in adrenal hypoplasia congenita or in the hereditary ACTH unresponsiveness syndrome, and many malignant tumors can be usefully diagnosed by imaging studies. However, many adrenal adenomas are too small to be detected. Thus, imaging studies may establish the presence of pituitary or adrenal tumors but they can never establish their absence.

LABORATORY EVALUATION

The diagnostic evaluation of adrenal function is essentially chemical. The nonspecificity of many of the clinical signs described previously and the disappointing results with imaging studies remind us that any proper evaluation of hypothalamic-pituitary-adrenal function must rely on a series of carefully performed physiologic maneuvers associated with hormonal assays. In the past, these tests relied principally on the physiologic effects of adrenal hormones such as the effects of cortisol on glucose metabolism as seen during a glucose tolerance test. However, the development of highly specific and exquisitely sensitive immunoassays that can be done on small volumes of plasma now permits the direct examination of virtually every hormone involved in adrenal metabolism.

Plasma Concentrations of Cortisol and Other Steroids

Plasma cortisol is measured routinely by a variety of techniques, including radioimmunoassay, immunoradiometric assay, and high-pressure liquid chromatography (HPLC). Other procedures, such as fluorimetric assays and competitive protein binding assays, are useful research tools but are not in general clinical use. It is of considerable importance to know what procedure one's laboratory is employing and precisely what it is measuring. All immunoassays have some degree of cross-reactivity with other steroids. Most cortisol immunoassays will detect cortisol and cortisone. By contrast, these are readily distinguished by HPLC.

Because the newborn's plasma contains mainly cortisone rather than cortisol during the first few days of life, comparison of newborn data obtained by HPLC to published standards obtained by immunoassays may incorrectly suggest adrenal insufficiency. Tables 12-1 and 12-3 summarize the normal plasma concentrations for a variety of steroids. With the notable exception of dehydroepiandrosterone sulfate, most adrenal steroids exhibit a diurnal variation based on the diurnal rhythm of ACTH. Because the stress of illness or hospitalization can increase adrenal steroid secretion and because diurnal

DOC = deoxycorticosterone.

All values in nmol/L except plasma renin activity (μg/L/s). To convert cortisol to μg/dL, multiply by 0.0363. To convert other values to ng/dL, multiply nmol/L times the following values: corticosterone, 34.7; 18OH corticosterone, 36.2; aldosterone, 36.0; DOC, 33.1.

[a] Two values separated by an arrow indicate those in supine and upright posture.

rhythms may not be well established in children under 3 years of age, it is best to obtain two or more samples for the measurement of any steroid.[214,215]

As shown in Tables 12-2 and 12-3, data exist for the concentrations of a large number of steroid hormones throughout normal infancy, childhood, and adolescence. Not all endocrine laboratories perform all of these assays, and depending on the assay procedures employed various laboratories may have different "normal" values. Most central hospital and commercial laboratories are designed primarily to serve adult, rather than pediatric, patients. Thus, it is important to know whether the available assays will be sufficiently sensitive with small volumes of blood to be useful in measuring pediatric values. This is especially true for the measurement of sex steroids (and gonadotropins), which can exhibit pathologic elevations in children and still remain below the limit of detection of most "adult" assays.

Plasma Renin

Renin is not generally measured directly but is assayed by its enzymatic activity. Plasma renin activity (PRA) is simply an immunoassay of the amount of angiotensin I generated per milliliter of serum per hour at 37° C. In normal serum, the concentration of both renin and angiotensinogen (the renin substrate) are limiting. Therefore, another test [plasma renin content (PRC)] measures the amount of angiotensin I generated in 1 hour at 37° C in the presence of excess concentrations of angiotensinogen. Immunoassays for renin itself have been developed but are not yet widely used.

Plasma renin activity is sensitive to dietary sodium intake, posture, diuretic therapy, activity, and sex steroids. Because PRA values can vary widely with these variables, it is best to measure renin twice: once in the morning after overnight supine posture and then again after maintenance of upright posture for 4 hours.[216] A simultaneous 24-hour urine for total sodium excretion is generally needed to interpret PRA results. Decreased dietary and urinary sodium, decreased intravascular volume, diuretics, and estrogens will increase PRA. Sodium loading, hyperaldosteronemia, and increased intravascular volume decrease PRA.

The greatest use of renin measurements is in the evaluation of hypertension and in the management of CAH. However, several additional situations require assessment of the renin-angiotensin system. Children with simple virilizing adrenal hyperplasia who do not have clinical evidence of urinary salt wasting (hyponatremia, hyperkalemia, acidosis, hypotension, shock) may nevertheless have increased PRA, especially when dietary sodium is restricted. This was an early clinical sign that this form of 21-hydroxylase deficiency was simply a milder form of the more common (severe) salt-wasting form.

Treatment of simple virilizing 21-hydroxylase deficiency with sufficient mineralocorticoid to suppress PRA into the normal range will reduce the child's requirement for glucocorticoids, thus maximizing final adult height. Children with CAH need to have their mineralocorticoid replacement therapy monitored routinely by measuring PRA. Measurement of angiotensin II is also possible in some research laboratories, but most antibodies to angiotensin II strongly cross-react with angiotensin I. Thus, PRA remains the most useful way of evaluating the renin-angiotensin-aldosterone system.

Urinary Steroid Excretion

The measurement of 24-hour urinary excretion of steroid metabolites is one of the oldest procedures for assessing adrenal function and is still useful. Examination of the total 24-hour excretion of steroids eliminates the fluctuations seen in serum samples as a function of time of day, episodic bursts of ACTH and steroid secretion, and transient stress (such as a visit to the clinic or difficult venepuncture). Collection of a complete 24-hour urinary sample can be quite difficult in the infant or small child. Two consecutive 24-hour collections should be obtained, and each should be assayed for creatinine to monitor the

completeness of the collection. Because of the diurnal and episodic nature of steroid secretion, one should never obtain 8- or 12-hour collections and attempt to infer the 24-hour excretory rate from such partial collections.

The analytic procedures for urinary steroid analysis typically rely on a chromatographic procedure for separating steroids followed by a colorimetric, immunologic, or other assay. Failure to employ a chromatographic separation step is the most common source of error. Such classic analyses of urinary steroids are now being replaced by gas chromatography followed by mass spectrometry (GC/MS). Recent advances in these techniques permit very sensitive and specific assays of urinary steroids. However, each secreted steroid is metabolized to multiple forms before being excreted in urine, and this metabolism can vary with age and sex in pediatric populations. The analyses are complex and require specialized expertise that is not yet widely available. Thus, analysis of urinary steroids by GC/MS is typically employed only in research settings.

Urinary 17-hydroxycorticosteroids (17OHCS), assayed by the colorimetric Porter-Silber reaction, measure 17, 21-dihydroxy-20-ketosteroids by the generation of a colored compound after treatment with phenylhydrazine.[217] The reaction is highly specific for the major urinary metabolites of cortisol and cortisone. It will also measure metabolites of 11-deoxycortisol, which will be increased in 11-hydroxylase deficiency or after treatment with metyrapone, a commonly used diagnostic agent (see material following).

Urinary 17OHCS secretion is increased in obesity, hyperthyroidism, and anorexia nervosa. It is decreased in starvation, hypothyroidism, renal failure, liver disease, and pregnancy. Drugs that induce hepatic enzymes, such as phenobarbital, can give low urinary 17OHCS values by stimulating hepatic metabolism of circulating steroids to excreted compounds not detected by the Porter-Silber reaction. Other drugs (including phenothiazines, spironolactone, hydroxyzine, and some antibiotics) can interfere with the colorimetric assay directly, giving falsely elevated values.

Measurement of 17OHCS should be replaced by measurement of urinary free cortisol, thus avoiding the nonspecificity and drug interference problems inherent in 17OHCS. In adults, this test is highly reliable in the diagnosis of Cushing syndrome. Free cortisol is extracted from the urine and measured by immunoassay or HPLC, providing the advantage of specificity. Excretion of urinary free cortisol and of total cortisol metabolites (typically 11 ± 5 $\mu g/m^2$/day) is closely correlated with age, body surface area, and adiposity.[218,219] Values vary substantially among different reference laboratories, reflecting variations in assay technologies. Thus, it is essential to utilize a laboratory with good data for normal children. It remains important to measure urinary creatinine to monitor the completeness of the collection. Some clinical experience indicates that urinary 17OHCS may be more reliable for the diagnosis of Cushing disease in children, possibly due to greater experience with 17OHCS.[220]

Urinary 17-ketosteroids (17KS), assayed by the Zimmerman reaction, measure 17-ketosteroids by the generation of a colored compound after treatment with meta-dinitrobenzine and acid.[221] The reaction principally measures metabolites of DHEA and DHEA sulfate and thus correlates with adrenal androgen production. Androstenedione will contribute significant 17KS, and if an alkali extraction is not used estrone will also contribute. The principal androgens, testosterone and dihydrotestosterone, have hydroxyl rather than keto groups on carbon 17. Hence, their metabolic products are not measured as 17KS. A wide variety of drugs (including penicillin, nalidixic acid, spironolactone, and phenothiazines, as well as nonspecific urinary chromagens) can spuriously increase values of 17KS. Measurement of urinary 17KS remains a useful inexpensive screening test, and some clinicians prefer to follow 17KS to monitor therapy of CAH. However, measurements of plasma steroids have now replaced the use of urinary 17KS in most centers.

Urinary 17-ketogenic steroids (17KGS) are occasionally confused with urinary 17-ketosteroids because of the similarity of the names. However, 17KGS are used to measure urinary metabolites of glucocorticoids (not sex steroids). Urinary 17KGS are assayed by oxidation of a variety of C-21 steroids to C-19 17-ketosteroids, which are then measured by the Zimmerman reaction as 17KS. All 17OHCS plus a number of other urinary steroids (including the 17KS) are measured, but the basal 17KS values are subtracted. In addition to all of the problems of specificity and drug interference previously described for 17OHCS and 17KS, a major disadvantage of 17KGS is that they will also detect pregnanetriol (the principal urinary metabolite of 17-hydroxyprogesterone). This is the steroid that shows the greatest elevations in congenital adrenal hyperplasia. Although some laboratories continue to perform measurements of 17KGS, this obsolete assay no longer has a place in modern pediatric practice.

Plasma ACTH and Other POMC Peptides

Accurate routine immunoassay of plasma ACTH is now available in most centers, but its measurement remains more difficult and variable than the assays for most other pituitary hormones.[222] Handling of the samples must be done with care. Samples must be drawn into a plastic syringe containing heparin or ethylenediaminetetraacetic acid (EDTA) and quickly transported in plastic tubes on ice because ACTH adheres to glass and is quickly inactivated.

Thus, elevated plasma ACTH concentrations can be highly informative, but most assays cannot detect low or low-normal values and such values can be spurious if the samples are handled badly. In adults and older children who have well-established diurnal rhythms of ACTH, normal 8:00 AM values rarely exceed 50 pg/mL—whereas 8:00 PM values are usually undetectable. Patients with Cushing disease often have normal morning values, but the diagnosis can be suggested by consistently elevated afternoon and evening values. Patients with the ectopic ACTH syndrome can have values anywhere from 100 to 1,000 pg/mL.

The carboxy portion of POMC, termed *β-LPH* (POMC 153-241), is released from POMC in equimolar amounts with ACTH. β-LPH has a longer circulating plasma half-life than ACTH, is more stable in the laboratory, and is

easier to assay than ACTH.[223] Investigational use of such assays indicates that they may be a useful adjunct to ACTH assays, but routine measurement of β-LPH is not available.

Secretory Rates

The secretory rates of cortisol and aldosterone (or other steroids) can be measured by administering a small dose of tritiated cortisol or aldosterone and measuring the specific activity of one or more known metabolites in a 24-hour urine collection. This procedure permitted measurement of certain steroids, such as aldosterone, before specific immunoassays became available. These procedures have also provided much information about the normal rate of production of various steroids. Based on this procedure, most authorities have agreed that children and adults secrete about 12 mg of cortisol per square meter of body surface area per day. However, more recent studies indicate a rate of 6 to 9 mg/m^2 in children and adults.[224,225] Such differences are of considerable importance in estimating "physiologic replacement" doses of glucocorticoids.

Dexamethasone Suppression Test

Administration of dexamethasone, a potent synthetic glucocorticoid, will suppress secretion of pituitary ACTH and of adrenal cortisol. Originally described by Liddle in 1960,[226] the dexamethasone suppression test remains the most useful procedure for distinguishing whether glucocorticoid excess is due primarily to pituitary disease or adrenal disease. As dexamethasone also suppresses adrenal androgen secretion, this test is useful for distinguishing between adrenal and gonadal sources of sex steroids.

A complete formal dexamethasone suppression test requires the measurement of basal values and those obtained in response to low- and high-dose dexamethasone. This is described in the section on the evaluation of Cushing syndrome. Variations of this test are commonly used, notably the single-dose 1.0-mg in adults[227] or 0.3 mg/m^2 in children.[228] This is a useful outpatient screening procedure for distinguishing Cushing syndrome from exogenous obesity. It can be useful for the same purpose in adolescents and older children, but is otherwise of limited utility in pediatrics. An overnight high-dose dexamethasone suppression test is probably more reliable than the standard 2-day high-dose test in differentiating adults with Cushing disease from those with the ectopic ACTH syndrome. However, the utility of this test in pediatric patients has not been established.

Stimulation Tests

Direct stimulation of the adrenal with ACTH is a rapid, safe, and easy way to evaluate adrenocortical function. The original ACTH test consisted of a 4- to 6-hour infusion of 0.5 U/kg of ACTH(1-39). This will maximally stimulate adrenal cortisol secretion, and thus effectively distinguish primary adrenal insufficiency Addison disease, in which the adrenal is incapable of responding, from secondary adrenal insufficiency due to hypopituitarism. In secondary adrenal insufficiency, some steroidogenic capacity is present. Therefore, some cortisol is produced in response to the ACTH. Thus, cortisol secretion is less than normal but greater than the negligible values seen in primary adrenal insufficiency.

The 4- to 6-hour intravenous ACTH test has been replaced in clinical practice by the 60-minute test, wherein a single bolus of ACTH(1-24) is administered intravenously and cortisol and possibly other steroids are measured at 0 and 60 minutes.[229] Normal responses to a 60-minute test are shown in Table 12-4.[230] Synthetic ACTH(1-24) (cosyntropin) is preferred, as it has a more rapid action and shorter half-life than ACTH(1-39). The usual dose is 15 μg/kg in children up to 2 years of age and 0.25 mg for adults and for children older than 2 years. All of these doses are pharmacologic. A very-low-dose (1 μg) test may be useful in assessing adrenal recovery from glucocorticoid suppression.[231]

Newer data show that maximal steroidal responses can be achieved after only 30 minutes, but the best available standards are for a 60-minute test. One of the widest uses of intravenous ACTH tests in pediatrics is in diagnosing congenital adrenal hyperplasia (CAH). Stimulating the adrenal with ACTH increases steroidogenesis, resulting in

TABLE 12-4

Responses of Adrenal Steroids to a 60-Minute ACTH Test

	Infants		Prepubertal		Pubertal	
	Basal	Stimulated	Basal	Stimulated	Basal	Stimulated
17OH-pregnenolone	6.8		1.7	9.6	3.6	24

accumulation of steroids proximal to the disordered enzyme. For example, inspection of Figure 12-3 shows that impaired activity of P450c21 (21-hydroxylase) should lead to the accumulation of progesterone and 17-hydroxyprogesterone (17OHP). However, progesterone does not accumulate in appreciable quantities because it too is converted to 17OHP.

In routine practice, measuring the response of 17OHP to a 60-minute challenge with intravenous ACTH is the single most powerful and reliable means of diagnosing 21-hydroxylase deficiency. Genetic testing can provide a useful confirmation. Comparing the patient's basal to ACTH-stimulated values of 17OHP against those from large numbers of well-studied patients usually permits the discrimination of normal persons, heterozygotes, patients with nonclassic CAH, and patients with classical CAH, although inevitably there is some overlap between groups[232] (Figure 12-9). Measurement of testosterone or Δ^4 androstenedione in response to ACTH can distinguish normal persons from patients with classical CAH, but heterozygotes and patients with cryptic CAH have values overlapping both normals and classic CAH (Figure 12-9).

Longer ACTH tests of up to 3 days have also been employed to evaluate adrenal function. It is important to remember that ACTH has both acute and chronic effects. Thus, short tests measure only the acute effects of ACTH; that is, the maximal stimulation of preexisting steroidogenic machinery. By contrast, a 3-day test will examine the more chronic effects of ACTH to stimulate increased capacity for steroidogenesis by increasing the synthesis of steroidogenic machinery. Few situations exist for which a 3-day intramuscular ACTH test is indicated, although it is useful in diagnosing the rare syndromes of hereditary unresponsiveness to ACTH.[233]

Insulin-induced hypoglycemia is another commonly used test. Insulin (0.1 U/kg/IV) is administered and blood is obtained at 0, 30, 45, and 60 minutes. The insulin-induced hypoglycemia will stimulate the release of counterregulatory hormones that have actions to increase plasma glucose concentrations: ACTH and cortisol, growth hormone (GH), epinephrine, and glucagon. Because of the inherent risk of convulsions as a result of hypoglycemia, an experienced physician must be in attendance, not merely "available", throughout the entire course of the test. Blood glucose must fall to half the initial value or to 45 mg/dL to achieve an adequate test, and it is wise to terminate the test if values of 30 mg/dL are reached. Most patients will experience hunger, irritability, diaphoresis, and tachycardia. When these are followed by drowsiness or sleep, blood sugar levels are likely below acceptable limits. If this occurs, a blood sample should be obtained and 2 mL/kg of 20% to 25% glucose given intravenously (to a maximum of 100 mL).[234]

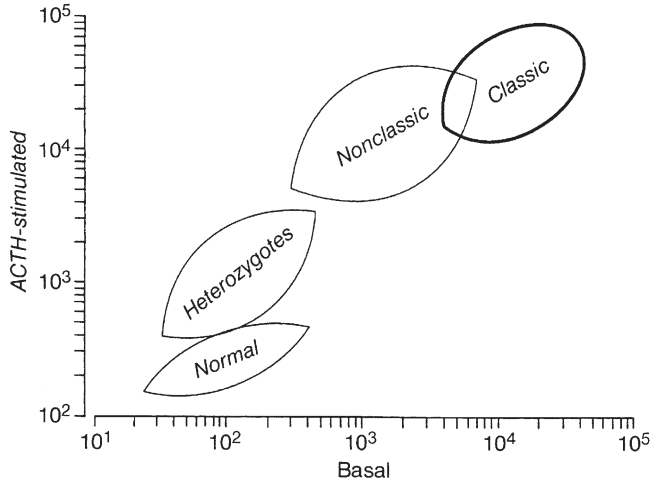

Figure 12-9 17OHP values (in ng/100 mL) before and after stimulation with ACTH in normals, patients with CAH, and heterozygotes.

Metyrapone Test

Metyrapone blocks the action of P450c11β, and to a much lesser extent of P450scc. It is thus a chemical means of inducing a transient deficiency of 11-hydroxylase activity, which results in decreased cortisol secretion and subsequent increase in ACTH secretion. Metyrapone testing is done to assess the capacity of the pituitary to produce ACTH in response to a physiologic stimulus. This test is useful in evaluating the hypothalamic-pituitary axis in the presence of central nervous system lesions after neurosurgery or long-term suppression by glucocorticoid therapy.[235] Patients with a previous history of hypothalamic, pituitary, or adrenal disease or those who have been withdrawn from glucocorticoid therapy should be reevaluated with a metyrapone test or with an insulin tolerance test. A normal response indicates recovery of the hypothalamic-pituitary-adrenal axis and predicts that the patient will respond normally to the stress of surgery.

Metyrapone is generally given orally as 300 mg/m^2 every 4 hours for a total of six doses 24 hours. Unlike many other drugs, it is appropriate to continue to increase the dose in older or overweight patients, but the total dose should not exceed 3.0 g.[236] Blood should be obtained for cortisol, 11-deoxycortisol, and ACTH before and after the test, and a 24-hour urine collection should be obtained for 17OHCS before and during the test. In a normal response to metyrapone, cortisol decreases, ACTH increases, and 11-deoxycortisol, the substrate for P450c11β, increases greatly to about 5 μg/dL. Metabolites of 11-deoxycortisol result in a doubling in urinary 17OHCS excretion. Adults and older children can be tested with the administration of a single oral dose of 30 mg/kg at midnight, given with food to reduce gastrointestinal irritation.[236] Blood samples are drawn at 8:00 AM the mornings before and after administering the drug.

CRF Testing

CRF is now generally available as a test of pituitary ACTH reserve.[237] At the present time, CRF testing remains experimental in adults, and little experience has accumulated in children. It is not yet clear what role CRF testing will assume, although early data suggest it may be useful for distinguishing hypothalamic from pituitary causes of ACTH deficiency and may be a useful adjunct in establishing the diagnosis of Cushing disease.[238]

Genetic Lesions in Steroidogenesis

Autosomal-recessive genetic disorders disrupt each of the steps in the pathway shown in Figure 12-3. Most of these result in diminished synthesis of cortisol. In response to adrenal insufficiency, the pituitary synthesizes increased amounts of POMC and ACTH, which promotes increased steroidogenesis. ACTH and possibly other peptides derived from the amino terminal end of POMC also stimulates adrenal hypertrophy and hyperplasia. Thus, the term *congenital adrenal hyperplasia* refers to a group of diseases traditionally grouped on the basis of the most prominent finding at autopsy.

In theory, the congenital adrenal hyperplasias are easy to understand. A genetic lesion in one of the steroidogenic enzymes interferes with normal steroidogenesis. The signs and symptoms of the disease derive from deficiency of the steroidal end product and the effects of accumulated steroidal precursors proximal to the blocked step. Thus, reference to the pathways in Figure 12-3 and knowledge of the biologic effects of each steroid should permit one to deduce the manifestations of the disease.

In practice, the congenital adrenal hyperplasias can be confusing both clinically and scientifically. The key clinical, laboratory, and therapeutic features of each form of CAH are summarized in Table 12-5. Because each steroidogenic enzyme has multiple activities and many extra-adrenal tissues contain enzymes that have similar activities, the complete elimination of a specific adrenal enzyme may not result in the complete elimination of its steroidal products from the circulation. In the past, disorders of steroidogenic enzymes had to be studied by examining their steroid metabolites in serum and urine, an indirect approach that led to numerous misconceptions about the steroidogenic processes. The cloning of the genes for the steroidogenic enzymes has now permitted the direct study of these diseases, permitting an accurate understanding of their disordered physiology.

CONGENITAL LIPOID ADRENAL HYPERPLASIA

Lipoid CAH is the most severe genetic disorder of steroid hormone synthesis. This disorder is characterized by the absence of significant concentrations of all steroids, high basal ACTH and plasma renin activity, an absent steroidal response to long-term treatment with high doses of ACTH or hCG, and grossly enlarged adrenals laden with cholesterol and cholesterol esters.[239-242] These findings indicate a lesion in the first step in steroidogenesis: the conversion of cholesterol to pregnenolone. It was initially thought that the lesion was in an enzyme involved in this conversion, and before the role of P450scc was understood lipoid CAH was misnamed 20,22-desmolase deficiency.[242-247]

However, the gene for P450scc is normal in these patients[247], as are the mRNAs for adrenodoxin reductase and adrenodoxin.[247] Furthermore, placental steroidogenesis persists in lipoid CAH, permitting normal term gestation, which would not happen if P450scc were involved.[248] The normal P450scc system plus the accumulation of cholesterol esters in the affected adrenal suggested that the lesion lay in an upstream factor involved in cholesterol transport into mitochondria. This factor was identified by cell biologic studies,[37-39] cloned and named StAR,[40] quickly found to be expressed in the adrenal and gonad but not in the placenta, and then identified as the disordered step in lipoid CAH.[41,42,249]

Lipoid CAH is a StAR gene knockout experiment of nature, revealing the complex physiology of the StAR protein.[250] StAR promotes steroidogenesis by increasing the movement of cholesterol into mitochondria, but in the absence of StAR steroidogenic cells make steroids at about 14% of the StAR-induced level.[41,42,161,249] This observation led to the two-hit model of lipoid CAH[42] (Figure 12-10). The first hit is the loss of StAR itself, leading to a loss of most but not all steroidogenesis, leading to a compensatory rise in ACTH and LH. These hormones increase cellular cAMP, which increases biosynthesis of LDL receptors, their consequent uptake of LDL cholesterol, and de novo synthesis of cholesterol. In the absence of StAR, this increased intracellular cholesterol accumulates as in a storage disease, causing the second hit, which is the mitochondrial and cellular damage caused by the accumulated cholesterol, cholesterol esters, and their autooxidation products.[42]

The two-hit model explains the unusual clinical findings in lipoid CAH. In the fetal testis, which normally makes large amounts of testosterone in fetal life,[251] the Leydig cells are destroyed early in gestation, eliminating testosterone biosynthesis. Hence, an affected 46,XY fetus does not undergo normal virilization and is born with female external genitalia and a blind vaginal pouch. However, Wolffian duct derivatives are well developed, indicating the presence of some testosterone synthesis early in fetal life,[252] as predicted by the two-hit model. The undamaged Sertoli cells produce Müllerian inhibitory hormone, and thus the phenotypically female 46,XY fetus has no cervix, uterus, or fallopian tubes.

The steroidogenically active fetal zone of the adrenal is similarly affected, eliminating most DHEA biosynthesis and hence eliminating the feto-placental production of estriol. Thus, mid-gestation maternal and fetal estriol levels are very low.[248] The definitive zone of the fetal adrenal, which differentiates into the zonae glomerulosa and fasciculata, normally produces very little aldosterone, and because fetal salt and water metabolism are maintained by the placenta stimulation of the glomerulosa by angiotensin II generally does not begin until birth. Consistent with this, many newborns with lipoid CAH do not have a salt-wasting crisis until after several weeks of life, when chronic stimulation then leads to cellular damage.[42,253]

The two-hit model also explains the spontaneous feminization of affected 46,XX females who are treated in infancy and reach adolescence.[254,255] The fetal ovary makes little or no steroids and contains no steroidogenic enzymes after the first trimester.[251] Consequently, the ovary remains largely undamaged until it is stimulated by gonadotropins at the time of puberty, when it then produces some estrogen by StAR-independent steroidogenesis. Continued stimulation results in cholesterol accumulation and cellular damage, and thus biosynthesis of progesterone in the latter part of the cycle is impaired.

TABLE 12-5

Clinical and Laboratory Findings in the Congenital Adrenal Hyperplasias

Enzyme Deficiency	Presentation	Laboratory Findings	Therapeutic Measures
Lipoid CAH (StAR or P450scc)	• Salt-wasting crisis • Male pseudohermaphroditism	• Low/absent levels of all steroid hormones • Decreased/absent response to ACTH • Decreased/absent response to hCG in male pseudohermaphroditism • ↑ ACTH and PRA	• Glucocorticoid and mineralocorticoid replacement, salt supplementation • Estrogen replacement at age ≧12 years • Gonadectomy of male pseudohermaphrodite
3β-HSD	• Salt-wasting crisis • Male and female pseudohermaphroditism	• ↑Δ^5 steroids before and after ACTH • ↑Δ^5/Δ^4 serum steroids • Suppression of elevated adrenal steroids after glucocorticoid administration • ↑ ACTH and PRA	• Glucocorticoid and mineralocorticoid replacement • Salt supplementation • Surgical correction of genitalia • Sex hormone replacement as necessary
P450c21	• Classic form: • Salt-wasting crisis • Female pseudohermaphroditism • Pre- and postnatal virilization • Nonclassic form: • Premature adrenarche, menstrual irregularity, hirsutism, acne, infertility	• ↑ 17OHP before and after ACTH • ↑ Serum androgens and urine 17KS • Suppression of elevated adrenal steroids after glucocorticoid Rx • ↑ ACTH and PRA	• Glucocorticoid and mineralocorticoid replacement • Salt supplementation • Surgical repair of female pseudohermaphroditism
P450c11β	• Female pseudohermaphroditism • Postnatal virilization in males and females	• ↑ 11-deoxycortisol and DOC before and after ACTH • ↑ Serum androgens and urine 17KS • Suppression of elevated steroids after glucocorticoid administration • ↑ ACTH and ↓ PRA • Hypokalemia	• Glucocorticoid administration • Surgical repair of female pseudohermaphroditism
P450c11AS	• Failure to thrive • Weakness • Salt loss	• Hyponatremia, hyperkalemia • ↑ Corticosterone • ↓ Aldosterone ↑ PRA	• Mineralocorticoid replacement • Salt supplementation
P450c17	• Male pseudohermaphroditism • Sexual infantilism • Hypertension	• ↑ DOC, 18-OHDOC, corticosterone, 18-hydroxycorticosterone • Low 17α-hydroxylated steroids and poor response to ACTH • Poor response to hCG in male pseudohermaphroditism • Suppression of elevated adrenal steroids after glucocorticoid administration • ↑ ACTH and ↓ PRA • Hypokalemia	• Glucocorticoid administration • Surgical correction of genitalia and sex steroid replacement in male pseudohermaphroditism consonent with sex of rearing • Estrogen replacement in female at ≧12 years • Testosterone replacement if reared as male (rare)
POR	• Male and female pseudohermaphroditism • Antley-Bixler syndrome • Infertility in adults	• ↑ ACTH, prog, 17OHP • ↓ DHEA, andro, T • Normal electrolytes	• Glucocorticoid and sex steroid replacement • Surgical correction of skeletal anomalies

ACTH, adrenocorticotropic hormone (corticotropin); DOC, deoxycorticosterone; hCG, human chorionic gonadotropin; PRA, plasma renin activity; 17OHP, 17-hydroxyprogesterone; 17KS, 7-ketosteroids; and 18-OHDOC, 18-hydroxydeoxycorticosterone.

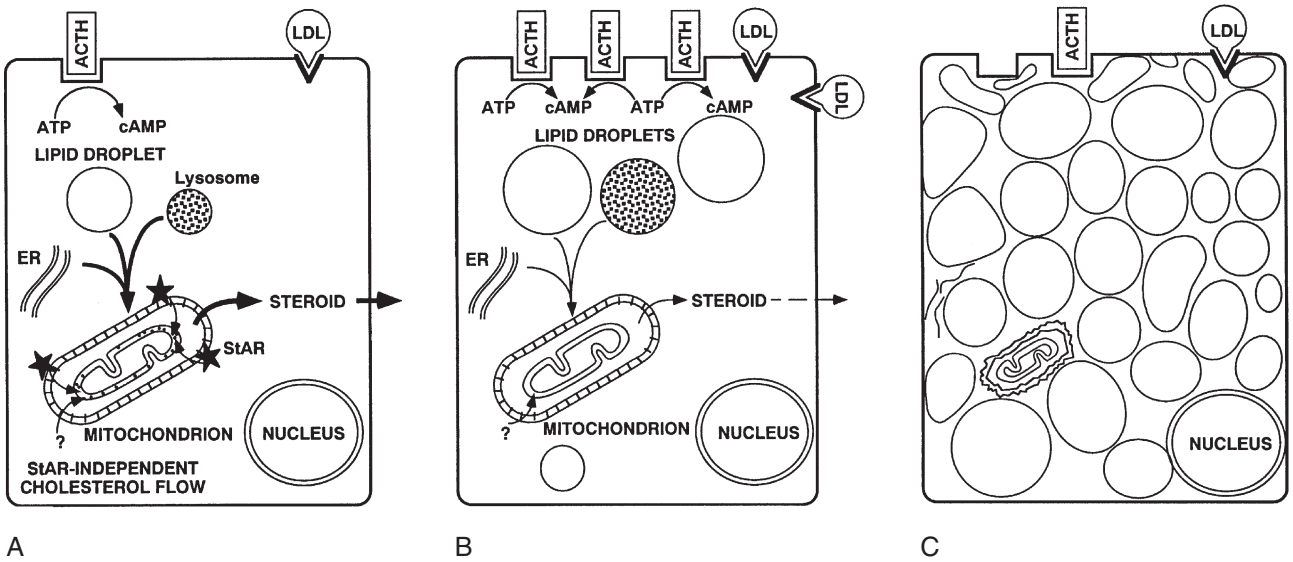

Figure 12-10 Two-hit model of lipoid CAH. (*A*) In a normal adrenal cell, cholesterol is primarily derived from LDL by receptor-mediated endocytosis and is processed in lysosomes before entering the cellular pool. However, cholesterol can also be synthesized de novo from acetyl CoA. Cholesterol from both sources is stored as cholesterol esters in lipid droplets. Cholesterol reaches the mitochondria by poorly defined processes, and then travels from the outer to inner mitochondrial membrane by both StAR-dependent and StAR-independent mechanisms. (*B*) In early lipoid CAH, the absence of StAR reduces cholesterol flow and steroidogenesis. However, some steroidogenesis persists via the StAR-independent pathway. The decreased secretion of cortisol leads to increased ACTH, which stimulates further cholesterol uptake and synthesis. This cholesterol accumulates in lipid droplets. (*C*) Accumulating lipid droplets damage the cell through physical disruption of cytoarchitecture and by the chemical action of auto-oxidation products, eventually destroying all steroidogenic capacity. In the ovary, follicular cells remain unstimulated and undamaged until they are recruited at the beginning of each cycle. They can then produce small amounts of estradiol, as in panel B, leading to feminization and anovulatory cycles in affected females.

Because gonadotropin stimulation only recruits individual follicles and does not promote steroidogenesis in the entire ovary, most follicles remain undamaged and available for future cycles. Cyclycity is determined by the hypothalamic-pituitary axis, and remains normal. With each new cycle, a new follicle is recruited and more estradiol is produced by StAR-independent steroidogenesis. Although net ovarian steroidogenesis is impaired, enough estrogen is produced, especially in the absence of androgens, to induce breast development, general feminization, monthly estrogen withdrawal, and cyclic vaginal bleeding.[42,254]

However, progesterone synthesis in the latter half of the cycle is disturbed by the accumulating cholesterol esters, with the result that the cycles are anovulatory. Measurements of estradiol, progesterone, and gonadotropins throughout the cycle in affected adult females with lipoid CAH confirms this model.[255] Similarly, examination of StAR-knockout mice confirms the two-hit model.[256] Thus, examination of patients with lipoid CAH has elucidated the physiology of the StAR protein in each steroidogenic tissue.

Genetic analysis of patients with lipoid CAH has revealed numerous mutations in the StAR gene.[42,257] Lipoid CAH is common in Japan, and about 65% to 70% of affected Japanese alleles and virtually all affected Korean alleles carry the mutation Q258X.[41,42,242,257-259] The carrier frequency for this mutation appears to be about 1 in 300,[42,258] and 1 in every 250,000 to 300,000 newborns in these countries is affected, for a total of about 500 patients in Japan and Korea. Other genetic clusters are found among Palestinian Arabs, most of whom carry the mutation R182L[42], in eastern Saudi Arabia carrying R188C[253] and in Switzerland carrying the mutation L260P.[260]

Deletion of only 10 carboxy-terminal residues reduces StAR activity by half,[261] and deletion of 28 carboxy-terminal residues by the common Q258X mutation eliminates all activity. By contrast, deletion of the first 62 amino terminal residues has no effect on StAR activity even though this deletes the entire mitochondrial leader sequence and forces StAR to remain in the cytoplasm.[261] Physical studies and partial proteolysis indicate that residues 63-193 of StAR (i.e., the domain that lacks most of the crucial residues identified by missense mutations) are protease resistant and constitute a "pause-transfer" sequence that permits the bioactive loosely folded carboxy-terminal molten globule domain to have increased interaction with the outer mitochondrial membrane.[49]

The clinical findings in most patients with lipoid CAH are quite similar. An infant with normal-appearing female genitalia experiences failure to thrive and salt loss in the first weeks of life.[42,242,257] However, more recent studies have revealed other clinical presentations, including apparent sudden infant death syndrome (SIDS)[262] and late initial presentation of salt loss at about 1 year of age.[253] An attenuated disease caused by mutations that retain about 20% to 25% of normal StAR activity has been described recently and is called nonclassic lipoid CAH.[263] These children initially experienced symptoms of adrenal insufficiency at 2 to 4 years of age, and two 46,XY patients had normal-appearing male external genitalia.

Thus, the spectrum of clinical presentation of congenital lipoid adrenal hyperplasia is substantially broader than initially appreciated.

Mutations in several other genes can produce a clinical phenotype that is essentially indistinguishable from that caused by StAR mutations, but these disorders should not be called congenital lipoid adrenal hyperplasia. Several patients have now been described with mutations in P450scc.[264-267] It would seem logical that elimination of all P450scc activity would be incompatible with term gestation because the placenta, a fetal tissue, must produce progesterone in the second half of pregnancy to suppress maternal uterine contractions and thus prevent miscarriage.[268]

It is most likely that these few fetuses with P450scc mutations reached term gestation because of unusually protracted maintenance of the maternal corpus luteum of pregnancy, which normally involutes in the second trimester. However, this has not been investigated directly. Three patients have also been described carrying mutations in the gene for steroidogenic factor 1 (SF1), a transcription factor required for adrenal and gonadal but not for placental expression of genes for the steroidogenic enzymes.[269-271] Two of these patients were 46,XY with a female phenotype and had adrenal failure, thus resembling lipoid CAH.

Treatment of lipoid CAH is straightforward if the diagnosis is made. Physiologic replacement with glucocorticoids, mineralocorticoids, and salt will permit survival to adulthood.[241,242] The glucocorticoid requirement is less than in the virilizing adrenal hyperplasias because it is not necessary to oversuppress excess adrenal androgen production. Thus, growth in these patients should be normal.[242] Genetic males have female external genitalia and should undergo orchiectomy and be raised as females.[42,241,242]

3β-HYDROXYSTEROID DEHYDROGENASE DEFICIENCY

3βHSD deficiency is a rare cause of glucocorticoid and mineralocorticoid deficiency that is fatal if not diagnosed early in infancy.[272] In its classic form, genetic females have clitoromegaly and mild virilization because the fetal adrenal overproduces large amounts of DHEA, a small portion of which is converted to testosterone by extra-adrenal 3βHSD1. Genetic males also synthesize some androgens by peripheral conversion of adrenal and testicular DHEA, but the concentrations are insufficient for complete male genital development and thus these males have a small phallus and severe hypospadias.

There are two functional human genes for 3βHSD: the type 1 gene is expressed in the placenta and peripheral tissues[55,57] and the type 2 gene is expressed in the adrenals and gonads.[273,274] Genetic and endocrine studies of 3βHSD deficiency show that the gonads and the adrenals are affected as a result of a single mutated 3βHSD2 gene expressed in both tissues. However, hepatic 3βHSD1 activity persists in the face of complete absence of adrenal and gonadal 3βHSD2 activity, thus complicating the diagnosis. Genetic studies have identified numerous mutations causing 3βHSD deficiency, all found in the type 2 gene.[275-279] Mutations have never been found in 3βHSD1, presumably because this would prevent placental biosynthesis of progesterone and result in a spontaneous first-trimester abortion.

The presence of peripheral 3βHSD activity complicates the hormonal diagnosis of this disease. One would expect that affected infants should have low concentrations of 17OHP, yet some newborns with 3βHSD deficiency have very high concentrations of serum 17OHP approaching those seen in patients with classical 21-hydroxylase deficiency.[280] The high 17OHP concentrations are due to extra-adrenal 3βHSD1. The adrenal of a patient with 3βHSD2 deficiency will secrete very large amounts of three principal Δ^5 steroids: pregnenolone, 17-hydroxypregnenolone, and DHEA.

Some of the secreted 17-hydroxypregnenolone is then converted to 17OHP by 3βHSD1. This 17OHP is not effectively picked up by the adrenal for subsequent conversion to cortisol because the circulating concentrations are below the K_m of P450c17, which is 1 μM 17OHP, or about 40,000 ng/dL. The ratio of Δ^5 to Δ^4 compounds remains high, consistent with the adrenal and gonadal deficiency of 3βHSD.[280] Thus, the principal diagnostic test in 3β-HSD deficiency is intravenous administration of ACTH with measurement of the three Δ^5 compounds and the corresponding Δ^4 compounds. Unlike the case of 21-hydroxylase deficiency, in which heterozygotes can be diagnosed by the response of 17OHP to ACTH, steroidal responses to ACTH cannot be used to identify carriers of 3βHSD deficiency.[281]

Mild or "partial" defects of adrenal 3βHSD activity have been reported on the basis of ratios of Δ^5 steroids to Δ^4 steroids following an ACTH test that exceed 2 or 3 standard deviations above the mean. These patients are typically young girls with premature adrenarche or young women with a history of premature adrenarche and complaints of hirsutism, virilism, and oligomenorrhea.[282-284] However, the 3βHSD2 genes are normal in these patients, and even patients with mild 3βHSD2 mutations have ratios of Δ^5 to Δ^4 steroids that exceed 8 standard deviations above the mean.[278,285-288] The basis of the mildly elevated ratios of Δ^5 to Δ^4 steroids in these hirsute individuals with normal 3βHSD genes is unknown. In adult women, the hirsutism can be ameliorated and regular menses can be restored by suppressing ACTH with 0.25 mg of dexamethasone given orally each day, but such treatment is contraindicated in girls who have not yet reached their final adult height.

17α-HYDROXYLASE/17,20-LYASE DEFICIENCY

P450c17 is the single enzyme that catalyzes 17α-hydroxylase and 17,20-lyase activities. 17-hydroxylase deficiency has been studied in detail at both clinical and genetic levels[289] and appears to be especially common in Brazil.[290] Deficient 17α-hydroxylase activity and deficient 17,20-lyase activity have been described as separate genetic diseases, but it is now clear that they represent different clinical manifestations of different lesions in the same gene. Deficient 17α-hydroxylase activity results in decreased cortisol synthesis, overproduction of ACTH, and stimulation of the steps proximal to P450c17.

These patients may have mild symptoms of glucocorticoid deficiency, but this is not life-threatening because the lack of P450c17 results in the overproduction of corticosterone which also has glucocorticoid activity. This is similar to the situation in rodents, whose adrenals lack P450c17[291] and consequently produce corticosterone as their glucocorticoid. Affected patients also typically overproduce DOC in the zona fasciculata, which causes sodium retention, hypertension, and hypokalemia and suppresses plasma renin activity and aldosterone secretion from the zona glomerulosa, although the suppression of aldosterone is rather variable. When P450c17 deficiency is treated with glucocorticoids, DOC secretion is suppressed and plasma renin activity and aldosterone concentrations rise to normal.[292]

The absence of 17α-hydroxylase and 17,20-lyase activities in complete P450c17 deficiency prevents the synthesis of adrenal and gonadal sex steroids. As a result, affected females are phenotypically normal but fail to undergo adrenarche and puberty[293] and genetic males have absent or incomplete development of the external genitalia (male pseudohermaphroditism).[294] The classic presentation is that of a teenage female with sexual infantilism and hypertension.[294] The diagnosis is made by finding low or absent 17-hydroxylated C-21 and C-19 plasma steroids, which respond poorly to stimulation with ACTH. Serum levels of DOC, corticosterone, and 18-OH-corticosterone are elevated, hyperresponsive to ACTH, and suppressible with glucocorticoids.

The gene for P450c17[70] is located on chromosome 10q24.3.[68,69] The molecular basis of 17α-hydroxylase deficiency has been determined in numerous patients by the cloning and sequencing of the mutated gene, which have identified more than 50 distinct mutations. Four mutations appear recurrently: a duplication of four nucleotides causing a frame-shift is found among descendents of Dutch Frieslanders,[295] in-frame deletion of residues 487 through 489 is found throughout Southeast Asia,[296] and a deletion of phenylalanine at position 53 or 54[297] and the common W406R and R362C mutations are found respectively among Brazilians of Spanish and Portuguese ancestry.[290] The genetic lesions identified include 12 mutations that cause frame-shifts or premature translational termination. As expected, none of these mutants has any detectable 17α-hydroxylase or 17,20-lyase activity. Eleven missense and in-frame mutations have been found, most of which also eliminate all activity, whereas others, such as P342T, reduce both activities by 80%.

Selective deficiency of the 17,20-lyase activity of P450c17 has been reported in about a dozen cases,[298] which initially led to the incorrect conclusion that 17α-hydroxylase and 17,20-lyase are separate enzymes. One of the original patients was studied at the genetic level, showing two wholly inactivating mutations[299], which led to a corrected diagnosis of the patient as having complete 17α-hydroxylase deficiency.[300] Because the 17α-hydroxylase and 17,20 lyase activities of P450c17 are catalyzed on the same active site, it was not clear that a syndrome of isolated 17,20 lyase deficiency could exist until two patients with genital ambiguity, normal excretion of 17OHCS, and markedly reduced production of C_{19} steroids were studied at the molecular genetic level.[301]

One patient was homozygous for the P450c17 mutation R347H, and the other was homozygous for R358Q. Both mutations changed the distribution of surface charges in the redox partner binding site of P450c17.[301] When assayed in vitro, both mutants retained nearly normal 17α-hydroxylase activity but had no detectable 17,20 lyase activity[301,302], and enzymatic competition experiments showed that the substrate binding site remained normal.[302] When an excess of P450 oxidoreductase and cytochrome b_5 was provided, some 17,20 lyase activity was restored, demonstrating that the loss in lyase activity was caused by impaired electron transfer.[302] Several additional patients have been described with similar mutations,[303] and an active site mutation causing isolated 17,20 lyase deficiency has been described.[304]

Computational modeling of P450c17 predicts the effects of all known mutations, including those with partial retention of both activities and those causing selective 17,20 lyase deficiency.[305] The model identifies Arg 347 and Arg 358 and several other arginine and lysine residues in the redox partner binding site. Mutation of these residues causes varying degrees of selective loss of 17,20 lyase activity.[301,302,305,306] Another example of the critical nature of redox partner interactions comes from the sole reported case of cytochrome b_5 deficiency. This patient was a male pseudohermaphrodite, but was not evaluated hormonally.[307] Thus, the central role of electron transfer in 17,20 lyase activity is now well established.

21-HYDROXYLASE DEFICIENCY

21-hydroxylase deficiency, which is due to mutations in the gene encoding adrenal P450c21, is one of the most common inborn errors of metabolism and accounts for about 95% of all forms of CAH. Because of success in diagnosis and treatment in infancy, many patients with severe forms of 21-hydroxylase deficiency have now reached adulthood, indicating that management issues in CAH concern all age groups. Detailed reviews of the complex physiology and molecular genetics of this disorder are available.[78-81,150,308]

Pathophysiology

For patients with a complete absence of P450c21, the clinical manifestations can be deduced from Figure 12-3. Inability to convert progesterone to DOC results in aldosterone deficiency, causing severe hyponatremia (Na^+ often below 110 mEq/L), hyperkalemia (K^+ often above 10 mEq/L), and acidosis (pH often below 7.1), with concomitant hypotension, shock, cardiovascular collapse, and death in an untreated newborn infant. High concentrations of cortisol in the adrenocortical capillary effluent that bathes the medulla are needed for the conversion of norepinephrine to epinephrine. Hence, children with CAH have low epinephrine concentrations, which may exacerbate the hypoglycemia associated with cortisol deficiency.[309] Because the control of fluids and electrolytes in the fetus can be maintained by the placenta and the mother's kidneys, this salt-losing crisis develops only after birth, usually during the second week of life.

The inability to convert 17OHP to 11-deoxycortisol results in cortisol deficiency, which impairs postnatal carbohydrate metabolism and exacerbates cardiovascular collapse because a permissive action of cortisol is required for full pressor action of catecholamines. Although the role of cortisol in fetal physiology is not well established,[141,145] cortisol deficiency is manifested prenatally. Low fetal cortisol stimulates ACTH secretion, which stimulates adrenal hyperplasia and transcription of the genes for all steroidogenic enzymes, especially for P450scc, the rate-limiting enzyme in steroidogenesis. This increased transcription increases enzyme production and activity, with consequent accumulation of non-21-hydroxylated steroids, especially 17OHP. As the pathways in Figure 12-3 indicate, these steroids are converted to testosterone.

In the male fetus, the testes produce large amounts of mRNA for the steroidogenic enzymes, and concentrations of testosterone are high in early to midgestation.[251] This testosterone differentiates external male genitalia from the pluripotential embryonic precursor structures. In the male fetus with 21-hydroxylase deficiency, the additional testosterone produced in the adrenals has little if any demonstrable phenotypic effect. In a female fetus, the ovaries lack steroidogenic enzyme mRNAs and are quiescent.[251] No sex steroids or other factors are needed for differentiation of the female external genitalia.[310]

The testosterone inappropriately produced by the adrenals of the affected female fetus causes varying degrees of virilization of the external genitalia. This can range from mild clitoromegaly with or without posterior fusion of the labioscrotal folds to complete labioscrotal fusion that includes a urethra traversing the enlarged clitoris Figure 12-11. These infants have normal ovaries, fallopian tubes, and a uterus but have ambiguous external genitalia or may be sufficiently virilized so that they appear to be male, resulting in errors of sex assignment at birth.

The diagnosis of 21-hydroxylase deficiency is suggested by genital ambiguity in females, a salt-losing episode in either sex, or rapid growth and virilization in males or females. Plasma 17OHP is markedly elevated at >2,000 ng/dL after 24 hr of age in an otherwise healthy full-term infant and hyperresponsive to stimulation with ACTH (Figure 12-9). Measurement of 11-deoxycortisol, 17OHP, DHEA, and androstenedione is important to distinguish among the forms of CAH and because adrenal or testicular tumors can also produce 17OHP.[311] Similarly, ACTH will induce a substantial rise in serum 21-deoxycortisol in all forms of 21-hydroxylase deficiency but not in normals, providing a useful adjunctive test when this steroid can be measured.[312] High newborn 17OHP values that rise further after ACTH can also be seen in 3βHSD and P450c11 deficiencies.[280]

17OHP is normally high in cord blood but falls to normal newborn levels after 12 to 24 hours (Figure 12-12), and thus assessment of 17OHP levels should not be made in the first 24 hours of life. Premature infants and term infants under severe stress (e.g., with cardiac or pulmonary disease) may have persistently elevated 17OHP concentrations with normal 21-hydroxylase, although longitudinal studies of 17OHP values in the premature have not been reported. Newborn screening programs for CAH are being instituted throughout the world based on 17OHP measurements on the "Guthrie cards" typically used for newborn screening of metabolic disorders. The technologies employed and "cutoff" values used vary substantially in different health care systems. In general, when testing is done on full-term infants more than 24 hours after birth the screening is highly reliable. Each endocrinologist and neonatologist must become familiar with local assays and the values found in the extremely premature, which may be read as false positives for CAH.

Clinical Forms of 21-Hydroxylase Deficiency

There is a broad spectrum of clinical manifestations of 21-hydroxylase deficiency, depending on the particular mutations of the gene for P450c21. These different forms

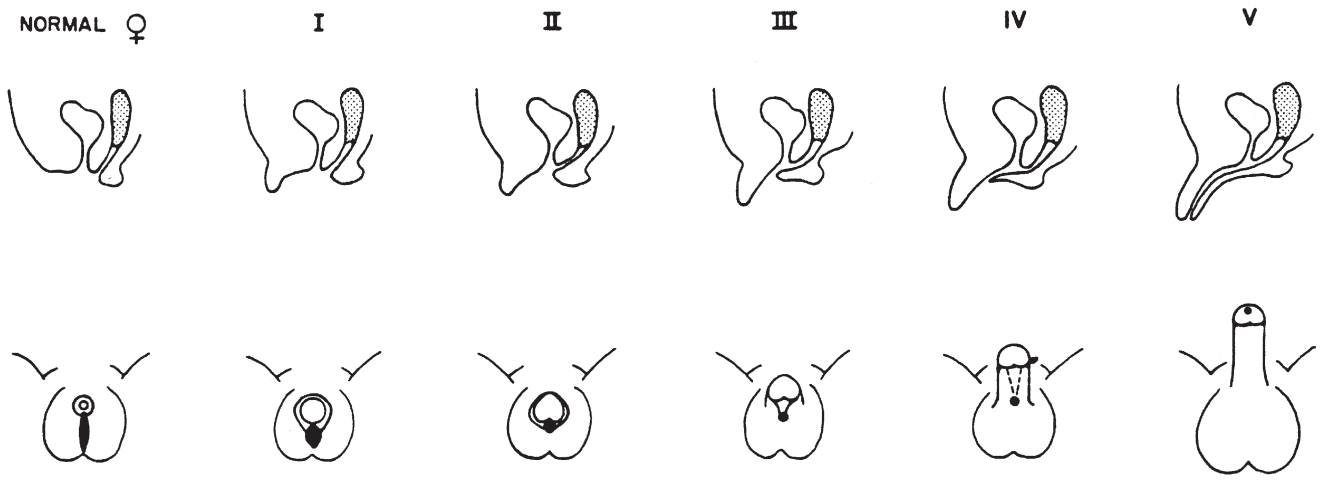

Figure 12-11 Virilization of the external genitalia. A continuous spectrum is shown from normal female to normal male in both saggital section (above) and perineal views (below), using the staging system of Prader. Disorders of external genitalia can occur either by the virilization of a normal female, as in congenital adrenal hyperplasia, or due to an error in testosterone synthesis in the male. In females with congenital adrenal hyperplasia due to 21-hydroxylase deficiency, the degree of virilization correlates poorly with the presence or absence of clinical signs of salt loss.

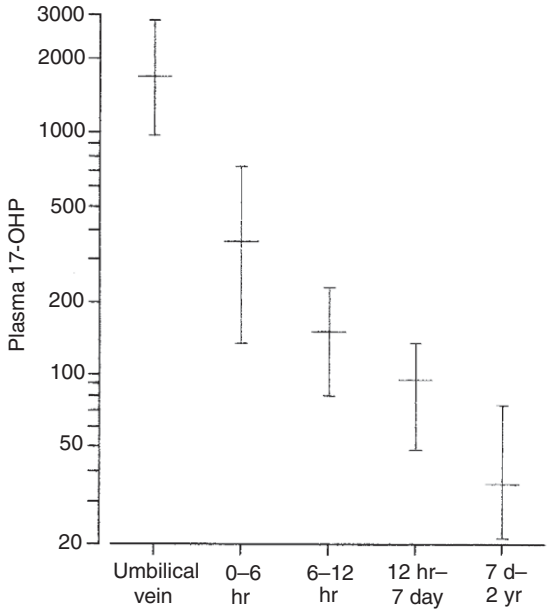

Figure 12-12 Means and ranges of 17OHP in normal newborns (data are in ng/100 mL). Note that values can be very high and quite variable for the first 24 hours of life.

of 21-hydroxylase deficiency are not different diseases because there is a continuous spectrum of manifestations, ranging from the severe salt-wasting form to clinically inapparent forms that may be normal variants. Thus, the typical disease forms discussed in the material following are mainly a clinical convenience.

Salt-Wasting CAH. Salt-wasting CAH is due to a complete deficiency of P450c21 activity, effectively eliminating glucocorticoid and mineralocorticoid synthesis. Females with this disorder are frequently diagnosed at birth because of masculinization of the external genitalia. After appropriate resuscitation of the cardiovascular collapse, acidosis, and electrolyte disorders, the mineralocorticoids and glucocorticoids can be replaced orally and the ambiguous genitalia can be corrected with a series of plastic surgical procedures. The steroidal replacement management is difficult because of the rapidly changing needs of a growing infant or child. Drug doses must be adjusted frequently, and there is considerable individual variability in what constitutes "physiologic" replacement.

As an underdosage of glucocorticoids can be life-threatening, especially during illness, most pediatricians have tended to err on the "safe side" and thus these children usually receive inappropriately large doses of glucocorticoids. It is not possible to compensate for the growth lost during the first 2 years of life, when growth is fastest, and thus these children almost always end up shorter than predicted from their genetic potential. Female survivors may have sexual dysfunction, marry with a low frequency, be more reluctant to form intimate relationships, and have decreased fertility.[313-316] Prenatal androgens appear to affect behavior but not sexual identity.[317] Males with this disorder are generally undiagnosed at birth and either come to medical attention during the salt-losing crisis that follows 5 to 15 days later or die, invariably with an incorrect diagnosis.

Simple Virilizing CAH. Virilized females who have elevated concentrations of 17OHP but who do not suffer a salt-losing crisis have long been recognized as having the "simple virilizing" form of CAH. Males with this disorder often escape diagnosis until age 3 to 7 years, when they come to medical attention because of early development of pubic, axillary, facial hair, and phallic growth. An astute physician can readily differentiate boys with sexual precocity caused by CAH from boys with true central precocious puberty, as the testes remain of prepubertal size in CAH whereas gonadotropic stimulation in true precocious puberty results in pubertal-size testes.

These children grow rapidly and are tall for their age when diagnosed, but their epiphyseal maturation (bone age) advances at a disproportionately rapid rate so that their ultimate adult height is invariably compromised. Untreated or poorly treated children with CAH may fail to undergo normal puberty, and boys may have small testes and azoospermia because of the feedback effects of the adrenally produced testosterone. When treatment is begun at several years of age, suppression of adrenal testosterone secretion may remove tonic inhibition of the hypothalamus, occasionally resulting in true central precocious puberty requiring treatment with a GnRH agonist.

High concentrations of ACTH in some poorly treated boys may stimulate the enlargement of adrenal rests in the testes. These enlarged testes are usually nodular, unlike the homogeneously enlarged testes in central precocious puberty. Because the adrenal normally produces 100 to 1,000 times as much cortisol as aldosterone, mild defects, or amino acid replacement mutations, in P450c21 are less likely to affect mineralocorticoid secretion than cortisol secretion. Thus, patients with simple virilizing CAH simply have a less severe disorder of P450c21. This is reflected physiologically by the increased plasma renin activity seen in these patients after moderate salt restriction.

Nonclassic CAH. Many people have very mild forms of 21-hydroxylase deficiency. These forms may be evidenced by mild to moderate hirsutism, virilism, menstrual irregularities, and decreased fertility in adult women, so-called late-onset CAH,[318-320] or there may be no phenotypic manifestations at all other than an increased response of plasma 17OHP to an intravenous ACTH test, so-called cryptic CAH.[321] Despite the minimal manifestations of this disorder, these individuals also have hormonal evidence of a mild impairment in mineralocorticoid secretion as predicted from the existence of a single adrenal 21-hydroxylase.[322]

There is some inconsistency in classifying patients into these three categories because each diagnostic category is not a separate disease but represents a typical picture in a continuous spectrum of disease caused by a broad spectrum of genetic lesions in the P450c21 gene. Furthermore, because some mutant P450c21 alleles are common in the general population most patients are compound heterozygotes, carrying a different mutation on the allele inherited from each parent. Finally, factors other than the specific mutations found in P450c21 will influence the clinical phenotype, including the presence of extra-adrenal 21-hydroxylases other than P450c21, undiagnosed

P450c21 promoter mutations, and variations in androgen metabolism and sensitivity. These discordances between genotype and phenotype are to be expected.

Incidence of 21-Hydroxylase Deficiency

Perinatal screening for elevated concentrations of serum 17OHP in several countries has shown that the incidence of classic CAH (i.e., salt-wasting and simple virilizing CAH) is about 1 in 14,000, yielding a heterozygous carrier rate of 1 in 60.[323] The screening of 1.9 million newborns in Texas yielded an overall incidence of 1 in 16,000, including incidences of 1 in 15,600 Caucasians, 1 in 14,500 Hispanics, primarily Mexican Americans of indigenous American ancestry, and 1 in 42,300 African Americans.[324] Because about 20% of the African American gene pool is of European descent, the calculated incidence in individuals of wholly sub-Saharan African ancestry is about 1 in 250,000.

Nonclassical CAH is clearly much more common, but these data are also variable. One group has reported very high incidences: 1 in 27 for Ashkenazi Jews, 1 in 53 for Hispanics, 1 in 63 for Yugoslavs, 1 in 333 for Italians, and 1 in 1,000 for other whites.[325-327] These data would indicate that one-third of Ashkenazi Jews, one-fourth of Hispanics, one-fifth of Yugoslavs, one-ninth of Italians, and one-fourteenth of other Caucasians are heterozygous carriers. However, other studies have shown carrier rates of 1.2%[319] to 6%[328,329] for Caucasian populations that were not subdivided further. The considerable differences in the reported incidences reflect differences in the small populations examined and the errors in distinguishing nonclassic CAH from heterozygous carriers of classic CAH when an ACTH test is not performed.

In homozygotes for classic and nonclassic CAH, serum concentrations of 21-deoxycortisol rise in response to ACTH. However, ACTH-induced 21-deoxycortisol remains normal in heterozygotes for classic and nonclassic CAH.[312] These studies have, however, classified individuals by hormonal phenotype without examining the P450c21 genes directly to establish these incidences. Therefore, the diagnosis of nonclassic CAH requires family studies because the hormonal data, 17OHP responses to ACTH, in these individuals may be indistinguishable from those for unaffected heterozygous carriers of the more severe forms. The high incidence, lack of mortality, and lack of decreased fertility in most individuals with nonclassic CAH indicate that this is probably a variant of normal and is not a disease in the classic sense. Nevertheless, patients with nonclassic CAH may seek help for complaints of virilism and menstrual disorders.

Genetics of the 21-Hydroxylase Locus

21-Hydroxylase Genes. There are two 21-hydroxylase loci: a functional gene (formally termed *CYP21A2*) and a nonfunctional pseudogene (formally termed *CYP21A1P*).[330] These genes, generally termed *P450c21B* (functional gene) and *P450c21A* (pseudogene), are duplicated in tandem, with the C4A and C4B genes encoding the fourth component of serum complement[331,332] (Figure 12-13). Although the P450c21A locus is transcribed, the resultant RNAs do not encode protein,[333] only the P450c21B gene encodes 21-hydroxylase. The P450c21 genes consist of 10 exons, are about 3.4 kb long, and differ in only 87 or 88 of these bases.[83-85]

This high degree of sequence similarity indicates that these two genes are evolving in tandem through intergenic exchange of DNA. The P450c21 genes of mice[334] and cattle[335,336] are also duplicated and linked to leukocyte antigen loci. However, wheras only the P450c21B gene functions in human beings only the P450c21A gene functions in mice[337,338], and both genes function in cattle.[339] Sequencing of the gene duplication boundaries shows that the human locus was duplicated after mammalian speciation,[340] consistent with data that indicate that other mammals have single P450c21 gene copies.[341]

HLA Linkage. The 21-hydroxylase genes lie within the class III region of the human major histocompatibility complex (MHC) (Figure 12-13). Thus, HLA typing has been widely used for prenatal diagnosis and to identify heterozygous family members. Statistical associations (linkage disequilibrium) are well established between CAH and specific HLA types. Salt-losing CAH is associated with HLA-B60 and HLA-40 in some populations,[342] and the rare HLA type Bw47 is very strongly associated with salt-losing CAH.[343,344]

HLA-Bw51 is often associated with simple virilizing CAH in some populations,[345] and 30% to 50% of haplotypes for nonclassic CAH carry HLA-B14.[346] HLA-B14 is often associated with a duplication of the C4B gene.[347,348] By contrast, all HLA-B alleles can be found linked to CAH. HLA-identical individuals in a single family may have different clinical features of CAH despite HLA identity,[349-352] possibly representing extra-adrenal 21-hydroxylation, de novo mutations, or multiple genetic crossover events.

Other Genes in the 21-Hydroxylase Locus. The tandemly duplicated C4A and C4B loci produce isoforms of complement component C4 that can be distinguished functionally and immunologically. The C4B protein has substantially more hemolytic activity despite greater than 99% sequence identity with C4A.[353] The C4A gene is always 22 kb long, but there are long (22 kb) and short (16 kb) forms of C4B due to a variation in one intron.[354] The 3' ends of the C4 genes are only 2466bp upstream from the transcriptional start sites of the P450c21 genes. Promoter sequences needed for the transcription of the human P450c21B gene lie within intron 35 of the C4B gene.[355,356] In addition to the P450c21 and C4 genes, there are several other genes within 100 kb of the P450c21 gene, including the genes for complement factor C2 and properdin factor Bf (Figure 12-13). Lying just 3' of the Bf gene on the opposite strand of DNA from P450c21 is the STK19 gene, also variously called RD, RP, and G11, which encodes a nuclear serine/threonine kinase.[357]

A pair of genes, termed *XA* and *XB,* is duplicated with the C4 and P450c21 genes. These genes lie on the strand of DNA opposite the C4 and P450c21 genes and overlapping the 3' end of P450c21. The last exon of XA and XB lies within the 3' untranslated region of exon 10 in P450c21A and P450c21B, respectively.[358] The XA gene was truncated during the duplication of the ancestral C4-P450c21-X genetic unit, but is transcribed in the adrenal.[340] The XB gene encodes a large extracellular matrix protein called Tenascin X, which is expressed in most

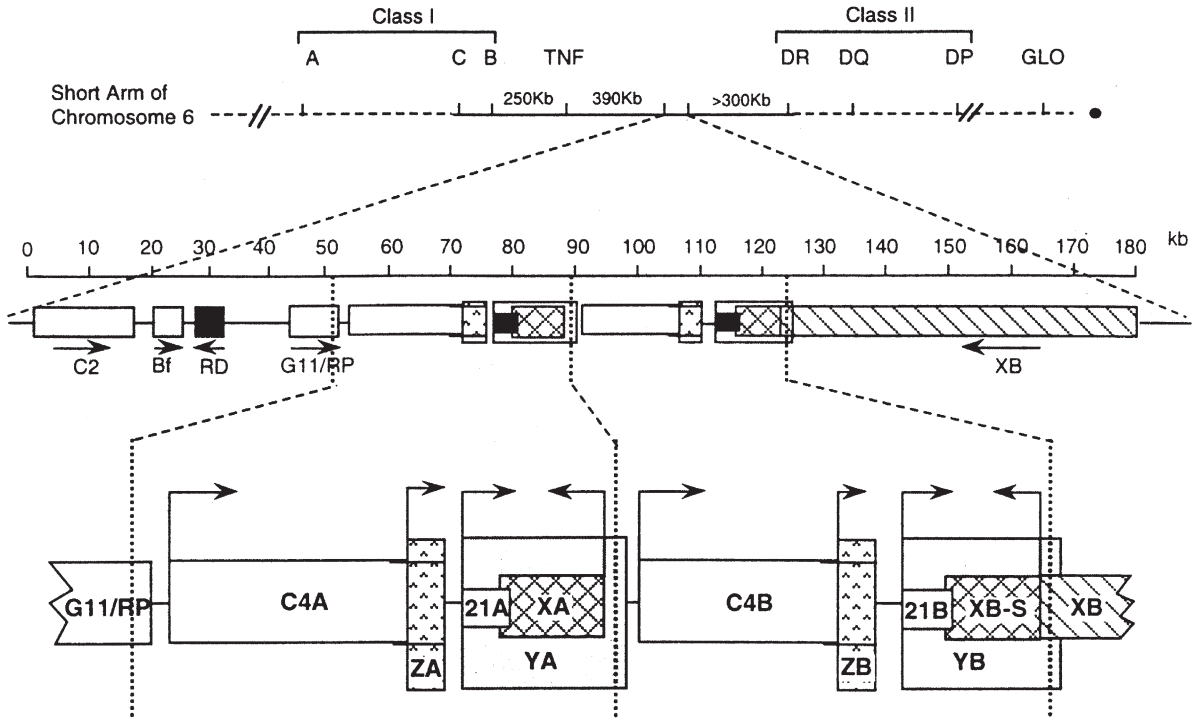

Figure 12-13 Genetic map of the HLA locus containing the genes for P450c21. The top line shows the p21.1 region of chromosome 6, with the telomere to the left and the centromere to the right. Most HLA genes are found in the class I and class II regions. The class III region containing the P450c21 genes lies between these two. The second line shows the scale (in kilobases) for the diagram immediately below, showing (from left to right) the genes for complement factor C2, properedin factor Bf, and the RD and G11/RP genes of unknown function. Arrows indicate transcriptional orientation. The bottom line shows the 21-hydroxylase locus on an expanded scale, including the C4A and C4B genes for the fourth component of complement, the inactive CYP21A gene (21A), and the active CYP21B gene (21B) that encodes P450c21. XA, YA, and YB are adrenal-specific transcripts that lack open reading frames. The XB gene encodes the extracellular matrix protein tenascin-X. XB-S encodes a truncated adrenal-specific form of the tenascin-X protein, whose function is unknown. ZA and ZB are adrenal-specific transcripts that arise within the C4 genes and have open reading frames. However, it is not known if they are translated into protein. Nevertheless, the promoter elements of these transcripts are essential components of the CYP21A and CYP21B promoters. The arrows indicate transcriptional orientation. The vertical dotted lines designate the boundaries of the genetic duplication event that led to the presence of A and B regions.

tissues, especially connective tissue.[359,360] The XB gene spans about 65 kb of DNA and includes 43 exons encoding a 12-kb mRNA.[359,361]

The XB gene also encodes a short truncated form of Tenascin X having unknown function and arising from an intragenic promoter.[362] Identification of a CAH patient with a "contiguous gene syndrome" comprising a deletion of the P450c21B and XB genes demonstrated that Tenascin X deficiency results in Ehlers-Danlos syndrome (EDS).[363] Most forms of EDS are caused by autosomal-dominant mutations in collagen genes. The recessive forms are caused by mutations in genes for collagen-modifying enzymes, including Tenascin-X, which is associated with and stabilizes collagen fibrils.[364,365] Tenascin-X deficiency causes a clinically distinct, somewhat more severe, recessive form of Ehlers-Danlos syndrome, with or without associated 21-hydroxylase deficiency.[366]

P450c21 Gene Lesions Causing 21-Hydroxylase Deficiency

21-hydroxylase deficiency can be caused by P450c21B gene deletions, gene conversions, and apparent point mutations. Most of the point mutations in the P450c21B gene are actually small gene conversion events,[78,79,367] and thus gene conversions account for about 85% of the lesions in 21-hydroxylase deficiency. The P450c21 genes are autosomal, and hence each person has two alleles, one contributed by each parent.

Most patients with 21-hydroxylase deficiency are compound heterozygotes, having different lesions on their two alleles. Because gene deletions and large conversions eliminate all P450c21B gene transcription, in the homozygous state these lesions will cause salt-losing CAH. Some microconversions, such as those creating premature translational termination, are also associated with salt-losing CAH. Milder forms, such as simple virilizing and nonclassic CAH, are associated with amino acid replacements in the P450c21 protein caused by gene microconversion events. Patients with these forms of CAH are usually compound heterozygotes bearing a severely disordered allele and a mildly disordered allele and thus the clinical manifestations are based on the nature of the mildly disordered allele.

Mapping of P450c21 Genes in Normals and in CAH. Although the P450c21B and P450c21A loci differ by only 87 or 88 nucleotides, they can be distinguished by restriction endonuclease digestion and Southern blotting. Two

unusual and related features of the 21-hydroxylase locus complicate its analysis. First, the gene deletions in this locus are most unusual in that they extend 30 kb from one of several points in the middle of P450c21A to the precisely homologous point in P450c21B. Thus, the 15% of alleles that carry deletions do not yield a typical Southern blotting pattern with a band of a size different from that of one of the normal unless one uses very rarely cutting enzymes and analyzes the resulting large DNA fragments by pulsed-field gel electrophoresis. The second unusual feature of this locus is that gene conversions are extremely common.[368,369]

Gene Conversions. If a segment of gene A replaces the corresponding segment of the related gene B, the structure of recipient gene B is said to be "converted" to that of donor gene A. The hallmark of gene conversion is that the number of closely related genes remains constant, whereas their diversity decreases. Two types of gene conversions commonly cause 21-hydroxylase deficiency: large gene conversions that can be mistaken for gene deletions and small microconversions that resemble point mutations. The relative frequency of large gene conversions versus gene deletions was formerly controversial, principally because initial studies used relatively small groups of patients from single locations or ethnic groups.

A compilation of the world literature on the genetics of CAH found that 19% of mutant alleles had gene deletions, 8% had large gene conversions, 67% had microconversions, and 6% had uncharacterized lesions[79] (Figure 12-14). However, such statistics must be viewed with caution because there is considerable ascertainment bias in favor of the more severely affected patients[348] and because some studies excluded mildly affected patients. Thus, the previously cited statistics are weighted in favor of gene deletions and large conversions, which can only yield a phenotype of salt-wasting CAH.

Point Mutations Microconversions Causing CAH. About 75% of mutated P450c21 genes appear to be structurally intact by Southern blotting and thus appear to carry point mutations.[348,368] Many mutant P450c21B genes causing CAH have been cloned and sequenced (Table 12-6), revealing that a relatively small number of mutations cause CAH, virtually all of which are also found in the P450c21A pseudogene. These observations indicate that most CAH alleles bearing apparent point mutations actually carry microconversions.[78,79,367]

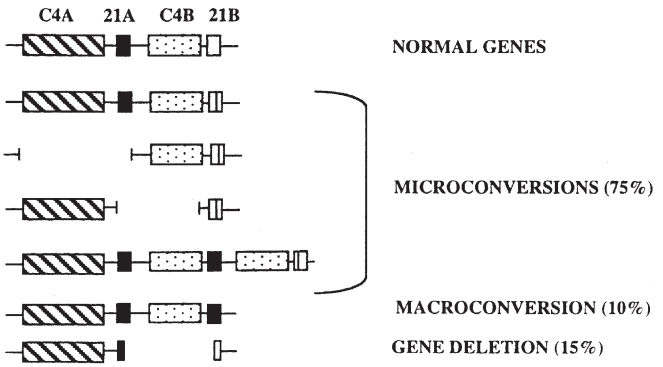

Figure 12-14 Classes of genetic rearrangements causing 21-hydroxylase deficiency. Deletions or duplications of the C4A and C4B genes can occur with or without associated lesions in the P450c21B gene. Note that virtually all "point mutations" in P450c21B are actually microconversion. Many authors combine the gene deletion and macroconversion groups because these are difficult to distinguish by Southern blotting in that both result in a loss of the P450c21B gene. However, the genotypes are clearly distinct (as shown).

TABLE 12-6

Microconversions of the P450c21B Gene That Cause 21-Hydroxylase Deficiency

Mutation	Location	Associated Phenotypes	Activity
Pro 30→Leu	Exon 1	NC/SV	30%-60%
A→G	Intron 2	SV/SW	minimal
8 bp deletion	Exon 3	SW	0
Ile 172→Asn	Exon 4	SV	3%-7%
Ile 236→Asp Val 237→Glu Met 239→Lys	Exon 6	SW	
Val 281→Leu	Exon 7	NC	18% ± 9%
Gly 292→Ser	Exon 7	SW	
T insertion @ 306	Exon 7	SW	0
Gly 318→Stop	Exon 8	SW	0
Arg 339→His	Exon 8	NC	20%-50%
Arg 356→Trp	Exon 8	SV/SW	2%
Pro 453→Ser	Exon 10	NC	20%-50%
GG→C @ 484	Exon 10	SW	0

Three changes in the P450c21A pseudogene (8bp deletion, exon 3; T insertion, exon 7; Gly 318 stop, exon 8) render its product nonfunctional. Each change results in an altered reading frame and/or premature stop codon, eliminating all activity. All of these have been found in P450c21B alleles that cause severe salt-losing CAH. Three closely clustered base changes alter the normal amino acid sequence Ile-Val-Glu-Met at codons 236 to 239 in exon 6 to Asn-Glu-Glu-Lys in P450c21A and in a small number of genes causing severe salt-losing CAH.

The most common lesion in classic CAH is an A→G change in the second intron, 13 bases upstream from the normal 3→ splice acceptor site of this intron, a microconversion found in more than 25% of severely affected CAH alleles. This intronic mutation causes abnormal splicing of the mRNA precursor, destroying activity. However, a small portion of this mRNA may be spliced normally in some patients, with the result that the phenotypic presentation is variable. Most such patients are salt losers, but some have non–salt-losing CAH.

This intron 2 microconversion is often associated with the Ser/Thr polymorphism at codon 268. This is a true polymorphism because S268T does not alter enzymatic activity.[370] The microconversion R356W, which is found in about 10% of severely affected alleles,[371] eliminates all detectable activity[372], apparently because it changes a residue in the binding site for P450 oxidoreductase.[305] This mutation may retain slight activity and has been found in simple virilizing CAH. Other extremely rare mutations have been described in single individuals.[373-375]

Missense Mutations Causing Simple Virilizing and Nonclassic CAH. The microconversion I172N is the

most common cause of simple virilizing CAH.[372,376,377] Ile 172 is conserved in the other known mammalian proteins and may contribute to the hydrophobic interactions needed to maintain the correct conformation of the enzyme. When Ile 172 was changed to Asn, Leu, Gln, or His and the constructed mutants were expressed in mammalian cells, the mutant constructions yielded only 3% to 7% of the 21-hydroxylase activity of normal P450c21.[372,378] The intron 2 microconversion is occasionally seen in simple virilizing CAH. The microconversion P30L is generally associated with nonclassic CAH but is found in some patients with simple virilizing CAH.

The most common mutation causing nonclassic CAH is V281L. This microconversion is seen in all patients with the form of nonclassic CAH linked to HLA-B14 and HLA-DR1 but is also found in patients with other HLA types. This mutation does not alter the affinity of the enzyme for substrate but drastically reduces its V_{max}.[379] The microconversion P30L is found in about 15% to 20% of nonclassic alleles. In addition, the mutations R339H and P453S have been associated with nonclassic CAH.[380,381] Initial surveys of the mutations in P450c21A failed to reveal these mutations, suggesting that they are bona fide point mutations rather than gene microconversions. However, examination of large numbers of P450c21A pseudogenes shows that at least the P453S mutation is polymorphic in about 20% of P450c21A pseudogenes, and hence also represents a microconversion event.

Structure-Function Inferences from P450c21 Mutations

Each P450c21 missense mutation appears to occur in a functional domain of P450c21. By analogy with the computationally inferred structure of the closely related enzyme P450c17,[305] Arg 356 may be part of the redox partner binding site. Val 281 appears to participate in coordinating the heme moiety, and Cys 428 is the crucial cystine residue in the heme-binding site found in all cytochrome P450 enzymes. The N-terminal region of P450c21, including Pro30, appears to be required for membrane insertion and enzyme stability.[382]

Finding most mutations in the amino terminal portion of P450c21 is consistent with finding most gene conversion and gene deletion events occurring in exons 1 through 8 of the P450c21B gene. Changes in exons 9 and 10 are very rare, possibly as a result of evolutionary pressure to retain the 3′ untranslated and 3′ flanking DNA of the P450c21B gene because this DNA also contains the 3′ end of the XB gene.[358,359]

Prenatal Diagnosis of CAH

The prenatal diagnosis of 21-hydroxylase deficiency has been approached by several tactics. First, the steroids produced by the disordered adrenal of the CAH fetus, 17OHP[383-385] and Δ^4-androstenedione[386], can be measured in amniotic fluid, but these assays are reliable only for identifying fetuses with severe salt-losing CAH because these steroids may not be elevated above the broad range of normal in non–salt-losing or nonclassic CAH.[387,388] Second, the intimate HLA linkage of the CYP21 genes means that HLA typing of fetal amniocytes can be informative.

This would require previous linkage analysis of an affected index case and parents. However, only HLA-A and HLA-B can be determined reliably in cultured amniocytes, some HLA-B alleles are expressed weakly in these cells, and there is a relatively high incidence of HLA-B homozygosity among CAH patients. These and other technical considerations have substantially limited the usefulness of HLA typing for prenatal diagnosis. Third, if the genetic lesion in a previously affected sibling is established, DNA-based diagnosis (including DNA sequencing) provides the most reliable tactic. However, the complex genetics of the 21-hydroxylase locus described previously can still render this approach problematic.

Diagnosis

Genital ambiguity or a salt-losing crisis will generally alert pediatricians to most cases of severe 21-hydroxylase deficiency. Salt-losing crises generally occur in the second week of life, and the child presents with vomiting, diarrhea, dehydration, hyperkalemia, and hyponatremia. Occasionally, such infants are thought to have viral syndromes or gastrointestinal obstructions. Such a failure to make the diagnosis can result in the infant's death. Similarly, boys with simple virilizing CAH often escape diagnosis until they are 3 to 7 years old, when they present with isosexual precocity, advanced bone age, and characteristically prepubertal testes. Teenage and adult females with nonclassic CAH may consult an internist, obstetrician, or dermatologist for virilism, hirsutism, menstrual irregularity, infertility, or acne.

The key diagnostic maneuver in all forms of 21-hydroxylase deficiency is the measurement of the 17OHP response to intravenous synthetic ACTH. The usual doses are 15 μg/kg in children up to 2 years of age and 0.25 mg in older children and adults. 17OHP and cortisol should be measured at 0 and 60 minutes. Individual patient responses must be compared to age- and sex-matched data from normal children.[230] Normal responses are outlined in Table 12-4 and shown in Figure 12-9. Both basal and stimulated levels of 17OHP are markedly elevated in patients with salt-losing and simple virilizing forms of 21-hydroxylase deficiency. Basal levels are usually greater than 2,000 ng/dL and increase to more than 5,000 to 10,000 ng/dL after ACTH (Figure 12-9).

Patients with the milder late-onset or cryptic forms typically have normal to mildly elevated basal levels but have supranormal responses to ACTH stimulation (i.e., 1,500 to >10,000 ng/dL).[232,389] The cortisol response to ACTH is absent or subnormal in patients with the classic forms of CAH and is normal in patients with late-onset and cryptic forms. Basal plasma ACTH levels reflect the extent of 21-hydroxylase and cortisol deficiency, i.e., they are markedly elevated in severe forms and may be normal in patients with the milder forms who are not overtly adrenal insufficient.

Other ancillary tests are listed in Table 12-5. Urinary excretion of 17-ketosteroids will generally be elevated, but this test is more useful for monitoring the efficacy of suppressive therapy than for initial diagnosis. When urinary

steroids are measured, a complete 24-hour sample must be obtained, and a concomitant measurement of creatinine excretion is required to monitor the completeness of the collection. Less than 24-hour urine collections are not accurate because of diurnal variations in steroid excretion.

Plasma renin activity and its response to salt restriction constitute an especially useful test. Most patients with simple virilizing 21-hydroxylase deficiency have high plasma renin activity, which increases further on sodium restriction, confirming that these patients are partially mineralocorticoid deficient and can maintain normal serum sodium only by hyperstimulation of the zona glomerulosa.

Treatment

Although Wilkins[7] and Bartter[8] first demonstrated effective treatment of 21-hydroxylase deficiency with cortisone in 1950, the management of this disorder remains difficult. Overtreatment with glucocorticoids causes delayed growth even when the degree of overtreatment is insufficient to produce signs and symptoms of Cushing syndrome. Undertreatment results in continued overproduction of adrenal androgens, which hastens epiphyseal maturation and closure, again resulting in compromised growth and other manifestations of androgen excess.

Doses of glucocorticoids should be based on the expected normal cortisol secretory rate. Widely cited classic studies have reported that the secretory rate of cortisol is 12.5 ± 3 mg/m^2 per day[390-392] and have led most authorities to recommend doses of 10 to 20 mg of hydrocortisone (cortisol)/m^2 per day. However, the actual cortisol secretory rate is substantially lower, at 6 to 7 ± 2 mg/m^2/per day.[224,225] Although no single formula can be applied to all patients and extensive experience and judgment are needed, we consider the cortisol secretory rate to be about 6 to 8 mg/m^2 per day. It must be stressed, however, that newly diagnosed patients, especially newborns, will require substantially higher initial dosages to suppress their hyperactive CRH-ACTH-adrenal axis.

The glucocorticoid used is important. Most tables of glucocorticoid dose equivalencies are based on their equivalence in anti-inflammatory assays. However, the growth-suppressant equivalences of various glucocorticoids do not parallel their anti-inflammatory equivalencies.[393] Thus, long-acting synthetic steroids such as dexamethasone have a disproportionately greater growth-suppressant effect and hence must be avoided in treating growing children and adolescents (Table 12-7). Most authorities favor the use of oral hydrocortisone or cortisone acetate in three divided daily doses in growing children. However, adults and older teenagers whose epiphyses are already fused may be managed very effectively with prednisone or dexamethasone.

Mineralocorticoid therapy in these patients returns plasma volume to normal and eliminates the hypovolemic drive to ACTH secretion. Thus, mineralocorticoid therapy often permits the use of lower doses of glucocorticoids in patients with simple virilizing CAH, optimizing growth in children and diminishing unwanted weight gain in adults.

Only one oral mineralocorticoid preparation, fludrocortisone (9α-fluorocortisol), is generally available. When the oral route is not available in severely ill patients, mineralocorticoid replacement is achieved through intravenous hydrocortisone plus sodium chloride. About 20 mg of hydrocortisone has a mineralocorticoid effect of about 0.1 mg of 9α-fluorocortisol (Table 12-7). Mineralocorticoids are unique in pharmacology in that their doses are not based on body mass or surface area. In fact, newborns are quite insensitive to mineralocorticoids, as reflected by their high serum aldosterone concentrations (Figure 12-14), and often require larger doses than do adults (0.15 to 0.30 mg/day, depending on the sodium supplementation).

In older children, the replacement dose of 9α-fluorocortisol is 0.05 to 0.15 mg daily. It must be emphasized that a mineralocorticoid is essentially useless unless adequate sodium is presented to the renal tubules. Thus, additional salt supplementation, usually 1 to 2 g NaCl/day in the newborn, is also needed. Patients with severe salt-losing congenital adrenal

TABLE 12-7

Potency of Various Therapeutic Steroids (Set Relative to the Potency of Cortisol)

Steroid	Anti-inflammatory Glucocorticoid Effect	Growth-retarding Glucocorticoid Effect	Salt-retaining Mineralocorticoid Effect	Plasma Half-life (min)	Biological Half-life (hr)
Cortisol (hydrocortisone)	1.0	1.0	1.0	80-120	8
Cortisone acetate (oral)	0.8	0.8	0.8	80-120	8
Cortisone acetate (IM)	0.8	1.3	0.8		18
Prednisone	4	5	0.25	200	16-36
Prednisolone	4		0.25	120-300	16-36
Methyl prednisolone	5	7.5	0.4		
Betamethasone	25		0	130-330	
Triamcinolone	5		0		
Dexamethasone	30	80	0	150-300	36-54
9α-fluorocortisone	15		200		
DOC acetate	0		20		
Aldosterone	0.3		200-1,000		

hyperplasia can in some cases discontinue mineralocorticoid replacement and salt supplementation as adults. Perhaps adults become more sensitive to the mineralocorticoid action of hydrocortisone via a developmental decrease in renal 11βHSD activity, which normally inactivates cortisol to cortisone.

Long-term management is difficult to monitor and requires careful clinical and laboratory evaluation. Measurements of growth should be made at 3- to 4-month intervals in children, along with an annual assessment of bone age. Each visit should be accompanied by measurement of blood pressure, plasma renin activity, and serum Δ^4-androstenedione, DHEA, DHEA sulfate, and testosterone. Measurement of urinary 17-KS and plasma 3α-androstenediol glucuronide may also be useful. In general, plasma 17OHP is not a useful indicator of therapeutic efficacy because of its great diurnal variation and hyperresponsiveness to stress (e.g., clinic visits).

Experimental Prenatal Treatment of CAH

Because the treatment of CAH involves administering a glucocorticoid to suppress the hypothalamic-pituitary-adrenal axis, this approach has been proposed for treating the affected fetus by administering glucocorticoids to the mother. Female fetuses affected with CAH begin to become virilized at about 6 to 8 weeks gestation, the same time at which the testes of normal male fetuses produce testosterone, causing fusion of the labioscrotal folds, enlargement of the genital tubercle into a phallus, and the formation of the phallic urethra.[310] The adrenals of female fetuses with CAH may produce concentrations of testosterone that approach those of a normal male, resulting in varying degrees of masculinization of the external genitalia. If fetal adrenal steroidogenesis is suppressed in a female fetus with CAH, the virilization can theoretically be reduced or eliminated. Thus, some authorities have advocated administering dexamethasone to the mother as soon as pregnancy is diagnosed.[394-398]

This can be done only when the parents are known to be heterozygotes by having already had an affected child. However, even in such pregnancies, only one in four fetuses will have CAH. Furthermore, as no prenatal treatment is needed for male fetuses affected with CAH only one in eight pregnancies of heterozygous parents would harbor an affected female fetus that might potentially benefit from prenatal treatment. However, treatment must be started at about 6 weeks postconception (8 weeks of amenorrhea), but prenatal diagnosis cannot be done until 12 to 13 weeks and at least a week is required for the assays. Thus, seven of eight pregnancies must be treated needlessly to treat one affected female fetus.

The efficacy, safety, and desirability of such prenatal treatment remain highly controversial.[79,150,385,397-410] The rationale is that dexamethasone, which is not metabolized by placental 11βHSD2, will cross the placenta, suppress fetal ACTH, and consequently suppress adrenal steroidogenesis. However, it is not known precisely when the fetal hypothalamus begins to produce CRH, when the fetal pituitary begins to produce ACTH, whether all fetal ACTH production is regulated by CRH, or whether these hormones are suppressible by dexamethasone in the early fetus.

Although there is considerable evidence that pharmacologic doses of glucocorticoids do not harm pregnant women, few data exist for the fetus. Pregnant women with diseases such as nephrotic syndrome and systemic lupus erythematosus are generally treated with prednisone, which does not reach the fetus because it is inactivated by placental 11βHSD. Treatment of a fetus with CAH requires the use of fluorinated steroids that escape metabolism by these enzymes, and few data are available about the long-term use of such agents throughout gestation. The available preliminary studies also indicate that the response of the fetal genital anatomy to treatment is generally good if the treatment is started very early, before week 6. Thereafter, the virilization is reduced. However, it may not be eliminated, and thus at least one reconstructive surgical procedure may still be needed in the infant.[150,384,397,398,405,411]

Successful treatment requires dexamethasone doses of 20 μg/kg of maternal body weight. For a 70-kg woman, this is 1.4 mg, which is equivalent to that in the low-dose dexamethasone suppression test and is at least three times physiologic replacement. However, the fetus normally develops in the presence of very low cortisol concentrations of only about 20 to 60 nmol/L (0.7 to 2.0 μg/dL)[266,412], which is only about 10% of the corresponding maternal level. Thus, the doses used in prenatal treatment appear to achieve effective concentrations of active glucocorticoid that may be up to 60 times physiologic for the fetus. Treatment of pregnant rats with 20 μg/kg dexamethasone predisposes the fetuses to hypertension in adulthood,[413] and some studies indicate that even moderately elevated concentrations of glucocorticoids can be neurotoxic.[414-417]

The potential benefits of prenatal treatment are reduction or elimination of the genital virilization, reducing the risk of gender confusion and the need for surgery. The advocates of prenatal treatment report modest Cushingoid features in the mother and no untoward effects in the offspring, including the seven of eight fetuses in whom the treatment is stopped once the diagnosis is made.[397,409,418] However, there are concerns based on studies using comparable doses of dexamethasone showing reduced weight and growth and adult hypertension in rats.[419,420] Furthermore, short-term high-dose glucocorticoids cause hippocampal damage in monkeys[421] and in newborn children.[408,422]

However, a recent study of 26 dexamethasone-exposed children aged 8 to 17 years and a matched control group showed that the short-term treated children without CAH had poorer working memory and poorer self-perception of scholastic competence (both at $p = 0.003$) and increased self-rated social anxiety ($p = 0.026$).[410] If confirmed, such negative outcomes in unaffected children treated needlessly would indicate that prenatal treatment with dexamethasone should not be pursued and obviate the suggestion that dosing can be reduced in the second half of pregnancy. Alternative approaches, such as preimplantation genetic diagnosis,[423] should be considered, although this also carries some risk.

Experimental Postnatal Treatment of CAH

Children with CAH tend to be short. A meta-analysis of 18 studies of growth in CAH showed final height about 1.4 standard deviations below target height. Most notably, every one of these studies showed a height loss of at least 0.8 standard deviations.[424] Adequacy of salt supplementation appears to have an underappreciated influence on growth.[425] The loss of height in CAH is partially due to the effect of sex steroids on epiphyseal closure and partially due to glucocorticoid-induced resistance to the action of GH. Consequently, multiple studies have addressed optimizing the final height of children with CAH.

Antiandrogens and Aromatase Inhibitors. Antiandrogens and aromatose inhibitors have been tried in the presence of lower doses of glucocorticoids.[426] This approach derives from its successful use in slowing the rapid advancement of bone age found in gonadotropin-independent male sexual precocity (familial testotoxicosis).[427] Estrogen, not androgen, is the key hormone in promoting epiphyseal fusion.[125] Hence, inhibiting the conversion of androgen to estrogen with testolactone promotes growth, whereas antiandrogen treatment ameliorates virilization.

The principal benefit of this approach is that it permits the use of physiologic replacement doses of glucocorticoids (8 mg/m^2/day of hydrocortisone, rather than the traditional supraphysiologic dose of 12 to 15 mg/m^2/day), thus further promoting normal growth. Two-year follow-up data show normal growth and bone maturation,[428] but final heights have not been reported. The drugs are also expensive and not approved for this use, and the child needs to take a very large number of pills, making compliance an issue. Nevertheless, this approach appears to hold great promise, especially if improved aromatase inhibitors and antiandrogens are developed.

Adrenalectomy. Adrenalectomy has been proposed in severe CAH. Because the adrenal carrying severe P450c21 mutations (e.g., gene deletions) cannot produce aldosterone or cortisol, it has been argued that these affected glands do more harm than good and should be removed.[429] The advent of laparoscopic adrenalectomy has made this suggestion feasible without undue trauma to the patient. Among 18 adrenalectomized patients, 5 had adrenal crises when therapy was suboptimal and 2 became hypoglycemic during intercurrent illnesses.[430]

These risks are similar to those faced by children with CAH who do not receive stress-dose steroids. The concern that adrenalectomy will predispose to hypoglycemia because of the removal of adrenal medullary tissue has not been borne out. It should be noted that children with CAH are typically deficient in epinephrine.[309] Thus, although adrenalectomy is an extreme measure it may be appropriate in selected cases.[430]

Growth Hormone and GnRH Agonist Therapy. GH and GnRH agonist therapy have been proposed in children near the age of puberty.[431] Pharmacologic GH therapy may partially overcome the effects of higher doses of glucocorticoids, and GnRH agonist will delay the progression of puberty, permitting more time to grow. Preliminary results with a small group of 14 children experimentally treated with both agents for about 4 years showed an improvement in final height of 0.8 standard deviations compared to historic controls.[432] Both agents are expensive, and further studies are needed to assess the safety and efficacy of this approach.

P450 OXIDOREDUCTASE DEFICIENCY

P450 oxidoreductase (POR) deficiency is a newly recognized form of CAH.[433-438] POR is the protein that transfers electrons from NADPH to all 50 microsomal forms of cytochrome P450, including P450c17, P450c21, and P450aro, and to the drug-metabolizing P450 enzymes of the liver. Because POR participates in so many functions, its mutation might be expected to yield a very severe phenotype. POR-deficient mice die during fetal development.[439,440] However, beginning in 1985 several patients were described with apparent combined deficiencies of P450c17 and P450c21[441-445] and it was suggested that a mutation in POR was responsible,[446] but this was not proven until 2004.[433]

A wide array of POR mutations has now been described, affecting various P450 enzymes to differing degrees, apparently explaining the great variability in the clinical and hormonal findings in POR deficiency.[437] The serum and urinary steroids indicate defects in P450c17 and P450c21, and clinical findings vary from severely affected infants with ambiguous genitalia, cortisol deficiency, and the Antley-Bixler skeletal malformation syndrome (ABS) to mildly affected women who appear to have a form of polycystic ovary syndrome or mildly affected men with gonadal insufficiency. ABS is characterized by craniosynostosis, brachycephaly, radioulnar or radiohumeral synostosis, bowed femora, arachnodactyly, midface hypoplasia, proptosis, and choanal stenosis.

When ABS is seen in association with abnormal steroids and ambiguous genitalia in either sex, the cause is an autosomal-recessive mutation in POR.[433,435-437] By contrast, when ABS is seen without a lesion in steroidogenesis or genital development the cause is an autosomal-dominant gain-of-function mutation in fibroblast growth factor receptor 2.[437,438] Thus, the term *Antley-Bixler syndrome* should be reserved for the phenotypic description of the skeletal malformations and should not be equated with POR deficiency, which may or may not be associated with ABS.[433,434,437,438]

Patients with POR deficiency will typically have normal electrolytes and mineralocorticoid function, nearly-normal levels of cortisol that respond poorly to stimulation with ACTH, high concentrations of 17OHP that respond variably to ACTH, and low levels of C19 precursors to sex steroids. A remarkable feature of POR deficiency is that there is genital ambiguity in both sexes. Females may be virilized, and males may be underdeveloped, although there is considerable variation among individuals. As the 17,20 lyase activity of P450c17 is especially sensitive to perturbations in electron transport,[28,301,302] defects in fetal testicular steroidogenesis leading to incompletely developed external genitalia in 46,XY males is the predicted outcome.

By contrast, the partial virilization seen in 46,XX genetic females appears to be due to two causes. First,

placental aromatase (P450aro) requires POR. Some mothers of infants with POR deficiency experience virilization during pregnancy[433,437,438] similar to that experienced by women carrying a fetus with P450aro deficiency.[125,127] The fetus normally disposes of large amounts of adrenal C19 steroids by excreting them through the placenta, which aromatizes them to the maternal estrogens of pregnancy.[145] A defect in this placental aromatase activity, from mutation of POR or P450aro itself, will permit large amounts of fetal C19 steroids to enter and virilize the mother. This is evidenced by the low estriol values seen in women carrying a fetus with POR deficiency.[447,448]

Second, an alternative "backdoor" pathway of androgen biosynthesis has been described in fetal marsupials in which 17OHP is eventually converted to dihydrotestosterone without utilizing androstenedione and testosterone as intermediates.[449,450] Analysis of urinary steroids from patients with POR deficiency suggests that this pathway also applies to the human fetus.[141,435,438,447,448] The relative importance of these two distinct mechanisms for virilizing the fetus with POR deficiency remains unresolved.

The incidence of POR deficiency is unknown. Because the disorder is newly described, it may seem rare. However, the rapid description of large numbers of patients[437,438] and the potentially very subtle clinical manifestations in individuals carrying mutations with partial activity suggest that POR deficiency may be fairly common. Two mutations are especially common: A287P, the predominant mutation in patients of European ancestry, and R457H, the predominant mutation in patients of Japanese ancestry. Because few patients have been studied in the newborn period, it has not been established whether newborn screening of 17OHP designed to detect 21-hydroxylase deficiency will also detect POR deficiency.

The mechanism linking defective POR activity to the ABS skeletal phenotype remains unclear, although this may be related to the POR-associated defect in cholesterol synthesis. Whereas mice harboring POR defects confined to the liver metabolize drugs poorly and accumulate hepatic lipids,[451,452] similar problems have not yet been described in patients with POR deficiency, although it has been suggested that the presence of POR deficiency in a fetus may render maternally ingested fluconazole teratogenic.[438] Thus, much remains to be learned about POR deficiency.

LESIONS IN ISOZYMES OF P450c11

11β-Hydroxylase Deficiency

There are two distinct forms of 11-hydroxylase. P450c11β mediates the 11β-hydroxylation of 11-deoxycortisol to cortisol and that of DOC to corticosterone in the zonae fasciculata and glomerulosa. P450c11AS (aldosterone synthase) is found only in the zona glomerulosa and mediates 11β-hydroxylation, 18-hydroxylation, and 18-oxidation; thus, it is the sole enzyme required to convert DOC to aldosterone. P450c11β is found in the glomerulosa and fasciculata, and mediates 11β-hydroxylation and some 18-hydroxylation but has no 18-methyl oxidase activity. Deficient P450c11β activity is a rare cause of CAH in persons of European ancestry but accounts for about 15% of cases in Muslim and Jewish Middle Eastern populations.[453]

Severe deficiency of P450c11β decreases the secretion of cortisol, causing CAH and virilization of affected females. The defect in the pathway to cortisol results in accumulation of 11-deoxycortisol, and the defect in the 17-deoxy pathway in the synthesis of corticosterone in the fasciculata may lead to overproduction of DOC. Because DOC is a mineralocorticoid, these patients can retain sodium. Although DOC is less potent than aldosterone, it is secreted at high levels in 11β-hydroxylase deficiency. Thus, salt is retained and serum sodium remains normal.

Overproduction of DOC frequently leads to hypertension. As a result, 11β-hydroxylase deficiency is often termed the *hypertensive form of CAH* when detected in older children. However, newborns often manifest mild transient salt loss,[453,454] presumably as a result of the normal newborn resistance to mineralocorticoids (Figure 12-15). This may lead to incorrect diagnosis and treatment. Thus, there may be a poor correlation among DOC concentrations, serum potassium, and blood pressure or between the degree of virilization in affected females and the electrolyte and cardiovascular manifestations.[455]

Newborns may also have elevated concentrations of 17OHP, presumably as a "backup" phenomenon of high concentrations of 11-deoxycortisol inhibiting P450c21. Thus, P450c11β deficiency may be detected in newborn screening for P450c21 deficiency.[324] The diagnosis is established by demonstrating elevated basal concentrations of DOC and 11-deoxycortisol, which hyperrespond to ACTH. A normal or suppressed plasma renin activity is also a hallmark of this disease.[456]

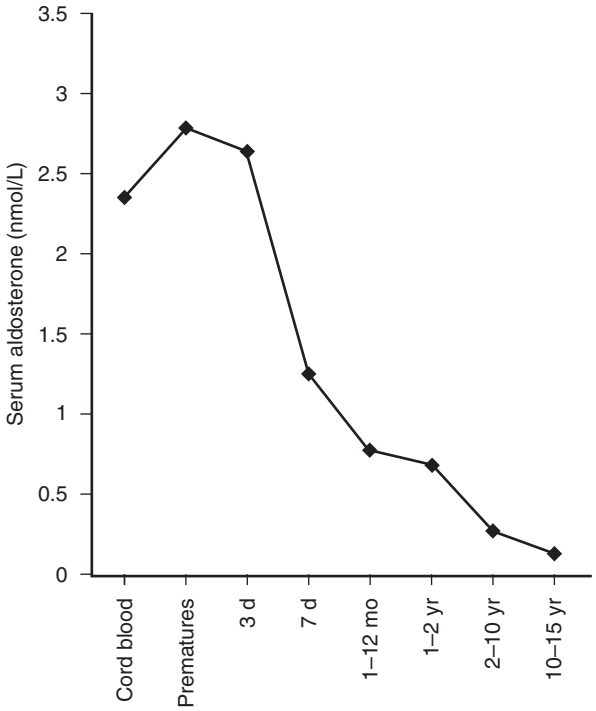

Figure 12-15. Concentrations of aldosterone as a function of age.

The genetic lesions causing 11β-hydroxylase deficiency are in the CYP11B1 gene that encodes P450c11β. In a study of Sephardic Jews of Moroccan ancestry, 11 of 12 affected alleles bore the mutation R448H.[96] However, several other mutations have been described in other populations.[90] A milder nonclassic form of 11β-hydroxylase deficiency analogous to nonclassic 21-hydroxylase deficiency has been reported in otherwise asymptomatic women with hirsutism, virilism, and menstrual irregularities.[453,457]

However, true nonclassic 11β-hydroxylase deficiency is rare. Only two of five hyperandrogenemic women who had 11-deoxycortisol values more than three times higher than the 95th percentile in response to stimulation with ACTH had mutations of P450c11β, all of whom retained 15% to 37% of normal activity.[458] Repeated ACTH testing in two of the three women who lacked mutations showed much lower (but still elevated) 11-deoxycortisol values. Thus, just as in the case of nonclassic 3βHSD deficiency an abnormal steroid response to ACTH is not sufficient to diagnose a genetic lesion.

Corticosterone Methyl Oxidase Deficiencies

P450c11AS, the isozyme of P450c11β that is 93% identical in its amino acid sequence, is expressed exclusively in the zona glomerulosa, where it catalyzes 11β-hydroxylase, 18-hydroxylase, and 18 methyl oxidase activities. P450c11AS and P450c11β are expressed in the human zona glomerulosa, and both can convert DOC to corticosterone. However, the conversion of corticosterone to 18OH-corticosterone and subsequently to aldosterone is exclusively performed by P450c11AS. Disorders of P450c11AS cause the so-called corticosterone methyl oxidase (CMO) deficiencies, wherein aldosterone biosynthesis is impaired but the zona fasciculata and reticularis continue to produce corticosterone and DOC.

The absence of aldosterone biosynthesis will generally result in a salt-wasting crisis in infancy, at which time the normal secretory rate of DOC is insufficient to meet the newborn's mineralocorticoid requirements similarly to the newborn with P450c11β deficiency. Thus, these infants typically present with hyponatremia, hyperkalemia, and metabolic acidosis. However, the salt-wasting syndrome is typically less severe than in patients with 21-hydroxylase deficiency or lipoid CAH because of the persistent secretion of DOC. These patients may recover spontaneously and grow to adulthood without therapy. This probably reflects the increasing sensitivity to mineralocorticoid action with advancing age in childhood, as reflected by the usual age-related decrease in serum aldosterone (Figure 12-15). Consistent with this, plasma renin activity is markedly elevated in affected children but may be normal in affected adults.[459]

CMOI deficiency results from a complete loss of P450c11AS activity, and thus no 18-hydroxylase or 18 methyl oxidase activity persists, eliminating the biosynthesis of 18OH-corticosterone and aldosterone while preserving the biosynthesis of corticosterone by P450c11β. Thus, the diagnosis for CMOI deficiency is usually based on an increased ratio of corticosterone to 18OH corticosterone.[98] Only three cases of CMOI deficiency have been fully characterized genetically, including a frame-shift mutation,[460] a premature stop codon,[461] and the missense mutation R384P.[462]

CMOII deficiency results from amino acid replacement mutations in P450c11AS that selectively delete the 18 methyl oxidase activity while preserving the 18-hydroxylase activity. The diagnosis of CMOII deficiency requires an increased 18OH corticosterone and very low aldosterone concentration. CMOII deficiency is common in Sephardic Jews of Iranian origin, where all affected individuals appear to be homozygous for two different mutations, R181W and V385A.[97] Family members who were homozygous for only one of these mutations were clinically unaffected; both mutations are required to cause disease.

The distinction between CMOI and CMOII is not always clear. One patient with the clinical history and hormonal phenotype of CMOII had two mutations on each parental allele.[99] The mother's allele carried R181W and a deletion/frame-shift mutation that deleted all activity; the father's allele carried T318M and V386A. Thr318 is predicted to be the universally conserved Thr residue in all P450 enzymes that participates in cleavage of the dioxygen bond of O_2 to create the iron-oxy intermediate required for P450 catalysis. When the T318M/V386A double mutant was recreated in vitro, there was no detectable activity.[99] These data would have predicted the CMOI phenotype instead of the patient's CMOII phenotype. Similarly, another patient was homozygous for the missense mutations E198A and V386A. When recreated in vitro, the double mutant enzyme behaved similarly to the mutant enzyme found in the Iranian Jewish CMOII patients. However, the patient's clinical phenotype was CMOI.[463] This patient also carried R173K, but that is a normally occurring polymorphism that has no effect on the enzyme's K_m or V_{max}.[464] Thus, the distinction between CMOI and CMOII is not precise, and these disorders should be regarded as different degrees of severity on a continuous clinical spectrum, just as the various forms of 21-hydroxylase deficiency are part of a broad clinical spectrum.

Although rats have four CYP11B genes encoding three P450c11 enzymes, it is clear that there are only two CYP11B genes in the human genome, encoding P450c11β and P450c11AS.[465] This genetic anatomy is reminiscent of the P450c21A and P450c21B genes. Although gene conversion can cause CMO II deficiency,[466] gene conversion appears to be much rarer than in the P450c21 locus. This may be due to the higher recombinational frequency in the HLA region carrying the P450c21 genes, or it may be related to the abundant antisense transcripts produced in the P450c21 locus.[333,467]

Glucocorticoid-Suppressible Hyperaldosteronism

Although gene conversions events in the P450c11 locus are rare, an unusual gene duplication causes glucocorticoid-suppressible hyperaldosteronism.[468-470] This homologous recombination event creates a third CYP11B gene that fuses the 5 flanking DNA of the CYP11B1 gene for P450c11β onto the CYP11B2 gene for P450c11AS. In two such patients, the genetic crossover occurred in intron 2, and in two other patients it occurred in intron 3 or exon

4.[469] All of these hybrid genes produce a hybrid P450c11 that retains aldosterone synthase activity. However, as the hybrid gene has P450c11β regulatory regions its transcription is induced by ACTH and cAMP, as is the normal gene for P450c11β. Thus, these patients make P450c11AS in response to physiology that should stimulate P450c11β. The excess P450c11AS causes hyperaldosteronism and hypertension. This is then suppressible by glucocorticoid suppression of ACTH, which normally suppresses P450c11β.

It is conceivable that localized microconversions, similar to those that cause most cases of 21-hydroxylase deficiency, could insert sequences crucial for aldosterone synthase activity into the gene encoding P450c11β. Expression of chimeric proteins produced in vitro identified the residues Ser288 and Val320 as important to this activity.[471] Similarly, activating mutations that increase the aldosterone synthase activity of P450c11AS have been created in vitro.[472] However, examination of large numbers of patients with low-renin hypertension has failed to show mutations in this gene system other than the gene conversions described previously that cause glucocorticoid-suppressible hypertension.[464,473,474]

LESIONS IN ISOZYMES OF 11β-HYDROXYSTEROID DEHYDROGENASE

Cortisone and prednisone are inactive pro-hormones that must be reduced to cortisol or prednisolone in order to bind to and activate the glucocorticoid receptor. The interconversion of these keto- and hydroxysteroids is catalyzed by the two isozymes of 11β-hydroxysteroid dehydrogenase, 11βHSD1 and 11βHSD2. Both enzymes are reversible in vitro, and hence both can act as an oxidase or reductase, depending on the availability of cofactors. However, under physiologic situations 11βHSD1 generally acts to activate cortisone to cortisol and 11βHSD2 reverses this activation.[23,475]

Thus, 11βHSD1 is primarily expressed in liver and fat[476] and 11βHSD2 is expressed in mineralocorticoid-responsive tissues, where it inactivates cortisol, permitting low concentrations of aldosterone to activate mineralocorticoid receptors, which also bind cortisol. 11βHSD2 is inactive against aldosterone, DOC, and fludrocortisol. Interest in these enzymes extends far beyond their deficiency states, as they play central roles in metabolism.[476,477]

Lesions in 11βHSD1—Apparent Cortisone Reductase Deficiency

Defects in 11βHSD1 impair cortisol feedback at the hypothalamic/pituitary axis, increasing the secretion of ACTH and consequently increasing adrenal C19 steroid secretion, resulting in hyperandrogenism, sexual precocity, and polycystic ovaries. Only about 10 such patients have been described.[475] A similar clinical picture is seen in disorders of hexose-6-phosphate dehydrogenase (H6PDH), which generates the NADPH used by 11βHSD1 in the lumen of the endoplasmic reticulum.[139,478] Both disorders are diagnosed from urinary steroids, which show a marked reduction in ratio of metabolites of cortisol to those of cortisone. Variations in 11βHSD1 appear to make a relatively minor contribution to the common forms of polycystic ovary syndrome.[479-481]

Lesions in 11βHSD2—Apparent Mineralocorticoid Excess

Patients with apparent mineralocorticoid excess (AME) have hypervolemic hypertension, salt retention, and hypokalemic alkalosis—the classic picture of hyperaldosteronism, but with suppressed plasma renin activity and without measurable serum mineralocorticoids due to recessive mutations of 11βHSD2.[132] About 30 different mutations in 11βHSD2 have been described in about 60 patients with AME.[482,483] Preliminary evidence suggests that heterozygous carriers may have an increased risk of hypertension.[484]

Typical features of children with AME include failure to thrive, delayed puberty, polydipsia, polyuria, muscle weakness, and hypertension. The hypertension is severe, often causing end-organ damage at an early age. Diagnosis is made from the high ratio of urinary metabolites of cortisol to cortisone. Treatment includes antagonism of the mineralocorticoid receptor with spironolactone, correction of the hypokalemia, low-salt diets, and diuretics. Treatment is only partially successful, and 10% of patients die from cerebrovascular accidents.[485]

Adrenal Insufficiency

Many conditions will cause adrenal insufficiency, including CAH, hypopituitarism with ACTH deficiency, and primary adrenal disorders. Primary adrenal insufficiency is commonly termed *Addison disease,* but this is a vague term that encompasses many disorders. Up to World War II, most patients with "Addison disease" had tuberculosis of the adrenal, but more than 80% of contemporary adult patients have autoimmune adrenalitis. Therefore, the term *Addison disease* is now widely used to indicate an autoimmune or idiopathic cause.[486]

The spectrum of adrenal disorders presenting in infants, children, and adolescents differs from that presenting in adulthood (Table 12-8). CAH and autoimmune adrenal disease represent the largest proportions of cases, but some of the inherited developmental and metabolic causes of adrenal failure are also fairly common.[486,487] Diagnosing some of these disorders is important to assessing potential associated features, initiating long-term management, and instituting genetic counseling.[488] Adrenal disorders are typically divided into chronic and acute causes, but many acute presentations reflect an undiagnosed underlying chronic or developmental process (Table 12-9). Acute presentations may be triggered by intercurrent illness, trauma, or surgery, with poor fluid and sodium intake.

ACUTE PRIMARY ADRENAL INSUFFICIENCY

Acute adrenal crisis occurs most commonly in the child with undiagnosed chronic adrenal insufficiency who is subjected to an additional severe stress such as major illness, trauma, or surgery. The major presenting symptoms and signs include abdominal pain, fever, hypoglycemia

TABLE 12-8

Causes of Adrenal Insufficiency

Primary Adrenal Insufficiency
- Congenital adrenal hyperplasia
- Autoimmune disorders
  - Autoimmune adrenalitis
  - Autoimmune polyglandular syndromes
- Adrenal hypoplasia congenita
  - X-linked adrenal hypoplasia
  - Other (SF1, IMAGe syndrome)
- ACTH resistance syndromes
  - Familial glucocorticoid deficiencies, types 1 and 2
  - Triple A (Allgrove) syndrome
- Metabolic disorders
  - Adrenoleukodystrophy
  - Peroxisome biogenesis disorders (e.g., Zellweger)
  - Cholesterol metabolism (Smith-Lemli-Opitz, Wolman)
  - Mitochondrial (Kearn-Sayres, mitochondrial deletions)
- Infectious disorders
  - Sepsis
  - Tuberculosis
  - Fungal infections
  - Viral
- Infiltrative/destructive causes
  - Hemorrhage
  - Amyloidosis, sarcoidosis, metastases
- Drugs inhibiting steroid biosynthesis

Secondary Adrenal Insufficiency
- Hypothalamic tumors, radiation or surgery
- Hypopituitarism
- Isolated ACTH insufficiency
- Defects in POMC synthesis and processing
- Withdrawl from glucocorticoid therapy

TABLE 12-9

Signs and Symptoms of Adrenal Insufficiency

Features Shared by Acute and Chronic Insufficiency
- Anorexia
- Apathy and confusion
- Dehydration
- Fatigue
- Hyperkalemia
- Hypoglycemia
- Hyponatremia
- Hypovolemia and tachycardia
- Nausea and vomiting
- Postural hypotension
- Prolonged neonatal jaundice
- Salt craving
- Weakness

Features of Acute Insufficiency (Adrenal Crisis)
- Abdominal pain
- Fever

Features of Chronic Insufficiency (Addison Disease)
- Decreased pubic and axillary hair
- Diarrhea
- Hyperpigmentation
- Low-voltage electrocardiogram
- Small heart on x-ray
- Weight loss

with seizures, weakness, apathy, nausea, vomiting, anorexia, hyponatremia, hypochloremia, acidemia, hyperkalemia, hypotension, shock, cardiovascular collapse, and death. Treatment consists of fluid and electrolyte resuscitation, ample doses of glucocorticoids, chronic glucocorticoid and mineralocorticoid replacement, and treatment of the precipitating illness.

Massive adrenal hemorrhage with shock due to blood loss can occur in large infants who have had a traumatic delivery.[489] A flank mass is usually palpable and can be distinguished from renal vein thrombosis by microscopic rather than gross hematuria. The diagnosis is then confirmed by CT or ultrasonography.[490] Massive adrenal hemorrhage is more commonly associated with meningococcemia (Waterhouse-Friderichsen syndrome). Meningitis is often present. The characteristic petechial rash of meningococcemia can progress rapidly to large ecchymoses. The blood pressure drops and respirations become labored, frequently leading rapidly to coma and death. Immediate intervention with intravenous fluids, antibiotics, and glucocorticoids is not always successful. A similar adrenal crisis may also occur rarely with septicemia from *Streptococcus, Pneumococcus, Pseudomonas*, diphtheria, and methicillin-sensitive and -resistant isolates of *Staphylococcus aureus*.[491] Adrenal hemorrhage has also been reported with the antiphospholipid syndrome and in patients on anticoagulant therapy.

CHRONIC PRIMARY ADRENAL INSUFFICIENCY

Autoimmune Disorders

Autoimmune adrenalitis is most commonly seen in adults 25 to 45 years old, about 60% to 70% of whom are women. The prevalence in adults is about 1 in 25,000.[492] Autoimmune destruction of other endocrine tissues is frequently associated with autoimmune adrenalitis. Chronic adrenal insufficiency is suggested by poor weight gain or weight loss, weakness, fatigue, anorexia, hypotension, hyponatremia, hypochloremia, hyperkalemia, frequent illnesses, nausea, and vague gastrointestinal complaints (Table 12-9), reflecting chronic deficiency of glucocorticoids and mineralocorticoids.

Early in the course of autoimmune adrenalitis, one may see signs of glucocorticoid deficiency (weakness, fatigue, weight loss, hypoglycemia, anorexia) without signs of mineralocorticoid deficiency (hyponatremia, hyperkalemia, acidosis, tachycardia, hypotension, low voltage on EKG, small heart on chest x-ray) or evidence of mineralocorticoid deficiency without glucocorticoid deficiency. Thus, an initial clinical presentation that spares one category of adrenal steroids does not mean it will be spared in the long run. The symptoms listed in Table 12-9 can be seen in primary or secondary chronic adrenal insufficiency. In primary chronic adrenal insufficiency, the low concentrations of plasma cortisol stimulate the hypersecretion of ACTH and other POMC peptides, including the various forms of melanocyte-stimulating hormone (MSH). Consequently, chronic primary adrenal insufficiency is

also characterized by hyperpigmentation of the skin and mucous membranes, whereas secondary adrenal insufficiency is not.

Such hyperpigmentation is most prominent in skin exposed to sun and in flexor surfaces such as knees, elbows, and knuckles. The diagnosis is suggested by the previosly cited signs and symptoms, verified by a low morning cortisol level with a high ACTH and confirmed by a minimal response of cortisol to a 60-minute intravenous ACTH test. Hyponatremia, hyperkalemia, low aldosterone, and elevated PRA suggest a disturbance in mineralocorticoid production. Associated findings may include the appearance of a small heart on chest x-ray, anemia, azotemia, eosinophilia, lymphocytosis, and hypoglycemia. Treatment of chronic primary adrenal insufficiency consists of physiologic glucocorticoid and mineralocorticoid replacement therapy.

Autoimmune adrenalitis is strongly associated with specific HLA haplotypes and with polymorphisms in the gene for cytotoxic T-lymphocyte-associated antigen 4 (CLTA 4), which may be broadly involved in susceptibility to autoimmune disease.[493-495] The diagnosis of autoimmune chronic adrenal insufficiency is based largely on finding circulating antibodies directed against adrenal cells or adrenal cellular content. In many cases, the adrenal antigens are steroidogenic cytochrome P450 enzymes, especially P450scc, P450c17, and P450c21.[492,496,497]

It is not clear how these enzymes reach immune cells to elicit an antibody response, but autopsy studies show infiltration of the adrenal cortex.[486] Thus, it is likely that cell-mediated immunity is responsible for destruction of adrenocortical cells, resulting in a secondary discharge of cellular content including P450 enzymes into the circulation, with subsequent development of secondary "marker" antibodies against these P450s. About half of adult patients with lymphocytic adrenalitis will also have autoimmune disease of another endocrine tissue with high titers of antibodies directed against specific content of the affected tissue. This finding has led to the definition of specific autoimmune polyendocrine syndromes (APS), some of which are more prevalent in childhood.

Type 1 Autoimmune Polyendocrine Syndrome. Type 1 autoimmune polyendocrine syndrome (APS1), also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dysplasia (APECED), is characterized by chronic mucocutaneous candidiasis, autoimmune Addison disease, and hypoparathyroidism.[492,498] At least two of these features must be present to make the diagnosis, and their age of onset can be highly variable. In general, chronic mucocutaneous candidiasis appears in early childhood and affects the mouth and nails. Acquired hypoparathyroidism can present with clinical hypocalcemia during mid or late childhood, although in some cases hypocalcemia may be masked by untreated adrenal insufficiency. The adrenal disorder usually presents in childhood or adolescence. Autoimmune adrenal disease may be a presenting feature in about 5% of cases.[498]

Additional autoimmune features of this condition include alopecia and vitiligo; gastritis, chronic diarrhea, and malabsorption with or without pernicious anemia; hypergonadotropic hypogonadism, especially in women; and less commonly hepatitis, thyroiditis, interstitial nephritis, myositis, dental enamel hypoplasia, acquired asplenia, and type 1 diabetes mellitus. Keratoconjunctivitis is an important associated feature that requires careful monitoring and treatment to prevent blindness. Oral or esophageal squamous cell carcinoma occurs in 10% of individuals as adults.[498] APS1 is rare in most populations, but is common among people of Finnish (1:15,000), Sardinian, and Iranian Jewish (1:9,000) ancestry.[486]

APS1 is caused by recessively inherited mutations in a 58-kDa transcription factor called AIRE for autoimmune regulator.[499,500] More than 50 different mutations in this gene have been described, although the homozygous or compound heterozygous R257X change is especially common in the Finnish population. The AIRE gene is widely expressed in developing tissues of the immune system. The specific mechanisms by which these mutations result in the pleotropic findings of APS1 are not yet clear, although deletion of AIRE in mice results in ectopic expression of peripheral tissue antigens in thymic medullary epithelial cells, resulting in the development of an autoimmune disorder similar to APS1/APECED.[501,502]

Type 2 Autoimmune Polyendocrine Syndrome. Type 2 autoimmune polyendocrine syndrome (APS2), also known as Schmidt's syndrome, refers to the relatively common association of autoimmune adrenalitis with thyroiditis and/or type 1 diabetes.[492] APS2 is more common in females (3:1 ratio), is HLA linked, and is generally seen in young or middle-aged adults. However, it can present at almost any age. Primary (hypergonadotropic) ovarian failure is seen in up to one-quarter of postpubertal females with APS2, but primary testicular failure is rare.[486] Pernicious anemia, hepatitis, vitiligo, and alopecia may also be seen, but the hypoparathyroidism and mucocutaneous candidiasis typical of APS1 are not seen in APS2. APS2 is associated with the same HLA markers as idiopathic autoimmune adrenalitis, which may simply be a form of APS2.

Adrenal Hypoplasia Congenita

Adrenal hypoplasia congenita, also known as congenital adrenal hypoplasia, is a disorder of adrenal development resulting in primary adrenal insufficiency. This condition can occur with several different inheritance patterns, and with a variety of associated or syndromic features.

X-Linked Adrenal Hypoplasia Congenital. Adrenal hypoplasia congenital (AHC) is caused by mutations of the DAX1 (NR0B1) gene on chromosome Xp21. It is the most prevalent form of primary adrenal hypoplasia, with more than 200 individuals or families identified to date.[503,504] In AHC, the definitive zone of the fetal adrenal does not develop, and the fetal zone is vacuolated and cytomegalic. About half of boys with AHC present with salt loss and glucocorticoid insufficiency in early infancy. The rest present more insidiously with chronic adrenal insufficiency throughout childhood.[487] Hypogonadotropic hypogonadism or arrested puberty is an associated feature, although early puberty with subsequent pubertal arrest has been reported in rare cases. An underlying defect in spermatogenesis may also be present.

DAX1 encodes a nuclear transcription factor involved in adrenal and testicular development, as well as being

expressed in the pituitary gonadotropes. About two-thirds of boys with AHC have DAX1 point mutations.[487,504] The other third have DAX1 gene deletions either in isolation or as part of a contiguous gene deletion syndrome involving a telomeric X-linked mental retardation locus (IL1RAPL1) and/or centromeric loci for glycerol kinase deficiency (GKD), and sometimes ornithine transcarbamylase (OTC) and Duchenne muscular dystrophy (DMD). An adult-onset form of AHC due to point mutations in DAX1 has also been described in several patients.[505]

Boys with AHC respond well to glucocorticoid and mineralocorticoid replacement therapy; sexual maturation with testosterone is required in adolescence. Spontaneous fertility is rare, and attempts to induce spermatogenesis with gonadotropins are rarely successful. Alternative forms of fertility treatment such as intracytoplasmic sperm injection have not been reported. Female carriers of DAX1 mutations or deletions are unaffected, but half of their sons will be affected. Close monitoring and genetic counseling can help prevent life-threatening adrenal crises in other family members or future pregnancies.[506] Thus, a family history of adrenal failure, unexplained death, or pubertal abnormalities in the male relatives of a boy with adrenal insufficiency should suggest AHC. Indeed, a substantial proportion of boys with sporadic adrenal hypoplasia have DAX1 mutations.[487]

Autosomal Forms of Adrenal Hypoplasia. Autosomal forms of adrenal hypoplasia exist, but the underlying basis for these conditions is poorly understood. Heterozygous or homozygous mutations in the nuclear receptor steroidogenic factor-1 (SF1, NR5A1) have been reported in 46,XY phenotypic females with spontaneous or recessively inherited primary adrenal failure, and a heterozygous SF1 mutation has been described in a 46,XX girl with adrenal dysfunction.[269-271] However, SF1 mutations have not been found in phenotypic males with adrenal hypoplasia or adrenal steroidogenic defects.[487]

Primary adrenal failure has been associated with Pena-Shoekir syndrome type I, pseudotrisomy 13, Meckel syndrome, Pallister-Hall syndrome (GLI3), and defects in WNT3.[14] Primary adrenal hypoplasia also appears to be part of the IMAGE (intrauterine growth retardation, metaphyseal dysplasia, adrenal hypoplasia, genitourinary anomalies) syndrome.[507] A number of individuals and families with this syndrome have now been reported, but the underlying etiology of this condition remains unknown.[508]

ACTH Resistance Syndromes

Hereditary unresponsiveness to ACTH (familial glucocorticoid deficiency) can present as an acute adrenal crisis precipitated by an intercurrent illness in an infant or with the signs and symptoms of chronic adrenal insufficiency in childhood. A number of distinct recessively inherited causes of FGD have been identified and mutations in these genes have been found in over half the patients with these conditions.[509]

Unlike individuals with autoimmune adrenalitis, adrenal hypoplasia, or other forms of destruction of adrenal tissue patients with hereditary unresponsiveness to ACTH typically continue to produce mineralocorticoids because production of aldosterone by the adrenal zona glomerulosa is regulated principally by the renin-angiotensin system. Thus, the presenting picture consists of failure to thrive, lethargy, pallor, hyperpigmentation, and hypoglycemia, often associated with seizures. Rare cases may also entail electrolyte abnormalities or increased plasma renin activity, leading to misdiagnosis as a different form of adrenal insufficiency.[510]

Familial Glucocorticoid Deficiency Type 1. Familial glucocorticoid deficiency type 1 results from autosomal recessive mutations in the G-protein–coupled ACTH receptor (MC2R).[233,509,511] More than 20 MC2R mutations have been reported in more than 40 individuals or families, accounting for approximately 25% of cases of ACTH resistance. The mutation S74I is especially prevalent. Individuals with FGD1 have the typical presentation of glucocorticoid deficiency; hypoglycemia is common, and ACTH levels can be markedly elevated with consequent hyperpigmentation. Tall stature and increased head circumference have been reported in several cases.[511,512] Treatment with replacement doses of glucocorticoids typically prevents adrenal crises, but may not suppress elevated ACTH levels completely. Nevertheless, the use of supraphysiologic doses of steroids to suppress ACTH should be avoided.[509]

Familial Glucocorticoid Deficiency Type 2. Familial glucocorticoid deficiency type 2 is clinically indistinguishable from FGD1 and is caused by mutations in the melanocortin 2 receptor accessory protein, MRAP,[509,513] accounting for about 20% of cases of ACTH resistance. The MRAP protein (α-isoform) is expressed in a variety of tissues, where it seems to play a role in trafficking the ACTH receptor from the endoplasmic reticulum to the cell membrane. Whether the MRAP protein plays a role in the trafficking of other melancortin receptors, or whether and extended phenotype exists, remains to be seen. Additional genetic loci for other forms of FGD are under investigation (e.g., FGD3, 8q12.1-21.2).[509]

Triple A (Allgrove) Syndrome. Triple A (Allgrove) syndrome consists of ACTH-resistant adrenal (glucocorticoid) deficiency (80% of individuals), achalasia of the cardia (85%), and alacrima (90%).[514] Mineralocorticoid insufficiency is reported in about 15% of cases, and many patients have progressive neurologic symptoms such as intellectual impairment, sensorineural deafness, peripheral and cranial neuropathies, optic atrophy, Parkinsonism, and autonomic dysfunction.[233,515,516] Triple A syndrome is caused by autosomal-recessive mutations in AAAS, which encodes a WD-repeat protein termed *ALADIN*.[517,518] This protein localizes to the cytoplasmic side of the nuclear pore, where it may play a role in nuclear import.[519] Clinical findings can be quite variable even within the same family. Adrenal insufficiency is rarely the presenting feature. Thus, a detailed family history of achalasia, alacrima, or neurologic disorders is important when evaluating a patient with primary adrenal failure.

Metabolic Disorders

Metabolic disorders can also cause chronic primary adrenal insufficiency, including adrenoleukodystrophy (Schilder disease), peroxisome biosynthesis disorders (e.g.,

Zellweger syndrome spectrum), disorders of cholesterol synthesis and metabolism (e.g., Wolman disease, cholesterol ester storage disease, Smith-Lemli-Opitz syndrome), and mitochondrial disorders (e.g., Kearns-Sayre syndrome).

Adrenoleukodystrophy. Adrenoleukodystrophy (ALD) is the most common metabolic disorder causing adrenal failure. Most cases are caused by mutations in the peroxisomal membrane protein ALDP (ABCD1, Xq28),[520,521] which belongs to the superfamily of ATP-binding cassette transporters. The prevalence of this condition is generally reported to be between 1:20,000 and 1:100,000, although the overall frequency may be as high as 1:17,000.[522] A rare autosomal-recessive form of this condition also exists, which usually presents in infancy. ALDP imports activated acyl-CoA derivatives (VLCFA-CoA) into peroxisomes, where they are shortened by β-oxidation.[523,524] Consequently, ALD is characterized by high ratios of C26 to C22 very-long-chain fatty acids in plasma and tissues, permitting the diagnosis of individual patients and affected fetuses.[525] Carriers can usually be detected by very-long-chain fatty acid screening, although genetic analysis may be necessary in some cases. Symptoms of X-linked ALD commonly develop in midchildhood, but a variant of the disorder, termed *adrenomyeloneuropathy*, presents in adulthood.[526] The same ALDP mutation can cause adrenoleukodystrophy and adrenomyeloneuropathy, and hence it is likely that other genetic loci are involved.[527] Earliest findings are associated with the central nervous system leukodystrophy and include behavioral changes, poor school performance, dysarthria, and poor memory progressing to severe dementia.

Symptoms of adrenal insufficiency usually appear after symptoms of white matter disease, but adrenal insufficiency may be the initial finding in up to 20% of children or young adults.[522,528,529] By contrast, adrenomyeloneuropathy typically begins with adrenal insufficiency in childhood and adolescence, and signs of neurologic disease follow 10 to 15 years later. About 1% to 3% of female carriers of X-linked ALD may develop neurologic symptoms or adrenal dysfunction. Because screening is accurate and the diagnosis has long-term implications, very-long-chain fatty acids should be analyzed in all boys presenting with adrenal failure where the diagnosis is not clear. Dietary therapy with so-called Lorenzo's oil, a 4:1 mixture of glyceryl-trioleate and glyceryl-trierucate, improves VLCFA levels, but it has been ineffective for the treatment of established cerebral disease, although a role in preventing the onset of cerebral disease is being evaluated.[522,527] Other therapeutic options include hematopoietic stem cell transplantation for early cerebral disease and lovastatin.[522,524]

Peroxisome Biogenesis Disorders. Peroxisome biogenesis disorders (PBDs) are a group of autosomal-recessive conditions caused by mutations in PEX proteins that include Zellweger syndrome (ZS), neonatal adrenoleukodystrophy (NALD), infantile Refsum's disease (IRD), and rhizomelic chondrodysplasia punctata (RCDP).[530,531] ZS, NALD, and IRD form the "Zellweger spectrum" and are clinically distinct from RCDP. These disorders are characterized by developmental delay, hypotonia, neurosensory deafness, optic atrophy, and dysmorphic facial development. The diagnosis can be confirmed by the presence of C26:1, increased C26:0, and an increased ratio of C26:C22 and C24:C22 very-long-chain fatty acids. Most children with the severe forms of ZS and NALD do not survive past 2 years, although other variants of the Zellweger spectrum are associated with longer survival.[532]

Wolman Disease. Wolman disease or primary xanthomatosis, and cholesterol ester storage disease are disorders in the secreted form of lysosomal acid lipase (cholesterol esterase) that mobilizes cholesterol esters from adrenal lipid droplets.[533] The gene for this enzyme, LIPA, has been cloned and mutations causing Wolman disease have been identified.[534] Because insufficient free cholesterol is available to P450scc, there is adrenal insufficiency.

The disease is less severe than congenital lipoid adrenal hyperplasia with respect to steroidogenesis, and patients may survive for several months after birth. However, the disease affects all cells, not just steroidogenic cells, as all cells must store and utilize cholesterol. Hence, the disorder is relentless and fatal. Vomiting, steatorrhea, failure to thrive, and hepatosplenomegaly are the usual presenting findings. Characteristic bilateral adrenal calcification may be seen on pre- or postnatal ultrasound scan. The diagnosis is established by bone marrow aspiration yielding foam cells containing large lysosomal vaccuoles engorged with cholesterol esters, and is confirmed by finding absent cholesterol esterase activity in fibroblasts, leukocytes, or bone marrow cells. Cholesterol ester storage disease appears to be a milder defect in the same enzyme, generally presenting in childhood or adolescence among the few reported cases.

Smith-Lemli-Opitz Syndrome. Smith-Lemli-Opitz syndrome is a defect in cholesterol biosynthesis, resulting from abnormalities in the sterol Δ-7-reductase gene DHCR7.[535] Associated features of this condition include microcephaly, developmental delay, a typical facial appearance, proximal thumbs and syndactyly of the second and third toes, cardiac abnormalities, and underdeveloped genitalia in males. Adrenal insufficiency is present in a proportion of cases, especially during times of stress or when LDL-derived cholesterol sources are inadequate (e.g., dietary insufficiency/bile salt depletion).[536] Biochemical analysis of sterol Δ-7-reductase activity, coupled with genetic analysis, can confirm the diagnosis.

Mitochondrial Disorders. Mitochondrial disorders can be associated with primary adrenal dysfunction.[537] Typical clinical features include lactic acidosis, cataracts, sensorineuronal deafness, and myopathy/ophthalmoplegia. The Kearns-Sayre syndrome results from large-scale deletions of mitochondrial DNA and can be associated with additional endocrinopathies such as hypothyroidism, hypogonadism, diabetes, growth failure, and hypoparathyroidism.

Other Causes

Chronic adrenal insufficiency may result from other causes. Hemorrhage and infections, discussed previously as causes of acute primary adrenal insufficiency, may

spare some adrenal tissue, leaving severely compromised rather than totally absent adrenal function. The result, as with autoimmune adrenalitis, is a chronic disorder with insidious onset of the broad range of nonspecific findings described previously. Tuberculosis, fungal infections (e.g., histoplasmosis, coccidiomycosis), viral infections (e.g., HIV, CMV), metastases, amyloidosis, and sarcoidosis may cause a similar clinical picture. Cortisol biosynthesis can also be inhibited by aminoglutethimide, etomidate, suramin, and ketoconazole.

SECONDARY ADRENAL INSUFFICIENCY

ACTH is required for adrenal cellular growth and for transcription of genes for steroidogenic factors. Hence, any impairment of ACTH synthesis or release can cause secondary adrenal insufficiency. Examples include hypothalamic defects, hypopituitarism, disorders of POMC synthesis and processing, and suppression of the hypothalamic-pituitary axis following exogenous steroid treatment.

Most forms of secondary adrenal insufficiency affect glucocorticoid and androgen synthesis rather than mineralocorticoid release because angiotensin II is the primary drive to the zona glomerulosa. However, the clinical and biochemical assessment may be complicated because glucocorticoids are necessary for renal free water clearance and concomitant vasopression (AVP, ADH) insufficiency may be present. In fact, treatment of secondary adrenal insufficiency can unmask a previously inapparent deficiency of antidiuretic hormone (ADH) and thus precipitate diabetes insipidus. Therefore, close attention must be given to fluid and electrolyte balance when steroid replacement is introduced. Conversely, the hypothyroidism resulting from TSH deficiency will result in slowed metabolism of the small amount of cortisol produced and therefore protect the patient from the symptoms of adrenal insufficiency. Treatment of hypothyroidism with thyroxine will accelerate metabolism of these small amounts of cortisol, thus unmasking adrenal insufficiency due to ACTH deficiency and on occasion precipitating an acute adrenal crisis. Therefore, careful evaluation of the pituitary-adrenal axis is required in hypopituitarism with secondary hypothyroidism.

Many clinicians will choose to "cover" a patient with small doses of glucocorticoids (one-fourth to one-half of physiologic replacement) during initial treatment of such secondary hypothyroidism. Finally, it is important to appreciate that combined deficiency of GH and ACTH will strongly predispose the patient to hypoglycemia because both hormones act to raise plasma glucose. This effect is especially important in infancy and early childhood, when children are vulnerable to hypoglycemia during periods of prolonged fasting.

Hypothalamic Causes

Hypothalamic causes of ACTH insufficiency include tumors and radiotherapy. Tumors, such as craniopharyngioma,[538] are associated with ACTH deficiency in about 25% of patients.[539,540] The frequency may be higher in tumors such as germinoma and astrocytoma.[541] Adrenal insufficiency is rarely the presenting complaint but may contribute to the clinical picture. After surgery and/or radiation therapy, the great majority of patients with hypothalamic tumors will have ACTH deficiency as part of their surgical or radiation-induced hypothalamic-pituitary damage. Therefore, all such patients should receive glucocorticoid coverage during treatment irrespective of the status of the hypothalamic-pituitary-adrenal axis at the time the tumor is identified.

Because treatment of secondary adrenal insufficiency can precipitate diabetes insipidus, close attention to water balance is essential. ACTH insufficiency can also result following whole-brain irradiation for brain tumors and other central malignancies. This may involve both hypothalamic and pituitary mechanisms. The frequency of ACTH insufficiency in such cases is much lower than following the treatment of hypothalamic tumors, but may manifest some years after treatment.[542]

ACTH Deficiency

ACTH may be deficient as part of a multiple pituitary hormone deficiency (MPHD, panhypopituitarism) or as isolated ACTH insufficiency. MPHD can result from pituitary surgery or radiotherapy, from an infiltrative process (e.g., Langerhans cell histiocytosis), or from a poorly understood form of hypothalamic dysfunction. In most cases, GH secretion is lost first, followed in order by gonadotropins, TSH, and ACTH. Thus, ongoing vigilance and assessment of these patients is required for many years. MPHD can also result from disorders of hypothalamic-pituitary development involving transcription factors such as HESX1, LHX4, and SOX3. Associated features such as optic nerve hypoplasia (HESX1) and cerebellar abnormalities (LHX4) may help to focus the diagnosis. Impaired ACTH secretion has also been described in individuals with PROP1 mutations, one of the most frequent genetic causes of MPHD. This finding can occur many years after presentation with GH, TSH, and gonadotropin deficiency, highlighting the importance of long-term follow-up of patients with pituitary disorders.[543,544]

Patients with MPHD often have a relatively mild form of adrenal insufficiency. Mineralocorticoid secretion is normal, whereas cortisol secretion is reduced but not absent. However, adrenal reserve is severely compromised by the chronic understimulation of steroidogenic enzyme biosynthesis. Because some cortisol synthesis continues, the diagnosis may not be apparent unless a CRF or metyrapone test of pituitary ACTH production capacity and an intravenous ACTH test of adrenal reserve are performed. This can be especially true when TSH deficiency is a component of hypopituitarism, as outlined previously. Treatment of secondary hypothyroidism with thyroxine will accelerate metabolism of these small amounts of cortisol, thus unmasking adrenal insufficiency due to ACTH deficiency and, on occasion, precipitating an acute adrenal crisis.

Isolated ACTH insufficiency is a rare condition that can be caused by recessively inherited mutations in TPIT (TBX19). TPIT encodes a T-box factor that regulates

transcription of the POMC promoter in corticotropes.[545] These patients usually present with severe early-onset ACTH insufficiency.[546,547] Hypoglycemia and prolonged jaundice are frequently present, and neonatal death may result.[548] Because this defect is confined to POMC synthesis in the corticotropes, the additional features of generalized POMC deficiency outlined in material following are not present. TPIT mutations are not found in approximately half of patients with isolated ACTH insufficiency, suggesting that other causes are yet to be found. Hypocortisolemia due to isolated ACTH insufficiency has also been described with hippocampal (memory) defects and hair abnormalities (alopecia) as part of the triple H syndrome, a possible autoimmune association.[549]

Disorders of POMC

Defects in POMC synthesis and processing can also cause abnormal ACTH production and action. Recessively inherited mutations or deletion of the POMC gene will affect multiple POMC peptides, including MSH and β-endorphin. Thus, red hair, pale skin, and obesity are associated features of this form of secondary adrenal insufficiency.[165] These clinical signs may be more subtle in individuals with naturally dark hair and pigmented skin, or red hair may darken in adulthood.[550] Mutations in prohormone convertase 1 (PC1, PCSK1), required for the processing of POMC to ACTH, cause abnormal cleavage and processing of several hormone systems, including the generation of bioactive ACTH from POMC.[551] Patients with this rare recessive disorder can have hypocortisolemia together with abnormal glucose metabolism, obesity, hypogonadotropic hypogonadism, and persistent malabsorptive diarrhea.[551,552]

Long-Term Steroid Therapy

Long-term glucocorticoid therapy can suppress POMC gene transcription and the synthesis and storage of ACTH. Furthermore, long-term therapy apparently decreases the synthesis and storage of CRF and diminishes the abundance of receptors for CRF in the pituitary. Therefore, recovery of the hypothalamic-pituitary axis from long-term glucocorticoid therapy entails recovery of multiple components in a sequential cascade and hence often requires considerable time (see section on glucocorticoid therapy and withdrawal). Patients successfully withdrawn from glucocorticoid therapy or successfully treated for Cushing disease may exhibit a fairly rapid normalization of plasma cortisol values while continuing to have diminished adrenal reserve for more than 6 months.

Inhaled steroids, nasal sprays, and even steroid eye drops can cause suppression of the adrenal axis. Thus, vigilance may be needed following their withdrawal or at time of additional stress (e.g., surgery, intercurrent illness).[553-555] Although treatment with cortisone and prednisone during pregnancy will result in minimal suppression of the fetal adrenal, because of the protective effects of placental 11βHSD, dexamethasone treatment in pregnancy can affect fetal adrenal steroidogenesis.

Adrenal Excess

CUSHING SYNDROME

The term *Cushing syndrome* describes any form of glucocorticoid excess. Cushing disease designates hypercortisolism due to pituitary overproduction of ACTH. The related disorder caused by ACTH of nonpituitary origin is termed the *ectopic ACTH syndrome*. The term *Cushing syndrome* is sometimes used to refer specifically to hypersecretion of cortisol from adrenal tumors, but this is ambiguous and should be avoided. Other causes of Cushing syndrome include adrenal adenoma, adrenal carcinoma, and multinodular adrenal hyperplasia. All of the previously cited conditions are distinct from iatrogenic Cushing syndrome, which is the clinical constellation resulting from administration of supraphysiologic quantities of ACTH or glucocorticoids.

Although generally described in great detail and illustrated with striking photographs in endocrine texts, Cushing disease is fairly rare in adults.[556] Furthermore, about 25% of patients referred to large centers for Cushing disease are children. Thus, it is becoming increasingly clear that pediatric Cushing disease is more common than previously recognized. Many patients first seen as adults actually experience the onset of symptoms in childhood or adolescence. Harvey Cushing's original patient was a young woman of only 23 years whose history and clinical features indicated long-standing disease.[2] Hence, many patients with Cushing syndrome can be detected in the pediatric age group.

In adults and children over 7 years of age, the most common cause of Cushing syndrome is true Cushing disease, adrenal hyperplasia due to hypersecretion of pituitary ACTH.[557] Boys are more frequently affected than girls in the prepubertal period, although the sex ratios are equal during adolescence and women have a higher incidence of Cushing disease in adulthood.[558] In infants and children under 7 years, adrenal tumors predominate. Among 60 infants under 1 year of age with Cushing syndrome, 48 had adrenal tumors[559] (Table 12-10).

TABLE 12-10

Etiology of Cushing Syndrome in Infancy

	Males	Females
Adrenal tumors (n = 48)		
Carcinoma	5	20
Adenoma	4	16
Not defined	2	1
Ectopic ACTH syndrome	1	1
Nodular adrenal hyperplasia	1	4
Undefined adrenal hyperplasia	2	2
ACTH-producing tumor	1	0
TOTAL	16	44

Data from Miller WL, Townsend JJ, Grumbach MM, Kaplan SL (1979). An infant with Cushing's disease due to an adrenocorticotropin-producing pituitary adenoma. J Clin Endocrinol Metab 48:1017–1025.

Clinical Findings

The physical features of Cushing syndrome are familiar to virtually all physicians. Central obesity, "moon facies," hirsutism, and facial flushing are seen in more than 80% of adults with Cushing syndrome. Striae, hypertension, muscular weakness, back pain, "buffalo hump" fat distribution, psychological disturbances, acne, and easy bruising are also very commonly described (35% to 80%). However, these are the signs and features of advanced Cushing disease. When annual photographs of such patients are available, it is often apparent that these features can take 5 years or longer to develop. Thus, the classic "Cushingoid appearance" will usually not be the initial picture seen in the child with Cushing syndrome. The earliest and most reliable indicators of hypercortisolism in children are weight gain and growth arrest[560] (Table 12-11).

Cumulative data from three large studies of pediatric Cushing disease identified weight gain at presentation in 91/97 (94%) cases and growth failure in 82/95 (86%) cases.[560-562] Thus, any overweight child who stops growing should be evaluated for Cushing syndrome. Glucocorticoids suppress growth by increasing hypothalamic secretion of somatostatin, by suppressing GH receptor and insulin-like growth factor 1 production, and by acting directly on the epiphyses to inhibit sulfation of cartilage, inhibit mineralization, and inhibit cell proliferation. By contrast, children with simple dietary obesity often grow more rapidly and are tall for their age, presumably due to chronic secondary hyperinsulinism. The obesity of Cushing disease in children is initially generalized rather than centripetal, and a buffalo hump is evidence of long-standing disease.

Psychological disturbances, especially compulsive overachieving behavior, are seen in about 40% of children and adolescents with Cushing disease[560] and are distinctly different from the depression typically seen in adults.[563] Emotional lability has been described in approximately 30% of cases.[562] An underappreciated aspect of pediatric Cushing disease is the substantial degree of bone loss and undermineralization in these patients.[560,564,565] It is likely that Cushing disease is generally regarded as a disease of young adults because the diagnosis was missed, rather than absent, during adolescence. Rarely, Cushing syndrome caused by adrenal carcinoma or the ectopic ACTH syndrome can produce a rapid fulminant course.

TABLE 12-11

Findings in 39 Children with Cushing Disease

Sign/Symptom	No. of Patients	%
Weight gain	36/39	92
Growth failure	31/37	84
Ostopenia	14/19	74
Fatigue	26/39	67
Hypertension	22/35	63
Delayed or arrested puberty	21/35	60
Plethora	18/39	46
Acne	18/39	46
Hirsutism	18/39	46
Compulsive behavior	17/39	44
Striae	14/39	36
Bruising	11/39	28
Buffalo hump	11/39	28
Headache	10/39	26
Delayed bone age	2/23	13
Nocturia	3/39	8

Data from Devoe DJ, Miller WL, Conte FA, Kaplan SL, Grumbach MM, Rosenthal SM, et al. (1997). Long-term outcome of children and adolescents following transsphenoidal surgery for Cushing disease. J Clin Endocrinol Metab 82:3196–3202.

Cushing Disease

The recent development of transsphenoidal surgical approaches to the pituitary has led to pituitary exploration in large numbers of patients with Cushing disease. Among adults, more than 90% of such patients have identifiable pituitary microadenomas.[563,566] These tumors are generally 2 to 10 mm in diameter, are not encapsulated, have ill-defined boundaries, and are frequently detectable with a contrast-enhanced pituitary MRI. These tumors are often identifiable only by minor differences in their appearance and texture from surrounding tissue. Thus, the frequency of surgical cure is correlated with the technical skill of the surgeon. Although histologic techniques may not distinguish the tumor from normal tissue, molecular biologic techniques confirm increased synthesis of POMC in these tissues.[567]

Among children and adolescents, about 80% to 85% of those with Cushing disease have surgically identifiable microadenomas.[220,560,568] Although removal of the tumor usually appears curative, 20% of such "cured" patients suffer relapse and again manifest Cushing disease within about 5 years. The net cure rate is thus 65% to 75%.[560-562,569,570] Transsphenoidal surgery offers the best initial approach for rapid and complete cure of most patients, but alternative approaches may be necessary in younger children if sphenoid sinus aeration has not yet occurred.

Control of hypercortisolemia is important in the perioperative period. Careful monitoring for recovery of the hypothalamic-pituitary-adrenal axis is necessary over several months because stress responses may be diminished despite normal basal cortisol secretion. Short-term consequences of transsphenoidal surgery include transient diabetes insipidus and cerebrospinal fluid rhinorrhea.[561,562,571] Persistent panhypopituitarism is rare, but the effects of hypercortisolism on GH secretion may remain for 1 to 2 years after treatment, and GH deficiency can occur even in those children who have not received irradiation.[561,562,571] Final height may be reduced by 1.5 to 2.0 standard deviations by the long-term hypercortisolism.[560,572] Treatment with GH may ameliorate this growth loss in patients with GH insufficiency.[573,574]

The high cure rate of transspenoidal microadenomectomy in Cushing disease indicates that the majority of such patients have primary disease of the pituitary itself, rather than secondary hyperpituitarism resulting from hyperstimulation of the pituitary by CRF or other agents. Careful follow-up studies of these patients confirm this.[560,568,569] In most postoperative patients, the circadian rhythms of ACTH and cortisol return to normal, ACTH and cortisol respond appropriately to hypoglycemia, cortisol is easily

suppressed by low doses of dexamethasone, and the other hypothalamic-pituitary systems return to normal.

However, some patients with Cushing disease have no identifiable microadenoma, and some "cured" patients relapse. This suggests that this smaller population of patients may have a primary hypothalamic disorder, or that the region of the pituitary responsible for ACTH hypersecretion was not excised. Effective treatment of Cushing disease with cyproheptidine, a serotonin antagonist, has been reported in adults, further suggesting a hypothalamic disturbance. Thus, present clinical investigation suggests that Cushing disease is usually caused by a primary pituitary adenoma but can sometimes be caused by hypothalamic dysfunction. Microsurgery can be curative in the former but not the latter. Unfortunately, no diagnostic maneuver is available to distinguish the two possibilities. Thus, transsphenoidal exploration remains the preferred initial therapeutic approach to the patient with Cushing disease.

The management of nonresponsive or relapsed Cushing disease is challenging. Repeat transsphenoidal surgery is typically the first approach, especially if there is evidence of a distinct lesion or unilateral hypersecretion of ACTH. Second-line approaches include hypophysectomy, gamma-knife irradiation, cyproheptidine, adrenalectomy, and drugs that inhibit adrenal function. All have significant disadvantages, especially in children.

Hypophysectomy will also eliminate pituitary secretion of GH, TSH, and gonadotropins, causing growth failure, hypothyroidism, and failure to progress in puberty respectively. Although hypothyroidism is easily treated with oral thyroxine replacement, GH deficiency requires very expensive replacement therapy. Sex steroid replacement can be used to achieve secondary sexual characteristics at the age of puberty. However, gonadotropin replacement or pulsatile gonadotropin-releasing hormone therapy will be needed to achieve fertility. Pituitary irradiation has been touted to avoid many of these problems and is effective in treating Cushing disease, but GH deficiency occurs in most cases and additional endocrinopathies can occur with time.[575] The interval from radiotherapy to cure can be more than 1 year, during which time therapeutic blockage of hypercortisolemia is necessary to prevent the ongoing effects of Cushing disease on growth, weight, and bone mineralization. Furthermore, large doses of radiation increase the risk of cerebral arteritis, leukoencephalopathy, leukemia, glial neoplasms, and bone tumors involving the skull. Stereotactic radiotherapy may reduce these potential effects, but few data exist yet in children. Cyproheptidine has met with virtually no success in pediatric Cushing disease, in part due to the unacceptable side effects (weight gain, irritability, hallucinations) often seen with the needed doses.

Adrenalectomy is the preferred approach in our centers when two transsphenoidal procedures fail. In addition to the obvious effects of eliminating normal production of glucocorticoids and mineralocorticoids, removal of the adrenal eliminates the physiologic feedback inhibition of the pituitary. In some adults, this results in the development of pituitary macroadenomas, producing very large quantities of ACTH. These can expand and impinge on the optic nerves and can produce sufficient POMC to yield enough MSH to produce profound darkening of the skin (Nelson syndrome). However, this is rarely seen in children.

There is relatively little pediatric experience with ketoconazole and other drugs that inhibit steroidogenesis, but these may provide a useful form of therapy for selected patients or for controlling hypercortisolemia in the short term.[576] Metyrapone is not useful for long-term therapy. Ortho-para DDD (mitotane), an adrenolytic agent, may be used to effect a "chemical adrenalectomy." However, its side effects of nausea, anorexia, and vomiting are severe. Etomidate may be useful in the acute setting for severe or life-threatening Cushing disease prior to surgery.[577,578]

Other Causes of Cushing Syndrome

Ectopic ACTH Syndrome. Ectopic ACTH syndrome is commonly seen in adults with oat cell carcinoma of the lung, carcinoid tumors, pancreatic islet cell carcinoma, and thymoma. Ectopically produced POMC and ACTH are derived from the same gene that produces pituitary POMC,[154] but the ectopic form is not sensitive to glucocorticoid feedback in the malignant cells. This phenomenon permits distinction between pituitary and ectopic ACTH by suppressibility of the former by high doses of dexamethasone. Although the ectopic ACTH syndrome is rare in children, it has been described in infants younger than 1 year of age. Associated tumors have included neuroblastoma, pheochromocytoma, and islet cell carcinoma of the pancreas.[579]

The ectopic ACTH syndrome is typically associated with ACTH concentrations 10 to 100 times higher than those seen in Cushing disease. However, both adults and children with this disorder may show little or no clinical evidence of hypercortisolism, probably due to the typically rapid onset of the disease and to the general catabolism associated with malignancy. Unlike patients with Cushing disease, adults and children with the ectopic ACTH syndrome frequently have hypokalemic alkalosis, presumably because the extremely high levels of ACTH stimulate the production of DOC by the adrenal fasciculata and may also stimulate the adrenal glomerulosa in the absence of hyperreninemia.[579]

Adrenal Tumors. Adrenal tumors, especially adrenal carcinomas, are the more typical cause of Cushing syndrome in infants and small children[580] (Table 12-10). These tend to occur with much greater frequency in girls. The reason for this is unknown.[581] Adrenal adenomas almost always secrete cortisol, with minimal secretion of mineralocorticoids or sex steroids. By contrast, adrenal carcinomas tend to secrete both cortisol and androgens and are often associated with progressive virilization.[582,583] Adrenal adenoma or carcinoma may be associated with congenital bodily asymmetry (hemihypertrophy), sometimes as part of the Beckwith-Wiedemann syndrome, or with germ-line mutations or loss-of-heterozygocity of the tumor suppressor gene p53, sometimes as part of the Li-Fraumeni syndrome.[584]

CT and MRI are useful in the diagnosis of adrenal tumors, and steroid analysis can be informative at the time

of presentation and for monitoring for potential relapse. The treatment for both adenoma and carcinoma is surgical, and complete resection is needed for cure. In some cases, the histologic differentiation of adrenal adenomas and carcinomas is difficult. However, a worse prognosis is associated with increased tumor size, capsular and/or vascular invasion, or metastases.[583,585,586] Although a few patients with residual or metastatic disease have done well with adjunctive therapy with ortho-para DDD or other chemotherapeutic strategies, the general prognosis is poor.

ACTH-Independent Multinodular Adrenal Hyperplasia. ACTH-independent multinodular adrenal hyperplasia, also called primary pigmented adrenocorticoid disease (PPNAD), is a rare entity characterized by the secretion of cortisol and adrenal androgens.[587,588] It is seen in infants, children, and young adults, with females affected more frequently. It is usually seen as part of the Carney complex, which is a form of multiple endocrine neoplasia (MEN) consisting of pigmented lentigines and blue nevi on the face, lips, and conjunctiva and a variety of tumors, including schwannomas and atrial myxomas, and occasionally GH-secreting pituitary adenomas, Leydig cell tumors, calcifying Sertoli cell tumors (which may secrete estrogens), and medullary carcinoma of the thyroid.[588,589]

Typical features of Cushing syndrome are often seen in the pediatric population.[590] The adrenals are not truly hyperplastic but consist of discrete pigmented nodules surrounded by atrophic tissue, which permits their identification by MRI or CT. Because the hypercortisolism is resistant to suppression with high doses of dexamethasone and because both glucocorticoids and sex steroids are produced, this entity was difficult to distinguish from the ectopic ACTH syndrome before plasma ACTH assays became routinely available. Complete adrenalectomy is usually indicated, although some successes have been reported with subtotal resections.

Carney complex, like other MEN disorders, is typically autosomal dominant. Loss of heterozygosity and mutations in a regulatory subunit of protein kinase (PRKAR1A) on chromosome 17q22-24 have been found in about 40% of patients with Carney complex,[591-593] or as sporadic germ-line or somatic events in adrenal tumors.[594] Mutations in the gene encoding phosphodiesterase 11A4 (PDE11A) have also been reported in individuals with adrenocortical hyperplasia.[595] Together with reports of multinodular adrenal hyperplasia due to gain-of-function G-protein (GNAS) mutations in the McCune-Albright syndrome, it is becoming clear that abnormalities in signaling pathways play an important role in adrenal hyperplasia and even tumorigenesis.[596]

Differential Diagnosis

The suspicion of Cushing syndrome in children is usually raised by weight gain, growth arrest, mood change, and change in facial appearance (plethora, acne, hirsutism). The diagnosis in children may be subtle and difficult when it is sought at a relatively early point in the natural history of the disease. Absolute elevations above the upper limits of normal for concentrations of plasma ACTH and cortisol are often absent. Rather than finding morning concentrations of cortisol >20 μg/dL or of ACTH >50 pg/mL, it is more typical to find mild and often equivocal elevations in the afternoon and evening values. This loss of the diurnal rhythm, evidenced by continued secretion of ACTH and cortisol throughout the afternoon, evening, and nighttime, is usually the earliest reliable laboratory index of Cushing disease. A single plasma cortisol measurement obtained at midnight from an in-dwelling venous catheter while the patient remains asleep should be less than 2 μg/dL in normal individuals and more than 2 μg/dL in Cushing disease.[597] By contrast, the values for ACTH and cortisol are typically extremely high in the ectopic ACTH syndrome, whereas cortisol is elevated but ACTH suppressed in adrenal tumors and in multinodular adrenal hyperplasia (Table 12-12).

Petrosal sinus sampling is widely used in adults with Cushing disease to distinguish pituitary Cushing disease from the ectopic ACTH syndrome. The smaller vascular bed in children increases the risk of this procedure, but inferior petrosal venous sampling has been used with some success in adolescents in an attempt to localize pituitary adenomas prior to surgery.[598] Such approaches should only be undertaken in specialist centers. Jugular venous sampling may provide an alternative approach, although extensive data in the pediatric population are not available.[599]

In all forms of Cushing syndrome, monitoring of the 24-hour urinary free cortisol assists in deciding whether further investigations are warranted in the obese child. Several repeat collections should be taken, and it is important to use normal ranges adjusted for size as well as age because children with simple obesity have higher cortisol secretion rates.

Low- and high-dose dexamethasone suppression tests can be useful when done with care. To achieve reliable results in pediatric patients, children should be hospitalized, preferably on a "metabolic ward" or pediatric clinical research ward. Two days of baseline (control) data should be obtained. Low-dose dexamethasone (20 μg/kg/day, up to a maximum of 2.0 mg) should be given, divided into equal doses given every 6 hours for 2 days followed by high-dose dexamethasone (80 μg/kg/d) given in the same fashion. Eight AM and 8:00 PM (or midnight) values for ACTH and cortisol and 24-hour urine collections for 17OHS, 17KS, free cortisol, and creatinine (to monitor the completeness of the collection) should be obtained on each of the 6 days of the test.

Measurements of either urinary free cortisol or 17OHCH are probably equally reliable if the laboratory has established good pediatric standards. Because of variations due to episodic secretion of ACTH, the 8:00 AM and 8:00 PM blood values should be drawn in triplicate at 8:00, 8:15, and 8:30. In patients with exogenous obesity or other non-Cushing disorders, cortisol, ACTH, and urinary steroids will be suppressed readily by low-dose dexamethasone. Plasma cortisol should be less than 5 μg/dL, ACTH less than 20 pg/mL, and 24-hour urinary 17OHS less than 1 mg/g of creatinine. Patients with adrenal adenoma, adrenal carcinoma, or the ectopic ACTH syndrome will have values relatively insensitive to both low- and high-dose dexamethasone, although some patients with multinodular adrenal hyperplasia may respond to high-dose suppression, and a

TABLE 12-12

Diagnostic Values in Various Causes of Cushing Syndrome

Test		Normal Values	Adrenal Carcinoma	Adrenal Adenoma	Nodular Adrenal Hyperplasia	Cushing Disease	Ectopic ACTH Syndrome
Plasma cortisol concentration	AM	>14	↑	↑	↑	±	↑↑
	PM	<8	↑	↑	↑	↑	↑↑

Plasma concentration DHEA or DHEA-S			↑↑	↓	± ↑	↑	↑

Cortisol concentration in μg/dL.
ACTH concentration in pg/mL.
Dex = dexamethasone.
17OHCS in mg/24 hr.
AM typically refers to 8:00 AM PM refers to 4:00 PM

paradoxical rise in cortisol following dexamethasone has been reported with the Carney complex.[589,600]

Patients with Cushing disease classically respond with a suppression of ACTH, cortisol, and urinary steroids during the high-dose treatment but not during the low-dose treatment. However, some children, especially those early in the course of their illness, may exhibit partial suppression in response to low-dose dexamethasone. Thus, if the low dose that is given exceeds 20 μg/kg/day or if the assays used are insufficiently sensitive to distinguish partial from complete suppression false negative tests may result. In general, the diagnosis of Cushing disease is considerably more difficult to establish in children than in adults.

VIRILIZING AND FEMINIZING ADRENAL TUMORS

Most virilizing adrenal tumors are adrenal carcinomas producing a mixed array of androgens and glucocorticoids. Virilizing and feminizing adrenal adenomas are quite rare. Virilizing tumors in boys will have a presentation similar to that of simple virilizing congenital adrenal hyperplasia. There will be phallic enlargement, erections, pubic and axillary hair, increased muscle mass, deepening of the voice, acne, and scrotal thinning. However, the testicular size will be prepubertal. Elevated concentrations of testosterone in young boys alter behavior, with increased irritability, rambunctiousness, hyperactivity, and rough play, but without evidence of libido. Diagnosis is based on hyperandrogenemia unsuppressable by glucocorticoids. The treatment is surgical. All such tumors should be handled as if they are malignant, with care exerted not to cut the capsule and seed cells onto the peritoneum. The pathologic distinction between adrenal adenoma and carcinoma is difficult.

Feminizing adrenal tumors are extremely rare in either sex. P450aro, the enzyme aromatizing androgenic precursors to estrogens, is not normally found in the adrenals but is found in peripheral tissues such as fat. It is not known whether most feminizing adrenal tumors exhibit ectopic adrenal production of this enzyme, whether some other enzyme mediates aromatization in the tumor, or whether these are truly androgen-producing virilizing tumors occurring in a setting where there is unusually effective peripheral aromatization of adrenal androgens.

Feminizing adrenal or extra-adrenal tumors can be distinguished from true central precocious puberty in

girls by the absence of increased circulating concentrations of gonadotropins and by a prepubertal response of luteinizing hormone to an intravenous challenge of gonadotropin-releasing hormone (LRF, GnRH). In boys, such tumors will cause gynecomastia, which will resemble the benign gynecomastia that often accompanies puberty. However, as with virilizing adrenal tumors, testicular size and the gonadotropin response to LRF testing will be prepubertal. The diagnosis of a feminizing tumor in a pubertal boy can be extremely difficult, but it is usually suggested by an arrest in pubertal progression and can be proved by the persistence of circulating plasma estrogens after administration of testosterone.

OTHER DISORDERS

Conn Syndrome

Conn syndrome, characterized by hypertension, polyuria, hypokalemic alkalosis, and low plasma renin activity due to an aldosterone-producing adrenal adenoma, is well described in adults but is exquisitely rare in children. The diagnostic task is to differentiate primary aldosteronism from physiologic secondary hyperaldosteronism occurring in response to another physiologic disturbance. Any loss of sodium, retention of potassium, or decrease in blood volume will result in hyperreninemic secondary hyperaldosteronism. Renal tubular acidosis, treatment with diuretics, salt-wasting nephritis, and hypovolemia due to nephrosis, ascites, or blood loss are typical settings for physiologic secondary hyperaldosteronism. Primary aldosteronism is characterized by hypertension and hypokalemic alkalosis. The cause is a small adrenal adenoma, usually confined to one adrenal. Both adrenals need to be explored surgically because adrenal vein catheterization is not possible in children and is difficult in adults.

Familial Glucocorticoid Resistance

Familial glucocorticoid resistance is a very rare disorder caused by mutations in the α-isoform of the glucocorticoid receptor. Decreased glucocorticoid action results in grossly increased ACTH secretion, which in addition to stimulating the production of cortisol stimulates the production of other adrenal steroids. Thus, these patients may present with fatigue, hypertension, and hypokalemic alkalosis, suggesting a mineralocorticoid excess syndrome but may also have hyperandrogenism.[601] Circadian rhythmicity is maintained and resistance to dexamethasone suppression is observed. Patients have been described who are homozygous for missense mutations[602] or who are heterozygous for a gene deletion.[603] Thus, in each case some receptor activity remains. Heterozygous point mutations with incomplete dominant negative activity or multiple effects on GRα action have also been described.[604] About 10 different GRα mutations have been reported, half of which are familial and half of which appear sporadic. These point mutations may interfere with GRα-dependent transcriptional regulation through altered DNA binding, impaired ligand binding, delayed nuclear localization, abnormal nuclear aggregation, and disrupted interaction with coactivators, depending on the position of the mutation.[601] No patients have been described with homozygous deletion of this receptor. However, glucocorticoid receptor-knockout mice also have disordered hepatic gluconeogenesis, absent adrenomedullary chromaffin cells, and die from neonatal respiratory distress syndrome.[605] Thus, familial glucocorticoid resistance is a syndrome of only partial resistance to the action of glucocorticoids.

Pseudohypoaldosteronism

Pseudohypoaldosteronism (PHA) is a rare salt-wasting disorder of infancy characterized by hyponatremia, hyperkalemia, and increased plasma renin activity in the face of elevated aldosterone concentrations. The more common autosomal-recessive form of PHA (pseudohypoaldosteronism type II) is caused by inactivating mutations in any of the three subunits (α, β, γ) of the amiloride-sensitive sodium channel ENaC.[606] This condition is often associated with lower respiratory tract disease consisting of chest congestion, cough, and wheezing, but not pulmonary infections, because ENaC mutations increase the volume of pulmonary fluid.[607] This disease persists into adulthood, requiring vigorous salt-replacement therapy throughout life. Gain-of-function mutations due to carboxy-terminal truncation of β-ENaC cause Liddle's syndrome, an autosomal-dominant form of salt-retaining hypertension.[606]

Autosomal-dominant type 1 pseudohypoaldosteronism (PHA type I) is caused by inactivating mutations in the mineralocorticoid receptor.[608] Approximately 20 different mutations have been found in this receptor, which interfere with mineralocorticoid binding and gene transcription.[609] This disease is milder than the recessive forms of PHA caused by ENaC mutations and remits with age, but requires sodium replacement therapy in infancy and childhood. Rarely, point mutations in the mineralocorticoid receptor have been found in association with an autosomal-dominant form of severe hypertension, which begins in adolescence and worsens in pregnancy.[610] In these cases, alterations in the structure of the ligand-binding domain of the mineralocorticoid receptor result in mild constitutive activation as well as permitting binding and activation of the receptor by progesterone.

An acquired transient form of PHA is often seen in infants with obstructive uropathy, especially shortly following surgical relief of the obstruction.[611] The lesion is renal tubular[612] and thus mineralocorticoid treatment is generally ineffective. Salt replacement generally suffices while the renal lesion resolves.

Glucocorticoid Therapy and Withdrawal

Since their introduction into clinical medicine in the early 1950s, glucocorticoids have been used to treat virtually every known disease.[613] At present their rational use falls into two broad categories: replacement in adrenal insufficiency and pharmacotherapeutic use. The latter category is largely related to the anti-inflammatory properties of glucocorticoids but also includes their actions to lyse

leukemic leukocytes, lower plasma calcium concentrations, and reduce increased intracranial pressure.

Virtually all of these actions are mediated through glucocorticoid receptors, which are found in most cells. Because there appears to be only one major type of glucocorticoid receptor, clearly all glucocorticoids will affect all tissues containing such receptors. Thus, with the exception of the distinction between glucocorticoids and mineralocorticoids, tissue-specific, disease-specific, or response-specific analogues of naturally occurring glucocorticoids cannot be produced. The only differences among the various glucocorticoid preparations are their ratio of glucocorticoid to mineralocorticoid activity, their capacity to bind to various binding proteins, their molar potency, and their biologic half-life. Dexamethasone is commonly used in reducing increased intracranial pressure and brain edema. Neurosurgical experience indicates that the optimal doses are 10 to 100 times those that would thoroughly saturate all available receptors, suggesting that this action of dexamethasone may not be mediated through the glucocorticoid receptor.

Glucocorticoids are so termed because of their major actions to increase plasma concentrations of glucose. This occurs by their induction of the transcription of the genes encoding the enzymes of the Embden-Meyerhof glycolytic pathway and other hepatic enzymes that divert amino acids, such as alanine, to the production of glucose. Thus, the coordinated action to increase the transcription of these genes can result in increased plasma concentrations of glucose, obesity, and muscle wasting. The other features of Cushing syndrome are similarly attributable to the increased transcriptional activity of specific glucocorticoid-sensitive genes.

REPLACEMENT THERAPY

Glucocorticoid replacement therapy is complicated by undesirable side effects with even minor degrees of overtreatment or undertreatment. Overtreatment can cause the signs and symptoms of Cushing syndrome; and even minimal overtreatment can impair the growth of children. Undertreatment will cause the signs and symptoms of adrenal insufficiency (Table 12-9) only if the extent of undertreatment (dose and duration) are considerable. However, undertreatment may impair the individual's capacity to respond to stress. Glucocorticoid replacement therapy is most commonly employed in congenital adrenal hyperplasia. However, in this setting undertreatment will lead to overproduction of adrenal androgens, which will hasten epiphyseal maturation and closure and thus compromise ultimate adult height. Therefore, when formulating a program of adrenal replacement therapy for the growing child, it is crucial to mimic the normal endogenous production of glucocorticoids.

To optimize pediatric glucocorticoid replacement therapy, astute physicians have gauged their therapy to resemble the endogenous secretory rate of cortisol. Based on studies from the 1960s, most authorities recommend treatment equivalent to a secretory rate of 12.5 mg of cortisol/m^2 of body surface area per day. It is important to remember that when this value was determined experimentally it was reported as 12.5 ± 3.0 mg/m^2/day, and thus the normal range of requirements was 9.5 to 15.5 mg/m^2/day. Thus, the range of normal values varies considerably, indicating that therapy must be tailored and individualized for each patient to achieve optimal results. More recent data suggest that the time-honored value of 12.5 mg/m^2 may be too high, and that appropriate replacement might be as low as 6 mg/m^2 in younger children and 9 mg/m^2 in older children and adolescents.[224,225]

The management of this delicate balance between overtreatment and undertreatment of the child requiring replacement therapy is thus confounded by considerable variation in the "normal" cortisol secretory rate among different children of the same size and the probability that most conventional guidelines err on the side of overtreatment. However, several additional factors must be considered in tailoring a specific child's glucocorticoid replacement regimen.

The specific form of adrenal insufficiency being treated significantly influences therapy. When treating autoimmune adrenalitis or any other form of "Addison disease," it is prudent to err slightly on the side of undertreatment. This will eliminate the possibility of glucocorticoid-induced iatrogenic growth retardation and will permit the pituitary to continue to produce normal to slightly elevated concentrations of ACTH. This ACTH will continue to stimulate the remaining functional adrenal steroidogenic machinery and will provide a fairly convenient means of monitoring the effects of therapy. By contrast, when treating severe virilizing congenital adrenal hyperplasia, the adrenal should be suppressed more completely because essentially all adrenal steroidogenesis will result in the production of unwanted androgens, with their consequent virilization and rate of advancement of bony maturation that is more rapid than the rate of advancement of height. As stated previously, however, overtreatment will also compromise growth.

The presence or absence of associated mineralocorticoid deficiency is an important variable. Children with mild degrees of mineralocorticoid insufficiency, such as those with "simple virilizing" congenital adrenal hyperplasia, may continue to have mildly elevated ACTH values, suggesting insufficient glucocorticoid replacement in association with elevated PRA. In some children, the ACTH is elevated in response to chronic compromised hypovolemia, attempting to stimulate the adrenal to produce more mineralocorticoid. In these children, who do not manifest overt signs and symptoms of mineralocorticoid insufficiency, treatment with mineralocorticoid replacement may permit one to decrease the amount of glucocorticoid replacement needed to suppress plasma ACTH and urinary 17KS. This reduction in glucocorticoid therapy reduces the likelihood that adult height will be compromised.

The specific formulation of glucocorticoid used is also of great importance. Extremely potent long-acting glucocorticoids, such as dexamethasone or prednisone, are preferred in the treatment of adults but are rarely appropriate for replacement therapy in children. Because children are continually growing and changing their weights and body surface areas, it is necessary to adjust their dose frequently. Small incremental changes are more easily done with relatively weaker glucocorticoids. It is easy to

change from 25 to 30 mg of hydrocortisone but virtually impossible to change from an equivalent 0.5 to 0.6 mg of dexamethasone. Tablets are not available in 0.1-mg increments.

The efficacy of attempting to mimic the physiologic diurnal variation in steroid hormone secretion remains controversial. Because ACTH and cortisol concentrations are high in the morning and low in the evening, it is intellectually and logically appealing to attempt to duplicate this circadian rhythm in replacement therapy. However, the results do not clearly indicate that better growth is achieved by giving relatively larger doses in the morning and lower doses at night. This probably reflects the fact that ACTH and cortisol secretion are episodic throughout the day and that this well-established circadian variation is not smooth. The pattern of high in the morning and low in the evening is only an averaged result. Furthermore, the adrenal releases cortisol episodically throughout the day in response to various physiologic demands such as hypoglycemia, exercise, stress, etc. Thus, under normal circumstances, the plasma concentrations are high when the clearance and disposal rates are also high. A planned program of replacement therapy cannot possibly anticipate these day-to-day variations.

Finally, dosage equivalents among various glucocorticoids can be misleading. Virtually all handbooks of therapy publish tables of equivalency for the most commonly used pharmaceutical preparations of glucocorticoids. A similar set of equivalencies is outlined in Table 12-7. Because most preparations of glucocorticoids are intended for pharmacotherapeutic use rather than replacement therapy, and because the most common indication for pharmacologic doses of glucocorticoids is for their anti-inflammatory properties, virtually all tables of glucocorticoid equivalencies are based on anti-inflammatory immunosuppressive equivalencies.

However, the differences in the plasma half-life and ability to bind to plasma proteins result in different biologic equivalencies when one assesses, for example, anti-inflammatory versus growth-suppressant equivalencies. For example, dexamethasone is widely reported as being 25 to 30 times more potent than cortisol when its anti-inflammatory capacities are measured. However, the growth-suppressant activity of dexamethasone is about 80 times that of cortisol[393] (Table 12-7). Thus, all of the variables discussed previously explain why there is little unanimity in recommendations for designing a glucocorticoid replacement regimen. However, an understanding of these variables will permit appropriate monitoring of the patient and encourage the physician to vary the treatment according to the responses and needs of the individual child.

COMMONLY USED GLUCOCORTICOID PREPARATIONS

Numerous chemical derivatives and variants of the naturally occurring steroids are commercially available in a huge array of dosage forms, vehicles, and concentrations, all carrying confusing and uninformative brand names. Choosing the appropriate product can be simplified by considering only the most widely used steroids listed in Table 12-7. As indicated in the table, there are four relevant considerations in the choice of which drug to use.

First, the glucocorticoid potency of the various drugs is generally calculated and described according to the anti-inflammatory potency. The pharmaceutical industry has chosen this standard for convenience and because the majority of their sales are to physicians using pharmacologic doses of these steroids to achieve anti-inflammatory effects.

Second, the growth-suppressant effect of a glucocorticoid preparation may be significantly different from its anti-inflammatory effect. This is due to differences in half-life, metabolism and protein binding, and receptor affinity potency but is not due to receptor specificity because all known receptor-mediated effects of glucocorticoids are mediated through a single type of receptor.

Third, the mineralocorticoid activity of various glucocorticoid preparations varies widely. Glucocorticoid and mineralocorticoid hormones can bind to glucocorticoid (type I) and mineralocorticoid (type II) receptors, and most authorities now regard these as two different types of glucocorticoid receptors and find that there is no true specific mineralocorticoid receptor. Mineralocorticoid activity is intimately related to the activity of 11βHSD, which metabolizes glucocorticoids but not mineralocorticoids to a form that cannot bind the receptor. Thus, the relative mineralocorticoid potency of various steroids is determined by their affinity for the type II receptor and their resistance to the activity of 11βHSD. An understanding that some commonly used glucocorticoids, such as cortisol, cortisone, prednisolone, and prednisone, have significant mineralocorticoid activity is especially important when large doses of glucocorticoids are used as "stress doses" in a patient on replacement therapy. Such stress doses of the glucocorticoid preparation may provide sufficient mineralocorticoid activity to meet physiologic needs. Therefore, mineralocorticoid supplementation is not needed.

Fourth, the plasma half-life and biological half-life of the various preparations may be discordant and will vary widely. This is mainly related to binding to plasma proteins, hepatic metabolism, and hepatic activation. For example, cortisone and prednisone are biologically inactive, and even have mild steroid antagonist actions until they are metabolized by hepatic 11βHSD-I to their active forms (cortisol and prednisolone). Thus, the relative glucocorticoid potency of these preparations will also be affected by hepatic function. Cortisone and prednisone are cleared more rapidly in patients receiving drugs such as phenobarbital or phenytoin, which induce hepatic enzymes and are cleared more slowly in patients with liver failure.

In addition to these chemical considerations in the choice of glucocorticoid, the route of administration is a critical variable. Glucocorticoids are available for oral, intramuscular, intravenous, intrathecal, intra-articular, inhalant, and topical use. Topical preparations include those designed for use on skin, mucous membranes, and conjunctiva. Each preparation is designed to deliver the maximal concentration of steroid to the desired tissue while delivering less steroid systemically. However, all such preparations are absorbed to varying extents, and

thus the widely used inhalant preparations used to treat asthma can, in sufficient doses, cause growth retardation and other signs of Cushing syndrome.

In general, and in contradistinction to many other drugs, orally administered steroids are absorbed rapidly but incompletely, whereas intramuscularly administered steroids are absorbed slowly but completely. Thus, if the secretory rate of cortisol is 8 mg/m^2 of body surface area, the intramuscular or intravenous replacement dose of cortisol (hydrocortisone) would be 8 mg/m^2. However, because only about one-half of an oral dose is absorbed intact, the oral equivalent would be about 15 to 20 mg of hydrocortisone. The efficiency of absorption of glucocorticoids can vary considerably depending on diet, gastric acidity, bowel transit time and other individual factors. This emphasizes that the dosage equivalents listed in Table 12-7 and similar tables are only general approximations. The equivalencies shown are estimated biologic equivalencies with a broad range of variability and are not physical chemical equivalents.

ACTH can also be used for glucocorticoid therapy by its action to stimulate endogenous adrenal steroidogenesis. Although intravenous and intramuscular ACTH are extremely useful in diagnostic tests of adrenal function, the use of ACTH as a therapeutic agent is no longer favored, principally because it will stimulate synthesis of mineralocorticoids and adrenal androgens as well as glucocorticoids. Furthermore, the need to administer ACTH parenterally further diminishes its usefulness.

Intramuscular ACTH 1-39 in a gel form is the treatment of choice for infantile spasms and possibly for other forms of epilepsy in infants resistant to conventional anticonvulsants. Whether this action is mediated by ACTH itself, by other peptides in the biologic preparation, by ACTH-induced adrenal steroids, or by ACTH-responsive synthesis of novel "neurosteroids"[614] in the brain has not been determined. When pharmacologic doses of ACTH are used therapeutically, as in infantile spasms, the patient should be given a low-sodium diet to ameliorate steroid hypertension. Although greatly elevated concentrations of ACTH as in the ectopic ACTH syndrome will cause pituitary suppression, treatment with daily injections of ACTH results in less hypothalamic-pituitary suppression than does treatment with equivalent doses of oral glucocorticoids, presumably because the effect on the adrenal is transient. In addition, adrenal suppression obviously does not occur in ACTH therapy. Because the effects of ACTH on adrenal steroidogenesis are highly variable it is even more difficult to determine dosage equivalencies for ACTH and oral steroid preparations than it is among the various steroids. A very rough guide from studies in adults is that 40 units of ACTH(1-39) gel are approximately equivalent to 100 mg of cortisol.

PHARMACOLOGIC THERAPY

Pharmacologic doses of glucocorticoids are used in a variety of clinical situations, including immune suppression in organ transplantation, tumor chemotherapy, treatment of "autoimmune" collagen vascular and nephrotic syndromes, regional enteritis, and ulcerative colitis. Asthma, pseudotumor cerebri, dermatitis, certain infections, neuritis, and certain anemias are also often treated with glucocorticoids. The choice of glucocorticoid preparation to be used is guided by the pharmacologic parameters described previously and listed in Table 12-7, and by custom (e.g., the use of betamethasone rather than dexamethasone to induce fetal lung maturation in impending premature deliveries). There is substantial variation in the relative glucocorticoid and mineralocorticoid activities of each steroid, depending on the assay used.[615] Hence, Table 12-7 is an integration of multiple studies and can only be taken as a rough guide.

Pharmacologic doses of glucocorticoids administered for more than 1 or 2 weeks will cause the signs and symptoms of iatrogenic Cushing syndrome. These are similar to the glucocorticoid-induced findings in Cushing disease but may be more severe because of the high doses involved (Table 12-13). Iatrogenic Cushing syndrome is also not associated with adrenal androgen effects, and mineralocorticoid effects are rare. Alternate-day therapy can decrease the toxicity of pharmacologic glucocorticoid therapy, especially suppression of the hypothalamic-pituitary-adrenal axis and suppression of growth. The basic premise of alternate-day therapy is that the disease state can be suppressed with intermittent therapy, while there is significant recovery of the HPA axis during the "off" day. Thus, alternate-day therapy requires the use of a relatively short-acting glucocorticoid administered only once in the morning of each therapeutic day to ensure that the off day is truly "off." Long-acting glucocorticoids, such as dexamethasone, should not be employed for alternate-day therapy. Results are best with oral prednisone or methyl prednisolone.

WITHDRAWAL OF GLUCOCORTICOID THERAPY

Withdrawal of glucocorticoid therapy can be difficult and can lead to symptoms of glucocorticoid insufficiency. When glucocorticoid therapy has been used for only 1 week or 10 days, therapy can be discontinued abruptly, even if high doses have been used.[616] Although only one

TABLE 12-13

Complications of High-Dose Glucocorticoid Therapy

Short-Term Therapy	Long-Term Therapy
Gastritis	Gastric ulcers
Growth arrest	Short stature
↑ Appetite	Weight gain
Hypercalciuria	Osteoporosis, fractures
Glycosuria	Slipped ephiphises
Immune suppression	Ischemic bone necrosis
Masked symptoms of infection, esp. fever and inflammation	Poor wound healing
Toxic psychosis	Catabolism
	Cataracts
	Bruising (capillary fragility)
	Adrenal/pituitary suppression
	Toxic psychosis

or two doses of glucocorticoid are needed to suppress the hypothalamic-pituitary-adrenal axis, this axis recovers very rapidly from short-term suppression.

When therapy has persisted for 2 weeks or longer, recovery of hypothalamic-pituitary-adrenal function is slower and tapered doses of glucocorticoids are indicated. Acute discontinuation of therapy in such patients will lead to symptoms of glucocorticoid insufficiency, the so-called steroid withdrawal syndrome. This symptom complex does not include salt loss because adrenal glomerulosa function, regulated principally by the renin-angiotensin system, remains normal. However, blood pressure can fall abruptly because glucocorticoids are required for the action of catecholamines in maintaining vascular tone. The most prominent symptoms of the steroid withdrawal syndrome include malaise, anorexia, headache, lethargy, nausea, and fever. In reducing pharmacologic doses of glucocorticoids, it might appear logical to reduce the dosage precipitously to "physiologic" replacement doses. However, this is rarely successful and is occasionally disastrous.

Even when given physiologic replacement, patients who have been receiving pharmacologic doses of glucocorticoids will experience steroid withdrawal. Although the mechanism is not known with certainty, it is most likely that long-term pharmacologic glucocorticoid therapy inhibits transcription of the gene(s) for glucocorticoid receptors, thus reducing the number of receptors per cell. If this is so, physiologic concentrations of glucocorticoids will elicit subphysiologic cellular responses, resulting in the steroid withdrawal syndrome. Thus, it is necessary to taper gradually from the outset. The duration of glucocorticoid therapy is a critical consideration in designing a glucocorticoid withdrawal program. Therapy for a couple of months will completely suppress the hypothalamic-pituitary-adrenal axis but will not cause adrenal atrophy. Therapy of years' duration may result in almost total atrophy of the adrenal fasciculata/reticularis, and hence may require a withdrawal regimen that takes months.

Procedures for tapering steroids are empirical. Their success is determined by the length and mode of therapy and by individual patient responses. Patients who have been on alternate-day therapy can be withdrawn more easily than those receiving daily therapy, especially in cases of daily therapy with a long-acting glucocorticoid such as dexamethasone. In patients on long-standing therapy, a 25% reduction in the previous level of therapy is generally recommended weekly. A patient with a body surface area of 1 m^2 will have a secretory rate of cortisol of about 9 mg/day, equivalent to 20 mg/day of orally administered cortisone acetate. If the patient has been on daily therapy equivalent to 100 mg of cortisone acetate for many months, a tapering protocol over 8 to 10 weeks may be needed. A protocol of 75% of the previous week's dose would thus be 75 mg/day for the first week, 56 mg/day for the second, and then 42, 31.5, 24, 18, 13.5, 10, 7.5, and 5.5 mg/day and then off treatment. A more practical regimen based on the sizes of tablets available would be 75, 50, 37.5, 25, 17.5, 12.5, 10, 7.5, and 5 mg/day. Most patients can be tapered more rapidly, but all patients need to be followed closely. When withdrawal is done with steroids other than cortisone or cortisol, measurement of morning cortisol values can be a useful adjunct. Morning cortisol values of 10 μg/dL or greater indicate that the dose can be reduced safely.

Even after the successful discontinuation of therapy, the hypothalamic-pituitary-adrenal axis is not wholly normal. Just as in the patient successfully treated for Cushing disease, the hypothalamic-pituitary-adrenal axis may be incapable of responding to severe stress for 6 to 12 months after successful withdrawal from long-term high-dose glucocorticoid therapy. Thus, evaluation of the hypothalamus and pituitary by a CRF or metyrapone test, and evaluation of adrenal responsiveness to pituitary stimulation with an intravenous ACTH test, should be done at the conclusion of a withdrawal program and 6 months thereafter. The results of these tests will indicate if there is a need for "steroid coverage" in acute surgical stress or illness.

STRESS DOSES OF GLUCOCORTICOIDS

The cortisol secretory rate increases significantly during physiologic stress such as trauma, surgery, or severe illness. Patients receiving glucocorticoid replacement therapy or those recently withdrawn from pharmacologic therapy need coverage with "stress doses" of steroids. However, the specific indications for this coverage and the appropriate dosage are controversial and difficult to establish. Most practitioners prefer to err on the "safe" side of steroid overdosage. This is the safest tactic in the short term, but it can have a significant effect on growth over a period of years.

It is generally said that doses 3 to 10 times physiologic replacement are needed for the stress of surgery. The stress accompanying a surgical procedure can vary greatly. Modern techniques of anesthesiology; better anesthetic, analgesic, and muscle-relaxing drugs; and increased awareness of the particular needs of children in managing intraoperative fluids and electrolytes have greatly reduced the stress of surgery. In the past, a significant portion of such stress had to do with pain and hypovolemia, but these are less important in contemporary pediatric services. Similarly, part of the stress of acute illness is fever and fluid loss, factors now familiar to all pediatricians. Although it remains appropriate and necessary to give about three times physiologic requirements during such periods of stress, it is probably not necessary to give much higher doses. Similarly, it is not necessary to triple a child's physiologic replacement regimen during simple colds, upper respiratory infection, and otitis media or after immunizations.

The preparation of the hypoadrenal patient on replacement therapy for surgery is simple if planned in advance. Although stress doses of steroids can be administered intravenously by the anesthesiologist during surgery, this may be suboptimal. Doses administered as an intravenous bolus are short acting and may not provide coverage throughout the procedure. The transition from hospital ward to surgical theater to recovery room usually involves a transition among three or more teams of personnel, increasing the risk for error. Because intramuscularly administered cortisone acetate has a biologic half-life of about 18 hours, we recommend intramuscular administration of twice the day's physiologic requirement

at 18 hours before surgery and again at 8 hours before surgery. This provides the patient with a body reservoir of glucocorticoid throughout the surgical and immediate postoperative period. Regular therapy at two to three times physiologic requirements can then be reinstituted on the day after the surgical procedure.

MINERALOCORTICOID REPLACEMENT

Replacement therapy with mineralocorticoids is indicated in salt-losing congenital adrenal hyperplasia and in syndromes of adrenal insufficiency that affect the zona glomerulosa. Only one mineralocorticoid, 9α-fluorocortisol (Fluorinef), is currently available. There is no parenteral mineralocorticoid preparation, hydrocortisone plus salt must be used.

Mineralocorticoid doses used are essentially the same irrespective of the size or age of the patient. In fact, newborns are quite insensitive to mineralocorticoids and may require larger doses than adults. The replacement dose of 9α-fluorocortisol is usually 0.05 to 0.10 mg daily. Sodium must be available to the nephrons for mineralocorticoids to promote reabsorption of sodium. Thus, the newborn with salt-losing congenital adrenal hyperplasia must be treated with mineralocorticoids and sodium chloride. Similarly, mineralocorticoids will cause hypertension only by retaining sodium.

Cortisol has significant mineralocorticoid activity. Approximately 20 mg of cortisol or cortisone intravenously has a mineralocorticoid action equivalent to 0.1 mg of 9α-fluorocortisol. Thus, when cortisol or cortisone is given in stress doses it provides adequate mineralocorticoid activity and mineralocorticoid replacement can be interrupted. This is frequently seen when patients with salt-losing congenital adrenal hyperplasia undergo surgery. The stress doses of intramuscular cortisone acetate and the intravenous saline solutions administered during and after surgery suffice for the patient's mineralocorticoid requirements. Additional 9α-fluorocortisol is not needed until the supraphysiologic stress doses of cortisol are decreased. Because 9α-fluorocortisol can be administered only orally and because this may not be possible in the postoperative period, the appropriate drug for glucocorticoid replacement is cortisol or cortisone, which have mineralocorticoid activity, rather than synthetic steroids such as prednisone or dexamethasone, which have little mineralocorticoid activity.

Concluding Remarks

Because the adrenal cortex is principally concerned with steroid synthesis, most of its disorders reflect genetic lesions in adrenal development and steroidogenesis. Overproduction and underproduction of steroids having varied and complex physiologic actions lead to complex phenotypes and clinical presentations. These primary genetic disorders typically present themselves in infancy and childhood. By contrast, secondary disorders such as Cushing disease (usually a disorder of the pituitary) and Addison disease (usually a disorder of cellular immunity) may be seen at any age.

Thus, the pediatric endocrinologist must have a detailed understanding of the cell biology, genetics, and biochemistry of steroid hormone biosynthesis. Future refinements improving the speed, efficiency, accuracy, and economy of DNA sequencing will eventually permit direct genetic diagnosis of genetic diseases. However, it is unlikely that measurements of steroid hormones will become obsolete in the forseeable future, and an understanding of steroid physiology will always be needed to understand clinical presentations, formulate differential diagnoses, choose genes for study, and monitor therapy. Thus, genetics will continue to enhance clinical physiology but will not replace it.

Introduction

The multiple endocrine neoplasia (MEN) syndromes and pheochromocytomas are fascinating disorders with an intricate network of genetic etiologies. The field has advanced tremendously over the past decade, including the identification of additional genetic causes of pheochromocytoma, the ability to risk-stratify patients with MEN 2 based on genotype, and the ability to use such information to drive management decisions—all accompanied by a firmer understanding of the underlying pathophysiology. In cases of pheochromocytoma, the type of operation selected may depend on whether there is a germline mutation and in what particular gene.

For families with MEN 2, the timing of thyroidectomy is dictated in part by the specific *RET* mutation involved. Therefore, it is now essential that the evaluation and management of these patients involve experts in cancer genetics and include formal genetic counseling. Gene testing should be offered and performed in the setting of a cancer genetic consultation that includes pre-test and post-test genetic counseling. Subsequently, once a family-specific mutation is found the genetics consultant can offer mutation-specific predictive testing to all appropriate relatives of the proband.

Pheochromocytoma

Pheochromocytomas are catecholamine-producing tumors that arise from the chromaffin cells of the adrenal medulla or sympathetic ganglia.* Chromaffin cells, named because of the characteristic staining observed with chromium salt treatment, are neural crest derivatives that

* Some use the term paraganglioma for the extra-adrenal forms.

populate the adrenal medulla and sympathetic ganglia. Although most often found in the adrenal, pheochromocytomas can arise anywhere in the sympathetic chain and can produce a wide variety of symptoms.[1] Often, extra-adrenal pheochromocytomas that may not secrete catecholamines are referred to as paragangliomas. The tumors are usually sporadic, but they sometimes appear as a component of a familial syndrome such as multiple endocrine neoplasia type 2, von Hippel-Lindau disease, pheochromocytoma-paraganglioma syndrome, and rarely type 1 neurofibromatosis.

Pheochromocytomas are very rare, with a reported incidence of approximately 1 case per 100,000 patient-years.[2] In a report of 520 cases, only 50 were under age 16 years.[3] Although infrequent, appreciation of the diagnosis and treatment is important because the disease can be deadly if unrecognized. In one autopsy series,[4] the diagnosis was made antemortem only 24% of the time, even though 90% of the patients had symptoms of catecholamine excess.

Pheochromocytoma was traditionally described as a tumor of 90s: 90% are found in the adrenal, 90% are benign, 90% are sporadic, and 90% are unilateral.[5] However, in children the percentages differ—with approximately 70% being unilateral and 70% confined to the adrenal (the majority of the remainder arise in abdominal sympathetic ganglia).[6,7] and a greater likelihood of malignancy.[8,9] In addition, those earlier studies underestimated the frequency of pheochromocytomas occurring in association with specific genetic syndromes.

More recent data indicate that up to 25% of individuals with apparently sporadic pheochromocytomas actually harbor germ-line mutations in one of six genes known to predispose to pheochromocytoma formation.[10] Heritable pheochromocytomas, whether apparently sporadic or familial, frequently occur in the context of multiple endocrine neoplasia type 2 (MEN 2),[11,12] von Hippel-Lindau disease,[13,14] the pheochromocytoma-paraganglioma syndrome,[10,15] and rarely neurofibromatosis type 1.[16,17] It is important to realize that pheochromocytoma, especially in the pediatric setting, may be the initial or sole clinical manifestation of any of four heritable cancer syndromes caused by six distinct susceptibility genes (Table 13-1).

BIOSYNTHESIS AND ACTIONS OF CATECHOLAMINES

The pathophysiology of pheochromocytoma is best appreciated with an understanding of catecholamine biochemistry. The synthesis and metabolism of the catecholamines are illustrated in Figure 13-1. The conversion of tyrosine to dihydroxyphenylalanine (DOPA), catalyzed by the enzyme tyrosine hydroxylase, is the rate-limiting step in catecholamine biosynthesis within chromaffin tissue. Subsequent enzymatic steps yield norepinephrine, the neurotransmitter of the sympathetic nervous system.

The high concentrations of glucocorticoids in the adrenal medulla (reflecting cortical production) induce the enzyme phenylethanolamine-N-methyl transferase—which is responsible for converting norepinephrine to epinephrine in the adrenal medulla (the only location in the sympathetic chain in which this conversion occurs).[18] The catecholamines are stored in granules and released by exocytosis. Norepinephrine released by sympathetic neurons normally undergoes rapid reuptake by the presynaptic neurons. Nonresorbed norepinephrine and secreted epinephrine are enzymatically catabolized, as shown in Figure 13-1. Measurement of epinephrine and norepinephrine and their catabolic products is very useful in defining catecholamine hypersecretion and is the cornerstone of diagnosing pheochromocytoma.

The actions of the catecholamines are mediated by the α- and β-adrenergic receptors (Table 13-2).[19] The initial classification was based on the dissimilar responses of the vasculature to catecholamine exposure. The α-receptors are excitatory for smooth muscle, whereas the β-receptors are inhibitory. Subsequent subtypes (α_1, α_2, β_1, and β_2) were identified by differing responses to catecholamine analogues. The α_1-receptors are postsynaptic excitatory receptors present in the smooth muscle of the vasculature, gut, and genitourinary system as well as cardiac muscle.

TABLE 13-1

Genetic Causes of Pheochromocytoma

Syndrome	Gene	Function	Other Component Features
MEN 2	*RET*	Growth factor receptor	Medullary thyroid carcinoma; hyperparathyroidism
von Hippel-Lindau	*VHL*	Tumor suppressor	Cerebellar hemangioblastoma, retinal angioma, renal cell carcinoma
Neurofibromatosis	*NF1*	Tumor suppressor	Café-au-lait spots, neurofibromas, Optic nerve glioma
Familial paraganglioma	*SDHD*	Mitochondrial complex II subunit	Parasympathetic paraganglioma, especially in head and neck location
Familial paraganglioma	*SDHB*	Mitochondrial complex II subunit	Parasympathetic paraganglioma, renal cell carcinoma, papillary thyroid cancer
Familial paraganglioma	*SDHC*	Mitochondrial complex II subunit	Parasympathetic paraganglioma

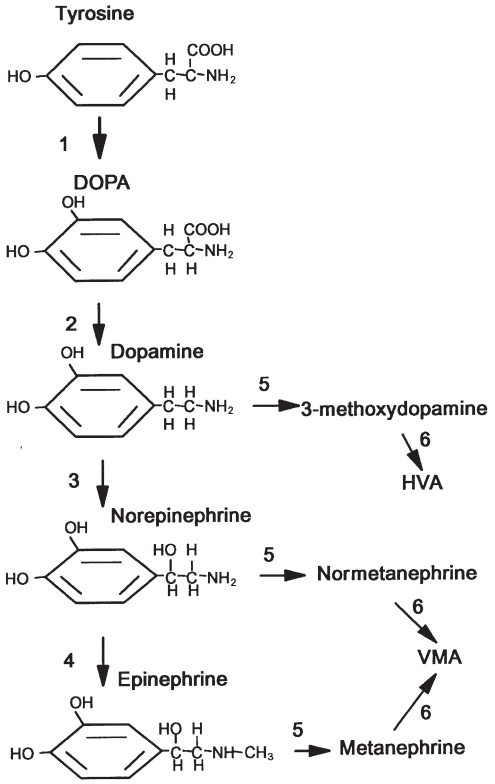

Figure 13-1 Biosynthesis and metabolism of catecholamines. The specific enzymes in the synthetic pathway are (1) tyrosine hydroxylase, (2) aromatic L-amino acid decarboxylase, (3) dopamine ß-hydroxylase, (4) phenylethanolamine N-methyl transferase, (5) catechol-O-methyl transferase, and (6) monoamine oxidase. DOPA, dihydroxyphenylalanine; HVA, homovanillic acid; and VMA, vanillylmandelic acid. [Data from Keiser HR (1995). Pheochromocytoma and related tumors. In DeGroot LJ (ed.), *Endocrinology, Third edition*. Philadelphia: WB Saunders 1853; and from Lefkowitz RJ, et al. (1990). Neurohumoral transmission: The autonomic and somatic motor nervous systems. In Gilman AG, et al. (eds.), *The pharmacologic basis of therapeutics*. New York: Pergamon Press 187.]

The α_1-receptor acts via phospholipase C and produces increases in intracellular calcium. The α_2-receptors are presynaptic and are responsible for feedback inhibition of norepinephrine secretion. Ligand binding by α_2-receptors inhibits adenylyl cyclase by interacting with the inhibitory G protein G_i. The β_1-receptors are found in the myocardium, whereas β_2-receptors are found in most other sites. A β_3-receptor, identified through molecular cloning, is present in adipose tissue. All β-receptor subtypes act by stimulating adenylyl cyclase via the stimulatory G protein G_s. Specific agonists and antagonists characterize the receptor subtype and are useful therapeutic agents.[20]

CLINICAL PRESENTATION

The clinical presentation of pheochromocytoma is highly variable. Symptoms may be absent or unrecognized in the early phase of the disease, as demonstrated by the results of screening families with MEN 2 and by studies that show many pheochromocytomas are first discovered at autopsy.[4] For patients with symptoms, adrenergic paroxysms with headache, palpitations, hypertension, and sweating constitute the classic presentation.

In adults, the hypertension is sustained in approximately 50% and typically responds poorly to standard antihypertensive agents, especially β-blockers. [5] Many patients have orthostatic changes in blood pressure upon physical examination. In children, the most frequent symptom is headache (75%), followed by sweating in two-thirds and nausea and vomiting in one-half of patients.[7,21] Hypertension appears to be uniformly present and is sustained in 80% to 90% of affected children at the time of diagnosis.[7,22,23]

DIAGNOSIS

The diagnosis of pheochromocytoma is typically made by demonstrating increased catecholamine secretion in a patient with suspicious symptoms or known to be at risk

TABLE 13-2

Adrenergic Receptor Classification, Function, and Pharmacology

Adrenergic Receptor Type	Pharmacologic Agonist	Pharmacologic Antagonist	Major Biologic Effect
α1	Phenylephrine	Prazosin, phenoxybenzamine, phentolamine	Arteriolar constriction
α2	Clonidine, methyldopa	Yohimbine, phenoxybenzamine, phentolamine	Mediates presynaptic feedback inhibition of norepinephrine release; decreases insulin secretion
β1	Dobutamine	Atenolol, metoprolol, propranolol	Increases cardiac rate and contractility
β2	Terbutaline, albuterol	Propranolol	Arteriolar and venous dilation; relaxation of tracheobronchial muscles

Data from articles by Lefkowitz and colleagues[19] and Hoffman and Lefkowitz.[20,21]

because of family history or genetic syndrome. Most show increases in a variety of urinary catecholamines and metabolites in a 24-hour specimen.[5,24] Determination of fractionated metanephrines (i.e., separate measures of metanephrine and normetaphrine), in plasma or urine, is the test of choice and is recommended for initial evaluation.[25,26] These o-methylated metabolites are released from chromafin tumors independently of the catecholamines in a more or less continuous manner.

The consistency of production enhances sensitivity, which approaches 100% (97%–99%) for detecting pheochromocytoma while maintaining acceptable specificity (70%–90%).[27,28] It is best if patients receive no medications during the tests, but several antihypertensive agents (e.g., diuretics, calcium channel blockers, angiotensin-converting enzyme inhibitors) do not materially affect results.[5] Special diets are not usually necessary. Recommendations for plasma free metanephrine collections include samplings in the fasting state from a patient who has maintained a supine position for 20 minutes.[25] In a recent study, plasma free metanephrines were elevated in all children diagnosed with pheochromocytoma.[28]

Diagnosis in the few patients with episodic hypertension can be problematic. Normal catecholamine excretion may not exclude a tumor if an episode does not occur during the collection period. Instructing the patient to collect a timed urine specimen after an episode has been proposed as a method of diagnosing such patients.[5] In young children in particular, neuroblastoma enters into the differential diagnosis of increased catecholamine excretion. In such cases, hypertension is usually minimal and homovanillic acid (HVA) is the dominant metabolite in the urine.

GENETIC DIFFERENTIAL DIAGNOSIS

The genetic differential diagnosis of pheochromocytoma comprises von Hippel-Lindau disease (VHL), MEN 2, pheochromocytoma-paraganglioma syndrome, and NF 1. (MEN 2 is discussed in detail in subsequent sections.) An ill-recognized genetic differential diagnosis for paraganglioma is MEN 1, although this is an uncommon neoplasia for this syndrome.

VHL is a heritable disorder predisposing to retinal angiomas, central nervous system hemangiomas and hemangioblastomas, renal cell carcinoma, pheochromocytoma, pancreatic islet cell tumors, and endolymphatic sac tumors.[29] It has an estimated birth incidence of 1 in 36,000 per year and is inherited in an autosomal-dominant manner with a high degree of inter- and intrafamilial variability. The VHL susceptibility gene, *VHL,* encodes a tumor suppressor. Approximately 28% of mutations in the *VHL* gene are partial or complete deletions. The remaining 72% are small deletions/insertions or point mutations. Therefore, genetic testing for VHL should use methods that detect both abnormalities (i.e., Southern blot analysis and DNA sequencing). The sensitivity of this combined approach is nearly 100% when performed on patients with a clinical diagnosis of VHL.[30]

Relatively clear genotype-phenotype correlations have been described for VHL. VHL families are categorised into two subtypes based on a low (type 1) or high (type 2) risk of pheochromocytoma. VHL type 2 has been further divided based on a low risk (type 2A) or high risk (type 2B) of renal cell carcinoma. In a third subtype, VHL 2C, pheochromocytoma is the only manifestation. Among those with VHL type 1, 50% will have large deletions or truncating mutations—whereas the majority (~95%) of patients with VHL type 2 (with pheochromocytoma) have missense mutations. Interestingly, when a population-based study of families fitting the VHL type 2C description (isolated pheochromocytoma with no other syndromic features) was conducted 11% had a germ-line *VHL* mutation.[10] Of the 11% found to have germ-line *VHL* mutations, ¾ presented with pheochromocytoma under the age of 20 years.

Three new susceptibility genes for pheochromocytoma and paranganglioma have been isolated within the last decade.[31-33] These three genes (*SDHB, SDHC,* and *SDHD*) are autosomal genes encoding three of the four subunits of succinate dehydrogenase (SDH) or mitochondrial complex II. SDH is the enzyme that participates in the electron transport chain and the Krebs cycle. Interestingly, whereas homozygous or compound heterozygous mutations in *SDHA* cause Leigh syndrome heterozygous mutations in *SDHB, C,* or *D* cause heritable pheochromocytoma-paraganglioma syndrome.[15] In a population-based registry of apparently sporadic symptomatic pheochromocytoma or paraganglioma presentations, approximately 15% to 20% were found to carry a germ-line mutation in one of the three *SDH* genes.[10,34] None of those presenting with adrenal pheochromocytoma were found to carry *SDHC* mutations.[35] Among those found to be *SDH* mutation positive, approximately 25% to 30% present before the age of 20 years.[10]

Genotype-phenotype relationships are still being refined for these SDH-associated pheochromocytoma-paraganglioma syndromes. *SDHC* and *SDHD* mutations tend to be associated with head and neck paragangliomas, whereas *SDHB* is associated with intra-abdominal disease and malignant pheochromocytomas.[10,34-36] *SDHB* mutations seem to also predispose to non-paraganglial neoplasias such as very-early-onset (<30 years) renal cell carcinoma and perhaps epithelial thyroid carcinomas.[37] NF 1 is a rare cause of heritable pheochromocytoma. Among 27 population registry-based cases of apparently sporadic pheochromocytomas who were mutation negative at *SDHB/C/D, VHL,* and *RET,* only 1 (4%) was found to carry a germ-line mutation in *NF1*.[17]

TUMOR LOCALIZATION

Imaging studies (Figure 13-2) that localize a suspected pheochromocytoma should take place after excessive catecholamine secretion has been demonstrated. Most silent adrenal masses are not pheochromocytomas. A report of incidentally discovered adrenal masses in 1,000 adults found pheochromocytoma 4% of the time. Only half had hypertension, but the majority had increased catecholamine production.[38]

Computed tomography (CT) and magnetic resonance imaging (MRI) are most helpful in localizing pheochromocytomas. The average diameter of a pheochromocytoma is approximately 5 cm at the time of diagnosis, and the sensitivity of CT or MRI approaches 100%—although the specificity is substantially lower.[39] Scintigraphy with radiolabeled metaiodobenzylguanidine (^{131}I or ^{123}I-MIBG)

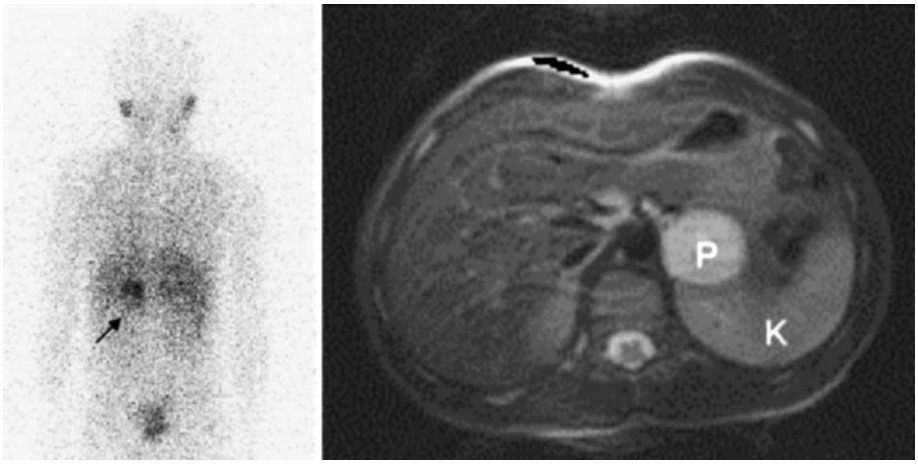

Figure 13-2 Imaging studies in pheochromocytoma. The patient was a 5-year-old with hypertension and a family history of pheochromocytoma. Urinary catecholamines were as follows: norepinephine = 728 µg/24 hr (upper limit 65), epinephrine = 8 µg/24 hr (upper limit 10), and metanephrines = 4.7 mg/24 hr (upper limit 1.3). Left: MIBG imaging, posterior view. Right: MRI, transaxial view. Pheochromocytoma is indicated as P. K denotes kidney.

is very specific for pheochromocytoma, with increased uptake of the compound evident in 90% to 100% of pheochromocytomas.[40,41]

The test is more difficult to perform and slightly less sensitive than CT and MRI.[41] However, a positive MIBG scan provides an independent confirmation of the diagnosis and may reveal disease that is more extensive than that observed by CT or MRI.[42] Therefore, some recommend combining MIBG scanning with CT or MRI to provide additional diagnostic information about adrenal masses found with conventional techniques.[25] Given these available and precise imaging techniques, arteriography and selective venous sampling (which place the patient at greater risk) are almost never indicated.

MANAGEMENT

Surgical removal of a pheochromocytoma was first performed by Charles Mayo in 1926[43] and remains the treatment of choice for this disorder. Nowadays, endocopic removal of a solitary and bilateral pheochromocytomas is effective and safe in the hands of experienced surgeons and is preferred for most patients.[44] However, there is always the potential for disaster when anesthesia and surgery are applied to patients harboring pheochromocytomas.

Hypertensive crises, myocardial dysfunction, arrhythmias, hypotension, and shock can occur during the perioperative period and result from the acute and chronic effects of the catecholamine excess. In 1963, Stackpole and colleagues[7] reported a 22% intraoperative mortality in a review of 100 children with pheochromocytoma. Careful attention to intravenous fluid management and pharmacotherapy before and during the procedure (Table 13-3) has improved the outcome, and thus intraoperative deaths are now rare.[45] Even so, one study[46] found that 4 of 15 children undergoing pheochromocytoma removal had complications—including myocardial failure in 2 patients.

Preoperative treatment to control blood pressure is recommended, but there is no consensus on which

TABLE 13-3

Useful Agents in the Management of Pheochromocytom$^{\alpha}$

Drug	Mechanism of Action	Comments
Phenoxybenzamine	α1 and α2 antagonist	Preoperative α-adrenergic blockade
Prazocin	α1 antagonist	Preoperative α-adrenergic blockade
Labetalol	Combined α- and β-adrenergic blockade	Fixed ratio α:β effect disadvantageous
Propranolol	β1 and β2 antagonist	Adjunctive for cardiac effects
Nifedipine	Calcium channel blocker	
Metyrosine	Inhibits catecholamine synthesis	Adjunctive therapy
Phentolamine	α1 and α2 antagonist	Intravenous intraoperative therapy, diagnostic tests, treat hypertensive crisis
Nitroprusside	Nonspecific vasodilation, nitric oxide generation	Intraoperative blood pressure control

Data from Keiser HR (1995). Pheochromocytoma and related tumors. In DeGroot LJ (ed.), *Endocrinology, Third edition*. Philadelphia: WB Saunders 1853-1877.

regimen is best.[26,47] Preoperative α-blockade with phenoxybenzamine remains a widely accepted method of preparing patients for surgery.[24,47] Treatment is begun at least 1 to 2 weeks before planned surgery (dosage, 5 to 10 mg b.i.d.; 0.25 to 1.0 mg/kg/day in divided doses). The dose is increased gradually until the patient's hypertension and symptoms have substantially improved. Because the initial dose may induce or worsen postural hypotension, it is typically given in the evening before bedtime.

Propranolol can be added if tachycardia or arrhythmias occur during phenoxybenzamine therapy, but it must not be used in the absence of α-receptor antagonists. Such preoperative α-blockade appears to work well in children.[22] The α-adrenergic receptor antagonist prazosin, the calcium channel blocker nifedipine, labelatol (a combined α- and β-receptor antagonist), and metyrosine (α-methyl tyrosine, an inhibitor of catecholamine synthesis) have also been used alone or adjunctively to prepare patients for surgery.[5,47]

The reported experience in children treated with these various regimens is necessarily limited. In the study by Deal and colleagues,[22] patients who had no complications during surgery typically had resolution of the signs and symptoms of catecholamine excess with preoperative medical therapy. Although preoperative treatment is commonly used, there are reports of good results in selected patients using principally intraoperative blood pressure control with nitroprusside, nitroglycerin, or both without preoperative α-blockade.[45]

Intraoperative severe hypertension can be managed with phentolamine or nitroprusside. Hypotension that occurs after tumor removal reflects the relaxation of the vascular tone that has maintained a volume-contracted state and should correct with judicious replacement of fluids. Careful and intense monitoring of the patient's status throughout the perioperative period is imperative. Some patients may develop pulmonary edema, possibly as a result of impaired myocardial function and the inability to tolerate the intravenous fluids.

Most patients with solitary adrenal pheochromocytomas are cured by the operation. However, the risk of developing a second primary in the contralateral adrenal is high in those with heritable forms. All pheochromocytoma presentations, especially under the age of 20, have a high likelihood of being heritable irrespective of other features or family history.[10] Therefore, adrenocortical sparing surgery is highly recommended in patients at substantial risk for bilateral disease so that they may avoid the requirement of lifelong glucocorticoid therapy and the risks that accompany adrenal insufficiency.[44,48,49] Finding a gene mutation usually mandates a conservative approach and adrenal-sparing surgery. Depending on the gene involved, different organs are at risk for different neoplasias.[10]

Pheochromocytomas are reported to be malignant in 12% to 47% of pediatric cases.[23,50] The prognosis for malignant pheochromocytoma is variable. Some patients die within months from metastatic disease, whereas others live for decades.[51,52]

SUMMARY OF PHEOCHROMOCYTOMA

Pheochromocytoma is rare but important to diagnose and treat appropriately. In perhaps one in two affected children, the tumor is caused by an underlying diagnosable genetic abnormality with health implications for family members. Indeed, the penetrance of pheochromocytoma/paraganglioma may approach 100% in *RET, VHL,* and *SDH* mutation carriers. All presentations of pheochromocytoma should be offered genetic testing in the setting of a genetics consultation that includes genetic counseling. Measurement of catecholamine metabolites (metanephrines) is the cornerstone of diagnosis, followed by CT imaging or MRI for localization.

Because of its low frequency, the evaluation should generally be limited to children who have hypertension and symptoms suggestive of pheochromocytoma, who have symptoms strongly suggestive of pheochromocytoma in the absence of hypertension, or who are at increased risk for pheochromocytoma because of an inherited condition (Table 13-4). The treatment of choice is surgical removal after successful pharmacotherapy to block the effects of the catecholamines. The procedure should take place in a hospital, with the capability for intense intraoperative and postoperative monitoring and therapy.

MEN Syndromes

The MEN syndromes are genetic disorders in which there is a propensity to develop glandular hyperplasia and malignant neoplasia of endocrine organs (Table 13-5).[53-55] Patients with MEN syndromes suffer from the consequences of glandular hypersecretion and the mass effects of tumors. Untreated, the diseases cause significant morbidity and excess mortality. Because of this, much effort has been directed toward identifying susceptible individuals, screening them for the presence of disease, and preventing and treating their endocrine or

TABLE 13-4

Indications for Pheochromocytoma Evaluation

- Triad of episodic headache, diaphoresis, and tachycardia with or without hypertension
- Family history of pheochromocytoma, VHL or MEN 2 syndrome
- Clinical features compatible with MEN 2, VHL, or pheochromocytoma-paraganglioma syndrome
- Known germ-line mutation in a pheochromocytoma-predisposing gene in the patient and/or his family
- An undefined adrenal tumor
- Hypertension unexplained and poorly responsive to standard therapies
- Significant hypertension and tachycardia in response to general anesthesia, surgery, or drugs known to provoke attacks in patients with pheochromocytomas

TABLE 13-5

Classification of MEN Syndromes

Syndrome	Principal Endocrine Disorder	Additional Features	Etiology
MEN 1	Parathyroid hyperplasia, pituitary adenomas, islet cell tumors	Carcinoid, adrenocortical hyperplasia, lipoma, cutaneous collagenoma	*MEN1* mutation
MEN 2A	Medullary thyroid carcinoma, parathyroid hyperplasia, pheochromocytoma		*RET* mutation
MEN 2B	Medullary thyroid carcinoma, pheochromocytoma	Marfanoid habitus, mucosal neuromas	*RET* mutation
FMTC	Medullary thyroid carcinoma		*RET* mutation

FMTC, familial medullary thyroid carcinoma; and MEN, multiple endocrine neoplasia.

neoplastic disease very early in order to improve their health and prolong their lives.

In most cases, it is now possible to establish a specific molecular diagnosis in affected individuals and then use the information to identify susceptible relatives. Recommendations as to whom genetic testing should be applied and how such information should be used depend on the specific clinical syndrome in question.

This chapter reviews the pathophysiology, diagnosis, and management of multiple endocrine neoplasia types 1 and 2 and the Carney complex. These specific syndromes were selected because the endocrine manifestations predominate and they are among the most relevant to pediatrics. They share several characteristics. They are inherited as Mendelian autosomal-dominant traits with high penetrance. A specific subset of glands is affected with multicentric and recurrent disease. The diseases become manifest over decades of life. Despite these obvious similarities, there are important differences. For example, MEN 2 is caused by a relatively few specific gain-of-function mutations of a growth factor receptor (RET) and prophylactic surgery is recommended for children with the mutant gene. In contrast, MEN 1 is caused by a variety of inactivating mutations in a tumor suppressor gene. Biochemical monitoring, rather than prophylactic surgery, is the standard approach.

In the text that follows, the clinical features of these syndromes are described—along with their putative pathogenic mechanisms. Newer information from research into the molecular genetic aspects of the conditions has been incorporated as possible. Because this field of medicine is in rapid evolution, the reader should continue to seek the most current information for important clinical decisions.

MULTIPLE ENDOCRINE NEOPLASIA 1 (MEN 1)

MEN 1 is typified by hyperplasia/neoplasia of parathyroid, pituitary, and pancreatic islet cells.[53,56-58] Additional features include carcinoid tumors, adrenal cortical hyperplasia, and lipomas. Extra-adrenal paragangliomas may be rare components of MEN 1 as well. Cutaneous lesions (collagenomas, facial angiomata) are very common features, being found in nearly 90% of patients in one series.[59] Genetic linkage analysis among families with MEN 1 first localized the inherited abnormality to a small region on the long arm of chromosome 11 (11q13),[60,61] which ultimately led to identification of germ-line mutations in several families with typical MEN 1.[62,63]

The gene, aptly named *MEN1,* encodes MENIN* (a protein unlike any other known biological molecule at that time). Menin was subsequently shown to be expressed by a wide variety of tissues and localized to the nucleus.[64-66] It interacts with specific intracellular proteins involved in growth control pathways [67] and plays a broad role in the transcriptional regulation (including chromatin modification) of many genes.[68,69]

A large body of evidence, experimental and clinical, indicates that menin functions as a "tumor suppressor."[70] Mice lacking one copy of *MEN1* develop tumors in the same organs affected in the MEN1 syndrome.[71] In vitro, reduction of *MEN1* expression results in enhanced cell proliferation—whereas overexpression of menin triggers apoptosis.[70] The proposed mechanism of disease is illustrated in Figure 13-3. Patients with MEN1 carry one normal and one inactive mutant allele of the *MEN1* gene in all cells (a germline mutation).[72] This in itself is insufficient to induce tumor formation. Subsequently, loss of heterozygosity (a "second hit") in a single somatic cell deletes the only normally functioning *MEN1* gene and the ordinary constraints on cell growth from MENIN are attenuated. Tumor growth is thus initiated from a single clone of cells.

The mutations found in MEN 1 families show that they are both various and widely distributed throughout the gene (Figure 13-4), frequently truncating the translation product.[62,73,74] Thus, these are inactivating mutations and are consistent with the tumor suppressor role.

Clinical Presentation

There is significant variation in clinical presentations among and between families affected by MEN 1.[57,58,75-78] The typical patient presents in the third to fifth decades

*Menin as all caps refers to human protein, other species are lowercase.

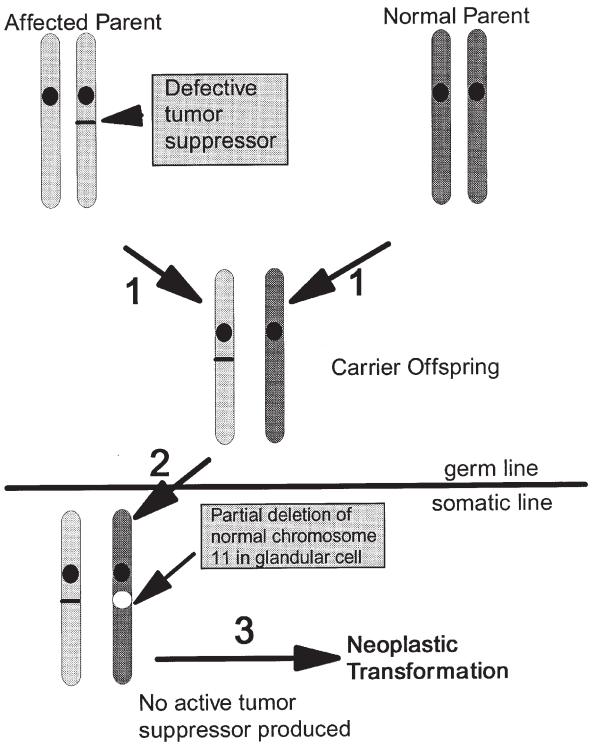

Figure 13-3 Pathogenesis of MEN 1. (1) Affected parent passes mutant MEN1 gene to offspring, who inherits a normal gene from the other parent. (2) Loss of heterozygosity in a somatic cell deletes remaining normal *MEN1* gene. (3) The absence of the tumor suppressor activity in specific cells accompanied by some other cellular event (a "second hit") leads to tumor formation.

of life with single or multiple manifestations of the condition. Hyperparathyroidism is the most common endocrine abnormality and thus hypercalcemia is usually the first sign of disease.[58,75,77,78] It is followed by lesions of the pancreatic islet and pituitary in frequency. Skin lesions are also commonly found in adults with MEN 1. The prevalence of cutaneous angiofibromas and collagenomas is reported to be 88% and 72%, respectively, with more lesions tending to occur in older patients.[59] The penetrance of disease in carriers of the *MEN1* genetic abnormality approaches 100% over a lifetime.[77,79]

Patients who undergo routine biochemical screening are diagnosed much earlier than those who present with symptoms (Figure 13-5). It appears that affected patients can be detected by routine biochemical screening approximately 10 years prior to the onset of symptoms. A large study evaluated the age-related penetrance in 63 unrelated kindreds with MEN 1 and found <1% penetrance in gene carriers before age 5 years, 7% penetrance by age 10 years, and 28% and 52% penetrance by ages 15 and 20 years, respectively.[73] Thus, even though MEN 1 is generally considered a disease of adults under careful surveillance nearly half of the gene carriers manifest biochemical signs within the pediatric age range.

The treatment of the various conditions and tumors that arise in MEN 1 syndrome are covered in other parts of this textbook. However, it is appropriate to discuss certain aspects that relate particularly to the MEN 1 syndrome.

Hyperparathyroidism

This is the most common manifestation of MEN 1 and occurs in nearly all affected patients. The disease differs from that of sporadic primary hyperparathyroidism in that there is a slow but inexorable progression of hyperparathyroidism over time, with development of oligoclonal adenomas/hyperplasia in multiple glands.[80,81] These features form the basis of the recommendation that patients at risk be screened with annual serum calcium and intact parathyroid hormone measurements, and receive treatment when there is evidence of clinically significant hyperparathyroidism and/or when there is an increasing trend of ionized calcium levels.

Subtotal parathyroidectomy of three and a half glands or total parathyroidectomy with reimplantation represent

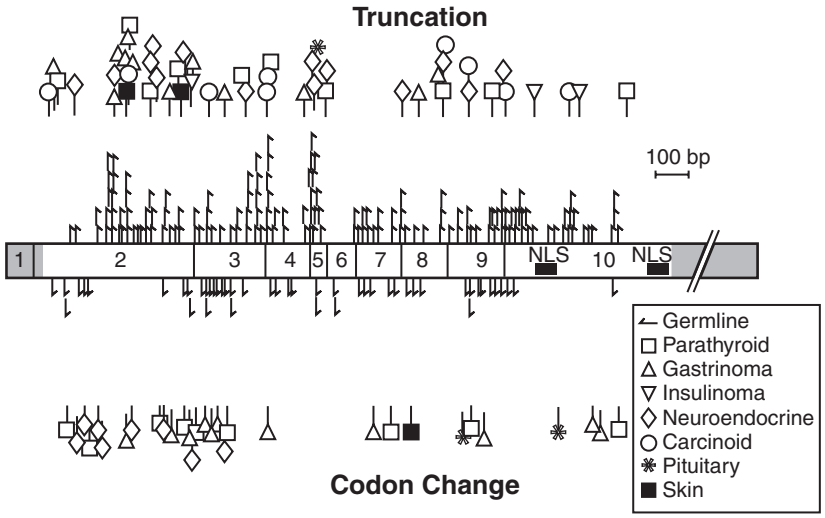

Figure 13-4 Representative germ-line and somatic mutations in the *MEN1* gene. Gene exons are numbered, with the hatched area demarcating untranslated regions. Mutations listed above the gene are those that would result in a truncated mRNA that would either yield a highly abnormal protein or be unstable (e.g., nonsense mutations, frame-shifting deletions/insertions). Those below are missense changes. [Used with permission from Marx, SJ et al. (1999). The gene for multiple endocrine neoplasia type 1: Recent findings. Bone 25:119.]

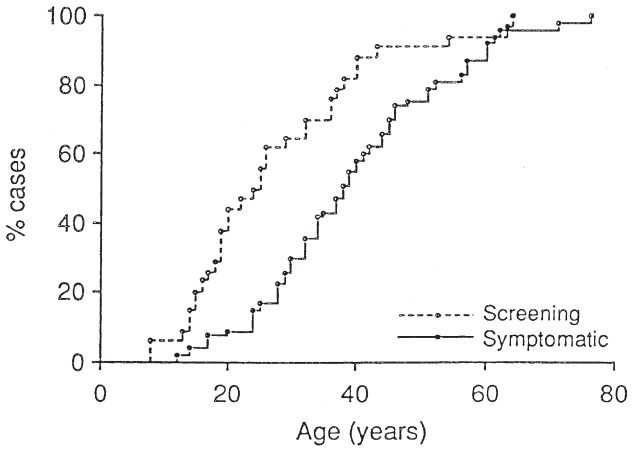

Figure 13-5 Age-related onset of multiple endocrine neoplasia type 1. Patients were divided into those detected by a biochemical screening versus those identified because of symptoms of MEN 1 disease. Data indicate that screening detects individuals with MEN1 before symptoms at almost all ages and decreases the average age at detection by approximately 10 years. The graph was constructed from data for 87 patients. [Graph from Thakker RV (1993). The molecular genetics of multiple endocrine neoplasia syndromes. Clin Endocrinol 38:1.]

the standard treatment, but could be considered palliative because the recurrence rate approximates 20%.[82] Mallette[81] recommended total parathyroidectomy with autologous transplantation of a portion of one of the parathyroid glands in the forearm. This allows a much simpler reoperation if hypercalcemia recurs. Others suggest that subtotal parathyroidectomy is sufficient and perhaps results in a lower rate of postoperative permanent hypoparathyroidism.[83,84] Regardless of the surgical approach selected, it must deal with all parathyroid glands because disease in multiple glands is the rule.

Because the first manifestation of MEN 1 in the large majority of cases is hyperparathyroidism, it would be important to consider the genetic differential diagnosis of parathyroid disease. Although only 2% to 3% of patients presenting with primary HPT have MEN 1,[85] in familial isolated hyperparathyroidism 20% of probands harbor a germ-line *MEN1* mutation.[86] Also important in the differential diagnosis is the hyperparathyroidism-jaw tumor syndrome caused by germline mutations in *HRPT2* on 1q25-q31.[87]

Enteropancreatic Islet Cell Tumors

These tumors are the second most common manifestation of MEN 1, being found in up to 60% to 80% of affected patients over their lifetimes.[58,79,88] Approximately half are gastrinomas, and a third are β-cell tumors.[78,89,90] Tumors that secrete pancreatic polypeptide are also found.[88] The elevated circulating concentrations of pancreatic polypeptide do not appear to produce significant symptoms or functional abnormalities, although they may be sign of clinically important pancreatic tumors. Clinically silent lesions can also be detected by endoscopic ultrasonography. In one prospective study, 41% of MEN 1 patients with lesions detected by ultrasound were asymptomatic.[91]

It is important to note the significant morbidity and mortality that results from pancreatic islet cell disease in MEN 1. About half of patients with MEN 1 die from a MEN-1-related condition, most often from peptic ulcers (the Zollinger-Ellison syndrome) or from the mass effects of a malignant islet cell tumor.[76] Multiple insulinomas are frequent, and partial pancreatectomy may be required.[92] Although there are suggestions that earlier detection of the tumors and subsequent removal may improve long-term survival,[93] this is not clearly established at this time.

The major genetic differential diagnosis of islet cell tumors is MEN 1. It is important to recognize that a third of all patients with Zollinger-Ellison syndrome will have MEN 1.[94] Islet cell tumors can also be components of VHL and NF 1. In VHL, pancreatic cysts are common—and approximately 10% to 15% will have islet cell tumors, the latter of which have a high likelihood of malignancy. Surgery is indicated when VHL-related pancreatic islet cell tumors are >3 cm, whereas lesions <1 cm can be safely monitored.

Pituitary Tumors

Approximately 15% to 50% of individuals with MEN 1 develop a pituitary tumor.[95] Two-thirds are microadenomas (<1.0 cm in diameter), and the majority are prolactin secreting.[96] Among patients with pituitary tumors, the prevalence of MEN 1 is 2.5% to 5%[96,97] (but as high as 14% in patients with prolactinoma).[96] These results underscore the importance of carefully taking a thorough medical and family history in patients with a diagnosis of an MEN-1-associated endocrine tumor, even seemingly in isolation. Even so, there are rare cases and families that appear to have MEN 1 or a MEN ½ overlap who do not have *MEN1* or *RET* mutations.[98] For example, probands with only pituitary and parathyroid disease harbor germ-line *MEN1* mutations only 7% of the time.[98]

Screening

At the present time, there is no specific treatment that will prevent the disease manifestations—nor do any prophylactic therapies appear to be warranted. Thus, the goal of screening in MEN 1 is to detect clinical manifestations before there has been spread of tumors or serious ramifications from excess hormone secretion. Prior studies have described results of episodic biochemical screening programs designed to meet this end.[75,77,78,88] However, because of the long latency for disease manifestation many unaffected individuals were required to undergo years of episodic testing.

It is possible to use molecular genetic methods to determine carrier status, although the wide range of genetic mutations (more than 400 germ-line mutations identified) means that it may be necessary to sequence the entire gene to identify the abnormality in the index case. A mutation within the *MEN1* gene can be detected in 70% or more of typical MEN 1 cases with this approach.[99] It is believed that the remainder also bear *MEN1* mutations that affect *MENIN* abundance. They are just not detected by PCR-based sequencing of the coding region.[55]

Genetic testing should be offered to index cases with familial endocrinopathies consistent with MEN 1 or

apparently sporadic cases with two or more MEN-1-type tumors.[100] Once a mutation is identified in the index case, the optimal ages for offering genetic testing, beginning screening for disease, and determining the frequency and extent of testing for relatives are not clearly established. Certainly, genetic testing in the young (if clearly negative) would avoid unnecessary biochemical and other monitoring. Consensus guidelines, published in 2001, suggested that screening begin at age 5—with annual biochemical testing for insulinoma and anterior pituitary disease and less frequent imaging studies.[100]

Testing for gastrinoma, other enteropancreatic tumors, and carcinoid could be delayed until age 20. It is important to remember that morbidity from MEN 1 in preadolescence is very rare,[101] even though biochemical abnormalities may be detected. Furthermore, establishing a molecular diagnosis presently offers no therapeutic advantage to the affected. Therefore, some advocate waiting until the patient is old enough to give informed consent before performing genetic testing to determine risk status. Acknowledging the caveats, the authors believe that combining molecular genetic testing with periodic biochemical assessment is the most rational approach.

Useful screening tests are listed in Table 13-6. Probably the minimal requirements in the pediatric population would be history and physical examinations on an annual basis beginning at age 5, and basal ionized calcium, prolactin, and IGF-I measurements every 1 to 2 years thereafter in patients at risk. Whether the patient was at risk would be determined by assessment of *MEN1* gene mutation carrier status, in the setting of genetic counseling, at the age biochemical screening was contemplated. When abnormalities are found on screening tests, further studies (including imaging) are warranted to confirm the diagnosis and to determine the course of therapy.

MULTIPLE ENDOCRINE NEOPLASIA 2

Multiple endocrine neoplasia type 2 (MEN 2) serves as the paradigm for the practice of clinical cancer genetics. Historically, MEN 2 encompasses at least three subtypes: MEN 2A, MEN 2B, and familial medullary thyroid carcinoma (FMTC).[102-104] Each subtype is characterized by C-cell hyperplasia, which progresses to multicentric MTC. Patients with MEN 2A and 2B also develop pheochromocytomas. Parathyroid hyperplasia/adenomata occur in MEN 2A but are rare in MEN 2B.

TABLE 13-6

Major Clinical Features of MEN 1

Organ	Neoplasia	Symptomatic Manifestation	Clinical Detection	Comments
Parathyroid	Hyperparathyroidism	Arthralgia, bone pain, renal stone	Plasma Ca^{2+}, PTH	Present in 95%
Pituitary	Prolactinoma	Galactorrhea, hypogonadism	Plasma prolactin	60% of pituitary tumors in MEN 1
	GH or GH/Prl-secreting tumor	Acromegaly-gigantism	IGF-I, GH	25% of pituitary tumors in MEN 1
Pancreas	Insulinoma	Hypoglycemia	Glucose/insulin	One third of pancreatic tumors in MEN 1
	Gastrinoma	Zollinger-Ellison syndrome	Gastrin	Most common; principal cause of death
	PP producing VIP producing	Usually asymptomatic Diarrhea	Plasma PP, imaging	

GH, growth hormone; IGF-I, insulin-like growth factor-I; PP, pancreatic polypeptide; Prl, prolactin; PTH, parathyroid hormone; and VIP, vasoactive intestinal polypeptide.

Germ-line RET Proto-oncogene Mutations Cause MEN 2

All three clinical subtypes of MEN 2 are caused by germ-line mutations of the *RET* proto-oncogene on 10q11.2.[105] Pathogenic gain-of-function germ-line *RET* mutations are found in more than 95% of patients with the MEN 2A or MEN 2B clinical phenotype—and in ~85% of individuals with FMTC.[100,104,106] As might be expected, the *RET* proto-oncogene is expressed by and plays a prominent role during the development of neural crest and its derivatives as well as the parathyroid anlage.[107,108]

The 21-exon *RET* proto-oncogene encodes the RET protein, which is structured like many other cell surface growth factor receptors with an extracellular binding domain and an intracellular tyrosine kinase (Figure 13-6). The RET receptor tyrosine kinase mediates the signals of the glial-derived neurotrophic factor family of peptide growth factors (GDNF), which are involved in the regulation of neural tissue development—including that of the peripheral and enteric nervous systems.[109] Family members include GDNF, neuturin, persephin, and artemin. Rather than binding directly to RET, these ligands need to interact with RET and one of the latter's four membrane-bound coreceptors—known as the GDNF family receptor α family (GFRA1-4 encoding GFRα1-4)—to elicit autophosphorylation of RET and phosphorylation of cytoplasmic signal-transducing molecules.[104] Each member of the GDNF family appears to bind predominantly to a specific GFRα. Thus, the GFRα coreceptor appears to be responsible for the specificity of *RET* signaling.[110]

The specific germ-line mutations found in the *RET* proto-oncogene dictate to a large extent the phenotype of patients and the aggressiveness of the MTC.[100,111] Nearly all *RET* mutations reported in patients with MEN 2A involve missense mutations that replace one of the six extracellular cysteine residues close to the transmembrane domain of the RET protein (Figure 13-6).[105,112,113] Codon 634 mutations (in particular, C634R) are highly associated with the MEN 2A phenotype.[104,106,114] Mutations associated with FMTC are more evenly distributed across the hot-spot cysteine codons, usually favoring the more N-terminal ones. In addition, mutations in some intracellular residues appear to favor FMTC—although rarely MEN 2A phenotype is seen. Although there is a clear genotype-phenotype association in MEN 2, the correlations are imperfect. For example, an identical germ-line RET mutation may produce FMTC in one family and MEN 2A in another. The basis for this remains unclear, but is thought to be due to the influence of additional genetic modifiers within *RET* itself as well as other loci.[104,115]

The great majority (>98%) of MEN 2B appears to be produced by two specific missense mutations in the tyrosine kinase domain of the *RET* proto-oncogene. These are M918T (>95% of MEN 2B) and A883F (2%-3%).[104,116-118] Unlike loss-of-function mutations (e.g., MEN 1), gain-of-function mutations typically occur at select loci. This is precisely the case for the *RET* mutations associated with MEN 2. As noted previously, ligand-induced receptor dimerization followed by autophosphorylation and activation of an intracellular tyrosine kinase domain are mechanisms that operate commonly among growth factor receptors (e.g., receptors for EGF and PDGF).

The mutations that characterize MEN 2A and most FMTC appear to force ligand-independent dimerization because unpaired cysteine residues in the mutant receptor form inter-receptor disulfide bridges that yield stable functional homodimers that maintain an activated state

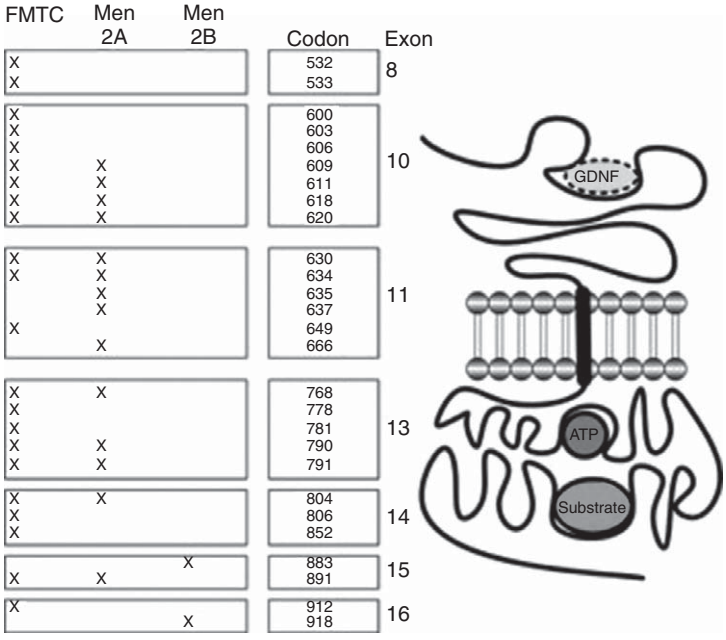

Figure 13-6 Genotype-phenotype relationships in patients with medullary carcinoma of the thyroid due to germ-line *RET* mutations. RET protein structure is shown with ligand glial-derived neurotrophic factor (GDNF). Positions (codon numbers) where missense mutations alter amino acid in families with MEN 2A, familial medullary carcinoma of the thyroid (FMTC), and MEN 2B are shown. [Used with permission from You YN, Lakhani V, Wells SA Jr. (2006). Medullary thyroid carcinoma. Surg Oncol Clin North Am 15:644.]

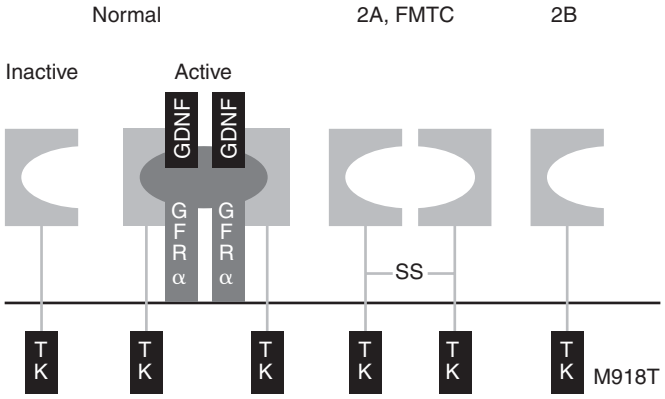

Figure 13-7 Mechanisms of RET activation. Ligand-induced dimerization stabilizes the dimeric form of the receptor in which the tyrosine kinase is active. In the case of MEN2A and familial medullary thyroid carcinoma (FMTC), disulfide bridges form between monomers—yielding a stable (active) homodimer. In MEN 2B, mutation in the intracellular catalytic domain constitutively activates the receptor. TK, tyrosine kinase; and GDNF, glial-derived neurotrophic factor.

(Figure 13-7). C634R (the most common MEN 2A mutation) has been shown to be the most transforming in vitro compared to mutations in the more 5' cysteines.[119] Very rarely, non-cysteine missense mutations have been found in MEN 2A/FMTC, but the mechanism is usually similar (e.g., a small deletion or splice mutation removes one or more of the cysteines, resulting in the same intermolecular disulfide bridging).[120]

The mechanism differs for MEN-2B-related *RET* germline mutations, but the result is similar. The most common MEN 2B mutation, M918T, occurs within the catalytic domain at the heart of the residues dictating substrate specificity. The replacement of methionine by threonine at codon 918 causes RET to favor substrates normally used by cytoplasmic kinases, instead of its native receptor tyrosine kinase substrates, and to lose responsiveness to normal autoinhibitory feedback signals.[121,122]

Constitutive activation or enhanced function of the RET protein (receptor) over time leads to hyperplasia and, in the context of other oncogenic events, subsequent malignant transformation.[119,121,122]

An important clue to RET function in endocrine neoplasia development came from the observation of the coexistence of MEN 2A or FMTC with Hirschsprung disease (HSCR). Germline loss-of-function mutations in *RET* have been found to cause familial and sporadic HSCR in some cases.[123]

Finding MEN 2A/FTMC with HSCR in an individual or segregating in a family appeared paradoxical at the molecular level in that MEN 2 resulted from RET superfunction whereas HSCR was due to attenuated RET signaling.

This conundrum remained until further functional analyses demonstrated that missense mutations that are more 5' in the gene [i.e., mutations in cysteines 611, 618, and 620 (exon 10)[124]] resulted in RET receptors that were trapped in the golgi and never reached the cell surface, resulting in functional haploinsufficiency.[125] Based on these data, the coexistence of MEN 2A/FMTC and HSCR can be explained by the fact that neoplasia results from constitutive activation of RET whereas normal development of the enteric ganglia is dependent on adequacy of RET dosage. Similarly, the phenotypic variation of MEN 2A and FMTC can be explained by the balance between constitutive RET signaling and the number of RET receptors generating the signals.[104] Thus, C634R is associated with the most fulminant disease—resulting in MTC, pheochromocytoma, and hyperparathyroidism compared to missense mutations in C609 and C611 in FMTC with the lowest penetrance and later onsets.[106]

Calcitonin and C Cells

The parafollicular (C) cells originate from the neural crest and migrate during development into the thyroid gland of humans and higher vertebrates. In lower vertebrates, such as fish, these cells constitute the ultimobranchial body. The C cells secrete calcitonin, a 32-amino-acid single-chain peptide that has calcium-lowering properties in vivo. Calcitonin is synthesized as part of a larger precursor containing katacalcitonin, which is cleaved from calcitonin proper before secretion.

In addition, calcitonin-gene-related peptide is produced by alternate splicing during transcription of the calcitonin gene. Calcitonin is abundant only in the thyroid.[126] Calcitonin-gene-related peptide is most abundant in the nervous system[127] but is also secreted by medullary thyroid carcinomas[128] (a C-cell malignancy). The degree of elevation of the plasma concentration of calcitonin is the traditional marker of medullary carcinoma of the thyroid.[129]

In MEN 2, the C cells are believed to undergo progressive changes—beginning with simple hyperplasia and ending with malignancy. MTC frequently spreads to regional lymph nodes but eventually may metastasize to liver, lung, and bone. Medullary carcinoma of the thyroid is the principal MEN-related cause of death in patients with MEN 2A,[130] which results from the distant metastases or local complications.[102]

Clinical Presentation

MEN 2A/FMTC. The majority of patients present because they were the first to develop MCT in their family or have a relative affected with the disease. The mean age for diagnosis of a C-cell abnormality by biochemical screening is approximately 15 years,[131] whereas palpable tumors are not typically evident until many years later.[130] Increased calcitonin secretion in response to stimulation, reflecting C-cell hyperplasia or carcinoma *in situ,* is evident by the age of 30 years in nearly all individuals bearing the disease gene.[131,132]

Approximately 50% of those with MEN 2A eventually develop pheochromocytomas,[133] usually after detection of a C-cell abnormality. MEN-2A-related hyperparathyroidism is less common, being found in between 15 and 35% of patients—depending on the thoroughness of the investigating physician and the age of the patient because there appears to be a clear age-related penetrance.[114] Studies whose cohorts are very mature have a higher frequency of hyperparathyroidism in MEN 2A cases than in those who have shorter follow-up times. The mean age at diagnosis of symptomatic

pheochromocytoma is 36 years, with occasional patients presenting with pheochromocytoma first.[10]

MEN 2B. MEN 2B is much less common, and most patients (60%) with MEN 2B represent de novo mutations rather than being members of large kindreds. In addition, MEN 2B patients have a distinctive appearance with marfanoid body habitus, unusual facies, and multiple mucosal neuromas (Figures 13-8 and 13-9). These neuromas are classically described as occurring on the tongue but in fact occur throughout the oromucocutaneous ragions and gastrointestinal tract—and are frequently associated with gastrointestinal symptoms.

In many patients, the poor intestinal function appears to mimic HSCR—and GI symptoms with failure to thrive may be the presenting symptoms even in the neonatal period.[134] Mucosal neuromas, gastrointestinal symptoms secondary to ganglioneuromatosis of the gut, and other characteristic physical traits are frequently the key features that lead to the diagnosis of MEN 2B.[135] Hypertrophy of the corneal nerves can be observed with slit-lamp examination and can be helpful in establishing the diagnosis.[136,137] Hyperparathyroidism is rare with MEN 2B, and some believe that clinically evident parathyroid disease never occurs in MEN 2B.

Of great importance is the fact that MEN-2B-related MTC occurs on average 10 years earlier than that in MEN 2A and is more aggressive.[130,138] It follows that prophylactic thyroidectomy is recommended at the youngest age (<1 year) once the molecular or clinical diagnosis of MEN 2B is established.

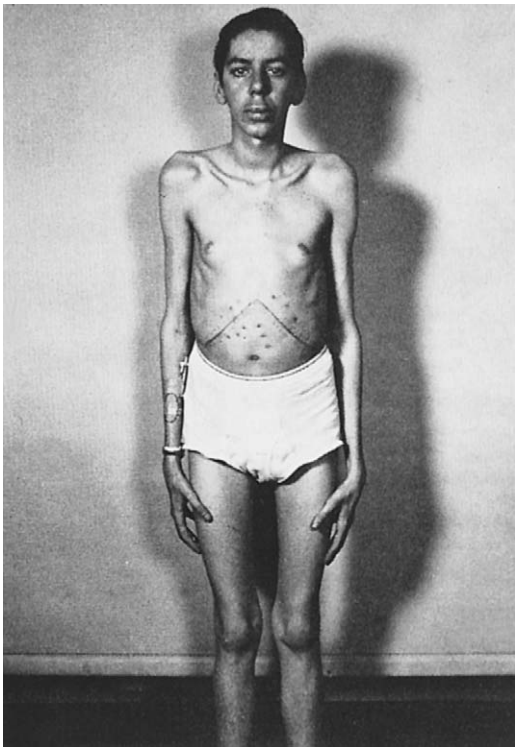

Figure 13-8 Patient with typical features of multiple endocrine neoplasia type 2B. Note the Marfanoid body habitus, thickened lips due to mucosal neuromas, and abdominal scars that reflect surgery for pheochromocytoma. [From Melvin KEW, Tashjian AH Jr., Miller HH (1972). Studies in familial [medullary] thyroid carcinoma. Recent Progr Horm Res 28:399.]

Indications and Use of Molecular Genetic Testing. Identification of a *RET* gene mutation within a MEN 2 family is of great benefit for those affected because MTC can be prevented or cured when prophylactic thyroidectomy is performed at an early stage[133,139-141] and because biochemical monitoring for pheochromocytoma allows its early detection and therapy. It is obvious that any family with hereditary MTC with or without pheochromocytoma needs testing. Individuals with apparently sporadic MTC should be tested as well because the prevalence of unexpected germ-line *RET* mutations is approximately 5% to 10%.

When the prevalence of germ-line mutations is in this range and/or if testing gives significant information, the American Society of Clinical Oncology Guidelines for Cancer Genetic Testing recommends offering genetic analysis in the setting of genetic counseling.[142] Individuals with pheochromocytoma, especially the familial forms, should also be offered *RET* analysis (see previous section on pheochromocytomas).

RET gene analysis is widely available and generally straightforward because of the limited number of mutations that produce MEN 2/FMTC. Once a germ-line mutation is identified, the approach is partly determined by the particular mutation involved. For those at highest risk for an aggressive form of MTC (MEN 2B; codon 883, 918, and 922 mutations), prophylactic thyroidectomy in infancy is recommended. For those at intermediate risk of aggressive MTC (codon 611, 618, 620, or 634), thyroidectomy by age 5 years is recommended. Children with *RET* mutations with the lowest risk (typically those associated with FMTC) should also have thyroidectomy by age 5 to 10.

Circulating concentrations of calcitonin following stimulation were formerly used as an index of C-cell disease and to identify carriers.[143,144] The superiority of molecular genetic testing became evident shortly after the discovery that MEN 2 was caused by mutations of the *RET* proto-oncogene and molecular biological techniques were used to determine carrier status.[145-147] Lips and colleagues[146] studied 300 subjects in four families segregating MEN 2A. Most of the patients had been previously screened with stimulated calcitonin measurements. Of the patients with abnormal stimulation tests who underwent thyroid surgery, all with histologically diagnosed medullary carcinoma of the thyroid were shown to have the characteristic germ-line mutations of the RET proto-oncogene.

Of special interest were eight children with normal calcitonin stimulation tests who underwent thyroidectomies because they harbored the RET proto-oncogene mutation. Each had microscopic medullary carcinoma of the thyroid. In addition, there were six patients who underwent thyroidectomies because of positive stimulation tests. These were subsequently shown not to be carriers of the mutation. These patients all showed C-cell hyperplasia (known to affect 3% to 5% of the normal population) without medullary carcinoma of the thyroid.

Pheochromocytoma. The pheochromocytomas associated with MEN 2 are usually diagnosed in the third to fifth decades of life and are frequently bilateral.[148,149] Malignant pheochromocytoma is rare. Annual screening through measurement of fractionated metanephrines (urine or plasma) is

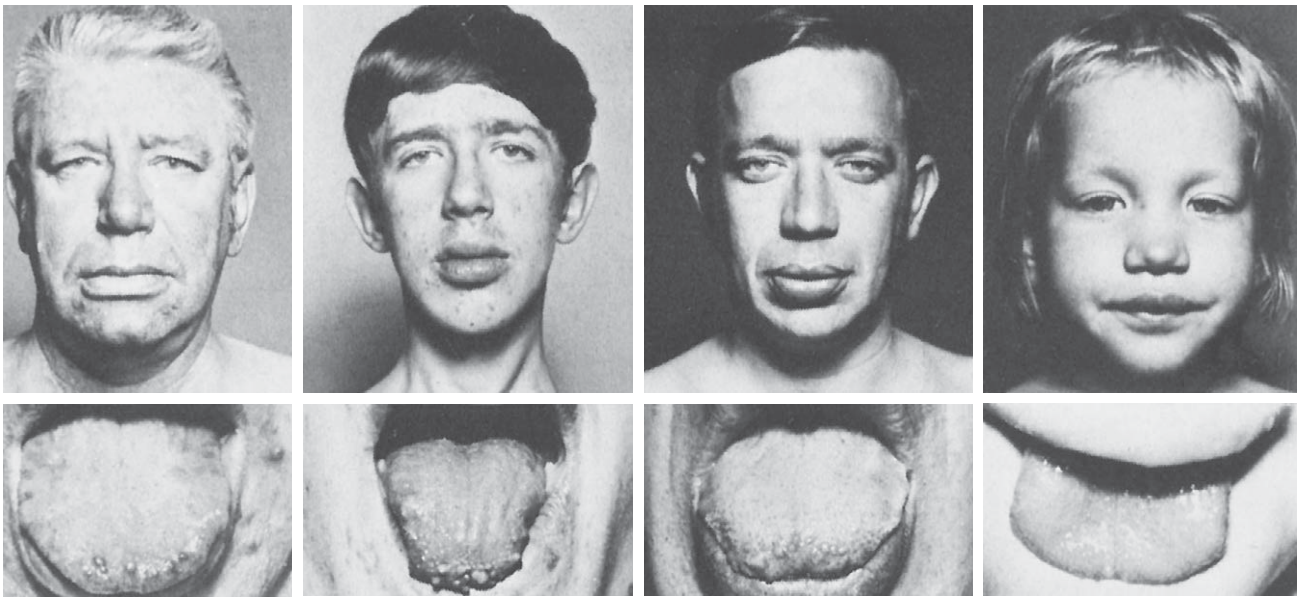

Figure 13-9 Typical facies for multiple endocrine neoplasia 2B. All individuals were from a single kindred. Note the thickened lips, ganglioneuromas of the tongue, and thickened eyelids. [From Sizemore GW, Heath H III, Carney JA (1980). Multiple endocrine neoplasia type-II. Clin Endocrinol Metab 9:299.]

indicated, even though some patients with pheochromocytoma present with radiographic abnormalities before increased excretion of catecholamines.[150] This is probably a reflection of the adrenal medullary hyperplasia (the presumed precursor to the pheochromocytoma) found in many patients with MEN 2.[151] Any child at risk for MEN 2 who develops signs and symptoms of pheochromocytoma (such as headache, irritability, or hypertension) should be completely evaluated (as outlined in the previous section).

The pharmacologic preparation of patients for pheochromocytoma surgery was reviewed earlier in this chapter. If the disease appears to be unilateral at the time of operation, only the affected gland is operated on—even though patients with MEN 2 syndrome have a 40% to 50% chance of developing a second primary in the contralateral adrenal.[133,149,150] A decade may pass before the appearance of a second pheochromocytoma.[133,150] As noted previously, partial adrenalectomy with preservation of adrenal cortical function is recommended in MEN 2.[49,152]

RET Testing and Hirschsprung Disease. HSCR is common in pediatric practice. Because HSCR is a genetically complex trait, performing genetic testing specifically for management of HSCR is currently not recommended. Instead, what is commonly done is to look for RET mutations that also confer risk of MEN 2A—such as germ-line mutations in C620 and C618 and in C609 and C611.[106,153] It is estimated that in MEN 2 cases with C620 or C618 mutations, approximately ⅓ to ½ may actually have HSCR as well.

Carney Complex

Carney complex is a genetic condition that leads to endocrine gland tumors and hyperfunction by mechanisms analogous to those involved in the other conditions reviewed in this chapter.[154] It is characterized by the development of myxomas in multiple tissues (skin, heart, and breast), endocrine tumors/hyperfunction, primary pigmented nodular adrenal hyperplasia (PPNAD)-associated Cushing syndrome, and acromegaly differentiated epithelial thyroid carcinoma and spotty, pigmentation of the skin in select areas.[155]

Molecular Genetics. Two distinct genetic loci are associated with Carney complex. One is found on chromosome 2 (2p16), but that susceptibility gene is yet to be identified.[156] The other is the gene (PRKAR1A) encoding a regulatory subunit of protein kinase A on chromosome 17.[157] The germ-line mutations found in PRKAR1A are characteristically loss-of-function, and it is postulated that PRKAR1A functions as a "tumor suppressor." Most of the germ-line mutations in this gene are truncating, and interestingly lead to nonsense-mediated decay of the mRNA transcript.

Clinical Presentation. No clinical features appear to distinguish the two genetic forms. The diagnosis may be made at any age, usually because of myxoma development. The main sites for these tumors are the skin and heart, with cardiac myxomas being a major cause of morbidity. Thyroid nodules, large-cell calcifying Sertoli cell tumors, and PPNAD (see material following) may also develop during childhood. The lentigenes (spotty skin pigmentation), which may be present at birth, appear primarily around the lips, eyes, and genital mucosa in the postpubertal period. Pigmentation on the ocular canthae is relatively specific for Carney complex. This sign is rarely seen in other pigmentary disorders, such as Peutz-Jeghers syndrome.

Endocrine Manifestations. Acromegaly and Cushing syndrome due to PPNAD are the most common. PPNAD is a form of ACTH-independent hypercortisolism found in approximately one in four patients with Carney complex. Most patients with PPNAD are diagnosed in the

second and third decades of life, but some cases appear in early childhood. Many show an unusual response during standard dexamethasone testing, with an increase in cortisol excretion.[158]

Acromegaly is due to GH-producing adenomas and is said to be clinically subtle. Thyroid function is normal, but thyroid neoplasms (follicular adenoma, differentiated nonmedullary thyroid cancer) are common, with up to 75% of patients having nodular disease by ultrasound.

Management. Once the syndrome is identified, the patients must be monitored for the development of the tumors and endocrine disorders characteristic of the syndrome. This should include periodic thyroid and cardiac ultrasonography and measures of adrenocortical function. The pathways for diagnosis of Cushing syndrome and acromegaly and the management of thyroid nodules are described elsewhere in this textbook. As noted previously, a paradoxical response for cortisol excretion during standard suppression testing should be a clue that one may be dealing with PPNAD. The treatment for symptomatic PPNAD at present is bilateral adrenalectomy.

Pediatrics and the MEN Syndromes

The preceding sections describe the clinical manifestations of the MEN syndromes and their therapies. It is relatively uncommon for a child to present with clinical disease. However, when a child does present with an endocrine neoplasia the possibility of a genetic etiology is high. In pediatric practice, the question of MEN more often arises when the relative of an otherwise healthy child is discovered to have a glandular lesion suspicious for an MEN syndrome. For patients with a pedigree clearly demonstrating either the MEN 1 or MEN 2 phenotype, the approach to screening and treatment is as described.

More problematic is the child whose relative, frequently not first degree, has an endocrine neoplasm that may or may not reflect a heritable MEN syndrome. In light of the value of screening and prophylactic therapies, it is imperative that the possibilities be investigated fully. A detailed family history is the first step. It is very important to emphasize that if the presence or absence of disease in the pedigree is based solely on symptomatic clinical manifestations and not on biochemical or genetic screening a MEN syndrome might be present even though only one individual appears to be affected. This is because of the relatively advanced age characteristic of clinical disease in the MEN syndromes. Thus, the best strategy and current standard of care involves molecular examination of the affected relative to determine whether he or she carries a typical germ-line mutation. Although it is possible to analyze the unaffected relatives (e.g., the child in question) without examining the proband, it is generally better when possible to determine whether the affected individual bears a characteristic mutation. Many medical centers have programs for genetic cancer assessment, and a few centers specialize in MEN patients. Consultation with physicians at such centers is indicated for diagnosis and management.

Summary and Future Developments

The advent of new molecular tactics changed the way physicians manage patients with the diseases discussed in this chapter. The utility of using molecular genetic testing to more efficiently and effectively address serious clinical problems can hardly be more evident than in the MEN 2 situation. In the last seven years, the genetic etiologies of pheochromocytoma and paraganglioma have expanded such that this armamentarium is also available for routine clinical management. With these advances in genomic medicine, accurate molecular diagnosis and predictive testing are possible. Furthermore, gene-guided medical management has become possible. Typically, these involve surveillance strategies and prophylactic surgery.

Despite these encouraging developments, problems remain. There are two broad issues. The first is metastatic disease and the second is the effective treatment of the benign neoplasias with the fewest side effects. Metastatic neuroendocrine tumors are not amenable to standard cytotoxic therapies. For example, patients with metastatic MTC are particularly difficult to treat because standard chemotherapy and radiation are ineffective[159] and subsequent surgical cure difficult.[129] Patients with hyperparathyroidism frequently end up with permanent hypoparathyroidism or have recurrent disease.

There are recent therapeutic advances that may prove helpful in these situations. A new class of molecular targeted therapies that inhibit tyrosine kinases have been developed and shown to be efficacious in certain cancers, and show some promise in preclinical models of MTC.[160,161] In addition, calcimimetic agents[162] (calcium-sensing receptor agonists) have the potential to slow the development of parathyroid hyperplasia and theoretically could delay the need for parathyroidectomy in MEN 1. Thus, there are good reasons to expect further improvements in the health and quality of life of probands and their families who are affected by these conditions.

Future Directions

Introduction

Puberty is the stage of development during which secondary sexual characteristics appear and there is a transition from the sexually immature to the sexually mature stage. Adolescence is widely used as a generally synonymous term for puberty, but it is often used to convey an added cultural connotation as a psychosocial coming of age.

By the mid 1960s, a general concept of the major factors involved in the initiation of puberty was established (Figure 14-1).[1,2] A decrease in sensitivity of the brain "gonadostat" to sex hormone negative feedback was thought to be the primary event. This signaled the hypothalamus to discharge neurohumors (then unidentified), which in turn stimulated the pituitary to release gonadotropins. The resultant rise in secretion of the gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), was thought to account directly for increased estrogen production by the ovary. A mature relationship was thought to develop in which the blood levels of estrogen and gonadotropins were regulated reciprocally via the gonadostat,[3] much as a furnace is regulated by a thermostat. The pineal was identified as having gonadal-suppressive properties. The increased adrenocortical secretion of 17-ketosteroids (17-KS), which becomes apparent at about the time of puberty (adrenarche), was thought to be due to a pituitary factor stimulating adrenal androgens in synergism with adrenocorticotropic hormone (ACTH).[4]

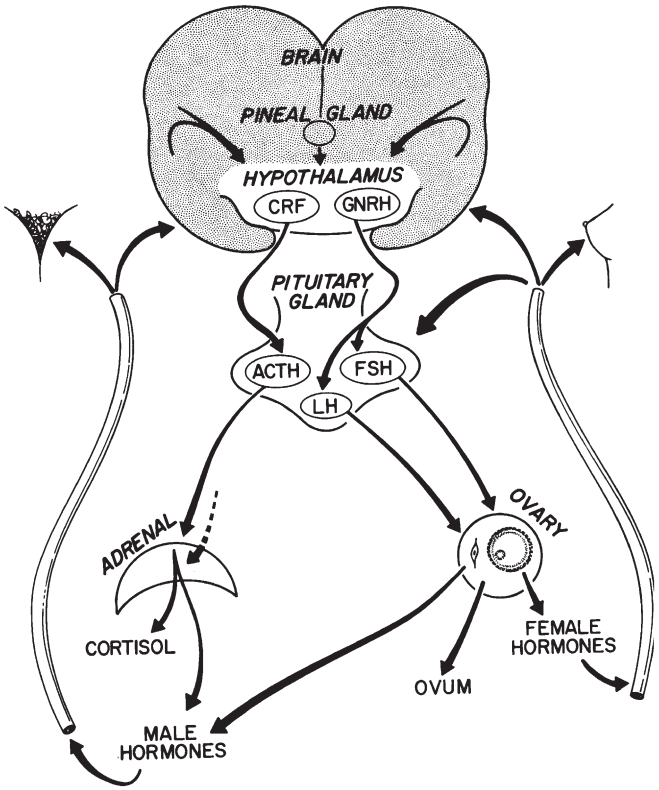

Figure 14-1 Schematic representation of the neuroendocrine-ovarian axis involved in normal pubertal development. ACTH, adrenocorticotropic hormone; CRF, corticotropin-releasing factor; GnRH, gonadotropin-releasing hormone; FSH, follicle-stimulating hormone; and LH, luteinizing hormone.

The rapid scientific advances since 1965 have permitted this concept to be tested in increasingly sophisticated ways. In the subsequent decade, radioimmunoassay (RIA)—originally developed by Yalow and Berson—was applied to the measurement of gonadotropins and sex steroids. The gonadotropin-releasing hormone (GnRH) for both LH and FSH was isolated, identified, and synthesized by Guillemin's and Schally's groups. Cyclic adenosine-3',5'-monophosphate (cAMP), postulated by Sutherland to mediate the action of peptide hormones, was found to mediate gonadotropin effects on the ovarian follicle. The initial steps in the mechanism of action of steroid hormones were defined by Jensen, Gorski, and their groups. The landmark nature of many of these discoveries has been recognized by the awarding of Nobel Prizes in Medicine to Sutherland in 1971 and to Yalow, Schally, and Guillemin in 1977.

Our present view of the mechanisms controlling puberty is more refined and complex than it once was, although the previously cited schema is correct in a general sense. The gonadostat is a patently oversimplistic concept for but one aspect of a complex system that regulates the hypothalamic GnRH pulse generator, a functionally interconnected and synchronized network of GnRH neurons.[5] The gonadostat setting seems to change throughout childhood in a biphasic manner. This concept is illustrated in Figure 14-2.[6,7] During fetal and perinatal life, the gonadostat is insensitive to negative feedback by sex hormones. At this time, the nascent neuroendocrine-gonadal axis functions at a pubertal level. The gonadostat becomes increasingly sensitive to negative feedback during infancy but does not become highly sensitive until mid-childhood, at which time GnRH pulse generator activity is minimal.

During late prepuberty, the gonadostat begins to relinquish its inhibition. This permits the onset of puberty. The changing set-point initially permits increasing episodic secretion of GnRH. Increasing sensitivity of the pituitary gonadotropic cells to GnRH follows. The change in LH and FSH secretion is first detectable at night. Gradually, the gonads become increasingly sensitized to gonadotropin stimulation, grow at an increased rate, and bring about sustained rises in plasma sex hormone levels. Some of these phenomena synergize with others, and thus autoamplification occurs and the pace of change accelerates. Eventually, the set-point for gonadotropin release comes to vary sufficiently to encompass a positive feedback mechanism.

The data on which this model is based are presented in material following. The most recent data on the hormonal milieu and accompanying physical stages of normal puberty are then presented. Abnormal puberty is subsequently discussed: causes, differential diagnosis, and management.

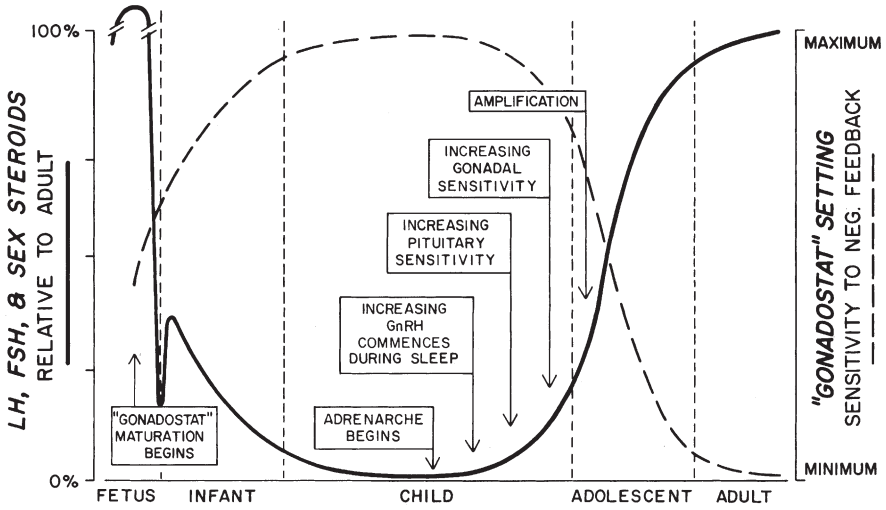

Figure 14-2 The changing pattern of serum gonadotropins and sex hormones from fetal life to maturity in relationship to the apparent sensitivity of the central nervous system "gonadostat" to the negative feedback effect of sex hormones and the underlying hormonal events. FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; and LH, luteinizing hormone. [Modified from Grumbach M, Grave C, Mayer F (eds.), *The control of the onset of puberty.* New York: John Wiley & Sons.]

Development of the Female Reproductive System

MATURATION OF THE NEUROENDOCRINE OVARIAN AXIS

Fetus

Neuroendocrine Unit. The anterior lobe of the pituitary gland (of stomal ectodermal origin) and the posterior lobe (of neural origin) differentiate by 11 weeks' gestational age.[8] By this time, GnRH neurons have migrated from the olfactory placode into place in the medial basal hypothalamus.[9] Hypothalamic GnRH rises in parallel with fetal pituitary and serum LH and FSH from this time.[10] All peak at about 20 to 24 weeks, as the connections of the pituitary portal system become complete, to levels not again seen until the mature midcycle surge.[11,12]

Serum LH and FSH levels are higher in female than male fetuses.[11] In rats, GnRH-containing neurons develop earlier in females than in males[13] and there are sexual dimorphisms in the degree of synapsing of specific tracts with dendritic spines in the preoptic nucleus—one of the major GnRH-containing areas of the hypothalamus.[14,15] These differences may be determined by gonadal sex hormone output. In sheep fetuses, secretion of LH (particularly LH pulse frequency) is permanently desensitized to estradiol negative feedback by high fetal testosterone.[16]

In late gestation, fetal hypothalamic GnRH and pituitary gonadotropin secretion fall to low levels. These changes seem explicable by the negative feedback effect of the high sex steroids produced by the fetoplacental unit. In addition, maturation of the central nervous system (CNS) tracts that inhibit hypothalamic GnRH secretion appears to progress throughout gestation.[12]

The production of gonadotropins by the fetal pituitary seems to facilitate normal ovarian development. Hypophysectomy of rhesus fetuses has been reported to reduce the number of germ cells and oocytes as well as the integrity of the rete ovarii.[17] Therefore, it seems that survival of gametes depends on the secretions of the fetal pituitary. The mechanism is unclear. This pituitary effect may be mediated through accelerated atresia, lack of support of the rete system, or lack of stimulation of the follicle.

Ovary. The ovaries differentiate in the urogenital ridge adjacent to the anlage of adrenal cortex and the kidney. The granulosa cells are the homologues of the Sertoli cells of the testes. The theca, interstitial, and hilus cells are the homologues of the Leydig cells. Hilus cells may even contain crystalloids, like Leydig cells. Adrenocortical rests have occasionally been found in the hilus of the ovary.[18] Conversely, ovarian rests have been identified in the adrenal glands.[19]

The primitive germ cells migrate into the ovary from the yolk sac endoderm during the first month of gestation. The WT-1, LIM-1, SF-1, and possibly DAX-1 genes are known to play roles in the formation of the ovaries.[20] The ovaries begin to become distinguishable from testes by 8 weeks of gestation.[21] In the absence of testicular development being switched on by the SRY gene on the Y chromosome,[22] Wnt-4 signaling sustains oocyte and granulosa cell development, and suppresses Sertoli and Leydig cell differentiation,[23] critical steps in ovarion differentiation. Mitotic division of oogonia is maximum before the third month and comes to an end by the seventh month. Oogonia then undergo oogenesis, entering the prophase of meiosis to become primary oocytes during the final 5 to 6 months of gestation.[24] The number of oocytes reaches a peak at the fifth month, when there are 6.8 million germ cells—of which 80% appear to be viable (Figure 14-3).[25]

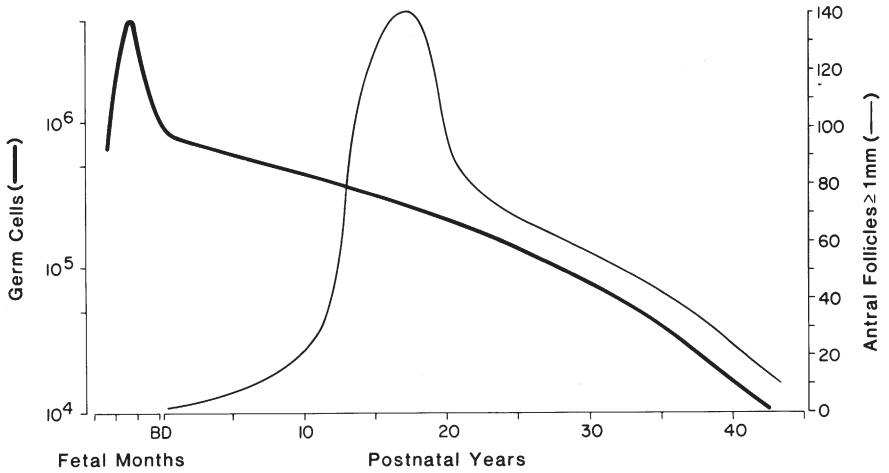

Figure 14-3 The development of ovarian follicles from fetal life to maturity. Curves for total number of viable germ cells (thick line) and large antral follicles (thin line) smoothed from the data of Baker and Block. The number of germ cells is maximal at the fifth month of fetal life. The loss of germ cells is exponential throughout postnatal life. At puberty, a marked shift occurs in the pattern of development of follicles. An increased fraction grows to large antral size.

When oocytes enter the diplotene stage of meiotic prophase they must be furnished with granulosa cells to form a primordial follicle. Otherwise, they undergo atresia.[26]

Primordial follicles appear in the fourth month, when the epithelium of the secondary sex cords provides granulosa cells to the oocytes—and they peak in number between the fifth and ninth months. They become primary follicles when the encircling granulosa cells become cuboidal. Primordial and small primary follicles (Figure 14-4)[27,28] are resting follicles that are the major repository of germ cells.[29] This stock of germ cells is depleted only very slowly during childhood (Figure 14-3).

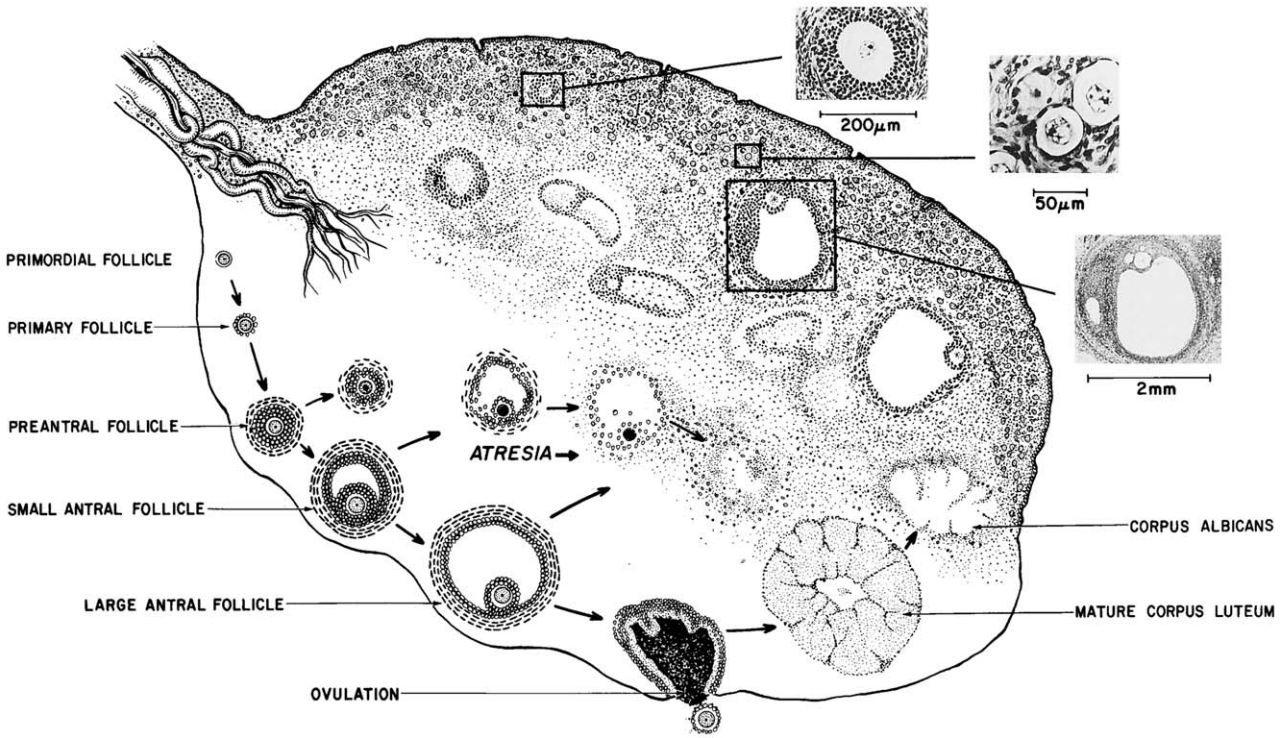

Figure 14-4 The human ovary. The lower portion of the figure shows the classification of follicles. Preantral follicles contain as many as 300 granulosa cells, and their diameter ranges from 50 to 200 m. The oocyte diameter increases from 25 or less to 80 m. Antral (graafian, tertiary, or vesicular) follicles have a fluid-filled antrum and a full-grown oocyte, are lined with more than 300 granulosa cells, and have a well-developed theca. They are greater than 200 m in diameter. The dimensions of the mature ovary are approximately 1.25 x 2.75 4 cm. The upper portion of the figure illustrates the histologic appearance of the perimenarcheal ovary. [Photomicrographs of ovarian details are reproduced from Peters H (1979). The human ovary in childhood and early maturity. Eur J Obstet Gynecol Reprod Biol 9(3):137.]; modified from Ross GT, Schreiber JR (1978). The ovary. In Yen SSC, Jaffe R (eds.), *Reproductive endocrinology*. Philadelphia: WB Saunders 63.]

Secondary follicles and preantral follicles, characterized respectively by a larger granulosa cell population and organization of theca, then appear successively. After the seventh month, antral (Graafian) follicles appear.[28,30,31] Typically, one or two antral follicles of 1 to 2 mm in diameter are present in the ovary by term, at which time the number of small preantral follicles is at its peak. At birth, ovarian follicle development is complete[28,30,31] and the complement of ova is greater than at any other time during postnatal life (Figure 14-3)—totaling 2 million, of which half appear atretic.[25,32]

Both X-chromosomes are active in oocytes,[33] and these are necessary for the full induction of the granulosa cell layer necessary to oocyte survival.[30,34] Oocyte-derived growth differentiation factor-9 is critical to signaling by the specialized granulosa cells of the cumulus to induce the theca cell layer, which in turn through the production of other autosomally determined paracrine factors, including several other members of the TGF-β superfamily, is necessary to the survival of oocytes and the further differentiation and growth of follicles.[35-39] Because ovarian germ cells, unlike male ones, are a nonrenewing population the regulation of atresia is a critical determinant of follicle number.[40] The endowment of follicles may be influenced by environmental factors such as toxins,[41] thymic factors,[42] and placental insufficiency.[43] There has also been considerable interest in the possibility that placental insufficiency, via hypoxemia and resultant overactivation of fetal prostaglandin production and cortisol secretion, is a factor predisposing to postnatal insulin resistance[44] (which has consequences for reproductive function in later life).

The major source of sex hormones in the female fetus is the fetoplacental unit. Theca-interstitial cells of the fetal primordial follicle appear to form androstenedione and dehydroepiandrosterone as early as 3 months in man, but estradiol formation probably does not occur until antral follicular development begins.[21,45] The contribution of the ovaries to fetal sex steroid levels is probably relatively low, however.

Testis. In males, the physiologic consequences of the increase in the levels of gonadotropins and sex steroid hormones include differentiation of male internal and external genitalia and descent of the testes to their scrotal position, as discussed in other chapters.

Infant and Child

Neuroendocrine Unit. The neonate undergoes a transient activation of the hypothalamic-pituitary-gonadal axis. The mechanism of gonadotropin secretion in the neonate, like that governing the onset of central activation during pubertal development, is unknown. There is reason to suspect that some of the regulatory processes may be different.[46-50] Serum FSH and LH are low in cord blood and remain so until estrogen concentrations fall from inhibitory levels upon disruption of the fetoplacental unit at birth. The LH and FSH levels of neonates then promptly begin to rise in pulsatile fashion to early pubertal levels in the first week of life (Figure 14-5).[7,11,51-54]

Serum LH rises less in girls than in boys, possibly because of lesser prenatal androgen accentuation of GnRH pulsatility.[55,56] Responses to GnRH and GnRH agonist are early pubertal (Figure 14-6).[12,57-60] In congenital agonadism, gonadotropins reach postmenopausal levels.[61] Prematurely born girls develop serum LH and FSH levels that transiently rise into the post-menopausal range, and fall to pubertal levels by about 40 weeks postconceptional age.[12] These gonadotropins appear to be bioactive judging from the reports of ovarian hyperstimulation in preterm infants.[61a] They also have higher prolactin levels than normal adults. These phenomena seem to be related to immaturity of the CNS tracts that will increasingly come to inhibit these pituitary functions in older infants.

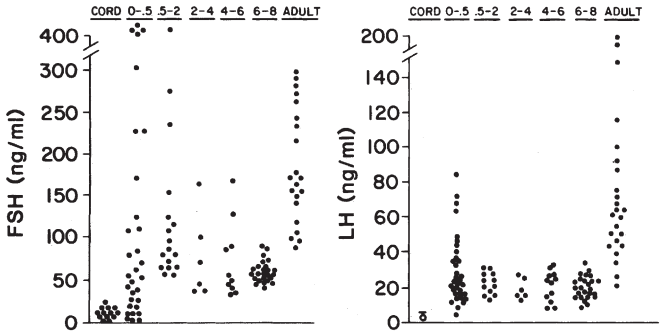

Figure 14-5 Left: The distribution of follicle-stimulating hormone (FSH). Right: Luteinizing hormone (LH) levels from infancy through adulthood (age in years). Umbilical cord level of LH measured by -subunit-specific radioimmunoassay. Pubertal values given in Figures 14-8 and 14-12. Programmed cell death in the ovary: insights and future prospects using genetic technologies. Mol Endocrinol 15:845–853.]

Gonadotropin levels then begin to gradually fall after about 4 months of age (Figure 14-5). FSH is higher in girls than in boys, a tendency that tends to persist into early childhood.[51,62] This appears to be related to an intact negative feedback system for the inhibin-B/activin-A system, with higher activin-A and lower inhibin-B levels in girls than in boys.[63] Immunoreactive GnRH excretion also tends to be greater in girls than in boys at this time.[64]

The subsequent decline in gonadotropins may well be related to an increase in hypothalamic estrogen receptors. Hypothalamic estradiol receptors increase in a pattern reciprocal to the fall in serum gonadotropins in the rat (Figure 14-7),[65] as do hypothalamic dihydrotestosterone (DHT) receptors.[66] These changes in the seeming efficiency with which the hypothalamus can recognize sex hormones could account for its increasing sensitivity to the inhibitory effect of small amounts of circulating estradiol and testosterone. However, another mechanism for the fall in gonadotropins seems to be the further

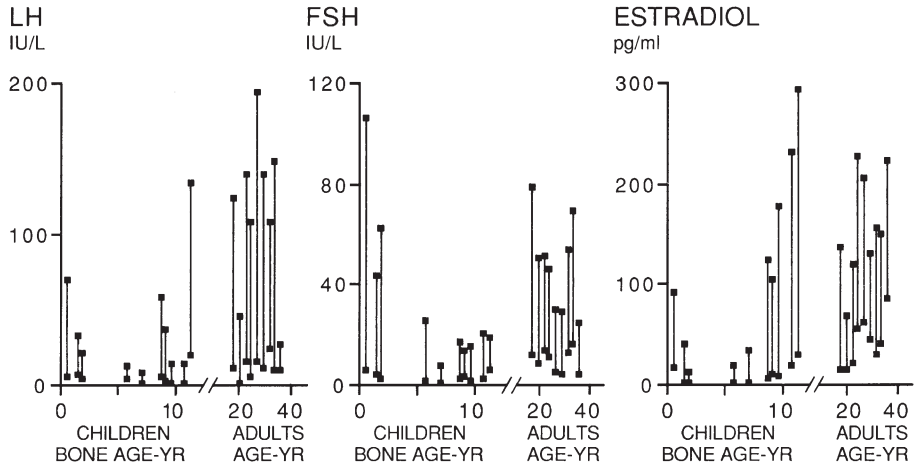

Figure 14-6 Basal and peak responses to the gonadotropin-releasing hormone agonist nafarelin (1μg/kg subcutaneously) during development. Lines connect the basal and peak responses in control children. The responses are related to bone age in children and chronologic age in adults. Note the biphasic pattern of the responses. They are high in infancy, lower in mid-childhood, and rise again during puberty. The peak gonadotropin responses occur at approximately 4 hours, and peak estradiol responses occur at 20 hours. FSH, follicle-stimulating hormone; and LH, luteinizing hormone. [From Rosenfield RL, Burstein S, Cuttler L, et al. (1989). Use of nafarelin for testing pituitary-ovarian function. maturation of neural tracts that conduct inhibitory signals from the CNS to the hypothalamus.

A nadir in both serum gonadotropins occurs by about 6 years of age (Figures 14-2 and 14-5). At this age, the LH and FSH response to GnRH is minimal—apparently because gonadotropes are sluggish from lack of GnRH stimulation. Furthermore, at this stage agonadism is seldom reflected in a rise in serum gonadotropins or gonadotropin reserve.[7,61]

However, gonadotropin production is not completely suppressed in mid-childhood. Gonadotropins have been detected in the urine of young prepubertal children, at the limits of sensitivity of classic bioassays. LH excretion averaged 3% and FSH 15% of the adult amounts.[67] Polyclonal RIA shows that gonadotropins in serial urine specimens rise intermittently.[67,68] The more specific monoclonal antibody-based assays have revealed that the very small amounts of gonadotropins produced at this age are secreted in pulses at intervals of 1 to 2 hours, rise in association with sleep, and fall to less than about 0.15 U/L during the day.[69] The gonadotropins detected by these methods also appear to be bioactive, judging from their sensitivity to estradiol negative feedback in the primate[70] and the active formation of antral follicles during childhood—which indicates gonadotropin stimulation, as discussed in the following section on the adult.

Between 7 and 10 years of age, even girls that remain prepubertal experience a doubling in the output of LH and a lesser increase in that of FSH.[71] This change corresponds with rising excretion of immunoreactive GnRH.[64] These data indicate that the hormonal secretory pattern of the prepubertal 10-year-old child is different from that of the 7-year-old and indicate that the hormonal changes signaling the development of puberty are found late in the first decade of life, antedating by some time the development of secondary sex characteristics.

Ovary. The ovary of the infant and child is not quiescent. Reinitiation of growth and development of resting follicles occurs throughout an individual's life span, although

restrained by postnatal expression of anti-Müllerian hormone (AMH).[72] The neonatal ovary typically contain an antral follicle with thecal luteinization.[73,74] Follicles start to grow, and many reach the antral stage at all ages.[26]

By 7 years of age, the number of large antral follicles approximately doubles over that in infancy—and quadruples by 9 years (Figure 14-3). The ovaries of normal girls have up to five antral follicles 4 to 9 mm in diameter in mid-childhood. More begin to appear just before the onset of puberty.[26,75-78] However, all of these large antral follicles normally undergo atresia in childhood—and this augments the amount of stroma.[26] As a result, throughout childhood ovarian volume increases (up to 4 cc by 7 years and 5.5 cc in late prepuberty).

During the first few months of life, early pubertal blood levels of ovarian hormones are found as part of the transient activation of the hypothalamic-pituitary-gonadal axis that occurs in the newborn. Plasma estradiol levels parallel those of FSH. In the neonatal period, they begin rising to early pubertal levels, remain there for the first several months of life, and fall gradually thereafter (Figure 14-8).[57] According to an ultrasensitive recombinant cell bioassay, girls' estrogen levels in late infancy are severalfold greater than those of boys, averaging 1 pg/mL and ranging up to 3 pg/mL.[79]

On occasion, there may be subclinical but detectable estrogen effects on urogenital cytology.[80] Provocation of an acute but transient increase in endogenous gonadotropins by GnRH agonist testing elicits a prompt, though tiny, rise in estradiol secretion in midchildhood.[81,82] As girls begin to experience increasing diurnal production of gonadotropins in late prepuberty, estradiol levels rise in diurnal fashion to peaks of about 6 to 12 pg/mL at midmorning.[71,83] FSH sometimes reaches the adult range in childhood (Figure 14-5). The reason more ovaries do not secrete pubertal amounts of estrogen is probably because the FSH reaches a pubertal height only episodically and/or because LH levels are not coincidentally high enough to stimulate sufficient synthesis of estradiol precursors.

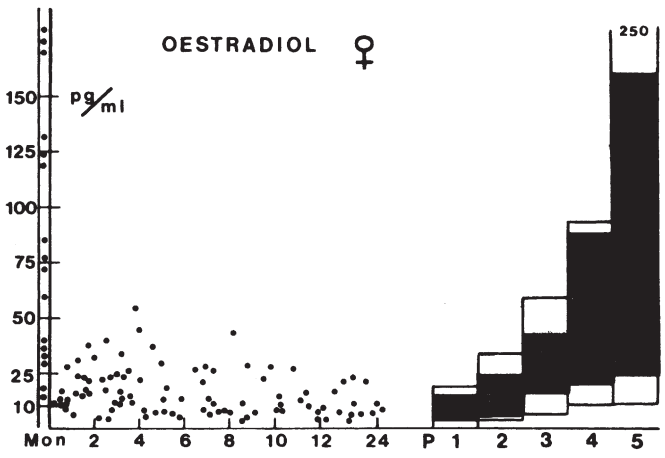

Figure 14-8 The distribution of plasma estradiol levels in infant females compared with pubertal and adult female levels. The columns represent the normal ranges for the various stages of puberty. The area between 10th and 90th percentiles is dark. Stage P1 includes all prepubertal girls older than 2 years. The values between the ordinates were found between 2 and 5 days of age. [From Bidlingmeier F, Knorr D (1978). Oestrogens: Physiological and clinical aspects. Pediatr Adolesc Endocrinol 4:43.]

Adolescent

The endocrinologic changes of puberty actually begin in late preadolescence, before secondary sex characteristics appear. The underlying basic event is increasing secretion of hypothalamic GnRH. The current concept is that puberty results when the hypothalamus begins to release GnRH with increasing frequency and amplitude, first only at night and then gradually throughout the day.

Increased GnRH secretion in man was initially deduced when Kastin et al. demonstrated that preadolescent children had GnRH-releasable pituitary stores of LH and FSH (Figures 14-6 and 14-9).[84] Subsequently, it was reported that in man the excretion of an immunoreactive fragment of GnRH increases to adult levels during puberty.[64,85] Studies in the rat suggest that hypothalamic GnRH granules increase through puberty.[86]

Knobil subsequently showed that puberty can be induced in the immature female rhesus monkey by administering GnRH in hourly pulses that yield blood levels of about 2,000 pg/mL.[87] Prolonged administration of GnRH according to this regimen first gradually brings about transient increases in LH and FSH. This then induces

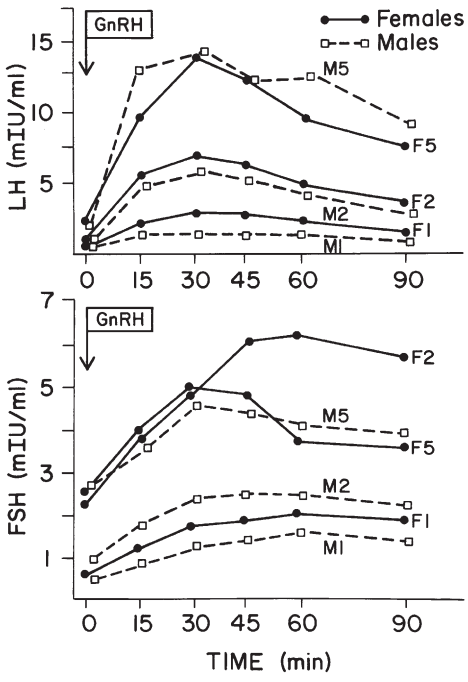

Figure 14-9 The luteinizing hormone (LH) and follicle-stimulating hormone (FSH) responses to gonadotropin-releasing hormone (GnRH) bolus (50 μg/kg/day) in males (M) and females (F) in prepuberty (age 5 to 6 years: F1, M1), early puberty (F2, M2), and later puberty (F5, M5). The responses to GnRH tend to progress with advancing puberty. However, early pubertal girls have a readily releasable FSH pool that is greater than that of more advanced adolescents. The peak responses of girls tend to be somewhat greater than those of boys at comparable stages. [Data from Dickerman Z, Prager-Lewin R, Laron Z (1976). Response of plasma LH and FSH to synthetic LHRH in children at various pubertal stages. Am J Dis Child 130:634.]

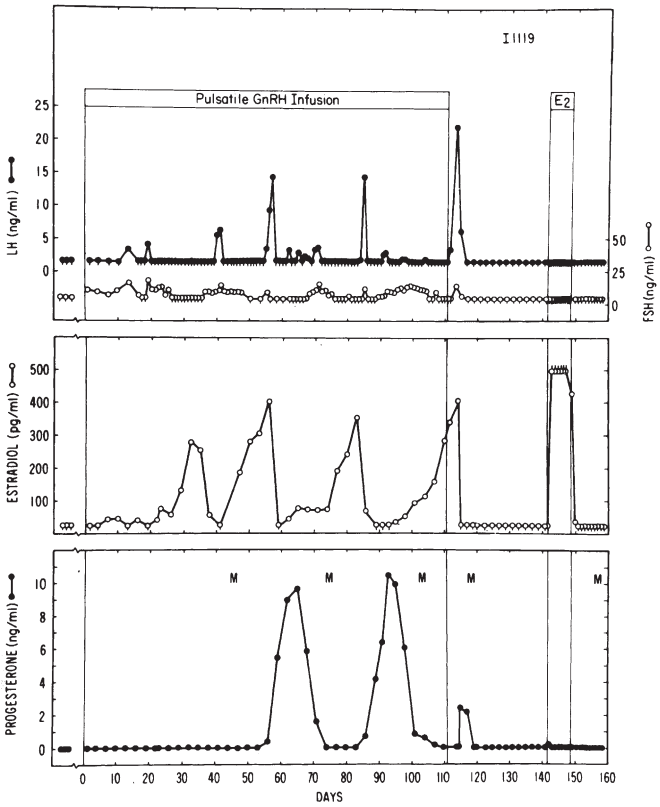

Figure 14-10 Induction of puberty in a 13-month-old prepubertal rhesus monkey by an unvarying pulsatile gonadotropin-releasing hormone (GnRH) regimen (1 μg/min × 6 min hourly). Luteinizing hormone (LH), folliclestimulating hormone (FSH), estradiol (E2), and progesterone were undetectable before the GnRH infusion. On GnRH infusion, a rise in FSH was the first change detectable by mid-morning sampling midway between GnRH pulses. A substantial E2 surge occurred approximately 1 month later. The subsequent LH surge was too modest to elicit ovulation, but menses (M) occurred a few days after subsidence of the week-long E2 surge—menarche resulting from an anovulatory cycle. Continuation of the GnRH led to the sustained occurrence of ovulatory menstrual cycles at 28-day intervals. An identical outcome results if an arcuate-lesioned adult animal undergoes this GnRH regimen. The third of the LH surges occurred 2 days after GnRH was discontinued. Progesterone secretion from the corpus luteum was blunted and transient in the absence of sustained LH secretion. A subsequent increase in plasma E2 produced by E2 implantation subcutaneously failed to elicit a gonadotropin surge, indicating that the animal had reverted to an immature state. Menarche eventually spontaneously recurred in such animals at the usual age (approximately 27 months). Small vertical lines beneath data points indicate values below the sensitivity of the assay. Note that gonadotropins and E2 were often undetectable (prepubertal range) during the induced puberty. [From Knobil E (1980). The neuroendocrine control of the menstrual cycle. Recent Prog Horm Res 36:53.]

cyclic follicular development. The resultant moderate estradiol surge is of such magnitude as to result in menarche due to withdrawal menstrual bleeding in an anovulatory cycle (Figure 14-10). Continuation of the same GnRH regimen leads to development of normal monthly ovulatory menstrual periods. Physiologic pulses of GnRH in man probably attain lower concentrations (200 pg/mL) and occur at slightly wider intervals than in monkeys.[88] Consequently, LH pulses in mature women occur at intervals of approximately 1 to 1.5 hours during the follicular phases—slowing during the luteal phase.[89]

Puberty begins in girls when serum FSH begins to rise disproportionately to the level of LH.[51,90] In part, FSH predominates because the relatively infrequent GnRH pulses of very early puberty favor the accumulation of FSH because of its slower clearance. FSH also seems to become less regulated by GnRH.[69] The possible explanations for differential regulation of FSH and LH are discussed later in this chapter. This early predominance of FSH has important biologic consequences. It leads to relatively selective growth and development of the follicular compartment of the ovary. Furthermore, the pubertal gonadotropin changes seem to become cyclic well before menarche[7,91] and are capable of inducing cyclic estrogen production.[80,91] Our working model of the nature of pituitary-ovarian dynamics in early puberty is illustrated in Figure 14-11.

Puberty progresses as LH rises. Whereas serum FSH levels rise about 2.5-fold over the course of puberty, LH levels rise 25-fold or more.[69] The initial change in LH secretion at the beginning of puberty is a nightly increase in LH secretion that begins within 20 minutes of the onset of sleep. Subsequently, LH increases more with the onset of sleep, stays up longer, and falls less during waking hours. As the child approaches menarche, the daytime LH levels continue to increase until the diurnal rhythm is typically lost. FSH levels follow a similar pattern, although the FSH changes are less striking. The gonadotropin diurnal rhythm is more resistant to acute sleep reversal than is that of growth hormone (GH).[92] There is a delay of about 12 hours between the peak LH level during sleep and the estradiol zenith, and thus estradiol levels are maximal at mid-morning.[83] The gonadotropin and estradiol rhythms in an early pubertal girl are shown in Figure 14-12.[93]

Augmentation of the bioactivity of plasma LH seems to occur during puberty. Plasma LH bioactivity rises nearly fivefold more during the course of puberty than does LH as measured by polyclonal RIA (Figure 14-13).[94,95] The change in bioactive LH is mirrored well by the third-generation ("pediatric") monoclonal antibody-based immunometric assays, which have very high specificity for bioactive LH epitopes. However, disparities in the ratio of bioactive to immunoreactive LH (B/I) persist with these assays, for reasons related to the molecular microheterogeneity of gonadotropins (discussed later in the chapter). Serum FSH rises during puberty by immunoassay more than by bioassay.[96]

Estradiol output increases rapidly in the year approaching menarche.[97] This seems to be the result of a variety of autoamplification phenomena that facilitate puberty, maturation of the dominant follicle, and ovulation. These are summarized in Table 14-1.[98-111] These phenomena occur at all levels of the axis. The CNS is stimulated by preovulatory levels of estradiol to increase GnRH pulse size. At the pituitary level, there is the self-priming effect of GnRH whereby a pulse of GnRH sensitizes the pituitary to have a greater LH response to a subsequent identical GnRH pulse. Critical patterns of estradiol and progesterone secretion enhance the pituitary LH and FSH responsiveness to GnRH. At the gonadal level, the cascade of events is

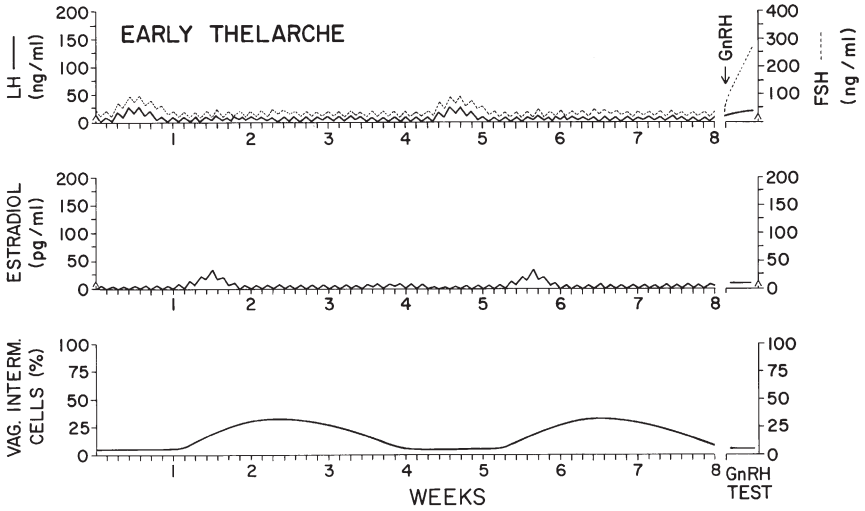

Figure 14-11 Diagram depicting our working hypothesis of the hormonal patterns in girls during very early puberty. We conceptualize this pattern as occurring both cyclically in the earliest stage of normal puberty and occasionally in unsustained sexual precocity (i.e., most U.S. cases of idiopathic premature thelarche). Daytime and nighttime serum concentrations of hormones (gonadotropins relative to the LER-907 standard) and the percentage of intermediate cells on vaginal smear are shown. The typical response to a gonadotropin-releasing hormone (GnRH) test is illustrated. Subclinical hormonal cycles lasting approximately 1 month result from a few days of increased follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretion. Because the drive to gonadotropin release is relatively weak, FSH and LH production are suppressed promptly and for long periods of time by the resultant modest amounts of estradiol (E2) secretion. Estradiol is detectable in plasma for only a few days a month. Maturation of the vaginal mucosa, however, is detectable for approximately 2 weeks after E2 production has waned.

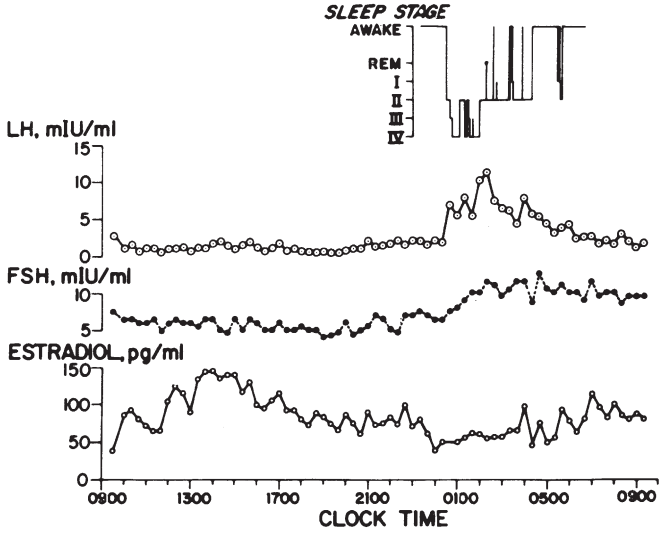

Figure 14-12 The patterns of serum luteinizing hormone (LH), follicle-stimulating hormone (FSH), and estradiol (E2) typical of early female puberty. Note that daytime gonadotropin levels are in the prepubertal range. Note also the episodic nature of LH release at intervals of 1 to 3 hours. Estradiol levels are seen to fluctuate considerably in the course of the daytime, rising to peak levels about 12 hours after the maximum nocturnal gonadotropin surges. [From Boyar RM, Wu RHK, Roffwarg H, et al. (1976). Human puberty: 24-hour estradiol patterns in pubertal girls. J Clin Endocrinol Metab 43:1418.]

augmented by the FSH induction of aromatase activity and progestin production in granulosa cells—phenomena in which androgens play a synergistic role. Furthermore, FSH stimulates granulosa cell mitosis and induces LH receptors—phenomena in which estradiol may play a synergistic role. Subsequently, LH is able to further enhance the aromatase and progesterone effects. Progesterone itself plays a synergistic role in stimulating granulosa cell progesterone and prostaglandin synthesis in concert with FSH and LH. In the rat, ovarian GnRH receptor sites also diminish just before ovulation[112]—and at about this time the ovary changes its pattern of metabolism so that the secretion of androstanediol-3β-monosulfate decreases to levels that are no longer inhibitory to LH secretion.[113]

The preovulatory gonadotropin surge occurs when all of these cascading processes culminate in activation of the positive feedback mechanism, the hallmark of sexual maturity in the female. "Positive feedback" refers to the

TABLE 14-1

Autoamplification Processes Involved in Pubertal Progression, Follicle Maturation, and Ovulation

Central nervous system GnRH secretion increases[98,99] via:
- E2-inducing progesterone receptors[100]
- Progesterone synergization with E2[101]

Pituitary LH and FSH responsiveness to GnRH increases via:
- GnRH self-priming[102]
- Critical patterns of E2 secretion-stimulating LH/FSH responsiveness,[103-105]
- Progesterone synergization with E2[104-106]
- LH bioactivity increases[94]

Gonadal responsiveness to FSH and LH increases via:
- FSH-inducing aromatase and progesterone in granulosa cells: androgens and progesterone synergization with this effect[107-109]
- FSH-stimulated granulosa meiosis[29] and FSH-inducing granulosa LH receptors; IGF-1 synergization[110]

E2, estradiol; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; IGF-1, insulin-like growth factor-1; and LH, luteinizing hormone.

neuroendocrine system acquiring the ability to secrete a midcycle surge of LH when the ovary signals via increasing estrogen secretion that it is prepared for ovulation.

Menarche does not necessarily indicate full maturation of the neuroendocrine-ovarian axis. As the studies of Knobil illustrate (Figure 14-10), the first menstruation can be due to estrogen-withdrawal bleeding (half of the time) but ovulatory cycles may follow in short order. General characteristics of the mature ovary are shown in Figure 14-4.

The morphology of the normal adolescent ovary has long been considered polycystic, and histologic examination has typically shown thecal luteinization.[73,114] In the perimenarcheal period, the combination of a high number of follicles and mature gonadotropin stimulation leads to a greater number of large antral follicles than at any other stage (Figure 14-3). Ultrasound imaging has shown that about one-quarter of normal adolescents develop "multifollicular" ovaries (containing four to ten follicles of 4-10 mm diameter in the maximum plane without increased ovarian stroma),[115,116] which are considered to be a variation of normal. Polycystic ovaries (over ten follicles and/or increased size) occur in only 10% of regularly menstruating schoolgirls.[116a] Regression of polycystic ovaries probably occurs in fewer than 10% of cases.[76,117] The ovary normally achieves adult size and ultrasound morphology by 14 years of age.[115,117]

Adult

Normal Menstrual Cycle: Hormone Patterns. In many respects, puberty is recapitulated during the follicular phase of each menstrual cycle. The pattern of gonadotropin and steroid hormone levels is shown in Figure 14-14.[118,119] Gonadotropin and sex hormone levels are low during the premenstrual phase of the mature cycle (Figure 14-14A). Gonadotropin concentrations then increase at the time of menstruation, FSH predominating in the early follicular phase while nocturnal LH pulsation is slow[120] (Figure 14-14B). Luteinizing hormone pulsation increases to a circhoral pattern around a stable baseline, and estradiol production slowly begins (Figure 14-14C). Estradiol levels gradually increase, and serum FSH levels fall reciprocally (Figure 14-14D). The subsequent geometric increase in plasma estradiol

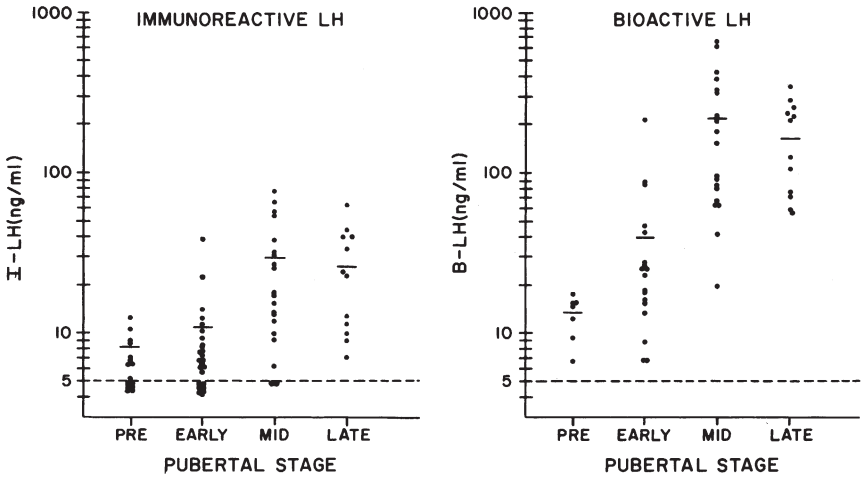

Figure 14-13 Bioactive luteinizing hormone (B-LH) (right) and immunoreactive LH (I-LH) (left) in the same daytime serum samples of girls 10 to 16 years of age at various pubertal stages. The dashed lines indicate the limit of sensitivity of the assays. B-LH rises relatively more than I-LH in the course of puberty. The peak in the apparent biopotency of LH, estimated from the ratio of B-LH to I-LH, occurs at about the time of menarche. "Late" indicates early follicular phase normally menstruating postmenarcheal girls. Standard LER-907: 100 ng equivalent to 6 mIU LH of First International Reference Preparation of human pituitary gonadotropin. The disparity between immunoreactivity and bioactivity is principally due to the presence of different proportions of immunoreactive and bioactive LH moieties in serum and standards. The ratio of bioactivity to immunoreactivity is closer to unity when sera are assayed against highly purified standards (like the first and second IRP of human luteinizing hormone), which have about fivefold higher specific activity and yield dose response relationships with serum LH that are more linear. [Data from Lucky AW, Rich BH, Rosenfield RL, et al. (1980). LH bioactivity increases more than immunoreactivity during puberty. J Pediatr 97:205; and from Rosenfield RL, Helke J (1992). Is an immunoassay available for the measurement of bioactive LH in serum? J Androl 13:1.]

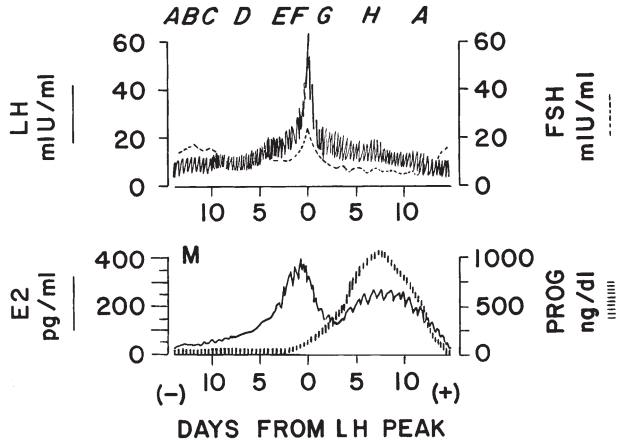

Figure 14-14 Mean gonadotropin and sex steroid levels during the normal menstrual cycle. The data are centered in reference to days before or after the day of the luteinizing hormone (LH) peak (day 0). Letters A through F above the top panel correspond to stages of follicular development in Figure 14-15. G and H are discussed in text. M (bottom panel) shows time of menses. E2, estradiol; FSH, follicle-stimulating hormone; and PROG, progesterone. (Data from Abraham GE (1974). Ovarian and adrenal contributions to peripheral androgens during the menstrual cycle. J Clin Endocrinol Metab 39:340; and from Ross GT, Cargille CM, Lipsett MB, et al. (1970). Pituitary and gonadal hormones in women during spontaneous and induced ovulatory cycles. Recent Prog Horm Res 26:1.]

concentrations then selectively amplifies the pituitary's LH response to GnRH as estradiol reaches about 90 pg/mL for longer than 3 days[103-105] (Figure 14-14E).

When the plasma estradiol rises to greater than 200 to 300 pg/mL for 36 hr, the positive feedback mechanism is activated and the midcycle gonadotropin surge commences (Figure 14-14F). Estradiol then induces progesterone receptor (PR) expression in the hypothalamus and pituitary.[100] Progesterone increasing to 100 ng/dL facilitates the LH surge, shortens the duration of time over which estradiol is required for the surge to 24 hours, and brings about an FSH surge. The mechanism of progesterone action involves inhibition of GnRH cleavage.[106] Androgens may also play a role in facilitating FSH and GnRH release.[121,122] The LH surge is then primarily responsible for luteinizing the preovulatory ovarian follicle (Figure 14-14F). At this time, LH pulses become larger in amplitude but slower in frequency and their apparent bioactivity increases. Ovulation then results.

Estrogen levels fall when the follicle is disrupted (Figure 14-14G). As the corpus luteum begins to form, progesterone increases steadily to be sustained at very high levels for several days—along with lesser but substantial increases in estradiol and 17-hydroxyprogesterone levels (Figure 14-14H). In response to the high progesterone level, gonadotropin pulsation slows.[120] In the absence of increasing human chorionic gonadotropin (hCG) from a conceptus, the corpus luteum's life span is exhausted and its production of progesterone and estradiol wanes. Subsequently, FSH begins to rise out of proportion to LH. Shortly after the sex steroids withdraw from the scene, the endometrium sloughs—giving rise to menstrual flow. Meanwhile, the follicular growth induced earlier by FSH begins to gain momentum and the next cycle begins.

Follicular (Proliferative) Phase Ovary. The hormonal functions of the follicle have dual purposes that must be closely coordinated: to change the milieu of the ovum to prepare for ovulation and to signal the pituitary to send the signal to ovulate (the LH surge). Thus, the ovary is the zeitgeber for the cycle: the normal cyclic pattern of ovarian hormone secretion induces the midcycle surge of pituitary gonadotropins in the presence of unchanging circhoral pulses of GnRH.[87] The processes triggered also autoamplify the gonadotropin signal (Table 14-1). Ovarian hormones also play a facilitating role in this event by augmenting the amplitude of the GnRH response,[98-101] thereby "guaranteeing" a preovulatory gonadotropin surge.

Ovarian follicular development and steroid secretion in relationship to changing gonadotropin levels are illustrated in Figure 14-15.[29,35,123,124] FSH and LH play major roles in granulosa and thecal cell differentiation, respectively, whereas a host of local factors modulate gonadotropin action. For example, follicular maturation in response to gonadotropins is enhanced by insulin-like growth factors (IGFs), transforming growth factor (TGF)-β, and fibroblast growth factor—whereas it is inhibited by TGF-α, epidermal growth factor, and other factors.

Primordial follicle growth and development is gonadotropin independent. Subsequently, granulosa cells of preantral follicles develop FSH receptors—and theca cells, which encircle granulosa cells, develop LH receptors (Figure 14-15A). Activin can cause FSH-independent upregulation of FSH receptors in preantral follicles,[111] although it opposes FSH stimulation of antral follicle development.[29] The forkhead transcription factor Foxo3a seems to be an important suppressor of early follicle growth, and in its absence follicles initially overgrow and then undergo premature atresia.[125] Fetal undernutrition has been suspected of restricting the follicular endowment.[126]

The initiation of antrum formation is promoted by the presence of FSH, although it is unclear in man whether FSH is absolutely required or is required in only trace amounts (Figure 14-15B).[29,127-129] FSH stimulates androgen receptor expression in primary follicles.[130] Androgen action is necessary to the early stages of follicular growth and development of a full complement of follicles, and androgen excess stimulates excessive follicle number.[131,132] Luteinizing hormone stimulates the appearance in thecal cells of the enzymes necessary to androgen biosynthesis.[133] Androgens in turn stimulate further expression of FSH receptors and the early stages of follicular growth.[130] Some theca cells of small antral follicles are also capable of producing small amounts of estradiol.[134]

As antral follicles reach approximately 1 mm in diameter, their granulosa cells begin to form estradiol from androgen supplied by theca cells (Figure 14-15C).[135-139] Androgen production at low levels may synergize with FSH to stimulate aromatase activity within the granulosa cells.[107,140,141]

For growth beyond 2 mm in diameter, follicles are increasingly FSH dependent and consequently uniformly FSH responsive.[29,127] Antral follicles do not develop without the FSH receptor,[142] and do not grow over 5 mm in diameter without FSH.[129] IGF-I is required for follicular growth

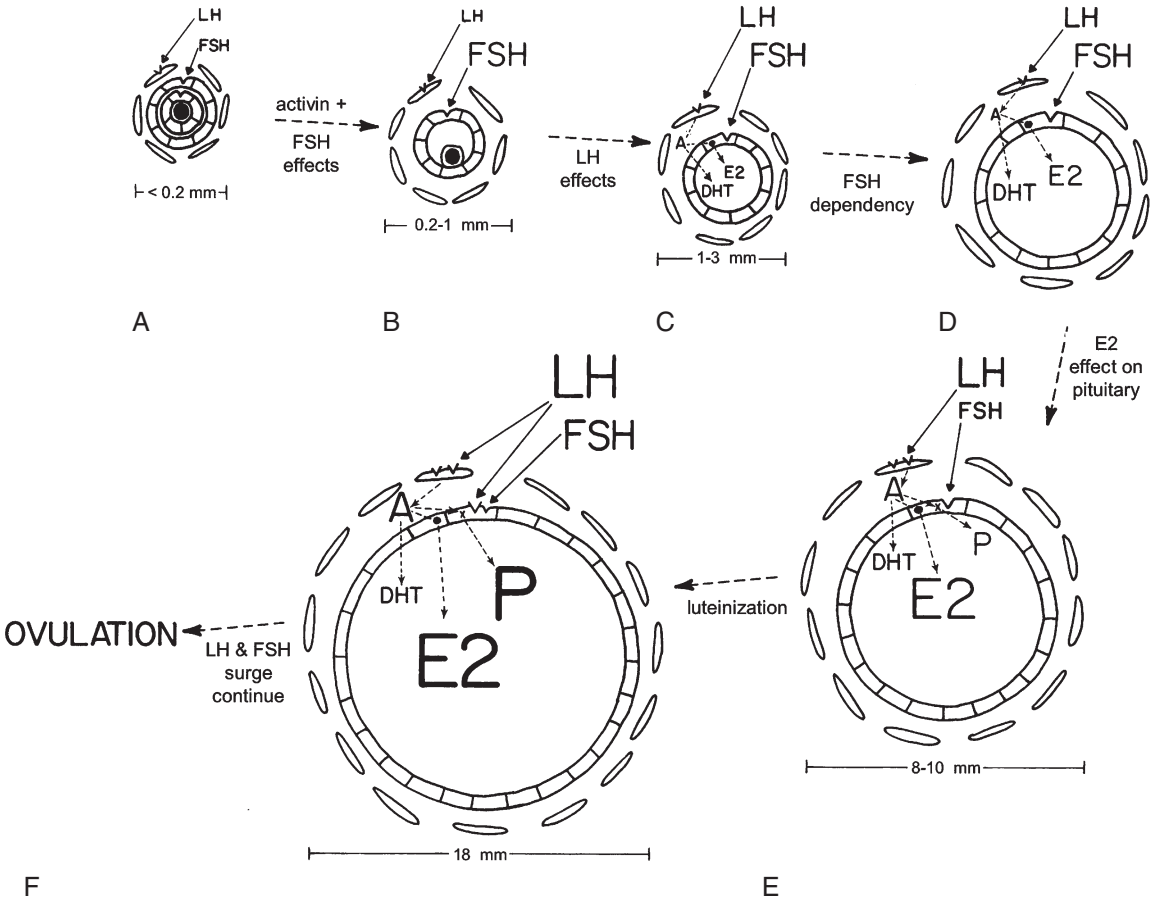

Figure 14-15 Relationships among gonadotropins, the ovarian follicle, and ovarian steroids according to the two-cell two-gonadotropin model of ovarian steroidogenesis. A through F: Stages of ovarian follicular development found during the times of the menstrual cycle designated by the corresponding letters on Figure 14-14. The size of the letters designating hormones relates to the magnitude of their serum and/or follicular concentrations. *(A)* Preantral follicle with luteinizing hormone (LH) and follicle-stimulating hormone (FSH) receptors in theca and granulosa cells, respectively. There is no antrum surrounding the ovum (stippled in center). *(B)* Small antral follicle. This appears to develop in response to FSH. The ovum, which becomes eccentric, is not shown in larger antral follicles. *(C)* Large antral follicle (1 mm or larger). Aromatase activity (.) has been induced in granulosa cells. Interactions between theca and granulosa cells, the former producing androgens (androstenedione: A), result in increasing estradiol (E2) and dihydrotestosterone (DHT) synthesis. A small amount of E2 secretion probably also occurs in theca cells at this stage (not shown). *(D)* FSH-dependent follicular growth results in more E2 synthesis. *(E)* Estradiol enhances pituitary LH secretion in response to GnRH, while at the same time inhibiting pituitary FSH secretion. The increased LH induces more theca LH receptors and stimulates androgen production. Androgens serve as substrate for E2 formation and synergize with FSH to stimulate progesterone (P) secretion. *(F)* In the preovulatory follicle, FSH induces LH receptors on the granulosa cell—which completes luteinization. Steroid secretion is augmented further. Then, increasing progesterone amplifies the positive feedback effect of E2 to initiate the preovulatory gonadotropin surge.

beyond the early antral stage in response to FSH.[143] By the mid-follicular phase, the proliferation of FSH-responsive granulosa cells results in an accelerating rate of estradiol production and preferential conversion of androstenedione to estradiol rather than to DHT by these cells (Figure 14-l5D).[135-137,139,144,145] Estradiol itself clearly stimulates proliferation of granulosa cells in rats, and estrogen receptors are necessary to postpubertal maintenance of granulosa cell differentiation and oocyte survival in mice.[146] Recent evidence suggests that estradiol promotes antral growth independently of LH in humans, too.[146a]

A dominant follicle is selected at the beginning of the menstrual cycle from a crop of follicles that were recruited 2.5 months prior.[29] Recruitment of a group of follicles is normally promoted by the midcycle FSH surge and regresses with increasing corpus luteum progesterone secretion. Another wave of follicle growth in the late luteal phase is promoted by the rise of FSH as luteal progesterone and estradiol secretion wanes. The selected follicle is the one most sensitivite to FSH (lowest "FSH threshold"). FSH is critically important during the follicular phase for optimal development of this dominant follicle. By the mid-follicular phase of the cycle, this follicle becomes virtually the sole source of estradiol (Figure 14-15E). Typically, there is only one such follicle. Only this follicle continues to grow, reaching a diameter of 10 mm or larger. All other gonadotropin-dependent follicles undergo atresia.

At this stage, the rising estradiol level is suppressing FSH secretion and augmenting pituitary LH responsiveness to GnRH. FSH is more bioactive in the dominant follicle because it is more efficiently concentrated[144] and

because local factors increase ovarian responsiveness to FSH. The increased LH causes further proliferation of thecal cells and an increase in their LH receptor content.[108] Androgen production is consequently increased. This synergizes with FSH to augment aromatase activity and bring about increasing progesterone secretion by the well-estrogenized granulosa cells of these follicles. Progesterone then enhances the synthesis of itself and of estradiol.[108,109] The increased thecal androstenedione production is diverted much more to estradiol than to dihydrotestosterone biosynthesis. Antral fluid steroid concentrations reflect these changes (Figure 14-16).[135,136,144] Activin acts to prevent premature luteinization of granulosa cells, and activin tone seems to wane as the preovulatory phase approaches.[29,111]

FSH next induces LH receptors in the granulosa cells (Figure 14-15F).[110] These luteinized granulosa cells are capable of augmenting estradiol and progestin production in response to LH as well as FSH. The LH and FSH surge then occurs in response to the positive feedback action of estradiol at both the CNS and pituitary levels, an effect amplified by the rising levels of progesterone. The final steps in follicle maturation ensue rapidly: the LH surge induces granulosa cell PR and prostaglandin synthase

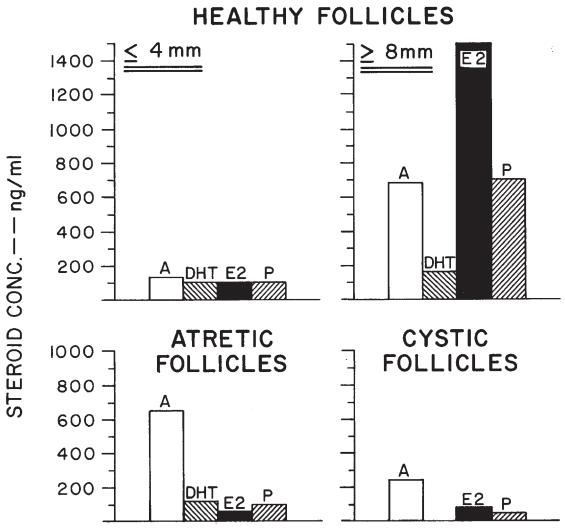

Figure 14-16 Normal human antral fluid steroid concentrations. Healthy follicles are well populated by granulosa cells (50% or more of maximal complement). Healthy follicles seem capable of further development because many of them (75%) contain healthy-appearing oocytes (histologically intact germinal vesicles), 96% of which are viable in culture. Moderately large follicles (8 mm or larger in diameter) make their appearance only in the mid-follicular phase of the cycle and contain follicle-stimulating hormone. Data are shown only for those large follicles well populated by granulosa cells, only one of which usually arises in the follicular phase of each menstrual cycle. Atretic follicles are small follicles beginning to show degenerative changes in the number of granulosa cells and appearance of the oocyte. Cystic follicles tend to be larger follicles with only a sparse granulosa cell lining. The testosterone content of antral fluid is about a third that of dihydrotestosterone (DHT) owing to the pattern of granulosa cell metabolism of androstenedione (A). E2, estradiol; and P, progesterone. [Interpolation based on the data of McNatty KP, Makris A, Reinhold VN, et al. (1979). Steroids 34:429. J Clin Endocrinol Metab 49:851, 1979.]

while inhibiting cyclin gene transcription. These are all critical steps in preparing for ovulation. In their absence, ovulation and follicular rupture do not occur.[147]

The follicle then promptly becomes desensitized to LH and FSH and ceases to grow.[148] This is followed by an inflammatory-type response. Protease activity, prostaglandin production, plasminogen activitor production, and vascular permeability increase; the intercellular spaces fill with mucopolysaccharides; and cell junctions loosen. Meiosis resumes in response to a specific phosphodiesterase,[149] forming the haploid gamete (secondary oocyte) and the first polar body in response to the LH surge.[150] (A premature LH surge in a subject with an unripe follicle will not result in ovulation.) Ovulation then occurs. Meiosis will go to completion, and the second polar body will be extruded only in response to contact with a sperm.

The processes stimulating dominant follicle emergence are delicately balanced by those preventing it. It seems critical that the intraovarian concentration of androgens not become excessive or no follicles will remain viable beyond about the 8-mm stage.[137] Androgen excess seems to prevent the emergence of dominant follicles by antagonizing granulosa cell proliferation and development.[151] The mechanisms involved include inhibition of aromatase in situations of low FSH activity[107,140] and antagonism of LH receptor formation and action.[109,152] Follicles arrested in their growth become atretic, and atretic follicles contain relatively high concentrations of androgens (Figure 14-16). Progesterone also suppresses further differentiation of nondominant follicles[153] by some of the same mechanisms.[154] High concentrations of estrogen play a critical role in inhibiting selection of the dominant follicles in primates.[155] If there is interference with estrogenization, multiple large cystic follicles develop that are impaired in their abiity to ovulate and undergo androgen-dependent atresia.[156-158]

AMH and inhibins have recently emerged as other important follicular factors important to the direct and indirect regulation of follicular development. Granulosa cells of preantral and small antral follicles produce AMH, which exerts a paracrine negative feedback effect on the differentiation of primordial follicles and inhibits aromatase activity.[72,159-161] They also produce inhibins, which are regulated by FSH in a negative feedback loop and up-regulate thecal steroidogenesis (discussed later in the chapter). Inhibin-B is the predominant form of inhibin. Inhibin-A is a product of the preovulatory follicle (and corpus luteum) that responds to LH and FSH.[162,163]

Atresia is the fate of all except the few hundred follicles chosen for ovulation during an individual's life span. Most follicles beyond the primordial stage become atretic. Atresia occurs by the process of programmed cell death.[29] This apoptotic process has diverse determinants, including cell death inducer and repressor genes.[40,124] FSH support becomes increasingly necessary to survival as the follicle matures, and it is normally only the follicle that has the lowest FSH threshold that escapes atresia.

Luteal (Secretory) Phase Ovary. Following ovulatory rupture of the Graafian follicle, capillaries and fibroblasts from the theca proliferate and break down the separating

basement membrane. The luteinized granulosa and theca cells then intermingle and complete the luteinization process. These two cell types contribute about equally to corpus luteum steroidogenesis.[164] Histologically, luteinization is a process of lipid accumulation. The biochemical hallmark of luteinization is the capacity for progesterone biosynthesis in response to LH. This is accompanied by increased estrogen secretion in man.[165,166]

During its functional life span the corpus luteum is normally the major source of the sex hormones secreted by the ovary. Corpus luteum function reaches its peak about 4 days after ovulation and begins to wane about 4 days before menstruation (Figure 14-14H). Loss of sensitivity to LH and estradiol heralds luteal senescence. Regression of the corpus luteum-luteolysis occurs if pregnancy does not provide chorionic gonadotropin (hCG). Luteolysis is probably mediated by prostaglandin. Transformation of the corpus luteum into an avascular scar, the corpus albicans, then occurs.

Early luteal-phase increases in secretion of estradiol and progesterone cause secretory transformation and hyperplasia of the endometrium. Later falloff in secretion of female hormones to a level insufficient to maintain the endometrium results in menstruation. Withdrawal of progesterone is specifically responsible for constriction of spiral arteries, local prostaglandin accumulation, and subsequent ischemic necrosis of the endometrium. Normal menstrual flow then results from a complete slough of the secretory endometrium.

A major determinant of normal corpus luteum formation and function is optimal development of the corpus luteum predecessor, the dominant follicle. Experimental lowering of FSH levels in the early follicular phase has been shown to impair subsequent corpus luteum function.[167]

REGULATION OF THE NEUROENDOCRINE-OVARIAN AXIS

Factors Controlling the Onset of Puberty

The mechanisms by which neuroendocrine and genetic factors control pubertal development remain unknown. Epidemiologic studies indicate that nutrition and environmental chemicals, as well as ethnicity and genetic factors, are important in the pubertal process.[168] Evidence that there are genetic factors involved at the time of puberty comes from multiple studies.[169-179] It has been estimated that between 50% and 80% of the variation in the timing of puberty is determined by genes. Hypogonadotropic hypogonadism has been associated with mutations in single genes, including GnRHR, KAL-1, FGFR-1, GPR54, and LHX3.[180-182a]

Although mutations in these genes have been shown to cause physiologic interruptions in development, their role in the initiation of puberty remains unknown. Single nucleotide polymorphisms (SNPs) for GnRH and GnRH receptor genes used to detect associations with late pubertal development have not accounted for variations in the timing of puberty in the general population.[183] The key in the initiation of puberty is the activation of the hypothalamic GnRH pulse generator. The molecular events that control the pulse generator include a complex interplay between inhibitory and stimulatory factors. The mechanism of central activation of puberty first appears to be a consequence of a removal of a restraint mechanism, with a rise in gonadotropin secretion (initially nocturnally).[46]

This restraint in the GnRH pulse generator is independent of the presence of gonads[61] and is more intense in males.[184] However, the high levels of testosterone to which the male fetus was exposed during the period of sexual differentiation may be responsible for the more prolonged suppression of GnRH release in males than in females. A role for decreased estrogen feedback sensitivity by the hypothalamic pulse generator near the time of puberty has also been shown.[185] Several factors have been shown to have a role in restraining the GnRH pulse generator. They include GnRH itself, NPY, GABA, leptin, and TGF-alpha, and their receptors.

Recent evidence points to an important role for GPR54 (a G-protein–coupled receptor) and its ligand (kisspeptin) as a signal for pubertal GnRH release. Expression of both proteins has been found to increase prior to pubertal resurgence associated with the increase in GnRH pulse generator activity in the hypothalamus.[49] Activation of GPR54 by kisspeptin stimulates LH and FSH release via the activation of GnRH. This activation can be abolished by GnRH antagonists. Mutations in the GPR54 gene result in hypogonadotropic hypogonadism.[181,186,187] However, mutations in GPR54 have not been found in boys with pubertal delay. Nor have polymorphic sequences been associated with delay of pubertal development.[188]

Elegant studies in primates have demonstrated an increase in kisspeptin in pubertal development, with a corresponding increase in GPR54 associated with an increase in LH. However, whether this increase is dependent on activation of the neuronal pulse generator is unclear. The maximum level of expression of kisspeptin and GPR54 in the hypothalamus in both males and females occurs at puberty.[47,189] Chronic administration of kisspeptin to immature female rats induces precocious activation of the central axis.[189] In addition, chronic treatment with kisspeptin restores pubertal development in a rat model of undernutrition.[190] Kisspeptin may thus influence the priming of puberty and the integration of nutritional and energy status. Although it is clear that kisspeptin activation of GnRH neurons occurs at puberty and that GnRH is increasingly sensitive to kisspeptin activation during development,[191] it is unknown whether kisspeptin is the trigger of mammalian puberty or the effector of higher regulatory substances.

Initiation of puberty involves coordinated changes in transsynaptic and glial-neuronal communication.[48] The major inhibitory systems are GABAergic and opioidergic, whereas the major excitatory systems involve glutamate and kisspeptin—with glial cells facilitating GnRH secretion in diverse ways (Figure 14-17). Decreased GABA signaling via $GABA_A$ receptors and increased glutamate signaling via glutamate receptors of several types (ionotropic and metabotropic) are the major proximate changes in neurotransmission involved in the onset of puberty.[46,48,184] Glial cells facilitate the process through elaboration of transforming growth factors (TGFs), other growth factors, prostaglandin E_2, and the elaboration of enzymes that control the concentration

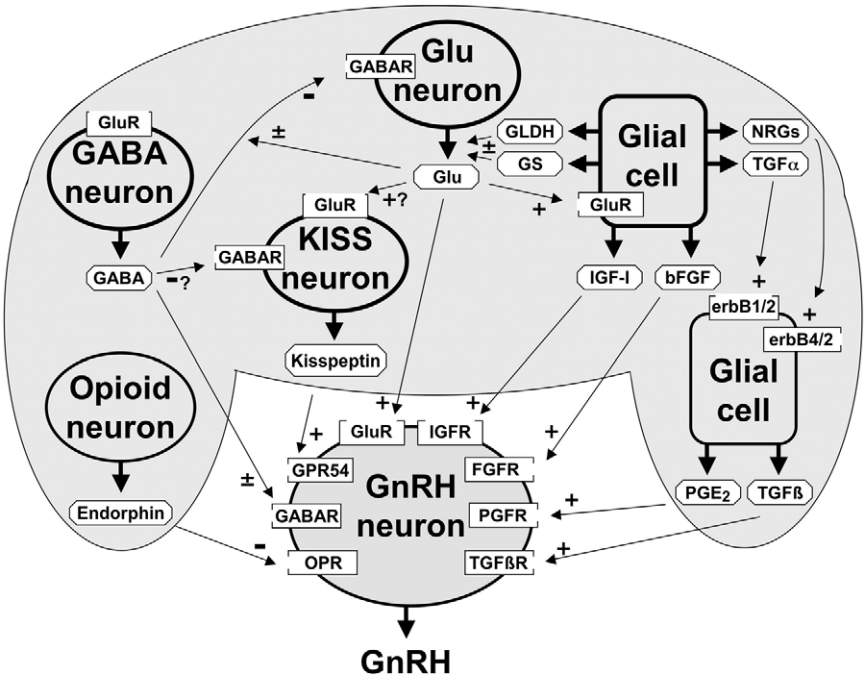

Figure 14-17 The molecular biological basis for the major known proximate hypothalamic pathways regulating GnRH secretion. The left-hand column depicts the major inhibitory pathways, which involve GABA signaling through the GABA receptor and opiodergic signaling through the endorphin receptor (OPR). The central column depicts the major excitatory pathways, which involve glutamate (Glu) signaling through the family of glutamate receptors and kisspeptin (KISS) signaling through GPR54. The right-hand column shows the major glial factors that facilitate GnRH release. These include the elaboration of the enzymes glutamic dehydrogenase (GLDH) and glutamine synthase (GS), which regulate the concentration of glutamate and the elaboration of a variety of growth factors. The KISS neuron has not been isolated at this time, and thus its illustrated signaling pathways are based on indirect evidence. bFGF = basic fibroblast growth factor, erbB 1-4 are subunits for the TGFα and NRG receptors, IGF-I = insulin -like growth factor, NRG = neuroregulins, PGE = prostaglandin E, R = receptor, TGFα = tumor growth factor-α, TGFß = tumor growth factor ß, + = positive stimulation, - = inhibition, ± = either, and ? = unknown. [Modified from Ojeda SR, Lomniczi A, Mastronardi C, Heger S, Roth C, Parent AS, et al. (2006). The neuroendocrine regulation of puberty: Is the time ripe for a systems biology approach? Endocrinology 147:1166–1174.]

of glutamate [glutamic dehydrogenase (which catalyzes the synthesis of glutamate) and glutamine synthase, which converts glutamate to glutamine].

The basis of the change in neurotransmitter balance is becoming clearer. A second tier of control seems to be modulation of these processes by increased hypothalamic expression at puberty of tumor-suppressor genes that act to integrate glial-neuronal interactions. A yet higher echelon of candidate hypothalamic genes has been identified. These are transcriptional regulators of the second-tier genes. These genes include Oct-2 (a regulator of the POU-domain homeobox genes), EAP-1 (enhanced at puberty-1), and thyroid transcription factor-I (TTF-1)—knockout of which delays puberty and decreases fertility in mice.

Genes contiguous with elastin appear to be involved in the pace of puberty. Deletion of chromosome 7q11.23 in Williams syndrome typically leads to an early normal onset but rapid pace of puberty, with an abbreviated pubertal growth spurt.[192] Lesioning studies suggest that two sets of tracts carrying opposing stimuli are involved. Inhibitory tracts mainly seem to be routed through the posterior hypothalamus, and stimulatory tracts through the anterior hypothalamic preoptic area.[1,193]

An overview of the systems involved in regulating the initiation of puberty is shown in Figure 14-18. Pubertal maturation and skeletal maturation seem to have common determinants. Abundant clinical evidence indicates that sex hormones are one of these.[194,195] Thus, genes involved in sex hormone metabolism and action are candidate regulators of the onset of puberty—and there has been speculation that fetal or early childhood exposure to hormonally active environmental chemicals (environmental disruptors) may influence the onset of puberty.[168]

The GH-IGF system is another determinant. GH facilitates the onset and tempo of puberty.[196] Experimental studies suggest that this occurs through GH or IGF actions at all levels of the neuroendocrine-ovarian axis.[197,198] Girls generally enter puberty when they achieve a pubertal bone age. Pubertal stage normally correlates better with bone age ($r = 0.82$) than with chronologic age ($r = 0.72$, unpublished data), particularly as menarche approaches.[199] Skeletal age correlates better with menarche than with chronologic age, height, or weight—and its variance at menarche is half that of chronologic age.[200]

The bone age at the onset of breast development averages about 10.75 years, and that at menarche averages about 13.0 years. Disorders that accelerate bone maturation, such as congenital adrenal hyperplasia or hyperthyroidism, tend to advance the age of onset of true puberty.[201] Disorders that retard skeletal maturation (such as GH deficiency, hypothyroidism, and anemia) tend to delay the onset of puberty.[202] On the other hand, some data suggest that factors linked to intrauterine growth

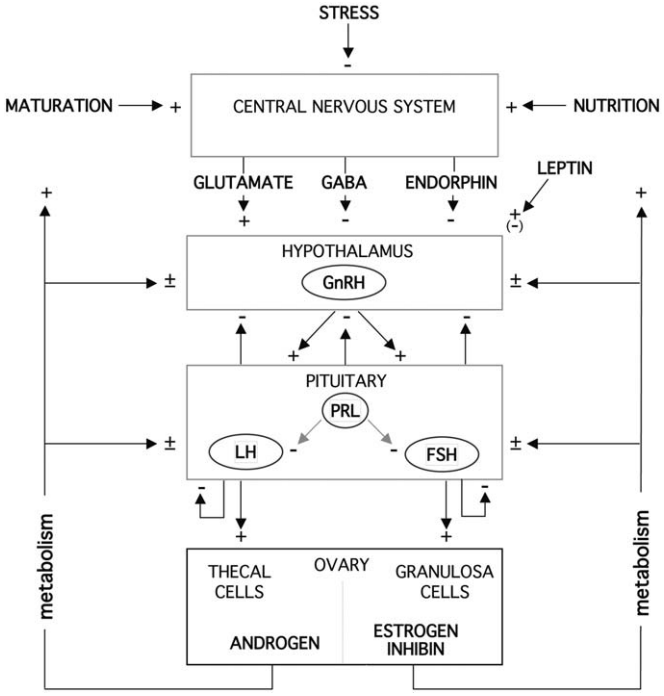

Figure 14-18 Diagram of the major mechanisms controlling the development and function of sex hormone secretion by the unripe antral follicle. Regulation may be either stimulatory (+) or inhibitory (−). The central nervous system (CNS) influences gonadatropin-releasing hormone (GnRH) secretion both negatively and positively. For the CNS to relinquish its inhibitory control over GnRH secretion, it must achieve a high level of maturity. Even after this is achieved, psychological or physical stress may negatively influence the system. Nutrition must be optimal. Its effects are reversible. Leptin is a critical mediator of the nutrition effect. Sex steroids have a maturing effect. Whether efferent tracts from the hypothalamus to the cerebrum play a role in reproductive function is unknown. Pineal secretion of melatonin and other substances are known to exert inhibitory influences on GnRH in lower animals (not shown). GnRH stimulates luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Paracrine and autocrine feedback of the gonadatropins on GnRH release and their own release, respectively, are shown. Prolactin (PRL) has multiple effects on gonadotropin secretion. In unripe antral follicles, LH acts on thecal and interstitial cells and FSH acts on granulosa cells. Androstenedione and testosterone secreted by the theca cells are aromatized by the granulosa cell, under the influence of FSH, to estradiol. The granulosa cell is also the site of production of the FSH inhibitor inhibin B. Estradiol has a diphasic effect on the mature pituitary and on hypothalamic GnRH release as well. Androgens seem normally to be of minor importance in regulating gonadotropin release in females. Intraovarian mechanisms seem to modulate LH action so as to coordinate thecal formation of androgens with granulosa cell formation of estrogens. Paracrine and autocrine factors, including insulin-like growth factors, are involved. GABA, gamma-aminobutyric acid.

retardation (although not necessarily the growth retardation itself) predispose to sexual precocity.[168]

Optimal nutrition is clearly necessary to initiation and maintenance of normal menstrual cycles. The hypothesis that body fat is the weight-related trigger for pubertal development originated with the discovery by Frisch and co-workers that weight correlated with initiation of the pubertal growth spurt, peak growth velocity, and menarche better than with chronologic age or height.[203] Mid-childhood may be a critical period for weight to influence the onset of puberty.[168] Suboptimal nutrition related to socioeconomic factors is more of an important factor in the later onset of puberty in underdeveloped than in developed countries.[168] Conversely, obesity appears to be an important factor in advancing the onset of puberty in the United States.[204,205]

Leptin appears to be an important link between nutrition and the attainment and maintenance of reproductive competence.[184,206,207] Leptin deficiency causes obesity and gonadotropin deficiency. Paradoxically, prolonged leptin excess down-regulates GnRH release.[208] Leptin is secreted by fat cells. It acts on the hypothalamus to reduce appetite and to stimulate gonadotropin secretion. Inhibition of hypothalamic neuropeptide Y formation mediates part of the leptin effect.[209] A critical threshold level appears to signal that nutritional stores are sufficient for mature function of the GnRH pulse generator and are thus permissive of puberty. Blood leptin levels rise throughout childhood and puberty to reach higher levels in girls than in boys.[210] Leptin-binding protein, a truncated form of the leptin receptor, falls as puberty begins—which suggests that circulating leptin becomes more bioavailable at this time. Whether leptin has a direct role in the pubertal activation of the GnH pulse generator is unknown. In models of leptin insufficiency, the administration of kisspeptin-induced LH secretion indicates that the role of leptin in the initiation of puberty is upstream of kisspeptin.[189]

Other factors link nutrition and gonadotropic function. Other cues that provide information on nutritional status to the central reproductive axis may include glucose,[211] ghrelin,[212] and insulin.[213] The effect of these factors on LH pulstility may be mediated directly at the level of the gonadotroph or indirectly by changes in GnRH secretion. There is little evidence for the role of pineal secretions in human reproduction that is found in lower animals.[214, 215]

The essential element for the onset of puberty is an increase in pulsatile hypothalamic GnRH secretion that is regulated by a complex interplay of excitatory and inhibitory signals that have yet to be fully understood or elucidated.[48] During childhood the activity of the GnRH pulse generating system is restrained for reasons that are unclear. An awakening of the pulse generator occurs gradually during late childhood with an increasing tempo during early puberty. The mechanism for the increasing GnRH neuronal activation at the initiation of puberty is also unknown. The pubertal diminution in tone of the CNS centers that inhibit hypothalamic GnRH secretion during childhood has traditionally been considered to result from decreasing sensitivity of a "gonadostat" to negative feedback by sex steroids.[6,216,217] However, this now seems an overly simplistic concept for a mechanism that seems to involve a change in the balance of neural inhibitory and stimulatory signals that impinge upon the GnRH neuron.

Many studies have been performed to help understand the initiating developmental events or the "trigger" for pubertal onset. In fact, it is becoming increasingly clear that there is no single 'trigger' for puberty, but a gradual

increase in GnRH pulsatility associated with a complex interplay of factors and hypothalamic developmental programs. The integration of hypothalamic signaling systems along with the developmental changes in the control of GnRH neuronal function converge to trigger the onset of puberty. Thus, the apparent "sensitivity of the gonadostat" seems increasingly likely to reflect the degree of activity of the GnRH neuron. That is, when GnRH secretory activity is attenuated the pulse generator is easily inhibited. When the GnRH neuron is active, the pulse generator is relatively insensitive to negative feedback.

Regulation of Gonadotropin Secretion

An essential feature of the mature hypothalamic-pituitary-gonadal axis is the long-loop negative feedback control of gonadotropin secretion by gonadal secretory products, as depicted in Figure 14-18. The generally tonic nature of gonadotropin secretion is punctuated by two types of periodicity: two- to threefold pulsations of LH above trough levels at 1.5- to 2.0-hour intervals, and in the sexually mature female by a transient midcycle preovulatory gonadotropin surge. The latter is characterized by a greater than tenfold rapid rise of LH and a lesser rise of FSH. This surge is brought about by positive feedback when a critical level of estradiol, facilitated by a modest rise in progesterone, is achieved for a critical period of time (as discussed in relation to Figure 14-14).

Estradiol, in concert with inhibin, reciprocally regulates FSH in a sensitive, log-dose, negative-feedback arrangement.[251] Progesterone in high (luteal phase) concentrations appears to be the major negative regulator of GnRH-LH pulse frequency.[100] Androgens at normal levels do not contribute to long-loop negative feedback regulation of gonadotropins.

Estradiol exerts triphasic, and progesterone biphasic, effects on gonadotropin secretion. As estradiol rises into the late follicular phase range it reduces FSH levels, at preovulatory levels it transiently induces positive feedback, and at sustained high levels it suppresses gonadotropins. As progesterone reaches a preovulatory level, it enhances the estradiol positive feedback effect, but at sustained high levels it suppresses LH pulse frequency while enhancing LH pulse amplitude.[100]

The GnRH neurons primarily responsible for maintenance of the reproductive cycle are those of the arcuate (infundibular) nucleus (Figure 14-19).[87] GnRH neurons are inherently pulsatile.[219] Synchrony is promoted by fluxes of ionic calcium into these cells and autocrine GnRH inhibitory feedback. GnRH secretion is modulated by the variety of neurotransmitters and growth factors involved in initiating puberty.[48] Synchrony of the network of GnRH neurons that comprises the pulse generator is conferred when the hypothalamic concentration of GABA periodically falls from levels inhibitory to $GABA_A$ receptors in the presence of an excitatory neurotransmitter.[220,221]

Sex steroid signals are in part conveyed to GnRH neurons indirectly from higher centers. Regulation of GnRH secretion by estrogen also involves induction of PRs in the hypothalamus.[100,222] GnRH neuronal cell lines have been studied in which estradiol has been shown to directly stimulate and inhibit GnRH gene expression under different experimental conditions.[223,224] Progesterone also exerts its main inhibitory effect on GnRH secretion.[225,226] Prolactin suppresses both hypothalamic and gonadotropin GnRH receptor expression.[227,228]

Other clinically relevant factors affecting GnRH release are endorphins (endogenous opioids) and interleukins. Endorphins are important physiologic regulators of

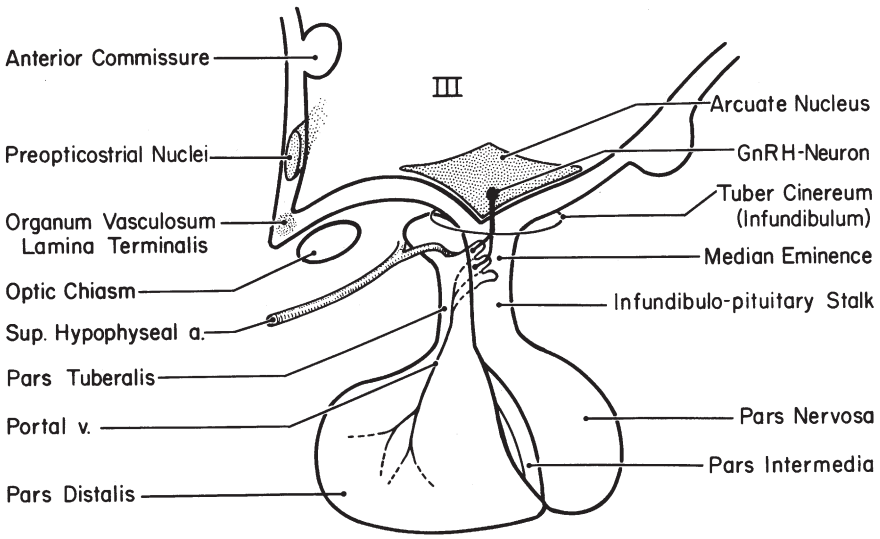

Figure 14-19 The location of major gonadotropin-releasing hormone (GnRH)-containing neurons (shaded) in relation to the hypothalamus and pituitary gland. The neurons are of greatest density in the arcuate nuclei and in the periventricular wall of the medial basal hypothalamus. These neurons project to the adjacent median eminence, the second most dense population of GnRH neurons lies in the preopticostrial area. The development of some is altered by early androgenization. Some are connected by the stria terminalis to the amygdalae. Other projections from this area appear to connect indirectly with the median eminence, perhaps via the organum vasculosum lamina terminalis—a midline structure that resembles the median eminence. The pituitary portal veins transport blood rich in releasing factors to sinusoids engulfing anterior pituitary cells.

GnRH release after puberty has begun. Hypothalamic β-endorphin suppresses oophorectomy-initiated GnRH secretion, and opiate antagonists reverse this effect. The inhibitory effect of stress on gonadotropin release appears to be mediated by β-endorphin released from proopiomelanocortin in response to corticotrophin-releasing hormone.[229] Interleukins inhibit gonadotropin release.[230]

A variety of other neuropeptides influence GnRH release.[5,209,231] Neuropeptide-Y (NPY) is a potent appetite-stimulating member of the pancreatic polypeptide family that stimulates appetite and directly inhibits GnRH release during food deprivation.[209] However, on a background of estrogenization it stimulates GnRH release—an effect mediated by a different neural network acting on a different NPY receptor subtype on the GnRH neuron.[232] Other peptides may also be involved in facilitating the LH surge.[233]

GnRH receptors are maintained in an optimally active state only when GnRH is delivered in pulses approximately 1 to 2 hours apart in man.[87,234,235] Pulses substantially less frequent result in a hypogonadotropic state. Paradoxically, continuous administration of an initially stimulatory dose of GnRH results in down-regulation of gonadotropin production after an initial burst of gonadotropin release. This is the physiologic basis for the success of long-acting gonadotropin agonists in suppressing puberty in children with true central precocious puberty. Pituitary GnRH receptors appear to be directly and indirectly down-regulated by GnRH, inhibins, and sex steroid.[235] LH and FSH themselves inhibit GnRH release (short-loop feedback) and inhibit their own release (ultra-short-loop or autocrine feedback).[236,237]

How is differential regulation of LH and FSH release accomplished in response to a single GnRH pulse? Considerable research has been devoted to potential modulators of the GnRH signal. The frequency of the GnRH pulse is one determinant. Slowing this signal moderately stimulates FSH β-subunits and suppresses follistatin gene expression, raising the FSH/LH ratio.[238] Pituitary-adenylate-cyclase-activating polypeptide amplifies LH responses to GnRH while blocking its effect on FSH.[239]

The sex hormone milieu is also clearly a major differential modulator of LH and FSH release.[87,240-243] FSH is more sensitive than LH to inhibition by estrogen. This effect of modest levels of estradiol is of rapid onset and is sustained. LH is the more sensitive to the stimulatory effects of higher estradiol levels. This effect is of later onset and is short-lived. Similar relationships pertain to aromatase null mice. Estrogen receptor (ER) null mice have identified estrogen receptor alpha as the predominant receptor isoform that conveys negative feedback regulation to the gonadotroph.[244] Progesterone exerts both negative and positive feedback effects at the pituitary level, and these effects are antagonized by androgen. The progesterone metabolite 3β-hydroxyprogesterone suppresses FSH release.[245]

Inhibins of gonadal origin seem to be the major nonsteroidal-specific negative feedback regulator of pituitary FSH synthesis and secretion.[246,247] Inhibins may not only inhibit FSH release at the pituitary level but may act at a higher level.[248] Serum levels of both inhibins rise upon FSH stimulation.[162,163] Inhibin-B, produced by small developing follicles in response to FSH, is virtually the only inhibin moiety in blood during puberty. Its blood levels rise during the early follicular phase and then fall thereafter except for a small postovulatory peak, generally paralleling the changes in serum FSH. The latter peak may function to attenuate the FSH surge. Serum inhibin-A, a marker of the preovulatory follicle and corpus luteum, begins to rise in the late follicular phase and thereafter parallels those of progesterone. Its fall late in the luteal phase appears to contribute to the early follicular phase rise in the FSH level.

Inhibins also have important local effects, and the structurally related activins seem to be normally important entirely as regulators of both pituitary and ovary function.[249] The primary role of activin in the pituitary is to signal the release of FSH. It is formed by gonadotropes themselves, as is the activin binding protein follistatin.[209,250] It also stimulates the secretion of follistatin within folliculostellate cells of the anterior pituitary. Follistatin, by competitively inhibiting binding of activin to its receptor, specifically inhibits activin stimulation of FSH secretion.[251]

Regulation of Ovarian Secretion

Ovarian secretion results from the combined actions of LH and FSH (Fig. 14-20), as discussed previously in regard to Figures 14-14 and 14-15. Androstenedione is the most abundant steroid formed in the ovary, and it is secreted by the theca-interstitial-stromal (thecal) cell compartment in response to LH. Estrogen is predominantly formed from precursor androgen in response to FSH in granulosa cells. FSH also stimulates granulosa cells to secrete inhibins. Androgen formation by the ovary is primarily regulated by LH. As by-products of the secretion of both ovarian estradiol and adrenal cortisol, androgens do not normally contribute to negative feedback regulation of gonadotropins. However, they have a biphasic effect on gonadotropin secretion: modest elevations increase GnRH pulse frequency by interfering with progesterone negative feedback[252, 253] and very high levels directly inhibit gonadotropin secretion.

The regulation of the intraovarian androgen concentration is critical to ovarian function.[254] Androgens are obligate substrates for estradiol biosynthesis and promote the growth of small follicles. However, in excess they appear to interfere with the process of follicular maturation—preventing the emergence of the dominant follicle and committing the follicle to atresia, as well as interfering with LH action on luteinized granulosa cells. Therefore, androgen synthesis must be kept to the minimum necessary to optimize follicular development. This means that the synthesis of ovarian androgens must be coordinated with the needs of the follicle. This is achieved by intraovarian intracrine, autocrine, and paracrine modulation of LH action.

A model of the interaction among some of the major factors regulating steroidogenesis is shown in Figure 14-20.[255] Stimulation of androgen secretion by LH appears to be augmented by specific intraovarian FSH-dependent factors, such as inhibins and IGF's.[129] These processes seem to normally be counterbalanced by other FSH-dependent processes that down-regulate androgen formation as LH stimulation increases. Androgens and

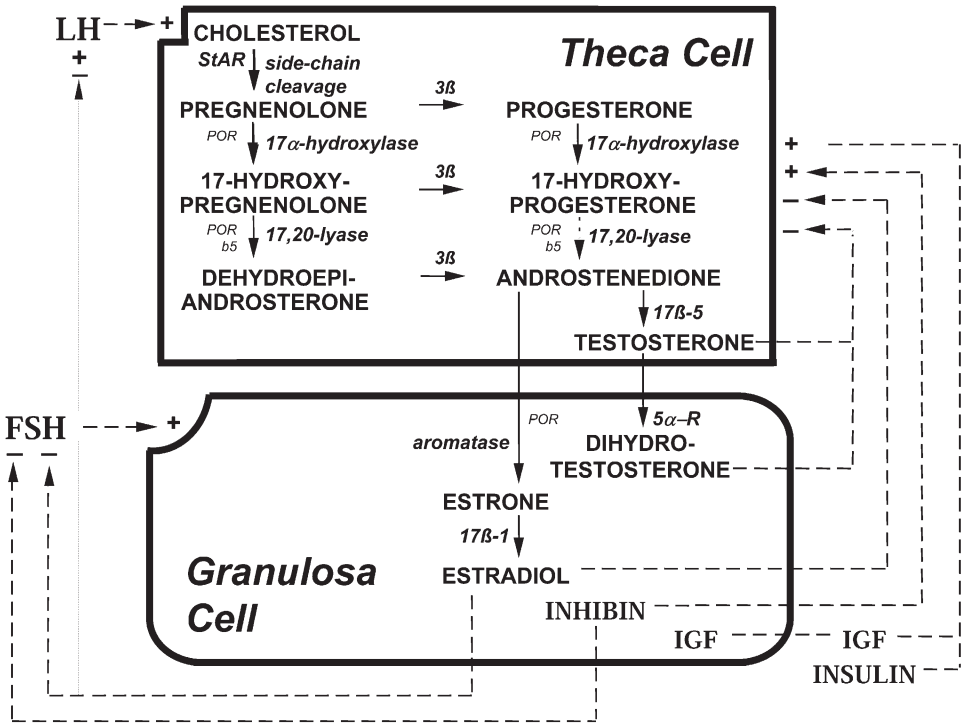

Figure 14-20 Major factors regulating ovarian androgen and estrogen biosynthesis depicted according to the two-cell two-gonadotropin model. Luteinizing hormone (LH) stimulates androgen formation within theca cells by means of the steroidogenic pathway common to the gonads and adrenal glands. Follicle-stimulating hormone (FSH) regulates estradiol biosynthesis from androgen by granulosa cell. Estradiol at early to mid-follicular phase levels does not exert a long-loop negative feeback effect on LH. Androgen formation in response to LH appears to be modulated by intraovarian and endocrine feedback at multiple levels, prominently including 17-hydroxylase and 17,20-lyase—both of which may be activities of cytochrome P-450c17 and side-chain cleavage. Androgen (via dihydrotestosterone) and estradiol inhibit (_), and inhibin, insulin, and insulin-like growth factors (IGFs) stimulate (_) enzyme activities. The sites of aromatase and IGF gene expression appear to vary with the stage of follicular development. Other peptides probably also modulate the steroidogenic response to LH. 3_, _5-Isomerase-3_-hydroxysteroid dehydrogenase (HSD): 17β-HSD5, type 5 17β-HSD; 5α-R, 5α-reductase. [Modified from Ehrmann DA, Barnes RB, Rosenfield RL (1995). Polycystic ovary syndrome as functional ovarian hyperandrogenism due to dysregulation of androgen secretion. Endocr Rev 16:322.]

estrogens themselves seem to mediate at least a portion of this desensitization to LH, with estrogens being critical through an ERα-dependent mechanism.[243]

Insulin and insulin-like growth factors are important co-regulators of ovarian function. The entire IGF system is represented in the ovary. The IGF system is essential to full FSH action. Indeed, IGF-I augments FSH receptor expression.[143, 256] Insulin is a potent augmentor of androgen and estrogen biosynthesis in response to gonadotropins, and insulin receptor mRNA is ubiquitous in all ovarian compartments at all phases of the cycle. In addition, insulin may exert its effects indirectly by its interactions with the IGF system in multiple ways. These include binding to the IGF-I receptor, up-regulating that receptor, and lowering the concentration of IGF binding protein-1 in the blood. GH also promotes granulosa cell steroidogenesis.[257,258]

Many other peptides modulate ovarian cell growth or function in response to gonadotropins.[254,255] Inhibin stimulates ovarian androgen production, whereas androgens reciprocally stimulate ovarian inhibin production. Activin opposes the inhibin effect. A variety of other ovarian peptides are also capable of modulating thecal androgen synthesis.[255] Stimulators include catecholamines (for which an intraovarian system exists[259]), prostaglandin, and angiotensin. Inhibitors include leptin, corticotrophin-releasing hormone, epidermal growth factor, tumor necrosis factor, TGF-β, and growth differentiation factor-9.[36] Leptin antagonizes IGF-1 effects.[260]

TGF-β is particularly interesting because it suppresses androgen biosynthesis and stimulates aromatase activity. It also stimulates meiotic maturation of the oocyte.[261] Other peptides acting on granulosa cells include cytokines (which have diverse effects)[256] and AMH, which inhibits aromatase.[159] GnRH is also capable of modulating thecal steroidogenesis. A GnRH-like protein has been described in the ovary that may act through ovarian GnRH receptors to suppress steroidogenesis in the human ovary.[262,263] It inhibits FSH induction of progesterone secretion, aromatase activity, and LH receptors in granulosa cells; down-regulates LH receptors; and inhibits the hCG stimulation of progesterone secretion by luteal cells.[110,123]

Prolactin has complex effects on steroidogenesis. In low concentrations, it enhances ovarian estradiol and progesterone secretion by increasing LH receptors.[264] On the other hand, high levels of prolactin inhibit ovarian estradiol and progesterone biosynthesis.[265] Prolactin also stimulates adrenal androgen production.[266]

ADRENARCHE AND THE REGULATION OF ADRENAL ANDROGEN SECRETION

Adrenarche is the onset of the adrenal androgen production that gradually begins in mid-childhood well before the pubertal maturation of the neuroendocrine-gonadal axis.[267,268] It represents a change in the pattern of adrenal secretory response to ACTH (Figure 14-21). It is characterized by disproportionate rises in the responses to ACTH of the Δ^5-3β-hydroxysteroids 17-hydroxypregnenolone and dehydroepiandrosterone (DHEA), whereas cortisol secretion does not change. Dehydroepiandrosterone sulfate (DHEAS) is the predominant marker for adrenarche. A DHEAS level greater than 40 μg/dL is usually considered adrenarcheal. Other plasma androgens and precursors are ordinarily at the upper end of the prepubertal range at the onset of adrenarche.

Adrenarche reflects the development of the adrenocortical zona reticularis. This zone becomes continuous at about 6 years of age and enlarges steadily over the subsequent decade. Its increasing development correlates with DHEAS levels. This zone's secretion pattern results from a unique enzyme expression profile: it expresses low 3β-hydroxysteroid dehydrogenase type 2 (3βHSD2) but high cytochrome b5 (an enhancer of the 17,20-lyase activity of cytochrome P450c17) and steroid sulfotransferase (SULT2A1) activities.

The zona reticularis may originate from persistent cells of the fetal adrenocortical zone that have failed to undergo involution. A pituitary hormone ("adrenarche factor") may well be required to bring about their adrenarcheal development.[4] It has been postulated to be an ACTH-related hormone distinct from ACTH because adrenal androgen production is more sensitive to glucocorticoid suppression than is cortisol production,[269] falls more slowly than cortisol after dexamethasone administration,[118] and rises more sluggishly after its withdrawal.[270] Candidates for a dexamethasone-suppressible adrenarchal factor include pro-ACTH-related peptides and corticotropin-releasing hormone (CRH). However, the data have not been convincing.[271] Prolactin may be involved.[272]

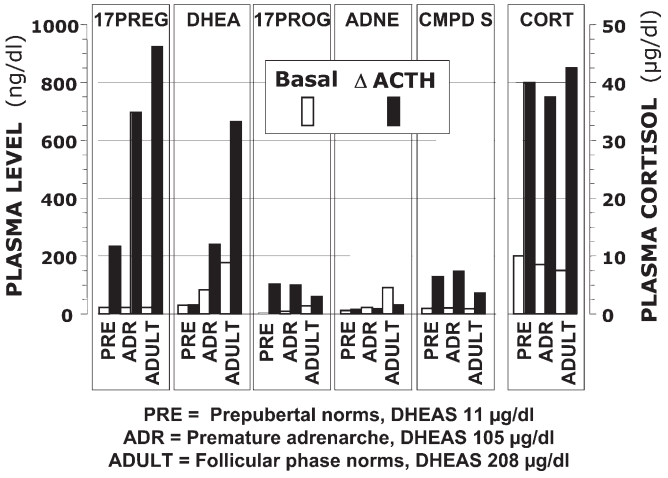

Figure 14-21 Changing pattern of adrenal steroidogenic response to adrenocorticotropic hormone with maturation. Shown are plasma steroid levels before (basal, 8:00 a.m. after dexamethasone 1 mg/m^2) and the rise (Δ) 30 minutes after cosyntropin (ACTH) administration (10 μg/m^2) in healthy prepubertal children, children with premature adrenarche as an isolated phenomenon, and follicular phase adult women. Note that 17-hydroxypregnenolone (17PREG) and dehydroepiandrosterone (DHEA) responses of children with premature adrenarche are intermediate between prepubertal and adult responses. 17PROG, 17-hydroxyprogesterone; ADIONE, androstenedione; CMPD S, 11-deoxycortisol; and DHEAS, DHEA sulfate. [Based on data from Rich BH, Rosenfield RL, Lucky AW, Helke JC, Otto P (1981). Adrenarche: Changing adrenal response to adrenocorticotropin. J Clin Endocrinol Metab 52:1129.]

Currently, the only established adrenal-androgen-stimulating hormone in postnatal life is ACTH. Because the adrenarchal secretion pattern represents a change in the pattern of steroidogenic response to ACTH, an adrenarche factor need only control the growth and differentiation of the zona reticularis or regulate its unique pattern of steroidogenic enzyme expression. A number of factors are known to enhance adrenal androgen output. Insulin and IGF-I particularly stimulate expression of adrenal 3β and P450c17 activities. Leptin has been reported to stimulate P450c17 activity.[273] In addition, interleukin-6 is strongly expressed in the zona reticularis and stimulates DHEA secretion.[274] Whereas gonadal dysgenesis is associated with earlier adrenarche,[275] paradoxically ovariectomy precipitates an early decline in DHEAS levels that is not reversed by estrogen replacement.[276]

Whether adrenarche plays a more fundamental role in puberty than contributing to the growth of sexual hair is unknown. Adrenal androgen formation may serve as a "safety valve" that protects against hypercortisolism by providing an alternate pathway for steroidogenesis. DHEAS and an immediate precursor, pregnenolone sulfate, have been found to be stimulatory neuroactive steroids.[277] Adrenal androgens may contribute to cortical bone accrual,[278] whereas their effect on mid-childhood growth is unclear.[279] DHEA has been suspected of having a number of other functions, but these seem inconsistent. Whether they differ from those of low-dose testosterone remains to be established.[280,281]

HORMONAL SECRETION, TRANSPORT, METABOLISM, AND ACTION

Peptide Hormones

Peptide hormones act after binding to specific receptors located in the plasma membranes of target cells. GnRH receptors and gonadotropin receptors are members of the 7-transmembrane receptor family. These receptors are necessary to the actions of their cognate hormones. However, receptors expressed in nonclassic sites are not necessarily functionally mature.[282] Mature receptors signal after coupling to the guanine nucleotide (G-protein) subunit cluster (Figure 14-22).[5,233,234,283,284] Two modes of signal transduction are then utilized. G proteins activate adenylate cyclase or phospholipase C. The first mode signals via phosphodiesterase-regulated cAMP levels to activate protein kinase A.

The second mode signals via protein kinase C and Ca^{2+}, the latter of which may be mobilized by other factors that influence ion channels. Tyrosine kinase signaling may also be involved in gonadotropin action.[285]

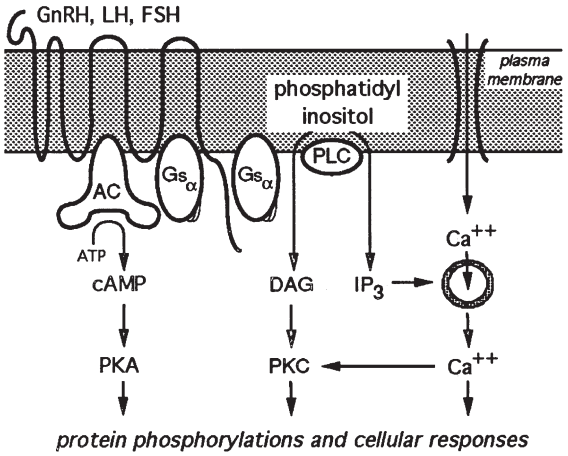

Figure 14-22 Overview of the pathways established to mediate gonadotropin-releasing hormone (GnRH) and gonadotropin action. The receptors for these hormones are members of the seven-transmembrane family of receptors. Hormone-receptor binding alters receptor configuration. One consequence is to couple the receptor to adenylate cyclase (AC) via the stimulatory α-subunit of G protein (GSα). This permits the efficient generation of cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP). Another consequence is to couple phospholipase C (PLC) to the receptor through another subtype of GS_. PLC is a phosphodiesterase that hydrolyzes phosphatidyl inositol to diacylglycerol (DAG) and inositol-1,4,5-triphosphate (IP3). DAG stimulates the calcium-sensitive protein kinase C (PKC). IP3 mobilizes ionic calcium (Ca_2_) from intracellular organelles and stimulates Ca_2_ influx through calcium ion channels. PKA, PKC, and Ca_2_ then bring about cellular responses through protein phosphorylations. FSH, follicle-stimulating hormone; and LH, luteinizing hormone.

Phosphorylation of various cytoplasmic and nuclear proteins is ultimately thought to mediate the action of the peptide hormones. The diversity among target cells in their responses to the action of protein kinases in part relates to diversity and type of kinase, intracellular compartmentalization, substrate availability, and other factors determined by the genome of the target cell.

Gonadotropin-releasing hormone is a decapeptide [pyro]Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2.[233] One gene encodes the single precursor protein for GnRH and prolactin release-inhibiting factor.[286] Gonadotropin-releasing hormone not only effects prompt release of preformed gonadotropins (the readily releasable pool) but stimulates the synthesis of gonadotropins (the reserve pool).[287] Repeated administration of GnRH augments the pituitary responsiveness to subsequent GnRH pulses (self-priming).[102] This has been ascribed partly to up-regulation of GnRH receptors. Gonadotropin-releasing hormone has important paradoxical effects. As discussed previously, it acutely stimulates gonadotropin secretion. However, upon protracted continuous administration it down-regulates pituitary gonadotropin secretion.

An evolutionarily conserved form of GnRH (GnRH-II) was recently discovered that acts primarily through the type 2 GnRH receptor.[288] GnRH-II and the type 2 GnRH receptor are products of unique genes, rather than being modified products of the GnRH or type 1 GnRH receptor genes.[289] The cell bodies of the GnRH-II neurons lie predominantly in the midbrain and only a minority project to the hypothalamic-pituitary area. Its function in humans is unknown, but it may be more important as a neurotransmitter involved in sexual behavior than in reproduction.

Luteinizing hormone and FSH are synthesized in a single type of cell, and both are sometimes identified within the same cell.[290] A vestigial population of hCG-secreting pituitary cells has been described.[291] Luteinizing hormone, FSH, and hCG are glycoprotein hormones that consist of two chains.[292] After synthesis of these hormones on the ribosomes, the carbohydrate moieties (which constitute about 16% of the weight) are added in the rough endoplasmic reticulum and golgi apparatus. The α chains of LH, FSH, hCG, and thyroid-stimulating hormone (TSH) are identical in amino acid sequence (92 amino acids).

Although the β chain of each hormone is different in both primary amino acid sequence and length, these β chains nevertheless share considerable amino acid homology (ranging from 30% to 80%). The α and β subunits contain a cystine knot structure like other growth factors such as platelet-derived growth factor and nerve growth factor. Biological activity is conferred when an α and β chain are glycosylated and assemble within the cell. The αβ dimer is stabilized by a β−subunit-derived "seatbelt" β-subunit-derived that wraps around the α subunit. Neither the isolated α nor the β glycosylated protein subunit exhibits biologic activity unless noncovalently bound in a heterodimer.

The gonadotropins exhibit considerable molecular heterogeneity. The major basis for this is variation in glycosylation, which confers differing degrees of in vitro and in vivo bioactivity.[95,293-295] Mutations in the LH-β and FSH-β subunits that affect gonadotropin bioactivity have also been described.[296] There are also reports of polymorphisms in amino acid sequence of the LH-β and hCG-β genes, which may affect the expression or bioactivity of LH or hCG.[297-299]

Different LH and FSH standards contain different proportions of immunoreactive material, which is of low bioactivity. The immunoreactive isoforms in the pituitary and serum also contain different proportions of bioactive material, and the isoform distribution differs with reproductive status. Androgens increase and estrogens decrease the apparent LH biopotency by altering LH sialylation.[300,301] The apparent FSH biopotency is reduced after treating women with GnRH antagonist.

One corollary of the molecular heterogeneity is that the antibodies generated from these gonadotropin moieties detect heterogeneous epitopes that are not necessarily bioactive. Indeed, some may even act as gonadotropin antagonists.[302] These factors combine to cause the B/I gonadotropin ratio to vary in a wide variety of circumstances.[95,293] The purest of standards, even recombinant ones, interact very differently in the diverse immunoassay systems. Likewise, the putative level of LH or FSH in a serum sample differs substantially among assays.

This is principally because of lack of specificity of immunoassays for bioactive LH and FSH. However, bioactivity assessments vary with the bioassay model system.[95,303] Monoclonal antibody-based immunometric assays yields results that correlate with but are not necessarily equivalent

to those results derived by bioassay.[95,304] The best of these third-generation immunometric assays have the advantage of being more sensitive and specific for low levels of gonadotropins in serum than polyclonal-antiserum-based RIA, but B/I discrepancy remains considerable.

Luteinizing hormone is cleared more rapidly from the blood than FSH or hCG.[305,306] Luteinizing hormone disappears from blood in an exponential pattern. RIA indicates that the half-life of the initial component is about 20 minutes and the half-life of the second component about 4 hours (the bioactive LH half-life is about one-third shorter).[307] These respective components for FSH are 4 and 70 hours. Those for hCG are 11 and 23 hours. Gonadotropins are primarily metabolized by the liver after the removal of the terminal sialic acid residues, which retard clearance. About 10% to 15% of gonadotropins are excreted in urine.[308] Only about a third of this is in a biologically active form.[309] The metabolic clearance rate of LH is 35 L/day, and that of FSH is 20 L/day. Hormone production rates in follicular phase women, which approximate mid-pubertal values, are given in Table 14-2.[310-316] During the luteal phase of the menstrual cycle, estradiol production doubles[315] and progesterone production rises fifteenfold or more.[317]

Prolactin has structural and functional similarities to GH and placental lactogen. Prolactin has a considerable degree of structural heterogeneity. This results from genetic and post-translational events within pituitary cells as well as metabolic processes such as glycosylation in the periphery.[318] Lactotroph growth and prolactin secretion are stimulated by estrogens. Prolactin release from the anterior pituitary is primarily under the control of hypothalamic inhibition, probably mediated by dopamine[319] and prolactin release-inhibiting factor.[286] The latter is contained within the same precursor protein as GnRH, thus providing a potential mechanism for reciprocal control of these two peptides. Prolactin secretion is also inhibited by thyroxine and is directly responsive to thyrotropin-releasing hormone (TRH). Estrogen and suckling are stimulatory. These signals may be positively mediated by α-melanocyte-stimulating hormone.

Inhibins and activins are members of the TGF-β superfamily, and signal accordingly.[249,320] Inhibin was discovered as the result of the search for the nonsteroidal gonadal hormone capable of specifically suppressing FSH. Activin was serendipitously discovered as the FSH-stimulating activity in the side fractions in these studies. These hormones are formed by the differential disulfide-linked dimerization of two of three subunits (α β_A, and β_B), each encoded by a distinct gene. The combination of an α- and β-subunit yields inhibin-A ($\alpha\beta_A$) and inhibin-B ($\alpha\beta_B$). Activins are dimers of β-subunits $\beta_A\beta_A$, $\beta_B\beta_B$, and $\beta_A\beta_B$ (activin-A, -B, and -AB). Inhibin antagonizes all known actions of activin. The genes for all three subunits are differentially expressed in a wide variety of tissues. Furthermore, these factors (particularly activin) have proven to exert effects not only on gonadotropes but within other pituitary cells and the gonads and in nonsexual target tissues.

TABLE 14-2

Average Hormone Blood Production Rates in Mid-follicular Phase Women[a]

Hormone	Production Rate	Pertinent References
Luteinizing hormone	615 IU/day†	310
Follicle-stimulating hormone	215 IU/day†	311
Androstenedione	3.4 mg/day	312
Dehydroepiandrosterone	7.0 mg/day	312
Dehydroepiandrosterone sulfate	7.0 mg/day‡	313, 314
Dihydrotestosterone	0.06 mg/day	312
Estradiol	0.1 mg/day	315
Estrone	0.1 mg/day	315
Progesterone	1.1 mg/day	316
17-OH-progesterone	1.2 mg/day	316
Testosterone	0.2 mg/day	312

[a]These production rates are roughly equivalent to those in mid-puberty. The average daily production of those hormones that fluctuate cyclically is substantially greater. For example, E_2 production transiently peaks to about 0.5 mg/day, and thus the average production over the monthly cycle is about 0.2 mg/day or 6 mg/mo.

† In terms of second International Reference Preparation, human menopausal gonadotropin.

‡ Approximate urinary production rate, expressed as unconjugated dehydroepiandrosterone.

Steroid Hormones

The ovary and adrenal cortex share the core of the steroid biosynthesis pathway (Figure 14-23).[254,321] Low-density and high-density lipoproteins are used as steroidogenic substrates.[322] Most steroidogenic steps are mediated by cytochrome P450 family members, which are the terminal enzymes in electron transfer chains.[323] The initial step in the biosynthesis of all steroid hormones is the conversion of cholesterol to pregnenolone. This is a two-stage process. The rapidity of the process depends on the transport of cholesterol from the outer to the inner mitochondrial membrane by the steroidogenic acute regulatory protein (StAR). The conversion itself is carried out by the cholesterol side chain cleavage activity (scc) of cytochrome P450scc.

The next step is the Δ^5-isomerase-3β-hydroxysteroid dehydrogenase (3β-HSD) step or 17α-hydroxylation. The conversion of Δ^5-3β-hydroxysteroids to steroids with the Δ^4-3-keto configuration (e.g., pregnenolone to progesterone, 17-hydroxypregnenolone to 17-hydroxyprogesterone, or DHEA to androstenedione) is accomplished by 3β-HSD. This step is obligatory in the synthesis of all potent steroid hormones. The type 2 3β-HSD isozyme accounts for the vast majority of the 3β activity in the human ovary and adrenal. The type 1 isozyme accounts for 3β-HSD activity in liver and skin.[324]

Pregnenolone alternatively undergoes a two-step conversion to the 17-ketosteroid DHEA along the Δ^5-steroid pathway. This conversion is accomplished via cytochrome P450c17. P450c17 is a single enzyme with 17α-hydroxylase and 17, 20-lyase activities, the latter being of lesser efficient and critically dependent on electron transfer from P450 oxido-reductase (POR) activity and cytochrome b. Progesterone undergoes a parallel transformation to androstenedione

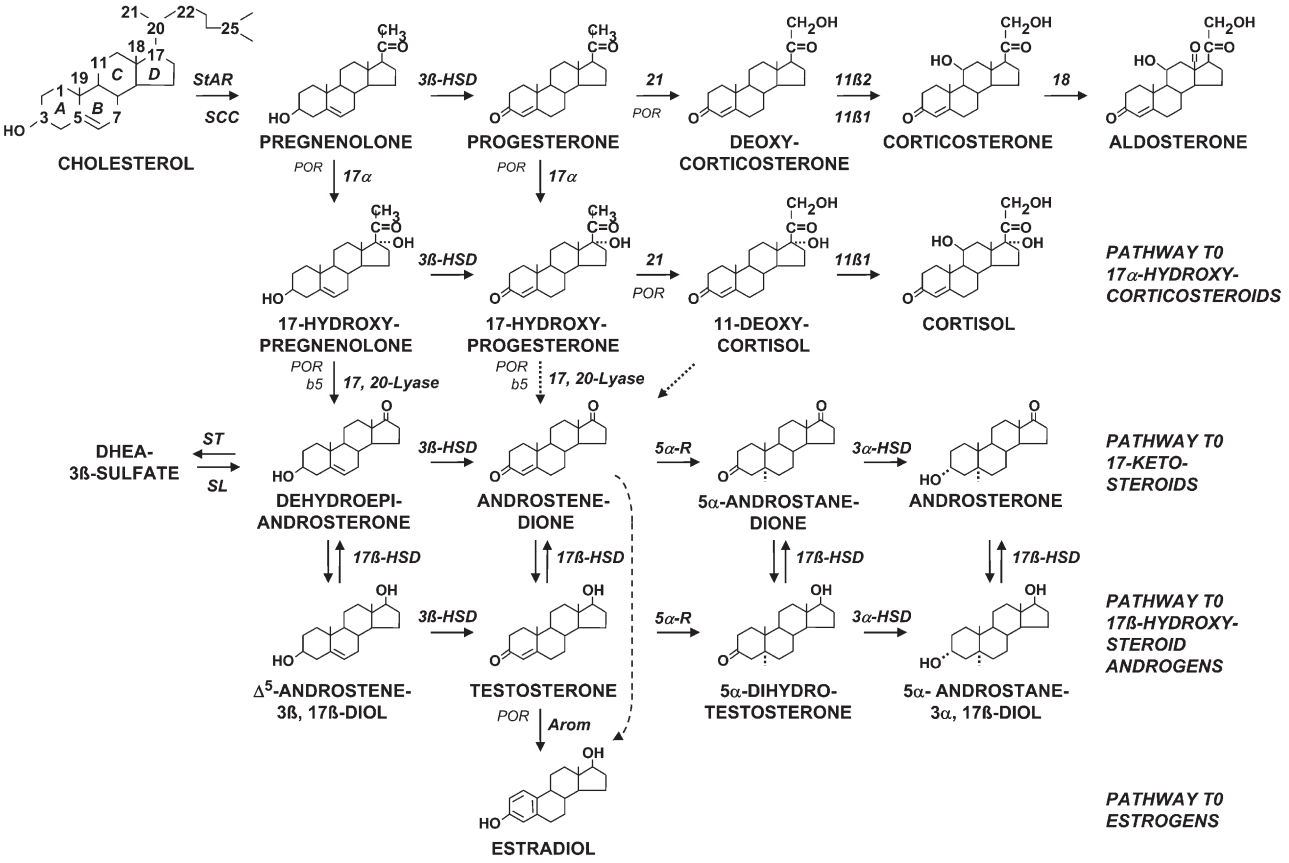

Figure 14-23 Major pathways of steroid hormone biosynthesis from cholesterol. Relevant carbon atoms of cholesterol are designated by conventional numbers. Rings are denoted by letters. The flow of hormonogenesis is generally downward and to the right. The top line shows the pathway to progestins and mineralocorticoids, the second line the pathway to glucocorticoids, the third line the pathway to 17-ketosteroids, and the fourth line to androgens. The bottom and dotted lines indicate the pathways to estrogen [the long dotted line involves the 17-keto-estrogen estrone (not shown) as an intermediate]. The steroidogenic enzymes are italicized. Cytochrome P450 enzyme steps are: side-chain cleavage (scc); 17α-hydroxylase/17,20-lyase; 21 hydroxylase (21); 11ß-hydroxylase (11ß2); 18-hydroxylase-dehydrogenase (aldosterone synthase, 11ß1,18); and aromatase (arom). Non-P450 enzyme steps are steroidogenic acute regulatory protein (StAR); Δ5-isomerase-3ß-hydroxysteroid dehydrogenase (3ß); 17ß-hydroxysteroid dehydrogenase (17ß); sulfotransferase (ST), and sulfokinase (SK). Clinically relevant electron transfer enzymes are P450 oxidoreductase (POR) and cytochrome b5 (b5). [Modified from Rosenfield RL, Lucky AW, Allen TD (1980). The diagnosis and management of intersex. Curr Prob in Pediatr 10:1.]

in the Δ4-steroid path. 17α-hydroxylation of progesterone by P450c17 forms 17-hydroxyprogesterone, but in humans P450c17 does not efficiently utilize 17-hydroxyprogesterone as a substrate for 17,20-lyase activity and thus P450c17 seems to form little if any androstenedione.

There is some evidence for the existence of a P450c17-independent Δ^4-pathway to androstenedione, but most seems to be formed from DHEA by the action of 3β-HSD.[325] The conversion of 17-ketosteroids to 17β-hydroxysteroids by 17β-HSD is essential to the formation of the potent sex steroids, testosterone, dihydrotestosterone, and estradiol. In the ovary, androstenedione is the major precursor for sex steroids. Testosterone is formed by 17β-HSD type 5[326] and estradiol by aromatase. Cytochrome P450arom carries out aromatase activity.[327] Alternate promoters are utilized by the P450arom gene in the gonads, placenta, and adipose tissue—which yields alternatively spliced forms of aromatase.

The ovary normally accounts for about 25% of testosterone secretion in the mature female (0.06 mg daily), but it secretes about 30 times as much androstenedione (1.6 mg daily).[312] These amounts are similar to those secreted by the adrenal. However, the ovary secretes less than 10% as much DHEA as the adrenal. The "production rate" of a hormone equals its secretion rate plus (in the case of hormones formed outside of endocrine glands) the rate of formation of the hormone by peripheral conversion of secreted precursors. The "blood production rate" is calculated as metabolic clearance rate (MCR) multiplied by plasma concentration. This is because in the steady state the amount of hormone irreversibly leaving the plasma compartment equals the amount entering it.

Because of extensive steroid interconversions, the quantity of these hormones excreted in urine is not necessarily proportional to the amount reaching target tissues.[312] For example, so large a fraction of urinary testosterone glucuronide is formed directly from androstenedione by compartmentalized metabolism within the liver that the range of urinary excretion of testosterone in women overlaps that in men (Figure 14-24).[328] Estrone sulfate, like DHEAS in the androgen pathway, forms a circulating reservoir of inactive estrogen that can be returned to the active pool by

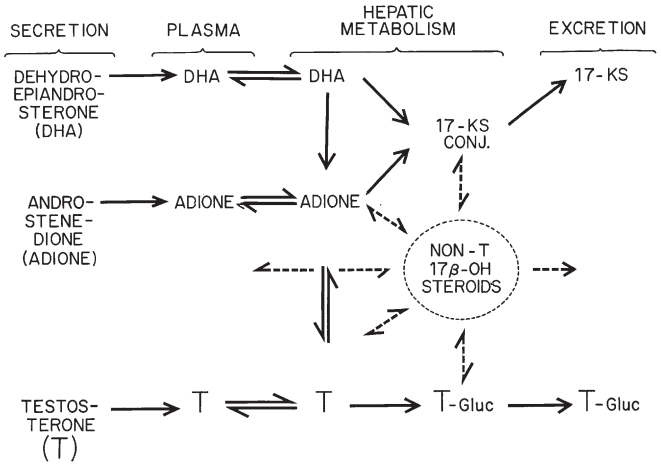

Figure 14-24 Diagram illustrating the relationship among secreted, plasma, and urinary steroids. 17-ketosteroid (17-KS) excretion does not reflect accurately the excretion of the most important plasma androgens. Only 25% or less of testosterone is excreted as 17-KS metabolites. Therefore, important changes in testosterone production may not appreciably affect urinary 7-KS excretion. Futhermore, even the major 17-KS (the sulfate of DHA) is excreted poorly until its production rate becomes quite high. On the other hand, about 50% of the Zimmermann chromogens are not identifiable as 17-KS, and 2 mg daily results from hydrocortisone metabolism. In additon, 17-KS metabolism differs in the child and adult. Testosterone glucuronide excretion does not accurately reflect the plasma testosterone level. Less than 2% of testosterone appears in the urine as such. In addition, plasma 17-KS (such as androstenedione) may be converted to testosterone glucuronide without ever circulating as unconjugated testosterone. [From Rosenfield RL (1973). Relationship of androgens to female hirsutism and infertility. J Reprod Med 11:87.]

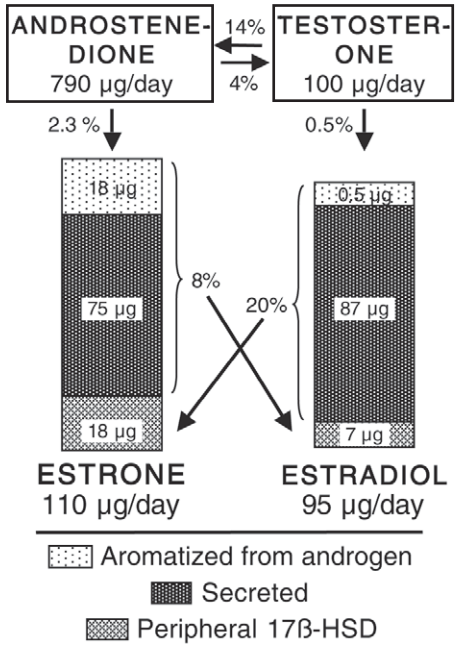

Figure 14-25 Sources of estrone and estradiol in blood of follicular phase premenopausal women. Estrogen is derived from direct secretion by the gonad, aromatization of androgen, or conversion of an estrogen precursor by 17ß-HSD activities. The percentage of substrate converted per day and total approximate production in micrograms per day are noted for each source. [Modified from Alonso LC and Rosenfield RL (2002). Oestrogens and puberty. Best Pract Res Clin Endocrinol Metab 16:13.]

desulfation in the liver.[329] The blood production rates of representative steroid hormones are given in Table 14-2 and are shown for estrogens in Figure 14-25.

Sex hormones also have environmental origins. Natural biologic estrogens include equine estrogens and plant-derived phytoestrogens. Synthetic estrogens include pharmacologic compounds such as ethinyl estradiol, diethylstilbestrol, selective estrogen receptor modulators (SERMs), and some industrial chemicals such as organochlorines and plasticizers. Environmental estrogens act as "endocrine disrupters" by activating diverse estrogenic pathways in animal models.[329]

Peripheral conversion of secreted prehormones by nonendocrine organs accounts for a major portion of sex hormone production. The ovary and the adrenal cortex are the sources of prehormones as well as secreted hormones. About 50% of plasma testosterone (0.1 mg daily) is normally formed indirectly by peripheral conversion. Although 85% of normal estrogen production in women arises by secretion in midcycle, 50% of estrogen production can arise from extraglandular sources during the low-estrogen phases of the menstrual cycle.[330] Peripheral formation of active steroids occurs in a wide number of sites, including liver, fat, and target organs.[254,331] For example, the liver has high levels of 3α-, 3β-, and 17β-hydroxysteroid dehydrogenase and 5α-reductase activities (Figure 14-23).

Peripheral steroid metabolism is not tightly regulated. It seems determined to some extent by the perinatal androgenic milieu,[332] the effect of which is possibly mediated by GH.[333] Postnatally it is influenced by the sex hormone binding globulin level (SHBG) and the state of nutrition. Adipose tissue becomes a major site of conversion of androstenedione to estrone and testosterone in the obese.[334] Cytochrome P450 mixed-function oxidases, some of which are inducible by drugs or nutritional status, form hydroxylated steroid metabolites of varying potency.[335] Phytoestrogens increase estradiol bioavailability by inhibiting hepatic sulfotransferase.[336]

Plasma steroids mainly reach their sites of action and metabolism by simple diffusion from the vascular compartment.[337] The bioactive portion of plasma testosterone seems to be the free testosterone and a portion of the albumin-bound testosterone that differs among tissues according to characteristics of the vascular bed.[338,339] About 98% of plasma testosterone and estradiol are bound to albumin and SHBG. The SHBG concentration determines the fraction of plasma testosterone and other ligands that are free or bound to albumin. It is also a major determinant of ligand egress from plasma (Figure 14-26).[340] Recent data indicate that the SHBG may exert independent effects.[341] For example, the SHBG-bound sex steroid complex may stimulate growth after SHBG binding to membrane receptors and activation of adenylate cyclase.[342] A number of physiologic and pathologic states affect the SHBG level. It is increased by estrogen and thyroid hormone excess. It is decreased by androgen, insulin, glucocorticoid, and GH.[339,343]

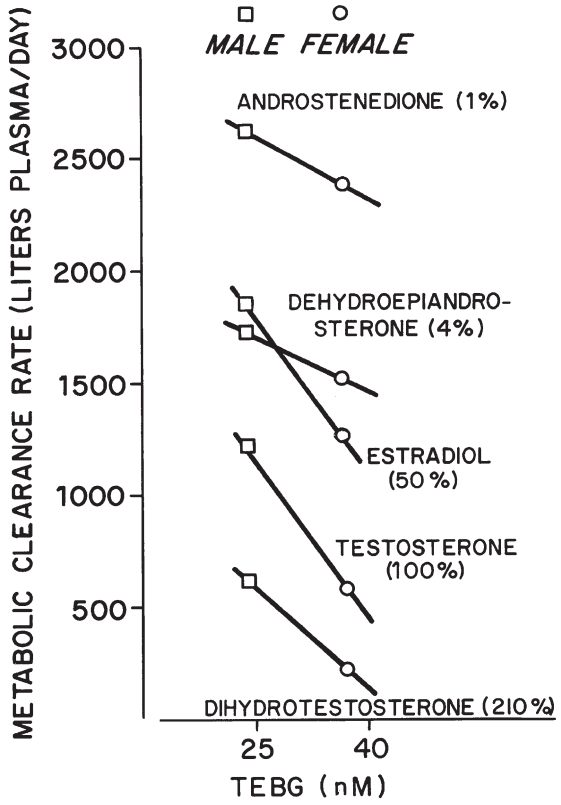

Figure 14-26 The relationship between the metabolic clearance rate (MCR) and binding of sex hormones to sex hormone binding globulin (TEBG). The MCR of each steroid has been related to the mean TEBG levels of men and women. The approximate affinity of each steroid for TEBG relative to testosterone is indicated in parentheses. [From Rosenfield RL (1975). Studies of the relation of plasma androgen levels to androgen action in women. J Steroid Biochem 6:695.]

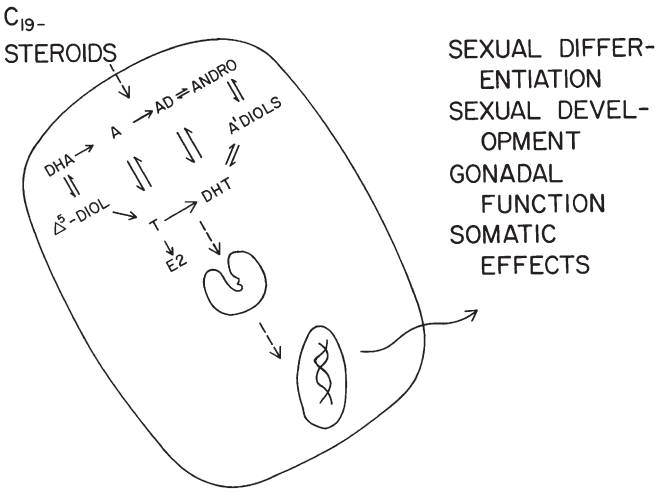

Figure 14-27 Model of the mechanism of androgen action emphasizing the effect of steroid metabolism within a target cell on the mode of action. Solid arrows indicate pathways of steroid metabolism from 17-ketosteroid precursors as laid out in Figure 14-23. Broken arrow indicates transport. The cell-specific intracellular pattern of C19-steroid metabolism determines the relative availability of testosterone or dihydrotestosterone (DHT) to the cytosol receptor for translocation to the nucleus. In cells such as the rat granulosa cell in which Δ^5,3β-hydroxysteroid dehydrogenase activity is high, androstenediol (Δ^5-diol) is as potent as testosterone. The human sebaceous gland has a similar pattern of steroid metabolism. A, androstenedione; AD, androstanedione; and DHA, dehydroepiandrosterone. [From Nimrod A, Rosenfield, RL, Otto P (1980). Relationship of androgen action to androgen metabolism in isolated rat granulosa cells. J Steroid Biochem 13:1015, with permission from Elsevier Science.]

Target cell metabolism influences the cell's response to the steroid hormones that reach it (Figure 14-27).[344] Although transformation is not fundamental to the mode of action of estradiol, estradiol effectiveness can be influenced by target cell metabolism. The induction of 17β-hydroxysteroid oxidation in target tissues by progesterone, resulting in conversion of estradiol to the less potent estrogen estrone, counterbalances estrogenization.[345] The intracellular conversion of testosterone to dihydrotesterone by one of the two isozymes of 5α reductase is important to many but not all effects of testosterone,[346] dependent on the tissue-specific pattern of steroid metabolism. An important mode of testosterone action is via estradiol, notably within the brain. There is also evidence that novel steroid metabolites exert tissue-specific effects.[347,348]

Within target cells, all steroid hormones activate the genome similarly—starting with binding to high-affinity intracellular receptors (Figure 14-28).[349,350] The steroid hormone receptors belong to the superfamily of nuclear hormone receptors. The estrogen, progesterone, and androgen receptors are thus homologous. Classic sex hormone effects are exerted by the interaction of steroid with receptor, not by either alone. Steroid binding triggers the dissociation of inhibitory chaperone heat shock proteins from the receptor.[351] The active receptor-ligand complex then undergoes noncovalent dimerization and binding to its specific hormone response element on the gene. The DNA-bound steroid-receptor complex acts as a transcriptional regulator of the target gene promoter. Sensitivity to steroids is also modulated by molecular chaperone proteins that influence receptor configuration, intracellular trafficking, and receptor turnover—all of which are determinants of steroid action.[352,353]

The binding properties of steroids to their cognate receptors are the initial determinants of steroid action (Figure 14-28).[349,350] Ligand-based selectivity is one element of this interaction. Estradiol is a more potent estrogen than estrone and estriol partly because it binds best to the steroid-binding domain of the estrogen receptor.[354] Dihydrotestosterone is an inherently more potent androgen than testosterone, mainly because of its higher association rate constant and its lower dissociation rate constant.[355]

The antiestrogens tamoxifen and clomiphene and the antiandrogens cyproterone acetate and spironolactone competitively inhibit the active ligands from binding to their specific receptor sites by weakly and transiently occupying receptor sites. These differences result from potent agonists fitting into the binding pocket more snugly, which induces a receptor conformation different from that of antagonist-bound receptor. One such change is the C-terminal tail of the receptor flipping over to "close the door" when a potent agonist enters. This simultaneously provides a different outer surface for interaction with co-regulator proteins.

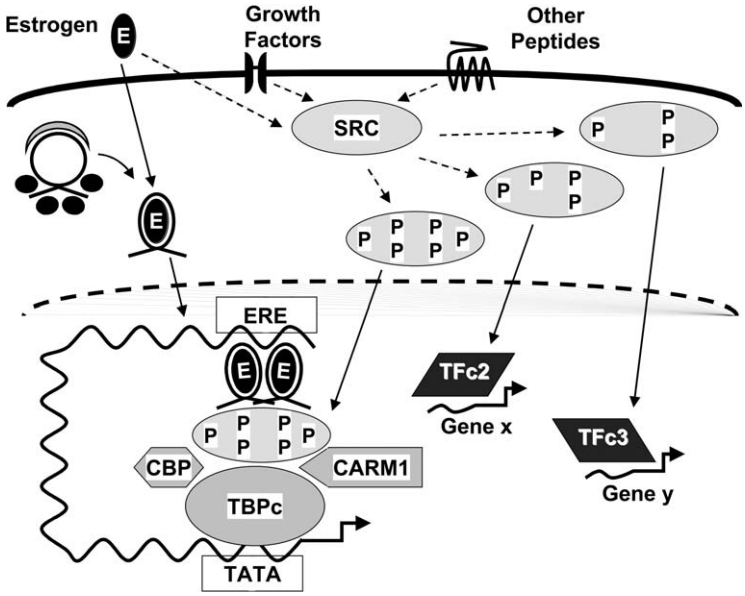

Figure 14-28 A model for the mechanism of estrogen (E) action that emphasizes the role of interaction of the estrogen receptor with co-regulators and other signaling pathways. Estrogen causes the 4S subunit and heat-shock proteins to dissociate from the unliganded estrogen receptor. Then estrogen entry into the binding pocket causes a conformational change in the receptor. Estrogen also stimulates steroid receptor coactivator (SRC) phosphorylation (P) in a specific pattern and recruits it to the nuclear DNA steroid-receptor complex with the estrogen response element (ERE). SRC in turn recruits other coactivators [such as the dual-function cAMP response element binding protein-binding protein (CBP) and coactivator-associated methyltransferase (CARM1)] to the hormone binding complex. This aggregate then interacts with the TATA binding protein initiation complex (TBPc) to initiate estrogen-specific gene transcription. The effect is modified by the effects of environmental signals on other cell-specific transcription factors (TF), some of which involve differentially phosphylated SRC complexes (TFc) in gene activation. Fine dotted lines indicate diverse kinase pathways. ER recycling is not shown. [Modified from Katzenellenbogen BS, Montano MM, Ediger TR, Sun J, Ekena K, Lazennec G, et al. (2000). Estrogen receptors: Selective ligands, partners, and distinctive pharmacology. Recent Prog Horm Res 55:163–193; and from O'Malley BW (2005). A life-long search for the molecular pathways of steroid hormone action. Mol Endocrinol 19:1402–1411.]

Thus, ligand-based selectivity arises not only because of tighter ligand binding but because alternative ligands produce intermediate and unique conformational changes in the receptor—which in turn induce altered receptor interactions with co-regulator proteins that result in a spectrum of activities.[356] Thus, steroids do not simply switch receptors on. They induce selective functions that depend on the nature of the co-regulators that are recruited to the complex.[357-360] In part, this selectivity arises because different domains of these receptors mediate these different functions. For example, the AF-1 domain of the ER mediates interactions with MAP kinase and TGF-β3—whereas the AF-2 domain mediates interactions with co-regulator proteins.[361] Coactivators in turn regulate alternative splicing, gene activation and repression (in some cases via their dual enzymatic functions), and ubiquitin-proteosome-mediated turnover of the receptor-coregulator complex.[362] They also determine cell-specific site-based actions,[350] as discussed in material following.

Receptor-based selectivity is a second element in steroid action. There are now known to be two isoforms of each of the sex steroid receptors. The α and β forms of the estrogen receptor, though homologous, are coded by separate genes.[156] A and B forms of the progesterone and androgen receptors exist.[363,364] These forms of the PR arise by transcription from alternative promoters within the same gene, whereas those of the androgen receptor arise from post-translational modification of a single mRNA. These isoforms have variously been shown to manifest a differential tissue expression pattern and respond differentially to antagonists. Interactions of a steroid with different forms of receptor can regulate some target genes differentially.

One role of ERβ is apparently to modulate ERα activity. ERα and ERβ can have opposite actions at AP-1 and SP-1 sites, and studies of transcriptional activity in bone and breast tissue of mice indicate a restraining effect of ERβ on responses to estradiol.[156,365] Thus, different target tissues exposed to the same hormone may respond selectively because of a distinct repertoire of receptor isoform expression. Some examples are notable. Although both forms of estrogen receptor are expressed in most target tissues, the classic form of the estradiol receptor (ERα) plays the key role in regulation of LH and estrogen actions on the uterus, breasts, sex-specific behavior, and bone.[156,243,366,367]

In the mouse ovary, knockout experiments show that ERα is expressed in thecal cells—where it prevents androgen excess in response to LH. In contrast, ERβ is expressed only in granulosa cells—where its inhibition of androgen receptor expression is critical in preventing premature follicular atresia.[158] Both forms of the receptor are necessary to oocyte survival and the ability of preovulatory follicles to rupture. Furthermore, loss of both causes transdifferentiation of granulosa cells to Sertoli-like cells and massive oocyte death.[146] Liganded progesterone receptor$_A$ is essential to ovulation[368] and is the more effective antagonist of estrogen receptor action.[349] In addition, sequence variation in hormone response elements contributes to differential gene regulation.[369]

Effector-site-based selectivity is a third variable in sex hormone action. In other words, the potency and character of a response to a ligand-receptor complex is not simply an inherent property of the complex. Rather, they depend on the array of effector molecules present in the site of action. Thus, the array of genes expressed locally and the relative expression level of co-regulators (coactivators and co-repressors) are extremely important in the determination of appropriate and graded responses to a ligand by a target cell.[349,370] Heterodimerization of the estrogen receptor with other nuclear receptors can modulate its action.[371] Androgens appear to exert some of their genomic effects by directly complexing with transcription factors other than the androgen receptor.[372] Estrogen and androgen appear to exert antiapoptotic effects in osteoblasts and osteocytes by activating a ligand-dependent but nongenomic kinase-mediated signaling pathway.[373]

Nuclear receptor coactivators are critical in sensing cell-specific environmental signals and to coordinate signals emanating from membrane receptors with nuclear receptor action.[350] Surface receptors send signals through kinase pathways that result in specific serine/threonine phosphorylation patterns of coactivators. These phosphorylation patterns serve as a code for the coactivator to preferentially bind and activate distinct sets of downstream transcription factors (Figure 14-28). Overexpression of steroid receptor coactivator-3 (SRC-3) is as important in the pathogenesis of some breast cancers as is estrogen receptor positivity.

The effects of a given ligand-ER complex often differ from those of the E2-ER complex among cell types. This is the basis for the development of SERMs. These compounds mediate variable effects in a tissue-specific manner, depending on the cell context.[349,356] The chemical structure of a SERM (or any ER ligand, for that matter) determines the configuration of the ER, resulting in a spectrum of activities from agonist to antagonist—depending on which co-regulators are available for recruitment in the target cell. Raloxifene is an estradiol agonist in bone and epiphyseal cartilage but is antiestrogenic in uterus and breast. Tamoxifen is estrogenic in uterus but antiestrogenic in breast and bone. Both appear to retain neural and endothelial estrogenic activity.[374,375]

Sex steroid receptor responsiveness can also be altered by signals emanating from the cell membrane.[376] In some cases, activation occurs independently of ligand binding.[377] For example, epidermal growth factor activates phosphorylation of the estrogen receptor and simulates diverse estrogen effects.[378] In addition, various cell surface signals activate unliganded estrogen receptor and cause it to act as a co-regulator.[379] This may be involved in the mechanism by which ERα represses expression of the androgenic 17β-HSD testicular isoform in the ovary.[243]

Sex steroids also exert rapid (within seconds to minutes) nongenomic effects by membrane signaling in a variety of cells. These can mediate cell proliferation, apoptosis, migration in cell-specific ways. E2 nongenomic actions can be mediated by binding to nuclear ER in plasma membrane domains provided by such scaffolding proteins as caveolin.[373,380,381] On such platforms, the E2-ER complex acts like a membrane receptor—coupling with G proteins and activating cytoplasmic pathways involving SRC and MAP kinase. Androgens appear to act similarly.[373,382,383] Nongenomic actions of nuclear PR have been reported.[384] Signaling also has recently been identified via specific G-protein coupled transmembrane receptors for E2 and progesterone.[385385a]

Steroids that act by binding to membrane-bound receptors in the brain are termed *neuroactive*.[277] Neuroactive steroids synthesized in the brain are termed *neurosteroids*.[386-388] The best documented of these effects are on neurotransmitters that control ion channels. Allopregnanolone (3α-hydroxy-5α-tetrahydroprogesterone) is an inhibitor of the $GABA_A$ receptor and thus has sedative properties. Pregnenolone sulfate and DHEAS have the opposite effect, being $GABA_A$ receptor agonists. The former is also a positive regulator of the NMDA receptor. Receptors for 5-hydroxytryptamine have been implicated in mediating some of effects of sex steroids and certain of their metabolites.[389,390] Some estrogen effects in brain are membrane mediated.[391]

The tissue-specific post-transcriptional events involved in sex steroid signaling are poorly understood. Estradiol and progesterone modulate the actions of each other through effects on their specific receptors. Increased estrogens in the preovulatory phase of the cycle induce target organ receptors for estradiol and progesterone. Luteal phase levels of progesterone then suppress the production of both receptors.[392,393] However, estrogen prevents bone loss by blocking the production of proinflammatory cytokines.[394] Androgen action seems to involve the arachidonic acid cascade in genitalia[395] and peroxisome proliferator-activated receptors in sebaceous cells,[396] whereas in epiphyseal cartilage testosterone stimulates the IGF-I system.[397]

MATURATION OF SEX HORMONE TARGET ORGANS

Genital Tract

The Müllerian system of the embryo gives rise to the uterus, cervix, upper vagina, and fallopian tubes in the absence of AMH secretion by fetal testes during the first trimester of gestation.[321] Diethylstilbestrol induces dysplasia of the genital tracts.[398] Estrogen receptors are expressed in the labia minora, prepuce, and glans in females, but not in the homologous structures of males.[399] Genital swelling develops to engulf the base of the penis-like clitoris between 11 and 20 weeks gestation in parallel with the development of the ovarian follicular system.[400] In addition, antiestrogen has been reported to cause genital ambiguity.[401] These data suggest that estrogen may play a direct role in female genital tract differentiation. However, knockout of estrogen receptors has no obvious effect on genital tract differentiation.[146]

The infantile uterus and cervix enlarge under the influence of estrogen during puberty. The endometrium and cervical glands then undergo cyclic changes in concert with cyclic ovarian function. In response to estrogen during the follicular phase of the cycle, the endometrial epithelium and stroma proliferate. The uterine glands increase in number and lengthen.

Endometrial hyperplasia is inhibited by hyperandrogenemia.[402] In response to progesterone secretion after ovulation, the endometrium increases in thickness. Stromal edema occurs, and the uterine glands enlarge, become sacculated, and secrete a glycogen-rich mucoid fluid. The coiled arteries lengthen further during this time and become increasingly spiral. These changes are critical to implantation. Antiprogestin therapy is an effective postcoital contraceptive.[403] High-dose progestin is effective in preventing implantation if taken within 3 days of unprotected intercourse.[404]

The major cyclic change in the cervix is in the secretion of the endocervical glands, which lubricate the vaginal vault. The endocervical mucus is scanty and relatively thin during the low-estrogen phase of the cycle. The increase in mucus flow with advancing follicular development seems to require tissue-specific stimulation of the cystic fibrosis transmembrane regulator by estrogen.[405] This mucus becomes more viscous and elastic as estrogens rise in the later follicular phase of the cycle. The extent to which it can be stretched into a long spindle (spinnbarkeit) is a function of the estrogen level.

The mucosa of the vagina and the urogenital tract consists of hormone-responsive stratified squamous epithelium (Figure 14-29).[2] The basal layer is the regenerative area. In the absence of estrogen, there is only a parabasal layer of cells over this—and the vagina is thin, with a tendency to alkalinity [which predisposes it to local infection (nonspecific vaginitis)].[406] In response to estrogen, epithelial proliferation occurs—with formation of successive intermediate and superficial layers. With this maturation, the cytoplasm of each cell first expands—leading to formation of small intermediate cells. With further estrogenization, the nuclei become pyknotic and large intermediate cells form.

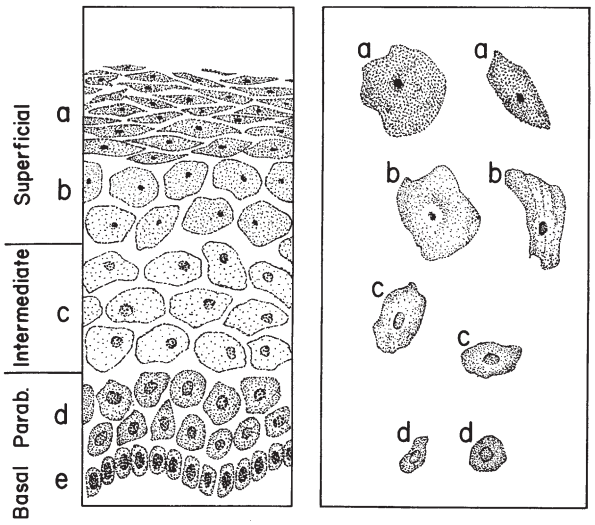

Figure 14-29 The layers of vaginal epithelium of the well-estrogenized adult. The superficial layer contains surface cells that are cornified (squamous) with eosinophilic cytoplasm and pyknotic nuclei (a) as well as large intraepithelial cells that are also karyopyknotic but basophilic (b). The intermediate zone contains basophilic cells that have less cytoplasm and intermediate-size nuclei (c). The basal and parabasal cells have a relatively small amount of basophilic cytoplasm and relatively vesicular nuclei (d, e). [Redrawn from Wilkins L (1968). *The diagnosis and treatment of endocrine disorders in childhood and adolescence*. Springfield, IL: Charles C Thomas.]

Greater estrogenization brings about their transformation to superficial cells. The cytoplasm changes from basophilic to acidophilic with the accumulation of glycogen. Resistance to infection of the fully developed vaginal mucosa results from its thickness and from its acid pH, which occurs from the fermentation of the glycogen of the superficial cells. In response to luteal phase progesterone, degenerative changes appear in vaginal mucosal cells: superficial cells decrease, the cytoplasm assumes a "crinkled" appearance, cells degenerate, and bacterial proliferation increases.

Vaginal smears show the characteristic cyclic changes in the cell types comprising the vaginal epithelium (Figure 14-29).[407] In the prepubertal years, parabasal cells predominate—and characteristically 10% or less are small intermediate cells. A pattern consisting entirely of intermediate cells is typical of early puberty. The early follicular phase of the menstrual cycle is characterized by the predominance of large intermediate cells with few, if any, superficial cells. Peak maturation is reached at midcycle, at which time 35% to 85% of the cells seen on vaginal smear are superficial. The remainder are large intermediate cells. This cornification develops over a 1-week period in response to estradiol levels of about 70 pg/mL and persists 1 to 2 weeks after estrogen withdrawal (Figure 14-11).[408] Many normal variations have been recognized in the appearance of the hymen. The transverse diameter increases with age.[409,410]

Mammary Glands

Multiple rudimentary branching mammary ducts are found beneath the nipple in infancy. They grow and branch very slowly during the prepubertal years.[411] Estrogen stimulates the nipples to grow, mammary terminal duct branching to progress to the stage at which ductules are formed, and fatty stromal growth to increase until it constitutes about 85% of the mass of the breast. GH (via IGF-I) and glucocorticoids play a permissive role.[412, 413]

These hormones interact with breast stroma and local growth factors to stimulate the development of breast epithelium. Lobulation appears around menarche, when multiple blind saccular buds form by branching of the terminal ducts. These effects are presumably due to the presence of progesterone. The breast stroma swells cyclically during each luteal phase. Full alveolar development normally only occurs during pregnancy under the influence of additional progesterone and prolactin. Prolactin does not play a role in breast growth without priming by female hormones.[414]

Estrogen and progesterone also play a role in breast cancer susceptibility. The BRCA1 gene normally restrains mammary growth (at least in part) by inhibiting expression of ERα and PRs, and cancer-related mutations reverse these processes.[415]

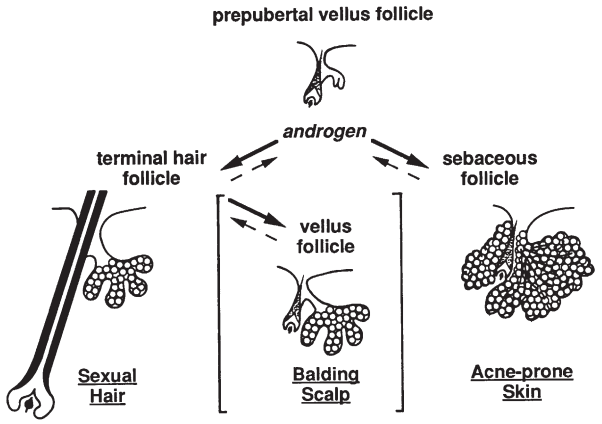

Figure 14-30 Role of androgen in the development of the pilosebaceous unit. Androgens (solid lines) are responsible for the patterned differentiation of the pilosebaceous unit at puberty. Dotted lines indicate effects of antiandrogens. Hairs are depicted only in the anagen (growing) phase of the growth cycle. In balding scalp (bracketed area), terminal hairs not previously dependent on androgen regress to vellus hairs under the influence of androgen. [From Rosenfield RL, Deplewski D (1994). Role of androgens in the developmental biology of the pilosebaceous unit. Am J Med 97(5A):80.]

Pilosebaceous Unit

The pilosebaceous unit (PSU) with but few exceptions consists of a piliary and a sebaceous component.[416] Androgens are a prerequisite for the growth and development of PSUs in their characteristic pattern. Before puberty, the androgen-dependent PSU consists of a prepubertal vellus follicle in which the hair and sebaceous gland components are virtually invisible to the naked eye (Figure 14-30). Under the influence of androgens, in the sexual hair areas the PSU switches to producing a type of terminal hair follicle. This androgen effect seems to be mediated via its action on the dermal papilla.

The difference in the apparent density of sexual hair between men and women is due to differences in the density of fully terminal hairs. In acne-prone areas, androgen causes the prepubertal vellus follicle to develop into a sebaceous follicle. In the balding-prone area of scalp in individuals genetically predisposed to pattern alopecia, PSUs respond to androgen by changing to a mature vellus follicle. Adrenarchal levels of androgens suffice to successively initiate sebaceous gland development and the growth of pubic hair. Progressively greater amounts of androgen are in general required to stimulate terminal hair development along a pubic to cranial gradient. All of these effects of androgen are reversible by antiandrogens.

Estrogens have a modest stimulating effect on hair growth. This may well be due to induction of androgen receptors by estrogen. They are also direct inhibitors of sebum secretion. GH synergizes with androgen action on the PSU, possibly by acting through insulin-like growth factor-I. Retinoic acid receptor agonists antagonize the effects of androgen on the sebaceous gland. To a great extent, this is due to inhibition of sebocyte proliferation and differentiation. Prolactin, glucocorticoids, thyroxine, and catecholamines also play roles in PSU growth, development, and function.

Bone

Increased secretion of sex hormones clearly initiates the pubertal growth spurt. About half of this effect of sex hormones is due to their stimulation of the GH-IGF axis.[417] The remainder of the effects of sex steroids on growth are direct.[418,419] Differences between the actions of sex hormones contribute to women's bones being shorter and narrower than men's.[420,421] The bases for these differences are complex and only beginning to emerge, with studies showing diverse effects on cortical and cancellous bone and periosteal bone formation.

Estrogen and androgen both stimulate epiphyseal growth. However, estradiol is the critical hormone that brings about epiphyseal closure.[419] Estrogen is also particularly effective in reducing bone turnover. To some extent, these effects may be prenatally programmed.[422] Bone accrual during puberty is a major determinant of adult fracture risk. Menarche after 15 years carries a 1.5-fold increase in fracture risk, and the risk rises with age of menarche.[423]

Adipose Tissue

Women have a greater percentage of body fat than men.[210,424] Serum levels of the adipocyte hormone leptin rise throughout puberty to reach higher levels in females than in males. Women have both more and larger fat cells than men in the lower body. Adipose tissue from different body sites has different metabolic activities and responses to sex steroids, with androgens generally promoting lipolysis and upper body (visceral) fat accumulation and estrogen promoting lipogenesis and a lower body (gluteofemoral) fat distribution.[425-427] In addition, androgens lower the antilipolytic adipocytokine adiponectin.[428] The lipolytic effect of androgenic progestins in contraceptives appears to account for their induction of insulin resistance.[429] Paradoxically, estrogen deficiency underlies the increased fat stores of hypogonadism.[156]

Central Nervous System

Considerable evidence supports the possibility that sex hormone exposure prenatally or during the period of transient activation of the hypothalamic-pituitary-gonadal axis of the neonate organizes neural substrates in a sexually dimorphic manner that predisposes to sex-typical behavior or function to become manifest when the child is exposed to the sex-specific pubertal hormonal milieu.[430] However, other factors (biologic, social, and psychological) seem equally important determinants of gender-related aspects of human behavior.[431,432]

Several human brain structures are sexually dimorphic, some becoming so at puberty.[432-434] In lower species, sexually dimorphic nuclei develop only if the brain is exposed to androgen during a critical time in the newborn period—but not if the androgen exposure is too late or too little. For example, in rats the preoptic nucleus of the hypothalamus is larger in males due to prevention of apoptosis in a site-specific fashion—and treatment of newborn females with testosterone or estradiol permanently increases neuronal development

and causes subsequent masculinized sexual behavior and anovulation.[14,434]

This and many other such effects appear to be mediated by intraneuronal aromatization of testosterone to estradiol in a manner that is regulated in site-specific fashion by androgen and estrogen.[435, 436] Thus, it has been postulated that low levels of estradiol promote the development of the brain. Greater amounts, as males normally form from secreted testosterone in neurons containing androgen receptors, masculinize it. Estrogen receptor-α knockout in female mice reduces sexual behavior and parental behavior while increasing aggressiveness.[437] On the other hand, some masculinizing effects of testosterone on behavior are androgen specific.[438]

Androgen has been shown to up-regulate brain 5α-reductase and aromatase only in the perinatal period.[439,440] There is also sexual dimorphism in cerebral progestin receptors, and progesterone attenuates the testosterone effect on the brain and reduces the number of estrogen receptors in the cerebral cortex.[441,442]

Sex hormones also have diverse effects on those areas of the adult brain that exhibit apoptosis-mediated morphologic plasticity in synaptic patterns and are involved in reproductive behavior and function and nonreproductive functions such as memory and learning. Estrogen, for example, alters the pattern of synaptic connections in spatially specific and precise patterns, that appear to fine-tune the sensitivity of certain regions of the brain to excitatory and inhibitory aminoacids.[443, 444] Hypothalamic changes in synaptic remodeling have been correlated with the preovulatory surge of GnRH. Androgen stimulation of androgen receptor levels and nuclear size of sexually dimorphic hypothalamic areas of the brain have been shown to occur in adult animals.[445,446]

On average, women tend to perform better than men on tasks that involve verbal skills, processing speed and accuracy, and fine-motor skills—whereas men tend to excel in visual-spatial memory and mathematical ability. The sexes do not differ in vocabulary skills.[430,447,448] These differences are quantitatively modest, of the order of 0.4 to 1.0 standard deviations. The male advantage in visual-spatial skills is established by 4.5 years of age. Because both boys and girls who are congenitally sex hormone deficient are relatively poor in visual-spatial abilities, and sex hormone treatment at puberty does not ameliorate these deficits, this difference seems to be the result of estrogen-mediated patterning in both sexes.

A wide variety of sexual behaviors are found in young children, but normally they have a different character than in adults.[449] Gender identity is established by 3 years of age, and sexual orientation is established by 10 years of age.[432,450] The extent to which this is dependent on subclinical adrenarcheal or pubertal changes is unknown. Early pubertal amounts of androgen or estrogen have little effect on sexual behavior but increase some aspects of aggressive behavior.[451,452] Only later in puberty is there activation of the sex drive, which has been organized in early development.

A male level of androgen acting through the androgen receptor pre- or perinatally seems to be an important determinant of male gender role behavior and mildly disruptive to female gender identity.[431,432] Differences in the size of specific brain structures in men with gender identity disorders has raised the possibility that these disorders similarly have a biologic basis. In homosexuals, the human homologue of the rat preoptic nucleus is smaller (as in females)[453] and the anterior commissure is larger than that of men or women.[454] In male-to-female transsexuals, a nucleus within the stria terminalis is female-sized.[455] Male homosexuals have a pattern of nuclear activation in response to pheromone-like chemosignals (like heterosexual women) rather than like heterosexual men, and homosexual women have an intermediate type of activation.[456]

Androgen and estrogen metabolites in sweat and urine have been found to exert sexually dimorphic activation of the anterior hypothalamus that is independent of their odor.[456] Therefore, they have been postulated to act as pheromone-equivalent chemosignals. It is likely that a dedicated population of olfactory receptors act as pheromone receptors that project to GnRH neurons.[457]

Other Targets of Sex Hormone Action

It is now clear that sex hormones exert effects in a wide variety of tissues. Estrogen down-regulates blood levels of the inflammatory cytokine interleukin-6.[458] Estrogens and progestins also exert hemostatic effects associated with increased resistance to the anticoagulant action of activated protein C.[459]

The cardiovascular effects of estrogen include up-regulation of estrogen and progesterone receptors in vascular tissue and nongenomic effects on endothelial nitric oxide synthase.[460] Although estrogen is generally cardioprotective and the disturbed endothelial dysfunction of young hypogonadal women is improved by estrogen, unexpected risks of conjugated estrogen use with and without medroxyprogesterone have recently emerged in postmenopausal women.[461] Whether or not these risks translate into risks in premenopausal females or to other forms of estrogen and/or progestin replacement is unclear. It has been suggested that estrogen protects against the development of atherosclerosis, having deleterious effects after atherosclerosis has formed.[462] This is an area of controversy and active research.

Normal Sexual Maturation: Hormonal and Physical Stages

THE FETUS AND NEONATE

Hormone levels through puberty are outlined in Table 14-3.[268,463-465] The fetus grows in a richer steroidal milieu than the pubertal female owing to the function of the fetoplacental unit. Concentrations of estrogens in fetal serum are extremely high. The umbilical cord plasma free testosterone level is modestly greater than that in normal adult females.[312] Dehydroepiandrosterone sulfate is at an adrenarchal level. Daily 17-keto steroid (KS) excretion may be as high as 2.5 mg at birth.

The newborn shows some signs of this hormonal stimulation. Hypertrophic labia minora and superficial cell transformation of the urogenital epithelium are

[a]. Ranges for radioimmunoassay after preparatory chromatography, except for cortisol and DHEAS. Values differ slightly among laboratories. Data from Rosenfield et al. and co-workers; [268, 463, 464]; Winter and Faiman;[51] Forest;[465] Esoterix, Tarzana, CA and Quest Laboratories, San Juan Capistrano, CA.

[b]. 17-hydroxyprogesterone early and mid-follicular phase baseline levels >140 ng/dL are found in normal women who are heterozygous for 21-hydroxylase deficiency, and they often have responses to ACTH greater than those shown. 17PROG begins rising in the preovulatory phase and peaks as high as 400 ng/dL in the luteal phase of the cycle.

consistently observed estrogen effects, and a palpable breast bud appears at term in one-third of babies.[465] Menstrual bleeding and colostrum production sometimes occur in neonates as the baby is withdrawn from the estrogenic environment. Sebaceous gland hypertrophy results from the androgenic state,[466] and the clitoral shaft is sometimes prominent—particularly in small premature babies.[400]

The transient activation of the hypothalamic-pituitary-gonadal axis of the newborn that occurs before the neuroendocrine-gonadal axis comes under CNS inhibition (Figures 14-5 through 14-8) is maximal at approximately 3 to 4 months of age. This may be sufficient to sustain breast development through early infancy. These phenomena then regress gradually over the first 2 years of life as the inhibitory tone of the neuroendocrlne-gonadal axis undergoes juvenile maturation. Whether this transient activation has an influence on subsequent puberty remains unclear.[50]

CHILDHOOD

As the neuroendocrine-gonadal axis becomes quiescent and the fetal zone of the adrenal cortex regresses, steroid hormone levels fall through infancy to reach a nadir in mid-childhood (Table 14-3). Although their levels fall, there is considerable evidence for the secretion of bioactive gonadotropins at low levels (Figure 14-13). Although there is seldom obvious sexual development as a consequence of these changes, there is evidence of a low level of ovarian activity and occasional evidence of transient estrogen secretion.[467]

ADOLESCENCE

Typical Developmental Pattern

Hormonal. The earliest hormonal changes of puberty occur in late preadolescence. Clinically prepubertal 10-year-olds have greater average gonadotropin and sex hormone levels than do prepubertal 7-year-olds.[71] The earliest change in the late preadolescent years is the adrenarchal rise in DHEAS (Table 14-3).

In the average girl, serum gonadotropins begin to rise gradually after 9 years of age. However, the chronologic age at which this rise occurs varies considerably among children. Therefore, the pubertal rise in gonadotropins is best appreciated by relating gonadotropin levels to pubertal stage. Daytime serum LH rises 25-fold from prepuberty to late puberty according to bioassay, but this rise is underestimated by polyclonal radioimmunoassay (Figure 14-13).[94] Third-generation immunometric assays, using monoclonal antibodies and a more purified standard than earlier radioimmunoassays, shows a rise similar to that found by bioassay.[69,71]

The hallmark of early puberty is a sleep-related increase in LH (Figure 14-12).[71,93,] Daytime sampling underestimates the rise in gonadotropins in early puberty because it does not detect most of this sleep-related increase. In early puberty, third-generation assays show that LH rises during sleep to reach peaks in the lower adult range (generally above 1.0 U/L) and then typically falls during the day to 0.6 U/L or less.[71,468,468a] A single daytime sample does not necessarily truly represent a child's pubertal status because it does not account for episodic and cyclic changes in gonadotropin secretion (Figure 14-12).[68,91]

The serum LH response to GnRH is more characteristic of the pubertal status than a daytime basal sample (Figure 14-9).[84,468,468a] A peak LH response to GnRH over 4.2 U/L is indicative of the onset of puberty in girls, although some early pubertal girls have lesser responses. The response of LH to GnRH or GnRH agonist administration increases more than that of FSH during puberty, with a resultant increase in the LH:FSH ratio.[69,81] GnRH agonists add a dimension to GnRH testing: they provide a sufficiently potent and prolonged stimulus to LH and FSH release to bring about an increase in ovarian estradiol secretion in pubertal girls.[81] These responses likewise increase characteristically with sexual maturation (Figure 14-6).[59]

Sex hormone levels rise further as the consequence of ovarian and adrenal maturation. Pubertal levels are intermediate between those of prepubertal and sexually mature individuals. Table 14-3 outlines typical normal ranges for serum levels of the major steroid hormones. Once pubertal levels of estrogens and androgens are achieved, their effects ordinarily become obvious within 6 months. Serum prolactin rises moderately in females at about 14 years of age.[469] This may be a response to estrogen secretion because it does not occur in boys.

Clinical. The first physical sign of puberty is usually breast development (breast stage 2, thelarche) but may be pubic hair development (pubic hair stage 3, pubarche). Thelarche represents a response to estrogen, and pubarche a response to androgen. The stages of breast and pubic hair development are shown in Figure 14-31.[470,471] Tanner stage 1 is prepubertal. Breast development stage 2 (B2) is appreciated as a palpable subareolar bud before it can be seen as an elevation. Stage B3 is obvious enlargement and elevation of the entire breast. Stage B4, the phase of areolar mounding, is very transient and may not necessarily appear. Stage B5 is the stage of attainment of mature breast contour.

Presexual pubic hairs (PH2) (i.e., short, light, and straight) are often not obvious except upon close examination and may be related to hypertrichosis rather than puberty. Sexual pubic hair (PH3; long, dark, and curly hairs) subsequently appears, usually commencing

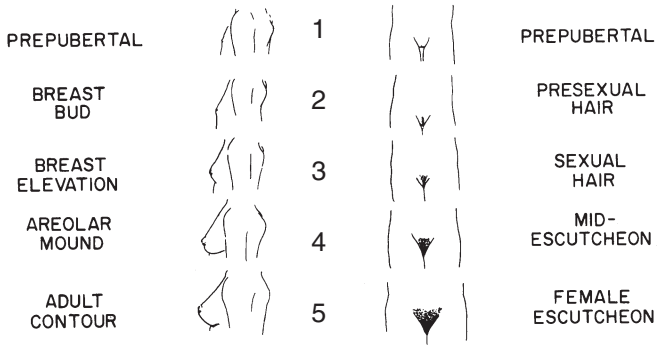

Figure 14-31 The stages of breast and pubic hair development. [Redrawn from Ross GT, Vande Wiele R (1974). The ovary. In Williams RH (ed.), *Textbook of endocrinology, Fifth edition*. Philadelphia, WB Saunders.]

on the labia majora before spreading to the pubis. Pubic hair then gradually progresses to the mature female escutcheon (inverted triangle pattern, stage 5). Axillary hair usually appears about a year later than pubic hair and passes through similar stages.

The age at which pubertal milestones are normally attained is not known with certainty. There has been considerable debate about the normalcy of pubertal changes between 6.0 and 8.0 years of age.[168,178,472] The debate stems from office practice observations that breast and pubic hair development were found more frequently than expected in black girls in this age range, whereas the age of menarche was unremarkable. The increasing prevalence of obesity interacting with ethnic factors now appears to be a major factor in this early onset of puberty.[204,205,464,473]

The prevalence of pubertal milestones has been estimated for the general U.S. population by modeling data collected on children 8.0 years of age and older by the National Health and Nutrition Examination Survey III (NHANES III).[173,174,474] Although NHANES III data has sampling advantages, the quality of the data for early breast and pubic hair development is questionable—and modeling assumptions that permit extrapolation to younger ages may not be valid.[474-476] The ages at which the major pubertal milestones are currently attained in normal-weight U.S. girls according to this database are given in Table 14-4.[474] It appears that puberty begins before 8.0 years in <5% of the normal general female population, while the appearance of breasts is normal in 7 year-old Blacks and Mexican-Americans.

An important normal variable is the span of time between the onset of breast development (B2) and menarche. The concept that this is constant at 2.3 ± 1.0 year regardless of the age at which B2 occurs[470] has recently been challenged. In several normal populations of girls observed longitudinally, the onset of puberty was only weakly correlated with the age at menarche, and the earlier puberty began, the longer its duration and the greater the incremental growth so that height potential was preserved.[477,478,479] These studies suggest that the factors governing the onset of puberty and its tempo differ. However, longitudinal studies reach conflicting conclusions on whether excess adiposity advances the onset or the tempo of puberty.[477-479a] A sub-group of early maturers with a history of intrauterine growth retardation seems to have an unusually rapid tempo of puberty and lose height potential.[479,480]

The onset of puberty is more closely related to an individual's bone age than to chronologic age. This is particularly important in the case of subjects who are later than average in entering puberty, as discussed previously. The great majority of girls can be expected to begin puberty by the time their skeletal age reaches 12.5 years, and to experience menarche by the time skeletal age reaches 14 years.

The pubertal growth spurt occurs during early adolescence. The peak of linear growth velocity corresponds most closely with stage B2,[481] and the increase in serum alkaline phosphatase levels with B3.[482] Fat accumulation increases and fat distribution changes as well.[477] As a consequence of these pubertal changes occurring out of phase with chronologic age, girls begin to differ considerably in size and habitus during the ninth year of life.

Normal Variations in Pubertal Development

Although the onset of breast development (stage B2) characteristically precedes the appearance of sexual pubic hair (PH3) and the onset of menses substantially (Table 14-4), there is normally considerable variation in the sequence of these events. Pubic hair may appear before breasts begin to develop, a situation arising from lack of direct linkage between adrenarche and gonadarche. Menarche may occur within months after the appearance of breasts. However, this is so unusual that its occurrence demands exclusion of an abnormal hyperestrogenic state.

A common normal variant is the unilateral onset of breast development. Unilateral breast development may exist up to 2 years before the other breast becomes palpable. This phenomenon seems related to an asymmetry that normally persists into adulthood. Excisional biopsy of a normal unilateral breast papilla in search of a nonexistent tumor should be avoided because such a procedure

TABLE 14-4

Pubertal Milestone Attainment in Normal BMI Girls (Estimated Age in Years, 95% CI).*[474]

Stage	5%	50%	95%
Breast Stage 2	8.25 (7.8, 8.6)	10.2 (9.9, 10.4)	12.1 (11.8, 12.5)
Pubic Hair Stage 3	9.25 (8.9, 9.6)	11.6 (11.3, 11.9)	13.9 (13.3, 14.7)
Menarche	11.0 (10.7, 11.3)	12.6 (12.4, 12.8)	14.1 (13.8, 14.6)

a. Breasts appear before age 8.0 years in 12-19% and sexual pubic hair in ≤3% of normal-BMI non-Hispanic Black and Mexican-American girls. Menarcheal milestones are attained at similar ages in these ethnic groups except for the 5th percentile being significantly earlier in Blacks (10.5 yr, 9.9, 10.9) than non-Hispanic Whites (11.3 yr, 9.9, 10.9).

Adapted from Rosenfield RL, Lipton RB, Drum ML. Pubertal milestone attainment in normal-weight girls. Pediatric Academic Society Annual Meeting,Toronto, Canada, May 3-8, 2007; E-PAS2007:61:7914.11.

excises the entire breast anlage. Two extreme variations of normal are the most common causes of premature sexual development.[483] These are the isolated appearance of breast development (idiopathic premature thelarche) and the isolated appearance of sexual hair (idiopathic premature pubarche).

Premature Thelarche. Breast development before 8 years usually seems to be due to idiopathic subtle overfunction of the pituitary-ovarian axis, occurring in those girls whose FSH levels tend to be sustained about the upper end of the prepubertal normal range.[467] Average serum levels of FSH at baseline and in response to GnRH are significantly increased, whereas those of LH are not. Intermittent low-grade estrogenization of the urogenital mucosa or slight or intermittent elevation of the plasma estradiol is sometimes found (Figure 14-11).[79] Examination via ovarian ultrasound shows an increased prevalence of antral follicles (microcysts). Nevertheless, a growth spurt does not occur, the bone age does not advance abnormally, and menses does not appear until the usual age.

In infants the syndrome seems to be due to a lag in inhibition of the transient activation of the hypothalamic-pituitary-gonadal axis of the newborn and is usually unsustained. In older children, the breast development is more likely to persist. A subgroup with "exaggerated thelarche" has an increased growth rate with relatively proportionate bone age advancement. Their unsustained or intermittent neuroendocrine activation seems to lie on a spectrum between ordinary premature thelarche and true sexual precocity (Figure 14-32).[484] However, the McCune-Albright syndrome mutation is found in the peripheral blood of about 25% of such patients.[485] Premature thelarache may be the first sign of transient autonomously functioning ovarian cysts, complete precocious puberty, or occasionally polycystic ovary syndrome. Therefore, follow-up of these patients is indicated.

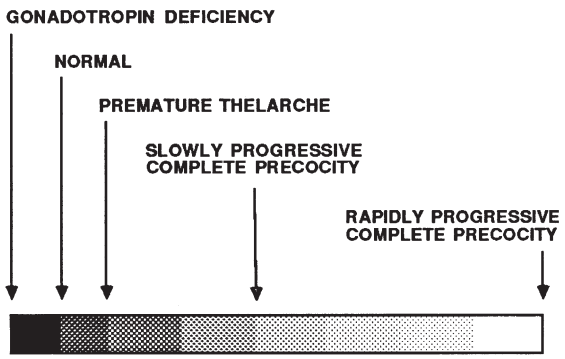

Figure 14-32 The spectrum of gonadotropin secretion in girls. Normal girls are conceptualized as having a small amount of pituitary-ovarian axis activation, which is more than that of congenitally hypogonadotropic girls. Premature thelarche, exaggerated thelarche, slowly progressive precocity, and rapidly progressive precocity fall along a spectrum of increasing activation of the axis—with deterioration of height potential occurring only in those near the most activated end. [From Kreiter ML, Cara JF, Rosenfield RL (1993). Modifying the outcome of complete precocious puberty: To treat or not to treat. In Grave GD, Cutler GB (eds.), *Sexual precocity: Etiology, diagnosis, and management*. New York: Raven Press 109–120.]

Premature Pubarche. Pubarche before 9 years of age usually occurs at adrenarcheal androgen levels (e.g., DHEAS 40-130 μg/dL; Table 14-3), which is termed *premature adrenarche*.[268] However, it may occur at androgen levels that are lower (idiopathic premature pubarche) or higher. The androgen excess is ordinarily so subtle that the only other sign of increased androgen production may be microcomedonal acne and apocrine body odor. There is no obvious growth spurt, the bone age typically does not advance abnormally, and there are no other signs of sexual maturation.

Exaggerated adrenarche is an extreme type of premature adrenarche. These girls have clinical features that suggest subtle androgen excess (e.g., significant bone age advancement but not clitoromegaly) or insulin resistance (e.g., central adiposity or acanthosis nigricans). Such children generally have a slightly advanced onset of true puberty, but height potential is not compromised. Adrenal steroid levels are in the mid- or late pubertal range (e.g., DHEA-S >130–185 μg/dL, androstenedione >75–99 ng/dL, or post-ACTH 17-hydroxypregnenolone >750 ng/dL). Testosterone does not exceed the lower end of the adult female range.

It is unclear whether premature adrenarche is simply a normal variant due to advanced onset of normal zona reticularis development or an early manifestation of the steroidogenic dysregulation of polycystic ovary syndrome (PCOS). Carriers for congenital adrenal hyperplasia may be overrepresented in this group.[486,487] Premature pubarche appears to carry about a 15- to 20% risk of developing PCOS. It seems likely that the risk is relatively high in those with exaggerated adrenarche. Thus, girls with premature adrenarche should be followed through puberty.

Constitutional Delay of Pubertal Development. By statistical definition, puberty can be considered delayed in 3% of girls. Most of these girls are otherwise normal, in which case this is termed *constitutional delay of growth and pubertal development* (which is often familial). Girls do not usually become concerned about this until they enter high school at 14 years of age and realize that not only has pubertal development not begun but most of their friends are menstruating. When puberty does ensue in such subjects, it is perfectly normal in tempo. Endocrinologic status is normal for the stage of puberty. It may be difficult to distinguish constitutional delay of growth and pubertal development from gonadotropin deficiency, as discussed under that heading.

Physiologic Adolescent Anovulation. About half of menstrual cycles are anovulatory during the first two postmenarcheal (gynecologic) years.[488] This causes considerable variation in the length of time it takes for a girl to establish a menstrual pattern that is normal by adult standards. Cycles in the early years tend to be a few days longer than in adults, and long phases of irregularity of menses may occur (Figure 14-33).[489,489a] Nevertheless, even within the first year after menarche it is abnormal to have bleeding that is excessive or lasts over 7 days or occurs more frequently than every 21 days (dysfunctional uterine bleeding) or cycles that occur less frequently than every 90 days, i.e., missing more than 4 cycles per year (oligomenorrhea). By five gynecologic years the menstrual cycle is virtually sexually mature, with approximately 80 per cent

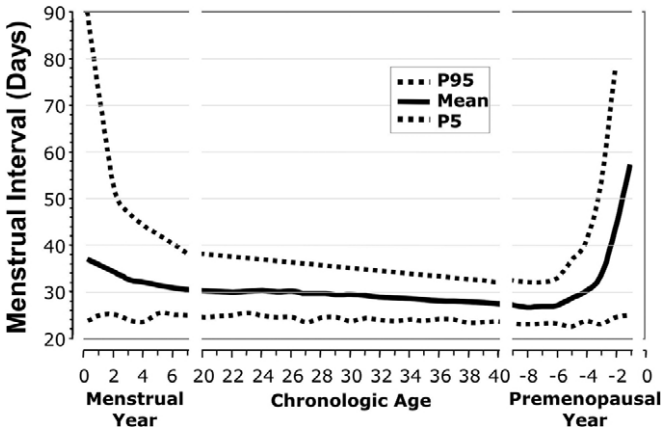

Figure 14-33 Normal range for interval between menstrual cycles. Note that cycle intervals averaging more than 90 days or fewer than 22 days are abnormal at any age. P5 and P95 = 5th and 95th percentiles, respectively. [Modified from Treloar A, Boynton R, Benn B, Brown B (1967). Variation of human menstrual cycle through reproductive life. Int J Fertil 12:77–84.]

of cycles being ovulatory. At this point, it is abnormal to miss more than 4 periods per year (oligomenorrhea). Primary amenorrhea is defined as failure to begin menses at a normal age (by 15 years of age or within 3 years of thelarche), and *secondary amenorrhea* as cessation of menstrual periods for 6 months or more after initially menstruating.

Serum LH, testosterone, and androstenedione levels are significantly higher in adolescents with anovulatory than those with ovulatory cycles.[490,491] It is unclear whether this is the cause or the result of the anovulation. However, if hyperandrogenemia is found it seldom regresses.[117] The distinction between multicystic ovaries, which are usually a variation of normal, and polycystic ovaries (which are not) is often subjective and problematic.[492,493] Failure to establish a normal adult menstrual pattern by 2 postmenarcheal years or to sustain a normal pattern for 2 years after one has been established carries a greater than two-thirds risk of persistent oligoovulation (Figure 14-34).[494] Thus, failure to establish regular cycles by this time is an indication to investigate the cause.

Other. There is considerable variation in the amount of acne, hirsutism, and adiposity among normal adolescent girls—most of which is related to familial factors. Three-quarters of adolescent girls experience some degree of acne, and one-quarter experience inflammatory acne.[495] The initiation of acne is more closely related to blood levels of DHEAS than to blood levels of other androgens.

Profound psychological changes occur during adolescence. Sexually immature girls tend to be socially immature, and the onset of puberty is associated with increased independence and profound changes in outlook

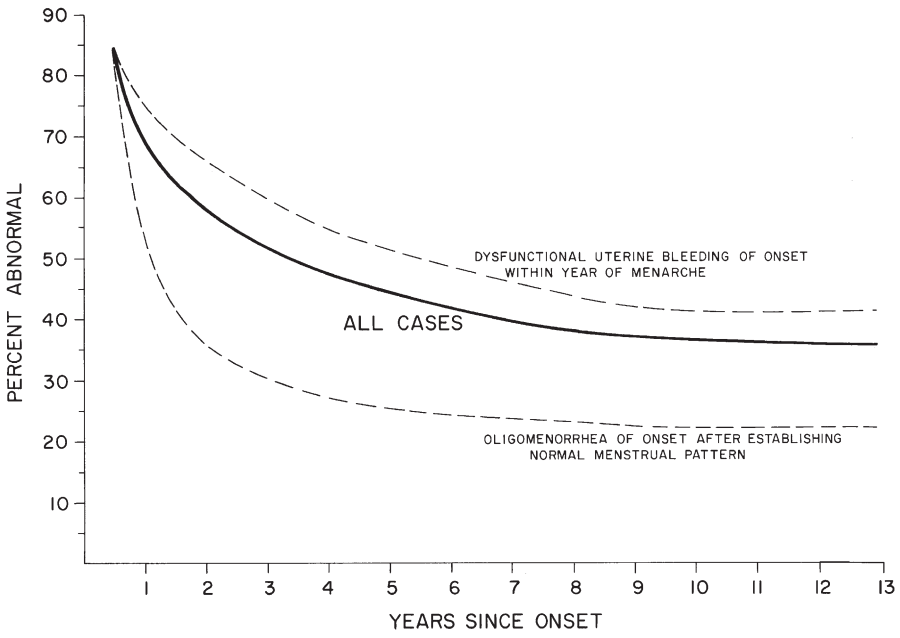

Figure 14-34 Probability that an adolescent with a menstrual abnormality severe enough to require gynecologic consultation will have continued menstrual abnormality. The lines show the cumulative rates at which subjects with menstrual abnormalities converted to normal patterns. The heavy curve shows the overall incidence of continued menstrual abnormality in adolescents when considering both types of anovulatory manifestation (dysfunctional uterine bleeding and oligomenorrhea) regardless of time of onset. The dotted lines show those subgroups that differ most from the overall pattern. Other subgroups fall within approximately 5% of the mean for the entire group. Note that dysfunctional uterine bleeding of onset within 1 year of menarche carries the worst prognosis for continuing menstrual abnormality (upper dotted line). Note also that oligomenorrhea of relatively short duration occurring after a normal menstrual pattern has been established carries the best overall prognosis. Nevertheless, it can be seen that if the menstrual abnormality persists for 2 years there is a 67% probability that the patient will not spontaneously evolve to normal cycles. That is, of the 60% of patients with an abnormal menstrual pattern of 2 years' duration, two-thirds (40% of the total group) will continue to have abnormal periods. Similarly, if the problem persists for 5 years there is an 80% likelihood of persistence of the abnormality. [Redrawn from Southam AL, Richart EM (1966). The prognosis for adolescents with menstrual abnormalities. Am J Obstet Gynecol 94:637.]

on life and in intellectual capacity. The extent to which these developments occur in reaction to the physical changes of puberty and the extent to which they are direct effects of sex hormones are unknown. Masculine tomboyish traits usually have no clear hormonal basis, although there is some evidence that they may have prenatal hormonal determinants. Social interactions have effects on these aspects of development. They affect even the synchrony of the menstrual cycle.[496]

Normal Variations in Mature Menstrual Cycles

The cyclic changes of LH, FSH, estradiol, and progesterone during the menstrual cycle are shown in Figure 14-14.[118,119] Some diurnal and episodic fluctuations are superimposed on these, as noted in the related discussion. Because testosterone and androstenedione have both adrenal and ovarian origins, their levels fluctuate to some extent in cyclic, diurnal, and episodic patterns. For example, testosterone levels tend to be 20% greater in the morning than in the evening—and to rise 50% to 100% in midcycle.[118,497] Normal ranges for most of the important sex hormone levels of women during the early follicular phase of the menstrual cycle are outlined in Table 14-3.

Progesterone levels are below 100 ng/dL until the periovulatory phase of the cycle, and then peak to greater than 500 ng/dL in the mid-luteal phase. Hormonal production rates for the mid-follicular phase in women are given in Table 14-2. Serum prolactin increases transiently in midcycle with maximum ovarian estradiol secretion.[498] Prolactin levels also transiently rise in response to mammary stimulation and psychological factors.[499]

The menstrual cycle of young adults averages 28 days in length (90% confidence limits, 22 to 40 days by the fifth gynecologic year).[489] The variation in cycle length is almost entirely due to differences in the duration of the follicular phase. The luteal phase, the time between ovulation and the onset of menses, invariably lasts 14 ± 1 (standard deviation) days.[119]

Recent evidence indicates that human pheromones modulate the timing of ovulation[500] and mood.[501] Unusual steroids, such as androst-4,16-diene-3-one, have been incriminated in this regard. Uterine cramping is characteristic of ovulatory cycles, presumably as a result of prostaglandins released within the endometrium upon the withdrawal of progesterone.

Abnormal Puberty

ABNORMAL DEVELOPMENT

Disorders of Sex Development

Patients with disorders of sex development (DSD, formerly termed *intersex*)—those whose genitalia are ambiguous or inappropriate for their gonadal sex as a result of endocrinopathy—may come to a physician's attention for the first time at puberty. These syndromes are termed *ovotesticular DSD* (true hermaphroditism), *46, XX DSD* (female pseudohermaphroditism), *46, XY DSD* (male pseudohermaphroditism), *46, XX testicular DSD* (XX male), and *46, XY complete gonadal dysgenesis*.[432]

Patients with any of these disorders may undergo inappropriate puberty. They may present with clitoromegaly and be found upon examination to have a degree of genital ambiguity previously overlooked. Virilization beginning at puberty is sometimes the presenting complaint. Ovotesticular DSD and 46, XX DSD due to congenital adrenal hyperplasia are compatible with fertility.[321] Androgen insensitivity syndrome may present as primary amenorrhea in an otherwise normal adolescent girl. The disorders of sexual differentiation are reviewed in detail in Chapter 4.

Other Dysgenetic Disorders

Failure of the onset of menses can result from structural abnormalities of the genital tract that do not have an endocrinologic basis. The vagina may be aplastic or have an imperforate hymen. If the uterus is intact, hydrometrocolpos will occur. The uterus may be congenitally aplastic. Uterine synechiae develop as the consequence of endometritis, which may result from infection or irradiation (Asherman's syndrome). Congenital absence of the vagina may be associated with varying degrees of uterine aplasia. This is the Rokitansky-Kustner-Hauser syndrome.[502] This syndrome seems to occur as a single gene defect or as an acquired teratogenic event involving mesodermal development and the mesonephric kidney, the latter resulting in abnormalities of the genital tract and sometimes the urinary tract. A subtype due to *Wnt 4* gene defects is associated with hyperandrogenism.[502a]

PRECOCIOUS PUBERTY

Causes

When breast development begins before the age of 8 years, sexual pubic hair before 8 years, or menses before the age of 9.5, puberty is traditionally considered precocious (premature). Puberty can occur prematurely as an extreme variation of normal because of a disturbance in the hormonal axis normally involved in sexual maturation or because of a disturbance outside that axis. Depending on which part of this hormonal axis is involved, different forms of precocious puberty are distinguished. A classification of the causes of premature puberty together with typical findings is given in Table 14-5.

It is important to distinguish between true precocious puberty and pseudoprecocious puberty. In true precocious puberty maturation is "complete." Breasts and pubic hair develop as the result of CNS activating pituitary secretion of the respective gonadotropins FSH and LH (although breast development may be the sole manifestation of early complete precocity for as long as 6 to 12 months). Thus, "central" is another term applied to this type of precocity. Patients with true precocious puberty have *isosexual* precocity because the secondary sexual characteristics are appropriate for the sex of the child.

In pseudoprecocious puberty, maturation is incomplete—with only one type of secondary sexual characteristic developing early. Pseudoprecocious puberty has diverse causes

TABLE 14-5

Typical Findings in Female Sexual Precocity

Locus	Type	HA*	BA*	Estrogens†	Androgens†	LH/FSH†	Pathology	Characteristics

and is not mediated by pubertal pituitary gonadotropin secretion. In some patients with pseudoprecocity, pubertal development is isosexual. In others it is "contrasexual," meaning that characteristics of the opposite sex are manifested.

Complete Precocious Puberty. True isosexual precocity results from pubertal function of the hypothalamic-pituitary-gonadal axis. About 95% of true precocity in girls is idiopathic. Idiopathic true sexual precocity seems usually to be due to premature triggering of the normal pubertal mechanism. Pubertal development is usually qualitatively and quantitatively normal except for its early occurrence. Progressive puberty with a growth spurt ensues when activation of the pituitary-ovarian axis is sustained. However, puberty is not necessarily intense enough or sustained enough to cause the inexorable progression of normal puberty or to cause deterioration of height potential.[503]

The predominance of the idiopathic syndrome in females and its benign nature are compatible with the likelihood that this disorder is an extreme exaggeration of the normal tendency of girls to have relatively high gonadotropin levels. Most cases are sporadic, a few familial. The majority of these patients seem to go on to have normal menstrual cycles.[504] Pregnancy has been documented to occur as early as 4 years of age. This is reminiscent of the experimental model in which certain hypothalamic lesions in rats cause premature puberty followed by constant estrus.[1] Rare causes of true sexual precocity include maternal uniparental disomy of chromosome 14, which causes the combination of intrauterine growth retardation and sexual precocity[505]—as well as hyperglycinemia.[506] A genetic variant of a hepatic mixed-function oxidase has been associated with the precocious onset of puberty in girls.[335]

Any type of intracranial disturbance can cause true isosexual precocity. These neurogenic disturbances are presumed to cause true sexual precocity by increasing the prevalence of excitatory inputs or by interfering with neurogenic inhibition of hypothalamic GnRH secretion.[507] These include congenital brain dysfunction (such as cerebral palsy and hydrocephalus) and acquired disorders, such as irradiation, trauma, chronic inflammatory disorders, and masses in the region of the hypothalamus. The activation of GnRH release by hypothalamic injury may be mediated by TGF-α elaborated by reactive astrocytes. An empty sella is occasionally found.[508]

The precocity of neurofibromatosis type I (von Recklinghausen disease) usually results from an optic glioma, which is often a low-grade malignancy, or from a hamartoma[509]—although occasionally from neither.[510] Hamartoma of the hypothalamus may cause sexual precocity by acting as an "accessory hypothalamus" that releases pulses of GnRH into the pituitary portal circulation[511] or by producing TGF-α.[512] Figure 14-35 shows a hypothalamic hamartoma.

A small proportion of pineal tumors cause true sexual precocity.[513, 514] The incidence of sexual precocity is about 3.5 times as great in nonparenchymatous neoplasms (such as gliomas and teratomas) as in parenchymatous pineal tumors. This suggests that these tumors cause sexual precocity via absence of a normal pineal inhibitory factor rather than via destructive effects on inhibitory tracts. Although pineal masses may cause paralysis of upward gaze by pressure on the corpora quadrigemina, this sign is present in only a minority of cases.

Advancement of somatic maturation due to noncentral endocrine disorders that advance the bone age to a pubertal level sometimes causes true sexual precocity. Thus, true puberty may begin after correction of virilizing or feminizing disorders that have advanced the bone age to 10 to 12 years.[194,195] The hypergonadotropinism of premature ovarian failure has been reported to cause sexual precocity or rapid progression of puberty prior to premature menopause.[515,516] The possibility must be considered that true sexual precocity may very occasionally be the first manifestation of polycystic ovary syndrome.[517-519]

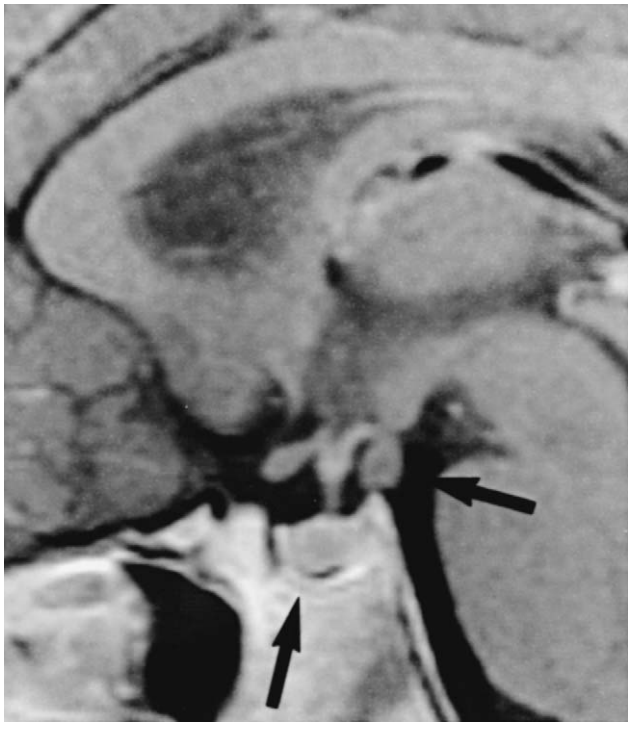

Figure 14-35 Magnetic resonance image showing a hypothalamic hamartoma (right-hand arrow) as the cause of true sexual precocity in a 2.5-year-old girl. The hamartoma is hanging from the floor of the hypothalamus just posterior to the pituitary infundibulum. The sella turcica (bottom arrow) contains a normal pituitary gland with pituitary stalk hanging from the infundibulum.

Incomplete Precocity. The most common causes of incomplete sexual precocity in girls are the extreme variants of normal premature thelarche and premature pubarche. These are incomplete forms of sexual precocity in which either breast development (thelarche) or sexual hair development (pubarche) is of a degree appropriate for an early stage of adolescence and hence isosexual. Isolated prepubertal menses is a rare disorder, which like premature thelarche has been attributed to transient ovarian activity.[520]

Girls with hCG-producing tumors rarely have sexual precocity.[521] Nevertheless, true sexual precocity has been reported in association with pineal or hypothalamic hCG-secreting germ cell tumors.[522,523] Because hCG is a LH receptor agonist, possible explanations for this unusual situation are disinhibition of hypothalamic GnRH release due to a mass effect, the weak FSH effect of massive elevation of hCG, and the capacity of some dysgerminomas to secrete not only hCG but estradiol.[524]

As with hCG-secreting tumors, one would not expect an isolated elevation of LH to cause precocious puberty. However, isolated elevation of LH has been reported as an unusual cause of contrasexual precocious puberty:[525] Mild virilizing signs were reported in siblings with isolated elevation of LH, one of whom was a girl. She developed pubic hair and clitoral hypertrophy at 4 years, with slight to moderate advances in height and bone age in association with an adrenarchal level of DHEAS and a moderately elevated testosterone level (91 ng/dL).

The van Wyk-Grumbach syndrome is one of the most puzzling pediatric complexes.[526] This is an unusual syndrome of sexual precocity associated with juvenile hypothyroidism. A case is illustrated in Figure 14-36. This syndrome is often characterized by galactorrhea, which is often subtle. The breasts must be specifically manipulated in order to express the few drops of milky fluid that may be present. Multicystic ovaries are often demonstrable by ultrasonography.[527] There is little, if any, sexual hair development. There is another clinically unique feature about the sexual precocity of hypothyroidism: it is the only form of sexual precocity in which growth is arrested rather than stimulated.

Van Wyk and Grumbach postulated that this syndrome resulted from hormonal "overlap" in the negative feedback regulation of pituitary hormone secretion, with overproduction of gonadotropins and TSH in response to the thyroid deficiency. The specific nature of hormonal overlap has been considerably clarified in recent years. The increases in plasma TSH and prolactin that characterize the syndrome could well be accounted for by common neurohumoral control systems, TRH stimulating and dopamine inhibiting both hormones.

Although the gonadotropins share a common alpha-subunit with TSH and seem to be elevated according to the early generation of polyclonal radioimmunoassays, they do not appear to be GnRH responsive or bioactive.[528,529] Furthermore, most children with prolonged hypothyroidism have delayed sexual maturation—as would be expected from the maturational retardation characteristic of states with delayed bone ages. Recently, the syndrome has been postulated to arise from the weak intrinisic FSH activity of extreme TSH elevation[530]—which

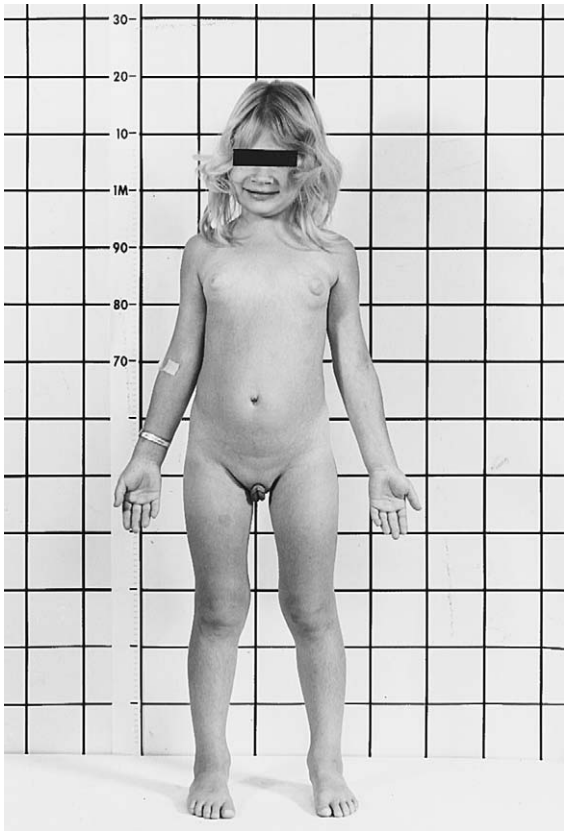

Figure 14-36 Sexual precocity caused by hypothyroidism (#UC 133-33-55-4) in a 9.1-year-old with breast development since 7 years and menarche at 9.0 years. Growth failure had occurred, and her height age was 6 years. In addition to breast enlargement and galactorrhea, the labia minora were noted to be enlarged and pigmented. There was no sexual hair or clitoromegaly. Rectal examination revealed an enlarged and palpable cervix without adnexal masses. There were typical physical findings of hypothyroidism. Bone age was 6.2 years. Thyroxine was less than 1 μg/dL. Thyrotropin-stimulating hormone was 438 μgU/mL. Prolactin was 66 ng/mL. Serum estrogens were 72 to 182 pg/mL. Vaginal smear showed 45% superficial cells and 55% large intermediate cells. Immunoreactive luteinizing hormone (LH) and follicle-stimulating hormone were 300 and 174 ng LER-907/mL, respectively. However, bioactive LH was undetectable. Immunoreactive gonadotropins failed to suppress upon estrogen administration. Their response to a 100-_g gonadtropin-stimulating hormone bolus was minimal, and they seemed responsive to thyrotropin-releasing hormone. All of these hormonal findings were not obviously different from those of hypothyroid girls without sexual precocity except for the higher estrogens. Patient had withdrawal bleeding and evidence of regression of breast development within the first 3 months of thyroid hormone replacement treatment. After 6 months' treatment, normal puberty began. Menarche occurred at 12.5 years of age.

would be analogous to the similarly rare ovarian hyperstimulation syndrome in adults.[531]

The concommittent hyperprolactinemia may play a role in the sexual precocity of hypothyroidism. It seems unlikely to be the primary cause, however, because prolactin levels do not correspond with pubertal development in normal or hypothyroid children. However, induced hyperprolactinemia causes sexual precocity in female rats.[264] Ovarian estrogen and progesterone responsiveness to hCG is increased by prolactin, possibly by its induction of ovarian LH receptors. Mean LH levels do not change, although an increase in episodic gonadotropin secretion has not been ruled out. Suppression of hyperprolactinemia in experimental hypothyroidism blocks the ovarian cyst formation characteristic of hypothyroidism.[532] These data suggest that hyperprolactinemia sensitizes the ovaries to the trace amounts of gonadotropin present prepubertally.

McCune-Albright syndrome is one of the most intriguing disorders causing incomplete isosexual feminization.[533,534] This is a syndrome of precocious puberty involving cafe-au-lait pigmentation occurring in nevi that have an irregular ("coast of Maine") border and polyostotic fibrous dysplasia. The disorder is caused by a somatic activating mutation in the alpha-subunit of the G protein that couples transmembrane receptors to adenylate cyclase. The syndrome occurs in incomplete and expanded forms. Precocious puberty or monoostotic bone lesions may occur in the absence of cutaneous pigmentation. Not all patients have sexual precocity. The disorder has been recognized predominantly in females. The sexual precocity is of the gonadotropin-independent type. Luteinized follicular cysts within the ovaries function autonomously. Pituitary adenomas capable of secreting excess LH, FSH, GH, and/or prolactin have been reported. Patients may have Cushing syndrome and hyperthyroidism due to autonomous multinodular hyperplasia. These girls may be at increased risk of breast carcinoma.[535] Nonendocrine abnormalities include cardiopulmonary disease, hypertension, and hepatobiliary disease.

Molecular studies have shown an R201H mutation in more than 90% of cases in which an affected tissue could be studied, but in only 50% of blood samples.[536] Because of the variation in the number and degree of tissue involvement in individual patients, due in large part to the extent of mosaicism present, precocious puberty may be the only feature present in an individual who is mosaic for the activating mutation of G_s-alpha. Thus, these mutations have been found in blood samples from 25% to 33% of subjects with isolated gonadotropin-independent precocity or exaggerated thelarche.[485,536]

Congenital adrenal hyperplasia (CAH) is a well-known cause of premature pubarche. Nonclassic CAH, a form of the disorder so mild that there is no genital defect, or poor control of classic CAH may be responsible. Each form has on occasion been reported to mimic true sexual precocity.[537,538]

The most common tumor associated with isosexual feminization is the benign ovarian follicular cyst.[539] The cells lining these cysts are often luteinized. Estrogen production is modest to marked. Testosterone levels tend to be in the adult female range (about 40 ng/dL). Some of these cysts may occur in the course of intermittent or unsustained true sexual precocity. They may be gonadotropin dependent. A case is illustrated in Figure 14-37. The second most common ovarian feminizing neoplasm in girls is the granulosa cell tumor.[540,541] These are on a spectrum that includes variable degrees of sex cord elements and stromal tissue. Granulosa cell tumors are

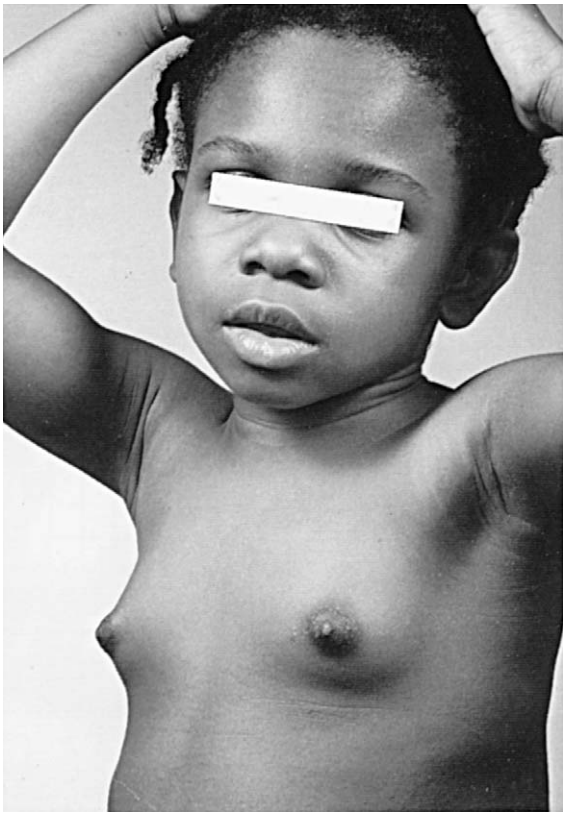

Figure 14-37 The appearance of a 5.2-year-old child with complete isosexual precocity caused by a luteinized follicular cyst. Her breast development is no different from that of girls with idiopathic premature thelarche. She presented at 4.7 years with a 2-week history of breast development. Height and bone ages were 5 years. Over a 5-month follow-up period, breast development progressed, she developed sexual pubic hair and presexual axillary hair, and menstrual flow commenced at 3- to 5-week intervals. Four weekly determinations of plasma unconjugated estrogens (estradiol and estrone) showed them to consistently range between 158 and 215 pg/mL. Luteinizing hormone and follicle-stimulating hormone averaged 50 and 13 ng LER-907/mL, respectively, by radioimmunoassay. Testosterone was 37 ng/dL, and dehydroepiandrosterone sulfate (DHEAS) was 82 μg/dL. Exploratory laparotomy was performed when she was 5.2 years old. Her height age was 5.8 years, and her bone age was 7.5. The laparotomy revealed a right ovarian cyst about 5 cm in diameter, which was removed. Subsequently, there was a rapid fall in plasma estrogens and testosterone to prepubertal levels. However, DHEAS was unchanged. Menses ceased, but intermittent vaginal cornification (maturation index 90/10/0 to 0/90/10) was repeatedly found. Breast enlargement and sexual hair development resumed at 8.5 years, with normal pubertal sex hormone levels. Menarche occurred at 9.5 years.

usually benign. They may produce hCG, AMH, and inhibin; [541,542] a variety of non-specific tumor markers are rarely reported. They are occasionally associated with mesodermal dysplasia syndromes.[543] Granulosa-theca cell tumor has been reported in the adrenal, presumbably arising in an ovarian rest.[544] Some ovarian sex cord-stromal tumors may be caused by loss of a tumor-suppressor gene, as in Peutz-Jeghers syndrome,[545] and others by activating mutations of stimulatory G proteins.[546]

Masculinizing tumors of the ovary (characteristically Leydig-Sertoli cell tumors or arrhenoblastomas) are unusual before the teenage years. The abnormal differentiation that underlies tumor formation typically leads to an abnormal pattern of steroid secretion, with androstenedione predominating over testosterone secretion.[547] Rare causes of masculinization and feminization are respectively granulosa-theca cell and interstitial cell tumors. Thecomas (luteomas) are unusual in children and are generally benign. Dysgerminomas virilize only if they have interstitial cell elements. Gonadoblastomas are virilizing tumors virtually confined to individuals with dysgenetic gonads with Y-chromosomal material in their genome. Adrenal rest and hilus cell tumors of the ovary are extremely rare causes of masculinization in childhood.[18,312]

Lipid cell tumors must be considered in the differential diagnosis of late-onset congenital adrenal hyperplasia because they tend to produce 17-hydroxyprogesterone and respond to ACTH and LH.[548] Some ovarian tumors are of adrenal origin.[549] Adrenal disorders cause pseudoprecocity, as discussed in Chapter 12 Adrenocortical tumors typically cause a rapid virilizing disorder characterized by very high DHEAS production, although androstenedione may instead be the predominant androgen secreted. A case discussion is given with Figure 14-38. On occasion, adrenal tumors cause feminization. When adrenal tumors secrete androgen and estrogen, the clinical picture may resemble complete isosexual precocity.[550] Structural abnormalities of chromosome 11p15 and mutations of the tumor suppressor p53 are fairly common in pediatric adrenocortical tumors.[551]

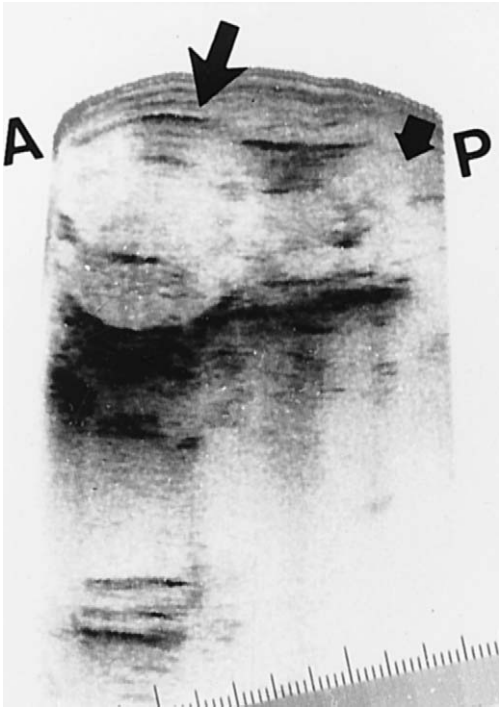

Figure 14-38 Abdominal ultrasound (decubitus view) showing a pedunculated encapsulated 5-cm adrenal adenoma (large arrow) near upper pole of kidney (small arrow). This 1.3-year-old girl was virilized. Pubic hair had appeared 2 months previously, height had changed from the 10th to the 30th percentile, and clitoromegaly had occurred. Bone age was 2.3 years. Dehydroepiandrosterone sulfate was 3,000 to 4,271 _g/dL. Testosterone was 121 ng/dL. Urinary 17-ketosteroids was 14 g/day. A, anterior; and P, posterior.

Exogenous steroids can cause sexual precocity. Estrogen-containing contraceptive pills and creams are widely available. Some cases of precocious thelarche may be caused by ingesting food contaminated with artificial estrogens.[552] Soy formulas are potential sources of phytoestrogens, as are many commonly consumed foods herbs and topicals.[553,554,544a] It has been proposed that childhood exposure to estrogenic chemical contaminants in underdeveloped countries predisposes to sexual precocity when children emigrate to developed countries.[168] Premature pubarche or acne can result from anabolic steroid use. Topical nonprescription androgen use by a parent, such as for sexual dysfunction or anabolic effects, can cause premature pubarche without necessarily being detectable by standard tests.[555]

Vaginal bleeding as an isolated phenomenon suggests a foreign body, sexual abuse, or tumors of the genital tract. Malodorous discharge is highly suggestive of a foreign body. A hymenal opening of greater than 5 mm and posterior notches are compatible with sexual abuse.[409,410] Neurofibromas have been reported to simulate breast development and clitoral hypertrophy. Aromatase excess syndrome has been reported to cause feminization of both sexes.[556] This is an autosomal-dominant disorder that results from aberrant aromatase gene transcription.

Differential Diagnosis

A physician need not be experienced in endocrinology to diagnose and manage most female patients presenting with early breast or pubic hair development. For the most part, the isolated appearance of one of these signs is due to the benign processes of premature thelarche and premature pubarche, respectively. An otherwise normal history and physical examination, together with a normal bone age, constitutes sufficient workup.

In the history, the physician should inquire about the possibility of exposure or access to exogenous steroids in the form of unusual creams, pills, or diet. The possibility of sexual abuse, vaginal infection, or a foreign body must be kept in mind when evaluating the child with isolated vaginal bleeding. In the examination, the physician should search for nevi, acanthosis nigricans, and signs that might suggest intracranial, abdominal, or pelvic disease. The child's height and weight should be carefully recorded and the growth curve examined.

If no other abnormalities are found upon physical examination, only a bone age determination is indicated to check whether the symptom is indeed an isolated phenomenon or whether appreciable hormone excess exists. If the skeletal age is not abnormally advanced relative to height age, it is likely that the presenting symptom is an isolated and benign extreme variant of normal that requires no treatment.[467,557] Support for this impression may be obtained if the serum level of the relevant female or male hormones is low (estradiol less than 10 pg/mL and testosterone less than 25 ng/dL).

To confirm the diagnosis of these benign nonprogressive disorders, the child must be similarly reevaluated after 6 months. The importance of this recheck is illustrated by the patient shown in Figure 14-37. If the results are still negative, the family can be reassured with a high degree of confidence that true puberty (including menses) will not occur until the usual age.

If more than one sign of precocious puberty is present or develops, if the growth is accelerated, or if the bone age is advanced more than 2 standard deviations above the mean for age (particularly if height potential is compromised), a more extensive investigation should be undertaken to rule out a discrete lesion affecting some part of the hormonal axis controlling puberty. For example, if a young girl with early breast development begins to grow pubic hair (or vice versa) something more than premature thelarche or premature adrenarche is involved. The same is true if she develops signs of a growth spurt, her bone age advances inordinately over the 6-month interval of initial observation, or if she begins menstruating. These additional signs indicate the need for more extensive studies. Isolated vaginal bleeding suggests sexual abuse, a foreign body, or tumor. Only rarely does it indicate isolated menarche. Cytology, anaerobic culture, plasma estradiol, and in some cases pelvic ultrasound examinations are indicated.

One must be particularly aware that girls with neurogenic precocity, especially those who have had cranial irradiation, are at risk of paradoxically having GH deficiency.[484] Coexistent GH deficiency masks the seriousness of the precocity. The growth rate is normal (not accelerated) and breast development is attenuated. However, the disparity between bone age and height age is extreme.

The laboratory investigation of premature pubertal development requires determinations of sex steroids, LH, and FSH by high sensitivity-specificity "pediatric" assays of high sensitivity and specificity in laboratories with well-established normal ranges for children. These assays should have a sensitivity of at least 10 pg/ml for estradiol, 10 ng/dl for testosterone, and 0.2 U/L for LH and FSH. Measurement of serum thyroxine and prolactin is indicated if the sexual precocity is accompanied by growth arrest and/or galactorrhea. Day time plasma estradiol concentration is usually pubertal, typically 10 pg/mL (37 pmol/L) or greater in true isosexual precocity.[558] An estradiol level at the upper end of the premenarcheal normal range (75 pg/mL) or greater is atypical and necessitates a prompt workup to distinguish ovarian or adrenal tumor from true isosexual precocity.[559]

Weekly determinations of estradiol may be necessary to determine whether the level is fluctuating in the normal cyclic fashion of true precocious puberty or is persistently elevated. Because of the episodic and cyclic nature of sex hormone secretion, examination of the vaginal mucosa for estrogen effect is a more accurate indicator of the presence of early puberty than is the estradiol blood level because the vaginal cytology represents the integrated effect of estrogen over the preceeding few weeks (Figure 14-11). Uterine size (e.g., uterine width >1.5 cm) is an objective indicator of overall estrogen effect.[78] Androgen levels are appropriate for the stage of pubarche in true precocity.

Third-generation monoclonal-antibody-based immunoassays for gonadotropins are important to the differential diagnosis. Daytime basal and GnRH-stimulated peak LH levels exceding 0.6 and 6.9 U/L in girls have been found to be respectively 70 and 92% sensitive for the

diagnosis of central precocious puberty.[468] FSH levels are not as helpful diagnostically. A GnRH agonist test yields similar diagnostic information and permits assessment of the ovarian secretory capacity. In response to these tests, children with unsustained pseudopuberty as variants of normal will have a minimal gonadotropin response—whereas children with gonadotropin-independent precocity will have suppressed responses.[81,82,560] Demonstration of a sleep-related rise of plasma LH is an alternative diagnostic procedure. Table 14-6 gives criteria for the diagnosis of the rapidly progressive type of complete sexual precocity that requires treatment.[561,562]

Determination of the plasma androgen pattern is useful in discriminating among the causes of premature pubarche and virilization. Androgen determinations are most accurately performed by a specialty laboratory.[339] Premature adrenarche is characterized by a pubertal level of DHEAS, whereas plasma testosterone and androstenedione are at most marginally elevated above the prepubertal range. A greatly elevated level of DHEAS is characteristic of adrenal tumors. Androstenedione and 17-hydroxyprogesterone levels are disproportionately elevated compared to testosterone or DHEAS levels in congenital adrenal hyperplasia and many ovarian tumors. Dexamethasone suppression testing and other means of determining the source of androgen excess are discussed in the section on hyperandrogenemia.

Ultrasonography is indicated to rule out abdominal or pelvic masses when feminizing or virilizing disorders are suspected. The ovaries of girls with true sexual precocity resemble those of normal pubertal girls.[75,562] A cyst of 10 mm or more in diameter is usually due to a transient preovulatory follicle. However, the differential diagnosis of a persistant cyst or of multicystic ovaries includes McCune-Albright syndrome,[534] tumor,[563] and premature ovarian failure.[564] Magnetic resonance imaging (MRI) of the hypothalamic-pituitary area is indicated in rapidly progressive true sexual precocity, especially for those less than 6 years old or those at risk of organic causes by virtue of their underlyng condition or neurologic symptoms and signs.[558,565]

TABLE 14-6

Laboratory Criteria for Rapidly Progressive Complete Precocious Puberty

- Sex hormone level pubertal (diurnal early)
  - Estrogen (girls, cyclical): E_2>9 pg/mL, vaginal cornification
  - Testosterone (boys): 20–1200 ng/dL
  - DHEAS normal for age> height age >
- Sex hormone excess is sustained:
  - Bone age > height age > chronologic age
- LH and FSH pubertal
  - Sleep-associated LH rise initiates puberty
  - Basal: LH.0.6 and FSH.2.0 IU/L or more (monoclonal RIA)[a]
  - Post-GnRH LH>4.2 IU/L[a]
- Exclude: tumor, hypothyroidism, gonadotropin-independent precocity

[a]. Exact values vary among laboratories.

DHEAS, dehydroepiandrosterone sulfate; E2, estradiol; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; and RIA, radioimmunoassay.

The situation of a girl presenting with the onset of breast development or pubic hair between 6 and 8 years of age warrants special consideration. Breast and pubic hair development have been reported in 15 to 20% of U.S. black girls in office practice, in contrast to less than 5% of white girls.[483] Subsequent studies have indicated that breast development between 7 and 8 years of age may be normal in blacks and Hispanics, whereas sexual pubic hair is not (Table 14-4). However, pubertal development in girls in the 6- to 8–year-old age range may be associated with pathology—with excessive adiposity an important factor in many.[204,205,464,566] Those with rapidly progressive precocity benefit from GnRHag therapy.[567-569]

On the other hand, many girls in this age range have slowly progressive precocity—with a normal timing of menarche—and are not at risk of short adult stature. Such girls achieve no increase in stature from GnRHag therapy.[503,569,570] We conclude that a less comprehensive investigation may be warranted in selected girls presenting with thelarche between 6 and 8 years of age. For most such girls, a complete history and physical exam (including obesity evaluation and a bone age determination) may be all that is needed—along with careful longitudinal follow-up.[472,503,570] However, 6- to 8-year-old girls with a suggestion of rapidly progressive or excessive androgenization or feminization, neurologic symptoms, linear growth acceleration, or significant bone age advancement should be more completely evaluated (as outlined previously).

Management

The guidelines for management are to rule out an organic disorder that requires treatment in and of itself and to ascertain whether sexual precocity is either rapidly compromising height potential or resulting in important secondary emotional disturbances in the child. Intracranial lesions must be treated by appropriate measures, such as neurosurgery or irradiation. Shunting for hydrocephalus may stop the precocity. Granulosa cell tumors confined to the ovary have a good prognosis for cure by unilateral oophorectomy. Recurrence of tumor may occur up to 20 years after the initial operation, however. Biopsy of the opposite ovary is indicated in unilateral ovarian neoplasms. Compensatory ovarian hypertrophy can be expected at any age after removal of a single ovary.[571]

The only permanent physical complication of true isosexual precocity, all else being normal, is short adult height. Excessive sex hormone production in the first decade of life causes early maturation of the epiphyses, resulting in their premature closure. About half the girls with this disorder reach an adult height of 53 to 59 inches, and the remainder are more than 60 inches tall.[484,503] The mismatch between physical, hormonal, and psychological development may cause behavior changes ranging from social withdrawal to aggression or sexuality. However, frank behavioral problems are unusual in girls and are therefore by themselves seldom indications for treatment.

When true sexual precocity is rapidly progressive to the point of significantly compromising height potential and its cause cannot be directly alleviated, the best mode of treatment is with GnRH agonists. The down-regulating effect of these agents on pituitary gonadotropin release inhibits gonadotropin secretion. Suggested criteria for the use of these drugs are presented in Table 14-7.[561] The most widely used agents in the United States are leuprolide acetate (ordinarily given as Lupron depot/ped 7.5–15 mg/mo IM) and nafarelin acetate (Synarel 800 µg bid IN). A long-acting histrelin implant was recently introduced.[571a] These doses are larger than the usual adult dosage in order to avoid worsening the status by an agonist effect. Dosage can be adjusted later as necessary. It is unclear whether the longer-acting depot forms of leuprolide are as effective.[572]

Treatment is adequate if the estradiol level becomes prepubertal[573] or LH is below 6.6 U/L 2 hours after GnRH agonist[574] 1 month after institution of therapy. A withdrawal period may occur at that time, but none should be expected thereafter. Puberty and the pubertal growth spurt are arrested. Concomitantly, epiphyseal closure is delayed and adult height potential is improved because a type of catch-up growth occurs in which height age catches up to bone age. Adult height is greatest when treatment is started soon after onset at an early age, yielding an average height gain above pretreatment height prediction of about 1.4 cm for each year of therapy.[503, 568,569] Prolonging treatment beyond a chronological or bone age of 12.0-12.5 years of age generally leads to little further increase in adult height potential, regardless of the prediction of residual height potential from bone age.

Coincident GH-deficiency must be treated for optimal growth.[575] GH-sufficient patients with central precocity who are started on treatment relatively late and whose height velocity falls below the prepubertal normal range after 2 to 3 years appear to gain an average of 2 cm per year when GH therapy is added.[576] Treatment is ordinarily continued until the normal age for puberty to begin.[568]

TABLE 14-7

Suggested Indications for Gonadotropin-Releasing Hormone Agonist Therapy of Precocious Puberty

Complete precocious puberty
Pubertal sex hormone levels (in sensitive assays)
plus
- Abnormal height potential (predicted adult height falling significantly or below 5th percentile)

or
- Psychosocial considerations, individualized
  - Menses in the mentally or emotionally immature
  - Other (e.g., behavorial or emotional disturbance)

Modified from Rosenfield RL (1994). Selection of children with precocious puberty for treatment with gonadotropin releasing hormone analogs. J Pediatr 124:989.

Use of the depot form of GnRH agonist is complicated by sterile abscesses at injection sites in about 5% of cases. Anaphylaxis is a rare complication.[577] No other serious side effects have come to light, but long-term safety remains to be established. The potential risk of bone demineralization has not proven to materialize after GnRH agonist therapy of precocious puberty.[504]

Girls with slowly progressive idiopathic puberty of onset between 6 and 8 years of age or early fast puberty between 8 and 9 years of age tend to be tall at the onset of puberty, follow an advanced growth pattern, and reach their target height without GnRH agonist therapy.[503,570,579-581] Therefore, this treatment is only indicated if there are other compelling reasons to slow the pace of puberty. Those who are obese may have slower pace of puberty if insulin resistance is ameliorated.[581a]

Medroxyprogesterone acetate (Depo-Provera) is useful for stopping menses and as a contraceptive in mentally retarded girls in whom preservation of height potential is not important. It is begun in a dosage commencing at 50 mg/month intramuscularly. Doses as high as 400 mg/month have been used, although Cushingoid side effects may be observed at this level.[582] Although this treatment reverses some of the physical changes of premature puberty, it does not reverse the inordinately rapid maturation of the skeleton—possibly because of its inherently weak androgenicity. In addition, use of medroxyprogesterone acetate is associated with a loss of bone mineral density—which must be considered if long-term use is being contemplated.[583]

A variety of drugs have been used off-label to treat gonadotropin-independent precocity. Antiestrogen and aromatase treatment for McCune-Albright syndrome has met with varying degrees of success.[584,585] Ketoconazole, an antifungal agent that inhibits 17,20-lyase activity and other steroidogenic enzymes, has been used to treat a similar condition in boys[586] and might be useful in girls as well. Gonadotropin-releasing hormone agonist treatment may be necessary for those in whom true puberty becomes superimposed because the bone age has reached a pubertal level.[194,195,587] The fibrous dysplasia of McCune-Albright syndrome may be amenable to treatment with bisphosphonates,[588,589] although this is not a suitable long-term treatment in childhood.[590]

Patients with premature thelarche or pubarche as variations of normal are counseled as follows. The child's early development seems to be a matter of a normal stage of puberty occurring early. It is due to an incomplete slow type of puberty or to increased sensitivity to the trace levels of hormones normally present in childhood. Feminization with breast development and eventual menstruation can be expected to occur at an appropriate age. No treatment is indicated. To exclude subtle sex hormone excess or eventual anovulatory syndromes, long-term follow-up is advisable.

In addition to dealing with the physical consequences of true isosexual precocity, the physician must be ready to help the family and child cope with the psychological problems that come with early physical maturation. The doctor can help the family by explaining that even though their child looks older and more mature than other children of the same age the child will not behave

more maturely. The libido of young children with precocity is not increased. The family should be advised to take some precautions to downplay their child's development (for example, in the choice of clothing and swimsuits). Friendships with children a bit older will help shorten the time affected children spend in social limbo. This may be more easily said than done, however, because the intellectual and social maturity of these patients is not advanced. Early on, any children with these disorders tend to be withdrawn because they feel that they are different from their peers. Later on, they tend to enter into romantic relationships early. It is important to remind the family and child that in a few years the child will not be unique from the standpoint of sexual development.[484] The following books may be helpful in explaining precocious puberty: for children, *What's Happening to Me?*, by Peter Mayle (Lyle Stuart, Inc., Secaucus, NJ, 1973); for parents, *Sex Errors of the Body, Second Edition*, by John Money (Paul H. Brookes Publishing Co., Inc., Baltimore, MD, 1994).

HYPOGONADISM

Causes

If hypogonadism is complete and present prepubertally, it causes sexual infantilism in females or disorders of sexual differentiation in genetic males. If it is slightly less severe or of onset in the early teenage years, it may permit too limited a degree of feminization to permit the onset of menses at a normal age (primary amenorrhea). Milder, partial, or incomplete forms of hypogonadism may cause secondary amenorrhea or oligomenorrhea.[489a]

At its mildest, hypogonadism may present with the anovulatory symptoms of dysfunctional uterine bleeding or with excessively frequent periods due to short luteal phase. Consequently, disorders causing hypogonadism appear in the differential diagnosis of disorders of sexual differentiation, sexual infantilism, failure of pubertal progression, and menstrual irregularity. The causes of hypogonadism are listed in the differential diagnosis of amenorrhea in Table 14-8.

Primary Ovarian Failure. Primary ovarian failure is characterized by high levels of gonadotropins, particularly FSH. Two exceptions exist to this rule. First, the gonadotropins may not be elevated until CNS maturation has reached a pubertal stage—as indicated by a bone age of approximately 10 to 11 years (Table 14-9).[591] Second, patients with partial ovarian failure (as is frequent in women during the menopausal transition) do not have high baseline gonadotropin levels.[592-594] FSH may hyperrespond to GnRH and estrogen may hyporespond to GnRH agonist challenge. It seems as if relatively few ovarian follicles (too few to permit the cyclic emergence of preovulatory follicles) suffice to prevent the characteristic rise in basal FSH levels.

Primary ovarian failure may occur before or during puberty (causing primary amenorrhea) or after puberty has occurred, causing secondary amenorrhea. The latter is termed *premature ovarian failure* and resembles premature menopause except that about half of cases sometimes ovulate.[595,596]

    - Oophorectomy
    - Oophoritis
    - Radiotherapy or chemotherapy
- Bioinactive gonadotropin

Hypoestrogenism, FSH Not Elevated
- Primary ovarian failure
  - Complete if BA <11 yr[α]
  - Incomplete if BA >11 yr
- Delayed puberty
  - Constitutional delay[α]
  - Growth-retarding disease
- Hypogonadotropic hypogonadism
  - Congenital
  - Acquired
    - Organic
    - Functional
  - Virilization

Estrogenized, FSH Not Elevated
- Hypothalamic anovulation
  - Hypothalamic amenorrhea
  - Athletic/psychogenic amenorrhea
  - Post-pill amenorrhea
- Nonhypothalamic extraovarian disorders
  - Pregnancy
  - Obesity or undernutrition
  - Cushing syndrome
  - Hypothyroidism
  - Hyperprolactinemia
  - Ectopic gonadotropin secretion
- Hyperandrogenism

[a]. Cause only primary amenorrhea.
BA, bone age; and FSH, follicle-stimulating hormone.

Gonadal dysgenesis due to deficiency of genes on the X-chromosome is the most common cause of primary ovarian failure. It is usually due to a relatively large scale deletion of X-chromosomal material, which is associated with a characteristic, but variable, phenotype and is termed Turner syndrome (see Chapter 15). Fetuses with a 45,X karyotype have a normal number of oocytes in the ovary at mid-gestation, but a drastic reduction in the number of follicles,[30] which appears to cause gonadal

TABLE 14-9

Bone Age in Workup of Sexually Infantile Girls with Normal Follicle-Stimulating Hormone Level

	Bone Age (Years)		
	<11	11–13	>13
Primary hypogonadism	Yes		
Delayed puberty	Yes	Yes	
Gonadotropin deficiency	Yes	Yes	Yes

Based on Rosenfield RL, Barnes RB (1993). Menstrual disorders in adolescence. Endocrinol Metab Clin North Am 22:491.

streaks via an accelerated rate of apoptosis. However, the gonadal dysgenesis (like other features of the syndrome) is often incompletely expressed.[596] Thus, Turner syndrome should be considered in all girls with primary hypogonadism or secondary amenorrhea whether or not they have the typical stigmata of Turner syndrome

Specific loci on the X-chromosome are associated with primary ovarian failure. Xp11.2 harbors BMP15, a specific ovarian differentiation factor, a heterozygous mutation of which is a rare cause of gonadal dysgenesis. Xq harbors two independent loci in addition to the fragile X premutation, which is associated with about 7-14% of primary ovarian failure.[595,596] Other genes have been incriminated in the ovarian failure of mouse models.[597]

Gonadal dysgenesis also results from 46, XY complete gonadal dysgenesis and certain forms of autosomal aneuploidy.[432,595,598] A variable degree of ovarian dysgenesis occurs in autosomal trisomy 21. Delayed menarche, anovulatory cycles, and primary gonadal failure are occasionally seen.[599] However, pregnancy has been reported. Trisomic offspring are common.[600] Oocytes are virtually absent in trisomies 13 and 18. Ovarian dysgenesis also occasionally occurs as part of the Denys-Drash syndrome due to a WT-1 mutation.[601] There are associations of primary ovarian failure with cerebellar ataxia.[602,26] Other autosomal genetic disorders causing premature ovarian failure include blepharophimosis, galactosemia, leukodystrophies, and myotonia dystrophica.[597,604]

Physical or medical destructive injury to the ovary is a common cause of primary ovarian failure. *Irradiation and chemotherapy* for childhood neoplasia are becoming increasingly frequent causes of primary ovarian failure now that life is effectively prolonged.[604,605] Ionizing radiation and alkylating agents damage DNA whether or not a cell is replicating.[606] A radiation dose of 20 Gy or more to the ovaries causes acute ovarian failure in about 85% of children and adolescents.[607] A cumulative cyclophosphamide dose of about 100 mg/kg causes equivalent damage. Fertility is even more rare when these modalities are combined. Prepubertal girls are about half as sensitive to these therapies as postpubertal females: among girls who receive 1-10 Gy, acute ovarian failure develops in about 10% of girls under 13 years, but in 25% of those ≥13. After prepubertal chemotherapy and radiotherapy for leukemia, half of patients can be anticipated to enter puberty and menstruate regularly, and one-quarter to have normal pituitary-ovarian function 7 years later.[608] Some with early hypergonadotropinism will experience ovarian recovery. However, all will develop premature menopause because of the reduced number of oocytes. Several non-alkylating chemotherapies are also gonadotoxic.[609,610] However, data are scarce and the interactions among various classes of chemotherapeutic agents is poorly understood. As a consequence of gonadotropin elevation when gonadal failure begins, puberty may progress rapidly.[516]

Sterilization by irradiation can be obviated by transposing the ovaries out of the irradiation field if possible. Administration of a GnRH agonist prior to cyclophosphamide administration may decrease ovarian injury.[606] Mumps oophoritis is a classic but rare cause of ovarian failure.

Functional ovarian failure can arise from autosomal-recessive ovarian mutations of the LH or FSH receptor.[595,603,611,612] These have been associated with a spectrum of defects ranging from primary amenorrhea to oligomenorrhea. Ovarian histology in typical resistance to gonadotropin action (Savage syndrome) shows a normal number of primordial follicles but a paucity of growing follicles. Partial gonadotropin resistance is common in the Albright osteodystrophy form of pseudohypoparathyroidism, in association with the generalized defect in G-protein signal transduction.[613] The carbohydrate-deficient glycoprotein syndrome reduces gonadotropin bioactivity and causes hypergonadotropic hypogonadism.[614]

Autoimmune oophoritis is the basis of approximately half of spontaneous premature ovarian failure,[618] *though estimates* vary from 5-85% in *various series*.[595,615,616] It is diagnosed by its association with any of a variety of autoimmune endocrine or nonendocrine disorders, manifest or subclinical, that have in common defects in T cell suppressor function. Autoimmunity may be directed against the granulose cell, oocyte, or theca cell. The clinical picture may resemble relatively selective resistance to FSH or, less frequently, to LH.[617] The latter results from lymphocytic infiltration of theca with sparing of primordial follicles. These patients have autoantibodies to steroidogenic cells and have or are at risk for adrenal failure. Usually these antibodies are directed against21-hydroxylase, less frequently to side chain cleavage or 17-hydroxylase, seldom to 3β-hydroxysteroid dehydrogenase. Replacement glucocorticoid therapy may temporarily ameliorate the immune oophoritis in such cases.[618] A case with autoantibodies to testosterone has been reported.[619] Autoimmune gene regulator (AIRE) gene mutations have been identified as causative of type 1 polyendocrine failure. Ultrasonographic and histologic findings are variable in premature ovarian failure and include large or small ovaries, inactive or polyfollicular ovaries, loss or preservation of primordial follicles, and infiltration by lymphocytes or plasma cells.

Functional gonadal failure can also result from specific autosomal-recessive defects in the biosynthesis of androgens and estrogens (or aromatase deficiency, a virilizing disorder). Enzyme blocks can cause gonadal insufficiency in genetic males who are phenotypic females. This occurs in lipoid congenital adrenal hyperplasia (StAR and side chain cleavage mutations, Figure 14-23), 17α-hydroxylase deficiency, 17,20-lyase deficiency, 3β-HSI deficiency, and

17β-HSD3 deficiency. All but the latter are associated with congenital adrenal hyperplasia. Congenital lipoid adrenal hyperplasia is unique in that underlying StAR deficiency has too little direct impact on ovarian function to interfere with the early phases of puberty. However, the gradual buildup of intraovarian lipid deposits resulting from enzyme deficiency (a "second hit") causes ovarian damage with anovulation and late ovarian failure.[620,621]

Gonadotropin Deficiency. Congenital gonadotropin deficiency can occur in association with cerebral, hypothalamic, or pituitary dysfunction or as an isolated defect.[622] Congenital defects in hypothalamic-hypophyseal formation may be associated with midline facial defects. Congenital hypothalamic dysfunction may be associated with other neurologic or endocrine dysfunction, such as in the Prader-Willi syndrome (congenital hypotonia and neonatal failure to thrive followed by hypothalamic obesity, sometimes with hypopituitarism) or the Laurence-Moon-Biedl syndrome (retinitis pigmentosa, obesity, mental deficiency). The autosomal-recessive form of congenital combined pituitary hormone deficiency due to PROP1 mutation is associated with gonadotropin deficiency. Leptin- and leptin-receptor-inactivating mutations cause gonadotropin deficiency in combination with extreme obesity.

Gonadotropin deficiency may be associated with anosmia (olfactory-genital dysplasia or Kallmann syndrome).[182] This syndrome is one-fifth as frequent in females as in males.[623] Mutations in the KAL-1 gene on the pseudoautosomal region of the X-chromosome cause the X-linked form, are highly penetrant, and account for 10% of cases. This mutation causes deficiency of anosmin-1. Inactivating mutation of the fibroblast growth factor receptor-1c isoform accounts for another 10% of cases, and these are inherited as an autosomal-dominant trait with variable penetrance and occasional association with cleft palate and facial defects. FGFR-1c signaling has been hypothesized to occur at least in part through anosmin-1.

Isolated gonadotropin deficiency arises from GnRH receptor mutations in about half of autosomal recessively inherited cases.[624] Partial gonadotropin deficiency can rarely result from mutation of the G-protein–coupled receptor GPR54.[186] The degree of hypogonadism is variable, even within a family, with delayed puberty and delayed menarche as one presentation.[625-627] Isolated hypogonadotropic hypogonadism has also been reported in a woman homozygous for a nonsense mutation of the X-linked DAX1 gene, which was associated with adrenal insufficiency in her brothers.[628] Isolated FSH deficiency due to mutation in the β-subunit has been reported to cause primary amenorrhea in association with a unique test panel of low FSH, elevated LH, and low testosterone levels.

Acquired gonadotropin deficiency can be a consequence of tumors, trauma, autoimmune hypophysitis,[629,630] degenerative disorders involving the hypothalamus and pituitary,[631] irradiation,[632] or chronic illness.[633] Pituitary adenoma, craniopharyngioma, and dysgerminoma are the most common neuroendocrine neoplasms responsible in children. Most "nonfunctioning" pituitary adenomas are gonadotrope adenomas that secrete gonadotropin subunits in response to thyrotropin-releasing hormone.[634] A case of hypothalamic tumor is presented with Figure 14-39. Pinealomas most commonly cause sexual infantilism. They may act by secreting an inhibitory substance, rather than by compressing key areas of the hypothalamus.[514]

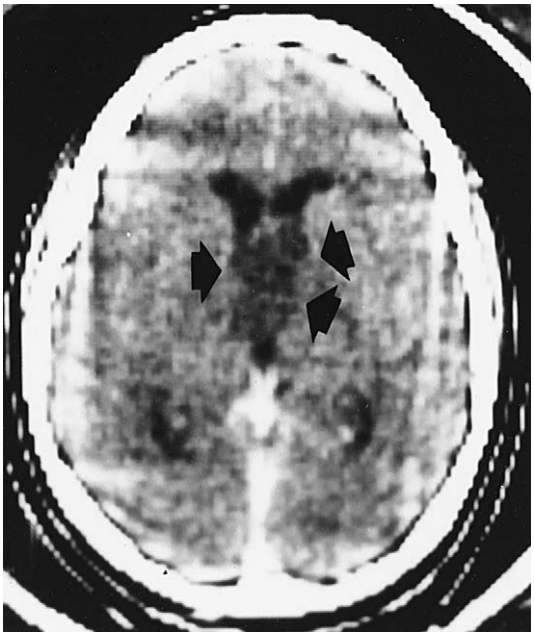

Figure 14-39 Computed tomography of the brain of a 16-year-old girl with hypothalamic astrocytoma. The low-density tumor mass (arrows) extends superiorly from the hypothalamus, obliterates the third ventricle, and partially compresses the frontal horns of the lateral ventricles (particularly the right). This patient presented with secondary amenorrhea. Menarche had occurred at age 13, and menses were normal until 15.3 years. The patient then became amenorrheic in association with ethargy, episodic headaches, polyuria, and weight gain—despite little change in appetite. Physical examination was negative. The skull radiograph, electroencephalogram, visual fields, and serum prolactin and thyroxine levels were normal—and urine-specific gravity was 1.016. After biopsy of the cyst wall, studies revealed her to have gonadotropin, growth hormone, and partial antidiuretic hormone deficiencies.

Anorexia nervosa is the prototypic form of eating disorder, a common cause of hypogonadotropinism in teenagers. It is a syndrome of undernutrition due to voluntary starvation with a particular psychological dysfunction that results in amenorrhea.[635-637] Patients uniformly consider themselves too fat in the face of objective evidence that they are underweight. The psychiatric criteria that distinguish this disorder from food faddism and fear of obesity consist of refusal to gain or maintain body weight to a minimally normal level for height and age (less than the 15th percentile; body mass index ≤ 17.5 for postmenarcheal cases) with all of the following being present: intense fear of gaining weight or becoming fat, even though underweight; an inaccurate perception of body weight, such that they have a disturbance in the way that body weight, size, or shape is experienced; undue influence of body shape and weight on self-evaluation or denial of the seriousness of current low body weight; and amenorrhea for 3 or more months in postmenarcheal females.

Bulimia nervosa, the binge-eating/purging variant eating disorder, is similar in the overevaluation of body shape and weight and the use of extreme weight control behaviors. Physical activity tends to be high. These disorders may be manifest at an early stage as atypical eating disorders, before weight or amenorrhea criteria are met or when the binge is subjective. The cognitive defect that weight can serve as the predominant value in judging self-worth is central to anorexia nervosa. In contrast to other depressive individuals, these patients are generally content with themselves in the areas of intellectual and vocational achievement.

The pathogenesis is multifactorial. It involves a genetic predisposition. Concordance rates for the anorexic type are about 50% for monozygous twins, compared with about 5% for dizygotic twins. Many other risk factors have been implicated. Familial factors also include eating disorders of any type, depression, substance abuse, and adverse family interactions. Premorbid experiences (such as sexual abuse or social pressures) or premorbid characteristics (such as low self-esteem, compulsiveness, and perfectionism) are also important. Dieting meets a need for approval in our culture, with its emphasis on dietary restriction and thinness as goals for women. Anorexia is often precipitated in vulnerable children by a new experience (such as puberty, leaving home, or beginning college) or by adverse life events. The disorder is perpetuated by the complications of starvation, such as depression and reduced gastric emptying.

The onset tends to be at 12 years of age or later. Earlier onset is associated with growth arrest, delay of puberty, and primary amenorrhea.[638] GH deficiency is common.[639,640] The medical complications of anorexia nervosa are serious. The risk of death is approximately tenfold increased. Electrolyte imbalance, hypoglycemia, cardiovascular instability, bone marrow hypocellularity predisposing to silent infection, and renal failure account for about half of the mortality. Suicide accounts for the rest.

The weight changes leading to cessation or restoration of menstrual cycles are in the range of 10% to 15% of body weight. Recovery is associated with achieving a critical level of body fat stores above the 10th percentile (>20% body fat) (Figure 14-40) at a BMI averaging 20.[641,642] There is an inverse relationship between body

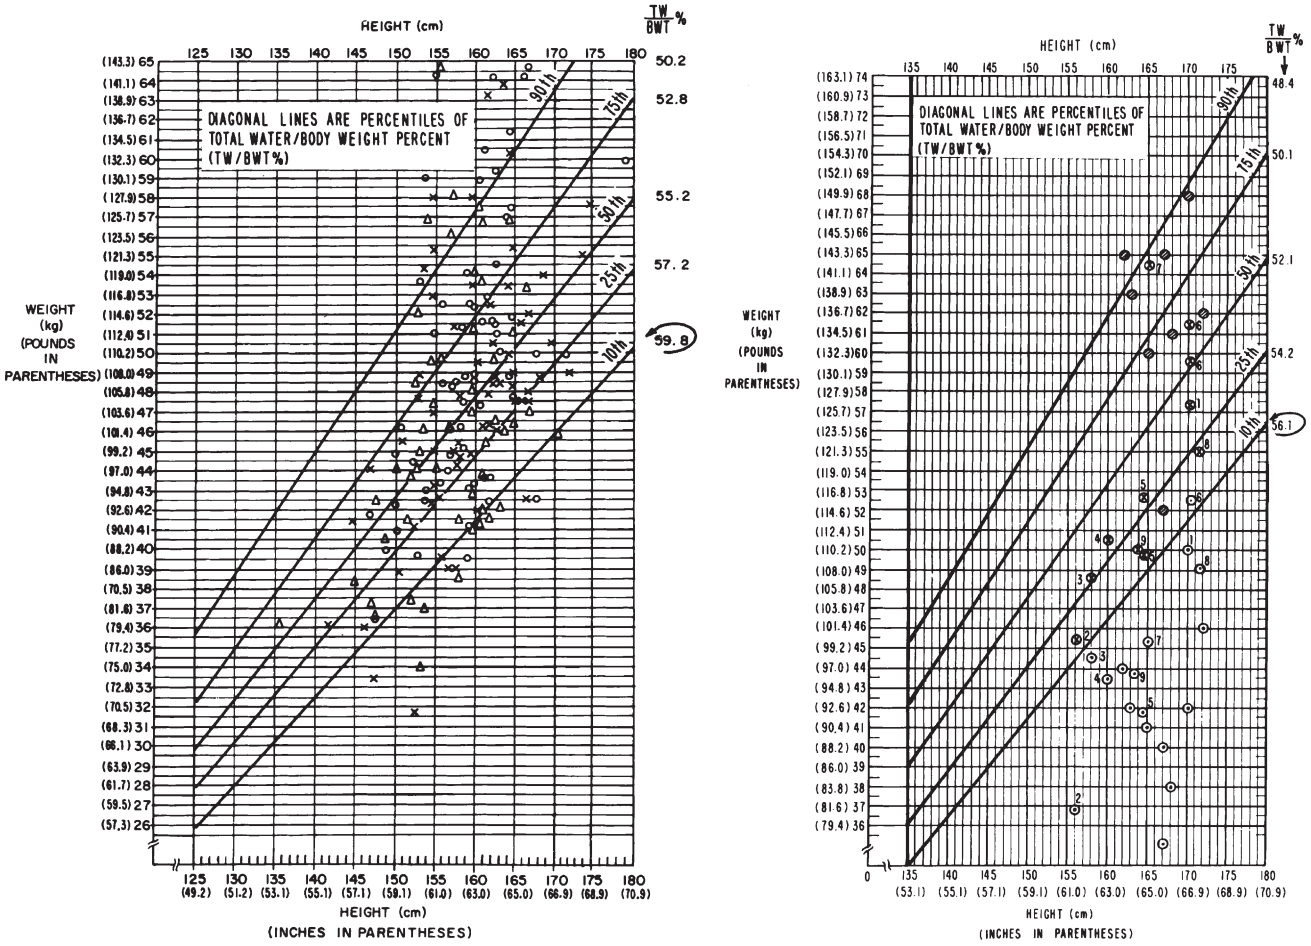

Figure 14-40 Percentiles of fatness (diagonal lines) for white girls at menarche (left) and after menarche (right) equated with computed percentiles of total water as a percentage of total body weight. The minimal weight necessary at a particular height for the onset or maintenance of menses is very close to the 10th percentile of fatness on these respective charts. Data for anorexia nervosa cases are shown on the right-hand chart: • at presentation; x at resumption of menses. [From Frisch RE, McArthur JW (1974). Menstrual cycles: Fatness as a determinant of minimum weight for height necessary for their maintenance or onset. Science 185:949. Copyright © by the American Association for the Advancement of Science.]

weight and the maturity of gonadotropin release in these patients. The 24-hour pattern of gonadotropin release tends to be immature (prepubertal or pubertal), and the diurnal LH pattern becomes mature upon recovery from undernutrition.[643] Luteinizing hormone pulsatility is low, and may be restored by opiate antagonists.[88] The gonadotropin response to GnRH and ovulatory response to clomiphene citrate are blunted in the malnourished state and become normal with weight gain to about 80% of ideal.[644,645] Leptin levels are significantly decreased and are a major contributor to the gonadotropin deficiency and to changes in the thyroid and GH axes.[646]

Mild hypercortisolism is frequent and may contribute to the anovulation by mechanisms discussed further under the section on hypothalamic anovulation.[647] Afternoon ACTH and cortisol levels are significantly higher than normal, and the response to CRH is significantly lower than normal. In contrast to Cushing syndrome, DHEAS levels tend to be blunted as a consequence of undernutrition.[648]

A fundamental neuropsychological flaw or hypothalamic disturbance[649] seems necessary to explain the high incidence of GH deficiency, why some patients become amenorrheic before losing weight, and why about half of the cases remain amenorrheic after treatment. The serotonergic systems implicated in the regulation of feeding and mood seem to remain altered even after weight restoration. The authors favor the concept that these psychological problems lead to amenorrhea only in women predisposed to it by a unique preexisting hypothalamic dysfunction. Evidence has recently been obtained for marked individual differences in reactivity of the neuroendocrine system to stress.[650]

A number of features attributed to hypothalamic dysfunction, such as cold intolerance, may be due to the subtle hypothyroid state secondary to the malnutrition.[647] Serum triiodothyronine levels are consistently low, serum thyroxine levels tend to be lower than average (although usually within normal limits), the pattern of TSH release indicates TRH deficiency, and the state of deep tendon reflexes and metabolism is consistent with hypothyroidism. Hypothyroidism may in part complicate malnutrition as a consequence of the interference with IGF-1 generation. Low IGF-I initiates GH excess, compensatory somatostatin release, and subsequent inhibition of the thyrotropin response to thyrotropin-releasing hormone. Undernutrition also diverts the generation of thyroxine metabolites away from triiodothyronine toward reverse triiodothyronine.

Hyperprolactinemia can cause functional gonadotropin deficiency.[651] Galactorrhea is present in about half of the patients, particularly those with residual estrogen production. The causes of hyperprolactinemia are diverse, including hypothalamic or pituitiary disorders, drugs, hypothyroidism, renal or liver failure, peripheral neuropathy, stress, autoimmunity, macroprolactinemia, and idiopathology.[652-654] Elevated serum prolactin levels occur with a variety of tumors that cause functional or anatomic pituitary stalk section, thereby preventing inhibitory pituitary control. About a third of hyperprolactinemic women have an identifiable pituitary adenoma. Prolactinomas less than 1 cm in diameter (microadenomas) cause no problems due to local extension. Prolactinoma may be associated with multiple endocrine neoplasia type 1.[655] In about a quarter of adult cases, the malfunction is due to the ingestion of drugs such as phenothiazines, estrogen, or cocaine.[656] Considerable hyperprolactinemia is idiopathic. Decreased sensitivity to dopaminergic inhibition may underlie such cases.[657]

Macroprolactinemia is due to a variant molecule or autoantibody formation. In this situation, direct immunoassay indicates elevated levels of prolactin. However, the biologically available or active prolactin level is normal. Thus, there is no physiologic consequence to the macroprolactinemia.

Hyperprolactinemia results in luteinizing hormone pulses that tend to be infrequent and LH secretion that is variable in response to GnRH.[658] Selective prolactin excess causes variable degrees of gonadotropin deficiency, ranging from severe to partial (hypothalamic amenorrhea). Adrenal hyperandrogenism, hirsutism, and seborrhea are common.[266] Frank virilization as a result of very high androgen levels suppresses gonadotropin levels and thus causes defeminization. However, the more common moderately hyperandrogenic disorders discussed in material following are associated with normal estrogenization.

Differential Diagnosis

The differential diagnosis of hypogonadism is included in Table 14-8. Investigation should be begun for hypogonadism when the onset of puberty has not begun by the chronologic or bone age of 13 years, if puberty has not progressed as indicated by failure of menses to occur within 4.5 years of the onset of puberty, or if secondary amenorrhea or oligomenorrhea has persisted for 2 years. A family history of delayed puberty is compatible with the delay being constitutional rather than having an organic basis. The history should include a thorough past medical history and systemic review, including systemic, intracranial, visual, olfactory, emotional, abdominal, and pelvic symptoms. It should be kept in mind that chronic endocine, metabolic, or systemic disease of almost any type can lead to delayed puberty.

Upon examining the patient, the height and weight should be carefully measured and growth rate and appropriateness of weight for height determined (Figure 14-40). Careful categorization of the stage of breast and sexual hair development are essential. Examination of the mature breast should include an attempt to express milk from the ducts to the nipple. The finding of a structural genital abnormality may indicate that amenorrhea is due to abnormal genital tract development, whereas clitoromegaly[659] is a clue to a virilizing disorder. Neurologic examination should include evaluation of eye movements, visual fields, and optic fundi—as well as a search for anosmia and midline defects.

An algorithmic approach to the workup of patients with menstrual disorders is shown in Figures 14-41 through 14-43.[660] The laboratory workup depends on the degree of estrogenization, as initially assessed from the stage of breast development. It includes a bone age radiograph in adolescents who are not sexually mature

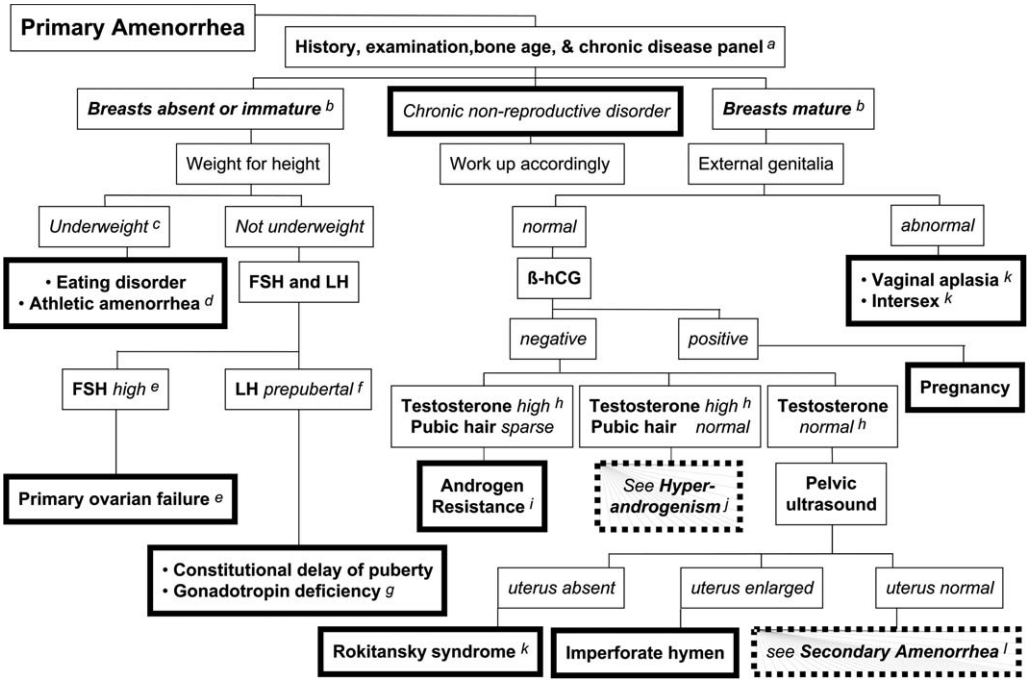

Figure 14-41 Differential diagnosis of primary amenorrhea. (*a*) Prime among the causes of primary amenorrhea are growth-retarding or -attenuating disorders. In the absence of specific symptoms or signs to direct the workup, laboratory assessment for chronic disease typically includes bone age radiograph if the adolescent is not sexually mature and a chronic disease panel (complete blood count and differential, sedimentation rate, comprehensive metabolic panel, celiac panel, thyroid panel, cortisol and insulin-like growth factor-I levels, and urinalysis). (*b*) Breast development ordinarily signifies the onset of pubertal feminization. However, mature breast development does not ensure ongoing pubertal estrogen secretion (see Figure 14-42 and 14-43). (*c*) Underweight is defined as body fat 20% or less of body mass. Although this generally corresponds to BMI $<$ 10th percentile, BMI may not accurately reflect body fat in serious athletes (who have a disproportionately greater muscle mass) or bulimia nervosa. (*d*) Low body fat is associated with amenorrhea in girls underweight (e.g., anorexia nervosa, a symptom complex consisting of amenorrhea, voluntary starvation, and a self-delusional disturbance in the perception of body fatness), not necessarily underweight (bulimia), and from athletic activity out of proportion to caloric intake (serious athletes). (*e*) FSH is preferentially elevated over LH in primary ovarian failure. The most common cause of primary amenorrhea due to primary ovarian failure is gonadal dysgenesis due to Turner syndrome, but acquired causes must be considered (such as cytotoxic therapy). The workup of primary ovarian failure is considered in detail in the next algorithm (Figure 14-42, secondary amenorrhea and oligomenorrhea). Lack of FSH elevation virtually rules out primary ovarian failure only when the bone age is appropriate for puberty (11 years or more). (*f*) A low LH level is more characteristic of delayed puberty and gonadotropin deficiency than a low FSH level. Congenital gonadotropin deficiency is closely mimicked by the more common extreme variation of normal, constitutional delay of puberty (Table 14-10). (*g*) History and examination may yield clues to the cause of hypogonadotropic hypogonadism, such as evidence of hypopituitarism (midline facial defect, extreme short stature) or anosmia (Kallmann's syndrome). Random LH levels in hypogonadotropic patients are typically below 0.15 IU/L, but often overlap those of normal pre- and mid-pubertal children. The GnRH test, measuring the gonadotropin response to a 50- to 100-µg bolus, in the premenarchial teenager strongly suggests gonadotropin deficiency if the LH peak is less than 7.0 IU/L by monoclonal assay. However, the GnRH test has limitations because of overlap between hypogonadotropic and normal teenager responses. GnRH agonist testing (e.g., leuprolide acetate injection 10 µg/kg SC) may discriminate better. It may not be possible to definitively establish the diagnosis of gonadotropin deficiency until puberty fails to begin by 16 years of age. (*h*) Plasma total testosterone is normally about 20 to 60 ng/dL (0.7–2.1 nM), but varies somewhat among laboratories. (*i*) Androgen resistance is characterized by a male plasma testosterone level (when sexual maturation is complete), male karyotype (46, XY), and absent uterus. External genitalia may be ambiguous (partial form) or normal female (complete form). (*j*) The differential diagnosis of hyperandrogenism is shown in Figure 14-46. (*k*) Vaginal aplasia in a girl with normal ovaries may be associated with uterine aplasia (Rokitansky-Kustner-Hauser syndrome). When the vagina is blind and the uterus aplastic, this disorder must be distinguished from androgen resistance. If the external genitalia are ambiguous, it must be distinguished from other disorders of sexual differentiation (intersex). (*l*) Secondary amenorrhea differential diagnosis is presented in Figure 14-42. [Modified with permission from Rosenfield RL (2003). Menstrual disorders and hyperandrogenism in adolescence. In Radovick S, MacGillivray MH (eds.), *Pediatric endocrinology: A practical clinical guide*. Totowa, NJ: Humana Press 451–478.]

and generally begins with a chronic disease panel and determining gonadotropins, estradiol, and testosterone level. A pregnancy test is indicated in a sexually mature adolescent. The diagnostic considerations differ in the anovulatory girl without FSH elevation, depending on whether she is hypoestrogenic or well estrogenized (Table 14-8) (Figures 14-41 and 14-42).

FSH elevation indicates primary ovarian failure (Figures 14-41 and 14-42). Chromosome abnormalities are ordinarily the first consideration because the most common cause is Turner syndrome and its variants. Those individuals with primary ovarian failure that is not due to Turner syndrome and its variants should be investigated for the fragile X premutation.

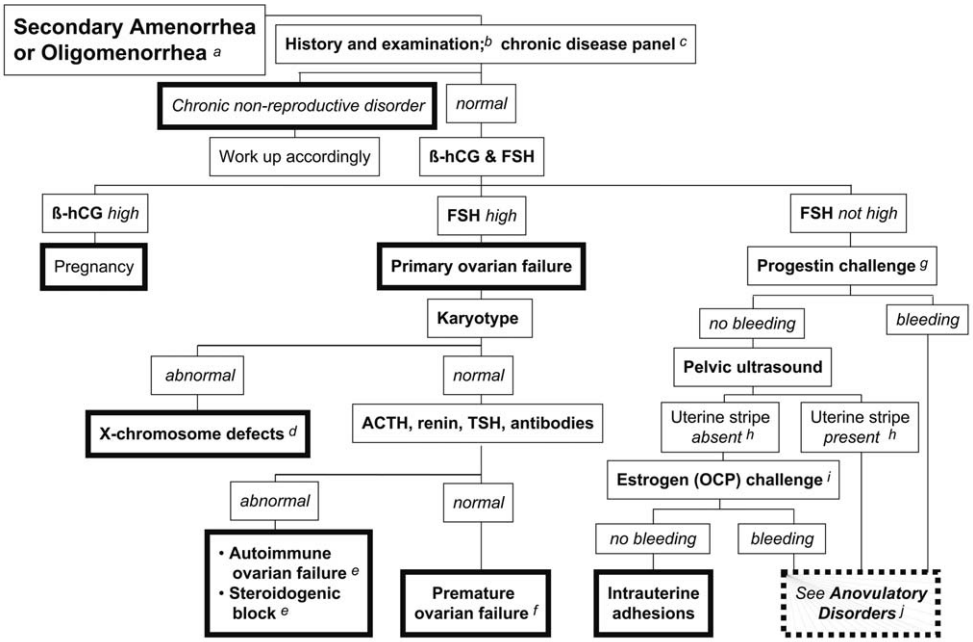

Figure 14-42 Differential diagnosis of secondary amenorrhea or oligomenorrhea. (*a*) Mature secondary sex characteristics are characteristic because the occurrence of menarche indicates a substantial degree of development of the reproductive system. (*b*) Diverse disorders of many systems cause anovulation. The history may reveal excessive exercise, symptoms of depression, gastrointestinal symptoms, radiotherapy to the brain or pelvis, or rapid virilization. Physical findings may include hypertension (forms of congenital adrenal hyperplasia, chronic renal failure), short stature (hypopituitarism, Turner syndrome, pseudohypoparathyroidism), abnormal weight for height (anorexia nervosa, obesity), decreased sense of smell (Kallmann's syndrome), optic disc or visual field abnormality (pituitary tumor), cutaneous abnormalities (neurofibromatosis, lupus), goiter, galactorrhea, hirsutism, or abdominal mass. (*c*) In the absence of specific symptoms or signs to direct the workup, evaluation for chronic disease in a sexually mature adolescent typically includes complete blood count and differential, sedimentation rate, comprehensive metabolic panel, celiac panel, thyroid panel, cortisol and insulin-like growth factor-I levels, and urinalysis. (*d*) Patients missing only a small portion of an X-chromosome may not have the Turner syndrome phenotype. Indeed, among 45,X patients the classic Turner syndrome phenotype is found in less than one-third (with the exception of short stature in 99%). Ovarian function is sufficient for about 10% to undergo some spontaneous pubertal development and for 5% to experience menarche. If chromosomal studies are normal and there is no obvious explanation for the hypogonadism, special studies for fragile X premutation and autoimmune oophoritis should be considered. (*e*) Autoimmune ovarian failure may be associated with tissue-specific antibodies and autoimmune endocrinopathies such as chronic autoimmune throiditis, diabetes, adrenal insufficiency, and hypoparathyroidism. Nonendocrine autoimmune disorders may occur, such as mucocutaneous candidiasis, celiac disease, and chronic hepatitis. Rare gene mutations causing ovarian insufficiency include steroidogenic defects that affect mineralocorticoid status (17-hydroxylase deficiency is associated with mineralocorticoid excess and lipoid adrenal hyperplasia with mineralocorticoid deficiency) and mutations of the gonadotropins or their receptors. Ovarian biopsy is of no prognostic or therapeutic significance. (*f*) The history may provide a diagnosis (e.g., cancer chemotherapy or radiotherapy). Other acquired causes include surgery and autoimmunity. Chromosomal causes of premature ovarian failure include X-chromosome fragile site and point mutations. Other genetic causes include gonadotropin-resistance syndromes such as LH or FSH receptor mutation and pseudohypoparathyroidism. A pelvic ultrasound that shows preservation of ovarian follicles carries some hope for fertility. (*g*) Withdrawal bleeding in response to a 5- to 10-day course of progestin (e.g., medroxyprogesterone acetate 10 mg HS) suggests an overall estradiol level greatert than 40 pg/mL. However, this is not entirely reliable and thus in the interest of making a timely diagnosis it is often worthwhile to proceed to further studies. (*h*) A thin uterine stripe suggests hypoestrogenism. A thick one suggests endometrial hyperplasia, as may occur in polycystic ovary syndrome. (*i*) A single cycle of an OCP containing 30 to 35 µg ethinyl estradiol generally suffices to induce withdrawal bleeding if the endometrial lining is intact. (*j*) The differential diagnosis of other anovulatory disorders continues in Figure 14-43. [Modified with permission from Rosenfield RL (2003). Menstrual disorders and hyperandrogenism in adolescence. In Radovick S, MacGillivray MH (eds.), *Pediatric endocrinology: A practical clinical guide*. Totowa, NJ: Humana Press 451–478.]

Lack of FSH elevation in a prepubertal patient does not rule out primary ovarian failure if bone age is below 11 years because neuroendocrine puberty may not have occurred, in which case primary ovarian failure is not hypergonadotropic (Table 14-9).[591] If gonadotropins are not elevated and bone age has reached 11 years, in a prepubertal girl without a growth-attenuating or growth-retarding disorder one is dealing with constitutional delay of puberty or isolated gonadotropin deficiency (Figure 14-41). "Constitutional" delay of puberty is the most likely diagnosis until the bone age reaches 11 to 13 years (Table 14-9).[591] Its distinction from isolated gonadotropin deficiency may be difficult.

The features that help to distinguish it from isolated gonadotropin deficiency are listed in Table 14-10 and discussed in the footnotes to Figure 14-41. The single most useful test is the LH level in response to GnRH testing because random LH levels in hypogonadotropic patients often overlap those of pre- and midpubertal normal children.[95] GnRH agonist testing may discriminate between these disorders better[81] and adds the dimension of assessing the gonadal secretory response to the secreted

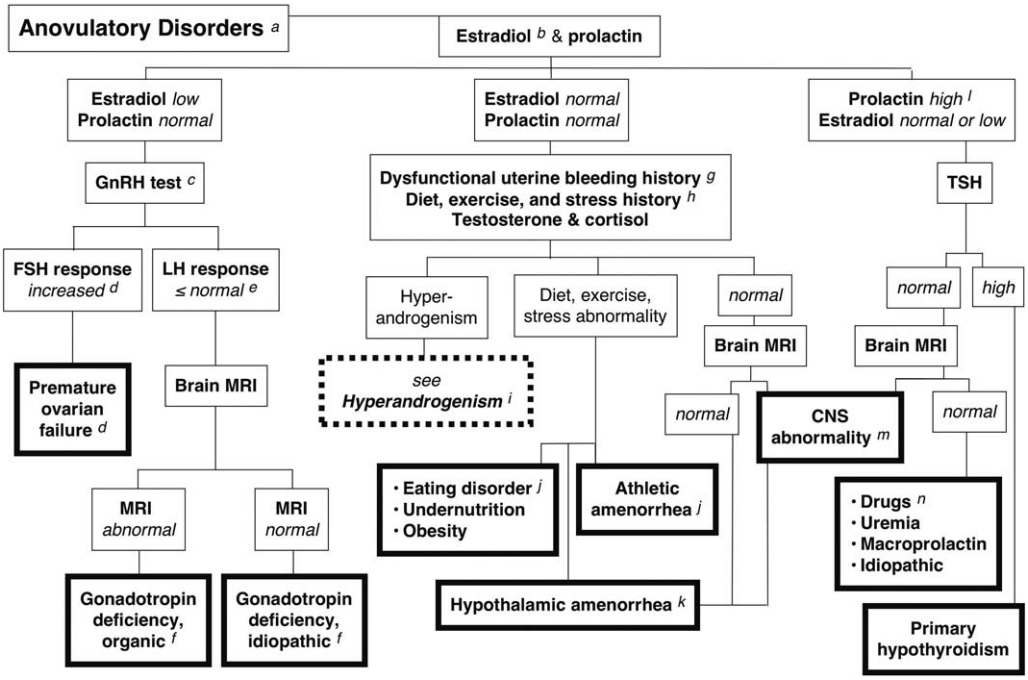

Figure 14-43 Differential diagnosis of anovulatory disorders. (*a*) Anovulatory disorders should be considered in any girl with unexplained amenorrhea or oligomenorrhea, irregular menstrual bleeding, short cycles, or excessive menstrual bleeding. The workup should be initiated as indicated in Figure 14-42, including history and examination, a chronic disease panel, pregnancy test, and gonadotropin levels. (*b*) Once breast development has matured, the breast contour does not substantially regress when hypoestrogenism develops. Hypoestrogenism is suggested if plasma estradiol is persistently <40 pg/mL in an assay sensitive to <10 pg/mL. However, a single estradiol level may be misleading because of cyclic or episodic variations. (*c*) Baseline gonadotropin levels may not be low in gonadotropin-deficient patients, especially according to polyclonal antibody-based assays. Gonadotropin-releasing hormone (GnRH) testing is usually performed by assaying LH and FSH before and 0.5 hour after the administration of 1 mcg/kg GnRH intravenously. GnRH agonist testing may alternatively be performed by administering 10 mcg/kg leuprolide acetate subcutaneously and assaying LH and FSH at 4 hours to assess gonadotropin reserve and at 24 hours to assess the ovarian steroid response to endogenous gonadotropin release. (*d*) Baseline gonadotropin levels may be normal as the ovary begins to fail, as in menopause, but an exaggerated FSH response to GnRH and subnormal E2 response to the gonadotropin elevation induced by acute GnRH agonist challenge are characteristic. The further workup is shown in Figure 14-42. (*e*) Responses to GnRH may vary from nil to normal in gonadotropin deficiency. Normal LH and FSH responses in the presence of hypoestrogenism indicate inadequate compensatory hypothalamic GnRH secretion. (*f*) Gonadotropin deficiency may be congenital or acquired, organic or functional. Congenital causes include midline brain malformations or specific genetic disorders such as Prader-Willi syndrome, Laurence-Moon-Biedl syndrome, or Kallmann syndrome. Kallmann's, the association of anosmia with gonadotropin deficiency, occurs in both the X-linked and autosomal-recessive forms. Special MRI views often demonstrate absence of the olfactory tracts. Acquired gonadotropin deficiency may be secondary to a variety of organic CNS disorders, varying from hypothalamic-pituitary tumor to radiation damage to empty sella syndrome. Autoimmune hypophysitis is a rare disorder, sometimes accompanying a polyendocrine deficiency syndrome. The prototypic form of functional gonadotropin deficiency is anorexia nervosa. Idiopathic hypogonadotropic deficiency may sometimes occur in families with anosmia, suggesting a relationship to Kallmann's syndrome. (*g*) Dysfunctional uterine bleeding or menorrhagia not controlled by progestin or OCP therapy additionally requires a pelvic ultrasound examination (for genital tract tumor or feminizing tumor), coagulation workup (which includes platelet count, prothrombin time, thromboplastin generation test, and bleeding time), and consideration of the possibility of sexual abuse. (*h*) The equivalent of 4 miles per day or more is generally required before body fat stores fall to the point where amenorrhea occurs. Physical or psychosocial stress may cause amenorrhea. (*i*) Hyperandrogenism differential diagnosis is outlined in Figure 14-46. (*j*) Mild forms of stress disorders associated with low body fat (anorexia nervosa, bulimia nervosa, and athletic amenorrhea) may cause acquired hypothalamic amenorrhea rather than frank gonadotropin deficiency. The low body fat content of athletic amenorrhea may not be reflected by weight for height because of high muscularity. Dual-photon absorptiometry scan may be useful in documenting body fat below 20%. Patients with anorexia nervosa may become amenorrheic before or when weight loss begins, indicating an important psychological component to the etiology. Obesity is also associated with anovulatory cycles. (*k*) Hypothalamic amenorrhea is a diagnosis of exclusion. It is a form of partial gonadotropin deficiency in which baseline estrogen secretion is normal but a preovulatory LH surge cannot be generated. It may result from organic CNS disorders. Functional hypothalamic amenorrhea may be stress or undernutrition related or idiopathic. It may be secondary to chronic illness or result from obesity or diverse types of endocrine dysfunction. Research studies show subnormal LH pulsatility or estrogen induceability of the LH surge. (*l*) Hyperprolactinemia is heterogeneous in its presentation. Galactorrhea is found in half of patients. Some have normoestrogenic anovulation, which may be manifest as hypothalamic anovulation, hyperandrogenism, dysfunctional uterine bleeding, or short luteal phase. On the other hand, some are hypoestrogenic. These do not have galactorrhea. (*m*) Hyperprolactinemia may be caused by prolactinomas, which secrete excess prolactin, or may be secondary to interruption of the pituitary stalk by large hypothalamic-pituitary tumors or other types of CNS injury. The latter cause variable pituitary dysfunction, which may include complete gonadotropin deficiency and various manifestations of hypopituitarism (including secondary hypothyroidism). (*n*) Drugs, particularly neuroleptics of the phenothiazone or tricyclic type, may induce hyperprolactinemia. [Modified with permission from Rosenfield RL (2003). TABLE 14-10

Features That Distinguish Gonadotropin Deficiency from Constitutional Delay of Puberty

In a healthy delayed prepubertal girl with BA >11 yr and prepubertal FSH, gonadotropin deficiency is:

- Possible if:
  - Weight loss greater than 5% to 8% (BMI <10th to15th percentile for height age)
  - Midline facial defect
  - CNS dysfunction
  - CT or MRI brain scan abnormal
- Probable if:
  - BA >13 yr and LH <0.15 U/L in early daytime
  - Anosmia or panhypopituitarism
- Diagnostic if:
  - Sleep-associated increase in LH lacking
  - GnRH (agonist) test → flat response
  - Chronologic age >16 yr

Reproduced with permission from Rosenfield RL, Barnes RB (1993). Menstrual disorders in adolescence. Endocrinol Metab Clin N Am 22:491–505.

gonadotropins.[594] Gonadotropin profiles during sleep have not proven to necessarily distinguish hypothalamic dysfunction from constitutional delay of puberty.[661]

The assessment of an adolescent's degree of estrogenization is often difficult. Breast development indicates that there has been estrogen exposure but does not mean that it is current. Determination of plasma estradiol is the simplest test, but diurnal and cyclic variations must be taken into account. Determination of hormonal effects on vaginal cytology is the most indicative of overall estrogen exposure (Figure 14-29), but is less well accepted by patients. A progestin withdrawal test is often helpful. A female who does not experience progestin withdrawal bleeding (Figure 14-42) probably has an ambient estradiol level of less than about 40 pg/mL.[662] If bleeding does not occur in response to this maneuver, the integrity of the uterus can be tested by the response to a 3-week course of estrogen-progestin—most conveniently administered in the form of birth control pills.

A prolactin level is indicated in the initial workup of normogonadotropic patients, regardless of their estrogen status. The prolactin level correlates with the size of prolactinomas, and a level greater than 200 ng/mL is typical of a macroprolactinoma. A prolactin level that does not correlate with the size of a large pituitary tumor suggests that the tumor is not a prolactinoma and is causing a functional pituitary stalk section or that the tumor is a macroprolactinoma elaborating such high levels of prolactin as to artefactually lower the immunoassayable prolactin level by a "hook effect."[663] Very high blood or cerebrospinal fluid prolactin levels suggest invasiveness. The workup for this should include formal testing of visual fields (Goldman perimetry or evoked response).

Pituitary microadenomas may be "incidentalomas" of no clinical significance, judging from an approximate 10% incidence in autopsy material.[664] However, they require careful assessment of pituitary function and follow-up.[665] Macroprolactinemia should be considered in the absence of clearly related symptoms, and when MRI is negative or in the setting of autoimmune disease.[653,654] Macroprolactinemia is confirmed when the prolactin level measured after precipitation of serum using polyethylene glycol is normal (or substantially reduced compared to the level measured in untreated serum.)

Imaging studies are important ancillary measures. Pelvic ultrasound may demonstrate hypoplastic ovaries, endometrial hypoplasia or disorders, and multicystic or polycystic ovaries. MRI of the hypothalamic-pituitary area is important in the workup of gonadotropin deficiency, hyperprolactinemia, and hypothalamic anovulation. Anorexic patients require psychiatric evaluation and consideration of brain tumor and partial bowel obstruction. Diet faddism and athletic addiction may be difficult to distinguish from anorexia nervosa. Constitutional thinness is a variant of normal with normal menses and a distinct hormonal profile.[666] It is unclear whether the superior mesenteric artery syndrome is a primary disorder that mimics anorexia nervosa or is a complication of it.[667]

Management

Underlying disorders must be treated appropriately. For example, tumors require surgery and/or radiotherapy. For prolactinoma, dopaminergic treatment is the initial treatment of choice unless the patient's conditon or eyesight is critical.[668] Hyperprolactinemia will be maximally suppressed within 1 month, and the menstrual cycle normalized within 3 months, by an effective dopaminergic agonist regimen. Cabergoline 0.5 to 1.0 mg once or twice weekly will usually control galactorrhea and shrink prolatinomas.[652,669] To minimize nausea, it is best to start with a low dose at bedtime.

Recent data implicate cabergoline as increasing the risk of cardiac valve regurgitation about fivefold in the elderly, albeit at generally tenfold or higher doses than used to treat hyperprolactinemia.[670,671] Bromocriptine does not activate the serotonin 5-HT(2B) receptor, the proposed mechanism through which cabergoline is thought to stimulate valve hypertrophy, and thus bromocriptine should not be associated with an increased risk of cardiac valve regurgitation and may be considered an alternative to cabergoline treatment—albeit a less effective one. The usual bromocriptine maintenance dose is 0.25 to 0.5 mg twice daily.

Anorexia nervosa is best managed by an experienced multidisciplinary team. Refeeding is the first priority, and once steady weight gain is evident the psychodynamic issues can be dealt with.[672] Family therapy, given on an outpatient basis, for medically uncomplicated cases of anorexia nervosa generally yields the best results—with good improvement in over half of patients. Inpatient intervention for rehydration and metabolic stabilization or failure of weight gain with ongoing cachexia may be required at any time. Menses resume when psychotherapy is effective and body fat is restored to normal (Figure 14-40). The induction of menses by estrogen-progestin replacement is usually injudicious because it provides a false sense of recovery and does not yield the recovery of bone loss that occurs with weight gain.[673] Although

the acute episode can usually be successfully treated, there is a high rate of ongoing psychiatric disability and medical complications. Anorexia nervosa "by proxy" has been described in the offspring of former patients.[674]

There are two aspects of therapy that are uniformly involved in managing hypogonadism: psychological support and hormone administration. Patients with delayed development that is a variation of normal should be reassured that there is nothing wrong. They are simply among those who are experiencing a delay in timing of the onset of puberty. The wide normal variation in the pattern and time of the pubertal growth spurt should be explained in detail and the girl should be informed of her predicted eventual height. The majority of children with delayed puberty do not have overt psychological symptoms. Complex compensations and sublimations obviously occur. However, peer group pressures may make adjustment to sexual infantilism especially difficult when the age of 13 is approached[675]—and a poor self-image may lead to social withdrawal and feelings of hopelessness. Physical immaturity may prolong psychological immaturity.

A short course of physiologic sex hormone therapy at this time may help alleviate these anxieties. The physician should discuss the fact, when the evidence favors it, that the odds are overwhelmingly in favor of the "timer in the subconscious area of the brain" eventually turning on. When this will happen can be approximated from the skeletal age. One should not hesitate to advise more intensive psychological counseling if it becomes apparent that the concern about puberty is but one aspect of a more general maladjustment. Ultimately, the decision as to whether to undertake treatment for delayed puberty is up to the patient and her family.

It is important to assure the teenager with an organic basis for hypoestrogenism that feminization will occur, although in response to appropriate hormone treatment. It should be kept in mind that attainment of normal breast development in the girl with panhypopituitarism requires replacement of GH and cortisol deficits. It is difficult, however, to induce secondary sex characteristics in some patients with systemic chronic inflammatory disease such as lupus erythematosus.

In patients in whom short stature is a major concern, as in Turner syndrome, growth potential must be considered before undertaking estrogen replacement. GH therapy improves the adult height potential of patients with Turner syndrome, especially when started as soon as growth failure becomes apparent.[676] GH therapy in the United States is generally initiated at the FDA-approved dose of 0.375 mg/kg per week. In older girls, or those with extreme short stature, therapy with oxandrolone [2-oxo-17α-methyldihydrotestosterone (Anavar)] 0.05 mg/kg/day (which augments GH action) can be considered.[677] Clitoromegaly is ordinarily negligble on this dosage. Liver function should be monitored.

Estrogen replacement therapy starting at about one-tenth of the adult dose does not seem to interfere with the positive effect that GH has on adult height.[676,678] A physiologic form of treatment is to begin with intramuscular depot E2 0.2 mg/month and to increase the dose by 0.2 mg every 6 months until a midpubertal dose is reached, at which time it can be increased by 0.5 mg every 6 months. Midpubertal sex hormone production is approximated by delivering 1.0 to 1.5 mg of depot E2 per month, which alone permits achievement of height potential and typically induces menarche within 1 year. An equivalent starting dose of transdermal E2 appears to be 6.25 μg daily, which requires intermittent or fractionated delivery of the lowest-dose patches currently available. A reasonable alternative regimen begins with 0.25 mg micronized E2 by mouth daily. Adult replacement doses are 100 μg transdermal or 2 to 4 mg oral E2 daily.

Progestin should be added to estrogenic regimens after 2 years of estrogen replacement treatment or after withdrawal bleeding occurs. A physiologic replacement regimen consists of micronized progesterone 200 mg daily for 10 days monthly. We typically begin with half of this dose to minimize premenstrual symptoms, but full replacement appears necessary to lower the risk of endometrial hyperplasia and endometrial carcinoma.[679,680] Once optimal height is achieved, most patients prefer to switch to birth control pills as a convenient form of estrogen-progestin therapy. The pills containing the lowest dose of estrogen that will result in normal menstrual cycles are advisable. The lowest estrogen dosages currently available in combination contraceptive pills in the United States contain 20 μg (Mircette) to 30 μg (Yasmin) ethinyl estradiol.

Hypogonadotropic patients can achieve ovulation with gonadotropin therapy. There has been considerable success in treating those patients with hypothalamic GnRH deficiency by pulsatile GnRH.[88,661] Fertility has been achieved by this means. Induction of ovulation is best carried out by a gynecologist specializing in reproductive endocrinology. Patients with primary ovarian failure can successfully achieve pregnancy after oocyte donation and in vitro fertilization.[681]

Turner syndrome patients are at high risk for obstetrical complications in the areas of uterine anomalies, carbohydrate intolerance, and cardiovascular complications. Oocyte cryopreservation and ovarian tissue cryopreservation and transplantation have been explored to preserve fertility in patients with gonadal dysgenesis and disorders requiring cytotoxic chemotherapy or gonadectomy.[682-684] Data are limited, but the modest success with the former outstrips the rare success with the latter. Each technique has limitations and risks. These procedures should currently be considered experimental until greater evidence for efficacy and safety is available.

NORMOESTROGENIC MENSTRUAL DISTURBANCES

Hypothalamic Anovulation

Hypothalamic anovulation causes menstrual disturbances in sexually mature well-estrogenized women through a deficiency in GnRH secretion too subtle to cause frank hypoestrogenism. The neuroendocrine system stimulates ovarian estrogen secretion to a level normal for an early- or mid-follicular-phase female, but follicular development is inadequate for a normal dominant follicle to emerge. Amenorrhea or oligomenorrhea may result.

However, in some patients sufficient estrogenization occurs to cause dysfunctional uterine bleeding (discussed in the next section).

Reduced LH pulsatility occurs in the great majority[685]—failure to generate a midcycle LH surge in the remainder.[686,687] The pathophysiology seems to involve varying degrees of undernutrition and/or CRH excess. Negative energy balance may be present even in patients of normal, but lower than average, weight and fat stores.[371,646] Leptin deficiency is an important determinant of the decreased LH pulsatility. The anovulation of psychic or physical stress may involve CRH excess.[647] In the brain, CRH releases β-endorphin from proopiomelanocortin. This endorphin in turn inhibits GnRH release. This seems to be the major mechanism of anovulation because naloxone blockade of opioid action normalizes gonadotropin secretion.[88]

In the pituitary, CRH increases the set-point for ACTH release. This brings about a new steady state of increased cortisol secretion. Further ACTH response to CRH is blunted by the negative feedback of this cortisol excess. The result is a mildly Cushingoid cortisol rhythm. Cortisol excess itself can contribute to the amenorrhea by inhibiting the response to GnRH,[688] as well as by antagonizing some sex hormone actions. Adrenal androgens are elevated in competitive athletes who maintain body fat stores.[689]

Causes. *Functional hypothalamic amenorrhea* is a term commonly used to describe unexplained hypothalamic anovulation. The endocrine features of these patients resemble those of patients with the athletic or psychogenic types of hypothalamic anovulation. A primate model indicates that hypothalamic anovulation develops in stress-sensitive individuals from an innocuous combination of mild stress and mild caloric restriction.[689a] *Athletic amenorrhea* is the term used for the hypothalamic anovulation associated with excessive exercise and with low body fat stores. The female athletic triad consists of menstrual disturbance, eating disorder, and osteoporosis.[690] Primary or secondary amenorrhea, oligomenorrhea, or short luteal phase are common in athletes.[691] Ovarian function decreases approximately in proportion to the amount of physical activity and dietary restriction. Weight-bearing exercise is only partly protective of the effects of hypoestrogenism on weight-bearing bone.

There is concern that amenorrheic athletes may be left with a pemanent deficit in bone mass.[692] Weight loss to 10% below ideal body weight and body fat less than 10% are risk factors for amenorrhea. Body mass index does not accurately reflect body fat stores in athletes.[693] Energy balance seems to be more critical than low body fat stores in mediating the anovulation.[691,694] Menarche may occur or menses resume when the athlete's activity level suddenly decreases and before weight gain occurs. Other factors contribute to cause amenorrhea. Nutritional deficiencies may coexist. Chronic undernutriton may suppress thyroid function, as in anorexia nervosa.[647] Delayed menarche may preexist, possibly indicating genetic susceptibility. Athletic amenorrhea resembles anorexia nervosa in patients' obsession with weight control.[691,695]

Psychogenic amenorrhea from severe psychic stress has long been known (e.g., "boarding-school amenorrhea").[696] The onset of psychogenic amenorrhea may be identified as being associated with a discrete event, but the ovarian dysfunction tends to be long lasting. Subtle nutritional deficits contribute.[371] Pseudocyesis is an extremely rare form of psychogenic amenorrhea that is due to persistence of the corpus luteum. This syndrome tends to occur in infertile women with an overwhelming desire for pregnancy and conversion hysteria. Prolactin and LH excess appear to mediate this rare syndrome.[697]

Post-pill amenorrhea has been a term applied to the amenorrhea that sometimes follows the long-term use of hormonal contraceptives. This in the past was attributed to oversuppression, but oversuppression should not be expected to be the case with the current generation of oral contraceptives.[242] About a third of patients with secondary amenorrhea after discontinuation of estrogen- and progestin-containing pills have a history of previous menstrual disturbance and ongoing menstrual problems.[698] Another third can expect spontaneous remission of the amenorrhea. About half of the remainder of cases will have resolution of their menstrual disturbance after induced pregnancy.

The most common cause of post-pill amenorrhea is probably hyperprolactinemia because more than 20% of such cases have galactorrhea. How often this antedates ingestion of the contraceptive pill is unknown. Menses may be restored in normoprolactinemic cases by dopaminergic treatment, which suggests that in such cases there is excessive pituitary prolactin secretion that is too subtle to be detected by measurement of plasma levels.[699] The anovulation resulting from depot-medroxyprogesterone acetate contraception is related to the extremely slow rate of absorption and metabolism of this steroid. Menses return when the blood levels of this progestin fall below the threshold for suppression of the LH surge,[700] and only rarely has it been associated with disturbed prolactin secretion.[701]

Differential Diagnosis. Disorders outside the neuroendocrine-gonadal axis may mimic hypothalamic anovulation. These include pregnancy, nutritional disturbance, glucocorticoid excess, disturbed thyroid function, drug abuse, chronic illness, hyperprolactinemia, and ectopic LH secretion. Pregnancy must be excluded in all sexually mature adolescents wtih amenorrhea. An elevation of the plasma β-hCG level is the earliest laboratory sign.[702] Constant overproduction of estrogens and progestins by the hCG-driven corpus luteum of pregnancy and the fetoplacental unit leads to the suppression of endogenous pituitary gonadotropin release that underlies the amenorrhea.

Overnutrition or undernutrition may cause hypothalamic amenorrhea. Overproduction of estrogen from plasma precursors in adipose tissue appears to mediate the effect of obesity.[334] The effect of undernutrition seems to be mediated by factors related to energy balance, as discussed previously. Cushing syndrome (glucocorticoid excess) seems to cause menstrual irregularity by mechanisms discussed earlier in this section. Thyroid hormone deficiency interferes with gonadotropin action on the ovary,[703] and may interfere with endometrial function by actions on steroid metabolism[704] and action.[705] Hypothalamic anovulation may be caused by drug abuse with tetrahydrocannabinol, ethanol, or opiates.[706,707]

Cocaine causes menstrual irregularity by suppressing gonadotropin secretion through mechanisms that include depletion of dopaminergic stores (resulting in hyperprolactinemia) and stimulation of CRH release.[656,708] Inflammatory illness acutely disrupts the estradiol-induced LH surge[709] and chronically causes gonadotropin deficiency, which may be mediated partly by undernutrition and partly by cytokines.[633] Disorders as diverse as diabetes mellitus and iron overload all impact GnRH secretion.[710,711] Chronic renal failure causes complex dysfunction of the reproductive system, including poor clearance of gonadotropins and prolactin in the presence of inhibition of gonadotropins by a nondialyzable factor.[712]

Hyperprolactinemia occasionally causes secondary amenorrhea without frank hypoestrogenism.[713] This situation probably results from a diminution in FSH secretion that is so marginal as to only inhibit the emergence of a dominant follicle. Ectopic LH or hCG secretion by a tumor can cause normoestrogenic anovulation.[714] Sex steroid levels are normal due to ovarian desensitization to LH. Hypothalamic anovulation is ordinarily a diagnosis of exclusion. The medical evaluation should be performed as discussed in the preceding section, with particular attention to the possibilities of emotional disturbances, excessive exercise, the use of birth control pills or other drugs, and state of health.

The physical examination should be particularly directed to the state of nutrition, the possibilities of intracranial or systemic disease, galactorrhea, thyroid dysfunction, glucocorticoid excess, hirsutism, and obesity. If this workup is negative, an MRI of the hypothalamic-pituitary area is indicated. The response to a GnRH test may be immature, but it is not necessarily helpful. Hypothalamic anovulation may be documented by demonstrating subnormal LH pulse frequency, but this is not generally practical. Leptin levels tend to be low but nondiagnostic.[646] Dysfunctional uterine bleeding from hypothalamic anovulation must be distinguished from that due to other causes (see next section).

Management. Many patients with hypothalamic anovulation will benefit from nutritional counseling. Diet faddists and athletes should be advised about the necessity of optimal body energy reserves for the maintenance of normal menstrual cycles (see Figure 14-40). The teleologic significance of this may be pointed out; namely, that inherent in the evolutionary process is the inhibition of pregnancy in times of inadequate food supplies. Ongoing psychological counseling is advisable for patients who cannot change their dietary or exercise patterns because of an abnormal body image. Mature athletes who are hypoestrogenic may benefit from estrogen replacement. Obese girls should be advised that there is a substantial possibility that reduction to a normal weight will result in restoration of menses and improved probability of fertility.

Mature teenagers whose amenorrhea is unexplained should be assured that they have a high likelihood of fertility with appropriate endocrinologic treatment. However, such treatment is unlikely to be of any benefit to them until such time as they desire to become pregnant. In the meanwhile, the main objective of therapy is to normalize the endometrial cycle by periodic progestin administration. For this purpose, medroxyprogesterone acetate (up to 10 mg at bedtime for 14 consecutive days) is usually effective in inducing withdrawal periods. During the first few years after menarche, it is reasonable to administer this treatment on alternate months to allow detection of late maturation of a regular menstrual cycle.

Induction of an ovulatory cycle has been reported to occasionally result in resumption of spontaneous normal menses.[698] An ovulatory cycle can normally be induced by the administration of clomiphene citrate once nightly for five doses. If treatment is successful, bleeding generally occurs about 1 month from commencement of the treatment. One should start with the 50-mg dose because larger doses may cause hyperstimulation of the ovaries with the development of ovarian cysts. For this reason, one should perform an ultrasound examination to rule out cystic ovaries before going successively to 100- to 150-mg dosage. This treatment is not generally recommended in the teenage years, however. Dopaminergic therapy has been reported to be successful in causing the resumption of ovulation in post-pill amenorrhea, modest undernutrition, and other unexplained cases of secondary amenorrhea. Otherwise, induction of ovulation is best left to the endocrinologic gynecologist to supervise at such time as the woman wishes to conceive. The vast majority of patients with no obvious cause for their secondary amenorrhea will become pregnant after appropriate treatment with estrogen, clomiphene, dopaminergic agonist, human menopausal gonadotropins, or pulsatile GnRH therapy.

Dysfunctional Uterine Bleeding

Causes. Dysfunctional uterine bleeding (anovulatory bleeding that is too frequent or excessive) is a manifestation of anovulatory cycles in which there is overall excessive estrogen production.[591] It is most often a manifestation of physiologic adolescent anovulation. Hyperandrogenism, particularly polycystic ovary syndrome and its variants, is a common cause of dysfunctional bleeding. In some cases it arises from hypothalamic anovulation (discussed previously). Less common are estrogen-producing cysts or tumors, hypothyroidism, hyperprolactinemia, and incipient premature ovarian failure. The workup should therefore include measurement of androgens, prolactin, thyroid function, and FSH blood levels.

Corpus luteum insufficiency presents as short (less than 22 days) ovulatory cycles, and thus excessively frequent menses. The immediate cause of an inadequate luteal phase is insufficent progesterone production to sustain a pregnancy.[715,716] This in turn may arise from subtle deficiency of FSH during the follicular phase, resultant incomplete emergence of a dominant follicle, and the subsequent formation of an inadequate corpus luteum. Alternatively, the corpus luteum may not be responsive to LH.[717] Luteal insufficiency may be the result of hyperprolactinemia,[718] obesity, or hyperandrogenism.

Differential Diagnosis. Dysfunctional uterine bleeding must be distinguished from the other causes of abnormal genital bleeding listed in Table 14-11.[591,719] The possibility that it is pregnancy related must be considered and a pregnancy test performed in a sexually active teenager. Sexual

TABLE 14-11

Differential Diagnosis of Abnormal Genital Bleeding

- Dysfunctional uterine bleeding (anovulation)
  - Physiologic anovulation (perimenarcheal)
  - Hyperandrogenism
    - Polycystic ovary syndrome
  - Hyperestrogenism
  - Hypothyroidism
  - Hypothalamic anovulation
    - Hyperprolactinemia
  - Chronic disease
  - Incipient premature ovarian failure
- Luteal phase defects
- Pregnancy-related bleeding
  - Threatened, missed, or incomplete abortion
  - Molar pregnancy
  - Ectopic pregnancy
- Vaginal bleeding
  - Trauma
  - Tumor
- Menorrhagia
  - Essential menorrhagia
  - Bleeding diathesis
  - Uterine tumor, polyp, adenomyosis, intrauterine device

Based on Rosenfield RL, Barnes RB (1993). Menstrual disorders in adolescence. Endocrinol Metab Clin North Am 22:491.

abuse is a prime consideration in recurrant vaginal bleeding. Genital tract or feminizing tumors characteristically cause bleeding that cannot be controlled with cyclic progestin or estrogen-progestin therapy. Menorrhagia can be pragmatically considered to exist if prolonged or excessive menses is associated with iron deficiency anemia.

Essential or idiopathic menorrhagia is the single most common cause in adolescents. It is theorized to result from imbalance of vasodilating and vasocontricting prostanoid action on the endometrium.[720] However, pathologic causes must be considered because bleeding disorders are present in about 20% of adolescents with menorrhagia requiring hospitalization and in 50% of those presenting at menarche.

Patients requiring hospitalization for abnormal bleeding should have a platelet count, prothrombin time, partial thromboplastin time, and bleeding time performed. Transvaginal ultrasound, which is not often feasible in the virginal adolescent, is as reliable as hysteroscopy in determining whether or not the endometrial cavity is normal. Failure of serum progesterone to rise above 500 ng/dL during the luteal phase is diagnostic of corpus luteum insufficiency. However, a higher progesterone level may be compatible with inadequacy if not sustained.

Management. Estrogen is required to stop an acute episode of dysfunctional bleeding. It can be given together with a progestin as a low-dose oral contraceptive pill, one tablet four times daily for 7 days. Treatment is then stopped for 5 days, and the patient warned that heavy withdrawal bleeding with cramps may occur. Therapy with a low-dose pill, given as for contraception, is then begun to prevent recurrence of dysfunctional bleeding and is continued for about three cycles. If the patient is sexually active, oral contraceptive therapy can be continued indefinitely as necessary.

A progestin can be used as an alternative to the oral contraceptive pill to prevent recurrent dysfunctional bleeding in a patient who is not sexually active. Medroxyprogesterone acetate 10 mg/day for 1 week is given at 3- to 4-week intervals. After the third month, therapy is stopped and the patient is observed for 1 to 2 months for spontaneous bleeding. If none occurs, the progestin can be given every other month in a dosage of 5 to 10 mg for 7 to 14 days to prevent recurrent dysfunctional bleeding. If in the progestin-free month spontaneous bleeding occurs, progestins are withheld in the subsequent month to determine if the patient has developed regular ovulatory cycles.

A patient who is hypovolemic because of rapid and heavy dysfunctional bleeding should be hospitalized and treated with intravenous fluids and blood products as necessary. Premarin can be administered in a dose of 25 mg intravenously every 3 to 4 hours for three to four doses. When medical management fails, a bleeding diathesis or uterine structural abnormality should be considered (see material following). If heavy bleeding persists, curettage should be performed by a gynecologist.

Unexplained ("essential") menorrhagia is treated much the same way as dysmenorrhea. The oral contraceptive pill will decrease menstrual blood loss by about 50% in women with essential menorrhagia. Antiprostaglandins, such as naproxen 500 mg twice a day, decrease blood loss nearly as effectively.

Perimenstrual Symptoms

Dysmenorrhea. Pain with menses becomes a source of morbidity in 14% of adolescents.[721] When pain is acute and qualitatively different from the usual menstrual pain, ectopic pregnancy must be considered.[702,722] An ectopic pregnancy often causes vaginal bleeding that occurs 2.5 weeks later than the time of the expected next menstrual period and is typically light. However, the bleeding may be heavy and thus resemble an episode of dysfunctional uterine bleeding. Ectopic pregnancy is usually diagnosable by a combination of ultrasonography, a serum β-hCG level >1,000 IU/L, and a progesterone level of <2,500 ng/dL.

In patients with chronic pelvic pain unresponsive to antiprostaglandins or the oral contraceptive pill, psychological overlay is possible. However, attention should be directed to the possibility of endometriosis, uterine outlet obstruction, or gynecologic tract masses. Ultrasonography and laparoscopy may be indicated to further evaluate these patients. Endometriosis accounts for approximately half of the cases of chronic pelvic pain in teenagers.[723] Genetic factors and congenital obstruction of the genital tract predispose to endometriosis, and aberrent estradiol formation in endometrial stroma[724] has been incriminated in the pathogenesis. Lack of expression of the cell adhesion molecule integrin in the luteal phase endometrium is associated with a form of endometriosis that is mild but accompanied by infertility.[725]

Dysmenorrhea may be ameliorated by antiprostaglandin therapy. Naproxen (275 mg qid after a 550-mg loading dose) has been shown to be superior to aspirin

(650 mg qid) or placebo when begun 2 days before the anticipated onset of menses.[726] The oral contraceptive pill is an alternative that will relieve dysmenorrhea in about 90% of cases, presumably by reducing endometrial mass.[591] Because smoking, alcohol intake, and excessive weight are risk factors, lifestyle counselling is advisable.

Premenstrual Syndrome. *Premenstrual syndrome* is the term applied when cylic mood changes confined to the second half of the menstrual cycle become debilitating.[727] It is often disruptive to women's personal, social, and occupational function. If symptoms of marked mood swings, depressed mood, anxiety, and irritability occur, it is classified as premenstrual dysphoric disorder.[728] Neuropsychiatric symptoms may include epilepsy[729] and bizarre behavior.[730] These seem to represent aberrant responses to normal cyclic hormonal changes.[731] Subnormal activation of the hypothalamic-pituitary-adrenal axis in response to progesterone has been found.[732]

Some evidence indicates that variation in the degree of progesterone metabolism to neuroactive steroids affects the severity of symptomatology.[733] Oral contraceptive therapy with the antimineralocorticoid progestin drospirenone is indicated if psychotropic therapy is unsuccessful. Down-regulation of pituitary gonadotropin secretion by GnRH agonist therapy is efficacious, but its usefulness is limited by the side effects of estrogen deficiency. The relationship of premenstrual syndrome to other luteal phase symptomatology, such as recurrent fever and autoimmune symptoms, is unclear.[734,735]

HYPERANDROGENISM IN ADOLESCENCE

Hyperandrogenism of a mild to moderate degree is the most common cause of normoestrogenic menstrual disturbances. It arises from ovarian or adrenal dysfunction in the vast majority of cases, and abnormal peripheral formation of androgen in most others (Table 14-12).[339,736,737] Virilizing tumors are rare (accounting for about 0.2% of hyperandrogenism). These are discussed in the section on precocious puberty.

Causes

Polycystic Ovary Syndrome. Polycystic ovary syndrome (PCOS) is the most common cause of hyperandrogenism presenting at or after the onset of puberty. It is a heterogeneous syndrome of unexplained chronic hyperandrogenism and oligo-anovulation, with a polycystic ovary being an alternative diagnostic criterion (Table 14-13).[268,736-738] Whether the syndrome can be diagnosed in the absence of hyperandrogenism is controversial. Insulin resistance and LH excess contribute to the pathogenesis of the syndrome, but neither is a criterion for diagnosis. The syndrome is variable both clinically and endocrinologically (Figure 14-44).[736] The syndrome in adolescents resembles that in adults. The cardinal symptoms typically begin in the perimenarcheal stage, and it has been documented in children as young as 10 years of age. Adolescents with classic PCOS develop higher LH levels and greater insulin resistance than normal.

The classic Stein-Leventhal form of PCOS is characterized clinically by menstrual irregularity, hirsutism (or hirsutism equivalents such as seborrhea, acne, and alopecia), and obesity (often with acanthosis nigricans). Endocrinologically, they are characterized by hyperandrogenemia and by polycystic ovaries or about twofold elevation of serum LH—although the more obese the patient the less likely serum LH is to be elevated.[739,740] However, half the cases are nonclassic or atypical. Nonclassic PCOS patients are hyperandrogenic and have anovulatory symptoms, but lack a polycystic ovary (meeting NIH criteria) or have normal menses yet a polycystic ovary (meeting Rotterdam criteria) (Table 14-13). The broad

TABLE 14-12

Causes of Adolescent Hyperandrogenism

Functional Gonadal Hyperandrogenism
- Primary (dysregulational) functional ovarian hyperandrogenism*
- Secondary polycystic ovary syndrome
  - Poorly controlled classic congenital adrenal hyperplasia
  - Ovarian steroidogenic blocks
  - Syndromes of severe insulin resistance
  - Portohepatic shunting
  - Epilepsy or valproic acid therapy
- Adrenal rests
- Ovotesticular disorder of sexual differentiation
- Chorionic gonadotropin related

Functional Adrenal Hyperandrogenism
- Primary (dysregulational) functional adrenal hyperandrogenism**
- Congenital adrenal hyperplasia
- Prolactin or growth hormone excess
- Dexamethasone-resistant functional adrenal hyperandrogenism
  - Cushing syndrome
  - Cortisol resistance
  - Apparent cortisone reductase deficiency

Peripheral Androgen Overproduction
- Obesity
- Idiopathic hyperandrogenism

Tumoral Hyperandrogenism

Androgenic Drugs

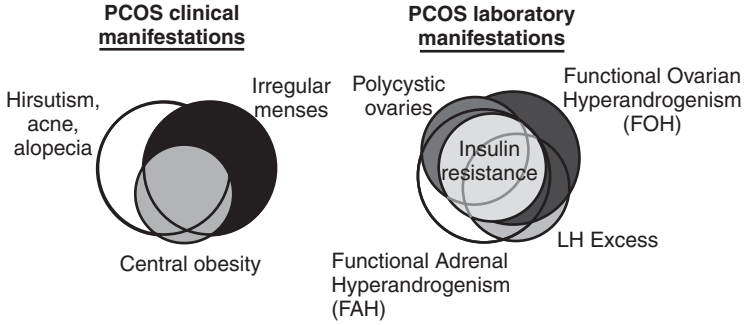

Figure 14-44 The major clinical and laboratory manifestations of PCOS are shown in approximate proportion to their relative incidence and coincidence. [Modified with permission from Buggs C, Rosenfield RL (2005). Polycystic ovary syndrome in adolescence. Endocrinol Metab Clin North Am 34:677–705.]

spectrum of the disorder includes atypical hyperandrogenemic cases with cutaneous manifestations or central obesity that do not fit current diagnostic criteria because they lack clinical or ultrasonographic evidence of ovarian dysfunction, although they have the typical endocrine dysfunction of the ovaries or adrenal glands.

Functional ovarian hyperandrogenism (FOH) is the source of the androgen excess in about 80% of cases. It is characterized by 17-hydroxyprogesterone (17PROG) hyperresponsiveness to the gonadotropin stimulation of GnRH agonist (GnRHag) or human chorionic gonadotropin testing and subnormal suppressibility of plasma testosterone upon adrenal suppression by glucocorticoid. About 60% of cases have a typical form of dexamethasone-suppressible functional adrenal hyperandrogenism (FAH) that is characterized by moderate 17-hydroxypregnenolone or DHEA hyperresponsiveness to ACTH. FAH accompanies FOH about half the time, but in atypical PCOS it may be the sole source of androgen excess.

Pathogenesis. The central abnormality in primary FOH usually seems to be intraovarian androgen excess (Figure 14-45). The hyperandrogenemia results in the pilosebaceous manifestations. The disproportionately high intraovarian androgen concentration arising from FOH seems to recruit excessive growth of small follicles while hindering the follicular maturation involved in the emergence of a dominant follicle, as well as causing thecal and stromal hyperplasia.

Dysregulation of steroidogenesis appears to account for primary FOH and primary FAH. Dysregulation is postulated to result from imbalance among the various intrinsic and extrinsic factors involved in the modulation of trophic hormone action. Within the ovary, there appear to be flaws in the processes that normally coordinate androgen and estrogen secretion (Figure 14-20). This causes the ovaries to hyperrespond to LH, rather than undergoing down-regulation in response to LH stimulation. The majority of cases appear to have an intrinsic theca cell defect that causes widespread overexpression of steroidogenic enzymes, particularly 17-hydroxylase and 17,20-lyase (both properties of P450c17, which are the rate-limiting steps in the biosynthesis of testosterone precursors).

As in the ovary, dysregulation of local steroidogenic regulatory processes within the adrenal cortex appears to cause excessive 17-ketosteroid formation as by-products of cortisol secretion. Granulosa cells also exhibit ste-

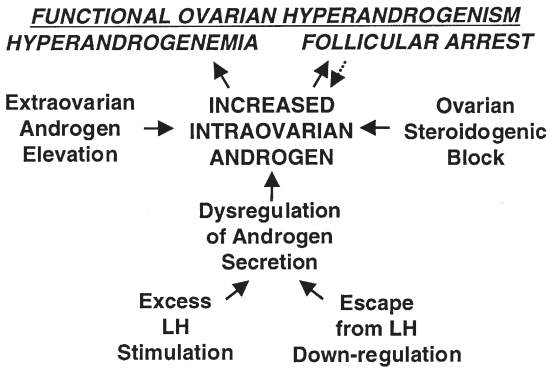

Figure 14-45 Model of the pathogenesis of functional ovarian hyperandrogenism. Increased intraovarian androgen concentration is central and causes hyperandrogenemia and follicular maturation arrest. It can also result from follicular atresia. Additional causes of increased intraovarian androgen levels include extraovarian androgen excess, ovarian steroidogenic blocks, and dysregulation of androgen secretion. The latter may result from luteinizing hormone (LH) excess or from escape from desensitization to LH action by insulin, insulin-like growth factors, or other peptides. [Modified from Ehrmann DA, et al. (1995). Polycystic ovary syndrome as functional ovarian hyperandrogenism as dysregulation of androgen secretion. Endocr Rev 16:322. Copyright © 1995 The Endocrine Society.]

roidogenic dysregulation. They are excessively responsive to FSH, particularly at high dosage. This accounts for the tendency of PCOS women to develop the dangerous ovarian hyperstimulation syndrome during fertility treatment. It may also aggravate thecal androgen secretion via a paracrine action.[129] The fundamental defect may be a generalized disorder involving specific transcriptional coregulators also involved in the regulation of glucose and fat metabolism.

Insulin excess appears to be an important extrinsic factor in dysregulation. As a group, PCOS patients are significantly hyperinsulinemic in association with a state of insulin resistance—and treatments that lower insulin levels reduce the androgen excess moderately. The insulin/IGF system seems to act in synergism with trophic hormones to cause ovarian or adrenal androgen excess. The ovaries and adrenal glands function as if responding to the hyperinsulinemic state in spite of the resistance to the effects of insulin on skeletal glucose metabolism. This paradox remains to be resolved.

Excessive LH secretion, found in 50% to 75% of cases, was once thought to be central to the pathogenesis of PCOS due to a complex cycle of events in which peripheral conversion of adrenal androstenedione to estrone-sensitized gonadotropes to GnRH.[741] However, evidence is accumulating that it results from hyperandrogenemia interfering with progesterone negative feedback effect on LH secretion.[55,252,253] Nevertheless, the possibility of a primary role for LH excess remains—particularly in the PCOS that is secondary to congenital virilizing disorders.

Etiology. Increasing evidence suggests that PCOS arises as a complex trait with contributions from both heritable and nonheritable factors. Polygenic influences appear to account for about 70% of the variance in pathogenesis. Hyperandrogenemia and polycystic ovaries each appear to be inherited as independent autosomal-dominant traits. Nearly half of sisters of women with PCOS have an elevated plasma testosterone level, although only half of them are symptomatic. Asymptomatic polycystic ovaries are found in about 10% of women, but they are often accompanied by a subclinical PCOS-type of ovarian dysfunction.

Central obesity and insulin resistance seem to play important roles in PCOS, perhaps by accentuating steroidogenic dysregulation—but perhaps more fundamentally because PCOS is closely related to metabolic syndrome in parents. Gestational factors have also been incriminated. The syndrome has been associated with high and low birth weight, and it can develop secondary to fetal virilization. Thus, the syndrome seems to arise from an intrinsic genetic trait that becomes manifest only when interacting with other congenital or environmental factors, excessive adiposity being the most common precipitant.

Other Causes of Functional Ovarian Hyperandrogenism. Secondary PCOS can result from several disorders (Table 14-12).[742] Extraovarian androgen excess (as in poorly controlled congenital adrenal hyperplasia) and ovarian steroidogenic blocks (such as 3β-hydroxysteroid dehydrogenase, 17β-hydroxysteroid dehydrogenase, and aromatase deficiency) are causes. Excessive stimulation of the LH receptor appears to mediate the hyperandrogenism reported in chorionic gonadotropin-related ovarian dysfunction during pregnancy, and appears to have played a role in a case of FSH-resistant ovarian follicles.[743]

All known forms of extreme insulin resistance (including hereditary cases of insulin receptor mutations, as well as acromegaly) are accompanied by PCOS, possibly by acting through the IGF-I signal transduction pathway to cause escape from desensitization to LH. Functional ovarian hyperandrogenism may also result from adrenal rests of the ovaries in congenital adrenal hyperplasia and from true hermaphroditism. PCOS has also been reported as a complication of portasystemic shunting. Impaired steroid metabolism has been postulated as the mechanism.

Other Causes of Functional Adrenal Hyperandrogenism. The PCOS type of primary (dysregulational) FAH occurs as an isolated entity, not associated with FOH, in about 25% of hyperandrogenic women. This may sometimes be an outcome of exaggerated adrenarche. This type of adrenal dysfunction was previously mistaken for nonclassic 3β-hydroxysteroid dehydrogenase deficiency, which is now known to be a rare disorder.[744] Less than 10% of adrenal hyperandrogenism can be attributed to the more well-understood disorders listed in Table 14-11. Most are due to nonclassic congenital adrenal hyperplasia, which accounts for less than 5% of hyperandrogenism in the general U.S. population, and to the various hyperandrogenic forms of Cushing syndrome. Prolactin excess causes adrenal hyperandrogenism, sometimes in association with polycystic ovaries. Adrenal hyperandrogenism can on rare occasions arise from cortisol resistance or apparent cortisone reductase deficiency.

Peripheral Androgen Overproduction. In nearly 10% of hyperandrogenic patients, an ovarian or adrenal source cannot be ascertained by thorough testing. This is idiopathic hyperandrogenemia. Obesity seems to explain some of these cases because adipose tissue has the capacity to form testosterone from androstenedione. Obesity may simulate PCOS by causing amenorrhea, acanthosis nigricans, and hyperandrogenemia. Other idiopathic cases may be due to hereditary quirks in peripheral metabolism of steroids.

Differential Diagnosis

Hyperandrogenism should be considered in any girl who presents with hirsutism or cutaneous hirsutism equivalents, menstrual disturbance, or central obesity during puberty. PCOS is by far the most common cause, and its manifestations are variable (Figure 14-44). Hirsutism, acne, and alopecia are inconsistently expressed manifestations of androgen excess. If acne vulgaris is unusually early in its age of onset, if severe acne is persistent, or if Accutane treatment is being considered, the possibility of hyperandrogenemia should be investigated. Androgenetic alopecia is manifest as a diffuse pattern in females.

Hyperhidrosis or hidradenitis suppurativa may be the only dermatologic manifestation. On the other hand, some of the cardinal symptoms or signs of androgen excess may not be present. Many cases of hyperandrogenemia are entirely cryptic. Menstrual irregularity of any sort (i.e., ranging from amenorrhea to dysfunctional uterine bleeding) that persists for 2 years has a two-thirds probability of being persistent and thus is an indication for workup for androgen excess. Conversely, a history of normal menstrual cyclicity does not necessarily indicate ovulatory cycles—and some cases are not diagnosed until they present as adults with unexplained infertility[745] or with recurrent miscarriages.[746]

Intractable obesity, large waist circumference (>88 cm), or acanthosis nigricans should raise concern for PCOS. The possibility of PCOS is heightened if the previously cited symptoms are associated with a history of prepubertal risk factors for PCOS, including congenital virilizing disorders; premature adrenarche, particularly exaggerated adrenarche; atypical sexual precocity; and intractable prepubertal obesity, particularly if associated with pseudo-Cushing syndrome, pseudo-acromegaly, or a family history of metabolic syndrome.

Most hyperandrogenic girls present when sexually mature and normoestrogenic. However, if there is any doubt about whether feminization is adequate and ongoing (as when the presenting symptom is primary amenorrhea) the

evaluation should include bone age, estradiol, and gonadotropin levels as outlined previously (Figure 14-41).

Hirsutism must be differentiated from hypertrichosis, the situation in which vellus hair predominates on "nonsexual" areas of the body. Hypertrichosis is not caused by sex hormone imbalance but appears with heredity, glucocorticoid excess, starvation, and medications such as phenytoins, cyclosporine, and valproic acid.[339]

The history and examination should also address risk factors for androgenic medications, other endocrinopathies (the most common of which are nonclassic congenital adrenal hyperplasia, Cushing syndrome, hyperprolactinemia, and thyroid dysfunction), and virilizing disorders. A rapid pace of development or progression of hirsutism, evidence of virilization (such as clitoromegaly, genital ambiguity, or increasing muscularity), or an abdominal mass would raise concern for an androgen-secreting neoplasm. However, tumors producing moderately excessive androgen can have indolent presentations.

The goals of the laboratory evaluation for PCOS are to attempt to document hyperandrogenism, to determine the specific etiology, and to provide a baseline in case it becomes necessary to reassess because of progression of the disorder. The diagnosis is on the firmest grounds if hyperandrogenism is demonstrated biochemically, rather than relying on hirsutism as a surrogate for it—although documentation of hyperandrogenemia can be problematic.

An approach to the workup that depends on assessing the degree of hirsutism and elucidating risk factors for virilizing disorders, androgenic medications, PCOS, and other endocrinopathies is suggested (Figure 14-46).[339] If hirsutism is mild and menses are regular with no evidence of risk factors that would suggest a secondary cause, it is reasonable not to pursue laboratory evaluation—given the high likelihood of idiopathic hirsutism (a cutaneous rather than endocrine disorder)—unless the patient is of Asian ethnicity. If hirsutism is moderate or severe or there are features to suggest an underlying disorder, excess androgen production should be ruled out. Risk factor assessment includes follow-up to evaluate response to therapy.

Plasma testosterone is the single most important androgen to evaluate. Plasma free testosterone is about 50% more sensitive in detecting excessive androgen production because hyperandrogenic women have a relatively low level of SHBG. Many commercial total and free testosterone assays are not suitable for the evaluation of women and children. Therefore, these assays are best performed by a specialty laboratory that has extensively validated them. Although other androgens are present in blood, their assessment makes little difference in management if plasma free testosterone is normal. However, the variation in androgen levels may miss an occasional case of nonclassic congenital adrenal hyperplasia and therefore further studies are indicated in patients at high risk by virtue of family history or ethnicity. These tests are most clearly interpreted when samples are drawn in the early morning of the mid-follicular (or anovulatory) phase of a menstrual cycle.

If androgen elevation is found, the next step in the differential diagnosis is ordinarily to obtain an ultrasound examination of the pelvis. A polycystic ovary is specifically defined as one that exceeds a critical volume (>10.8 cc in adolescents) or is polyfollicular (containing 10 or more follicles in the maximum plane).[463] The volume criterion assumes the absence of a dominant follicle (>10 mm in diameter) or a corpus luteum. Ovarian enlargement is the most solid criterion because multifollicular ovaries, normal in adolescence and present in other anovulatory states, are distinguishable from polycystic ovaries primarily on the basis of whether volume is normal or abnormal (which can be problematic).

These findings are not completely specific to PCOS and require excluding disorders that may secondarily cause PCOS. On the other hand, a negative ultrasound examination does not exclude nonclassic PCOS. However, it is useful in ruling out tumor and disorders of sexual differentiation as a cause of the androgen excess.[736] Simultaneous ultrasound imaging of the abdomen can be a cost-effective screening test for adrenal neoplasm in the hands of an experienced ultrasonographer.

Additional testing may include tests to exclude pregnancy and hyperprolactinemia. It may also include measurement of DHEAS and early-morning 17-hydroxyprogesterone if adrenal hyperandrogenism is suspected, and assessment for Cushing syndrome, thyroid dysfunction, or acromegaly if clinically indicated. If this evaluation for the most common disorders that mimic polycystic ovary syndrome is negative, the association of testosterone elevation with anovulatory symptoms or a polycystic ovary fulfills standard diagnostic criteria for polycystic ovary syndrome (Table 14-13). However, it does not exclude some fairly rare hyperandrogenic disorders. The approach to further studies to determine the source of hyperandrogenemia varies among subspecialists and with the needs of the individual patient.

Our preference is to use a dexamethasone suppression test to attempt to make a positive diagnosis of the ovarian or adrenal dysfunction of PCOS or to determine whether further workup is necessary for rare forms of CAH or other rare adrenal disorders (Figure 14-47).[736] The degree of suppression of plasma androgens and cortisol in response to a low-dose dexamethasone suppression test segregates patients diagnostically. Total testosterone levels of adrenal tumors fail to suppress more than 40% after a 2-day test.[747] A more prolonged course of low-dose dexamethasone is normally required to lower adrenal androgens below normal levels, and thus we prefer a "dexamethasone androgen-suppression test" (Figure 14-47).

Subnormal androgen suppression with normal adrenocortical suppression indicates a source of androgen other than an ACTH-dependent adrenal one. This is typical of PCOS if tumor or other ovarian pathology has not been found by ultrasound examination. If both cortisol and androgen suppression are subnormal, the androgen excess may be secondary to noncompliance with taking dexamethasone, to Cushing syndrome, or to defective cortisol metabolism or action. If androgen suppression is normal, ACTH (cosyntropin) stimulation testing to assess 17-hydroxyprogesterone and other steroid intermediates is recommended.

Further extensive diagnostic studies are seldom indicated unless there is reason to suspect a virilizing tumor

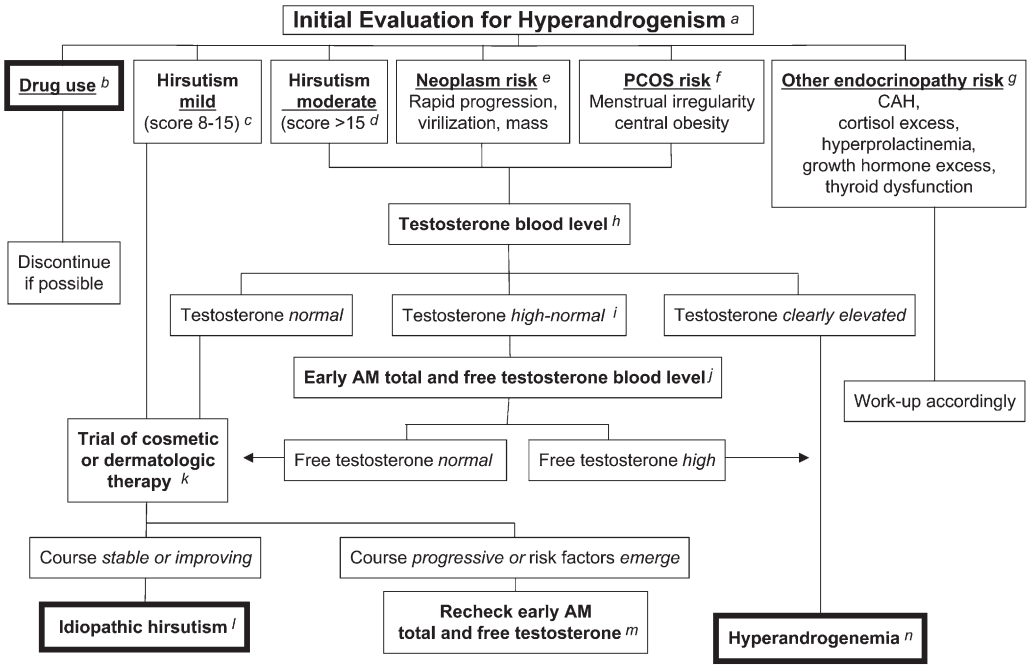

Figure 14-46 Differential diagnosis of hyperandrogenism and hirsutism. (*A*) Risk assessment includes assessment for the degree of hirsutism, menstrual irregularity, central obesity, and the other risk factors shown. Acne vulgaris, seborrhea, pattern alopecia, hyperhidrosis, and hidradenitis suppurativa are "cutaneous hirsutism equivalents" and may be alternative signs of hyperandrogenism. A small amount of sexual hair growth is normal (Ferriman-Gallwey score <8). However, if other risk factors are present (even in the absence of hirsutism) androgen excess should be considered. (*B*) Medications that cause hirsutism include anabolic or androgenic steroids (consider in athletes and patients with endometriosis or sexual dysfunction). Valproic acid, an antiepileptic drug, raises testosterone levels. (*C*) Mild hirsutism in the absence of the risk factors shown is likely to be idiopathic and to respond to cosmetic or dermatologic therapy. Therefore, it is reasonable to embark on these treatments without an endocrine evaluation. (*D*) Acne vulgaris of early onset or unresponsive to ordinary dermatologic measures, including antibiotic therapy, and pattern balding are similarly risk factors for hyperandrogenism. (*E*) Neoplasm risk is suggested by sudden onset, rapid progression, virilization, or an abdominal or pelvic mass. (*F*) In some hyperandrogenic cases, there is no cutaneous symptomatology ("cryptic hyperandrogenism") and androgen excess is suspected only because of menstrual irregularity, central obesity, or acanthosis nigricans. (*G*) The most common hyperandrogenic endocrine disorder other than PCOS in adolescents is nonclassic congenital adrenal hyperplasia (CAH). Risk is increased if family history is positive or in certain ethnic groups, such as Ashkenazi Jews (prevalence 1:27), Hispanics (1:40), and Slavics (1:50). (*H*) A random sample for plasma total testosterone is a reasonable screening test if reliable assessment of free testosterone is not available. At 8:00 a.m. during the mid-follicular phase of the menstrual cycle (days 4–10), the normal upper limit for plasma total testosterone is typically about 60 ng/dL (2.1 nM) for postmenarcheal adolescents when determined by a specialty laboratory. The upper limit of normal for plasma free testosterone under these conditions is 9 pg/mL (32 pM) in our laboratory. Unfortunately, the methodology for plasma free or bioavailable testosterone yields method-specific norms. (*I*) A high-normal testosterone level may not reflect a hyperandrogenic state if drawn after the early morning because of diurnal variation—or if only the total testosterone is initially assayed because the plasma free testosterone can be high when total testosterone is normal in that sex hormone binding globulin (SHBG), the major determinant of the bioavailable testosterone, is commonly low in hyperandrogenic women. (*J*) An early-morning plasma free testosterone determined by a specialty laboratory is indicated on days 4 through 10 of the menstrual cycle or during a period of amenorrhea, when the plasma testosterone is high-normal in patients with moderate or severe hirsutism, if features suggestive of other disorders are present or emerge, or if the response to cosmetic-dermatologic therapy is unsatisfactory. Simultaneous assay of 17-hydroxyprogesterone is indicated in subjects at high risk for CAH, which is suggested by a level greater than 150 ng/dL (4.5 nM)—and is virtually assured by a level greater than 1,200 ng/dL (36 nM). (*K*) Cosmetic therapies include bleaching, shaving, and waxing. Dermatologic therapies include topical eflornithine and laser treatment. OCP treatment is a useful and effective adjunct if hirsutism is more than minimal. (*L*) Idiopathic hirsutism may be mimicked by otherwise asymptomatic idiopathic hyperandrogenism, which may be due to atypical polycystic ovary syndrome or abnormal peripheral metabolism of prohormones. (*M*) Because testosterone undergoes episodic and cyclic changes in addition to diurnal ones, recheck is indicated if the course is progressive or risk factors emerge. (*N*) Hyperandrogenism with a polycystic ovary or menstrual irregularity in the absence of drug use, neoplasm, or other endocrinopathy meets standard criteria for the diagnosis of PCOS. Therefore, ultrasonic imaging of the ovaries and adrenal glands is usually advisable. See Figure 14-47 for potential further workup to determine the source of androgen excess. [Modified with permission from Rosenfield RL (2005). Clinical practice: Hirsutism. N Engl J Med 353:2578–2588.]

or a disorder of sexual differentiation. Further or alternative workup may include computed tomography for adrenal tumor, acute gonadotropin-releasing hormone agonist administration, or assessment of the response to hormonal suppression treatment to determine the source of androgen.

Management

Management is individualized according to symptoms and patient goals (e.g., hirsutism, acne, and alopecia; menstrual irregularity; obesity and insulin resistance) and the source of androgen excess.[339,736,737] Because PCOS is

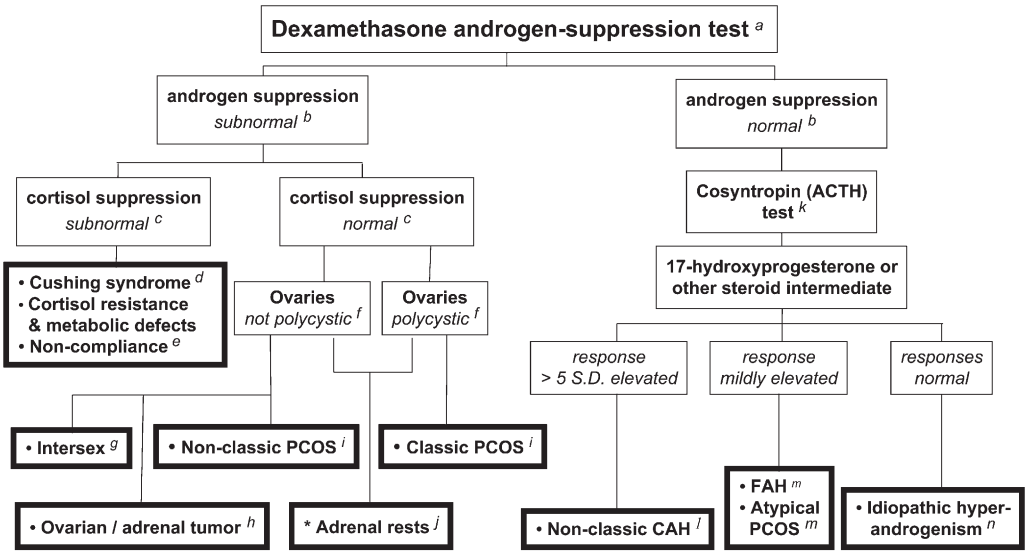

Figure 14-47 An approach to determining the source of androgen excess. The association of testosterone elevation with otherwise unexplained anovulatory symptoms (see Figures 14-42 and 14-43) or a polycystic ovary fulfills standard diagnostic criteria for PCOS, which in its various forms accounts for about 80 to 90% of adolescent hyperandrogenism. Determination of the source of excess androgen often permits a positive diagnosis of the characteristic FOH or FAH and rules out rare disorders that mimic PCOS. (*A*) Our standard dexamethasone androgen suppression test dose is 1 mg/m^2 in four divided doses (0.5 mg qid in adult) for 4 days, and plasma cortisol, free testosterone, 17-OHP, and DHEAS are measured on the morning of the fifth day after the final dexamethasone dose. For individuals weighing 100 kg or more, dexamethasone is given for 7 days. (*B*) Dexamethasone suppression of ACTH-dependent adrenal function normally causes plasma total testosterone to fall below 35 ng/dL (1.2 nM), free testosterone to below 8 pg/mL (28 pM), DHEAS by 75% to below 80 µg/dL (2.1 µM), and 17-OHP to less than 50 ng/dL (1.5 nM). Total testosterone is not as discriminating a criterion as the free testosterone (unfortunately, a method-dependent criterion) or 17-OHP criteria. Subnormal androgen suppression with normal adrenocortical suppression indicates a source of androgen other than an ACTH-dependent adrenal one. (*C*) Normally, cortisol falls below 1.5 mcg/dL (45 nM). (*D*) Cushing syndrome is an infrequent cause of hyperandrogenism and requires a more definitive workup. Hyperandrogenism has been reported in the rare conditions of cortisol resistance and cortisone reductase deficiency. (*E*) Subnormal cortisol suppression is most often due to noncompliance with taking dexamethasone tablets. (*F*) Ultrasonographic visualization of the ovaries by the vaginal route yields better definition than by the abdominal route, but this is not a generally acceptible technique in the virginal child. An adolescent polycystic ovary is defined as one with a volume greater than 10.8 cc or maximal area greater than 5.5 cm^2 or with 10 or more follicles in the maxmum plane. (*G*) Ovotesticular DSD patients may only have a clearly elevated plasma testosterone level in response to a midcycle LH surge, hCG, or GnRH agonist test. (*H*) The baseline pattern of plasma androgens may yield a clue to the type of tumor. A DHEAS level greater than 700 mcg/dL (19 µmol/L) is suspicious for adrenal tumor. In the absence of a high DHEAS, disproportionate elevation of plasma androstenedione relative to testosterone or elevated 17-hydroxyprogesterone is typical of a virilizing tumor. Poor dexamethasone suppressibility of testosterone and/or DHEAS is very suggestive of adrenal tumor. CT scan of the abdomen may be indicated in such cases. (*I*) Polycystic ovary syndrome (PCOS) is a symptom complex with various combinations of hirsutism or its cutaneous equivalents anovulation and central obesity. A polycystic ovary is a classic diagnostic criterion, but is not necessary or specific for the diagnosis. Nonclassic PCOS includes anovulatory hyperandrogenic girls who lack a polycystic ovary. Most have the typical PCOS-type of functional ovarian hyperandrogenism on dexamethasone suppression or GnRH agonist testing. (*J*) Virilizing adrenal rests of the ovaries may complicate congenital adrenal hyperplasia. They may resemble a polycystic ovary. (*K*) The standard ACTH test is performed by infusing 250 mcg ACTH1-24 intravenously over a period of 1 minute and obtaining a blood sample before injection 1 hour later. (*L*) Congenital adrenal hyperplasia (CAH) cannot be confirmed upon mutation analysis unless the steroid intermediates immediately prior to the enzyme block rise 5 standard deviations above average in response to ACTH. For 17-OHP, this is greater than 1,200 ng/dL (36.5 nmol/L). For DHEA, this is greater than 3,000 ng/dL (104 nmol/L) in adolescents. (*M*) *Primary functional adrenal hyperandrogenism* (FAH) is a term for idiopathic ACTH-dependent (dexamethasone-suppresible) adrenal hyperandrogenism in which modest rises in DHEA, 17-OHP, and so on do not meet the criteria for the diagnosis of congenital adrenal hyperplasia. It is often found in atypical PCOS. (*N*) Idiopathic hyperandrogenemia is distinguished from idiopathic hirsutism. About 8% of chronic hyperandrogenemia remains unexplained after intensive investigation, which includes GnRH agonist testing to detect the occasional case of ovarian hyperandrogenism not detected by the dexamethasone test. [Modified with permission from Buggs C, Rosenfield RL (2005). Polycystic ovary syndrome in adolescence. Endocrinol Metab Clin North Am 34:677–705.]

associated with metabolic syndrome, a fasting lipid panel and oral glucose tolerance test are recommended in patients with central obesity or hypertension.[748] The two-hour blood sugar during an oral glucose tolerance test deteriorates at an average rate of 9 mg/dL/year.[749] Because PCOS is closely related to parental metabolic syndrome, we recommend a similar evaluation of primary relatives.

Cosmetic measures are the cornerstone of care for hirsutism. Bleaching and shaving suffice for many. Depilating agents and waxing treatments are useful but are prone to causing skin irritation. Eflornithine hydrochloride cream brings about marked improvement of hirsutism in about a third of patients, with the maximal effect by 2 to 6 months. The FDA has permitted marketing of many laser devices, and equivalents such as diode and flashlamp, as effective for permanent hair reduction—for which the criterion is persistant reduction in hair density by 30% or more after three to four treatments of a site.

Wavelengths between 694 and 1064 nm damage hair follicles by combining relatively selective absorption of heat by dark hairs with penetration into the dermis. Light-skinned individuals are the best candidates, requiring the lower energy pulses. Those with heavily tanned or darker skin require the use of cooling procedures and adjustment of energy levels to minimize the risk of skin side effects. Laser treatment is coming to be preferred to electrolysis, but both types of treatment require trained personnel; are repetitious, expensive, and painful; are practical only for treating limited areas; and may result in local reactions, including burns, dyspigmentation, and scarring. Endocrine therapy is directed at interrupting androgen production or action. This causes the pilosebaceous unit to revert toward the prepubertal vellus type.

Endocrinologic treatment of cutaneous symptoms is indicated before undertaking treatment with laser treatment—using Accutane or Rogane if standard cosmetic or topical dermatologic measures are inadequate. The maximal effect on the sebaceous gland occurs within 3 months, but that on sexual hairs requires 9 to 12 months of treatment because of the long duration of the hair growth cycle. All are effective only as long as the patient wishes to maintain her improvement in hirsutism.

Combination oral contraceptive pills (OCPs) are the first-line endocrine treatment for women with the dermatologic or menstrual abnormalities of PCOS. They act by suppressing plasma androgens, particularly free testosterone, mainly by inhibiting ovarian function. They also raise SHBG and modestly lower DHEA sulfate levels. They normalize androgen levels within the first month of therapy.

All estrogen-progestin combinations generally suffice for women with acne or mild hirsutism, in combination with cosmetic measures. Those with nonandrogenic progestins, such as norgestimate or ethynodiol diacetate combined with 35 μg ethiny E2, have generally favorable risk-benefit ratios and optimize lipid profiles. Those with antiandrogenic progestins in low dose may confer an additional benefit. Drospirenone is available in the United States (with 30 μg ethinyl E2) and in Canada, Mexico, and abroad (with cyproterone acetate 2 mg with 35 μg ethinyl E2). The larger estrogen doses may be necessary in larger girls to provide menstrual regularity.

OCPs are also effective in management of menstrual irregularity, which requires treatment because chronic anovulation is associated with increased risk of developing endometrial hyperplasia and carcinoma. There are, however, several potential disadvantages to the use of OCPs in the management of PCOS in adolescents. They will bring growth to end in perimenarcheal girls. OCPs, particularly some third-generation OCPs, may be contraindicated in patients who are at risk for venous thrombosis. In patients with migraine headaches, OCPs should be used with caution and in the lowest estrogen dose possible. Patients may use OCPs as an excuse for not losing weight. The patient may believe that the treatment is curative and defer a definitive diagnostic workup. OCPs do not permit conception if and when it is desired. The long-term consequences of these agents on fertility are unknown. There is the theoretic possibility of post-pill amenorrhea because high-dose estrogen begun in early adolescence may increase the risk of infertility.[750]

It is advisable to recheck patients after 3 months of therapy to assess the efficacy of treatment and normalization of androgen levels. As a general rule, OCP treatment should be continued until the patient is gynecologically mature (5 years postmenarcheal) or has lost a substantial amount of excess weight. At that point, withholding treatment for a few months to allow recovery of suppression of pituitary-gonadal function and to ascertain whether the menstrual abnormality persists is usually advisable. In doing so, however, one must keep in mind that the anovulatory cycles of PCOS lead to relative infertility (not absolute infertility). The need for continued use of OCP for contraceptive purposes must be considered.

Progestin monotherapy is an alternative to OCPs for the control of menstrual irregularities. Micronized progesterone (Prometrium) 100 to 200 mg daily at bedtime for 7 to 10 days induces withdrawal bleeding in the majority of patients, but some do not respond—apparently because of an antiestrogenic effect of androgen excess on the endometrium. Breakthough bleeding is more likely with progesterone than with OCPs. Progestin therapy has the appeal of permitting the detection of the emergence of normal menstrual cyclicity. However, it does not normalize androgen levels and is not an adequate treatment if hirsutism or hirsutism equivalents are a problem. The perimenarcheal girl who responds well to progestin therapy can be maintained at approximately 6-week cycles to permit the detection of spontaneous menses. Side effects of progestin include mood symptoms (depression), bloating, and breast soreness. Patients must be informed that oral progestin dosed in this way is not a means of contraception.

Antiandrogens generally yield improvement in hirsutism beyond that attainable with OCPs. They can be expected to reduce the Ferriman-Gallwey score by 15% to 40%, although there is considerable variation among individuals. Antiandrogen use for this purpose is off-label because all carry the risk of causing pseudohermaphroditism of the male fetus. Therefore, all antiandrogens should be prescribed with a contraceptive—preferably an OCP. They may have a modest effect on the metabolic abnormalities associated with PCOS.[751]

Spironolactone in high dosage is the safest potent antiandrogen in the United States. We recommend starting with 100 mg twice a day until the maximal effect has been achieved, and then attempting to reduce the dose to 50 mg twice a day for maintenance therapy. Spironolactone is usually well tolerated, but it is contraindicated in patients with adrenal, hepatic, or renal insufficiency. Women are at risk of hyperkalemia if on potassium-sparing diuretics, potassium supplements, daily nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors, heparin, or such drugs. Therefore, electrolytes should be monitored. Alone, spironolactone tends to cause irregular bleeding.

Other antiandrogens used to treat hirsutism and hirsutism equivalents include cyproterone acetate, flutamide, and finasteride. Cyproterone acetate is a potent progestational antiandrogen used with estrogen in a reverse sequential regimen: 50 to 100 mg is given during days 1 to

10 of cycles in which estrogen is given from days 1 to 21. Flutamide is a more specific antiandrogen with efficacy similar to that of cyproterone and spironolactone, but it is more expensive and rarely causes fatal hepatic failure. Finasteride, a type-1 5-alpha-reductase inhibitor, seems less effective than other antiandrogens in the treatment of hirsutism and less effective in pattern hair loss in females than in males.

Although topical minoxidil is the only medication approved for alopecia treatment, antiandrogen-OCP therapy may be superior in those with PCOS. Insulin-lowering treatments, from weight loss to drug treatment, have about a 50% probability of improving menstrual cyclicity and ovulatory status—which seems greater than explicable by the modest reduction in androgen levels that they bring about.[268] The effect on hirsutism is neglible. Although weight reduction is indicated in obese PCOS patients, it is typically difficult to achieve.

Metformin appears to have more utility than thiazolidines in the management of adolescents because it suppresses appetite and enhances weight loss, albeit to a modest degree. It is most effective in combination with a behavioral weight-reduction program.[751] Therapy should start with 500 mg daily of the extended release form before the evening meal, with an increase in the dose by 500 mg per week to a maximal dose of 2,000 mg daily as tolerated. The larger doses are often better tolerated when divided into two daily doses. It is advisable to obtain a comprehensive metabolic panel at baseline and every 3 to 6 months, or as necessary, because of the rare complication of lactic acidosis.

Other hormonal manipulations may be useful in specific unusual situations. Prednisone therapy has little utility in the management of the hirsutism or menstrual irregularity of PCOS, although it may potentially be worth a trial in the atypical nonobese hirsute patient with isolated FAH as a single 5% to 7.5-mg bedtime dose. Gonadotropin-releasing hormone agonists are an oral contraceptive alternative when OCPs are contraindicated. They should be used with estradiol replacement therapy.

Future Directions

Tremendous advances continue to occur in our understanding of puberty. The identification of genes involved in ovarian differentiation, the discovery of new hormones and hormone receptors, new insights into the regulation of gene transcription and signal transduction, further identification of the role of genetic factors and prenatal imprinting on pubertal disorders, and advances in the application of mass spectrometry to steroid assays can also be anticipated to occur in the next 5 years.

We are in the midst of an explosion of information in the biological sciences. It is becoming clear that the body puts a wide but finite repertoire of hormones and growth factors to myriad and unexpected uses. Many concepts we hold dear at this moment are at the best likely to be shown to be oversimplifications; at worst, wrong. New information comes to light faster than we can assimilate it. The understanding of the interactions of the human genome with environmental factors can be expected to yield new insights into our understanding of puberty and its disorders.

Introduction

It has been more than 60 years since Henry Turner, an internist, reported the clinical characteristics of the seven patients whose phenotype now bears his name.[1] Six of these women are shown in Figure 15-1. These women had short stature in association with sexual infantilism, webbing of the neck, low posterior hairline, and increased carrying angle of the elbows (cubitus valgus). In 1930, Ullrich described an 8-year-old girl with short stature; lymphedema of the neck, hands, and feet; subsequent neck webbing, cubitus valgus, and other phenotypic abnormalities (including a high arched palate, ptosis, low-set auricles, and small upwardly curved nails); and several other features that are now associated with Turner syndrome. This gave rise to the less common but more appropriate eponym *Ullrich-Turner syndrome.*

Ullrich later recognized that his patients and those of Turner appeared to have the same condition.[2] He also called attention to the work of Bonnevie, who described a group of congenital anomalies in mice consisting of distention of the neck and malformations of the ears, face, and limb buds—all secondary to dissection of the subcutaneous tissues by fluid. This "bleb" mechanism for producing multiple anomalies was suggested by Ullrich as being responsible for the cervical lymphangiectasia noted in some human female abortuses that appeared to produce a scarred webbed neck (pterygium colli). Ullrich

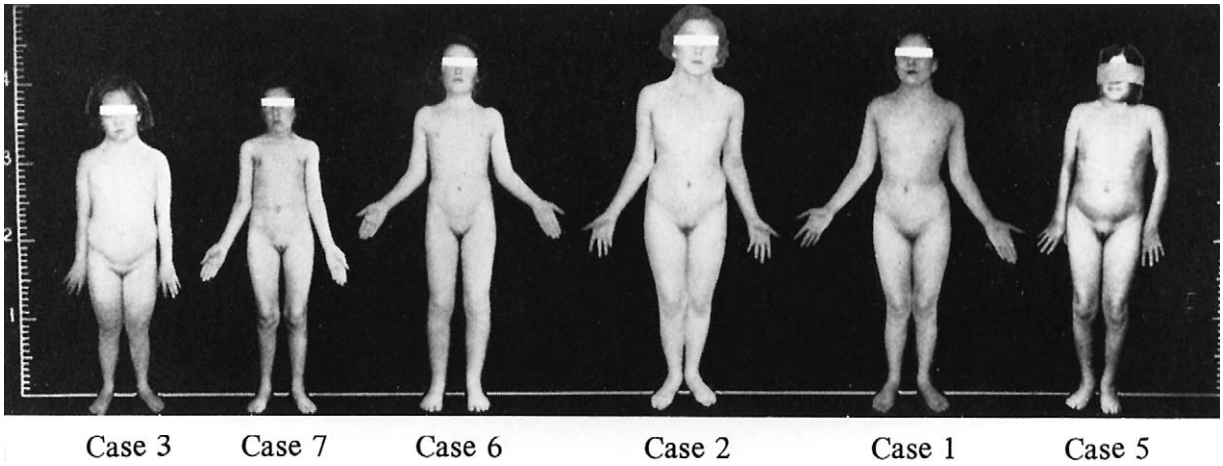

Figure 15-1 Patients exhibiting the syndrome of infantilism, webbed neck, and cubitus valgus. Note the height marker at the left indicating the short stature. [From Turner HH (1938). A syndrome of infantilism, congenital webbed neck and cubitus valgus. Endocrinology 23:566.]

proposed the eponym *status Bonnevie-Ullrich* to describe the set of specific anomalies arising from a single mechanism (lymphangiectasia) and resulting in the phenotype of Turner syndrome.

The links among these phenotypic descriptions, the pathologic evidence of streak ovaries, and the abnormal X chromosomes came with the introduction of the technique for sex chromatin identification by Barr and the demonstration that most patients with Turner syndrome lacked the sex chromatin material.[3] Initially, this absence of sex chromatin (or lack of a Barr body) was associated with "maleness" because a similar pattern was found in normal phenotypic males. Only after it was demonstrated that it was the second X chromosome that in the inactivated state constituted the Barr body was it clear that the 45,X karyotype would result in a chromatin pattern similar to the normal 46,XY karyotype.

It was not until 1961 that techniques became available for the analysis of the chromosomal constitution and the sex chromosome constitution was shown in a 14-year-old phenotypic female with Turner syndrome to be indeed 45,X.[4] Thus, Turner syndrome patients were not XY males but in most cases 45,X females. The original patient of Ullrich was studied in the 1960s and found to have a 45,X karyotype (D. Knorr, personal communication to the author). One of the original seven patients Turner described was also reinvestigated and found to have a 45,X chromosomal karyotype.[4]

The X Chromosome and the Chromosomal Karyotype

A chromosomal karyotype (prepared from peripheral leukocytes, skin fibroblasts, bone marrow elements, or tissue samples) should always be used in making the definitive diagnosis of Turner syndrome. The normal karyotype consists of 22 pairs of homologous autosomes and 1 pair of sex chromosomes. The chromosomes were classified originally into seven groups, A through G, according to the length of the chromosome and the position of the centromere. By convention, the short arms were designated by lowercase p (petit), whereas the long arms were assigned the next letter in the alphabet (lowercase q). The X chromosome has the characteristic of a C-group chromosome. It is similar in size and has a metacentric centromere. The Y chromosome, on the other hand, is a small structure—similar in configuration to the G-group chromosomes.[5]

If part of the short arm of one of the X chromosomes were missing, the karyotype would be reported as 46,XXp2. Similarly, if part of the long arm were deleted this would be designated 46,XXq2. Should a ring (r) chromosome be identified, composed of material with X-like staining patterns of both the short and long arms, it would be designated 46,X,r(X). In some cases, the ring X chromosome is tiny. Those patients with a small ring X may be much more severely affected than those with a nonmosaic 45,X karyotype. They may have severe mental retardation, developmental delay, profound growth retardation at birth, and multiple congenital anomalies—including dysmorphism (coarse facial features), epicanthal folds, upturned nares, long philtrum, hypertelorism, strabismus, soft-tissue syndactyly of upper and lower limbs, and increased frequency of heart defects (particularly ventricular septal defects and mitral valve stenosis).[6-8]

Small ring X chromosomes are more detrimental than large ones because they are unable to inactivate, and therefore some genes (those within the ring) are expressed from both the X ring and the normal X chromosome. It has also been shown that the X inactivation specific transcript (XIST) locus on the X chromosome is uniquely transcribed on the inactive X chromosome. It has been proposed that this locus is required for a chromosome to become inactive. Failure of X inactivation has been observed to result from deletion of the XIST gene or deficient transcription of XIST. Ring chromosomes may have a functional disomy for genes present on the ring, leading to the more severe phenotype. The XIST locus is expressed only from the inactive X chromosome residing at the putative X inactivation center. In patients

with tiny ring X chromosome XIST, transcription is therefore absent and the inability of these rings to be inactive is responsible for the severe clinical phenotype often associated with severe mental retardation.[9,10]

Another recognized rearrangement is when the entire X chromosome appears to consist of almost two complete long arms with little short-arm material or two short arms with little or no long-arm material. These structurally abnormal chromosomes are called isochromosomes, and the most common one is for the long arm [X,i(Xq)]. Banding and other molecular marker techniques have been used to number all regions of the chromosome, and very specific deletions, translocations, and rearrangements are designated by their numerical region on the short arm or on the long arm.

X CHROMOSOME GENES

Concurrent with the development of techniques for chromosome identification, cytogenetic, clinical, and experimental investigations were carried out to attempt to localize specific genes to the X chromosome and to characterize which regions of the chromosome are responsible for the genotypic and phenotypic abnormalities that occur in women with X chromosome disorders. It is beyond the scope of this discussion to review the historical data localizing the genes for such factors as the Xga blood group antigens and the genes for enzymes such as phosphoglycerate kinase and α-galactosidase to the X chromosome, except to mention that genetic studies of families often use the measurement of these gene products in linkage analysis.

Similarly, although a complete review of X-linked disorders (such as hemophilia A,[11] red-green color blindness, ocular albinism, muscular dystrophy, and ichthyosis) is not feasible here, it is noteworthy that full expression of these disorders has been reported in females with Turner syndrome. Genetic determinants for thyroxine-binding globulin is X linked as well, and thyroxine-binding globulin deficiency has been reported in a 45,X member of an affected kindred.[12]

With the introduction of molecular techniques for the exploration of the human genome, the X chromosome is being mapped at a rapidly expanding pace. The techniques include classic Southern blot analysis of DNA with X- or Y-specific probes, fluorescence in situ hybridization,[13] bivariate flow karyotyping,[14] and polymerase chain reaction amplification. Parenthetically, the fluorescence in situ hybridization technique (with both X and Y probes) can be applied to entire cells and tissues—not unlike a molecular version of the historical buccal smear—and is especially useful in identifying low-frequency cell lines and unknown markers.[15]

Numerous studies have examined the relationship between the chromosomal karyotype and the phenotypic characteristics that appear in Turner syndrome. In a classic article by Ferguson-Smith,[16] the karyotypes of 307 patients with various forms of gonadal dysgenesis were correlated with their clinical findings. He noted that short stature was the only clinical finding invariably associated with the 45,X karyotype. Complete gonadal insufficiency was not always present because seven patients with a 45,X karyotype demonstrated evidence of spontaneous puberty. He also noted that as a whole patients with mosaic karyotypes, including one normal XX line (i.e., 45,X/46,XX), tended to have fewer phenotypic abnormalities.

Save for a very few mosaic patients who were not short, however, on physical examination individual patients with mosaicism could not be readily distinguished from patients with the monosomic karyotype. Finally, he proposed that the area of the X chromosome responsible for the disturbance in growth was localized to the short arm of the X chromosome. Although banding studies were not yet available at the time of this study, the majority of these observations are still valid. A subsequent study of a large group of patients, which included banding,[17] confirmed that short stature is the only characteristic present in virtually 100% of patients.

Phenotypic abnormalities are most easily understood as resulting from altered dosage of certain genes.[18] Genes expected to have an altered dose in Turner individuals are those that escape the process of X inactivation and that have functional homologues on the Y chromosome. Molecular studies to further correlate critical regions with phenotype have tended to confirm the distal pseudoautosomal region (the region that participates in X-Y meiotic pairing and in which recombination takes place) of the short arm as the putative site of at least one stature gene.[19]

Although this idea was proposed in the pathogenesis of Turner syndrome for many years, only in the past several years have strong candidate genes emerged (Figure 15-2). Zinn et al.[20] have argued that there is locus in the interval Xp11.1-p22 encoding for the gene (or genes) pertinent to stature, and have proposed that the transcriuption factor ZFX is the likely candidate gene. To date, there are no genetic data available that would explain the soft tissue and visceral stigmata (such as lymphedema, webbing of the neck, and congenital heart failure) in Turner syndrome… It has been proposed that in primary lymphatic hypoplasia tissues and organs in the vicinity of the affected lymphatic system are secondarily affected.[21,22] In analogy to genes affecting skeletal and statural growth, it is inferred that a lymphogenic gene escaping X inactivation is present on the sex chromosomes. It has been suggested that genes residing in the vicinity of Xp11.3 are relevant to this issue.

USP9X (DFRX) is a second candidate for the Turner syndrome gonadal dysgenesis gene. DFRX (drosophila fat facets related X) is the human homologue of a fruit fly gene involved in oogenesis and eye development. DFRX escapes X inactivation and maps to Xp11.4, a region of proximal Xp implicated in ovarian failure. Two other candidate genes have been described on Xq. RPS4X encodes an isoform of ribosomal protein S4, which lies within a critical region for the lymphedema-related Turner syndrome phenotype and may also relate to poor viability in utero. Evidence against such a role has been reported.[20,21] DIAPH2 is the second gene and is the human homologue of the drosophila diphanous (DIA) gene. DIAPH2 is required for normal ovarian function.[2,22]

The prototypes of genes that would escape X inactivation and show expression from the Y chromosome are

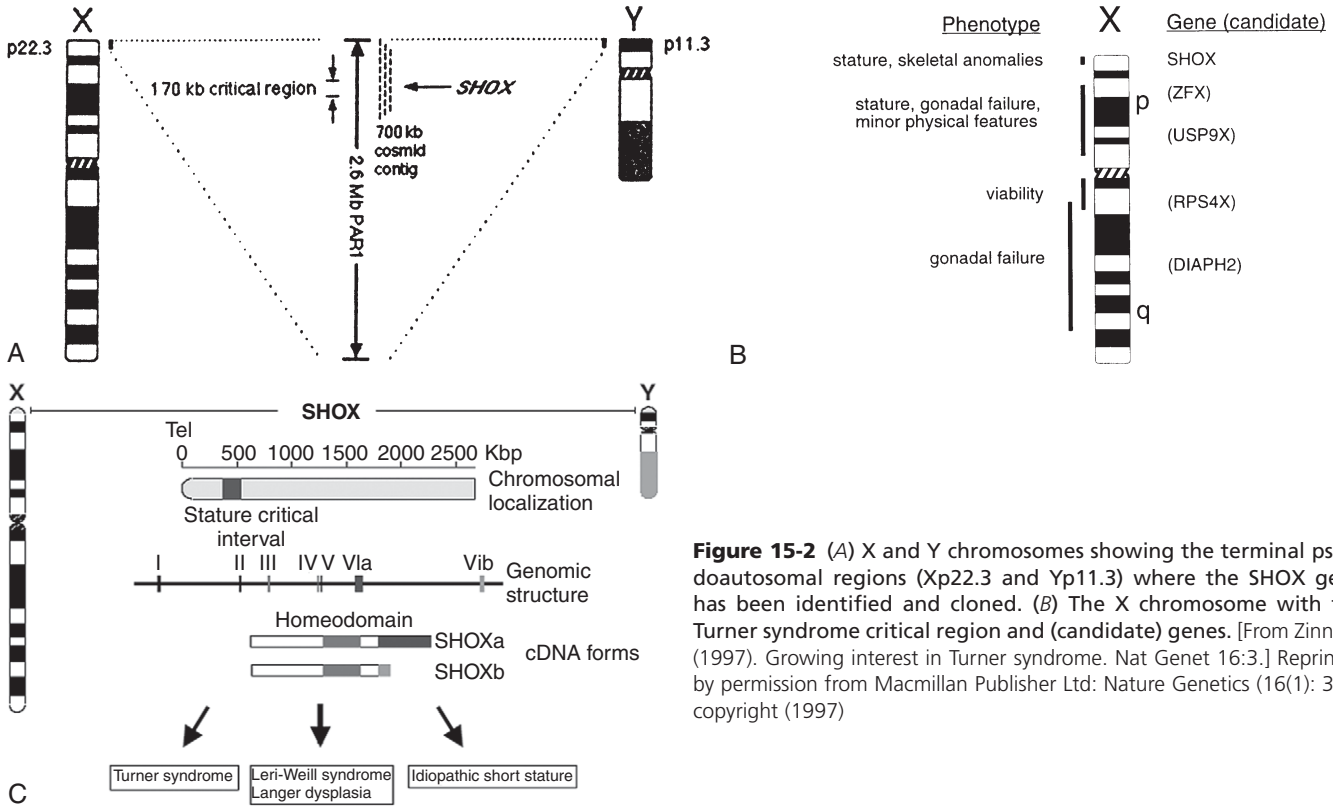

Figure 15-2 (*A*) X and Y chromosomes showing the terminal pseudoautosomal regions (Xp22.3 and Yp11.3) where the SHOX gene has been identified and cloned. (*B*) The X chromosome with the Turner syndrome critical region and (candidate) genes. [From Zinn AR (1997). Growing interest in Turner syndrome. genes in the pseudoautosomal region (PAR) of the X and Y chromosomes located at the distal ends of the short and long arms. In 1997, two groups[18,24] described independently a pseudoautosomal gene—both using a positional cloning strategy. The gene is 500 kb from the telomere of the sex chromosomes (Figure 15-2). It is located in the pseudoautosmal region 1 (PAR 1) on the distal end of the X and Y chromosomes at Xp22.3 and Yp11.3. Because genes in PAR 1 do not undergo X inactivation, healthy individuals express two copies of the SHOX gene: one from each of the sex chromosomes in 46,XX and 46,XY individuals. Because this gene contained a homeobox, it was named SHOX for "short stature homeobox-containing" gene.

There are two isoforms, SHOX A and SHOX B. Both forms were shown to be expressed from the active as well as the inactive X chromosome, with the highest expression levels in bone marrow fibroblasts. The SHOX gene covers a genomic region of approximately 40 kb, consists of seven exons, and encodes two transcripts generated by alternative splicing of its 39 prime exons. It is expressed highly in bone morphogenetic tissues. SHOX mutations have also been described in Leri-Weill dyschondrosteosis, a pseudoautosomal-dominant condition with greater penetrance in females than in males. These patients have shortening and bowing of the radius (with a dorsal subluxation) of the distal ulna, resulting in a dinner-fork-like twist (Madelung deformity) and with distal hypoplasia of the ulna and proximal hypoplasia to aplasia of the fibula (mesial segments). Haploinsufficiency of SHOX is thus the cause of Leri-Weill dyschondrosteosis deformity and probably part of the cause for the short stature seen in Turner syndrome.[25]

The rare homozygous (or compound heterozygous) form of SHOX deficiency is referred to as Langer mesomelic dysplasia. It is characterized by extreme dwarfism, profound mesomelia, and severe limb deformity. The elucidation of the role of SHOX in the growth failure of Leri-Weill dyschondrosteosis and Turner syndrome adds to our understanding of the multifactorial nature of growth.[26] SHOX is so far the only molecularly characterized growth gene on the X chromosome. Further evidence for SHOX as the short stature gene in Turner syndrome comes from XY females with interstitial Yp deletions and from 45,X/46,X,der (X) patients. These patients have Turner stigmata but are of normal size.

The Turner growth gene in the pseudoautosomal region is present in double dosage in these females.[22,27] Could SHOX haploinsufficiency also account for additional somatic features in Turner syndrome? SHOX expression also occurs in the first and second pharyngeal arches, ulna, radius, elbow, wrist, and equivalent bones of the leg. This suggests an involvement of SHOX-related growth impairment in the expression of additional somatic Turner syndrome stigmata such as high arched palate, abnormal auricular development, cubitus valgus, genu valgum, and appearance of the carpal bones (including the characteristic short fourth metacarpals).

The protein is specifically expressed in the growth plate in hypertrophic chondrocytes undergoing apoptosis, and appears likely to play an important role in regulating chondrocyte differentiation and proliferation.[28-31] The state of SHOX haplonsufficency appears to be substantially responsible for the average 20-cm height deficit in untreated women with Turner syndrome. These studies have led to the concept of SHOX

haploinsufficiency as a common underlying mechanism in the short stature of Turner syndrome, Leri-Weill dyschondrosteosis, and 2% to 15% of children with idiopathic short stature.[25,30]

Variations in the expression level of the remaining (intact) SHOX gene copy help to explain the variable severity in the manifestations of SHOX mutations. Alternatively, the cause for phenotypic variability might reside in chemical properties of the SHOX encoded transcription factor. An additional area that requires further study is the association of features of Turner syndrome with karyotypes that have no apparent X chromosome abnormality. One group of patients consists of those in whom the phenotype of webbed neck and short stature is associated with normal chromosomes in XX females and XY males. A group of these patients was described by Noonan,[32] who noted the frequent occurrence of pulmonic valvular heart disease. The eponym *Noonan syndrome* is applied to these patients.

This syndrome is often confused with Turner syndrome, and when it occurs in males it has been referred to as the male Turner syndrome phenotype. The chromosomes are normal in 46,XX females and 46,XY males who bear this phenotype, however. No point mutations in the SHOX gene have been described in patients with Noonan syndrome.[33] Their growth failure must have other causes, and a gene PTPN 11 encoding a tyrosine phosphatase SHP-2 as one of the causes of Noonan syndrome has been identified.[34]

Noonan syndrome patients with short stature (approximately 50%) respond poorly to growth hormone and may have some form of growth hormone resistance The gonads of the females do not show the early follicular loss or fibrosis characteristic of X chromosome abnormalities, nor is there a chromosomal abnormality in those males in whom cryptorchidism occurs. Therefore, Noonan syndrome in both males and females should be clearly separated from Turner syndrome. The nomenclature, evaluation, genetic counseling, and endocrine management that are appropriate to the female with Turner syndrome do not apply to patients with Noonan syndrome.

Another area of confusion arises from the demonstration of gonadal dysgenesis or aplasia in 46,XX females without demonstrable chromosomal abnormalities. In this condition, often called "pure gonadal dysgenesis," most of these patients tend to have normal phenotypes and normal stature—and some have similarly affected siblings, which is consistent with an autosomal-recessive pattern of inheritance. Finally, there is a group of phenotypic female patients with gonadal dysgenesis and a 46,XY karyotype. These patients (who should not be confused with those with testicular feminization) also have a genetic disorder affecting testicular induction such that gonads do not form. Thus, the concept of gonadal dysgenesis (elegantly reviewed by Opitz and Pallister[35]) includes a large number of disorders. For the purpose of this chapter, Turner syndrome will be used to describe the patient with an abnormality of the chromosomal karyotype involving loss of part or all of the X chromosome associated with phenotypic abnormalities that include short stature and the potential for or the presence of ovarian failure.

GENOMIC IMPRINTING

The selective silencing of certain alleles depending on the parent of origin is known as genomic imprinting. The putatively imprinted traits in Turner syndrome reflect typical differences between eukaryotic males and females. So far there are three areas in which X-imprinting effects have been found: cognitive function, statural growth, and possible visceral adiposity and lipid metabolism. They are at present rather preliminary and require independent confirmation as well as further work to define the genetic and epigenetic mechanisms.[36]

MULTIPLE X CHROMOSOMES

When there is an excessive rather than deficient number of X chromosomes, ovarian function may also be impaired. The incidence of the 47,XXX (triplo-X) karyotype in newborn phenotypic female infants is approximately 1:1,000.[37] The majority of these patients do not have obvious phenotypic or developmental abnormalities and would be unrecognized except for the research-based chromosome screening programs that identified them. When prospective studies are performed on women with the 47,XXX karyotype, however, infertility and gonadal failure are noted more frequently than in the normal population.[38]

Gonadotropins are increased in the plasma, indicating that the hypogonadism is caused by primary gonadal failure. Histologic data are scanty, but the mechanism of ovarian failure is presumed to be accelerated follicular atresia. Therefore, the manner in which this diagnosis is established is somewhat similar to that of the phenotypically normal patient with Turner syndrome. Primary gonadal failure per se, whether short stature is present or not, necessitates a complete chromosomal karyotype. Should the triplo-X karyotype be identified in a girl before pubertal development, however, assurance may be given that the majority of the patients are fertile. They appear to have a spectrum of neurodevelopmental disorders characterized by gross and fine motor dysfunction,[39] speech and language deficiencies, and a high incidence of psychiatric disturbances.[40] There is also a low incidence of chromosomal aneuploidy among their offspring.[41] Although amniocentesis might be performed during pregnancy, the value of this procedure in prenatal counseling is debatable.

The 48,XXXX karyotype is exceedingly rare,[42] with fewer than 50 cases reported. These patients are also phenotypic females, but they tend to have more phenotypic abnormalities—including skeletal dysplasias, intellectual impairment, and speech dysfunctions.[43] The skeletal abnormalities, including those of carrying-angle varus disturbances and radioulnar synostosis, are similar to those in Klinefelter syndrome. Thus, in contrast to the increased carrying angle of the 45,X patient or the normal angle of the 46,XX patient the angle of the 48,XXXX patient may be decreased to an extent indistinguishable from that of the 47,XXY or 48,XXXY male.

In these so-called tetra-X women fertility appears to be decreased to an extent even greater than in triplo-X patients. Again, primary gonadal failure is responsible.

Plasma gonadotropin concentrations in adolescence are helpful in predicting whether ovarian function and fertility will be normal. We reported one such patient in whom ovarian development was virtually absent. This case represents one extreme within the spectrum of the abnormality.[42] The penta-X karyotype 49,XXXXX has also been reported.[44,45] It is extremely rare, and the principal phenotypic features are those associated with microcephaly, postnatal growth failure, cardiac defects, and skeletal dysplasia (including radioulnar synostosis). The frequency with which gonadal function is impaired, however, is less well documented because the oldest patient was only 16 years old when reported.

This patient was still not fully pubertal, and this suggests that she had ovarian dysfunction. Thus, the evidence confirms that ovarian function may be adversely affected by the presence of multiple X chromosomes. The mechanism is unknown because the precise effect of aneuploidy, be it autosomal or X chromosomal, is unclear. The presence of an additional X chromosome or multiple X chromosomes, however, appears to accelerate the rate of follicular atresia in most patients. In some patients, such as our patient with apparent ovarian agenesis, normal induction of the ovaries may be impaired in the fetus. A possible mechanism for the ovarian failure could be impaired migration of the abnormally constituted germ cells. In no cases without demonstrable or presumptive Y chromosomal material has ovarian neoplasia been documented, and surgical intervention is therefore not indicated.

Turner Syndrome

INCIDENCE AND ETIOLOGY

The incidence of abnormalities in the sex chromosomal karyotype resulting in the loss of all or part of an X chromosome has been variously reported as 1:2,000 to 1:5,000 in live-born phenotypic females.[46,47] Population screenings by Barr body assessment were likely to have underestimated the incidence because mosaic or structural X abnormalities may have been missed. Studies with lymphocyte chromosomal analysis would have detected some mosaic karyotypes such as 45,X/46,XX [as well as some nonmosaic karyotypes such as 46,X,r(X)], but may have missed deletions and rearrangements. Finally, studies with banding techniques applied to the lymphocyte karyotype analysis would tend to detect minor changes in the architecture of the X chromosome (such as partial deletions or an X isochromosome) and should yield a higher incidence.

A standard 30-cell karyotype is recommended by the American College of Medical Genetics. This karyotype identifies at least 10% of mosaicism with 95% confidence, although additional metaphases may be counted or fluorescent in situ hybridization (FISH) studies performed if there is suspicion of undetected mosaicism. In rare instances, additional tissues (such as skin) need to be examined if there is strong clinical suspicion of Turner syndrome.[48]

Although clinical series using these techniques report a distribution of karyotypes with 45,X approximating 50%,[49,50] prospective newborn series might differ. In one prospective study of 34,910 newborn children (17,038 girls) born in Arhus, Denmark,[30] cytogenetic analysis detected nine karyotypes consistent with Turner syndrome for an incidence of 1:1,893 live female births. Of note is that only one of the nine had a 45,X karyotype. The other eight were mosaic and included a wide range of abnormalities. A compilation of studies of newborns from centers throughout the world suggests not only that the prevalence might differ in different populations but that within the same center the distribution of karyotypes is shifting toward much higher rates of mosaicism.[51] Whether this represents increased technical sophistication in detection or some biologic variable remains to be determined.

Our data for a group of 205 patients are shown in Table 15-1. The 45,X karyotype was found in 54.6%, which is consistent with the distribution reported in retrospective clinical series. This percentage, coupled with the prospective incidence data from Aarhus (including the low percentage of 45,X in that series), supports the calculation that the incidence of Turner syndrome in live-born females is at least 1:2,000. All series, including our own, include a small percentage of patients with cytogenetic evidence of a cell line containing a Y chromosome. For the most part, when those patients are examined they show no evidence of virilization. The same is true for the patients in whom a small marker chromosome, which could be derived from the Y chromosome, is present. The use of molecular techniques has improved the ability to detect Y-specific sequences. Thus, the DNA from Turner syndrome patients can be examined to determine whether the marker chromosome is of Y origin and to detect putative Y sequences in patients with no cytogenetically detectable Y material.

The significance of the detection of occult Y chromosomal material is twofold: the association with the risk of gonadoblastoma (see later section on gonadoblastoma for a clinical discussion) and the issue of mosaicism as it relates to fetal survival. With regard to the risk of gonadoblastoma, in one study polymerase chain reaction was used to amplify the gene for the sex-determining region of the Y chromosome (SRY) in a group of 40 patients with Turner syndrome.[52]

Although the authors detected a very low frequency (1:40) of unrecognized Y material (in an adolescent who had clinical evidence of androgen excess), they suggested that this test may be useful in screening all patients regardless of phenotype. Others,[53,54] who reported an even higher frequency of apparent SRY positivity with variable centromeric data, have made the same recommendation.

There is no evidence that the SRY gene confers a risk for gonadoblastoma. In fact, there is evidence to the contrary. Deletion analysis of genomic material from numerous patients with gonadoblastoma suggests that the putative gonadoblastoma gene (GBY) is located near the centromere, not on distal Yp.[55] A putative candidate gene, TSPY, has been identified by one group.[56] In addition, in a report of a girl with Turner syndrome, a gonadoblastoma,[57] and a small Y fragment that contained

* DNA was examined with Y chromosome–specific probes and found to contain Y sequences. Gonadal streaks were removed, and an in situ gonadoblastoma was found.

† Leukocytes examined by fluorescent in situ hybridization with X- and Y-specific pericentromeric probes showed presence of one cell line positive only for X probe and one cell line positive for both probes. Gonadal streaks were removed and were tumor free.

‡ Eight patients had removal of gonadal streaks. One macroscopic calcified gonadoblastoma and three in situ gonadoblastomas were found. Two patients who did not have surgery were lost to follow-up.

pericentromeric material SRY analysis was negative. This supports the assertion of Page[58] that in the absence of the centromere the presence or absence of SRY probably has little bearing on the risk of gonadoblastoma.

Conversely, if there is a clinical reason to test for occult Y material to assess gonadoblastoma risk, fluorescence in situ hybridization technology with Y-specific centromeric probes may be the applicable method.[59] Finally, in one population study of 114 Turner women there were no gonadoblastomas identified among 7 women with occult Y chromosomal material identified only by polymerase chain reaction, and only one gonadoblastoma identified among the 7 women with a karyotypic Y chromosome.[60] Thus, in the absence of a demonstrable marker chromosome or clinical evidence of virilization screening of all patients with Turner syndrome for Y sequences is not recommended by the authors at this time.[61]

Testing for Y chromosome material should, however, be performed in any Turner syndrome patient with a marker[61] chromosome. It should be stressed that the prevalence and clinical significance of cryptic Y material detected only by FISH or DNA analysis in patients without virilization or a marker chromosome need additional investigation. False positives may be a problem with highly sensitive PCR-based Y detection methods.[62] According to recent analysis of pooled data, true presence of Y chromosome material is associated with an approximately 12% risk of gonadoblastoma.[63] The current recommendation is for laparascopic prophylactic gonadectomy. It is often assumed that gonads in Turner patients with Y chromosome mosaicism have no reproductive potential, but spontaneous pregnancies in such women have been reported. Thus, preservation of follicles or oocytes may be a future option for some patients undergoing gonadectomy.[64,65]

The presence of occult chromosomal mosaicism, whether a second cell line contains a second X or Y chromosome, may relate to fetal survival. It is known that the number of affected live births reflects only a small proportion of total conceptuses with X chromosome abnormalities. It is estimated that 99.9% of 45,X conceptuses do not survive beyond 28 weeks' gestation and that the 45,X karyotype occurs in 1 of 15 spontaneous abortions.

It is believed that mosaicism accounts for some of the survival of apparent 45,X fetuses owing to a fetoprotective effect of more than one dose of some loci on the long arm of the X. One piece of evidence to support this hypothesis is that live-born infants with the X,i(Xq) karyotype constitute an unusually large percentage of Turner syndrome individuals compared to the proportion of this karyotype found in early abortuses.[46,47] In a cytogenetic and molecular study of 91 patients, low-level mosaicism—attributable to a second cell line (containing small marker chromosomes or small ring chromosomes)—was detected in cell culture of fibroblasts and lymphocytes from a high proportion of individuals originally diagnosed as having 45,X.[66] Finally, the expanded use of prenatal chromosomal analysis obtained by chorionic villus sampling or amniocentesis may document mosaicism that is not present at birth. Chorionic villus sampling demonstrates 45,X monosomy at a frequency of 1% compared to 0.08% at amniocentesis.

Although part of the discrepancy can be explained by failure of some 45,X pregnancies to survive or a tendency of monosomic cell lines to die out,[67] a proportion may be caused by anaphase lag during development of the cytotrophoblast but not the mesenchymal core of the villus.[68] Some discrepancies have also been reported between mosaicism detected on amniocentesis and results of postnatal karyotype analysis.[69] The significance of mosaicism and the differences between prenatal and postnatal karyotype go beyond issues of mechanism to create a significant genetic counseling dilemma. Termination of pregnancy for false positive 45,X results on chorionic villus sampling has been pointed out as a danger of this method.[70] In addition, all infants who have been diagnosed prenatally with Turner syndrome merit a repeat karyotype on delivery because maternal cell contamination, placental mosaicism, and other factors could result in differences between the prenatal and postnatal karyotype.

The 45,X/46,XY karyotype present in multiple cultures of amniotic fluid cells presents a different problem because this may be associated with a spectrum of phenotypes from normal female to normal male to genital abnormalities, including the phenotype of mixed gonadal dysgenesis. In a large collaborative international survey of more than 730 cytogenetic laboratories, 92 cases of the 45,X/46,XY mosaicism were identified.[71] Seventy-six patients had physical examinations either at birth or at

termination of pregnancy. Ninety-five percent had normal male genitalia, and only 5% had genital ambiguity or female genitalia with features of Turner syndrome. There was no association between phenotype and the degree of mosaicism. Ultimate gonadal function, stature, and tumor risk remain to be studied. Similar data were reported by Hsu. In her series of some 80 prenatally diagnosed patients, 74 (92%) had normal male external genitalia.[72] The role of prenatal ultrasonography as an adjunct in counseling was not evaluated in the series but is advocated by Hsu. These data contrast with a large series of postnatally reported patients with this mosaicism.[73]

In this series, there was a wide spectrum of abnormal phenotypes that could not be correlated with the degree of mosaicism found in blood. Therefore, with prenatally diagnosed 45,X/46,XY mosaicism the majority of patients will have normally appearing male genitalia at birth. Only determination by physical examination, starting in utero and completed postnatally (not by karyotype), can distinguish patients in whom male gonadal function is sufficient for complete masculinization of external genital development from those with genital ambiguity or normal female genitalia and a Turner phenotype.

The high incidence of X chromosome monosomy raises multiple questions about etiology. In abortuses, there is an inverse correlation with maternal age for the 45,X karyotype but not for mosaic or structural X abnormalities.[74] There is no correlation with maternal age for viable 45,X infants, however. Thus, young women do not have an increased risk for having a term infant with Turner syndrome—only for having the abnormality in a fetus spontaneously aborted. There are no data to support a positive or negative correlation between the 45,X karyotype in aborted or term pregnancies and paternal age. There is a suggestion that the mechanism responsible for the 45,X conceptus may be different from that responsible for structural X chromosome rearrangements. There is evidence, for example, that the X,i(Xq) karyotype is associated with advanced paternal age.[75]

If the mechanisms responsible for the loss of the X chromosome are not directly age dependent, the question arises whether there is a relationship between which chromosomes are lost and which are retained. Early studies of the parental origin of the retained X chromosome were performed with Xg blood group linkage but were often uninformative. The introduction of molecular techniques has made it possible to assign parental origin of the single X in almost all affected individuals. With this technique, Mathur et al. and others[76-79] have determined that there is no significant parental age effect between the groups retaining the maternal X or the paternal X. In addition, the ratio of maternal X to paternal X is just over 2-3:1, which is consistent with the expected proportion of meiotic or mitotic products—with equal loss at each step, given the nonviability of 45,Y.

Finally, Tsezou et al. and others[80,81] were unable to find significant differences in physical phenotype between the two groups—providing no evidence for a parental X-imprinting effect. This lack of X imprinting on physical phenotype is also suggested by the finding that there are no significant clinical differences in patients with Klinefelter syndrome between those with two maternal X chromosomes and those with one,[82] and by the report of mild stigmata of Turner syndrome without any other significant phenotypic disturbances in a patient with 45,X/46,XX mosaicism in whom all X chromosomes are of paternal origin.[83] Conversely, there are data to suggest that X-linked imprinted loci may have a subtle effect on neuropsychological function.

Skuse and co-workers[84] found evidence of an X-linked imprinted locus by comparing females with Turner syndrome who had retained the maternal X (Xm) to those who had retained the paternal X (Xp). In 80 45,X females these authors found 25 to be 45,Xp and 55 to be 45,Xm. Females with a single paternal X chromosome possessed superior social-communicative skills and high-order executive function skills compared with those whose single X was maternal in origin. Neuropsychological and molecular investigation of eight females with partial deletion of the short arm of the X chromosome indicated that the putative imprinted locus escapes X inactivation and probably lies on Xq or close to the centromere on Xp. These preliminary findings, which await confirmation, provide evidence for the evolution of an imprinted X-linked locus that underlies the development of sexual dimorphism in social behavior.

The association of a seasonal incidence with a birth abnormality such as Turner syndrome would implicate an environmental cause or an environmental effect on preservation of prenatal viability. When such associations are sought in Turner syndrome, the results are somewhat conflicting. However, when all of the series are reviewed significant peaks do not appear to emerge.

Other etiologic factors examined previously include birth order and sibling sex (for which there were no apparent associations) and twinning. In the latter, there appears to be a slightly higher occurrence rate for the 45,X[85] and X,i(Xq) karyotypes, although not at a level of statistical significance. At least three cases of Turner syndrome resulting from artificial insemination have been reported.[86] In two, studies of blood group antigens suggest that the lost chromosome was of paternal origin. In our series, one patient was the offspring from pregnancy by artificial insemination.

The issue of the relationship between autoimmune disorders and chromosomal defects is unresolved. It has been well documented that autoimmune phenomena occur with increased frequency, not only in Turner syndrome but in trisomy 21 and Klinefelter syndrome.[87] It has also been suggested that autoimmune disorders occur with increased frequency in first-degree relatives of affected individuals. Preliminary studies of the human leukocyte antigens (HLAs) of Turner syndrome patients and their families failed to show any preponderance of those specific types most commonly associated with autoimmune disorders (HLA B8 and Bw15).[88]

The role of environmental factors (such as maternal or paternal drug abuse or ethanol consumption, therapeutic medications, cigarette smoking, and so on) in the pathogenesis of Turner syndrome has not been systematically investigated or reported. The lack of evidence for any etiologic mechanisms responsible for the occurrence of Turner syndrome applies equally to the occurrence of the Turner-Down polysomy, or double aneuploidy syndrome.

In this condition, trisomy 21 is associated with a 45,X karyotype or mosaic cell lines for the X chromosome. Although this is a rare occurrence, its frequency is estimated to be greater than that caused by chance alone.[89] Similarly, the double aneuploidy for Down syndrome and Klinefelter syndrome occurs with a frequency greater than that expected from chance alone.

There does not appear to be an increased risk for the recurrence of the 45,X karyotype in families. X chromosome structural abnormalities may have an increased risk of recurrence because some deletions, for example, may be transmitted by the carrier of a balanced translocation[90] and others may be transmitted on the X by a mother with the Turner phenotype but preserved fertility.[91] There also are reports in the literature of trisomy 21 and Turner syndrome occurring in the same sibship.[92] We have two such sibships in our series. Taken in conjunction with the evidence that there appears to be an increased risk of a second defect occurring in most other chromosomal disorders, one would have to counsel parents accordingly. In the absence of significantly increased parental age, assignment of a risk figure of 1% may be reasonable.

PRENATAL DIAGNOSIS

The use of multiple modalities for prenatal diagnosis and pregnancy monitoring (including chorionic villus sampling, amniocentesis, maternal serum screening, and fetal ultrasound) has increased the number of conditions diagnosed prenatally, including that of Turner syndrome. Although the pitfalls of trying to correlate phenotype with prenatal genotype have been discussed in the previous section, the methodologies that increase the ascertainment of a Turner pregnancy and the issues of outcome based on the diagnosis merit discussion.

The measurement of concentrations of human chorionic gonadotropin (hCG), a-fetoprotein (AFP), and unconjugated estriol (uE3) in maternal serum in conjunction with maternal age has been used as a prenatal screen for Down syndrome and trisomy 18. The basis for the utility of this screen is that in fetal trisomy 21 the average hCG is higher than normal and the AFP and uE3 are lower than normal in the presence of fetal trisomy 21. As the screening programs progressed, it was noted that fetuses affected with Turner syndrome were detected among the pregnancies identified at risk for Down syndrome or trisomy 18. In these pregnancies, the abnormality in the screen was most consistently that of high hCG—especially in those with hydropic pregnancies, with more variable findings of normal or low AFP and uE3.[93]

Subsequent studies of the association of fetal hydrops and increased hCG have concluded that the morphologic defect of hydrops rather than the chromosomal aneuploidy per se may be the reason for the positive detection of the Turner fetus by maternal screening. In addition, second-trimester maternal serum progesterone levels and inhibin A are also elevated in the presence of Turner syndrome with hydrops—further supporting the concept that placental hypersecretion may be a consequence of hydrops rather than aneuploidy.[94]

Because cystic hygroma, increased nuchal translucency, and overt hydrops can also be detected by ultrasound—and ultrasound has detected these abnormalities in some pregnancies identified as at risk for Down syndrome and Turner syndrome by maternal fetal screening—the utility of fetal nuchal translucency as a primary screen for chromosomal abnormalities was evaluated.[95] In an unselected population of pregnant adolescents and women, Taipale and co-workers found a 0.8% incidence of nuchal translucency or cystic hygroma. Of the detected fetuses, 24% had an abnormal karyotype and 28% of these had Turner syndrome.

All of the fetuses with Turner syndrome had nuchal translucency consistent with hygromas. When fetuses with cystic hygroma are classified by gestational age, autosomal trisomies with cystic hygromas are more often seen in the first trimester and those with Turner syndrome in the second trimester and the fetuses that already demonstrate hygroma in the first trimester are more likely to spontaneously abort.[96] A characteristic ultrasound of a 14-week-old Turner fetus with a cystic hygroma is shown in Figure 15-3a and b, compared with a normal fetus in Figure 15-3c. Ultrasound and maternal serum screening are not diagnostic, and to make a prenatal diagnosis of Turner syndrome karyotype confirmation is necessary. Chromosomes should be reevaluated postnatally in all cases. The degree of mosaicism detected prenatally is not generally predictive of the severity of the Turner syndrome phenotype.[97]

The issue of fetal outcome is affected not only by karyotype and phenotype (hydrops and cardiac abnormalities, in which more 45,X fetuses and those with abnormal phenotypes will spontaneously abort than those with mosaic karyotype) but by decision for elective termination. Buckway and colleagues have reviewed a summary of a series of 24 published studies that reported that only 25% of prenatally diagnosed Turner syndrome pregnancies were continued after counseling, whereas in specific instances in a center with a long-standing developmental focus more than 50% of 45,X pregnancies and more than 80% of mosaic pregnancies were continued.[98] They also note that even the hydropic 45,X fetus does not spontaneously abort 100% of the time. Therefore, karyotype and phenotype are not necessarily always a predictor of a poor outcome—and knowledge of the heterogeneity of the phenotype is essential to informed counseling.

INDICATIONS FOR KARYOTYPE

The diagnosis of Turner syndrome should be considered in any female with unexplained growth failure or pubertal delay or any constellation of the following clinical findings: edema of the hands and feet, nuchal folds, left-sided cardiac anomalies, low hairline, low-set ears, small mandible, short stature, markedly elevated FSH levels, cubitus valgus, nail hypoplasia, hyperconvex uplifted nails, multiple nevi, characteristic facies, short fourth metacarpal, high-arched palate, and chronic otitis media.[61] Newborn screening underdiagnosis and delayed diagnosis remain a problem.[99] PCR-based screening methods to detect sex chromosome aneuploidy are feasible but have not been validated on a newborn population sample.

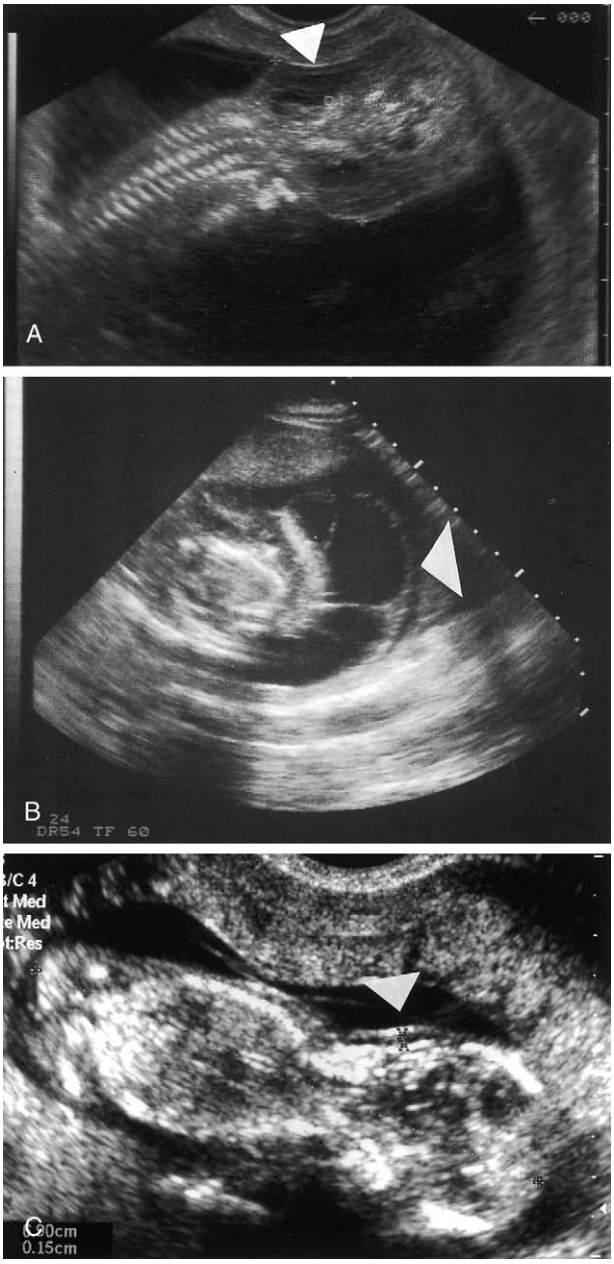

Figure 15-3 (*A*) Fourteen-week-old fetus with Turner syndrome and a cystic hygroma (arrow). (*B*) A 13-week-old fetus with a normal karyotype and normal nuchal translucency of 1.5 mm (arrow). (*C*) Same fetus as in view *A* in transverse plane. Large septated cystic hygroma (arrow) can be seen around the fetal neck. [Courtesy of Pekka Taipale, MD, PhD, Kuppio University Hospital, Finland.]

Again, positive findings will require karyotype confirmation. Screening using FSH levels at 1 to 2 years of age may also be useful.[100] Although upholding personal choice about reproduction is a widely embraced ethical principle, decisions to terminate a fetus with Turner syndrome should never be based on misunderstood or unbalanced information.[101-103] Outcomes of incidentally detected 45,X/46, XX mosaicism detected by screening on the basis of advanced maternal age, which incidentally is not associated with an increased incidence of Turner syndrome, often tend to be less affected than those diagnosed postnatally on clinical grounds.[97,104,105]

Clinical Findings

Since the original description of Turner, it has been recognized that there are a multiplicity of findings in patients with Turner syndrome—occurring with varying frequencies. More significantly, it has been recognized that the multiple findings may reflect a smaller number of fundamental events. In Table 15-2 and in the following discussion, the common features illustrated by the patients in our series are described—and when possible categorized according to the developmental defects proposed to be fundamentally responsible. What cannot be illustrated are the multiple combinations of findings that occur in any one patient. Thus, it is difficult to appreciate from Table 15-2 that in fact one patient may have only one of the many features described (whereas others may have multiple features).

Physical Features

SKELETAL GROWTH DISTURBANCES

The most common physical abnormality associated with Turner syndrome is short stature. The impairment is most pronounced along the longitudinal body axis (the entire problem of the growth disturbance in Turner syndrome is discussed in a subsequent section).[106] This gives affected individuals the visual appearance of being stocky or squarely shaped and accounts for the predominantly illusory finding of widely spaced nipples[107] and a shieldlike chest. In fact, when chest width and internipple distances are measured and ratios are calculated, the majority of patients do not differ from normal subjects of the same age. What differs is their overall height and the relative width to height of the thorax. Thus, the impaired longitudinal osseous growth is the primary defect.

Conversely, the short neck is not illusory but secondary in many cases to hypoplasia of one or more of the cervical vertebrae.[108] The osseous abnormalities responsible for the short stature are not limited to the cervical vertebrae. Our own data, and those of others, confirm that long bone growth may be impaired even to a greater degree than vertebral growth. Thus, there is disproportion in the axial segmental measurements resulting in short-leggedness and an abnormal upper-to-lower segment ratio.[109] The limbs themselves do not have the radiologic or histologic appearance of a true skeletal dysplasia, however. The low hairline, on the other hand, is secondary to the short neck and to the intrauterine mechanism responsible for the neck webbing (see "Lymphatic Obstruction").

Individual bones appear to be affected to varying degrees. For example, cubitus valgus is commonly appreciated. What this reflects is an increase in the carrying angle. Clinically, this can be measured as the angle of intersection of the long axis of the upper arm with the long axis of the supinated forearm when the elbow is fully extended. In radiographs, it is measured as the acute angle formed between the humerus and the ulna. Normally, in adult women this angle is approximately

TABLE 15-2

Clinical Findings Commonly Described in Patients with Turner Syndrome

Primary Defects	Secondary Features	Incidence (%)
Physical Features		
Skeletal growth disturbances	Short stature	100
	Short neck	40
	Abnormal upper-to-lower segment ratio	97

12 degrees—whereas in adult men it is approximately 6 degrees.[110] The major determinant of the angle is the depth of the inner lip of the trochlea of the ulna relative to the outer lip.

When this relationship is disturbed, abnormalities occur. In many patients with Turner syndrome the angle will be between 15 and 30 degrees (Figure 15-4) as a consequence of developmental abnormalities of the trochlear head. Thus, it is a skeletal abnormality responsible for a physical finding. That the development of the head of the ulna appears to be regulated by the sex chromosomes (and not, as has been previously inferred, primarily by sex hormones during puberty) is suggested by the abnormalities in Turner syndrome as well as by those in other disorders. The carrying angle is most pronounced with the 45,X karyotype, and the angle decreases progressively in association with XX and XY karyotypes. The angle further decreases, approaching cubitus rectus, in patients with an extra X or Y—and frank radioulnar synostosis and radial head dislocation occur in many patients with multiple extra sex chromosomes.[111]

The knuckle sign, a depression caused by diminished prominence of the head of the fourth metacarpal so that a straight edge can be placed between the third and fifth metacarpals, is another physical finding that occurs in a large number of patients. It, as well as the so-called knuckle-knuckle-dimple-dimple sign (reflecting a depression of both the fourth and fifth knuckles), is a consequence of abnormally small metacarpals. These signs may be seen on a bone age radiograph and are often clues to the possible diagnosis (Figure 15-5A). Short toes, owing to shortening of the metatarsals, may also be found.

Other deformities of the hand and wrist occur commonly. The carpal bones of the first line are frequently arched together abnormally. Superimposed on this is a further deformity (originally described by Madelung in 1898) occurring in 7.5% of our patients. This so-called bayonet deformity is caused by lateral and dorsal bowing

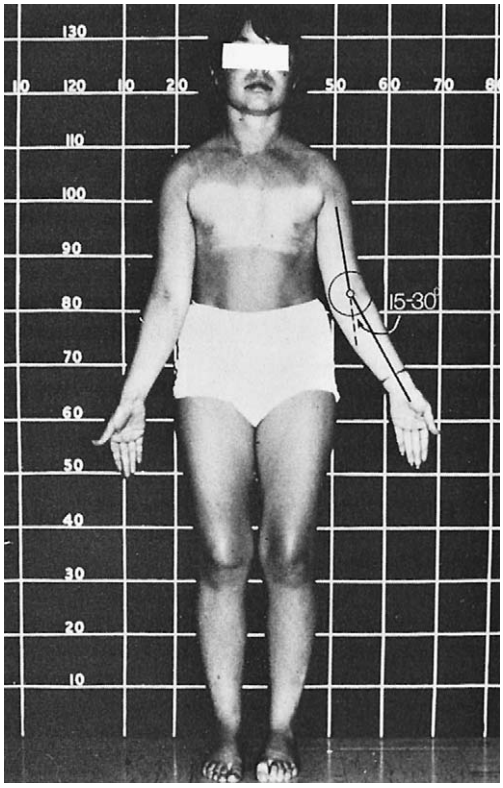

Figure 15-4 A 16-year-old girl with Turner syndrome and absence of puberty. Note absence of most characteristic stigmata save short stature and an increased carrying angle.

of the radius, coupled with the carpal crowding and dorsal dislocation or subluxation of the distal ulna (Figure 15-6).[112] It also occurs as part of the autosomal-dominant mesomelic chondrodystrophy, dyschondrosteosis, or Leri-Weill syndrome. We have discussed, in the section on the X chromosome, the SHOX gene on the short arm pseudoautosomal region (PAR 1) of the sex chromosomes.

Through other workers identifying the same gene simultaneously, the term *PHOG* (pseudoautosomal homeobox-containing osteogenic gene) was also introduced. Haploinsufficiency of SHOX has been shown to cause Leri-Weill dyschondrosteosis, as well as other limb skeletal anomalies—such as short fourth metacarpals and cubitus valgus. SHOX deletions or insertions accounted for all Leri-Weill syndrome cases in a recent review.[113] Thus, SHOX haploinsufficiency is common to Turner syndrome and Leri-Weill syndrome and accounts for the difficulty in the differential diagnosis. Although gonadal dysgenesis is not a feature of Leri-Weill syndrome, chromosomal analysis may be necessary to distinguish the two—especially in the prepubertal girl without an obviously affected parent. Conversely, gonadal estrogens may play a role in the development of skeletal lesions (in particular, the Madelung deformity) in both conditions.[114]

The mechanism may be that estrogens exert a maturational effect on skeletal tissues that are susceptible to premature fusion of growth plates because of haploinsufficiency of SHOX, thereby accelerating the development of skeletal lesions such as short fourth metacarpals and Madelung deformity. Both skeletal lesions are associated with premature fusion of epiphyses and may thus become evident in the peripubertal period. This may account for the more pronounced lesions in the girl with

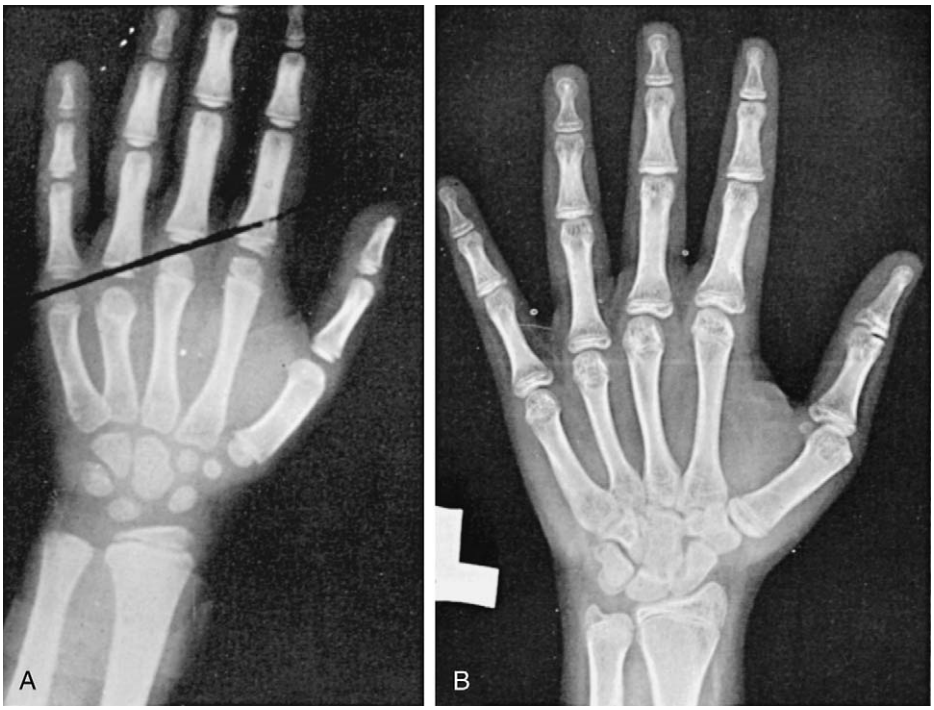

Figure 15-5 Two characteristic hand radiographs. (*A*) Short fourth metacarpal, the tip falling below a straight line drawn between the third and fifth metacarpals. (*B*) Generalized lacy ("fish net") appearance of the carpals and tufting of the distal phalanges, characteristic of the osteoporotic appearance of the bones of patients with Turner syndrome.

Leri-Weill dyschondrosteosis compared to the girl with Turner syndrome and for the failure of late estrogen therapy in the girl with Turner syndrome to induce Madelung deformity.

Scoliosis is reported in a significant number of patients. In our own series, 12.5% had a deformity. The cause was demonstrated radiologically to be secondary to obvious hemivertebrae in three patients and secondary to documented leg-length inequality, with a functional scoliosis occurring secondarily in two patients. In the remaining patients, no obvious bony deformities were noted—and the scoliosis was classified as idiopathic. That severity sufficient to warrant surgical correction has not been reported may be related to the lack of a pubertal growth spurt. As we begin to use more aggressive programs of hormonal treatment for growth acceleration, we may find an increase in clinically significant scoliosis—and appropriate measures should be taken to ensure its early detection.

The knock-kneed appearance of many patients described in the literature is caused by abnormalities in the medial tibial and femoral condyles. The medial tibial condyles are enlarged and project medially, the medial femoral condyles are enlarged and project downward below the levels of the lateral condyles, and the epiphyseal plates are deformed and displaced.[115]

The development of the face is also affected by a number of osseous malformations, contributing in part to the characteristic facies. The high incidences of micrognathia, antimongoloid palpebral fissures, downward droop of the outer corners of the eyes, and epicanthal folds are also consequences of defective facial morphogenesis. The palate is frequently abnormally arched, and when examined using maxillary casts exhibits deformities that differ from the more typical gothic or inverted V shape of other syndromes. Instead, an inverted U shape form and a form with a narrow vault and bulges of the lateral alveolar ridges have been described.[116]

Not manifest clinically but present radiologically is the osteoporotic appearance of the bones. Examination of the hand and wrist for bone age, a procedure frequently performed even before the diagnosis of Turner syndrome is established, often reveals this osteoporotic appearance. In some patients, the carpal bones may be so characteristically affected that the appearance (which we describe as fish net) has been reported as a clue to the diagnosis.[117] Others find that ballooning of the tips of the terminal phalanges is a most consistent finding.[118] Both findings are illustrated in Figure 15-5B.

That this osteoporotic appearance is observed in childhood suggests it may be more related to the developmental localization of SHOX than to primary estrogen deficiency. Both a primary skeletal disorder and estrogen deficiency could compromise bone mass, however. Bone mineral content and bone mineral density are reduced for age in children and adults with Turner syndrome, but these deficits are reduced or diminished when adjustments are made for small bone size and delayed bone maturation.[119-121] When looked at in a longitudinal fashion and when compared with control data related to body weight and pubertal status, no advantage was found with early estrogen replacement or growth hormone (GH) therapy in optimizing bone mineralization.[119,120]

Shaw and associates demonstrated normal bone density in children and adolescents with Turner syndrome using dual-energy x-ray absorptiometry.[122] In older adolescents and adults, a normal femoral neck bone mass is not achieved. This may be because of the low-dose estrogen therapy used by some (20 to 30 mg of ethinyl estradiol), which may simply not be enough. Thus, the risk of osteoporosis and fracture appear to be increased—particularly after age 45.[123-124] After adolescence, estrogen therapy seems to be the single most important factor in maintaining peak bone mass. In summary, the cause of the apparent early and true late osteopenia in Turner syndrome remains controversial. However, it is most likely the result of an intrinsic bone matrix defect combined with estrogen deficiency or inadequate estrogen replacement.[125]

LYMPHATIC OBSTRUCTION

The appearance of the 45,X fetus illustrated in Figure 15-7 dramatically shows the fetal edema that occurs in many concept uses with Turner syndrome. The edema appears to result from lymphatic malformations and obstruction.[126] This type of obstruction may result from a lag in the formation of a communication between the developing jugular lymph sac and the internal jugular vein. This communication normally develops between the fifth and sixth weeks of gestation, and failure to establish it appropriately results in lymphatic distention.[127] The search for the gene or genes on the X chromosome responsible for this developmental abnormality is underway.

The maldevelopment occurs most often in the nuchal region, with the dilatation of at least two cavities separated

Figure 15-7 A 45,X abortus demonstrating generalized lymphedema. Note the distended cervical region. With resolution of the edema, the redundant skin may cicatrize—resulting in a webbed neck. The edema of the hands and feet may persist and be present at birth. [From Gellis SS, Feingold M (1978). Picture of the month. Am J Dis Child 132:417. Figure 15-8 Lateral view of the face of a girl with Turner syndrome, demonstrating low posterior hairline, residual webbing, and micrognathia.

by the nuchal ligament. In many cases, each cavity is subdivided by incomplete septa. The cavities extend from the upper part of the occipital bone caudad to the scapular region and medially to beneath the sternocleidomastoid muscle. If the blockage persists, the increased pressure within the lymphatics may alter their development and result in the more generalized malformations of peripheral lymphatics. Peripheral lymphatic hypoplasia or aplasia has also been demonstrated using lymphangiography in adult patients with Turner syndrome.[21] Thus, as in the case of the mice with subcutaneous blebs described by Bonnevie a single process may be responsible for a host of the apparently varied physical findings in this syndrome.

Webbed neck, or pterygium colli, is perhaps the most obvious consequence of lymphatic obstruction. It results from a scarring process that affects the distended loose skin over the large cystic hygromas that were present in the nuchal region. Some patients may, therefore, have a severe anomaly. Others, however, who never had significant distention or in whom the obstruction was minimal or in whom rupture and decompression occurred early do not have a webbed neck. In fact, in some patients in whom neither webbing nor abnormalities of the cervical vertebrae exist the neck will appear long in proportion to the stature (Figure 15-4). Thus, webbing per se is not a primary anomaly. In our series, only 25% of patients had any webbing at all.

The dilatation of the nuchal region is also believed to be responsible for mechanical effects on the pattern of hair direction, resulting in the lower position of the posterior hairline (Figure 15-8). This may also be responsible for the heavy extended growth of the eyebrow. Similarly, the dilatation may result in rotation of the axis of the auricle posteriorly and elevation of the lower pinna—resulting in the prominent and low-set appearance of the ears.[128]

Edema of the dorsum of the hands and feet at birth is an obvious consequence of the incompletely resolved process if it involved peripheral lymphatics. Postnatally, the lymphedema usually resolves—although some patients demonstrate residual involvement. Others may complain of intermittent or recurrent edema, often after institution of estrogen replacement therapy. Less obvious are the mechanical effects the lymphedema may have had on the developing extremities. It is probable that the abnormalities in the nails described in many patients (deeply set into the nail bed with lateral hyperconvexity) are secondary to mechanical distortion of the developing nail bed.[129] Severely dysplastic or even absent nails are noted at birth in some patients as a more obvious consequence. The result on the fingertip pads is a predominance of dermal ridge whorl patterning, a characteristic dermatoglyphic feature.[129] A compressive or restrictive effect on the developing ossification centers resulting in some of what has been categorized as skeletal defects is also possible.

UNKNOWN FACTORS: EYE, EAR, SKIN

The factors responsible for several other common physical features are less clear. Strabismus and unilateral or bilateral ptosis occur more commonly than normal, contributing other features to the characteristic facies.

Multiple pigmented nevi, in excess of that expected from familial patterns, occur frequently and were noted in 26% of our patients. Several had surgical excisions of one or more lesions that had been subjected to trauma, and histologic examination did not show evidence of

Figure 15-9 Unilateral ptosis in a girl with Turner syndrome. Note also significant webbing of the neck on the affected side.

malignant degeneration. The mechanism responsible for the excessive presence of these lesions, especially on the face and arms, is unknown. Because migration of melanocytes into the skin begins at a relatively early stage (10 weeks), it is unlikely that this process is affected by the lymphedema.[130]

Physiologic Features

SKELETAL GROWTH FAILURE

Short stature appears to be the most common phenotypic feature of children and adults with Turner syndrome and has been noted in almost all articles and reviews since Turner's report in 1938. The first comprehensive assessment of cross-sectional and longitudinal growth and final height did not appear until the report of Ranke and colleagues in 1983.[131] Patterns of growth are illustrated in Figure 15-10, which shows cross-sectional height and velocity data from a series of 150 Turner children who had not received therapy for growth promotion.

These patterns described by Ranke and colleagues are distinguished by four components: intrauterine growth retardation [with mean birth length 1 standard deviation (SD) below the mean or an average reduction of 2.8 cm] and mean birth weight (not shown in the figure) of 2.18 kg, which is also 1 SD below the mean; a period of what initially appeared to be near-normal growth velocity for 2 to 3 years, which has now been characterized by growth deceleration to a mean of –2.18 SD at 1.5 years[132] and a further loss by age 3 years[133]; after age 3, continued deceleration, so that between ages 3 and 13 years the Turner syndrome girls fall farther and farther away from the normal height curves; and if untreated failure to experience a pubertal growth spurt but continued growth at a slow rate for several more years.

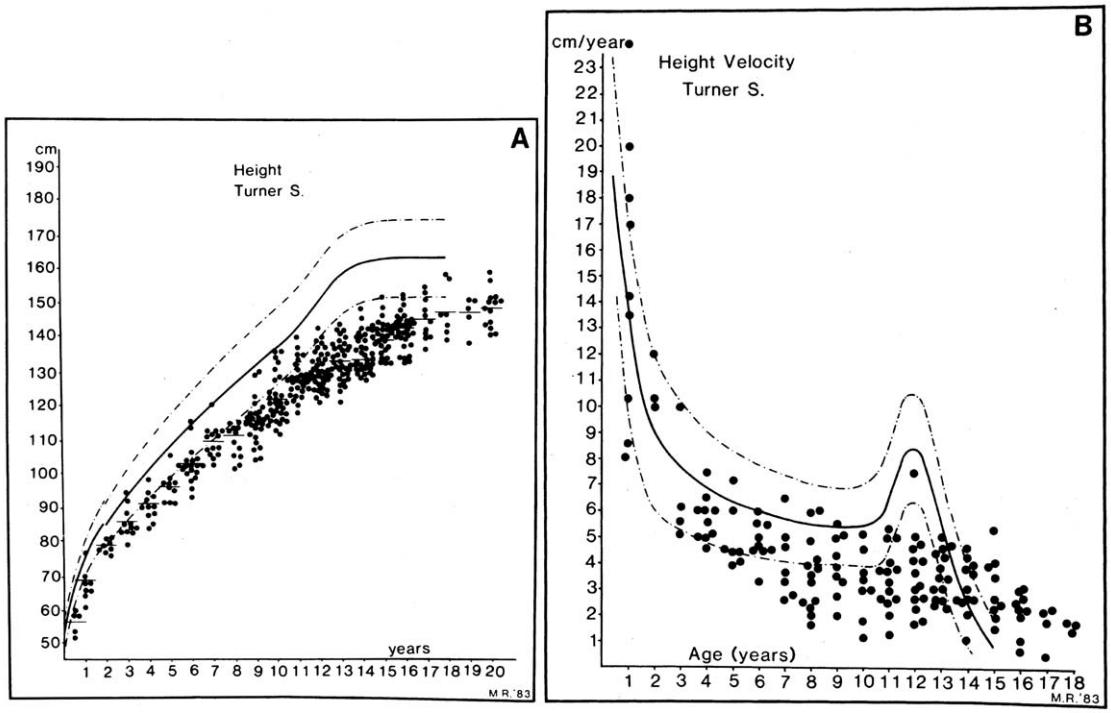

Figure 15-10 Height and height velocity in Turner syndrome. (*A*) Three hundred eighty-four single measurements of height for 150 children with Turner syndrome. (*B*) Height velocity from a total of 159 measurements. The normal ranges are shown by the heavy and dashed lines. [From Tanner JM, Whitehouse RH, Takaishi M (1965). Standards from birth to maturity for height, weight, height velocity and weight velocity: British children. Arch Dis Child 41:454, 613; and from Ranke MD, Pfluger H, Rosendahl W, et al. (1983). Turner syndrome: Spontaneous growth in 150 cases and review of the literature. Eur J Paediatr 141:81.]

A positive correlation is found among height at diagnosis,[134] ultimate height achieved, and midparental height.[135] The final height deficit, using comparative data on adult heights in patients with different ethnic backgrounds, is approximately 20 cm.[136] These authors concluded that the short stature was primarily the result of a generalized abnormality in the growth response of the skeleton but that other genetic factors such as a prolongation of cell generation time associated with the chromosomal disturbance per se[137] may also play a part.

Lippe et al.[138] have shown that disproportionate growth of the lower extremities appears to contribute, in some degree, to the short stature in Turner syndrome. In a group of 16 adult Turner syndrome patients not treated with growth hormone, the mean height was 144.2.0 cm, the sitting height was 79.6 cm, and the sitting height-to-height ratio was 0.55. This observation of a short lower segment has been confirmed by some,[139] but not all,[140] observers. In addition we found a significant negative correlation between the ratio of sitting height to lower segment and height, indicating that the patients with the greatest proportional reduction in the length of their legs were the shortest. The description of the SHOX gene and its role in statural growth, including mesomelic short stature, may explain the major component of the statural deficit (as discussed previously).

After the report of Ranke and colleagues,[131] Lyon and associates[141] used the data from that report and from three other European centers to synthesize a series of growth curves for Turner syndrome. The curves provided mean height and SD values for age. The mean adult height from these series was 143.1 cm. In the United States, we obtained 3,460 cross-sectional and longitudinal height determinations from 1,363 individuals to validate the applicability of these Western European–derived growth curves to U.S. girls with Turner syndrome.[142]

Our data (Figure 15-11, left) demonstrate that U.S. girls with Turner syndrome fit almost exactly the Lyon-Turner curve, with a final height of 144.3 cm, in 584 patients untreated with growth-promoting agents or estrogen before age 18 years. When the smoothed mean values (splines) are compared (right), there is a small but significant increase in the heights of U.S. girls between ages 12 and 16 that might represent the so-called spontaneous growth spurt that has been described by other groups with mathematical models.[143,144]

With their longitudinal patient data, Lyon and colleagues also noted a very strong correlation (0.95) between the initial height SD on these Turner curves and the adult height SD achieved regardless of whether the patient had received late estrogen replacement therapy and essentially independent of bone age at the time of the first height. Thus, they concluded that one could actually predict, or project, the adult height of a girl with Turner syndrome based on her height at an earlier age. In our study, we validated this projection method with a longitudinal assessment of 56 patients who had not received growth-promoting therapy and for whom we had both childhood heights and heights after the age of 18 years. The results showed a mean difference of less than 1 cm between the projection and the final height achieved. Data such as these have proved invaluable in assessing the efficacy of growth-promoting therapy.

Growth-Promoting Therapy

Early studies on the use of growth hormone (GH), dating back to the 1960s, yielded conflicting and inconclusive results.[145] Some studies were very short term, others did not use comparable doses of GH—and few patients were followed to adult height. This failure to confirm or preclude a role for GH was confounded by the debate

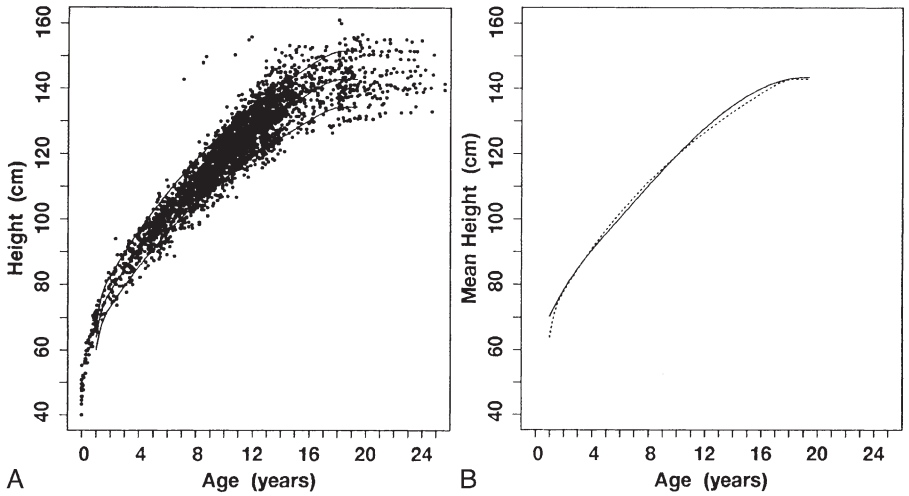

Figure 15-11 (*A*) Heights of American girls with Turner syndrome (superimposed on curves of Lyon and associates) representing the 10th, 50th, and 90th percentiles. (*B*) Spline fit to the American heights (solid curve) together with a dashed curve showing spline fit of Lyon European data. [From Lippe B, Plotnick L, Attie K, et al. (1993). Growth in Turner syndrome: Updating the United States experience. In Hibi I, Takano K (eds.), *Basic and clinical approach to Turner syndrome*. Amsterdam: Elsevier Science.]

over the status of GH secretion in Turner syndrome. Although it is clear that girls with Turner syndrome as a group do not have classic GH deficiency, there is no consensus on the nature of their secretory dynamics. In an international workshop on Turner syndrome, four groups reported differing data with regard to spontaneous GH secretion.[146-149] These differences in data persist even when age-matched groups are compared. For example, several groups found normal GH secretion in younger girls with Turner syndrome compared with their peers but not in older girls compared with normal adolescents.[150-151]

Although this might be expected because girls with Turner syndrome do not for the most part experience an estrogen increase with puberty, other groups have not found this difference at puberty.[152] In addition, when studied in a longitudinal manner ethinyl estradiol treatment resulted in increased GH pulse amplitude. However, in a cross-sectional study there was no difference in GH secretion between Turner syndrome girls with or without spontaneous breast development or with or without estrogen therapy.[153] These data are further confounded by methodologic differences in assessment,[154] assay differences,[155-156] and biologic variables such as body weight differences[157] between Turner syndrome girls and normal girls. Because the consensus is that there is no GH deficiency, however, provocative GH testing is obsolete and need not be performed unless growth velocity is abnormal relative to that expected for Turner syndrome.

The use of anabolic steroids in Turner syndrome also dates back to the 1960s,[158] but their efficacy in increasing final adult height is still being debated. Some studies indicate that augmented growth velocity may not be accompanied by a concomitant bone age increase and suggest that ultimate height is increased.[159-161] Others either found no differences in adult height between androgen- and estrogen-treated girls[162] or pointed out that over time changes in stature could make the results difficult to interpret if treated patients were compared with untreated controls of previous years.[163]

Of the more recent studies, two conclude that androgens alone do have a positive effect on final height[165-166] and two conclude that they do not.[166-167] Our retrospective analysis of growth data failed to demonstrate that anabolic steroids promoted a statistically significant increase in final adult height. We and others,[169,170] however, have confirmed that they do promote marked growth acceleration in the first year or more of therapy—which was perceived as highly beneficial by the patients and their families.

The use of a combination of androgen and GH was first reported in 1980, and it was suggested that short-term combination therapy might promote more rapid growth than either agent alone.[170,171] The availability of unlimited recombinant human GH has made it possible to conduct carefully designed studies and to evaluate the growth response to GH and the combination of GH with androgens and/or estrogens. This forms the basis for a large U.S. multicenter study that has now been completed.[171] In 1983, this multicenter prospective randomized trial of recombinant human GH alone and in combination with oxandrolone was initiated.

The mean adult height for the 17 recipients of GH alone was 150.5 cm, which was 8.5 cm above their projected adult heights. For the 43 subjects treated with a combination of GH and oxandrolone, the mean adult height was 152.2 cm—10.4 cm taller than their projected adult heights. Fifty-eight of the 62 GH-treated subjects (94%) attained an adult height greater than their projected adult heights. The mean adult height attained by a retrospective control group as part of this study was 144.3 cm (Figure 15-12). These results compare favorably not only with the matched American control group but with previous reports of final heights in girls with untreated Turner syndrome from the United States and many other countries.[131,142,147,172-176]

The increment in final height, above the projected adult height, of the group receiving combination therapy was modestly but significantly greater than that in the group receiving GH alone (2.9 + 0.5 cm). This improved growth response was attained despite the fact that GH administration in the combination group was 1.5 years briefer than in the group receiving GH alone.

Combination therapy appears to offer certain advantages over GH alone: increased growth over the first 6 years of treatment (37.3 cm for the combination group versus 31.2 for GH alone), thereby allowing for better normalization of height during childhood; potential for earlier initiation of estrogen replacement because girls will have attained greater heights by adolescence with

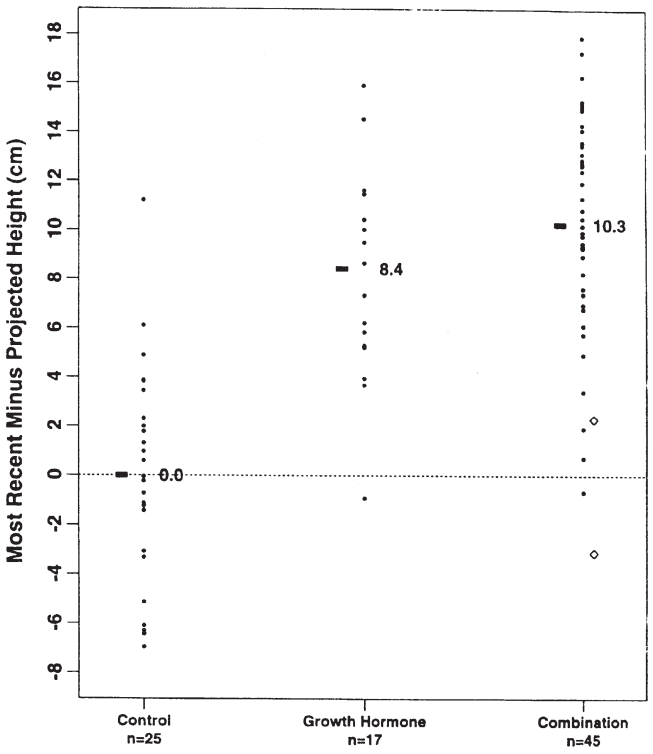

Figure 15-12 Most recent height of each subject (or American historical control subject) relative to each subject's projected adult height (indicated by dotted zero line). Mean increment in height (in centimeters) relative to projected adult height is indicated. Diamond symbols in the combination group indicate the two subjects who discontinued treatment early. [From Rosenfeld RG, Attie KM, Frane J, et al. (1998). Growth hormone therapy of Turner's syndrome: Beneficial effect on adult height. J Pediatr 132:319.]

combination treatment; and a briefer requirement for GH. Side effects associated with oxandrolone, 0.0625 mg/kg/ day, were minimal—and skeletal maturation averaged only 1.04 years per year of treatment. Experience with oxandrolone in young girls with Turner syndrome (6 years old) is limited, however, and it remains unclear whether it is better in young patients to initiate therapy with GH alone or in combination with oxandrolone.[170] In several other studies in which older Turner syndrome patients were treated with lower doses of GH, improvement of height was not as satisfactory.[176]

The results of the U.S. study also compare favorably to preliminary data from a second U.S. study[177] looking both at the role of GH and at the role of early versus late estrogen therapy. Twenty-nine girls receiving GH alone (plus estrogen replacement at 15 years of age) achieved a mean height of 150.5 cm, which was 8.5 cm above their projected adult heights. This is almost identical to the results of the first U.S. study. The 26 patients in whom estrogen therapy was initiated at age 12 gained only 5.1 cm on average beyond their projected height and achieved a final height of 147.1 cm (Figure 15-13).

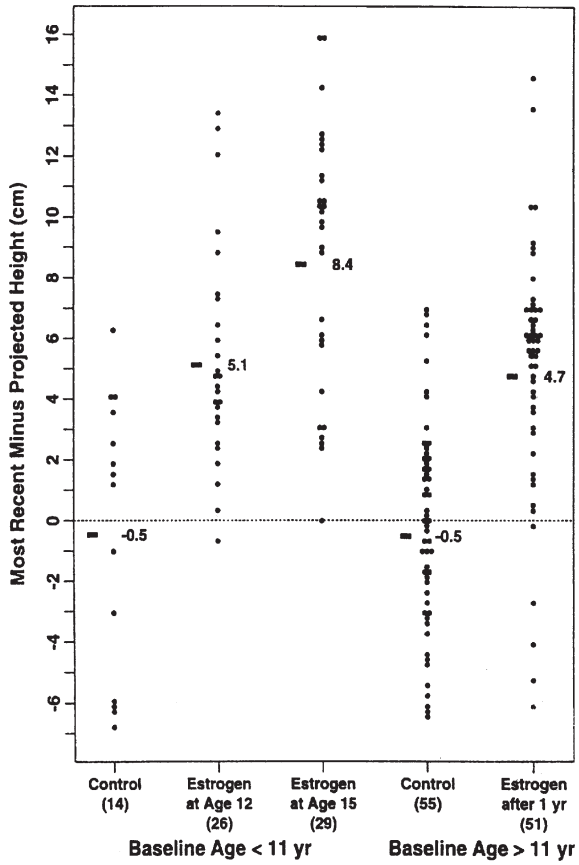

Figure 15-13 Height gain for patients treated with growth hormone compared with controls. Data are plotted for individual patients, with the most recent height minus the pretreatment projected height determined as indicated in the text. The mean values for each group are indicated by a dash. Control patients were matched from a historical database (as described in the text). [From Chernausek S, Attie KM, Cara JF, et al. (2000). Growth hormone therapy of Turner syndrome: The impact of age of estrogen replacement on final height. J Clin Endocrinol Metab 85:2439.]

A multivariate analysis was used to examine several factors that might influence the gain in stature. The number of years of GH therapy before estrogen treatment was a strong predictor. These data show that the early introduction of estrogen has a significant negative impact on adult height. Several published studies have reported that GH therapy results in an average height gain of 5 to 10 cm, a range that represents a surprising variability in outcome.[171-182] It appears that at least some of this variability may be caused by differences in the ages in which estrogen therapy was begun in these patients. Some of the reports showed that patients who had more modest apparent gains in final height also had relatively short periods of GH administration before the introduction of estrogen therapy.[180,182]

The method used to estimate what the adult height would have been without treatment with GH will affect the observed gain in height. Attie and Frane[183] compared five methods of predicting adult height in patients with Turner syndrome, using data from patients with Turner syndrome in the United States who had not been given growth-promoting drugs. They found that the Lyon projection method,[141] used in the two U.S. studies previously discussed,[171,177] was one of the most reliable means of predicting adult height—with the mean error of overprediction being only 0.3 cm.

Several studies that did not achieve such reassuring gains in final height[180,182] were also utilizing lower GH doses than the U.S. study groups.[171,177] This became particularly apparent in elegant studies carried out by the Dutch Advisory Group on GH.[184] Their final assessment of 7-year data clearly shows that in a carefully conducted dose-response study the increased dose of GH led to impressive increases in final height exceeding even the data seen in the U.S. studies. These investigators treated 68 patients with chronologic ages between 2 and 11 years and heights below the 50th percentile for healthy Dutch girls. The dosages employed were from 1.3 mg/m^2/day (0.23 mg/kg/week) to as high as 2.7 mg/m^2/day (0.63 mg/kg/week). It is clear from this study that there is a dose-response curve and that patients with the higher GH dose grew significantly better.

The patients were divided into three groups. In the first year, all three groups received GH at the starting dose of 1.3 mg/m^2/day. In the second year, two groups were switched to doses of 2 mg/m^2/day. In the third year, one of these two groups was switched to 2.7 mg/m^2/day. All were then treated at these doses for the remainder of the study period. After 7 years of GH treatment, mean final heights were 159.1, 161.8, and 162.7, respectively, for the three groups. These investigators concluded that after 7 years of GH treatment most girls with Turner syndrome are growing within the height range for healthy normal girls (Table 15-3, Figure 15-14). In fact, adult height was above 170 cm in 5 girls and above 160 cm in 17 girls. Growth-promoting therapy in these patients was not marked by any major clinical or metabolic side effects (see "Safety of Growth-Promoting Therapy"). Concerns about elevation of IGF-1 levels during GH therapy in Turner syndrome would suggest that inappropriate elevation of IGF-1 levels in the long term should be avoided.[185]

TABLE 15-3

Final Height in Turner Syndrome

	Dose	Final Height (CM)	Gain (CM)	Duration of Treatment (YR)
U.S. study (Genentech)* GH (n517)	0.375 (mg/kg/wk)	150.465.5	8.464.5	7.662.2

GH, growth hormone; and NCGS, Genentech's National Cooperative Growth Study.

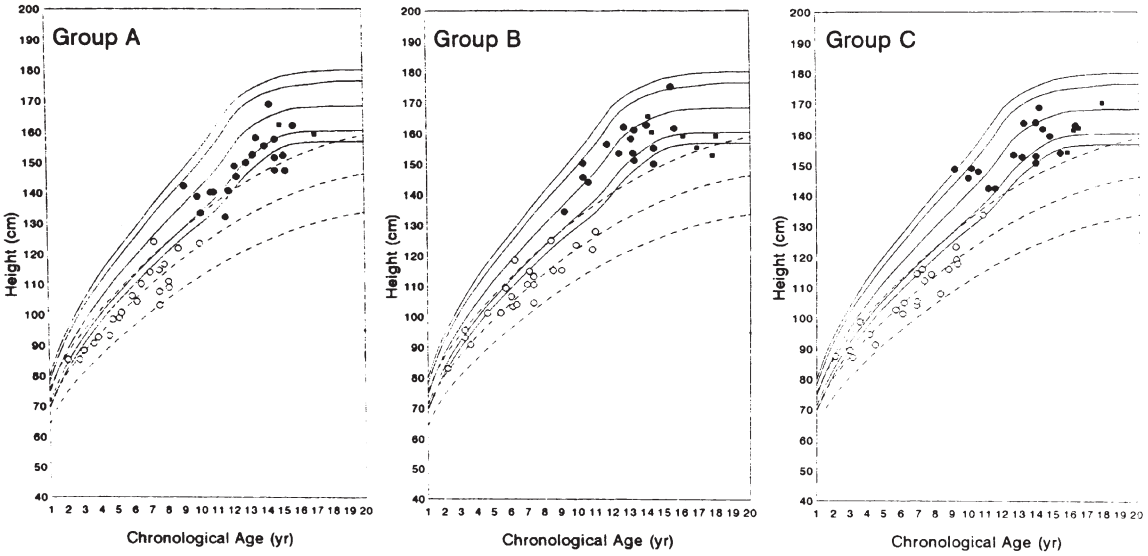

Figure 15-14 Individual heights at the start of the study (s) and after 7 years of growth hormone (d) in groups A, B, and C, respectively. Twelve girls had completed the trial during the 7-year study period (j). Reference curves for healthy Dutch girls (3rd, 10th, 50th, 90th, and 97th percentiles) and for untreated girls with Turner syndrome (North European references for 3rd, 50th, and 97th percentiles) are given. [From Sas TCJ, de Munick Keizer-Schrama SMPF, Stijnen T, et al. (1999). Normalization of height in girls with Turner syndrome after long-term growth hormone treatment: Results of a randomized dose-response trial. J Clin Endocrinol Metab 84:4607.]

In summary, it should be pointed out that final height data reported by many groups in different countries using different study protocols are most likely conservative estimates of the effect of therapeutic intervention with GH on height potential in patients with Turner syndrome. Many of these patients were enrolled at older ages, thus limiting the duration of GH therapy. Doses of GH employed were often well below the mean dose of 0.33 mg/kg/week used in the United States.[186] Some investigators began estrogen replacement in patients as early as age 12 years and used relatively high dosages of estrogen. This will only hasten epiphyseal fusion and thus compromise height potential.

In general, one can expect only 18 to 24 months continued growth after the initiation of estrogens. If there is still a large height deficit at 12 to 13 years of age, estrogen therapy should be delayed. There is no evidence that low-dose estrogen given at any age in growth-promoting dosages before it is used for induction of puberty is advantageous, and it may even curtail final height[187] (although spontaneous puberty per se does not appear to reduce final height).[188] However, the magnitude of the benefit has varied greatly depending on study designs and treatment parameters. Factors predictive of taller adult stature include a relatively tall height at initiation of therapy, tall parents, young age at initiation of therapy, a long duration of therapy, and a high GH dose.[61,189]

Therapeutic regimens aiming at early GH treatment initiation and optimizing the dose of GH may well allow for normalization of height during school-age years and thus earlier introduction of estrogens.[170,177,189] The recently

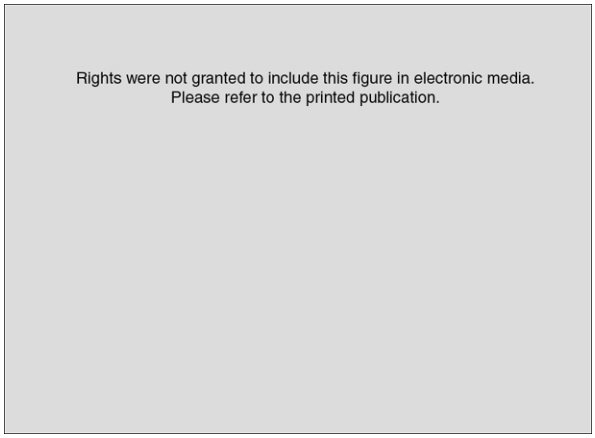

Figure 15-15 Length/height SDS for the nontreatment control group (open symbols) and the growth hormone treatment group (filled symbols) of toddlers with Turner syndrome during the 2-year study. Between-group difference at endpoint was 1.6 + 0.6 SDS ($p < 0.0001$). Mean age at baseline was 24 + 12.1 months. Published with permission from Davenport ML, Crowe BJ, Travers SH, et al. (2007). Grwoth Hormone Treatment of Early Growth Failure in Toddlers with Turner Syndrome: A Randomized, Controlled, Multicenter Trial. JCEM 93(9): 3406-3416.

completed toddler Turner study in the United States began GH treatment between 9 months and 4 years in 88 girls. GH therapy is effective as early as 9 months of age. Treament with GH should be considered as soon as growth failure (decreasing height percentiles on the normal curve) is demonstrated and its potential risks and benefits have been discussed with the family[81] (Figure 15-15).

SAFETY OF GROWTH-PROMOTING THERAPY

Human recombinant growth hormone (hrGH) was introduced into the United States in 1985, and worldwide shortly thereafter. Its introduction followed on the heels of the recognition that Creutzfeldt-Jacob disease had been transmitted to patients from some batches of human pituitary-derived GH.[190] This serious safety issue, coupled with the fact that hrGH was the first recombinant protein available as a pharmaceutical, has resulted in extensive worldwide scrutiny of this drug. Because it is beyond the scope of this chapter to discuss GH safety in its entirety, we will focus on several specific clinical and metabolic issues related to GH therapy in Turner syndrome.

The issue of whether GH alters the body proportions of girls with Turner syndrome has been of interest since the early studies of GH use.[191] The report by Sas and associates[192] of more than 60 girls observed for up to 7 years on increasingly high doses of GH addresses this issue in depth. Height, sitting height, hand and foot length, and biacromial and bi-iliacal diameters were measured. They note that at the outset Turner syndrome girls have relatively large trunks, hands, and feet and broad shoulders and pelvis compared with height. This is in concert with the reference data,[193] illustrating the relative disproportion that these girls have before GH is initiated.

Long-term GH therapy tends to normalize height, improve the disproportion between height and sitting height, and have little effect on hand length or shoulder or pelvic proportions. Foot length increases disproportionately in a dose-dependent fashion and in their series played a role in the decision of some patients to discontinue GH therapy in the last phases of growth. Scoliosis was not specifically addressed in this paper. The incidence of scoliosis is as high as 35% (Table 15-2) in untreated patients with Turner syndrome. Although it is also reported to be increased after GH treatment compared with GH-deficient patients so treated, it may not be increased compared with untreated patients. In addition, progression to surgical intervention is rare in both the treated and the untreated patient.

Sas and associates also evaluated the effect of GH on cardiac left ventricular dimensions and blood pressure in this cohort.[193] They found that the growth of the left ventricle was comparable to that of healthy girls, confirming the earlier findings of Saenger and colleagues.[192] Sas and associates[194] also found that whereas blood pressure in these girls was within the normal range for age at the start of therapy it was significantly higher than in healthy control subjects. Seven years of GH therapy had no significant effect on systolic blood pressure and had a small lowering effect on diastolic blood pressure. Finally, during the course of this 7-year GH trial there was no significant dilation of the aortic root (S.M.P.F. de Muinck Keizer-Schrama, MD, personal communication).

Two studies have looked at long-term effects on plasma lipids. van Teunenbroek and co-workers evaluated the effects of GH in two different study groups over time and found that in one group the atherogenic index improved with long-term treatment, whereas in the other it remained the same.[196] Querfeld and co-workers evaluated the effect of GH on lipoprotein(a) and found no effect, either alone or in combination with oxandrolone, on lipoprotein(a) levels after a median of 27 months of therapy.[197] Lanes and colleagues found normal lipoproteins in the untreated state and a decrease in total and low-density lipoprotein cholesterol during treatment.[198] Thus, long-term GH therapy does not appear to have a deleterious effect on cardiac structure or on cardiovascular risk factors and in a high-dose study led to a cardioprotective profile.

Other aspects of the safety assessment of GH therapy in these clinical trials showed there were no adverse effects of GH treatment on carbohydrate metabolism. Hgb A1c levels did not change, and glucose levels remained normal. In most studies, fasting and postprandial insulin levels increase during GH therapy but return to normal after GH treatment is stopped.[199,200] Liver abnormalities, characterized by transient increases in transaminase and/or g-glutamyl transpeptidase concentrations, have been occasionally reported in GH-deficient and Turner syndrome 2 children during GH therapy.[201,202] Spontaneous resolution usually takes place within 3 to 6 months of identification.

In Turner syndrome specifically, treatment with estrogens or androgens or the presence of autoimmune liver disease was more commonly associated with the increase in liver enzymes than was GH treatment.[201] Conversely, in adult women with Turner syndrome hepatic enzyme levels are higher than in normal women but have been found to decrease with estrogen therapy.[203] Thus, the

tendency of liver enzymes to be increased in both girls and women with Turner syndrome appears to reflect both intrinsic and exogenous mechanisms but rarely reflects active dysfunction or disease. Finally, what appears to be hepatic enzymes may be confounded by transient increases in muscle creatine phosphokinase (CK) that has been reported after GH therapy.[204]

In 1993, Bourguignon and colleagues[205] reported that melanocytic nevi may grow more rapidly during GH therapy based on clinical observation and immunoantibody staining for actively growing melanocytes. Subsequently, the issue has been of concern—albeit there are no reports of increased melanoma frequency in patients with acromegaly. Zvulunov and associates evaluated this question in two studies,[206,207] concluding that whereas the number of nevi are increased in Turner syndrome GH therapy in GH deficiency is not associated with an increased count or density of nevi (both factors in increasing melanoma risk) and is therefore unlikely to potentiate the risk for melanoma in Turner syndrome. To date, this conclusion is supported by a lack of reports indicating an increased incidence of melanoma in Turner syndrome patients treated with GH.

The role of GH as an immunoregulator has been reviewed.[208] Although there are data that suggest that GH replacement therapy has a transient effect on B cells,[209] clinically significant effects of GH on immune function have not been described. Because Turner syndrome patients are known to have a high incidence of autoimmune thyroiditis, the effect of GH therapy on the incidence of thyroid antibodies was studied.[210] No increase in the prevalence of thyroid antibodies was observed.

Among adverse events related to GH reported in the Pharmacia International Growth Study database (KIGS), the incidence of pseudotumor cerebri appears to be higher in Turner syndrome patients (and in patients with chronic renal failure and organic GH deficiency) than in other subgroups of patients treated with GH. Scoliosis is also higher in Turner syndrome and in Prader-Willi syndrome patients, conditions known to be associated with scoliosis in the untreated state. Malignancy rates are not increased in Turner syndrome during GH therapy.[211]

OTITIS AND HEARING LOSS

Perhaps the most common medical problem reported by patients with Turner syndrome is bilateral otitis media. In a series of 76 patients, Anderson and co-workers[212] recorded medically significant middle ear infection in 68%—with more than one half of these patients reporting not only recurrent episodes but spontaneous perforations, the need for surgical treatment, or both. Hearing problems and ear malformations correlate with karyotype.[213-215] In Figure 15-16, the audiogram shows the typical dip in sensorineural hearing paricularly prevalent in higher frequencies.

In our series, complete system reviews were recorded for more than 80% of patients. Of these, almost 75% had undergone tonsillectomy and adenoidectomy because of recurrent otitis or had had polyethylene tubes placed for the drainage of serous otitis media or had both procedures performed. Of these, five patients had also undergone mastoid surgery. The cause of otitis does not appear to be related to a specific or generalized immunologic dysfunction. Other infections, as well as other disorders of the mucous membranes, are not reported to occur with increased frequency in Turner syndrome.

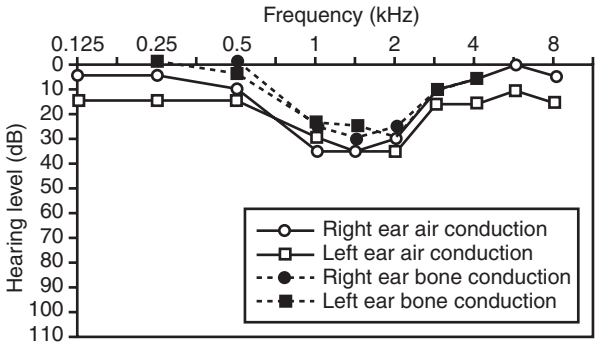

Figure 15-16 Audiogram showing the typical dip with the peak of 35 dB in the 1.5-kHz frequency region in a 12-year-old girl with Turner's syndrome (karyotype 45,X). This girl has no subjective hearing problems.[From Stenberg AE, et al. (1998). Otological problems in children with Turner syndrome. Hearing Research 124:85–90.]

Although levels of secretory immunoglobulins have not been reported, serum concentrations are not abnormal. IgG and IgA concentrations, however, appear to be in the adult male range—which is significantly lower than the adult female range.[216] Instead, frequent occurrence of otitis may be the consequence of abnormalities in growth of the cranial base in Turner syndrome. Cephalometry[212,217] has demonstrated that both structural growth of the temporal bone and growth of the condylar cartilage and spheno-occipital synchondrosis are abnormal. The result is that the final development of the facial skeleton reaches a level only corresponding to that of an 11-year-old girl, whereas that of the posterior portion of the cranial base is even less advanced. As a consequence, not only is the position of the external auditory meatus abnormal (giving the appearance of low-set ears) but the relationship of the middle ear to the eustachian tube is disturbed. These factors, coupled with abnormalities in the shape of the palate, create a predisposition to fluid collection and secondary infection. Marked hypocellularity of the mastoid air cells may also be found, further predisposing the individual to acute and chronic suppurative disease.[218]

The relationship of chronic otitis media to hearing deficit was also explored by Anderson and colleagues.[188] Their data suggest that a component of the hearing loss reported to be a common occurrence in Turner syndrome is conductive in nature. A high incidence of eardrum disease and conductive hearing loss (43%) was also reported more recently.[219] True sensorineural hearing impairment was also documented in both series. This was generally bilateral and characterized by symmetrical sensorineural dips in the audiogram in the midfrequency range. Audiologic manipulations tended to identify the defect as one of recruitment and specifically localized the defect to the outer hair cells of the organ of Corti.

When older patients were compared with children younger than the age of 10, conductive losses were more frequently found in the children and sensorineural losses

were more frequently found in the adults. Thus, the sensorineural losses appear to develop with age and represent a degenerative rather than a congenital abnormality. In addition to the findings reported previously, high-frequency audiometry also reveals a high prevalence of hearing loss that may precede the mid-frequency dip.[220] A relationship between auricular abnormalities and hearing loss and those karyotypes with complete loss of the X or Xp2 is suggested and may confirm the hypothesis that growth dysregulation of the cranial base owing to loss of the growth-regulating genes such as SHOX is in part responsible for the findings.[221]

Alternatively, growth dysregulation of the cranial base may be secondary to delayed cell cycle caused by chromosomal aberrations per se and not only genes deleted on the X chromosome.[222] In older girls and women with Turner syndrome with no history of hearing loss, audiologic surveillance is warranted every 2 to 3 years. The assiduous treatment of ENT problems in childhood and avoiding potential injuries to the inner ear may reduce the risk of hearing loss.[61] Removal of the adenoids may exacerbate palatal dysfunction and negatively influence quality of speech, factors that must taken into consideration prior to surgery.

GERM CELL CHROMOSOMAL DEFECTS

Gonadal Failure

Histologic evidence suggests that the ovary of the fetus with a 45,X karyotype (and presumably the ovary of the fetus with karyotypes with X chromosome deletions, rings, or mosaicism) undergoes an initial phase of differentiation that is the same as that in the 46,XX fetus. If the ovary is examined at 14 to 18 weeks of gestation, no abnormalities are seen. Subsequently, however, when there is a chromosomal defect in the germ cells the process of oocyte loss appears to be accelerated—with a concomitant acceleration of stromal fibrosis. Thus, what is considered the normal process of oocyte loss (beginning prenatally and continuing over 30 to 50 years of postnatal life in normal females) occurs entirely prenatally or in the first few months or years of postnatal life in most females with Turner syndrome.[223,224]

The triggering mechanism for this premature follicular atresia is postulated to be in part secondary to meiotic pairing anomalies in prophase,[225] and may be seen in other chromosomal abnormalities (such as trisomy 13 and trisomy 18).[226] The molecular mechanisms presumably involve the acceleration of an oocyte-intrinsic apoptosis defect regulated by members of the Bcl-2 gene family[198] and the caspase family of proteases.[227] The processes of oocyte loss and fibrosis are, however, neither absolute nor inevitable. Whereas the older literature documents both spontaneous puberty and menarche in a small number of patients with Turner syndrome,[228-231] the low percentages reported may be the result of ascertainment of only the most phenotypically obvious Turner syndrome patients.

The report of Pasquino and co-workers,[188] which includes more than 500 patients older than the age of 12 years, documents a high rate of spontaneous puberty—with an incidence of 14% in monosomic X patients and 32% in patients with cell lines with more than one X. In the series of Lippe et al.[232] of 141 girls who were in the pubertal age range, 29 (21%) had the onset of breast development to Tanner III or more—with menses occurring at least once in 25 and menses persisting into at least young adulthood in 15 (50% of those with initial ovarian function, or 11% of the entire pubertal age group).

Seven of the 29 with some degree of ovarian function had a 45,X karyotype. Of note is that although these 7 girls had some phenotypic features of Turner syndrome they did not have the webbed neck phenotype we associate with the presence of fetal lymphedema. The remaining 22 patients had mosaicism or structural abnormalities, with the highest number of girls with menses in the 45,X/46,XX group. Again, these girls lacked the webbed neck phenotype. Thus, maintenance of some degree of ovarian function can occur in Turner syndrome patients regardless of karyotype—although it is more common in those with cell lines with more than one X, and clearly more common in those who lack the webbed neck phenotype.

Pregnancy has been reported in more than 60 patients with Turner syndrome, including those with a 45,X karyotype on multiple tissues.[234-238] Although these latter cases remain rare enough to continue to merit individual reports, they illustrate the spectrum of ovarian function in this condition. Counseling about the expectations and future management of the patient with Turner syndrome diagnosed before puberty needs to include the probability of gonadal failure and infertility but not its inevitable occurrence. Even in those instances in which fertility does occur, however, reproductive failure is high and the risk of an abnormal offspring (notably one with trisomy 21) appears significant.[237-239]

In the series of Pasquino and co-workers,[188] there were three patients with spontaneous pregnancies (3.6%). One patient had two pregnancies, one with a normal male karyotype and one female with the same structurally abnormal X as the mother (i.e., Turner syndrome). One patient had twins with normal karyotype but severe cleft palate, and one patient had a normal infant. Ultimately, morethan 90% of indiduals with Turner syndrome will have gonadal failure.[61] Physiologic evidence for gonadal failure in Turner syndrome is provided by the response of the hypothalamic-pituitary axis to functional agonadism.

It has long been recognized that the negative feedback loop between the gonad and the hypothalamic-pituitary axis is operative in the fetus and demonstrable at birth. In normal infants, follicle-stimulating hormone (FSH) and luteinizing hormone (LH) rise after birth. In the male, the gonadotropin rise is accompanied by a significant surge in plasma testosterone in the first months of life. Gonadotropin and testosterone then gradually decline to prepubertal concentrations by the end of the first year. In the female, although the gonadotropin rise does not appear to be accompanied by as striking a response in estradiol secretion from the ovary the plasma FSH remains slightly elevated for a period of several years.

In Turner syndrome, a markedly exaggerated rise in both plasma gonadotropins (but especially in FSH) has

been demonstrated as early as 5 days of age in one study.[240] In a more recent study, however, with the blood spot obtained used for neonatal screening[241] a clear-cut elevation of FSH could not be demonstrated in patients with known karyotype abnormalities consistent with Turner syndrome—suggesting that FSH cannot be used for neonatal screening for Turner syndrome. In the series by Lippe et al.,[232] the investigators evaluated 14 patients with karyotypes consistent with Turner syndrome at 2 weeks of age or later in the first year of life. Of those who presented with lymphedema at birth, all had FSH determinations of more than 40 mIU/mL.

Conversely, of the patients who had the diagnosis of an X chromosome abnormality made by amniocentesis only 50% had evidence of castrate levels of FSH. Thus, although an abnormally high FSH in the neonatal or infancy period is useful to detect gonadal failure a normal level does not preclude the diagnosis of Turner syndrome. Whether the girls with normal FSH levels in infancy will go on to have gonadal failure at adolescence or will turn out to be the 10% to 30% who have some gonadal function remains to be determined. Pelvic ultrasound may have prognostic value in predicting the future sexual development of patients with normal gonadotropins. Data of Mazzanti and associates[242] suggest that detection of ovaries bilaterally in patients without castrate levels of gonadotropins and mosaic karyotypes correlated best with preservation of some ovarian function at puberty.

When abnormally elevated in infancy, the gonadotropin levels decline again after the first 2 years—although to mean concentrations significantly higher than those in gonadally competent female children. Between ages 4 and 10 to 11 years, a trough is noted, which is followed by the gradual rise of gonadotropins in normal children and a more rapid and exaggerated rise in most children with Turner syndrome. This diphasic pattern of FSH, determined on a large number of patients with gonadal dysgenesis, is illustrated in Figure 15-17A. In Figure 15-17B, serial determinations graphically demonstrate the fall that occurs in the first years of life and the abrupt rise that occurs in early adolescence. The range of values considered normal for a female varies with the assay method and the standard used, and thus the values in the figure are illustrative but will not be normative for most current commercial assays.

The mechanisms responsible for the feedback suppression of gonadotropin secretion in the normal child and the similar pattern, although at a higher set point, in the child with gonadal dysgenesis are unclear. It has been presumed that increased sensitivity to circulating steroids of gonadal and adrenal origin results in decreased hypothalamic gonadotropin-releasing hormone (GnRH) release in the prepubertal subject. Studies in primate species suggest that one component of the feedback inhibition may be at the level of the pituitary and that another may be at the hypothalamic level. There may also be significant central neuronal inhibition that is not affected by gonadal steroids.

Plasma gonadotropin concentrations can be assessed at the time of diagnosis and again in early adolescence before the institution of steroid hormone therapy and counseling

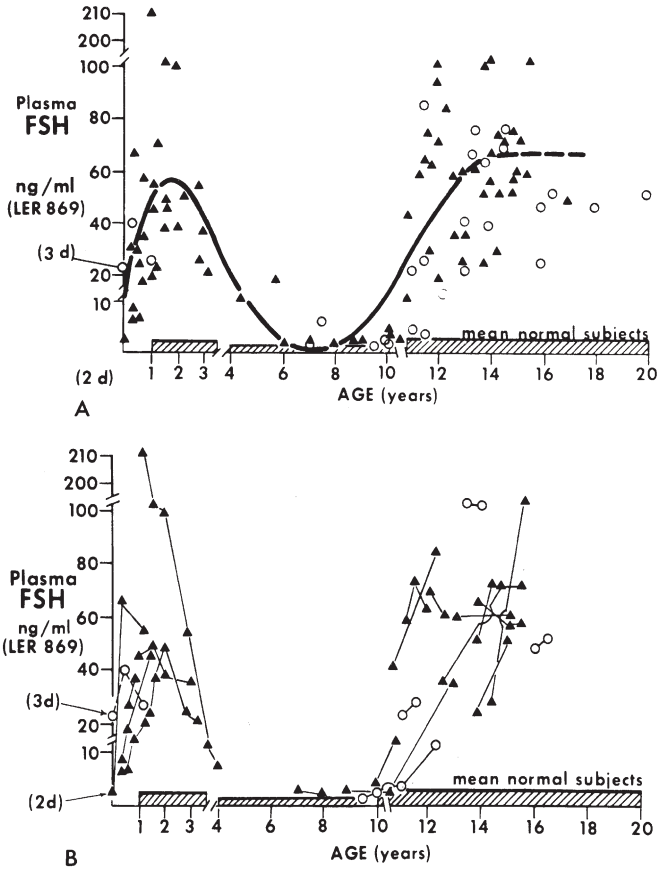

Figure 15-17 (*A*) Plasma follicle-stimulating hormone (FSH) values in patients with Turner syndrome. Triangles (m) indicate patients with 45,X karyotype, and circles (s) denote those with X chromosome mosaicism or structural abnormalities of the X. The curve is a polynomial regression plot. The hatched lines indicate mean plasma FSH values in normal females. Note the very high levels in infancy and adolescence, with lower levels in the mid first decade. FSH is expressed as nanograms per milliliter of standard LER-869. To convert these values to milli-International Units per milliliter of the second IRP, multiply by 3.5. (*B*) Symbols indicating that serial plasma FSH values in several individuals are connected by straight lines. Note the rise and fall in infancy and the dramatic and abrupt rises in adolescence. [From Conte FA, Grumbach MM, Kaplan SL (1975). A diphasic pattern of gonadotropin secretion in patients with the syndrome of gonadal dysgenesis. J Clin Endocrinol Metab 40:670.]

about ultimate fertility. When GnRH is administered to assess the function of the hypothalamic-pituitary axis, the responses of patients with Turner syndrome with gonadal failure are exaggerated compared with normal subjects.[243] This procedure may be used to provide a second test for gonadal integrity in some patients. In one study of two 45,X menstruating adolescents with both documented anovulatory cycles and ovulatory cycles with a prolonged follicular phase and short luteal phases, however, GnRH testing did not show exaggerated responses.[244]

Nevertheless, in most adolescent patients a single determination of plasma FSH and LH is sufficient to document gonadal failure. In the absence of estrogen replacement therapy, gonadotropin secretion will continue unabated and unmodulated. Although no systemic manifestations are known to result from these excessive concentrations of

FSH and LH, reactive pituitary abnormalities have been reported in some patients.[245] Skull radiographs may show enlargement of the pituitary fossa, which is suggestive of pituitary hyperplasia or microadenoma formation. Although enlargement sufficient to result in organic dysfunction has not yet been reported, the recognition of this phenomenon is important so that the gonadal dysgenesis is not misdiagnosed as being secondary to a pituitary tumor. The potential for progressive pituitary enlargement is an additional reason for instituting estrogen replacement therapy.

Gonadoblastoma

Gonadoblastomas are distinctive tumors composed of at least two different cell types. The large cells have the appearance and ultrastructure of oogonial germ cells, and the small cells are ovarian stromal cells that are not clearly differentiated.[246] The small cells most closely resemble primitive sex-cord mesenchymal cells and are termed *granulosa-Sertoli cells*. The tumor arises in a gonad that is dysgenetic; that is, a gonad that has not completely differentiated into a normal ovary or normal testis or that does not behave like a normal ovary or normal testis. The dysgenesis that leads to gonadoblastoma formation almost invariably occurs in patients with Y chromosome material in their karyotype. In the case of Turner syndrome, most karyotypes do not contain a Y. The ovary is induced normally and then usually rapidly degenerates into fibrous streaks with loss of oogonial germ cells. These ovaries are not believed to be at risk for gonadoblastoma formation.

There is a small percentage of patients (between 2 and 5% in most series and 5% in our series), however, who fit all of the criteria for Turner syndrome and in whom the karyotype contains a Y chromosome. There is an even smaller percentage with a marker chromosome. Most often, the karyotype is the mosaic 45,X/46,XY. More complex karyotypes (including 46,XX/45,X/46,XY and even 46,XY), however, have been associated with Turner syndrome. Thus, the karyotype per se does not determine the phenotype.

What defines these patients as having Turner syndrome (rather than being hermaphrodites or having mixed gonadal dysgenesis) is their short stature, their symmetrical female external genitalia, and their normal female internal genitalia (bilateral fallopian tubes, uterus, and vagina). The only expression of the Y may be its effect on gonadal ridge induction, with the result that a number of cells no longer resemble differentiated ovarian stroma. In this case, all of the oogonial germ cells that develop in these dysgenetic ridges do not necessarily undergo atresia as rapidly as they do in typical Turner syndrome. Instead, some may persist, continue to divide, and develop into a gonadoblastoma.

In some patients with a Y in their karyotype, the granulosa/Sertoli cell stroma more closely resembles a testis and produces some androgen. This may occur regardless of whether a gonadoblastoma will eventually develop. These patients, although still having the Turner phenotype, may show some evidence of virilization—including clitoromegaly or partial fusion of the posterior labia. Virilization is in itself an indication for gonadectomy, whether a gonadoblastoma is present or not. Because many patients bearing the Y will not virilize, however, these findings are not necessarily helpful in deciding which Turner syndrome patient may be at risk for gonadoblastoma. For this reason, it is essential to obtain a complete chromosomal karyotype even in the most obvious of Turner syndrome patients. If a marker or fragment chromosome is detected that cannot be assigned to a specific chromosome, more specific studies can be performed (see "Incidence and Etiology" for a discussion of the role of Y chromosome-derived genes in gonadoblastoma formation).

The risk for the development of the tumor, unilaterally or bilaterally, in the patients with the Y-bearing dysgenetic gonad has been estimated to be as high as 15% to 25%[247]—although in the recent population study from Denmark by Gravholt and co-workers the risk appears to be much lower.[60] In the series by Lippe et al.,[232] four of the eight patients with an intact Y chromosome and one of the two with a Y-derived marker had histologic gonadoblastomas. As discussed previously, these data do not pertain to use of molecular markers for any Y-derived genetic material and should not be extrapolated to imply that patients should be screened with molecular markers to detect Y material to monitor them for gonadoblastoma or perform gonadectomy.

Although gonadoblastomas usually do not metastasize, local invasion of the surrounding stroma to form microscopic or gross germinomas is seen in about half of cases.[248] Gonadoblastomas may also be found in conjunction with malignant germinomas, although these latter tumors tend to occur in conditions other than Turner syndrome. The age at which these tumors are detected varies, but a number have been reported in early childhood.[249,250] In some patients, calcification is present—which assists in detection. In others, a tumor mass may be demonstrated with ultrasound, magnetic resonance imaging (MRI), or computed tomography. In many, however, the disease is microscopic.

Recommendations for dealing with the problem vary from prophylactic removal of the gonadal ridge streaks in all Turner syndrome patients with an intact Y or marker chromosome in their karyotype to prospective monitoring of the patient at risk with some visualization technique such as ultrasonography. Until the gonadoblastoma gene locus is identified, we do not recommend removal of gonadal streaks based on molecular marker testing in the absence of a cytogenetic Y but do recommend prophylactic removal if a cytogenetic Y or marker chromosome or virilization is present. Gravholt's data might indicate that even this is too aggressive in all cases, however, and monitoring alone may be sufficient in some. Examples of ultrasonographic studies in a normal pubertal female, a girl with Turner syndrome, and a girl with Turner syndrome and a gonadoblastoma are shown in Figure 15-18.

CARDIOVASCULAR ABNORMALITIES

The association of cardiovascular abnormalities, notably coarctation of the aorta, with Turner syndrome has been well documented.[16,251-254] The haploinsufficency of the X

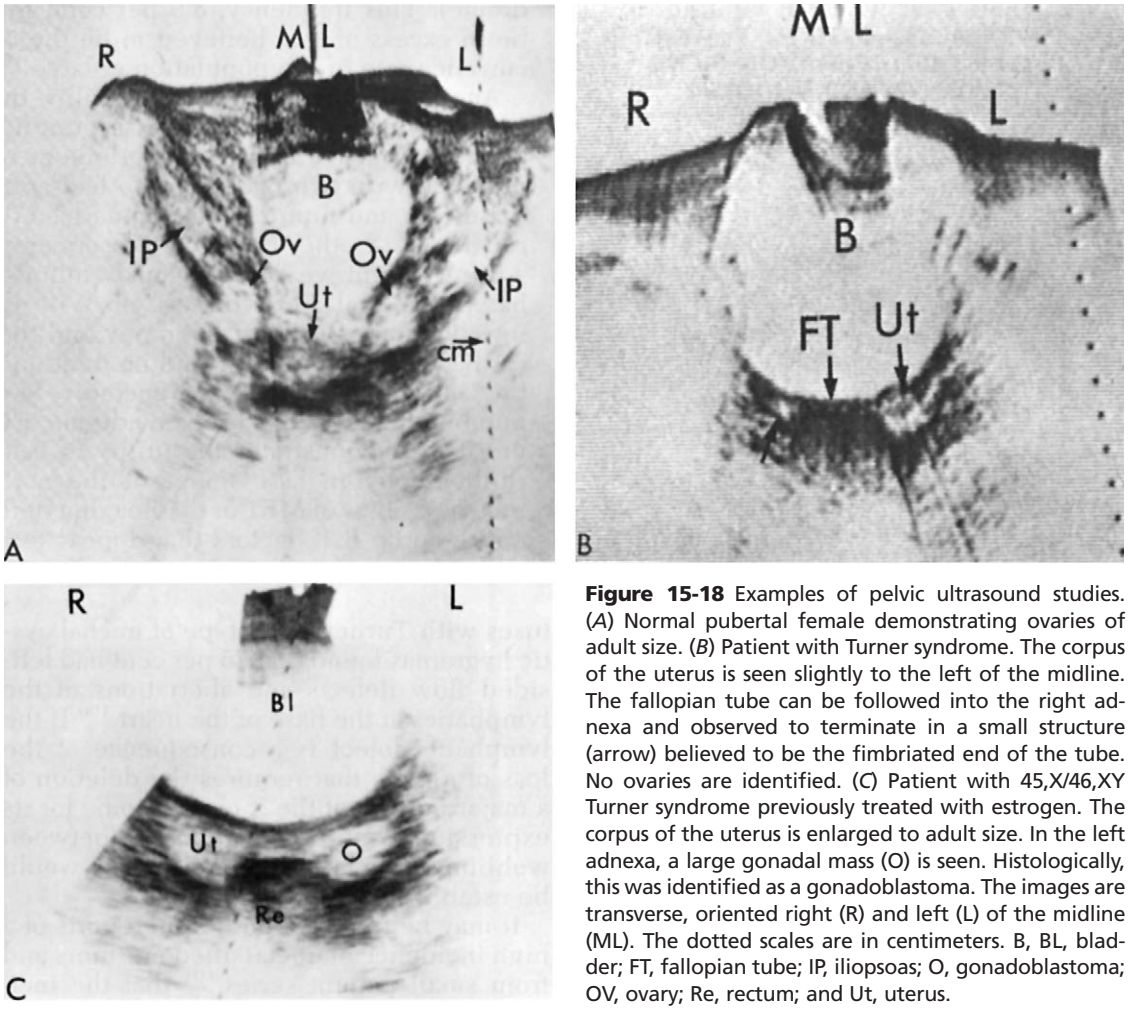

Figure 15-18 Examples of pelvic ultrasound studies. (*A*) Normal pubertal female demonstrating ovaries of adult size. (*B*) Patient with Turner syndrome. The corpus of the uterus is seen slightly to the left of the midline. The fallopian tube can be followed into the right adnexa and observed to terminate in a small structure (arrow) believed to be the fimbriated end of the tube. No ovaries are identified. (*C*) Patient with 45,X/46,XY Turner syndrome previously treated with estrogen. The corpus of the uterus is enlarged to adult size. In the left adnexa, a large gonadal mass (O) is seen. Histologically, this was identified as a gonadoblastoma. The images are transverse, oriented right (R) and left (L) of the midline (ML). The dotted scales are in centimeters. chromosome causes the most serious life-threatening consequences involving the cardiovascular system. The determination of its frequency, however [as well as the clarification of the conflicting reports of occurrence of other major structural cardiovascular malformations (CVMs)], was impaired by the lack of chromosomal karyotyping in early series.

One of the major sources of confusion was the inclusion of patients with normal chromosomes but phenotypic abnormalities, of whom a large number may have had Noonan syndrome.[254,255] CVMs occur in approximately 75% of spontaneously aborted Turner fetuses and 30% of living patients. Obstructive lesions of the left side of the heart predominate, ranging in severity from nonstenotic bicuspid aortic valve to aortic stenosis, coarctation of the aorta, and mitral valve anomalies (Table 15-4).[256-264] The most severe form of left-sided hypoplasia (hypoplastic left heart syndrome) also occurs, although it is uncommon.[265,266] The association of Turner syndrome and the entire spectrum of left-sided cardiovascular malformation is distinctive among malformation syndromes.

Only Williams syndrome, commonly associated with supravalvar aortic stenosis, shares this left-sided association. The largest series of patients comes from Italy, where Mazzanti and colleagues[259] analyzed the cardiac evaluation of 594 Turner syndrome patients ranging from 1 month to 24 years of age. In addition, various other authors[260,262] have over the past years published type and frequency of cardiovascular malformations (Table 15-4). The prevalence of congenital heart disease and the relative risk in Turner syndrome patients compared to the general population are shown in Table 15-5.

Coarctation per se (especially the preductal adult-type coarctation most characteristic of this condition) is not likely to result from the same mechanisms as other congenital heart defects. Although the final structure of the four chambers of the heart and the orientation of the great vessels are established by 6 to 7 weeks after fertilization, the preductal area of the aorta subject to coarctation may be affected at any time. Moreover, coarctation occurring in this isthmus region has been considered in some cases to be a result of the differential flows through the two fetal circulatory systems that interface at this point (the ductal-placental flow and the systemic-cardiac-pulmonary flow).

Clark[267] elegantly reviewed the embryology of lymphatic sac drainage into the venous system and noted that in the chick disordered drainage implicates a mechanism that distends the cardiac lymphatics. He proposed that this would encroach on the ascending aorta and alter

intracardiac blood flow. A more recent pathologic examination of 12 fetuses with Turner phenotype of nuchal cystic hygromas found that 75% had left-sided flow defects and aberrations of the lymphatics at the base of the heart.[268]

These cystic hygromas resolve as lymphatic ducts open in later gestation but often result in residual webbing of the neck. Finally, Miyabara and co-workers[269] analyzed 13 fetuses with 45,X karyotypes with cystic hygroma and documented that almost all had bicuspid aortic valves and many tubular hypoplasias of the aortic arch. They postulated that a homeobox gene or genes, not SHOX, could be responsible for what appears to be a generalized hypoplasia of tissues of the fourth branchial arch. This further confirms a relationship between the nuchal hygroma/webbed neck phenotype and the cardiac defects found clinically in the 45,X karyotype.

Mazzanti and co-workers[259] showed that a 45,X karyotype is more likely to be associated with webbing, more severe CVMs, and in particular coarctation and partial anomalous pulmonary venous return. We and others also showed a similar association between the webbed neck phenotype and coarctation.[253,269] In contrast, X-structural abnormalities are more likely to be associated with bicuspid

aortic valve and aortic valve disease. Less frequent than a left-sided obstruction, CVMs are membranous ventricular septal defects, secundum-type atrial septal defects, partial anomalous pulmonary venous return, and mitral valve prolapse.[259-262,268]

Another cardiovascular abnormality that occurs in Turner syndrome is aortic dilation, dissection, or rupture. Approximately 90% of the cases of dissection or rupture had an associated cardiac malformation, including previous coarctation, "pseudocoarctation," bicuspid aortic valve, or some degree of hypertension.[271] Other large series of Turner syndrome patients have also provided data on aortic root dilation, although the prevalence and natural history remain incomplete.[259,260,262] One large series of 244 patients followed in a Turner syndrome clinic in Seattle, Washington, provided both cross-sectional and longitudinal data about cardiac anomalies.[262] The frequency of aortic dilation was not reported, but aortic dissection occurred in three patients (1%): one with chest trauma, one with previous coarctation repair, and one with chronic hypertension and obesity.

We also analyzed the responses of 245 of 1,000 members of the Turner's Syndrome Society of the United States.[261] Confirmation of karyotype, however, was not obtained. Thirty-five percent were 10 years of age or younger, and a substantial 14% were 41 years or older. Among all respondents, 15 (6%) reported aortic dilation (8% of those who had specifically been evaluated). Of those reporting dilation, 80% reported having a CVM—usually bicuspid aortic valve, aortic valve stenosis, or coarctation (alone or in combination).

About two-thirds of the patients with aortic dilation were younger than 21 years of age, and most had an associated CVM. However, two of the three patients who had aortic dilation without a CVM or other risk factor were also in this younger age group. Despite the limitations of a self-reporting survey, the study provided a conservative estimate of the frequency of aortic dilation. The vast majority of Turner syndrome patients in this survey and the literature have an associated risk factor for aortic dilation. Nevertheless, of concern to patients and health care professionals are the small number in whom there is no risk factor.[272,273]

Figure 15-19 and Figure 15-20 demonstrates the utility of echocardiography in assessment of the aortic root, as well as of MRI in the imaging of the entire aorta. A prospective study of thoracic cardiovascular MRI of 40 girls with Turner syndrome revealed an overall frequency of anomalies of more than 45%.[274] These included not only bicuspid aortic valve (17.5%) and aortic coarctation

Figure 15-19 Cardiac imaging in Turner syndrome. In older children, MRI is the preferred study because it gives better resolution. In younger children, ultrasonography is still the method of choice. This panel shows coractation of the aorta (R) and elongated transverse aortic arch (ETA) (L), which my lead to coarctation. Courtesy of C. Bonoly.

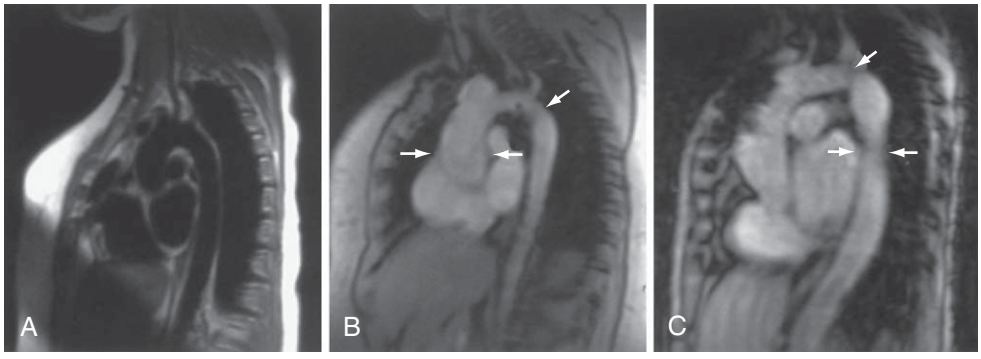

Figure 15-20 Three examples of coarctation of the aorta as seen on MRI studies. Please note the poststenotic dilatation, seen especially in panels B and C. Courtesy of G. Conway.

(12.5%) but dilated ascending aorta (12.5%). Aortic coarctation and bicuspid aortic valve are each almost fourfold more frequent in patients with webbed necks (e.g., 37% of patients with neck webbing have a BAV, compared to 12% in those without webbing).[275]

The authors point out that three of five aortic coarctations and four of five ascending aortic dilations were solely detected with MRI and were not evident on echocardiographic examination. Thus, these findings and other series[276,278] suggest an MRI is a valuable adjunct in the cardiovascular evaluation of girls with Turner syndrome. In fact, MRI may dectect coarcation missed by echocardiography in infancy.[279-281] The risks associated with BAV in Turner syndrome are probably similar to those for nonsyndromic cases. The abnormal valve is at risk for infective endocarditis, and over time it may deteriorate—leading to clinically significant aortic stenosis or regurgitation. BAV can also be associated with aortic wall abnormalirties, including ascending aortic diltation, aneurysm formation, and aortic dissection.[282]

Recent studies suggest a broader spectrum of CVM than previously recognized. Magnetic resonance angiographic (MRA) screening studies of asymptomatic inviduals with Turner syndrome have identified a high prevalence of vascular anomalies of uncertain clinical significance. Almost 50 have an unusual elongation and angulation of the aortic arch termed *elongated transverse arch* (ETA) by Ho et al.[280] This may reflect an abnormal aortic wall prone to dilation. Additional anomalies are partial anomalous pulmonary connection (PAPVC) and persistent left superior vena cava, affecting 13 versus <1% b in the general population. Whether this defect is clinically significant depends on the degree of the left to right shunt.[283-285] There seems to be a generalized dilation of major vessels in women with Turner syndrome, including the brachial and carotid arteries as well as the aorta. The distal extent of this vasculopathy is unknown. Estrogen deficiency contributes to greater intima medial thickness and altered arterial wall dynamics but not the increased caliber of the vessels[286-287] (Figure 15-19).

The data from this group and another using echocardiography suggest that aortic root diameters are greater in 45,X patients than in matched controls.[288] Whereas both studies compared aortic root dimensions to body surface area, which in a condition of short stature may not be the appropriate control group (may be more appropriate to match for age),[271] the findings suggest a degree of intrinsic primary abnormality. Pathologic evidence of cystic medial necrosis is reported in some cases of dissection and suggests that the intrinsic disorder might represent an example of a mesenchymal defect in Turner syndrome. This may explain the increased incidence of mitral valve prolapse as well.

Alternatively, the tendency toward significant aortic root dilation may be related to the intrauterine hemodynamic events that are a consequence of the lymphatic disorder. The longitudinal survey report that 25% of normal patients had increased aortic root diameters 2 years after the first study[277] (coupled with a report that death from aortic dissection was greatly in excess of that expected in a large prospective study of Turner syndrome patients registered with a karyotype registry[289]) prompted us to adopt an aggressive approach to diagnosis, follow-up, and risk factor management in these patients. Data at present are not adequate to recommend routine prophylaxis with beta-blocking drugs, although this therapy may be appropriate for those with significant aortic root dilation (e.g., Marfan syndrome)—especially those with bicuspid aortic valve.[290]

Of particular importance is the increased risk of aortic dissection in pregnancy among Turner syndrome women.[291] As more Turner syndrome women contemplate pregnancy, it seems prudent to identify those with aortic root dilation before the pregnancy. Those with a previous risk factor (bicuspid aortic valve, coarctation, hypertension) should be monitored very closely. Those women without abnormal risk factors also require close attention.[236,291-296]

It is also clear from reports of a high incidence of unclassified murmurs and from early patient series[297] that the incidence of aortic valvular abnormalities is also increased in Turner syndrome. With the introduction of echocardiography, we were able to undertake a study of the frequency of this association.[256] Of 67 patients without coarctation studied with two-dimensional or M-mode echocardiography (or both), 20 (almost 30%) have findings characteristic of bicuspid aortic valve. Some of these valves are anatomically tricuspid but have eccentric closure and are functionally bicuspid, whereas the majority are actually bicuspid.

Our data, and the more recent confirmatory data from Mazzanti and co-workers,[259] indicate that the percentage distribution of patients with isolated bicuspid valve does not appear to be confined to any karyotype—nor does there appear to be a preponderance of the webbed neck phenotype. Thus, bicuspid aortic valve not only may be more common than coarctation but may represent a more fundamental manifestation of an X chromosome defect in Turner syndrome. We also diagnosed six patients as having mitral valve prolapse (Barlow syndrome), a finding confirmed by a second group.[257] The frequency, 10% to 15%, is in excess of that believed to be the occurrence rate in the population at large.[298]

Mazzanti and co-workers also found a significant number of patients with partial anomalous pulmonary venous return, a rare malformation, and thus the malformation with the highest relative risk of occurrence compared with normals[259] (Table 15-5). In a follow-up study of adult Turner women, only 11 of 25 adult women with Turner syndrome had normal cardiac findings using a combined echocardiography and MRI screen of the aorta. Twelve had aortic root dilation, three had bicuspid aortic valve, and five had pseudocoarctation of the aorta.[299] Finally, hypoplastic left heart syndrome has been described during prenatal echocardiography[266]—and four Turner syndrome infants are described in a large outcome study, with limited survival in two.[267]

Adults with Turner syndrome have a high prevalence of electrcardiographic conduction and repolarization abnormalities, as well as prolonged QT intervals. Therefore, monitoring of echocardiograms (ECGs) in Turner syndrome appears warranted.[300] In addition to congenital structural anomalies, there are several acquired cardiac

problems that have been noted in Turner syndrome women—although their prevalence is not well established. In some series, hypertension occurs in about 15% to 25% of girls (and in a larger percentage of adults with Turner syndrome).[259,262,301,302] A threefold relative risk for high blood pressure was noted in Denmark, but patients with repaired coarctation had not been removed from the sample.[303]

Stratification by age and weight has not been performed. Several large series from different countries also support an increased prevalence of hypertension. These analyses did not consistently analyze patients based on age, weight, and coarctation repair. Nevertheless, in the Danish study of morbidity in Turner syndrome women along with hypertension there were also marked increases in ischemic heart disease and stroke.[303] In a Swedish morbidity study, cardiac anomalies and hypertension were common but plasma lipid levels did not differ from those of normal subjects.[304]

Although a renovascular abnormality is considered the most likely mechanism for development of hypertension, especially in younger patients, obvious structural renal lesions are not always present. Similarly, a history of infectious nephritis or even urinary tract infection is usually absent. Thus, in the majority of patients the cause of the hypertension is unknown. In our series, nine patients with hypertension were identified and in only one did it appear to be of renovascular origin (Figure 15-21). One of the earliest abnormalities in blood pressure regulation is the disappearance of the physiologic nighttime dipping in blood pressure as prodromal state of hypertension[61] (Table 15-6). Systemic hypertension is an important risk factor for aortic dilation and dissection. Therefore, blood pressure should be monitored frequently and treated vigorously in all patients with Turner syndrome.

If the baseline ECG reveals a significantly prolonged QTc, medications that might further prolong the QT should be avoided.[61] There was no apparent relationship to any particular karyotype or phenotype. Other infrequent abnormalities include endocardial fibroelastosis[258] and cardiomyopathy.[305] In two studies of Turner syndrome girls without major cardiac abnormalities who received GH treatment there was no evidence of left ventricular hypertrophy or hypertension.[194,195] In one, after 7 years there was no significant dilation of the aorta (S.M.P.F. de Muinck Keizer-Schrama, MD, personal communication).

TABLE 15-6

Cardiovascular Screening and Monitoring Algorithm for Girls and Women with Turner Syndrome

Screening (All Patients at Time of Diagnosis)

- Evaluation by cardiologist with expertise in congenital heart disease.
- Comprehensive exam, including blood pressure in all extremities.
- All require clear imaging of heart, aortic valve, aortic arch, and pulmonary veins.
- Echocardiography is usually adequate for infants and young girls.
- MRI and echo for older girls and adults.
- ECG.

Monitoring (Follow-up Depends on Clinical Situation)

- For patients with apparently normal cardiovascular system and age-appropriate blood pressure.
  - Reevaluation with imaging at timely occasions (e.g., at transition to adult clinic), before attempting pregnancy, or with appearance of hypertension. Girls that have only had echocardiography should undergo MRI when old enough to cooperate with the procedure.
  - Otherwise, imaging about every 5 to 10 years.
- For patients with cardiovascular pathology, treatment and monitoring determined by cardiologist.

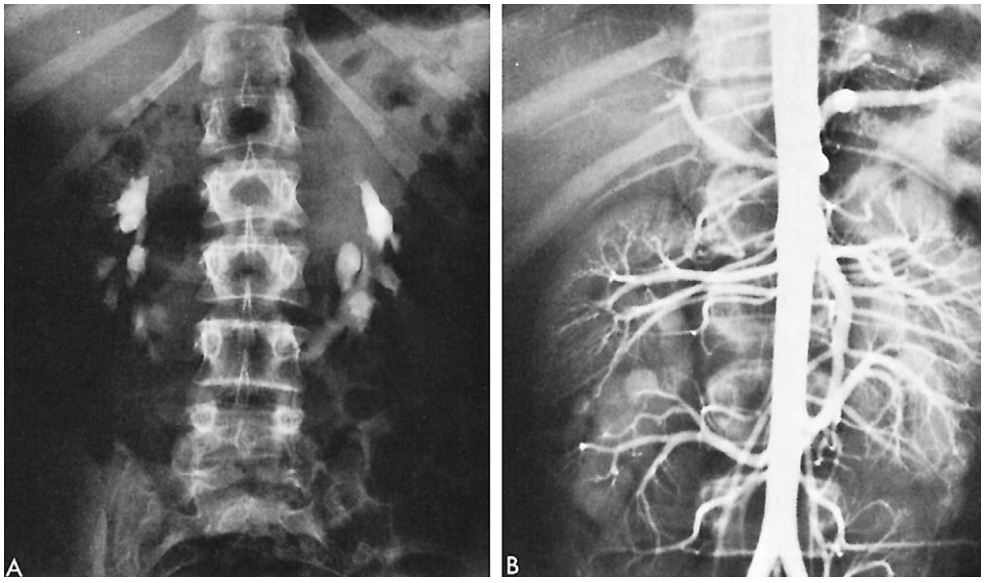

Figure 15-21 *(A)* Radiograph from an intravenous pyelogram demonstrating a horseshoe kidney deformity. *(B)* Radiograph after an aortic injection, illustrating multiple renal arteries in a patient with Turner syndrome and hypertension.

Ongoing Cardiac Care

For the patient with no identified cardiovascular defects, routine pediatric care is advised with continued monitoring of blood pressure. It seems also prudent to reevaluate aortic dimension at 5- to 10-year intervals. Patients with significant cardiovascular defects need continued monotoring by a cardiologist, with frequency of monitoring determined by circumstances. Children considered at increased risk for hypertension should be educated about this risk, the need for compliance with medical monitoring and treatment, and the possible presenting symptoms (e.g., chest or back pain). Patients with multiple risk factors (BAV, dilated aortic root, hypertension) that put them at high risk for aortic deterioration might want to consider carrrying a medical ID bracelet. They also need to be informed that prophylactic antibiotics should be given before dental procedures or surgery.

MONITORING FOR AORTIC DILATION

All measurements of the aorta should be done at end systole. The ascending aorta should be measured at the level of the annulus at the hinge points of the valve, at the level of the sinuses of valsalva perpendicular to the ascending aorta long axis, and at the ascending aorta 10 mm above the sinotubular junction. Normative data for aortic diameters as a function of body surface area are available.[282,286,306] Review of available data suggests that unadjusted values greater than 28 to 32 mm will identify patients with diameters greater than 95% of controls, which would clearly be abnormal for women with Turner syndrome who are generally smaller. When aortic root enlargement is found, medical therapy and detailed imaging is recommended.

In hypertensive patients with aortic root enlargement who also have resting tachycardia, beta adrenergic receptor blockade is an excellent therapeutic option. Beta-blockers have been shown to reduce the rate of aortic dilation and dissection in Marfan syndrome,[307] although efficacy in treating aortic dilation in Turner syndrome has not yet been investigated.

Heart-healthy exercise with moderate aerobic exercise is emphasized and should be encouraged. Eligibility for competitive sports for all those with Turner syndrome should be determined by a cardiologist after a comprehensive evaluation that includes an MRI of the aorta. Experts polled on this issue at the most recent Turner syndrome guidelines meeting agreed that aortic enlargement in Turner syndrome may be defined as an aortic sinus of valsalva or ascending aorta, body size adjusted Z score >2 plus evidence of increasing Z score on a subsequent imaging study of the aorta or a single Z score >3. In those cases, participation in competitive sports is contraindicated.[308]

PREGNANCY AND CARDIAC CARE

Spontaneous or assisted pregnancy in Turner syndrome should be undertaken only after thorough cardiac evaluation. Alarming reports of fatal aortic dissection during pregnancy and the postpartum period have raised concern about the safety of pregnancy in Turner syndrome. If pregnancy is being considered, preconception assessment must include cardiology evaluation with imaging of the aorta. A history of surgically repaired cardiovascular defect, the presence of BAV, or current evidence of aortic dilation or systemic hypertension should probably be considered as relative contraindications to pregnancy.[309]

GROWTH HORMONE TREATMENT AND THE CARDIOVASCULAR SYSTEM

Several echocardiographic studies reported normal left ventricular and septal morphology and function in GH-treated girls with Turner syndrome,[310] and two recent MR studies found no deleterious effect of GH treatment on aortic diameter[311] or compliance.[312] It is particularly reassuring that when adult Dutch Turner women were examined for aortic distensibility and the effects of growth hormone on aortic dimensions the patients who had received the higher growth hormones doses (47 mg/kg/week) had better cardiac health based on the parameters measured.[312]

In regard to the lymphatic system, abnormalities of cardiovascular and lymphatic development are found in most TS fetuses that fail to survive the first trimester.[21,269,313] For those girls who survive, the residua of the fetal lymphedema and cystic hygromas are peripheral lymphedema and webbed neck. Often the newborn lymphedema resolves by 2 years of age without therapy. It may recur at any age and may be associated with initiation of GH or estrogen therapy. Some children and adolescents may require support stockings. Complete decongestive physiotherapy (a four-step process involving skin and nail care, massage for manual lymph drainage, compression bandaging, and a subsequent remedial exercise regimen) is recommended for those with more significant lymphedema.[314] Long-term diuretic use should be avoided, as should vascular surgery. Families should be directed to the National Lymphedema Network (*http://www.lymphnet.org*) for more information.[61]

RENAL AND RENOVASCULAR ABNORMALITIES

Renal and renovascular abnormalities occur in Turner syndrome with greatly increased frequency. Although the incidence varies from 25% to 70% among different series reported,[315-319] the abnormalities tend to be of three specific types: those that primarily involve the pelvocaliceal collecting system, such as complete or partial duplication; those associated with the position and alignment of the organ, such as horseshoe kidney and retrocaval ureter; and those associated with abnormal vascular supply. In a recent study,[320] no patient with a normal baseline ultrasound developed renal disease during a follow-up period averaging 6 years. However, some of those with malformations developed hypertension and urinary tract infections.

The development of the collecting system begins with the formation of the ureteric bud, its dorsocranial migration, and its penetration of the metanephric blastema. At

about 5 weeks of gestation it dilates into a primitive pelvis and simultaneously splits into cranial and caudal portions—forming the future major calyces. Thus, duplications of the collecting system are caused by abnormal or early splitting of the ureteric bud at or before 5 fetal weeks and are therefore primary malformations of organogenesis. Conversely, the upward migration of the already preformed kidney from its position in the pelvis to the lumbar region is a somewhat later event. The kidney must pass through the arterial fork formed by the umbilical arteries, and if there are disturbances in either the anatomy of these vessels or the path of migration secondary positional malformations occur. If one kidney fails to traverse the arterial fork, it will remain ectopically in the pelvis. If there is a partial mechanical effect on the kidney during migration, rotational abnormalities may result.

The vascular supply of the kidneys may be anomalous (Figure 15-20B), secondary to the multiple budding segments of the kidney, the final positioning, or the presence of an aberrant vessel crossing the upper renal pole. Finally, the horseshoe kidney [which occurs with increased frequency (Figure 15-20A)] may represent a primary defect in embryogenesis resulting in the union of the two metanephric blastemas or a secondary defect caused by malposition of the umbilical arteries.

In the experience of Lippe et al.[142] patients studied with intravenous pyelography, with contrast medium enhancement at the time of cardiac catheterization, or with ultrasonography we found that 47 patients (33%) had some structural. The lesions we detected covered the spectrum of defects described previously, except that we did not have a case of retrocaval ureter.[321,322] Ultrasound, as the initial screening method in recent years, was effective in demonstrating all anomalies previously seen with intravenous pyelography except for mild clinically insignificant rotational abnormalities.

Although the overall morbidity of the renal lesions is relatively low (with only four patients requiring surgery, one requiring long-term antibiotic therapy, and four having an absent kidney), the potential for caliceal obstruction, parenchymal infection, and secondary renal impairment is real—and we therefore suggest that all patients should undergo an ultrasound imaging study. The high percentage of horseshoe kidneys (up to 7%[320]) merits further comment because there may be an increased incidence of Wilms' tumor in the horseshoe kidney.[322]

If the increased incidence of Wilms' tumor results from an abnormal proliferation of the metanephric blastema and if that were the mechanism in Turner syndrome, these patients would be at the same risk as other patients with a horseshoe kidney—and the incidence of Wilms' tumor in Turner syndrome should be high. Alternatively, if the mechanism in Turner syndrome is vascular these patients should be at no greater risk for Wilms' tumor than the general population. At present, only one patient with both Wilms' tumor and Turner syndrome has been reported—suggesting that the latter hypothesis is correct. In a recent paper by Sagi et al.,[316] kidney malformations were exclusively found in those patients who had retained the maternal X chromosome.

UNKNOWN METABOLIC FACTORS

Autoimmune Disorders

An apparent increased frequency of autoimmune disorders has been noted in patients with Turner syndrome. The reason for this increase is unknown, but it has been theorized that families with a high frequency of autoimmune diseases may be prone to nondisjunctional events. This hypothesis is based on the observations that there is also an increased frequency of autoimmune disorders in other nondisjunctional chromosomal disorders, such as Down and Klinefelter syndromes, and that when the families of patients with Turner and Down syndromes are investigated autoimmune disease appears to be reported or diagnosed frequently. It should be noted, however, that these studies were retrospective and did not test the parents for antibodies at the time of delivery.

A recent prospective study of thyroid antibody positivity as a risk factor for nondisjunction failed to show an association.[323] A second theory that autoimmune diseases might result from, or be associated with, genes or gene mutations on the X chromosome is supported by the increased incidence of these disorders in X chromosomal disorders as well as by their increased incidence in women. A third theory, that familial (maternal) autoimmunity may lead to the preferential survival of a fetus with chromosomal aneuploidy (albeit a general risk for pregnancy loss),[324] remains to be investigated.

The most prevalent autoimmune disorder in Turner syndrome appears to be Hashimoto lymphocytic thyroiditis. Depending on the series reported and on the methods used to measure the antibodies, the prevalence of significant titers may be as high as 50%.[210] Although originally described in association with structurally abnormal X chromosomes, notably the isoX,[325] increased titers of antithyroid antibodies with or without thyroid failure have been reported in 45,X individuals as well as in patients with mosaic karyotypes without a structurally abnormal X (i.e., 45,X/46,XX).[326-328]

In our series, approximately 30% of patients have positive antithyroid antibodies at the time of first testing. Of six patients who were overtly hypothyroid, however, two did not have abnormal antibody titers at the time of diagnosis. This is not unexpected because it is well known that children with biopsy-proven Hashimoto thyroiditis often do not have abnormal titers of circulating antithyroid antibodies.[329] The clinical picture of overt hypothyroidism in Turner syndrome may be different from the normal population because it has been reported that even severely affected individuals may not show any signs or symptoms of the disease.[330] This, coupled with the high frequency, mandates periodic screening of all Turner syndrome patients.

There are reports that indicate that Grave's hyperthyroidism[331] may also occur more commonly than previously recognized in girls with Turner syndrome, and we have one affected girl in our series. One report notes that in one patient during the hyperthyroid phase there was a marked increase in growth velocity.[332] Final height, however, did not appear to be adversely or positively influenced. In a

recent study, 24% of 84 children (0–19 years old) with Turner syndrome who were followed (longitudinally mean duration = 8 years) developd hypothyroidism (and 2.5% developd hyperthyroidism).[333] Thyroid disease has been reported as early as 4 years.[334] Therefore, all patients with Turner syndrome should be screened annually for autoimmune thyroid disease with a TSH and a free T4 level from 4 years of age onward.

We also have two patients with vitiligo and three with alopecia. Other forms of polyglandular autoimmunity (such as Addison disease, hypoparathyroidism, and pernicious anemia) have not been noted to be increased in frequency in Turner syndrome patients. The association of juvenile rheumatoid arthritis and Turner syndrome had only been reported in single case reports until the study of Zulian and colleagues.[335]

The authors conducted a survey of 28 pediatric rheumatology centers (15 U.S., 10 European, 3 Canadian) comprising an aggregate patient population of some 15,000 patients. Eighteen cases of juvenile rheumatoid arthritis were found in patients with Turner syndrome, of which 7 were polyarticular and 11 monoarticular. The authors calculated that this represented a sixfold increase over what would be expected, thus strongly suggesting an association between Turner syndrome and the occurrence of juvenile rheumatoid arthritis. The karyotypes of the affected individuals varied, but there appeared to be a predominance of 45,X patients with the more severe polyarticular form.

Gastrointestinal Disorders

A number of reports have called attention to gastrointestinal bleeding, often massive, occurring in patients with Turner syndrome.[336,337] The bleeding has been ascribed to intestinal telangiectasia, hemangiomatoses, phlebectasia, or dilated veins and venules. These vascular malformations occur without evidence of mesenteric, portal, or hepatic vascular abnormalities—which suggests a developmental rather than acquired cause. They do not appear to be associated with cutaneous hemangiomas reported in some Turner syndrome patients, however.[338] It is not known which patients may be at risk for development of vascular bleeding. Whether these vascular abnormalities are a consequence of the same obstructive processes that result in the lymphedema is not known.

Because large segments of bowel may be involved, we recommend conservative management when possible to avoid massive resections. If the patient has discontinued estrogen-progesterone replacement therapy, we recommend that it be reinstituted because this therapy appears to be efficacious in treating the bleeding of severe gastrointestinal vascular malformations[339] and was reported as appearing to help one affected patient with Turner syndrome.[340]

A second cause of gastrointestinal bleeding and dysfunction appears to be inflammatory bowel disease. Several reports suggest an increased incidence of Crohn disease and ulcerative colitis in infants and children with Turner syndrome.[341-345] Whether this increase may represent another autoimmune phenomenon or is associated with a particular genetic haplotype (HLA type) that may also prove to be increased in Turner syndrome remains to be established. Similarly, there is no conclusive evidence for a genetic or familial predisposition to ulcerative colitis in these patients. Because growth retardation and delayed sexual maturation are characteristic manifestations of inflammatory bowel disease and of Turner syndrome, careful attention must be paid to the review of systems in these patients. Conversely, short girls with inflammatory bowel disease and growth and pubertal delay may need assessment of gonadal function (measurement of gonadotropins) before their sexual delay is ascribed to their bowel disease alone.

Celiac disease is also being detected in Turner syndrome patients in frequencies that may exceed ethnic population norms.[346-348] There is also a suggestion that this may occur in association with immunoglobulin A deficiency, a known risk factor for the development of celiac disease.[337] Considering that growth failure and pubertal delay can be manifestations of celiac disease and Turner syndrome, consideration has to be given to testing short girls with celiac disease with or without pubertal delay (especially if they are on dietary management and have not had catch-up growth) for Turner syndrome. In addition, the issue is raised whether screening girls with Turner syndrome for celiac disease is warranted in the absence of clinical symptoms.

Based on recent data, the risk of celiac disease is increased in Turner syndrome (up to 6% of individuals are affected). Turner syndrome girls should be screened by measurement of tissue tranglutaminase IgA antibodies. Periodic screening is best begun at age 4, and should be repeated every 2 to 5 years.[349,350] Whereas hepatic abnormalities have not in the past been reported to be a typical finding in Turner syndrome individuals, a report by Salerno and co-workers[201] references 10 papers that describe a range of hepatic disorders/dysfunction in children and adults with Turner syndrome. A second paper[351] describes three additional adult patients with varying forms of hepatic disease. In the pediatric age group, Salerno's group followed some 70 girls prospectively for a mean of 7.6 years for the development of increased hepatic serum enzymes. They found a significant increase in liver enzymes in 20% over time. The majority appeared to be associated with the institution of oral androgen therapy for growth promotion or oral estrogen therapy for feminization, which were reversed with cessation of drug therapy.

That the association was with the estrogen and not the progestational agent is supported by a previous report.[352] As previously discussed, GH replacement does not appear to be associated with this finding. Among Salerno's patients,[201] however, were several who were thought to have autoimmune disease (one associated with celiac disease and one with hypergammaglobulinemia and a biopsy consistent with autoimmune hepatitis). In addition, two patients had mild steatofibrosis of unknown cause. Thus, there may be an increase (starting in childhood) in evidence of mild hepatic dysfunction from a variety of causes.

Steatosis, steatofibrosis, and steatohepatitis are frequently seen.[353] In a review of the Danish Cytogenetic Central Registry, a cohort of more than 500 adult patients with Turner syndrome was identified.[303] These were

cross referenced against the Danish National Registry of Patients to obtain data on first hospitalization diagnoses for these patients. Statistical analysis was done by comparing the patients with population controls to determine the relative risks for the diagnoses given.

The relative risk for a diagnosis of cirrhosis of the liver was 5.69 (1.55 to 14.56). Therefore, adult Turner syndrome individuals appear to be at risk for progressive hepatic disease. Regular monitoring of hepatic enzymes, at least in adults, may be indicated. Consideration can be given to using transdermal estrogen therapy rather than oral therapy in girls and women who appear to show liver abnormalities because the transdermal route results in fewer effects on hepatic metabolism than does the oral route.[354] Conversely, a study of transdermal estrogen replacement therapy in young healthy women with Turner syndrome showed mildly elevated liver enzymes at the time of estrogen washout—which normalized with oral estrogen replacement.[355] Thus, multiple mechanisms for the liver enzyme abnormalities appear to be operative.

CARBOHYDRATE TOLERANCE

The high incidence of carbohydrate intolerance, including frank diabetes in patients with Turner syndrome, has been documented over the past 40 years.[356-359] In our series, 40% of patients tested with oral glucose tolerance tests showed abnormal responses.[360] The clinical features are those of type 2 diabetes mellitus. Patients are non insulin dependent and are not ketosis prone. The abnormality may be reflected in a hyperglycemic response to oral glucose or to a meal, or it may progress to fasting hyperglycemia and polyuria. Insulin levels in the serum may be elevated, in the normal range, or low.

Some genetic evidence suggests that the diabetes is the familial type 2 variety because abnormal or borderline glucose tolerance tests have been demonstrated in 51% of parents of patients.[360] In that series, however, only one parent had clinical diabetes—which is far fewer than the usual clinical expression in type 2 families. Type 1 diabetes mellitus is infrequent, and in children most reports indicate that it is not in excess of that seen in the childhood population. There are no data on islet cell antibodies or glutamic acid decarboxylase antibodies available in Turner syndrome patients.

The metabolic/endocrine abnormality most frequently reported in children and adolescents with Turner syndrome not receiving GH replacement therapy is a greater glucose response to an oral glucose challenge than that noted in age-matched control subjects.[361,362] Insulin responses vary from series to series, and when increased in young patients may be related to concomitant androgen or estrogen therapy. Particularly, oxandrolone has been shown to be causing higher insulin levels in glucose tolerance tests than GH alone.[363,364]

When the metabolic defect was studied with a euglycemic insulin clamp technique to evaluate insulin sensitivity, and with indirect calorimetry to study whole-body glucose and lipid oxidation, insulin resistance was documented.[365] The defect appeared to be restricted to nonoxidative pathways of intracellular glucose metabolism and was present in a group of young girls who had never received any form of hormone therapy. The authors concluded that the defect is similar to that found in type 2 diabetes mellitus. These data suggest that in naive patients with Turner syndrome insulin resistance is a very early metabolic defect. Other groups have not found this abnormality, however. A possible explanation may be the fact that the clamp studies were methodologically different, employing differing insulin levels.[366]

A number of physiologic factors are known to be associated with this form of diabetes. Their role in contributing to the insulin resistance of Turner syndrome has not been clearly documented. Obesity per se could be a factor, but when assessed by measurements of skin-fold thickness the majority of the patients are not obese.[367] When this method was used in conjunction with standards for ideal body weight appropriate for height and age, we found that the degree of fat or percentage of ideal body weight did nor correlate with their carbohydrate intolerance.[360] In the study by Caprio and colleagues,[365] body mass index alone was used and there was no correlation between body mass index and insulin-stimulated glucose metabolism.

Estrogen-progesterone replacement therapy is known to be associated with changes in carbohydrate tolerance. Data now suggest that it is the chemical structure of the progestins used in oral contraceptives that contributes most to the defect.[367] In Turner syndrome, the use of estrogen replacement is probably not an important factor in pathogenesis or progression of insulin resistance. In a 6-month intervention study in adult Turner syndrome patients, a deterioration took place in the glycemic response during treatment with sex hormones (without a change in insulin sensitivity)—although a significant reduction in the level of fasting insulin was seen.[368] Others have found a slight improvement in glycemia and insulin when formally testing insulin sensitivity.[369] Longer-term treatment with sex hormones may show an improvement in the indices of carbohydrate metabolism, perhaps partly through the expedient effects of sex hormone replacement on physical fitness, body composition, and blood pressure. Hormone replacement therapy did have a beneficial effect on aortic stiffness and cholesterol levels.[370]

The use of GH alone or in combination with anabolic steroids has prompted a reassessment of the carbohydrate status of girls with Turner syndrome, with specific focus on the effects of these agents. In a study of 71 girls enrolled in the previously discussed GH/oxandrolone protocol of Rosenfeld and colleagues,[146] glucose tolerance status was evaluated acutely (before and after 5 days) and after longer-term (2 and 12 months) administration of GH alone, oxandrolone alone, or combination therapy. Pretreatment fasting glucose concentrations were normal in the Turner syndrome patients, but their glucose responses to an oral glucose challenge were higher than in control subjects—with 15% classified as having impaired glucose tolerance. Insulin responses were so varied as to be impossible, as a group, to distinguish from normal. After acute or chronic GH therapy, carbohydrate tolerance as measured by integrated insulin or glucose responses did not change in the GH group.[371]

In the Dutch Turner syndrome study, in which there was a higher than conventional GH treatment group, Hgb

A1c levels did not change from baseline yet decreased after discontinuation of GH treatment.[200] Although there was clearly a trend toward higher fasting insulin levels with the higher GH doses after 4 years of treatment, no significant differences in the change of fasting insulin level or area under the curve for insulin between the GH dosage groups were found. After a mean period of 7.3 years of treatment, insulin levels decreased to values close to or equal to pretreatment values after discontinuation of GH treatment. Long-term results of the effect of GH treatment on lipid metabolism showed no abnormal effects.[196]

In another analysis of U.S. patients treated with GH, mean Hgb A1c levels also remained within the low to middle end of the normal range. Fasting insulin levels remained unchanged, whereas postprandial insulin levels rose and yet remained within the normal range at the 5-year mark.[372] In a few patients, insulin responses were studied after GH was discontinued. Levels returned to normal except in those patients markedly obese (P.H. Saenger, unpublished data). Although the reversibility of the effects of long-term GH is reassuring, the consequences of hyperinsulinism lasting for several years during GH therapy are still unknown.

In summary, glucose-stimulated insulin responses may be increased in children with Turner syndrome whether or not they are treated with GH, but these alterations may be further exaggerated by GH treatment[373,374]—with hyperinsulinemic responses appearing to compensate for reductions in insulin sensitivity.

Data on disease prevalence in adult patients with Turner syndrome suggest an increased incidence of both type 2 and type 1 diabetes mellitus, suggesting an influence of haploinsufficiency of genes on the X chromosome. In adults, the relative risk of type 2 diabetes mellitus was 11.56%. The relative risk of type 1 diabetes mellitus was 4.38%. Because these data are from a medical registry, the risk of misclassification between type 2 diabetes mellitus and type 1 diabetes mellitus cannot be ruled out. The relative risk of diabetes certainly does not seem to be below 2, however. The increased risk for type 2 diabetes mellitus may be secondary to the increased prevalence of obesity in adult women with Turner syndrome.[303,368,369] The data on lipid metabolism are more heterogenous and more studies are needed to determine whether or not lipid metabolism is really altrered in Turner syndrome.[370]

Neuropsychological Features

The consensus regarding the currently available evidence is that the intelligence of persons with Turner syndrome is normal. There does not appear to be an increased incidence of moderate or severe mental retardation, nor do the individuals differ from their siblings in overall intelligence.[375] The only clearly documented association among karyotype, phenotype, and the occurrence of mental retardation is the presence of a small ring X chromosome.[6-10] In these patients, the high risk of mental retardation is most likely caused by the lack of lyonization of the ring X from loss of the X inactivation center—thus creating disomy for some X genes (see section on X chromosome genes).

Of note is a report from 1973 of two severely retarded institutionalized patients with the Turner syndrome phenotype. In these patients, in addition to the 45,X karyotype extrachromosomal material (believed to be of chromosome 21 in origin) was described.[316] Thus, some of the earlier reports of mental retardation[16] may be the result of a small ring X or unrecognized coexistent autosomal aneuploidy—a condition recognized to occur in association with Turner syndrome. We have also found a potential physiologic or genetic correlate with IQ. In a group of 33 Turner syndrome patients who underwent neuropsychological testing, we also tested for thyroid autoimmunity.[377]

The group of 9 girls who had positive antithyroid microsomal antibodies had significantly lower verbal and full-scale IQ scores than the 24 patients in the antibody negative group and the 24 control children. Although overt hypothyroidism was not the mechanism, subclinical or variably transient periods of hypothyroidism could not be ruled out. Alternatively, because thyroid autoimmunity may be familial two other explanations are tenable. One is that the mothers of these patients had subclinical hypothyroidism, a mechanism now documented to account for statistically lower IQ scores in their offspring.[378] A second is that there may be a genetic linkage of autoimmunity and learning disability. At this time, we consider that thyroid autoimmunity may be a marker of cognitive impairment in Turner syndrome and recommend early screening; periodic follow-up of thyroid function, including autoantibodies; and careful developmental assessment.

Whereas individuals with Turner syndrome have normal intelligence and are characterized by normal verbal skills, they have selective impairments in nonverbal skills—including visual-spatial information processing, arithmetic skills, and the coordination of motor and visual-perceptual skills[379-381] (coupled in some with a degree of hyperactivity).[382] Studies suggest that these individuals also have an associated movement (motor) problem in daily life that cannot be directly attributed to cognitive dysfunction.[383,384] As a group, Turner syndrome children also exhibit delayed emotional maturity, poor relations with peers, timidity, and negative body image.[385]

This negative body image may also be secondary to the fact that their short stature could negatively affect psychosocial function and self-esteem, although the severity of psychosocial problems associated with short stature is quite variable.[386] Although Rovet and Holland reported a positive correlation between height and social competence in patients with Turner syndrome,[387] in a more recent study no significant changes in psychosocial function were seen during GH therapy of 2 years.[386]

Although almost all investigators concur that specific cognitive deficits are present, the areas of presumed cognitive dysfunction differ in different reports—and interpretation of the results depends on numerous variables relating to the testing instrument and data analysis. The discrepancy between verbal and performance IQ appears to be, however, confirmed by many studies and may range between 10 and 15 points—with verbal being higher than performance.[379-381,388-390]

In a study dividing patients by karyotype, the 45,X group showed the greatest discrepancy compared with patients with the mosaic or the structurally abnormal X group.[388] The performance task was clearly affected and involved mental rotation tasks, particularly of the block design and object assembly type.[320,388] Turner syndrome girls are also described as exhibiting deficits in tasks of left/right discrimination, road map skills, mental rotation, line orientation rotation, and integration of motor and visual-perceptual skills.[382,389]

Abnormalities in the cognitive and psychosocial abilities in persons with Turner syndrome likely reflect underlying atypical brain development and function.[391] Therefore, investigators have attempted to use specific tests of brain function in an attempt to more clearly elucidate the neuropathologic basis for these performance differences as well as to examine the more general question of the role of the sex chromosomes and/or gonadal hormones in brain development and hemispheric specialization. Qualitative and quantitative analyses of electroencephalographic background data suggested transiently appearing hypofunction at the parietal, temporal, and occipital areas.[392] Lateralization, however, was inconsistent. Electrical activity, measured as event-related brain potential and reaction time to auditory stimuli, was assessed in groups of young and older Turner syndrome girls.[393]

Their event-related brain potential data suggested a slower than normal maturational change, whereas their reaction time responses were less than those of control subjects in both age groups. In one study of a pair of prepubertal monozygotic twins discordant for X monosomy, extensive neurobehavioral and anatomic (MRI) data are presented.[394] The data demonstrate that although both sisters scored in the superior range of intelligence the affected twin had a wide discrepancy in her performance compared with her verbal scores, which was not present in the unaffected twin. The neuroanatomic findings for both sisters fell in the range of normal, but there were significant differences between the twins—the relevance of which is unknown.

In a more extensive MRI study comparing 18 adult women with Turner syndrome and appropriate controls, the subjects had significantly smaller values than the control subjects in MRI-measured volumes of multiple nuclei as well as in bilateral parieto-occipital brain matter.[395] The authors postulate that the X chromosome modulates development of gray matter in striatum, diencephalon, and cerebral hemispheres. Others,[396] including the group of Lippe et al.,[397] have used positron emission tomography in an attempt to correlate regional abnormalities in cerebral metabolic rates with neuropsychological profiles.

These initial studies suggest that hypometabolism in the parietal and occipital lobes may be common among Turner syndrome girls with learning disabilities and also may help explain the impaired visual-spatial information processing. In addition, preliminary studies using functional MRI show activation deficits, particularly in the dorsal lateral prefrontal area of the cortex. This area may be related to executive function, another area of deficit observed in women with Turner syndrome,[398] and together with the other findings may account for the neurobehavioral phenotype in this condition.

Recently published results of neurogenetic research have stimulated interest and controversy. Thus, the differential gene expression known to depend on the parental origin of chromosomes (genomic imprinting) is now being associated with the possibility that in Turner syndrome genes may be differentially expressed according to the origin of the X chromosome present. It is known that in 45,X Turner syndrome the X chromosome is of maternal origin in about 70% to 80.5% of cases.[76-78] Skuse and associates investigated 80 females with Turner syndrome, of whom 25 (the expected proportion) had an X chromosome of paternal origin (Xp). These girls showed satisfactory social adjustment and had higher verbal and executive functional skills than the larger group of girls with the retained X chromosome of maternal origin (Xm).[84]

In an extension of these studies, the Skuse group investigated the relationship of verbal and nonverbal memory with origin of the X chromosome.[399] They observed that 45,Xp Turner females matched controls in verbal memory, whereas this was not the case in the 45,Xm females. In contrast, the results of 45,Xm patients matched those of controls in visual-spatial memory tests but the 45,Xp group did not. The authors conclude that these data indicate an imprinted locus for social cognition on the X chromosome that is not expressed (silenced) on the maternally derived X (putting males and Xm Turner females at risk for developmental disorders of language and social cognition but protecting girls and Xp Turner females). This defect in social cognition may translate into difficulties or lack of understanding of social and nonverbal cues. For example, a young sibling of an adolescent Turner syndrome patient commented about her sister, "She just doesn't get the point and that isolates her"—and a mother commented that her daughter "was not street wise." Many of the girls and women tend not to "read" sarcastic facial expressions or understand double entendres.

The differences in cognition associated with parental X chromosome origin, however, have not been reported by all investigators and need to be corroborated by other groups. For example, Haverkamp and co-workers also examined parental origin of the X chromosome in relation to cognition and came to the conclusion that age and familial covariance also influence cognitive function in Turner syndrome patients.[400] These factors may not have been controlled for in the previous studies. In other words, social cognition and visual-spatial abilities change with age—and differences were no longer apparent in the Haverkamp cohort of adolescent Turner syndrome patients when compared with the normal population.

The role of estrogen deficiency and estrogen replacement therapy also needs to be considered in the context of organic causes for the cognitive, social, and functional profiles of girls and women with Turner syndrome. Indeed, estrogen replacement has been suggested as an explanation for improved motor speed, nonverbal processing, and memory in estrogen-treated Turner syndrome patients compared with placebo-treated patients.[401,402] Whether these findings will influence the

quality of life of females with Turner syndrome is not yet known, although the positive effect on motor function could mitigate the findings of motor impairment described in prepubertal girls.

Some of these deficits may be improved by hormonal therapy at puberty.[402,403] Difficulties in visual-spatial organization, social cognition, and problem solving (mathematics) and motor deficits describe specific neuropsychological deficits that do not improve with time or estrogens.[404-408] As a group, girls and women with Turner syndrome excel at verbal skills, and many adults with Turner syndrome have university level education.[408-409] Recent studies do not support the influence of height as influential on dating and initiation of sexual activities, but the role of physical abnormalities is unclear.[410-412] The developmental process is likely affected by treatment with GH and estrogen that potentially may influence the child's perception of herself.[61] In open-ended interviews, women with Turner syndrome reported that dealing with premature ovarian failure and loss of fertility was the most difficult part of having the condition.[413]

Psychiatric disorders have not previously been reported to be increased in Turner syndrome, but there have been a number of reports describing the occurrence of anorexia nervosa in patients with Turner syndrome.[414] It is presently unclear whether this is increased in comparison with normal girls. Kron and colleagues[414] have pointed out the danger of overlooking an X chromosomal disorder in a patient in whom growth arrest and pubertal delay are attributed to excessive weight loss alone. This is especially relevant because gonadotropins may revert to prepubertal levels.[415] One report, in which the literature was reviewed as well as reporting two patients, suggests that schizophrenia may be increased in women with a mosaic chromosomal karyotype[416] (but again this remains to be confirmed).

Finally, Skuse and co-workers have reported what appears to be a significantly increased risk of autism among Turner syndrome individuals.[417] They noted that this appeared to be in excess in those girls who had retained the maternal X chromosome (Xm) and had either a missing or a structurally abnormal second X. A report of a Turner individual with autism and an Xm genotype[418] is supportive but not confirmatory of this hypothesis because the majority of patients with Turner syndrome are Xm. The hypothesis of Skuse and co-workers that unmaking of a familial predisposition toward autism may occur by the deletion of the protective paternal X chromosome remains to be tested.[419]

A final aspect of the neuropsychological profile of girls and women with Turner syndrome might be called personality. The first systematic investigation of the personality of girls and women with Turner syndrome was conducted in the 1970s.[420] This study and subsequent studies indicate that some personality traits are common to the majority of women and that Turner syndrome individuals had a high stress tolerance, a tendency toward overcompliance, and a higher degree of dependence and limitations in emotional competence.[382,421,422] They also may have an impairment of self-esteem.[423]

The role of the previously described cognitive differences in affecting adaptive personality traits needs to be investigated. Studies indicate that women with Turner syndrome have a typically female pattern of development with unambiguous female gender identification.[424] The scant data available indicate that heterosexual romantic fantasies are common but that dating and initiation of sexual activities may be somewhat delayed or infrequent and that they leave home later than their siblings. A Swedish psychosocial report from 22 middle-aged women with Turner syndrome notes adequate adjustment as adults but a prolonged and isolated adolescence, concerns about infertility, and poor compliance with hormone replacement therapy.[425]

Another report from Israel, however, notes a high degree of adjustment that may relate to the more structured environment.[426] In the context of psychosexual adaptation, attention should be paid to sex education and orientation in adult sexuality. Because some of these girls mature more slowly than their peers, they may not be ready for or interested in sex education when it is given at school. They may also be more self-conscious in relation to beginning a sexual relationship because of being "different." More attention to sex education and sex therapy may be necessary to address this area. Information about assisted reproductive techniques should also be provided.

RECOMMENDATIONS

Whether this complex psychosocial behavior is endogenous or adaptive, as more aggressive and innovative endocrine therapies begin to alter the outlook for stature, timing of feminization, and fertility attention should still be paid to assessment of psychosocial adaptation. Because the factors that affect the quality of life are the same as those that affect the rest of society, psychological care should be provided within the context of helping to prevent difficulties and normalizing the developmental process rather than operating from an illness model. Plans for both medical and psychological intervention should be developed so as to reinforce and support the individual's self-esteem and to ensure that individuals with Turner syndrome remain in the mainstream of social, educational, and employment activities.

A comprehensive psycho-educational evaluation is recommended preceding school entry. Children with Turner syndrome may have other conditions (e.g., dyslexia or attention deficit) that need to be addressed. In view of slower processing speed, untimed testing may be appropriate. Age-appropriate pubertal induction is recommended. It is important to address all issues surrounding sexuality, infertility, and reproductive options in an honest and open manner because "secret-keeping" may have unintended negative consequences and actually amplify the problems.[61,427]

Many of these issues are discussed in patient-oriented material available through the Turner's Syndrome Society of the United States web site (*www.turner-syndrome-us.org*). Similar web sites exist for other national Turner syndrome organizations. Patients with Turner syndrome and their parents need to be well informed about the learning problems associated with Turner syndrome because most individuals are affected by these difficulties,

if only to a mild degree. They need to understand that even with intervention some of these learning difficulties do not disappear with age but persist throughout adult life. Learning disabilities can be a major impediment to emancipation from family and to career enhancement, although many women with Turner syndrome do achieve high professional status.[428]

Management: Pediatric And Adult

EVALUATION

The clinical aspects of which child should be evaluated for Turner syndrome, and at what age, have been addressed in part in this chapter and in the previous chapter on disorders of puberty. Nevertheless, certain clinical aspects warrant review. It is obvious that the female neonate with a webbed neck or edema of the hands and feet merits further investigation. Similarly, the girl with multiple physical stigmata, the girl with coarctation of the aorta, or the girl with radiologic evidence of abnormalities in the urinary collecting system or a horseshoe kidney should also be considered for evaluation. What is less obvious is which girl without obvious stigmata or highly suggestive organic defects should be evaluated (Tables 15-7 and 15-8).

Many girls with Turner syndrome do not have obvious physical stigmata, and it is necessary to recognize that the diagnosis may be difficult in such cases. We reviewed the records of 144 of our patients and found that only 41 had been diagnosed as neonates or toddlers because of obvious physical stigmata. The remaining 103 (71%) presented with short stature or short stature and pubertal delay.[424] In a report of 100 patients, a similar finding was noted.[111] Only 15% were diagnosed at birth. The remaining patients were diagnosed often only after 12 years of age.[134]

The incidence of Turner syndrome is about 1:2,000 live female births, but the statistics change as one considers stature. For example, among 2,000 girls in childhood only 60 are at or below the third percentile—leaving most of the group at risk (excluding infancy and early childhood, and even if no stigmata are present) much smaller. Given other genetic causes for short stature among this group (as well as other acquired causes, and the possible presence of one or more clinical features), the number of girls who might need evaluation becomes less than 1 in 60. Thus, the rationale for considering performing a complete chromosomal karyotype on a girl with short stature becomes even more obvious. The role and utility of SHOX gene testing as part of a short stature evaluation remains to be evaluated.

Once the diagnosis of Turner syndrome has been established and a chromosome analysis has been carried out, additional diagnostic procedures are indicated. These diagnosis and management strategies have been published as recommendations from a consensus workshop. As participants in that workshop, our recommendations tend to be consistent with these recommendations.[61,428]

TABLE 15-7

Screening at Diagnosis of Turner Syndrome in Children and Adults

All Patients
- Cardiovascular evaluation by specialist[a]
- Renal ultrasound
- Hearing evaluation by an audiologist
- Evaluation for scoliosis/kyphosis
- Evaluation for knowledge of Turner syndrome; referral to support groups
- Evaluation for growth and pubertal development

Ages 0-4 Years
- Evaluation for hip dislocation
- Eye exam by pediatric ophthalmologist (if age ≥1)

Ages 4-10 Years
- Thyroid function tests (T_4, TSH) and celiac screen (TTG Ab)
- Educational/psychosocial evaluation
- Orthodontic evaluation (if age ≥ 7)

Ages ≥ 10 Years
- Thyroid function tests (T_4, TSH) and celiac screen (TTG Ab)
- Educational and psychosocial evaluations
- Orthodontic evaluation
- Evaluation of ovarian function/estrogen replacement
- LFTs, FBG, lipids, CBC, Cr, BUN
- BMD (if age 18)

BUN, blood urea nitrogen; CBC, complete blood count; Cr, creatinine; FBG, fasting blood glucose; and LFTs, liver function tests.

Initial and Follow-up Studies in Adolescence and Adulthood

Because the clinical manifestations of gradually developing thyroid failure can be subtle and easily overlooked in a short child, routine serum thyroid function tests (including thyroxine, thyroid-stimulating hormone, and antithyroid antibodies) are indicated. Subsequently, thyroxine and thyroid-stimulating hormone or thyroid-stimulating hormone alone should be determined at 1- to 2-year intervals in all patients regardless of whether significant titers of antithyroid antibodies were detected initially. This follow-up should be continued as an adult. Routine testing for other autoimmune glandular failures does not appear necessary unless other evidence of autoimmune disease develops, such as alopecia, vitiligo, or a glandular failure (other than the ovary).

Routine renal ultrasound may detect structural abnormalities in renal architecture or collecting system anatomy. If no abnormalities are present, follow-up studies are not routinely indicated. If significant abnormalities are detected, follow-up evaluation and therapy may be indicated and long-term screening for urinary tract infection may be necessary.

Infants with Turner syndrome may have an increased risk of congenital hip dislocation,[428] and care should be taken to evaluate the infant. Poor management in childhood can result in serious morbidity in the adult woman. Although the other osseous abnormalities of Turner syndrome may be multiple, unless they cause significant morbidity radiologic survey of the entire skeleton is not routinely recommended. Once a skeletal deformity is noted, however, orthopedic consultation may be indicated. In addition, the practical effects of having an increased carrying angle (e.g., interference with activities such as swimming using a backstroke) need to be recognized and discussed.

Abnormalities of the fingernails and toenails are usually only of mild cosmetic interest. A report of cellulitis and infection secondary to ingrown toenails warrants calling attention to the toenail deformity (if present) and its predisposing conditions (including intermittent lymphedema) and taking care to prevent the ingrown condition.[430] This issue may continue into adulthood. Scoliosis is common but usually does not progress rapidly and can most often be managed conservatively. If growth-promoting regimens are used, careful attention should be paid to detecting progressive scoliosis.

If noted, its cause should be determined radiographically. We have observed two patients in whom it was caused by leg-length inequality. Madelung deformity requires recognition so as to exclude other causes of this bony malposition, but it does not require orthopedic correction. It is actually rather infrequent in Turner syndrome.[431] Girls with Turner syndrome have higher risks for scoliosis and kyphosis than the general population. Ten to twenty percent of girls with Turner syndrome develop scoliosis and kyphosis. Vertebral wedging also appears to be more common.[432,433] Both problems can be accentuated with rapid growth. Phalangeal bone density has been reported to be normal during childhood.[434]

Plasma FSH and LH concentrations at the time of diagnosis may or may not be elevated. They could serve as an indication of future gonadal function but should not be used to screen for the diagnosis of Turner syndrome. In addition, we observed two girls with significantly elevated FSH levels in early childhood who went on to spontaneous onset of puberty (although subsequent ovarian failure). Therefore, predictions of gonadal failure based on high infant/childhood FSH may be given, but with care. Pelvic visualization techniques, including ultrasound and MRI, appear to be clinically indicated only in those situations in which there is a question of gonadal anatomy or potential pubertal function.

The absolute indication is the patient with a Y chromosome or marker chromosome in the karyotype because she is at risk for the development of gonadoblastoma. The ultrasound may demonstrate an adnexal mass in the patient with the Y chromosome in comparison with the normal female (Figure 15-18). Surgical removal of the bilateral adnexal structures is then indicated. The recommendation for concomitant hysterectomy as a prophylactic measure against endometrial carcinoma in an agonadal individual who will be on long-term estrogen replacement therapy is controversial.

Some physicians believe that because it lends little extra morbidity to the indicated pelvic surgery it is a warranted consideration. Others believe that the psychological benefit of monthly menstruation, independent of the artificiality of its method of production and its irrelevance to fertility, precludes the procedure unless there is evidence of local spread of the gonadoblastoma. Finally, oocyte donation, in vitro fertilization, and embryo transfer are being performed successfully in agonadal women—including women with Turner syndrome who have an intact uterus.[435-437] Thus, the issue bears complete discussion with the individual patient and physicians involved—as well as informed patient consent.

A more difficult management decision concerns the method of follow-up of the patient with a cytogenetically documented Y chromosome or molecularly detected Y-derived marker chromosome in the karyotype in whom the initial radiographic studies are normal. The question of whether prophylactic removal of the adnexal streaks should be performed electively or delayed until the ultrasound or MRI suggests a mass has not been entirely resolved. Data indicating that tumor formation may be present microscopically at a very young age are a strong argument for elective surgery, however, even in the absence of a demonstrable mass.[228] However, data from the Danish cancer registry failed to show the presence of gonadoblastoma or dysgerminoma in 29 women with a Y chromosome—suggesting that the risk may be overestimated.[60]

Pelvic visualization techniques may also be useful in patients with evidence of some gonadal function at puberty.[438] In such patients, unilateral or bilateral ovarian structures indistinguishable from normal may be demonstrable. The anatomic findings would lend supportive evidence to the clinical or gonadotropin data and might deter the physician from the institution of hormonal replacement therapy. It is important to point out that spontaneous puberty, even with menses that appear cyclic,

does not always mean that normal ovulatory cycles are occurring or will continue to occur normally in these patients.[232,244] Anovulatory cycles do not result in normal endometrial histology and could impair the capacity for successful ovum implantation and predispose to endometrial hyperplasia or cancer. Although it is clinically impractical to study a complete cycle, efforts should be made to ensure that most cycles are ovulatory. If not, the patient should be either cycled artificially or given periodic courses of progesterone for withdrawal.

Otologic abnormalities are very frequent. Deformation of the pinna is most frequent in patients with the lymphedema phenotype. Otitis media is extremely common and should be treated immediately. The high prevalence of hearing loss, either primary or secondary to residual serous otitis media, suggests that otorhinolaryngologic evaluation with audiometry may be indicated in a large number of patients. In infancy, feeding techniques such as those used for cleft palate patients may also be indicated. We have the clinical impression that mild abnormalities in phonation, independent of hearing impairment, are present in a number of our older patients.

Because these abnormalities in speech may be a consequence of a palatal deformity, speech evaluation may also be indicated. Myringotomy and polyethylene tube placement are considered the primary modes of therapy for serous otitis media in Turner syndrome, and tonsillectomy or adenoidectomy or both should be avoided if possible. Removal of the tonsils and adenoids may not be advisable because of its dubious value for the treatment of serous otitis media and because the pharyngeal tissue often serves as an anatomic prosthesis for pharyngeal competence.

Ophthalmologic abnormalities are common, and an appropriate examination should be performed.[130] Ptosis, hypertelorism epicanthal folds, and upward slanting palpebral fissures are common in Turner syndrome. Red-green color deficiency is present in 8% of the population, a percentage similar to that found in most males. Strabismus and hyperopia occur in 25% to 35% of these children, putting them at high risk for amblyopia. To promote early detection and treatment and to prevent visual loss, children with Turner syndrome should be evaluated by a pediatric ophthalmologist at 12 to 18 months of age.[61]

Hypertension is common in Turner syndrome, and blood pressure should be measured at each visit. Renal arteriography, selective venous catheterization, or both may be indicated in some patients with hypertension. Although the evidence of multiple arterial and venous abnormalities in Turner syndrome suggests that gross or segmental renal vascular disease may be responsible for the hypertension, the disordered anatomy may also render detection of treatable lesions difficult. An example of a study performed in an 11-year-old patient with significant hypertension is shown in Figure 15-20B.

Multiple renal arteries and veins were noted, and selective catheterization was virtually impossible. Nevertheless, in some patients surgically treatable lesions may be apparent. The risk of hypertension continues into adulthood and is a major risk factor for aortic dilation. Adult women with Turner syndrome are also at risk for cardiovascular disease. Therefore, when hypertension is detected in the child or in the adult it should be treated aggressively to minimize the risk of cardiovascular disease as well as of progressive dilation and aortic dissection.[439]

Because the detection of cardiovascular abnormalities requires specialized diagnostic and clinical evaluation, and because their presence may indicate the need for cardiac surgery or lifelong antibiotic therapy for subacute bacterial endocarditis prophylaxis, a cardiologic consultation should be obtained for all patients and should include an ECG. A prenatal ECG does not obviate the need for a postnatal examination because bicuspid aortic valve and coarctation may not be detected in utero. A cardiologist skilled in the assessment of congenital heart disease should interpret the ECG.

If no abnormalities are detected in childhood, a repeat cardiovascular examination and ECG should be conducted during adolescence because aortic dilation may occur without any other risk factors. If bicuspid aortic valve or mitral valve prolapse is detected, subacute bacterial endocarditis prophylaxis is recommended and follow-up should be more frequent. If aortic root dilation is found, the cardiologist should obtain follow-up ECGs at a frequency based on the severity of the dilation present and the presence or absence of other risk factors for dilation (such as hypertension, bicuspid aortic valve, and previously repaired coarctation).

Although we consider the potential morbidity and mortality of this condition (when present) to be similar to that of Marfan syndrome, there are no outcome data to absolutely recommend Marfan management strategies. The role of long-term prophylactic β-adrenergic blockade to slow the rate of dilation and lessen the development of aortic complications in some patients needs to be assessed.[420] Prophylactic aortic root repair may have to be considered for the patient with marked and progressive dilation, however. If unexplained chest pain occurs, even with initially normal studies, the diagnosis of aneurysm or dissection must always be considered.

Coarctation of the aorta is treated surgically in most cases. Although the postoperative risk of the development of mesenteric arteritis is higher in males than in females,[441] we have observed this syndrome in a patient with Turner syndrome. Long-term prognosis is generally good, with few reports of recurrence or complications. However, asymptomatic poststenotic aneurysmal dilation of the aorta may be detectable on screening chest radiography or cardiac MRI (Figure 15-19B and C) and should be followed carefully to prevent dissection or rupture.

The decision to seek consultation for plastic surgery to correct the webbed neck deformity or the forwardly displaced ears is individual. It must be pointed out to the patient and family that in addition to the webbing the neck may also be short. Therefore, cosmetic surgery may be somewhat disappointing. In some cases, however, satisfactory results are achieved. The apparent predisposition toward the development of keloids in these patients must also be taken into account. There is some evidence to suggest that early surgery may have a better cosmetic result.[442] Keloids have also been seen in conjunction with ear piercing, suggesting that this procedure should be avoided or performed with great care.

If, or when, psychometric testing should be performed is an individual family decision. Nevertheless, a preschool evaluation to rule out major areas of cognitive dysfunction might be advisable. In light of the previous discussion, school performance should be monitored—and specific problems should be attended to with skilled cognitive specialists.

Endocrinologic Management

The data show that GH safely increases growth velocity and final adult height in Turner syndrome and have led to regulatory approval for the use of GH in many countries. The criteria for which girls are potential candidates for GH vary. The previously cited guidelines suggest GH should be initiated when the Turner syndrome girl drops below the 5th percentile of the normal curve. This may delay therapy, however, in some girls who could benefit from early therapy and earlier initiation of estrogen replacement (see Turner Toddler study[81]). It also fails to consider genetic midparental target height.

An alternative is to use Lyon curves for Turner syndrome patients as previously described, project their final height if untreated, and initiate therapy if this falls below the 5th through 10th percentiles for normal girls or –1 to –2 SDs below their genetic target midparental height if they are from tall families. A target goal should be set after discussion with the family or with the patient and family, with the emphasis that therapy will be a long process and will not necessarily result in complete normalization of target midparental height.

There are data to document that the response to GH in Turner syndrome does not differ between patients with normal GH responses to pharmacologic stimuli and those with insufficient responses.[443,444] Therefore, GH-provocative testing is neither required by regulatory agencies for GH use nor recommended unless the patient's growth velocity is significantly below the Turner velocity for age (suggesting the presence of hypothalamic-pituitary disease). When GH is started in young girls, concomitant anabolic steroids may not be needed—and there might be some theoretical reasons to avoid years of anabolic steroid therapy.

In older girls (9 to 12 years) or in girls older than 8 in whom therapy is started at a significant height deficit, consideration should be given to starting combined therapy with GH and a nonaromatizable androgen such as oxandrolone because it is aromatization to estrogen that promotes epiphyseal fusion. The recommended dose of oxandrolone should not be above 0.05 mg/kg/day, significantly lower than that used as the initial dose, and slightly lower than that finally used in an often cited study.[171]

Dosing with GH has been previously discussed in the section on growth-promoting therapy. The starting dose is 0.05 mg/kg/day. Individualization of dose can be considered, depending on the patient's growth response. Prediction models may help in this respect.[445] GH should be continued until the final target height previously agreed on with the family (or patient and family) is achieved or until near epiphyseal fusion precludes a significant effect. If androgen is being used, it should be discontinued when the decision is made to begin estrogen therapy.

The issue of when to begin estrogen therapy in this paradigm of GH treatment is less clear. The earlier discussion in this chapter reviews data that suggest that estrogen alone is not useful for augmentation of final height. There are also data that suggest that epiphyseal fusion progresses significantly after 12 to 18 months of estrogen therapy. In addition, when estrogen is used for feminization in conjunction with ongoing GH therapy further growth augmentation may not occur.[446] Finally, in one paper it was documented that the longer the estrogen-free years of GH therapy the taller the final height.

The data in this report also showed that if GH is begun early, however, estrogen treatment could be begun at a younger more appropriate age and still have a greater gain in projected final height.[447] Thus, in aggregate the data suggest that estrogen therapy for feminization should not begin until the patient has reached the estimated height at which she will require only 1 to 2 more years of GH therapy. With the early initiation of GH therapy, that age is likely to be one that is socially acceptable and physiologically normal.

In a recent report,[448] Quigley et al. report positive data of the synergistic effect of early low-dose estrogen (ethinyl estradiol 25 ng/kg/day from age 5 years on) and growth hormoone on adult height. An additional management issue has developed with respect to girls with spontaneous ovarian function. Although studies done before GH treatment suggest that final height does not appear to differ between those girls with spontaneous and induced puberty,[231] there are few data that are applicable to the GH-treated girl.

In one study,[449] four girls developed spontaneous puberty during the first year of GH treatment. They appeared to have an augmented growth velocity compared with the prepubertal girls that persisted into the second year of therapy. Final height data are not available, however. In the study of Reiter and associates, the relationship to estrogen-free years held whether the estrogen was exogenous or endogenous.[447] Thus, if a girl has been treated for several years with GH and has achieved significant height augmentation spontaneous puberty may be of no concern with respect to final height. If it occurs in a girl who is just beginning therapy, however, the initial augmentation could be offset by subsequent epiphyseal closure. Therefore, in a very short girl in whom a significant height augmentation has not yet been achieved and puberty occurs relatively early some consideration may be in order to inhibit puberty with long-acting GnRH analogues.

If GH therapy is not available or otherwise contraindicated, consideration of the use of anabolic steroids as a growth promoter before estrogen therapy in girls 10 to 13 years old who have no clinical or hormonal evidence of ovarian function might be appropriate. The rationale for this, recognizing that it may not increase final adult height, is that it could provide a growth spurt so that when feminization is induced the patient is at a height somewhat closer to that which appears appropriate for obvious signs of puberty. Oxandrolone, 0.05 mg/kg/day, could be used—with side effects (including clitoromegaly and facial hair) monitored.

If the growth velocity begins to decline (usually after 12 months) and if epiphyseal fusion has not taken place, the steroid dose could be increased (0.075 to 0.1 mg/kg/day) to see whether a second spurt can be induced. After that, the medication is discontinued, gonadal status is reassessed, and estrogen therapy is initiated. Finally, some have considered orthopedic leg lengthening as an alternative approach for correction of short stature in Turner syndrome. Experience with this procedure in this condition is still very limited, however.

Although there is controversy over the risks and benefits of hormone replacement therapy in the postmenopausal woman,[450,451] the psychological needs for estrogen in the induction and maintenance of secondary sexual characteristics in young women—and the physiologic needs, among others, for induction of peak bone mass and mineral maintenance and metabolism—are well accepted. Compared with the emphasis on developing optimal regimens for postmenopausal hormonal replacement therapy,[450-455] however, there are few reviews of the optimum preparation and dose schedule for long-term use in younger agonadal women.

With regard to maintenance of bone mineral, the issue is further confounded in Turner syndrome by the difficulty in deciding what standards to apply to the measurements of bone mineral density,[121] the presence of an intrinsic appearance of osteopenia,[456] and the role GH therapy might have in altering bone mineral content.[457] Nevertheless, extrapolation from previous clinical practice and the newer data allow clinicians to develop a rational approach to the principles of therapy. These include long-term cyclic therapy to prevent estrogen-related uterine neoplasia and adequate estrogen to achieve and maintain bone mineral content and preserve the cardioprotective effects on plasma lipids and lipoproteins.

Cyclic therapy is recommended, not only for its positive psychological effect in the adolescent but for its uterine protective effect.[429,458] Data on steroid receptors in hormone-dependent target tissues suggest that progesterone down-regulates or blocks the estrogen receptors,[459] and that when given in conjunction with estrogen may be protective against estrogen-induced neoplasia. Progestins also act to attenuate the action of estrogen by increasing the activities of enzymes that convert estrogen into biologically less active estrone and inactive estrogen sulfate.

When endometrial responses were prospectively evaluated in Turner syndrome patients receiving long-term replacement therapy, hyperplastic changes were noted in only a small percentage of those receiving combined therapy compared with those receiving cyclic estrogen alone.[460] The goal is the complete conversion of the endometrium from a proliferative to a wholly or predominantly secretory state. The dose of progesterone should be minimized to prevent an adverse effect on carbohydrate tolerance[461] and lipid metabolism.[462,463] Therefore, the use of traditional-dose oral contraceptives as long-term therapy is not ideal—given that their progesterone content may be higher than is necessary or optimal.

The estrogen dose needed to achieve maximum bone mineral and to prevent bone mineral loss in Turner syndrome is not known. There are data in adult women with Turner syndrome, however, to show that there is a positive correlation between bone mineral content and the duration of estrogen treatment.[464] A short-term study compared the metabolic effects of low-dose oral conjugated estrogen (0.625 mg) with relatively high-dose ethinyl estradiol (30 ug) combined with progesterone in young women with Turner syndrome.[465] Whereas both regimens normalized the hypotrophic endometria and suppressed hyperinsulinemia, only the higher dose normalized FSH. Neither agent completely normalized the bone metabolic profile, although the higher-dose ethinyl estradiol regimen was more effective in normalizing bone turnover markers. Future investigations of selective estrogen receptor modulators, as well as calcium and vitamin D, were suggested.

Thus, the recommendations for postmenopausal women (0.625 mg of conjugated equine estrogen or its equivalent)—which approximates 60 pg/mL estradiol—may not be adequate long-term replacement for the agonadal woman. Therefore, although this was our previous recommendation for the patient with Turner syndrome it is unlikely that it represents sufficient physiologic long-term replacement. Somewhat higher doses (to achieve the equivalence of 90 to 120 pg/mL) would appear to be more logical. A dose of 2 mg of micronized 17b-estradiol, which is relatively equal to 1.25 mg conjugated estrogen (Premarin), has been shown to have a greater effect in increasing spinal trabecular bone density in postmenopausal women than did the more commonly used 1-mg dose.[465] These estrogen doses are still lower than those in most oral contraceptives.

As most girls are treated from infancy or early childhood on with GH, they are at a better height percentile by age 12 to 13 years. Based on these considerations, hormone replacement therapy may begin sooner (Table 15-9). To initiate feminization, one can begin with 0.3 to 0.625 mg conjugated estrogen daily for 6 to 12 months. After initiation and progression of breast development and uterine growth, the estrogen may be increased to 0.9 to 1.25 mg and cyclic therapy with progesterone [e.g., 10 mg medroxyprogesterone (Provera)] begun. Alternatively, progressive doses of 17β-estradiol can be used (if available), culminating in a final maintenance dose of 2 mg. A calendar month can be used for convenience, beginning with estrogen on day 1 and continuing it through day 23.

Progesterone is started on day 10 and continued through day 23. No medication is ingested for the remainder of the calendar month, when withdrawal menses usually ensue. Estrogen is then restarted on day 1 of the next calendar month, and the cycles are repeated. Follow-up includes monthly breast self-examination. Pelvic examinations and Papanicolaou smears should commence yearly if the patient is sexually active. Otherwise, frequency of these examinations can be determined by the gynecologist to whom the patient is referred as an adult. Cyclic therapy, and maintaining a normal adult uterine endometrium, also enhances the potential for success for reproductive options such as in vitro fertilization.

In addition, for those girls with some residual ovarian function advances are now being made in the area of oocyte cryopreservation coupled with later intracytoplasmic sperm injection.[189] This potential option also enhances the reasons for preservation of the uterus. When

Turner women are older, the issue of whether cyclic therapy should be converted to continuous therapy to prevent menopausal symptoms in the "off week" needs to be considered. This can be achieved safely if the progesterone dose is sufficient to prevent hyperplasia.

The use of other preparations of estrogen and progesterone should also be assessed for long-term use as replacement therapy. These include oral synthetic ethinyl estradiol, transdermal estradiol-17β, and transvaginal suppositories of estrogen and progesterone. The issues that need to be considered are the route of administration and effects of different preparations on systems (such as the hepatic enzymes) that contribute to the potential adverse affects of estrogen on blood pressure, clotting, and gallstone formation. Transdermal estrogen, for example (unlike oral estrogens), avoids the first-pass effect on the liver and may therefore obviate adverse effects on hepatic proteins.[466]

Our initial experience with transdermal estradiol was in a Turner syndrome patient who had recurrence of pedal lymphedema with the institution of oral estrogen replacement. She experienced less swelling with the transdermal preparation. Other patients were started on oral estrogen and then switched to patch estrogen with oral progesterone. For this form of therapy, one can use a 100-mg patch—which appears to be similar in potency to 1.25 mg of conjugated estrogen or 2 mg of estradiol. The patient changes the patch after 3.5 days (two per week) for the first 21 days (3 weeks) of the calendar month. Progesterone is taken from days 10 through 21, and no patch or progesterone is used after day 21 until the next month. Follow-up is the same as for oral estrogen therapy.

An additional comment should be made about breast development in response to estrogen replacement in Turner syndrome. We have observed that the final size of the breast appears to be more consistent with genetic predisposition than with the dose of estrogen or the time it was initiated. The only clear exception appears to be in the girl in whom there are marked clinical signs of extensive fetal edema of the upper body. This includes severe webbing and/or marked nipple hypoplasia at birth. It appears that some of these girls develop very little breast tissue in response to estrogen and that this may be caused by mechanical damage to the breast primordium in utero. In such patients, breast augmentation in late adolescence may be necessary (if the patient is so inclined and if she has not had a problem with keloid formation).

Finally, it must be emphasized that repeated discussion of important issues must take place among family, patient, and clinician. After years of follow-up, one tends to overlook the fact that the patient is no longer a child—and reeducation and new lines of communication need to be established with the patient as an emerging adult.

Transition Management

The transition from pediatric to adult health care should occur at the completion of growth and puberty during late-stage adolescence (usually by 18 to 21 years). However, transition should be initiated as a staged process. Beginning at approximately 12 years of age, the center of care should be shifted incrementally from the parent to the adolsecent with Turner syndrome.The health care focus also shifts from maximizing height to including feminization, counseling the adolescent with Turner syndrome about the evolving impact of her condition into adulthood, and promoting the development of independent self-care behaviors.[61,467]

The Adult with Turner Syndrome

The number of recent excellent papers and reports that now deal with adult women with Turner syndrome strengthens the fact that awareness is growing that this is a large segment of the adult population and that a comprehensive approach to care is needed.[299,425,441,469,470] Most importantly, it needs to be stressed that cardiac care continues. It also must be stressed that women with Turner syndrome receive cylical estrogen and progestin and discontinuation should occur at the age of normal menopause and not before.

Recent studies show that women with Turner syndrome become pregnant as easily as other women with other types of infertility and carry their pregnancies to term without an increased miscarriage rate.[470,471] Because of their small size and and the narrow android pelvis, most women with Turner syndrome need to deliver by Cesarean section. Most critically, the risk for dilatation and dissection of the aorta appears to increase during pregnancy.[471] New data have emerged showing that adolescents with only few signs of spontaneous puberty may still have ovaries with functioning follicles.[472] The possibility of using cryopreserved ovarian tissue and immature oocytes, obtained before regression of follicles occurs, is currently under intense investigation and results seem promising.[61]

With unpredictable changes occurring in health care delivery, however, it is of concern that patients who require a long-term multidisciplinary approach to management may be lost in the medical system. We attempted to reach a consensus in the recently published *Guidelines for the Care of Girls and Women with Turner Syndrome*,[61] which together with previous recommendations[430] reflects our desire to make these guidelines for pediatricians and internists more broadly known.

The consensus document suggests that puberty should be induced at a physiologically appropriate age to optimize self-esteem, social adjustment, and the potential for initiation of sexual relationships. With the quest for earlier diagnosis and hence earlier introduction of growth-promoting therapy, these recommendations (based on a French survey of 566 Turner women aged 18 to 31 years) should guide the clinician in future therapy.[411]

Because the parental origin of the missing X chromosome appears to have an impact on renal development and on ocular features, weight, and academic achievement, it may be appropriate to determine parental origin of the X chromosome using polymorphic microsatellite markers on the X and Y chromosomes.[317,473] It is clear, however, that the pediatric health care provider will be the major resource for translating the ideas expressed

into a future management plan for these patients. The strongest ally the practitioner has may be the patient herself. A well-informed and educated patient will become her own best advocate. Information and materials are available from the Turner's Syndrome Society of the United States (*www.turner-syndrome-us.org*), regional affiliates, and international societies. With the intervention strategies described, girls and women with Turner syndrome now—more than ever—have the capability of achieving their full potential.

The Testes: Disorders of Sexual Differentiation and Puberty in the Male

IEUAN A. HUGHES, MD, FRCP

Introduction
Fetal Male Development
  Embryology
  Genetic and Hormonal Control
Disorders of Sex Development
Defect in Testis Determination
  Sex Chromosome Anomalies
  Gonadal Dysgenesis
  Mixed Gonadal Dysgenesis
Disorders of Androgen Synthesis
  General
  Leydig Cell Hypoplasia
  17β-Hydroxysteroid Dehydrogenase Deficiency
  5α-Reductase Deficiency
Disorders of Androgen Action
  General
  Molecular Pathogenesis of Androgen Insensitivity Syndromes

Introduction

Development of the testes is essential for three key components of male reproductive function: sex determination and differentiation, stimulating the somatic components of male puberty, and development of spermatogenesis and acquisition of reproductive capacity. A trio of cells orchestrates these developments: Leydig cells, Sertoli cells, and germ cells. This chapter focuses on the genetic and hormonal factors that enable a testis to develop, the production of testicular androgens and their mode of action, and how disturbances in these pathways result in disorders seen in pediatric endocrine practice. Endocrine disorders are confined to those resulting from an intrinsic abnormality in testicular function, including a section on testicular tumors. Disorders of male puberty are also covered in this chapter.

Fetal Male Development

EMBRYOLOGY

Sex development comprises the dual components of sex determination (the process whereby the bipotential gonad develops as a testis or as an ovary) and sex differentiation (the phenotypic expression of the action of testicular hormones). The summation and amplification of these processes postnatally is manifest at puberty and followed by the acquisition of reproductive capacity. The entire process, extending from fetal life to adulthood, is a dynamic process dependent on the appropriate and timely interaction of a multitude of genes, proteins, signaling molecules, paracrine factors, and endocrine stimuli.[1-4]

The bipotential primitive gonad arises from a condensation of the mesoderm at the medioventral region of the urogenital ridge (Figure 16-1). This process begins at about 4 to 5 weeks of gestation in humans. The urogenital region is the site of development of the kidney, gonad, and adrenals. Consequently, when disrupted in mice genes (such as WT1 and SF1) that are key to urogenital development result in absent kidney/gonad and adrenal/gonad development (respectively). Inactivating mutations of these genes in humans lead to syndromes [such as Denys-Drash and Frasier (WT1)] and to XY sex reversal with adrenal failure (SF1).[5,6]

Once the urogenital ridge is formed, the mesonephros becomes essential to the development of the testis as a source of somatic cells—which migrate to encompass the primordial germ cells that have also migrated to this site from the yolk sac. The testis and ovary are morphologically indistinguishable until about 6 weeks of gestation. Then, the appearance of Sertoli cells and seminiferous cords developing adjacent to a prominent coelomic blood vessel are the hallmarks of the developing testis. No such morphologic differentiation occurs in the developing ovary until weeks later. Later, interstitial cells differentiate in the testis into Leydig cells and start producing testosterone for the next stage in development: sex differentiation.

The adrenal primordium separates from the developing gonad at about 8 weeks of gestation. However, when the testis later migrates trans-abdominally to reach its scrotal position a nidus of adrenal cell rests may also be sited in this position. It is estimated that adrenal rests are found within, or adjacent to, the testis in up to 15% of neonates.[7] These rests usually regress in later infancy, although they may persist and form testicular "tumors" in males with congenital adrenal hyperplasia.[8] This tissue has characteristics of adrenocortical tissue, such as the production of adrenal-specific steroids and expression of adrenal-specific steroidogenic enzymes.

The internal genitalia are also bipotential, with the anlage for development of the male and female internal genital ducts initially present in both sexes. In the male, regression of the Mullerian ducts (destined to form the uterus and fallopian tubes) and stabilization of the Wolffian ducts (destined to form the vas deferens, epididymis, and seminal vesicles) are prerequisites of normal development. This is mediated by the anti-Mullerian hormone (AMH) acting on its type II AMH receptor expressed in the Mullerian mesenchyme.[9] Maximum sensitivity to AMH action occurs in a window of 9 to 12 weeks of gestation. Wolffian duct stabilization and differentiation is mediated by testosterone produced in large concentrations by the ipsilateral testis and acting predominantly in a paracrine manner.[10]

The external genitalia develop from a common anlage, with androgens playing a trophic role to enable the external genitalia to become sexually dimorphic. Thus, under the influence of androgens the genital tubercle differentiates and enlarges to become a penis, the urethral folds form the penile urethra, and labioscrotal swellings fuse to form the scrotum. The 5α-reduced metabolite of testosterone, dihydrotestosterone (DHT), appears to be essential to this component of sex differentiation based on the anatomic consequences of the human syndrome of 5α-reductase deficiency.[11]

The final step in fetal male development is descent of the testis in two stages: trans-abdominal and transinguinal. The

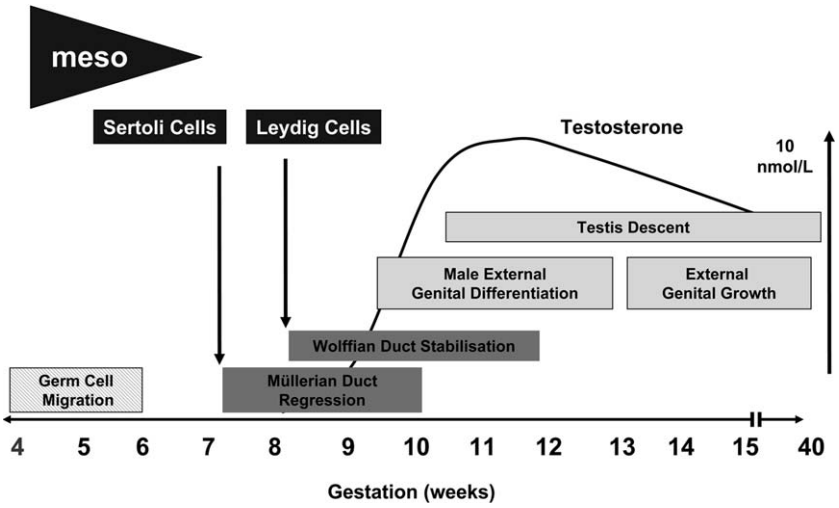

Figure 16-1 Schematic of the embryology of fetal sex development in the male. The continuous line denotes the rise in fetal serum testosterone during the period of sex differentiation.

first stage, which begins at about 12 weeks of gestation and is completed by the middle of the second trimester, involves contraction and thickening of the gubernacular ligament.[12] This phase of descent appears to be controlled by a Leydig cell product [insulin-like 3 (INSL3)] binding to its G-protein–coupled receptor [GREAT, also known as leucine-rich repeat-containing G-protein–coupled receptor 8 (LGR-8) and as GPR106].[13] The phase of transinguinal descent is predominantly androgen dependent.

GENETIC AND HORMONAL CONTROL

A panoply of genes is involved in fetal sex determination and sex differentiation. Much of the knowledge gained, particularly in relation to the genetic control of urogenital development and testis determination, has arisen from mouse models of targeted disruption of candidate genes. However, several of these genes (such as Lim1, Emx2, Pdgfrα, testatin, and SOX3) have not yet been shown to be key components in human sex development based on the effects of inactivating mutations. Figure 16-2 shows a simplified outline of those genes relevant to human fetal sex development. The SRY gene remains the key orchestrator of testis determination, with the most profound evidence illustrated by its expression in more than 90% of phenotypic human males with an XX karyotype[14] and the induction of an XX male mouse by transgenesis.[15]

Inactivating mutations in SRY are found in only 10% to 15% of sex-reversed females with complete XY gonadal dysgenesis. Consequently, genes additional to SRY are required for testis determination. Although SRY is a known transcription factor, little is known of the nature of downstream genes controlled by SRY. It is linked to SOX9, another member of the high-mobility group (HMG) box family of proteins to which SRY belongs, and it is possible that SRY acts by disrupting the binding and function of a repressor—thus allowing activation of downstream genes (such as SOX9).[16] The genes involved in mediating sex differentiation are well characterised and are predominantly those that encode for peptide hormones, such as AMH, and for the steroidogenic enzymes required for androgen biosynthesis. For androgen signaling, the ligand-activated nuclear androgen receptor (AR) is a crucial element in the pathway of male sex development.

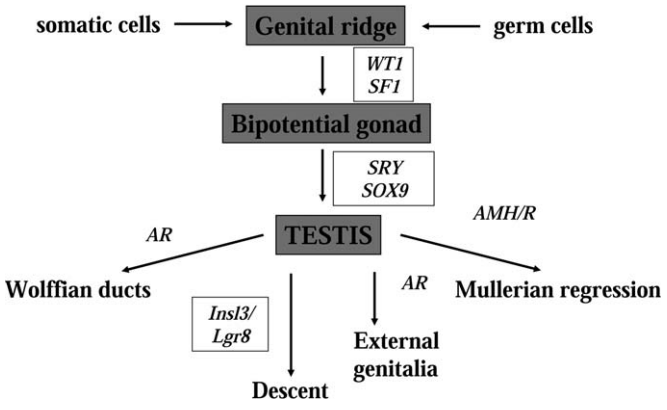

Figure 16-2 Genetic control of sex determination and differentiation in the male related to morphogenetic events.

The pathway of fetal testicular steroidogenesis is shown in Figure 16-3. The production of androgens by fetal Leydig cells occurs as early as 8 to 9 weeks of gestation and is initially autonomous, before becoming dependent on placental hCG secretion.[17] Fetal serum testosterone concentrations increase between 10 and 16 weeks of gestation to levels approaching the adult male range. The pathways shown in Figure 16-3 highlight the importance of CYP17 and the POR gene as regulators of androgen biosynthesis. It is possible that the cytochrome P450 oxidoreductase (POR) enzyme is used preferentially to synthesise DHT by an alternative pathway specific to the fetal testis.[18]

All androgens bind intracellularly with high affinity to a single nuclear AR to mediate androgenic effects, including sex differentiation. The AR is a transcription factor encoded by a gene on chromosome Xq11-q12. The receptor, in common with other members of the large nuclear receptor family, comprises an N-terminal domain (involved in transcriptional activity), a central DNA-binding domain, and a C-terminal domain involved in hormone binding.[19] Subdomains are involved in intramolecular interactions, as well as binding to a number of co-regulators that bridge the AR to the general transcriptional machinery.[20] The AR is ubiquitously expressed, including the fetal reproductive tract.

Disorders of Sex Development

Normal testis development and production of its hormones in an optimal concentration and time-dependent manner is crucial to enable male development to occur against a constitutive background of female fetal development. Consequently, an abnormality of testis function may manifest as a disorder of sex development (DSD). Indeed, it ranks second only to congenital adrenal hyperplasia as the most common cause of ambiguous genitalia of the newborn. This clinical disorder is discussed further in Chapters 4 and 12. The recent changes in terminology and classification of DSD[21,22] (which provide a more rational approach to considering causation related to testicular disease) are outlined in Tables 16-1 and 16-2. From an endocrine perspective, the broad categories of causation are threefold: testicular dysgenesis (a defect in testis determination), a defect in testicular hormone production, and a defect in testicular hormone signaling or action.

Defect in Testis Determination

SEX CHROMOSOME ANOMALIES

Klinefelter syndrome is the male exemplar of the gonadal manifestation of an abnormality in sex chromosomes. This is the most frequent form of sex chromosome aneuploidy. An incidence of about 1 in 600 live births is approximately quadruple the figure obtained in adulthood based on karyotype analysis.[23] This mismatch, indicating a significant rate of underdiagnosis, is presumably the result of not recognizing the pathognomonic sign of small firm testes. Not surprisingly, less than 10% of cases are recognized before puberty. The classic 47,XXY karyotype

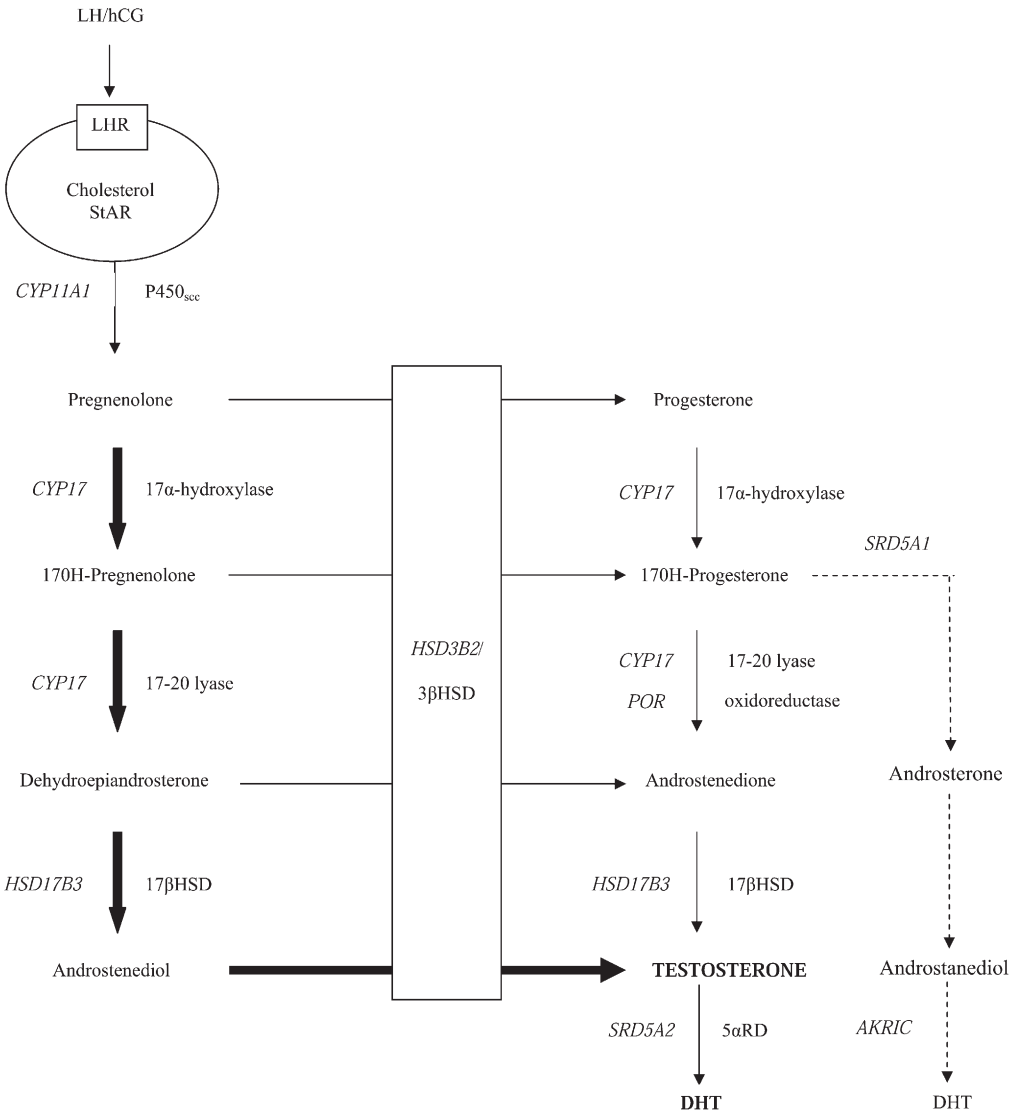

Figure 16-3 Pathway of testicular steroidogenesis. Bold arrows indicate a predominant Δ^5 pathway of steroid production. The dotted lines denote a "backdoor" pathway to DHT synthesis postulated to be specific to the fetus. The steroidogenic enzymes and their cognate genes are shown.

is the result of meiotic non-disjunction during gametogenesis, of which 60% occur during oogenesis.

About 10% of cases are mosaic (46,XY/47,XXY) and tend to have a milder phenotype. Typically, the external genitalia are normal at birth—although there may be anomalies such as hypospadias, micropenis, and undescended testes.[24] The reduced testis size in Klinefelter syndrome is the result of degeneration of the seminiferous tubules. The process has its onset in the fetus, progresses through infancy, and accelerates at puberty.[25] Although the number of germ cells is reduced, there is preservation of Leydig cell development—which is reflected in spontaneous onset of puberty in the majority of boys with Klinefelter syndrome.[26]

Seldom is it necessary to induce puberty with androgens, although supplementary testosterone may be required in adulthood. Fertility has occurred in association with the mosaic forms of Klinefelter syndrome, but with the use of testicular sperm extraction and intracytoplasmic sperm injection (ICSI) a significant number of pregnancies can now be attained in men with the 47,XXY karyotype.[27] Other variants of Klinefelter syndrome can be associated with 46,XY/47,XXY mosaicism and karyotypes as diverse as 48,XXYY, 48,XXXY, 49,XXXYY, and 49,XXXXY. All have in common small testes, tall stature, some genital anomalies, and varying degrees of abnormal cognitive performance.

The XX male syndrome is also similar in nature to Klinefelter syndrome, as characterized by small testes but with some features that differ. The testes are more likely to be undescended, and the incidence of genital anomalies is higher. Adult XX males are shorter, and gynecomastia is more common.[28,29] Azoospermia is universal so that infertility is absolute. The incidence is about 1 in 20,000 phenotypic males. About 10% of XX males lack translocation of the Y-chromosomal SRY gene. They have a higher incidence of genital anomalies such as micropenis, hypospadias, and undescended testes.

TABLE 16-1

Nomenclature Relating to Disorders of Sex Development

Previous	Proposed
Intersex	Disorders of sex development (DSD)
Male pseudohermaphrodite Undervirilization of an XY male Undermasculinization of an XY male	46,XY DSD
Female pseudohermaphrodite Overvirilization of an XX female Masculinization of an XX female	46,XX DSD
True hermaphrodite	Ovotesticular DSD
XX male or XX sex reversal	46,XX testicular DSD
XY sex reversal	46,XY complete gonadal dysgenesis

It is also possible that XX ovotesticular DSD (true hermaphroditism) is part of this subgroup etiologically, subject to ovarian-tissue-containing follicles having been confirmed in an affected individual. There is yet no molecular explanation for male development in the absence of Y-chromosomal material. Proposals include a loss-of-function mutation in a gene that normally inhibits testis formation in the XX female, a gain-of-function mutation in a gene downstream of the SRY transcription factor, and mosaicism for a Y-bearing cell line expressed in the gonads.[30,31] These unidentified genes could be autosomal or X-linked.

GONADAL DYSGENESIS

The term *dysgenesis* should only strictly be used where the definition is based on histology of the gonad. In relation to the testis and disorders of sex development, the appearances on histology accepted to define dysgenesis include carcinoma in situ, immature tubules with undifferentiated Sertoli cells, the presence of microliths (sometimes visible on testicular ultrasound), and a Sertoli cell-only pattern.[32,33]

TABLE 16-2

A Proposed Classification of Causes of DSD

Sex Chromosome DSD	46,XY DSD	46,XX DSD
	A: Disorders of gonadal (testicular) development	A: Disorders of gonadal (ovarian) development
A: 47,XXY (Klinefelter syndrome and variants)	1. Complete or partial gonadal dysgenesis (e.g., SRY, SOX9, SF1, WT1, DHH, etc.)	1. Gonadal dysgenesis
	2. Ovotesticular DSD	2. Ovotesticular DSD
	3. Testis regression	3. Testicular DSD (e.g., SRY+, dup SOX9, RSP01)
B: 45,X (Turner syndrome and variants)	B: Disorders in androgen synthesis or action	B: Androgen excess
	1. Disorders of androgen synthesis	1. Fetal
	LH receptor mutations	3β-hydroxysteroid dehydrogenase 2HSD3B2
	Smith-Lemli-Opitz syndrome	21-hydroxylase (CYP21A2)
	Steroidogenic acute regulatory protein mutations	P450 oxidoreductase (POR)
C: 45,X/46,XY (mixed gonadal dysgenesis)	Cholesterol side-chain cleavage (CYP11A1)	11β-hydroxylase (CYP11B1)
	3β-hydroxysteroid dehydrogenase (HSD3B2)	Glucocorticoid receptor mutations
	17α hydroxylase/17,20-lyase (CYP17)	2. Fetoplacental
D: 46,XX/46,XY (chimerism)	P450 oxidoreductase (POR)	Aromatase (CYP19) deficiency
	17β-hydroxysteroid dehydrogenase (HSD17B3)	Oxidoreductase (POR) deficiency
	5α-reductase (SRD5A2)	3. Maternal
	2. Disorders of androgen action	Maternal virilizing tumors (e.g., luteomas)
	Androgen insensitivity syndrome	Androgenic drugs
	Drugs and environmental modulators	
	C: Other	C: Other
	1. Syndromic associations of male genital development (e.g., cloacal anomalies, Robinow, Aarskog, hand-foot-genital, popliteal pterygium)	1. Syndromic associations (e.g., cloacal anomalies)
		2. Mullerian agenesis/hypoplasia (e.g., MURCS)
	2. Persistent Mullerian duct syndrome	3. Uterine abnormalities (e.g., MODY5)
	3. Vanishing testis syndrome	4. Vaginal atresia (e.g., KcKusick-Kaufman)
	4. Isolated hypospadias (CXorf6)	5. Labial adhesions
	5. Congenital hypogonadotropic hypogonadism	
	6. Cryptorchidism (INSL3, GREAT)	
	7. Environmental influences	

Gonadal dysgenesis as applied to the testis arises from a defect in sex determination during embryogenesis, which may be associated with a sex chromosome anomaly (as in Klinefelter syndrome) or due to inactivation of a testis-determining gene such as SRY or SF1.

The term *gonadal dysgenesis* is also used more loosely in association with indirect evidence of gonadal dysfunction such as elevated gonadotrophin and decreased testosterone levels in an XY subject with failure of Mullerian duct regression. A wide range of genital anomalies occurs with gonadal dysgenesis, and some classification systems are all embracing—including Turner syndrome. In the context of this chapter on the testis, Table 16-2 lists the disorders that need to be considered.

Complete or pure XY gonadal dysgenesis is also known as Swyer syndrome, and is characterized by complete phenotypic sex reversal in an XY female. There are normal female genitalia at birth, but breast development is delayed at puberty. The uterus and fallopian tubes are present, but Wolffian duct remnants are not found. Gonadotrophin levels are characteristically markedly elevated by the time of puberty. Histology shows "streak" gonads indicating no morphological definition of testis development. There is a high risk of tumor development. The incomplete form is defined by any evidence of some masculinizing effects such as ambiguity of the genitalia at birth or virilization at puberty in the form of clitoromegaly, hirsutism, and deepening of the voice.

Histology may reveal some evidence of testis development, but dysgenetic in nature. The molecular pathogenesis of XY gonadal dysgenesis should be explained by a mutation in one of a number of genes involved in testis determination, but only 10% to 15% of individuals with the complete form have a mutation of the SRY gene.[34,35] SRY mutations are rarely found in partial XY gonadal dysgenesis. The first reports of SF1 mutations in humans described the expected phenotype of gonadal dysgenesis and primary adrenal failure.[36] Now, there are examples identified in which adrenal failure does not appear to be a concomitant component of the syndrome of SF1 deficiency.[37] This implies that the yield for identifying mutations in cases of gonadal dysgenesis may be higher if clinicians are more aware of expanded phenotypic spectra associated with testis-determining gene mutations.

MIXED GONADAL DYSGENESIS

This form of gonadal dysgenesis is typically associated with a mosaic 45,X/46,XY karyotype, although additional karyotypes include 45,X/47,XXY and 45,X/46,XY/47,XYY. The phenotype is highly variable. There is a referral bias toward the spectrum of ambiguous genitalia manifest generally as micropenis, severe hypospadias, and bifid scrotum. Such a clinical presentation can be seen with so many causes of DSD. The clinical phenotype in mixed gonadal dysgenesis may range from almost normal female external genitalia with mild clitoromegaly, through ambiguous genitalia, to isolated hypospadias or normal male external genitalia. Indeed, when a 45,X/46,XY karyotype has been found serendipitously on prenatal testing most infants have normal male external genitalia at birth.[38]

There is no information on the longer-term follow-up of these infants with respect to growth, pubertal development, fertility, and risk of gonadal tumors. It is clear that there are normal men in whom this mosaic karyotype is present but unknown, as rarely this sex chromosome anomaly is identified in an infertility clinic setting. The internal genital ducts in mixed gonadal dysgenesis align in general with the nature of the ipsilateral gonad, with retention of a fallopian tube on the side adjacent to a severely dysgenetic streak gonad. The presence of a 45,X line may manifest with Turner-like somatic features of nuchal folds and low-set hairline, associated cardiac and renal anomalies, and short stature.

The gonads in this disorder are generally a combination of a well-formed testis on one side and a streak dysgenetic gonad on the contralateral side. Their positions are usually inguinal/scrotal and intra-abdominal, respectively. The assignment of gender in the biased referred population can be difficult and depends on several factors. Many are now assigned male and will require careful long-term monitoring at puberty and beyond with respect to malignancy risk. The streak gonad is usually removed during early childhood. Infants with female or only mild clitoromegaly are assigned female. The presence of Mullerian remnants in the form of a uterus or hemi-uterus provides an option later for pregnancy by ovum donation. It is essential to remove dysgenetic/streak gonadal material. Mutations in testis-determining genes such as SRY are not generally found in this condition.[39]

Ovotesticular DSD (also previously termed *true hermaphroditism*) can only be defined on histologic criteria according to the presence of ovarian tissues (containing follicles) and testicular tissue present in the same gonad (ovotestis) or as the morphologic appearance of the contralateral gonad. Often, the internal gonads may be in the form of bilateral ovotestes. The most common karyotype is 46,XX, with about 10% of cases having a 46,XY karyotype. An ovotestis is the most frequent gonad, and about a third of 46,XX cases are SRY positive.[40]

Rarely, an SRY mutation may be identified in XY ovotesticular DSD.[41] The phenotype in ovotesticular DSD is variable, although the predominant presentation is ambiguous genitalia or severe hypospadias. In 46,XX cases with an ovotestis and contralateral ovary, sex assignment is generally female with spontaneous onset of breast development and menses at puberty. All testicular tissue should be removed as completely as possible, and remnants monitored by serum AMH levels and the testosterone response to HCG stimulation. Pregnancies are reported in ovotesticular DSD.[42,43] Those raised male will generally require hypospadias repair, orchidopexy, and removal of Mullerian remnants. Any ovarian tissue must be removed before puberty to avoid the risk of breast development. Scrotally sited testicular tissue can be monitored for tumor development, a rare occurrence in this type of DSD. Fertility is uncommon.[44]

Disorders of Androgen Synthesis

GENERAL

The pathway of testicular steroidogenesis is outlined in Figure 16-3. A number of defects in the more proximal intratesticular pathway of steroidogenesis are also manifest as defects in adrenal steroidogenesis (see Chapter 12). These include StAR protein defect (lipoid congenital adrenal hyperplasia), P450 side-chain cleavage deficiency (CYP11A1), 3β-hydroxysteroid dehydrogenase deficiency, 17α-hydroxylase/17,20-lyase deficiency (CYP17), and P450 oxidoreductase (POR) deficiency. The predominant mode of presentation is generally adrenal failure with associated varying degrees of genital anomalies. In contrast, the classic presentation of combined CYP17 deficiency is absent puberty in a phenotypic XY female with low renin hypertension and hypokalemic alkalosis.

Allied to this enzyme, central to androgen production is the co-enzyme P450 oxidoreductase—which is a key participant in the transfer of electrons to P450 enzymes, including the 17,20-lyase reaction of the CYP17 enzyme.[45] Uniquely, deficiency of this enzyme can lead on the one hand to virilization of an affected female (XX, DSD) and on the other to undermasculinization of an affected male (XY,DSD). The underlying mechanism is explained by an apparent combined deficiency of two P450 enzymes (CYP17 and CYP21) and a hitherto unrecognized alternative pathway of androgen biosynthesis specific to the fetus.[46]

P450-oxidoreductase deficiency is also a feature of a subset of cases of Antley-Bixler syndrome.[47] This is characterized by ambiguous genitalia and skeletal dysplasia, the latter comprising craniosynostosis, brachycephaly, midfacial hypoplasia, synostosis of the radioulnar or radiohumeral joints, bowing of the femora, and arachnodactyly. The syndrome also manifests in the absence of a defect in steroidogenesis. This is caused by mutations in the FGFR2 gene (fibroblast growth factor receptor) and is autosomal dominant. The defects in androgen synthesis confined solely to the production and testicular androgens include Leydig cell hypoplasia and deficiencies of the 17β-hydroxysteroid dehydrogenase and 5α-reductase enzymes.

LEYDIG CELL HYPOPLASIA

Placental HCG during early gestation and pituitary LH thereafter in late fetal and postnatal development stimulate testicular androgen synthesis through binding to the LH receptor expressed in Leydig cells. Both ligands bind with similar affinity. The LH receptor is a glycoprotein hormone receptor and a member of the large group of G-protein–coupled receptors. These receptors are characterized by a large extracellular domain of about 400 amino acids and a transmembrane domain comprising a 7-transmembrane serpentine structure.[48] If the receptor is inactivated, the result is a spectrum of undermasculinization in affected males ranging from a complete female phenotype to isolated micropenis. Inactivating mutations of the LH receptor are rare, and usually present with genital anomalies such as severe hypospadias and cryptorchidism.

More than 30 loss-of-function homozygous or heterozygous mutations of the LH receptor gene (residing on chromosome 2p21) are now described.[49,50] Complete resistance may present with primary amenorrhoea and lack of breast development in a phenotypic female who has XY chromosomes. The lack of breast development is a distinguishing clinical feature from the complete androgen insensitivity syndrome. The endocrine profile is as expected: elevated serum LH but normal FSH and low testosterone, which does not respond to HCG stimulation.

Mullerian structures are absent, indicative of normal testicular AMH function. However, the epididymis and vas deferens may be present. It is not clear how Wolffian ducts are stabilized in the absence of fetal androgens. Inactivating LH receptor mutations manifest differently in affected females, who develop puberty normally but thereafter have ovarian dysfunction. There is a tendency for partial loss-of-function mutations that result in mild hypospadias or isolated micropenis to localize in the seventh transmembrane domain. Histology of the gonads shows decreased or absent Leydig cells after puberty. These appearances are less definitive in the prepubertal testis.

17β-HYDROXYSTEROID DEHYDROGENASE DEFICIENCY

The 17β-hydroxysteroid dehydrogenase reaction is mediated by six isoenzymes in humans that convert androstenedione to testosterone, dehydroepiandrosterone to androstenediol, and estrone to estradiol (Figure 16-3). The type 3 enzyme encoded by HSD17B3 located on chromosome 9q22 is testis specific and is key to converting the weak androgen androstenedione to the potent major androgen testosterone.

17β-HSD deficiency (also termed *17β-hydroxysteroid oxidoreductase* or *17-ketosteroid reductase*) is now a well-characterized cause of 46,XY DSD.[51-53] Most affected males have female external genitalia at birth but may present with inguinal swellings similar to infants with complete androgen insensitivity syndrome. Alternatively, the presentation is at puberty when an affected individual (whose sex is assigned female at birth) becomes profoundly virilized—with deepening of the voice, hirsutism, muscle development, and clitoromegaly. Why such virilization should occur at puberty and yet the fetus not masculinized in utero is not adequately explained.

The gonadotrophin rise at puberty increases androstenedione substrate, which can be metabolized to testosterone by extraglandular conversion via alternative 17βHSD isoenzymes (such as the aldoreductase type 5 17β-HSD isoenzyme AKRIC3).[54] The development of gynecomastia occurs by converson of androstenedione by aromatase enzyme in extraglandular tissues and the action of type 1 or type 2 17β-HSD isoenzymes. The virilization that occurs at puberty is occasionally followed by gender role reassignment from female to male, similar to that observed in 5α-reductase deficiency. If the gender remains female, urgent gonadectomy is required—with clitoroplasty and usually vaginoplasty. The deepening of the voice is seldom completely reversible.

More than 20 mutations in the HSD17B3 gene have now been described.[4] Most are missense mutations, with some patients displaying compound heterozygosity. Functional studies of mutant enzymes expressed in vitro generally show complete lack of ability to convert androstenedione to testosterone. Consequently, these studies bear little relationship to predicting the degree of virilization expected at puberty. An inbred population in Gaza has the more frequent mutation causing 17β-HSD deficiency, resulting from conversion of arginine to glutamine (R80Q) at codon 80.[55] This population also serves to illustrate that deficiency of this enzyme in females has no functional consequences because females homozygous for the mutation were normal.

5α-REDUCTASE DEFICIENCY

This cause of XY DSD is also characterized by profound virilization at puberty in an affected individual/raised female. The condition came to prominence through the reporting of a genetic isolate in the Dominican Republic, where gender role changes at puberty are not uncommon.[56,57] However, unlike 17β-hydroxysteroid dehydrogenase deficiency the external genitalia are more ambiguous at birth—with severe hypospadias, micropenis, bifid scrotum/labioscrotal folds, and a urogenital sinus.

The testes transcend the abdomen to lie in the inguinal canals or within the bifid/labioscrotal folds. There are no Mullerian structures, and the Wolffian ducts are normally stabilized to form the epididymis, vas deferens, and seminal vesicle. The prostate gland remains hypoplastic at puberty, indicating the specific dependence of this structure on DHT. Furthermore, adult males do not develop acne or temporal hair recession. Fertility is reduced probably as a result of the mal-positioned testes. However, there are reports of fertility—spontaneous and by artificial reproductive techniques.[58,59]

The enzyme deficiency is caused by mutations in the SRD5A2 gene located on chromosome 2p23. More than 40 mutations have been identified, the majority being missense mutations.[4] A genetic isolate affecting the New Guinea population is due to a complete gene deletion. Females homozygous for 5α-reductase deficiency have normal fertility.[60] The biochemical diagnosis centers on demonstrating an elevated ratio of testosterone to dihydrotestosterone (DHT) in serum (following HCG stimulation in prepubertal patients) and a diminished ratio of urinary 5α to 5α-reduced C_{19} and C_{21} steroids. Even after gonadectomy, a biochemical diagnosis can still be ascertained because of the role of 5α-reductase in metabolism of glucocorticoids.

Disorders of Androgen Action

GENERAL

The key role of androgens in male sex differentiation is vividly illustrated by the consequence of a total lack of response to androgens in target tissues—a complete female phenotype in a 46,XY individual with normally formed testes producing age-appropriate testosterone levels. This is the paradigm of a hormone resistance syndrome. Formerly called the testicular feminization syndrome, the favored terminology is now *androgen insensitivity syndrome* (AIS)—subclassified into complete (CAIS) and partial (PAIS) forms.[61,62]

Male sex differentiation and the subsequent acquisition of secondary sex characteristics at puberty, and the onset of spermatogenesis, are all mediated by androgens binding to a single intracellular androgen receptor (AR) ubiquitously expressed in target tissue. The AR is one of a quartet of nuclear receptors (glucocorticoid, mineralocorticoid, progesterone, and androgen) closely related within a large superfamily. It can activate gene transcription via a common hormone response element. The single-copy gene encoding the AR is located on Xq11-q12 and is made up of 8 exons that encode a protein of 919 amino acid residues. The major functional domains comprise an N-terminal transactivation domain (NTD), a central highly conserved DNA-binding domain (DBD), and a hinge region that connects the DBD to the C-terminal ligand-binding domain (LBD) (Figure 16-4).

The DBD contains cysteine residues that coordinate zinc atoms to form the zinc fingers characteristic of all nuclear receptors and many other transcription factors. The main domains comprise subsidiary functions that include dimerization, binding to co-regulator proteins, interaction with heat shock proteins, and transcriptional regulation.[63] The two subdomains most involved in activation of transcription are the motif activation function-1 (AF1) in the NTD and the motif activation function-2 (AF2) in the LBD. AF2 also interacts with steroid receptor coactivators such as SRC1, SRC2/TIF2, and SRC3 via their LXXLL motifs—where L is a leucine and X is any amino acid.[64] This interaction is weaker in the case of the androgen receptor AF2 subdomain, which uniquely interacts in an intramolecular manner with its cognate AF1 subdomain in the NTD.[64] N- and C-terminal interaction stabilizes the AR and slows down the dissociation of the ligand from its receptor.

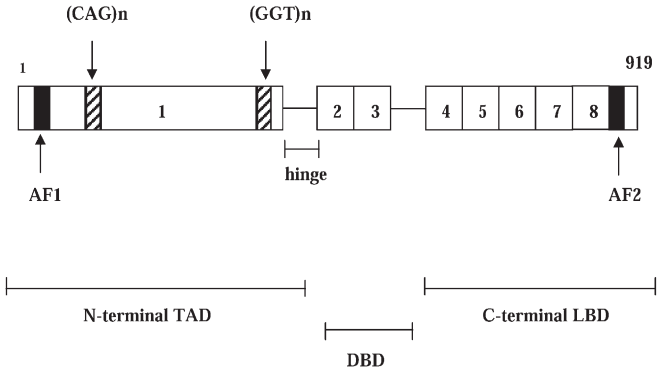

Figure 16-4 A schematic of the functional domains of the androgen receptor. Numbers inside boxes refer to exons 1 through 8. AF1 is activation function 1. AF2 is activation function 2. (CAG)n encodes for a polyglutamine stretch. (GGT)n encodes for a polyglycine stretch. The three main domains are TAD (transactivation domain), DBD (DNA-binding domain), and LBD (ligand-binding domain).

A sequence of CAG repeats in exon 1 of the AR gene encodes for a homopolymeric stretch of glutamines, which ranges from 11 to 31 repeats in the general population. Another repeat of glycines ranges from 10 to 25. In vitro studies show that the length of the CAG repeat is inversely proportional to the activity of the AR as a transcription factor.[65]

Figure 16-5 shows a schematic of how androgens interact with the AR on entering target cells. The figure also shows subsequent activation of target genes. A single receptor binds testosterone and DHT, the latter being a biologically more potent androgen because of dissociating from the AR at a slower rate. The AR in the unliganded state is located in the cytoplasm complexed to heat shock proteins (HSPs) such as HSP70 and HSP90. These in turn are also complexed to co-chaperone proteins such as FKBP52.[66] Ligand binding initiates dissociation to allow translocation of the AR to the nucleus, where it binds as a homodimer to DNA hormone response elements. The action of the AR is further modulated by interaction with co-regulatory proteins, which function either as coactivators or co-repressors. These proteins act as a physical bridge connecting the receptor to the basal transcription machinery. Coactivators ARA24, ARA55, and ARA70 are AR specific.

The three-dimensional structure of a nuclear receptor LBD comprises 12α helixes associated with anti-parallel β sheets arranged in the form of a tripartite sandwich. A hydrophobic pocket is formed by helixes, 4, 5, 7, 11, and 12—to which the ligand is bound on contact with its cognate receptor. Helix 12 is the outermost α-helix, which folds back on top of the ligand hydrophobic pocket like a lid closing on a box. This has been referred to as the "mousetrap effect" to capture the ligand and retain it by slowing the rate of ligand-receptor dissociation. This trapping effect by helix 12 also permits interaction between the LBD and AF2 subdomain and the LXXLL motif in associated co-regulator proteins. Much information about the structural and functional aspects of the AR has been obtained through studying the functional effects of AR mutations that lead to AIS.

The phenotype of CAIS is that of a normal female, with a prevalence for this X-linked recessive disorder ranging from 1 in 20,400 genetic males to 1 in 99,000 genetic males.[67,68] The typical presentation is primary amenorrhoea in an otherwise normally developed adolescent female. The uterus is absent as a result of normal AMH action. The Wolffian ducts are surprisingly stabilized in many patients.[69] The main differential at this age is XY complete gonadal dysgenesis (Swyer syndrome), which is distinguished by poor breast development and a shorter stature. The other typical presentation in early life for CAIS is with bilateral inguinal or labial swellings. This can also occur in 17β-HSD deficiency.

Bilateral inguinal herniae are rare in girls, and it has been estimated that 1% to 2% of such cases have CAIS. Consequently, it is now generally recommended that a CAIS diagnosis be considered in all girls with this type of hernia and the presence of a Y chromosome be checked by FISH analysis and a full karyotype. If the content of the

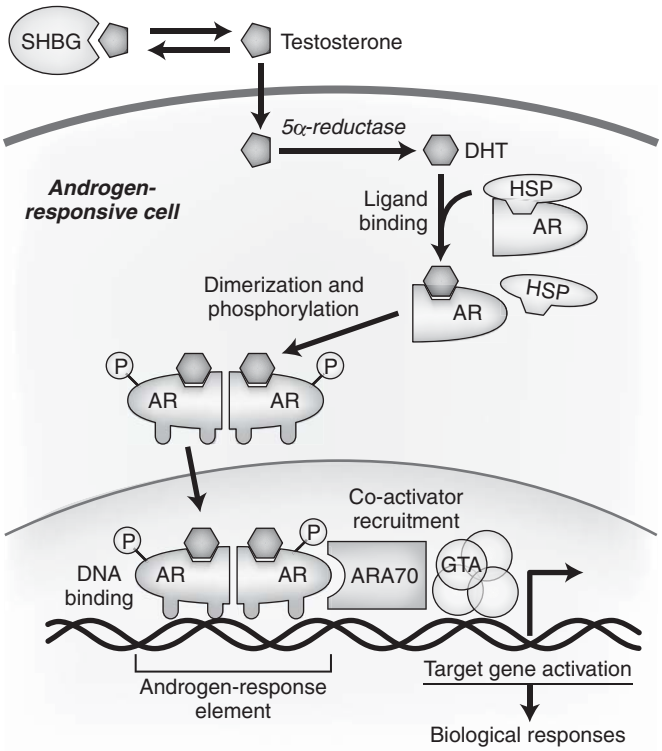

Figure 16-5 A schematic of the mechanism of androgen activation of the androgen receptor and gene transcription. The development of androgen-independent prostate cancer. Nature Rev Cancer 1:34–45. Copyright © of and adapted by permission from Macmillan Publishers Ltd.]

hernial sac contain gonads, a biopsy should be taken in concert with the cytogenetic studies.[70] A family history of an older female sibling having had an inguinal hernia repair in infancy but with the diagnosis of CAIS missed is not unusual. Another mode of presentation is mismatch between a prenatal XY karyotype and a female phenotype at birth.

The syndrome of PAIS occurs when there is some biologic response to androgens. The external genitalia may be ambiguous at birth, but the prototypic phenotype for PAIS is perineoscrotal hypospadias, micropenis, bifid scrotum, and undescended testes. The more severe form of PAIS presenting as isolated clitoromegaly is only marginally different from CAIS. At the other end of the phenotypic spectrum there may be just isolated hypospadias or even normal male development at birth but gynaecomastia and infertility presenting in adulthood. Surveys of male factor infertility characterized by elevated LH and testosterone levels have revealed a minority to have a mutation in the AR gene.[71] High doses of androgens may lead to fertility.[72] The list of disorders to consider within the 46,XY DSD category is much larger with the PAIS phenotype. They can be broadly classified as partial gonadal dysgenesis, a defect in androgen biosynthesis (LH receptor, SF1, 17β-HSD and 5α-RD deficiencies), and mixed gonadal dysgenesis in association with 45,X/46,XY mosaicism.

The hormone profile in AIS shows an increased age-related testosterone level, increased LH, and only a slightly elevated FSH level. Serum estradiol is increased at puberty from aromatization of testosterone. Concentrations of sex hormone binding globulin (SHBG), a protein produced by the liver, are sexually dimorphic—with levels in CAIS similar to those found in normal females. This hepatic resistance to the action of androgens has been proposed as a biologic marker of androgen responsiveness in AIS.[73] Stanazolol, a synthetic nonaromatizable androgen, is administered orally—and the decrement in serum SHBG levels measured. There is normally a 50% reduction, but the change is insignificant in CAIS. There is a moderate response in PAIS, but overlapping with normals.

A further biochemical test, available only in research laboratories, used in the investigation of androgen resistance is measurement of androgen binding in genital skin fibroblasts. The AR is ubiquitously expressed, and in greater quantities in genital versus nongenital skin. A small genital skin biopsy collected at genitoplasty or during an examination under anesthetic can be used to generate a cell line to perform a binding assay using radiolabeled androgens. A quantitative and qualitative measure of binding can be determined from a Scatchard plot analysis. Typically, there is absent binding when a nonsense mutation results in a truncated AR. Such a mutation is sufficiently pathogenic to lead to a CAIS phenotype. Alternatively, there may be binding of androgens to the AR—but with lower affinity. A missense mutation is generally associated with such findings, resulting usually in a PAIS phenotype. The cell line is also a source of RNA, which can be analyzed for length if a mutation is suspected to be residing in the noncoding region of the AR gene.

MOLECULAR PATHOGENESIS OF ANDROGEN INSENSITIVITY SYNDROMES

Information about the various mutations that affect the AR and give rise to clinical disease is recorded on an International Mutation Database at McGill University (*http://www.androgendb.mcgill.ca*). The majority of mutations relate to syndromes of androgen insensitivity, but in addition somatic mutations identified in prostate carcinoma are listed. The database records more than 300 different mutations that can cause AIS. These are distributed throughout the gene, with no specific "hot spot" of mutations but about two-thirds are located in the LBD.

The range of mutations identified through the Cambridge DSD database is shown in Figure 16-6. Identifying a mutation, particularly if missense, does not necessarily imply pathogenicity. If the mutation is novel, it is advisable to recreate the mutant AR for functional studies using a reporter gene assay. It is also possible to undertake structure-guided modeling of the mutant protein to provide insight into AR dysfunction.[74] There is considerable heterogeneity in the phenotypic expression of a particular mutation, sometimes even within families. For example, a missense mutation at codon 703 in exon 4 of the LBD (which changes a serine to a glycine) is reported in four separate individuals on the McGill database. One patient had a normal female phenotype, whereas the other three cases all had ambiguous genitalia consistent with PAIS. However, the degree of androgenization of the external genitalia was sufficiently variable that two were raised male and the other female.[75,76] Rarely, two affected members in the same family can be respectively phenotypically CAIS and PAIS.

X-linked disorders are associated with a high rate of mutations that are de novo. The rate in AIS is about 30%. Such mutations arise as a single mutational event in a parental germ cell (maternal in the case of AIS) or as a germ cell mosaicism in the maternal gonad. Somatic mosaicism occurs when the mutation arises at the post-zygotic stage. Consequently, there is expression of both mutant and wild-type AR in different target tissues, including the external genitalia. About a third of de novo mutations in AIS arise at the post-zygotic stage, thereby explaining some of the variable phenotype in PAIS.[77] Other modulatory factors may include differences in 5α-RD 2 expression and reduced AR transcription and translation.[78,79]

No AR gene mutation is found in a minority of cases of CAIS or in a significant number of cases of PAIS. Nevertheless, it appears that there is clinical and biochemical evidence of androgen resistance. It is possible that patients with CAIS or PAIS in whom no mutation has been found in the AR gene may have a mutant coactivator protein to explain the androgen resistance. There is increasing evidence that nuclear receptor co-regulators play a role in the formation of mammalian phenotypes and perhaps in human disease.[20,81] In a study of the two AR-related coactivators, ARA24 and ARA 70, no substantive variations were found in amino acid residues in a series of patients with PAIS and a normal AR.[81,82]

Disruption of the steroid receptor coactivator-3 (SRC) in mice results in a phenotype of general hormone resistance, including features consistent with PAIS.[83] The SRC3

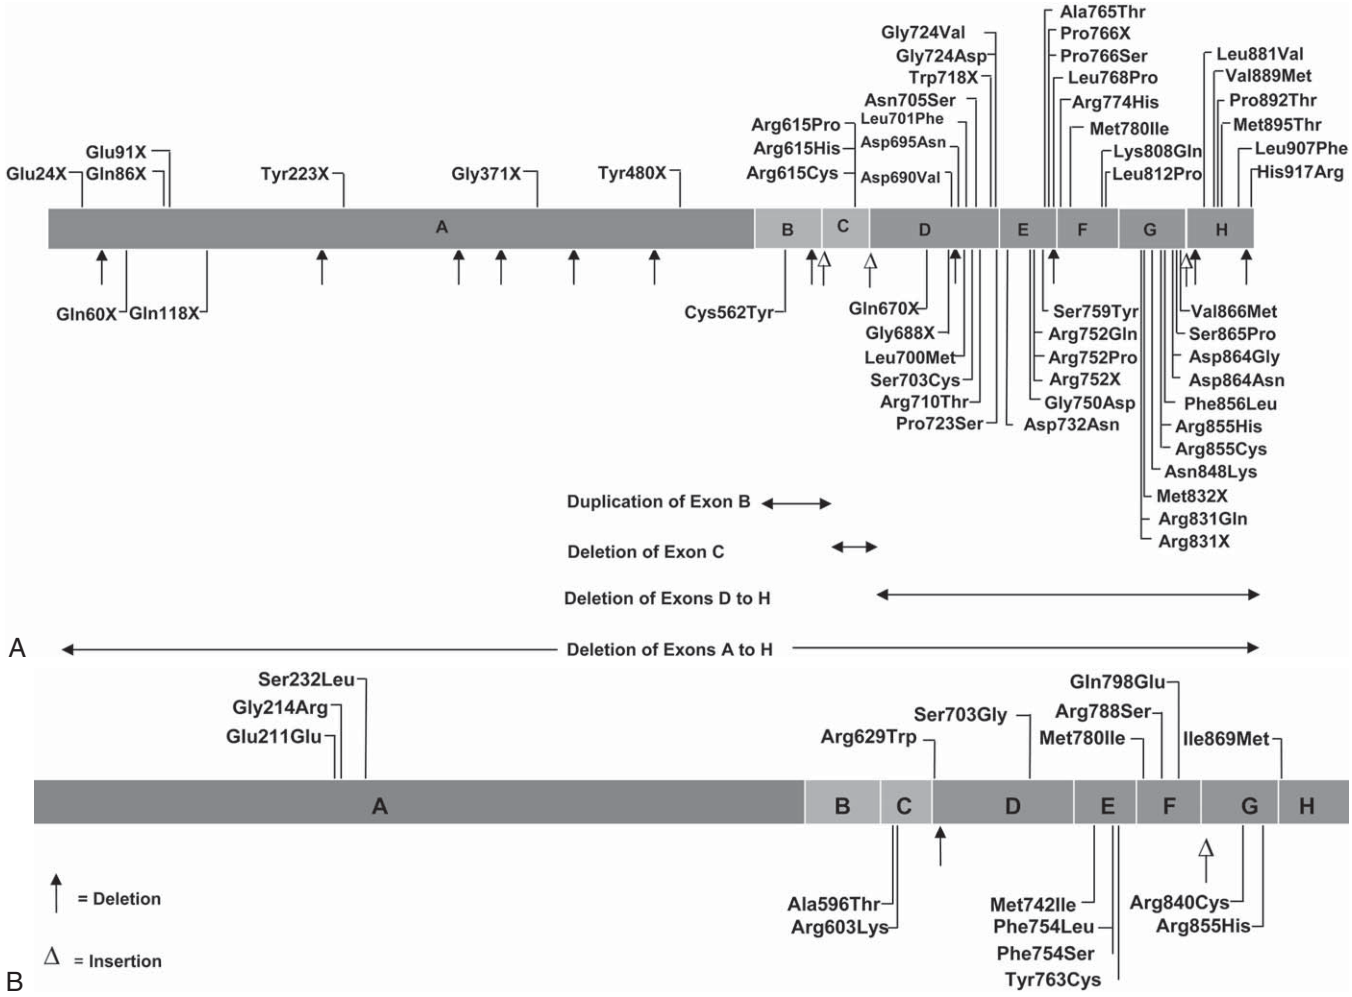

Figure 16-6 Androgen receptor mutations recorded on the Cambridge DSD database. *(A)* Mutations associated with CAIS phenotype. *(B)* Mutations associated with PAIS phenotype.

gene contains a variable track of CAG/CAA triplets that encode a polyglutamine repeat. The lengths of glutamine repeats were found to be shorter in PAIS subjects compared with controls.[84] The large number of co-regulator proteins (more than 300), their array of mechanisms to modulate transcription, and promiscuous binding to nuclear receptors in general makes it unlikely that a single mutant protein in this family would explain the mechanism of androgen resistance in CAIS or PAIS patients who have a normal AR. One patient with CAIS with a normal AR, in whom a subdomain of the AR failed to stimulate transcription of AR target genes, was suggested as evidence for a defect in an AR-specific coactivator.[85,86]

The polymorphic region in the N-terminal domain of the AR of glutamine repeats has biologic relevance to human disease. A toxic gain-of-function from hyperexpansion (>40 repeats) is found in Kennedy's disease and in spinal and bulbar muscular atrophy (SBMA).[87] Affected males have testicular atrophy, decreased spermatogenesis, and gynaecomastia despite elevated androgen levels (in keeping with a degree of androgen resistance). Variations in the length of the polyglutamine tract within the normal range are reported in association with disorders such as hypospadias,[88] reduced spermatogenesis,[89] and the phenotype of Klinefelter syndrome.[90]

Shorter glutamine repeats and relative hyperandrogenic states are reported in prostate cancer[91] androgenetic alopecia and acne,[92] and ovarian hyperandrogenism.[93] The polymorphic stretch of glycines is also significantly longer in patients with cryptorchidism and in a separate group with hypospadias compared with controls.[94] When CAG (glutamine) and GGN (glycine) lengths are analyzed together in the context of a missense mutation in the AR gene causing AIS, the combined effects appear to modulate the phenotypic expression of a given AR mutant in different affected individuals.[95]

Disorder of AMH

PERSISTENT MULLERIAN DUCT SYNDROME

Anti-Mullerian hormone (AMH) is a Sertoli-cell-produced glycoprotein homodimer encoded by a 2.75-kb gene on chromosome 19p13.3. The AMH type II receptor is a serine/threonine kinase with a single transmembrane

domain encoded by a gene located on 12q13.[96] Persistent Mullerian duct syndrome (PMDS, *herniae uteri inguinale*) is a condition affecting males who have normally developed testes, internal male ducts, and external genitalia but persistent Mullerian duct derivatives. The diagnosis is often made when a fallopian tube and uterus are found during an inguinal hernia repair or an orchidopexy procedure. The hernia contains a partially descended or scrotal testis, as well as an ipsilateral tube and uterus. Sometimes the contralateral testis is also present in the hernial sac. Such transverse testicular ectopia is virtually pathognomonic of PMDS.

PMDS in normally differentiated males may result from failure of the Sertoli cells to synthesize AMH or from resistance to the action of AMH because of an AMH type II receptor defect. There is an even distribution of genetically proven cases of PMDS being the result of AMH or AMH type II receptor gene mutations.[97] AMH gene mutations are most common in Mediterranean, Northern African, and Middle Eastern countries and are usually familial homozygous mutations.[98] In contrast, mutations in the AMH type II receptor gene are more common in France and Northern Europe and are often compound heterozygous in nature.[99] Serum AMH measurement is a useful marker of the likely gene affected. Thus, low or undetectable levels are indicative of a mutation in the AMH gene—whereas a normal or increased serum concentration of AMH points to a defect in the AMH type II receptor gene.

Other Testis-Related Disorders

ANORCHIA AND CRYPTORCHIDISM

The term *vanishing testis syndrome* was coined for the phenotype of bilateral anorchia in an otherwise normally developed male infant. It recognizes the presence of normal testes in early gestation functioning to induce Mullerian duct regression, stabilize Wolffian duct development, and differentiate male external genitalia. Any ambiguity of the external genitalia suggests a variant of the syndrome related to some form of XY gonadal dysgenesis. Bilateral anorchia with normal differentiated but small phallus (micropenis) is also a recognized variant of the syndrome.[100]

A rare finding in such cases is a heterozygous partial loss-of-function mutation in SF1.[101] Otherwise, the cause is unknown other than invoking an interruption to the testis blood supply from a torsion or vascular occlusion event in utero. Surgical exploration and histologic findings typically show nubbins of fibrous tissue as remnants of gonads, associated with a vas deferens in the majority and some epididymal tissue.[102,103] The presence of hemosiderin-laden macrophages and dystrophic calcification is in keeping with the vascular accident hypothesis.

Establishing complete anorchia is based on a combination of biochemical tests, imaging studies, and surgical exploration.[104] An undetectable serum AMH level is a reliable marker when evaluating infants with nonpalpable gonads.[105] This, coupled with elevated serum gonadotrophins and an absent testosterone response to hCG stimulation, is predictive of the absence of testes. A low inhibin B level is also confirmatory. Imaging with CT or MRI may be useful prior to laparoscopy. Most centers would currently still undertake surgical exploration to remove testicular remnants, even though there is usually no evidence of malignancy found. Such a procedure could be deferred until the time of insertion of testicular prostheses.

Testes that have not descended at birth (cryptorchidism) is the most common congenital abnormality in boys, affecting 2% to 9% male live births.[106] The strong association with low birth weight is well recognized, as are disorders of the pituitary-gonadal axis [such as hypogonadotrophic hypogonadism (HH) and the androgen insensitivity syndrome]. The association with disorders of androgen production or action is in keeping with the role of androgens in the inguinoscrotal phase of testis descent. Mutations in INSL3 and GREAT (also known as LGR8) are reported in a minority of boys with cryptorchidism.[107-109]

Greater exposure to pesticides has been reported in cryptorchid boys based on analyses of breast milk samples as a proxy for fetal exposure.[110] Epidemiologic evidence for secular trends in the prevalence of cryptorchidism, and geographic variations in birth prevalence, point to environmental chemicals having an adverse effect on the genetic and hormonal control of testis descent.[111-115] Cryptorchidism may be associated with hypospadias. In turn, both are coupled to an increased risk for abnormal spermatogenesis and testicular cancer—two male reproductive tract disorders also increasing in prevalence.[116,117] This quartet of disorders constitutes a testicular dysgenesis syndrome (TDS) postulated to be of fetal origin and triggered by environmental chemicals disrupting an androgen/estrogen balance critical to normal sex development.[118]

The clearest evidence that certain chemicals (such as herbicides, fungicides, bisphenol A, and phthalates) can act as endocrine disruptors is derived from observations of wildlife and laboratory animal experiments. It remains uncertain whether there is also a new and emerging public health problem.[119] Direct evidence of toxic effects in humans has yet to be established. The previous practice of using diethyl stilbestrol (DES) to prevent recurrent miscarriages has resulted in transgenerational effects in the form of urogenital anomalies, including cryptorchidism in male offspring.[120] Sons of agricultural workers have an increased risk of cryptorchidism, which is related to levels of pesticide exposure.[121] The anogenital distance is a measurement used by reproductive toxicologists as a sensitive marker of prenatal exposure to androgen action in rodent studies.[122] In a human study, there was an inverse relationship between the anogenital distance in male infants and the levels of several phthalates measured in maternal urine.[123] Furthermore, the anogenital distance was shorter in boys with cryptorchidism.

HYPOSPADIAS

Hypospadias is incomplete fusion of the penile urethra defined by an arrest in development of the urethral spongiosum and ventral prepuce.[124] The normal embryologic correction of penile curvature is also interrupted. It is a common congenital anomaly, with birth prevalence estimated at about 3 to 4 per 1,000 live

births. Despite extensive effort at investigation, the cause is unknown in the majority of cases.[125,126] An occasional case of isolated hypospadias has been identified with a mutation in WT1, SF1, LHR, CYP17, or the AR gene. The CXorf6 gene on chromosome Xq28 has been found to be mutated in some cases of hypospadias.[127] The mouse homologue is expressed in Leydig and Sertoli cells coincident with the period of sex differentiation (E12.5-E14.5).

Because expression of this gene is insignificant in the external genital anlagen, this suggests a transient Leydig cell dysfunction as an explanation for hypospadias in these cases. A mutation screen of BMP4, BMP7, HOXA4, and HOXB6 identified mutations in 14 of 90 cases of hypospadias in a Chinese population (all in the heterozygous state).[128] Mutations in HOXA13 are found in the hand-foot-genital syndrome, which includes hypospadias.[129] There is generally a familial clustering of cases in hypospadias, with a 7% incidence of one or more additional affected family members.[130] Furthermore, the twinning rate is higher than in the general population—of which two-thirds are monozygotic.

Associations observed in hypospadias include increased maternal age, mother exposed to DES in utero, paternal subfertility, maternal vegetarian diet, maternal smoking, assisted reproductive techniques, paternal exposure to pesticides, and fetal growth restriction.[131] The association with low birth weight suggests a link between factors operating to cause fetal growth restriction and the process of completing fusion of the urethral folds by the early second trimester. Gene expression profiles during urethral development in the mouse indicate that a number of signaling pathways are involved.[132]

Testis Tumors

GENERAL

Testis cancer is rare and has the highest prevalence in young men in the third and fourth decades of life.[133] The majority are germ cell in origin, manifesting as seminoma or nonseminoma tumors. The World Health Organization (WHO) classification system is the basis on which histologic typing of testis tumors is practiced.[134-136]

Tumors arise from the three principal cell types that comprise the formation of the testis: germ cells derived from primitive gonocytes, the supporting cells that differentiate as Sertoli cells, and the stromal interstitial cells that differentiate as Leydig cells. Rarely, tumors can arise from nonspecific testis tissue such as muscle (rhabdomyosarcoma), blood vessels (hemangioma), fibrous tissue (fibroma), and as a result of infiltration (leukemias, lymphoma). Germ cell tumors account for the vast majority, some of which manifest in early life. Leydig cell tumors also occur in childhood.

GERM CELL TUMORS

There are five categories of germ cell tumors described, of which types I through III involve the testis.[137] The WHO histologic classification of germ cell tumors is shown in Table 16-3. The teratoma/yolk sac tumor presents in infancy and childhood and is not confined to the testis. Other sites include the mediastinum, retroperitoneum, sacral region, and midline brain. Yolk sac tumor is the most common testis tumor occurring before puberty, followed by embryonal carcinoma.[138] Type II tumors (comprising seminoma, nonseminoma, and dysgerminoma) originate from primordial germ cells or gonocytes.

A premalignant lesion develops initially, termed *intratubular germ cell neoplasia unclassified* (IGCNU) or *carcinoma in situ* (CIS). When the gonad is dysgenetic in nature, the premalignant condition is in the form of a gonadoblastoma. They progress to an invasive tumor manifest as a seminoma or nonseminoma and as a dysgerminoma in a dysgenetic gonad or an ovary.[139] The existence of a locus on the Y chromosome predisposes a gonadoblastoma to form in dysgenetic gonads. The TSPY (testis-specific protein Y-encoded) gene located on the short arm of the Y chromosome is one such oncogene that is abundantly expressed in the germ cells of XY individuals with DSD.

Gonocytes and CIS cells share similarities in morphology and in the expression of certain fetal proteins.[140] It is hypothesized that CIS represents delayed maturation of germ cells, which gives rise to an increased risk of germ cell tumors. This is found not only in XY DSDs but in trisomy 21, where there is a fiftyfold higher incidence of seminoma.[141] CIS is generally associated with germ cells developing in a depleted androgen environment, whether it be the result of insufficient androgen production or resistance to the action of androgen (as in syndromes of androgen insensitivity).

The propensity for gonadoblastomas to develop in gonadal dysgenesis (92%, as opposed to only 8% incidence of CIS) may be explained by the undifferentiated state of dysgenetic gonadal tissue. Invasive germ cell tumors are

TABLE 16-3

Classification of Germ Cell Tumors

Type	Site	Phenotype	Age
I	Testis/ovary/ retroperitoneum Mediastnum/ midline brain	Teratoma/ yolk sac tumor	Neonates Children
II	Testis	Seminoma/ non-seminoma	Young adult
	Ovary	Dysgerminoma	Childhood → young adult
	Dysgenetic gonad	Dysgerminoma/ non-seminoma	congenital
III	Testis	Spermatocytic seminoma	>50 yr
IV	Ovary	Dermoid cysts	Children/young adults
V	Placenta/uterus	Hydatidiform mole	Fetal life

Adapted from Cools M, Drop SLS, Wolffenbuttel KP, Oosterhuis JW, Looijenga LHJ (2006). Germ cell tumors in the intersex gonad: Old paths, new directions, moving frontiers. Endocr Rev 27:468-484.

rare before puberty in CAIS. Thereafter, with the rise of estrogens at puberty there may be estrogen-stimulated induction of the c-kit ligand—which can stimulate primordial germ cell growth.[142] In contrast, germ cell tumors occur at an earlier age in gonadal dysgenesis as a result of progressive genetic instability.[137,140,143]

A number of tumor markers can be used for immunohistochemical analysis to identify a premalignant state. These include placental-like alkaline phosphatase (PLAP), KIT (a membrane tyrosine kinase receptor for stem cell factor), AP2 gamma (activator protein-2 gamma), and OCT ¾.[139] These protein markers are normally expressed by fetal germ cells (and occasionally in postnatal life) until about 12 months of age. Thereafter, any expression in germ cells is abnormal and indicative of CIS or IGCNU. These tumor markers are not detected in serum, but have been identified in semen samples.[144] The risk of gonadal tumor in various causes of DSD can now be quantified reasonably well, particularly for gonadal dysgenesis and AIS (Table 16-4).

NON GERM CELL (SEX CORD STROMAL) TUMORS

Other tumors of the testis of relevance to infancy and childhood include Sertoli cell, Leydig cell, and adrenal rest tumors—which are stromal in origin and generally benign. Sertoli cell tumors can be bilateral, large and calcified, and associated with syndrome complexes such as the Peutz-Jeghers syndrome[145] and the Carney complex.[146] A feature of such tumors is associated breast development from increased estrogen production. Inhibin B, a product of the Sertoli cell, may be elevated in serum as a marker of Sertoli cell tumors.[147]

Leydig cell tumors are rare and comprise only 1 to 3% of testis tumors.[148] They are most common in the prepubertal age group, where they are always benign. In adults, 10% of cases are malignant. Leydig cell tumors are characterized clinically by the manifestations of their increased steroid production, which is generally androgenic. Consequently, precocious puberty is the hallmark in childhood. Estrogens can also be produced, either directly by the tumor or via peripheral aromatization. A testicular mass may be palpable, but the tumor can be occult and only visible on ultrasound examination. Characteristic histologic features include abundant cytoplasmic lipofuscin pigment and Reinke crystals.[149] Immunohistochemical markers specific for Leydig cell tumors include α-inhibin (particularly useful to distinguish from germ cell tumors), calretinin, and Melan-A.

Aberrant adrenal "tumors" may develop from the rest cells found within the testis in up to 15% of neonates.[7] The aberrant cells remain ACTH responsive and express adrenal-specific steroidogenic enzymes.[150] Consequently, the cells can become hyperplastic to form testicular adrenal rest tumors (TARTs) under states of ACTH hypersecretion in congenital adrenal hyperplasia (CAH), Addison's disease, and Nelson's syndrome.[151-153] There is almost uniform prevalence of TART in adult male patients with CAH when screened routinely by testicular ultrasound examination.[151] Even in male children with CAH, the prevalence is 24%.[154] The tumors are usually bilateral and benign. Histologically, they are sometimes difficult to separate from Leydig cell tumors—although the absence of Reinke crystals is a distinguishing feature.[155] The tumors are sited adjacent to the mediastinum testis, which can cause obstruction of the seminiferous tubules. This is invoked as one possible reason for gonadal dysfunction and infertility associated with TART.[156]

An endocrine explanation of infertility centers on the inhibitory role elevated endogenous levels of adrenal steroids may have on gonadotrophin secretion in males with inadequately treated CAH.[157,158] Fertility may be restored with improved medical control.[159] Testis-sparing surgery by tumor enucleation does not appear to improve pituitary-gonadal function.[160] Due recognition must be given to a testicular mass in males with CAH as most likely being a TART. Orchidectomy is not the preferred treatment.

There are other causes of testis enlargement that are not tumor related. Macro-orchia is a feature of the fragile

TABLE 16-4

Estimated Risks of Gonadal Tumors in Various Forms of DSD

Risk Group	Disorder	Malignancy Risk (%)	Recommended Action	Numbers: Studies (n)	Numbers: Patients (n)

	Leydig cell hypoplasia	0	unresolved	2	

X syndrome, which is associated with mental retardation.[161] The cytogenetic fragile site on Xq27.3 harbors the FMRI gene, which has a tandem repeat of CGG trinucleotides in its 5' untranslated region. Expansion of this repeat is responsible for the syndrome, with its onset occurring before germ line segregation based on analysis of allele expansions in early fetal ovaries and testes.[162] The FMRP protein is widely expressed and is predominant in the brain and testes (mainly Sertoli cells), consistent with the key clinical features of the syndrome.

Macro-orchidism is most obvious after puberty, with testicular volume greater than 30 mL characteristically present. However, anthropometric measurements of males with fragile X syndrome from birth to adulthood shows an increase in testicular volume already in childhood—with the 50th percentile equivalent to the normal 95th percentile by 6 years of age.[163] Indeed, macro-orchidism has been documented as early as 5 months of age postnatally[164]—and in the fetus by 24 weeks of gestation.[165] Information on testicular histology is scanty. The mass of Sertoli cells is the primary determinant of testis volume. Biopsy studies of macro-orchid adult testes showed interstitial edema, increased lysosomal inclusions in Sertoli cells, and abnormal spermatogenesis.[166] In the male Fmr1 mouse knockout model, the rate of Sertoli cell proliferation is increased and is independent of any change in FSH signaling.[167]

The dominance of Sertoli cells in constituting testis volume is further illustrated by the observation of testis enlargement in males with the McCune-Albright syndrome.[168,169] In contrast to affected females, however, precocious signs of hyperandrogenism are often absent. The Gs-alpha-activating mutation, the cause of this syndrome, is manifest in somatic cells and occurs early in development.[170] The prevalence of this apparent sex dimorphism in sexual precocity is explained by the observation that in one affected patient of the typical Gs-alpha mutation (Arg201His) the GNAS1 allele was present only in Sertoli cells—explaining the lack of Leydig cell hyperfunction.[171]

Macro-orchidism may occur without any known cause, including the exclusion of activating mutations in the FSH receptor gene.[172] Severe hypothyroidism of long standing can paradoxically result in precocious puberty, particularly in girls (VanWyk-Grumbach syndrome). The manifestation when it occurs in boys is with macro-orchidism.[173,174] It has been postulated that the markedly elevated TSH levels have additional gonadotrophin-stimulating effects by binding promiscuously to the FSH receptor.[175] Restoring a euthyroid state with thyroxine replacement leads to resolution of the early signs of puberty. There is no evidence to indicate that early puberty in primary hypothyroidism is due to activating mutations in the FSH receptor gene.[176]

Puberty and the Testis

GENERAL

The testis is clearly an essential conduit in producing the sex steroid endpoint for translating activation of the GnRH pulse generator into the somatic features characteristic of male puberty. Although most pubertal disorders are not the result of a primary testis dysfunction, an overview of puberty and its disorders in the male is briefly provided in this chapter. The control of the onset of puberty remains an enigma because the primary mechanism that awakens the dormant neuroendocrine machinery remains unclear.[177] The physiologic paradigm of puberty centers on a period of "restraint" on gonadotrophin secretion during childhood that when released via genetic and extrinsic mechanisms allows puberty to be reactivated. This is based on evidence of prior increased gonadotrophin activity during fetal life and early infancy.

Placental gonadotrophin (HCG) and fetal pituitary gonadotrophins (FSH/LH) secretion are essential to sufficient production of testosterone for male genital differentiation and descent of the testes. Placental HCG secretion rises abruptly after 6 weeks, reaching a peak at about 12 weeks of fetal life and then declining to low levels by 18 to 20 weeks of gestation. The rise in fetal HCG is mirrored by a sharp rise in fetal circulating testosterone, essential to the normal development of the internal and external male genitalia. The second half of gestation is characterized by increasing FSH and LH secretion, which stimulate testicular size, descent, and penile growth. At birth, after separation of the umbilical cord there is a rapid rise in testosterone—reaching levels as high as 400 ng/dL in the first day of life.

Testosterone levels then decline rapidly during the first week to levels of 20 to 50 ng/dL but then increase again to levels between 60 and 400 ng/dL between 20 and 60 days of life. Thereafter, levels decline to the prepubertal range of less than 10 ng/dL by the end of the first year of life. These surges in testosterone are induced by gonadotrophins. A GnRH stimulation test evokes a greater rise in FSH than LH at these times. What purpose is served by the gonadotrophin-induced surge in testosterone in the first hours and days of neonatal life is less clear. Penile length increases during infancy, particularly during the first 3 months, and is positively correlated with serum concentrations of testosterone.[178] Inhibin B, a marker of Sertoli cell mass, is also elevated at 3 months of age and remains so for about another year.[179] Sertoli cell numbers proliferate during fetal and early postnatal life, the total number ultimately being a determinant of sperm quantity in adulthood.[180]

That these changes are FSH dependent is suggested by the observation of larger testis volume at 3 months of age in normal Finnish versus Danish male infants, and related to higher FSH and inhibin levels.[181] Furthermore, boys with cryptorchidism have higher FSH levels compared with controls.[182] Collectively, these observations indicate that the testis is responsive to a surge in gonadotrophin secretion during infancy. However, FSH and LH secretion abate (and serum levels are quite low) in the prepubertal years. Puberty is heralded by the appearance of nocturnal-sleep-related FSH and LH pulses, a reflection of the reawakening of the GnRH pulse generator (which has been "restrained" by an as yet unidentified mechanism).

If puberty is indeed the result of removing a restraint mechanism, it is not initiated by the gonads because a rise in gonadotrophins occurs at the expected time of puberty in girls with Turner syndrome, boys with Klinefelter syndrome, and boys with anorchia.[183] Studies in agonadal

nonhuman primates show similar findings.[184] In addition, severe head injuries and irradiation of the skull may be associated with precocious puberty (Table 16-5)—implying damage to the region that regulates the restraint of puberty. Thus, the restraint of puberty is orchestrated in the brain (not the gonad).[185-186]

The first sign of puberty in boys is an increase in testis volume from a prepubertal value of 3 to 4 mL. This occurs on average between 11 and 11.5 years of age. The timing and tempo of puberty are related to a host of interacting factors comprising GnRH, neuropeptide-Y, gamma aminobutyric acid (GABA), leptin, and transforming growth factor-alpha (TGFα). A recent addition to this list is a G-protein–coupled receptor (GPR54) and its ligand (kisspeptin 54), which act upstream of the GnRH pulse generator (Figure 16-7). The kisspeptins appear to be a gatekeeper to puberty and to play a key role in the negative and positive feedback control of gonadotrophin secretion by sex steroids.[187,188] Mutations in the GPR54 gene in humans results in delayed puberty due to HH.[189,190] Treatment with exogenous kisspeptin induces a rapid increase in LH and FSH levels in humans and can induce puberty in primates.[184,191,192]

TABLE 16-5

General Classification of Causes of Precocious and Delayed Puberty in the Male

Precocious Puberty

Gonadotrophin-Dependent
- Idiopathic central precocious puberty
- Organic central precocious puberty
  - Hypothalamic hamartoma
  - Post head trauma
  - Post cranial radiotherapy
  - Neurofibromatosis
  - HCG-secreting germ cell tumor

Gonadotrophin-Independent
- Activating LH receptor mutation (*testotoxicosis*)
- McCune-Albright syndrome
- Leydig cell tumor
- Extratesticular hyperandrogenism
  - Congenital adrenal hyperplasia
  - Adrenal tumor

Delayed Puberty

Hypogonadotrophic Hypogonadism
- Genetic
  - KAL1, FGFR1, GnHR, GPR54, SF1, DAX1, Leptin R, STAT5b
- Organic
  - Craniopharyngioma
  - Post head trauma
  - Cranial irradiation
  - Multiple pituitary hormone deficiency
  - Isolated gonadotrophin deficiency
- Syndromal
  - Prader-Willi syndrome
  - Lawrence-Moon-Biedl syndrome
  - Kallmann syndrome
- Chronic disorders
  - Inflammatory bowel disease
  - Renal failure
  - Thalassemia
  - Emotional deprivation
  - Cystic fibrosis

Hypergonadotrophic Hypogonadism
- Syndromal
  - Klinefelter syndrome
  - XX male
  - Noonan syndrome
  - Frasier syndrome
- Primary testicular
  - Gonadal dysgenesis
  - Androgen biosynthetic defects
  - Anorchia/cryptorchidism
  - Chemotherapy

DISORDERS OF PUBERTY

It is generally accepted that the age boundaries for the first sign of puberty (Tanner stage G2) in normal males extends from 9 years to 13.5 years. Thus, a boy starting puberty before 9 years of age is deemed precocious in development—whereas delayed puberty warrants investigation if G2 is not reached by 13 to 14 years of age. By far the most common clinical scenario to investigate is constitutional delay in pubertal development, a condition that implies normal but delayed onset of puberty in otherwise healthy boys. There is often a positive family history of similar delay in pubertal onset in the mother or father, suggesting a genetically regulated timing in the awakening of the GnRH pulse generator.

This is not a disorder per se, but can cause significant problems relating to self-esteem. It should be distinguished from HH, but this distinction is not easy because low basal FSH and LH levels with a prepubertal low response to a pulse of GnRH will occur in both. Some advocate a short course of exogenous testosterone (100-200 mg IM monthly for 4 to 6 injections). Such treatment improves self-image, promotes linear growth without impairing final adult height, and may result in the initiation of puberty—reflected in part by growth of the testis, which occurs in constitutional delay but not in disorders of HH.[193]

Because the disorders of puberty are primarily extratesticular in origin, reference to Tables 16-5 and 16-6 will suffice to summarize a general classification for disorders

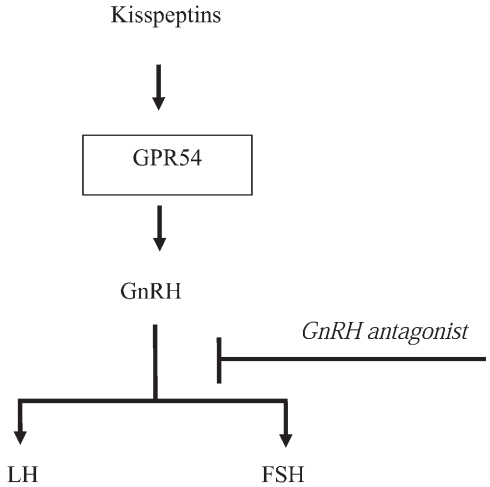

Figure 16-7 GPR54 as a gate to puberty.

of precocious and delayed puberty. Precocious puberty involves the gonads (gonadarche) and must not be equated with premature adrenarche, a condition in which adrenal androgens induce premature pubic hair development without virilization or advanced bone age (as discussed in detail in Chapters 4 and 12). It is logical and practical to base classification on the status of gonadotrophin secretion, the prime driver of normal puberty. Some testis-specific disorders are mentioned in further detail.

Constitutive activation of mutant LH receptors leads to precocious puberty. This condition is limited to males (testotoxicosis) and is familial in a heterozygous (autosomal-dominant) manner.[50] Puberty occurs in early childhood and is characterized by elevated serum testosterone and suppressed serum LH levels. Missense mutations are confined to exon 11 of the LH receptor gene, which encodes for the signal-transducing transmembrane domain of the receptor. This contrasts with inactivating LH receptor mutations causing DSD, which are distributed throughout the gene.

Mutant LH receptors causing testotoxicosis, when expressed in vitro, show basal constitutive activation of the cAMP signaling pathway in transfected cells in the absence of agonist compared with wild-type receptor. Mutant receptors also demonstrate a dose-response relationship with added LH or HCG.[194] It is a curious observation that females heterozygous for LH receptor mutations do not develop early puberty. The explanation lies with the observation that LH receptor expression in the ovary is dependent on FSH levels. Because FSH levels are low in childhood, ovarian follicles do not differentiate and hence LH receptor expression is also not enacted at this time. However, it is not clear why mothers of sons with LH-receptor-activating mutations have no discernible phenotype.

There is a relative hot spot of mutations at codon 578 in the sixth transmembrane helix, where aspartic acid (Asp) can be changed to glycine, tyrosine, or glutamic acid. A mutation at this codon (Asp578His) is found in somatic form only, and results in precocious puberty due to a Leydig cell adenoma.[195,196] This particular mutation is highly active basally when expressed in transfected cells but does not respond to LH or HCG. Furthermore, the mutant LH receptor constitutively activates an alternative signal transduction pathway involving the phospholipase C pathway.[197] The management of precocious puberty due to germline-activating mutations of the LH receptor is a challenge because the conventional approach of using a GnRH analogue to desensitise the gonadotrophes is not applicable.

The mainstay of current treatment is to use a combination of an antiandrogen to block the direct biologic effects of androgens and an aromatase inhibitor to reduce the accelerating effects on growth plate closure from estrogens produced from aromatization of increased androgens. An effective combination appears to be bicalutamide (a nonsteroidal antiandrogen) and anastrozole, a third-generation aromatase inhibitor.[198] This combination has produced a reversal of signs of hyperandrogenism, as well as reduction in growth velocity and rate of skeletal maturation.

A similar gonadotrophin-independent increased sex steroid secretion is the cause of precocious puberty in the McCune-Albright syndrome.[170] In this case, the pathophysiology relates to an activating mutation in the ubiquitously expressed G-protein α-subunit (Gsα), a major product of the GNAS gene.[199] The classic features of the syndrome comprise gonadotrophin-independent precocious puberty, café-au-lait lesions of the skin of a specific distribution, and polyostotic fibrous dysplasia. The pubertal manifestation occurs mainly in affected females. When it occurs in males, there is asymmetric enlargement of the testes. The Gsα mutation is somatic and is invariably a substitution of glycine for arginine at codon 201. Treatment for pubertal precocity associated with the McCune-Albright syndrome is similar to that used for LH-receptor-activating mutations.

Treatment of central precocious puberty relies primarily on the use of long-acting GnRH agonists that suppress the ability of endogenous GnRH to bind to its cognate receptor and evoke an appropriate increase in FSH and LH. It is based on the discovery that a single pulse of GnRH evokes an appropriate gonadotrophin response, whereas continuous infusion of GnRH down-regulates and abrogates the response.[200] Until recently, such GnRH long-acting agonists were administered by monthly IM injections—adjusting the dose to ensure suppression of response to exogenous GnRH.

A long-acting form of GnRH that can be implanted subcutaneously and last for 1 year has recently been introduced.[201] In addition to suppressing GnRH secretion, a form of reversible "medical castration," a primary underlying cause must be excluded by appropriate investigation—including cranial imaging. "Idiopathic" precocious puberty is more common in girls than in boys. The causes of delayed puberty can also be classified according to the status of gonadotrophin secretion. Table 16-6 outlines a general classification of causes in males.

GENETIC CAUSES OF HYPOGONADOTROPHIC HYPOGONADISM

The genetic causes of HH have been the subject of interest and investigation, resulting in the discovery of novel genes involved in the regulation of puberty via the hypothalamic-pituitary-gonadal axis. Kallmann syndrome consists of isolated HH plus anosmia. An X-linked form and several variants encoded by autosomal genes are described. The gene for the X-linked form KAL1 encodes the protein anosmin, which is a major regulator of the migration of GnRH neurones and olfactory nerves from the olfactory placode to the hypothalamus.

Males with this condition have agenesis of the olfactory lobes, which may be detected on MRI imaging, as well as hypogonadism secondary to deficiency of hypothalamic GnRH. Transmitting females may have partial or complete anosmia. Renal agenesis, high-arched palate, cerebellar ataxia, and mirror movements of the hands (synkinesia) have been described. The X-linked form due to KAL1 is listed as Kallmann syndrome 1 in the Online Mendelian Inheritance in Man (OMIM) database (*www.ncbi.nlm.nih.gov*). Kallman syndrome 2, KAL2, is an autosomal-recessive form due to a mutation in the gene encoding fibroblast growth factor receptor-1 (FGFR-1) and is associated with cleft lip or palate plus tooth agenesis in addition to the anosmia and hypogonadism. KAL 3 is caused by a mutation in the PROKR2 gene, and KAL 4 is caused by a mutation in PROK 2.

Together, these gene abnormalities account for about a third of all cases of Kallmann syndrome. Treatment with GnRH injected subcutaneously as pulses via a programmable pump can restore normal gonadal development and function. In some, the treatment can be discontinued while the patient retains normal gonadal function.[202] The role of Kisspeptin and its cognate receptor in regulating GnRH secretion and hence puberty has been described.[189,191,192] The DAX1 and SF1 genes interact in a complex manner in the formation of the GnRH region of the hypothalamus, as well as the formation of the adrenal gland. They are discussed in detail in Chapter 12.

Leptin secreted by fat tissue also regulates gonadotrophin secretion. Inactivating mutations in the genes for leptin or its receptor lead to obesity.[203,204] Leptin may be a signal in the initiation of puberty, indicating a link between nutritional status and reproductive capacity and the secular trend of pubertal onset in well-nourished societies. That leptin may be regarded as a metabolic gate to puberty is illustrated by the effect of leptin facilitating appropriately timed puberty when administered to children with congenital leptin deficiency.[205] Leptin signaling may play an important role in the HH of chronic wasting illnesses, including anorexia nervosa and the chronic disorders listed in Table 16-6.

The Prader-Willi syndrome is typically characterized by hypotonia, developmental delay, hypogonadism, and obesity. Stereotypic behavioral abnormalities also occur. The defect is encoded by a gene or genes on the paternal short arm of chromosome 15. Most disorders primarily testicular in nature have been discussed. Management of delayed puberty in the male is dependent on the underlying etiology. The overriding practical issue is to induce somatic signs of puberty in the event of this not occurring spontaneously from endogenous androgen production.

A commonly used treatment is Sustanon, a mixture of testosterone esters, given by monthly intramuscular injections at a starting dose of 25 mg and thereafter increasing to adult doses of 250 mg monthly. A wide variety of injectable, oral, implantable, cutaneous patch, and gel preparations of androgens are available.[206,207] Although the low-dose Sustanon modality is suited to replicate pubertal changes in a slow and timely fashion, regular hormone replacement in adulthood for persistent hypogonadism is increasingly employing topical delivery systems that appear to provide serum testosterone and DHT profiles similar to those found in normal males.[208,209]

TABLE 16-6

General Classification of Causes of Delayed Puberty in the Male

Hypogonadotrophic Hypogonadism[229,230]
- Genetic
  - KAL1, FGFR1, GnRH, GPR54, SF1, DAX1, Leptin R, STAT5b
- Organic

Investigating Testis Function

GENERAL

There is no algorithmic-based panacea on how to investigate testis function. The choice of tests should be dictated by the clinical problem to be addressed and the nature of the questions posed. A number of sources provide recipes for investigation of the endocrine system.[210-212]

AMBIGUOUS GENITALIA (also see Chapter 14)

The approach to the investigation of a newborn infant with ambiguous genitalia requires a two-tierd approach to the choice of tests (Table 16-7). Establishing the karyotype, together with confirming or excluding CAH (the most common cause of ambiguous genitalia of the newborn), is the first task to be undertaken. The clear presence of a uterus/cervix on ultrasound and a markedly elevated serum 170H-progesterone level in a full-term infant with a 46,XX karyotype confirms a diagnosis of CAH due to 21-hydroxylase deficiency.

If the karyotype is 46,XY (or 45X/46,XY), one determines whether testes are present—and if present whether they produce normal age-related amounts of testosterone. Table 16-7 does not contain an exhaustive list for this second-tier level of investigation but should allow resolution of the determinations cited. An understanding of the DSD classification shown in Table 16-2 is a guide to a logical pathophysiologic approach to investigation.

The HCG stimulation test is the bedrock of investigation for the XY DSD infant. The protocol and timing for this test varies considerably among centers.[213] The author's center uses as a standard three daily injections of HCG (1,500 units by intramuscular injection). A post-HCG

TABLE 16-7

A Two-Tiered Approach to Investigation of Ambiguous Genitalia

Tier 1: Establish DSD Category
- FISH and full karyotype
- Pelvic ultrasound
- Serum 17-OH progesterone (save serum)
- Blood sugar, electrolytes
- Save urine for steroid metabolites

Tier 2: In the Event of an XY or XO/XY DSD Category
- Serum AMH, LH, FSH (save serum/DNA)
- HCG stimulation test (see text for details)
- Urinary steroid analysis
- Imaging (MRI)
- Laparoscopy/gonadal biopsy

blood sample is collected 24 hours after the last injection for analysis of testosterone (coupled with androstenedione and DHT tests if indicated). An acute LHRH stimulation test may also be undertaken just prior to the first HCG injection. Occasionally, the HCG stimulation test is extended over 3 weeks (twice-weekly injections).

This protocol has the potential for coupling investigation and management where the clinical problem is testis maldescent.[214] The timing of an HCG test should be planned to coincide with the endogenous LH-induced rise in testosterone production at about 4 to 8 weeks of postnatal age, but local circumstances may dictate that the test be performed shortly after birth. This may create difficulties with the interpretation of neonatal serum steroid levels if nonextraction or non-chromatographic assays are performed.[215] Analysis of urinary steroid metabolites by sensitive highly specific chromatographic techniques may delineate defects in androgen biosynthesis such as P450-oxidoreductase deficiency and 5α-reductase deficiency.

ABSENT TESTES

When testes are not palpable at birth in an otherwise normal male infant, a karyotype is still mandatory. The phenotype may be the result of a fully virilized 46,XX infant with CAH. The main question asked of an endocrine investigation of a 46,XY infant with nonpalpable testes is whether testes are present. The HCG stimulation test and baseline LH and FSH measurements will generally answer the question. In addition, serum AMH is proving to be a reliable additional test—measuring levels otherwise almost undetectable in the case of anorchia.[216-219] Measurement of serum inhibin B levels appears to be equally effective as a marker of loss of Sertoli cells.

Undetectable levels of testosterone after HCG stimulation, elevated gonadotrophins (particularly FSH), and very low or undetectable levels of AMH are strongly suggestive of absent testicular tissue. However, efforts are usually made to locate testicular tissue and imaging is not sufficiently reliable for this purpose. Laparoscopic exploration generally reveals just nubbins of fibrous tissue at the end of a vas deferens.[102,103] If the genitalia are not otherwise completely normal (for example, an associated micropenis), the anorchia may be a form of gonadal dysgenesis in which there is occasionally a mutation in the SF1 gene.[220]

TESTIS TUMORS

Imaging, together with histology and immunohistochemical analysis of a testicular biopsy, is the key investigation for a testis mass. The relevant tumor markers have been listed previously. Ultrasound distinguishes among cystic, solid, or complex scrotal masses and is useful in longitudinal screening of patients with testicular microlithiasis.[221] However, microlithiasis is present in 5.6% of the young adult male population—and most men with such an isolated finding do not develop testis cancer.[222] Regular self-examination of the testes is the recommended surveillance procedure.

PUBERTAL DISORDERS

A basal and acute LHRH-stimulated LH and FSH level, with interpretation of age-appropriate serum testosterone measurements, is the mainstay of the investigation of puberty-related testis disorders. The original term, *testotoxicosis*, for the clinical syndrome due to LH-receptor-activating mutations is affirmation that elevated testosterone with totally suppressed LH levels is akin to the TSH/FT4 profile in thyrotoxicosis (Grave's disease). Assessment of LH/FSH levels provides the division between hyper-/hypogonadotrophic states and gonadotrophin dependency, as outlined in Tables 16-4 and 16-5. In pituitary-gonadal interrelationships, the negative feedback effect appears to be more profound on FSH levels than on LH levels.

In gonadal dysgenesis, for example, basal FSH levels are usually more elevated than LH levels. Primary hypogonadism may be the result of chemotherapy for cancer in childhood. The germ cells are more susceptible to damage than Leydig cells, and thus boys often develop puberty spontaneously. Fertility is a later problem, with lower than normal testosterone levels for young adulthood subsequently found.[223] Whereas the basal FSH level is usually a reliable indicator of germ cell damage and is a predictor of abnormal spermatogenesis, the basal LH is not as predictive of androgen deficiency.

It is generally not appropriate to undertake seminal fluid analysis in pubertal boys as a measure of testis function, although obtaining a semen sample for cryopreservation is offered to pubertal boys undergoing cancer treatment.[224] Inhibin B levels increase markedly at puberty and correlate with measurements of testis volume and testosterone, LH, and FSH levels.[225] The level of inhibin is inversely correlated with FSH levels at mid-puberty (G3-G4), when spermatogenesis is becoming established. This concurs with the results of indirect semen analysis using the observation that spermatozoa can be identified in early-morning urine samples from pubertal boys.[226]

Spermaturia as an index of the onset of spermatogenesis (spermarche) is possible at a median age of 13.4 years, although there is a large variation between boys of the same pubertal stage.[227] Nevertheless, this minimally invasive method of assessing developing germ cell function in adolescent boys has applicability in epidemiologic

studies—including the effects of changes in the environment on male reproductive function. Thus, the effects of exposure to toxic chemicals before birth may be measurable by spermaturia analysis at puberty.[228] The assessment of testis function needs to be designed not only to determine the cause of intrinsic disorders related to the pituitary-gonadal interplay but to account for the increasing evidence that disorders of the testis may have a causation in part environmental in origin.

Osteochondrodysplasias
Concluding Remarks

Introduction

Disorders of calcium, magnesium, and phosphate metabolism (and of bone formation, accrual, and maintenance) during the first two decades of life result from suboptimal ingestion, absorption, or retention of constituent nutrients; abnormal vitamin D metabolism or bioactivity; disorders of parathyroid hormone (PTH) synthesis, secretion, or function; and intrinsic aberrations in cartilage and bone cells. For an integrated overview of calcium, mineral, and skeletal homeostasis, the reader is referred to Chapter 3.

Mineral Homeostasis: Conception Through Adolescence

PREGNANCY AND LACTATION

The fetus is entirely dependent on the mother for its calcium and phosphate requirements for skeletal formation and cell and tissue growth and function. The fetal-placental unit actively extracts calcium from the maternal circulation, as the mother doubles her rate of intestinal calcium absorption.[1-3] During the first trimester of pregnancy, maternal serum concentrations of total calcium decline and remain low through gestation due to a fall in albumin values and expansion of extracellular fluid volume—whereas serum concentrations of ionized calcium (Ca^{2+}_e) and phosphate remain relatively constant (Figure 17-1).

PTH values decline to 10% to 30% of the nonpregnant range in the first trimester of pregnancy, and then rise to mid nonpregnant levels in the latter half of gestation. The secretion of PTH-related peptide (PTHrP) by the placenta, amnion, decidua, umbilical cord, breast, and fetal parathyroid glands increases severalfold beginning early in the first trimester, and maternal levels rise throughout gestation. Maternal calcitonin values also increase during gestation. Serum concentrations of calcidiol do not change, but levels of calcitriol (synthesized primarily by the maternal kidney but also in part by the placenta, decidua, and fetal kidneys) increase more than twofold as pregnancy advances and substantially accelerate the rate (and augment the amount) of calcium absorbed by the maternal small intestine.

Increased renal synthesis of calcitriol is stimulated primarily by PTHrP but also by prolactin, estrogen, and human chorionic somatomammotropin. Maternal urinary calcium excretion rises (+125%), reflecting the increased absorption of ingested calcium.[4] The rate of maternal bone resorption increases in the first trimester of gestation, as determined by histomorphometric analysis of bone biopsies and by the increase in the urinary excretion rates of pyridinoline (Pyr), desoxypyridinoline (Dpd), N-telopeptide (NTx), and hydroxyproline that occur in early gestation and continue to rise through gestation. Markers of osteoblast activity and bone formation (bone-specific alkaline phosphatase, osteocalcin, carboxyl, and amino terminal propeptides of type I collagen) decline during the first trimester but increase in the third trimester.[4,5]

During a normal 40-week gestation, maternal whole-body bone mineral density (BMD) does not change. Cortical BMD increases (arms +2.8%, legs +1.8%), whereas trabecular BMD declines (vertebrae –4.5%, pelvis –3.2%). However, pregnancy does not appear to have any long-term adverse effects on maternal bone mineralization or fracture risk.[3] Maternal serum values of insulin-like growth factor-I (IGF-I) increase 67% by the third trimester of pregnancy, and the increment correlates positively with the increase in markers of bone turnover and inversely with the change in maternal vertebral BMD. Thus, early in gestation the pregnant woman meets fetal demand for calcium by increasing the rate of resorption of stored bone calcium—whereas the calcium requirement of the more mature fetus is met by a substantially increased rate of maternal intestinal calcium absorption.

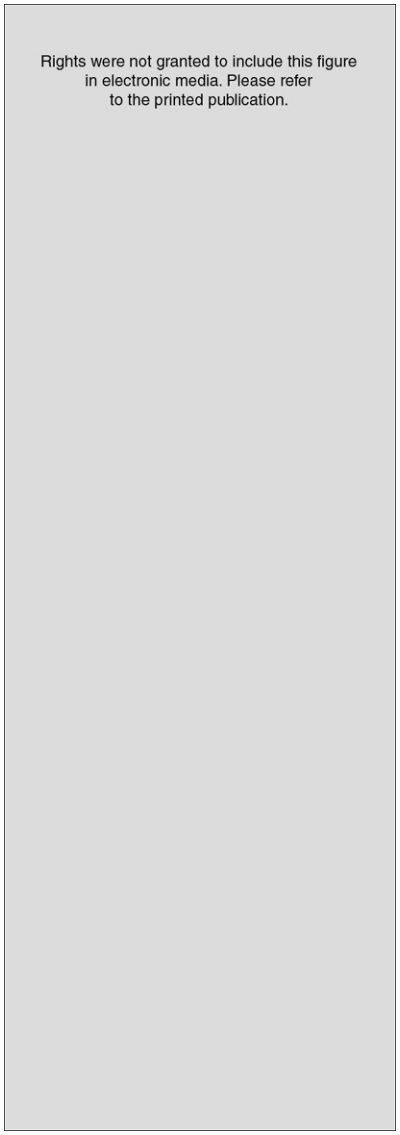

Figure 17-1 Schematic changes in mineral and calciotropic hormone values during pregnancy. The shaded areas represent normal adult ranges. To convert calcium in mmol/L to mg/dL, multiply by 4; to convert phosphate in mmol/L to mg/dL, multiply by 3.097; to convert PTH in pmol/L to pg/mL, multiply by 9.50; and to convert calcitriol in pmol/L to pg/mL, multiply by 0.4166. [Reproduced with permission from Kovacs CS, Kronenberg HM (1997). Maternal-fetal calcium and bone metabolism during pregnancy, puerperium, and lactation. Endocrine Reviews 18:832–872.]

During lactation, the nursing mother daily transfers to her suckling infant 280 to 400 mg of calcium mobilized from her skeleton in response to PTHrP secreted primarily by the breast.[3] Calcium concentrations are low in colostrum, being approximately 25 mg/dL in breast milk during the first 6 months of lactation and 21 mg/dL during months 6 to 12 of nursing.[6] Maternal total calcium, calcitriol, and calcitonin values are normal, while Ca^{2+}_e, phosphate, and PTHrP levels are increased during lactation.

Urinary levels of markers of bone resorption and serum values of markers of bone formation are elevated

during lactation, implying rapid turnover of maternal bone mineral during nursing. Maternal bone mineralization declines 3% to 10% during lactation, only to reaccrue rapidly after weaning.[7] As there is an increasing incidence (or awareness) of vitamin D deficiency in breast-fed infants, supplementation of the breast-fed infant with 400 IU of vitamin D daily and higher than recommended intake (200 IU/day) of vitamin D (up to 2,000 to 4,000 IU/day) have been suggested for pregnant and lactating women.[8-10]

FETUS

During gestation, the fetus accrues 30 to 35 g of calcium. Approximately 80% of calcium accretion occurs in the third trimester.[1,3] At 28 weeks of gestation, calcium is deposited into the fetal skeleton at the rate of approximately 100 mg/day—whereas at 35 weeks calcium is deposited at the rate of approximately 250 mg/day.[2,5,11,12] At birth, whole-body bone mineral content (BMC) is positively related to gestational age, to body length, and most closely to body weight—as are lumbar spine (L1-L4) BMC and BMD (Figures 17-2 and 17-3).[12,13] The fetal skeleton serves two roles: it is a metabolically important source of calcium mobilized by fetal PTH and/or PTHrP acting through the PTH/PTHrP receptor (PTHR1) when the supply of calcium from the mother is limited, and it provides a rigid structural and protective framework for fetal soft tissues.[2]

Fetal serum calcium levels are established independently of, and are not directly related to, maternal calcium concentrations. From at least 15 weeks of gestation, serum concentrations of total calcium (and particularly Ca^{2+}_e) are substantially higher in the human fetus and other mammals (rat, sheep) than in the mother (1.4:1). The physiologic significance of this finding is unknown. In addition, fetal serum concentrations of magnesium and phosphate are greater than maternal values. The parathyroid glands (PTG) are essential to maintenance of normal fetal calcium concentrations. By the tenth week of gestation, they secrete PTH and possibly PTHrP—and both peptides function additively to maintain fetal serum calcium levels. PTH does not stimulate placental calcium transport, but it is secreted by the fetal PTG in response to hypocalcemia. Fetal mice in which the expression of PTH has been ablated (e.g., *Hoxa3* null mice) are hypocalcemic, and their skeletal mineralization is impaired.[1,14]

Maternal hypercalcemia suppresses, and maternal hypocalcemia stimulates, secretion of fetal PTH. Both amino and mid-molecule fragments of PTHrP (e.g., $PTHrP^{1\text{-}86}$, $PTHrP^{67\text{-}86}$) produced by the fetal PTG (possibly), placenta (primarily), amnion, chorion, and umbilical cord maintain high fetal serum calcium concentrations by stimulating active maternal-to-fetal transport of calcium across the placental syncytiotrophoblast against a concentration gradient. This PTHrP effect is mediated in part by receptors that recognize mid-molecule and/or carboxyl terminal fragments of PTHrP, as evidenced in fetal mice in which *Pthr1* has been ablated (placental calcium transport remains active, whereas fetal serum calcium levels are low).

In fetal mice in which the expression of *Pthrp* itself has been impaired, serum calcium levels are lower than control

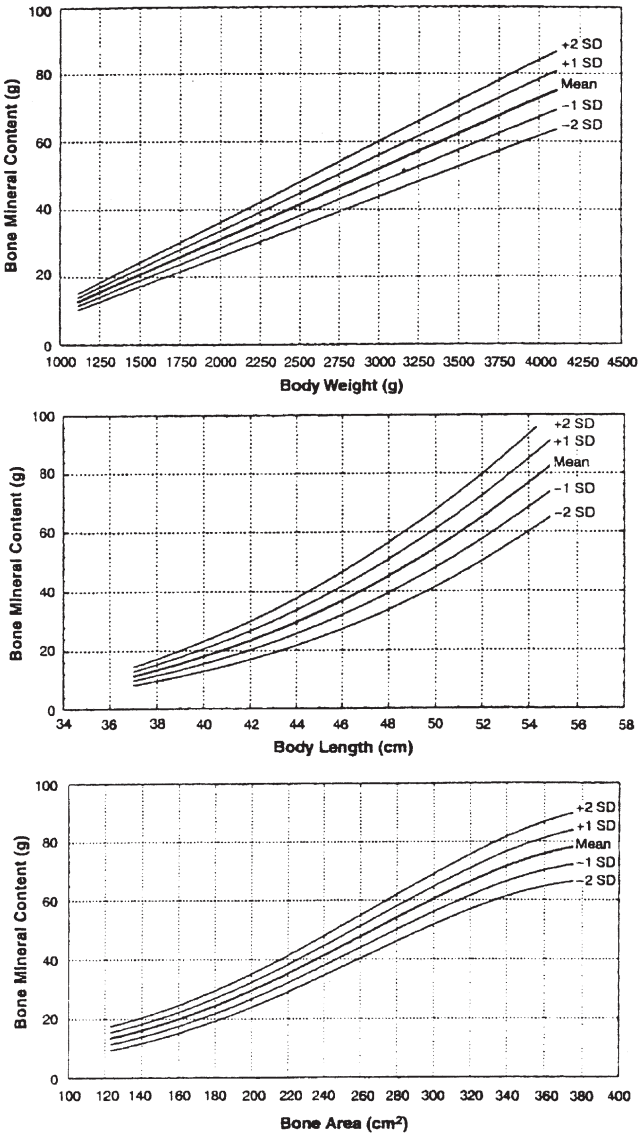

Figure 17-2 Whole-body bone mineral content of the preterm and term neonate relative to body weight, body length, and bone area as determined by dual X-ray absorptiometry near birth. [Reproduced with permission from Rigo J, et al. (2000). Bone mineral metabolism in the micropremie. Clin Perinatol 27:147–170.]

values and are maintained by fetal PTH at values comparable to those of the mother. In *Pthrp* null fetal mice, placental calcium transfer is decreased—and chondrocyte maturation and bone development are abnormal.[1] Although serum concentrations of PTHrP are quite high in the human fetus (term cord blood 2–5 pmol/L), PTH levels are lower than those in maternal serum. *In utero,* calcitonin concentrations are quite high (an appropriate response to the increased serum calcium levels of the fetus)—but this peptide does not have a major impact on fetal calcium homeostasis.[1]

Calcium and magnesium regulate fetal calcium levels through the calcium-sensing receptor (CaSR) that controls the synthesis and secretion of fetal PTH. Thus, in fetal mice in which *Casr* has been knocked out the serum calcium concentration is further elevated—as are values

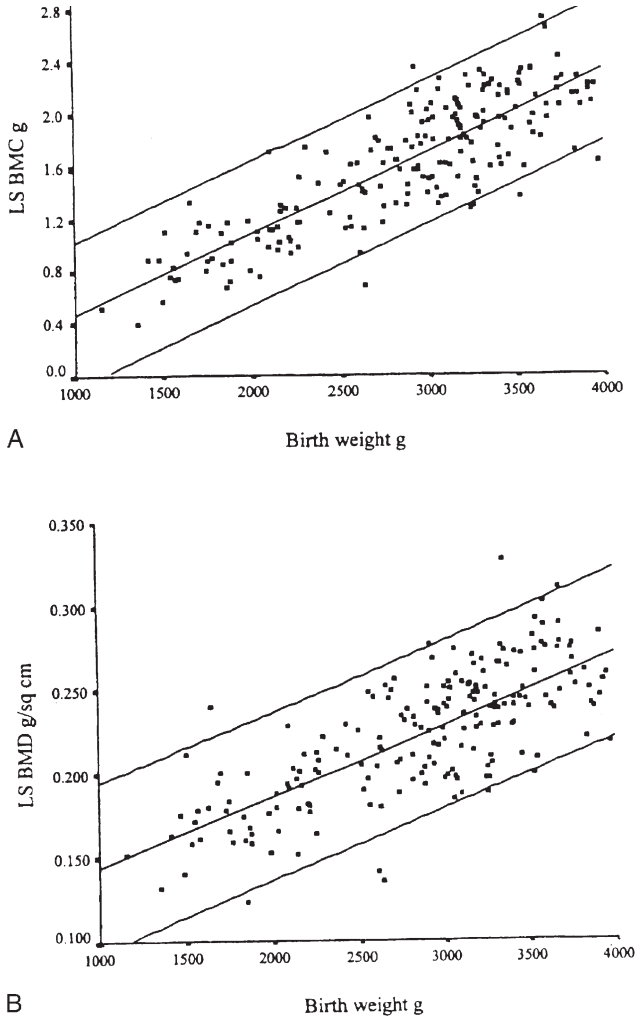

Figure 17-3 Lumbar spine (L1-L4) bone mineral content (BMC). (*A*) Bone mineral density (BMD). (*B*) BMD of preterm and term neonates relative to body weight as determined by dual X-ray absorptiometry near birth. [Reproduced with permission from Koo WWK, Hockman EM (2000). Physiologic predictors of lumbar spine bone mass in neonates. Pediatr Res 48:485–489.]

of PTH and calcitriol.[1,15] The CaSR is also expressed in the human placenta in the first trimester and is involved in placental calcium transport.[16] Calcium-selective ion channels (TPRV5, TPRV6) located at the apical surface of trophoblast cells facilitate maternal-fetal transplacental transfer of calcium.[17] Fetal serum calcitriol concentrations are a bit lower than those of the mother. Experimentally, fetal serum calcium values and mineralization of the fetal skeleton are normal in the presence of maternal vitamin D deficiency or an inactive vitamin D receptor (VDR). In the VDR-null fetal mouse, if the mother ingests a diet enriched with calcium and phosphate, indicating that the fetus does not have an absolute requirement for calcitriol or the VDR for normal mineral metabolism.[1,18]

In man, the fetal cartilaginous skeleton is present by the eighth week of gestation. Primary ossification centers appear in the long bones and vertebrae by the twelfth week, and secondary centers at the femoral ends are noted by the thirty-fourth week.[1] Fetal PTHrP secreted by juxta-articular cells of the long bone regulates the orderly rate of chondrocyte maturation, whereas fetal PTH maintains serum calcium and phosphate values appropriate to bone mineralization. Magnesium is actively transported across the placenta.[19] *In utero* fetal magnesium concentrations exceed maternal values and are inversely related to gestational age, reflecting the third trimester decline in maternal magnesium concentrations.

NEONATE AND INFANT

Calcium levels in cord blood correlate with gestational age and exceed maternal values by 1 to 2 mg/dL as a result of an active placental calcium pump. When the neonate is abruptly removed from the transplacental infusion of maternal calcium, total calcium and Ca^{2+}_e concentrations decline rapidly in the first 6 to 12 hours after delivery to nadir values (from 12 to 9 mg/dL and 1.45 to l.20 mmol/L, respectively) by 24 to 72 hours of age.[1,2,20] Calcium levels are a bit lower and PTH values higher in neonates delivered by cesarean section than in those delivered vaginally.[21] After birth, PTHrP values decline rapidly. Thus, to maintain mineral homeostasis the neonate becomes dependent on endogenous PTH, exogenous vitamin D, ingested and absorbed calcium, renal tubular reabsorption of calcium, and bone calcium stores for its calcium needs.

In response to the fall in Ca^{2+}_e values, serum levels of PTH begin to increase on the first day of life—resulting in normal calcium values (8.8–11.3 mg/dL) at 48 hours of age, followed by rise in calcitriol concentrations and slow decline (after an initial postnatal rise) in calcitonin values (Figure 17-4).[22] For the first 2 to 4 weeks after birth, there is increased efficiency of intestinal calcium absorption by passive means that are independent of vitamin D—perhaps due to the lactose content of milk, which affects paracellular transport of Ca^{2+}_e (1,2). Later in the neonatal period, vitamin-D-dependent intestinal calcium absorption increases. Renal tubular handling of calcium and the response to PTH mature during the first several weeks of life. Bone calcium accretion continues at the rate of 150 mg/kg/day for several months after birth, a vitamin-D-dependent process.

Due to decreased glomerular filtration and increased tubular reabsorption, serum concentrations of phosphate are maximal in the neonate. After delivery, serum phosphate concentrations increase from cord values of 3.8 to 8.1 mg/dL to levels that range between 4.5 and 9.0 mg/dL during the first week of life and that then stabilize at values between 4.5 and 6.7 mg/dL through the first year of life.[23] In preterm or acutely ill neonates, the fall in calcium values is often exaggerated and more prolonged—and bone mineralization is frequently impaired in very preterm newborns and infants. Maternal hypercalcemia suppresses, and maternal hypocalcemia stimulates, secretion of fetal PTH—effects that may carry over to the neonate for several days. In infants and children, serum magnesium concentrations are quite stable—ranging between 1.5 and 2.2 mg/dL through 4 months of age and between 1.7 and 2.3 mg/dL through 5 years of age.

Human breast milk contains (on average) calcium at 28 mg/dL, phosphate at 13 mg/dL, and vitamin D 15 to

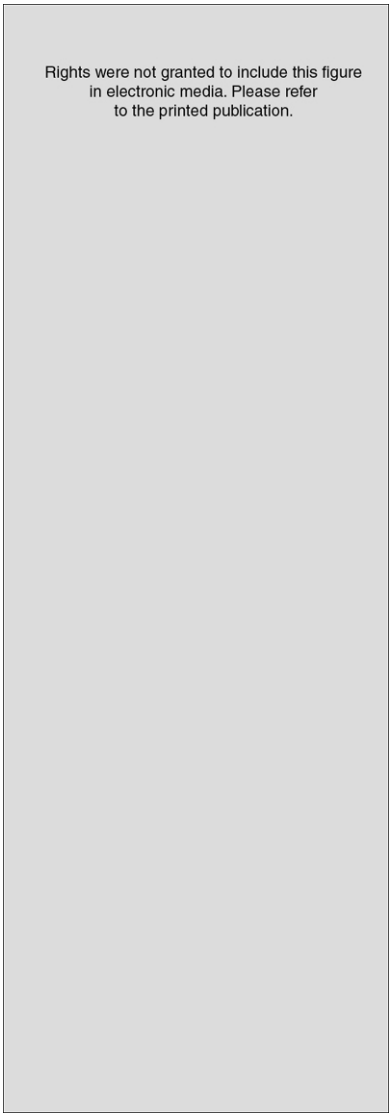

Figure 17-4 Schematic changes in mineral and calciotropic hormone values during the first 4 days of life in normal full-term neonates. The shaded areas represent normal adult ranges. The PTHrP values are depicted by a dashed line to indicate their speculative nature. To convert calcium in mmol/L to mg/dL, multiply by 4; to convert phosphate in mmol/L to mg/dL, multiply by 3.097; to convert PTH in pmol/L to pg/mL, multiply by 9.50; and to convert calcitriol in pmol/L to pg/mL, multiply by 0.4166. [Reproduced with permission from Kovacs CS, Kronenberg HM (1997). Maternal-fetal calcium and bone metabolism during pregnancy, puerperium, and lactation. Endocrine Reviews 18:832–872.]

50 IU/L. Thus, vitamin D supplementation (200–400 IU/day) is necessary during breast feeding.[6] Cow's milk formulas contain calcium at ~40 to 60 mg/dL, phosphate at ~30 to 40 mg/dL, and vitamin D at ~30 to 40 IU/dL. The bioavailability of calcium (that which is accessible for normal metabolic usage) varies dependent on its source and the formulaic content and source of protein, fat, and carbohydrates. For example, infants fed formulas that contain palm olein absorb less calcium than those receiving a formula fortified with another form of fat or human breast milk—and these infants have lower total body bone mineral content.[24]

Phytate (inositol hexaphosphate) present in soy formulas and infant cereals chelates calcium, and oxalate (a constituent of spinach) precipitates calcium—thereby reducing intestinal absorption of this mineral, a difficulty overcome by increasing dietary calcium content. Optimizing calcium, vitamin D intake, and bone mineralization during infancy (and childhood) may substantially contribute to achievement of an adult peak bone mass of sufficient density to avoid osteopenia and osteoporosis and their adverse consequences in later life.[6]

CHILD AND ADOLESCENT

During childhood and adolescence, serum concentrations of total calcium (8.8–10.8 mg/dL, depending on the analytical laboratory) and magnesium (1.7–2.2 mg/dL) remain relatively constant.[22] Serum phosphate levels are higher in children (4.5–6.2 mg/dL) than in adults (2.5–4.5 mg/dL), and attain maximum values several months before the peak height velocity of adolescence is achieved. The rise has been attributed to augmentation of the renal tubular reabsorption of phosphate due to the combined effects of the increased secretion of growth hormone (GH), IGF-I, and sex hormones—factors that contribute to the pubertal growth spurt.[25]

Total serum alkaline phosphatase activity is also higher in children than in adults, and increases transiently during the pubertal growth spurt. Levels of bone-specific alkaline phosphatase (the major isoform of this enzyme in normal adolescents) increase between 9 and 12 months before peak height velocity and reach maximum at Tanner male genital stage III. These levels are directly related to the secretion of testosterone in boys.[26] In females, serum bone-specific alkaline phosphatase activity peaks at Tanner stage III breast development and correlates with serum osteocalcin concentrations. Serum concentrations of PTH fluctuate very little during adolescence, whereas levels of calcitriol rise transiently.

Serum values of osteocalcin, a bone matrix γ-carboxyl-glutamic acid whose concentration reflects osteoblast activity, are higher during infancy than childhood and increase during adolescence—reaching peak values at 12 years of age in girls and at 14 years in boys.[27,28] Mean 24-hour levels of osteocalcin are not related to mean 24-hour GH concentrations or to growth rates in prepubertal children, but random and 24-hour mean osteocalcin concentrations are substantially lower in GH-deficient children than in children of normal stature. Serum levels of the carboxyl-terminal propeptide of procollagen type I (PICP) also reflect osteoblast activity. These levels are highest in infancy, fall during childhood, increase briefly during puberty, and then decline to adult values.

Serum levels of the amino-terminal extension of procollagen type III (PIIINP) reflect soft-tissue growth and to a limited extent bone formation. Values decline between infancy and childhood, increase during adolescence, and then fall to adult concentrations.[29,30] Mean 24-hour concentrations of PICP and PIIINP correlate with mean 24-hour GH values and growth rates. Their levels are significantly lower in GH-deficient children than in normal children.[31]

Serum concentrations of cross-linked carboxyl-terminal telopeptide of type I collagen (ICTP) and urinary excretion of the nonreducible pyridinium compounds and the carboxyl- (CTx) and amino-terminal (NTx) telopeptides of type I collagen are markers of bone resorption. Values of ICTP peak between 9 and 13 years in girls at Tanner stage III breast development and at 14 years and Tanner male genital stage IV in boys. In both cases, they then decline.[32] Pyr (hydroxylysyl-pyridinoline; present in bone and cartilage) and Dpd (lysyl-pyridinoline; found primarily in bone) are derivatives of the amino acids lysine and hydroxylysine, respectively—which cross-link adjacent telopeptide regions of collagen fibers in mature bone.[33]

The urinary excretion of both compounds is independent of diet and reflects collagen degradation. The urinary excretion of the pyridinium cross-links fluctuates diurnally with highest values in the morning. The 24-hour urinary excretion of both pyridinium compounds is greatest in the child 2 to 10 years of age, declines between 11 and 17 years, and still further thereafter as values approach adult levels.[28] Urinary levels of NTx, a reliable index of bone resorption, may be determined in spot or 24-hour urine specimens and are expressed as nmol of bovine cartilage equivalent (BCE) units/mmol of creatinine. Values are highest in infancy and decline steadily with age.[34]

The urinary excretion of hydroxyproline is a less specific marker of bone resorption because it is present in the collagen of connective tissue in many sites other than bone—particularly skin, as well as in dietary protein. Urinary excretion increases during puberty, and in girls peaks (150 mg/day) in the year before menarche coincident with maximal growth rate.[29] Tartrate-resistant acid phosphatase activity (TRAP), a marker of osteoclast activity, is released when bone collagen is degraded. In adolescents, markers of bone formation (bone-specific alkaline phosphatase, osteocalcin, and PICP) and of bone resorption (TRAP, ICTP, and urine excretion of NTx and the pyridinolines) increase to a similar extent and then decline in tandem—reflecting the tight link between bone formation and resorption. In females, these measurements correlate inversely with serum concentrations of estradiol—reflecting the maturational effect of estrogen on epiphyseal cartilage and its inhibitory effect on growth.[35]

The rate of bone accretion is steady throughout childhood, and increases substantially during adolescence—the physiologic interval in which up to 50% of adult bone mass is acquired. Indeed, in the 2 years that bracket the peak growth rate of puberty 25% of peak bone mineral mass is accumulated.[36] Approximately 90% of peak bone mass is accrued by 18 years of age in normal subjects, and peak BMC is achieved between 20 and 25 years of age. During puberty, trabecular bone volume and mineralization increase appreciably in response to GH, IGF-I, estrogens, and androgens and are maximal by the end of the second decade of life in females (and perhaps in the male).

However, the timing of peak bone mass of the axial skeleton is more variable—being attained between 17 and 35 years of age. Most often this occurs near the age when adult sexual maturity is achieved. At all ages, vertebral cross-sectional size is smaller in females than in males—even when controlling for height. However, femoral dimensions are similar in both genders when matched for height and weight. Trabecular bone mass becomes greater in black than in white subjects at adolescence, when trabecular bone mineral density increases 34% in black and 11% in white subjects. The difference persists thereafter. The cross-sectional area of the femur is also greater in black than in white adolescents and adults.

Disorders of Mineral Homeostasis in the Neonate and Infant

HYPOCALCEMIA

Clinical manifestations of hypocalcemia (total calcium <7.5 mg/dL; Ca^{2+}_e <1.20 mmol/L) in neonates include irritability, hyperacusis, jitteriness, tremulousness, facial spasms, neuromuscular excitability (tetany), laryngospasm, and focal or generalized seizures.[20] Nonspecific symptoms such as apnea, tachycardia, cyanosis, emesis, and feeding problems may also occur. Traditionally, neonatal hypocalcemia develops after 3 days of age in offspring born in the late winter to early spring of the year to multiparous women of lower socioeconomic status with inadequate intake of vitamin D or exposure to sunlight. Causes of neonatal hypocalcemia may be considered in relation to the age of onset (before or after 72 hours of life, Table 17-1).

Early Neonatal Hypocalcemia

In the absence of hypoproteinemia, hypocalcemia occurring within the first 72 hours after birth is considered "early neonatal hypocalcemia." It occurs most commonly in premature or small-for-gestational-age, low birth weight, or asphyxiated neonates—or in those born to women with gestational or permanent forms of diabetes mellitus. It occurs as a consequence of suppression of PTH secretion, prolonged secretion of calcitonin, and/or hypomagnesemia.[20] Total calcium and Ca^{2+}_e concentrations decline more rapidly and to lower nadir values in preterm than in term neonates. In premature infants, early neonatal hypocalcemia has been attributed to blunting of the physiologic postnatal rise in PTH secretion and to the relative resistance of the renal tubule to PTH-mediated phosphate excretion—leading to hyperphosphatemia.

Prolonged elevation of circulating levels of calcitonin also contributes to early neonatal hypocalcemia. In low birth weight (LBW) neonates, hypocalcemia may be further attributed to the rapid accretion of skeletal calcium in the presence of relative resistance to the calcium absorptive and reabsorptive effects of calcitriol on the intestinal tract and bone, respectively. Offspring of severely vitamin-D-deficient mothers may become hypocalcemic shortly after birth. Hypocalcemia develops in approximately 33% of asphyxiated newborns who are products of complicated and compromised deliveries. In these infants, increased phosphate load due to cellular injury, reduced calcium intake, and hypercalcitonemia

TABLE 17-1

Causes of Hypocalcemia

I. Neonatal

A. Maternal Disorders

1. Diabetes mellitus
2. Toxemia
3. Hyperparathyroidism
4. High intake of alkali or magnesium sulfate

B. Neonatal

1. Low birth weight, intrauterine growth retardation
2. Asphyxia, sepsis
3. Hyperbilirubinemia, phototherapy, exchange transfusion
4. Hypomagnesemia, hypermagnesemia
5. Acute/chronic renal insufficiency
6. Nutrients/medications: high dietary phosphate, fatty acids, phytates, bicarbonate, citrated blood, anticonvulsants, aminoglycosides
7. Hypoparathyroidism
8. Vitamin D deficiency or resistance
9. Osteopetrosis type II

II Hypoparathyroidism

A. Congenital

1. Transient neonatal
2. Dysgenesis/agenesis of the parathyroid glands
   a. Isolated hypoparathyroidism (*GCM2, PTH, SOX3*)
   b. Hypercalciuric hypocalcemia *(CASR)*
   c. DiGeorge syndrome (*TBX1*)
   d. Sanjad-Sakati syndrome (short stature, retardation, dysmorphism - HRD)
      Kenny-Caffey syndrome 1 (short stature, medullary stenosis) *(TCBE)*
   e. Barakat syndrome (sensorineural deafness, renal dysplasia - HDR) *(GATA3)*
   f. Lymphedema-hypoparathyroidism-nephropathy, nerve deafness
   g. Mitochondrial fatty acid disorders (Kearns-Sayre, Pearson, mitochondrial encephalopathy, lactic acidosis, stroke-like - MELAS)
3. Insensitivity to parathyroid hormone
   a. Blomstrand chondrodysplasia (*PTHR1)*
   b. Pseudohypoparathyroidism - type IA *(GNAS)*
   - Pseudohypoparathyroidism - type IB
   - Pseudohypoparathyroidism - type IC
   - Pseudohypoparathyroidism - type II
   - Pseudopseudohypoparathyroidism

   c. Hypomagnesemia
4. Dyshormonogenesis

B. Acquired

1. Autoimmune polyglandular syndrome - type I (*AIRE1*)
2. Activating antibodies to the calcium-sensing receptor
3. Post surgical, radiation destruction
4. Infiltrative [excessive iron (hemochromatosis, thalassemia) or copper (Wilson disease) deposition; granulomatous or neoplastic invasion; amyloidosis, sarcoidosis]
5. Maternal hyperparathyroidism
6. Hypomagnesemia

III. Vitamin D Deficiency

IV. Other Causes of Hypocalcemia

A. Calcium Deficiency

1. Nutritional deprivation
2. Hypercalciuria

B. Hypomagnesemia/Hypermagnesemia

1. Congenital
   a. Malabsorption
   b. Hypermagnesuria
   - Primary *(CLDN16)*
   - Bartter syndrome (3)
   - Renal tubular acidosis

2. Acquired
   a. Acute renal failure
   b. Chronic inflammatory bowel disease, intestinal resection
   c. Diuretics

C. Hyperphosphatemia

1. Renal failure
2. Phosphate administration (intravenous, oral, rectal)
3. Tumor cell lysis
4. Muscle injuries (crush, rhabdomyolysis)

D. Miscellaneous

1. Hypoproteinemia
2. Hyperventilation
3. Drugs - furosemide, bisphosphonates calcitonin, anticonvulsants, ketoconazole, anti-neoplastic agents (plicamycin, asparaginase, cisplatinum, cytosine arabinoside, doxorubicin), citrated blood products
4. Hungry bone syndrome
5. Acute and critical illness - sepsis, acute pancreatitis, toxic shock
   a. Organic acidemia - propionic, methylmalonic, isovaleric

are important pathogenetic factors in the development of hypocalcemia.

Fifty percent of infants of mothers with diabetes mellitus develop early neonatal hypocalcemia. The incidence may be reduced by strict maternal glycemic control.[2,20] Its causes are multifactorial and include reduced placental transfer of calcium due to substantial maternal urinary excretion of calcium and magnesium, decreased neonatal secretion of PTH, hypercalcitonemia, hypomagnesemia (occurring in 40% of offspring), and limited intake and impaired absorption of ingested calcium.[37]

Maternal hypercalcemia due to unsuspected hyperparathyroidism leads to increased transfer of calcium to the fetus, and still further increase in fetal calcium

concentrations that suppress fetal PTH synthesis and release and stimulate calcitonin secretion—aberrations in homeostatic mechanisms that persist postpartum and may result in hypocalcemic tetany/seizures in the mother's offspring. Suppression of PTH secretion may persist for several months and be undetected until symptomatic hypocalcemia develops after weaning of the infant from breast milk to higher-phosphate-containing cow's milk formula. Maternal ingestion of large quantities of calcium carbonate in antacids has also led to neonatal hypocalcemia.[38]

Hypocalcemia has occurred in neonates with hyperbilirubinemia undergoing exchange transfusion and in those exposed to phototherapy.[39] Neonates with acute rotavirus infection and severe diarrhea may present with hypocalcemic seizures.[40] Aminoglycoside antibiotics (e.g., gentamycin) increase urinary excretion of calcium and magnesium and facilitate the development of neonatal hypocalcemia. Compounds that complex with and sequester calcium—such as citrate (present in transfused blood), phosphates (that alter the calcium X phosphate product), and fatty acids (given as caloric supplements)—lower Ca^{2+}_e levels. Bicarbonate administered to correct acidosis increases calcium binding to albumin and thus lowers Ca^{2+}_e values. Hypocalcemia may also occur in hyperventilated infants with severe respiratory alkalosis, as well as in those with other causes of metabolic alkalosis. Phytates in soy milk bind calcium and phosphate and interfere with their absorption. Neonates with osteopetrosis type II and impaired osteoclastogenesis may present with early or late neonatal manifestations of hypocalcemia.[41,42]

Late Neonatal Hypocalcemia

Hypocalcemia developing after 72 hours of postnatal age may be due to increased intake of phosphate, hypomagnesemia, hypoparathyroidism, or vitamin D deficiency (Table 17-1). One of the most frequent causes of late neonatal hypocalcemia is excessive phosphate intake in evaporated milk or modified cow's milk formulas. Phosphate forms poorly soluble calcium salts and limits the intestinal absorption of calcium while raising serum phosphate values. Premature introduction of fiber-containing cereals into the infant's diet also decreases calcium absorption. Affected infants may have an associated defect in renal phosphate excretion or a coexisting deficiency in vitamin D.

Hyperphosphatemia and hypocalcemia may initially suggest hypoparathyroidism, but serum PTH concentrations are high in infants with excessive phosphate loading in response to reciprocal reduction in serum calcium values. Newborns and infants with chronic renal insufficiency due to renal hypoplasia or obstructive nephropathies are often hypocalcemic and hyperphosphatemic, with elevated serum PTH levels as well. However, they are also azotemic. Hypomagnesemia leads to impaired secretion of PTH and decreased peripheral responsiveness to PTH, and may be transient or related to congenital abnormalities of intestinal absorption or renal tubular reabsorption of magnesium.[20] Hypermagnesemia may occasionally be associated with neonatal hypocalcemia.

Hypocalcemia due to fetal/neonatal deficiency of vitamin D occurs in offspring of mothers deprived of vitamin D (for cultural or socioeconomic reasons). Impaired renal 25-hydroxyvitamin D-1α hydroxylase activity and loss-of-function mutations of the vitamin D receptor also lead to hypocalcemia (and hypophosphatemia). Hypovitaminosis D may develop in the breast-fed infant of a vegetarian mother who shields herself from sunlight and ingests a diet low in vitamin D. However, marginal deficiency of vitamin D in neonates and infants is likely much more common than has been recognized heretofore.[8,9,11,43]

Late neonatal hypocalcemia occurs in premature infants with osteopenia at 3 to 4 months of age in whom the intake of calcium, phosphate, and vitamin D has been marginal. It is perhaps due to avid deposition of all available calcium into bone.[20] Hypocalcemia due to vitamin D deficiency may develop acutely, and in the absence of clinical or radiographic signs of rickets, in the older infant and young child ingesting an elimination diet low in vitamin D because of severe allergies and/or maintained indoors with limited exposure to sunlight.

Hypoparathyroidism

Hypoparathyroidism presenting in infancy is most often transient and related to delayed developmental maturation of PTG function. It frequently resolves within the first several weeks of life. When prolonged, hypoparathyroidism is often due to an error in the embryogenesis of the PTGs. Occasionally, it may be due to defects in the synthesis of PTH or to peripheral unresponsiveness to PTH. Hypercalciuric hypocalcemia is a form of autosomal-dominant hypoparathyroidism (OMIM 146200) due to gain-of-function mutations in *CASR* (Table 17-2) that result in enhanced sensitivity to Ca^{2+}_e. A lowered set-point enables PTH secretion to be suppressed, and renal tubular reabsorption of calcium to be depressed, by extremely low concentrations of Ca^{2+}_e. This disorder may present in the newborn period.[44,45] Mutations may be scattered throughout the gene, but occur predominantly in the extracellular domain of the CaSR.

Activating mutations (Cys141Trp) of the CaSR may also inhibit function of the renal outer medullary potassium channel (*KCNJ1,* OMIM 600359), leading to a Bartter-like syndrome with hypokalemic metabolic alkalosis, hyperreninemia, and hyperaldosteronism as well as hypercalciuric hypocalcemia. The paired metabolic defects are in part responsive to treatment with hydrochlorothiazide and low doses of calcitriol.[46]

Children with hypercalciuric hypocalcemia due to gain-of-function mutations in *CASR* are very sensitive to even low doses of calcitriol that can lead to even more marked hypercalciuria and to nephrocalcinosis. Thus, management of these patients has been quite difficult. Administration of recombinant human $PTH^{1\text{-}34}$ (0.7 μg/kg/day) to a 14-month-old hypocalcemic male infant with a de novo nonsense mutation in *CASR* (Leu727Gln) for 17 months in part restored calcium homeostasis, with increased but still subnormal serum levels of calcium (whereas urinary excretion of calcium decreased into the normal range).[47] During treatment, the child was

clinically asymptomatic, did not develop nephrocalcinosis, and tolerated the drug well.

The most common form of dysgenesis of the PTGs in neonates and infants is that associated with the DiGeorge syndrome (DGS, OMIM 188400), a disorder that occurs with a frequency of 1:4,000 to 1:8,000 births and is present in approximately 70% of children with isolated hypoparathyroidism.[48,49] The DGS is a neurocristopathy, the result of disturbed migration of cervical neural crest cells and consequent maldevelopment of tissues of neural crest origin derived from the third and fourth pharyngeal pouches and first to fifth branchial arches. It is usually associated with microdeletions of chromosome region 22qll.2 (del22q11.2, DGCR) and is thus a contiguous gene syndrome (a disorder caused by deletion of several adjacent genes that when individually mutated may result in a distinctive clinical feature and when collectively lost lead to a group of apparently unrelated clinical findings).

Although the clinical severity and phenotype of patients with this chromosomal anomaly are variable, characteristically subjects with DGS have the triad of hypocalcemia due to hypoplasia of the PTGs (often manifest in the neonatal period but which may not be detected until an older age), defective T-lymphocyte function and impaired cell-mediated immunity due to partial or complete absence of thymic differentiation (leading to increased frequency of viral and fungal infections), and conotruncal defects of the heart or aortic arch (Tetralogy of Fallot, truncus arteriosus, interrupted or right aortic arch, aberrant right subclavian artery).[20,48,50] Indeed, delq2211 has been associated with three overlapping disorders—DGS and the conotruncal anomaly face and velocardiofacial syndromes.

Collectively, these syndromes are associated with a quite typical face (ocular hypertelorism, lateral displacement of inner canthi, short palpebral fissures, swollen eyelids, dysmorphic segmented nose, small mouth, low-set ears with abnormally folded pinnae, short philtrum, micrognathia, malar hypoplasia, velopharyngeal insufficiency (with/without cleft palate), olfactory dysfunction, short stature, nonverbal learning disabilities, and various psychological maladies.[49,51,52] DGS may occur sporadically or be transmitted as an autosomal-dominant characteristic. Takao velocardiofacial syndrome (included in OMIM 188440) consists primarily of the typical cardiac

defects described previously, which may also be associated with hypocalcemia.

Shprintzen velocardiofacial syndrome (OMIM 192430) is characterized by craniofacial and palatal defects and cardiac anomalies. Cayler cardiofacial syndrome (OMIM 125520) is associated with partial unilateral facial paresis (due to hypoplasia of the depressor angularis muscle) and with anomalies of the heart and aorta. These syndromes have been grouped as the CATCH-22 syndromes of Cardiac defects, Abnormal face, Thymic hypoplasia, Cleft palate, and Hypocalcemia. In addition to the anomalies and clinical findings listed, a litany of abnormalities may be seen in patients with del22q11.2.[53] Disparate manifestations of these syndromes may be observed in different members of the same family, indicating the variable clinical expressions that accompany del22q11.2.[54]

A two-megabase microdeletion at chromosome 22q11.2 leads to loss of several contiguous genes within this region, including *HIRA* (histone cell cycle regulation, OMIM 600237)—a transcription factor (expressed in developing heart and upper body neural crest elements) necessary to normal cardiac development.[55] Also within this region is *TBX1* encoding T-BOX-1, a transcription factor with a highly conserved DNA-binding sequence (the T-box) essential for organogenesis and pattern formation and expressed in the pharyngeal arches and pouches. Experimental disruption of *Tbx1* impairs development of the pharyngeal arch arterial vasculature, whereas introduction of null mutations in *Tbx1* results in anomalies of the cardiac outflow track and hypoplasia of the thymus and PTGs.[56]

Evaluation of patients with clinical characteristics of the CATCH-22 syndromes but intact 22q11.2 has revealed heterozygous loss-of-function mutations in *TBX1* in patients with the DGS (Phe148Tyr, Gly310Ser) and Shprintzen velocardiofacial syndrome.[49,57] Thus, haploinsufficiency of *TBX1* alone can account for the cardiac defects, abnormal face, thymic and parathyroid hypoplasia, and velopharyngeal insufficiency with cleft palate but not for the developmental delay characteristic of CATCH-22. Another candidate gene for the DGS sited at chromosome 22q11.2 is *UFD1L* (ubiquitin fusion degradation 1-like, OMIM 601754), whose product is important in the posttranslational processing of proteins and/or their degradation by interaction with the ubiquitin fusion protein.

Experimentally, the DGS and related disorders have also been linked to genes encoding endothelin-1, vascular endothelial growth factor, and fibroblast growth factor-8 (a target gene for TBX1)—as well as to genes within the DGCR at chromosome 22q11.2 [CRKL (*OMIM* 602007) and *DGCR6* (OMIM 601279)]. In the mouse hypomorphic for *Fgf8,* there are cardiovascular, craniofacial, parathyroid, and thymic defects—an experimental phenocopy of the human del22q11.2 syndrome.[58] Fgf8 functions through stimulation of transcription of *Crkl*. Its product is an adaptor protein that transduces intracellular signals from several tyrosine kinase receptors, one of which is the receptor for Fgf8, Interestingly, Fgf8 interacts with Tbx1 as well. The DGS has also been associated with microdeletions of chromosomes 10p13, 18q21.33, and 4q21.2-q25—indicative of the cascade of genes likely involved in the generation of this phenotype.

There are several other syndromes with multisystem involvement and hypoparathyroidism. The Barakat or HDR syndrome (OMIM 146255) of hypoparathyroidism, sensorineural deafness, and renal disease (steroid-resistant nephrosis with progressive renal failure) has been attributed to haploinsufficiency of *GATA3*—a zinc-finger transcription factor important in the embryonic development of the PTGs, kidneys, and inner ear and in normal function of the immune system as an essential T-cell receptor enhancer.[59]

The PTGs of these children are dysgenetic (hypoplastic or absent). Hypocalcemia may be present in the newborn period or unrecognized until later childhood.[60] Heterozygous deletions, insertions, and missense and nonsense mutations in *GATA3* have been identified in patients and families with HDR.[61,62] Interestingly, subjects with isolated loss of *GATA3* function do not have other features common to patients with larger terminal deletions of 10p—such as growth and developmental retardation, dysmorphic facial features, and congenital heart disease.

Biallelic mutations in the gene encoding tubulin-specific chaperone E *(TBCE)* have been identified in the Sanjad-Sakati syndrome of hypoparathyroidism mental retardation dysmorphism (HRD, OMIM 241410) and the Kenny-Caffey syndrome type 1 of hypocalcemia, cortical thickening, and medullary stenosis (KCS1, OMIM 244460). Children with HRD are short, developmentally delayed, and seizure prone. They have medullary stenosis and other skeletal anomalies. They are microcephalic, with faces characterized by deeply recessed eyes or microphthalmia, depressed nasal bridge, beaked nose, long philtrum, thin upper vermillion border, micrognathia, and large earlobes. The HRD syndrome often presents in infancy with symptomatic hypocalcemia associated with low serum concentrations of PTH and normal phosphaturic response to exogenous PTH.

The cardiovascular system of these patients is intact, but as infants they are susceptible to life-threatening pneumococcal infections.[63] Neonates with KCS1 are severely hypocalcemic early in the neonatal period. As children they are short, with craniofacial anomalies (due to absence of diploic space in the skull), osteosclerosis, and thickening of the cortices of the long bones with narrowing of the medullary compartment and normal or mildly delayed development. They too are susceptible to recurrent bacterial infections. TBCE is essential for formation of microtubules—cytosolic structures composed of heterodimeric α- and β-tubulin subunits that form the cytoskeleton, mitotic apparatus, cilia, and other cellular components. This chaperonin assists in the correct folding of α- and β-tubulin subunits and the formation of α- β-tubulin heterodimers.

The α- and β-tubulin subunits and TCBE are necessary to normal embryogenesis of the PTGs. Mutations in *TCBE* result in lowered microtubule formation and consequently in decrease in subcellular components such as the golgi apparatus and endosomal compartments required for normal intracellular movement of proteins. Interestingly, the identical mutation in *TCBE* (a homozygous 12 bp deletion in exon 2) may result in the HRD or KCS1 phenotype in a specific family.[64] A child with autosomal-recessive HRD syndrome and intact *TCBE* has been identified, suggesting

that this disorder is likely to be genetically heterogeneous.[65] In KCS type 2 (OMIM 127000), the phenotype is similar to that of KCS1 but transmission is as an autosomal-dominant trait for which no gene mutation has been identified to date.

Familial isolated congenital or later-onset hypoparathyroidism may be transmitted as an autosomal-recessive, autosomal-dominant, or X-linked recessive trait. It has been associated with loss-of-function mutations of *GCM2, PTH,* and possibly *SOX3,* and gain-of-function mutations in *CaSR. GCM2* encodes a 506-aa DNA-binding protein whose expression is restricted to the PTGs. Knockout of *Gcm2* in mice leads to agenesis of the PTGs and hypoparathyroidism. Biallelic intragenic deletion or homozygous missense mutations of *GCM2* result in hypoparathyroidism in humans.[66-68]

Homozygous loss-of-function mutations in PTH have been detected in neonates with autosomal-recessive familial isolated hypoparathyroidism. In one family, substitution of proline for serine at the –3 position of the signal peptide of prepro-PTH likely prevented its normal post-translational processing and accelerated protein product degradation within the endoplasmic reticulum.[69] As previous described, hypoparathyroidism due to a heterozygous activating mutation in *CASR* have been found in a hypocalcemic neonate. One mutation (Phe806Ser) occurred in the sixth transmembrane domain of this G-protein–coupled receptor (GPCR) near its site of interaction with $G_s\alpha$.[44] X-linked hypoparathyroidism (OMIM 307700) is associated with agenesis of the PTGs. The disorder has been mapped to Xq27 and may involve a deletion-insertion mutation that adversely affects the position of *SOX3*.[70] Because *Sox3* is expressed in embryonic mouse PTGs, it is likely an important transcription for normal embryologic development of the PTGs.

In the neonate with Blomstrand osteochondrodysplasia (OMIM 215045), hypocalcemia is secondary to loss-of-function mutations in *PTHR1* and hence insensitivity to the calcemic effects of PTH.[71] Transmitted as an autosomal-recessive trait, its clinical characteristics include polyhydramnios, hydrops fetalis, short-limbed dwarfism, facial anomalies, aberrant tooth development, aplasia of the nipples and breasts, hypoplastic lungs, and preductal aortic coarctation. Serum concentrations of PTH are elevated. Skeletal maturation is advanced. Histologically, the proliferative zone of the cartilage growth plate is narrowed—with relatively few resting and proliferating chondrocytes—whereas the hypertrophic zone is composed of irregular columns of chondrocytes.

Although Blomstrand osteochondodysplasia has been lethal to date, skeletal malformations may be more (type I) or less severe (type II). Mutations in *PTHR1* that result in complete absence of product (e.g., Arg104Ter) lead to type I, whereas mutations that permit some PTHR1 synthesis (Pro132Leu) result in type II.[72] Loss-of-function mutations in *GNAS,* the gene encoding the $G_\alpha s$ subunit of the activating G protein, lead to PTH insensitivity and pseudohypoparathyroidism (PHP)—a disorder that may be suspected in the neonate with hypocalcemia in whom hyperthyrotropinemia has been detected in the neonatal screening study for congenital hypothyroidism.[73] As a consequence of the loss-of-function mutation in *GNAS* in the thyroid gland, the $G_\alpha s$ subunit required by the thyrotropin GPCR is also impaired. In some neonates with elevated serum concentrations of PTH and phosphate and blunted phosphaturic response to PTH, neonatal pseudohypoparathyroidism is transient and resolves within the first few months of life.[74]

Abnormalities of the mitochondrial genome have also been associated with hypoparathyroidism. In addition, patients with the Kearns-Sayre syndrome (OMIM 530000) manifest ophthalmoplegia, retinal pigmentation, and cardiomyopathy. Point mutations, duplications, and deletions of various length of the mitochondrial genome (16,569 bp) have been found in these patients. Hypoparathyroidism has been observed in patients with the syndrome of mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS) and the mitochondrial trifunctional protein deficiency syndrome (MTPDS)—a disorder of fatty acid oxidation.[71,75]

Evaluation and Management

Evaluation of the neonate with hypocalcemia begins with review of the maternal, gestational, peripartum, postnatal, and family histories and physical examination (Figure 17-5). Historical data include those related to maternal parity and complications of pregnancy such as maternal diabetes mellitus (gestational, types I or II), toxemia of pregnancy or ingestion of excessive alkali, or abnormalities of delivery, low birth weight, neonatal sepsis, or other early postpartum illnesses. The family history is examined for members with abnormalities of mineral metabolism such as renal calculi, rickets, or hypocalcemia (e.g., seizure disorders).

The social history provides information about the socioeconomic status of the mother and her cultural beliefs that may have impacted on maternal diet and exposure to sunlight during gestation. The physical examination (abnormal face, cardiac murmur) may suggest a complex form of hypocalcemia. Determination of a complete blood count; serum concentrations of total calcium, Ca^{2+}_e, magnesium, phosphate, creatinine, intact PTH, calcidiol, and calcitriol; and urinary calcium and creatinine concentrations in a spot urine should precede initial therapy of the hypocalcemic newborn whenever possible.

Decreased serum concentrations of PTH are common in neonates with early-onset hypocalcemia, but persistently low PTH levels suggest impaired PTH secretion. High PTH concentrations are present in patients with vitamin D deficiency or insensitivity, PTH resistance due to loss-of-function mutations in *PTHR1* or *GNAS,* or impaired renal function. Low levels of calcidiol signify decreased maternal (and hence fetal) vitamin D stores or rarely a defect in vitamin D-25 hydroxylase, whereas calcitriol concentrations are inappropriately low in subjects with severely compromised renal function, hypoparathyroidism, or deficiency of 25OHD-1α-hydroxylase. Elevated calcitriol values suggest vitamin D resistance due to an abnormality in *VDR,* a disorder that may be associated with alopecia. Skeletal radiographs may disclose osteopenia, whereas chest X-ray may not identify a thymic shadow (an unreliable sign in a severely ill or

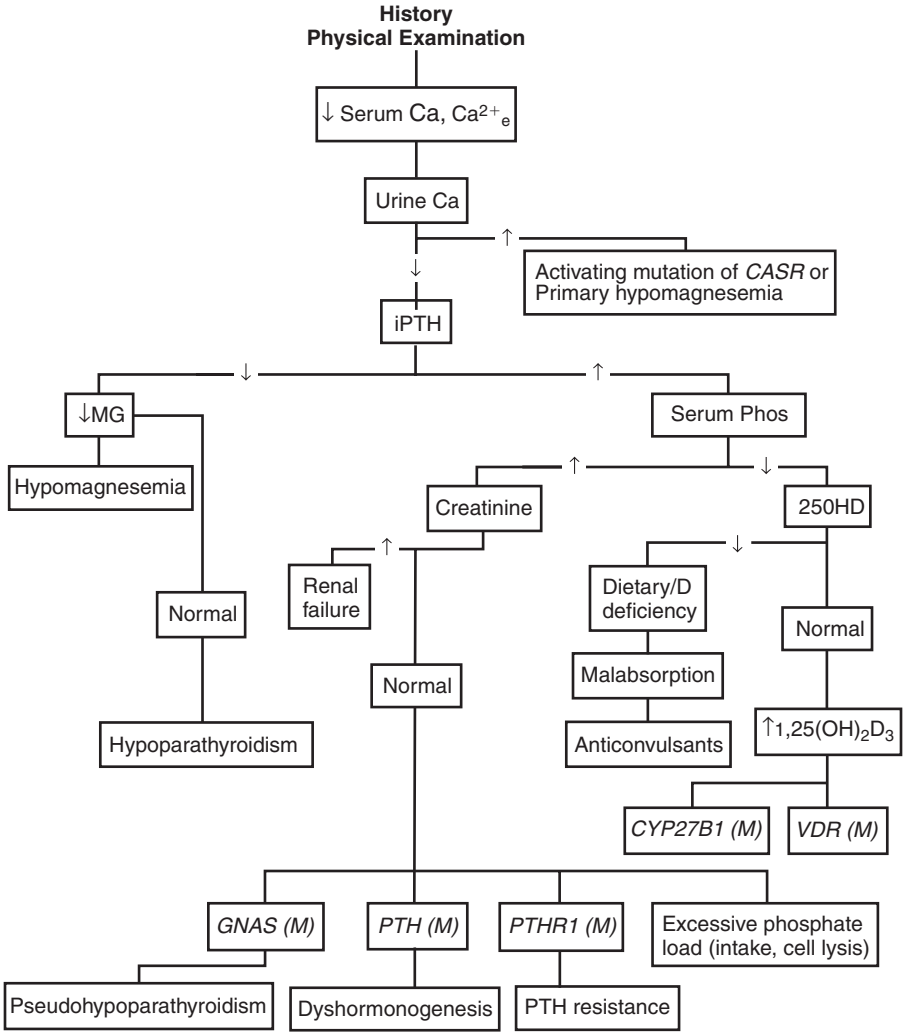

Figure 17-5 Evaluation of hypocalcemia. Abbreviations: Ca (serum total calcium), Ca^{2+}_e (extracellular ionized calcium), Phos (serum phosphate), Mg (magnesium), PTH (parathyroid hormone), 25OHD [25-hydroxyvitamin D (calcidiol)], 1, 25 $(OH)_2$ D_3 [1, 25-dihydroxy vitamin D_3 (calcitriol)] PTHR1 (PTH receptor), VDR (vitamin D receptor), D (vitamin D), and M (mutation).

stressed neonate). Serum levels of calcium, Ca^{2+}_e, phosphate, and intact PTH should be measured in the mothers of neonates with unexplained hypocalcemia.

In neonates with hypocalcemia not otherwise explained, evaluation for possible DGS should be undertaken—particularly when physical examination reveals an abnormal face and a congenital anomaly of the outflow tract of the heart. The white blood and T (CD4) lymphocyte counts are low in DGS, and the thymic shadow often absent. The diagnosis of the DGS is confirmed by the presence of a microdeletion of chromosome 22q11.2 as demonstrated by fluorescent in situ hybridization (FISH).

Occasionally, sequence analysis of *TBX1* may be needed to establish this diagnosis if the *FISH* study is normal. Because the DGS may be heritable, examination of the karyotype of the parents of a DGS infant is indicated (as well as those of the siblings if the parent also has delq22.11). It should be noted that the majority of neonates and infants with DGS are recognized primarily because of cardiac anomalies and that subjects without these lesions may not be identified until mid or late childhood or adolescence.[76] Neonates with PHP type I usually do not have the characteristic skeletal phenotype (brachymetacarpals) of Albright hereditary osteodystrophy, but if this diagnosis is suspected analysis of GNAS is indicated.

Early neonatal hypocalcemia is often asymptomatic, but nevertheless treatment is indicated when the total serum calcium concentration is below 6 mg/dL in the preterm infant and less than 7 mg/dL in the term infant.[20] Asymptomatic neonates are most easily managed by increasing the oral intake of calcium and establishing an overall ratio of calcium:phosphate intake of 4:1 (including that in feedings with a low phosphate formula such as Similac PM $60/40^R$, calcium:phosphate ratio 1.6:1), with calcium glubionate or calcium carbonate administered in divided doses every 4 to 6 hours (Table 17-3).

Eucalcemia is almost always restored in these subjects within 3 weeks after birth, and often earlier. In the hypocalcemic infant with tetany or frank seizures, 10% calcium gluconate (elemental calcium 9.3 mg/mL) at a dose of

TABLE 17-3

Preparations of Calcitriol, Calcium, Magnesium, and Phosphate

Medication	Content	Elemental Mineral
Vitamin D		
Vitamin D	8,000 IU/mL	
	25,000 or 50,000 IU/tablet	
Calcidiol	20 or 50 μg/tablet	
Calcitriol	1 μg/mL	
	0.25 μg or 0.5 μg/casule	
Dihydrotachysterol	0.2 μg/5 mL	
	01.25, 0.2, 0.4 mg/tablet	
Calcium		
Calcium gluconate (iv)	93 mg/g	93 mg/10 mL
Calcium glubionate (solution)	64 mg/g	115 mg/5 mL
Calcium carbonate	400 mg/g	500 mg/tablet
Calcium carbonate (suspension)	1,250 mg/5 mL	500 mg/5 mL
Calcium citrate	210 mg/g	200 mg/tablet
Magnesium		
Magnesium sulfate (50% im soln)		49 mg/mL
Magnesium oxide	603 mg/g	241 mg/tablet
Mg gluconate	54 mg/g	27 mg/tablet
Magnesium chloride	120 mg/g	64 mg/tablet
Phosphorus		
Sodium phosphate (phospha-soda)		127 mg/mL
Sodium/potassium phosphate (Neutraphos)		250 mg/packet (powder)
Potassium phosphate (Neutraphos-K)		250 mg/packet (powder)
Potassium phosphate (K-Phos Original)		114 mg/tablet
Sodium/Potassium phosphate (K-Phos MF)		126 mg/coated tablet
Sodium/Potassium phosphate (K-Phos #2)		250 mg/coated tablet
Sodium/Potassium phosphate (K-Phos Neutral)		250 mg/tablet

1 to 3 mg/kg and rate of less than 1 mL/minute and a total dose not to exceed 20 mg of elemental calcium/kg may be administered by intravenous infusion. Often seizures will cease after 1 to 3 mL of 10% calcium gluconate has been administered.[20,22] Cardiac rate and rhythm must be carefully monitored to prevent bradycardia and asystole.

Further intravenous bolus doses of calcium (~10 mg/kg at 6-hour intervals) should be used sparingly because they result in wide excursions in serum calcium values. These infants too should receive supplemental oral calcium. Depending on the cause of the hypocalcemia, supplemental vitamin D or calcitriol may also be needed. Serum and urine calcium and creatinine levels should be determined frequently, and treatment modified to maintain eucalcemia and the urine calcium/creatinine ratio <0.2 in an effort to avoid iatrogenic hypercalcemia, hypercalciuria, nephrocalcinosis, and renal insufficiency.

After restoration of eucalcemia in the infant with DGS, the other components of this disorder must be addressed. Cardiac anomalies usually require surgical correction, as do palatal clefts. In DGS infants with immunocompromise and recurrent infections due to thymic aplasia, appropriate anti-infectious therapy is mandatory. Transplantation of fetal or cultured postnatal thymic tissue, bone marrow, or peripheral blood mononuclear cells has restored immune function in infants with the DGS.[77,78] Supplemental calcitriol (20–60 ng/kg/day) and calcium are necessary for restoration and maintenance of eucalcemia in infants with hypoparathyroidism. Poor growth due to feeding difficulties and learning disabilities due to developmental delay must be managed on an individual basis and illustrate the need for a multidisciplinary approach to the care of DGS patients.[76] Hypocalcemia due to hypomagnesemia is managed acutely by the intravenous infusion or intramuscular injection of 50% magnesium sulfate at a dose of 0.1 to 0.2 mL/kg while monitoring cardiac status.

HYPERCALCEMIA

Although hypercalcemia in neonates and very young infants is defined as total blood calcium concentration >10.8 to 11.3 mg/dL (depending on the analytical laboratory), substantial symptoms (anorexia, gastroesophageal

reflux and emesis, constipation, lethargy and hypotonia, or irritability and seizures) usually do not occur until the total calcium level exceeds 12 to 13 mg/dL.[22,79] These infants frequently have polyuria, and may become dehydrated due to renal resistance to antidiuretic hormone if oral fluid intake is restricted.

Due to the vasoconstrictive effect of calcium, the hypercalcemic infant may be hypertensive. Hypercalcemia also shortens the S-T segment and can lead to heart block and ultimately to asystole. In older infants and young children with chronic hypercalcemia, poor growth and failure to thrive are often presenting manifestations. Hypercalcemia also leads to hypercalciuria and the complications of nephrocalcinosis and nephrolithiasis.

Etiology

Neonatal/infantile hypercalcemia may be iatrogenic in origin (e.g., administration of excessive calcium or vitamin D) at times in the breast milk of mothers ingesting large amounts of cholecalciferol. It may also be due to maternal ingestion of thiazide diuretics that increase renal tubular absorption of calcium or purposeful restriction of phosphate that leads to hypophosphatemia and reciprocal increase in serum calcium concentrations as hypophosphatemia stimulate renal tubular 25OHD-1α-hydroxylase activity, calcitriol synthesis, and increased intestinal absorption of calcium (Table 17-4). Hypercalcemia, hypophosphatemia, hyperphosphatasemia, and radiographic evidence of rickets develop in premature infants receiving intravenous alimentation deficient in phosphate or in those fed only human breast milk—the phosphate content of which is low.

The problem may be prevented or treated by increasing the amount of parenteral phosphate administered to the extent possible or by the use of breast milk fortified with phosphate.[80] Adequate extrauterine mineralization of the preterm skeleton requires intakes of calcium and phosphate of approximately 200 mg/kg/day. Extracorporeal life support may also be associated with hypercalcemia in neonates.[81]

Hypervitaminosis D may be due to prolonged feeding of an improperly prepared formula or commercial dairy milk containing excessive vitamin D; iatrogenic prescription of vitamin D, calcidiol, or calcitriol; or increased endogenous production of calcitriol from inflammatory sites.[79] In infants with severe birth trauma or perinatal asphyxia, subcutaneous fat necrosis may develop in tissues that have sustained direct trauma and be manifested by indurated extremely firm violaceous nodules on the cheeks, trunk, buttocks, and legs.[22] Hypercalcemia may be present when the lesions first appear or develop as the nodules resolve several weeks later.

Histologically, the skin lesions are composed of adipocytes, an inflammatory lymphohistiocytic infiltrate, and multinucleated giant cells in a bed of calcium crystals. The hypercalcemia of subcutaneous fat necrosis is attributable not only to reabsorption of precipitated calcium but to extrarenal synthesis of calcitriol by local macrophages and resultant hyperabsorption of ingested calcium. The 25OHD-1α-hydroxylase activity of these inflammatory macrophages is not under the control of PTH, calcium, or phosphate levels but is suppressible by glucocorticoids.[22]

TABLE 17-4

Causes of Hypercalcemia

I. Neonate/Infant

A. Maternal Disorders

1. Excessive vitamin D ingestion, hypoparathyroidism, pseudohypoparathyroidism

B. Neonate/Infant

1. Excessive intake of calcium or vitamin D
2. Phosphate depletion
3. Subcutaneous fat necrosis
4. Williams-Beuren syndrome
5. Familial hypocalciuric hypercalcemia/neonatal severe hyperparathyroidism
6. Metaphyseal chondrodysplasia, Jansen type
7. Persistent parathyroid hormone related protein
8. Bartter syndrome with excessive production of prostaglandin E
9. Lactase/disaccharidase deficiency
10. Infantile hypophosphatasia
11. Mucolipidosis type II
12. Post bone marrow transplantation for osteopetrosis
13. Idiopathic
14. Endocrinopathies: primary adrenal insufficiency, severe congenital hypothyroidism, hyperthyroidism

II. Hyperparathyroidism

A. Sporadic

B. Familial

1. Neonatal severe hyperparathyroidism (*CASR*)
2. Multiple endocrine neoplasia, type I (*MEN1*)
3. Multiple endocrine neoplasia, type Iia (*RET*)
4. McCune-Albright syndrome (*GNAS*)
5. Familial hyperparathyroidism 2 -jaw tumor syndrome (*HRPT2*)
6. Jansen's metaphyseal dysplasia (*PTHR1*)

C. Secondary/Tertiary

1. Postrenal transplantation
2. Chronic hyperphosphatemia

D. Ectopic Production of PTHrP

III. Familial Hypocalciuric Hypercalcemia (CASR)

A. Loss-of-Function Mutations in *CASR*

B. Inhibitory Autoantibodies to the Calcium-Sensing Receptor

IV. Excessive Intake of Calcium or Vitamin D

1. Nutritional - milk-alkali syndrome
2. Exogenous ingestion (vitamin D) or topical application (calcitriol or analog)
3. Ectopic production of calcitriol associated with granulomatous diseases: sarcoidosis, inflammatory bowel disease; tuberculosis, histoplasmosis, coccidioidomycosis, leprosy; human immunodeficiency virus; neoplasia: lymphoma, dysgerminoma

V. Immobilization

VI. Other Causes

A. Neoplasia: Osseous metastases, production of PTHrP, cytokines/osteoclast activating factors

B. Hypophosphatasia

C. Drugs: thiazide diuretics, lithium, vitamin A and analogs, calcium, alkali, anti-estrogens, aminophylline

D. Total parenteral nutrition

E. Endocrinopathies: hyperthyroidism, hypoadrenocorticism, pheochromocytoma

F. Vasoactive intestinal polypeptide-secreting tumor

G. Acute or chronic renal failure/administration of aluminum

H. Juvenile rheumatoid arthritis, cytokine mediated

Excessive production of prostaglandin E and interleukins (IL) -1 and -6 further contributes to hypercalcemia in this disorder by increasing the rate of bone turnover.[82] Hypercalcemia attributable to subcutaneous fat necrosis is managed by the ingestion of a low-calcium formula, avoidance of vitamin D, and administration of fluids, furosemide, calcitonin, glucocorticoids, or bisphosphonate (etidronate, pamidronate) as needed.[83] Hypercalcemia due to subcutaneous fat necrosis has also been observed in older children with major trauma or disseminated varicella.[79] Congenital lactase deficiency has been associated with infantile hypercalcemia, perhaps due to increased intestinal absorption of calcium directly promoted by lactose.

Neonatal severe hyperparathyroidism (NSHPT) is a potentially lethal form of familial (hereditary) hypocalciuric hypercalcemia (HHC), with very high serum calcium concentrations. NSHPT is most commonly due to homozygous or compound heterozygous inactivating mutations of *CASR* that greatly increase the serum concentration of Ca^{2+}_e needed to suppress PTH synthesis and secretion. However, in several infants with NSHPT there have been heterozygous inactivating mutations of *CASR* (e.g., Arg185Gln, Arg227Leu)—suggesting that the products of these mutations possibly exert a dominant-negative effect on the normal allele, perhaps by interfering with migration of wt receptors to the cell surface or inactivation of wt receptor by linking to the mutated CaSR once embedded in the cell membrane, or by sequestration of G-proteins.[84]

In addition, the heterozygous fetus who has inherited only one inactivated CaSR allele from an affected father and is delivered by a normal mother may have been relatively hypocalcemic in utero, leading to hyperplasia of the fetal PTGs that persists after birth. Conversely, homozygous mutations near the amino terminal of *CASR* (e.g., Leu13Pro) may not become manifest until mid childhood or even adulthood.[85,86] The clinical spectrum of NSHPT ranges from mild—(constipation, polyuria) with calcium concentrations ranging from 12 to 13 mg/dL—to severe and life-threatening (dysrhythmia, respiratory distress due to hypotonia, demineralization and fractures of the ribs) when calcium levels exceed 15 mg/dL.[87]

NSHPT may present within the first few days of life to several months of age, depending on the degree of hypercalcemia. Search of the family history may identify members with autosomal-dominant HHC1. The serum calcium concentration is usually markedly elevated (>14–17 mg/dL), as is the PTH value. There are hypermagnesemia, normal to low serum phosphate levels, hyperphosphatasemia, elevated calcitriol values, low renal tubular reabsorption of phosphate, and relative hypocalciuria. Radiographically, osteopenia, metaphyseal widening and irregularity, subperiosteal resorption, and varus angulation of the hips may be seen in response to the bone resorptive effects of PTH.

Treatment of NSHPT includes induction of sodium diuresis (fluids, furosemide) in order to increase urinary calcium excretion and intravenous administration of a bisphosphonate (pamidronate, zoledronic acid) to acutely lower serum calcium values. Calcimimetic drugs that act directly on the CaSR have also been effective in lowering serum calcium values in infants with NSHPT.[88,89] Parathyroidectomy may be a requisite life-saving measure at times. Children with NSHPT who remain hypercalcemic are anorectic, fail to thrive, and are at risk for developmental delay.[22]

Secondary hyperparathyroidism in the neonate may be the result of maternal hypocalcemia due to hypoparathyroidism or PHP.[22] Maternal hypocalcemia reduces placental transport and net delivery of calcium to the fetus, resulting in relative fetal hypocalcemia and leading to hyperplasia of the fetal PTGs and secondary hyperparathyroidism proportional to the maternal calcium deficit. Although 25% of infants of hypocalcemic mothers are hypercalcemic, most have skeletal changes that reflect PTH excess that vary from severe demineralization with fractures to osteopenia detectable only by absorptiometry. Secondary hyperparathyroidism usually resolves within a few weeks after birth as the infant ingests adequate calcium and phosphate.

Another cause of neonatal secondary hyperparathyroidism is mucolipidosis type II (OMIM 252500). This Hurler-like disorder is characterized by facial abnormalities (asymmetry, flat nasal bridge), hepatosplenomegaly, skeletal deformities (dysostosis multiplex), and developmental delay and is due to inactivating mutations in a gene (*GNPTAB*- N-acetyglucosamine-1-phosphotransferase, α/β subunits) encoding a phosphotransferase required for synthesis of mannose 6-phosphate.[90] In this disease, maternal calcium concentrations are normal but placental histology is abnormal—suggesting impaired placental transport of calcium and fetal hypocalcemia, leading to compensatory increase in in utero PTH generation. In turn, skeletal evidence of PTH excess (osteopenia, fractures) develops. Secondary hyperparathyroidism and its adverse effects remit within the first several weeks to months after birth.

Murk-Jansen metaphyseal chondrodysplasia (OMIM 156400) is an autosomal-dominant chondrodystrophy associated with marked hypercalcemia as a consequence of heterozygous mutations that lead to constitutive ligand-independent activation of PTHR1 expressed in the kidney, bone, and growth plate chondrocytes.[91] Phenotypically, there are marked short-limbed dwarfism; deformities of the long bones, digits, spine, and pelvis; choanal atresia; highly arched palate; micrognathia; widely open cranial sutures (in infancy); sclerosis of the basal cranial bones; disorganization of the metaphyses (delayed chondrocyte differentiation, irregularly calcified cartilage protruding into the diaphysis); and excessive loss of cortical bone but normal trabecular bone.

Interestingly, birth length and physical appearance are usually normal in these neonates—although radiographic evidence of the chondrodysplasia is present. In affected neonates and infants, there are hypercalcemia, hypophosphatemia, increased serum concentrations of calcitriol, and elevated urinary excretion of nephrogenous cyclic adenosine monophosphate but low or undetectable serum levels of PTH and PTHrP. Constitutively activating mutations of *PTHR1* in these subjects include His223Arg at the junction of the first intracellular loop and second transmembrane domain and Thr410Pro in the sixth transmembrane domain—sites specifically

important in conferring ligand-independent activity upon PTHR1.[79,92] Excessive secretion of PTHrP and resultant hypercalcemia have been observed in infants with neonatal iron storage disease and embryonal renal tumors (Wilms', mesoblastic nephroma). In these infants, intravenous pamidronate (0.5 mg/kg in 30 mL of normal saline over 4 hours repeated once or twice) has restored eucalcemia.[93]

The Williams-Beuren syndrome (OMIM 194050) is characterized by intrauterine and postnatal growth retardation; hypercalcemia in infancy in 15% of patients that usually resolves by 1 year of age but may occasionally persist into adulthood; consistent hypercalciuria; supravalvular aortic stenosis in 30% of subjects; stenoses of the pulmonary, renal, mesenteric, and celiac arteries; microcephaly; elfin face (epicanthal folds, stellate iris pattern, esotropia, short nose with full nasal tip, arched upper and prominent lower lips, long philtrum, full cheeks with flattened malar eminences, dental malocclusion); hoarse voice; radioulnar synostosis; renal hypoplasia or unilateral agenesis; hypertension; and developmental delay (poor visual-motor integration, attention deficit disorder, IQ 20–106).[22]

Although most patients with the Williams-Beuren syndrome are developmentally challenged, they have unique and proficient verbal skills with a large vocabulary and enhanced auditory memory (particularly for names), adept social language skills, and exceptional musical aptitude—including the ability to memorize and sing many musical compositions and play many instruments.[79] The pathophysiology of hypercalcemia in this syndrome is unknown. No consistent abnormalities of vitamin D metabolism or of PTH or calcitonin secretion have been found in patients with the Williams-Beuren syndrome. Interestingly, many patients with this disorder have hypoplasia of the thyroid gland and elevated serum concentrations of thyrotropin. However, the significance of these findings to the pathophysiology of the syndrome itself is unclear.[94]

The Williams-Beuren syndrome may be transmitted as an autosomal-dominant trait. It has been localized to chromosome 7q11.23, where microdeletions of 0.9 to 2.5 Mb and hemizygous loss of perhaps as many as 17 contiguous genes combine to produce the syndromic phenotype. The microdeletions may arise in the maternal or paternal seventh chromosome. Hemizygous deletions of *ELN* have been found in more than 90% of patients with the Williams-Beuren syndrome and likely account for the abnormalities of vascular connective tissue present in these subjects, but not the other manifestations of this disorder. Singular deletion and intragenic loss-of-function mutations of *ELN* lead to isolated supravalvular aortic stenosis without other features of the Williams-Beuren syndrome.

Hemizygosity for *ELN* leads to compensatory increase in the number of rings of smooth muscle and elastic lamellae, resulting in arterial thickening and increased risk of obstruction.[95] Additional genes at chromosome 7q11.23 whose haploinsufficiency may be responsible for aspects of the Williams-Beuren phenotype include *RFC2* (OMIM 600404, encoding a subunit of a DNA replication factor whose loss might account for disturbed growth), *LIMK1* (OMIM 601329, encoding LIM kinase-1, a protein expressed in the brain that may be important in visual-spatial constructive cognition), *GTF2I* (OMIM 601679, a constituent of a growth factor signal transduction pathway whose hemizygous loss may contribute to developmental delay), *GTF2IRD1* (OMIM 604318, a transcription factor whose heterozygous loss may lead to abnormalities of neurologic development and craniofacial and somatic growth).

CYLN2 (OMIM 603432) is a cytoplasmic protein that links membranous organelles and microtubules and whose haploinsufficiency results in mild growth retardation and neural defects.[96] Microdeletions of chromosome 7q11.23 arise by unequal crossing over of chromosomal segments between homologous seventh chromosomes during meiosis or by intrachromosomal recombination. The Williams-Beuren phenotype has also been associated with interstitial deletion of chromosome 6q22.2q23 as well as defects in chromosomes 4, 11, and 22, implying that the syndrome is quite genetically heterogeneous (involving a number of genetic cascade systems). The diagnosis of the Williams-Beuren syndrome is suspected on the basis of the characteristic clinical phenotype (with/without hypercalcemia) and confirmed by demonstration of the microdeletion at chromosome 7q11.23 or of *ELN* by FISH, although a normal chromosome analysis does not entirely eliminate this diagnosis. Hypercalcemia is managed by ingestion of a low-calcium, vitamin-D-free formula. Occasionally, short-term glucocorticoid therapy may be necessary to restore eucalcemia.

Idiopathic infantile hypercalcemia is clinically similar to the Williams-Beuren syndrome (hypertension, hyperacusis, strabismus, radioulnar synostosis), and the distinction between the two entities is sometimes difficult.[79] Prolonged hypercalcemia and elevated serum concentrations of the amino-terminal fragment of PTHrP have been recorded in some children with this disorder in the absence of a neoplasm, but in the majority of patients the pathophysiology of this disorder is not known. In most patients, hypercalcemia resolves within the first several years of life (but may persist to older ages). Avoidance of vitamin D, low dietary calcium intake, and glucocorticoids to reduce intestinal absorption of calcium are therapeutic modalities for this disorder.

Antenatal Bartter syndromes, type 1 (OMIM 601678) and type 2 (OMIM 600839), are quite similar clinically and biochemically and are due to loss-of-function mutations in genes controlling transepithelial transport of chloride and potassium (respectively) across the renal tubular thick ascending limb of the loop of Henle (TALH). Affected fetuses develop polyhydramnios, leading to premature delivery with postnatal salt wasting, hypokalemic metabolic alkalosis, hypercalciuria (and occasionally hypercalcemia), failure to thrive, and often death. The type 1 disorder is due to inactivating mutations of the gene encoding sodium/potassium/chloride cotransporter-2 *(SLC12A1)*—the mediator of active reabsorption of sodium chloride in the TALH. The type 2 syndrome is due to an inactivating mutation in the gene encoding an inwardly rectifying potassium channel *(KCNJ1)*.[97]

Hypokalemia (occasionally transient hyperkalemia in the type 2 syndrome), reduced intravascular volume, and

increased levels of angiotensin sum to increase renal and systemic production of prostaglandin E2 that further inhibits sodium and chloride reabsorption in the TALH and enhances juxtaglomerular renin release. Hypochloremic, hypokalemic alkalosis, hyperprostaglandin E, hypercalciuria leading to nephrocalcinosis and osteopenia, and hypercalcemia suggest neonatal Bartter syndrome. Replacement of fluid and electrolytes and administration of potassium-sparing diuretics and the cyclooxygenase inhibitors (indomethacin or a specific inhibitor of cyclooxygenase type 2) are usually effective in ameliorating the biochemical and clinical manifestations of the disease.

Perinatal hypophosphatasia is a lethal disorder manifested during gestation by marked skeletal hypomineralization. At times only the base of the skull may be calcified. Usually, the calvarium and vertebrae are partially mineralized, rachitic changes are present at the distal ends of the long bones, and fractures are common.[98] Infantile hypophosphatasia (OMIM 241500) is an often fatal autosomal-recessive disorder recognized clinically by 6 months of age and characterized by rickets, demineralization of the calvarium and peripheral skeleton, increased intracranial pressure, flail chest, hypercalcemia, and hypercalciuria. Radiographically, spurs of cartilage and bone extend from the sides of the knee and elbow joints. The disease is due to defective osteoblast synthesis of tissue non-specific alkaline phosphatase because of loss-of-function missense, nonsense, and donor splice site mutations of *ALPL*.

The lethal homozygous or compound heterozygous mutations of *ALPL* are located within or near the enzyme domain and/or the homodimer and tetramer interfaces.[99,100] Decreased alkaline phosphatase activity leads to a deficit in phosphate ions for combination with calcium at the site of hydroxyapatite formation, whereas continued intestinal calcium absorption results in hypercalcemia. Inappropriately low serum bone alkaline phosphatase activity differentiates this condition from other rachitic states in which alkaline phosphatase activity is usually elevated.

Increased urine phosphoethanolamine and serum inorganic pyrophosphate and pyridoxal-5'-phosphate values are consistent with the diagnosis of hypophosphatasia, whereas analysis of *ALPL* identifies the gene mutation(s) itself. Hypophosphatasia can be diagnosed prenatally by *ALPL* genotyping.[98] The hypercalcemia of infantile hypophosphatasia is managed by hydration, diuretics that act at the TALH (e.g., furosemide), and administration of bisphosphonates (pamidronate), calcitonin, or glucocorticoids as necessary. Dietary calcium intake should be restricted, and vitamin D and its metabolites avoided. Bone marrow transplantation and stem cell boosts of transfused donor osteoblasts have also been used to treat affected patients.

Evaluation and Management

After completing the historical review (during which the family history is explored for members with mineral disorders and the patient's intake of calcium, phosphate, and vitamin D are estimated) and physical examination (searching for the facial and cardiovascular signs of Williams-Beuren syndrome, the subcutaneous nodules associated with subcutaneous fat necrosis, or the deformities of metaphyseal chondrodysplasia and infantile hypophosphatasia), evaluation of the hypercalcemic neonate and infant continues with total calcium and Ca^{2+}_e, phosphate, alkaline phosphatase, PTH, calcidiol, and calcitriol measurements as indicated and appropriate (Figure 17-6). In infants with suspected Williams-Beuren syndrome, FISH analysis of chromosome 7q11.23 or for ELN should be undertaken.

Treatment of hypercalcemia in neonates and infants must be directed to its cause and severity. Use of a formula low in calcium and avoidance of vitamin D (excessive intake or sunlight) are helpful in the majority of neonates with modest hypercalcemia.[22] Significantly elevated serum calcium levels that must be rapidly decreased may require infusion of 0.9% sodium chloride (10–20 mL/kg over 1 hour), followed by an intravenous bolus injection of furosemide (1–2 mg/kg) when adequate urine flow has been established. Hydrocortisone (l mg/kg intravenously every 6 hours) reduces intestinal calcium absorption, and salmon calcitonin (10 units/kg subcutaneously) inhibits calcium mobilization from bone.

Currently, bisphosphonates (analogs of pyrophosphate that adsorb to the surface of hydroxyapatite crystals in bone and inhibit osteoclast function and bone resorption) are the agents of choice for the treatment of

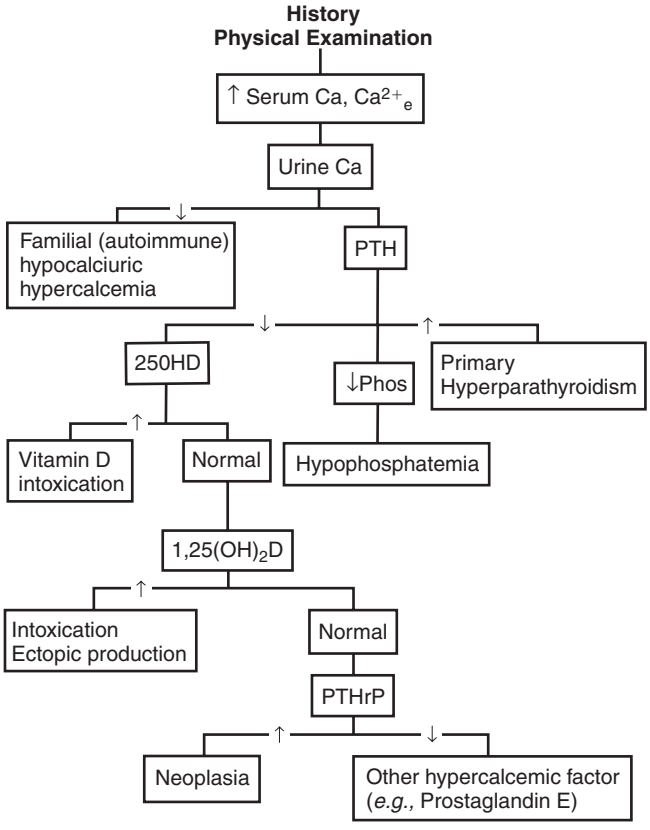

Figure 17-6 Evaluation of hypercalcemia. Abbreviations: Ca (serum total calcium), Ca^{2+}_e (extracellular ionized calcium), Phos (serum phosphate), PTH (parathyroid hormone), 25OHD [25-hydroxyvitamin D (calcidiol)], and $1,25(OH)_2$ D-[1,2,5-RTHnP RTH related protein dihydroxyvitamin D (calcitriol)].

substantial hypercalcemia in infants. Etidronate (5 mg/kg twice daily orally) and pamidronate (0.5–2.0 mg/kg in 30 mL normal saline intravenously over 4 hours) have been successfully employed in infants with hypercalcemia due to vitamin D intoxication, subcutaneous fat necrosis, and other causes.[83,101-103] Parathyroidectomy may be urgently required in the newborn with NSHPT and life-threatening hypercalcemia.

DISORDERS OF BONE MINERALIZATION

Low Bone Mass and Rickets

Approximately 80% of total bone calcium in the full-term neonate is accrued in the last trimester of pregnancy as the in utero rate of calcium deposition increases more than twofold between 28 and 36 weeks of gestation. LBW (<1,500 g) and very low birth weight (VLBW <1,000 g) infants are particularly vulnerable to the development of bone disease of prematurity because they are unable to maintain the in utero rate of synthesis of organic bone matrix (osteoid) or the rate of calcium and phosphate deposition into osteoid from the minerals provided via the gastrointestinal tract or by parenteral nutrition.[104] Decreased calcification of bone matrix results in low bone mineral content (BMC), whereas depressed calcification of the cartilage growth plate leads to rickets and its characteristic deformities.

In general terms, osteopenia may be defined as too little bone tissue with decreased thickness of bone cortex and/or decreased thickness or number of bone trabeculae. Osteoporosis is present when bone mass is so low that fractures occur after minor trauma.[104] (Thus, in this population of LBW and VLBW neonates these terms are not necessarily defined by the same quantitative measurements of bone density as employed in adults.) Postpartum, hypocalcemia, and decrease in spontaneous movement against the force exerted by the muscular wall of the uterus depress the rate of bone mineral acquisition—whereas an increased rate of bone resorption further decreases skeletal mass in premature infants.[105,106]

Approximately 30% of preterm infants with birth weights <1,500 g develop bone disease.[107] Birth weight and rate of postnatal weight gain, as well as umbilical cord concentrations of IGF-I, are important determinants of bone mass in premature infants.[108,109] Necrotizing enterocolitis, a disorder that affects approximately 10% of LBW infants, increases the rate of bone resorption as assessed by measurement of serum (ICTP) and urinary (Dpd) markers of this process.[110] Interestingly, neonatal sepsis is not associated with increase in levels of bone resorption markers.[110,111] Malrotation of the intestinal tract or catastrophic necrotizing enterocolitis leading to intestinal infarction requiring extensive small bowel resection substantially increases the risk of malabsorption and subsequent low bone mass.

Parenteral alimentation of LBW or VLBW neonates restricts administration of fluid, calcium, and phosphate (in part, because of the incompatibility of the coinfusion of these ions in high concentrations). Excessive aluminum in parenteral fluids also adversely affects bone formation. Another factor that may contribute to the bone disease of prematurity is decreased synthesis of glucagon-like peptide 2 (GLP2, OMIM 138030, chromosome 2q36-q37), a 33-aa post-translational derivative of proglucagon whose production is depressed by small intestinal resection or atrophy during prolonged parenteral alimentation. GLP-2 promotes intestinal calcium absorption and depresses osteoclastic activity.[110] Increased maternal parity, male gender, severe systemic disease (bronchopulmonary dysplasia), immobility, and pharmacologic agents (glucocorticoids, methylxanthines such as theophylline, diuretics such as furosemide) also adversely impact bone formation in these neonates.[106,112]

Theophylline and furosemide increase urinary excretion of calcium.[113] A polymorphic variant of estrogen receptor α with multiple TA repeats (>18) at 1174 bp upstream appears to protect LBW neonates from development of bone disease of prematurity, and a variant with a low number of TA repeats increases the risk of bone disease. The mechanism of this effect is not known at present.[107] Two prenatal factors that contribute to low bone mass in VLBW and LBW neonates include intrauterine growth retardation (possibly by reducing placental transport of calcium and decreasing the rate of bone formation) and prenatal exposure to large amounts of magnesium sulfate administered repeatedly to the mother in preterm labor that leads to hypocalcemia and osteopenia by suppressing PTH secretion through its interaction with the CaSR and by competing with calcium for deposition at bone surfaces, respectively.[114]

In preterm neonates, serum levels of total and bone-specific alkaline phosphatase, PICP, and osteocalcin (markers of osteoblast activity and bone formation) are elevated relative to full-term neonates and older infants and continue to rise over the first 10 weeks of life.[115] Urinary hydroxyproline and Pyr/Dpd values (markers of osteoclast activity and bone resorption) are also increased, although serum concentration of ICTP (another marker of bone resorption) decline during the first 10 weeks after premature delivery.

Overall, the data indicate that intrauterine and postnatal rates of bone turnover in preterm newborns are rapid and persistently elevated through 40 weeks postconceptual age—a conclusion confirmed by bone histomorphometry.[105,112,116] By photon absorptiometry and quantitative ultrasonography, bone mass of preterm infants appears to decline during the first several weeks after birth.[116a] Serum levels of alkaline phosphatase and osteocalcin and urinary excretion of Pyr and calcium may remain elevated in LBW infants with bone disease of prematurity relative to values in LBW infants without bone disease for the first year of life, even though radiographic improvement in skeletal mineralization is usually evident by 6 months of age.[107]

Because standard roentgenograms may not detect low bone mineralization before deficits of 20 to 30% or greater have occurred in the second month of life, estimation of BMC by dual-energy X-ray absorptiometry (DEXA) has become the preferred method of assessing bone mineralization in infants because of its accuracy, reproducibility, rapidity of performance, and low radiation exposure (2–3 mrems).[12,117] Mean total body BMC in the first 2 days of life ranges from 21.7 g in newborns with birth weights of 1,001 to 1,500 g to 78.8 g in neonates

with birth weights of 3,501 to 4,000 g, whereas BMD varies from 0.146 mg/cm^2 (1,001–1,500 g) to 0.234 gm/cm^2 (3,501–4,000 g). In full-term healthy neonates, the mean whole-body BMC measured by newly introduced fan beam DEXA is 89.3 (SD ∀ 14.1) g.[118]

BMC and BMD increase through the first year of life and beyond as measured by DEXA (see Chapter 3, Table 8). No racial, gender, or seasonal factors affect bone mineralization at this age. Body weight is best correlated with bone mass.[119] There is increasing use of quantitative ultrasound (QUS) to assess bone integrity and strength in preterm and other LBW infants because the study may be performed at the crib side, there is no exposure to radiation, and it may be repeated as frequently as necessary.[120] QUS measures the speed of sound (SOS) through a bone (humerus, tibia, radius, patella, os calcis, metacarpal, phalanx), a measurement correlated with the strength of the bone. Mineral content is but one of several skeletal components (elasticity, cortical thickness, microstructure) that collectively contribute to bone strength.

QUS also permits calculation of bone transmission time, a measurement that determines the difference in the velocity of sound as it travels through bone and surrounding soft tissue. There is considerable overlap of SOS values at various ages and somatic sizes. However, bone transmission times may discriminate to a greater extent between these parameters. Humeral QUS measurements are lower in preterm than term infants and correlate positively with gestational age, length, and weight.[121] In neonates with intrauterine growth retardation, tibial SOS levels may be appropriate for gestational age or may even be elevated.[122,123]

With prolonged deprivation of calcium, phosphate, and vitamin D, not only does the LBW infant lag in accumulation of bone mass but clinical and radiographic evidence of rickets also develops—usually between the sixth and twelfth postnatal weeks—and fractures may occur in as many as 24% of VLBW infants.[116a] The LBW neonate at risk for low bone mass and/or rickets is best managed preventively by the daily enteral administration of as much of the needed amounts of calcium (140–160 mg/100 kcal), phosphate (95–108 mg/100 kcal of formula), and vitamin D (400 U)—as well as protein (for collagen synthesis) and energy (carbohydrates, lipids)—as possible.

When parenteral administration of nutrients is necessary in the LBW or VLBW neonate, an attempt should be made to administer the maximum amounts of calcium and phosphate safely attainable. The solubility of calcium and phosphate depends not only on their quantities but on the forms selected for infusion (i.e., calcium chloride, gluconate, glycerophosphate, monobasic phosphate, or dibasic phosphate). Utilizing monobasic phosphate and glycerophosphate, it is possible to infuse as much as 86 mg of calcium/kg/dL and 46 mg/kg/dL of phosphate.[12] Enteral feeding should begin as soon as possible in the LBW infant. Fortification of human breast milk with calcium glycerophosphate (calcium 170 mg/kg/day, phosphate 87 mg/kg/day) permits 57% absorption and 91% retention (88 mg/kg/day) of calcium and 94% absorption and 61% retention (50 mg/kg/day) of phosphate.[12]

Prepared formulas for feeding of LBW neonates can also provide up to 90 mg/kg/day of retained calcium and 40 mg/kg/day of retained phosphate. The type of prepared formula (sources of protein, fat, and carbohydrates) and its lipid and mineral additives determine the rate of intestinal calcium absorption and retention. Therefore, the choice of formula must be carefully considered before it is selected.[6] Nevertheless, parenteral nutrition, fortified human milk, and current preterm formulas are unable to provide the amounts of calcium and (in particular) phosphate that would normally accrue to the fetus in utero. Vitamin D 400 IU/day should also be provided to the preterm infant either enterally or parenterally.

Monitoring of serum levels of calcium, phosphate, creatinine, and alkaline phosphatase (and urinary excretion of calcium, phosphate, and creatinine) is essential in order to prevent hypercalcemia, hypercalciuria, and nephrocalcinosis. It is also important to avoid hypocalcemia because of the avidity of bone matrix for calcium once remineralization has commenced (hungry bone syndrome). Passive physical activity (daily range of motion with extension/flexion of all joints of each extremity in the supine infant for 4 weeks, beginning after the neonate has been stabilized between 2 and 6 weeks of postnatal age) with or without gentle massage of the prone infant from head to toe increases serum levels of markers of bone formation as well as bone mineralization by DEXA and QUS changes consistent with augmented bone strength.[116a,124]

Administration of estrogen and progesterone to VLBW female infants in sufficient amounts to maintain intrauterine levels of these hormones for 6 weeks postnatally does not increase the retention of calcium or phosphate during this interval or bone mineralization in later infancy.[125,126] The efficacy and safety of bisphosphonates or of PTH$^{1\text{-}34}$ in the management of osteopenia of prematurity remain to be examined. Although in the prematurely born infant bone mass may remain low through infancy and early childhood, bone mineralization eventually catches up to the norms.[127-130]
