Osteogenesis imperfecta congenita (OIC) [type II (OMIM 166210)] is a perinatal lethal disorder most commonly associated with heterozygous newly developed loss-of-function mutations in the genes encoding collagen-α1(I) *(COL1A)* or collagen-α2(I) *(COL1A2)*. The mutations may be partial gene deletions resulting in decreased synthesis of type I collagen or missense mutations that lead to amino acid substitutions (e.g., arginine, aspartic acid, cysteine) for the glycine residues essential to the normal three-dimensional conformation of collagen-α1(I) and synthesis of the triple helix and structural integrity of type I collagen in extracellular matrix of bone upon which hydroxyapatite is deposited. Osteogenesis imperfecta type II may rarely be transmitted as an autosomal-dominant trait by a parent mosaic for a heterozygous mutation in collagen-α1(I) or -α2(I).[131]

Clinical manifestations of OIC are variable and include fractures present at birth (which may also occur in newborns with osteogenesis imperfecta types I and III), deformities of the long bones, osteopenia of the skull with large fontanelles, intrauterine growth retardation, premature delivery, and death (usually in infancy) due to respiratory insufficiency. Radiologically, OIC has been categorized into three subgroups: A (short, broad, and crumpled long

bones, angulation of the tibia, and continuous beading of the ribs), B (similar femoral and tibial configurations but incomplete beading of the ribs), and C (thin long bones with many fractures and thin beaded ribs). The diagnosis of OIC is most often made clinically by its differentiation from campomelic dysplasia, achondrogenesis type I, thanatophoric dysplasia, and perinatal hypophosphatasia and is confirmed by quantitation of subnormal amounts of collagen synthesis by fibroblasts in vitro and identification of the mutation in *COL1A1* or *COL1A2* by direct genotyping.

The lethal mutations in collagen-α1(I) are clustered at sites at which the collagen monomer binds integrins, matrix metalloproteinases, fibronectin, and cartilage oligomeric matrix protein. Those in collagen-α2(I) coincide with binding sites for proteoglycans. Administration of the bisphosphonate pamidronate has been helpful in infants with severe manifestations of osteogenesis imperfecta types III and IV but has been ineffective in the lethal form of osteogenesis imperfecta type II.[132,133]

Lysinuric protein intolerance (OMIM 222700) is an autosomal-recessive disorder of hepatic and renal tubular transport of dibasic amino acids (lysine, arginine, ornithine) that manifests itself in infancy and childhood by vomiting, diarrhea, failure to thrive, developmental delay, hepatomegaly, and cirrhosis. Affected infants and children have impaired urea synthesis due to decreased hepatic uptake of ornithine but are episodically hyperammonemic with increased urinary excretion of the dibasic amino acids. There is extremely low bone mass due to marked protein deprivation and perhaps due to increase in cytokine-induced bone resorption.[134] Administration of citrulline has been reported to increase growth and bone mass in some of these patients. Lysine protein intolerance is due to loss-of-function deletion, duplication, missense, nonsense, and splice-site mutations in *SLC7A7* encoding an amino acid transporter.[135]

INCREASED BONE MASS

Increased bone mass may be generalized or localized. Osteosclerosis refers to thickening of trabecular bone, and hyperostosis refers to increase in cortical bone mass.[136] The infantile malignant form of osteopetrosis (OMIM 259700) is an autosomal-recessive disorder due to abnormal osteoclast differentiation or function resulting in defective resorption of the mineral phase of bone. Affected infants manifest failure to thrive, delayed development, nasal obstruction, loss of sight, hearing and other cranial nerve functions, and intense bone overgrowth leading to pancytopenia and increased susceptibility to infection, hepatosplenomegaly as sites of extramedullary hematopoiesis, increased susceptibility to fracture because of decreased bone strength despite high bone mass, mandibular osteomyelitis, and death (often within the first several years of life) due to sepsis, anemia, or hemorrhage.

Physical examination reveals impaired linear growth, enlarged head circumference, nystagmus, and hepatosplenomegaly. The radiographic hallmark of infantile osteopetrosis is relatively uniform increase in bone density of the skull, vertebrae, and axial skeleton, Ehrlenmeyer flask deformity at the distal ends of the long bones in older children, and alternating bands of sclerotic and lucent bone in the iliac wings. This usually lethal form of osteopetrosis may be due to homozygous or compound heterozygous loss-of-function mutations in one of three genes: *TCIRG1, CLCN7,* and *OSTM1. TCIRG1* encodes a subunit of the vacuolar proton pump within the osteoclast ruffled border through which hydrogen ions are transported from the cytosol into the subosteoclast resorption lacuna.

CLCN7 encodes a chloride channel required for movement of this cation into and acidification of the resorption lacuna. *OSTM1* encodes a subunit of CLCN7 necessary to its normal post-translational processing. In selected subjects, bone marrow transplantation effectively supplies sufficient osteoclast precursors to halt the progression of this disorder—albeit often with substantial residual deficits. Transient but substantial hypercalcemia may occur after this procedure. Osteopetrosis (OMIM 259730) due to deficiency of *CA2* encoding carbonic anhydrase II may present in infancy with failure to thrive or fracture with insignificant trauma. Disproportionate short stature is the cardinal manifestation of pycnodysostosis (OMIM 265800) and is manifest during infancy or early childhood.[136]

In subjects with pycnodysostesis, there is relative macrocranium with open fontanelles and cranial sutures, dysmorphic facial features (fronto-occipital prominence, proptosis, bluish sclerae, hypoplastic maxilla, micrognathia, highly arched palate, malocclusion, beaked nose), stubby and clubbed fingers with hypoplastic nails, narrow thorax, pectus excavatum, lumbar lordosis, kyphoscoliosis, and increased fracture risk. Radiographically, there is marked osteosclerosis that increases with age, open fontanelles and cranial sutures, thin clavicles with hypoplastic lateral ends, erosion and hypoplasia of the distal phalanges and ribs, and dense vertebrae yet normal transverse processes. Histologically, there are decreased numbers of osteoblastic and osteoclastic activity.

Pycnodysostosis is due to homozygous or compound heterozygous loss-of-function mutations (stop, missense, nonsense) in *CTSK,* the gene encoding cathepsin K—a lysosomal cysteine protease expressed in osteoclasts. Loss of cathepsin K activity impairs degradation of collagen and the resorption of organic matrix but not that of the mineral component of bone.[137] Isolated decreased stimulated secretion of GH has been recorded in some subjects. Administration of GH has improved the rate of linear growth of some patients with pycnodysostosis, but no effective treatment of the abnormal bone mineralization has been reported.[138]

Disorders of Magnesium Metabolism

In serum, magnesium is present complexed to proteins and ionized or free. Approximately 50% of body magnesium stores are deposited within bone adsorbed to the surface of hydroxyapatite. The CaSR binds magnesium as well as calcium. Magnesium regulates the secretion but not the synthesis of PTH and the generation of calcitriol.[20] In addition, experimental magnesium deficiency leads to decreased bone mineralization in mice, and magnesium oxide supplements increase BMC in healthy girls.[139,140]

HYPOMAGNESEMIA

Hypomagnesemia (serum total magnesium concentration <1.5 mg/dL) leads to hypocalcemia by inhibiting the release of PTH and by interfering with its peripheral action and may mimic congenital hypoparathyroidism, which is itself often associated with hypomagnesemia. In neonates and infants, hypomagnesemia may be clinically silent or present with neuromuscular irritability or seizures often in association with hypocalcemia. Hypomagnesemia occurs in infants born to mothers deficient in magnesium, those with preeclampsia or gestational or type 1 diabetes mellitus, and in neonates with low birth weight (prematurity or intrauterine growth retardation).[141]

Prolonged nasogastric suctioning, malabsorption disorders due to extensive intestinal resection (short gut syndrome), intestinal fistulas, or other diseases associated with chronic diarrhea and steatorrhea also lead to infantile hypomagnesemia. In renal tubular disorders such as Gitelman (OMIM 263800) and Bartter (OMIM 242200) syndromes, as well as in subjects exposed to diuretics and nephrotoxic (cisplatin, cyclosporin, mercury, gentamycin) agents, hypermagnesuria leads to hypomagnesemia.[97,142]

In children and adolescents, hypomagnesemia is manifested by heightened neuromuscular irritability (carpal pedal spasm, tetany, seizures)—and when prolonged and profound by muscle wasting, weakness, apathy, and tachycardia with prolonged PR and QT intervals by electrocardiography. In these age groups, hypomagnesemia may be primary and due to a specific defect in the intestinal absorption of magnesium or in the renal tubular resorption of filtered magnesium. It may also be secondary and due to gastrointestinal losses (chronic vomiting or diarrhea or malabsorptive states due to inflammatory bowel disease, bowel resection or fistulas, or pancreatitis); to associated renal tubulopathies (Gitelman and Bartter syndromes); to exposure to alcohol, diuretics, and chemotherapeutic agents; or to specific endocrinopathies (diabetes mellitus, primary hyperparathyroidism, hyperaldosteronism).[143]

Familial hypomagnesemia with hypocalcemia (OMIM 602014) is an autosomal-recessive disorder pathophysiologically due to a selective small intestinal defect in magnesium absorption. The disease presents with hypocalcemic tetany and/or seizures in the neonatal period and can lead to myocardial, renal, and arterial calcinosis. Renal excretion of magnesium is normal in subjects with this disease. Hypocalcemia is attributable to decreased secretion of and peripheral sensitivity to PTH. This disorder is due to biallelic loss-of-function mutations in *TRPM6* (transient receptor potential cation channel, subfamily M, member 6), encoding a 2,022-aa bifunctional protein with two domains: a calcium- and magnesium-permeable ion channel domain and a protein tyrosine kinase domain expressed in the kidney and colon.[144]

For full functional activity, TRMP6 must team with its homolog TRPM7 (OMIM 605692) and form a functional TRPM6/TRPM7 complex at the surface of the cell.[145] Although most mutations of *TRPM6* associated with this disease (nonsense, deletion) have resulted in extensive loss of product, the naturally occurring missense mutation Ser141Leu specifically disrupts formation of the complex. Oral ingestion of large quantities of magnesium is effective therapy for this illness. Primary hypomagnesemia (OMIM 248250) is an autosomal-recessive disorder due to decreased renal tubular resorption of filtered magnesium linked to biallelic loss-of-function mutations in *CLDN16*.[146]

This disease often presents in infancy and is associated with tetany, hypermagnesuria, hypercalciuria, mild hypocalcemia, nephrocalcinosis, impaired renal function, and secondary hyperparathyroidism. Claudin 16 (also termed paracellin 1) is a 305-aa protein with four transmembrane domains and intracellular amino and carboxyl terminals that is expressed within the intercellular tight junctions of renal epithelial cells in the TALH and distal convoluted tubule, where it facilitates paracellular transport and reabsorption of magnesium and calcium from the renal tubule. The first extracellular loop of claudin 16 bridges the intercellular space and is the site of paracellular conductance of ions. A number of missense mutations in *CLDN16* have been identified in this gene, particularly at leucine 151 (Leu151Phe, Leu151Trp, Leu151Pro).[147]

Most of the mutations in *CLDN16* impair its normal movement to the renal epithelial cell's lateral surface. In other mutations (Ala62Val, His71Asp), products localize to the tight junctions but are functionally defective.[148] Oral administration of 20 times the normal daily requirement of magnesium has been successful therapy in these subjects.[149] Hypomagnesemia, hypercalciuria, and visual impairment (macular colobomata, myopia, nystagmus; OMIM 248190) have been associated with loss-of-function mutations in CLDN19—a second renal epithelial tight junction protein localized to the distal renal tubule and eye and necessary for paracellular transport of calcium and magnesium.[150] Calcium and magnesium are also reabsorbed from the renal tubule by transcellular passage from apical to basolateral surfaces of the renal epithelial cell.

The presence of hypomagnesemia is identified by measurement of serum magnesium concentrations, whereas its pathophysiologic etiology is determined by concurrent assay of calcium, phosphate, sodium, potassium, chloride, bicarbonate, creatinine, PTH, and vitamin D levels and assessment of its urinary loss and intestinal absorption.[141] Hypomagnesemic hypocalcemic seizures are only transiently responsive and sometimes resistant to parenteral administration of elemental calcium alone. Intravenous or intramuscular administration of a 50% solution of magnesium sulfate ($MgSO_4.7H_20$ 0.05–0.1 mL/kg, or 2.5–5.0 mg/kg elemental magnesium with cardiac monitoring) is often necessary to control convulsions in the hypomagnesemic neonate.[20,141] Oral magnesium supplements may also be helpful (50% $MgSO_4.7H_20$, 0.2 mL/kg/day). Chronic hypomagnesemic states are treated with oral magnesium supplements as tolerated because large doses may lead to diarrhea.

HYPERMAGNESEMIA

Hypermagnesemia (>2.5 mg/dL) is frequently recorded in the neonatal period because magnesium sulfate has been administered to pregnant women with hypertension, preeclampsia, or toxemia of pregnancy. Most neonates with hypermagnesemia are asymptomatic. However,

when serum magnesium concentrations are exceptionally high hypotonia and depression of the central nervous system may be present—and when extended,metabolic bone disease may develop.[141] Thus, prolonged (9–10 weeks) administration of intravenous magnesium sulfate to women with multiple fetuses who have entered labor prematurely has been associated not only with hypermagnesemia but with marked hypocalcemia in the offspring (and with significant osteopenia).[114]

Hypermagnesemia may also result from its parenteral administration or oral ingestion of magnesium-containing antiacids or enemas. In large amounts, magnesium sulfate suppresses secretion of PTH and decreases renal tubular reabsorption of calcium—factors contributing to hypocalcemia. The hypermagnesemic neonate is most appropriately managed by adequate hydration to permit urinary excretion of the high magnesium load. If the newborn is also hypocalcemic and osteopenic, administration of calcium and calcitriol is indicated. Hypermagnesemia may also develop in patients with renal insufficiency receiving magnesium-containing antiacids. Magnesium concentrations are modestly increased in patients with familial hypocalciuric hypercalcemia.

Disorders of Mineral Homeostasis in the Child and Adolescent

HYPOCALCEMIA

Etiology

Causes of hypocalcemia in the child and adolescent are listed in Table 17-1. Hypocalcemia is defined by the norms of the analytical laboratory and is dependent on the age of the subject (total calcium concentrations: 1–5 years, 9.4–10.8; 6–12 years, 9.4–10.2; >20 years, 8.8–10.2 mg/dL).[22] Total calcium levels are low in the hypoalbuminemic patient. A correction for hypoalbuminemia may be calculated by adding 0.8 mg/dL to the recorded total calcium concentration for every decrease in albumin concentration of 1 g/dL.[151] For this and other reasons, it is appropriate to measure total and Ca^{2+}_e values when evaluating the hypocalcemic child. However, reliance on Ca^{2+}_e determinations alone is discouraged given the technical difficulties with this assay.

Hypocalcemia develops as a consequence of too little inflow of calcium from the gastrointestinal tract, bone, or kidney into the extracellular and vascular spaces or excessive loss of calcium from these spaces into urine, stool, and bone. Thus, hypocalcemia may be due to decreased intake or absorption or excessive loss of calcium, decreased production of bioactive PTH due to congenital abnormalities of PTG development or PTH synthesis or of the CaSR, destruction of PTGs by autoantibodies, metal overload (copper, iron), surgical or radiation insults, granulomatous infiltration, or impaired cellular responsiveness to PTH. Restricted exposure to sunlight or reduced intake, absorption, metabolism, or activity of vitamin D leads to hypocalcemia.

Hypomagnesemia impairs the secretion of (but not the synthesis of PTH), and blunts tissue responsiveness to, PTH. Hypocalcemia occurs in the very ill child or after exposure to a number of drugs and medications. Hypocalcemic tetany may develop after the administration of phosphate-containing enemas by rectum or laxatives by mouth.[152] At times, the hypocalcemic child or adolescent may be asymptomatic and identified by chemical screening for an unrelated problem—or may present with intermittent muscular cramping at rest or during exercise (when the increase in systemic pH due to hyperventilation lowers still further the concentration of Ca^{2+}_e); paresthesias of fingers, toes, or circumoral regions; tetany (carpopedal spasm, laryngospasm, bronchospasm); or seizures (grand mal, focal, petit mal, adynamic, or syncopal). Physical examination often reveals a positive Chvostek and/or Trousseau sign (carpopedal spasm) and hyperreflexia. However, a Chvostek sign is commonly present in normal adolescents also.

Hypoparathyroidism may occur as a solitary disorder, as part of a multidimensional autoimmune polyendocrinopathy, or as one manifestation of a group of complex congenital anomalies (DiGeorge, HRD, Kenny-Caffey, Barakat, Blomstrand, and other syndromes). There are sporadic and familial forms of hypoparathyroidism. When familial, hypoparathyroidism may be transmitted as an autosomal-dominant, autosomal-recessive, or X-linked recessive trait (Tables 17-1 and 17-2). Abnormalities in the development of the PTGs, transcription of PTH, and processing of the translated product have been associated with inherited forms of hypoparathyroidism.

In a family with autosomal-dominant dyshormonogenic hypoparathyroidism, a *TΨC* transition in codon 18 of the 25-aa signal peptide of prepro-PTH that altered cysteine to arginine (Cys18Arg) has been identified.[153] This heterozygous mutation within the hydrophobic region (aa 10 to 21) of the signal sequence (a domain necessary for efficient transport of protein from the ribosome and interaction of prepro-PTH with the signal recognition particle) impairs movement of the precursor peptide into and exit from the rough endoplasmic reticulum, its cleavage by a signal peptidase, and its incorporation into a secretory granule.[154] The autosomal-dominant transmission of hypoparathyroidism in this family suggests that the mutant pre-pro-PTH exerted a dominant-negative effect on the synthesis of normal PTH directed by the wild-type allele.

Autosomal-recessive dyshormonogenic hypoparathyroidism has been associated with a homozygous *GΨC* transversion in nucleotide 1 of intron 2 of PTH within the signal sequence that prevented normal cleavage of prepro-PTH and decreased secretion of PTH.[155] However, inactivating mutations in PTH are uncommon in patients with sporadic idiopathic hypoparathyroidism.[156] Isolated hypoparathyroidism may be found in patients with del22q11.2 but no other signs or symptoms of the DGS or the velocardiofacial syndrome.[157]

Autosomal-dominant hypoparathyroidism (OMIM 146200) due to heterozygous gain-of-function mutations in the extracellular, transmembrane, and intracellular domains of *CASR* (OMIM 600199) that transcribe a CaSR that is not intrinsically constitutively active but is exceptionally sensitive to and easily activated by very low serum Ca^{2+}_e concentrations may be identified in infancy or in

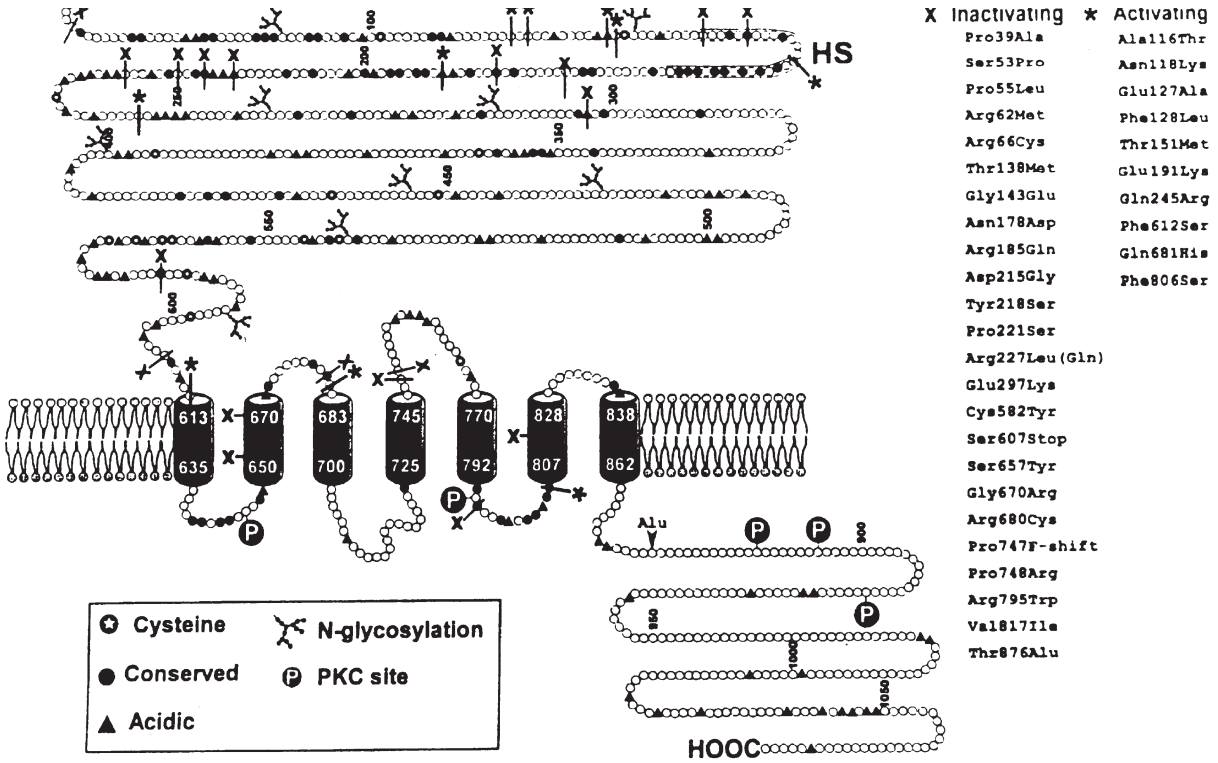

Figure 17-7 Schematic view of the calcium-sensing receptor (CaSR). Gain(*)- and loss(X)-of-function missense and nonsense mutations associated with autosomal-dominant hypoparathyroidism, familial hypocalciuric hypercalcemia, and neonatal severe hyperparathyroidism are depicted. Abbreviations: NCM (normal amino acid-codon-mutation), SP (signal peptide), and HS (hydrophobic segment). [Reproduced with permission from Brown EM, et al. (1997). Familial benign hypocalciuric hypercalcemia and other syndromes of altered responsiveness to extracellular calcium. In Krane SM, Avioli LV (eds.), *Metabolic bone diseases, Third edition.* San Diego: Academic Press 479–499.]

older subjects (Figure 17-7).[84] Even at hypocalcemic levels, Ca^{2+}_e binds avidly to the CaSR and activates phospholipase C-β1—increasing cytosolic levels of inositol phosphate and Ca^{2+}_i and stimulating the mitogen-activated protein kinase (MAPK) signal transduction pathway in parathyroid chief cells (suppressing PTH synthesis and secretion). In the kidney, it decreases renal tubular calcium and magnesium resorption—leading to urinary wasting of these cations (hypercalciuric hypocalcemia). Urinary concentrating ability is also depressed.

Serum levels of phosphate are increased and magnesium values decreased. PTH concentrations are low or inappropriately normal in these subjects. Affected patients frequently have symptomatic hypocalcemia such as tetany and seizures. They are very sensitive to vitamin D, and its administration can lead to hypercalciuria (even when serum calcium levels remain subnormal), nephrocalcinosis, and functional renal insufficiency. Administration of recombinant human (rh)$PTH^{1\text{-}34}$ restores calcium homeostasis in this disorder, although experience with treatment in childhood is limited at present.[47,158] There has been reluctance to administer rhPTH to children because there is an increased incidence of bone tumors in young rats receiving very large amounts of this agent. However, primates appear to be less susceptible to PTH-induced bone tumor formation than rodents.[159]

Development of stimulatory autoantibodies to the CaSR results in an acquired variant of spontaneous hypoparathyroidism that may be isolated or part of a complex autoimmune endocrinopathy.[160,161] Indeed, in perhaps as many as one-third of patients with acquired isolated idiopathic hypoparathyroidism antibodies directed against epitopes in the extracellular domain of the CaSR may be present. This form of acquired hypoparathyroidism may be reversible, as these antibodies do not destroy the PTGs. In patients with other forms of autoimmune hypoparathyroidism, the antibodies are likely cytotoxic and accompanied by lymphocytic infiltration, atrophy, and fatty replacement of parathyroid tissue.

In mid-childhood and adolescence, acquired hypoparathyroidism may be a late manifestation of a congenital abnormality (e.g., DGS). However, it is also likely to be the result of destruction of the PTGs by autoimmune disease or surgical removal or operative trauma to the vascular supply of these structures. Unusual causes of acquired hypoparathyroidism in this age group include infiltration by iron (hemochromatosis, thalassemia) or copper (Wilson's hepatolenticular degeneration), granulomatous diseases, or radiation (mantle radiation for Hodgkin/non-Hodgkin lymphoma or radioiodine therapy of hyperthyroidism).[162,163]

Autoimmune hypoparathyroidism may occur as an isolated disorder or as part of the complex of autoimmune polyendocrinopathy syndrome type I.[163,164] Development of an autoimmune endocrinopathy begins with presentation of a peptide specific for a target organ to a subgroup of T cells that recognize that peptide. When immunologic tolerance for that peptide is lost, clones of

CD4 T cells for the peptide expand. Type 1 helper T cells secrete inflammatory cytokines such as interferon-γ, whereas type 2 helper T cells stimulate B-cell function and lead to autoantibody-mediated inflammation. Loss of immune tolerance may be the consequence of the postinfectious inflammatory state due to activation of the innate immune system or due to a gene mutation that depresses immune tolerance and permits expansion of a CD4 T-cell clone after exposure to quantitatively small amounts of antigen.

Genetic variations within the major histocompatibility complex (HLA-DQ, HLA-DR) that determines peptide (antigen) presentation to CD4 T cells join with genetic abnormalities in immune regulation to induce autoimmune disease. As noted, in 30% of patients with isolated idiopathic hypoparathyroidism the disorder is due to antibodies to the extracellular domain of the CaSR and thus functionally inhibitory but potentially reversible. In approximately 33% of patients, serum antibodies to other components of the parathyroid chief cell may be present.[160,161]

Autoimmune polyendocrinopathy syndrome type I (OMIM 240300) is an autosomal-recessive disorder with the classic triad of autoimmune polyendocrinopathy, mucocutaneous candidiasis, and ectodermal dystrophy (APECED).[165] In a Finnish cohort of 91 patients with APECED, the cardinal manifestations were mucocutaneous candidiasis involving the nails and mouth occurring in 100% of patients (often in the first two years of life), hypoparathyroidism, and hypoadrenocorticism (both of the latter illnesses developed in 80% to 90% of affected subjects).[166] Hypoparathyroidism occurred most often between 2 and 10 years of age, and hypoadrenocorticism developed between 5 and 15 years of age.

Almost all females with APECED developed hypoparathyroidism, whereas 80% of affected males did so. Hypomagnesemia, often severe and recalcitrant to therapy, was common in patients with hypoparathyroidism due to APECED. The most frequent presenting manifestations of APECED were mucocutaneous candidasis (60%), hypoparathyroidism (32%), and hypoadrenocorticism (5%). The disease first became apparent between 2 months and 18 years of age. However, 10% of patients presented with another manifestation of APECED. In addition to hypoparathyroidism and hypoadrenocorticism, other endocrinopathies encountered in APECED included autoimmune oophoritis leading to ovarian failure (70%), orchitis resulting in testicular failure (30%), diabetes mellitus (30%), thyroiditis (30%), and hypophysitis (4%). Besides mucocutaneous candidiasis, dermatologic manifestations and complications of APECED in the Finnish cohort included alopecia (40%), vitiligo (30%), and rashes with fever (15%).

Keratoconjunctivitis developed in 20% of affected subjects, pernicious anemia in 30%, hepatitis in 20%, and chronic diarrhea in 20%. In a Norwegian population of 36 patients with APECED, 13 had clinical evidence of disease at or before 5 years of age—and an additional 15 subjects presented at or before 15 years of age.[167] Clinical manifestations of APECED and their age of onset vary between subjects and even between siblings. Later manifestations of APECED include esophageal and oral squamous cell carcinoma, asplenia, and interstitial nephritis. The diagnosis of APECED usually requires the presence of two of three of its primary manifestations (mucocutaneous candidiasis, hypoparathyroidism, hypoadrenocorticism), but occasionally hypoparathyroidism may be its only sign.

Autoimmune polyendocrinopathy syndrome type I is due to homozygous or compound heterozygous loss-of-function mutations in *AIRE* (autoimmune regulator), a 14-exon gene with 1,635 base pairs encoding a 545-aa with two zinc-finger motifs that is expressed in nuclei of thymic medullary epithelial cells and in lymph nodes, spleen, monocytes, and other tissues where it functions as a transcription factor.[168] AIRE also serves as an E3 ubiquitin ligase, an essential component of the ubiquitin-proteasomal system for protein modification and destruction involved in cellular division and differentiation, protein transport, and intracellular signaling.[169]

Structurally, AIRE contains two plant homeodomains in an amino acid sequence composed of an octet of cysteines and histidines that coordinate two zinc ions. The first plant homeodomain is essential to the E3 ubiquitin ligase activity of the protein, and the second plant homeodomain is required for its transcription-regulating action. Functionally, AIRE may assist in the elimination of forbidden clones of T cells from the thymus—or it might promote expression of peripheral antigens in the thymus, thereby increasing immune tolerance.[164] In the Finnish population with APECED, the most common loss-of-function mutation in *AIRE* was a homozygous truncating mutation at codon 257 (Arg257Ter). More than 55 pathogenic mutations in *AIRE* [missense, nonsense (Arg139Ter), insertion, and deletion (e.g., 13 base pair deletion; 964del13, NT 1094, exon 8)] that alter the subcellular distribution of AIRE and/or decrease its transcriptional activation capacity and/or its E3 ubiquitin ligase activity have been detected in patients with APECED.[168,169]

Pseudohypoparathyroidism (PHP) is a heterogeneous group of disorders associated with resistance to the action of PTH—classified as types IA, IB, IC, and II and pseudopseudohypoparathyroidism (PPHP). PHP is due to inactivating mutations in *GNAS* (guanine nucleotide-binding protein, α-stimulating activity polypeptide 1). PHP type IA (OMIM 103580) is the result of heterozygous inactivating mutations in *GNAS,* a gene with a complex structure of 13 exons that encodes the α subunit of stimulatory G protein ($G_s\alpha$).[170,171] After binding of PTH to the PTHR1, the receptor is linked through its carboxyl terminal to a stimulatory signal transduction protein whose $G_s\alpha$ subunit then binds guanosine triphosphate (GTP). GTP-binding proteins (G proteins) are heterotrimers with α, β, and γ subunits. Individual genes encode each of 16 α, 5 β, and 11 γ peptides—leading to multiple potential combinations and functions primarily defined by the Gα subunit.[172]

After binding of PTH (or PTHrP) to PTHR1, there is a change in the three-dimensional configuration of PTHR1 leading to replacement of guanosine diphosphate (GDP) on $G_s\alpha$ by GTP. $G_s\alpha$ then dissociates from its βγ companion subunit complex and stimulates membrane-bound adenylyl cyclase activity, generating in turn cyclic adenosine monophosphate (AMP) and activating protein kinase A and phosphorylating serine and tyrosine residues of specific proteins. Interaction of PTH with its receptor

also leads to activation of $G_q\alpha$ and $G_{11}\alpha$, with stimulation of phospholipase C and breakdown of membrane phosphoinositides resulting in increase in intracellular $Ca^{2+}{}_i$ levels and stimulation of signal transduction pathways that lead to cellular action and the physiologic response(s) to PTH. $G_s\alpha$ has two distinct domains. One of these is a GTPase domain that degrades GTP to inactive GDP, thus terminating $G_s\alpha$ activity. Within this domain are binding sites for GTP/GDP, the GPCR, and the intracellular second messenger effector protein.

The second domain is a helical domain that may be necessary for maintenance of guanine nucleotide binding.[173] Upstream (5') of exon 2 of *GNAS* are four alternative first exons that can link to exons 2 through 13 of *GNAS*. The most upstream of these promoters is termed *NESP55*, which generates a transcript for a chromogranin-like protein with a coding region limited to the specific first exon. Exons 2 through 13 form its 3' untranslated region (Figure 17-8). NESP55 is expressed in neuroendocrine tissues and is parentally imprinted. Thus, it is only expressed by the maternally transmitted allele. (There is also a NESP antisense transcript in this region.)

The next promoter (XLαs) yields a $G_s\alpha$ isoform also specific for neuroendocrine tissues and identical to $G_s\alpha$ except that it has a very long amino terminal sequence of amino acids. XLαs is also imprinted. It is expressed only by the paternally acquired allele. Exon 1A contains a differentially methylated region (DMR) that is methylated on the maternal allele and unmethylated on the paternal allele and is expressed only by the paternal allele. Exon 1A generates an untranslated mRNA transcript. Exon 1 (and thus $G_s\alpha$) is generally expressed in most tissues by both parental alleles.

However, in the renal proximal tubules, thyroid, pituitary, and ovaries $G_s\alpha$ is expressed primarily by the maternal allele.[171] Tissue-specific parental imprinting of $G_s\alpha$ is not related to differential methylation within its CpG island but rather with differences in the extent of methylation of histone H3 lysine 4 in the region of exon 1 of *GNAS*. Thus, *GNAS* has several independent imprinting sites and mechanisms. Bioactive isoforms of $G_s\alpha$ are also formed by inclusion (long transcript variant of $G_s\alpha$ = $G_s\alpha$-L) or exclusion (short transcript variant of $G_s\alpha$ = $G_s\alpha$-S) of exon 3 in the mRNA transcript.[174]

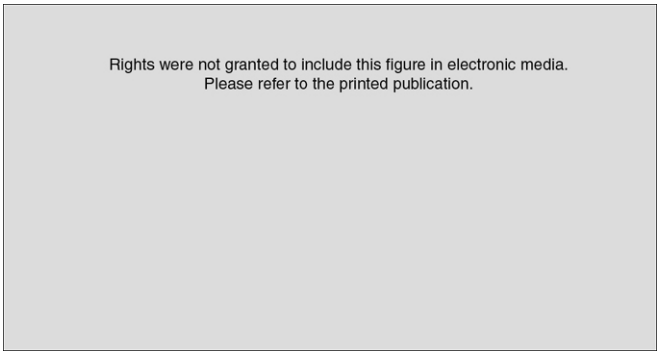

Figure 17-8 Schematic view of the first two of the 13-exon *GNAS* gene complex. Three alternate exons (NESP55, XLas, and 1A) are upstream of exon 1. The pattern of methylation, and hence the expression of the alternate exons, is dependent on the parent of origin of the allele and the specific tissue in which GNAS is expressed. [Reproduced with permission from Weinstein LS, Liu J, Sakamoto A, et al. (2004). GNAS: Normal and abnormal functions. Endocrinology 145:5459–5464.]

Patients with PHP type IA have the distinct phenotype of Albright hereditary osteodystrophy (AHO), including short stature, husky to obese body habitus, shortening of the third through fifth metacarpal bones and distal phalanx of the first finger (brachydactyly), syndactyly between the second and third toes, round face, flat nasal bridge, short neck, subcutaneous calcifications (heterotopic ossification), and cataracts—and in some subjects developmental delay in association with hypocalcemia, hyperphosphatemia, hyperphosphaturia, and elevated serum concentrations of PTH. Administration of exogenous PTH ($rhPTH^{1\text{-}34}$) does not increase serum concentrations of calcium or urinary excretion of nephrogenous cyclic AMP or phosphate.

The phenotype of AHO but with normal serum calcium, phosphate, and PTH concentrations and response to exogenous $PTH^{1\text{-}34}$ is termed PPHP. Normocalcemic PHP (eucalcemia with elevated serum concentration of PTH) has also been described.[174] Clinically, subnormal thyroid function with hyperthyrotropinemia is a common presenting manifestation of PHP type IA—particularly in infants less than 2 years of age.[175] Subcutaneous calcifications also appear early in life. Hypocalcemia is commonly identified in infancy but may not be recognized until mid-childhood or early adolescence.

Heterozygous loss-of-function mutations in *GNAS* (nonsense, missense, splice site, and base pair deletions) have been identified throughout the genomic structure of *GNAS* in subjects with PHP-IA and PPHP. These mutations lead to abnormal transcription and translation of *GNAS* and decreased expression of the mutated allele, resulting in approximately 50% of normal $G_s\alpha$ activity in most cells. Because $G_s\alpha$ is essential for normal chondrocyte differentiation by mediating the effects of PTH and PTHrP on this process, the skeletal manifestations of AHO reflect partial loss of $G_s\alpha$ activity in chondrocytes.[176]

If the mutated *GNAS* allele is of maternal origin, the kidney, thyroid, pituitary, and ovary have extremely low levels of $G_s\alpha$ activity and function in these tissues is almost nil—resulting in renal tubular resistance to PTH, thyroid insensitivity to thyroid-stimulating hormone, somatotroph resistance to GH-releasing hormone, and ovarian resistance to gonadotropins.[173,177,178] Thus, PHP type IA occurs in the offspring when mutated *GNAS* is transmitted from mother to child. In PPHP, the clinical phenotype is that of AHO but the patient is eucalcemic. Because the mutated *GNAS* has been transmitted from father to child and the proximal renal tubule, thyroid gland, pituitary somatotroph, and ovary express the intact maternal *GNAS* allele, near-normal $G_s\alpha$ activity is retained in these tissues. However, chondrocyte differentiation is impaired because in this tissue *GNAS* is expressed from both the maternal and paternal alleles and levels of $G_s\alpha$ activity are only one-half normal.

Mutations in $G_s\alpha$ can also result in progressive osseous heteroplasia (POH, OMIM 166350)—severe ectopic

ossification of skin, skeletal muscle, and deep connective tissue—because $G_s\alpha$ and cyclic AMP play important inhibitory roles in the differentiation of osteoblasts.[171,173] The same mutation in *GNAS* can manifest itself clinically in the same family as POH or AHO. Localized dermal calcifications are frequently encountered in subjects with AHO/PHP type IA. Olfactory sense may also be decreased in patients with PHP type IA and IB. More than 80 heterozygous loss-of-function mutations in *GNAS* have been described to date. A four base pair deletion in exon 7 (codons 188 and 189) in *GNAS* that leads to a frame-shift and premature stop codon has been found in a number of families with PHP type IA and appears to be an amutational hotspot because it impairs DNA polymerization and replication.

Other mutations alter intracellular movement of GNAS protein (Leu99Pro, Ser250Arg), increase the rate of release of GDP (Arg258Trp, Ala366Ser), or impair coupling of G protein to PTHR1 (Arg385His). In the only mutation identified in exon 3 to date, insertion of adenosine in codon 85 led to a frame-shift and a stop sequence at codon 87 in exon 4—resulting in isolated deficiency of only the long transcript variant of $G_s\alpha$.[174] $G_s\alpha$ activity was 75% of normal in the tissues of this patient, who had the AHO phenotype, developmental delay, and hyperthyrotropinemia. Serum calcium levels were normal, but PTH values increased (normocalcemic PHP).

In patients with PHP type IB (OMIM 603233), the phenotype is normal but $G_s\alpha$ activity is deficient in the proximal renal tubule and thyroid. Thus, these patients are resistant to PTH (and in part to thyrotropin) and develop hypocalcemia and hyperphosphatemia.[171,173] This disorder is the result of an epigenetic defect: loss of the maternal pattern of *GNAS* expression due to an imprinting error and failure of methylation of the DMR of maternal exon 1A. Thus, in PHP type IB both *GNAS* alleles have a paternal imprinting pattern (nonmethylation of exon 1A on both alleles; i.e., a paternal epigenotype). Thus, there is a quantitatively normal amount of $G_s\alpha$ in most tissues (including the osteoblast and chondrocyte accounting for the normal skeletal phenotype).

When occurring sporadically, the primary abnormality in PHP type IB may lie within the DMRs of antisense NESP and/or exon 1A. When transmitted as a familial autosomal-dominant characteristic, PHP type IB develops only in the offspring of female obligate carriers and might at times be the result of partial deletion of *STX16* (Syntaxin 16)—a gene centromeric to NESP55 and exon 1A of *GNAS* that contains a cis-acting element(s) that regulates imprinting (methylation) of the DMR in maternal exon 1A of *GNAS*.[173,179] Loss of this element within the maternal *STX16* perhaps results in failure of methylation of the DMR in exon 1A of maternal *GNAS* and consequently a paternal pattern of *GNAS* expression with decreased synthesis of $G_s\alpha$ in the proximal renal tubule.

As anticipated, uniparental paternal disomy for chromosome 20 or familial mutations within *GNAS* itself may also result in the PHP type IB phenotype.[180] Epigenetic defects in methylation of structurally intact *GNAS* have also been described in patients with PHP type IA, variable $G_s\alpha$ activity in peripheral tissues, and mild skeletal abnormalities (designated PHP type IC).[171,181] In PHP type II, the phenotype is normal, serum calcium concentrations are low, phosphate and PTH levels elevated, and in response to exogenous PTH urinary cyclic AMP excretion increases but phosphate excretion does not.

The pathogenesis of this disorder is unknown but may be related to unsuspected deficiency of vitamin D.[171] In several unrelated boys with PHP type IA/AHO, Ala366Ser and Arg231His mutations in *GNAS* have been associated with gonadotropin-independent isosexual precocity. Their mutated $G_s\alpha$ products were quickly degraded at body temperature, leading to PHP type IA, but quite stable at scrotal temperature—resulting in increased Leydig cell function.[182,183]

Hypocalcemia occurs in patients with deficiency of vitamin D intake, metabolism, or bioactivity.[75] In the subject with skeletal demineralization due to marked vitamin D deficiency, serum calcium concentrations may fall precipitously after administration of even small amounts of vitamin D as renewed mineralization of bone matrix due to accelerated osteoblastic activity consumes calcium and phosphate (the "hungry bone" syndrome). After parathyroidectomy for primary hyperparathyroidism, calcium concentrations often decline rapidly by the same mechanism. Drugs that inhibit PTH secretion (excessive magnesium), osteoclast resorption of bone (bisphosphonates), or renal resorption of calcium (furosemide) may lead to hypocalcemia.

Intravenous infusion or rectal administration of phosphate (in enemas), acute cellular destruction by tumor cell lysis or rhabdomyolysis, and acute and chronic renal failure increase serum phosphate levels and lead to reciprocal decline in calcium values. Serum calcium concentrations decline in patients receiving multiple transfusions of citrated blood or during plasmapheresis. In subjects with acute pancreatitis, calcium complexed with free fatty acids generated by pancreatic lipase is deposited in necrotic tissue.[184] Acute severe illness of diverse pathogenesis is often associated with hypocalcemia. This has been attributed to hypoalbuminemia, functional hypoparathyroidism, hypercalcitonemia, hypomagnesemia, decreased calcitriol synthesis, alkalosis and increased serum concentrations of free fatty acids (the latter increase binding of Ca^{2+}_e to albumin), and increased cytokine activity.

Evaluation

Figure 17-5 outlines the evaluation of the child/adolescent with hypocalcemia. Hypocalcemia may be asymptomatic until detected by a multiassay chemical profile obtained for another purpose. It may be first identified during evaluation of a long QT interval noted by electrocardiography obtained for evaluation of a functional heart murmur or arrhythmia.[185] Clinical symptoms that suggest hypocalcemia include paresthesias, muscular cramping (particularly during vigorous exercise), tetany (uncontrollable muscular contractions, including laryngospasm), carpal-pedal spasm (flexion of the elbow and wrist, adduction of the thumb, flexion of the metacarpal/metatarsal-phalangeal joints, and extension of the interphalangeal joints), or seizure.[151]

Review of the past medical history may reveal symptoms consistent with or illnesses associated with

hypocalcemia (recurrent infections, congenital cardiac anomalies, surgical procedures in the neck, cervical radiation, infiltrative diseases), or the family history may reveal members with hypoparathyroidism, dysmorphic physical characteristics, autoimmune endocrinopathies, or hypomagnesemia. Physical examination will disclose characteristic abnormalities in children with PHP type IA in whom the AHO phenotype is present (short stature, round face, subcutaneous hard nodules, brachymetacarpals), the DGS (typical face, recurrent infections, cardiac murmur), and familial autoimmune polyendocrinopathy syndrome type I (chronic mucocutaneous candidiasis and other ectodermal abnormalities such as vitiligo, alopecia, keratoconjunctivitis)—whereas rachitic deformities in the hypocalcemic child imply the presence of a form of hypovitaminosis D.

Most commonly, however, the physical examination reveals no striking abnormality in the hypocalcemic child other than those of increased neuromuscular irritability: hyperreflexia [e.g., positive Chvostek sign (twitching of the circumoral muscles when tapping lightly over the seventh cranial nerve)], Trousseau sign (carpal pedal spasm when maintaining the blood pressure cuff 20 mm Hg above the systolic blood pressure for three minutes), and occasionally cataracts, papilledema, or abnormal dentition. (Tetany also occurs in subjects with hypo- and hypernatremia, hypo- and hyperkalemia, and hypomagnesemia. A positive Chvostek sign may be found in many normal adolescents.)

After confirmation of the hypocalcemic state (by measuring serum total calcium and Ca^{2+}_e levels, the latter to exclude hypoalbuminemia as a cause of a low total calcium value), urine calcium excretion is determined. In most hypocalcemic patients, urine calcium excretion is low (Figure 17-5). If the urine calcium excretion is inappropriately normal or high, disorders such as autosomal-dominant hypoparathyroidism (gain-of-function mutation in *CASR*) may be considered. *CASR* may then be analyzed or antibodies to CaSR determined as clinically indicated. The frequency with which antibodies to the CaSR are detected in patients with autoimmune hypoparathyroidism depends on the method employed for their identification.

Thus, antibodies to CaSR have been found in 86% of subjects with APECED employing an immunoprecipitation assay with the full-length CaSR expressed in human embryonic kidney cells and in 50% of the same subjects utilizing a flow cytometry assay but in none of these patients applying a radiobinding assay.[186] The serum levels of intact PTH, magnesium, phosphate, creatinine, and alkaline phosphatase are to be measured. Determination of the serum concentration of intact PTH (by ultrasensitive assay) permits differentiation between low (or inappropriately anormal) and high PTH secretory states.

The child/adolescent with hypocalcemia, hypocalciuria, hyperphosphatemia, and low or undetectable serum PTH concentration (and normal or only slightly low serum magnesium level) likely has hypoparathyroidism due to a primary defect in PTH synthesis or secretion related to congenital malformation or acquired destruction of the PTGs. Patients with hypoparathyroidism often have low serum concentrations of calcitriol, normal levels of calcidiol, decreased excretion of urinary nephrogenous cyclic AMP, and increased renal tubular reabsorption of phosphate.[163] The DGS may be identified by abnormal FISH analysis of chromosome 22q11.2 or by *TBX1* genotyping. Analysis of *GCM2* or *SOX3* and genes associated with syndromic hypoparathyroidism *(TCBE, GATA3)* is indicated in the appropriate clinical context (Table 17-1).

The diagnosis of autoimmune polyendocrinopathy syndrome type I is based on clinical and laboratory findings and genotyping of *AIRE*. The presence of two of three of its major manifestations (candidasis and/or ectodermal dystrophy, hypoparathyroidism, hypoadrenocorticism) is accepted for its clinical diagnosis, but isolated hypoparathyroidism may occasionally be its only manifestation. Antibodies to the CaSR or other cellular components of the PTGs, the adrenal glands (side-chain cleavage, 21-hydroxylase, 17α-hydroxylase enzymes), neurotransmitters (aromatic L-amino acid decarboxylase, tryptophan hydroxylase), and interferons-α and -ω may be determined. Antibodies to interferon-ω are commonly present in patients with APECED.[167]

Genotyping of *AIRE* and identification of the mutations confirm the diagnosis of APECED. There is wide variability in the clinical expression of APECED between families and among siblings because the phenotype is not directly related to the genotype.[187] In patients with isolated idiopathic hypoparathyroidism, a search for antibodies to the CaSR and/or to parathyroid tissue is warranted. In hypomagnesemic subjects, magnesium and PTH levels are quite low—and PTH secretion increases rapidly after intravenous administration of magnesium. Primary hypomagnesemia should be considered when hypocalcemia and hypercalciuria coincide and serum PTH and magnesium values are low. Urinary magnesium excretion should then be quantitated and *CLDN16* genotyped. Because hypomagnesemia may also be due to a selective small intestinal defect in magnesium absorption, mutations in *TRPM6* should be examined as warranted. Primary hypomagnesemia must be differentiated from that due to the Gittleman and Bartter syndromes.

An elevated serum concentration of PTH in a hypocalcemic subject suggests that the patient is secreting an abnormal PTH molecule, is resistant to PTH, or is experiencing a compensatory (secondary) PTH secretory response to hypocalcemia (Figure 17-5). Physicochemical characterization of the PTH molecule and analysis of *PTH* enable one to define the abnormality in PTH synthesis, post-translational processing, secretion, or activity leading to the functionally hypoparathyroid state. Analysis of *GNAS* and its pattern of imprinting permit identification of the specific genetic defect in the majority of patients with clinical PHP type IA and PPHP.

Skeletal and renal responsiveness to PTH may be assessed if warranted by measurement of changes in serum calcium, phosphate, cyclic AMP, and calcitriol concentrations and measurement of urinary nephrogenous cyclic AMP and phosphate excretion following administration of biosynthetic $PTH^{1\text{-}34}$ (Elsworth-Howard test). In the normal subject and in the patient with primary hypoparathyroidism, urinary cyclic AMP excretion increases tenfold to twentyfold and that of phosphate several fold. In the patient with PHP types IA and IB, there is less than a threefold increase in the excretion of cyclic AMP.

The diagnosis of PHP type IB may be established by examining the imprinting pattern of GNAS (paternal pattern only) and analysis of STX16 as indicated. In the child with vitamin D deficiency, serum levels of calcidiol are subnormal. In patients with decreased renal $25OHD_3$-1α-hydroxylase activity, serum concentrations of calcidiol are normal and those of calcitriol are inappropriately low. Increased concentrations of calcitriol suggest the presence of a defect in its nuclear receptor. The patient with renal failure is recognized by an increased serum creatinine value. Other findings in hypocalcemic subjects include prolongation of the QT interval by electrocardiography and calcification of the basal ganglia by cranial computerized tomography.

Management

The primary goal in the care of the hypocalcemic child and adolescent is to increase serum calcium concentrations to levels at which the patient is asymptomatic and as close to the lower range of normal as possible. The secondary goal is to identify the cause of hypocalcemia as quickly as possible in order to provide disease-specific management.[75,163] Asymptomatic hypocalcemia (total calcium >7.5 mg/dL) may not require immediate intervention. With lower serum calcium levels or when hypocalcemia is symptomatic (tetany, seizures), acute management may require the intravenous administration of calcium gluconate (93 mg of elemental calcium/10 mL vial) at a slow rate (not greater than 2 mL/kg over 10 minutes) while closely monitoring pulse rate (and the QT interval).

Acutely, intravenous administration of calcium is intended to ameliorate the more serious consequences of hypocalcemia such as seizures—not to restore and maintain the eucalcemic state. Intravenously, calcium should not be administered with phosphate or bicarbonate because these salts may co-precipitate. Extravascular extravasation of calcium is to be avoided because it may precipitate and cause local tissue injury. After the acute symptoms have resolved, calcium gluconate (10 mL in 100 mL 5% dextrose/0.25 N saline) may be temporarily infused intravenously at a rate sufficient to maintain calcium levels in the asymptomatic low-normal range while the cause of the hypocalcemia is identified and more specific therapy for persistent hypocalcemia prescribed. The evaluation should proceed as rapidly as possible, and oral therapy begun reasonably quickly. In the child with marked hyperphosphatemia as a cause of hypocalcemia, in addition to parenteral calcium administration infusion of normal saline sufficient to maintain urine output at or above 2 mL/kg per hour is necessary.[152] Frequent measurement of serum calcium and phosphate concentrations permits rapid adjustment of fluid and electrolyte therapy.

After stabilization, patients with hypoparathyroidism or PHP may be treated with calcitriol (20–60 ng/kg/day) and supplemental calcium (calcium glubionate or calcium citrate 30–75 mg elemental calcium/kg/day in divided doses, Table 17-3) to restore eucalcemia. The serum calcium concentration should be maintained within the low-normal range. Each patient must be carefully monitored to avoid hypercalcemia, hypercalciuria, nephrocalcinosis, and nephrolithiasis. Basal and periodic measurements of serum concentrations of calcium, phosphate, and creatinine and urinary calcium and creatinine excretion and renal sonography are mandatory. Children with autosomal-dominant hypoparathyroidism due to gain-of-function mutations in *CASR* are extremely sensitive to vitamin D and its metabolites.

Even small doses of calcitriol may lead to hypercalciuria, with minimal increase in serum calcium levels. In this instance, addition of hydrochlorothiazide (0.5–2.0 mg/kg/day) may increase renal tubular reabsorption of calcium and lower the calcitriol requirement. In adults with primary hypoparathyroidism due to a variety of causes, the use of $rhPTH^{1\text{-}34}$ (0.5 μg/kg every 12 hours subcutaneously) together with calcium carbonate (1,000 mg/day of elemental calcium in four equally divided doses) has proven effective and safe for as long as 3 years—perhaps even safer than calcitriol because $rhPTH^{1\text{-}34}$ did not lead to hypercalciuria.[158] $rhPTH^{1\text{-}34}$ led to acceleration of bone turnover, as reflected by increases in serum alkaline phosphatase and osteocalcin and urinary Pyr and Dpd values without substantial changes in bone mass.

Because PHP type IA is associated with resistance to a number of peptide hormones that act through GPCRs, periodic assessment of pituitary-thyroid and pituitary-ovarian function and GH secretion is necessary—and hormone replacement therapy begun as indicated. In general, the short stature of PHP type IA reflects the AHO phenotype and not GH deficiency. Transient hypoparathyroidism of infancy may be the initial manifestation of later-onset hypoparathyroidism. Thus, it is important to assess calcium homeostasis in such subjects throughout childhood. Patients with apparently isolated hypoparathyroidism of unknown etiology should be reevaluated periodically to identify the development of autoimmune disorders in the patient or family. Assessment of thymic function is important in those subjects with findings suggestive of the DGS.

When hypomagnesemia is symptomatic, administration of magnesium sulfate parenterally may be necessary (50% solution, 0.1–0.2 mL/kg intramuscularly, repeated after 12–24 hours if needed). The patient with primary hypomagnesemia may require daily parenteral (intramuscular, intravenous) doses of magnesium sulfate in order to prevent tetany, seizures, and other neurological symptoms (slurred speech, choreo-athetoid movements, weakness) and to enable normal growth and development.[188] Calcitriol alone raises serum calcium levels in hypomagnesemic subjects but is ineffective in the prevention of tetany. Continuous overnight nasogastric infusion of magnesium may help alleviate the gastrointestinal side effects of multiple large doses of oral magnesium. More mild and transient forms of hypomagnesemia may be treated with oral magnesium gluconate or tribasic magnesium citrate (Table 17-3).

HYPERCALCEMIA

Etiology

Causes of hypercalcemia in children and adolescents are listed in Table 17-4. In the presence of a normal serum protein concentration, hypercalcemia occurs when the

rate of entry of calcium into the extracellular and circulatory compartments exceeds its rate of loss and develops when the set-point for serum Ca^{2+}_e is increased due to a loss-of-function mutation in *CASR,* when the resorption rate of bone mineral (e.g., excessive secretion of PTH or PTHrP, constitutive activation of PTHR1, increased production of osteoclast-activating inflammatory cytokines, localized osteolytic processes such as metatastic neoplasms) or the absorption rate of intestinal calcium (hypervitaminosis D) exceeds the renal excretory capacity for calcium, or when there is augmented renal tubular absorption of calcium (e.g., administration of calcium-sparing diuretics such as thiazides).[151]

The total serum calcium concentration is increased in the presence of hyperalbuminemia, whereas the Ca^{2+}_e concentration is normal. Venous stasis (e.g., by tourniquet) results in spuriously altered local pH and Ca^{2+}_e values. Familial hypocalciuric hypercalcemia type 1 (HHC1, OMIM 145980) is an autosomal-dominant disorder with 100% penetrance at all ages characterized by PTH-dependent usually asymptomatic, total and ionized hypercalcemia with hypocalciuria, slight hypermagnesemia, hypomagnesuria, and hypophosphatemia due to heterozygous loss-of-function mutations in *CASR*.[189] Serum concentrations of PTH may be normal or slightly elevated, but inappropriately high for the Ca^{2+}_e level. Calcidiol and calcitriol values are normal.

In children, HHC1 is most commonly suspected initially by the presence of unexpected hypercalcemia (11–14 mg/dL) in a chemistry profile or through family screening of a parent or other relative with hypercalcemia. Older subjects with HHC1 may complain of fatigue, weakness, or polyuria. There is a slightly increased incidence of relapsing pancreatitis, cholelithiasis, chondrocalcinosis, and premature vascular calcification in HHC1. However, bone mass and fracture rate are normal. Because of decreased parathyroid chief cell membrane CaSR number and/or function, the set-point for Ca^{2+}_e suppression of PTH secretion is reset upward.[84,189] The PTGs are slightly hyperplastic.

In renal tubular cells, decreased CaSR number and activity lead to increased renal tubular reabsorption of calcium and relative hypocalciuria (ratio of calcium clearance to creatinine clearance <0.01). Renal tubular reabsorption of magnesium is also increased. Urinary concentrating ability and other measures of renal function are normal. In hypercalcemia of other pathogenesis, urinary calcium excretion is increased and renal concentrating ability depressed. Usually, HHC1 requires no therapy—but must be differentiated from mild primary hyperparathyroidism in which hypomagnesemia and hypercalciuria are present. Subtotal parathyroidectomy in HHC1 does not lower calcium levels as the residual PTGs hypertrophy. Total parathyroidectomy is unnecessary except in infants with NSHPT.

Approximately 70 nonsense, missense, insertion, and deletion mutations in *CASR* associated with HHC1 or NSHPT have been identified—mostly in the receptor's extracellular Ca^{2+} binding domain. These mutations decrease receptor affinity for Ca^{2+} or alter intracellular processing of the CaSR (glycosylation, dimerization; e.g., Arg66His, Asn583Stop) in the endoplasmic reticulum, preventing its translocation to the surface of the cell membrane[190] (Figure 17-7). Many of the mutations are located in the extracellular domain of CaSR between codons 39 and 300, a region rich in aspartate and glutamate residues in which Ca^{2+} may nestle.[71]

Glycosylation is necessary for dimerization and trafficking of the CaSR. Missense mutations involving arginine at codon 66 (Arg66His, Arg66Cys) result in a product that is able to be only partly glycosylated. It can form homodimers in the endoplasmic reticulum but cannot enter the golgi apparatus and be transported to the cell plasma membrane.[190] Mutations in *CASR* tend to be unique to the affected family. In approximately one-third of families with HHC, no mutations in the coding region of *CASR* have been identified. They may have a mutation in a noncoding region of *CASR* or an abnormality in genes associated with the HHC phenotype that have been identified on chromosomes 19p13.3 (HHC2, OMIM 145981) and 19q13 (HHC3, OMIM 600740).[189] Autoantibodies against the amino-terminal extracellular domain of the CaSR that reversibly inhibit receptor activity have been identified in a few patients with acquired HHC. This disorder may be responsive to glucocorticoid therapy.[191] In some patients with primary or uremic secondary hyperparathyroidism, there is reduced expression of *CASR* and an increased set-point for suppression of PTH secretion.[192]

Primary hyperparathyroidism is an unusual childhood disorder with an incidence of 2–5/100,000 compared to that in adults of approximately 100/100,000.[193,194] In adults with hyperparathyroidism, females outnumber males 3:1. In children, the female/male ratio is closer to one. In older children and adolescents, primary hyperparathyroidism is most often a sporadic disease and usually the result of a single parathyroid adenoma. It also occurs as an autosomal-dominant disorder in familial isolated primary hyperparathyroidism (OMIM 145000) due to germline mutations in the genes responsible for multiple endocrine neoplasia (MEN) type I *(MEN1),* the hypoparathyroidism-jaw tumor syndrome *(HPRT2),* or HCC1.[75,79,193,195]

Many children (80% to 90%) with hyperparathyroidism and hypercalcemia are symptomatic at the time of diagnosis [headache, fatigue, abdominal pain, nausea and vomiting, polydipsia, and behavioral changes (particularly depression)] or present with symptoms reflecting the consequences of this disorder, including flank pain due to renal calculi (hypercalciuria) and pathologic fractures (through areas of osteopenia or lesions of osteitis fibrosa cystica).[194] It is unusual to palpate a cervical mass in these patients.

Hypercalcemia, hypophosphatemia, and elevated serum concentrations of intact PTH are present in the majority of children with hyperparathyroidism. Ultrasonography, magnetic resonance imaging, computed tomography, and radionuclide scans (^{99m}Tc-SestaMIBI) have been employed to localize the abnormal PTG(s). Occasionally, the parathyroid tumor may be located ectopically in the thymus, thyroid gland, or mediastinum.

In subjects with primary hyperparathyroidism, hypercalcemia is the result of increased secretion of PTH due to loss of the normal relationship between the set-point of serum Ca^{2+}_e and PTH synthesis and release and to Ca^{2+}-independent (constitutive) PTH secretion related to

the mass of parathyroid tissue.[193] Pathologically, hyperparathyroidism in children is most often due to a chief cell adenoma involving one PTG. Hyperplasia (particularly in MEN) and rarely carcinoma of the chief cells may occur. The majority of PTG neoplasms are monoclonal in origin. That is, a single mutant cell develops into a tumor.

In adolescents, parathyroid tumors may rarely develop after external radiation of the neck for treatment of lymphoma. In some parathyroid tumors, increased expression of cyclin D1 (encoded by *CCND1,* OMIM 168461, chromosome 11q13) has been demonstrated. Cyclins are intracellular proteins that regulate cyclin-dependent protein kinases that control the rate of transition of G1 to S in the cycle of cell division.[71] Overexpression of *CCND1* in parathyroid chief cells is at times the result of a somatic chromosome mutation-inversion (rotation) of regions 11p15 and 11q13 in which the promoter region of PTH is repositioned to serve as a promoter for CCND1, thereby increasing the rate of chief cell division whenever the (hypocalcemic) stimulus for PTH generation is received and leading ultimately to (benign) tumor formation.

However, in many parathyroid adenomas there is increased activity of cyclin D1 without this chromosomal rearrangement.[193] In patients with parathyroid adenomas and carcinomas, overexpression of the retinoblastoma and p53 tumor-suppressor genes (whose products inhibit the cell cycle at the G1/S step) has been demonstrated.[71] Chronic renal insufficiency leads to secondary hyperparathyroidism due to hyperplasia of the PTGs and to monoclonal parathyroid tumors (tertiary hyperparathyroidism) associated with somatic chromosomal deletions. In approximately 17% of sporadic parathyroid adenomas, a somatic loss-of-function mutation of the tumor suppressor factor menin (the germ-line aberration in patients with MEN type I) can be identified.[196] Germ-line loss-of-function mutations in *MEN1* and *CASR* have also been detected in patients with isolated hyperparathyroidism in association with multiglandular involvement. In this instance, patients with *CASR* mutations did not have the typical biochemical findings of HHC1.[195,197]

Autosomal-dominant familial primary hyperparathyroidism associated with multiple ossifying fibromas of the jaw (HRPT2, OMIM 145001) is due to loss-of-function heterozygous germ-line mutations in the tumor suppressor gene encoding parafibromin *(HRPT2).*[198] Hyperparathyroidism occurs in 80% of subjects with a mutation in *HRPT2* at a mean age of 32 years, but may also appear in children before 10 years of age.[199]

In these patients, the parathyroid lesion may be an atypical potentially premalignant cystic adenoma (65%), hyperplasia (20%), or even carcinoma (15%). The parathyroid tumor may be isolated or associated with maxillary and/or mandibular tumors composed of ossified fibrous tissue. Renal (Wilms' tumor, papillary renal cell carcinoma, hamartoma, polycystic kidney), pancreatic (carcinoma), and uterine (tumor) lesions may also develop in these patients.[71,195] Lesions within the PTGs may develop asynchronously. *HRPT2* is a 17-exon gene that encodes parafibromin, a 531-aa protein that is a component of a complex of accessory factors that modulate RNA polymerase II activity, gene transcription, and cell proliferation.

For a parathyroid tumor to develop, a second hit must occur that results in loss-of-heterozygosity (i.e., the germ-line inactivating mutation of *HRPT2* on one allele must be matched by a mutation in or deletion of *HRPT2* in the remaining normal allele).[200] When a germ-line mutation in *HRPT2* has been detected, screening of family members for this mutation and longitudinal evaluation of affected subjects is recommended because asymptomatic individuals with atypical adenoma or carcinoma of the PTGs may be so identified.[201] Somatic mutations in HPRT2 have also been identified in atypical parathyroid adenomas and carcinomas, but are distinctly unusual in the typical sporadic parathyroid adenoma.[202] Familial isolated hyperparathyroidism type 3 (HRPT3, OMIM 610071) has been linked to chromosome 2p14-p13.3, but a specific mutated gene in this region has not as yet been identified.

The syndromes of multiple endocrine neoplasia (MEN) are familial autosomal-dominant diseases of high penetrance associated with the development of tumors in two of three primary endocrine tissues (PTG, pituitary, pancreas) within the same person and multiple tumors in the same tissue (Table 17-5).[195,203-206] Within a single family, there is a high degree of uniformity in the clinical expression of MEN1. Hyperparathyroidism (due to a parathyroid adenoma or tumors within or hyperplasia of all four parathyroid glands) is the most common manifestation of MEN1, occurring in more than 90% of affected patients. It is the most frequent endocrinopathy in children with MEN1, at times appearing before 10 years of age. There are equal numbers of males and females with hyperparathyroidism in MEN1.

Pituitary tumors secreting prolactin and/or GH often (30% of MEN1 subjects) develop, as do gastrin- (Zollinger-Ellison syndrome), insulin-, and glucagon-secreting tumors of the pancreatic islets (40% of patients). These neoplasms also occur in children and adolescents with MEN1.[71,204] The Cushing syndrome that develops in patients with MEN1 may be due to excessive secretion of adrenocorticotropin by a pituitary adenoma or ectopically by a neoplasm or to a primary adrenal tumor. Benign and malignant thyroid tumors occur in 25% of patients with MEN1. Nonendocrine tumors such as facial angiofibroma (90%), collagenomas (72%), lipomas (34%), intestinal and bronchial carcinoids, and other intestinal neoplasms are reasonably common in subjects with MEN1.

Indeed, the dermatologic manifestations of MEN1 (more than three angiofibromas and any collagenomas) are extremely sensitive and specific indicators of this disease.[207] Patients with MEN1 may also develop a Schwannoma or a pheochromocytoma, the latter a tumor most often present in patients with MEN types IIA and IIB. Although most of the tumors that develop in MEN1 are benign but functionally hyperactive, those of pancreatic, intestinal, and foregut origin may be malignant. Germ-line mutations in *MEN1,* a 10-exon gene that encodes a 610-aa nuclear protein termed menin, have been demonstrated in the majority of patients with familial and sporadic forms of MEN1.[204] Menin localizes to the nucleus through two nuclear localization signals in its carboxyl terminus (aa 479-498, 589-608), where it is involved directly in the regulation of transcription, replication, and the cell cycle.

TABLE 17-5

Multiple Endocrine Neoplasia Syndromes

Subtype	Gene	Chromosome	Tumors	Sites of Frequent Mutations
MEN I	*MEN1*	11q13	Parathyroid (90%) Pancreatic (50%) - gastrinoma, insulinoma pancreatic polypeptide, glucagonoma, VIPoma somatostatinoma, nonfunctional Anterior pituitary (35%) - prolactinoma, GH, ACTH, TSH, nonfunctional Adrenocortical (25%) - diffuse and nodular hyperplasia, adenoma, carcinoma Intestinal - foregut carcinoid tumor, gastric enterochromaffin-like Carcinoid - gastric, thymic, bronchial Other: facial angiofibroma, collagenoma, lipoma, pheochromocytoma (rare)	Intron 4 N:5168 G→A (10%) Codons 83-84 (4%) Codons 118-119 (3%) Codons 209-211 (9%) Codon 418 (4%) Codon 516 (7%)
MEN II	*RET*	10q11		
Familial MCT			MCT (100%)	Codon 618 (>50%)
MEN IIA			MCT (95%) Pheochromocytoma (50%) Parathyroid hyperplasia (30%) Cutaneous lichen amyloidosis Megacolon	Codon 634 (Cys→Arg >80%)
MEN IIB			MCT (100%) Pheochromocytoma (50%), ganglioneuroma Associated: Marfanoid habitus (100%) Mucosal neuromas (90%) Medullated corneal nerves	Codon 918 (Met→Thr >95%)

MCT - Medullary carcinoma of thyroid

Compiled from Marx SJ, et al. (1999). Multiple endocrine neoplasia type 1: Clinical and genetic features of the hereditary endocrine neoplasias. Rec Prog Horm Res 54:397–438; from Marx SJ, Simonds WF (2005). Hereditary hormone excess: Genes, molecular pathways, and syndromes. Endocrine Reviews 26:615–661; from Root AW (2000). Genetic disorders of calcium and phosphorus metabolism. Crit Rev Clin Lab Sci 37:217–260; and from Thakker RV (1998). Editorial: Multiple endocrine neoplasia, syndromes of the twentieth century. J Clin Endocrinol Metab 83:2617–2620.

Menin is a tumor suppressor factor. By binding directly to JunD, menin blocks JunD-mediated inhibition of transcription of activating protein-1 (and consequently cell division). Many of the mutations in *MEN1* in patients with MEN1 cluster in exon 4 and interrupt the binding of these two proteins (between menin aa 139-142 and 323-428). However, loss of inhibition of JunD is but one of several mechanisms that lead to unrestricted cell growth in targeted MEN1 tissues.[208] By interacting with SMAD3 (OMIM 603109, chromosome 15q21-q22), menin inhibits signaling by transforming growth factor (TGF) β and impairs TGFβ-mediated inhibitory control of cell replication.[209] Interaction of menin with the SMAD 1/5 complex inhibits signaling by bone morphogenetic protein (BMP) 2. Menin also inhibits the transcription-regulating protein nuclear factor κB (NFκB).[71,210]

In subjects with heterozygous germ-line loss-of-function mutations in *MEN1,* unregulated cell growth and tumor formation occur when a second insult leads to loss of *MEN1* on the normal allele within susceptible tissues. As with *HPRT2,* the two-hit hypothesis of tumorigenesis in MEN1 denotes that the patient receives germ-line susceptibility to neoplasia superimposed on which is a second insult leading to loss of heterozygosity for chromosome segment 11q13 and biallelic loss of *MEN1*. The second hit may be deletion of a segment of chromosome 11 that includes 11q13 or a mutation (missense, frame-shift) within the wt *MEN1* allele itself, an observation that also extends to MEN type I tumors with somatic mutations in *MEN1*.[195,204,211]

Several hundred germ-line mutations in MEN1 have been identified in patients with MEN1, of which 25% have been nonsense mutations, 15% missense mutations, and 45% frame-shift insertions or deletions. More than 80% have led to the synthesis of an inactive product due to loss of the nuclear localization signal or the ability to bind to JunD or other downstream factor (Figure 17-9).[204,212] Especially susceptible germ-line mutational hot spots in *MEN1* are nucleotide 5168 G→A transition that results in a novel splice site in intron 4 (codons 83, 84, 118, 119, 209–211, 418, and 516), where collectively mutations have been identified in 37% of patients with MEN1.[213]

On either side of many of these sites are segments of repeat DNA sequences of single nucleic acids or of

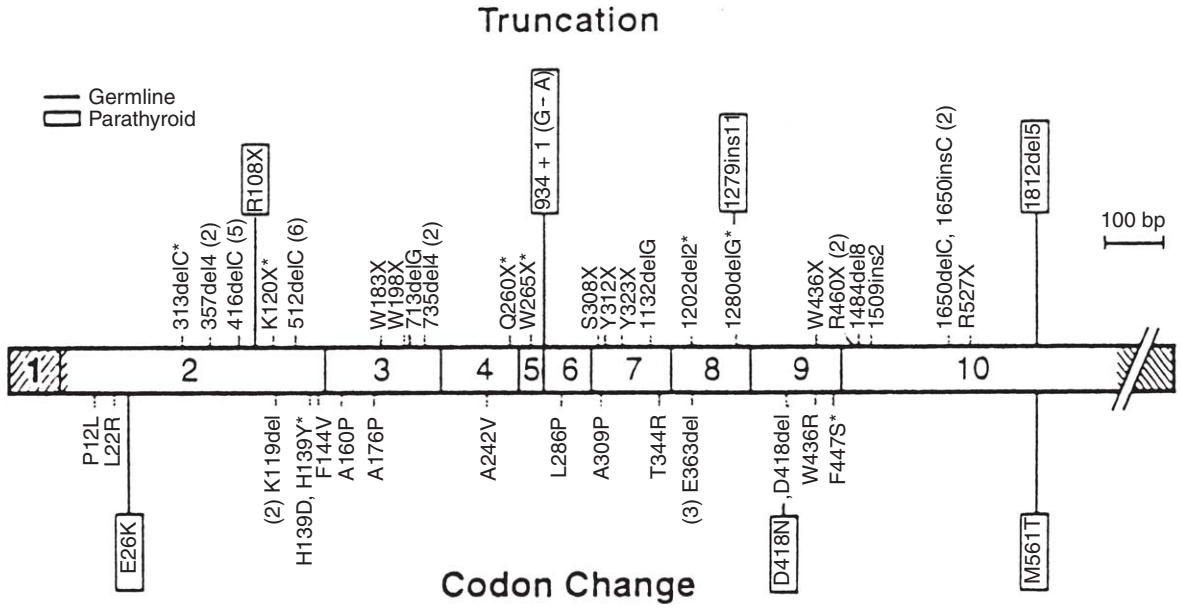

Figure 17-9 Mutations in MEN1 associated with multiple endocrine neoplasia type 1. Long tethered boxes represent mutations in isolated parathyroid tumors. Nonsense, frame-shift, and splice site mutations are depicted above, and missense and in-frame deletions below the outline of the codons of *MEN1*. [Reproduced with permission from Marx SJ, et al. (1998). Germline and somatic mutation of the gene for multiple endocrine neoplasia type 1 (MEN1). J Intern Med 243:447–453.]

dinucleotides to octanucleotides. This configuration may lead to increased susceptibility to replication-slippage because of misalignment of the nucleotide repeat segments during DNA replication, permitting deletion or insertion of nucleotides at inappropriate sites. To date, no significant correlation between genotype and phenotype has been recognized in MEN1. The tissue-specific susceptibility to tumor formation with a mutation in *MEN1* remains unexplained at present.[195]

Mutations in *MEN1* have been detected in approximately 75% to 95% of patients with familial MEN1. In only 7% of patients with a variant of MEN1 in which only tumors of the PTG and the adenohypophysis are present has a mutation in MEN1 been identified.[214] Familial autosomal-dominant isolated primary hyperparathyroidism has been variably associated with germline mutations (e.g., Val184Glu, Glu255Lys, Gln260Pro) in *MEN1* as well.[215] Somatic mutations in *MEN1* have also been identified in patients with sporadic isolated tumors of the PTGs, pancreatic islet cells, anterior pituitary, and adrenal cortex.[71]

Clinically apparent disease due to mutations in *MEN1* increases with advancing age. At 10 years of age, 7% of children with a mutation in *MEN1* have a detectable endocrinopathy. Fifty-two percent of affected 20-year-old subjects manifest one or more tumors. Penetrance increases to 87% by 30 years, to 98% by 40 years, and to 100% by 60 years.[216] New mutations of *MEN1* occur sporadically in 10% of patients with MEN1. In 5% to 20% of families with MEN1, no mutation in the coding region of *MEN1* has been identified—suggesting that there may be mutations in the untranslated regions of *MEN1* or that another unrecognized gene(s) may be involved in the pathogenesis of the MEN1 phenotype.

Medullary carcinoma of the thyroid (MCT) is the most common neoplasm encountered in MEN IIA, occurring in 95% of patients (OMIM 171400, Table 17-4). These subjects also develop pheochromocytomas, parathyroid hyperplasia or adenoma, localized cutaneous lichen amyloidosis (suprascapular pruritic deposits of subepidermal keratin), and partial or complete megacolon. In addition to MCT and pheochromocytoma, patients with MEN IIB (OMIM 162300) have a Marfanoid habitus, mucosal neuromas of the lips and tongue, and gastrointestinal ganglioneuromas.[195,206,217] Familial isolated MCT is a variant of these disorders. Germline gain-of-function mutations in the *RET* proto-oncogene underlie the pathogenesis of the type II hereditary endocrine neoplasias (Figure 17-10). *RET* is a 20-exon gene encoding three isoforms of a glycosylated cell membrane tyrosine kinase receptor with extracellular, transmembrane, and intracellular domains that is expressed in tissue of neural crest origin (sympathetic ganglia, adrenal medulla, thyroid parafollicular cells).

The natural ligand of this receptor is glial-cell-line-derived neurotrophic factor (GDNF, OMIM 600837, chromosome 5p13.1-p12).[218] Constitutively activating mutations among five cysteine residues in the extracellular domain of RET, particularly at codon 634 (Cys→Arg), are present in patients with MEN IIA. Loss of but one cysteine residue facilitates receptor homodimerization without ligand binding, activation of the RET intracellular tyrosine kinase domain, autophosphorylation of critical tyrosine residues (particularly at codons 1015 and 1062), and subsequent signal transduction.[195]

An activating mutation has been identified at codon 918 (Met→Thr) in more than 95% of patients with MEN IIB. This site lies within the tyrosine kinase domain and this mutation permits signal transduction and neural cell transformation and differentiation in the absence of ligand binding and receptor homodimerization. Missense mutations at codons 618 (Cys→Arg/Gly) or 620 (Cys→Arg/Ser) permitting receptor dimerization in the absence

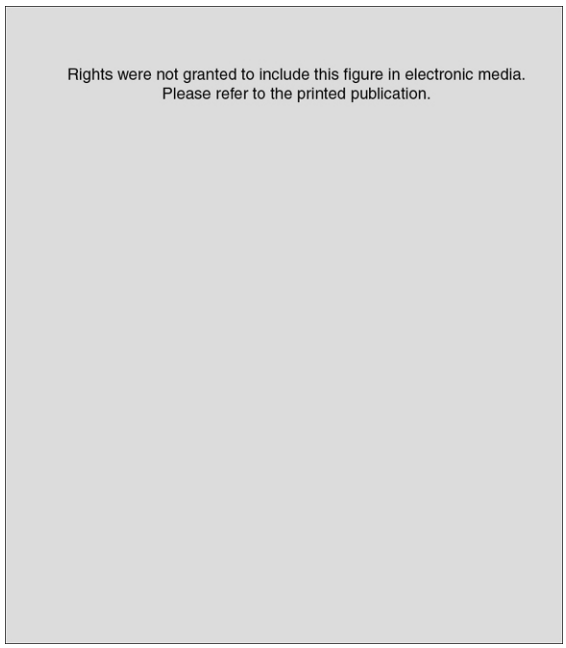

Figure 17-10 Schematic depiction of the domains of the *RET* proto-oncogene with sites of activating mutations in *RET* associated with multiple endocrine neoplasia types IIA and IIB and familial medullary carcinoma of the thyroid. [Reproduced with permission from Marx SJ, Simonds WF (2005). Hereditary hormone excess: Genes, molecular pathways, and syndromes. Endocrine Reviews 26:615–661.]

of GDNF have been found in more than 50% of patients with familial MCT. Mutations within the tyrosine kinase domain (Val804Leu) have also been identified in some of these families.

Two co-receptors, GFRA1 and GFRA2, interact with *Ret* protein—but the role of the co-receptors in the pathogenesis of MEN II, if any, has not been identified. In addition to the disorders designated multiple endocrine neoplasia, other familial syndromes associated with multiple tumors of the endocrine system include Von-Hipple Lindau (adrenal medulla, pancreas, neuroendocrine), Carney complex (adrenal cortex, testes, pituitary, thyroid), McCune-Albright (pituitary, adrenal cortex), and neurofibromatosis type I (adrenal medulla, thyroid).[195,217] In children, hyperparathyroidism is an unusual manifestation of the McCune-Albright syndrome due to a postzygotic activating mutation of *GNAS*.[219]

Ingestion of excessive amounts of vitamin D or calcitriol for therapeutic reasons (treatment of rickets, hypoparathyroidism, or other causes of hypocalcemia), megavitamin intake, and inappropriate fortification of milk are the major causes of hypervitaminosis D.[220-222] Topical application of creams containing vitamin D or an analogue (e.g., 22-oxacalcitriol) for treatment of psoriasis might also lead to hypercalcemia, particularly if the urinary excretion of calcium is compromised.[223,224]

Patients with granulomatous diseases (noninfectious sarcoidosis, berylliosis, eosinophilic granuloma, subcutaneous fat necrosis, and inflammatory bowel disease and infectious tuberculosis, histoplasmosis, coccidioidomycosis, candidiasis, and cat-scratch disease) and neoplastic disorders (B-cell lymphoma, Hodgkin disease, dysgerminoma) develop hypercalcemia due to associated monocytic (macrophage and other cells) expression of $25OHD_3$-1α-hydroxylase activity and production of calcitriol.[225] Unlike renal tubular cells (in which this enzyme is within mitochondria and the transcription of *CYP27B1* is closely regulated by PTH, calcitriol, calcium, and phosphate), in monocytes $25OHD_3$-1α-hydroxylase is microsomal in location and its gene is constitutively expressed and calcitriol synthesis regulated by the amount of substrate.

The monocytic expression of *CYP27B1* is very sensitive to stimulation by interferon-γ and its postreceptor signal transducer nitric oxide, as well as by leukotriene C_4. It is easily suppressed by glucocorticoids, ketoconazole, and chloroquine. Subjects with acquired immunodeficiency disease may become hypercalcemic because of being infected with granuloma-forming organisms or by osteoclast-activating cytokines elaborated during the course of this disorder. Elevated serum calcium concentrations have been recorded in children with congenital hypothyroidism, primary oxalosis, congenital lactase deficiency, and trisomy 21.[226]

Hypercalcemia has occurred in adolescents with juvenile rheumatoid arthritis due to increased synthesis of the osteoclast-activating cytokine interleukin-1β.[227] In some hypercalcemic children, excessive prostaglandin production may be of pathogenetic significance. Hypercalcemia develops frequently in the infantile form of hypophosphatasia, likely a consequence of the dissociation of the rates of low bone formation and normal bone resorption.[228] Hypercalcemia may follow successful bone marrow transplantation in infants with osteopetrosis because functional osteoclasts rapidly reabsorb excess bone mineral.

Oncogenic hypercalcemia may be the consequence of secretion of PTHrP, (rarely) PTH, or calcitriol—or of direct invasion and destruction of bone by the neoplasm.[229] Although hypercalcemia occurs in less than 1% of children with cancer, it may develop in patients with leukemia, Hodgkin and non-Hodgkin lymphoma, rhabdomyosarcoma, hepatoblastoma, neuroblastoma, and Ewing sarcoma.[230] Acute immobilization of the rapidly growing child with a femoral fracture or a spinal cord injury results in decreased bone mineral accretion and uncoupling of the interaction of osteoblasts and osteoclasts with increased rate of bone resorption, leading to hypercalciuria and "acute disuse osteoporosis."[231]

When the rate of bone resorption exceeds the renal tubular capacity for excretion of calcium, hypercalcemia ensues. Acute disuse osteoporosis and hypercalcemia can even occur in the immobilized hypoparathyroid or vitamin-D-depleted individual. Increased intake of calcium and absorbable alkali (milk or calcium-containing antacids such as calcium carbonate) for peptic ulcer disease or as dietary supplements leads to absorptive hypercalcemia, hypercalciuria, and nephrocalcinosis. Parenteral nutrition with excessive calcium or aluminum or too little phosphate also leads to hypercalcemia. Hypophosphatemia of various etiologies leads to hypercalcemia as the body attempts to maintain the calcium X phosphate product over 30.

Drugs causing hypercalcemia include thiazide diuretics (which increase renal tubular resorption of calcium and decrease plasma volume), vitamin D and analogs

(which increase intestinal absorption of calcium), vitamin A and its retinoic acid analogs (which stimulate bone resorption), and lithium (which increases the set-point for PTH secretion, thereby increasing serum calcium concentrations while lowering urinary calcium excretion and thus mimicking HHC1). In the thyrotoxic subject, hypercalcemia is the result of thyroid-hormone-mediated stimulation of osteoclast function and subsequent increase in the rate of bone resorption. Pheochromocytomas and some islet cell tumors may be associated with hypercalcemia, in some instances because of co-secretion of PTHrP. Hypercalcemia in the hypoadrenal patient is of uncertain pathogenesis but is not related to increased serum concentrations of PTH, calcidiol, or calcitriol—or with augmented bone resorption.

During recovery from acute renal failure, serum calcium levels may increase due to mobilization of calcium from ectopic sites in which it had been deposited during the hyperphosphatemic phase of the illness. Hypercalcemia can develop in patients with chronic renal failure due to a combination of factors, including immobilization, aluminum toxicity, excessive ingestion of calcium antacids or vitamin D or its analogs, and hyperparathyroidism. After renal transplantation, hypercalcemia is the result of secondary hyperparathyroidism due to hypertrophy and hyperplasia of parathyroid chief cells that occurred in response to the PTH stimulatory effects of hyperphosphatemia, hypocalcemia, and decreased synthesis of and response to calcitriol during the period of chronic renal insufficiency.

In patients with compromised renal function, mild hypocalcemia and calcitriol deficiency develop when the glomerular filtration rate falls below 80 to 60 mL/min/1.73 m^2—whereas phosphate retention occurs after the glomerular filtration rate has fallen to 60 to 30 mL/min/1.73 m^2.[232] The secretion of PTH rises in these patients in an effort to increase the synthesis of calcitriol, raise calcium levels, and lower phosphate values. Prolonged uncontrolled secondary hyperparathyroidism can lead to relatively autonomous parathyroid hyperfunction ("tertiary hyperparathyroidism") and hypercalcemia, primarily in patients with chronic renal failure.

Hyperplasia of chief cells is followed by defects in function of the CaSR and loss of effective down-regulation of PTH secretion refractory to increased serum concentrations of Ca^{2+}_e. There is an expanded number of monoclonal chief cells in which the expression of *CASR* and the number of vitamin D nuclear receptors have declined. Secondary and tertiary hyperparathyroidism have occurred in patients with prolonged nutritional vitamin D deficiency rickets and in subjects with X-linked hypophosphatemic rickets receiving large amounts of phosphate.[232,233] Enhanced but transient secretion of PTH may accompany the administration of GH to adolescents with chronic renal failure, likely the result of superimposing upon a high basal rate of PTH secretion further increase in the rate of bone remodeling related to GH and sex hormones.[234] In acutely ill adults, GH administration has been associated with hypercalcemia as well.[231]

Isolated hypercalciuria in the eucalcemic child may be idiopathic or due to renal medullary or tubular dysfunction, mutations in the gene encoding the CLCN5 chloride channel, demineralizing disorders such as juvenile rheumatoid arthritis, hyperalimentation, metabolic acidosis, excessive protein ingestion, diabetes mellitus, hypomagnesemia, Bartter syndrome, and other disorders.[235] Secondary hyperparathyroidism (in which by definition serum calcium concentrations are normal) also develops in patients with inadequate dietary calcium, impaired intestinal absorption of calcium (lactose intolerance, ingestion of phytates, malabsorption syndromes due to pancreatic insufficiency or celiac disease), or excessive calcium loss in the urine or soft tissues.[232]

Evaluation

When hypercalcemia is mild (total calcium concentration <12 mg/dL), there may be few (if any) symptoms. Such children/adolescents are often identified by a multichannel screening study obtained for some other purpose. Hypercalcemia may also be detected during studies for renal calculi, abnormal bone mass, pathologic fractures, or during screening of families for associated problems. It should also be recognized that an elevated serum (total or ionized) calcium concentration in a single specimen may reflect assay variability and must be verified by repeated determinations in a reliable laboratory. Pseudohypercalcemia is the presence of persistently elevated total calcium concentrations while the Ca^{2+}_e is normal and is found in hyperalbuminemia and other dysproteinemic states.[226]

Symptoms attributable to hypercalcemia are independent of its cause and are related to the degree of hypercalcemia and include intestinal symptoms [anorexia, nausea, vomiting, abdominal pain (peptic ulceration, acute pancreatitis)] and constipation, urinary symptoms [polydipsia, nocturia, and polyuria (calcium acts as an osmotic diuretic while hypercalcemia impairs the concentrating function of the distal renal tubule)], skeletal symptoms (bone pain), and nervous system symptoms [headache, muscular weakness, impaired ability to concentrate, increased requirement for sleep, altered consciousness (ranging from lethargy and confusion to irritability, delirium stupor, and coma)]. On occasion, depression may be the major presenting concern in an adolescent with hypercalcemia.[151,236,237]

In the toddler and young child, hypercalcemia is manifested by anorexia, constipation, poor weight gain, and impaired linear growth (failure to thrive). In a series of 52 children and adolescents with hypercalcemia due to primary hyperparathyroidism, 80% were symptomatic. The most common symptoms were fatigue/lethargy (35%), headache (35%), nausea (29%), vomiting (23%), and polydipsia (21%).[194] Bone involvement (low bone mass, fractures) was present in 30%, and 14% of these subjects were depressed. All of the children (N = 17) with nephrolithiasis in this series were symptomatic.

Evaluation of the hypercalcemic child begins with the historical review (Figure 17-6), during which the family/patient is queried not only about symptoms related to hypercalcemia and its consequences (renal calculi) but about possibly excessive intake of vitamin D, vitamin A, and related compounds (such as retin A for treatment of

acne); of calcium (perhaps to "prevent" osteoporosis), and of alkali or drugs that affect calcium metabolism (thiazide diuretics may "unmask" hyperparathyroidism by increasing renal tubular resorption of calcium and thereby raising borderline calcium concentrations into the hypercalcemic range). The family history is explored for members with known disorders of calcium metabolism (HHC1, hyperparathyroidism, renal calculi) or familial neoplasms (galactorrhea as a sign of a prolactinoma, and severe peptic ulcer disease as an indicator of a gastrinoma and the Zollinger-Ellison syndrome).

Except in extreme instances [when hypertension (if normally hydrated) or bradycardia, dehydration, decreased muscular strength, or altered consciousness may be present or in the subject with MEN IIB], physical examination of the hypercalcemic child and adolescent is usually normal. Rarely is a paratracheal (parathyroid) mass palpable in the hyperparathyroid patient. Subjects with hypercalcemia due to subcutaneous fat necrosis have firm to hard irregular movable masses scattered about the trunk and extremities. Those with the Williams-Beuren syndrome have a typical face, whereas those with Jansen metaphyseal chondrodysplasia have characteristic skeletal deformities.

After confirming the presence of total and ionized hypercalcemia, the urinary excretion of calcium is next measured (Figure 17-6). If calcium excretion is low, it is most probable that the patient has HHC1. This diagnosis can be substantiated by the finding of asymptomatic hypocalciuric hypercalcemia in one of the parents and further defined by identification of the inactivating mutation in *CASR*. If the patient is hypercalciuric, other causes of hypercalcemia should be sought. With highly sensitive and moderately specific immunoradiometric and immunochemiluminometric assays for intact $PTH^{1\text{-}84}$ (these assays may also measure larger carboxyl-terminal fragments of PTH; e.g., $PTH^{7\text{-}84}$) in comparison to serum calcium values, separation of patients with hyperparathyroidism from those with other causes of hypercalcemia in whom PTH values are low or normal is usually possible.

In the absence of secondary hyperparathyroidism (chronic renal insufficiency, malabsorption syndromes, ingestion of thiazide diuretics or lithium), consistently elevated PTH concentrations in the hypercalcemic, hypophosphatemic, hypercalciuric child or adolescent are consistent with primary hyperparathyroidism. Although the diagnosis of primary hyperparathyroidism is usually quite apparent in children and adolescents, there is an occasional patient in whom serum calcium and/or PTH values may not be elevated in a single specimen and in whom repeated measurements of serum and urine calcium and PTH values are necessary before this diagnosis can be established. In the series of 52 children/adolescents with hyperparathyroidism previously described, serum calcium values were normal in 10% and PTH levels in 15%. However, in all subjects the PTH concentration was inappropriately increased relative to the calcium level.[194]

Phosphate values are usually low for age in this group. Osteitis fibrosa cystica, brown tumors (localized non-neoplastic areas of bone resorption composed of osteoclast-like multinuclear giant cells, fibroblast-like spindle-shaped cells, and hemorrhagic infiltrates), and subperiosteal and endosteal bone resorption can be detected radiographically in some children with hyperparathyroidism. Cortical (distal radial) bone mineral density is likely to be decreased in these subjects. Nonspecific findings in the hypercalcemic subject of diverse etiology include shortening of the QT interval by electrocardiography because the rate of cardiac repolarization is increased by increased calcium levels, bradycardia, and first-degree atrioventricular block—and nephrocalcinosis and renal calculi detected by abdominal ultrasonography. Serum concentrations of PTHrP should be measured when clinical and laboratory findings are consistent with primary hyperparathyroidism, but PTH values are low and humoral hypercalcemia of malignancy is suspected. When PTH concentrations are low in the hypercalcemic patient, metabolites of vitamin D (calcidiol, calcitriol) should be measured and other causes of hypercalcemia sought.

Preoperatively, a parathyroid adenoma may be localized by high-resolution ultrasonography, computed tomography, magnetic resonance imaging, or radionuclide scanning with ^{99m}Tc-sestamibi. The latter radionuclide is taken up by the thyroid and parathyroid glands but quickly washed out from the thyroid gland. Thus, two scans obtained 2 hours apart permit differentiation of parathyroid from thyroid tissue.[193] Alternatively, a simultaneously administered second radionuclide selectively accumulated by the thyroid (^{123}iodine) may be employed to visualize parathyroid tissue.

Scans may be obtained by conventional two-dimensional or computed tomographic techniques, the latter offering a three-dimensional image. Only occasionally is it necessary to undertake selective venous catheterization with sampling of local PTH levels and/or arteriography to identify the site of a parathyroid adenoma. Evaluation for associated endocrine tumors is necessary if the family history suggests the possibility of MEN I or MEN IIA or if there are clinical findings (galactorrhea, excessive growth, hypertension) to suggest the presence of a prolactinoma, somatotropinoma, or pheochromocytoma.

Patients at risk for MEN may be screened by determining basal and stimulated serum concentrations of prolactin, GH, IGF-I, gastrin, glucagon, pancreatic polypeptide, calcitonin, catecholamines, and other substances as warranted. Indeed, it is reasonable to consider screening children with hyperparathyroidism preoperatively for an associated pheochromocytoma or tumors of the maxilla and mandible and for mutations in *RET, MEN1,* and *HPRT2*.[195,204] Prior to surgery, survey of the pattern of bone mineralization for preferential loss of cortical rather than cancellous bone might also be considered.

In the patient with hypercalcemia due to ingestion of excessive amounts of vitamin D, serum concentrations of calcidiol are markedly elevated. In those receiving exogenous calcitriol or in hypercalcemic patients with granulomatous, chronic inflammatory and lymphomatous diseases serum levels of calcitriol are increased. Other disorders associated with hypercalcemia (Table 17-4) should be eliminated by appropriate historical findings and laboratory studies.

Management

Appropriate management of the patient with hypercalcemia depends on the severity and the cause of the high calcium levels. It is important to identify the patient with a pathologic cause of hypercalcemia so that effective medical and surgical therapy may be initiated promptly. It is equally important to recognize the child/adolescent with HHC1 so that aggressive therapy is avoided. When the calcium concentration is <12 mg/dL in the asymptomatic subject, treatment may be delayed until the cause of the hypercalcemia is understood. In the interim, it is reasonable to recommend that the patient increase fluid intake, avoid calcium and vitamin D supplements, and discontinue drugs associated with hypercalcemia if possible.

The child with HHC1 often has serum total calcium concentrations between 11 and 13 mg/dL but no clinical symptoms and requires no therapy under usual circumstances. In the absence of HHC1, if the total serum calcium concentration exceeds 12 mg/dL or if the child is symptomatic efforts to lower this level are necessary because of the adverse effects of hypercalcemia on cardiac, central nervous, renal, and gastrointestinal function. In these children, diagnostic studies as outlined previously and treatment should begin simultaneously.

The first tool of therapy of severe hypercalcemia is hydration [with 0.9% saline (twice maintenance volume over 24-48 hours), which restores intravascular volume, dilutes and decreases serum Ca^{2+}_e levels, increases glomerular filtration of Ca^{2+}, decreases reabsorption of Ca^{2+} in the proximal and distal renal tubules, and promotes calciuresis]. Hydration alone usually lowers the total serum calcium concentration 1 to 3 mg/dL. A second tool is calciuresis. Intravenous infusion of the loop diuretic furosemide (1 mg/kg slowly) initiated only after restoration of extracellular fluid volume with saline further lowers calcium levels by inhibiting resorption of calcium (and sodium) by the TALH. Thiazide diuretics are to be avoided because they increase renal tubular reabsorption of calcium and increase serum calcium concentrations and are clearly contraindicated in the management of hypercalcemia. A third tool is inhibition of bone resorption. If hypercalcemia does not respond to the above measures, specific inhibitors of osteoclast function may need to be employed.

Bisphosphonates (pamidronate, etidronate, zoledronic acid) are the agents of choice in the acute management of hypercalcemia in children and adolescents. Bisphosphonates are phosphatase-resistant analogs of pyrophosphate. In vivo, they inhibit osteoclast function by impeding osteoclast differentiation. By binding to and coating the hydroxyapatite crystal beneath the osteoclast, they interfere with its attachment and functional ability to dissolve bone.[236] Pamidronate (0.5–1.0 mg/kg/dose by intravenous infusion over 4–6 hours) has effectively lowered serum calcium concentrations in hypercalcemic infants and children.[102,103,230]

The hypocalcemic effect of bisphosphonates is variable in duration (days to weeks). Transient systemic side effects (fever, myalgia) may accompany the administration of pamidronate and other bisphosphonates. Salmon calcitonin also acts rapidly, but transiently, to lower serum calcium concentrations by inhibiting osteoclast activity and increasing urinary calcium excretion. It must be administered by multiple daily subcutaneous injections (2–4 U/kg/injection every 6–12 hours). Calcitonin may be paired with a bisphosphonate at the beginning of treatment of hypercalcemia in order to lower serum calcium levels more rapidly.[151]

Glucocorticoids do not lower calcium levels in patients with hyperparathyroidism or solid tumor malignancies but are quite effective in the management of hypercalcemia due to excess vitamin D ingestion or calcitriol production by activated monocytes or hematologic malignancies. Rarely, it may be necessary to dialyze (peritoneal or hemodialysis) with low- or zero-calcium dialysate the severely hypercalcemic patient resistant to conventional therapy. During acute treatment of hypercalcemia, Ca^{2+}_e concentrations may be assessed indirectly by monitoring the (shortened) QT interval by electrocardiography.

Although in older adults (>50 years) with asymptomatic primary hyperparathyroidism (without bone disease or renal stones) no immediate intervention may be advised at times, in younger adults, children, and adolescents with hyperparathyroidism surgical intervention is recommended when the diagnosis is established. Although hyperparathyroidism in youth is most often (>60%) due to an adenoma, hyperplasia of the parathyroid glands is also common (~30%).[194] In the pediatric population, efforts are undertaken to localize a parathyroid adenoma before its removal by a surgeon with experience and expertise in parathyroid surgery.[238]

In adults and older adolescents, minimally invasive procedures for removing a parathyroid adenoma(s) may be employed. ^{99m}Tc-sestamibi is administered 2 hours before surgery in conjunction with single-photon emission computed tomography. If the scan is consistent with an adenoma, skin and subcutaneous tissue are infiltrated with a local anesthetic, a horizontal 2.5-cm incision is made on the side of and slightly above the suspected parathyroid adenoma, and dissection directed by insertion of a handheld gamma probe until the adenoma is located and removed. Video assistance is an alternative method for localization of a parathyroid adenoma.

A complementary technique for assessing the completeness of the removal of the adenoma intraoperatively is to measure peripheral levels of PTH by rapid immunoassay before and 10 minutes after removal of the adenoma. A 50% decline in PTH levels indicates complete excision. If the PTH concentration does not decline following removal of suspected abnormal parathyroid tissue, further exploration is undertaken and additional tissue removed as guided by the serum PTH level. These procedures are reported to be cost effective because they decrease operative time and patient morbidity. Many patients return home within hours after leaving the operating suite. These techniques have been applied to the surgical management of the child and infant with a parathyroid adenoma or hyperplasia of multiple PTGs.

If there is parathyroid hyperplasia, subtotal (3.5 glands) or total parathyroidectomy is performed and autotransplantation of small fragments of one gland to a forearm pocket considered. Following removal of a parathyroid adenoma, many patients develop transient hypocalcemia

that may be managed by the administration of supplemental oral calcium. When there is severe osteitis fibrosa cystica and marked demineralization, substantial hypocalcemia may occur as a result of the "hungry bone" syndrome. Other complications of surgery include (transient) vocal cord dysfunction and the need for further operations because of development of a second adenoma. If permanent hypoparathyroidism develops postoperatively, it is treated by the administration of calcitriol and supplemental calcium as needed.

Calcimimetic agents (phenylalkylamines) bind to and activate the membrane CaSR on the parathyroid chief cell and thereby increase cytosolic levels of Ca^{2+}_i and depress secretion of PTH in adults with mild primary hyperparathyroidism.[193] The use of these agents in children and adolescents with this disorder remains to be assessed, but they offer a potential treatment pathway for subjects with diffuse parathyroid hyperplasia. The secondary hyperparathyroidism of chronic renal disease is best managed by lowering serum phosphate concentrations to the extent possible by limiting intake and by administration of oral phosphate binding agents and by maintaining serum Ca^{2+}_e levels within the low-normal range by the administration of calcitriol or analogue. Calcimimetic agents (e.g., cinacalcet) may also be useful in this situation.[239] Parathyroidectomy may be necessary for effective management of refractory secondary and tertiary hyperparathyroidism as manifested by severe renal osteodystrophy, hypercalcemia, and systemic symptoms such as pruritus and bone pain.[232]

Hypercalcemia due to hypervitaminosis D or excessive production of calcitriol by granulomatous and chronic inflammatory tissues may be treated with glucocorticoids to suppress activity of $25OHD_3$-1α-hydroxylase. Ketoconazole (3–9 mg/kg/day in three divided doses) is an antifungal agent that also inhibits $25OHD_3$-1α-hydroxylase activity, and that promptly lowers calcitriol and calcium values in children and adults with similar disorders.[240] Side effects of therapy with ketoconazole include nausea, vomiting, abdominal pain, depressed secretion of gonadal steroids, and adrenal production of cortisol. Therefore, careful monitoring of patients receiving ketoconazole is essential.

Glucocorticoids ameliorate the hypercalcemia related to excessive interleukin-1β production in adolescents with juvenile rheumatoid arthritis.[227] An attempt should be made to prevent hypercalcemia in the immobilized child or adolescent by ingestion of a low-calcium diet, avoidance of vitamin D, copious fluid intake, and early mobilization. Serum and urine calcium levels should be monitored frequently, and fluids increased still further if hypercalciuria occurs.

Once present, hypercalcemia is best treated by mobilization. Saline diuresis and/or bisphosphonate administration may be necessary until eucalcemia is restored. Restriction of dietary calcium and limitation of exposure to sunlight may be appropriate in the long-term management of some patients with hypercalcemia not amenable to more specific treatment. Antiprostaglandin agents may be useful in the child with hypercalcemia associated with excessive production of these compounds. Specific treatment of diseases accompanied by hypercalcemia (thyrotoxicosis, hypoadrenocorticism) restores the eucalcemic state.

Disorders of Bone Mineralization and Formation

Bone formation may be impaired because of lack of minerals (calcium and/or phosphate) or because of deficient production of bone matrix. Bone mineralization may be excessive because of increase in the rate of mineral deposition or decrease in the rate of resorption of the mineral phase of bone. Ectopic calcification of extraskeletal tissues may occur when local calcium and phosphate levels are high, whereas extraskeletal ossification may ensue when the regulation of bone formation is deranged.

RICKETS

Rickets and osteomalacia are disorders that result from decreased mineralization of bone matrix due to deficiencies of calcium and/or phosphate[241-243] (Table 17-6). During endochondral bone formation in children, matrix is elaborated and subsequently mineralized. When endochondral osteoid is not fully mineralized, the ends of the long bones (particularly those that are weight bearing) deform and rickets ensues. During the processes of modeling and remodeling of trabecular bone and the periosteal and endosteal surfaces of cortical bone, osteoid is formed by osteoblasts. Failure to mineralize bone matrix in these regions results in osteomalacia.

During intervals of calcium and/or phosphate deprivation, the actively growing weight-bearing child with open cartilage growth plates develops rickets and osteomalacia—whereas adults develop only osteomalacia during remodeling as unmineralized bone matrix accumulates. Thus, rickets is the expression of defective endochondral mineralization at the growth plate and osteomalacia is the failure of mineralization of bone cortex and trabeculae. Clinically, rickets is manifested by skeletal deformities such as delayed closure of the fontanelles, craniotabes (reversible compression of the skull's outer table), frontal bossing (expansion of cranial bones), and occasional craniosynostosis in infants; delayed tooth eruption with poor enamel formation and propensity to caries; pectus carinatum, prominence of the costochondral junctions, and flaring of the lower rib cage; scoliosis and kyphosis; and genu varum and/or valgum, flaring of the metaphyses of the long bones, and tibial or femoral torsion.

Radiographically, rickets is characterized by cupping, splaying, and fraying of the metaphyses of long bones and demineralization. Osteomalacia is associated with increased fracture risk as well as limb deformities. Histologically, as a consequence of impaired calcification within the cartilage growth plate the pattern of chondrocyte differentiation and maturation is disrupted and disorganized—whereas osteoid seams widen at other sites of bone formation.[241] In subjects deprived of phosphate, it is the trabeculae that are primarily undermineralized. Impaired mineralization of osteoid may be due to dietary deficiencies or depressed intestinal absorption of calcium, phosphate, or vitamin D; inadequate amounts of these nutrients in fluids utilized in total parenteral nutrition; metabolic errors in the metabolism or action of

TABLE 17-6

Disorders of Bone Mineralization: Rickets

I. Vitamin D Deficiency

A. Decreased Intake, Endogenous Synthesis, Retention, or Sequestration

1. Maternal vitamin D deficiency - breast feeding
2. Reduced skin synthesis - sunlight deprivation, sunscreen use, increased skin pigmentation
3. Malabsorption - celiac disease, hepatobiliary dysfunction, short gut syndrome, cystic fibrosis, inflammatory bowel disease, gastric bypass surgery
4. Drugs - anticonvulsants, glucocorticoids, cholestyramine
5. Nephrotic syndrome
6. Obesity

B. Metabolic Errors

1. Deficiency of 25-hydroxylase
a. Loss-of-function mutation of *CYP2R1*
b. Hepatic dysfunction
2. Deficiency of 25OH-vitamin D_3-1-hydroxylase
a. Loss-of-function mutation of *CYP27B1*
b. Decreased renal mass - hypoplasia, chronic renal insufficiency
3. Loss-of-function mutation of vitamin D receptor (*VDR*)

II. Calcium Deficiency

A. Nutritional Deprivation

B. Hypercalciuria - Hyperprostaglandin E2 Syndromes

III. Phosphate Deficiency

A. Nutritional Deprivation

1. Low-birth-weight infant
2. Aluminum-containing antacids

B. Hyperphosphaturia

1. X-linked-dominant familial hypophosphatemic rickets (*PHEX*)
2. Autosomal-dominant hypophosphatemic rickets (*FGF23*)
3. Autosomal-recessive hypophosphatemic rickets with hypercalciuria (*SLC34A3*)
4. Autosomal-recessive hypophosphatemic rickets (*DMP1*)
5. X-linked-recessive hypophosphatemic rickets (*CLCN5)*
6. Oncogenic hypophosphatemic osteomalacia (*FGF23*, *sFRP4*, *MEPE*, *FGF7*)
7. Renal tubular acidosis
   a. Renal tubular acidosis - Fanconi syndrome
   - Heritable - cystinosis, tyrosinemia, hereditary fructose intolerance, galactosemia, idiopathic (AD, AR, XLR)
   - Acquired - nephrotic syndrome, vitamin D deficiency, renal vein thrombosis, cadmium, lead, bismuth, outdated tetracycline, 6-mercaptopurine, valproic acid, ifosfamide, saccharated ferric oxide

IV. Hypophosphatasia

A. Perinatal, Infantile, Childhood, and Adult Forms (ALPL)

B. Odontohypophosphatasia

C. Pseudohypophosphatasia

V. Inhibitors of Mineralization

A. Aluminum - Parenteral

B. Bisphosphonates

C. Fluoride

vitamin D; defects in renal tubular conservation of phosphate or calcium; or abnormalities of alkaline phosphatase generation and function (Table 17-6).

Broadly, rickets may be considered calciopenic—usually related to nutritional deprivation of vitamin D (or rarely to a defect in its metabolism to the active metabolite calcitriol or in its cellular action), to decreased intake of calcium or its excessive loss in urine, or phosphopenic (related to renal phosphate wasting due to primary renal tubular defects in phosphate reabsorption or to generation of excessive amounts of phosphatonins, compounds that inhibit normal renal handling of phosphate). Thus, nutritional rickets may be due to decreased intake of vitamin D (or inadequate exposure to sunlight) or calcium or to marginal intakes of both nutrients. Dietary deficiency of phosphate is unusual, given its wide availability. However, this nutrient may be deficient in parenteral fluids. Bone mineralization may also be directly impaired by abnormalities of alkaline phosphatase generation or by agents such as aluminum or fluoride.[241]

Calciopenic Rickets

Neonates born to severely vitamin-D-deficient mothers may display signs of rickets at birth, including fractures and hypocalcemia. Clinical manifestations of rickets in preambulatory infants include bowing of the forearms, craniotabes, frontal bossing, and delayed closure of the cranial fontanelles.[243] In older infants and children, genu varum or valgum (bowed legs or knock knees) or a windswept deformity involving both legs, flaring (widening) of the metaphyses of the long bones with markedly enlarged wrists, prominence of the costochondral junctions (rachitic rosary), and indentation of the lower anterior thoracic wall (Harrison's groove) are noted. Tooth eruption may be delayed, and the enamel hypoplastic (predisposing to dental caries). Short stature and suboptimal weight are also frequently present.[244]

Because vitamin D has so many extraskeletal sites of action, there are a number of nonosseous systemic symptoms observed in children with vitamin-D-deficiency rickets. These include muscular weakness (manifested by hypotonia and delay in walking), anorexia, and increased susceptibility to infection—particularly pneumonia (due both to the lack of the stimulatory effect of vitamin D on the immune system and weakness of the thoracic wall).[245] Occasionally, reversible cardiomyopathy may develop.

Hypocalcemia, tetany, and seizures may occur in a severely vitamin-D-deficient infant without gross clinical or radiographic signs of rickets. Rarely, vitamin D deficiency in an adolescent may be associated with hypocalcemic seizures and fractures.[246] Radiographically, osteopenia with cortical thinning and thin stress fracture lines—as well as cupping, widening, and irregularity (fraying) of the distal metaphyses of the long bones—are observed in the rachitic subject.[12,242] Areas of osteitis fibrosa cystica associated with secondary hyperparathyroidism may sometimes develop. Bone pain is the most common symptom of osteomalacia in the adult.

After the introduction of cod liver oil as a dietary supplement in 1918 (and the later fortication of infant formulas and milk and other foods with irradiated ergosterol) and the discovery in 1919 that exposure to sunlight prevented development of rickets, nutritional deficiency of vitamin D became relatively unusual in North America—only to reemerge seven decades later.[247] Presently, deficiency of vitamin D occurs predominantly in darkly

skinned black or brown infants and young children who ingest a diet low in vitamin D (breast milk from a vegetarian or poorly nourished mother or one with little or no dietary milk, meat, eggs, or fish) without supplemental vitamin D and who have limited exposure to sunlight because they are confined indoors due to illness, the climate, or parental choice or because they wear clothing that shields the entire body from sunlight.[244,245]

More than half of 30 infants with nutritional vitamin D deficiency cared for at two North Carolina medical schools between the years 1990 and 1999 were identified in 1998 and 1999, suggesting an increasing incidence of this problem. The median age at diagnosis was 15.5 months. Presenting complaints included failure to thrive, skeletal deformities, and hypocalcemic tetany/seizures.[244] During the same interval, 30 infants with vitamin-D-deficient rickets were identified in Maryland. All were black and had been breast fed for 6 or more months, and 90% had not received vitamin D supplements.[248] Vitamin D deficiency is more common in breast-fed black infants than in white infants due in large part to increased maternal skin pigmentation and decreased endogenous synthesis of cholecalciferol that coupled with socioeconomic circumstances leads to lower levels of 25OHD in maternal serum and of vitamin D in breast milk. These infants are also more likely to be weaned to diets low in calcium and vitamin D.[241]

Subtle forms of vitamin D deficiency or insufficiency are prevalent throughout the North American population, particularly in the winter months when there is little sunlight exposure and the ultraviolet light requisite for endogenous synthesis of vitamin D is limited.[12,43] In a group of 307 healthy urban male and female adolescents 11 to 18 years of age in the northeastern United States, 42% had serum concentrations of 25OHD less than 20 ng/mL.[249] The prevalence of very low 25OHD values (<15 ng/mL) was most common in black (36%) and Hispanic subjects (22%), whereas 6% of white students had such levels. There was an inverse relationship between serum levels of 25OHD and PTH, with secondary hyperparathyroidism present in many subjects and with low 25OHD concentrations implying the likelihood of incipient metabolic bone disease.

In addition to skin pigmentation and northern latitude, low 25OHD values were attributable to meager consumption of milk and multivitamins due to a large intake of phosphate-containing soft drinks and to increase in fat mass into which vitamin D had been deposited and thus not bioavailable. Similar findings have been recorded in otherwise healthy adolescent females in the United Kingdom.[250] Interestingly, women with low milk intake during childhood are at increased risk for low bone mass and increased fracture rate as adults.[251] Inasmuch as there is reasonable evidence that serum values of 25OHD below 30 to 32 ng/mL are suboptimal, the prevalence of vitamin D deficiency or insufficiency may be far greater than is currently acknowledged.[43,252]

Assuming a reliable assay such as those employing liquid chromatography-tandem mass spectrometry that measure both $25OHD_2$ and $25OHD_3$, 25OHD concentrations below 12 to 15 ng/mL in children clearly indicate vitamin D deficiency and values between 15 to 31 ng/mL are consistent with vitamin D insufficiency.[241,253] Serum levels of 25OHD that exceed 60 to 100 ng/mL are indicative of vitamin D excess. Subtle dietary deficiency of calcium may accentuate the adverse effects of borderline vitamin D stores.[254]

Vitamin D deficiency may also be the consequence of intestinal malabsorptive disorders (such as celiac disease, biliary obstruction, gastric resection or bypass, or pancreatic exocrine insufficiency), ingestion of calcium-binding agents such as cholestyramine, or the accelerated degradation by anticonvulsant drugs (such as phenytoin) of vitamin D to water-soluble forms that increase its urinary loss.[43] In the majority of infants and children with rickets due to vitamin D deficiency, serum concentrations of total calcium are borderline-normal or low, phosphate levels low, and alkaline phosphatase activity and PTH concentrations increased (Table 17-7). Secondary hyperparathyroidism develops as the intestinal absorption of calcium is reduced, resulting in lowered serum levels. PTH increases urinary phosphate loss and lowers serum phosphate concentrations while enhancing the rates of bone resorption and turnover.[242]

PTH also increases synthesis of calcitriol, which may increase the rate of calcidiol metabolism and further deplete the body's store of vitamin D.[241] Typically, in vitamin D deficiency serum concentrations of calcidiol are low—whereas calcitriol values may be normal, high, or low (depending on whether vitamin D deficiency is modest, moderate, or severe). Serum concentrations of osteocalcin are low. Serum levels of PICP (a marker of bone formation) and ICTP and urinary excretion of NTx (markers of bone resorption) are substantially increased in infants with vitamin D deficiency rickets, indicating increased collagen turnover in this disorder.[255] With treatment, these values increase transiently and then fall to age-appropriate norms before radiographic healing of the rachitic lesions is complete.

Prevention of vitamin D deficiency is its most effective management. Because the amount of vitamin D in human breast milk is approximately 20 IU/L and vitamin D supplementation of the breast-feeding mother may be inadequate to ensure normal calcidiol levels in her infant (unless she is receiving approximately 2000 IU per day), it is important that all breast-fed infants receive a supplement of vitamin D daily (200–400 IU/day). By extension, this recommendation is also appropriate for infants who are not receiving adequate amounts of vitamin D in their prepared formulas or diet or have suboptimal exposure to sunlight.[43,241,243,244,247,256] It is somewhat ironic that an increase in the incidence of vitamin D deficiency in infants and children coincides with well-intentioned recommendations that exposure to sunlight be limited by sunscreen and protective clothing.

Vitamin D supplementation (at least 400 IU/day and perhaps as high as 800 to 1,000 IU/day) is appropriate throughout life if sunlight exposure is limited.[43,252] In the active lightly dressed white child with skin that normally tans with exposure to sunlight and who plays outdoors 30 minutes thrice weekly, endogenous vitamin D synthesis is usually sufficient to obviate the need for supplementation.[241,243] A brown or black-skinned child requires several fold longer sunlight exposure for a comparable biologic effect. The latitude in which the child lives, season of the

year, time of day, local environmental pollutants, amount of clothing, and use of sunscreen affect the time required for sunlight exposure to evoke adequate vitamin D synthesis in the individual child.[256] Between November and February, little or no vitamin D can be synthesized above 35 degrees latitude (Atlanta, GA)—but vitamin D insufficiency is also prevalent in lower latitudes.[43,257]

Once established, vitamin D deficiency in the child or adolescent may be treated by the oral ingestion of vitamin D_3 2,000 to 10,000 IU daily for 4 to 6 weeks or 50,000 IU weekly for 8 weeks or by the administration of a single oral (or intramuscular) dose of 150,000 to 600,000 units of vitamin D_3—depending on patient age and other individual circumstances.[43,220,241] At the beginning of treatment, elemental calcium (40 mg/kg/day in divided doses) must also be administered to the vitamin-D-deficient child receiving vitamin D in order to avoid the hypocalcemia that accompanies rapid remineralization of bone matrix (the hungry bone syndrome). Serial measurement of total and/or bone-specific alkaline phosphatase values is an effective tool for monitoring the efficacy of treatment as levels decline progressively in tandem with the roentgenographic healing of the rachitic lesions.[255] Care should be exercised to avoid hypercalcemia, hypercalciuria, and nephrocalcinosis.

Rickets due primarily to low dietary intake of calcium has been observed in infants who ingest low-calcium-containing formulas and in children from developing countries receiving a diet with 200 mg (or less) of elemental calcium per day despite normal intake of phosphate and adequate endogenous stores of vitamin D as determined by serum calcidiol levels.[241] Calcium intake in these infants and children is well below that recommended (375 mg/day in infants, 500 mg/day in children below 4 years of age, 800–1300 mg/day in older children and adolescents). Histologically, bone biopsies from children with calcium-deficiency rickets reveal widened seams of unmineralized osteoid and low bone turnover rates—findings compatible with rickets.

In Nigerian infants, rickets due to vitamin D deficiency is most prevalent between 4 and 12 months of age. In 123 older Nigerian children (34–63 months of age) with rickets, low serum concentrations of calcium, normal phosphate levels, normal to low calcidiol, and elevated calcitriol concentrations, administration of calcium alone (1,000 mg daily in divided doses orally over 24 weeks) resulted in more rapid decline in serum levels of alkaline phosphatase and in radiographic healing of rickets than did administration of vitamin D (600,000 IU intramuscularly at inception of the study and at +12 weeks)—data supportive of the concept that calcium deficiency alone was the cause of the rickets in this population.[258]

Interestingly, calcidiol values rose and calcitriol levels declined with calcium supplementation alone—suggesting that a low-calcium diet and attendant calcium deficiency led to increased secretion of PTH and accelerated conversion of calcidiol to calcitriol. Calcium deficiency rickets also occurs in the United States when after completion of breast feeding infants and children are weaned to low-calcium-containing foods.[254] Calcium deficiency rickets may also develop as a consequence of impaired intestinal absorption of dietary calcium that has been bound by ingestion of high fiber- and phytate-containing cereals. Calcium deficiency is best addressed by its prevention, ensuring adequate intake of this element according to established guidelines for growing children and adolescents. When present, calcium deficiency rickets may be effectively treated by ensuring an intake of 1,000 mg of elemental calcium daily for 6 months—with provision of normal amounts of vitamin D by sunlight exposure or supplementation.[242]

Dietary phosphate deficiency is unusual because it is present in large amounts in most foods. Phosphate deficiency occurs in patients receiving parenteral nutrition with fluids low in this cation, in those ingesting large

amounts of aluminum-containing antiacids as aluminum and phosphate co-precipitate in the intestinal tract, and in premature infants drinking human breast milk without supplemental phosphate.[242] In very premature infants receiving long-term parenteral nutrition, development of metabolic bone disease is frequent and related to deficiencies of calcium, phosphate, and vitamin D and to excess aluminum in the infusates.

Infants receiving large amounts of aluminum-containing antiacids over prolonged periods for treatment of gastroesophageal reflux may also have substantially low bone mass. Aluminum lowers the rate of bone formation by several mechanisms. Administered orally, aluminum binds intestinal phosphate—thereby impeding its absorption and leading to phosphate depletion. Administered intravenously during total parenteral nutrition or during hemodialysis, aluminum inhibits osteoblastic function and prevents mineralization of osteoid. It also impairs the secretion of PTH and decreases 25OHD-1α hydroxylase activity.[242] Patients requiring total parenteral nutrition should receive as much calcium and phosphate as can be administered safely—as well as supplemental vitamin D 400 IU/day.

Periodic measurements of serum levels of calcium, phosphate, alkaline phosphatase, PTH, and calcidiol (and serial skeletal radiographs and estimations of skeletal mineralization) are recommended in patients receiving total parenteral nutrition. If metabolic bone disease develops in spite of these efforts, serum aluminum levels should be measured. If they are elevated (>100 μg/L), a search for the source of the aluminum should be initiated and that product eliminated from the infusate if possible. Cadmium, fluoride, and saccharated ferric oxide are also able to impede normal bone mineralization.[242]

Metabolic and functional defects of vitamin D lead to rare forms of rickets. Rickets due to a defect in 25-hydroxylation has been described in two brothers of Nigerian origin in whom a homozygous loss-of-function mutation (Leu99Pro) in *CYP2R1* eliminated hydroxylase activity of this 501aa protein.[259,260] Hypocalcemia, hypophosphatemia, skeletal abnormalities of rickets, and low plasma levels of 25OHD were present in these siblings. Vitamin-D-dependent rickets type 1 (OMIM 264700) or pseudovitamin D deficiency rickets (PDDR) type 1 is due to loss-of-function mutations in *CYP27B1*—the enzyme in the renal proximal tubule that catalyzes 1α-hydroxylation of 25OHD to 1,25$(OH)_2$D or calcitriol, the biologically active metabolite of vitamin D.[261,521] PDDR type 1 is an autosomal-recessive disease whose clinical manifestations [including bone deformities (bowing of the forearms), growth retardation, weakness, and/or seizures] appear in the first year of life. Biochemically, hypocalcemia, hypophosphatemia, hyperphosphatasemia, and markedly elevated serum levels of PTH are typical. Radiographs reveal rachitic deformities of the long bones.

The diagnosis of PDDR type 1 is established by finding normal serum concentrations of calcidiol but extremely low calcitriol values that do not increase after administration of vitamin D or calcidiol. The diagnosis is confirmed by identification of the mutation in *CYP27B1* (Table 17-7). The clinical, biochemical, and radiographic manifestations of PDDR resolve completely and reasonably rapidly following treatment with physiologic amounts of calcitriol (10–20 ng/kg/day). Serum calcium concentrations often begin to rise within the first 24 hours of treatment. Life-long therapy is necessary, and calcitriol doses usually need to be increased during pregnancy. PDDR type 1 is found with high frequency in a Quebec French-Canadian population but occurs in all races and in diverse geographic regions.

CYP27B1 encodes a 508aa mitochondrial cytochrome P450 hydroxylase with conserved sites that bind ferrodoxin and heme. Many loss-of-function missense, nonsense, splicing, and duplication or deletion/frame-shift mutations in *CYP27B1* lead to inactive or truncated protein products that are unable to bind substrate (calcidiol) or heme—the latter defect preventing electron transfer and inhibiting catalysis (Figure 17-11).[262] The most common mutation in *CYP27B1* in the Quebec French-Canadian population at risk for PDDR type 1 is deletion of guanine at nucleotide 958 (codon 88, exon 2), which changes the reading frame and results in premature termination of translation and an inactive product (the Charlevoix mutation). A second common mutation in this population is triplication of a normally duplicated sequence in exon 8. However, this mutation is also found in patients of other ethnicities (Asian, Hispanic).

Homozygous or compound heterozygous inactivating mutations of *VDR,* the gene encoding the vitamin D receptor, lead to resistance to the biologic effects of calcitriol (autosomal-recessive vitamin-D-dependent rickets type II or vitamin-D-resistant rickets, OMIM 277440).[261,263] In addition to the radiographic findings of rickets, clinical and biochemical manifestations of resistance to calcitriol include severe infantile-onset bony deformities characteristic of rickets, growth retardation, varying degrees of alopecia, hypocalcemia, hypophosphatemia, and extraordinarily high serum concentrations of calcitriol (300–1,000 pg/mL) and PTH. Serum levels of 24,25-dihydroxyvitamin D are often low (Table 17-7).

Figure 17-11 Genetic errors in *CYP27B1* leading to absence of P450c1α activity, decreased synthesis of calcitriol, and pseudovitamin D deficiency rickets. IVS3 + 1g6a is guanine-to-adenosine transition in the first nucleotide of intron 3, resulting in retention of intron 3 in the transcribed product and introduction of a premature stop codon. Mutations have been identified in each of the nine exons of CYP27B1—including Q65H (exon 1), W241Ter (exon 4), S323Y (exon 6), R429 P (exon 8), P497R (exon 9)—and in introns 2, 3, 6, and 7. Abbreviations: C (cysteine), D (aspartic acid), E (glutamic acid), G (glycine), H (histidine), L (leucine), N (asparagine), P (proline), Q (glutamine), R (arginine), S (serine), T (threonine), W (tryptophan), Y (tyrosine), and X (termination). [Reproduced with permission from Kitanaka S, et al. (1999). No enzyme activity of 25-hydroxyvitamin D_3 1α-hydroxylase gene product in pseudovitamin D deficiency rickets, including that with mild clinical manifestation. J Clin Endocrinol Metab 84:4111–4117.]

The high calcitriol values reflect the combined stimulatory effects of hypocalcemia, hypophosphatemia, and secondary hyperparathyroidism on the activity of $25OHD_3$ 1α-hydroxylase together with decrease in its rate of catabolism due to depressed calcitriol-dependent 1,25α-dihydroxyvitamin D_3 24-hydroxylase activity. Alopecia is the result of impaired vitamin D function in epithelial nuclei and those of the outer root-sheath cells of the hair follicle. Loss-of-function mutations (particularly in the DNA-binding region) of *VDR* result in a phenocopy of the generalized alopecia associated with loss of *HR* function (Hairless, OMIM 602302, chromosome 8p21.2). Interestingly, the role of the VDR in the maintenance of normal hair growth is not dependent on its binding to ligand.[261,264]

Although striking in infancy and early childhood, clinical manifestations of this disorder may vary and patients with milder defects in VDR may not be identified until adolescence or adulthood. The *VDR* consists of DNA-, ligand-, and retinoid-X-receptor-binding domains and a transactivation domain to which many co-modulators of VDR function are recruited. Loss-of-function mutations have been found in each of these domains. The mutated VDR may be unable to bind calcitriol because of decreased receptor number or affinity for ligand, incapable of forming heterodimers with the retinoid X receptor or translocating to the targeted gene in the nucleus, unable to bind to the vitamin D response element (VDRE) or to initiate gene transcription once bound to the VDRE (Figure 17-12).

Spontaneous remission of the rachitic process may occur rarely, most often between 7 and 15 years of age and when the patient enters puberty.[265] The diagnosis of vitamin-D-resistant rickets is suggested by the finding of elevated serum concentrations of calcitriol in the rachitic patient and confirmed by identification of the loss-of-function mutation in *VDR*. In general, patients with vitamin-D-resistant rickets without alopecia may be more responsive to treatment.[263] Administration of high doses of calcitriol (1 to 6 μg/kg/day) and supplemental calcium (1 to 3 g of elemental calcium

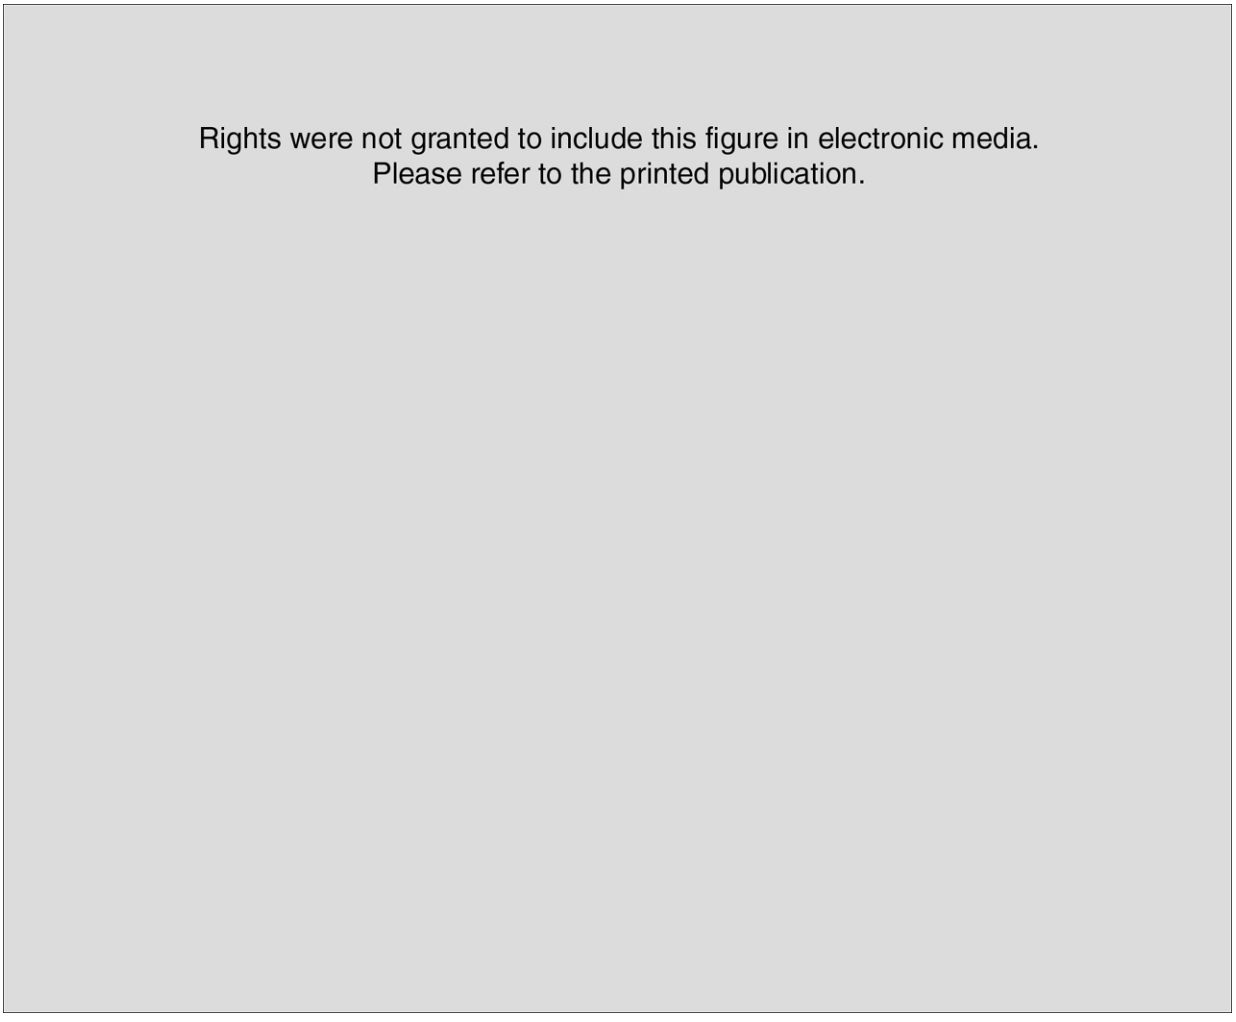

Figure 17-12 Mutations in the zinc-finger DNA-binding (*A*) and ligand-binding (*B*) domains of the vitamin D receptor (VDR) in patients with end-organ insensitivity to vitamin D. Shaded amino acids are conserved. Large circled amino acids denote missense mutations. Abbreviations: FS (frame-shift), H (α helixes), E1 (helixes within the ligand binding domain involved in transactivation), β-turn (change in spatial orientation of the VDR protein). daily) has been effective in increasing serum calcium concentrations and healing rickets in patients with nonsense and missense mutations in *VDR* that lead to decreased affinity for ligand or alter nuclear targeting. It is appropriate to provide a trial of high-dose calcitriol/calcium therapy to each patient with vitamin-D-resistant rickets regardless of the *VDR* mutation.[261,263]

During treatment, serum values of calcium, phosphate, alkaline phosphatase, creatinine, and PTH; urinary calcium and creatinine excretion; skeletal radiographs; and renal ultrasounds for development of nephrocalcinosis are monitored serially. In patients refractory to oral therapy, continuous intravenous or intracaval administration of large amounts of calcium (0.4–1.4 g of elemental calcium/m^2/day) normalizes calcium, phosphate, alkaline phosphatase, and PTH values; heals rickets; and increases growth rate in selected children. If this mode of therapy is employed, careful monitoring for catheter sepsis and cardiac arrhythmia (as well as hypercalcemia, hypercalciuria, and nephrocalcinosis) is mandatory.

After healing of the rickets by parenteral calcium, maintenance therapy with large doses of oral calcium (3.5–9 grams of elemental calcium/m^2/day) is appropriate. In younger infants with vitamin-D-resistant rickets prior to development of florid rickets, high doses of oral calcium may ameliorate the rachitic process. These clinical observations indicate that the major defect in patients with vitamin-D-resistant rickets is lack of calcium. With treatment, growth may normalize in patients with vitamin D resistance. However, if alopecia is present the condition is unlikely to resolve.[265]

Genetically engineered mice in which the VDR has been inactivated by ablation of the second zinc finger in the DNA-binding domain *($Vdr^{-/-}$)* are normal at birth, but develop an expanded zone of hypertrophic chondrocytes in the cartilage growth plate at 15 days, hypocalcemia at 21 days, alopecia at 28 days, and rickets by 35 days of age.[266] Except for alopecia, all of these abnormalities can be prevented (including the histomorphometric abnormalities characteristic of calciopenic rickets) by feeding these animals a diet known to prevent rickets in vitamin-D-deficient rats that is high in calcium (2% versus 1%), phosphorus (1.5% versus 0.67%), and lactose (20% versus none, lactose being a disaccharide that increases intestinal mucosal transport of calcium) beginning at 16 days of age.[266,267]

Clinical and experimental observations suggest that despite its known effects on osteoblast and osteoclast differentiation and function the primary role of the vitamin-D/VDR system in bone formation is to increase intestinal absorption of calcium in order to provide sufficient amounts of this cation for hydroxyapatite formation. Furthermore, in the mouse model of vitamin-D-resistant rickets maintenance of eucalcemia prevents secondary hyperparathyroidism—indicating that Ca^{2+} is a more potent regulator of PTH expression than is calcitriol and that secondary hyperparathyroidism is of fundamental pathophysiologic importance in the development of rickets of different etiologies.

A second form of vitamin D resistance (OMIM 600785) but with intact VDR and a phenotype similar to that of vitamin-D-dependent rickets type II (except for alopecia) is due to inhibition of binding of the VDR-retinoid X receptor heterodimer to the VDRE by a member of a family of heterogeneous nuclear ribonucleoproteins.[268,269] *HNRPA1* encodes one of several ribonucleoproteins that are able to bind the VDRE and to inhibit its transactivation by the VDR-retinoid X receptor heterodimer. The mechanism by which overexpression of these otherwise normal ribonucleoproteins occurs is unknown at present.

Phosphopenic Rickets

Hypophosphatemia in childhood may be due to hereditary or acquired disorders (Table 17-8). Acute hypophosphatemia is accompanied by paresthesias, muscle weakness, and confusion. Chronic hypophosphatemia is often manifested by rickets. One of the most common (1:20,000

TABLE 17-8

Disorders of Phosphate Homeostasis in Children

I. Hypophosphatemia

A. Decreased Intestinal Absorption

1. Decreased intake/absorption - parenteral hyperalimentation, antacid abuse, starvation (anorexia nervosa)
2. Malabsorption - vitamin D deficiency, metabolism, function

B. Increased Urinary Excretion

1. Hypophosphatemic rickets - X-linked (*PHEX*), autosomal dominant (*FGF23*), autosomal recessive (*DMP1*), autosomal recessive with hypercalciuria (*SLC34A3*), X-linked recessive (*CLCN5*), tumor-induced osteomalacia, fibrous dysplasia (*GNAS*)
2. Renal tubular defects - Dent and Fanconi syndromes, postrenal transplantation, hypomagnesemia, fructose intolerance, macrophage activation syndrome
3. Hyperparathyroidism, acidosis, respiratory alkalosis
4. Drugs - diuretics, bicarbonate, glucocorticoids, calcitonin
5. Expansion of extracellular fluid volume

C. Shift from Extracellular to Intracellular Space

1. Recovery from diabetic ketoacidosis/insulin administration, sepsis, salicylate intoxication
2. Administration of glucose, nutritional repletion, hungry bone syndrome

II. Hyperphosphatemia

A. Increased Intake

1. Intravenous, oral, rectal

B. Decreased Urinary Excretion

1. Renal insufficiency
2. Hypoparathyroidism, acromegaly
3. Pseudohypoparathyroidism (*GNAS*)
4. Familial tumoral calcinosis (*FGF23*, *GALNT3*)

a. Hyperostosis hyperphosphatemia syndrome (*FGF23*, *GALNT3*)

5. Drugs - growth hormone, bisphosphonates

C. Excess Bone Resorption

1. Severe illness - acidosis (metabolic or respiratory), hemolytic anemia, diabetic ketoacidosis, hepatitis, catabolic states, rhabdomyolysis, hyperthermai
2. Drugs - cytotoxic therapy

Modified from Hruska KA (2006). Hyperphosphatemia and hypophosphatemia. In Favus MJ (ed.), *Primer on the metabolic bone diseases and disorders of mineral metabolism, Sixth edition*. Washington, D. C.: American Society for Bone and Mineral Research 233–242; and from Ward LM (2005). Renal phosphate-wasting disorders in childhood. Pediatr Endocrinol Rev 2:342–350.

births) forms of clinically evident rickets encountered in developed countries is X-linked hypophosphatemic rickets (XHR, OMIM 307800). XHR is an X-linked dominant disorder manifested in affected hemizygous males and heterozygous females, albeit with substantial inter- and intrafamilial variability in its clinical expression. Physical findings in children with XHR include short stature, genu varum or valgum that develops when the infant begins to walk, flaring of the metaphyses, rachitic rosary, frontal bossing, increased frequency of dental decay and/or periradicular abscesses in teeth free of caries, and bone, muscle, and joint aching and stiffness.

Craniotabes, tetany, and muscular weakness are not found in patients with XHR as they are in those with vitamin D deficiency. Adults with XHR have osteomalacia and increased fracture rate, dental abscesses, and bone pain. They may also develop stenosis of the spinal canal. Enesopathy (calcification of tendons, ligaments, and joint capsules) is common in adults and may be present in children with XHR. Whereas serum levels of total calcium and Ca^{2+}_e are normal, hypophosphatemia is marked due to urinary wastage because of substantially decreased renal tubular reabsorption of filtered phosphate and limited intestinal absorption of this anion. Serum concentrations of PTH and calcidiol are normal, but calcitriol values are inappropriately low for the degree of hypophosphatemia. Serum alkaline phosphatase activity is increased.[270]

Because the serum Ca^{2+}_e concentration is normal, secondary hyperparathyroidism does not occur unless the patient receives excessive amounts of supplemental phosphate. Phosphate induces differentiation and death of hypertrophic chondrocytes in the cartilage growth plate by activating the mitochondrial apoptotic pathway that is caspase 9 dependent.[261,271] Thus, hypophosphatemia leads to delayed loss and increased numbers of hypertrophic chondrocytes and expansion of the growth plate characteristic of rickets. Histomorphometrically in XHR, unmineralized osteoid accumulates along the trabeculae within cancellous bone.

Classic XHR is caused by loss-of-function mutations in *PHEX* (phosphate-regulating endopeptidase homolog, X-linked).[272] *PHEX* is a 22-exon gene that encodes a 749-aa integral membrane protein with very long extracellular (702 aa), transmembrane (27 aa), and short intracellular (20 aa) domains that structurally resembles several neutral endopeptidases (endothelin-converting enzyme-1, Kell antigen). The extracellular domain has 10 conserved cysteine residues and a pentapeptide motif (His-Glu-Phe-Thr-His) characteristic of zinc metallopeptidases that may either convert propeptides to active forms or degrade and inactivate their substrates. *PHEX* is expressed in bone (osteoblasts), muscle, lung, liver, testis, and ovary. Its expression by osteoblasts is downregulated by calcitriol.[273]

In most patients with XHR, inactivating mutations of *PHEX* have been found primarily in the extracellular domain and include frame-shift deletions (16%), duplications, insertions (8%), deletional-insertional, splice site (15%), nonsense (27%), and missense (34%) mutations—many in exons 15 and 17. A mutation has also been identified in the 5'-untranslated region (A→G transversion 429 bp upstream of the ATG initiation site, Figure 17-13).[272,274,275] Because PHEX is a glycosylated protein, failure of glycosylation leads to its sequestration within the endoplasmic reticulum—thus impeding its movement (trafficking) to the cell membrane. Other mutations interfere with the catalytic function of the protein or its three-dimensional conformation.[276] Mutations in *PHEX* arise spontaneously in more than 20% of patients with XHR. There is no correlation between the location or type of mutation in *PHEX* and the clinical manifestations or severity of the disease.[277,278]

Fibroblast growth factor (FGF)-23 (OMIM 605380, chromosome 12p13.3), is a phosphate-wasting element present in high concentrations in the serum of patients with XHR and serum concentrations of FGF23 correlate with the degree of hypophosphatemia.[279] FGF23 is a 251-aa that inhibits sodium-dependent phosphate uptake by renal proximal tubular cells and depresses 25OHD-1α hydroxylase activity and thus synthesis of calcitriol—characteristics that define a phosphatonin (a family of phosphaturic agents that includes in addition to FGF23, matrix extracellular phosphoglycoprotein and serum frizzled related protein-4).[280] FGF23 inhibits phosphate reabsorption by down-regulating expression of the genes encoding type II (a and c) sodium-phosphate co-transporters present in the apical membrane of the renal tubule. FGF23 is expressed and secreted primarily by osteoblasts and osteocytes.

FGF23 is coexpressed with PHEX in these cells. Normally, FGF23 is cleaved to biologically inactive products between amino acids Arg179 and Ser180 by metallic endopeptidases such as PHEX. Although the natural endogenous substrate for PHEX was thought likely to be FGF23, this peptide is not a substrate for PHEX action.[281,282] Rather, FGF23 is cleaved by subtilisin-like proprotein and furin-like convertases. In normal adults, the mean serum FGF23 concentration utilizing an immunometric assay that detects intact FGF23 is 29 pg/mL. FGF23 levels decline in response to phosphate deprivation and increase with phosphate loading, consistent with an important role for FGF23 in the normal regulation of serum phosphate concentrations and phosphate homeostasis.[283]

In the Hyp mouse model of XHR, there is increased expression of *Fgf23* in bone and in osteoblasts in vitro. Because normally *PHEX* is also expressed in bone, these observations suggest that decreased expression of *PHEX* in the Hyp mouse (and the patient with XLH) may upregulate expression of *Fgf23*.[282] Although serum levels of matrix extracellular phosphoglycoprotein have been reported to be increased in some patients with XHR, it plays no role in the pathogenesis of XHR in the Hyp mouse (and its role in the human disorder is likely to be limited).[280,284]

When renal function is normal, rickets of diverse pathogenesis is commonly associated with hypophosphatemia. Secondary hyperparathyroidism as a cause of hypophosphatemia may be suspected by the presence of elevated serum concentrations of PTH (e.g., vitamin D deficiency). Serum PTH values are normal in subjects with primary hypophosphatemia due to an abnormality in renal tubular resorption of phosphate intrinsic to the renal cell or mediated by a circulating phosphatonin.[272]

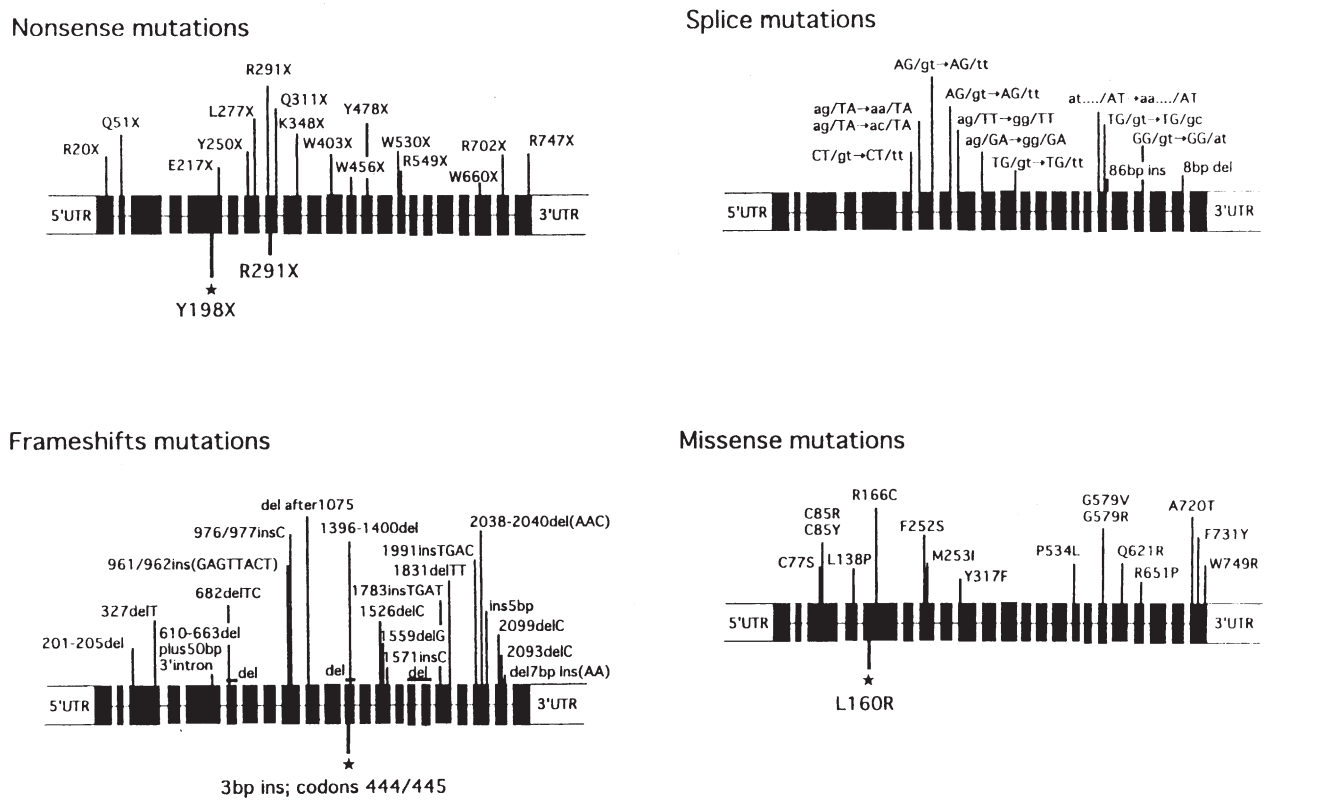

Figure 17-13 Nonsense, splice, frame-shift, and missense mutations in PHEX in patients with X-linked hypophosphatemic rickets. [Reproduced with permission from Sato K, et al. (2000). Three novel *PHEX* gene mutations in Japanese patients with X-linked hypophosphatemic rickets. Pediatr Res 48:536–540.]

The diagnosis of XHR is established when the typical family history (if the patient is not the initial mutant), clinical findings (deformities of the lower extremities, flaring of the metaphyses), and roentgenographic (rachitic changes) and laboratory data (hypophosphatemia, hyperphosphaturia, inappropriately low serum level of calcitriol, normal serum concentration of PTH, calcium, creatinine, and 25OHD) are present and when other causes of hypophosphatemia and hyperphosphaturia have been excluded (Tables 17-6 through 17-8).

The diagnosis of XHR may be confirmed by identification of the *PHEX* mutation, although occasionally no mutation is detected by current methods.[277] Rarely, somatic and germ-line mosaicism for a mutation in *PHEX* may mimic autosomal-dominant transmission of hypophosphatemic rickets.[285] The primary therapeutic agents employed in the treatment of XHR are calcitriol (25–70 ng/kg/day) administered in two doses (with the larger dose given at night when PTH secretion tends to increase) and elemental phosphorus 0.25 to 3 g daily (beginning at a dose of 30 mg/kg/day and increasing to 70 mg/kg/day) administered in four to six divided daily doses depending on age, size, compliance, and response to therapy.[272]

Table 17-3 lists the preparations of oral phosphate. Infants and young children may tolerate a phospha-soda solution more readily than other preparations. When able, most older children prefer a chewable phosphate tablet to the powder form that is dissolved in water or juice. Acidic potassium phosphate products are preferred because they do not increase intravascular volume and phosphate excretion and because they acidify the urine, thereby increasing the solubility of calcium phosphate. Calcitriol (Rocaltrol, Roche Pharmaceuticals) is available as an oral solution at a concentration of 1 μg/mL and as capsules with either 0.25 or 0.5 μg per capsule.

If hypercalcemia or hypercalciuria (urine calcium excretion more than 4 mg/kg/day) occurs during treatment, the dose of calcitriol should be lowered. If that leads to exacerbation of the rachitic process, an agent (e.g., amiloride) that increases renal tubular resorption of calcium may be added cautiously to the therapeutic program. Frequent (every 3 months) clinical evaluation and measurement of serum and urine calcium, phosphate, alkaline phosphatase, and creatinine levels and serum intact PTH values are essential to avoid hypercalcemia, hypercalciuria, nephrocalcinosis, and secondary hyperparathyroidism because high doses of phosphate may lead to counterproductive secondary (and sometimes tertiary) hyperparathyroidism.

Two goals of therapy of XHR are to maintain serum phosphate concentrations determined before a daytime dose of phosphate in the low normal range and alkaline phosphatase values within the high normal range. Renal sonograms prior to treatment and at 12-month intervals during therapy to identify early-stage nephrocalcinosis (and yearly skeletal radiographs to assess the degree of healing of the rickets) are recommended. Complete radiologic healing of XHR is often difficult to attain. Development of nephrocalcinosis (and compromise of renal

function in some patients) is directly related to the amount of phosphate the patient receives. Hyperoxaluria has also been implicated in the pathogenesis of nephrocalcinosis.

Co-management with an experienced orthopedist is important because the orthopedist may prescribe braces, or in patients with extreme and progressive deformities perform corrective osteotomies. However, bracing is unpredictable and poorly tolerated—and osteotomies are often followed by complications. Femoral and tibial hemiepiphysiodeses may offer alternative surgical procedures for the correction of lower limb deformities in children with XHR younger than 10 years of age.[286]

The birth length of children with XHR is normal, but growth rate is slow during the first several years of life—leading to progressive shortening of height. Many children with XHR are significantly short by 5 years of age, although some patients (particularly girls) with minimal involvement may grow normally.[287] Treatment of the older child with XHR with calcitriol and phosphate may improve growth rate, in part due to correction of the deformities of the lower extremities.[288] During puberty, gain in height is normal in boys (+28.2 cm) and girls (+24.2 cm) with XHR. Thus, the compromised adult stature in XHR is related to impaired early childhood and preadolescent growth.

In a series of 19 closely monitored children with XHR, initiation of treatment with calcitriol and phosphate at a mean chronologic age of 4.2 months (range of 7 weeks to 6 months, N = 8) resulted in greater adult stature [–0.2 versus –1.2 standard deviations (SD)] than when treatment began at a mean age of 2.1 years (range of 1.3 to 8.0 years, N = 11)—with no difference in complication rate (secondary hyperparathyroidism, nephrocalcinosis, craniosynostosis) between the two groups.[289] The enhanced growth response to early treatment was likely related to the normal length and mild skeletal and biochemical signs of rickets in early infancy and the prevention of more clinically significant bone disease as the child aged.

Despite close adherence to treatment, many children with XLH retain mild to moderate radiographic signs of rickets and mildly elevated serum alkaline phosphatase activities—although the extent of lower limb deformities is often ameliorated by good compliance. GH increases glomerular filtration rate, renal tubular resorption, serum concentrations of phosphate, and rate of accrual of bone mineral. In the short term (6–12 months), GH accelerates the velocity of linear growth of children with XHR.[290-292] Approximately 90 children with XHR who have been treated with rhGH combined with conventional therapy have been reported. The majority have experienced improved linear growth, and some have achieved normal adult stature.[293] Whether GH therapy will increase adult stature in larger series of XHR subjects remains a matter of further clinical investigation. Future treatment of XHR may include development of agents that decrease production of FGF23, accelerate its degradation, or block its action in the renal tubule.

The majority of untreated adults with XHR are hypophosphatemic. Serum alkaline phosphatase activity is increased, and osteomalacia is present on bone biopsy. Nevertheless, these patients are often clinically asymptomatic except for frequent dental abscesses, degenerative hip disease due to deformities of the lower limbs, and hearing impairment.[272] Occasionally, a female with XHR may be clinically well despite isolated hypophosphatemia. Roentgenographic manifestations of XHR in adults include thickening of the spinous processes and fusion of the vertebrae and stenosis of the spinal canal.

BMD determined by single and dual-photon absorptiometry tends to be normal in adults with XHR (despite the histomorphologic abnormalities), suggesting that most of these subjects are not at increased risk for osteoporotic fractures. However, in approximately 25% of adults with XHR there is clinical evidence of osteomalacia such as progressive lower limb deformities, bone pain, fractures, and pseudofractures.[294,295] Treatment of these patients with calcitriol and phosphate can be beneficial.[296]

Autosomal-dominant hypophosphatemic rickets (ADHR, OMIM 193100) is a partial phenocopy of XHR with hyperphosphaturia and inappropriately low serum levels of calcitriol that is due to mutations (Arg176Gln, Arg179Trp) in *FGF23* that render the product less susceptible to cleavage between amino acid residues 179 and 180 by furin, a pro-protein convertase.[297] ADHR may be incompletely penetrant, variable in age of onset (childhood to adult), and rarely self-limiting.[298] The clinical, biochemical, and radiographic findings in ADHR are similar to those of XHR except that ADHR subjects manifest muscle weakness as a consequence of hypophosphatemia.[299]

ADHR may be identified by its pattern of transmission and detection of a mutation in *FGF23.* Treatment involves administration of calcitriol and phosphate, with close serial monitoring for safety and because hyperphosphaturia may occasionally resolve spontaneously. Excessive production of FGF23 with hypophosphatemia and inappropriately low calcitriol values has also been documented in patients with autosomal-recessive hypophosphatemic rickets, fibrous dysplasia due to a gain-of-function mutations in *GNAS,* the linear nevus sebaceous syndrome associated with hypophosphatemic rickets (OMIM 163200), osteoglophonic dysplasia (OMIM 166250; craniosynostosis, rhizomelic shortening of the limbs, noncalcifying bone lesions), and opsismodysplasia [OMIM 258480, a spondylo(epi)metaphyseal dysplasia with delayed ossification, micromelia, platyspondyly, and vertebral hypoplasia].[280,300]

Tumor-induced osteomalacia/rickets is an acquired disorder due to excessive production of one of several phosphatonins by a tumor of mesodermal origin. The majority of such tumors have secreted FGF23, but these neoplasms have also synthesized secreted frizzled related protein-4, matrix extracellular phosphoglycoprotein, and FGF7—all of which increase urinary phosphate excretion and suppress renal synthesis of calcitriol, albeit perhaps not to the same extent as FGF23.[280,301] The identification of an FGF23-secreting tumor is dependent on the sensitivity of the FGF23 assay employed.[302]

Although unusual in children, tumor-induced osteomalacia/rickets has been described in this age group. For example, an 11-year-old girl had significant bone pain and functional limitation associated with biopsy-proven hypophosphatemic osteomalacia/rickets and markedly

elevated serum levels of FGF23.[303] Following removal of a benign fibro-osseous tumor from a small exostosis on a distal ulnar metaphysis, serum FGF23 concentrations normalized within 7 hours postoperatively and phosphate levels were normal 2 weeks later. Clinical symptoms abated, and radiographic and histomorphometric abnormalities resolved within 1 year after surgery.

In an 11-year-old boy with severe bone pain, weakness progressing to confinement to a wheelchair, hyperphosphaturia, and hypophosphatemia, elevated levels of FGF23 (1874 RU/mL) declined to normal values (43 RU/mL) within 48 hours after removal of a FGF23-containing hemangiopericytoma from his left iliac wing.[304] This lesion had not been identified by routine roentgenograms, computed tomographic or magnetic resonance imaging, or technetium bone scan. The tumor was demonstrated only by gradient recall echo magnetic resonance imaging (Figure 17-14). Within 2 weeks after surgery, the lad was walking without assistance—and several weeks thereafter he resumed normal activity.

Autosomal-recessive hypophosphatemic rickets (ARHR, OMIM 241520) is clinically, biochemically, and histomorphometrically similar to XHR and ADHR except for its mode of transmission and for the development of osteosclerosis at the base of the skull and in the calvarial bones. Serum concentrations of FGF23 are elevated in these subjects, and calcitriol values are inappropriately normal. Urinary calcium excretion is normal. Familial ARHR has been associated with homozygous loss-of-function mutations in the gene encoding dentin matrix acidic phosphoprotein 1 *(DMP1)*.[305,306] DMP1 is a member of a class of tooth and bone noncollagenous matrix proteins termed SIBLING proteins (small integrin-binding ligand, N-linked glycoproteins) that include osteopontin and bone sialoprotein.

These substances regulate phosphorylation of proteins essential to initial nucleation of calcium and phosphate, as well as to early formation of hydroxyapatite crystals and hence to mineralization of osteoid.[307] *DMP1* is expressed in osteocytes. Rickets and osteopenia develop in mice in whom *Dmp1* has been deleted.[305,308] In osteocytes without *Dmp1,* the expression of *Fgf23* is increased and secondarily hyperphosphaturia develops—suggesting that Dmp1 regulates expression of *Fgf23.* This disorder has permitted identification of a bone-renal axis essential to normal bone mineralization, although the mechanism by which Dmp1 may regulate expression of *Fgf23* has not yet been elucidated.

Autosomal-recessive hereditary hypophosphatemic rickets with hypercalciuria (OMIM 241530) is due to renal wastage of phosphate and is the consequence of a loss-of-function mutation in *SLC34A3* encoding sodium-dependent phosphate co-transporter type IIC (NPT2c). This 599aa protein with eight transmembrane domains is located in the brush border of juxtamedullary proximal renal tubular cells. Because calcitriol synthesis is normal in these subjects, its production is substantially elevated in response to hypophosphatemia. Thus, intestinal absorption of calcium and its urinary excretion are increased.

Heterozygotic carriers of inactivating mutations in *SLC34A3* also have moderately increased serum concentrations of calcitriol, hyperphosphaturia, and hypercalciuria but do not have identified metabolic bone disease. Loss-of-function missense and nonsense mutations have been found throughout the coding region of *SLC34A3,* as well as deletions in introns 9 and 10.[309,310] This disorder may be treated with phosphate salts in conjunction with hydration and avoidance of a high-sodium diet. Supplemental vitamin D is not needed, and may even be detrimental.

Increased urinary phosphate excretion due to acquired and heritable disorders of the proximal renal tubule is characteristic of the metabolic bone disease that accompanies various forms of the Fanconi syndrome of renal tubular acidosis, glucosuria, and amino aciduria (heritable:cystinosis, tyrosinemia, galactosemia, oculo-cerebral-renal syndrome, fructose intolerance, and Wilson disease, and acquired renal transplantation,

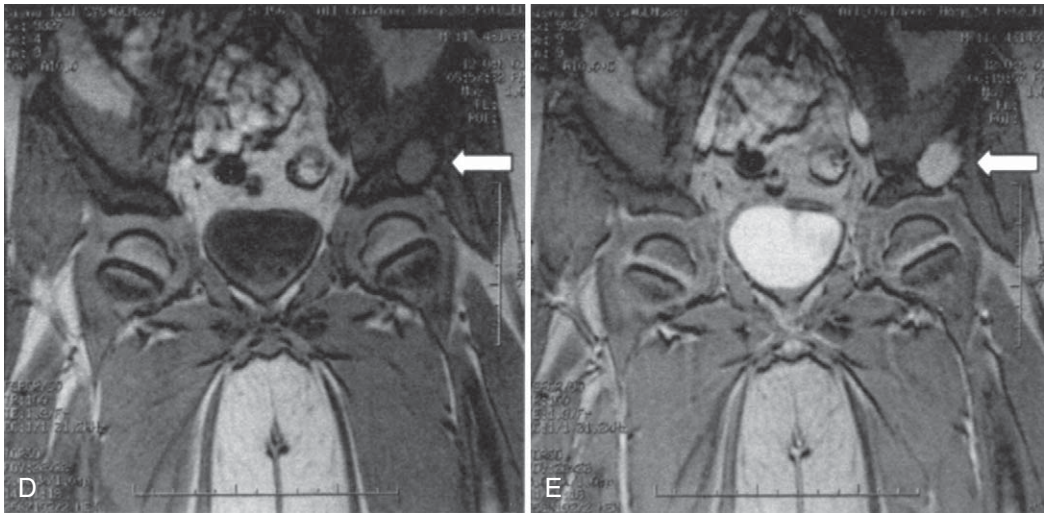

Figure 17-14 Demonstration by gradient recall echo magnetic resonance imaging of a FGF23 producing hemangiopericytoma in the left iliac wing of an 11-year-old boy with tumor-induced rickets. [Reproduced with permission from Shulman DI, et al. (2004). Tumor-induced rickets: Usefulness of MR gradient echo recall imaging for tumor localization. J Pediatr 144:381–385.]

nephrotic syndrome, renal vein thrombosis, mercury, lead and copper poisoning, and outdated tetracycline).[311,312] In addition to hypophosphatemia, acidosis contributes to the pathogenesis of bone disease in Fanconi syndrome by increasing the solubility of the mineral phase of bone, increasing urinary loss of calcium, and impairing conversion of calcidiol to calcitriol.

Inactivating mutations in *CLCN5* encoding a voltage-gated proximal renal tubular chloride channel lead to X-linked recessive hypophosphatemic rickets (XLRH, OMIM 300534); X-linked nephrocalcinosis, nephrolithiasis, and renal failure (OMIM 310468); and Dent disease (aminoaciduria, proteinuria, glycosuria, hypercalciuria, nephrocalcinosis, nephrolithiasis; OMIM 300009).[311,313] Mutations in different domains of this 12exon 746aa transmembrane chloride channel result in varying clinical and biochemical manifestations. The Ser244Leu mutation in *CLCN5* has ben particularly associated with X-linked recessive hypophosphatemic rickets.[314] Causes of hyperphosphatemia are also listed in Table 17-8.

Disorders of Alkaline Phosphatase

In its severe forms, hypophosphatasia is an autosomal-recessive disorder due to loss-of-function mutations in *ALPL*—the gene encoding the isoenzyme of tissue-nonspecific (bone/liver/kidney) alkaline phosphatase (TNSALP).[98] TNSALP is a homodimeric phosphomonoesterase anchored through its carboxyl terminal to the exterior of the cell membrane (i.e., an ectophosphatase) by a phosphatydylinositol-glycan moiety.[315] Pathophysiologically, decreased TNSALP activity leads to accumulation of its endogenous substrates pyrophosphate, pyridoxal 5'-phosphate, and phosphoethanolamine. Pyrophosphate is an inhibitor of osteoid mineralization. Calcification of bone matrix is impaired because pyrophosphate coats the surface of hydroxyapatite crystals, restricting crystal growth. In addition, inability to raise bone matrix phosphate levels to values sufficient to permit normal deposition of hydroxyapatite contributes to decreased bone mineralization.

Clinical manifestations of inactivating mutations of *ALPL* reflect the extent of loss of function of mutant ALPL. The younger the age of onset the more severe the disease is likely to be. The perinatal form is often a lethal disorder (at times in utero) due to marked osteopenia leading to cranial malformation; intracranial hemorrhage; pyridoxine-dependent seizures; short, bowed, and fractured extremities; and fractures of the ribs and deformities of the chest wall resulting in respiratory insufficiency and apnea. Survival is unusual. The infantile form (OMIM 241500) develops in the first 6 months of life and is characterized by anorexia, impaired linear growth and weight gain, deformities of the long bones and rib cage, widely open fontanelles and sutures (calvarial hypomineralization) with functional craniosynostosis with increased intracranial pressure manifested by prominence of the anterior fontanelle, proptosis, papilledema, pyridoxine-dependent seizures, hypotonia, constipation, hypercalcemia, hypercalciuria, and radiographic evidence of rickets with marked skeletal hypomineralization. Approximately 50% of these infants die of respiratory failure before their first birthday.

During childhood (OMIM 241510), clinical findings range from isolated premature shedding of deciduous teeth to physical and radiographic evidence of low bone mass and rickets. Spontaneous clinical improvement may occur during puberty and evolve into the adult form (OMIM 146300), which may be subclinical and identified when studying the family of an offspring with hypophosphatasia. The parent may have a history of premature loss of teeth, increased susceptibility to recurrent fractures predominantly of the metatarsal bones, pseudofractures of the proximal femur, chondrocalcinosis, or pseudogout due to articular deposition of calcium pyrophosphate dihydrate crystals.

Odontohypophosphatasia (OMIM 146300) is manifested only by premature shedding of primary teeth without radiologic abnormalities. Periodontitis may also develop. Pseudohypophosphatasia is phenotypically and biochemically similar to the classic disease, but serum alkaline phosphatase activity in vitro is normal—indicating that in this disorder enzyme activity toward fabricated substrates is preserved but alkaline phosphatase activity toward endogenous substrates is abnormal. The perinatal and infantile forms of hypophosphatasia are usually inherited as autosomal-recessive diseases, whereas childhood and adult forms may be transmitted as autosomal-recessive or autosomal-dominant traits.

In addition to the site(s) of mutation of *ALPL,* the clinical severity of hypophosphatasia is related inversely to the age at which skeletal disease is evident and to individual biologic factors that affect the expression of the disease. In the lethal perinatal form of hypophosphatasia, missense, nonsense, and frame-shift mutations in TNSALP cluster in crucial segments of the protein within (Ala94Thr, Arg167Trp) or near (Gly103Arg, Gly317Asp) its enzyme active site or at the homodimer interface (Ala23Val, Arg374Cys).[315] These mutations interrupt binding to the phosphate ligand or destabilize attachment of necessary cofactors. On the other hand, *ALPL* mutations associated with infantile and childhood forms of hypophosphatasia (Arg119His, Asp361Val) tend to cluster on the three-dimensional surface of the enzyme molecule (at sites that relate to its tethering to the cell surface or its formation of tetramers) and retain substantial residual bioactivity.

In some patients with moderately severe hypophosphatasia, heterozygotic mutations in *ALPL* (Gly46Val, Arg167Trp, Asn461Ile) exert a dominant-negative effect on the intact TNSALP dimer. These mutations have been clustered at the enzyme active site or at the domain(s) involved with dimerization, tetramerization, or membrane anchoring.[316] Odontohypophosphatasia has been associated with heterozygotic mutations in *ALPL* (Pro91Leu, Ala99Thr). In a mouse knockout model of hypophosphatasia with inactivating mutations of *Alpl,* the clinical, biochemical, radiographic, and histologic findings are similar to those in infants with this disease.[317]

These animals are small at birth, grow poorly, and succumb within the first several months of life. Bone roentgenograms and histology are normal at birth and through 8 days of age, even though no TNSALP activity can be demonstrated. They become increasingly abnormal thereafter. There is developmental arrest of chondrocyte differentiation, with failure of hypertrophic

zone differentiation, formation of secondary ossification centers, and marked accumulation of unmineralized bone matrix—leading to skeletal deformities and fractures. In addition, these animals have seizures due to deficiency of pyridoxine—the product of TNSALP dephosphorylation of pyridoxal 5'-phosphate and the cofactor form of vitamin B_6 necessary for the synthesis of neural γ-aminobutyric acid.

Diagnostically, in addition to the clinical findings and radiographic features of rickets patients with hypophosphatasia have low serum levels of total and bone-specific alkaline phosphatase activity, increased serum concentrations of pyrophosphate and pyridoxal-5'-phosphate (~5,000 nM), and elevated urinary excretion of phosphoethanolamine (0.5–1.5 mmol/g of creatinine, control 0.15 mmol/g) and pyrophosphate (500–1,000 μmol/g of creatinine, control 200 μmol/g). In contrast to other forms of rickets, serum concentrations of calcium and phosphate are normal or even elevated—likely because intestinal absorption of calcium and renal tubular reabsorption of phosphate are normal, whereas the bone formation rate is depressed. In the perinatal and infantile forms of hypophosphatasia, hypercalcemia is frequent.[98,228]

There are normal serum levels of PTH and no evidence of secondary hyperparathyroidism. Although serum alkaline phosphatase activity in vitro is normal in patients with pseudohypophosphatasia, it is functionally inadequate in vivo—perhaps because the TNSALP protein is sequestered within the cell due to a defect in its transport to the cell surface or because the protein is active with artificial substrate but not with natural substrates at physiologic pH. There is no specific or effective therapy for hypophosphatasia currently available. Enzyme replacement by infusion of serum from patients with Paget disease and high alkaline phosphatase activity has been of only occasional and limited benefit. Administration of even small doses of vitamin D or its metabolites should be avoided because these patients easily develop hypercalcemia. Hypercalcemia in infants with hypophosphatasia responds to bisphosphonates and transiently to calcitonin.[318] Bone marrow transplantation may be effective therapy but requires further evaluation.[98] Seizures may be responsive to pyridoxine administration. Milder adult forms of hypophosphatasia may be responsive to teriparatide ($rhPTH^{1\text{-}34}$).[318a]

Serum bone-specific alkaline phosphatase activity is normally increased during puberty and in response to skeletal injuries and reflects osteoblastic activity. Hyperphosphatasemia is encountered transiently in clinically well infants and children less than 5 years of age (median age 16 months). In this situation, serum activities of bone and liver alkaline phosphatases isoforms are increased, but there are no skeletal abnormalities. It is a self-limited process, with alkaline phosphatase values returning to normal within several months.[319] Rarely, hyperphosphatasemia may be familial and transmitted as a benign autosomal-dominant trait.[320] Occasionally, an adolescent with persistent nonfamilial benign hyperphosphatasemia may be encountered. In one family, familial hyperphosphatasemia has been associated with mental retardation (OMIM 239300).

Juvenile Paget disease (OMIM 239000), also termed *hyperostosis corticalis deformans juvenilis*, often begins in early childhood and is characterized clinically by expanded and bowed extremities, nontraumatic fractures of the long bones, kyphosis, macrocephaly, and muscular weakness. This disorder may progress to wheelchair dependence. Serum levels of alkaline phosphatase are markedly increased—a coupled response to increased osteoclastic action. Radiographic skeletal abnormalities include cortical thickening, osteosclerosis and osteopenia, coarse trabeculations, and progressive skeletal deformities. The disorder is due to biallelic loss-of-function mutations of *TNFRSF11B* encoding osteoprotegerin—a member of the tumor necrosis factor (TNF) receptor superfamily that functions as a decoy acceptor for receptor activator of nuclear factor κB-ligand (RANKL)—thereby modulating osteoclastogenesis. Hence, inactivating mutations of *TNFRSF11B* are associated with enhanced osteoclastic activity.

The severity of juvenile Paget disease depends on the site of mutation. Those that result in deletion of the entire gene or those in the ligand-binding domain that involved loss of cysteine residues result in marked clinical disease.[321-323] Treatment with recombinant osteoprotegerin has resulted in clinical and radiologic improvement.[324] Familial expansile osteolysis (OMIM 174810) is an autosomal-dominant disorder pathophysiologically similar to juvenile Paget disease but clinically and etiologically distinct.

Focal areas of increased bone turnover in the appendicular skeleton appear in the second decade of life, followed by medullary expansion, pathologic fractures, and skeletal deformities. Deafness and premature loss of dentition may occur. The disorder is due to monoallelic gain-of-function mutations (insertion duplications of 18 and 27 bases in the signal peptide region of exon 1) of the gene *(TNFRSF11A)* encoding RANK that result in an increase in NFκB signaling, as a consequence of which there is augmented osteoclastogenesis.[325]

RENAL OSTEODYSTROPHY

Renal osteodystrophy is the metabolic bone disease that accompanies chronic renal failure. It is most commonly associated with a high rate of bone remodeling (increased rates of bone resorption and formation) due to secondary hyperparathyroidism (high-turnover lesions of osteitis fibrosa). Dynamic (low-turnover) bone disease with relatively low PTH secretion and osteomalacia due to accumulation of aluminum may also occur. Generally, areas of low- and high-turnover skeletal abnormalities (termed mixed renal osteodystrophy) are detected by histomorphometry.[326,327] The pathogenesis of secondary hyperparathyroidism is multifactorial (Figure 17-15).

When the glomerular filtration rate declines to less than 30% of normal, urinary phosphate excretion is impaired—leading to its intracellular and extracellular accumulation, hyperphosphatemia, and very slight hypocalcemia (the latter two leading to secondary increase in PTH generation). In addition, down-regulation of the expression of *CASR* in uremic PTGs (raising of the set-point) contributes to chief cell hyperplasia and augmented PTH release—as do decline in calcitriol synthesis and relative skeletal insensitivity to PTH. Phosphate may also slow the rate of

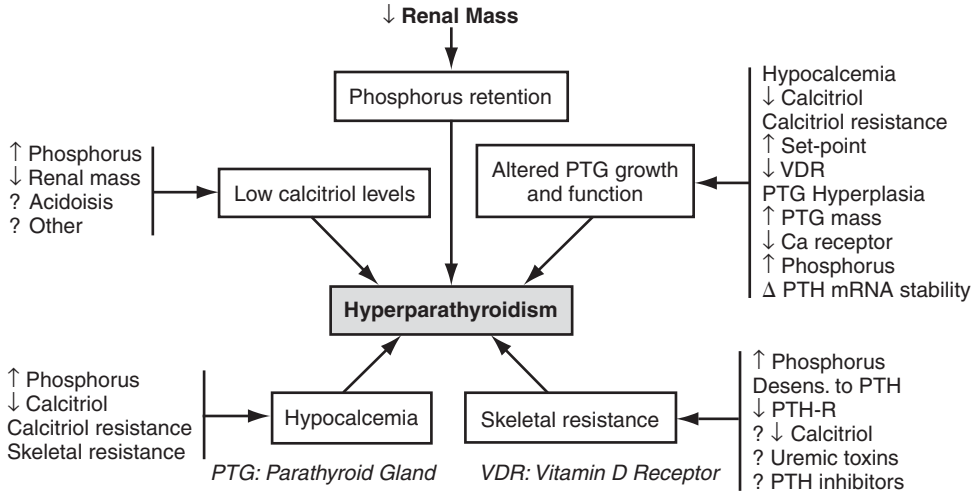

Figure 17-15 Pathophysiology of renal osteodystrophy. [Reproduced with permission from Martin KJ, et al. (2006). Renal osteodystrophy. degradation of PTH mRNA within the PTG and exert a direct enhancing effect on PTG growth.

Because calcitriol inhibits PTG growth and function, decrease in its synthesis also results in increased proliferation of parathyroid chief cells and synthesis of PTH. In the presence of elevated PTH secretion and various cytokines [IL-1, -6, and -11; TNF; and macrophage-colony stimulating factor (M-CSF)], osteoclastogenesis and the rates of bone resorption and formation are increased. Acidosis contributes to the dissolution of the mineral phase of bone directly and by impairing osteoprotegerin-mediated inhibition of osteoclast generation.

Chronic renal disease and osteodystrophy in children may be clinically silent except for failure of linear growth. As the disease progresses, deformities of the extremities, slipped epiphyses, fractures, bone and joint pain, and weakness and lassitude develop. In patients in whom the rate of bone formation is diminished and the volume of unmineralized bone (i.e., osteomalacia) increased, the process has been due to accumulation of aluminum at the mineralization front. However, with discontinuation of aluminum-containing phosphate binders osteomalacia in renal failure is now unusual.[326] In the absence of osteomalacia, adynamic bone disease in chronic renal failure is the result of decreased PTH generation due to improved control of serum phosphate levels, increased calcium stores, higher levels of PTH$^{7\text{-}84}$ and other carboxyl terminal fragments of PTH that inhibit bone resorption, and other factors that affect tissue response to PTH.

Biochemically, renal osteodystrophy is marked primarily by hyperphosphatemia and increase in serum PTH concentrations and alkaline phosphatase activity. Radiographic signs of rickets, low bone mass, and pseudofractures are often present in children with renal osteodystrophy. Therapeutically, the goals in treating a child with chronic renal failure in an effort to minimize renal osteodystrophy are to maintain (near) normal serum calcium, phosphate, and alkaline phosphatase values and to prevent the development or progression of secondary hyperparathyroidism. To do so, supplemental vitamin D and calcium may be needed—and dietary phosphate restriction imposed.

Calcitriol is able to decrease the rate of bone formation in patients with chronic renal insufficiency by inhibiting osteoblast differentiation or function, decreasing PTH synthesis, altering intra-PTG degradation of PTH, and decreasing expression of *PTHR1*. Calcium-containing oral phosphate binders may also be useful. Dialysis fluids must be prepared with aluminum-free water. When indicated, suppression of PTH secretion may be further achieved with the use of calcitriol analogues such as paricalcitol or of a synthetic ligand of the CaSR (cinacalcet hydrochloride).[326]

After successful renal transplantation, secondary hyperparathyroidism may persist for months or years—its extent and intensity reflecting the severity and duration of chronic renal failure before renal transplantation, development of nodular or monoclonal hyperplasia of the PTGs, and the 20-year life span of the parathyroid chief cell.[328] In one study of 47 childhood kidney recipients, 3 years after renal transplantation iliac crest bone biopsies revealed normal bone formation in 65% but persistent mild hyperparathyroidism in 25% and adynamic bone disease in 10%.[329] In all children in whom prerenal transplantation iliac crest biopsy revealed normal bone formation rates, the post-transplantation biopsy was also normal.

In approximately 50% of those patients with an abnormal pretransplantation biopsy, normal bone formation rates were achieved in the post-transplantation period. However, in many subjects secondary hyperparathyroidism or adynamic bone disease persisted or evolved—and random measurements of serum PTH concentrations did not necessarily correlate with or predict the histologic picture. Five years after renal transplantation during childhood, serum concentrations of PICP, osteocalcin, and ICTP remain significantly increased—indicating accelerated bone turnover rate—whereas areal and volumetric bone mineral densities at the distal third of the nondominant radius are normal for height but subnormal

for age.[330] Hypercalcemia and persistent secondary or tertiary hyperparathyroidism requiring parathyroidectomy may become apparent in children after renal transplantation.[331] The osteopenic effects of glucocorticoids and immune suppressive agents such as cyclosporin are observed in postrenal transplantation patients as well.

LOW BONE MASS

Osteopenia and osteoporosis (porous bone) designate states of reduced bone mass and abnormalities of bone microarchitecture that increase the risk for fracture (osteomalacia refers primarily to decrease in the mineral phase of bone).[332,333] Osteoporosis in adults is defined by the World Health Organization (WHO) as a BMD at a specific bone site that is –2.5 or more SD below the mean peak young adult value for gender (T score). In adults, osteopenia is present when the BMD lies between –1.1 and –2.4 SD below the mean peak young adult value for gender—and a normal BMD is one that is not more than 1 SD below or above the mean peak young adult value.

When the BMD is more than +2 SD above the mean for age and gender, bone mass is considered high. The WHO-designated categories of low bone mass do not necessarily apply to children and adolescents in whom variability in height, weight, and stage of sexual maturation affect bone mineralization. Use of the terms osteopenia and osteoporosis has been discouraged (although not eliminated) when describing mineralization in children. Presently, children may be identified as those with low bone density (Table 17-9) for chronologic age or height or stage of sexual maturation (reported as less than –2 SD or Z score for gender)—provided the method employed for determination of bone mineralization [DEXA, quantitative computed tomography (QCT), QUS] and the specific instrument, software version utilized for analysis, and ethnic mix of the reference population are stated.[334-337]

Despite its limitations (provision of areal rather than volumetric BMD data and failure to distinguish between trabecular and cortical bone), DEXA is the most widely employed bone densitometric method in children at this time—although peripheral (p) QCT may become the method of choice in the future. In infants, children, and adolescents, DEXA whole-body bone mineral measurement (BMC, BMD) rather than regional measurements is the currently preferred index of mineralization status. The inclusion or exclusion of head measurements in the determination of whole-body BMC and BMD by DEXA should also be stated.[338,339] Relative to bone strength determined by calculation of the stress-strain index of a long bone with data garnered by pQCT, the DEXA whole-body areal BMC (minus the skull) for height appears to afford the most reliable measurement for determining cortical bone strength and hence fracture risk.[338]

Although heritable factors account for 60 to 80% of optimal bone mineralization, modifiable factors that contribute to the development of osteopenia and osteoporosis in adulthood (weight-bearing exercise, nutrition, body mass, hormonal milieu) have their genesis in utero, infancy, childhood, and adolescence.[332,333] In children (as in adults), bone mass, composition, and size determine bone strength. Decreased bone strength is associated with

TABLE 17-9

Disorders of Bone Mineralization: Low Bone Mass

I. Primary
A. Osteogenesis Imperfecta (Types I–VIII)
B. Osteoporosis-Pseudoglioma Syndrome *(LRP5)*
C. Idiopathic Juvenile Osteoporosis
D. Marfan Syndrome *(FBN1)*
E. Ehlers-Danlos Syndrome *(COL1A1)*
F. Homocystinuria *(CBS)*
G. Idiopathic Hypercalciuria
H. Fibrous Dysplasia *(GNAS)*
I. Glycogen Storage Disease Type I *(G6PC)*
J. Menkes Kinky Hair Syndrome *(ATP7A)*
II. Secondary
A. Suboptimal Nutrition
1. Socioeconomic
2. Cultural
3. Excessive exercise
4. Anorexia nervosa
5. Malabsorption - cystic fibrosis, celiac disease, biliary atresia, short gut syndrome, gastric bypass

B. Endocrinopathies/Metabolic Diseases
1. Constitutional delay in growth and sexual development
2. Hypogonadism
   a. Hypergonadotropic - gonadal dysgenesis (Turner, Klinefelter syndromes), aromatase deficiency, estrogen receptor deficiency
   b. Hypogonadotropic - Kallmann syndrome, excessive physical activity, hyperprolactinemia
3. Diabetes mellitus
4. Hyperglucocorticoidism
5. Hyperthyroidism
6. Hyperparathyroidism
7. Growth hormone deficiency
8. Inborn errors - homocystinuria, lysinuric protein intolerance, propionic aciduria, methylmalonic aciduria

C. Disuse/Immobilization
1. Femoral fracture
2. Cerebral palsy
3. Muscular dystrophy
4. Quadriplegia/paraplegia
5. Spina bifida

D. Drugs
1. Glucocorticoids, immune suppressants, anticonvulsants, antiretroviral therapy, warfarin, lithium, methotrexate, cyclosporine A
2. Alcohol, tobacco

E. Chronic Illness
1. Rheumatologic disease
2. Inflammatory bowel disease
3. Hemoglobinopathies - thalassemia, sickle cell disease
4. Hemophilia
5. Cranial radiation
6. Renal failure, transplantation
7. Malignancy - leukemia, lymphoma
8. Human immunodeficiency virus infection

Adapted from Bachrach LK (2005). Osteoporosis and measurement of bone mass in children and adolescents. Endocrinol Metab NA 34:521–535; and from Rauch F, Bishop N (2006). Juvenile osteoporosis. In Favus MJ (ed.), *Primer on the metabolic bone diseases and disorders of mineral metabolism, Sixth edition.* Washington, D.C.: American Society for Bone and Mineral Research 293–296.

a greater risk of forearm fractures in children.[340] Because many youths consume excessive amounts of carbonated beverages and diluted fruit juices (thus limiting their intake of milk), most children and adolescents ingest only 55% to 70% of the recommended daily calcium allowance (1,300 mg/day)—although late pubertal males tend to consume more than do pubertal females.[341-343]

In adolescent and adult females, excessive intake of cola drinks with high phosphoric acid content lower body calcium content because of the sequestration of dietary calcium in the intestinal tract and the needed dissolution of bone mineral to neutralize acid—with consequent development of mild secondary hyperparathyroidism.[344,345] Sedentary non weight-bearing activities encouraged by television, video, and computer games also impair bone mineralization.[346] It had been suggested that fat may enhance bone mineralization through increased mechanical stress and estrogen production and through the stimulatory effects of leptin on osteoblast differentiation.

Although body weight and fat mass have correlated with bone mass in many studies, other data suggested that fat has a negative effect on the accrual of bone mass.[347,348] In a study of 300 male and female adolescents and young adults (13–21 years of age) employing DEXA assessment of body composition and QCT measurement of the axial and appendicular skeletons, a positive correlation between lean mass and all bone measurements was demonstrated in both genders—whereas fat mass had an inverse relationship or no relationship to bone mass. These observations strongly suggest that bone mass and strength are determined by dynamic muscular force and not by static load.[348] The mechanism(s) through which fat might exert an inhibitory effect on bone mass is unknown but may be related to the synthesis of cytokines that negatively affect bone accrual. An alternative postulated mechanism is through diversion of the mesenchymal stem cell (common to adipocytes and osteoblasts) into the adipogenic pathway.

The longer and more intense the weekly sporting activity (soccer, basketball, gymnastics, tennis) in children and adolescents the greater the vertebral and femoral BMDs independently of calcium intake.[343,346] In pre- and peripubertal children, simple school physical education programs utilizing jumping, hopping, and skipping exercises two to three times weekly significantly increase areal BMD at the femoral trochanter in as little as 8 months relative to children engaged in a standard physical education curriculum.[349-351] Thus, suboptimal nutrition and sedentary activities during childhood and adolescence (as well as consumption of colas and alcohol and smoking of cigarettes) prevent optimal bone mineralization and increase the likelihood of later development of osteoporosis and its complications.[342,352]

Because the risk of developing an osteoporotic fracture declines by 40% for every 5% increase in peak bone mineral mass, the foundation for the prevention of osteoporosis in the adult must be constructed in the child and adolescent by maintaining adequate calcium intake (1–3 years, 500 mg/day; 4–8 years, 800 mg/day; 9–18 years, 1,300 mg/day; >19 years, 1,000 mg/day), vitamin D stores (serum concentrations of 250 HD >30–32 ng/mL), and complementary weight-bearing activity during these formative years.[341,353] Discouragingly, combined quantitative analysis of multiple trials of calcium supplementation (usually of relatively short duration) in children revealed little effect on BMD or reduction of the risk of fracture.[354] However, the effects of sustained calcium supplementation over the many years of childhood and adolescence on future fracture risk has not been systematically examined.

Magnesium supplementation for 1 year increased BMC of the hip in healthy girls.[139] Sufficient protein, vitamins C and K, and copper must also be consumed for optimal bone matrix synthesis. It may be possible to identify the child or early pubertal subject at (genetic) risk for accrual of low peak bone mass and thus for later development of osteopenia/osteoporosis (e.g., offspring of a mother with osteopenia or osteoporosis). Axial and appendicular BMD and bone size determined by central or pQCT in the normal early pubertal boy and girl may accurately predict these measurements at sexual maturity.[355] If so, children at risk for low peak bone mass might benefit by a diet and exercise program during puberty that increases these values.

Nutritional deprivation depresses the rate of bone accrual, a process observed most dramatically in subjects with anorexia nervosa. The majority of postmenarchal late adolescent females with anorexia nervosa have significantly decreased total body, vertebral, and femoral neck areal BMDs—although volumetric BMDs may be normal for their small bone size.[356,357] In adolescent females with anorexia nervosa, decreased bone mineralization is associated with a slow rate of bone turnover—as demonstrated by lower serum concentrations of osteocalcin, estradiol, free testosterone, IGF-I, leptin, and bone-specific alkaline phosphatase and depressed urinary excretion of Dpd relative to normal-weight subjects.[356,358] In these patients, serum levels of osteoprotegerin correlate negatively with fat mass and leptin values and with lumbar spine areal and apparent BMDs. (by DEXA)

The decline in bone mass in adolescents with anorexia nervosa may be attributed to nutritional deprivation, chronic acidemia, and functional hypogonadism. Thus, the osteopenia encountered in patients with anorexia nervosa is the result of generalized nutritional deprivation with suboptimal intake of protein, calcium, and vitamin D; hypercortisolemia; and lowered IGF-I generation—leading to decreased osteoblast-mediated bone formation. Hypoestrogenism enhances to a limited extent osteoclast-stimulated bone resorption.[359] The bone loss of the patient with anorexia nervosa is not fully recovered even after return to normal weight, resulting in a several fold increase in fracture risk for these women.

In adolescents with anorexia nervosa, administration of estrogen/progestin does not increase bone mass or prevent its loss.[360] Bisphosphonates, IGF-I, and dehydroepiandrosterone have been reported to increase or maintain BMD in small series of patients with anorexia nervosa. However, their use should be limited presently to investigational studies.[359] Experimentally, in young adult female rats isocaloric restriction of protein alone lowers plasma concentrations of IGF-I—resulting in a decreased

rate of periosteal cortical bone formation and impaired osteoblastic responsiveness to IGF-I.[361] The athletic triad of suboptimal body fat mass, amenorrhea in women, and osteoporosis is encountered in the highly trained female athlete and in male elite long-distance runners.

Acute immobilization of the healthy active child and adolescent leads to sudden reduction in weight bearing, and to consequent decrease in the mechanical load on bones and thus a lowered rate of bone formation. In the presence of continued bone resorption, hypercalciuria and later hypercalcemia and lowered bone mass develop.[362] In the chronically partially or fully immobilized child or adolescent (cerebral palsy, spastic quadriplegia, muscular dystrophy), the fracture rate (primarily of the femur) is high during such simple maneuvers as turning, dressing, or feeding. In this group of subjects, not only lack of weight bearing but the severity of the primary illness, body size and pubertal status, state of general nutrition, vitamin D and calcium intake, coexisting inflammatory states, medications (e.g., anticonvulsants, glucocorticoids), and indoor confinement adversely impact bone mass and fracture risk.[363-365]

In a study group of 117 patients (2 to 19 years of age) with moderate to severe cerebral palsy, distal femoral BMD Z scores were below –2.0 in 77%—and the incidence of low femoral and vertebral BMDs as well as fractures increased with advancing age.[363] Distal femoral and lumbar vertebral BMDs increase at slower than normal rates as the child with spastic cerebral palsy ages, resulting in diminution of BMD Z score in the older subject.[364] Intravenous administration of pamidronate in a small (N = 6) selected group of children with quadriplegic cerebral palsy increased distal femoral BMD by +88% over 18 months, with mean Z score increasing from –4.0 to –1.8 over the interval of treatment.[366] In 5 lads with spastic cerebral palsy, daily administration of recombinant human GH (0.35 mg/kg/week) increased vertebral BMD assessed by DEXA by +1.17 SD over 18 months of therapy without altering the quality of life of these subjects.[367] Assisted standing alone increases BMD in children with severe cerebral palsy.[368,369]

The fundamental importance of normal gonadal sex steroid secretion during age-appropriate sexual maturation is emphasized by the observation that in adult males with delayed sexual development radial, vertebral, and femoral areal BMDs are lower than in males with normal timing of pubertal maturation.[370] Volumetric BMD has been reported to be normal or subnormal in young adult men with a history of delayed adolescence.[371,372] In prepubertal children of both genders with constitutional delay in growth, areal vertebral (trabecular) and nondominant radial (cortical) BMC and BMD are decreased relative to values in age and size-matched subjects with familial genetic short stature before and after correction for height, weight, bone age, and sex.[373,374] This finding suggests that factors other than sex hormones may also impair bone mineralization in short children with delayed skeletal maturation.

Osteoporosis with reduced bone mass and abnormal microarchitecture results in decreased skeletal strength and increased risk of fracture. Histomorphometrically, in sex-steroid-deprived osteoporotic bone there is decrease in bone cortical width, trabecular number, osteoid, and mineralization activity.[375] As a consequence of estrogen (and androgen) deficiency, there is increase in the production but decline in the life span of osteoblasts and osteocytes—whereas osteoclastogenesis is stimulated and the life span of osteoclasts prolonged. These events reflect the sum of the activities of multiple pro-osteoclastogenic cytokines (including M-CSF, IL-1, IL-6, TNF, RANKL), whose synthesis is regulated by estrogen.[375,376]

Although osteopenia responsive to estrogen has been recorded in adult males with aromatase deficiency, mature women with complete androgen insensitivity are also osteopenic despite normal to increased estrogen production—clearly indicating that androgens are also important to normal bone mineralization.[377] In prepubertal children and in adolescents with Turner syndrome, there is osteopenia with decreased cortical and trabecular bone mass.[378] Although decreased relative to chronologic age, areal and volumetric BMDs may be normal relative to height or bone age in girls with Turner syndrome. Nevertheless, the frequency of wrist fractures is increased during childhood—as may be the general risk for fractures in adults with Turner syndrome.

Estrogens, GH, and particularly the administration of both agents increase bone calcium deposition and BMD in adolescents with Turner syndrome.[378-380] In adults with Turner syndrome, however, there appears to be intrinsic reduction in cortical bone that is independent of sex hormones and might possibly be related to elevated levels of follicle-stimulating hormone—which may have intrinsic proresorptive properties distinct from its effect on estrogen synthesis.[307,381]

Pubertal subjects with primary (Klinefelter syndrome, galactosemia, postradiation, or chemotherapy) or secondary hypogonadism (anorexia nervosa, excessive physical training, hypogonadotropism) also have decreased bone mineralization. By decreasing estrogen production, even short-term (6 months) use of the intramuscular contraceptive depot medroxyprogesterone acetate (MPA) results in significant loss in bone mass in adolescent females and young women (18–21 years of age) when BMD would ordinarily be increasing. However, bone mass increases over time after this agent is discontinued.[359]

The adverse impact of depot MPA on BMD may be prevented by concomitant administration of estrogen. Estrogen-/progestin-containing oral contraceptives do not decrease bone mass in adolescent females, although they do slow its rate of acquisition. After treatment of the child with central precocious puberty for 1 to 2 years with a gonadotropin-releasing hormone analogue that suppresses pituitary-gonadal function, there may be arrest or even decline in bone mineral accumulation in the peripheral and axial skeletons—a process that can be prevented or reversed by the co-provision of 1 g of calcium per day during analogue therapy.[382]

The low bone mass of glucocorticoid excess is the result of inhibition of osteoblastogenesis and increase in the rate of apoptosis of the osteoblast and osteocyte leading to decrease in the rate of bone matrix formation and microfracture repair, and of enhanced osteoclastogenesis and decrease in the rate of apoptosis of the

osteoclast—permitting prolonged and excessive bone resorption.[383] Thus, during each remodeling cycle the amount of bone replaced is far less than the amount removed and skeletal microarchitecture is degraded—resulting in declining bone strength. At the molecular level, glucocorticoids suppress expression and synthesis of RUNX2 and BMP-2—factors essential to prenatal and postnatal osteoblast differentiation, respectively—and increase osteoblast expression of RANKL and decrease expression of osteoprotegerin, changes that favor osteoclastogenesis.[383-385]

Glucocorticoids inhibit synthesis of collagen type I and increase its rate of degradation. They impair IGF-I formation and function. To a limited extent, glucocorticoids inhibit normal vitamin D metabolism and thereby vitamin-D-dependent intestinal absorption of calcium. They also increase renal loss of calcium by a direct effect on the renal tubule, leading to secondary hyperparathyroidism.[383,384] Glucocorticoids also reduce production of sex hormones in the adolescent and adult. The muscle weakness of chronic glucocorticoid exposure reduces the impact of mechanical forces on bone formation. Finally, the disease for which glucocorticoids have been prescribed may contribute to decreased bone mass by impairing mobility and by elaboration of osteoclastogenic cytokines.

The risk of glucocorticoid-induced low bone mass is far greater with oral than with inhaled glucocorticoids in children with asthma.[386] However, in young adults with asthma there is an inverse relationship between vertebral and femoral BMDs and cumulative dose of inhaled glucocorticoid—with increasing fracture risk as the dose and duration of glucocorticoid administration increases. A cumulative dose of 5,000 mg leads to a 1 SD decline in vertebral BMD.[387] In adult women with 21-hydroxylase-deficient congenital adrenal hyperplasia treated with glucocorticoids, bone mineralization is modestly reduced—in part related to the extent of suppression of adrenal androgen production.[388]

In children experiencing adverse effects of glucocorticoids on growth and bone mineralization, it is important to lower their steroid dose to the greatest extent possible and to withdraw them if at all feasible. Increased weight-bearing exercise (walking) and supplemental calcium and active vitamin D metabolites may be helpful. In 7 of 10 children with juvenile rheumatoid arthritis and other rheumatic disorders and glucocorticoid/illness-mediated low bone mass, pamidronate at a dose to 2 to 4 mg/kg per infusion administered at 6-month intervals was followed by decline in bone pain, improved ambulation, and progressive increase in BMD of the lumbar spine.[389] PTH^{1-34} increases bone mass in adults with glucocorticoid-induced osteoporosis, but its efficacy and safety in children with this problem have not yet been evaluated.[390]

Low bone mass is often encountered in GH-deficient children and in adults with GH deficiency of childhood or adult onset. In part, low bone mass may be attributed to the small bone size of the short child compared to age peers. It is also due to loss of direct and indirect actions of GH (particularly impaired local generation of IGF-I) on osteoblast differentiation, proliferation, and function. GH enhances osteoblastic expression of IGF-I and IGF binding protein-3 and stimulates their synthesis of osteocalcin, bone-specific alkaline phosphatase, and procollagen type I—thus increasing bone matrix formation.[391] Secondarily, it increases osteoclastogenesis and bone resorption. Thus, administration of GH to GH-deficient children and adults increases the rates of bone formation and destruction—the latter predominating initially. Over long periods of treatment (12–18 months), GH increases BMD in these patients. To achieve peak bone mass, however, GH therapy must be continued into adulthood.

Nevertheless, in many untreated adults with congenital GH deficiency volumetric BMD is often normal—reflecting the smaller size of their bones.[392] In normal short children, GH administration also increases areal BMD.[393] Thyroid hormone, through direct action on the osteoblast, increases synthesis of osteocalcin, alkaline phosphatase, and IGF-I. It also enhances osteoclastogenesis, and thus the rate of bone resorption—the latter effect predominating.[394] With excess thyroid hormone there is increase in the rate of bone turnover but decrease in the length of the bone remodeling cycle (primarily due to shortening of the bone formation phase), resulting in a net loss of mineralized bone.

As in adults with thyrotoxicosis, whole-body, vertebral, and femoral BMDs are low in children and adolescents with hyperthyroidism—but substantially increase within the first 12 to 24 months after restoration of the euthyroid state.[395] Administration of physiologic replacement doses of thyroxine to children with acquired or congenital hypothyroidism does not adversely affect bone mineralization during childhood, although adults with congenital hypothyroidism have a 10% reduction in radial bone mass.[396] In adolescents with type 1 diabetes mellitus, whole-body, axial, and appendicular bone mass assessed by DEXA is decreased relative to control subjects and inversely related to hemoglobin A1c values—reflecting the adverse effects of chronic hyperglycemia and insulin deficiency on bone formation.[397,398] Utilizing pQCT in young prepubertal subjects with type 1 diabetes mellitus, cortical bone cross-sectional area and BMD were found to be decreased—implying an increased risk for fracture.[399]

Bone mass is decreased in 80% of children with acute lymphoblastic leukemia, and 40% sustain a fracture within the first 2 years of treatment.[400] Pathogenetic factors involved in the development of low bone mass in these subjects include adverse effects of the disease itself directly on bone; radiation injury of bone; inhibitory effects of glucocorticoid, chemotherapeutic, antibiotic, and immunosuppressive agents on bone formation; decreased caloric, protein, and vitamin D intake; sex hormone deficiency due to delayed or arrested adolescent development; and GH deficiency in children who have received cranial radiation. Cyclosporine A induces bone loss in organ transplant recipients by increasing osteoblast expression of RANKL and decreasing production of osteoprotegerin, thereby augmenting osteoclastogenesis.[401]

Leukemic patients should receive appropriate calcium and vitamin D supplements, and treatment with GH if they are GH deficient after the primary illness has been in prolonged remission. Adult survivors of childhood-onset acute lymphoblastic leukemia also have significant

osteopenia of the lumbar spine, femur, and radius—primarily related to GH deficiency.[402] Decreased bone mineralization is common in the post-bone-marrow or post-solid-organ transplant subject. Its diverse pathogenesis includes the primary disease itself and the chronic illness that may accompany it, the use of high-dose glucocorticoids and antirejection medications, and altered intestinal and renal function.[403]

In addition to provision of adequate nutrition, calcium, and vitamin D, in adults the effects of transplantation may be partially ameliorated by administration of bisphosphonates. Their usefulness and safety in pediatric transplant patients has not yet been fully evaluated. In severely burned patients and in children with hemophilia, sickle cell disease, central diabetes insipidus, Marfan syndrome, homocystinuria, lysinuric protein intolerance, propionic, and methylmalonic aciduria, BMD is also decreased.[404,405]

Children with cystic fibrosis may have low vertebral and femoral neck BMD Z scores as a consequence of suboptimal nutrition, chronic inflammation, concomitant diabetes mellitus, pubertal delay, and drug therapy. However, approximately one-third of optimally managed cystic fibrosis patients with good clinical control may nevertheless have subnormal BMDs (Z score below –1 but seldom below –2.5)—although this is not necessarily translated into increased fracture risk.[406,407] Low bone mass and vertebral collapse may be early manifestations of chronic inflammatory bowel disease.[408]

Vitamin D deficiency and secondary hyperparathyroidism, as well as the chronic inflammatory state and therapeutic agents (such as glucocorticoids), likely contribute to decreased bone formation and increased bone resorption in this illness. That whole-body BMC in children, adolescents, and young adults with chronic inflammatory bowel disease is reportedly normal relative to lean body mass (although reduced relative to racial, age, and height norms) does not necessarily imply that bone strength in these patients is normal—as evidenced by the increased fracture risk of adults with this disorder.[409,410] Low bone mass is common in children and adults with celiac disease.[411]

In children and adolescents infected with the human immunodeficiency virus, whole-body BMD is decreased as a consequence of the infective agent itself, the chronic inflammatory state it induces, suboptimal nutrition, and the administration of highly active antiretroviral therapy that may have direct effects on osteoblast and osteoclast generation and function.[412,413] Despite clinical well-being and normal linear growth, the rate of accrual of bone mass is decreased in these subjects—whereas the rate of bone resorption is increased. Bone mass is reduced in children with a variety of rheumatic diseases (juvenile idiopathic arthritis, systemic lupus erythematosus, juvenile dermatomyositis) due to the chronic inflammatory state, production of pro-osteoclastic cytokines, and therapy with glucocorticoids.[414]

Idiopathic juvenile osteoporosis (OMIM 259750) is an unusual disorder of generalized low bone mass of unknown pathogenesis that appears in mid to late childhood and often resolves as sexual maturity is achieved.[415] In affected subjects, roentgenograms obtained for evaluation of joint, muscle, and/or back pain; difficulty walking; foreshortening of the trunk; and/or the presence of kyphosis reveal biconcave vertebrae and/or vertebral compression and long bone radiolucent areas and fractures in the metaphyses. Chemical studies are normal. Histomorphometry reveals findings consistent with a low rate of bone turnover, with reduction in cancellous bone volume, trabecular thickness, and bone formation due primarily to decreased osteoblast activity on the endosteal but not the periosteal bone surface. There is no evidence of increased bone resorption.

Idiopathic juvenile osteoporosis is quite likely to be genetically heterogenous in origin. Mutation analyses of *COL1A1* and *COL1A2* have been normal in these subjects. In 15% of patients with juvenile osteoporosis, a familial heterozygous loss-of-function mutation in the gene encoding LDL receptor-related protein 5 *(LRP5)* has been detected.[416] Homozygous loss of *LRP5* results in the osteoporosis-pseudoglioma syndrome. The most difficult diagnostic problem is the clinical distinction between idiopathic juvenile osteoporosis and osteogenesis imperfecta type I (Table 17-10).

This form of osteogenesis imperfecta is characterized clinically by a positive family history, onset in early infancy, lifelong persistence, diaphyseal fractures, blue sclerae, abnormal dentition, wormian bones, and high bone turnover.[131,415] In children with idiopathic juvenile osteoporosis, symptomatic treatment is offered. In some patients, calcitriol or supplemental sodium fluoride has been of benefit. Although the disorder ameliorates and even disappears at puberty, treatment of the prepubertal patient with sex steroids does not seem to accelerate the healing process. Administration of the bisphosphonate pamidronate has been helpful in reducing bone pain and increasing vertebral BMD in a small group of children with idiopathic juvenile osteoporosis.[417]

The osteoporosis-pseudoglioma syndrome (OMIM 259770) is characterized clinically by congenital or early infantile onset of severe visual impairment due to hyperplasia of the vitreous (pseudoglioma that may be erroneously identified as retinoblastoma), leading to retinal detachment, glaucoma, and blindness; marked osseous fragility with craniotabes and fractures during late infancy, childhood, or adolescence; and variable cognitive impairment, ligamentous laxity, and hypotonia.[418] The disorder is transmitted as an autosomal-recessive trait and is due to biallelic (homozygous or compound heterozygous) inactivating [missense (Arg494Gln), nonsense (Arg428Ter), frame-shift, splice-site] mutations in *LRP5*—primarily located in the extracellular domain of this protein.[419]

Missense mutations likely prevent normal binding of LRP5 to the product of the mesoderm development gene (OMIM 607783, chromosome 15), a chaperone protein that directs LRP5 to the cell membrane. Although often asymptomatic, heterozygous carriers are usually osteopenic. However, vision is not impaired. Mutations in *LRP5* have also been associated with familial exudative vitreoretinopathy (OMIM 133780), a developmental disorder of retinal vasculature that may be transmitted as an autosomal-dominant (Leu145Phe) or autosomal-recessive (Arg570Gly, Arg752Gly) trait. These patients also have reduced

TABLE 17-10

Classification of Osteogenesis Imperfecta

Type - OMIM	Severity	Clinical features	Growth impairment	Blue sclera	Inheritance	Gene defect
I - 166200	Mild	Few fractures, little deformity, hearing loss in 50%; rarely dentinogenesis imperfecta	Minimal	Present	AD	Nonsense & frameshift mutations resulting in premature STOP codons in *COL1A1*
IIA - 166210	Perinatal lethal	Many rib & long bone fractures at birth, severe long bone deformities, unmineralized calvarium	—	Present	AD, parental mosaicism	A - Glycine substitutions in *COL1A1* or *COL1A2*.
IIB - 610854					AR	B - Inactivating mutations of *CRTAP*
III - 259420	Severe, progressive deforming	Moderate to severe bowing, multiple fractures, dentinogenesis imperfecta, hearing loss	Severe	Present but lighten with age	AD	Glycine substitutions in *COL1A1* or *COL1A2*
IV -166220	Moderately deforming	Mild to moderate bowing, fractures	Moderate, variable	Greyish or absent	AD	Glycine substitutions in *COL1A1* or *COL1A2*
V - 610967	Moderately deforming, clinically similar to Type IV	Mild to moderate bone fragility, ossification of interosseous membranes of forearm, hypertrophic callus formation at fracture site	Mild to moderate	Absent	AD	Unknown
VI - 610968	Moderately to severely deforming, clinically similar to Type IV	Onset of fractures in infancy; increased osteoid, fish-scale@ pattern of lamellation	Moderate	Absent or faint	Unknown	Unknown
VII - 610682	Moderately deforming	Fractures present at birth with frequency declining with age, rhizomelia, limb deformities	Moderate	Absent or faint	AR	Inactivating mutation (duplication) of *CRTAP*
VIII- 610915	Severely deforming, overlaps type II & III	Phenotype overlaps those of types II and III	Severe	Absent	AR	Inactivating mutations of *LEPRE1*

AD, autosomal dominant; and AR, autosomal recessive.

bone mass. LRP5 is a membrane protein that transduces the signals of two extracellular ligands: Wnt10b (OMIM 601906, chromosome 12q13) and Norrin (OMIM 310600, chromosome Xp11.4).

Wnt signaling increases the accrual of bone by activating β-catenin, a transcription factor that enhances differentiation of pluripotential mesenchymal precursor cells into the pathway of chondrogenesis and osteogenesis and impedes their differentiation into the pathway of adipogenesis.[420] By stimulating Runx2, β-catenin further directs the osteochondroprogenitor cell into the osteoblastic track. In the mature osteoblast, β-catenin enhances expression of osteoprotegerin and hence depresses osteoclastogenesis.[421] Norrin signaling modulates vitreoretinal formation in the eye.

In addition to the primacy of genetic and hormonal factors, the most important considerations for the accrual and maintenance of bone mass are those that relate to diet (sufficient intake of calcium and protein), sustained normal vitamin D stores by exposure to sunlight or ingestion of supplements, and consistent weight-bearing exercise. Therapeutically, when trying to prevent bone loss or restore lost bone initial efforts are directed to the assurance that these basic approaches are being utilized to the fullest extent possible for the specific patient. Therapeutic agents that increase bone mass act by inhibiting resorption (antiresorptive or antiremodeling drugs) or by stimulating bone formation (anabolic medications).[390] The most widely employed antiresorptive medications are sex hormones, selective estrogen receptor modulators, calcitonin, and bisphosphonates.

Selective estrogen receptor modulators are triphenylethylene-, benzothiophene-, or naphthalene-related compounds (e.g., raloxifene) that bind with high affinity to estrogen receptor α (perhaps to estrogen receptor β as well) in specific tissues—where they alter the three-dimensional configuration of the receptor and recruit tissue-selective cohorts of various coactivating factors, thus inducing receptor function in targeted sites (e.g., bone).[422] These compounds decrease osteoclast formation primarily at trabecular bone sites.[307] Nasal salmon calcitonin inhibits osteoclast function directly and has modest bone restorative effects.

Bisphosphonates are analogues of pyrophosphate, with carbon substituted for the oxygen bridge between two phosphate groups. Also attached to the carbon atom are two side chains. R1 is usually a hydroxyl group that together with the phosphate residues binds tightly to and coats bone surface.[423,424] The bisphosphonates impede osteoclast function by hastening their death by one of two mechanisms. After entering the osteoclast by endocytosis, etidronate forms cytotoxic acyclic analogues of adenosine triphosphate (ATP) that interfere with cellular metabolic processes and lead to apoptosis. After endocytosis nitrogen-containing pamidronate and alendronate inhibit the mevalonate pathway and the activity of farnesyl diphosphate synthase, a property shared with statin drugs.[425]

The resulting failure of transfer of fatty acids (prenylation) to guanosine-triphosphate-binding proteins such as Ras renders them inactive, impairs cell metabolism, and in turn begins the apoptotic process. As osteoclast function declines, bone mass increases. In addition, bisphosphonates are incorporated into the surface of hydroxyapatite and thereby block its dissolution. The biologic activity of bisphosphonates on osteoclast function is observed immediately after its administration as serum calcium concentrations decline rapidly. Indeed, this rapid effect has been utilized in the treatment of hypercalcemic infants and children. In adults, the effects of bisphosphonates on bone mass last long after the agent has been discontinued (the residence time)—enabling some compounds (zolendronate) to be given as infrequently as once yearly.

Indeed, bisphosphonates remain in bone for extremely long intervals—and their long-term effects appear to be cumulative. Histomorphometric analysis has revealed that bisphosphonates increase bone mineralization by decreasing the number of resorption cavities (and thus the remodeling space), preserving cancellous (trabecular) bone architecture, and decreasing porosity of cortical bone.[390] Bisphosphonates have been useful in improving mineralization in children with osteogenesis imperfecta, as well as in those with glucocorticoid induced osteoporosis, osteoporosis-pseudoglioma syndrome, Menkes disease, and cerebral palsy. In most infants and children, intravenous pamidronate (1 mg/kg/day on 3 consecutive days every 3 to 6 months to 2–15 mg/kg/year administered once every 3 to 6 months) has been utilized—although a number of different regimens have been employed with reasonably similar increases in BMD, decline in fracture incidence, and improved well-being.[423]

Limited data indicate that oral bisphosphonates (pamidronate, alendronate, olpadronate) administered daily also increase BMD in children with osteogenesis imperfecta and connective tissue disease, but with lower efficacy than intravenous administration. Side effects of bisphosphonates have been acute (fever, myalgia, abdominal pain, vomiting, hypocalcemia) and chronic (inflammatory disorders of the eye, osteonecrosis of the jaw in the elderly, and induced osteopetrosis).[423,426] Experimentally and in adults receiving long-term therapy, bisphosphonates can suppress bone turnover and contribute to hypermineralization—the latter leading to reduced mechanical strength and increased fracture risk.[427] Therefore, when selecting a child for treatment with bisphosphonates one must carefully considered the primary diagnosis and whether the patient's low bone mass and fracture frequency merit therapy in view of the potential side effects of bisphosphonates.

In addition, there are many unanswered questions concerning which bisphosphonate to use, its route of administration, the dose of the drug, the duration of therapy, and the method of outcome analysis. At this time, the use of bisphosphonates should be confined to centers with experience in the care and management of children with bone disease.[423,424] Treatment with bisphosphonates several years prior to conception does not appear to have an adverse effect on fetal outcome, but treatment during pregnancy is contraindicated because of possible toxicity.[428]

Administered intermittently in small amounts, PTH and its analogue $PTH^{1\text{-}34}$ (teriparatide) preferentially accelerate the rates of bone remodeling and of bone formation relative to that of bone resorption by direct stimulatory effects on the osteoblast.[390] PTH also acts on the osteocyte to decrease the production of sclerostin, an inhibitor of bone

synthesis that acts by repressing Wnt- and BMP-mediated bone formation.[429] The quantity of bone formed in each remodeling unit is increased, thus augmenting trabecular and cortical bone mass and strength. $PTH^{1\text{-}34}$ increases trabecular thickness and trabecular interconnectivity. By contrast, bisphosphonates preserve but do not alter trabecular architecture. $PTH^{1\text{-}34}$ increases periosteal new bone formation and cortical thickness and diameter (i.e., bone size)—thereby increasing bone strength and reducing fracture risk.[390]

Teriparatide is also capable of dissociating bone formation from resorption, doing so in part by decreasing the rate of osteoblast apoptosis. Side effects of $PTH^{1\text{-}34}$ administration include transient hypercalcemia, hypercalciuria, and development of antibodies to the peptide—all rather unusual events. Although osteosarcoma has been observed in mice receiving very high doses of PTH and $PTH^{1\text{-}34}$, no malignant disorders have been recorded in adults receiving either agent. To date, the pediatric use of $PTH^{1\text{-}34}$ has been limited to children with hypocalcemia due to a gain-of-function mutation in *CASR* and consequent hypercalciuric hypocalcemia—one form of familial isolated hypoparathyroidism. In development is an analogue of PTHrP ($PTHrP^{1\text{-}36}$) that increases lumbar spine BMD in postmenopausal women with osteoporosis by stimulating bone formation selectively without inducing hypercalcemia.[430,431]

Denosumab is a human monoclonal antibody to RANKL that binds tightly to its ligand and prevents its interaction with RANK, thereby inhibiting osteoclastogenesis. Denosumab thus acts as a pseudo-osteoprotegerin. In postmenopausal women with decreased bone mineralization, denosumab decreases bone resorption and increases lumbar spine BMD.[432] Strontium renalate is another agent in development for treatment of low bone mass in adults. Strontium is incorporated into the structure of bone mineral.[433]

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta (brittle bone disease) is a disorder of increased bone fragility due to low bone mass that varies in clinical severity from lethality in the perinatal period due to respiratory insufficiency to mildly increased susceptibility to fractures in later life.[132] The original Sillence classification of four types of osteogenesis imperfecta based on clinical characteristics and disease course has been expanded to include four additional types of this disorder and identification of mutant genes to which the illnesses can be attributed (Table 17-10).[132,434] The hallmark of each type is increased bone fragility, but severity varies—with type II being a lethal form and type I being a relatively benign form. In decreasing order of severity, type II > type VIII ≥ type III > types IV, V, VI, and VII > type I.

In osteogenesis imperfecta types I through IV, heterozygous loss-of-function mutations have been identified in one of the two genes *(COL1A1, COL1A2)* encoding procollagen subunits α1(I) and α2(I), respectively—which intertwine to form collagen type I in bone, skin, ligaments, tendons, sclerae, and teeth.[131,132] [As previously described, the triple helical structure of type I collagen consists of two collagen α1(I) (COL1A1) peptides and one collagen α2(I) peptide—each of which consists of triple repeats of glycine and two additional amino acids (often proline, hydroxyproline, or lysine).] Transmitted as an autosomal-dominant trait, insertion, duplication, frame-shift, or point mutations within *COL1A1* or *COL1A2* reduce the amount of collagen synthesized or alter its structure and properties—interfering with the assumption of a normal three-dimensional configuration and leading to decreased bone formation, low bone mass, and increased fracture risk (Figure 17-16).[435]

To an extent, the site of the more than 800 mutations identified within *COL1A1* or *COL1A2* is related to the clinical phenotype of osteogenesis imperfecta types I through IV. Mutations that lead to a stop codon result in a truncated procollagen product that is rapidly degraded. Thus, only normal collagen type I is produced (but in reduced mounts). Lethal mutations in *COL1A1* are those that alter an amino acid with a branched or charged side chain; those within the binding sites of the collagen monomer for integrins, matrix metalloproteins, fibronectin, and cartilage oligomeric matrix protein; and those that result in binding to and degradation of intact procollagen subunits.[131]

Lethal mutations in *COL1A2* are those that interfere with its binding to proteoglycans. Mutations (Arg-134Cys) in *COL1A1* may also be found in patients with classic Ehlers-Danlos syndrome (OMIM 130000) of hyperextensible skin and laxity of ligaments of the spine and large and small joints. Children with clinical features of osteogenesis imperfecta (osseous fragility) and Ehlers-Danlos syndrome have been described.[436] In these patients, the mutations have been concentrated within the first 90 aa of the helical region of collagen-α1(I) and prevent normal post-translational removal of the procollagen amino-propeptide. Although the mutant protein can be incorporated into collagen, the structural integrity of the product is impaired because its fibrils are thin and weak.[437]

Osteogenesis imperfecta type I (OMIM 166200) is an autosomal-dominant disorder (or new mutation in 33% of patients) due primarily to functionally null alleles—the result of splicing defects or point mutations that lead to insertion errors or truncation (COL1A1: Gly178Cys, Arg-963Ter, IVS26DS), which are mutations that result in decreased transport of procollagen-α1(I) into the cytoplasm or its release into matrix (thereby modestly decreasing production of intact procollagen type I). Its clinical manifestations are relatively benign: intensely blue sclerae present at birth that persist throughout adulthood, modestly low bone mass, infrequent fractures with little deformity (however, 15% of affected children develop deformities and 24% develop kyphoscoliosis before 10 years of age), low normal adult stature, hearing loss in 50%, mitral valve prolapse in 18%, and rarely dentinogenesis imperfecta (osteogenesis imperfecta type IB).

Mutations in *COL1A2* less frequently lead to the phenotype of osteogenesis imperfecta type I. Subjects with mutations in *COL1A1* more frequently have blue sclerae and taller stature than those with mutations in *COL1A2*. Osteogenesis imperfecta type II (OMIM 166210) is a disorder that is lethal in the perinatal period or in early infancy. It is

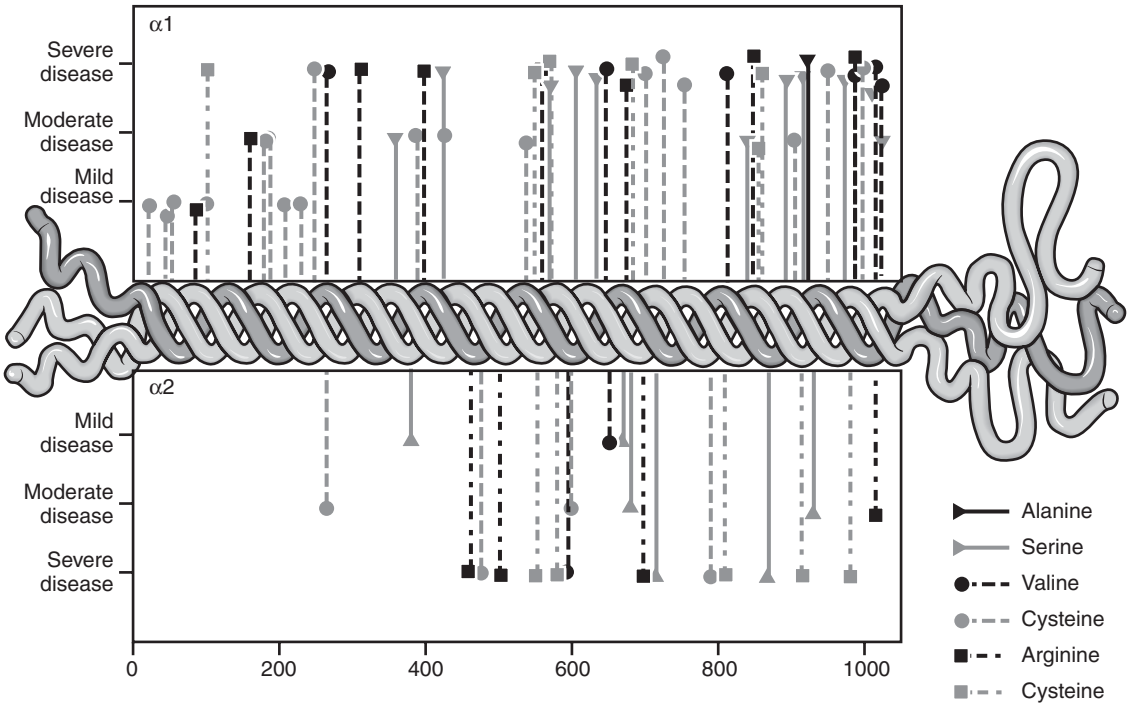

Figure 17-16 Mutations in *COL1A1* and *COL2A1* that result in glycine substitutions associated with osteogenesis imperfecta of variable clinical severity. [Reproduced with permission from Prockop DJ (2005). Type II collagen and avascular necrosis of the femoral head. N Engl J Med 352:2268–2270.]

usually the result of de novo heterozygous mutations in *COL1A1* or *COL1A2,* with alternative amino acid being substituted for glycine in the triple helical domains of the procollagen α1(I)/α2(I) chains (COL1A1: Gly94Cys, Gly391Arg, Gly1003Ser; COL1A2: Gly547Asp, Gly865Ser, Gly976Asp). These mutations lead to the synthesis of abnormal procollagen chains that bind to and thereby inactivate intact procollagen peptides in a dominant-negative manner, severely curtailing the synthesis of intact collagen type I.

Clinically, it is manifested by in utero fractures, long bone deformities, very little calvarial mineralization, and death due to respiratory insufficiency. A very similar phenotype (type IIB, OMIM 610854) is associated with homozygous loss-of-function mutations in the gene *(CRTAP)* encoding cartilage-associated protein. Osteogenesis imperfecta type III (OMIM 259420) is an autosomal-dominant trait due to point or frame-shift mutations in *COL1A1* (Gly154Arg, Gly844Ser) and *COL1A2* (Gly526Cys). It is characterized by recurrent fractures that lead to progressive bone deformities that are often apparent at birth, and by kyphoscoliosis, extreme short stature, blue sclerae that lighten with age, abnormal dentition (in 80% of children less than 10 years of age), and hearing loss.

Osteogenesis imperfecta type IV (OMIM 166220) is an autosomal-dominant disease usually associated with point mutations or small deletions in *COL1A2* (Gly586Val, Gly646Cys, Gly1012Arg) and occasionally in *COL1A1* (Gly175Cys, Gly832Ser). It is of variable severity, with prolonged survival, mild to moderate bone deformities, short stature, normal sclerae, dentinogenesis imperfecta, and hearing loss. One post-translational modification of type I procollagen is hydroxylation of proline and lysine residues by prolyl and lysyl hydroxylases, an essential step in normal collagen folding and stability. Prolyl 3-hydroxylase 1 [P3H1, also termed leprecan *(LEPRE1)*] specifically hydroxylates the proline residue at codon 986 in COL1A1, a reaction that requires interaction of P3H1 with CRTAP and cyclophilin B (chromosome 15, OMIM 123841).

CRTAP is expressed in the proliferative zone of developing cartilage and at the chondro-osseous junction. Cyclophilin B possesses peptidyl-prolyl cis-trans isomerase activity. *Crtap* knockout mice develop an osteochondrodysplasia (kyphoscoliosis, shortening of the proximal segment of the limbs consistent with rhizomelia) and severe osteopenia, the latter due to reduced production and alteration in the quality of osteoid and consequently decreased rate of mineral deposition.[438] Mice deficient in Crtap are unable to 3-hydroxylate the proline residue near the carboxyl terminus of bone COL1A1, leading to increased hydroxylation of lysine residues and resultant abnormal structure of the collagen fibril—changes that result in defective mineralization of bone collagen type I.

A recessive form of lethal osteogenesis imperfecta of unknown pathogenesis in which detailed analyses of *COL1A1* and *COL1A2* have been normal has been described. In 3 out of 11 patients with a recessive clinical form of lethal type II or severe osteogenesis imperfecta type III characterized by multiple fractures of the long bones (resulting in rhizomelic shortening of the limbs with externally rotated and abducted legs, poorly mineralized calvaria and ribs, proptotic eyes, and white or light blue sclerae), nonhydroxylated proline at codon 986 in bone COL1A1 has been demonstrated.[439]

This proved due to homozygous or compound heterozygous loss-of-function mutations in *CRTAP* [frame-shift

(c.879delT), 16 bp duplication in exon 1, nonsense (Gly276Ter), missense (Met1Ile), splice donor site of exon 1 at the first intronic nucleotide (IVS1 + 1G→C)] that interfered with effective hydroxylation of the proline residue at codon 986 of bone procollagen α1(I). Loss-of-function mutations in *LEPRE1* lead to impaired P3H1 activity and a severe form of osteogenesis imperfecta designated type VIII.[434] It seems likely that a mutation in the gene encoding cyclophilin B as well as in others that post-translationally modify collagen subunits may be identified in different patients with similar clinical manifestations but intact *COL1A1* and *COL1A2*.

Currently, there are four forms of osteogenesis imperfecta (types V, VI, VII, VIII) in which extensive analyses of the structures of *COL1A1* and *COL1A2* have been normal.[131,132] Osteogenesis imperfecta type V (OMIM 610967) is phenotypically similar to type IV and is characterized by autosomal-dominant transmission, moderate to severe bone fragility, moderate to mild growth retardation, dislocation of the radial head, mineralization of interosseous membranes, exuberant callous formation at fracture sites, white sclerae, and intact dental development. Histologically, there is irregular arrangement of lamellae. Approximately 5% of patients with osteogenesis imperfecta appear to have type V, the molecular cause of which is as yet unidentified.

Osteogenesis imperfecta type VI (OMIM 610968) is also phenotypically similar to type IV. It is characterized by a fish-scale pattern of lamellation of bone on microscopic examination. Type VI is found in approximately 4% of patients with osteogenesis imperfecta. Its inheritance pattern is unknown. Osteogenesis imperfecta type VII (OMIM 610682) has been identified in northern Quebec in a Native American population. Clinically, it is an autosomal-recessive disorder in which fractures are present at birth but the frequency of fractures declines with advancing age—particularly after adolescence. The sclerae are slightly bluish, and there is progressive skeletal deformation that leads to rhizomelic shortening of the limbs and restricted ambulation.

In patients with type VII, a homozygous mutation in *CRTAP* has been identified: specifically, inclusion of 73 bp of intron 1 into the genome of *CRTAP* due to alteration of one nucleotide (c.472, 1021C→G) that generates a cryptic splice donor site that extends exon 2. However, this alteration results in a frame-shift that permits more rapid degradation of CRTAP and consequently leads to decreased 3-hydroxylation of proline 986 in bone COL1A1. Thus, inactivating mutations in *CRTAP* can result in at least two clinically distinct forms of osteogenesis imperfecta (types IIB and VII)—as do mutations in *COL1A1* and *COL1A2*. The phenotype of osteogenesis type VIII (OMIM 610915) overlaps with those of types II and III. In addition to osseous fragility, it is associated with substantial growth retardation, white sclerae, and bulbous metaphyses. It is due to loss-of-function mutations in *LEPRE1* encoding P3H1.[434]

In addition to diffusely low bone mass, thin cortices, metaphyseal flaring, and fractures and bone deformities resulting therefrom, radiographic findings in subjects with osteogenesis imperfecta include wormian skull bones (frequent but not pathognomonic of osteogenesis imperfecta), platybasia that may compress overlying hindbrain, vertebral compression, and a triradiate pelvis.[131] Bone densitometry reveals decreased mineralization, the extent of which correlates to a degree with clinical manifestations. The diagnosis of osteogenesis imperfecta is established by clinical criteria and confirmed by genotyping of *COL1A1* and/or *COL1A2* or other pertinent gene(s)—although failure to detect a genetic mutation does not necessarily rule out this disorder. Occasionally, biopsy of the iliac crest and histologic examination of the bone may be necessary for subclassification of the disorder.

Determination of the rate of synthesis and forms of procollagen secreted by dermal fibroblasts in vitro permits identification of the forms and relative amounts of collagen subunits and intact proteins being synthesized (type I, type III, and so forth). Osteogenesis imperfecta type II can be identified prenatally by fetal ultrasonography. Types I, III, and IV can be determined prenatally by analysis of collagen synthesized by cells cultured from chorionic villus biopsies and by analysis of the procollagen genes.[440]

The basic management of patients with osteogenesis imperfecta is directed to prevention of fractures to the extent possible and to the treatment of fractures that occur by sound orthopedic procedures and by orthopedists familiar with this disorder. Rehabilitative services and physical therapy to improve muscle strength and mobility within the constraints of bone fragility are to be encouraged, as are protected ambulation and exercises such as swimming.[131] Introduction of bisphosphonates into the management of infants, children, and adolescents with osteogenesis imperfecta types I, III, and IV has been of substantial benefit. Patients with these disorders have responded to the intermittent intravenous administration of the bisphosphonate (pamidronate), with marked increase in bone mass and decline in fracture rate—as well as symptomatic improvement such as decreased pain and more facile mobility.[132,133,441]

Infants as young as 2 months of age have safely tolerated 4-hour intravenous infusions of pamidronate (0.5 mg/kg/day for 3 consecutive days every 6 to 8 weeks), realizing clinical improvement such as decline in bone pain (perhaps a placebo effect), increase in lumbar vertebral BMD of 86% to 227%, and decrease in fracture rate after 1 year of therapy.[131,442] In children (3–16 years of age), pamidronate administered as a 4-hour infusion (1.5–3.0 mg/kg/day) for 3 consecutive days every 4 months resulted in increases in lumbar spine BMD of 42% per year and increases in metacarpal cortical width of 27% per year. in decreased vertebral size, decline in vertebral fracture rate, and symptomatic improvement also occurred.

During 2 to 4 years of intravenous pamidronate administration, increase in vertebral (trabecular) bone mass and size are accompanied by decline in the extent of vertebral compression and fewer compressed vertebrae than in untreated patients.[443] In the iliac crest, bisphosphonates increase cortical bone thickness and trabecular number but not trabecular thickness. In metacarpals, bisphosphonates enhance cortical thickness. In treated subjects, the relative risk of long bone fracture may be a bit reduced—implying a beneficial effect of bisphospho-

nates on long bone cortical volume and hence on bone strength.[131,132,444] Oral alendronate (1 mg/kg/day) and intravenous pamidronate are reported to be equally effective in children with osteogenesis imperfecta, although data are limited and gastrointestinal side effects of oral bisphosphonate are of concern.[445]

Near-maximal benefits of bisphosphonates on lumbar vertebral BMD by DEXA (and on mean cortical width, cancellous bone volume, and trabecular bone formation rate by histomorphometric analysis of iliac crest bone biopsies) are achieved within the first 2 to 4 years of treatment, with little further change with more prolonged therapy.[446] Currently, because of the persistence of bisphosphonates in bone and their long-term effects it is suggested that these agents be administered to patients with osteogenesis imperfecta for approximately 2 to 4 years. Their positive effects on bone mass gain, reduced fracture rate, and functional well-being are often longer lasting.[447]

Care must be exercised when selecting a patient with osteogenesis imperfecta for treatment with bisphosphonates. It is currently recommended that these agents be employed only in patients with substantial disease, such as frequent fractures (more than two per year) and deformities of the long bones and vertebrae, irrespective of the specific mutation in the procollagen subunit, clinical type of osteogenesis imperfecta, or BMD.[133] Pamidronate has been the bisphosphonate most frequently administered to patients with osteogenesis imperfecta. Recent treatment recommendations utilizing this agent are: <2.0 years (0.5 mg/kg/day intravenously for 3 days every 2 months), 2.0 to 3.0 years (0.75 mg/kg/day for 3 days every 3 months), and >3.0 years (1 mg/kg/day to a maximum dose of 60 mg/day for 3 days every 4 months).[132]

Among the complications of bisphosphonate therapy are transient hypocalcemia and flu-like reaction of fever, vomiting, and rash after first exposure managed symptomatically. Although bisphosphonates decrease linear growth in experimental animals, experience in children indicates that over the span of several years these agents improve linear growth rate and height compared with untreated subjects with moderately severe forms of osteogenesis imperfecta.[441] Increase in the rate of linear growth has been reported during administration of recombinant human GH to children with osteogenesis imperfecta, but the effect has not been sustained—nor has treatment positively affected fracture risk.[132,441,448]

Bone marrow transplantation in five children with severe osteogenesis imperfecta has been reported to have been beneficial, but experience with this procedure has been variable.[449] As yet untested in osteogenesis imperfecta subjects is the use of PTH, $PTH^{1\text{-}34}$, or $PTHrP^{1\text{-}36}$. Gene therapy of osteogenesis imperfecta remains a goal. Selective inactivation of wt or mutant *COL1A1* in mesenchymal stem cells from two patients with severe forms of osteogenesis imperfecta (COL1A1: Gly773Ser, Gly1040Ser) has been accomplished. Cells in which survival and function of the wt gene and destruction of the mutant gene co-occur potentially permits their reintroduction into the affected host and normal collagen production.[450,451]

FIBROUS DYSPLASIA

Fibrous dysplasia involves the long bones and skull and may be monostotic, polyostotic, or panostotic. It primarily occurs in patients with the McCune-Albright syndrome (OMIM 174800) in association with large café-au-lait pigmentations and various endocrinopathies, including isosexual precocity, hypersomatotropism, thyrotoxicosis, and hyperadrenocorticism—as well as dysfunction in many other tissues (heart, liver, pancreas).[452] It is due to mosaicism for postzygotic somatic gain-of-function missense mutations (Arg201 to Cys, His, Ser, Gly) in *GNAS,* the gene encoding the α subunit of the Gs protein.[453]

The extent and severity of disease is determined by the point in development at which the mutation occurs and its tissue distribution. As a result of loss of intrinsic guanosine triphosphatase activity within the $G_s\alpha$ subunit, the stimulatory effect of $G_s\alpha$ on adenylyl cyclase is prolonged. The clones of mutated mesenchymal preosteoblasts proliferate, but their differentiation into mature osteoblasts is incomplete and their secreted matrix is abnormal. Continued expansion steadily erodes contiguous bone. These lesions can also synthesize FGF23 and lead to hyperphosphaturia, hypophosphatemia, and excess unmineralized osteoid and a rickets-like clinical state.[454]

Fibrodysplastic lesions are initially silent, whereas osteoclasts at the periphery of the lesions actively thin and compress bone cortices—ultimately resulting in bone pain and pathologic fractures of the long bones (particularly the proximal femoral metaphyses). Children between 6 and 10 years of age have the highest fracture rate (0.4 fractures per year). Within the skull base and facial bones, expansion of fibrous dysplastic lesions leads to disfiguration and compression of cranial nerves. Radiographically, the fibrodysplastic lesion is viewed as a cyst-like medullary structure with a ground-glass consistency. Histologically, there are abundant immature bone marrow stromal cells, incompletely differentiated osteoblasts, poorly formed bony trabeculae with excess undermineralized osteoid seams characteristic of osteomalacia, and islands of cartilage.

The clinical manifestations of fibrous dysplasia depend on the sites and extent of bone involvement and associated endocrinopathies, particularly GH excess.[455] Diagnosis of fibrous dysplasia is based on clinical characteristics and confirmation of the genetic mutation in *GNAS.* In addition to managing the multiple endocrinopathies and organ defects, attention must be paid to the osseous lesions. Fractures are repaired by standard techniques, including intramedullary nailing when indicated. Occasionally, it may be feasible to evacuate a fibrodysplastic lesion surgically and to fill the cavity with bone grafts. In children with fibrous dysplasia, the bisphosphonate pamidronate has proven useful in ameliorating bone pain (but not the skeletal lesions).[456,457]

HIGH BONE MASS

Abnormally increased bone mass is the consequence of disruption of the normal equilibrium between the velocities of bone formation and resorption. Thus, it may

be due to decrease in the rate of bone resorption or to an increase in the rate of bone formation. Increase in cortical bone width is termed hyperostosis. Thickening of trabecular bone is termed osteosclerosis.[136] Table 17-11 lists selected dysplastic, metabolic, and other diseases associated with increased bone density in children and adolescents.

Failure of osteoclast-mediated bone resorption leads to osteopetrosis ("marble bone disease"), a group of heritable disorders with heterogeneous manifestations.[458] Histologically, osteopetrotic bone is characterized by quiescent osteoclasts with few ruffled borders and retained calcified cartilage formed during endochondral ossification (primary spongiosa) due to failure of reabsorption of immature bone. Although densely packed with mineral, osteopetrotic bone is quite fragile because the abnormality in bone remodeling due to decreased osteoclastic bone resorption leads to incorporation of weak calcified growth plate cartilage into bone and to delay in repair of microfractures.

TABLE 17-11

Disorders of Bone Mineralization: High Bone Mass

I. Decreased Bone Resorption
A. Osteopetrosis
1. Autosomal recessive (infantile) (*TCIRG1*, *CLCN7*, *OSTM1*)
a. Transient
2. Intermediate (*CLCN7*)
3. Autosomal dominant (adult) (*LRP5*, *CLCN7*)
4. Immunodeficiency, lymphedema, ectodermal dysplasia (*IKBKG*)
5. Carbonic anhydrase II deficiency (*CA2*)
6. Pycnodysostosis (*CTSK*)
7. Neuronal storage disease
8. Drug-induced - bisphosphonates

II. Increased Bone Formation
A. Activating Mutations of *LRP*
1. Autosomal-dominant high bone mass
2. Endosteal osteosclerosis (van Buchem disease type 2)

B. Inactivating Mutations of *SOST*
1. Sclerosteosis
2. Van Buchem disease type 1

III. Osteosclerosis
A. Dysplasias
1. Dysosteosclerosis
2. Infantile cortical hyperostosis (Caffey disease) (*COL1A1*)
3. Juvenile Paget disease (*TNFRSF11B*)
4. Metaphyseal dysplasia (Pyle disease)
5. Osteopoikilosis (*LEMD3*)
6. Progressive diaphyseal dysplasia (Camurati-Engelmann disease) (*TGFB1*)
7. Tubular stenosis, type 1 (Kenny-Caffey syndrome) (*TBCE*)

B. Metabolic Disorders
1. Fluorosis
2. Heavy metal poisoning
3. Hypervitaminosis A, D
4. Hypoparathyroidism, pseudohypoparathyroidism
5. Milk-alkali syndrome

C. Other
1. Hepatitis C-associated osteosclerosis
2. Ionizing radiation
3. Sarcoidosis
4. Sickle cell disease (*HBB*)
5. Tuberous sclerosis (*TSC1*)

Modified from Whyte MP (2006). Sclerosing bone disorders. In Favus MJ (ed.), *Primer on the metabolic bone diseases and disorders of mineral metabolism, Sixth edition.* Washington, D.C.: American Society for Bone and Mineral Research 398–414.

Radiographically, osteopetrosis is characterized by diffuse increase in bone mass, diaphyseal/metaphyseal widening with an Ehrlenmeyer flask appearance, alternating bands of sclerotic and lucent bone at the ends of the long bones, iliac crest and vertebrae, sclerotic changes at the base of the skull, narrow medullary cavities, and pathologic fractures.[136] Cranial computed tomography often reveals narrowing of the bony canals through which cranial nerves (II, III, IV, VII, VIII) pass. Classically, three clinical forms of osteopetrosis have been delineated. However, as knowledge of the genetic mutations responsible for this disease are being identified this classification is being replaced.

The infantile form of osteopetrosis (OMIM 259700) is an autosomal-recessive disorder (Albers-Schonberg disease) with attenuated growth (particularly of the limbs), delayed development, increased fracture rate, and failure of tooth eruption. Bony overgrowth leads to maldevelopment of the paranasal sinuses and to symptomatic nasal stuffiness. Narrowing of cranial foramina compromises cranial nerve function (II, III, VII, VIII), with consequent blindness and deafness. Decrease in bone marrow volume leads to depressed intramedullary hematopoiesis, anemia, and leukopenia—partially compensated by extramedullary hematopoiesis and ensuing hepatosplenomegaly, with consequent increased susceptibility to infection and hemorrhage.

Retention of teeth within the sclerotic jaw leads to recurrent and persistent mandibular and maxillary osteomyelitis. Physical examination reveals short stature, macrocephaly, frontal bossing, and small facial features. Death usually occurs often within the first decade of life due to sepsis, anemia, or hemorrhage. Autosomal-recessive osteopetrosis may be due to biallelic mutations in a subunit of the osteoclast's vacuolar proton pump *(TCIRG1),* its chloride channel *(CLCN7),* or the osteopetrosis-associated transmembrane protein-1 *(OSTM1).*

The intermediate form of osteopetrosis is transmitted as an autosomal-recessive trait and is associated with short stature, macrocephaly, recurrent fractures, variable compromise of cranial nerve function, abnormal dental development predisposing to osteomyelitis of the mandible or maxilla, and anemia. Pathogenetically, it likely represents the variable penetrance of one of the genetic mutations associated with the infantile form of osteopetrosis—predominantly of *CLCN7.* There are two clinical and radiographic forms of autosomal-dominant osteopetrosis previously thought to be manifested only in the adult.

Type I (OMIM 607634) is characterized by an enlarged and dense cranial vault and diffuse vertebral sclerosis, and is related to activating mutations of *LRP5.* It is not associated with an increase in fracture rate as bone strength is increased. Type II (OMIM 166600) is typified by thickening of the vertebral end plates, resembling "bone within bone" and resulting in a "rugger jersey spine" and sclerotic

bands of bone in the pelvis and base of the skull.[459] It is a variant of Albers-Schonberg disease that results from heterozygotic mutations in *CLCN7.*[136,460] Affected subjects manifest cranial nerve compromise (16%), mandibular and nonmandibular osteomyelitis (19%), osteoarthritis of the hip (27%), and fractures (78%).[459]

Clinical evidence of the disease tends to worsen over time. However, the expression of the trait is variable. Thus, one-third of carriers of an inactivating mutation in *CLCN7* have no radiographic or clinical manifestations—although they do have significantly higher BMD than do subjects with the wt gene.[461] In one-quarter of clinically apparent patients with a heterozygous loss-of-function mutation in *CLCN7,* the expression of illness (fractures, osteomyelitis, compromised vision) is identifiable at birth or early in infancy or childhood. Patients with radiologic/clinical manifestations of this disorder have elevated serum concentrations of tartrate-resistant acid phosphatase and the BB isoform of creatine kinase elaborated by osteoclasts. These values are normal in unaffected carriers.[462]

Identification of many of the genes that regulate osteoclastogenesis and osteoclast function has greatly increased our understanding of the molecular mechanisms underlying experimental models of osteopetrosis. There are more than 17 murine models of osteopetrosis involving a litany of molecules that regulate osteoclastogenesis (Figure 17-17).[458,463] By mid 2007, five genetic mutations that impeded resorption of bone had been identified in patients with osteopetrosis. As anticipated, they related to abnormalities in osteoclastogenesis or function—particularly the efficiency of acidification of the resorption lacuna beneath the osteoclast's ruffled membrane and mineral dissolution or enzymatic degradation of organic bone matrix. The syndrome of osteopetrosis, lymphedema, anhidrotic ectodermal dysplasia, and immunodeficiency (OL-EDA-ID, OMIM 300301) has been linked to an inactivating mutation in a modulator of NFκB—an essential transcription factor for differentiation and function of osteoclasts.[464,465]

The inhibitor of the kinase of kappa light polypeptide gene enhancer in B cells gamma subunit *(IKBKG)* is also termed NFκB essential modulator (NEMO). IKBKG is a 412-aa component of the IκB kinase complex that activates NFκB. The substitution of guanine for adenine at N:1259 (A1259G) results in a change from a stop codon to tryptophan (Ter420Trp), permitting incorporation of an additional 27-aa component at the carboxyl terminus of the protein and resulting in decreased function of the product and 50% to 60% decline in activation of NFκB and hence in osteoclastogenesis.

Carbonic anhydrase II (one of several zinc metalloisoenzymes) is a protein expressed in osteoclasts, erythrocytes, brain, and kidney. It regulates the formation of carbonic acid from water and carbon dioxide (CO_2 + $H_2O \rightarrow H_2O_3$), which then dissociates to form proton/hydrogen (H^+) and bicarbonate ($HCO3^-$) ions. Loss-of function homozygous or compound heterozygous (Lys-17Glu, Tyr40Ter, His107Tyr) mutations in CA2 lead to an autosomal-recessive disease that presents in childhood with failure to thrive, short stature, visual impairment,

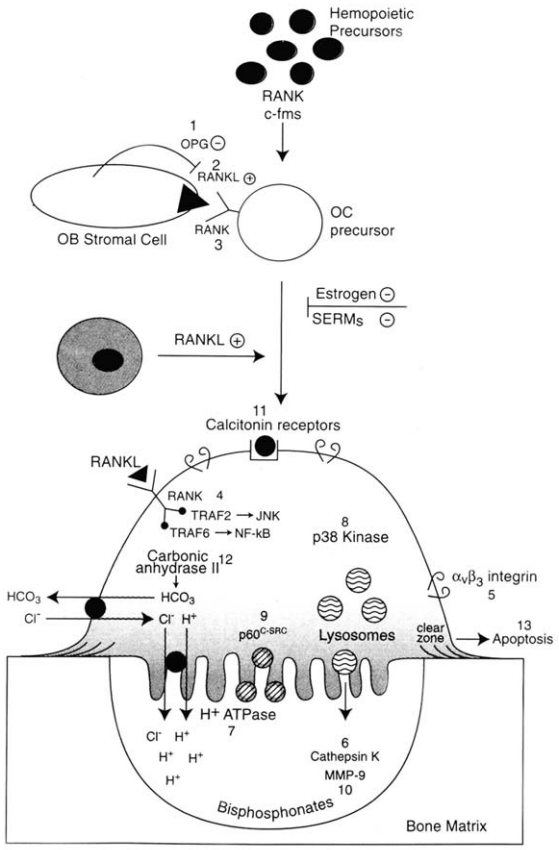

Figure 17-17 Sites at which pharmacologic agents may be targeted to affect osteoclast production and/or function: 1-4 (blockade of the RANK/RANK ligand/OPG signaling pathway of osteoclastogenesis), 5 (inhibition of $\alpha_v\beta_3$ integrin receptor binding to bone surface), 6 (antagonism of cathepsin K protease), 8 (inhibition of p38 kinase, an enzyme important in the inflammatory reaction), 9 (blocking of $p60^{C\text{-}SRC}$ kinase, an enzyme important in osteoclast activation), 10 (inhibition of matrix metalloproteinase-9), 11 (agonist ligands of the calcitonin receptor with enhanced function), 12 (inhibition of carbonic anhydrase II), and 13 (enhancement of osteoclast death). [Reproduced with permission from Rodan GA, Martin TJ (2000). Therapeutic approaches to bone diseases. Science 289:1508–1514.)

and developmental delay in association with mild proximal and severe distal renal tubular acidosis, cerebral calcifications within the cortex and basal ganglia, and osteopetrosis with increased fracture risk.[136] Osteopetrosis is of modest severity and is usually nonprogressive. It may even improve at puberty.

After generation by carbonic anhydrase II, H^+ is extruded from the osteoclast into the subobsteoclastic resorption lacuna through transporters and proton pumps. *TCIRG1* (T-cell immune regulator 1) encodes an 822-aa 116-kDa protein that is a subunit of the osteoclast's vacuolar proton pump (H^+-ATPase). [By alternative splicing, this gene also encodes a 614-aa protein (TIRC7) essential to activation of T lymphocytes.] Biallelic-inactivating (missense, nonsense, deletion, splice site) mutations in *TCIRG1* whose loss impairs transport of H^+ and thus

decreases bone mineral resorption have been found in 50% of subjects with the neonatal/infantile form of lethal osteopetrosis (OMIM 259700).[466,467]

Loss-of-function mutations in *CLCN7,* a chloride channel expressed in the ruffled membrane of the activated osteoclast, also impair acidification of the subosteoclastic resorption space and hence mineral dissolution. Heterozygotic-inactivating mutations (Arg767Trp) of *CLCN7* lead to the autosomal-dominant form of osteopetrosis (OMIM 166600)—whereas homozygous mutations (Leu766Pro) are found occasionally in infants with the lethal autosomal-recessive form of this disease (whose parents may even be clinically normal).[460,468] *CLCN7* is coexpressed with and complexed to osteopetrosis-associated transmembrane protein 1 *(OSTM1)* in endosomes and lysosomes and in the ruffled membrane of activated osteoclasts.[469] By decreasing post-translational stability of CLCN7, loss-of-function mutations in *OSTM1* have been pathogenetically related to autosomal-recessive lethal osteopetrosis in a subset of patients.[470,471]

The murine homolog of *OSTM1* is *Gl* (Grey-lethal), a mouse model of osteopetrosis. Related to the long-acting inhibitory effects of bisphosphonate on bone modeling and remodeling, administration of high doses of intravenous pamidronate (2800 mg) over a 3-year period resulted in an acquired osteopetrosis-like disorder in a 12-year-old boy with unexplained hyperalkaline phosphatasemia that persisted for at least several years after this agent was discontinued.[426] The metaphyses were extremely dense and club-shaped, the base of the skull sclerotic, and the vertebral endplates thickened. Histologically, iliac crest biopsy revealed bars of calcified cartilage and quiescent osteoclasts. Despite the severity of the radiographic and microscopic findings, the patient was clinically well—with normal growth and without evidence of bone marrow suppression or extramedullary hematopoiesis, although the risk for future fractures may have been increased.

A multidisciplinary team skilled in the management of patients with osteopetrosis is essential to the optimal care of infants and children with this disorder. In addition to appropriate orthopedic and neurosurgica input, medical therapy may at times be helpful. Nonspecific treatment with interferon-γ and high doses of calcitriol has led to arrest of disease progression and even its regression in some osteopetrotic children.[136,472] In this setting, calcitriol may act as an osteoclast-activating factor—whereas interferon γ indirectly stimulates osteoclast formation and increases generation of superoxide in osteoclasts, an important factor for osteoclast-mediated bone resorption.[473] Some children improve after bone marrow transplantation from human leukocyte antigen-identical donors with replacement of defective osteoclasts by normal osteoclast progenitor cells.[136]

Hypercalcemia may complicate the post-transplantation period as osteoclast function resumes. It can be managed with dietary restriction, calcitonin, and occasionally bisphosphonate administration. With improved treatment, there has been somewhat increased life span and improved developmental progress. Osteopetrosis due to deficiency of carbonic anhydrase II is not corrected by restoration of normal systemic acid-base balance, but bone marrow transplantation may be useful.[136] Identification and correction of the specific underlying gene defect may ultimately be feasible in patients with osteopetrosis.[467]

Pycnodysostosis (OMIM 265800) is clinically manifested by disproportionate short stature during infancy and childhood, with macrocranium and open cranial sutures, high forehead, small facial features, proptosis, bluish sclerae, beaked and pointed nose, micrognathia, highly arched palate, retained primary teeth, short fingers with hypoplastic nails, narrow thorax, pectus excavatum, and kyphoscoliosis with lumbar lordosis.[136] Radiologically, there is increased bone density that becomes progressively worse with age. Susceptibility to fractures is increased. The clavicles are slim and hypoplastic laterally. Ribs, distal phalanges, and hyoid bone may be partially or totally absent.

Laboratory data and bone histology are basically normal, although there is evidence of decreased osteoblastic and osteoclastic activity. An abundance of osteoclasts with ruffled borders surrounded by enlarged clear zones suggested that dissolution of bone mineral was normal but that degradation of matrix was abnormal in these patients. Indeed, pycnodysostosis is due to biallelic loss-of-function mutations in *CTSK*. This gene encodes cathepsin K, the osteoclast's lysosomal cysteine protease that degrades organic matrix after the mineral phase of bone has been reabsorbed.[137] Among the genetic abnormalities found in patients with pycnodysostosis have been unipaternal isodisomy for chromosome 1, with paternal *CTSK* harboring an inactivating Ala277Val mutation; Leu9Pro substitution in the signal peptide of the precursor form of the enzyme protein, preventing completion of its post-translational processing; and Ter330Trp substitution, permitting the addition of 19 amino acids to the carboxyl terminus of this enzyme.

In contrast with diseases that increase bone mass by decreasing bone resorption are those disorders that primarily increase bone formation. An example of the latter is the familial relatively benign form of autosomal-dominant high bone mass (OMIM 601884) that is associated with a heterozygous gain-of-function mutation (Gly171Val) in *LRP5*.[474] Loss-of-function mutations in the same gene are associated with idiopathic juvenile osteoporosis, the osteoporosis-pseudoglioma syndrome, and familial exudative vitreoretinopathy. LRP5 (and its homolog LRP6) is a co-receptor for Wnt proteins whose primary receptor is Frizzled.

After binding to LRP5 and Frizzled, the Wnt glycoprotein activates a canonical pathway that involves repression of glycogen synthase kinase 3 and leads to dephosphorylation of β-catenin—permitting its translocation to the nucleus, where it interacts with T-cell factor/lymphoid enhancing factor to control target genes that divert the mesenchymal stem cell into the track leading to osteoblastogenesis.[475] In the mature osteoblast, β-catenin stimulates expression of osteoprotegerin—thus impairing osteoclastogenesis. Dickkopf and sclerostin are proteins that bind to the extracellular domain of LRP5 and internalize the receptor complex, thereby blocking Wnt signaling.[476]

Mutations in *LRP5* associated with high bone mass are clustered near the amino terminal of its extracellular domain at the sites of binding to Dickkopf and sclerostin.[419] The Gly171Val mutation in *LRP5* interferes with the binding of LRP5 to Dickkopf and thus prolongs the interaction of LRP5 with Frizzled, thereby augmenting the Wnt signal and increasing bone formation.[477,478] Although generally benign, activating mutations of *LRP5* may also be associated with neurologic complications such as hearing loss, headaches, and pain in the extremities.[419]

In some families, heterozygous activating mutations (Ala242Thr) of *LRP5* and exuberant bone formation have been associated with autosomal-dominant generalized endosteal osteosclerosis (van Buchem disease type 2, OMIM 607636) or even osteopetrosis (Gly171Arg, Thr253Ile). However, the dense bones encountered in these subjects are not prone to fracture (as in classic forms of osteopetrosis). Sclerosteosis (OMIM 269500) is an autosomal-recessive disorder first manifested in childhood and characterized by very thick peripheral and cranial bones with calvarial overgrowth, leading to facial disfigurement, entrapment of cranial nerves VII and VIII, increased intracranial pressure, and brain stem compression.[136]

Affected patients also have variable asymmetric cutaneous or bony syndactyly of the index and middle fingers and excessive somatic growth. Sclerosteosis is due to biallelic loss-of-function mutations in *SOST,* the gene that encodes sclerostin—a 213-aa peptide secreted primarily by osteocytes embedded within bone. Normally, sclerostin inhibits Wnt-mediated bone formation by binding to and internalizing LRP5 (the co-receptor for Wnt).[475] When sclerostin activity is decreased, increased bone formation ensues. In heterozygous carriers of inactivating mutations in *SOST,* bone mass is increased (but not to pathologic levels).[479] van Buchem disease type 1 (OMIM 239100), an autosomal-recessive form of generalized osteosclerosis, is due to biallelic deletion of a 52-kb noncoding SOST-specific regulatory region approximately 35 kb downstream of the intact gene itself that results in loss-of-function of *SOST*.[480] Thus, van Buchem disease type 1 and sclerosteosis are allelic disorders.

Progressive diaphyseal dysplasia (Camurati-Englemann disease, OMIM 131300) is an autosomal-dominant cranial-peripheral hyperostotic disorder with variable expressivity that presents in children with problems such as limping, waddling gait, and/or leg pain, fatigue, and nonprogressive muscular weakness. Radiographically, there is symmetrical cortical thickening (hyperostosis) due to increased periosteal and endosteal bone formation in the diaphyses of the long bones, axial skeletons, and skull.[136,481] Pathogenetically, this disorder is primarily due to missense mutations within the latency-associated peptide domain of the precursor propeptide of TGFβ1 *(TGFB1)*.

Normally, after post-translational processing two latency-associated peptides are noncovalently linked to two mature TGFβ1 peptides to form a latency complex. Mutations within the latency-associated peptide domain of *TGFB1* (particularly at codon 218, a mutational hot spot) impair this association, resulting in premature activation of TGFβ1 and consequent stimulation of bone formation and repression of bone resorption.[482] TGFβ1 also inhibits myogenesis and adipogenesis. Because of the inhibitory effects of glucocorticoids on bone formation and its stimulatory effects on bone resorption, short courses of these agents have been useful in alleviating many of the clinical symptoms and radiologic abnormalities in patients with progressive diaphyseal dysplasia.[481] However, long-term therapy with glucocorticoids is not advised.

ECTOPIC CALCIFICATION AND OSSIFICATION

Extraskeletal calcification may occur in a number of hypercalcemic, hyperphosphatemic, or dystrophic states (renal failure, hypo- and hyperparathyroidism, sarcoidosis, after cell lysis induced by cancer chemotherapy, subcutaneous fat necrosis, dermatomyositis, atherosclerosis)—as well as in specific diseases (e.g., PHP type IA, McCune-Albright syndrome).[483] Familial tumoral calcinosis (OMIM 211900) presents in childhood with recurrent bone pain, extensive cutaneous, periarticular and vascular calcifications, and periarticular hard and lobulated masses. In some patients, the ectopic calcifications may be confined to the eyelids. It is characterized radiographically by cortical hyperostosis, periosteal reaction, and mineral deposits around large joints (particularly hips and shoulders).[484-486]

Laboratory studies reveal marked hyperphosphatemia and relative hypophosphaturia due to increased renal tubular reabsorption of phosphate and inappropriately normal or elevated serum calcitriol levels, because despite hyperphosphatemia PTH secretion is not increased and synthesis of calcitriol and intestinal calcium absorption persist. The disorder is due to functional loss of FGF23 action and consequently unhindered renal tubular reabsorption of phosphate. The pathophysiology of this disorder is thus the mirror image of that associated with XHR, ADHR, and tumor-induced osteomalacia in which there is exaggerated FGF23 production and activity leading to hyperphosphaturia and consequent hypophosphatemia, rickets, and osteomalacia.

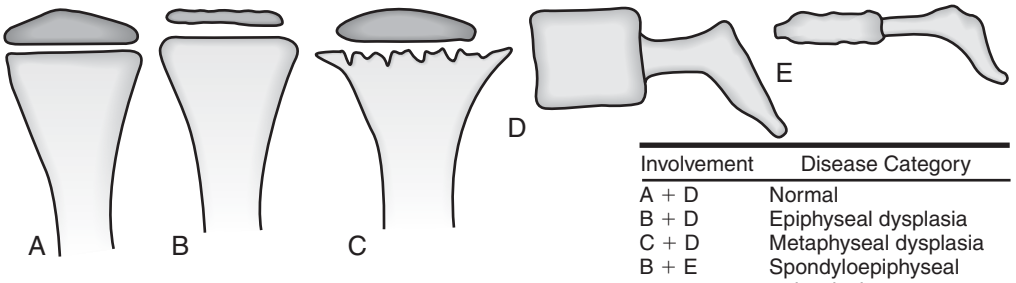
Familial tumoral calcinosis is genetically heterogeneous. Homozygous inactivating mutations (Met96Thr, Ser129Phe) in *FGF23* have been identified in a few patients with this disorder.[484,487] More commonly detected in patients with familial tumor calcinosis are biallelic loss-of-function microdeletions and splice site and missense mutations (Arg162Stop, Thr272Lys) in *GALNT3* (UDP-N-acetyl-alpha-D-galactosamine: polypeptide N-acetylgalactosaminyltransferase 3). The product of GALNT3 is a glycosyl transferase that initiates O-glycosylation in which N-acetylgalactosamine is the first sugar in the side chain, a step essential to secretion of intact and functional FGF23.[488] Failure to O-glycosylate FGF23 at Thr178 in the golgi apparatus permits its rapid intracellular cleavage between Arg179 and Ser180 to biologically inactive amino- and carboxyl-terminal fragments.[485,489]

Serum concentrations of intact FGF23 are low or nondetectable, whereas carboxyl-terminal FGF23 levels are elevated in patients with familial tumoral calcinosis due to either gene mutation. Therapy with an oral phosphate binder and the carbonic anhydrase inhibitor acetazolamide has resulted in hyperphosphaturia and reabsorption of

ectopic calcifications without change in serum phosphate or calcium concentrations.[485,490] The hyperostosis hyperphosphatemia syndrome (OMIM 610233) is a clinical variant of familial tumoral calcinosis and is due to mutations in *FGF23* or *GALNT3*. Symptoms and signs may precede development of the more typical phenotype of familial tumoral calcinosis.[489,491]

Fibrodysplasia ossificans progressiva (FOP, OMIM 135100) is a disabling disorder of ectopic bone formation that may develop spontaneously or at sites of injury. It leads to ankylosis of all major joints, which severely limits mobility.[492] It is characterized by progressive ectopic ossification of muscle and connective tissue, leading to immobility of the mandible, neck, spine, hips, and other joints and to the development of a second skeleton that encases and imprisons the body. The disorder may be present at birth and is often manifest by 5 years of age. It is also associated with monophalangic big toes, deafness, scalp baldness, and mild developmental delay. Microscopically, there is normal endochondral osteogenesis occurring at an ectopic site.

Although primarily sporadic because affected subjects rarely reproduce, FOP can be transmitted as an autosomal-dominant trait. This disease is due to a highly specific (Arg206His) mutation in *ACVR1* (activin A receptor, type 1), to date the only mutation identified in these patients. Activins are members of the TGFβ superfamily that includes the BMPs as well as the inhibins and Mullerian-duct-inhibiting factor. The Arg206His mutation in *ACVR1* resides at the junction of the receptor's glycine-serine activation and tyrosine kinase domains and results in a constitutively active receptor product that directs the pluripotent mesenchymal stem cell into the chondrogenic pathway, leading to (ectopic) endochondral new bone formation. BMPs alone are able to stimulate complete endochondral osteogenesis in ectopic sites.[493]



BMP4 induces osteogenesis but is also required for commitment of the stem cell to the adipocyte pathway of development.[494] *BMP4* and the genes encoding its coreceptors (e.g., *BMPR1A*) are not mutated in patients with FOP. *BMP4* (but not *BMPR1A*) is overexpressed in cells from patients with FOP. However, there is an increased number of plasma membrane BMPR1A receptors in their cells due to a slow rate of ligand-mediated receptor internalization and consequently decreased rate of degradation—which might lead to prolonged BMP4-mediated intracellular signaling and function.[493] Overall, data suggest that BMP4-directed osteogenic activity is enhanced and the adipogenic pathway circumvented in patients with FOP. However, the role that the mutated ACVR1 plays in the pathogenesis of this disease is unclear at present. Management of these patients is primarily symptomatic to the extent possible, although immunosuppression may diminish the intensity of extraskeletal ossification.[495]

Progressive osseous heteroplasia (POH, OMIM 166350) is characterized by multiple foci of dermal membranous bone formation (osteoma cutis) beginning in infancy in the absence of any local injury or inflammatory insult. Lesions may develop on the trunk, extremities, or digits and may be asymptomatic or painful. Over time, ossification involving skeletal muscle and deep connective issue evolves. The disorder occurs in both genders. POH is transmitted as an autosomal-dominant trait and is due to inactivating mutations of the *GNAS* allele inherited from the father.[496,497] Identical mutations in *GNAS* may be clinically manifested as POH or PPHP in different members of the same family.

Osteochondrodysplasias

The osteochondrodysplasias form a heterogeneous group of malformations of cartilage and bone that have been grouped according to clinical and radiologic characteristics into those involving long bone growth alone (epiphyseal, metaphyseal, and/or diaphyseal dysplasias), long bones and vertebrae (spondyloepiphyseal and/or spondyloepimetaphyseal dysplasias), and variants thereof (Figure 17-18).[498] The genetic skeletal disorders have been classified into 37 groups based on the underlying genetic mutations and/or radiographic manifestations.[499] Mutations in one gene may give rise to several clinically defined disorders (Table 17-12).

These disorders are of interest not only because of the diagnostic and therapeutic clinical challenges they present but because they have identified many factors that normally regulate cartilage and bone development. Achondroplasia (OMIM 100800), the most common of the human chondrodystrophies (1/15,000–40,000 live births), is due to gain-of-function mutations in *FGFR3*—the gene

Involvement	Disease Category
A + D	Normal
B + D	Epiphyseal dysplasia
C + D	Metaphyseal dysplasia
B + E	Spondyloepiphyseal dysplasia
B + C + E	Spondyloepimetaphyseal dysplasia

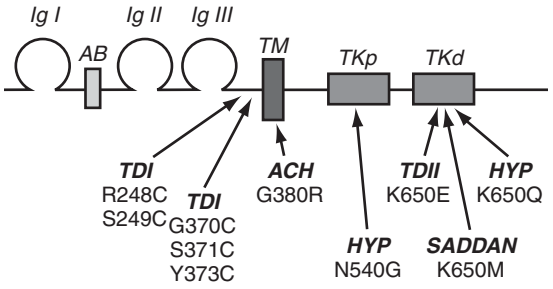

Figure 17-19 Mutations in fibroblast growth factor receptor-3 leading to achondroplasia (ACH), hypochondroplasia (HYP), thanatophoric dysplasia (TD) types I and II, and severe achondroplasia-developmental delay-acanthosis nigricans (SADDAN). [Reproduced with permission from Horton WA (2006). Molecular pathogenesis of achondroplasia. Growth Genet Horm 22:49–54.]

encoding fibroblast growth receptor 3. It is transmitted as an autosomal-dominant disorder but with a high rate of spontaneous mutations (primarily of the paternal allele). Clinically, it is manifested by short limbs but normal trunk length, large head, frontal bossing, and depressed nasal bridge. It is complicated by increased risk for cervical cord compression and spinal stenosis.[500,501]

FGFR3 is a transmembrane protein with three immunoglobulin domains in the extracellular region of the receptor and two tyrosine kinase domains in its intracellular portion (Figure 17-19). Three additional clinically distinct osteochondrodysplasias are associated with mutations in the same gene. Thanatophoric dysplasia is characterized by severe bony malformations, particularly of the skull, long bones, and ribs—the latter leading to respiratory insufficiency and early death. There are two radiographic forms of this disorder (I and II). Severe achondroplasia—developmental delay—acanthosis nigricans (SADDAN) is a clinical phenotype intermediate between those of thanatophoric dysplasia and achondroplasia. Hypochondroplasia is a clinically less severe manifestation of mild short-limbed (rhizomelic) short stature of variable severity that presents in mid-childhood.

Mutations in *FGFR3* correlate with the clinical phenotype. Achondroplasia is most often (98%) associated with a missense mutation (Gly380Arg) in its transmembrane domain. Thanatophoric dysplasia type I is related to mutations (Arg248Cys, Gly370Cys) in the extracellular ligand-binding region next to the transmembrane region of the receptor. Type II is related to a mutation (Lys650Glu) in the distal tyrosine kinase domain. SADDAN is also the result of a Lys650Met mutation. Hypochondroplasia has been associated with mutations within the proximal (Asn540Gly in 60%) and distal (Lys650Gln) tyrosine kinase domains, respectively, as well in the immunoglobulin domains of the extracellular region (Ser84Leu, Arg200Cys) and transmembrane domain (Val381Glu) of *FGF23*.[501,502]

It is noteworthy that different mutations at Lys650 result in three distinct clinical phenotypes. Patients with Muenke nonsyndromic coronal craniosynostosis also have a mutation (Pro250Arg) in FGFR3. In chondrocytes, constitutively active FGFR3 initiates ligand-independent autophosphorylation of tyrosine residues within its cytoplasmic domain that then propagate signal through the MAPK and signal transducer and activator of transcription pathways—resulting in inhibition of mitosis, matrix synthesis, and terminal (hypertrophic) differentiation. Thus, FGFR3 normally functions as a negative regulator of cartilage formation. As a single-gene disorder, it is possible to identify a mutation in *FGFR3* in an affected fetus by analysis of fetal cell-free DNA in maternal plasma if the mother is unaffected.[503]

A loss-of-function mutation (Arg621His within the distal tyrosine kinase domain) in *FGFR3* has been identified in a family whose members display the phenotype of tall stature, camptodactyly, and hearing loss.[504] Activating mutations in *FGFR1* and *FGFR2* have been associated with chondrodysplasias complicated by premature craniosynostosis (Pfeiffer, Apert, Crouzon, Jackson-White, and Beare-Stevenson cutis gyrata syndromes). Interestingly, mutations in *FGFR1* have also been associated with hypogonadotropic hypogonadism (OMIM 147950), as FGFR1 is an essential neuronal migration factor.[505] Mutations in *FGFR4* have not been associated with osteochondrodysplasias to date.

Defective formation of several types of collagen due to mutations in *COL2A1, COL9A1, COL9A2, COL10A1, COL11A1,* and *COL11A2* result in a large number of skeletal malformations depending on the site and developmental timing of the synthetic error (Table 17-12). Abnormalities of sulfate transport, collagen matrix protein sulfation, and sulfatase activity have resulted in several chondrodysplasias. Spondylepimetaphyseal dysplasia (OMIM 603005) is due to a biallelic loss-of-function mutation (Ser438Ter) in the gene *(PAPSS2)* encoding 3'-phosphoadenosine-5'-phosphosulfate synthase 2—an enzyme with dual activities. It catalyzes the synthesis of adenosine 5'-phosphosulfate and its phosphorylation to 3'-phospho-adenosine 5'-phosphosulfate, the universal sulfate donor necessary to sulfation of cartilage and bone matrix proteins.[506]

Clinical manifestations of this disorder include short limbs, kyphoscoliosis, brachydactyly, and enlarged knee joints. In the mouse model of this disease, there is decreased sulfation of matrix proteoglycans—resulting in short chondrocyte columns with irregularly aligned cells and decrease in the number and size of hypertrophic chondrocytes. Loss-of-function mutations (insertions, missense, nonsense) in *SOX9,* a transcription factor expressed in both developing chondrocytes (where it is coexpressed with *COL2A1)* and in the genital ridges during gonadal differentiation, cause campomelic dysplasia (OMIM 114290) and male-to-female sex reversal in 75% of affected 46XY subjects.

Clinically, this disorder is characterized by prenatal onset of bowing of tubular bones, hypoplastic scapulae, 11 ribs, cleft palate, and micrognathia—leading often to neonatal death. Heterozygous pseudoautosomal microdeletions and intragenic inactivating mutations (Leu 132Val, Arg195Ter) of the X (and Y) -linked pseudoautosomal gene *SHOX* (short stature homeobox-containing gene) resulting in haploinsufficiency are present in patients with Leri-Weill dyschondrosteosis (OMIM 127300)—typified by mesomelic limb shortening and growth retardation, Madelung deformity of the wrist, bowing of the

radius, and ulnar dislocation.[507] Patients with idiopathic short stature and no identifying skeletal characteristics have also been observed to have heterozygous loss-of-function mutations in *SHOX*.

The Leri-Weill phenotype has been recorded in patients with intact *SHOX* but with microdeletions of downstream segments of the X chromosome pseudoautosomal region, implying the presence of modifying genes in this region.[508] Homozygous loss of *SHOX* leads to Langer mesomelic dysplasia (OMIM 249700). Endogenous *SHOX* is primarily expressed in hypertrophic and apoptotic chondrocytes within the cartilage growth plate. It is a transcriptional activator whose gene targets are as yet unidentified but whose expression in osteogenic cells results in arrest of the cell cycle and in apoptosis.[509]

Gain- and loss-of-function mutations of *PTHR1* lead to abnormalities of bone formation and growth.[510] Blomstrand chondrodysplasia (OMIM 215045) is an autosomal-recessive disorder that is lethal in utero and that may be identified in the fetus with short extremely dense long bones and markedly advanced skeletal maturation (as well as somatic anomalies such as aortic coarctation and facial anomalies). Pathologically, epiphyseal cartilage is reduced—and there are irregular columns and erratic distribution of chondrocytes within matrix. The abnormality is the result of inactivating mutations (deletions, missense mutations, Pro132Leu) of the gene encoding the PTH/PTHrP receptor.

Patients with Murk-Jansen metaphyseal chondrodysplasia (OMIM 156400) have short limbs and fingers, micrognathia, and deformities of the spine and pelvis but survive to adulthood. The average adult height is 125 cm, and child bearing is possible. Characteristically, these patients have hypercalcemia, hypophosphatemia, and low or undetectable serum levels of PTH or PTHrP. The disorder is due to activating mutations (His223Arg, Thr410Pro) of *PTHR1* and is associated with extraordinary delay in chondrocyte differentiation and decreased mineralization due to excessive bone resorption. Both disorders reflect the functional effect of PTHrP in developing cartilage, where it normally acts to slow differentiation and decrease the rate of chondrocyte apoptosis—thus prolonging chondrocyte proliferation and enhancing long bone growth.

Anauxetic dysplasia (OMIM 607095) is a spondylometaepiphyseal dysplasia transmitted as an autosomal-recessive disorder characterized by intrauterine growth retardation (birth length <40 cm), severely compromised adult height (<85 cm), hypodontia, and mild mental retardation. All bones are malformed, and there are few chondrocytes in the cartilage growth plates. It is due to loss-of-function mutations (insertions) in *RMRP* (RNA component of mitochondrial RNA-processing endoribonuclease), a gene that encodes the untranslated RNA subunit of the endoribonuclease RNase MRP.[511]

This enzyme is involved in the assembly of ribosomes (the structural units in which translation and protein synthesis takes place), the generation of RNA primers for replication of mitochondrial DNA, and the regulation of the cyclin-dependent cell cycle. The mutations that result in anauxetic dysplasia impair ribosome assembly and protein synthesis exclusively. Inactivating mutations (duplications, insertions) in *RMRP* that modestly impair ribosomal assembly and regulation of the cell cycle have been found in patients with cartilage hair hypoplasia (OMIM 250250) and metaphyseal dysplasia without hypotrichosis (OMIM 250460).

Errors in the biosynthesis of cholesterol have been associated with several abnormalities of bone development (Table 17-12, Figure 17-20).[512] In patients with the Smith-Lemli-Opitz syndrome (OMIM 270400), inactivating mutations of the microsomal enzyme Δ^7-dehydrocholesterol reductase (DHCR7) impair synthesis of cholesterol and lead to intrauterine and postnatal growth retardation, short limbs, syndactyly and polydactyly, characteristic facial features (blepharoptosis, anteverted nares, broad alveolar ridges, cleft palate), congenital malformations of the heart and central nervous system, microcephaly, incomplete virilization of male external genitalia, hypoplastic thumbs, and developmental delay.[513] Stippled epiphyses are detected by radiologic examination. Hypocholesterolemia with elevated serum concentrations of 7-dehydrocholesterol are present.

Cholesterol covalently binds to the amino terminal and is essential to the function of Indian hedgehog, Sonic hedgehog, and Desert hedgehog—factors necessary to normal development of cartilage and bone, brain, and testes, respectively. However, substitution of 7-dehydrocholesterol for cholesterol does not impair the function of Sonic hedgehog. Therefore, it is likely that lack of cholesterol exerts its teratologic effect by impairing the intracellular signaling response(s) to these factors. Alternatively, the accumulation of precursors of cholesterol may exert toxic effects on the developing fetus. Cholesterol supplementation may improve the health, behavior, and growth of children with the Smith-Lemli-Opitz syndrome.

Chondrodysplasia punctata 2 (OMIM 302960) is an X-linked dominant disorder (Conradi-Hunermann-Happle syndrome) that is ordinarily lethal in the affected male and characterized clinically in the affected female by short stature with asymmetric short proximal limbs (rhizomelic dwarfism), frontal bossing, icthyosis in children and atrophic pigmentary lesions in adults, coarse hair with alopecia, and cataracts. Reflecting functional X-chromosomal mosaicism in females, the phenotype may vary from stillborn to mildly affected.[512] Radiographic examination reveals generalized osteosclerosis, irregular punctate calcification (stippling) of epiphyses in children, and hemivertebrae.

This disorder is due to loss-of-function mutations in *EBP* (emopamil-binding protein), the gene encoding 3β-hydroxysteroid-Δ^8,Δ^7isomerase—an enzyme important in sterol biosynthesis. In the serum of affected subjects, plasma concentrations of 8-dehydrocholesterol cholest-8(9)-en-3β-ol are elevated. This protein also binds many unrelated molecules. Its genetic designation derives from its ability to bind emopamil (i.e., EBP), a calcium ion antagonist. X-linked recessive and autosomal-recessive forms of the Conradi-Hunermann syndrome have also been reported, suggesting genetic heterogeneity for this phenotype. The X-linked recessive form of chondrodysplasia punctata (CDPX1, OMIM 302950) is due to inactivating mutations of the gene *(ARSE)* encoding aryl-sulfatase E. Affected males may

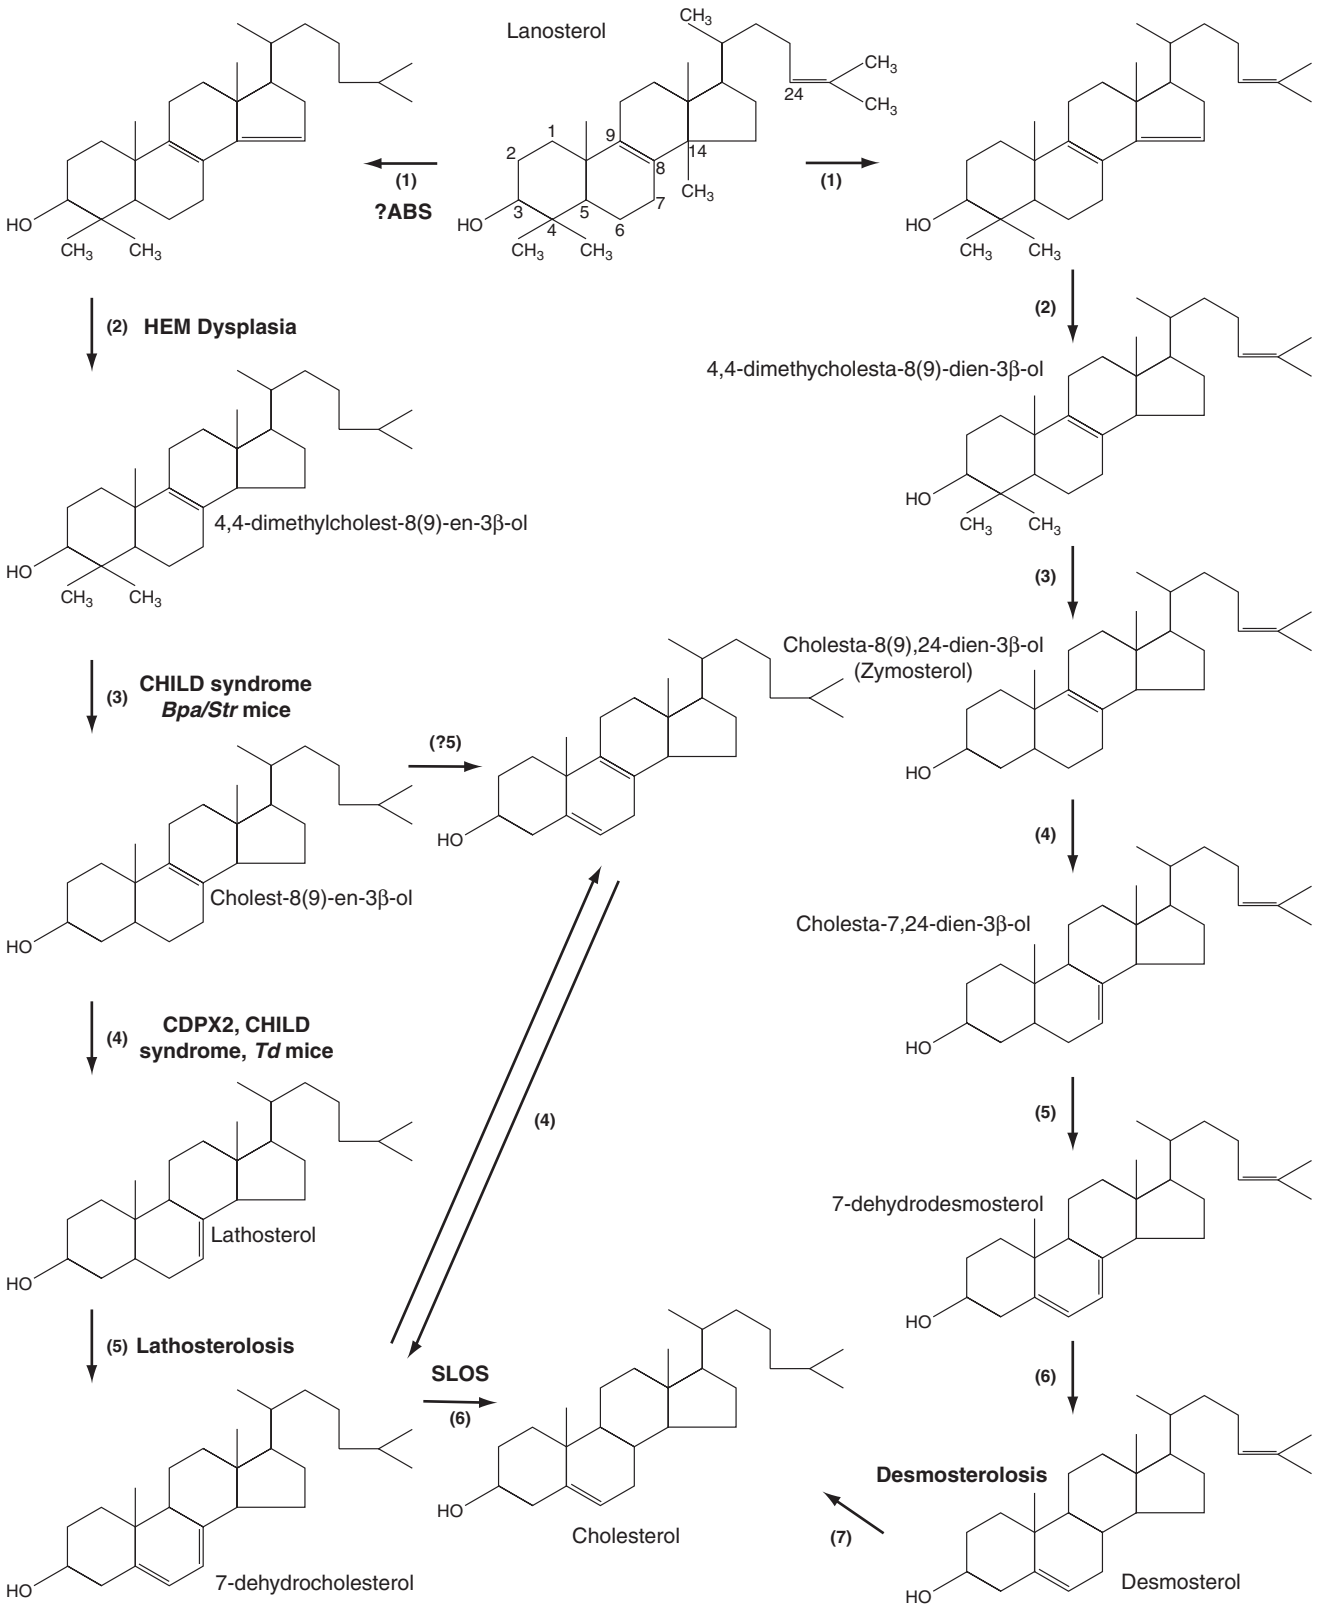

Figure 17-20 Biosynthesis of cholesterol depicting the sites of enzyme activity lost by inactivating mutations that lead to skeletal, genital, and other malformations. The numbers in parentheses denote specific enzymes: (1) lanosterol 14α-demethylase, (2) 3β-hydroxysteroid-Δ^{14}-reductase, (3) 3β-hydroxysteroid C-4 sterol demethylase complex, (4) 3 β -hydroxysteroid-Δ^{8}-Δ^{7}-sterol isomerase, (5) 3β-hydroxysteroid-α^{5}-desaturase, (6) 3β-hydroxysteroid-Δ^{7}-reductase, and (7) 3β-hydroxysteroid-Δ^{24}-reductase. [Reproduced with permission from Herman GE (2003). Disorders of cholesterol biosynthesis: Prototypic metabolic malformation syndromes. Hum Molec Genet 12:R75–R88.]

be stillborn or may survive, whereas female carriers may be asymptomatic or mildly affected.

Desmosterolosis (OMIM 602398) is an autosomal-recessive disorder whose skeletal manifestations include osteosclerosis, shortened limbs, macrocephaly, cleft palate, and thick alveolar ridges in addition to congenital heart disease and ambiguous genitalia in the affected female. It is due to inactivating mutations of the gene *(DHCR24)* encoding 3β-hydroxysterol-Δ^{24} reductase, the enzyme that converts desmosterol to cholesterol.[513,514] The rare lethal Greenberg dysplasia of hydrops ectopic calcification moth-eaten skeletal dysplasia (OMIM 215140) is transmitted as an autosomal-recessive trait associated with short-limbed dwarfism, polydactyly, and irregularly decreased calcification of the long bones together with calcification of the larynx and trachea. It is due to a loss-of-function mutation in the gene *(LRB)* encoding the lamin B receptor, a nuclear envelope inner membrane protein that not only binds lamin B but has 3β-hydroxysteroid-Δ^{14} reductase activity—an enzyme necessary to normal cholesterol biosynthesis.[515]

The CHILD syndrome (OMIM 308050) of congenital hemidysplasia with icthyosiform erythroderma (or nevus) and limb defects is remarkable for its unilateral distribution of anomalies that are confined to one-half of the body.[512] It is an X-linked disorder due to loss-of-function mutations in *NSDHL* (NADPH steroid dehydrogenase-like) encoding a sterol dehydrogenase or decarboxylase that is part of the 3β-hydroxysteroid C-4 sterol demethylase complex.

Concluding Remarks

In the past decade, our understanding of the complex mechanisms that underlie the pathophysiology of numerous illnesses that adversely affect the regulation of calcium, phosphate, and magnesium metabolism; chondrocyte differentiation and growth; and bone formation, mineralization, and strength has been transformed by the insights advances in genetics and proteomics have brought to these clinical problems. As further clarification of the very most basic mechanisms that underlie these disorders becomes available in the next decade, our ability to identify and specifically manage these problems will almost certainly experience another quantum leap forward.

Summary

Introduction

The autoimmune polyglandular syndromes (APS) I and II are uncommon constellations of organ-specific autoimmune diseases characterized by the occurrence of more than one autoimmune disease in an affected individual. More commonly, autoimmune disease of endocrine glands occurs in only a single organ. However, multiorgan involvement of endocrine and nonendocrine organs and tissues may be present.

Tolerance is an active state in which the immune system does not mount a reaction against self-antigens.[1-3] If tolerance is not established or is lost, autoimmunity and subsequent autoimmune disease can result. Although the breakdown in self-tolerance remains unexplained in most human autoimmunities, our improved understanding of normal immunologic processes has identified a number of possible mechanisms. To comprehend these mechanisms, a brief overview of how tolerance is maintained is essential.

Mechanisms Underlying Generation of Autoimmunity

INTRODUCTION

In a normal immune response, the host organism must differentiate self from non-self, generate an immune response to non-self, and eliminate non-self to protect the host from injury, organ dysfunction, and even death.[1-3] Endogenous antigens represent self, whereas exogenous antigens represent non-self. The adaptive immune system assumes that

all exogenous (foreign) antigens are potentially harmful and acts to eliminate non-self. Self/non-self discrimination is carried out by the adaptive (specific) immune system through the use of T- and B-cell surface receptors.[4]

These receptors recognize distinctive peptides or epitopes and are the keys to the specificity of the adaptive immune response. Whereas B cells and their receptors recognize soluble antigen or antigens on cell surfaces, T cells and their receptors only perceive short polypeptides presented by specialized cell-surface molecules encoded by the major histocompatibility complex (MHC).[5-7] The human MHC is termed the *human leukocyte antigen* (HLA) *complex*. Class I MHC (e.g., HLA-A, HLA-B, and HLA-C molecules) present peptides derived from the cell cytoplasm to CD8 T cells, whereas class II MHC (e.g., HLA-DP, HLA-DQ, and HLA-DR molecules) present peptides derived from the extracellular space and intravesicular space to CD4 T cells.

Regulation of self-tolerance occurs at two major levels. First, through a process of negative selection thymic medullary epithelial cells project an immunologic "self-shadow" and signal the removal or silencing of self-reactive thymocytes (central tolerance).[3,8] Negative selection occurs when double positive (CD4+, CD8+) alpha/beta T cells bind too tightly to dendritic cells and/or macrophages at the corticomedullary border in the thymus and are triggered to undergo apoptosis. Second, in lymphoid and non-lymphoid tissues mature self-reactive T cells are deleted or anergized (peripheral tolerance) when their receptors engage peptides plus MHC molecules in the absence of appropriate co-stimulatory molecules (Figures 18-1 and 18-2). Nevertheless, recent data have demonstrated that proteins previously thought to be expressed only in peripheral tissues are expressed in the developing thymus and therefore play a critical role in establishing tolerance.[9]

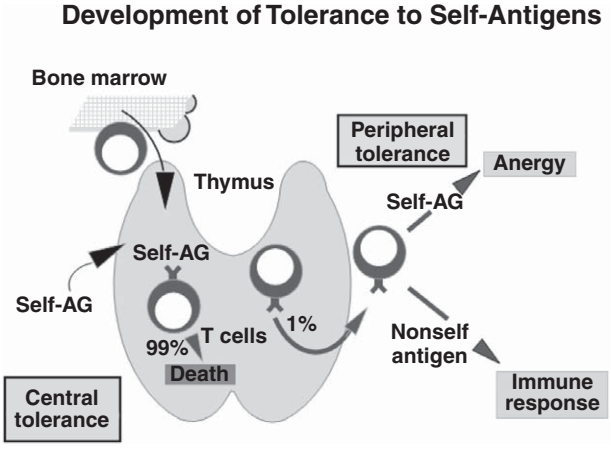

Figure 18-1 Normal tolerance pathways. T-cell precursors initially arise in the bone marrow. These progenitors enter the thymus and encounter self-antigen. Strong self-antigen stimulation of developing T cells induces apoptosis, with approximately 99% of all developing T cells dying. This is *central immunologic tolerance,* where strongly anti-self T cells are eliminated. Naive T cells that do leave the thymus can be subsequently tolerized to self-antigens if they encounter self-antigen without the normal co-stimulatory signals (B7-CD28; see Figure 18-3). Induction of tolerance outside the thymus is termed *peripheral tolerance* (top right), which is a complementary mechanism to central tolerance. Peripheral tolerance is functionally expressed as anergy: autoreactive cells are present but are inactive (top right). If non-self antigen is encountered, a normal immune response ensues (bottom right).

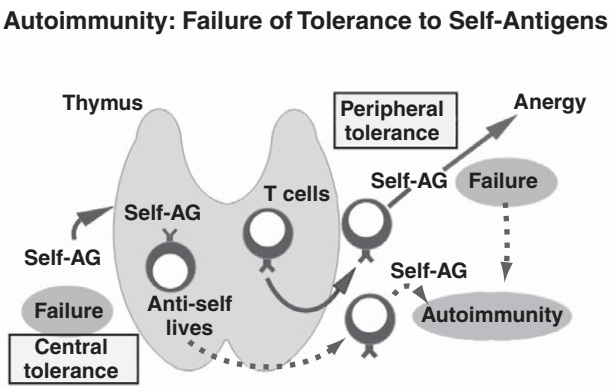

Figure 18-2 Autoimmunity: failure of tolerance to self-antigens. With a failure of central tolerance (bottom left), anti-self T cells survive that should not normally survive. When such anti-self T cells leave the thymus, autoimmunity may result (dashed arrows). Alternatively, with a failure of peripheral tolerance (top right) if anergy (solid arrow) does not occur after contact with self-antigen, an autoimmune response can occur (red arrow).

Although many of the mechanisms involved in establishing tolerance remain poorly understood, recent characterization of the autoimmune regulatory gene (AIRE) has improved understanding of positive and negative T-cell selection. AIRE plays a critical role in the expression of peripheral antigens and provides for the negative selection of autoreactive T-effector cells.[10] Deletions in the mouse AIRE homologue result in multiorgan autoimmunity, and mutations in the human AIRE gene result in APS I.[11,12]

Tolerance is initially developed in utero. During gestation and early life, tolerance is most easily induced by exposure of the host to a specific antigen. Although the thymus atrophies during puberty, residual thymic tissue provides for T-cell development throughout life. T cells do not require exposure to large doses of antigen to achieve tolerance during their thymic development. However, larger doses of antigen are required to induce B-cell tolerance (which is often short lived). B cells are produced by the bone marrow continuously throughout life. Tolerance is immunologically specific, learned or acquired, most easily induced in immature or developing lymphocytes, and potentially induced in mature lymphocytes when co-stimulatory signals are absent at the time of peptide recognition by the T lymphocyte.

CENTRAL T-CELL TOLERANCE

T cells are educated to distinguish self and non-self in the thymus.[13-15] Central T-cell tolerance is the process by which anti-self T cells are eliminated in the thymus. As many as 99% of developing thymocytes die in the thymus and never reach the periphery. T-cell tolerance is a function of the selection of the T-cell receptor (TCR) repertoire that exits the thymus. In the thymic cortex CD4+, CD8+ (double positive) T cells bearing alpha/beta TCRs

that bind to self-MHC initially survive (positive selection). In this way, the thymus initially chooses for survival T cells that bind to self-MHC—as opposed to TCRs that might bind to other self-molecules, leading to ineffective communication. This positive selection resulting from self-peptide-MHC presentation is carried out by thymic nurse epithelial cells in the cortex.

At the corticomedullary junction of the thymus, if such saved TCRs bind to self-MHC too tightly autoreactivity is possible and these T cells then undergo negative selection and suffer apoptotic death. The cells inducing negative selection are macrophages and dendritic cells. This process of positive selection for MHC binding in the thymic cortex and negative selection (at the thymic corticomedullary border) against tight binding to self-peptides accounts for central (thymic) immunologic tolerance.[3,8,10]

PERIPHERAL T-CELL TOLERANCE

Once in the circulation and in secondary lymphoid organs (e.g., lymph nodes and spleen), naive T cells still require multiple signals to become activated.[16] The initial signal is the presentation of antigen-specific peptides to TCRs by MHC molecules. CD4 and CD8 molecules on these T-cell subsets serve as antigen-nonspecific co-receptors binding to nonpolymorphic portions of the class II MHC molecules and class I MHC molecules, respectively. The second signal is antigen nonspecific and is provided by the B7 molecule of the antigen-presenting cell interacting with the CD28 molecule on the T-cell surface.

When both signals are perceived by the T cell, a cascade of intracellular signaling events occurs—leading to T-cell activation. Activated CD4 T cells express cytokines (including IL-2, IL-4, IL-5, and so on), cytokine receptors, and CTLA-4. Activated CD4 T cells then down-regulate TCR expression and acquire class II MHC expression. It is unknown why activated human T cells express class II MHC (activated T cells in mice do not express class II MHC). CTLA-4 expression by the activated T cell and its interaction with B7 provides an immunosuppressive signal to the T cell down-regulating the T-cell immune responses. Thus, CTLA-4 and CD28 act antithetically: B7-CD28 turns on T cells, whereas B7-CTLA-4 down-regulates them (Figure 18-3).

Functionally, helper CD4 T cells are predominantly subdivided into Th1 cells (which activate cell-mediated and some antibody responses) and Th2 cells, which predominantly activate antibody-mediated responses.[17] Th1 cells can activate macrophages, natural killer cells, and B cells—and they secrete predominantly IL-2, gamma interferon (IFN-γ), and IL-12. Th2 cells elaborate IL-4, IL-5, IL-6, and IL-10. Cross talk between Th1 and Th2 cells occurs: IFN-γ from Th1 cells suppresses Th2 cells and IL-10 from Th2 cells inhibits Th1 cells. Another subset of CD4 T cells has been described as regulatory T cells that secrete the immunomodulatory cytokines IL-10 and/or transforming growth factor-beta (TGF-beta).

Regulatory T cells include $CD4^+CD25^+$ T cells and Tr1 and Th3 cells. Tr1 and Th3 cells express CD4 but do not express CD25 (the IL-2 receptor alpha chain). Tr1 cells secrete IL-10 and TGF-beta, whereas Th3 cells secrete IL-4, IL-10, and TGF-beta. Although $CD4^+CD25^+$ T cells can

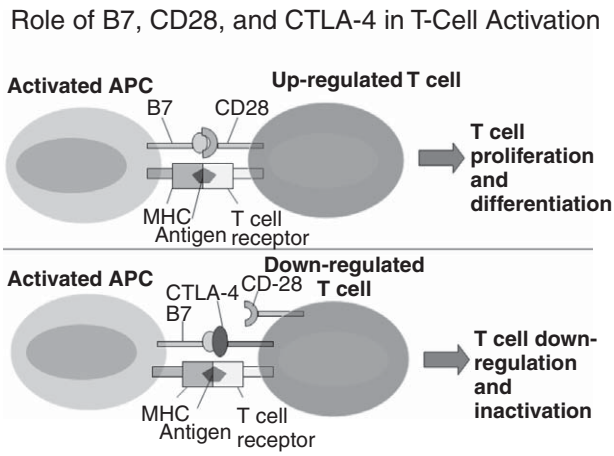

Figure 18-3 Role of B7, CD28, and CTLA-4 in T-cell activation. An activated antigen-presenting cell (APC) presents antigen on the multiple histocompatibility complex (MHC) and expresses B7 co-stimulators. When B7 is bound by CD28 and MHC is bound by a T-cell receptor, T-cell proliferation and differentiation of naive T cells ensues. Conversely, an activated T cell will now express CTLA-4 and bind to B7—thereby inducing down-regulation and inactivation of T cells.

secrete IL-10 and TGF-beta, their regulatory action on autoreactive T cells appears to occur through cell-to-cell contact. Upon activation, CD8 T cells (often with the help of Th1 cells supplying IFN-γ to up-regulate B7 expression on antigen-presenting cells) become functional cytotoxic T killer cells.

The requirement for two signals to activate naive T cells accounts for peripheral T-cell tolerance. When the naive T cell perceives antigen peptide presented by MHC molecules without the necessary co-stimulatory signal (e.g., B7-CD28), the T cell becomes unresponsive. This state of unresponsiveness is termed *anergy*. The T cell may also undergo apoptosis (programmed cell death) to be completely removed from the T-cell repertoire. Anergic T cells can generally not be restimulated with antigen peptide displayed by the antigen-presenting cell. Tolerance may also exist because the TCR does not come into contact with the relevant peptide. This has been termed *T-cell ignorance*.

Improvements in the characterization of regulatory T cells have recently allowed for further understanding of the peripheral tolerance pathway. Regulatory T cells play a critical role in suppressing the activity of effector T cells that escape negative selection to self-antigen in the thymus.[18] Functional regulatory T cells are able to anergize previously self-reactive T effector cells, resulting in improved tolerance to self. The expression of the forkhead transcription factor, FOXP3, is specific for identification of the $CD4^+CD25^+$ cell (T_{reg}) population.

First identified in the Scurfy mouse, a mouse model of immune dysfunction and polyendocrinopathy, abnormal FOXP3 expression is now known to be responsible for the failure in tolerance in humans affected with a similar polyendocrinopathy (discussed in material following).[19,20] The absence of normal FOXP3 expression in humans leads to an extremely rare recessively inherited (yet X-linked) and typically fatal autoimmune lymphoproliferative disease

known as IPEX (immune dysregulation, polyendocrinopathy, enteropathy, and X-linked inheritance). Defects in the forkhead transcription factor responsible for IPEX map to Xp11.23-Xq13.3.

B-CELL TOLERANCE

B cells are partially educated in the bone marrow to be anergized or undergo apoptosis in response to self-antigen when they are at the stage of development of the naive immature B cell (central B-cell tolerance). In the bone marrow, naive immature B cells that see multivalent antigens become anergized (unresponsiveness to subsequent stimulation)—whereas exposure to highly polyvalent antigens can induce apoptosis.

Naive immature B cells express IgM on their surface but are not yet IgD positive, as observed in naive mature B cells. Anergized B cells do not instantly die, but will live no longer than unstimulated naive immature B cells. Naive mature B cells expressing IgD on their surface require T-cell help for realization of their full potential through affinity maturation and class switching. The absence of T-cell help leads to B-cell tolerance.

AUTOIMMUNE DISEASES

The organ-specific nature of many autoimmune diseases results from abnormal immune system recognition of tissue-specific self-antigens. In many autoimmune endocrinopathies, the target molecule is a tissue-specific or tissue-limited (i.e., the protein is not unique to one tissue but is clearly restricted in its distribution) enzyme or cell-surface receptor[21,22] (Table 18-1).

TABLE 18-1

Autoantigens in Autoimmune Endocrine and Associated Diseases

Disease	Confirmed Autoantigens	Putative Autoantigens
Addison disease	P450c21	P450c17, P450scc
Hashimoto thyroiditis	Thyroid peroxidase Thyroglobulin	
Graves' disease	Thyrotropin receptor	
Diabetes	Insulin	Proinsulin
	Glutamic acid decarboxylase-65	Carboxypeptidase H ICA69
	IA-2 (ICA 512)	Glima 38
	IA-2β	
Premature gonadal failure		P450c17 P450scc 3BHSD
Pernicious anemia	H^+/K^+ ATPase Intrinsic factor	
Myasthenia gravis	Acetylcholine receptor	
Vitiligo		Tyrosinase Tyrosinase-related protein-2
Celiac disease	Transglutaminase	Reticulin Gliadin Endomyseum

The criteria for classification of a disease as autoimmune are not universally agreed upon.[23] However, major criteria generally accepted as strong evidence that the disease is autoimmune include detection of autoantibodies or autoreactive T cells, including lymphocytic infiltration of the targeted tissue or organ; disease transfer with antibodies or lymphocytes; disease recurrence in transplanted tissue; and ability to abrogate the disease process with immunosuppression or immunomodulation. Few, if any, human autoimmune diseases meet all four of these criteria. Further information supportive of (but not diagnostic for) an autoimmune disease includes increased disease frequency in women compared to men, presence of other autoimmune diseases in affected individuals, and increased frequencies of particular HLA alleles in affected individuals compared to an unaffected control population.

DEFECTS IN TOLERANCE THAT CAUSE AUTOIMMUNE DISEASES

Several hypotheses explaining defects in tolerance have been proposed.[24] Theoretically, autoimmunity may develop because tolerance never developed to specific self-antigens or because established tolerance was lost. If self-antigen is not efficiently presented in the thymus, tolerance may not be established during T-cell education within the thymic cortex.[25] For example, variations in the insulin gene VNTR (variable number of tandem repeats; ~500 base pairs upstream of the insulin gene promoter) influence the extent of insulin gene expression in the thymic cortex. Risk of developing type 1 diabetes is enhanced when certain VNTR alleles are present, which leads to lower mRNA expression of insulin in the thymus.

Specifically, class III alleles (greater number of VNTR) are associated with increased thymic expression of insulin and a decreased risk of developing type 1 diabetes—whereas class I alleles (smaller number of VNTR) are associated with decreased thymic expression of insulin and an increased risk of developing diabetes.[26] If there is failure to delete an autoreactive clone of T cells, autoimmunity could develop. If autoimmunity does result from defects in thymic tolerance, the defects must be antigen specific because organ-specific autoimmune diseases are usually extremely selective. For example, in type 1 diabetes the beta cells are attacked and ultimately destroyed by a cell-mediated autoimmune process but the remaining islet cells (including alpha cells, delta cells, and pancreatic polypeptide-producing cells) are unscathed.

Defects in peripheral tolerance could result from concurrent T-cell stimulation by self-antigen/MHC plus T-cell co-stimulation (e.g., B7-CD28), leading to aberrant T-cell activation and an autoimmune response. If tolerance has not been developed because an antigen is sequestered intracellularly or is not expressed in the thymus during T-cell ontogeny, T-cell reactivity in the periphery would not be abrogated. However, several antigens initially thought to be sequestered intracellularly have now been shown to circulate in low concentrations in normal individuals. Thyroglobulin is such a self-antigen in autoimmune thyroid disease.

The development of thyroglobulin autoantibodies was believed to follow the release of thyroglobulin from the thyroid gland as part of viral attack, trauma, or some other form of environmental damage. Hypothetically, this immunization then leads to an antithyroglobulin humoral response and autoimmune thyroid disease. However, we now know that thyroglobulin does circulate in low but appreciable quantities in normal individuals who show no serologic evidence of thyroid autoimmunity. Furthermore, thyroid follicular cell destruction in Hashimoto thyroiditis is cell mediated (not humorally mediated).

If sequestered antigens do play a role in autoimmune disease, viral infections, trauma, ischemia, or irradiation are all mechanisms that could disturb cellular integrity and lead to release of intracellular antigens.[27] Some self-antigens may never normally come into contact with the immune system unless there is a breakdown of anatomic barriers within the body. An example is the occurrence of autoimmunity to the eye following orbital trauma. Although a rare consequence of orbital damage, initiation of an autoimmune response to eye proteins in adjacent lymph nodes can generate autoreactive T cells that can invade and damage the contralateral eye (sympathetic ophthalmia).[28] Removal of the inciting damaged tissues and immunosuppression may be required to sustain vision in the undamaged eye. Similarly, transient autoantibody reactivity to cardiac myosin following myocardial infarction has also been described.[29]

Hypothetically, tolerance may not develop if self-antigen expression is delayed during negative selection. When the self-antigen is ultimately expressed, if tolerance has not previously been established the autoantigen is perceived as foreign and autoreactivity develops. No spontaneous examples of this process have been described. However, in experimental systems in which transgenes are placed under control of promoters that can be turned on by exogenous agents such as metals, autoreactivity can be elicited when gene expression is stimulated after the neonatal period.

Alteration of self-antigens as a result of infection or neoplasia is believed to be a plausible theory explaining some types of autoimmunity. As environmental triggers, viral infections could lead to modification of self-proteins and neoantigen expression (e.g., a new antigen is present on self-cells). Alternatively, a self-antigen may be partially degraded—leading to a "new" antigenic target for the adaptive immune system. This new antigen is recognized as foreign by the immune system, and the immune response to these new antigens results in autoimmunity.

Some self-cells/tissues may suffer unintended autoimmune damage when substances bind to the cells and elicit an initial immune response. For example, certain drugs bind to red blood cells and result in an immune hemolytic anemia. If an antibody response to the red-cell-bound drug is elicited, the antigen-antibody complex present on the red blood cell can lead to red blood cell destruction. This can occur through red blood cell phagocytosis by the monocyte-macrophage system or via complement-mediated lysis of the red blood cell. Thus, the red blood cell is an innocent bystander to the antidrug humoral immune response. Theoretically, this could also occur with viruses that serendipitously attach to tissues.

Molecular mimicry is one of the most popular explanations for autoimmunity.[27] Due to exposure to a dietary, viral, or bacterial antigen (e.g., infection) and molecular mimicry (similarity) between the self-antigen and the foreign antigen, the immune response to the foreign antigen leads to cross reactivity with self-antigen, autoimmunity, and disease.[30-32] For this theory to work, tolerance must not previously exist to the self-antigen. This might be true if the self-antigen is truly sequestered and the immune system has never developed tolerance to the self-antigen. Alternatively, the self-antigen peptides may be present in too low a concentration to elicit an immune response and initial immune system tolerization has not occurred.

Only with infection or novel dietary exposure would there be a sufficient degree of self-immunization to develop immune autoreactivity. With immune autoreactivity, self is now recognized as foreign during the response to the cross-reactive pathogen. If the self-antigen is a cell surface antigen, the "pathogen-induced" autoantibodies could fix to self and produce disease via complement fixation—or the antibodies could act as opsonins for fixed or circulating phagocytes (antibody-dependent-cell cytotoxicity). In rheumatic fever, cross reactivity between *Streptococcus M* protein and cardiac myosin have been described. In ankylosing spondylitis, cross reactions between Klebsiella nitrogenase and HLA-B27 have been described. In rheumatoid arthritis there is cross reactivity between cartilage protein and a mycobacterial proteoglycan wall component.

Aberrant class II MHC expression was a theory in vogue in the mid 1980s. In this hypothesis, cells elicit autoimmune reactions by presenting their own self-peptides via self-expressed class II MHC molecules. Indeed, class II MHC expression has been identified on various cells that are targets of autoimmune-mediated cell destruction. Examples include pancreatic islet beta cells in type 1 diabetes, biliary tract cells in primary biliary cirrhosis, and thyroid follicular cells in Hashimoto thyroiditis.

However, there are strong counterarguments to this theory. First, class II MHC molecules do not present intracytoplasmic antigens (which are often targets of attack). Instead, class II MHC molecules present peptides derived from extracellular proteins. Second, accessory molecules are typically needed to activate naive T cells. If, for example, pancreatic beta cells present peptides via their class II MHC molecules without B7 the naïve T cells seeing these peptides in the absence of B7 will actually be tolerized. Indeed, aberrant (or ectopic) class II MHC expression may be a mechanism cells use to actually induce a state of tolerance to down-regulate an immune response. Aberrant class II MHC expression may therefore serve an anti-inflammatory role in modulating an immune response to a lower level of intensity. Costimulator expression (e.g., B7) is highly regulated even among professional antigen-presenting cells. For example, in the basal state neither macrophages nor B cells express B7. Upon phagocytosis of bacteria species, macrophages will express class II MHC and B7. Whereas B cells express class II MHC in their basal state, internalization of bacterial antigen bound to their cell surface receptor antibody molecules will induce B7 expression.

Some cases of autoimmunity may result from superantigens initiating an anti-self immune response as part of the polyclonal immune activation process. Superantigens are polycolonal T-cell stimulators that have the ability to cross-link TCR beta chains and MHC molecules. Superantigens have been reported to activate as many as a third of all T cells in the body. In such cases, systemic disease can develop from massive cytokine release. This is the case in toxic shock syndrome, wherein a staphylococcal exotoxin acts as a superantigen. Mycobacterial antigens have been promulgated as possible superantigens in Crohn disease.[33] This theory presuposes that T cells bearing anti-self TCRs have not been deleted or permanently anergized. T cells with anti-self receptors may be stimulated, and if they encounter self-antigen they may further proliferate to develop an autoimmune response.

Similar to polyclonal T-cell activation, polyclonal B-cell stimulation has also been implicated in humoral autoimmunity. Indeed, autoreactive B cells can be found in normal individuals. If an autoreactive clone of B cells encounters self-antigen and a co-stimulator (which might be nonspecific, such as Epstein Barr virus or a bacterial product such as lipopolysaccharide), autoantibodies could be produced—bypassing the need for T-cell help.

However, which of these speculative theories applies to the APS is unknown. Human disease most often results from an interaction of environmental and genetic factors.[34] Many environmental factors are implicated in various autoimmune diseases: wheat gliadin ingestion and celiac disease, penicillamine exposure and myasthenia gravis, methimazole and autoimmune hypoglycemia from insulin autoantibodies, and amiodarone and thyroiditis. Cytokine exposure is also associated with autoimmune disease in the case of alpha interferon use in hepatitis and the apparent development of thyroiditis. Even cancer can be associated with the development of autoimmunity: thymoma and myasthenia gravis are associated, as are ovarian carcinoma and cerebellar degeneration, and breast cancer and stiffman syndrome. How this interaction among genes, the environment, and the immune system actually leads to autoimmunity and disease clearly needs to be elucidated.

Classification of the Autoimmune Polyglandular Syndromes

APS I, also known as APECED (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy), is an autosomal-recessive disorder mapped to a single gene (the autoimmune regulator or AIRE gene) on chromosome 21q22.3.[11,12] The presence of two of the following three conditions are prerequisites for diagnosis: adrenocortical failure (Addison disease) or serologic evidence of adrenalitis (e.g., adrenal autoantibodies), hypoparathyroidism, and mucocutaneous candidiasis.[35-37]

APS II is defined by the coexistence of autoimmune adrenocortical insufficiency or serologic evidence of adrenalitis with autoimmune thyroiditis (Schmidt syndrome) and/or type 1 diabetes mellitus (Carpenter syndrome, which is Schmidt syndrome plus type 1 diabetes) or serologic evidence of thyroid or islet autoimmunity[38-41] (Figure 18-4). The presence of thyroiditis without adrenal disease but associated with type 1 diabetes mellitus, pernicious anemia, vitiligo, or alopecia has been referred to as APS III. However, because APS II and III differ only by the presence or absence of adrenocortical disease and share similar susceptibility genes and immunologic features we do not recognize APS III as a unique syndrome and consider it an extension of the APS II constellation.

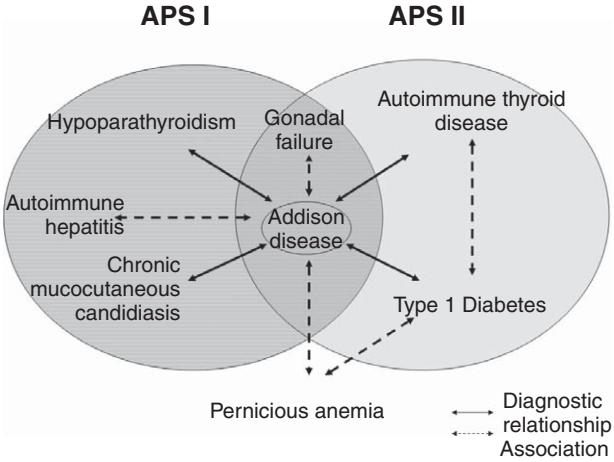

Figure 18-4 Diagnostic relationship and common associations of APS I and APS II. The solid lines indicate diagnostic relationships. The dashed lines indicate common associations. The diagnosis of APS I depends on the coexistence of Addison disease (or adrenal autoantibodies) and hypoparathyroidism or chronic mucocutaneous candidiasis, or both. The diagnosis of APS II depends on the coexistence of Addison disease (or adrenal autoantibodies) and autoimmune thyroid disease or type 1 diabetes, or both (or their associated autoantibodies).

Clinical Aspects

APS I

The major disease components, frequencies, and differences between APS I and II are outlined in Table 18-2. APS I (APECED) may occur sporadically or in families. Although the disease is not common, cohorts of patients have been reported from Finland and the United States and among Iranian Jews. Males and females are equally affected in this autosomal-recessive disorder.[35,37,42] Persistent mucocutaneous candidiasis is usually the first sign, which commonly appears during the first year or two of life. However, it may also have its onset in adulthood. Candidal infections in the region of the diaper area often present early, with vulvovaginal candidiasis commonly developing at puberty in females.

Colonization of the gut can lead to intermittent abdominal pain and diarrhea. The nails may be affected with chronic candidiasis, leading to a darkened discoloration, thickening, or erosion. Retrosternal pain occurring in patients with confirmed oral candidiasis suggests esophageal candidiasis and can be confirmed by esophagoscopy. It is extremely important that the candidiasis be

TABLE 18-2

The Autoimmune Polyglandular Syndromes I and II

Disease Characteristic	APS I	APS II
Comparative frequency	Less common	More common
Onset	Infancy/early childhood	Late childhood, adulthood
Heredity	Autosomal recessive	Polygenic
Gender	Males = females	Female predominance
Genetics	AIRE gene; no HLA association	HLA associated; DR/DQ
Hypoparathyoidism	77-89%	None
Mucocutaneous candidiasis	73-100%	None
Ectodermal dysplasia	77%	None
Addison disease	60-86%	70-100%
Type 1 diabetes	4-18%	41-52%
Autoimmune thyroid disease	8-40%	70%
Pernicious anemia	12-15%	2-25%
Gonadal failure		
Females	30-60%	3.5-10%
Males	7-17%	5%
Vitiligo	4-13%	4-5%
Alopecia	27%	2%
Autoimmune hepatitis	10-15%	Rare
Malabsorption	10-18%	Rare

aggressively treated. Carcinoma of the oral mucosa with its high mortality is well described in APS I patients with chronic mucosal candidiasis.

Any patient with refractory mucocutaneous candidiasis should be thoroughly investigated not only for a T-lymphocyte abnormality (absolute lymphocyte count, enumeration of T-cell subpopulations, assessment of T-cell function) but for the presence of a polyendocrinopathy. The largest cohort of longitudinally followed APS I patients resides in Finland. In Perhentupa's recent review of these 91 APS I patients, 60% presented with candidaisis as the first sign of APS I, 96% developed candidiasis by 20 years of age, and 100% developed candidiasis by 40 years of age.[35]

Addison disease is found in more than 85% of APS I patients, yet the disease is often missed—with the diagnosis commonly made late or at the time of a life-threatening adrenal crisis. Autoimmune adrenocortical failure usually has its peak onset before adolescence, when it is associated with APS I. However, Addison disease may have its onset in adulthood. Deficiencies of cortisol, aldosterone, and adrenal andogens may present simultaneously or may evolve over months to several years. The initial clinical features of Addison disease are often nonspecific mimicking psychiatric or gastrointestinal disease. These include fatigue, weight loss, myalgias, arthralgias, behavioral changes, nausea and vomiting, abdominal pain, and diarrhea. Hyperpigmentation (due to elevated ACTH) in non sun-exposed areas and postural hypotension can usually be found on careful examination. Unexplained hypotonic dehydration should raise the suspicion of Addison disease. Adrenal crises with hyponatremia, hyperkalemia, and hypoglycemia may be fatal unless recognized early and treated appropriately.

Like other components of APS I, hypoparathyroidism usually presents before puberty. Severe hypocalcemia as evidenced by seizures, carpopedal spasms, muscle twitching, and laryngospasm may be presenting features. Hyperphosphatemia with a low intact parathyroid hormone (PTH) level is diagnostic. These symptoms may, however, be masked in the presence of adrenal insufficiency.

Ectodermal dystrophy unrelated to hypoparathyoidism or to mucocutaneous candidiasis has been well characterized in the Finnish patients with APS I. Dental enamel hypoplasia of permanent (but not deciduous) teeth, as well as nail dystrophy, is commonly found. There may be complete absence of the enamel or transverse hypoplastic bands alternating with zones of well-formed enamel. Dystrophy of nails is manifest by 0.5- to 1-mm pits. Nearly a third of the Finnish patients also had calcification of the tympanic membranes.[43]

Premature gonadal failure is more common in females and may present in puberty. Less than 30% of men with APS I develop testicular failure, whereas more than 50% of women with APS I develop ovarian failure by 20 years of age.[35] In younger female patients, gonadal failure often presents with primary amenorrhea—and in time menstrual irregularities, polycystic ovaries, or infertility may manifest.[35,44]

As shown in Table 18-2, in contrast to patients with APS II type 1 diabetes and autoimmune thyroiditis occur far less frequently in APS I. When present, thyroiditis is typically atrophic rather than goitrous. Atrophic gastritis occurs in 15% to 30% of APS I cases, with a mean age of onset of 16 years.[35,43] Gastric-parietal cell autoimmunity, which leads to atrophic gastritis with resultant achlorhydria and intrinsic factor deficiency, typically presents as iron deficiency anemia or vitamin B_{12}-deficient pernicious anemia.

Nonendocrine organ-specific diseases include alopecia, vitiligo, autoimmune hepatitis, and malabsorption. All types of alopecia may occur, but progression to alopecia totalis (total loss of scalp hair) or universalis (total loss of all body hair including eyelashes, eyebrows, and scalp hair)—which are most common—usually occurs before puberty. Vitiligo presents initially as small pale pigment-lacking skin patches. These may be missed unless specifically sought with ultraviolet light examination of the skin.

The appearance of clay-colored stools, dark urine, and jaundice confirms the diagnosis of chronic active hepatitis—which is not related to infectious hepatitis. Hepatitis occurs in 10% to 15% of APS I patients and is the leading cause of death in these patients. Consequently, all patients suspected of having APS I should have their liver function regularly monitored. Intermittent malabsorption (typically of fat) has been linked to hypoparathyroidism, bacterial and fungal overgrowth, gluten sensitivity, and IgA deficiency. There have also been rare reports of APS I and associated diabetes insipidus, growth hormone deficiency, ACTH deficiency, rheumatoid arthritis, Sjögren's disease, and myopathy.[45]

APS II

APS II is the most common of the polyendocrinopathies, and unlike APS I usually has its onset in adulthood—particularly during the third or fourth decades. APS II is at least three times more common in females than in males. In 1926, Schmidt first described the association of adrenocortical and thyroid gland failure—and Carpenter extended this in 1964 to include insulin-dependent diabetes mellitus.[38,39] In 1957, the autoimmune nature of these diseases was suggested by Doniach and Roitt's discovery of thyroglobulin autoantibodies in patients with Hashimoto thyroiditis.[46] APS II was originally defined by the occurrence of adrenocortical insufficiency (Addison disease) in conjunction with autoimmune thyroid disease and/or type 1 diabetes mellitus.

Adrenocortical failure is the presentation in approximately 50% of APS II cases. The disease usually has its onset between ages 20 and 50 years, although it is not unusual to find cases before or after these ages.[41,47,48] Several of the disease components may be present at diagnosis. Type 1 diabetes coexists in nearly 50% of patients with Addison disease, whereas autoimmune thyroid disease (AITD) coexists in about two-thirds of patients with Addison disease. Thus, type 1 diabetes and AITD should be vigorously sought in any patient presenting with Addison disease.

The most common component of the APS II to occur as an isolated condition is AITD. AITD affects nearly 4.5% of the U.S. population,[49] and because of a strong female predominance 80% to 90% of all cases occur in females. AITD has an increased incidence during the teen years, with a peak appearing in the fifth and sixth decades. Chronic lymphocytic thyroiditis (Hashimoto disease) is by far the most common form of AITD, although Graves disease or postpartum thyroiditis may also occur. Several studies have reported on the coexistence of anti-islet immunity (3%-8%) or even overt type 1 diabetes and AITD.[50,51] Just 1% of patients with otherwise isolated thyroiditis have serologic evidence of adrenal autoimmunity.

Although polyglandular involvement in patients with autoimmune thyroid disease is infrequent, thyroid autoimmunity or a family history of thyroiditis is common in patients with pernicious anemia, vitiligo, alopecia, myasthenia gravis, and Sjögren syndrome.[52-54] More patients with APS I than APS II have vitiligo, but because APS I is far less common most patients with vitiligo who have another autoimmune disease have APS II. Twenty to 40% of vitiligo patients have another component of APS II, with thyrogastric autoimmunity being the most common.[55,56]

Thyrogastric autoimmunity is a descriptive term for the high frequency of concurrent AITD and autoimmune lymphocytic gastritis. Many of these patients with vitiligo are asymptomatic, and evidence of their autoimmunity can only be ascertained by autoantibody screening. Segmental vitiligo with involvement of dermatomal regions is not associated with autoimmunity, however.[57] Up to 15% of patients with alopecia (areata, totalis, universalis) and 5% of their first-degree relatives have thyroid disease.

Nearly 30% of patients with myasthenia gravis (autoimmune disease characterized by muscle weakness worsening during muscular contraction and caused by anti-acetylcholine receptor autoantibodies) have AITD. Both Hashimoto thyroiditis and Graves disease may occur in patients affected with myasthenia gravis.[58,59] Interestingly, these subjects with AITD appear more likely to have a milder expression of their myasthenia gravis and a lower incidence of thymic disease or autoantibodies to the acetylcholine receptor α-chain than AITD-negative patients. The proportion of ocular myasthenia is higher in patients with Graves disease.

Type 1 diabetes mellitus is also a diagnostic component of APS II. The worldwide incidence of type 1 diabetes continues to rise, particularly in children less than 5 years of age. The disease has a peak incidence during the teen years, with a smaller but increasing incidence occurring in the preschool years.[60] Nevertheless, the disease may have its onset at any age. Approximately 10% to 15% of diabetes patients with disease onset after 40 years actually have slowly progressive autoimmune disease [latent autoimmune diabetes of adults (LADA)], rather than insulin-resistant forms of diabetes (classic type 2 diabetes).[61] A gender bias is not present in patients with isolated type 1 diabetes. However, a female predominance occurs in APS II patients whose disease constellation includes type 1 diabetes.

This female bias in APS II is almost certainly related to the coexistence of AITD. The presence of thyroid microsomal (thyroid peroxidase) and/or thyroglobulin autoantibodies documents thyroiditis (often asymptomatic) in 20% to 25% of females with type 1 diabetes.[47] A female bias is also found in APS II patients with type 1 diabetes and gastric parietal cell autoimmunity. Gastric parietal cell autoantibodies (PCA) are present in approximately 10% of females and 5% of males with type 1 diabetes.[62] Although pernicious anemia typically affects women after the fifth decade, children at increased risk for pernicious anemia should be closely monitored when PCA are detected.

Atrophic gastritis may lead to the development of a megaloblastic anemia due an inability to produce intrinsic factor, and consequently to an inability to absorb vitamin B_{12}. Iron deficiency anemia secondary to an inability to absorb iron consequent to decreased acid production (achlorhydria) has also been reported in adolescents and adults.[63] Adrenocortical autoimmunity is much less frequent among patients with type 1 diabetes, with serologic evidence reported in 1.5% of cases.[64,65] Antibodies suggestive of celiac disease are present in up to 10% patients with type 1 diabetes. Endomysial or transglutaminase autoantibodies can be used to screen for celiac disease.[66] Although celiac disease should be suspected in patients with unexplained diarrhea, weight loss, failure to gain weight, or failure to thrive, biopsy-proven celiac disease is seen in less than 6% of type 1 diabetes patients.[67,68]

Approximately 10% of women with APS II who are less than 40 years of age develop ovarian failure presenting as primary or secondary amenorrhea. A female sex bias also occurs in the relationship between adrenocortical and gonadal autoimmunities. Among females with biopsy-proven lymphocytic oophoritis, adrenocortical failure or subclinical adrenal autoimmunity is often present.[69] Progression to gonadal failure is very rare among

males with Addison disease, even in the presence of the high-risk steroidal cell autoantibodies (SCA) that mark the disease in women. Pituitary involvement is occasionally seen in APS II.[70,71] Hypophysitis and empty sella syndrome have been described, usually leading to isolated failure of secretion of GH, ACTH, TSH, FSH, or LH. Several nonendocrinologic conditions have been reported in association with APS II. These include ulcerative colitis,[72] primary biliary cirrhosis,[73] sarcoidosis,[74,75] achalasia,[76] myositis,[77] and neuropathy.[78]

IPEX

In addition to the classic diagnoses of APS I and II, an improved understanding of abnormal FoxP3 expression and T-cell function has led to the characterization of yet another autoimmune polyendocrinopathy. As previously stated, the absence of normal FoxP3 expression leads to the extremely rare recessively inherited X-linked and typically fatal autoimmune lymphoproliferative disease known as IPEX.[79-82]

Neonatal onset type 1 diabetes can be observed in IPEX, as well as dermatitis, enteropathy, thyroiditis, hemolytic anemia, and thrombocytopenia. To date, long-term immunosuppression or bone marrow transplantation appears to be the only effective therapy for IPEX. Bone marrow transplantation may be effective due to the normalization of FOXP3 expression in T cells even in patients with only partial chimerism. Increased expression of FOXP3 has recently been shown to reprogram effector T cells to act as regulatory T cells.[83,84] Thus, enhancement of FOXP3 expression to augment the number and function of regulatory T cells has significant potential to treat human autoimmune diseases.

Diagnostic Approach and Follow-up

The approach to diagnosing polyglandular syndromes is threefold. First, autoantibody screening is used to verify the autoimmune nature of the suspected endocrinopathy and to test for the involvement of other organs and tissues. Second, a full assessment of endocrine function is required in patients with confirmed autoantibodies—as well as in those who may be autoantibody negative but in whom disease may be suspected clinically. Third, mutation analysis can now be used to confirm the diagnosis and to screen siblings and other relatives for their carrier status.

Recognition of multiorgan autoimmune diseases prior to their symptomatic phases is the best way to minimize their associated morbidity and mortality. A thorough history and physical examination should always be performed, and a high index of suspicion should be maintained. Another clue to the identification of asymptomatic polyglandular disease may come from the history of a relative who has a different component disease than the proband or has typical multiorgan disease.

Any patient with suspected APS should be screened with a panel of autoantibodies (Figure 18-5). These include adrenal cortex cytoplasmic autoantibodies or autoantibodies directed against 21 hydroxylase (markers for autoimmune Addison disease); GADA, IA-2A, IAA, and ICA (for type 1 diabetes); thyroid microsomal/thyroperoxidase and thyroglobulin autoantibodies (for autoimmune thyroid disease); steroidal cell autoantibodies (for ovarian failure); and endomysial or transglutaminase autoantibodies (for celiac disease). Other autoantibodies have been reported in autoimmune adrenal disease and/or gonaditis, such as those against 17-hydroxylase, the

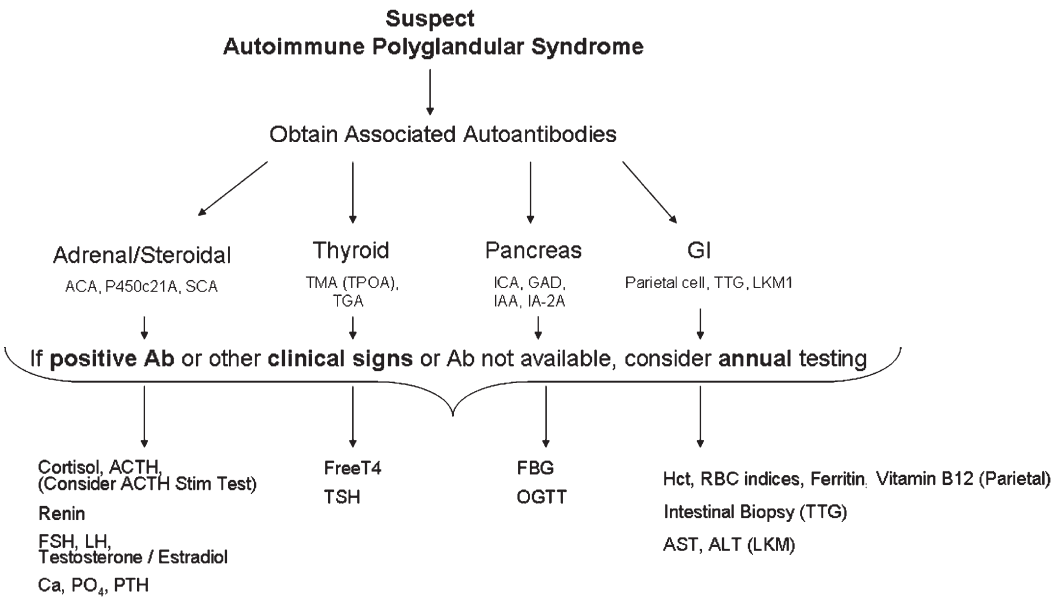

Figure 18-5 Antibody and end-organ testing in patients with suspected APS. This flow diagram shows which autoantibodies should be obtained when APS is suspected due to clinical signs and symptoms. Following autoantibody positivity, annual testing of end-organ function should be obtained as shown.

side-chain cleavage enzyme, and 3-hydroxysteroid dehydrogenase. However, clinical testing is only available for the adrenal cytoplasmic autoantibodies (as detected by indirect immunofluorscence) and 21-hydroxylase autoantibodies. There is a clear link between the presence of organ-specific autoantibodies and the presence of preexisting disease and subsequent progression to disease. However, in patients with APS the number of associated disorders that will develop and their age of appearance are clinically unpredictable. Thus, clinical long-term follow-up is necessary in both autoantibody positive and negative subjects.

All patients with a single autoimmune disease must be considered at risk for other autoimmune diseases. Whether and when to screen for other autoantibodies is based on the likelihood of finding another autoimmune disease, on cost effectiveness, and on the likelihood that screening will prevent morbidity and mortality from other diseases (e.g., diabetic ketoacidosis, Addisonian crisis, or hypocalcemia with seizures) in the future.

Because of the high incidence of AITD in patients with type 1 diabetes, we recommend that such patients have thyroid microsomal/thyroperoxidase and thyroglobulin autoantibodies measured biannually. This approach is preferred to assessing thyrotropin levels because autoantibody seroconversion is a much earlier event in the evolution of thyroid disease. In addition, measurement of thyroid microsomal/thyroperoxidase and thyroglobulin autoantibodies has close to 90% sensitivity. In those subjects who are positive, thyrotropin levels are measured annually. Most patients with isolated Hashimoto thyroiditis will not develop additional endocrine disease, but when they do the thyroid disease has usually been preceded by the overt failure of another gland.

Screening for APS is not recommended in patients with isolated autoimmune thyroid disease. However, several reports have demonstrated an increased incidence of parietal cell autoantibodies in patients with isolated autoimmune thyroid disease.[63,85] Thus, screening for parietal cell autoantibodies in children with AITD can be considered. In hypothyroid patients with confirmed APS, evidence for adrenal autoimmunity must also be sought before starting thyroid hormone replacement therapy because thyroid hormone replacement can precipitate an adrenal crisis in patients with marginal adrenocortical function (by increasing metabolism and catabolism of steroid hormones).

Delayed diagnoses and even preventable deaths unfortunately still occur in patients with undiagnosed adrenocortical failure. As mentioned previously, the presentation is often vague and nonspecific until an Addisonian crisis ensues. In patients with type 1 diabetes, unexplained hypoglycemia or other unexplained improvement in blood glucose control might be a clue to the diagnosis of Addison disease. Improved glycemia may represent the loss of anti-insulin activity associated with glucocorticoid deficiency.

As mentioned previously, any patient with prolonged or unexplained chronic mucocutaneous candidiasis or hypoparathyoidism should be evaluated for APS I. Screening for APS should also be performed in females with premature ovarian failure or young patients with vitiligo. Assessment of end-organ function in any patient with autoantibodies is recommended annually (Figure 18-5). Fasting and/or 2-hour postprandial blood glucose testing and testing of calcium, phosphate, and PTH and TSH levels can effectively assess pancreatic islet, parathyroid, and thyroid function in asymptomatic individuals. Gonadal failure can be diagnosed by the finding of elevated FSH and LH levels with concomitant low sex steroids.

Obtaining a hemoglobin and hematocrit together with indices can assess progression to atrophic gastritis in patients with gastric autoimmunity. The findings of a megaloblastic anemia with an elevated mean corpuscular volume (MCV) suggest vitamin B_{12} deficiency, whereas a microcytic hypochromic anemia confirms iron deficiency. However, vitamin B_{12} levels should be followed in all patients with parietal cell autoantibodies because neuropathy can develop without anemia. It is useful to obtain a vitamin B_{12} level and an iron profile prior to starting therapy. Methylmalonic acid levels are not routinely needed in patients with gastric autoimmuinity but can be helpful if the vitamin B_{12} levels are borderline low.[86] Liver function tests and antimitochondrial autoantibodies should be obtained in patients with APS I. Patients testing positive for endomysial or transglutaminase autoantibodies should have an intestinal biopsy to confirm the diagnosis of celiac disease.

Low early morning cortisol levels, electrolyte abnormalities (hyponatremia/hyperkalemia), and hypoglycemia represent late changes occurring at or just before the onset of adrenal insufficiency. Just as the natural history of pre type 1 diabetes has now been well described (see Chapter 10), there is now data to predict the subsequent development of adrenocortical insufficiency once adrenal autoantibodies are first recognized (Figure 18-6). During the development of adrenocortical insufficiency in adrenocortical autoantibody positive subjects, a regular progression of sequential findings is exhibited. Stage 1 involves increased plasma renin activity, with normal to low aldosterone. Stage 2 involves

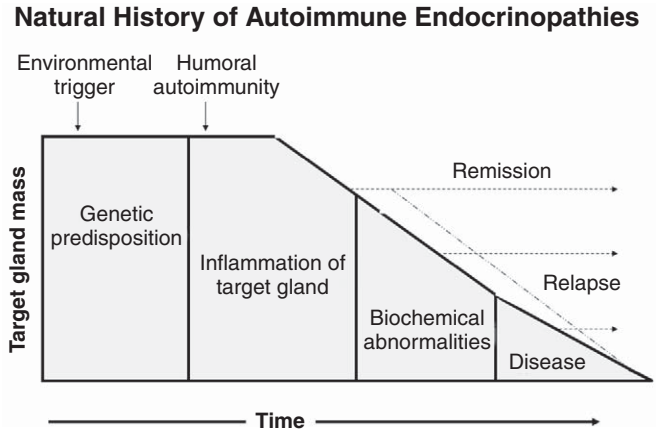

Figure 18-6 Proposed model of the natural history of an organ-specific autoimmune disease. In genetically susceptible individuals, the onset of autoimmunity (identified by the presence of serum autoantibodies) is thought to be triggered by environmental agents. These organ-specific autoantibodies can be identified months to years before the disease becomes clinically manifest—thus allowing for the prediction and early diagnosis of the disease before the clinical manifestations or metabolic abnormalities can usually be detected.

TABLE 18-3

Stages in the Development of Autoimmune Addison Disease

Stage	Renin	Aldosterone	Basal Cortisol	Cortisol Post-ACTH	Basal ACTH
1	Elevated	N or Low	N	N	N
2	Elevated	N or Low	N	Low	N
3	Elevated	N or Low	N	Low	Elevated
4	Elevated	Low	Low*	Low	Elevated

*Clinical Addison disease.
ACTH, adrenocorticotropic hormone; and N, normal.

decreased cortisol response after parenteral ACTH administration. Stage 3 involves elevated basal ACTH. Stage 4 involves low basal cortisol (Table 18-3).[87,88] In those individuals with adrenocortical autoantibodies, screening with mid-afternoon or later ACTH levels together with a supine renin should be carried out. Complete assessment of adrenocortical function should be carried out in those with ACTH levels >55 pg/mL or in those with elevated renins.

Treatment

Hormone replacement or other therapies for the component diseases of APS I and APS II are similar whether the ailments occur in isolation or in association with other conditions. Specific therapies are described in the individual chapters.

Genetics of APS I

For some time it had been recognized that APS I could be inherited in an autosomal-recessive fashion.[89] Unlike APS II, specific HLA alleles are not associated with APS I.[90] APS I was initially mapped to chromosome 21q22.1 in Finnish families, and the AIRE gene was subsequently cloned.[11] Individuals with APS I were found to be homozygous (possess two mutated copies) for the AIRE gene, with their parents being heterozygous for the mutated gene. AIRE is expressed in the thymus, lymph nodes, fetal liver, pancreas, adrenal cortex, and testes. The gene spans 11.9 kb and contains 14 exons. The predicted protein contains 545 amino acids.[12]

Initially, five AIRE mutations were described: one nonsense mutation and four frame-shift mutations.[11,90] Multiple shared and unique mutations in the gene have now been defined in Sardinians, Britains, Italians, Finns, Japanese, and North Americans.[37] Sequence analysis of the AIRE protein demonstrates that the predicted AIRE protein displays features common to other proteins that function as transcription factors (proteins that bind to the regulatory elements in the DNA regulatory region of genes).[3,91] Transcription factors act to modulate the rate of gene transcription, whereas regulatory elements include the promoter region, enhancers, silencers, and metabolic response units. Further understanding of the AIRE protein function may provide fundamental insights into the nature of polyglandular and uniglandular autoimmunity.

With recognition that APS I can be predicted in families with an index case, the focus of future therapy should be on the diagnosis of affected individuals using direct AIRE gene analysis, prediction of disease using autoantibody measurements, functional assessment (described previously), and the treatment of physiologic deficits prior to their clinical expression. More than 50 different mutations in the AIRE gene have now been reported, and mutations can be confirmed in more than 95% of patients with clinical diagnoses of APS I.[36,92-94] Thus, screening for mutations in the AIRE gene can be considered if the diagnosis is unclear. Mutational analysis should be offered to siblings of affected children in order to determine carrier status and possibly to allow for the diagnosis of endocrinopathies before the onset of symptoms. Despite the availability of mutational analysis, more studies are needed to determine the relative sensitivity and cost effectiveness of mutational analysis screening versus primary antibody screening.

Genetics of APS II

Whereas APS I displays an autosomal-recessive Mendelian pattern of inheritance, APS II is not inherited as a single gene mutation. APS II is much more typical of other autoimmune endocrinopathies wherein cases occur sporadically or within families. Overall, patients with APS II have HLA associations similar to those of patients with type 1 diabetes—especially having increased frequencies of HLA-DR3 (DQB1*0201) and DR4 (DQB1*0302).[95] This is not surprising because type 1 diabetes, a frequent component of APS II, is strongly HLA associated. However, when patients with type 1 diabetes are removed from the APS II subject group the association between HLA-DR alleles and APS II disappears.

Thus, in the absence of type 1 diabetes HLA-DR is not a major locus for the development of APS II. Previous studies have shown not only that Addison disease and type 1 diabetes share the major risk DR3/DR4 genotype but that Addison disease is particularly associated with DRB1*0404 and DRB1*0301 haplotypes.[96] It is estimated that 1 in 20 patients with type 1 diabetes with this haplotype will have adrenal autoantibodies.[97,98] Another high-risk allele for Addison disease is DRB5 (DQB1*0301). Graves disease

is more often associated with HLA-DR3 as opposed to Hashimoto thyroiditis, which is associated with HLA-DR4 or DR5.[99,100] Autoimmune hypoparathyroidism and mucocutaneous candidiasis do not display associations with specific HLA alleles.

Because the association of APS II with specific HLA alleles is only modest, other genes must be important in providing susceptibility. To identify non-HLA genes that influence susceptibility to APS II genome-wide scan or linkage studies are necessary. The G allele of the CTLA-4 exon 1 A/G diallelic polymorphism has been associated with Addison disease in APS II, and less strongly associated with isolated Addison disease.[101]

Autoantibodies in Autoimmune Polyglandular Syndromes

Autoantibodies are antibodies (predominantly IgG) that bind to self-antigens (e.g., autoantigens). Autoantibodies may be pathogenic, as observed in Graves disease or myasthenia gravis. In Graves disease, agonistic autoantibodies directed against the thyroid follicular cell TSH receptor stimulate overproduction of thyroid hormone—producing hyperthyroidism.[102] In myasthenia gravis, autoantibodies directed against the motor end plate acetylcholine receptor located on myocytes stimulate internalization of the acetylcholine receptor—producing weakness. Alternatively, autoantibodies may serve solely as serologic markers of autoimmunity—as in type 1 diabetes, in which islet cell cytoplasmic autoantibodies (ICA) and glutamic acid decarboxylase autoantibodies (GADA) are indicators of ongoing autoimmunity.[103,104]

Detection of autoantibodies in relation to autoimmune polyglandular syndromes serves several important functions. First, detection of autoantibodies implicates an autoimmune etiology as the cause of disease and allows a specific diagnosis to be established.[105] Second, autoantibody detection in asymptomatic individuals indicates an increased risk for the later development of clinical disease.[64] Third, the diagnosis of one autoimmune disease in an individual (or detection of predilection to one autoimmune disease by the presence of autoantibodies) suggests that this individual is at risk for associated autoimmune diseases.

ADRENAL CYTOPLASMIC AUTOANTIBODIES

Adrenal cytoplasmic autoantibodies (ACA) were first detected using a complement-fixation technique with saline extracts of adrenal tissue, and soon afterward by indirect immunofluorescence.[106] Usually, all layers of the adrenal cortex fluoresce—whereas the medulla does not usually fluoresce.[87] The microsomal localization of autoantigens has been confirmed using ultracentrifuged cellular components.[107] Other assays for adrenal autoantibodies include solid-phase radioimmunoassays and nonradioactive enzyme-linked immunoabsorbent assays.[88,108]

Up to 75 to 80% of new-onset subjects with Addison disease exhibit ACA.[87] In up to approximately half of asymptomatic ACA-positive individuals, Addison disease develops in less than 3 years. In a follow-up of 20 ACA-positive children followed for up to 11 years, the cumulative risk for developing Addison disease was 100%.[87] ACA are also predictive of the development of Addison disease in adults, although less frequently than in children. Higher titers of ACA and complement-fixing ACA might be associated with an increased risk of displaying clinical disease.[109]

Autoantibodies to the surface of adrenal cortical cells have been described but are not detected routinely because of the difficulty in obtaining fresh human or animal adrenal tissue that can be used for such assays. However, almost 90% of individuals with Addison disease were reported to exhibit such autoantibodies.[110] ACA are detected in all forms of autoimmune Addison disease, be it isolated Addison disease or as part of APS I or APS II. As stated previously, subjects with other forms of organ-specific autoimmune disease exhibit increased frequencies of ACA. In such circumstances, ACA predict an increased risk for developing biochemical and clinical evidence of adrenal insufficiency.

ADRENAL ENZYME AUTOANTIBODIES

Typical of many organ-specific autoimmune diseases, major autoantigens that serve as targets of autoantibodies in the autoimmune polyglandular syndromes are enzymes. Such enzymes are typically expressed in the tissues that are being targeted for humoral and/or cell-mediated autoimmune attack. Examples of various autoimmune diseases where enzymes are targeted are outlined in Table 18-1. (Adrenal hormone synthesis is discussed in Chapter 12.)

21-hydroxylase (P450c21) is a major autoantigen recognized by sera from patients with Addison disease.[111] There is a strong correlation between positivity for ACA and P450c21 autoantibodies.[112] Other enzymes have been identified as autoantigens in patients with isolated autoimmune Addison disease or in patients with an autoimmune polyglandular syndrome, including P450 cholesterol side-chain cleavage enzyme (P450scc), 17α-hydroxylase (P450c17), and 3β-hydroxysteroid dehydrogenase (not a P450 enzyme).[112]

ADRENAL ENZYME AUTOANTIBODIES IN APS I

Although autoantibodies to P450c21 (21-hydroxylase), P450ssc (side-chain cleavage enzyme), and P450c17 (17α-hydroxylase) have been reported, autoantibodies to P450c21 are most commonly identified in patients with adrenal autoimmunity. Nearly 75% of APS I and APS II patients reportedly have P450c21 autoantibodies present.[87] The autoantigenic epitopes of the P450c21 enzyme are located in the C-terminal end and in a central region of the enzyme.[113] Peterson et al. found that two of four epitopes recognized by P450c17 autoantibodies cross-reacted with P450c21, indicating that reactivity to one of these autoantigens could actually reflect molecular mimicry between such epitopes.[114] Except for the N-terminal amino acids 1-40 and the C-terminal

amino acids 456 to 521, immunoreactive epitopes have been described throughout P450c21.[115]

Higher titers of ACA and higher concentrations of P450c21 autoantibodies appear to correlate with more severe impairment of adrenocortical function and the predicted development of Addison disease.[87] Autoantibody concentrations appear to rise until the development of clinical Addison disease, at which time autoantibody reactivity disappear. This is consistent with the concept that once an autoantigen is completely destroyed the immune system is no longer stimulated to produce autoantibodies—with autoantibody prevalence and concentration diminishing.

ADRENAL ENZYME AUTOANTIBODIES IN APS II

When clinical or preclinical Addison disease is present, there is no unique combination of adrenal or gonadal antibodies that separate APS I from APS II.[105,116,117] The differentiation of APS I from APS II is made on clinical grounds or by detecting an autoantibody characteristic of a nonadrenal APS II–associated autoimmune disease. Furthermore, there are no unique epitopes recognized by P450c21 autoantibodies that allow differentiation of Addison disease as to etiology (e.g., isolated autoimmune Addison disease versus APS I versus APS II) other than indicating that the disease is indeed autoimmune.[118]

Autoantibodies to P450c21, P450scc, and P450c17 are common in APS II. Most patients with APS I or II with Addison disease have autoantibodies to one or more of these enzymes, compared to less than 25% of APS patients without adrenal insufficiency.[119] In one study (using an immunoprecipitation assay with ^{125}I-labeled 21-hydroxylase) it was demonstrated that nearly all patients with Addison disease and APS II were positive for autoantibodies to P450c21—compared to 92% of patients with APS-I, 72% of patients with isolated Addison disease, and 80% of non-Addisonian patients who were ACA positive.[120] Technical differences in the performance of the various assays contribute to the differences in reported frequencies as well as the presence or absence of SCA.

ADRENAL ENZYME AUTOANTIBODIES IN ISOLATED ADDISON DISEASE

Autoantibodies to P450c21 are common in Addison disease patients, whether isolated or part of APS I or APS II, and are rare in the absence of Addison disease.[87,121] P450c21 appears to be the major adrenal autoantigen in cases of isolated Addison disease, being detected in nearly 75% of patients. Autoantibodies to P450scc and P450c17 have been reported but are less frequently found (<30%) than P450c21 antibodies.[112]

STEROIDAL CELL/GONADAL AUTOANTIBODIES

In some individuals with ACA, their sera has also been shown to react with reproductive-steroid-producing tissues such as the theca interna of the graffian follicle, Leydig cells of the testis, and/or syncytiotrophoblastic layer of the placenta.[98,122] Sera that recognize antigens in adrenal and reproductive-steroid-producing tissues whose immunoreactivity cannot be absorbed with adrenal extracts are considered SCA. Sera may react to all tissues or to just one. The significance of whether a serum reacts with a single tissue or multiple tissues in defining SCA is unknown. Such variability may represent variations in the autoimmune epitopes recognized by the serum or differences in the tissue substrates relating to autoantigen densities or epitope availability.

SCA are associated with an increased risk of developing primary autoimmune gonadal failure that is expressed predominantly in women as either primary amenorrhea or premature menopause. Men are usually asymptomatic. When ACA are present in the absence of SCA, gonadal failure is unlikely to develop.[98] About a third of individuals with ACA upon initial screening using adrenal as the sole substrate have SCA using ovary, testis, or placenta as the antigen source. SCA can be observed in APS II patients, although gonaditis is more common in APS I than in APS II. It is estimated that 60% of subjects with APS I and Addison disease express SCA, versus 30% of subsets with APS II.

Primary hypogonadism can be observed in APS I or APS II manifesting as hypergonadotropic ovarian, or rarely as testicular failure. Premature ovarian failure independent of APS can also occur as a consequence of autoimmunity.[123] Nevertheless, Addison disease coexists in approximately 2% to 10% of women with ovarian failure.[124] Autoimmune ovarian failure is characterized histologically by ovarian infiltration with inflammatory cells.[125] Patients with isolated premature ovarian failure or premature ovarian failure associated with APS often express SCA. As early as 1968, SCA were described using indirect immunofluorescence.[126] Five of 5 women with SCA, all of whom also had ACA consistent with an autoimmune polyglandular syndrome, manifested ovarian failure. Autoantibodies reacting strongly to the pig zona pellucida as determined by indirect immunofluorescence were observed in 6 of 22 women with infertility.[127]

SCA, depending on the assay used, have been reported in 4% to 87% of women with premature ovarian failure.[122,128,129] SCA are also predictive of later gonadal failure in APS women with normal menses at the time of initial study. Ahonen et al. reported that 100% (11 of 11) of APS I patients who were positive for SCA developed primary ovarian failure during a follow-up period of up to 12 years.[130] The nature of the ovarian autoantigens in premature ovarian failure is controversial. Because the adrenal cortex and gonad share several synthetic pathways common to cells producing adrenocortical steroids and sex steroids, humoral autoimmunity to a shared autoantigen may be observed in adrenalitis and gonaditis.

The synthesis of sex and adrenal steroids requires P450scc, 3β-hydroxysteroid dehydrogenase, and P450c17. Therefore, it would be anticipated that these enzymes could also be autoantigens in some individuals with gonaditis. Data are however contradictory. In one study, SCA activity was removed by preabsorption with recombinant human 3β-hydroxysteroid dehydrogenase—suggesting that this enzyme was a major autoantigen

detected by SCA-positive sera.[131] Another study suggested that SCA correlated best with reactivity to P450scc and a 51-kilodalton autoantigen that binds to the aromatic L-amino acid decarboxylase present in granulosa cells, placenta, liver, and pancreatic beta cells.[132]

In the absence of adrenal autoimmunity, autoantibodies to P450c21, P450c17, or P450scc are rarely found in women with premature ovarian failure.[122] This suggests that in the absence of APS few cases of idiopathic premature ovarian failure result from autoimmune damage to the ovary. In another study, no autoantibodies to P450c17 or P450scc in 48 women with isolated premature ovarian failure were identified—whereas only 2 of these women had SCA and only 1 had autoantibodies to 3β-hydroxysteroid dehydrogenase.[133] However, in another study autoantibodies to 3β-hydroxysteroid dehydrogenase were observed in women with premature ovarian failure who did not have coexistent autoimmune diseases.[134]

An alternative hypothesis attempting to explain premature ovarian failure is the potential existence of antagonist autoantibodies directed against the FSH or LH receptors. Support for this hypothesis is weak, however, because recent studies have not been able to confirm the presence of gonadotropin receptor autoantibodies in the sera of a large group of women with premature ovarian failure.[135]

AUTOANTIBODIES IN HYPOPARATHYROIDISM

Autoimmune hypoparathyroidism is a characteristic disorder essentially unique to APS I. Hypoparathyroidism is absent in subjects with APS II. In Blizzard's original report of parathyroid autoantibodies detected using indirect immunofluorescence, nearly 40% of patients with autoimmune hypoparathyroidism were found to have parathyroid cytoplasmic autoantibodies—versus 6% of controls.[136,137] However, other laboratories did not confirm the initial reports of such parathyroid cytoplasmic autoantibodies.[138,139] It was shown that autoantibodies detected by indirect immunofluoresence directed against the parathyroid gland could be preabsorbed with human mitochondria, indicating that such autoantibodies were not tissue specific.[139]

Autoantibodies have also been identified that are cytotoxic for cultured bovine parathyroid cells in patients with hypoparathyroidism.[140] These autoantibodies also bind to cultured bovine endothelial cells.[141] Unrelated to APS I or APS II, autoantibodies that bind to anti-PTH antibodies employed in a PTH immunoassay (e.g., anti-idiotypic PTH autoantibodies) have also been described in a patient with hypoparathyroidism.[142] More recently, autoantibodies to the extracellular domain of the calcium receptor have been described in patients with hypoparathyroidism.[143] Similarly, autoantibodies that block the calcium receptor have been described that cause hyperparathyroidism (e.g., autoimmune hypercalcemia).[144]

OTHER AUTOANTIBODIES IN APS I AND II

Autoantibodies to thyroid follicular cell organelles in autoimmune thyroid disease (e.g., thyroid microsomal autoantibodies), follicular cell enzymes (e.g., thyroperoxidase) and products (e.g., thyroglobulin), and autoantibodies to pancreatic beta cells in type 1 diabetes (e.g., islet cell cytoplasmic autoantibodies) and beta cell proteins (e.g., glutamic acid decarboxylase and insulinoma-associated antigen-2) and products (e.g., insulin and carboxypeptidase H) are well described in patients with autoimmune polyglandular syndromes. Their frequency is especially high in patients with APS II. However, the biology of these autoantibodies will not be reviewed here. (See the specific chapters that address autoimmune thyroid disease and type 1 diabetes.)

Celiac disease is accompanied by mucosal (especially) IgA autoantibodies to reticulin, endomysium, transglutaminase, and jejunum.[145] Retrospective studies show that tissue transglutaminase autoantibodies can provide 100% sensitivity and specificity for biopsy-proven celiac disease.[146] There is a high prevalence of various autoimmune disorders [including type 1 diabetes (6% of type 1 patients reportedly have antiendomyseal antibodies), autoimmune thyroiditis, dermatitis herpetiformis, autoimmune alopecia, autoimmune hepatitis, and collagen vascular diseases] in patients with celiac disease.[145] In one study, 3.6% of new-onset type 1 diabetes patients had celiac disease.[147]

Autoantibodies to tyrosine hydroxylase have been reported in ~40% of patients with APS I and correlate with alopecia areata.[148] Antibodies to liver/kidney microsome type 1 (LKM1) are found in nearly 100% of patients with type 2 autoimmune hepatitis.[149] Forty percent of such patients have associated autoimmune disease commonly seen in APS I. The hepatic autoantigens P450IA2 and P4502A6 have been reported as targets of these antibodies. Autoantibodies to aromatic L-amino acid decarboxylase have also been recognized in APS I and isolated cases of Addison disease.[132]

Autoantibodies to the adrenal medulla may also occur in various autoimmune conditions, but especially so in type 1 diabetes.[150,151] Adrenal-medullary autoimmunity has been linked to autonomic dysfunction in individuals with diabetes mellitus.[152] Pteridin-dependent hydroxylases have also been proposed as autoantigens in APS I.[153]

Summary

The autoimmune polyglandular syndromes result from a loss of tolerance to self-antigens. A thorough understanding of tolerance induction and defects in tolerance is required to fully understand the immunopathogenesis of APS. APS I, an autosomal-recessive disorder mapped to the AIRE gene, is defined by the presence of two of the following: adrenocortical autoimmunity, hypoparathyroidism, and mucocutaneous candidiasis. APS II is defined by the coexistence of autoimmune adrenocortical insufficiency or serologic evidence of adrenalitis with autoimmune thyroiditis and/or type 1 diabetes mellitus.

The occurrence of any component disease of an APS may be linked to the occurrence of others through shared autoimmunity background genes that lead to a loss of tolerance. As such, a high index of suspicion should be maintained whenever one autoimmune disorder is diagnosed. For example, in type 1 diabetes it is

routine to screen for thyroid autoimmunity and celiac disease.

Treatment of APS should be aimed at optimal management of the specific underlying diseases. Screening for the presence of associated autoimmune disorders should be performed regularly. An improved understanding of the interaction among susceptibility genes, environmental triggers, and the development of impaired immune tolerance should prove to be the best path to improved diagnostic and therapeutic modalities in the care of patients with APS.

Introduction

Energy balance is the "final frontier" of endocrinology. Prior to 1994, with the discovery of leptin, the disorders of energy balance were not even considered endocrine diseases. Today, obesity can account for up to 25% of pediatric endocrine practice referrals—and type 2 diabetes accounts for up to 30% of the new referrals for diabetes, virtually all of whom are also obese. Since the discovery of leptin, the negative feedback pathway of energy balance has been elucidated—and endocrinologists have embraced disorders of energy balance as part of their portfolio.

Thus, the study of energy balance has become a matter of continuing education for pediatric endocrinologists. The entire field is a "work in progress," which is problematic because our knowledge, diagnostic armamentarium, and treatment options are still in their infancy. This chapter conveys a clear and up-to-date basic understanding of the energy balance pathway, and provides a clinical rationale and formulation for evaluating and treating patients with energy balance disorders.

Neuroendocrine Regulation of Energy Balance

The negative feedback axis of energy balance and its function during homeostasis has been largely delineated through studies in animal models. Human data are presented where available. The axis consists of three arms (Figure 19-1). The first is the afferent arm, which conveys in the form of hormonal and neural inputs peripheral information on hunger and peripheral metabolism to the hypothalamus. The second is a central processing unit, consisting of various areas within the hypothalamus.The ventromedial hypothalamus [VMH, consisting of the ventromedial (VMN) and arcuate (ARC) nuclei] integrates the afferent peripheral signals, along with other central stimuli. The paraventricular nuclei (PVN) and lateral hypothalamic area (LHA) serve as a gated neurotransmitter system to alter neural signals for changes in feeding and energy expenditure. The third component is the efferent arm, which consists of a complex network of autonomic effectors that regulate energy intake and monitor energy expenditure versus storage.[1,2] Anatomic disruptions or genetic or metabolic alterations of the afferent, central processing, or efferent arms can alter energy intake or expenditure in stereotyped ways—which can lead to obesity or cachexia.

THE AFFERENT SYSTEM

Alimentary Afferents

Hunger. *The afferent vagus:* The vagus nerve is the primary neural connection between the brain and the gut. The afferent vagus nerve conveys information regarding mechanical stretch of the stomach and duodenum and sensations of gastric fullness to the nucleus tractus solitarius (NTS).[3] Of note is that each of the alimentary neuropeptide effects on hunger and satiety discussed in the material following is obviated by concomitant vagotomy, implicating the afferent vagus as the primary mediator of alimentary energy balance signals.[4-6]

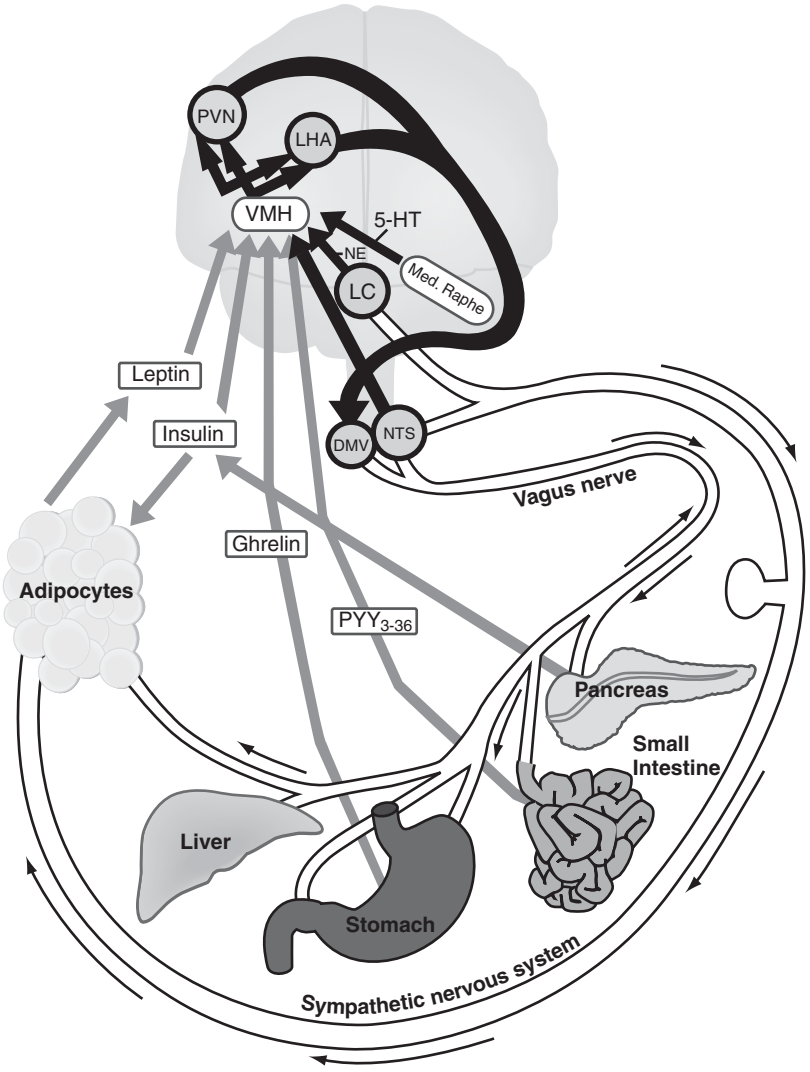

Figure 19-1 The homeostatic pathway of energy balance. Afferent (gray), central (black), and efferent (white) pathways are delineated. The hormones insulin, leptin, ghrelin, and peptide YY(3-36) (PYY3-36) provide afferent information to the ventromedial hypothalamus regarding short-term energy metabolism and energy sufficiency. From there, the ventromedial hypothalamus elicits anorexigenic (α-melanocyte-stimulating hormone, cocaine-amphetamine-regulated transcript) and orexigenic (neuropeptide Y, agouti-related protein) signals to the melanocortin-4 receptor in the paraventricular nucleus and lateral hypothalamic area. These lead to efferent output via the locus coeruleus, via the nucleus tractus solitarius, which activates the sympathetic nervous system—causing the adipocyte to undergo lipolysis. Alternatively, this is achieved via the dorsal motor nucleus of the vagus, which activates the vagus nerve to store energy by increasing pancreatic insulin secretion and (in rodents) by increasing adipose tissue sensitivity to insulin. 5-HT, serotonin (5-hydroxytryptamine); DMV, dorsal motor nucleus of the vagus; LC, locus coeruleus; LHA, lateral hypothalamic area; NE, norepinephrine; NTS, nucleus tractus solitarius; PVN, paraventricular nucleus; and VMH, ventromedial hypothalamus. [From Lustig RH (2006). Childhood obesity: Behavioral aberration or biochemical drive? Reinterpreting the first law of thermodynamics. Nature Clin Pract Endo Metab 2:447–458. Courtesy of Nature Publishing Group, with permission.]

Ghrelin: Ghrelin, an octanoylated 28-amino-acid peptide, was discovered serendipitiously while looking for the endogenous ligand of the growth hormone (GH) secretagogue receptor (GHS-R).[7] Ghrelin induces rat GH release through stimulation of the pituitary GHS-R. The endogenous secretion of ghrelin from the fasting stomach is high, but is decreased by nutrient administration. Volumetric stretching of the stomach wall has no effect. However, ghrelin also binds to the GHS-R in the VMH—which increases hunger, food intake, and fat deposition.[8,9]

Ghrelin also increases the respiratory quotient (RQ) in rats, suggesting a reduction of fat oxidation and promotion of fat storage. Ghrelin appears to tie the lipolytic effect of GH with the hunger signal, and is probably important in the acute response to fasting. In humans, ghrelin levels rise with increasing subjective hunger—and peak at the time of voluntary food consumption.[10] This suggests that ghrelin acts on the VMH to trigger meal initiation. Ghrelin infusion increases food intake in humans.[11] However, plasma ghrelin levels are low in obese individuals—and increase with fasting,[12] suggesting that ghrelin is a response to (rather than a cause of) obesity.

Satiety. *Peptide YY_{3-36} (PYY_{3-36})*: A recently identified hormonal signal to control meal volume is PYY_{3-36}.[13] This

peptide fragment is secreted by intestinal L cells in response to exposure to nutrient, crosses the blood-brain barrier, and binds to the Y_2 receptor in the VMH. Activation of this receptor causes a decrease in NPY mRNA in neurons of the orexigenic arm of the central processing system. In nonobese humans, infusion of $PYY_{3\text{-}36}$ during a 12-hour period decreased the total amount of food ingested from 2,200 to 1,500 k/cal—but without effect on food ingested during the next 12-hour interval.[13] Although the pharmacology of this peptide is being elucidated, its specific role in obesity is not yet known.

Glucagon-like peptide-1 (GLP-1): Those same intestinal L cells produce GLP-1 through post-translational processing of pre-proglucagon. Two equipotent forms of GLP-1 are generated: a glycine-extended form called $GLP\text{-}1_{(7\text{-}37)}$ and the amidated peptide $GLP\text{-}1_{(7\text{-}36)}$ amide.[14] GLP-1 acts on the stomach to inhibit gastric emptying. This prolongs the time of absorption of a meal. GLP-1 also activates its receptor on pancreatic β-cells to stimulate cAMP production, protein kinase A activation, and insulin secretion (Figure 19-2)—thereby improving glucose tolerance (a mechanism of the "incretin" effect). GLP-1 also acts on β cells to stimulate neogenesis, thereby increasing β-cell mass.[15]

GLP-1 also exerts potent effects on reduction of appetite, through reduction in gastric emptying and through direct decreases of corticotropin-releasing hormone (CRH) signaling in the PVN and increasing leptin signaling in the VMH.[16]

Cholecystokinin (CCK): CCK is an 8-amino-acid gut peptide released in response to a caloric load. It circulates and binds to CCK_A receptors in the pylorus, vagus nerve, NTS, and area postrema to promote satiety.[3]

Metabolic Afferents

Leptin. Energy intake versus expenditure is normally regulated very tightly (within 0.15% per year) by the hormone leptin. Leptin is a 167-amino-acid hormone produced by adipocytes, which transmit the primary long-term signal of energy depletion/repletion to the VMH.[17,18] Leptin's primary neuroendocrine role is to mediate information about the size of peripheral adipocyte energy stores to the VMH. Leptin is a prerequisite signal to the VMH for the initiation of high-energy processes, such as puberty and pregnancy.[19,20] Leptin reduces food intake and increases the activity of the sympathetic nervous system (SNS).[21]

Conversely, low leptin circulating levels infer diminished energy stores (which signal via the VMH to reduce energy expenditure), inhibit metabolic processes and increase appetite. Serum leptin concentrations drop precipitously (in excess of body fat loss) during periods of short-term fasting,[22,23] and it seems likely that leptin functions primarily as a peripheral signal to the hypothalamus of inadequate caloric intake rather than specifically as a satiety signal.[24]

In the fed state, circulating levels of leptin correlate with percentage of body fat.[25,26] Leptin production by adipocytes is stimulated by insulin and glucocorticoids,[27,28] and is inhibited by β-adrenergic stimulation.[24] Programming of relative leptin concentrations by early caloric intake may be one mechanism that links early overnutrition with later obesity.[29]

Leptin binds to its receptor (a member of the cytokine receptor superfamily) on target VMH neurons. There are four receptor isoforms formed by differential mRNA splicing: ObRa (an isoform with a shortened intracellular domain, which may function as a transporter), ObRb (the intact full-length receptor), ObRc (also with a short intracellular domain), and ObRe (without an intracellular domain, but which may function as a soluble receptor).[30] As leptin binds to its VMH receptor, three neuronal signals are transduced.

The first is opening of an ATP-sensitive potassium channel, which hyperpolarizes the neuron and decreases its firing rate.[31] The second is the activation of a cytoplasmic Janus kinase 2 (JAK2), which phosphorylates a tyrosine moiety on proteins of a family called signal transducers and activators of transcription 3 (STAT-3).[32] The phosphorylated STAT-3 translocates to the nucleus, where it promotes leptin-dependent gene transcription.[33] However, leptin also activates the insulin receptor substrate 2/phosphatidyl inositol-3-kinase (IRS2/PI3K) second-messenger system in VMH neurons—which increases neurotransmission of the central anorexigenic signaling pathway.[34]

Insulin. Insulin plays an extremely important role in energy balance[35] because it is part of the afferent and efferent systems. On the afferent side, there is a significant insulin receptor density in a subpopulation of VMH neurons[36]—and there is coordinated transport of insulin across the blood-brain barrier.[37] This suggests a central role for this hormone. In animals, acute intracerebroventricular (ICV) infusions of insulin decrease feeding behavior and induce satiety.[38-40] The data on acute and chronic peripheral insulin infusions are less clear.

Studies of overinsulinized diabetic rats demonstrate increased caloric intake (to prevent subacute hypoglycemia) and the development of peripheral insulin resistance.[41,42] Chronic experimental peripheral insulin infusions decrease hepatic and skeletal muscle glucose uptake by decreasing Glut4 expression, but do not alter adipose tissue glucose uptake.[43,44] One study in humans showed that injecting short-term insulin peripherally during meals did not have an effect on satiety.[45]

Insulin normally activates the insulin receptor substrate 2/phosphatidyl inositol-3-kinase (IRS2/PI3K) second-messenger system in VMH neurons,[46] which increases neurotransmission of the central anorexigenic signaling pathway. The importance of CNS insulin action was underscored by the construction of a brain/neuron-specific insulin receptor knockout (NIRKO) mouse, which cannot transduce a CNS insulin signal.[47] Such mice become hyperphagic, obese, and infertile—with high peripheral insulin levels. These data suggest that peripheral insulin mediates a satiety signal in the VMH to help control energy balance.[48] Various knockouts of the insulin signal transduction pathway that reduce insulin signaling lead to an obese phenotype,[49,50] whereas those that increase insulin signaling lead to a lean phenotype.[51,52]

CENTRAL PROCESSING

The peripheral afferent signals outlined previously reach neurons in the VMH, where they are integrated by a gated neural circuit designed to promote or diminish energy intake and expenditure (Figure 19-2). This circuit consists

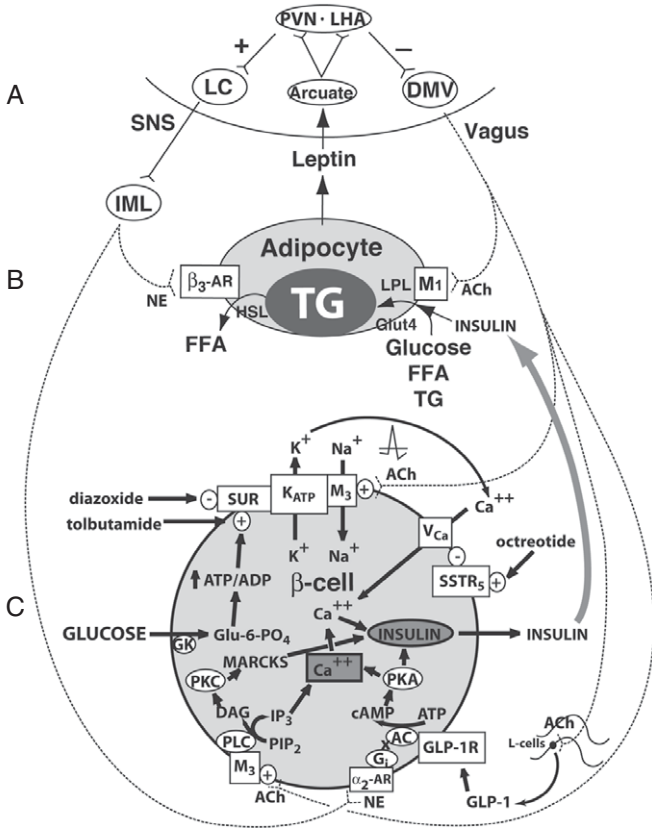

Figure 19-2 Central regulation of leptin signaling, autonomic innervation of the adipocyte and β cell, and the starvation response. *(A)* The arcuate nucleus transduces the peripheral leptin signal as one of sufficiency or deficiency. In leptin sufficiency, efferents from the hypothalamus synapse in the locus coeruleus—which stimulates the sympathetic nervous system. In leptin deficiency or resistance, efferents from the hypothalamus stimulate the dorsal motor nucleus of the vagus. *(B)* Autonomic innervation and hormonal stimulation of white adipose tissue. In leptin sufficiency, norepinephrine binds to the β_3-adrenergic receptor—which stimulates hormone-sensitive lipase, promoting lipolysis of stored triglyceride into free fatty acids. In leptin deficiency or resistance, vagal acetylcholine increases adipose tissue insulin sensitivity (documented only in rats to date), promotes uptake of glucose and free fatty acids for lipogenesis, and promotes triglyceride uptake through activation of lipoprotein lipase. *(C)* Autonomic innervation and hormonal stimulation of the β cell. Glucose entering the cell is converted to glucose-6-phosphate by the enzyme glucokinase, generating ATP—which closes an ATP-dependent potassium channel, resulting in cell depolarization. A voltage-gated calcium channel opens, allowing for intracellular calcium influx—which activates neurosecretory mechanisms, leading to insulin vesicular exocytosis. In leptin sufficiency, norepinephrine binds to α_2-adrenoceptors on the β-cell membrane to stimulate inhibitory G proteins and decrease adenyl cyclase and its product cAMP—and thereby reduce protein kinase A levels and insulin release. In leptin deficiency or resistance, the vagus stimulates insulin secretion through three mechanisms. First, acetylcholine binds to a M_3 muscarinic receptor, opening a sodium channel—which augments the ATP-dependent cell depolarization, increasing the calcium influx and insulin exocytosis. Second, acetylcholine activates a pathway that increases protein kinase C—which also promotes insulin secretion. Third, the vagus innervates L cells of the small intestine, which secrete glucagon-like peptide-1—which activates protein kinase A, contributing to insulin exocytosis. Octreotide binds to a somatostatin receptor on the β cell, which is coupled to the voltage-gated calcium channel—limiting calcium influx and the amount of insulin released in response to glucose. α_2-AR, α_2-adrenergic receptor; β_3-AR, β_3-adrenergic receptor; AC, adenyl cyclase; ACh, acetylcholine; DAG, diacylglycerol; DMV, dorsal motor nucleus of the vagus; FFA, free fatty acids; G_i, inhibitory G protein; GK, glucokinase; GLP-1, glucagon-like peptide-1; GLP-1R, GLP-1 receptor; Glu-6-PO_4, glucose-6-phosphate; Glut4, glucose transporter-4; HSL, hormone-sensitive lipase; IML, intermediolateral cell column; IP_3, inositol triphosphate; LC, locus coeruleus; LHA, lateral hypothalamic area; LPL, lipoprotein lipase; MARCKS, myristoylated alanine-rich protein kinase C substrate; NE, norepinephrine; PIP_2, phosphatidylinositol pyrophosphate; PKA, protein kinase A; PKC, protein kinase C; PLC, phospholipase C; PVN, paraventricular nucleus; $SSTR_5$, somatostatin-5 receptor; TG, triglyceride; V_{Ca}, voltage-gated calcium channel; VMH, ventromedial hypothalamus; and SUR, sufonylurea receptor. of two arms: the anorexigenic arm [which contains neurons expressing the colocalized peptides pro-opiomelanocortin (POMC) and cocaine/amphetamine-regulated transcript (CART)] and the orexigenic arm, which contains neurons with the colocalized peptides neuropeptide Y (NPY) and agouti-related protein (AgRP). Ghrelin receptor-immunoreactivity colocalizes with NPY and AgRP neurons, whereas insulin and leptin receptors are located on POMC/CART and NPY/AgRP neurons in the VMH[53]—suggesting divergent regulation of each arm. These two arms compete for occupancy of melanocortin receptors (MC_3R or MC_4R) in the PVN and LHA.

Anorexigenesis, POMC/α-MSH, and CART

POMC is differentially cleaved in different tissues and neurons. The ligand α-melanocyte-stimulating hormone (α-MSH) is the primary product involved in anorexigenesis. Overfeeding and peripheral leptin infusion induce the synthesis of POMC and α-MSH within the ARC.[54] α-MSH induces anorexia by binding to melanocortin receptors within the PVN or LHA. CART is a hypothalamic neuropeptide induced by leptin and reduced by fasting. Intrahypothalamic infusion blocks appetite, whereas antagonism of endogenous CART increases caloric intake.[55]

Orexigenesis, NPY, and AgRP

NPY and AgRP colocalize to a different set of neurons within the ARC, immediately adjacent to those expressing POMC/CART.[56] NPY has numerous functions within the hypothalamus, including initiation of feeding, initiation of puberty, regulation of gonadotropin secretion, and adrenal responsiveness.[57,58] NPY is the primary orexigenic peptide. ICV infusion of NPY in rats rapidly leads to hyperphagia, energy storage, and obesity[59,60] mediated through Y_1 and Y_5 receptors.

Fasting and weight loss increase NPY expression in the ARC, accounting for increased hunger—whereas $PYY_{3\text{-}36}$ (through Y_2 receptors) and leptin decrease NPY mRNA.[13,61] AgRP is the human homolog of the protein agouti, which is present in abundance in the yellow (A^y-a) mouse.[62] This protein is an endogenous competitive antagonist of all MCRs, accounting for the yellow color in these mice. In the presence of large amounts of AgRP at the synaptic cleft in the PVN, α-MSH cannot bind to the MC_4R to induce satiety.[63]

Other Neuroendocrine Modulators of Energy Balance

Norepinephrine. Norepinephrine (NE) neurons in the locus coeruleus synapse on VMH neurons to regulate food intake.[64] The actions of NE on food intake seem paradoxical because intrahypothalamic NE infusions stimulate food intake through effects on central α_2- and β-adrenergic receptors,[65] whereas central infusion of α_1-agonists markedly reduces food intake.[66]

Serotonin. 5-HT has been implicated in the perception of satiety based on many lines of evidence: injection of 5-HT into the hypothalamus increases satiety, particularly with respect to carbohydrate;[67] central administration of $5\text{-}HT_{2c}$ receptor agonists increases satiety, whereas antagonists induce feeding;[68] administration of selective 5-HT reuptake inhibitors induces early satiety;[69] leptin increases 5-HT turnover;[70] and the $5\text{-}HT_{2c}$R-KO mouse exhibits increased food intake and body weight.[71] The role of 5-HT in the transduction of the satiety signal may have central and peripheral components because intestinal 5-HT is secreted into the bloodstream during a meal, where it may impact on gastrointestinal (GI) neuronal function and muscle tone and may bind to 5-HT receptors in the NTS to promote satiety.[72]

Melanin-concentrating Hormone. MCH is a 17-amino-acid peptide expressed in the zona incerta and LHA. MCH neurons synapse on neurons in the forebrain and locus coeruleus. MCH appears to be important in conditions such as anxiety and aggression around food.[73] Expression of this peptide is upregulated in *ob/ob* mice. MCH-knockout mice are hypophagic and lean,[74] whereas transgenic MCH-overexpressing mice develop obesity and insulin resistance.[75] ICV administration of MCH stimulates food intake, similar to that seen with NPY administration.[76]

Orexins A and B. These 33- and 28-amino acid peptides, respectively, have been implicated in energy balance and autonomic function in mice.[77] Orexin-knockout mice demonstrate narcolepsy, hypophagia, and obesity[78]—suggesting that orexins bridge the gap between the afferent and efferent energy balance systems.[79] Orexins in the LHA stimulate NPY release, which may account for their effects on orexigenesis. They also stimulate the corticotropin-releasing factor (CRF) and SNS output to increase wakefulness and energy expenditure, learning and memory, and the hedonic reward system.[80] Conversely, orexin neurons in the perifornical and dorsomedial hypothalamus regulate arousal and response to stress.

Endocannabinoids. It has long been known that tetrahydrocannibinol stimulates food intake. This observation led to the identification of endogenous ECs and their receptor, termed CB1.[81] The CB_1 receptor is expressed in corticotropin-releasing hormone (CRH) neurons in the PVN, in CART neurons in the VMN, and in MCH- and orexin-positive neurons in the LHA and perifornical region. Fasting and feeding are associated with high and low levels of ECs in the hypothalamus, respectively. For example, CB_1 receptor-knockout mice have increased CRH and reduced CART expression.

In the *ob/ob* mouse, hypothalamic EC levels are increased—whereas leptin infused intravenously reduces these levels, indicating that a direct negative control is exerted by leptin on the EC system. Glucocorticoids increase food intake by stimulating EC synthesis and secretion, whereas leptin blocks this effect.[82] Finally, the presence of CB_1 receptors on afferent vagal neurons suggests that endocannabinoids may be involved in mediating satiety signals originating in the gut.

Melanocortin Receptors and Central Neural Integration

The human MC_4R localizes to chromosome 2 and is a 7-transmembrane G-coupled receptor encoded by an intronless 1-kB gene. The binding of hypothalamic α-MSH to the MC_4R in the PVN and LHA results in a state of satiety, whereas ICV administration of MC_4R antagonists stimulate feeding—suggesting that MC_4R transduces satiety information on caloric sufficiency. In the MC_3R knockout mouse, a different phenotype is seen. These animals are obese, but they are instead hypophagic and have increased body fat for their lean mass. They gain weight on low- or high-fat chow, and do not change caloric oxidation in response to changes in dietary fat content—suggesting a defect in energy expenditure.[83] Thus, these two hypothalamic MCRs appear to modulate different aspects of energy metabolism. One hypothesis is that the MC_4R modulates energy intake and the MC_3R modulates energy expenditure.[84]

THE EFFERENT SYSTEM

The MCRs in the PVN and LHA transduce the anorexigenic and orexigenic information coming from the VMH in order to modulate activity of the SNS, (which promotes energy expenditure) and of the efferent vagus, which promotes energy storage (Figure 19-2). In this way, peripheral energy balance can be modulated acutely to provide requisite energy for metabolic needs and to store the rest.

The Sympathetic Nervous System and Energy Expenditure

Anorexigenic pressure increases energy expenditure through activation of the SNS.[85] For instance, leptin adminstration to *ob/ob* mice promotes increased brown adipose tissue lipolysis, thermogenesis, renovascular activity, and increased movement—all associated with increased energy expenditure, which assists in weight loss.[86] Similarly, insulin administration acutely increases SNS activity in normal rats and in humans.[87,88] The magnitude of energy expenditure also has a salutary effect on quality of life. Those factors that reduce resting energy expenditure (REE; e.g., hypothyroidism) reduce quality of life, whereas those factors that increase REE (e.g., caffeine) increase quality of life (at least acutely).

The SNS increases energy expenditure in four ways: by innervating the hypothalamus and appetite centers in the medulla to reduce appetite, by increasing TSH secretion to increase thyroid hormone release and energy expenditure, by innervating skeletal muscles to increase energy expenditure, and by innervating β_3-adrenergic receptors in white adipose tissue to promote lipolysis. Activation of the SNS increases energy expenditure at the skeletal muscle by activating β_2-adrenergic receptors,[89] which in turn increase the expression of numerous genes in skeletal muscle[90]—especially those involved in carbohydrate metabolism. SNS activation stimulates glycogenolysis, myocardial energy expenditure, glucose and fatty acid oxidation, and protein synthesis.[91]

Activation of the SNS in rodents stimulates the β_3-adrenergic receptor of brown adipose tissue to promote lipolysis.[92] In humans, activation of the β_3-adrenergic receptor increases cAMP—which activates protein kinase A (PKA). PKA acts in two separate molecular pathways to increase energy expenditure. First, PKA phosphorylates cyclic AMP response element binding protein (CREB)—which induces expression of PPARγ-coactivator-1α (PGC-1α). PGC-1α then binds to enhancer elements on the uncoupling protein-1 (UCP1) gene, which increases the expression and activity of uncoupling proteins (UCPs) 1 and 2.[93,94] UCPs reduce the proton gradient across the inner membranes of mitochondria, which thereby diverts protons from storage in the form of ATP to heat production. Originally, UCPs were discovered in brown adipose tissue and were found to be responsible for thermogenesis.

UCP1 is an inner membrane mitochondrial protein that uncouples proton entry from ATP synthesis.[95] Therefore, UCP1 expression dissipates energy as heat—thus reducing the energy efficiency of the adipose tissue. However, UCP2 has been found in most tissues and UCP3 in skeletal muscle. Second, PKA activation activates the enzyme hormone-sensitive lipase (HSL), which is responsible for lipolysis of intracellular triglyceride to its component free fatty acids (FFAs). The FFAs also induce UCP1, further increasing energy expenditure. The FFAs released from the adipocyte also travel to the liver, where they are utilized for energy by metabolizing into two-carbon fragments. Lipolysis reduces leptin expression. Thus, a negative feedback loop is achieved between leptin and the SNS (Figure 19-2).

The Efferent Vagus and Energy Storage

In response to declining levels of leptin and/or persistent orexigenic pressure, the LHA and PVN send efferent projections residing in the medial longitudinal fasciculus to the dorsal motor nucleus of the vagus nerve (DMV)—activating the efferent vagus.[96] The efferent vagus opposes the SNS by promoting energy storage in four ways: by slowing the heart rate, myocardial oxygen consumption is reduced; the vagus nerve promotes alimentary peristalsis, pyloric opening, and energy substrate absorption; through direct effects on the adipocyte, the vagus nerve promotes insulin sensitivity to increase the clearance of energy substrate into adipose tissue; and through effects on the β cells, the vagus increases postprandial insulin secretion—which promotes energy deposition into adipose tissue.[97-100]

Retrograde tracing of white adipose tissue reveals a wealth of efferents originating at the DMV.[100] These efferents synapse on the M_1 muscarinic receptor on the adipocyte, which increases insulin sensitivity of the adipocyte. Denervation of white adipose tissue results in reduction of glucose and FFA uptake and in induction of HSL, which promotes lipolysis—both of which reduce the efficiency of insulin-induced energy storage. Thus, vagal modulation of the adipocyte augments storage of glucose and FFAs by improving adipose insulin sensitivity[101] (Figure 19-2).

The DMV also sends efferent projections to the β cells of the pancreas.[102] This pathway is responsible for the "cephalic" (preabsorptive) phase of insulin secretion, which is glucose independent and can be blocked by atropine.[103] Overactive vagal neurotransmission increases insulin secretion from β cells in response to an oral glucose load through the following three distinct but overlapping mechanisms[104] (Figure 19-2).

- Vagal firing increases acetylcholine availability and binding to the M_3 muscarinic receptor on the β cell, which is coupled to a sodium channel within the pancreatic β-cell membrane.[105] As glucose enters the β cell after ingestion of a meal, the enzyme glucokinase phosphorylates glucose to form glucose-6-phosphate—increasing intracellular ATP, which induces closure of the ATP-dependent potassium channel. Upon channel closure, the β cell experiences an ATP concentration-dependent β-cell depolarization[106,107] and opening of a separate voltage-gated calcium channel within the membrane. Intracellular calcium influx increases acutely, which results in rapid insulin vesicular exocytosis. Concomitant opening of the sodium channel by vagally mediated acetylcholine augments β-cell depolarization,

which in turn augments the intracellular calcium influx and results in insulin hypersecretion.[108-110]

- Vagally mediated acetylcholine increases phospholipases A_2, C, and D within the β cell—which hydrolyze intracellular phosphatidylinositol to diacylglycerol (DAG) and inositol triphosphate (IP_3).[104] DAG is a potent stimulator of protein kinase C (PKC),[111] which phosphorylates myristoylated alanine-rich PKC substrate (MARCKS)—which then binds actin and calcium-calmodulin and induces insulin vesicular exocytosis.[112] IP_3 potentiates release of calcium within β cells from intracellular stores, which also promotes insulin secretion.[113]
- The vagus also stimulates the release of GLP-1 from intestinal L cells, which circulates and binds to a GLP-1 receptor within the β-cell membrane. Activation of this receptor induces a calcium-calmodulin-sensitive adenyl cyclase, with conversion of intracellular ATP to cAMP—which then activates PKA. PKA causes the release of intracellular calcium stores and the phosphorylation of vesicular proteins, each contributing to an increase in insulin exocytosis.[14,114]

In the efferent pathway, insulin is responsible for shunting blood-borne nutrients into adipose for storage. Indeed, the primary hormonal signal for adipogenesis is insulin.[115] Within the adipocyte, insulin increases Glut4 expression, acetyl-CoA carboxylase, fatty acid synthase, and lipoprotein lipase.[116] Thus, the net effect of insulin on the adipocyte is the rapid clearance and storage of circulating glucose and lipid. Thus, insulin promotes energy storage.

NEGATIVE FEEDBACK MODULATION OF ENERGY BALANCE: THE STARVATION RESPONSE

The regulation of the components of the energy balance system is manifest during the starvation response. Everyone has a "personal leptin threshold" (probably genetically set) above which the brain interprets a state of energy sufficiency.[117] Thus, the leptin-replete state is characterized by increased physical activity, decreased appetite, and increased feelings of well-being. However, in response to caloric restriction leptin levels decline even before weight loss is manifest[22,23]—which is interpreted by the VMH as starvation. Gastric secretion of ghrelin is increased, which increases pituitary GH release in order to stimulate lipolysis to provide energy substrate for catabolism.

Ghrelin stimulates NPY/AgRP to antagonize α-MSH/CART. Decline of leptin reduces α-MSH/CART as well. This leads to decreased MC_4R occupancy. The resultant lack of anorexigenic pressure on the MC_4R results in increased feeding behavior and energy efficiency (with reduced fat oxidation) in order to store energy as fat. In response, the efferent pathway of energy balance coordinates efforts at improving energy efficiency and increasing energy storage. Total and resting energy expenditure decline in at attempt to conserve energy.[118] Specifically, UCP1 levels within adipose tissue decline[119] as a result of decreased SNS activity in response to starvation.[120]

However, in spite of decreased SNS tone at the adipocyte there is clearly an obligate lipolysis (due to insulin suppression and up-regulation of HSL)—which is necessary to maintain energy delivery to the musculature and brain in the form of liver-derived ketone bodies. In addition, in the starved state vagal tone is increased in order to slow the heart rate and myocardial oxygen consumption, increase β-cell insulin secretion in response to glucose, and increase adipose insulin sensitivity—all directed at increasing energy storage.[120] These revert back to baseline once caloric sufficiency is reestablished, and leptin levels rise.

THE HEDONIC PATHWAY OF FOOD REWARD

The negative feedback pathway delineated previously is not the only site of central regulation of food intake. Complementary to insulin and leptin's ability to alter energy balance, these hormones also modify the *hedonic pathway*—the pleasurable and motivating responses to food. This is the same pathway that responds to drugs of abuse, such as nicotine and morphine. The hedonic pathway comprises the ventral tegmental area (VTA) and the nucleus accumbens (NA), with input from various components of the limbic system—including the striatum, amygdala, hypothalamus, and hippocampus.

Food intake is a readout of the hedonic pathway. Administration of morphine to the NA increases food intake in a dose-dependent fashion.[121] When functional, the hedonic pathway helps curtail food intake in situations in which energy stores are replete. However, dysfunction of this pathway can increase food intake—leading to obesity. The VTA appears to mediate feeding on the basis of palatability rather than energy need. The dopaminergic projection from the VTA to the NA mediates the motivating, rewarding, and reinforcing properties of various stimuli (such as food and addictive drugs). Leptin and insulin receptors are expressed in the VTA, and both hormones have been implicated in modulating rewarding responses to food and other pleasurable stimuli.[122] For instance, fasting and food restriction (where insulin and leptin levels are low) increase the addictive properties of drugs of abuse—whereas ICV leptin can reverse these effects.[123]

In rodent models of addiction, increased addictive behavior and pleasurable response from a food reward (as measured by dopamine release and dopamine receptor signaling) are greater after food deprivation.[124] Acutely, insulin increases expression and activity of the dopamine transporter—which clears and removes dopamine from the synapse. Thus, acute insulin exposure blunts the reward of food.[125] Furthermore, insulin appears to inhibit the ability of VTA agonists (e.g., opioids) to increase intake of sucrose.[126] Finally, insulin blocks the ability of rats to form a conditioned place preference association to a palatable food.[127] However, insulin resistance of this pathway may lead to increased reward of food. The role of the hedonic pathway in human obesity is not yet elucidated, but may be surmised.

LEPTIN RESISTANCE

Most obese children have high leptin levels but do not have receptor mutations, manifesting what is commonly referred to as leptin resistance. Leptin resistance prevents

exogenous leptin administration from promoting weight loss.[128] The response to most weight loss regimens plateaus rapidly due to the rapid fall of peripheral leptin levels below a personal "leptin threshold,"[129] which is likely genetically determined. Leptin decline causes the VMH to sense a reduction in peripheral energy stores, which modulates a decrease in REE to conserve energy—analogous to the starvation response[118] but occurring at elevated leptin levels.

The cause of leptin resistance is unknown, but may have several etiologies. Leptin crosses the blood-brain barrier via a saturable transporter, which limits the amount of leptin reaching its receptor in the VMH.[130,131] Activation of the leptin receptor induces intraneuronal expression of suppressor of cytokine signaling 3 (SOCS-3), which limits leptin signal transduction.[51] Dietary fat limits access of peripheral leptin to the VMH, and interferes with leptin signal transduction upstream of STAT-3 (its primary second messenger).[132]

Two clinical paradigms have been shown to improve leptin sensitivity. After weight loss through caloric restriction, exogenous administration of leptin can then increase REE back to baseline and permit further weight loss[133,134]—suggesting that the weight loss itself improves leptin sensitivity. Second, suppression of insulin correlates with improvement in leptin sensitivity and promotes weight loss[135]—suggesting that hyperinsulinemia promotes leptin resistance by interfering with leptin signal transduction in the VMH and VTA.[136] Indeed, insulin reduction strategies can be effective in promoting weight loss in children with hyperinsulinemia by improving leptin sensitivity.[137] This has led to the hypothesis that chronic hyperinsulinemia functions to block leptin signal transduction at the VMH and VTA, which turns a negative feedback cycle into a vicious feed-forward cycle[18] (Figure 19-3). However, this hypothesis remains to be proven.

Energy Excess: Obesity

The rise in the prevalence of obesity in children and adolescents is one of the most alarming public health issues facing the world today. Obesity is associated with significant health problems in children and is an early risk factor for much of adult morbidity and mortality.[138] It is also a major contributor to increasing health care expenditures. Importantly, childhood obesity tends to track to adulthood and thus represents an early beginning of a potentially lethal pathologic process.

DEFINITION

The theoretical definition of obesity is a degree of somatic overweight that causes detrimental health consequences.[139] Based on morbidity and mortality statistics, and with a desire to prevent future risk of morbidity, we practically define obesity as a statistical magnitude of overweight for a population—keeping in mind that morbidity and mortality vary with degree of overweight in different racial, ethnic, and socioeconomic groups[140] and indeed among individuals. The World Health Organization[141] categorizes adult overweight into four subgroups based on body mass index [BMI; weight (kg) ÷ height (m^2)]: BMI 25 to 30 (overweight); BMI 30 to 35, grade 1 (moderately obese); BMI 35 to 40, grade 2 (severely obese); and BMI >40, grade 3 (morbidly obese). Some make a further delineation at BMI >60, denoting this as "superobesity" because even surgical therapies are less effective in this range.

The majority of obesity in adulthood has its origins in childhood,[142,143] making obesity a pediatric concern—and the prevention and treatment of obesity a pediatric goal. BMI is also the accepted marker in children.[144] In childhood, comparison of BMI to normal curves for age[145] allows for categorization of BMI above the 85th percentile as overweight and above the 95th percentile as obese (Figure 19-4A and B).

PREVALENCE AND EPIDEMIOLOGY

The prevalence of childhood obesity in the United States has increased dramatically during the past 30 years,[146,147] although the comparison of longitudinal and cross-sectional data is difficult due to different definitions and measurement parameters among epidemiologic studies. The most recent estimates of obesity prevalence in the United States are based on data from the 1999-2000 National Health and Nutrition Examination Survey (NHANES IV).[147] NHANES demonstrates that the epidemic of childhood obesity is occurring at earlier ages. Based on the

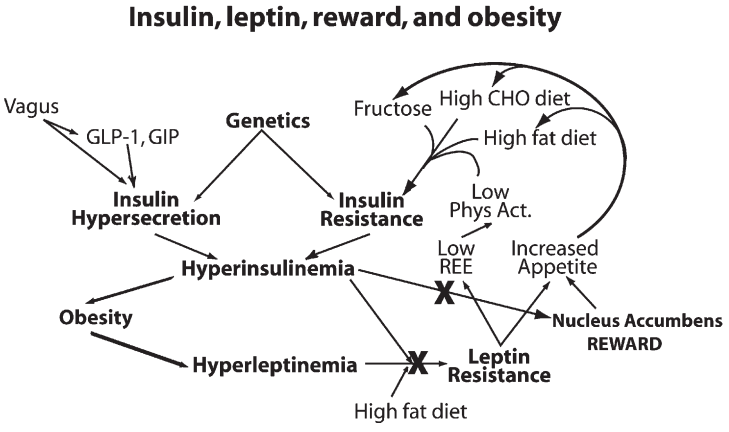

Figure 19-3 Postulated algorithm describing the role of hyperinsulinemia in the dysfunction of the energy balance pathway by promoting energy storage into adipocytes; by interfering with leptin signal transduction in the hypothalamus, promoting the starvation response; and by interfering with dopamine clearance at the nucleus accumbens, thereby increasing the reward of food. Each of these alterations turns a negative feedback pathway into a "vicious cycle." [From Isganaitis E, Lustig RH (2005). Fast food, central nervous system insulin resistance, and obesity. Arterioscler Thromb Vasc Biol 25:2451-2462. Courtesy of the American Heart Association, with permission.]

1999-2000 NHANES, 20.6% of 2- to 5-year-old U.S. children were overweight, defined as BMI for age ≥85th percentile.

The prevalence of obesity in older children was even higher: 30.3% of 6- to 11-year-old children and 30.4% of adolescents (12-19 years old) have now become obese. The prevalence of obesity (defined as weight for length ≥95th percentile in 2-year-old children or younger, or BMI greater than 95th percentile in older children) among children aged 0 to 23 months, 2 to 5 years, 6 to 11 years, and adolescents were 11.4%, 10.4%, 15.3%, and 15.5%, respectively. The prevalence of obesity among both sexes was not significantly different. It was slightly higher in 2- to 5-year-old females (11.0% versus 9.9%), 6- to 11-year-old males (16.0% versus 14.5%), and similar (15.5%) in adolescents. In all age ranges, the prevalence has increased compared with the previous report by NHANES III (1988-1994)—with the greatest change (from approximately 11% to 15%) among 6- to 19-year-olds.

GLOBAL PREVALENCE

Obesity has overtaken AIDS and malnutrition as the number one public health problem in the world.[148] The global prevalence of childhood obesity has been increasing worldwide at an alarming rate during the past 20 years. Rates have increased 2.7-fold to 3.8-fold over 29 years in the United States,[147] 2.0-fold to 2.8-fold over 10 years in England, 3.4-fold to 4.6-fold over 10 years in Australia, and 3.4-fold to 3.6-fold over 23 years in Brazil. In Asia, the prevalence has increased 1.1-fold to 1.4-fold over 6 years in China and 2.3-fold to 2.5-fold over 26 years in Japan. In Africa, the prevalence has increased 3.9-fold over 18 years in Egypt,

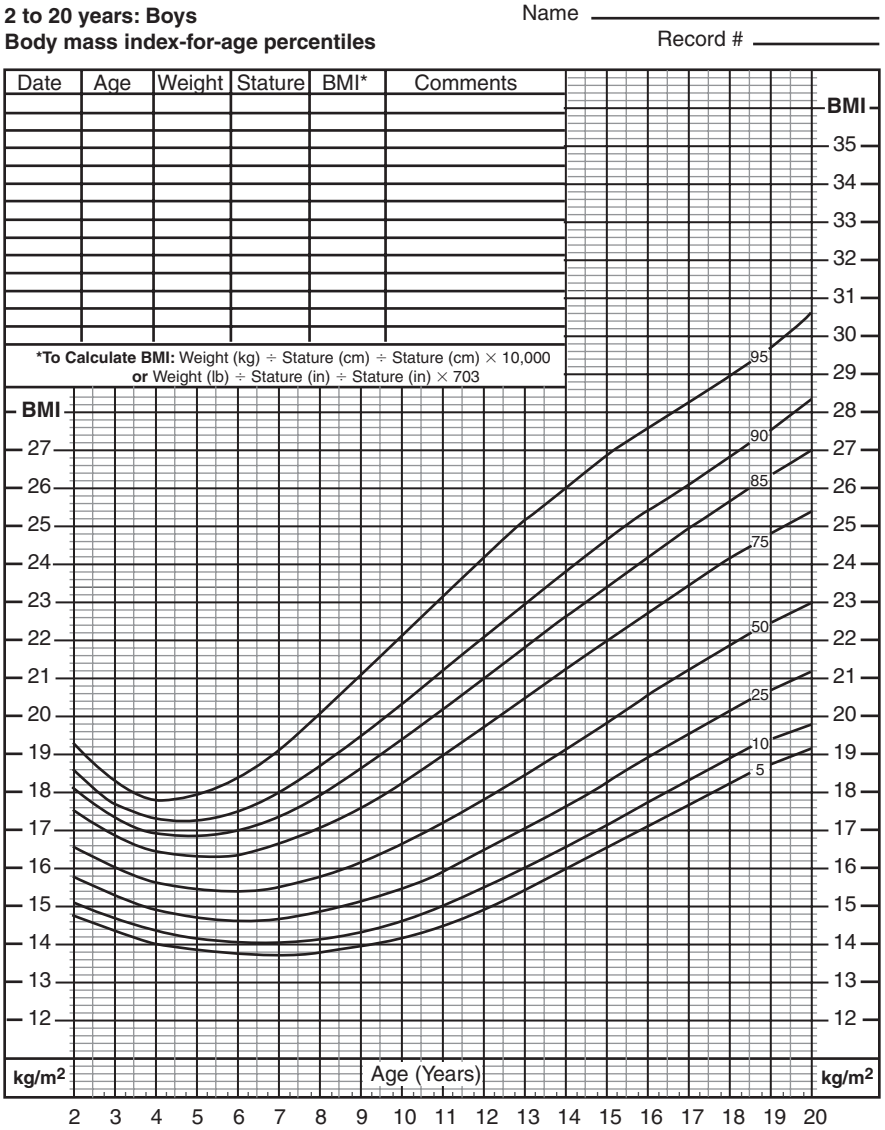

Figure 19-4 Body mass index (BMI)-for-age percentiles for *(A)* U.S. boys and *(B)* U.S. girls 2 to 20 years of age. Note that the 95th percentile signifies obesity. The adiposity rebound occurs at approximately 5 years of age in both sexes. The earlier the adiposity rebound occurs the more likely an organic etiology for the weight gain can be inferred. [From [Author] (2001). BMI curves. http://www.cdc.gov/growthcharts. National Center of Health Statistics, 2000.]

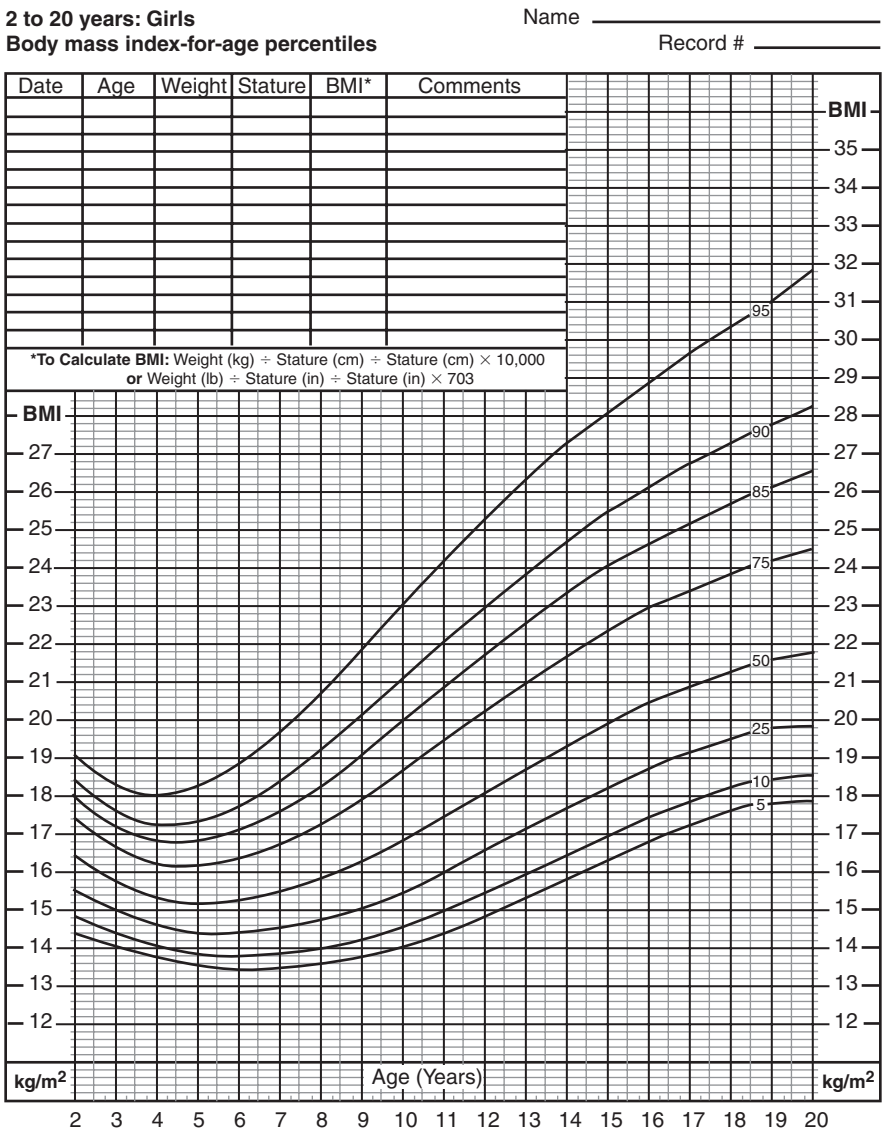

Figure 19-4 (cont'd)

3.8-fold over 6 years in Ghana, and 2.5-fold over 5 years in Morocco.[149] Even in Japan, the rate has doubled from 5% to 10% in the last 10 years.[150,151]

In developed countries, the urban poor are more susceptible to obesity, presumably due to poor dietary practices and limited opportunity for physical activity.[152,153] In contrast, obesity is more frequent in the upper socioeconomic class of developing countries—probably due to transition to a more Western lifestyle, with a more energy-dense diet consisting of higher fats and sugar (which tend to be more palatable at a lower cost).[154,155] This may be due to specific properties of processed food, which promote leptin resistance.[136]

RACIAL AND ETHNIC CONSIDERATIONS

The NHANES surveys only list prevalence among Caucasians, African Americans, and Hispanics despite the fact that Native Americans, Pacific Islanders, Asians, and other racial/ethnic groups are experiencing rapid increases in prevalence as well. Across racial groups, there is a marked dichotomy in the prevalence and rate of increase in childhood obesity.[147,156] For instance, the prevalence among African-American (23.6%) and Hispanic (23.4%) adolescents is twice that than among white adolescents (12.7%)—and the rate of increase in the prevalence of obesity among African-American and Hispanic adolescents almost doubled between 1988 to 1994 and 1999 to 2000, from 13.4% to 23.6% in African Americans and from 13.8% to 23.4% in Hispanics.

Analyses based on the adult definition of obesity (BMI $\geq$30 kg/m^2) indicated that 11.2% of adolescents in general (but approximately 20% of African-American female adolescents) fit into this category. Within these high-risk groups, female African-American adolescents and male 6- to 19-year-old Hispanics exhibit the highest prevalence of obesity (26.6%-27.5%). In the NHLBI Growth and Health Study,[157] the prevalence of obesity in 9-year-old African-American girls was 17.7% and in 9-year-old Caucasian girls 7.7%—and both of these prevalences doubled

over the 10 years of study. These prevalences are true at younger ages as well.

The 1994 Pediatric Nutrition Surveillance System (PedNSS) indicated that 12% of 2- to 4-year-old Native American children were overweight, which is similar to Hispanic children at the same age (12%) but much higher than white children (6%). The prevalence of overweight at 5 to 6 years in Native Americans is twice that in U.S. youth in general, and the prevalence of obesity is three times higher.[158] Among infants and toddlers less than 2 years of age, the prevalence of obesity is highest in African Americans (18.5%)—compared to 10.1% in Caucasians and 13.7% in Hispanics. It is possible that different dietary practices may account for some of these differences. For instance, a study of 2-year-old Latino children in California correlated obesity with early consumption of sugar-sweetened beverages.[159]

Within racial populations, ethnic variability in the prevalence of childhood obesity has also been noted. The United States National Longitudinal Study of Adolescent Health (Add Health) indicated that the BMI ≥85th percentile in adolescent Hispanics was more common among Mexican Americans (32.1%) and Puerto Ricans (30.3%) compared with Cuban Americans (27.1%) and Central/South Americans (26.2%).[153] Only 25% of first-generation Hispanic adolescents were overweight based on BMI≥ 85th percentile compared with 32% of second- and third-generation Hispanics.

The prevalence of overweight in Asian-American adolescents in this study was 20.6%, with comparable prevalence among Filipinos (18.5%) and Chinese (15.3%). Again, only 12% of first-generation Asian Americans were overweight—compared with 27% and 28%, respectively, of second and third generations. In Native Americans, among the studies performed between 1990 and 2000 there is great variation in the prevalence of obesity (12%-77%) based on tribe, age group, measurement tool, and cutoff value.[158] These studies indicate that obesity in Native Americans begins very early in childhood.

PREDICTIVE FACTORS

The higher the BMI during childhood the more likely adult obesity will manifest. In general, children with a BMI ≥95th percentile have a very high risk for adult obesity.[160] Obesity in adolescence is a primary risk factor for obesity in adulthood, with an increased odds ratio from 1.3 for obesity at 1 to 2 years of age to 17.5 for obesity at 15 to 17 years of age.[161] The change of BMI during and after adolescence was the most important predictive variable for adult obesity.[162] Long-term studies suggest that between 50% and 75% of all obese adolescents will become obese adults, and more than one-third of 18-year-olds with BMI greater than the 60th percentile will also be overweight as adults. Children and adolescents with BMI ≥95th percentile have a 62% to 98% chance of being obese at 35 years of age, with a 50% chance in males aged ≥13 years and 66% chance in girls aged ≥13 years.[163]

The age of adiposity rebound, the point of the BMI nadir before the body fatness begins to rise (between 5 and 6 years of age; Figure 19-4A and B), is also an important predictor for adult obesity.[164] Girls tend to have slightly earlier adiposity rebound than do boys. Children with early adiposity rebound have a fivefold greater chance of becoming obese as adults, compared with those with late adiposity rebound. At the age of adiposity rebound, children already overweight have a sixfold greater risk for adult obesity compared to lean children. Therefore, the earlier the onset of childhood obesity the greater the risk for adult obesity.

Infant overnutrition plays an extremely important role in the future development of obesity. Numerous studies have implicated bottle feeding as a specific risk factor.[165] The prevalence of obesity in children who were never breast fed was 4.5%, compared with 2.8% in breast-fed children—and a clear time-response effect was identified for the duration of breast feeding on the decline in prevalence of obesity.[166] Early overnutrition has been correlated with elevated leptin concentrations in later life.[29] Differences in volume and composition of commercial formula versus breast milk have been proposed as etiologic factors.

Parental obesity is also an important predictor of childhood obesity. Children with at least one overweight parent at the age of adiposity rebound have a four- to fivefold greater chance of becoming obese adults. Lean children 5 years or younger have a thirteenfold risk of adult obesity if both parents are obese. Conversely, older children (10–14 years of age) who are obese have a 22.3-fold increased risk of adult obesity regardless of parental weight.[143] Parental obesity is related to early adiposity rebound, suggesting that genetic influences predominate in childhood weight gain.[167] Obesity and type 2 diabetes often run in families, particularly in minorities with lower socioeconomic backgrounds.[168]

Metabolic Impact of Childhood Obesity

Many of the metabolic and CV complications of obesity are already evident during childhood, and are closely related to the development of insulin resistance and hyperinsulinemia—the most common biochemical abnormality seen in obesity. The obesity-related co-morbidities that emerge early in childhood are alterations in glucose metabolism, dyslipidemia, and hypertension. Although an accelerated atherogenic process is present in obese children, thrombotic CV events do not usually appear until adulthood. The clustering of these manifestations is termed the *metabolic syndrome*. In addition, nonalcoholic fatty liver disease (NAFLD) and polycystic ovarian syndrome are often related—as are other nonendocrine morbidities.

LIPID PARTITIONING

The term *lipid partitioning* refers to the distribution of excess body fat in various organs and compartments. The majority of excess fat is stored in its conventional subcutaneous depot, yet other potential storage sites exist—such as the intra-abdominal (visceral) fat compartment and insulin-sensitive tissues such as muscle and liver. One hypothesis to explain the relation between obesity

and insulin resistance is the "portal-visceral" paradigm.[169] Associations among visceral adiposity, insulin resistance, and co-morbidities have been demonstrated across most age groups and ethnicities.[170] This hypothesis claims that increased adiposity causes accumulation of fat in the visceral depot, leading to an increased portal and systemic free fatty acid (FFA) flux.[171] Increased circulating FFA inhibits insulin action in insulin-sensitive tissues by a "competitive" mechanism, proposed by Randle.[172] Of note, studies of *in vivo* FFA fluxes from the visceral and the subcutaneous truncal and abdominal depots have failed to demonstrate a substantial difference in net fluxes between these depots.

Recent studies demonstrate that subcutaneous fat, which does not drain into the portal system, is strongly related to insulin resistance in healthy obese and in diabetic men.[173] Similarly, truncal subcutaneous fat mass has been demonstrated to independently predict insulin resistance in obese women. Visceral and subcutaneous fat differ in their biologic responses,[174] with visceral fat more resistant to insulin and more sensitive to catecholamines. These observations emphasize that visceral and subcutaneous abdominal fat can contribute to insulin resistance, possibly by different mechanisms.[175]

An alternative theory to explain the relation between obesity and insulin resistance is the "ectopic lipid deposition" paradigm.[176] This theory is based on the observation that lipid content in muscle is increased in obesity and in type 2 diabetes mellitus (T2DM) and is a strong predictor of insulin resistance.[177] Moreover, in conditions such as lipodystrophies all fat is stored in liver and muscle due to lack of subcutaneous fat tissue—causing severe insulin resistance and diabetes.[178] In obese adults (BMI >30), muscle attenuation on CT (representing lipid content) is a stronger predictor of insulin resistance than is visceral fat.[179] Studies performed in vivo using ^{1}H-NMR spectroscopy demonstrated that increased intramyocellular lipid (IMCL) content is a strong determinant of insulin resistance in humans.[180]

Thus, obesity co-morbidity may begin when the subcutaneous fat reaches its capacity to store excess fat and begins to shunt lipid to ectopic tissues (such as liver and muscle)—leading to peripheral insulin resistance.[181] Another postulated cause of intramuscular lipid accumulation is a reduction of fat oxidation,[182] related to low aerobic capacity or reduced SNS tone. The effect of IMCL accumulation on peripheral sensitivity is postulated to be due to an alteration of the insulin signal transduction pathway in muscle caused by derivates of fat such as long-chain fatty acyl-CoA and diacylglycerol within the myocyte. These derivates activate the serine/threonine kinase cascade and cause serine phosphorylation of IRS-1, which inhibits insulin signaling.[183] A comparable mechanism has been demonstrated in the liver, where accumulation of lipids (in particular, diacylglycerol) activates the inflammatory cascade by inducing c-jun N-terminal kinase (JNK-1)—which causes serine rather than tyrosine phosphorylation of IRS-1, leading to inhibition of hepatic insulin signaling.[184,185]

Studies in obese children have shown a strong association between IMCL accumulation and peripheral insulin sensitivity.[186] In addition, IMCL is greater in those with impaired glucose tolerance in comparison to more insulin-sensitive adolescents with normal glucose tolerance.[184] Similarly, an inverse relation between the degree of visceral adiposity and insulin sensitivity has been shown in obese children.[187] These observations imply that IMCL and hepatic lipid accumulation may play a pivotal role in the development of peripheral insulin resistance.

ADIPOCYTOKINES

Leptin

The discovery of leptin in 1994 has dramatically changed the view of adipose tissue in the regulation of energy balance.[17] Adipocytes secrete several proteins that act as regulators of glucose and lipid homeostasis.[188] These proteins have been collectively referred to as adipocytokines because of their structural similarity with cytokines. Circulating leptin levels correlate with the degree of obesity. As stated previously, the primary role of leptin is to serve as an adiposity sensor to protect against starvation. Leptin probably has a permissive role in high-energy metabolic processes such as puberty, ovulation, and pregnancy. However, its role in states of energy excess is less known. In obesity, the development of leptin resistance may result in a breakdown of the normal partitioning of surplus lipids in the adipocyte compartment.[189]

Adiponectin

The cytokine adiponectin is peculiar in obesity because in contrast to the other adipocytokines its level is reduced in obesity.[190] The adiponectin gene is expressed exclusively in adipose tissue and codes a protein, a carboxyl-terminal globular head domain, and an amino-terminal collagen domain—which is structurally reminiscent of the complement factor 1q.[191] The gene is located on chromosome 3q27, a location previously linked to the development of type 2 diabetes and the metabolic syndrome. Several single-nucleotide polymorphisms (SNPs) in the adiponectin gene have been reported to be associated with the development of type 2 diabetes in populations around the world, suggesting that adiponectin plays a major role in glucose metabolism.[192]

Adiponectin circulates in plasma in three major forms: a low-molecular-weight trimer, a middle-molecular-weight hexamer, and a high-molecular-weight 12- to 18-mer.[193] Circulating plasma adiponectin concentrations demonstrate a sexual dimorphism (females have greater concentrations), suggesting a role for sex hormones in the regulation of adiponectin production or clearance. Dietary factors such as linoleic acid or fish oil versus a high carbohydrate diet or increased oxidative stress have been shown to increase or decrease adiponectin concentrations, respectively. These observations suggest that the circulating levels of adiponectin are regulated by complex interactions between genetic and environmental factors.[194]

The receptors for adiponectin have recently been characterized in rodent models and cloned. Two receptors (ADIPOR1 and ADIPOR2) have been characterized. ADIPOR1 is

expressed in numerous tissues, including muscle—whereas ADIPOR2 is largely restricted to the liver. Both receptors are bound to the cell membrane, yet are unique in comparison to other G-protein–coupled receptors in the fact that the C terminal is external and the N terminal is intracellular.[195] ADIPOR1 and ADIPOR2 are receptors for the globular head of adiponectin and serve as initiators of signal transduction pathways that lead to increased PPARα and AMP kinase activities, which promote glucose uptake and increased fatty acid oxidation. Adiponectin has been shown to have potent antiatherogenic functions because it accumulates in the subendothelial space of injured vascular walls to reduce the expression of adhesion molecules and the recruitment of macrophages.[196]

Studies in obese children and adolescents have shown that adiponectin is inversely related to the degree of obesity, insulin sensitivity visceral adiposity, and IMCL—whereas weight loss increases adiponectin. A fall in adiponectin has been shown to coincide with the onset of insulin resistance[197] and the development of diabetes in monkeys.[198] All of these observations, along with human clinical data, support a pivotal role for adiponectin in the prevention of the co-morbidities of the metabolic syndrome.

Inflammatory Cytokines

Recent accumulating evidence indicates that obesity is associated with subclinical chronic inflammation.[199] The adipose tissue serves not merely as a simple reservoir of energy stored as triglycerides but as an active secretory organ releasing many peptides, including inflammatory cytokines, into the circulation. In obesity, the balance among these numerous peptides is altered such that larger adipocytes and macrophages embedded within them produce more inflammatory cytokines (e.g., TNF-α, IL-6) and fewer anti-inflammatory peptides such as adiponectin.[200]

One theory posits that as energy accumulates in adipocytes the perilipin border of the fat vacuole breaks down, causing the adipocyte to die.[201] Cell death recruits macrophages in the adipose tissue, especially the visceral compartment, which in the process of clearing debris also elaborate inflammatory cytokines—initiating a proinflammatory milieu that predates and possibly drives the development of systemic insulin resistance, diabetes, and endothelial dysfunction.[202,203]

Systemic concentrations of C-reactive protein (CRP) and IL-6, two major markers and participants of the inflammatory process, are increased in obese children and adolescents. CRP levels within the high-normal range have been shown to predict CV disease[204] and the development of T2DM[205] in adults. Elevated levels of CRP correlate with other components of the metabolic syndrome in obese children.[206,207] Thus, inflammation may be one of the links between obesity and insulin resistance—and may promote endothelial dysfunction and early atherogenesis.

Other Adipocytokines

Several other novel adipocytokines have been identified recently, but their clinical significance in humans is unclear. Among them is visfatin,[208] which is secreted exclusively from adipose tissue, is correlated with the amount of visceral fat, and has insulin mimetic effects on adipogenesis in vitro. Another novel adipocytokine is resistin, a 12.5-kDa polypeptide hormone produced by adipocytes in rodents and by immunocompetent cells in humans. In rodents, resistin appears to have an important role in the development of hepatic insulin resistance. However, its role in humans is less clear but may be related to involvement in the regulation of inflammatory processes rather than in tissue-specific insulin sensitivity.

INSULIN RESISTANCE

Insulin resistance presents in the obese child as altered glucose metabolism manifest as impaired glucose tolerance or overt T2DM, dyslipidemia, vascular changes culminating in hypertension, NAFLD, and/or polycystic ovarian syndrome (PCOS). The development of T2DM is covered in depth in Chapter 10. However, it is worth noting that impaired glucose tolerance (IGT)—known as pre-diabetes—is a relatively common condition in obese children and adolescents. The prevalence of IGT among obese children and adolescents is reported to be greater than 20%.[209] Higher prevalence rates of IGT have been reported in obese children from Thailand and the Philippines, in Latino children living in the United States,[210] and in Germany[211]—whereas a lower prevalence rate (15%) was found in obese children in France. IGT in obese youth is typically characterized by obesity with an unfavorable pattern of lipid partitioning, with increased deposition of fat in the visceral and IMCL compartments.[212]

VASCULAR CHANGES

Early stages of the atherosclerotic process may be detected in obese children. In recent years, it has become clear that endothelial dysfunction represents a key early step in the development of atherosclerosis.[213] The hallmark and cause of endothelial dysfunction is impairment in nitric oxide (NO)-mediated vasodilatation.[214] This is due to decreased NO production by endothelial nitric oxide synthase (eNOS), which has been postulated to result from high levels of FFAs and inflammatory cytokines (IL-6, TNF-α; in insulin-resistant obese individuals), from increased reactive oxygen species, or from increased uric acid (which inhibits eNOS activity).[215]

Decreased NO bioavailability leads to an imbalance between vasodilating and vasoconstricting factors (such as endothelin), which leads to impaired vascular smooth-muscle relaxation, increased adhesion of inflammatory cells to the endothelium, increased expression of plasminogen activator inhibitor-1 (PAI-1; a prothrombotic molecule), and increased vascular smooth-muscle cell proliferation. Thus, decreased NO bioavailability is thought to create a proinflammatory prothrombotic environment that promotes atherosclerosis.[216] Endothelial function represents an integrated index of the overall CV risk burden in any given individual.

During the last decade, noninvasive techniques for the assessment of endothelial function [including high-resolution external vascular ultrasound to measure flow-mediated endothelium-dependent dilatation (FMD) of the brachial

artery during hyperemia] have been developed.[217,218] Impaired FMD correlates with arterial wall stiffness, coronary dilatation, and endothelial dysfunction in obese children.[219] Similarly, anatomic changes in peripheral arterial vessels [such as increased intimal medial thickness (IMT)] have also been demonstrated in obese children and adolescents.[220] These changes mimic early coronary pathology and predict adverse CV outcomes.

The landmark Bogalusa heart study demonstrated that CV risk factors present in childhood are predictive of coronary artery disease in adulthood.[221,222] Among these risk factors, LDL cholesterol and BMI measured in childhood were found to predict IMT in young adults.[223] There is now substantial evidence that the insulin resistance of childhood obesity creates the metabolic platform for adult CV disease.[224-226] Moreover, the constellation of peripheral insulin resistance, an unfavorable adipocytokine profile, subacute inflammation, and endothelial dysfunction work in parallel to promote the pathologic processes of aging.

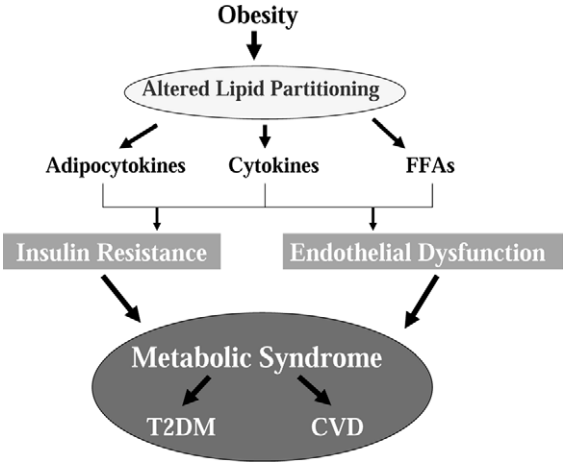

Figure 19-5 A hypothesis on the relation between obesity and the metabolic syndrome. The metabolic impact of obesity is determined by the pattern of lipid partitioning. Lipid storage in insulin-sensitive tissues such as liver or muscle and in the visceral compartment is associated with a typical metabolic profile characterized by elevated free fatty acids and inflammatory cytokines alongside reduced levels of adiponectin. This combination can independently lead to peripheral insulin resistance and to endothelial dysfunction. The combination of insulin resistance and early atherogenesis (manifested as endothelial dysfunction) drives the development of altered glucose metabolism and of cardiovascular disease.

THE METABOLIC SYNDROME

The association and clustering of T2DM, hypertension, dyslipidemia, and CV disease in adults has led to the hypothesis that they may arise from a common antecedent. The World Health Organization argues that this antecedent is insulin resistance and defines this association as the metabolic syndrome.[227-230] An alternative definition is provided by the National Cholesterol Education Program (NCEP) Adult Treatment Panel (ATP) III, which categorizes adults deemed to have the syndrome as meeting at least three of the following five criteria: elevated blood pressure, high triglyceride level, low HDL-cholesterol level, high fasting glucose, and central obesity. The metabolic syndrome affects approximately 25% of the U.S. adult population.[231] Because of its wide prevalence, the metabolic syndrome is of enormous clinical and public health importance even at its earliest stages.

Although still debated, one scheme of the pathophysiology of the metabolic syndrome is shown in Figure 19-5. According to this paradigm, the impact of obesity is determined by the pattern of lipid partitioning (i.e., the specific depots in which excess fat is stored). This pattern of lipid storage determines the adipocytokine secretion profile on circulating concentrations of inflammatory cytokines and on the flux of FFA. The combined effect of these factors determines the sensitivity of insulin target organs (such as muscle and liver) to insulin and impacts the vascular system by affecting endothelial function. Peripheral insulin resistance and endothelial dysfunction are the early promoters of overt pathology, culminating in T2DM and CVD. Of note is that formal criteria for the diagnosis of the metabolic syndrome in children have not yet been agreed upon.[232]

OTHER CO-MORBIDITIES RELATED TO INSULIN RESISTANCE

Nonalcoholic Fatty Liver Disease

NAFLD represents fatty infiltration of the liver in the absence of alcohol consumption.[233] The spectrum of NAFLD ranges from pure fatty infiltration (steatosis) to inflammation (nonalcoholic steatohepatitis, or NASH) to fibrosis and even cirrhosis.[234] NAFLD was found in the NHANES III survey to be more prevalent in obese African-American and Hispanic males with T2DM, hypertension, and hyperlipidemia.[235] These associations have led to the hypothesis that NAFLD may precede the onset of T2DM in some individuals.

NAFLD is now the most common liver disease among children in North America.[236,237] NAFLD in children is associated with increased visceral fat deposition,[238] and may progress to cirrhosis and related complications.[239] The association between abdominal obesity and fatty liver may be partially explained by sustained exposure of the liver to an increased flux of FFA from the visceral depot.[175] NAFLD may represent an early manifestation of ectopic lipid deposition in the liver and represents a challenge to the clinician due to the contrast of its minimal early manifestations and its potential serious outcomes.

Recent data indicate that insulin plays a key role in regulating transcription factors, such as sterol response element binding protein-1c (SREBP-1c), which are abundantly expressed in the liver.[240] SREBP-1c is pivotal in the control of hepatic lipogenesis and is increased in proportion to circulating insulin levels.[241] These data raise the possibility that fasting hyperinsulinemia may contribute to hepatic steatosis, rather than vice versa. Alternatively, inflammatory cytokines released by visceral fat or by the hepatic immunoreactive cells may contribute to altered hepatic lipid metabolism.[233]

The majority of patients probably experience NAFLD without progressing to NASH. It is likely that subsequent inflammation or increased oxidative stress is necessary to promote progression to NASH (the "second

hit" theory).[239] As hepatic imaging modalities improve, noninvasive quantification of hepatic lipid deposition may enable us to use it as a target for intervention. For the time being, NAFLD can be surmised by an elevated ALT or GGT—although the sensitivity and specificity of these enzymes are low.

Polycystic Ovary Syndrome

The association of hyperandrogenism and oligomenorrhea or amenorrhea (termed *PCOS*) in females is a frequent co-morbidity of obesity that can often be traced to childhood. This disorder is covered in detail in Chapter 14. A 2003 consensus statement[242] defined the diagnostic criteria for PCOS as two out of the following three (after exclusion of other hyperandrogenic disorders): oligo/anovulation, clinical or biochemical manifestations of hyperandrogenism, and polycystic ovaries by ultrasound. PCOS is the most common cause of infertility due to anovulation and a major risk factor for development of the metabolic syndrome and altered glucose metabolism in females. The antecedents of PCOS have been identified in prepubertal girls, suggesting a developmental lesion.[243]

About two-thirds of patients with classic PCOS have hirsutism, acne, or male-pattern alopecia—with a similar portion having manifestations of anovulation such as amenorrhea, dysfunctional uterine bleeding, or oligomenorrhea.[244] The biochemical manifestations of classic PCOS may include evidence of hyperandrogenism and an increased LH level (or an increased LH/FSH ratio) or the demonstration of polycystic ovaries by ultrasound. The nonclassic form of PCOS includes females with manifestations of hyperandrogenism and anovulation without evidence of alterations of gonadotropin levels or of polycystic ovaries on ultrasound.

Obesity characterizes about 50% of women with classic PCOS,[245] although it is even more common among adolescents. Increased peripheral insulin resistance occurs in approximately 50% of patients with PCOS, and almost certainly plays a role in the pathogenesis of this condition. On the other hand, almost all forms of severe insulin resistance (such as T2DM or rare lipodystrophy syndromes) are also associated with PCOS. Insulin resistance has not been included as a diagnostic criterion for PCOS mainly because it is difficult to measure or define.

Fasting hyperinsulinemia and an increased insulin secretory response to an oral glucose load have been demonstrated in girls with PCOS.[246] Indeed, obese adolescent girls with PCOS have been shown to be 50% more insulin resistant than weight-matched controls without PCOS.[247] The constellation of metabolic abnormalities typically seen in insulin-resistant individuals is commonly encountered in obese adolescents with PCOS, including NAFLD[248] and T2DM.[249] The increased prevalence of the metabolic syndrome may be related to the hyperandrogenism independent of obesity-related insulin resistance.[250] Early markers of accelerated atherogenesis are already present in young females with PCOS,[251] indicating that early intervention aimed at reducing CV risk may be beneficial.

Metabolic examination of patients with PCOS demonstrates hepatic and muscle resistance, but not ovarian insulin resistance—possibly accounting for insulin stimulation of theca cell androgen production.[252] The correlation between insulin resistance and hyperandrogenism begs a unifying hypothesis as to their pathogenesis, which is proferred by the "serine phosphorylation hypothesis"—which suggests that P450c17 and the insulin receptor are aberrantly serine phosphorylated. In the case of P450c17, this leads to excess activity and increased androgen production.[253] In the case of the insulin receptor, this leads to tissue-specific insulin resistance.[254] However, this hypothesis remains to be proven.

OTHER ENDOCRINE CO-MORBIDITIES

Obesity causes changes in other hormonal systems, some of which confer specific morbidities. The age at which pubertal initiation occurs continues to decrease, particularly in African Americans. This phenomenon is explained in part by the increasing overnutrition and BMI seen in this population.[255] Infertility in older adolescents and adult women may occur as a manifestation of PCOS due to excessive ovarian androgen production in females or to excessive aromatization of androgen to estrogen by peripheral adipose tissue (with suppression of the hypothalamic-pituitary gonadal axis in both sexes).[256] The hyperestrogenemia may also promote gynecomastia in males.[257] In addition, the hypercapnia associated with obstructive sleep apnea can suppress hypothalamic GnRH function—leading to a syndrome of delayed puberty.[258]

Obesity is associated with decreased GH secretion, and indeed most obese subjects (despite normal or excessive statural growth) fail GH stimulation testing. However, caloric restriction for 24 hours can restore normal GH responsivity.[259] Despite the functional GH inadequacy, statural growth is accelerated, bone age is advanced, and peripheral total and free IGF-1 levels are normal or elevated in obesity—suggesting normal or accentuated GH sensitivity[260] or the suppression of IGFBP-1 and the effects of hyperinsulinemia on activation of the growth plate IGF-1 receptor.[261] Free thyroxine levels tend to be lower and TSH higher in obese children, although still within the normal range. The mechanism is unknown. Last, obesity can be associated with increased cortisol exposure—possibly due to conversion of circulating cortisone to cortisol by the enzyme 11β-hydroxysteroid dehydrogenase-1 (11β-HSD1) located within visceral adipocytes.[262]

OTHER CO-MORBIDITIES

Childhood obesity is associated with numerous other co-morbidities. Pseudotumor cerebri[263] is a rare and poorly understood condition leading to incracranial hypertension, whose manifestations include papilledema and headache. Treatment includes serial lumbar puncture, acetazolamide to reduce CSF production, and occasionally optic nerve sheath fenestration to save eyesight. Obstructive sleep apnea occurs frequently in morbidly obese children, presumably due to the large amount of retropharyngeal fat (which compresses the upper airway during sleep).[264] Affected patients snore, often stop

breathing for more than 20 seconds during sleep, and wake up during the night with headache. Treatment includes nocturnal positive airway pressure, and when appropriate tonsilloadenoidectomy. However, symptoms often recur.

Obese children manifest numerous orthopedic difficulties, including fractures, knee pain, anatomic lower limb malalignment, and impairment in mobility.[265] Cholelithiasis occurs in approximately 2.5% of obese adolescents, especially in females, but is not usually seen in prepubertal obese children.[266] Last, psychological distress (including clinical depression) is clearly manifested in obese children.[267] These various co-morbidities all appear to be associated with BMI Z score in a curvilinear fashion.[268] Thus, the more obese the more likely patients will manifest co-morbidity.

Factors Associated with the Current Epidemic of Obesity

GENETICS

The association between obesity and genetics owes to two separate lines of investigation: the discoveries of monogenic disorders of the energy balance pathway, and studies of specific racial and ethnic groups in which obesity seems prevalent (such as the Pimas and other Hispanics in the Southwest United States).[269,270] These observations are combined with an attractive theory (termed the *thrifty gene hypothesis*[271]) on the natural selection of individuals in response to drastic environmental/ecologic pressure (e.g., famine) to yield a very strong driving force for the elucidation of specific genetic loci in the pathogenesis of obesity.[272]

However, the rapid timescale of increased prevalence of childhood obesity cannot possibly reflect a population genetic change. Therefore, the current model is that obesity is a result of gene-environment interactions—an ancient genetic selection to deposit fat efficiently that is maladaptive with our current food overabundance. In the common forms of obesity, relating single-nucleotide polymorphisms with associated risks for obesity is difficult because the effects are uncertain and the results not always confirmed. Despite feverish searches for specific candidate genes, none has thus far been discovered.[273]

EPIGENETICS AND FETAL AND NEONATAL PROGRAMMING

Follow-up studies of newborns born small for gestational age (SGA), large for gestational age (LGA), and premature have noted markedly increased risks for obesity and the metabolic syndrome. The "fetal origins hypothesis"[274] states that some aspect of the in utero environment contributes to the development of obesity and chronic disease in later life. The specific developmental aberration that promotes obesity remains unknown. However, each of these three antenatal conditions is associated with insulin resistance.

Documentation of the relationship of SGA with adult obesity and CV disease started with studies of the Dutch famine during World War II and its aftermath.[275] Several studies of newborns born SGA demonstrate that they are hyperinsulinemic and insulin resistant at birth, exhibit rapid catch-up growth in the early postnatal period, and develop obesity in childhood—which remains and promotes persistent insulin resistance and the metabolic syndrome.

An analysis of Indian newborns born in India versus in the United Kingdom[276] demonstrates that despite those born in India weighing 700 g less at birth, their glucose and insulin levels are markedly elevated. After adjustment for birth weight, the India-born babies demonstrate increased adiposity and four times higher insulin and two times higher leptin levels than the U.K.-born babies. Thus, these babies are insulin resistant even at birth—which translates into increased adiposity. Following such babies into childhood, there are numerous studies documenting insulin resistance during early childhood.[277-279]

Babies born LGA are hyperinsulinemic at birth.[280] Although LGA in most babies is due to gestational diabetes mellitus (GDM) and exposure to hyperglycemia throughout the pregnancy, this is not always the cause. Follow-up of LGA babies without GDM demonstrates a doubling of prevalence of insulin resistance and metabolic syndrome, whereas LGA babies resulting from GDM manifest a threefold increase.[281,282] Indeed, the "vertical" transmission of maternal diabetes to the offspring in the form of later obesity and diabetes has been documented in studies of Pima Indians.[283,284] Last, weight gain during pregnancy increases the risk for LGA and poor outcomes.[285]

Although there are no studies documenting hyperinsulinemia at birth in premature infants due to technical reasons, follow-up of these babies into early childhood also demonstrates increased weight gain—as well as insulin resistance and compensatory insulin secretion that are inappropriately high for the degree of weight gain.[286] The protective effect of breast feeding against development of future obesity has long been known,[166] and there appears to be a dose response (i.e., the longer the breast feeding the more protective).[287] However, this may be complicated by confounding factors such as socioeconomic status, maternal smoking in pregnancy, and maternal BMI.[288] The mechanism of breast feeding's antiobesity effect is also unclear. Some think infant feeding self-regulation is most relevant, whereas a recent study suggests that leptin in breast milk may contribute to this protection.[289] Concern regarding fructose/sucrose content in infant formula has also received attention.

ENVIRONMENT

Numerous environmental factors have also been associated with the obesity epidemic, particularly in children. However, most of these associations are cross-sectional rather than longitudinal—and in many cases a mechanism remains lacking.[290]

Stress and Cortisol

In humans, elevated cortisol or markers of HPA axis dysregulation correlate with abdominal fat distribution and the metabolic syndrome.[291] Although circulating cortisol is clearly important in determining visceral adiposity, the recent identification of reduction of circulating cortisone

to cortisol within visceral fat tissue by the enzyme 11β-hydroxysteroid dehydrogenase-1 (11βHSD1) has also been linked to the metabolic syndrome.[262,292] These data suggest that cortisol is important in increasing visceral adiposity and promoting the metabolic syndrome.

In adults, job stress and depression stress cause increased cortisol secretion[293]—which leads to insulin resistance and the metabolic syndrome. Psychosocial stresses correlate with risk of myocardial infarction in adults.[294] It is assumed that such patients exhibit increased HPA axis activation.[295] Even exogenous glucocorticoid administration is a risk factor for CV events.[296] Evidence of associations between elevated cortisol and psychological distress with abdominal fat distribution in adults is compelling. For instance, urinary glucocorticoid excretion is linked to aspects of the metabolic syndrome—including blood pressure, fasting glucose, insulin, and waist circumference.[291]

Although circulating cortisol is clearly important in determining visceral adiposity, the recent identification of reduction of circulating cortisone to cortisol within visceral fat tissue by 11βHSD1 has also been linked to the MetS. The role of cortisol in mediating visceral fat accumulation, insulin resistance, and T2DM has been elegantly demonstrated by the transgenic knockout and overexpression of 11βHSD1.[262,292] These data suggest that cortisol is important in increasing visceral adiposity and promoting the MetS—equivalent to Cushing syndrome of the abdomen.[297] However, the role of stress and cortisol in childhood obesity is currently speculative.

Sleep Deprivation

Americans get significantly less sleep than they did three decades ago. Adults in the United States currently average less than 7 hours of sleep per night, which is almost 2 hours less than in 1980 (and about one-third of them get less than 6 hours per night).[298] Analyses of data from the first NHANES revealed that adults (ages 32 to 49) who got less than 7 hours of sleep were more likely to be obese 5 to 8 years later than those who got 7 or more hours of sleep.[299] Similarly, a 13-year prospective cohort study in which participants were interviewed at ages 27, 29, 34, and 40 years of age found that sleep duration correlated negatively with obesity.[300]

The link between short sleep duration and obesity has also been observed among children.[301] Like adults, increasing numbers of children are chronically sleep deprived. This is especially true of obese children, who have been found to get less sleep than those of normal weight. In addition to its other effects, sleep is one of the most powerful cross-sectional[302] and longitudinal[303] predictors of childhood obesity in prepubertal children. Although relatively little is known about the mechanism for the sleep-obesity relationship, especially among children, there are reasons to assume increased stress and altered activity of various hormones (such as leptin, ghrelin, and cortisol).

Television Viewing and "Screen Time"

Television watching is considered one of the most modifiable causes of childhood obesity.[304] There are four possible mechanisms linking television watching and obesity. First, television watching may increase stress levels and cortisol—causing increased food intake and promotion of obesity.[305] Second, television watching displaces physical activity and reduces voluntary energy expenditure (VEE). Most studies find inverse correlations between television watching and physical activity and fitness.[306,307] Third, television watching increases calorie consumption from eating during viewing or from the effects of food advertising. Television viewing is also associated with increased high-fat food intake, decreased fruit and vegetable consumption, and increased soft drink intake.[308]

Junk food is the most frequently advertised product category on children's television. Last, REE and nonexercise associated thermogenesis (NEAT) appears to be decreased during television watching.[309] According to NHANES III (1988-1994), the prevalence of childhood obesity is lowest among children watching television ≤ 1 hour/day and highest among those watching 4 hours/day.[310] The relationship between television watching and obesity has been examined in large number of cross-sectional epidemiologic studies but in few longitudinal studies.[304]

Several experimental studies of reducing television watching have been conducted, and their results support the suggestion that reduced television watching may help to reduce the obesity risk or help promote weight loss in obese children.[311] These studies represent the strongest direct evidence that altering television watching alone is a promising strategy for prevention of childhood obesity. Other forms of "screen time," such as video games, computers, and cell phones, are also implicated in obesity pathogenesis.

Dietary Fat Versus Carbohydrate

Fat is generally considered more obesigenic than other macronutrients, given its more energy-dense, highly palatable, and effective conversion to body fat.[312] A high-fat meal induces decreased thermogenesis and a higher positive fat balance than an isocaloric and isoproteic low-fat meal.[313] Excessive fat intake is believed to cause weight gain,[314] but the relationship between dietary fat intake and childhood adiposity remains controversial.[315]

The prevalence of overweight in the United States has increased despite a decreased percentage of dietary energy derived from fat. A meta-analysis of 12 studies in overweight or obese adults who were given dietary advice on low-fat diet and followed for 6 to 18 months suggested that low-fat diets are no better than calorie-restricted diets in long-term weight loss.[316] Similarly, in children total fat consumption expressed as a percentage of energy intake has decreased.[317] This decrease in fat consumption is largely due to increased total energy intake in the form of carbohydrates. Much of this imbalance is attributed to changing beverage consumption patterns characterized by declining milk intake and substantial increases in soft drink consumption,[318] which may have its own etiopathogenesis. Most interventions with a low-fat heart-healthy diet have not been successful in childhood overweight prevention.[319]

Reduction in carbohydrate intake is taken to the extreme in the Atkins diet, which restricts adult subjects to less than 25 g/d of ingested carbohydrate. Adult evaluations of the diet for weight control have been disappointing

long-term,[320,321] and the popular diet has been abandoned recently. There are currently no data in children or adolescents. However, it should be noted that the ketogenic diet used for seizure control is similar in composition to the Atkins diet. A 2-year study of the ketogenic diet demonstrated persistent decreases in weight Z scores in children who were above average upon diet initiation, without significant compromise in general nutrition or in height.[322]

Glycemic Index and Fiber

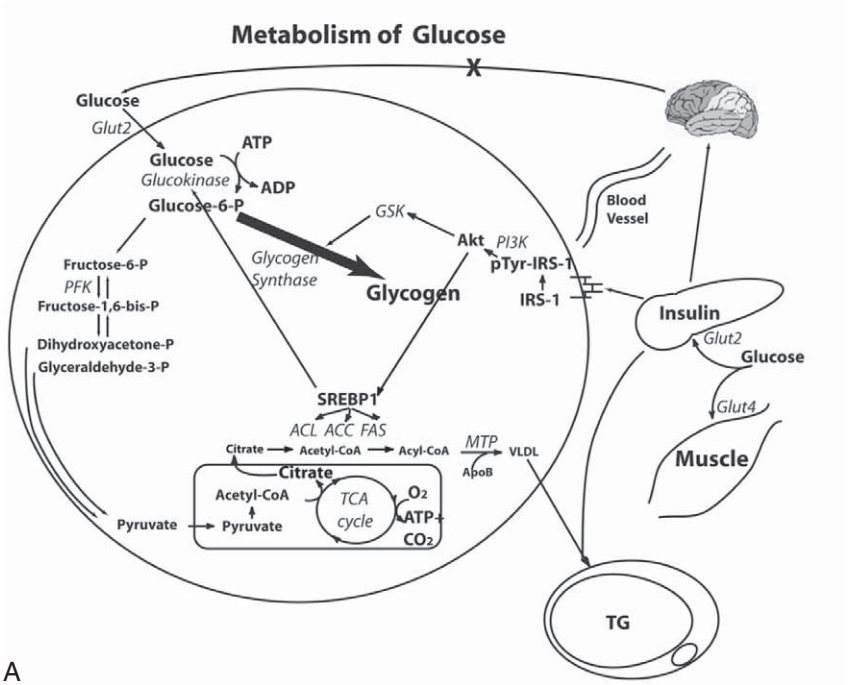
Not all sugars exert the same insulinogenic response. Complex carbohydrates can take two forms: a combination of α1-4 linkages and α1-6 linkages that gives the starch a globular stucture called amylopectin (as seen in bread, rice, pasta, potatoes, and glycogen) or a linear polymer of α1-4 linkages called amylose (as seen in beans, lentils, and other legumes). Digestion and absorption of the former in the intestine is rapid due to the simultaneous actions of α1-4 and α1-6 glucosidases, whereas that of the latter is much slower because the α1-4 glucosidase can only cleave single glucose moieties on either side of the polymer. This phenomenon constitutes the basis of the glycemic index (GI),[323] which refers to the glucose area under the curve after consumption.

High-GI foods lead to an accentuated insulin response, which can shunt energy substrate to adipose tissue.[324] In children, controlled studies with a high-GI diet demonstrate that energy intake is 53% higher than on low-GI diet.[325] One adolescent study demonstrated that an ad libitum low-GI diet was more effective in promoting weight loss than an energy-restricted low-fat diet.[326] Therefore, the GI may be a simple concept to institute—although the "toxic environment" of American foodstuffs may make it difficult to maintain.

Dietary fiber consists of the nonstarch polysaccharide portion of plant foods, including cellulose, hemicellulose, pectins, β-glucans, fructans, gums, mucilages, and algal polysaccharides. Major sources of dietary fiber include whole grains, fruits, vegetables, legumes, and nuts. Fiber content accounts for 50% of the variability in glycemic load (GL; GI × volume) among foods. Cohort studies of adults demonstrate that fiber intake is inversely associated with weight gain, fasting insulin levels, and risk of T2DM.[327,328] Fiber may influence body weight regulation by several mechanisms involving intrinsic, hormonal, and colonic effects—which eventually decrease food intake by promoting satiation (lower meal energy content) or satiety (longer duration between meals) or by increasing fat oxidation and decreasing fat storage.[329] A fiber-rich meal is processed more slowly and has less caloric density, fat, and added sugars.

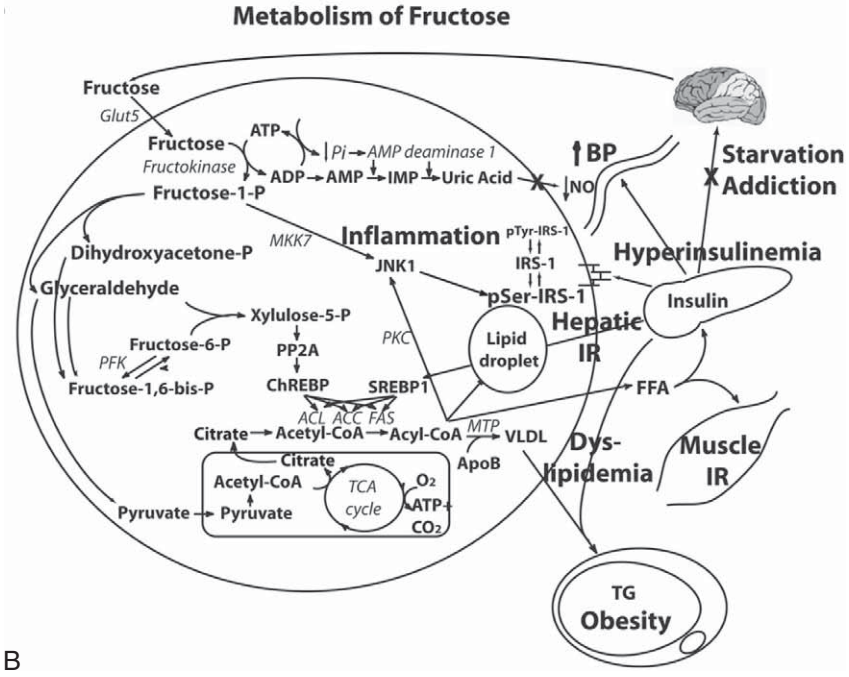
Fiber-containing foods engender slower glucose absorption, which lessens the postprandial insulin surge and decreases lipogenesis.[330] In addition, high-fiber meals allow for delivery of undigested triglyceride to the colon—where fermentation to short-chain fatty acids and their absorption improve lipids and insulin sensitivity.[331] Archeologists surmise that our ancestors used to consume 100 to 300 g of fiber a day.[332] However, the dietary fiber intake throughout childhood and adolescence currently averages approximately 12 g/day and has not changed during the past 30 years.[333] Therefore, parents and school foodservice personnel should strive to offer fiber-rich foods to children so that their acceptance and consumption of them will be increased.[334]

Fructose



The most commonly used sweetener in the U.S. diet is the disaccharide sucrose (i.e., table sugar), which contains 50% fructose and 50% glucose. However, in North America and many other countries non-diet soft drinks are sweetened with high-fructose corn syrup (HFCS)—which contains up to 55% of the monosaccharide fructose. Because of its abundance, sweetness, and low price, HFCS has become the most common sweetener used in processed foods. It is not that HFCS is biologically more ominous than sucrose. It is that its low cost has made it available to everyone, especially low socioeconomic groups.

HFCS is found in processed foods ranging from soft drinks and candy bars to crackers to hot dog buns to ketchup. Average daily fructose consumption has increased by more than 25% over the past 30 years. The growing dependence on fructose in the Western diet may be fueling the obesity and T2DM epidemics.[335] Animal models demonstrate that high-fructose diets lead to increased energy intake, decreased resting energy expenditure, excess fat deposition, and insulin resistance[336]—which suggest that fructose consumption is playing a role in the epidemics of insulin resistance and obesity and T2DM in humans.[337] The metabolism of fructose differs significantly from that of glucose (Figure 19-6). Fructose is absorbed in the intestine and enters the liver without insulin regulation. There, fructose is converted to fructose-1-phosphate and enters the glycolytic pathway without regulation. This leads to an excess accumulation of citrate outside the mitochondria, which then undergoes de novo lipogenesis and is reassembled into free fatty acids (which promote insulin resistance), very low-density lipoproteins (which promote atherogenesis and serve as a substrate for obesity),[338] and triglycerides (some of which precipitate in the liver, activate the inflammatory pathway, and cause nonalcoholic steatohepatitis).[339] Fructose also does not suppress secretion of the "hunger hormone" ghrelin, levels of which correlate with perceived hunger.



In sum, fructose consumption has metabolic and hormonal consequences that facilitate development of obesity and the metabolic syndrome.[340] The highest fructose loads are soda (1.7 g/oz) and juice (1.8 g/oz). Although soda has received most of the attention,[159,341] high fruit juice intake is also associated with childhood obesity—especially in lower income families.[342] Nonetheless, the American Academy of Pediatrics recommends that fruit juice consumption be allowed to 4 to 5 oz/day for 1- to 6-year-old children and 8 to 12 oz/day for 7- to 18-year-old children.[343]

Calcium and Dairy

There have been several reports of an inverse relationship between dietary calcium and obesity indices.[344,345] Dietary calcium plays an important role in energy metabolism

A

B

Figure 19-6 Hepatic (*A*) glucose and (*B*) fructose metabolism. Only 20% of an ingested glucose load is metabolized by the liver, whereas 100% of a fructose load is hepatically metabolized. Thus, in a 120-calorie glucose load (two slices of white bread) 24 calories are hepatically metabolized—whereas in a 120-calorie sucrose load (an 8-oz. glass of orange juice) a bolus of 72 calories reach the liver. In contrast to glucose, fructose induces substrate-dependent hepatocellular phosphate depletion, which increases uric acid and contributes to hypertension through inhibition of endothelial nitric oxide synthase and reduction of nitric oxide (NO); stimulation of de novo lipogenesis and excess production of VLDL and serum triglyceride, promoting dyslipidemia; accumulation of intrahepatic lipid droplets, promoting hepatic steatosis; production of FFA, which promotes muscle insulin resistance; c-jun N-terminal kinase (JNK-1) activation, which serine phosphorylates and the hepatic insulin receptor—rendering it inactive and contributing to hepatic insulin resistance, which promotes hyperinsulinemia and influences substrate deposition into fat; and CNS hyperinsulinemia, which antagonizes leptin signaling (see Figure 19-3) and promotes continued energy intake.

regulation. Increased calcitriol (1,25-dihydroxyvitamin D) in response to low-calcium diets stimulates Ca^{2+} influx in human adipocytes may lead to stimulation of lipogenic gene expression and lipogenesis, as well as inhibition of lipolysis.[345] This may result in an expansion of adipocyte triglyceride stores, which can promote adiposity.

Increased dietary calcium reduces calcitriol levels and leads to reduction of fat mass without caloric restriction in mice,[346] and this antiobesity effect of dietary calcium is supported by human clinical and epidemiologic studies.[347] Vitamin D deficiency correlates with increasing BMI, especially in African Americans.[348] However, it is not known if this is due to substitution of soft drinks for dairy, to lactose intolerance, or to other factors. One adult study[349] revealed a consistent effect of higher calcium intake on lower body weight and body fat. However, pediatric studies are lacking.

Trace Minerals

Chromium and vanadium appear to be involved in the insulin signaling process. In diabetic animals, chromium or vanadium supplementation results in improvement in insulin sensitivity and glycemic control[350,351]—and there is a suggestion of decreased weight. It is not yet known whether the pathogenesis of insulin resistance in humans involves a deficiency of a trace mineral. However, inadequate dietary intakes of vitamins and minerals are widespread—most likely due to excessive consumption of energy-rich micronutrient-poor refined food. Inadequate intake of micronutrients may result in chronic metabolic disruption, mitochondrial decay, DNA damage, oxidant leakage, and cellular aging associated with late-onset diseases such as obesity and cancer.[352]

Infectious Causes

The pattern of increase in prevalence during the current obesity epidemic is reminiscent of an infectious transmission. Studies in animals implicate adenovirus-36 in the conversion from lean to obese.[353] Studies in adults thus far demonstrate correlation between BMI and antibodies to this virus,[354] but mechanism is lacking. Alternatively, the predominance of certain human intestinal flora species (firmicutes versus bacteroides) may predispose animals and humans to obesity[355]—possibly by increasing efficiency of energy absorption. However, factors that determine their predominance are unknown.

Medications

Numerous medications promote excessive weight gain in children. The most commonly prescribed are pharmacologic doses of glucocorticoids (e.g., prednisone, methylprednisolone, dexamethasone), used for their antiinflammatory and antineoplastic activities. Patients so treated frequently become obese,[356,357] and develop many of the features of Cushing syndrome (e.g., visceral adiposity, hyperlipidemia, hypertension, glucose intolerance)—which typify the metabolic syndrome.[296]

Sex hormone administration also promotes excessive weight gain, presumably by inducing insulin resistance.[358] In an effort to improve type 1 diabetes glycemic control, many physicians will overinsulinize the patient—but at the expense of excessive weight gain.[359] Last, more and more children are being placed on the atypical antipsychotics risperidone, olanzapine, quetiapine, clozepine, aripriprazole, and ziprasidone to affect mood and behavior.[360] These medications induce insulin resistance, which foments persistent hyperphagia and weight gain and increases risk for the metabolic syndrome.[361]

Disorders of Obesity

The concept that obesity is a phenotype of numerous pathologies is evident from the examination of specific endocrine disorders leading to obesity in early childhood (Table 19-1). Some involve neural mechanisms, others classical hormonal mechanisms, and still others dysregulation of increased energy intake, decreased energy expenditure, and/or increased energy storage at the adipocyte.

CLASSIC ENDOCRINE DISORDERS WITH AN OBESITY PHENOTYPE

In children, linear or statural growth accounts for up to 20% of ingested calories. Endocrine states that allow for normal energy intake for age but inhibit linear growth will of necessity lead to excessive energy storage. This is the case for the four "classic" endocrine disorders associated with obesity. These can be distinguished from other causes of pediatric obesity on the basis of their suboptimal growth rate—as opposed to overnutrition, which tends to increase the rate of growth and skeletal maturation (probably due to excess insulin cross-reacting with the IGF-1 receptor).[261]

Hypothyroidism (see Chapter 1) results in a lower REE due to insufficient circulating T_3, along with decreased VEE due to fatigue. The decrease in total energy expenditure, despite a relatively low caloric intake, promotes persistent energy storage and increases adiposity. Thyroid hormone replacement is sufficient to increase growth, REE, and VEE to resolve the obesity over time.

Cushing syndrome (see Chapter 12) results in growth arrest and cortisol-induced hyperphagia,[362] with a decrease in REE and VEE due to muscle wasting. Reduction of circulating glucocorticoid through medical or surgical means usually reverses the obesity to some degree. Exogenous glucocorticoid therapy can result in the same obesity phenotype. Hypercortisolism may be more related to obesity than previously realized, due to the transgenic model of 11βHSD1 overexpression in visceral adipose tissue—which converts inactive circulating cortisone to cortisol.[262] However, its role in human obesity is not clear because correlations between 11βHSD1 polymorphisms and BMI or waist:hip ratio were weak at best[363]—and enzyme activity was not elevated in one human study.[364]

GH deficiency (see Chapter 8) prevents lipolysis and promotes visceral adiposity, although obesity is usually not severe. GH deficiency is also associated with fatigue and decreased VEE. GH deficiency is often accompanied by other pituitary hormone deficiencies (e.g., central hypothyroidism), which can also decrease REE. GH therapy

TABLE 19-1

Classification of Childhood Obesity Disorders

Mongenetic Disorders of the Energy Balance Pathway
- Leptin deficiency
- Leptin receptor deficiency
- POMC mutation ("red" hair, adrenal insufficiency)
- Prohormone convertase-1 deficiency
- MC_3R mutation
- MC_4R mutation
- SIM-1 mutation

Syndromic Disorders (Mental Retardation Prominent)
- Prader-Willi syndrome
  - Short stature
  - Hypogonadism
  - Hypotonia
  - Ghrelin overproduction
- Bardet-Biedl syndrome
  - Retinitis pigmentosa
  - Polydactyly
  - Hypogonadism
- TrkB mutation
  - Hypotonia
  - Impaired short-term memory
  - Decreased nociception
- Börjeson-Forssman-Lehmann syndrome
  - Microcephaly
  - Large ears
  - Hypogonadism
- Carpenter syndrome
  - Variable craniosynostosis
  - Brachdactyly, polydacytly, syndactyly
  - Congenital heart disease
  - Hypogonadism
- Cohen syndrome
  - Persistent hypotonia
  - Microcephaly
  - Maxillary hypoplasia
  - Prominent incisors
- Alström syndrome
  - Hypogonadism
  - Short stature
  - Neurosensory deficits

Classic Endocrine Disorders (Short Stature and Growth Failure Prominent)
- Hypothyroidism
  - Primary
  - Central
- Cushing syndrome (adrenal hypercorticism)
  - Adrenal adenoma/carcinoma
  - Adrenal micronodular hyperplasia
  - Pituitary ACTH-secreting tumor
  - Ectopic ACTH-secreting tumor
  - Exogenous glucocorticoid administration
- Growth hormone deficiency
- Pseudohypoparathyroidism 1a
  - Maternal transmission (AHO + multihormone resistance)
  - Paternal transmission (pseudopseudohypoparathyroidism, AHO only)

Insulin Dynamic Disorders
- Hypothalamic obesity (insulin hypersecretion)
- Insulin resistance
- Leptin resistance

is able to reverse these defects, increase muscle mass, and promote weight loss.

Pseudohypoparathyroidism type 1a (PHP1a) (see Chapters 2 and 17) is an autosomal-dominant mutation of GNAS1, which codes for the $G_{s\alpha}$ subunit necessary to peptide hormone signal transduction. Maternal transmission leads to PHP1a (multihormone resistance), along with Albright's heriditary osteodystrophy (AHO)—of which a cardinal feature is obesity, probably due to the inability to stimulate cAMP in response to β-adrenergic stimulation within adipocytes (due to defective G-protein signal transduction).[365] Paternal transmission leads to AHO without multihormone resistance, also known as pseudopseudohypoparathyroidism. Unfortunately, this form of obesity is not responsive to current medications.

MONOGENETIC DISORDERS OF THE NEGATIVE FEEDBACK PATHWAY

The elucidation of the regulation of the energy balance pathway is exemplified by the discovery of specific defects within that pathway leading to early-onset obesity. Numerous obesity syndromes within the pathway have been described over the past 10 years, and are reviewed in detail elsewhere.[366,367]

Leptin Deficiency

Mutations of the leptin gene in humans recapitulate the phenotype of the *ob/ob* leptin-deficient mouse.[368] Approximately 11 such patients have been described, primarily of Pakistani and Turkish descent expressing the products of consanguinity. These patients manifest hyperphagia from birth, with obesity documentable as early as 6 months of age. The lack of leptin induces the starvation response in the form of reduced thyroid hormone levels, lack of sympathetic tone, lack of pubertal progression, and defective immunity.[369]

Despite the modest hypothyroidism, the concomitant hyperinsulinemia allows excess insulin to cross-react with the IGF-1 receptor in order to maintain growth rate and bone age until the usual time of puberty. However, because of the important role of leptin in initiating and maintaining puberty, untreated patients with leptin deficiency are short due to the lack of a pubertal growth spurt. The diagnosis is made by demonstrating extremely low or unmeasurable serum leptin levels. However, treatment with recombinant leptin is effective in restoring leptin signaling—resulting in reduction of hyperphagia, resolution of obesity, induction of puberty, and restoration of immune regulation.[369] Heterozygotes for leptin deficiency assume an intermediate phenotype.[370]

Leptin Receptor Deficiency

Three family members in France of Algerian extraction were found to have a mutation truncating the leptin receptor prior to its insertion in the membrane.[371] This family had symptoms and signs similar to those with leptin deficiency, although they had growth retardation, low thyroid levels, and low IGF-1 and IGFBP-3 levels. The reason for this dichotomy is not known. Diagnosis

hinges on documenting extremely high leptin levels even for the degree of obesity. No other families have been described. Unfortunately, no treatment currently exists.

POMC Splicing Mutation

Inability to synthesize POMC due to missense or truncation mutations results in the inability to splice out α-MSH in the brain, leading to defective anorexigenesis at the MC_4R and early-onset obesity. In the periphery, this defect leads to "red" hair to due lack of α-MSH action at the skin MC_1R. In the pituitary, the defect results in inability to splice out ACTH—leading to secondary adrenal insufficiency.[372] Recently, a Turkish patient with this mutation was reported to have dark hair—indicating that pigmentation of the hair is not entirely explained by the mutation's effect on MC_1R.[373] Approximately six patients have thus far been reported, but are easily diagnosed due to their unusual phenotype, ACTH levels, and hypocortisolemia. There is currently no treatment for the obesity.

Prohormone Convertase-1 Deficiency

Defects in this enzyme lead to the inability to process various preprohormones to their active ligands, such as POMC to ACTH and α-MSH, proinsulin to insulin, and various gut propeptides to active hormones.[374] Only two unrelated patients have thus far been reported. They manifest severe early-onset obesity, ACTH deficiency, hypogonadism, hyperproinsulinemia, and small intestinal dysfunction—presumably on the basis of inability to cleave intestinal propeptides to their mature form. The diagnosis can be made by finding extremely high levels of proinsulin. No treatment currently exists for the obesity.

Melanocortin-3 Receptor Mutation

Two family members in Singapore with mutations of the MC_3R manifested with early-onset obesity.[375] This receptor appears to have a slightly different function from the MC_4R, as it seems to be involved in regulation of energy expenditure as opposed to energy intake.[84] Diagnosis can only be made by gene sequencing. No treatment currently exists.

Melanocortin-4 Receptor Mutation

Mutations in the MC_4R appear to account for up to 5% of morbid obesity, especially those beginning in childhood.[376,377] This mutation is transmitted as a co-dominant inheritance because homozygotes are more severely affected than heterozygotes, and not all carriers exhibit obesity. Patients exhibit early-onset hyperphagia and obesity, although not as severe as those with leptin deficiency. These patients grow rapidly, due to the hyperinsulinemia. Notably, their lean mass and their bone mineral density are increased commensurate with the adiposity.[377] The diagnosis is made by gene sequencing. There is currently no treatment for this disorder.

SIM-1 Mutation

SIM1 stands for "single-minded," a drosophila gene involved in neurogenesis—particularly the PVN, which expresses the MC_4R. SIM1 appears to act as a signal transduction mechanism integrating information downstream from MC_4R activation.[378] Heterozygous null mice for SIM1 are obese. The human homolog is on chromosome 6q. A girl with hyperphagia, obesity, and developmental delay with a balanced translocation between 1p22.1 and 6q16.2 was found to have a mutation of SIM1.[379] Only a few polymorphisms of SIM1 in obesity have been reported, and their significance is not yet established.[380]

PLEIOTROPIC OBESITY AND MENTAL RETARDATION DISORDERS

Approximately 30 different obesity syndromes have been described, and most (if not all) are associated with mental retardation.[381] Each has some other distinguishing phenotype, which makes the diagnosis obvious on clinical grounds. Various genetic linkages have been noted, but the etiologies for the obesity in these disorders remain obscure.

Prader-Willi Syndrome

Prader-Willi syndrome (PWS) is a defect in the paternal allele of chromosome 15q11-13[382] from deletion, mutation, defective imprinting, or uniparental disomy of chromosome 15. Subjects affected with PWS present with hypotonia and failure to thrive in the neonatal period, and as they get older they develop the classic findings of hypogonadism, short stature, mental retardation, and severe obesity.

PWS patients are classically described as voracious eaters, although they can be easily dissuaded from food if they are removed from behavioral signals for food intake. REE is approximately 60% of normal in PWS, promoting adiposity.[383] In addition, ghrelin levels are massively elevated in PWS[384]—which may be one etiology for their persistent hyperphagia. Others have suggested that the obesity in PWS is a function of GH deficiency, with defective lipolysis.[385]

Bardet-Biedl Syndrome

This syndrome is characterized by obesity, mild mental retardation, dysmorphic extremities (including polydactyly), retinitis pigmentosa, hypogonadism, and renal malformations. Its inheritance is complex, but is usually described as autosomal recessive. Eight different genetic loci have been implicated,[386] although their functions continue to remain elusive. The cause of the obesity remains unknown, but it is postulated to be due to failure of development of ciliated hypothalamic neurons.[387,388] Diagnosis usually rests on clinical grounds. Although there is no specific treatment available, anecdotal instances of efficacy of metformin exist.

TrkB Mutation

The NTRK2 gene codes for the ligand-specific subunit for the receptor TrkB, which has brain-derived growth factor (BDNF) as its ligand. TrkB is important for neural

development. An 8-year-old boy with early hypotonia, developmental delay, impaired short-term memory, decreased responsiveness to nociception, and severe hyperphagia starting at 6 months culminating in morbid obesity was reported recently.[389] Examination of the NTRK2 gene demonstrated a A to G transition in codon 722, substituting cysteine for tyrosine, which inhibited phosphorylation of TrkB. A second patient with obesity, impaired cognitive function, and hyperactivity was found to have an isocentric inversion at the BDNF locus.[390] The etiology of the hyperphagia and obesity remain unclear.

Carpenter Syndrome

This syndrome consists of obesity plus variable craniosynostosis, brachdactyly, polydacytly, syndactyly, congenital heart disease, and hypogonadism. Its etiology remains obscure.

Cohen Syndrome

This disorder presents with persistent hypotonia, microcephaly, maxillary hypoplasia, and prominent incisors. The gene for Cohen syndrome has been mapped to chromosome 8q,[391] and it codes for a transmembrane protein of unknown function.

Alström Syndrome

This syndrome presents with neurosensory deficits, such as deafness, with various other endocrinopathies that cause an early-onset type 2 diabetes. The ALMS1 gene has been discovered.[392] It appears to be important in cilia function,[388] and may account for abnormal neuronal migration.

Börjeson-Forssman-Lehmann Syndrome

This syndrome is characterized by microcephaly, seizures, large ears, and hypogonadism. The defective gene is a zinc-finger protein of unknown function.[393]

INSULIN DYNAMIC DISORDERS

Hypothalamic Obesity and Insulin Hypersecretion

It is well known that bilateral electrolytic lesions or deafferentation of the VMH in rats leads to intractable weight gain,[109,110,394-396] even upon food restriction.[397] Originally, the obesity was felt to be due to damage to a satiety center—which promoted hyperphagia and increased energy storage.[398] However, we now understand that dysfunction of leptin signal transduction in the VMH due to hypothalamic damage secondary to CNS tumor, surgery, radiation, or trauma can alter the afferent and efferent pathways of energy balance and lead to severe and intractable weight gain.[399,400]

In this syndrome of "hypothalamic obesity," hypothalamic insult prevents integration of peripheral afferent signals. The VMH cannot transduce these signals into a sense of energy sufficiency and a subjective state of satiety.[54,395] Children with hypothalamic obesity exhibit weight gain even in response to forced caloric restriction.[401] This seems paradoxical, as one would expect that if hyperphagia were the reason for the obesity caloric restriction would be effective. The reason for this paradox is that similar to the *db/db* mouse these subjects exhibit "organic leptin resistance" (that is, the inability to respond to their own leptin due to the VMH damage).

Numerous assessments of weight gain following cancer therapy in children have been performed. Most of these evaluations have been retrospective, and performed in the acute lymphoblastic leukemia (ALL) survivor population.[402] An extremely high frequency of hypothalamic obesity of 30% to 77% has been documented after craniopharyngioma treatment.[403] In each of these cancer types, hypothalamic damage is the primary risk factor for development of this syndrome.[404] However, the syndrome has also been reported in cases of pseudotumor cerebri, trauma, and infiltrative or inflammatory diseases of the hypothalamus.[399] Aside from the symptoms of tumor-induced increased intracranial pressure, patients with hypothalamic obesity classically exhibit signs of limbic system involvement such as hypogonadism, somnolence, rage, and hyperphagia.[405] However, such classic presentations are actually rare.[396]

Hypothalamic obesity is the result of "organic" leptin resistance due to death of VMH neurons. This leads to defective autonomic neurotransmission.[99] This is akin to the starvation response in that it manifests defective activation of the SNS (which retards lipolysis and energy expenditure)[406,407] and overactivation of the vagus,[408] which promotes an obligate insulin hypersecretion and energy storage.[409] In animals and in humans, vagal hyperreactivity can be prevented by pancreatic vagotomy.[110,410-412]

Primary Insulin Resistance

Insulin resistance is a primary entity in some pediatric populations. It is associated with the development of the metabolic syndrome, especially in certain racial and ethnic groups.[413] For example, the Pima Indians of Arizona exhibit a 50% incidence of obesity and type 2 diabetes.[414] Insulin resistance correlates with abdominal adiposity and CV morbidity.[415,416] The presence of acanthosis nigricans, a hyperpigmented and hypertrophic patch of skin at extensor surfaces such as the nape of the neck, is a clinical marker of hyperinsulinemia[417] due to cross reactivity between insulin and the epidermal growth factor receptor of the skin.[418] Fasting hyperinsulinemia, an indicator of inherent insulin resistance in children, is an important predictor of adult obesity.[419,420]

This is further exacerbated by sex hormones (especially estrogen), contributing to the increased incidence of insulin resistance and obesity in teenage girls. The cause is unknown, but primary insulin resistance may be a manifestation of all three inciting factors (genetic, epigenetic, and environmental). There may be specific genetic predispositions[269] that have been enriched by natural selection. In addition, the high incidence of gestational DM in Pima mothers promotes obesity and T2DM in the offspring.[284]

Last, the consumption of low-quality processed food[136] made available by government subsidies promote continued obesity. It should be noted that in primary insulin resistance dietary and exercise interventions have been notoriously ineffective at reducing the obesity.[421,422] The locus of the resistance to insulin is not defined. Reduced numbers and function of insulin receptors may in part be secondary to the hyperinsulinemia itself, rather than due to a primary defect.

Evaluation and Treatment of the Obese Child

WORKUP

The key to successful obesity therapy is accurate diagnosis. Our diagnostic armamentarium is not yet fully developed, and thus matching treatment to diagnosis is still uncertain. Specific points in the evaluation and their rationale are listed in Table 19-2. In eliciting the history, birth weight, parents' BMIs, gestational diabetes, prematurity, history of breast feeding, and neonatal complications (especially CNS injury) are all relevant. The earlier the patient's obesity is noted (i.e., early adiposity rebound) the more likely an organic reason will be discerned. Neurodevelopmental abnormalities may signify the need for a genetics referral.

The medication list must be reviewed, especially for atypical antipsychotics. Orthopedic pain, headache, and snoring must be assessed. Dietary history must include skipping breakfast, daily ingestion of sodas and juices, and frequency and type of snacking. The degree of perceived stress by the patient is also likely a major contributor to visceral adiposity. A corollary is the number of caretakers of the child because this increases stress, family chaos, and lack of child supervision.

On physical examination, linear growth is key because classical endocrine evaluation [e.g., hypothyroidism, Cushing syndrome, GH deficiency, pseudohypoparathyroidism (PHP)] is not necessary if linear growth is not attenuated. However, hyperinsulinemia and insulin resistance usually cause accelerated growth due to cross reactivity of insulin with the IGF-1 receptor.[261] Important physical features to assess include acanthosis nigricans and waist circumference (both of which are associated with insulin resistance and the metabolic syndrome), fundoscopic examination to rule out pseudotumor cerebri, liver enlargement to suggest hepatic steatosis, hirsutism to suggest PCOS, and muscle tone to evaluate hypotonia and myopathy (which reduce energy expenditure).

TABLE 19-2

Diagnostic Workup of Childhood Obesity and Its Co-morbidities

Etiology/Co-Morbidity	Evaluation
	Histroy
• Genetic etiology	• Parent BMI, race, mental retardation
• Epigenetic etiology	• Birth weight, gestational difficulties, prematurity
• CNS etiology	• CNS insult, mental retardation or developmental delay
• Endocrine etiology	• Slowdown in linear growth, red hair
• Medication etiology	• Medication history, especially atypical antipsychotics
• Dietary etiology	• Calorie recall, especially sugar-containing liquids, breast-feeding Hx
• Physical activity etiology	• Exercise history, television, computer, and cell phone recall
• Stress etiology	• Socioeconomic status, number of caregivers, television recall, sleep status, atypical depression
• Sleep apnea	• History of snoring, headache, waking up with headache
• PCOS	• Hirsutism, oligomenorhea, amenorrhea
• Type 2 diabetes	• Polyuria, polydipsia, nocturia, recent weight loss
• Orthopedic morbidity	• Knee or hip pain, limitation of motion
• Depression	• Affect, activity level, school performance
	Physical
• Insulin resistance	• Acanthosis nigricans, skin tags, waist circumference
• Hypertension	• SBP or DBP >90th percentile for age
• Pseudotumor cerebri	• Papilledema
• Hepatic steatosis	• Hepatomegaly
• PCOS	• Hirsutism
• Precocious/delayed puberty	• Gonadal and pubic hair status
• Sleep apnea	• Tonsillar hypertrophy
• Myopathy	• Decreased muscle tone, hyporeflexia
• Syndromic obesity	• Specific neurocutaneous stigmata (see Table 19-1), retardation
	Laboratory
• Hepatic steatosis	• ALT, hepatic ultrasound
• Glucose intolerance	• Fasting glucose >100 or 2-hr glucose >140
• Type 2 diabetes mellitus	• Fasting glucose >125 or 2-hr glucose >200; HbA1c >6.5%
• Dyslipidemia	• Lipid profile with increased VLDL, TG:HDL >2.5
• Insulin resistance	• Fasting insulin, glucose
• Insulin hypersecretion	• 3-hour OGTT with insulin levels
• CNS lesion	• MRI, especially with hypothalamic coned-down views

Laboratory evaluation includes tests of obesity-related morbidity (e.g., AST, ALT, lipids, fasting glucose and HbA1c, knee and hip x-rays, and sleep studies as necessary). Specific diagnostic studies must be tailored to the individual patient. For instance, growth attenuation requires endocrine evaluation—including thyroid function tests, IGF-1 and IGFBP-3, 24-hour urinary cortisol or midnight serum cortisol, and possibly magnetic resonance imaging (MRI) of the hypothalamus and pituitary. Patients with developmental delay will require karyotype and MRI.

Severe obesity in a toddler may require a leptin level and genetic testing for a MC_4R mutation. Fasting insulin and glucose allow for the computation of indices of insulin resistance, such as the homeostatic model of insulin resistance (HOMA-IR).[423] However, an OGTT may become necessary to evaluate for type 2 diabetes and for insulin hypersecretion.[409] Luteinizing hormone (LH), follicle stimulating hormone (FSH), and testosterone levels may be appropriate when evaluating for delayed puberty in males or PCOS in females.

LIFESTYLE MODIFICATION

Lifestyle modification is and remains the cornerstone of obesity therapy, especially in children. This approach is common sense, and based on a handful of early studies demonstrating efficacy of lifestyle in a select handpicked group of children with intensive follow-up.[424] Indeed, the Diabetes Prevention Trial for T2DM demonstrated efficacy of lifestyle on weight loss in adults. However, the cost per patient of administering such an intervention was astronomical.[425] Data supporting the efficacy of lifestyle modification in the "real world" is not particularly persuasive.

Indeed, one analysis of numerous methodologies concluded that lifestyle modification was effective in modulating reported behaviors but had little effect on BMI or prevalence of pediatric obesity.[319] In addition, follow-up studies often find a rapidly diminishing effect once the study is completed. Another meta-analysis concluded that the results of well-controlled studies were too weak to be definitive.[426] Finally, a meta-analysis of 39 published intervention studies designed to prevent childhood obesity showed that 40% of the 33,852 participating children had reduction in BMI and that the remaining 60% exhibited no effect.[427]

Although weight loss is the conventional goal for intervention among adults, weight maintenance is recommended for the majority of children. The prevention of weight gain is easier, less expensive, and more effective than treating obesity itself[428]—and the prevention of overweight among children prior to the presence of risk-related behaviors is crucial to stem the obesity epidemic. The primary goal of obesity prevention should be to promote physical activity and healthy diet, with emphasis on improving overall health rather than weight loss.[429]

There are at least four reasons to promote interventions to improve nutrition and physical activity in children.[430] First, the child may receive immediate benefits such as better fitness or energy or micronutrient intake. Second, intervention at critical periods may improve adult health. Third, modifying chronic disease risks in childhood may lead to lower rates and risk factors in adults. Last, modification of children's behaviors may lead to improved behaviors in adulthood that would protect against chronic diseases.

Behavioral-cognitive therapy is designed to deal with both parent and patient, with behavior restructuring and reinforcement. Behavior changes include counseling sessions, teaching parenting skills, praise and contracts, self-monitoring tools, stimulus control within the home, role-modeling of behaviors by parents, and vigorous and long-term exercise programs. These programs have been successful in small studies with handpicked subjects by specific investigators[431,432] but have not yet been successful when attempted in clinic populations.

One new clinical approach involves motivational interviewing,[433] a method for helping patients work through their ambivalence about behavior change. This method has been shown to be effective for substance abuse and in adult diabetes. Whether it will be successful in pediatric obesity remains to be seen.[434]

Dietary Intervention

Dietary intervention is essential to the reduction of caloric intake and to reduction of the insulin response that promotes excessive energy deposition into adipose tissue. A myriad of studies demonstrate an association between consumption of high-calorie high-fat high-carbohydrate low-fiber foods and the development of pediatric obesity.[319] Specific maneuvers that have been successful in reducing obesity in children include elimination of sugar-containing beverages (including soda and juice)[435,436] and a shift to a low-glycemic-load diet.[326]

Other common sense approaches in adults (although pediatric efficacy data are lacking) include eating breakfast, reducing portion sizes, increasing fruit and vegetable consumption, reducing between-meal snacking, and reducing fast-food consumption.[437,438] However, dietary intervention alone is not a successful strategy for reducing pediatric overweight unless the treatment is very intensive[439]—in which case, the majority drop out. Furthermore, studies of nonsupervised dieting have demonstrated the opposite effect. That is, increased attempts in female adolescents predict a greater increase in weight and risk for obesity.[440]

Physical Activity Intervention

In adults, exercise is not an effective means of inducing weight loss unless combined with reduction of caloric intake. The role of exercise may have a greater impact on weight maintenance, rather than weight loss.[441] Similarly, there is question as to whether physical activity regimens for children can stabilize or reduce BMI.[442,443] Short-term studies show that vigorous exercise can result in short-term reductions in adiposity[444] and improved insulin resistance.[445] This amounts to a minimum of 30 minutes of vigorous exercise 5 days per week.

This is still under the recently proposed activity guidelines from the Institute of Medicine.[446] However, such interventions eventually plateau in their effectiveness—and

even short-term cessation rapidly reverses any accrued benefit.[447] To succeed, physical activity interventions must be long-term, sustained, and incorporated into behavioral modifications aimed at the individual, at the family, at the school, and within the community in general.[444,447] In other words, to make physical activity work it must become a priority.

Appropriate interventions include making school-based physical education mandatory for every child and school, increasing access to after-school recreation, increasing culturally appropriate activities, reducing the competitive nature of sports so that more children will participate, increasing the incorporation of physical activity into daily life (e.g., stairs, walking to school as appropriate), and increasing participation of parents in physical recreation for their own weight management and as role models for their children.

Last, the effects of reducing sedentary behavior by restricting television viewing has been efficacious in small and large studies and in diverse ethnic groups[304]—although fitness is not improved. Restriction of television also has a secondary effect of reducing caloric intake while watching television. Results using dietary or exercise intervention alone are not encouraging. Those studies that use behavioral, dietary, and exercise components together appear to be more successful[319,448]—although long-term efficacy is lacking.

School Intervention

Numerous school-based interventions have focused on reducing obesity rates, most of which have not been successful—in part because school cafeteria fare in most districts remains problematic. However, interventions that increased time spent in vigorous physical activity (20 minutes in elementary schools and 30 minutes in middle schools) were more successful.[449] One approach is to improve self-esteem and self-efficacy of students, as opposed to simply educating them about eating disorders,[450] because this increases physical activity.[451] Schools can model health-promoting environments, provide appropriate health education, and engender increased self-efficacy in coping with stress—which can empower children to make healthy lifestyle choices.

Family Intervention

Invariably, the patient is not the only obese member of the family. There is frequently family chaos, which promotes obesity in other family members. Various caretakers (e.g., grandmothers, babysitters) will feed children and allow unrestricted television as a method of confining their activities indoors, particularly in dangerous neighborhoods. Some parents will not alter their shopping for junk food because they believe other sibs should not be deprived. Usually it is those same parents who do not want to be deprived.

Divorced parents will often use food as a reward for a child's love and loyalty. Thus, the family itself must be the target of lifestyle intervention. Parental involvement is critical, and the concept of "food is not love" must be emphasized. Families need training to modify behavior to make healthy dietary choices, increase activity, and reduce perceived stress. A recent meta-analysis of randomized trials of combined lifestyle interventions for treating pediatric obesity yielded a significant although underwhelming decrease in BMI of 1.5 kg/m^2, with targeted family intervention and a nonsignificant decrease in BMI of 0.4 kg/m^2 in those that targeted the patient alone.[452]

PHARMACOTHERAPY

Indications for Pharmacotherapy

Pharmacologic therapies in children must currently be considered adjuncts to standard lifestyle modification. At present, several limitations preclude physicians from early implementation of drug therapies for the treatment of childhood obesity, including: the youngest child for whom any obesity pharmacotherapy is currently Food and Drug Administration (FDA) approved is 10 years; the long-term use of pharmacologic intervention has not always proven to be more efficacious than behavior modification; there exists a limited number of well-controlled studies of safe and effective pharmacologic intervention in obese children; the relative risk for the development of adverse events in children must be weighed against the long-term potential for improvement of morbidity and mortality, which is difficult to estimate in children; and targeting the pathology is still in its infancy.

In addition, we cannot forget that many drugs used for treatment of adult obesity resulted in unforeseen complications—which resulted in their restriction (thyroid hormone, amphetamine) or recall (e.g., dinitrophenol, fenfluramine, dexfenfluramine, phenylpropanolamine, ephedra).[453-458] Despite these concerns, the negative health impact of childhood obesity may justify long-term medication to control its progression.

In the current pharmacopoeia of childhood obesity, nonspecific and specific strategies based on mechanisms of action within the energy balance negative feedback system are employed (Table 19-3). Currently, the approaches are suppression of caloric intake, limitation of the availability or absorption of nutrients, and insulin sensitization or suppression.

Reduction of Energy Intake: Sibutramine

Numerous anorexiant drugs have been used to treat obesity in adults. These drugs alter neurotransmission within the VMH in order to reduce caloric intake. Only sibutramine (a nonselective reuptake inhibitor of serotonin and norepinephrine) and dopamine are approved for children as young as 16 years.[459,460] Sibutramine effectively inhibits caloric intake[461] and stimulates thermogenesis in rats, although data on humans are contradictory.[462,463]

In adolescents, three randomized controlled trials (RCTs) document the safety and efficacy of sibutramine.[464-466] Tolerability and side effects of sibutramine are similar to adults.[466] Sibutramine can cause vasoconstriction and increase heart rate and blood pressure that persists even after significant weight loss.[454] Other adverse reactions include dry mouth, headache, insomnia, anxiety, nervousness, depression, somnolence or drowsiness, edema, palpitations,

TABLE 19-3

Medications for the Treatment of Pediatric Obesity

Drug	Dosage	Efficacy	Side Effects	Monitoring and Contraindications
Sibutramine Not FDA approved for <16 years of age.	5-15 mg PO qd	RCT: Wt 4.6 kg, BMI 4.5%, WC 5.4 cm over placebo at 6 months RCT: Wt 8.1 kg, BMI 2.5 kg/m^2 over placebo at 6 months	Tachycardia, hypertension, palpitations, insomnia, anxiety, nervousness, depression, diaphoresis.	Monitor HR, BP. Do not use with other drugs or MAO inhibitors.
Orlistat Not FDA approved for <12 years of age.	120 mg PO tid	Open-label: Wt 5.4 kg, BMI 2.0 kg/m^2 at 6 months; RCT: Wt 2.6 kg, BMI 0.85, WC 2.7 cm over placebo at 12 months	Borborygmi, flatus, abdominal cramps, fecal incontinence, oily spotting, vitamin malabsorption.	Monitor 25OHD$_3$ levels. MVI supplementation is strongly recommended. A lower dose preparation has been approved for over-the-counter sale.
Metformin Not FDA approved for treatment of obesity. Approved for 10 years of age for type 2 diabetes mellitus.	250-1,000 mg PO bid	RCT: BMI Z score 0.35 SD vs. placebo at 6 months RCT: Wt 2.7% vs. placebo at 6 months; Post hoc analysis: efficacy dependent on degree of insulin resistance; BMI Z score 0.23 SD in first 4 months, 0.12 SD in next year	Nausea, flatulence, bloating, diarrhea; usually resolves. Lactic acidosis not yet reported in children.	Do not use in renal failure or with intravenous contrast. MVI supplementation is strongly recommended.
Octreotide Not FDA approved for treatment of obesity; otherwise 18 years of age.	5-15 mcg/kg/d SQ ÷ tid	Open-label: Wt 4.8 kg, BMI 2.0 kg/m^2 in 6 months; RCT: 7.6 kg, BMI 2.5 kg/m^2 over placebo at 6 months Post hoc analysis: BMI Z score 0.70 SD in 6 months, dependent on insulin secretion and sensitivity	Gallstones, diarrhea, edema, abdominal cramps, nausea, bloating, reduction in thyroxine concentrations.	Monitor fasting glucose, FT$_4$, HbA$_{1c}$. Useful only for hypothalamic obesity. Ursodiol co-administration strongly recommended.
Leptin Not approved by FDA.	Titration of dose to serum levels, SQ	Anecdotal: BMI 19.0 kg/m^2 over 4 years	Local reactions.	Useful *only* in leptin deficiency.
Topiramate Not FDA approved for treatment of obesity.	96-256 mg PO qd	RCT: Wt 8.0% over placebo at 6 months	Paresthesias, difficulty with concentration/attention, depression, difficulty with memory, language problems, nervousness, psychomotor slowing.	No pediatric data.
Growth hormone Not FDA approved for treatment of obesity.	1-3 mg/m^2 SQ qd	Decreases in percentage body fat, with increases in absolute lean body mass	Edema, carpal tunnel syndrome, death in patients with preexisting obstructive sleep apnea.	Recommended only in Prader-Willi syndrome primarily to increase height velocity. It also decreases fat mass but should only be used in those have been after screening to rule out obstructive sleep apnea. Must closely monitor pulmonary function, glucose, HbA$_{1c}$.
Rimonabant Not FDA approved in the US. No pediatric data.	20 mg PO qd	RCT: Wt 4.8 kg over placebo at 12 months	Depressed mood, nausea, vomiting, diarrhea, dizziness, headache, anxiety.	40% dropout rate. No pediatric data.

Should be considered only after an unsuccessful 6-month trial of lifestyle intervention.
All drugs effective only when combined with appropriate lifestyle intervention.
RCT = randomized controlled trial, MVI = multivitamins.

diaphoresis, xerostomia, constipation, dizziness, paresthesias, mydriasis, and nausea. Sibutramine cannot be administered in conjunction with monoamine oxidase inhibitors or selective serotonin reuptake inhibitors.[453,467] Sibutramine is currently licensed in the United States for use in subjects 16 years of age and older. The FDA has extended the interval of treatment to 2 years.[466]

Reduction of Energy Absorption: Orlistat

This drug is a modified bacterial product that specifically inhibits intestinal lipase and can reduce fat and cholesterol absorption by approximately 30% in subjects eating a 30% fat diet.[468] Orlistat irreversibly binds to the active site of the lipase, preventing intraluminal deacylation of triglycerides—resulting in a 16 g/day increase in fecal fat excretion.[469] Orlistat does not inhibit other intestinal enzymes. It has minimal absorption and exerts no effect on systemic lipases.[470,471]

Although there have been several open-label trials of orlistat in adolescents, only two RCTs have been published.[472,473] The side effects with orlistat are predictable from its mechanism of action on intestinal lipase.[453] Orlistat appears to be well tolerated in adults, with the principal complaints being borborygmi, flatus, and abdominal cramps. The most troubling side effects are fecal incontinence, oily spotting, and flatus with discharge—which are highly aversive in the pediatric population. Orlistat does not affect the pharmacokinetic properties of most other pharmaceutical agents. Absorption of vitamins A and E and β-carotene may be slightly reduced, and this may require vitamin therapy in a small number of patients.

In one study,[474] vitamin D supplementation was required in 18% subjects despite the prescription of a daily multivitamin containing vitamin D—although in the company-sponsored study effects on vitamin levels were minor.[472] Orlistat must be taken with each meal, which reduces its attractiveness in children—who are in school during lunchtime. Orlistat is currently approved for treatment of children as young as 12 years. An over-the-counter lower-dose preparation recently obtained FDA approval.

Improvement of Insulin Resistance: Metformin

Metformin is a bisubstituted short-chain hydrophilic guanidine derivative used for the treatment of children and adults with T2DM.[475-478] Metformin also decreases fasting hyperinsulinemia, prevents T2DM,[479] and promotes weight loss in some obese individuals[480,481] by improving hepatic and muscle insulin sensitivity. Metformin has little effect on energy expenditure.[476] Although some believe that metformin promotes weight loss through a primary anorectic effect (as initial side effects of nausea and GI distress limit caloric intake acutely),[482] most believe that the decline in caloric intake observed with metformin is related to its enhancement of glucose clearance through reduction of hepatic glucose output and reduction in fasting hyperinsulinemia.[483,484]

Metformin improves hepatic insulin resistance by inducing hepatic AMP kinase,[485] which reduces hepatic gluconeogenesis. Therefore, pancreatic insulin secretion and peripheral insulin levels fall. Metformin also restores PI3-kinase and MAP kinase activity in muscle cells, improving muscle insulin sensitivity.[486] Another possible mechanism of metformin action is through stimulation of glucagon-like peptide-1 (GLP-1),[14,487] which may inhibit food intake through central actions on the VMH.[15]

Thus far, two RCTs and an observational prediction study in children and adolescents have been conducted.[488,489] Examination of the open-label responses to metformin in a multivariate analysis demonstrated two predictors for efficacy: race (Caucasian > African American) and the degree of insulin resistance prior to therapy.[137] Metformin has also been used "off-label" for treatment of polycystic ovarian syndrome and nonalcoholic steatohepatitis, with varying degrees of success.[490-495] One particular use for metformin may be to combat the weight gain associated with atypical antipsychotics.[496] However, cessation of metformin therapy leads to a rebound hypersinsulinemia and rapid weight gain, which may negate any beneficial effects seen during the medication window.

Side effects with metformin include nausea, flatulence, bloating, and diarrhea at initiation of therapy—which appears to be self-limited and resolves within 3 to 4 weeks of initiation of the drug. Approximately 5% of pediatric patients discontinue metformin therapy because of severity of side effects. The most feared complication of metformin in adults is lactic acidosis, which is estimated to occur at a rate of 3 per 100,000 patient-exposure years—primarily in patients with contraindications to the use of metformin. However, no documented cases in children have been reported. Metformin increases the urinary excretion of vitamins B_1 and B_6, which are important in the tricarboxylic acid cycle and which may hasten lactic acidosis.[497]

Vitamin B_{12} deficiency has also been reported in as many as 9% of adult subjects using metformin. Therefore, prophylactic multivitamin supplementation is recommended with metformin use. Contraindications to metformin use include renal insufficiency, congestive heart failure or pulmonary insufficiency, acute liver disease, and alcohol use sufficient to cause acute hepatic toxicity. Metformin should also be withheld when patients are hospitalized with any condition that may cause decreased systemic perfusion, or when use of contrast agents is anticipated.[483] It should be noted that metformin is FDA approved for treatment of T2DM in children but is unlikely to be approved for childhood obesity or insulin resistance due to the short exclusivity interval afforded the makers of metformin by the FDA upon its introduction to the United States in 1996.

Suppression of Insulin Hypersecretion: Octreotide

It is well known that bilateral electrolytic lesions or deafferentation of the VMH in rats leads to intractable weight gain,[109,110,394-396] even upon food restriction.[397] In humans, hypothalamic damage due to CNS tumor, surgery, radiation, or trauma can alter the afferent and efferent pathway of energy balance and lead to severe and intractable weight gain.[399,400] In this syndrome of hypothalamic obesity, hypothalamic insult confers an "organic leptin resistance" as the

VMH senses starvation.[54,395] Therefore, energy intake is high and expenditure is low.[403] Children with hypothalamic obesity exhibit weight gain (even in response to forced caloric restriction[401]) secondary to overactivation of the vagus (which promotes an obligate insulin hypersecretion and energy storage) and to defective activation of the SNS, which retards lipolysis and energy expenditure.[99,402]

Insulin hypersecretion with normal insulin sensitivity is noted on oral glucose tolerance testing in these children.[409] This same phenomenon of insulin hypersecretion has also been documented in a subset of obese adults without CNS damage.[498] The voltage-gated calcium channel of the β cell is coupled to a somatostatin ($SSTR_5$) receptor.[499,500] Octreotide binds to this receptor, which limits the opening of this calcium channel, reduces influx of calcium into the β cells, and in turn reduces calmodulin activation and vesicle exocytosis—thereby acutely decreasing the magnitude of insulin response to glucose[501] (Figure 19-2), which results in weight loss or stabilization. Two RCTs and an observational prediction study using octreotide for obesity have been performed.[502,503] An examination of BMI responses to octreotide in pediatric hypothalamic obesity in a multivariate analysis demonstrated that insulin hypersecretion with concomitant retention of insulin sensitivity prior to therapy augured success.[137]

Octreotide is usually well tolerated. The most common side effects include diarrhea, abdominal cramps, nausea, and bloating—which are self-limited and usually resolve in 3 to 4 weeks.[504,505] Other adverse events include gallstones (which are preventable by coadministration of ursodiol), edema, development of sterile abscess at the injection sites, B_{12} deficiency, suppression of GH and TSH secretion, and mild hyperglycemia—especially in those with severe insulin resistance.[506] At present, octreotide offers a promising approach to the treatment of insulin hypersecretion as seen in hypothalamic obesity but is not FDA approved for this use. The use of octreotide in obese children with acute glucose-stimulated insulin hypersecretion without cranial pathology has not yet been evaluated.

Other Targeted Therapies

Leptin. Mutations of the leptin gene in humans recapitulate the phenotype of the *ob/ob* leptin-deficient mouse.[368] Approximately 11 such patients have been described. They manifest hyperphagia from birth, with obesity documentable as early as 6 months of age. Leptin deficiency induces the starvation response,[369] with increased energy intake and decreased REE. The diagnosis is made by extremely low or unmeasurable serum leptin levels. In children with leptin deficiency, leptin therapy results in extraordinary loss of weight and fat mass[507,508]—along with reduction in hyperphagia, resolution of obesity, induction of puberty, and improvement in immunity.[369] Although leptin administration in adults did not prove effective by itself due to leptin resistance,[128] leptin may serve as an adjunct in combination with other medications after leptin sensitivity is ameliorated through weight loss.[133,509]

Growth Hormone. GH fosters anabolism and lipolysis. GH therapy has been shown to increase REE, promote linear growth, increase muscle mass, and decrease body fat percentage in Prader-Willi syndrome.[385,510] It has also been shown to decrease body fat percentage in children with GH deficiency[511] due to its effect on lipoprotein lipase.[512] However, it is not clear whether these reductions in body fat percentage are primary effects on the adipose tissue compartment or are due to the increase in lean body mass. Obesity results in a state of functional GH insufficiency, which can be ameliorated through weight loss.[513] GH therapy also improves the lipid profile in GH-deficient adults.[514] Currently, the role of GH therapy in the treatment of nonsyndromic childhood obesity is unclear and not approved.

The Future of Pediatric Obesity Pharmacotherapy

In response to the relative lack of efficacy of lifestyle interventions, the ever-expanding knowledge of the physiology of energy balance, and particularly as a business decision of potential financial reward, many pharmaceutical companies have launched obesity research programs. The agents discussed in the following are currently in human study. However, use of any of these new agents in children will depend on proof of safety and efficacy based on experience in adults. Oxyntomodulin is an analog of PYY(3-36), which has been shown in a 4-week RCT to reduce energy intake and weight in adults.[515]

Topiramate is a novel anticonvulsant that blocks voltage-dependent sodium channels, enhances the activity of the $GABA_A$ receptor, and antagonizes a glutamate receptor other than the N-methyl-D-aspartate (NMDA) receptor.[516] Topiramate promotes weight loss in a dose-dependent fashion.[517] A recent RCT in adults demonstrated a 9.1% weight loss in subjects taking topiramate 192 mg/day—along with significant improvements in blood pressure, waist circumference, and fasting glucose and insulin.[518] However, almost 33% of the subjects dropped out due to adverse events—which included paresthesias, somnolence, anorexia, fatigue, nervousness, decreased concentration, difficulty with memory, and aggression. There are currently no studies of topiramate in childhood obesity.

Rimonabant is an endocannabinoid receptor (CB_1) antagonist that reduces the reinforcement and reward properties of drugs of dependence at the level of the nucleus accumbens.[519] It also extinguishes the reward properties of food. A 1-year RCT in adults demonstrated a 6.6 ± 7.2 kg weight loss ($p < 0.001$), 6.5 ± 7.4 cm reduction in waist circumference ($p < 0.001$), and improvement in lipid profile.[520] Side effects included depressed mood, nausea, vomiting, diarrhea, dizziness, headache, and anxiety in 20% of subjects. Rimonabant was not FDA approved in the US and is under consideration for withdrawal in Europe due to these side effects.

BARIATRIC SURGERY

Indications for Bariatric Surgery

Conventional treatment of childhood obesity has proven to be time consuming, difficult, frustrating, and expensive. Although numerous short-term successes have been noted, long-term weight reductions are modest—and

recidivism is the rule. In adolescents with extreme and morbid obesity that may be life-threatening, surgical therapy may be indicated in extreme and defined circumstances.[521,522] However, in comparison to adults stricter and more conservative criteria must be applied to adolescents due to the following factors.

- Not all obese adolescents will become obese adults.[523]
- Modestly improved rate of lifestyle and pharmacotherapeutic efficacy.
- Longer time interval before co-morbidities become life-threatening.
- The inability of adolescents to give legal consent.

Therefore, it is virtually impossible to perform RCT surgical studies in children. Efficacy of any given approach will continue to be suspect, and different procedures cannot be compared. For all of these reasons, an expert panel with representation from the American Pediatric Surgical Association and the American Academy of Pediatrics[522] suggested that bariatric surgery in adolescence could be justified in situations in which obesity-related co-morbid conditions threaten the child's health. They provided stringent recommendations that bariatric surgery be limited to those adolescents with BMI >40 kg/m^2 with presence of severe co-morbidity, or BMI >50 kg/m^2 with a less severe co-morbidity. However, these stringent criteria are undergoing careful scrutiny in an attempt to liberalize them.[524]

Particular care should be taken to avoid bariatric surgery at very late stages of obesity, when the presence of obesity-related co-morbidities and the inaccessibility of imaging (most MRI scanners have a weight limit of 450 lbs.) may affect surgical outcome. Indeed, a review of eight retrospective studies in adolescents found that bariatric surgery in adolescents can promote durable weight loss in most patients. However, there appears to be a significant complication and mortality rate.[525] Therefore, guidance is needed to determine the ideal circumstances in which the balance of risk versus benefit favors health preservation and reversal of complications with the lowest risk of morbidity and mortality from the procedure.

Bariatric procedures for weight loss can be divided into malabsorptive, restrictive, and combination procedures. Purely malabsorptive procedures aim to decrease the functional length or efficiency of the intestinal mucosa through anatomic rearrangement of the intestine. These procedures include the jejunoileal bypass and the biliopancreatic diversion with duodenal switch. Due to the high morbidity and mortality of these procedures, they cannot be recommended in children and will not be discussed further. The restrictive procedures reduce stomach volume to decrease the volume of food ingested. They include the bariatric intragastric balloon (no data in children) and laparoscopic adjustable gastric band (LAGB). The Roux-en-Y gastric bypass (RYGB) is a combination procedure.[526] Other bariatric procedures, such as gastric pacing, are still research modalities.

Restrictive: Laparoscopic Adjustable Gastric Banding

LAGB utilizes a prosthetic band to encircle and compartmentalize the proximal stomach into a small pouch and a large remnant.[526] The theoretical advantage of this technique is decreased risk of staple line dehiscence. The more recent introduction of a new laparoscopic approach and the use of an adjustable band (allowing the stomach size to change) make this procedure more attractive. Finally, this procedure is reversible (at least theoretically, but there are some surgeons who scoff at this notion)—or can be modified into the RYGB at a later date. Results vary widely in adults. However, several small studies support the safety and efficacy of LAGB in morbidly obese adolescents.

In one study of 11 morbidly obese adolescents (11-17 years old), LABG resulted in decreased mean BMI from 46.6 to 32.1 kg/m^2 at a mean follow-up of 23 months—with improved co-morbidities. No patient experienced operative or late complications.[527] In another study following LAGB, BMI in 7 adolescents (12-19 years old) fell from a preoperative median of 44.7 kg/m^2 to 30.2 kg/m^2 at 24 months—which corresponded to a 59.3% loss of excess weight.[528] In a 3-year follow-up study of 41 adolescents, BMI was reduced from 42 ± 8 to 29 ± 6—with an excess weight loss of 70%.[529] Again, complications were minor—although erosion of the band through the stomach serosa is documented. Although this procedure is considered safer than RYGB, it has not yet been approved by the FDA for use in adolescents—despite several studies that now support such use.

Combination: Roux-en-Y Gastric Bypass

RYGB involves dividing the stomach to create a small (15-30 mL) stomach pouch into which a segment of jejunum approximately 15 to 60 cm inferior to the ligament of Treitz is inserted—with the proximal portion of the jejunum that drains the bypassed lower stomach and duodenum reanastomosed 75 to 150 cm inferior to the gastrojejunostomy.[526] This procedure combines the restrictive nature of gastrectomy with the consequences of dumping physiology as a negative conditioning response when high-calorie liquid meals are ingested. In addition, RYGB is associated with decline in the circulating level of ghrelin—which may be in part responsible for the decrease in hunger associated with this procedure.[12]

RYGB appears to result in significant early weight reduction in adults.[526,530] However, long-term studies demonstrate weight regain in many patients.[531,532] Limited data are available regarding the efficacy of these surgical procedures to induce weight loss in severely obese children and adolescents, and most of these are case series from individual surgeons or institutions.[467] In a case review, 10 severely obese adolescents (BMI 52.5 ± 10.0 kg/m^2) who underwent RYGB were followed for a mean of 69 months (range of 8-144 months).[533] In this series, weight loss was significant in 9 of 10 adolescents—and was maintained as long as 10 years. The average weight loss was 53.6 ± 25.6 kg, which represents approximately 59% excess weight lost. Weight loss was also associated with improvement of associated co-morbidities, including sleep apnea and hypertension.

Finally, a large retrospective series of 33 obese adolescents[534] age 16 ± 1 year with BMI 52 ± 11 (range of 38-91) and obesity co-morbidities followed these subjects up to

14 years after bariatric surgery (mostly RYGB). There were surgical complications in 13, which were treated. There were 2 sudden deaths, and 5 of the subjects regained their weight. However, the majority experienced significant weight loss—with resolution of their co-morbidities and improvement in quality of life. Adolescents participating in a multicenter study reported by the Pediatric Bariatric Study Group experienced excellent weight loss after laparoscopic RYGB, with mean BMI change from 58 kg/m^2 to 35.8 kg/m^2 at 1 year.[535] Gastrojejunostomy stenosis (21 patients) requiring endoscopic balloon dilation and internal hernia (14 patients) requiring laparoscopic or open reduction were the most common complications. This procedure appears to be safe and effective when candidates are carefully selected and the bariatric surgeon has advanced laparoscopic skills.

The most common reported complications of RYGB include iron-deficiency anemia (50%), transient folate deficiency (30%), and events requiring surgical intervention (40%: cholecystectomy in 20%, small bowel obstruction in 10%, and incisional hernia in 10%).[526] Because most of the stomach and duodenum is bypassed in this procedure, there is an increased risk for deficiencies in vitamin B_{12}, iron, calcium, and thiamine. Although beriberi has been reported in teenagers after RYGB,[536] compliance with daily supplementation and regular monitoring of patients can prevent such nutritional deficiencies.

Who Should Perform Bariatric Surgery in Children

Surgical outcomes in adults vary widely among surgeons and institutions.[537-539] Furthermore, there is a very clear learning curve because the morbidity of bariatric surgery varies inversely with the number of procedures performed.[540] In addition, because RCTs in adolescents are unlikely the only method to validate and refine the use of these procedures will come from following patients carefully and long-term. Last, the increased risk of readmission after bariatric surgery in adults[541] argues for close and careful follow-up and monitoring in adolescents. Therefore, it is essential that bariatric surgery in adolescents be performed in regional pediatric academic centers with programs equipped to handle the data acquisition and long-term follow-up involved in (and the multidisciplinary nature of) the treatment of these difficult patients.[522]

A multidisciplinary team with medical, surgical, nutritional, and psychological expertise should carefully select adolescents who are well informed and motivated to become potential candidates for LAGB or RYGB. Attention to the principles of growth, development, and compliance is essential to avoid adverse physical, cognitive, and psychosocial outcomes following bariatric surgery.[522] It must be clear to the subject and the parent that bariatric surgery is in fact an adjunct to a sincere commitment to lifestyle, rather than a "magic bullet." Indeed, evidence of recidivism in adults after RYGB is now commonplace.

Subjects and families must be well informed as to the risks and complications of such surgery. The medical team will require endocrine, GI, cardiology, pulmonary, and otolaryngologic support. Prophylactic tracheostomy is rarely required to maintain airway patency and to allow for resolution of the hypercapnia prior to surgery.[542] Adolescents undergoing bariatric surgery require lifelong medical and nutritional surveillance postoperatively.[521] Extensive counseling, education, and support are required before and after bariatric surgery. Patients left to their own devices tend to regain weight over time. Indeed, studies in adults document an increased risk of hospitalization after RYGB due to difficulties from the procedure.[541] Monitoring of long-term weight maintenance, improvements in CV morbidity, and longevity are all necessary to determine the cost effectiveness of bariatric surgery in the pediatric population.

Energy Inadequacy

STARVATION VERSUS CACHEXIA

Although both are weight loss syndromes, understanding the neuroendocrine mechanisms that distinguish starvation from cachexia is integral to understanding and treating these disorders properly. In starvation, the negative feedback energy balance pathway is intact. The signal of leptin inadequacy from the weight loss is transduced by the VMH neuron into reduced sympathetic activity (to conserve energy) and increased vagal activity (to store energy). However, in cachexia this pathway is short-circuited by cytokine action on the hypothalamus. The VMH POMC neuron expresses receptors for various cytokines, including IL-1 and TNF-α[543]

In response to cytokine exposure, POMC neurons are activated—resulting in anorexigenesis, increased sympathetic activity, decreased vagal activity, and energy wastage.[544,545] Proinflammatory cytokines increase epinephrine, GH, and cortisol, and reduce insulin. These long-term hormonal changes accelerate muscle proteolysis (cortisol), increase resting energy expenditure (SNS), contribute to insulin resistance (glucagon and cortisol), increase catabolism (cortisol), and suppress appetite and intestinal transit (vagus). This is clearly adaptive in the short term during times of infection (to generate body heat to eradicate the organism) but maladaptive in the long term, when chronic cytokine signaling can lead to cachexia. Thus, even in the situations of leptin decline or inadequacy cytokine activation of POMC neurons will promote continued cachexia and weight loss through persistent SNS activation.

FAILURE TO THRIVE

Failure to thrive (FTT) is not a disease per se but rather a sign of multiple organic and nonorganic conditions and the interactions between them that lead to compromised growth at a young age. FTT still represents a common pediatric medical problem largely managed in the outpatient setting. Although FTT can rarely be a manifestation of critical illness, the majority of cases are the result of undernutrition due to the combination of biologic, environmental, and psychological factors. The diagnosis of FTT requires a thorough, prudent, and oriented history

taking by the caregiver and is not always simple to establish. Moreover, this diagnosis may carry several legal implications (which are not within the scope of this text).

Definition

There is no consensus on a single definition of FTT. The condition reflects inadequate physical growth recorded over time using standard growth charts. The commonly used definitions in clinical practice include length and/or weight below the 5th percentile for age and gender, a downward cross of two major percentile lines of the growth chart over time, or a weight per height below the 10th percentile of expected. The practicality of usually using weight and not length curves evolves from the fact that undernutrition and chronic disease tend to primarily affect weight gain while preserving linear growth.

Ultimately, linear growth is also affected if these conditions persist. It is important to emphasize that single measurements without longitudinal follow-up growth points are inadequate to make the diagnosis of FTT, and a wrongful diagnosis may be established in infants who were born SGA or prematurely—and in some healthy infants growing along the lower percentiles.

Classification and Etiology

The traditional classification of FTT is to segregate organic and nonorganic causes. The nonorganic causes refer to environmental and psychological factors such as sensory deprivation, parental and emotional deprivation, and feeding difficulties of no organic source that occur in infancy. This traditional classification seems to lack the insight that the majority of cases suffer from a combination of the two, reflecting a mixed etiology.[546] A different approach is to classify the disorder based on the pathophysiology of the disorder (i.e., inadequate caloric intake, inadequate absorption, excess metabolic requirements, defective utilization of intake, and reduced growth potential).[547] Common causes of FTT based on this classification scheme are outlined in Table 19-4.

Of note, normal growth variation can confound the diagnosis of FTT because some infants may be born large for gestational age due to intrauterine causes (such as gestational diabetes) and later experience a "catch-down" pattern of growth during infancy toward the actual growth potential curves. Another cause of such negative crossing of percentiles can be constitutional growth delay. It is estimated that up to 25% of children can cross curves by more than 25 percentile lines (representing a cross of two major growth percentile lines) due to the previously cited reasons.[548] These infants reach a new point from which they display a normal growth rate and weight gain pattern, yet they do not have FTT.

Endocrine causes of FTT are uncommon, as typical hormonal deficiencies such as GH deficiency or hypothyroidism present as growth failure but with preserved or increased weight gain. Hyperthyroidism (representing a state of increased metabolic demands and characteristically manifested by increased linear growth) and disorders of salt metabolism (such as hypoaldosteronism and pseudohypoaldosteronism) may have FTT as part of their clinical manifestations.[549] Hypophosphatemic rickets may also present as FTT.

TABLE 19-4

Differential Diagnosis of Failure to Thrive

Inadequate Caloric Intake
- Poverty and low food resources
- Mechanical feeding difficulties (altered swallowing ability, congenital anomalies, central nervous system damage, severe gastroesophageal reflux)
- Wrongful preparation of infant formula (too diluted, too concentrated)
- Unsuitable feeding habits by parent
- Behavioral problems affecting eating
- Child neglect
- Poor parent-child interaction

Inadequate Absorption of Caloric Intake
- Reduced absorption surface area (short bowel syndrome, s/p necrotizing enterocolitis)
- Chronic liver disease, biliary atresia
- Celiac disease
- Cystic fibrosis
- Cow's milk allergy
- Chronic diarrhea
- Vitamin or mineral deficiencies (acrodermatitis enteropathica)
- Vomiting due to CNS abnormalities (tumor, raised ICP)

Increased Metabolism
- Hyperthyroidism
- Chronic infection (due to immune deficiency)
- Occult malignancy
- Congenital heart defects or acquired heart disease (mainly right to left shunts and heart failure)
- Chronic lung disease with hypoxemia (broncho-pulmonary dysplasia)
- Burns

Defective Utilization of Calories
- Renal failure, renal tubular acidosis
- Inborn errors of metabolism (storage diseases, amino acid disorders)

Reduced Growth Potential
- Genetic disorders (trisomies, skeletal dysplasias, Russel-Silver syndrome)
- Specific genetic syndromes
- Primordial dwarfism

Diagnosis and Evaluation

The key to making the diagnosis of FTT is in plotting anthropometric data (weight and length) during a reasonable follow-up period. Although a prudent and focused history and physical examination are the keys to diagnosis, often the correct diagnosis is made in retrospect. The lack of an organic etiology to explain the findings is not enough to establish a diagnosis of nonorganic FTT. A response to an active intervention, manifested at least as a limited period of adequate growth while altering a behavioral element by the caregiver or child, can help establish a diagnosis of nonorganic FTT.

History should focus on the dietary and feeding history, past and present medical history, social environment, and family history. The dietary history is aimed at

assessing as accurately as possible the actual caloric intake of the patient. An important tool for this assessment can be the use of food logs of several days. The important details are actual amounts of food, the way the food is prepared (specifically, relevant to the dilution technique of infant formulas and to cereals added to the formula), and beverages consumed (with specific emphasis on sweetened juices and formula). These details should allow the practitioner to estimate the caloric intake.

The important details regarding feeding begin with the location of the meals and their timing throughout the day. Who feeds the patient or supervises the feeding process is of major importance. The feeding technique should be appropriate to the developmental stage of the child. The timing is relevant in regard to frequent snacking between meals that may cause early satiety during mealtimes.

A standard pediatric medical history should be taken from all patients, yet it should be focused on details that may be relevant to the diagnosis of FTT. The pregnancy and birth history are important for differentiation of infants who were born SGA versus those who suffer from FTT. The timing at which poor weight gain began, especially in relation to changes in feeding, is critically important to the diagnosis. Chronic medical conditions such as congenital heart disease, asthma, multiple recurrent infections, and anemia can all be causes of organic FTT. Multiple hospitalizations and a history of injuries can raise the suspicion of parental neglect. GI manifestations of relevant medical conditions such as frequent vomiting (in cases of milk allergy or gastroesophageal reflux) and stool frequency and consistency (to rule out malabsorption, celiac, inflammatory bowel disease, or cystic fibrosis) should be elicited in detail.

The social history should focus on identifying the actual caregivers of the patient during the majority of the time and whether there are economic issues that may affect the ability to raise the patient adequately. Potential external and intrafamilial stressors that may affect the supply of food to the child should be sought (any stressor or life event that can affect the functioning of the caregiver in a way that could compromise the well-being of the child). The family history should focus on the body habitus of parents and siblings to obtain clues regarding genetic potential for height and weight. Medical conditions in siblings and relatives can suggest a predisposition to genetic disorders. The caregivers should be asked about mental illnesses (such as depression) that may hamper their ability to provide adequate care for the child. A family history of previous children who suffered from FTT should be investigated as well. A call to the local Department of Family Services may be warranted.

The physical examination begins with plotting the child's length, weight, and head circumference on standard growth charts—along with previous measurements (if available). The severity of the FTT can be estimated by assessing the present weight in comparison to the expected weight for age. If the weight is less than 60% of expected by the 50th percentile for age and length, the condition is severe—whereas a weight between the 60th and 75th percentile of expected is considered moderate FTT. Microcephaly accompanied by neurologic signs may suggest a CNS lesion. It should be remembered that head circumference is the last parameter to change in FTT, and only in the severest cases.

Detection of dysmorphism may suggest a genetic cause of impaired growth and development. Measures of nutritional status (such as thickness of skin folds and body fat distribution) can be examined. It is important to carefully observe the interaction of the caregiver and the child during feeding. Impaired parent-child interactions can have a major impact on feeding habits, and their identification is critical to the design of effective behavioral interventions tailored to the patient and family.

The majority of children with FTT have no laboratory abnormalities, and no hormonal alterations. There is minimal literature available about comprehensive laboratory workups in children with FTT, although a classic manuscript about the workup of more than 180 infants in an in-patient setting found laboratory abnormalities in less than 1.4% of tests taken.[550] The choice of tests that may be beneficial should be based on the history and physical examination, and usually should be focused on the assessment of malnutrition in severe cases. A minimal workup (although not cost effective) may include a blood count, chemistry panel (including liver and renal function tests, electrolytes, serum protein and albumin concentrations, and blood acid-base status), and urinalysis with pH.

Additional tests should be oriented toward specific findings from the history and physical examination. No hormonal tests are warranted initially unless a clinical suspicion of a specific disorder arises. In children older than 6 months, screening for iron deficiency and lead poisoning is warranted. Hospitalization and in-patient workup does not add any yield to the workup[551] unless the degree of FTT is severe or if there are concerns of child safety and neglect.

Management

The management of FTT is based on the identification of the underlying cause and its correction. The vast majority of cases are handled by a combination of nutritional and behavioral intervention. Importantly, the intervention should begin before the workup is complete (i.e., from the first evaluation). All medical problems are treated independently of nutritional and behavioral interventions and should not delay or hamper them. The mainstay of treatment of all infants with FTT is a calorie-rich diet accompanied by frequent and close monitoring of weight response. An effective intervention will document a catch-up weight and height gain that is maintained over time.

Feeding and eating behaviors should be addressed, walking the fine line between encouragement and pressure to promote eating. Timing meals and snacks and eating as a family in a pleasant environment of low stress may be important to the acquisition of improved eating and feeding practices. The feeding intervention is dependent on the infant's age at presentation. For breast-feeding infants, it is beneficial to attempt to increase breast milk supply[552] by pumping milk, treatment with metoclopramide to induce oxytocin secretion,[553] improving maternal nutrition and fluid intake, and making adaptations at the home and workplace that can promote and

simplify the breast-feeding process. Suckling problems in neurologically impaired infants can be solved by providing expressed human milk via bottle feeding. Bottle-fed and older infants allow more interventions to promote increased caloric content of the diet.

Infants with FTT should receive ~150% of the recommended daily caloric intake based on their expected weight (rather than based on their actual weight).[554] The enrichment of formula may be achieved by adding cereals, and toddlers may benefit from the addition of palatable high-energy-density foods (such as cheese and peanut butter) to their diet. High-calorie milk-based drinks (such as PediaSure, which provides 30 calories/oz.; in comparison to whole milk, which provides 19 calories/oz.) can be added alongside vitamin supplementation. Zinc supplementation has been shown to increase IGF-1 levels without affecting IGFBP-3 in infants with nonorganic FTT, yet this effect did not actually promote growth.[555]

Prognosis

The vast majority of infants and children with FTT show improvement with intervention. Others may even show progress when they achieve a more independent stage of development at which they can attain their own food. Those who require gastrostomy feeding due to neurologic dysfunction may require assisted enteral nutrition for life. The cognitive and intellectual function outcomes of those who suffered from FTT seem worse than their peers, although this association has only been well established in cases of iron deficiency anemia.[556]

It seems conceivable that deficiencies of other elements critical to brain development during infancy may have a similar adverse impact on intellectual properties at later ages, although this has not been studied systematically. The effects of nonorganic factors (such as emotional deprivation) on intellectual development, often coexisting with organic factors, may also contribute to decreased cognitive ability at later ages.

CANCER CACHEXIA

Cancer activates a complex set of CNS metabolic pathways, which result in cachexia[557] (Table 19-5). Peripheral cytokines gain access to the CNS through the central circumventricular organs that bypass the blood-brain barrier or through stimulation and amplification of CNS microglial cytokine or eicosanoid production. For instance, TNF-α stimulates VMH POMC neurons—which stimulates the SNS, which increases resting energy expenditure, increases cortisol and glucagon levels, and contributes to insulin resistance. IL-1 decreases neuropeptide Y within the VMH and thus decreases appetite. IL-1 also increases CRF, which indirectly inhibits appetite. IL-6 bears striking similarity to ciliary neurotrophic factor (CNTF), which has been shown to reduce weight by activating VMH POMC neurons through a leptin-independent mechanism.[558] Conversely, due to reduction in vagal activity, GI motility is impaired in cancer cachexia and is clinically manifest by early and inappropriate satiety—which occurs in 40% to 60% of cancer patients.

TABLE 19-5

Metabolic Changes in Cachexia

Expression of Cytokines
- Increased production of acute phase proteins (APP)
- Up-regulation of transcription factor NF Kappa B and AP-1
- Increased interleukin-1, IL-6, and tumor necrosis factor-α and interferon-γ
- Increased expression of tumor-specific cachexins (proteolysis-inducing factor, lipid-mobilizing factor, and anemia-inducing substance)
- Increased expression of ubiquitin, E_1, E_2, E_3, and proteasome components (cell death and removal)

Increased SNS Tone
- Increased expression of hormone-sensitive lipase in adipose tissue
- Up-regulation of uncoupling proteins (UCP2 and UCP3) in muscle and adipose tissue
- Increased hepatic gluconeogenesis

Reduced Vagal Tone
- Reduced lipoprotein lipase expression in adipose tissue
- Reduced intestinal transit
- Reduced hunger

In addition, cytokines have adverse peripheral effects. Uncoupling proteins are up-regulated by cytokines and contribute to increased energy expenditure. Cancer cachexia leads to overexpression of UCP1 in brown adipose tissue, UCP2 in brain, skeletal muscle and liver, and UCP3 in skeletal muscle. Levels of UCP2 and UCP3 in the liver and muscle are regulated by prostaglandins, and UCP3 is also regulated by triglycerides—all of which are increased in cancer.[559]

Cytokines cause insulin resistance in skeletal muscle, liver, and adipose tissue. TNF-α decreases insulin receptor and PPAR activity. In addition, there is an inverse correlation between interleukin-6 levels and insulin sensitivity.[560] Adipose tissue insulin resistance increases fat oxidation and decreases lipoprotein lipase activity, resulting in continued lipolysis.[561] The insulin resistance of cancer is not related to defective insulin clearance, and is therefore different than other forms of primary insulin resistance.[562]

Cancers are uniformly anaerobic and depend on glucose for survival. Thus, the glucose manufactured from gluconeogenesis secondary to hepatic insulin resistance is essential to tumor growth. Cancers release large amounts of lactate, which is converted in the liver back to glucose. Such gluconeogenesis consumes ATP, which also increases energy expenditure.[563] Additional raw materials for gluconeogenesis are alanine (derived from skeletal muscle proteolysis) and glycerol (from lipolysis).

Treatment is difficult. Many methods have been tried (SNS antagonists, prostaglandin inhibitors, omega-3 fatty acids, melatonin, thalidomide, interleukins, anticytokine monoclonal antibodies, IL-1 receptor antagonists, chemotherapy), but all are lacking. One promising new avenue is that of melanocortin antagonists,[543] but this is still in preclinical evaluation.

THE DIENCEPHALIC SYNDROME

Originally described by Russell in 1951,[564] this rare disorder presents in infants less than age 1 year and is an indication of a hypothalamic lesion—usually an anterior hypothalamic glioma or other neoplasm affecting hypothalamic function. Although the clinical spectrum is variable, emaciation with paucity of subcutaneous fat (but with normal linear growth and head circumference) is inviolate. Other frequent features include hyperalterness, hyperkinesis, nystagmus, and vomiting.[565,566]

Although numerous patients have been anecdotally reported and characterized, the cause of the emaciation remains unclear. Subjects with diencephalic syndrome have extremely elevated baseline GH levels, but with normal IGF-1 levels, suggesting a modicum of GH resistance.[565] It has been suggested that the high GH leads to lipolysis and accounts for the emaciation, but this finding is not consistent in all patients. Only one evaluation of energy balance has been performed, which demonstrated 30% to 50% greater REE in comparison to normal babies and 13% greater energy expenditure compared to intake.[567]

Treatment recommended is surgical extirpation of the lesion whenever feasible. Radiation is usually reserved for the very young patient. Frequently, these patients postoperatively manifest hypopituitarism—and ultimately develop hypothalamic obesity.[566]

ANOREXIA NERVOSA

Definition

Anorexia nervosa (AN) is an eating disorder that typically begins during adolescence and consists of persistent dieting and intense physical activity, usually accompanied by compulsive behavioral traits and sometimes with purging behavior and binge eating. Most subjects manifest a disturbed body image and a persistent fear of fatness, both of which promote further weight loss. The result of this behavior is a pathologic weight loss, with pathophysiologic consequences.

The risk of developing AN among females in Western societies is estimated to be between 0.5% and 1%.[568] There are two subtypes of anorexia: the food-restrictive type (characterized by very low caloric intake plus excessive exercise) and the purging type (characterized by varying levels of food purging, usually by way of self-induced vomiting and laxative abuse). Alongside the obvious mental elements, the definition in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) includes anthropometric as well as metabolic components: a significantly low weight (defined as a sustained weight below the 85th percentile of the expected weight per height due to weight loss or failure to gain weight during growth and development) and secondary amenorrhea in pubertal girls and women (defined as no menses in 3 months).

Medical complications driven by the chronically reduced caloric intake, purging behavior, and excessive exercise may affect several organ systems. Typically, patients develop a marked loss of subcutaneous fat tissue, impaired menstrual function, bradycardia and orthostatic hypotension, hypothermia, and increased hair loss. Importantly, anorexia nervosa that develops during adolescence may create adverse clinical effects that persist into adulthood[569]—including osteopenia and osteoporosis,[570] higher rates of miscarriage, and reduced offspring birth weight.[571] Anorexia may also alter cognitive abilities (as during extreme weight loss), and a reduction of gray and white matter occurs. Conversely, during weight restoration white matter returns to premorbid levels but gray matter does not.[572]

Anorexia carries an increased mortality risk—specifically for suicide, yet also from medical causes such as starvation per se and purging-induced arrhythmias. Full recovery of body habitus and of growth and development occurs in 50% to 70% of treated adolescents, yet achieving a full physiologic and psychological recovery may take a comprehensive treatment intervention that may last as long as 5 to 7 years.[573] Greater weight loss, lower sustained weight, and the coexistence of other psychiatric disorders adversely affect the probability of recovery. The outcomes for adults with AN are poorer than those who are diagnosed and treated in adolescence.

Endocrine Associations

Obesity and malnutrition usually result in opposing effects on normal physiology and are both associated with changes in the hormonal profile. The majority of these changes represents an adaptive response yet should be considered part of the differential diagnosis of specific hormonal excess or deficiency disorders. Figure 19-7 shows the typical hormonal profile of patients with AN, aimed at energy preservation and the cessation of energetically costly and nonvital processes.

Hypothalamic-Pituitary-Thyroid Axis. The starvation status of AN may resemble the sick euthyroid syndrome. In patients with AN, serum total and free T_4, total and free T_3, TSH, and TBG are significantly lower than normal—whereas rT_3 levels are significantly greater than healthy controls.[574] Most AN patients have a hyporesponsive or delayed responsiveness of TSH to TRH stimulation. Of note, weight regain reverses the effects of AN on the hypothalamic-pituitary-thyroid axis back to normal. Thus, the reduction in thyroxinemia may actually be a normal adaptive physiologic response to starvation.

The differential diagnosis of hypothyroidism should be considered in patients with AN because both disorders are characterized by low T_4 and T_3 levels. In primary hypothyroidism, TSH levels will be greater than those seen in patients with AN—although in mild secondary hypothyroidism this distinction may be difficult. Obtaining a serum reverse T_3 (rT_3) level may be helpful in distinguishing a true thyroid disorder from the euthyroid sick syndrome associated with systemic illness.

Growth Hormone-IGF-1 Axis. Patients with AN typically have GH hypersecretion accompanied by low IGF-1 levels. Whether this profile is due to a primary hypothalamic dysfunction, peripheral target organ resistance to GH, or an impaired negative IGF-1 central feedback mechanism is unclear. An increased GH response to GHRH has been demonstrated in AN, possibly reflecting an impairment of beta-adrenergic suppression of GH

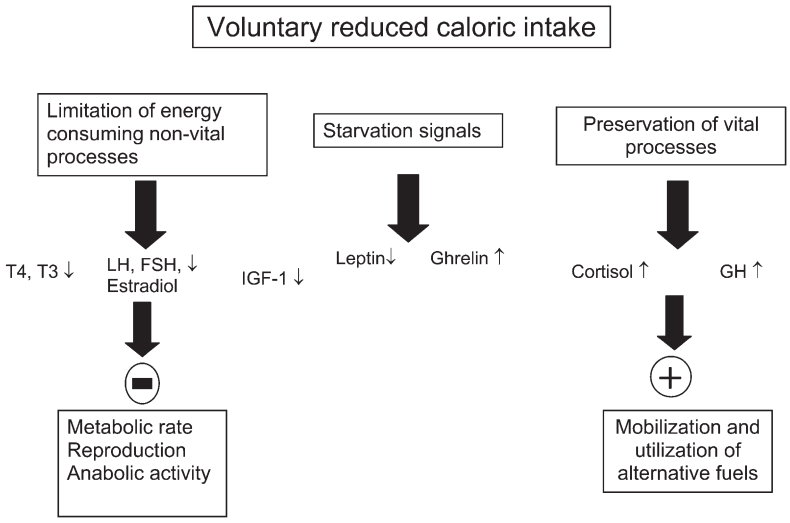


Figure 19-7 Hormonal changes in anorexia nervosa. The hormonal profile of the patient with anorexia nervosa represents an adaptive response aimed at conserving energy. Processes that require significant energy such as reproduction and growth are limited by a complete suppression of the gonadotropic axis and by reduced IGF-1 levels respectively. A seemingly chronic stress response characterized by increased growth hormone and cortisol is aimed at efficient utilization of the limited energetic sources present. Reduced leptin serves as a signal for down-regulating the hypothalamic-pituitary-gonadal axis. Reduced leptin also serves as a starvation signal, although this signal appears to be circumvented in this disorder.

secretion.[575] The clinical presentation of weight loss, cessation of menses, and cold intolerance alongside low levels of pituitary derived hormones may resemble panhypopituitarism—yet patients with AN present with GH hypersecretion.

Hypothalamic-Pituitary-Adrenal Axis. Patients with AN typically present with elevated cortisol levels in the presence of normal ACTH levels.[576] The elevated cortisol levels are apparently due to increased cortisol secretion alongside a reduction in cortisol clearance. Elevated CRH levels found in cerebrospinal fluid of patients with AN suggest that AN represents an overall state of activation of the hypothalamic stress response, manifested peripherally by hypercortisolemia. An abnormal response in the dexamethasone suppression test, mainly of reduced suppression, suggests that an element of decreased feedback sensitivity occurs in this disorder.

Bone Metabolism. Adolescence represents a critical period for the accumulation of bone mineral, thus building bone strength and density for later years. The achievement of peak bone mass is dependent on several hormonal effects characteristic of puberty (such as estradiol and IGF-1), as well as on being dependent on adequate nutrition—all of which are compromised in patients with AN. Adolescents and adults with AN have a low bone mineral density. Whereas in adults this is due to increased bone resorption and reduced bone formation, adolescents are characterized by an overall reduced bone turnover.[577]

The reduced bone density is caused by the typical hormonal profile of AN (i.e., reduced estrogens and androgens, low IGF-1, and relative hypercortisolemia). Moreover, the reduced lean body mass and lower mechanical forces acting on long bones may also contribute to the overall reduced BMD. Recent publications also suggest that elevated levels of gut-derived hormones $PYY_{(3\text{-}36)}$ and ghrelin may also contribute to impaired bone metabolism in AN.[578] Importantly, resolution of AN with weight gain often does not bring full recovery of the bone mineral density status. Osteopenia resulting from undernutrition and the typical hormonal dynamics of AN is one of severe long-term complications of AN during adolescence, and thus is a major treatment target.

Hypothalamic-Pituitary-Gonadal Axis. Amenorrhea is one of the hallmarks of AN, yet it is not always explained by the severe weight loss. Thus, hypothalamic amenorrhea in AN often precedes weight loss and may persist after re-feeding and achievement of normal weight. Gonadotropin levels are reduced in patients with AN, and GnRH stimulation testing in patients with AN demonstrates a blunted LH response with a preserved FSH response and very low levels of estradiol. LH pulsatility may revert to prepubertal patterns in adolescents who have previously achieved pubertal status. The amenorrhea of AN is also marked by strikingly reduced leptin levels.

Leptin serves as a metabolic signal of energy status and nutritional reserve and thus may have a permissive role in the initiation of the complex hormonal dynamics necessary to normal reproductive function.[579] Teleologically, conservation of energy for immediate and necessary metabolic demands while suppressing energetically expensive processes such as reproduction serves as a protective measure in severely malnourished individuals (as seen in AN). The rise in leptin upon weight gain is associated with increases in gonadotropin secretion, suggesting that leptin serves a permissive role in the activation of the hypothalamic-pituitary-gonadal axis.

Fat-derived Hormones. Adipocytes secrete a wide array of adipocytokines, the normal profile of which is altered in AN. Patients with AN typically have very low plasma leptin concentrations alongside a marked

disturbance of the leptin diurnal secretion profile.[580] The concentration of leptin-binding protein (the soluble isoform of leptin receptor) has been reported to be increased in patients with AN, contributing to a further reduction in concentration of free leptin.[581] Leptin has a major role in the neuroendocrine adaptations to the chronic starvation and undernutrition typical of AN, such as reduction in gonadotropins, reduction in thyroid hormone in order to conserve energy, a modified stress response manifested by hypercortisolemia, and elevated GH aimed at mobilizing and utilizing alternative energy sources.[582]

Weight gain in AN patients can induce relative hyperleptinemia in comparison to controls matched for BMI. Circulating leptin concentrations in AN patients thus traverse from subnormal to supranormal levels within a few weeks. Adiponectin is the only adipocytokine whose plasma concentrations are inversely related to fat mass. Conflicting results regarding adiponectin concentration in AN, ranging from hyperadiponectinemia[583] to hypoadiponectinemia,[584] have been reported. Interestingly, weight gain in AN is not necessarily associated with reciprocal changes in adiponectin concentration.[585]

Treatment

Indications for hospitalization and in-patient treatment of AN include dehydration, electrolyte disturbances (mainly hypokalemia), arrhythmias, CV instability (significant bradycardia, hypotension, and orthostatic changes), hypothermia, acute food refusal, acute complications of malnutrition (seizures, pancreatitis, cardiac failure), and psychiatric emergencies. Along with psychological interventions that may consist of psychotherapy and/or pharmacotherapy (based on the spectrum of psychiatric pathology), an increase in caloric intake must be part of the treatment protocol. Starting with 1,200 to 1,500 kcal per day and increasing by 500 kcal is aimed at a gain of 0.5 to 1 kg per week.[586] There is no superior feeding regimen as long as adequate caloric intake is supplied. Extreme cases may be handled through hospitalization in dedicated in-patient units, and caloric intake in this setting may initially be provided by nasogastric feeding—and in extreme cases by parenteral feeding.

One major treatment decision facing the caregiver of patients with AN is whether to utilize estrogen replacement therapy in order to treat amenorrhea and protect the skeleton from osteopenia. There is a lack of a proven efficacious beneficial effect of estrogen replacement therapy in regard to improved bone mass in AN in comparison to placebo,[587] although this treatment modality is still commonly used.[588] This treatment approach may have several adverse effects on the treatment of adolescents because it masks the beneficial effect of weight gain on the resumption of menses and may provide an erroneous sense of security in patients still at critically low weight status. Increased calcium intake alongside 400 IU of vitamin D to accelerate absorption should be encouraged in all patients with AN as another potential protective measure of bone status.

Conclusions

In childhood obesity, the overwhelming majority of cases are not due to a documentable genetic or neuroanatomic lesion. Indeed, although classic endocrinopathies account for less than 2% of childhood obesity in fact every obese patient does manifest an endocrine disturbance (e.g., insulin resistance and/or leptin resistance). We must acknowledge the obvious: that the child eats too much and exercises too little. The question physicians must internally pose when evaluating an obese patient is, "Where in the negative feedback energy balance pathway is this patient's dysfunction?" Only then can appropriate treatment be proffered. Similarly, in cachexia one must go beyond the lack of appetite to understand the reasons for the wasting and illness. These are endocrine paradigms that may permit modulation, especially with endocrine therapies. Understanding the energy balance pathway, and where these various disorders impair its regulation, is the key to further research and to successful prevention and treatment.

Conclusions and Future Directions

Introduction

Cardiovascular disease (CVD) is a major cause of morbidity and mortality among adults in industrialized countries. Dyslipidemia (specifically elevated LDL cholesterol, low HDL cholesterol, and high triglycerides) has been identified as an independent risk factor in the development of CVD. There is strong evidence that lipoprotein levels track from childhood into adulthood and that abnormal levels of LDL cholesterol and perhaps other lipoproteins are associated with atherosclerosis and therefore with related adverse outcomes.

This chapter reviews the evidence for the role of cholesterol abnormalities in the early natural history of atherosclerosis. In addition, a general overview of lipoprotein metabolism is provided—followed by a review of genetic disorders in the metabolism of lipoproteins. Secondary causes of high cholesterol are explained, including the increasing prevalence of obesity and metabolic syndrome as a cause of cholesterol abnormalities in the pediatric population. Standards and approaches to screening for hyperlipidemia in childhood are reviewed, as well as current approaches to the dietary and pharmacologic management of pediatric lipid disorders.

Metabolism

Lipid disorders in children and adolescents can result from defects in the production, transport, and/or degradation of lipoproteins. To understand the diverse causes of lipoprotein abnormalities, a brief review of lipoprotein structure, function, and metabolism is provided. Table 20-1 summarizes the lipoprotein subclasses, the source of

TABLE 20-1

Lipoprotein Subclasses and Associated Apolipoproteins and Lipid Constituents

Lipoprotein	Apolipoprotein	Source	Lipid Constituents
Chylomicrons	apoB-48, apoC-II*, apoC-III, apoE*	Intestine	Dietary triglycerides
VLDL	apoB-100, C-II*, C-III, apoE*	Liver	Endogenous cholesterol and triglyceride
IDL	apoB-100, apoE	VLDL metabolism	Cholesterol and triglyceride
LDL	apoB-100	VLDL metabolism	Cholesterol
HDL	apoA-I, apoA-II, apoC-II, apoE	Liver and intestine	Cholesterol and phospholipid

each, and the constituent lipids and apolipoproteins associated with each particle.

Triglycerides, cholesterol esters, phospholipids, and plant sterols within food postingestion are digested to fatty acids, 2-monoglycerides, unesterified cholesterol, lysophospholipids, and unesterified plant sterols. These lipid-soluble products diffuse through the apical surface of the enteric membrane and are reaggregated into lipoproteins through the action of a microsomal triglyceride transfer protein (MTP). MTP (and perhaps an additional transfer protein) conjugate triglycerides with cholesterol ester (a phospholipid monolayer) and apolipoprotein B-48 (apoB-48) to create a mature chylomicron.[1]

Most of the plant sterol ingested and about half of the absorbed cholesterol are excreted from the intestinal cell back into the lumen by two ATP-binding cassette (ABC) half-transporters, thus limiting the amount of these sterols that are absorbed.[2,3] Once formed, chylomicrons are too large to penetrate the capillary membrane. Consequently, they are secreted into the lymphatic system and enter the venous plasma compartment through the thoracic lymph duct. As the nascent particles are released into the plasma, several apolipoproteins (including apoC-II and apoE) are preferentially transferred to the chylomicrons from other lipoproteins (e.g., high-density lipoproteins, HDL).[4] Figure 20-1 depicts chylomicron metabolism.

Chylomicrons transport dietary triglyceride and cholesterol to sites of storage or metabolism.[5] They are rapidly cleared from the circulation through the action of lipoprotein lipase (LPL). LPL is a triglyceride hydrolase found on the capillary endothelium of various tissues, with highest concentration in muscle and adipose tissues.[6] LPL is activated by apo-CII on the chylomicron. As the triglyceride contained within the chylomicron is hydrolyzed, the particle decreases in size. When approximately 80% of the initial triglyceride has been removed, apoC-II dissociates from its surface.[4] The triglyceride-depleted chylomicrons, now considered chylomicron remnants, are taken up by the liver through a receptor that recognizes apoE on the particle surface. A smaller fraction of remnants may also be internalized via a low-density lipoprotein (LDL) receptor-like protein (LRP)-mediated endocytosis.[7,8]

Very-low-density lipoproteins (VLDLs) originate from the liver, and like chylomicrons are triglyceride-rich particles (Figure 20-2). In contrast to the intestinally derived chylomicrons, however, the fatty acids contained within the VLDL triglyceride come from de novo synthesis from dietary carbohydrate, lipoprotein remnants, or circulating fatty acids internalized by the liver from plasma.[4] Within the hepatocyte, triglyceride and cholesterol ester are assembled by an MTP and surrounded with a phospholipid membrane associated with apoB-100.[1] The mature VLDL particles are released into the lymph and ultimately into the vascular space, where other apolipoproteins (including apoC-II and apoE) adsorb to the VLDL surface.

The metabolism of the VLDL particle follows a route similar to that of the chylomicron: apo C-II on its surface activates LPL, LPL hydrolyzes the VLDL triglyceride, the particle decreases in size (80% loss of triglyceride), and ultimately apoC-II dissociates—resulting in the formation

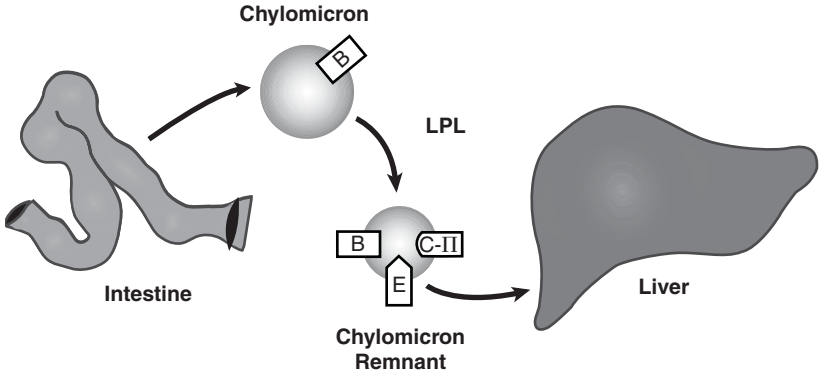

Figure 20-1 Exogenous lipoprotein metabolism. [Courtesy of Emilie Graham, University of Cincinnati.]

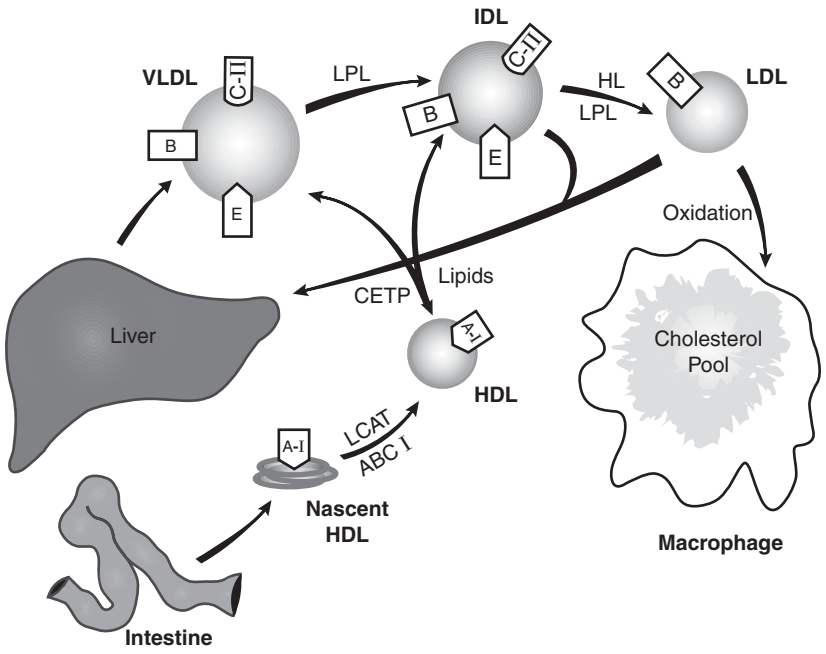

Figure 20-2 Endogenous lipoprotein metabolism. [Courtesy of Emilie Graham, University of Cincinnati.]

of VLDL remnants [also known as intermediate-density lipoproteins (IDLs)]. Approximately half of the IDL is then removed from plasma through the interaction of apoB with the apoB-100/apoE receptor on the surface of liver cells.[9] The rest of the IDL is converted to LDL through further hydrolysis of core triglycerides by hepatic triglyceride lipase (HL). ApoE is transferred from IDL to HDL during the transition of the remnant to LDL.[10]

LDL, the major carrier of cholesterol in plasma, is taken up into peripheral tissues and liver cells by the apoB-100/apoE receptor—which recognizes apoB-100 on the particle surface. Upon receptor binding, the LDL-receptor complex is rapidly internalized into clathrin-coated pits by endocytosis. Within the cell, the newly formed endosome becomes acidified through the action of an ATP-dependent proton pump.[11] Acidification causes degradation of the clathrin coat, dissociation of the receptor from LDL, and subdivision of the endosomal membranes. The endosome containing the LDL receptor recirculates back to the cell membrane for additional LDL uptake. It then fuses with lysosomes, where the lipoprotein is digested into its component parts: unesterified cholesterol, fatty acids, and free amino acids.[11]

The amount of cholesterol released from endosomal uptake regulates hepatic synthesis of LDL receptor and cholesterol. When cellular concentration of cholesterol is low, sterol receptor binding protein (SREBP) is released. SREBP is a nuclear factor that enhances the transcription of LDL receptor and hydroxy-methylglutaryl (HM6) CoA reductase, the rate-limiting enzyme of cholesterol biosynthesis.[12] In this way, intracellular hepatic cholesterol concentration regulates the amount of cholesterol internalized and synthesized by the cell.

When excess LDL is present in the plasma, the capacity of the LDL receptor to remove it is exceeded and LDL is more susceptible to oxidation. Oxidized LDL can be taken up by scavenger receptors on macrophages in the subendothelium of arteries and may contribute to the formation of atherosclerotic lesions.[13]

HDL transfers cholesterol and other lipids from peripheral tissues (including arterial atheroma) back to the liver. The particles are synthesized predominantly in the liver (and to a lesser extent in the intestine) as lipid-poor precursor particles (pre beta HDL) containing apoA-I. Nascent HDL interacts with the plasma membrane of cells, collecting lipid through an ATP-binding cassette transporter-A1 (ABCI) mechanism.[2,3] The cholesterol and phospholipids transferred through this process adsorb to the HDL, forming a disc-shaped particle referred to as HDL3. Within the plasma, HDL3 interacts with the enzyme lecithin cholesterol acyl transferase (LCAT)—which catalyzes the esterification of particle-associated cholesterol. ApoA-I on the HDL surface activates LCAT. Once formed, the cholesterol ester is more hydrophobic and moves to the interior of the particle—creating a sphere-shaped HDL particle known as HDL2.[14]

As HDL2 increases in size, the particle becomes substrate for cholesterol ester transfer protein (CETP). This enzyme promotes the exchange of esterified cholesterol within HDL2 for triglyceride contained within apoB-100-associated lipoproteins.[15] This lipid exchange is one mechanism whereby HDL indirectly participates in reverse cholesterol transport from tissues back to the liver. Two direct pathways in which HDL2 can transport cholesterol back to the liver involve holoparticle uptake via the apoB-100/apoE receptor and cholesterol ester transfer from HDL2 to the liver and other steroid-hormone-producing tissues through a scavenger receptor B1 (SRB1). This latter process may require the action of HL.[16]

Primary Dyslipidemias

Lipoprotein synthesis, transport, and metabolism occur in many steps and involve many specialized proteins. A number of genetic defects have been identified in these processes and are referred to as primary dyslipidemias. Most of these genetic defects present in childhood. Table 20-2 provides a summary of pediatric lipoprotein disorders with reference to the characteristic lipoprotein profile of each. The genetic and metabolic etiologies of these disorders are detailed in the material following.

DISORDERS OF CHOLESTEROL METABOLISM

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is the most common single gene disorder of lipoprotein metabolism. FH is inherited as an autosomal-dominant trait with relatively low prevalence in western countries. The heterozygous form is found in 1 in 500 persons and the homozygous form is found in 1 in 1,000,000 persons. The disorder is caused by a mutation in the apoB-100/apoE receptor or LDL receptor (LDLR) gene.[17,18] More than 900 mutations in this gene have been identified, including those that affect receptor synthesis, intracellular transport, ligand binding, internalization, and recycling.[19] In the heterozygous form, inheritance of one defective LDLR gene results in plasma LDL cholesterol levels two to three times higher than normal.[17]

Individuals with heterozygous FH are at an increased risk of developing early-onset coronary artery disease (CAD), usually between the ages of 30 and 60 years.[17,18] In the homozygous form, individuals inherit a mutant allele for FH from both parents—resulting in plasma LDL cholesterol concentrations that are five to six times higher than normal. Due to the excessively high plasma cholesterol levels in these individuals, cholesterol deposits are common in the tendons (xanthomas) and eyelids (xanthelasmas)—generally by the age of 5 years.[20] In the heterozygous form, xanthomas occur only rarely and generally not until older adulthood. Children with homozygous FH have early-onset atherosclerosis, and often have myocardial infarction in the first decade of life and death from CAD in the second decade.[20]

Autosomal-Recessive Hypercholesterolemia

Autosomal-recessive hypercholesterolemia (ARH) is another inherited disorder resulting in marked elevations in LDL cholesterol levels. This disorder is caused by a defect in the ARH protein.[21] ARH protein binds to the LDLR and clathrin, suggesting a role for ARH in the recruitment and retention of LDLR in clathrin coated pits.[22] Several different mutations in this protein have been identified, all leading to a lack of (or suboptimal internalization of) the LDLR.[22,23] Cholesterol levels in individuals with ARH are five to six times higher than normal. Children with this disorder are clinically similar to those with homozygous FH. However, their parents usually have normal lipoprotein profiles.[23]

Familial Ligand-Defective apoB-100

Familial ligand-defective apoB-100 (FDB) is a monogenic disorder resulting in moderate to markedly high plasma LDL cholesterol levels. The disorder is caused by poor binding of the LDL particle to the LDLR due to a mutation in apoB-100.[24] Such deficient binding results in decreased clearance of LDL from plasma. The disorder is most common in individuals of European descent (1 per 1,000).[9] Patients with FDB are at moderate risk of developing CAD.

Phytosterolemia

Phytosterolemia is a rare autosomal-recessive disease caused by a mutation in two genes (ABCG5 and ABCG8) encoding the ABC half-transporters.[9,25,26] These proteins limit the absorption of cholesterol and plant sterols (and possibly shellfish sterols) in the gut. They also promote biliary and fecal excretion of cholesterol and phytosterols.[26] Defective proteins result in an abnormally high absorption of plant sterols (and to a lesser extent, cholesterol) into the enterocyte and decreased excretion of these sterols from the liver into the bile. Plasma cholesterol can be mildly, moderately, or markedly elevated—whereas plant sterol concentrations in the plasma are markedly increased.[25,26] Patients with phytosterolemia

develop premature CAD, xanthomas in childhood, and may develop aortic stenosis.[25,27]

DISORDERS OF OVERPRODUCTION OF VLDL

Familial combined hyperlipidemia (FCHL) is an autosomal-dominant disorder with variable phenotypic expression, even within members of the same family.[28] In most cases of FCHL, the disorder is caused by an overproduction of VLDL in the liver, a reduction in fatty acid uptake and retention by adipose tissue, and a decreased clearance of chylomicron remnants. The most common lipoprotein pattern is high LDL cholesterol, high triglycerides, and low HDL cholesterol.[29] LDL particles tend to be small and dense. The prevalence of this disorder is estimated to be 0.5% to 1% of the adult population.[21]

Several studies identify FCHL as three times as common in clinical practice as FH.[30,31] FCHL is diagnosed based on a primary hyperlipidemia, including hypercholesterolemia and/or hypertriglyceridemia; multiple lipoprotein phenotypes within a family; and a positive family history of premature CHD.[21] Tendon xanthomas are usually not present in patients with FCHL. Patients with FCHL often have concurrent problems with insulin resistance, central obesity, and hypertension—and are at an increased risk of premature cardiovascular disease.[28]

Syndromes with a similar phenotype are hyperapobetalipoproteinemia, LDL subclass pattern B, and the metabolic syndrome.[29,32-34] Of the three, the latter syndrome is much more prevalent in children. Rates of metabolic syndrome are continuing to rise with the prevalence of obesity in the pediatric population.[34] There appears to be a mechanistic link between central obesity, insulin resistance, and dyslipidemia—with central obesity generally preceding both glucose and lipid abnormalities.

DISORDERS OF MARKED HYPERTRIGLYCERIDEMIA

Familial Hypertriglyceridemia

Familial hypertriglyceridemia (FHTG) follows an autosomal-dominant inheritance pattern expressed predominantly in adulthood. However, the prevalence in children is increasing.[9] Obesity is an important factor that can expedite the expression of FHTG, and patients often have concurrent glucose intolerance. The phenotype for FHTG is moderate to markedly high serum triglycerides and low to normal LDL and HDL cholesterol levels. The metabolic cause of the disorder is hepatic secretion of large triglyceride-rich VLDL particles that are catabolized slowly.[28] The fundamental genetic defect for FHTG has not been identified.

Familial Lipoprotein Lipase Deficiency

Familial lipoprotein lipase (FLPL) deficiency is rare. The disorder is expressed as elevated serum chylomicron levels due to diminished or absent hydrolysis of chylomicron associated triglycerides by lipoprotein lipase.[28] In the heterozygous state, patients have low to moderate levels of chylomicron catabolism and levels of serum triglycerides that range from 200 to 750 mg/dL.[9]

In patients in the homozygous state, serum triglycerides can reach 10,000 mg/dL or higher.[35] Blood from patients with homozygous FLPL has a viscous, creamy appearance due to the presence of large numbers of chylomicron particles. Risk for pancreatitis is increased in the homozygous state due to the markedly elevated serum triglycerides. In addition, eruptive xanthomas and neurologic symptoms may be apparent. The gene for LPL has been located on chromosome 8p22, and more than 50 different mutations have been identified in patients with FLPL.[36]

HYPOLIPIDEMIAS

Low HDL Cholesterol

In clinical practice, patients with low HDL cholesterol levels commonly have concurrent high triglycerides, with or without elevations in small dense LDL cholesterol.[37-39] These patients are usually obese, and the mechanistic explanation for this dyslipidemic triad is VLDL overproduction. Less common are familial disorders of HDL, including familial hypoalphalipoproteinemia, mutations of the apoA-1 protein, and Tangier disease. These disorders are characterized by low HDL level with no other lipid abnormality. Familial hypoalphalipoproteinemia follows an autosomal-dominant inheritance pattern.[9] ApoA-1 levels are also often low due to decreased production of HDL.

A number of mutations have been described in the apoA-1 gene and are associated with low HDL cholesterol and low apoA-1.[40,41] Tangier disease is due to mutations in the ABCI gene.[42,43] Patients affected by this disease are not able to actively withdraw cholesterol from cells onto nascent HDL particles, causing rapid degradation of the nascent HDL. ApoA-1 is rapidly cleared before it is able to acquire cholesterol.[43] In Tangier disease, HDL cholesterol levels are close to zero and the apoA-1 levels are less than 5 mg/dL. The risk of premature CAD in these patients is mild to moderate.[9]

Abetalipoproteinemia

Abetalipoproteinemia is associated with low serum cholesterol (<50 mg/dL) and triglycerides (2-45 mg/dL). Patients with this disorder present with steatorrhea and fatty liver. Without treatment, ataxia follows (with acanthocytosis and retinitis pigmentosis). Abetalipoproteinemia is caused by a defect in MTP.[28] Without MTP, no chylomicrons, VLDL, or LDL appear in the plasma. In these patients, HDL takes over as the primary cholesterol carrier. Thus, the defect is not fatal. Because of significant fat malabsorption, fat-soluble vitamin status is impaired.

In particular, because vitamin E absorption and cellular uptake require chylomicron and LDL transport, high doses of vitamin E are required to prevent retinal and sensory neuron degeneration. Additional dietary considerations include restricting long-chain dietary triglycerides to less than 15 g/day to alleviate the steatorrhea. Medium-chain triglycerides (MCT oils) can be used as an alternative source of energy.[44]

Hypobetalipoproteinemia

Hypobetalipoproteinemia is an autosomal-dominant disorder resulting from a defect in the apoB gene that produces a truncated apolipoprotein B.[28] Cholesterol levels in patients with heterozygous hypobetalipoproteinemia are usually 50% of those of an unaffected family member. The heterozygous form of this condition is benign. However, homozygous hypobetalipoproteinemia is associated with severe hypocholesterolemia, significant steatorrhea, fatty liver, acanthocytosis retinopathy, and peripheral neuropathy. Dietary considerations are the same as for patients with abetalipoproteinemia.[44]

DISORDERS WITH LIPOPROTEIN CLEARANCE VIA apoE PATHWAYS

Dysbetalipoproteinemia is characterized by elevated cholesterol and triglyceride levels.[28] The disorder results from the presence of a polymorphism of the apoE allele (apoE2, rather than the more common apoE3) along with the gene for FCHL.[44] Metabolically, this defect results in poor uptake of remnant particles and abnormal remnant catabolism because of the abnormal apoE. Increased remnants, VLDL, chylomicrons, and apoE are all present. Xanthomas may occur, and premature CAD has been reported. This lipoprotein disorder is rare in children and often presents in young adulthood.[28]

Secondary Causes

Secondary dyslipidemias can result from a variety of diseases and conditions (see Table 20-3 for a list). In the United States, the most prevalent cause of secondary dyslipidemia is overweight and obesity.[45] The dyslipidemic triad (namely, elevated triglycerides and small dense LDL and low HDL cholesterol) is commonly associated with overweight (in particular, with central adiposity).[45,46] In addition to dyslipidemia, insulin resistance and elevated blood pressure may be present. This cluster of abnormalities characterizes the metabolic syndrome and is associated with increased cardiovascular disease risk.[47,48] The prevalence of metabolic syndrome appears to be increasing in children and adolescents, along with the prevalence of obesity.[47] The primary approach to treating this disorder is weight management.

Metabolic lipid perturbations in adult patients with type 1 and 2 diabetes mellitus are similar to those found in patients with the metabolic syndrome, but often are more severe.[49] Generally in adults with diabetes, triglycerides are elevated and HDL-cholesterol is low—and LDL cholesterol can be normal or mildly or moderately elevated. Diabetes in adults is considered a CHD risk equivalent according to the National Cholesterol Education Program (NCEP). This means that the risk for developing CAD in patients with poorly controlled diabetes is equivalent to those with established CHD.[50] For this reason, the NCEP recommends aggressive treatment of dyslipidemia in adult patients with diabetes.

Although type 1 diabetes is currently the main form of diabetes seen in children, in the United States a growing number of patients with type 2 diabetes are under the age of 18 years.[51] Change in the prevalence of type 2 diabetes in youth is likely related to the growing obesity epidemic occurring in the pediatric population.[51,52] Data on lipid concentrations in children and adolescents with diabetes are few, particularly in those with type 2 diabetes. The Search for Diabetes in Youth Study assessed the prevalence of serum lipid abnormalities among a representative sample of U.S. children and adolescents with type 1 and type 2 diabetes.[53]

Findings from this study showed a substantial number of diabetic children over the age of 10 years with abnormal serum lipids: nearly 50% had an LDL cholesterol level above the optimal level of 100 mg/dL. For children with type 2 diabetes, 37% had elevated triglyceride levels and 44% had low HDL cholesterol. These data highlight the importance of serum lipid screening in children with diabetes. Recommended approaches to managing dyslipidemia in children and adolescents with diabetes are discussed later in the chapter.

Other causes of secondary dyslipidemia include hypothyroidism, nephrotic syndrome, other renal diseases, liver diseases, and infection.[54] Dylipidemias can also result from the ingestion of a variety of medications. These medications include progestins, estrogens, androgens, anabolic steroids, corticosteroids, cyclosporine, and retinoids. Secondary causes of dyslipidemias should be identified by patient historical data and a careful physical examination. Laboratory tests (including thyroid, renal, and liver function panels) would confirm the diagnosis.

The risk of development of atherosclerosis with these conditions is unknown but is likely proportionate to the length of exposure and extent of elevation in serum LDL cholesterol levels. Cardiovascular disease is common in patients with chronic renal insufficiency.[55] The treatment of dyslipidemia in patients with secondary causes is

focused on managing the underlying disease. Diet and physical activity changes may also be recommended to reduce elevated LDL cholesterol and triglyceride levels.

Vascular Changes and Dyslipidemia

It is well established that elevated concentrations of total cholesterol and LDL cholesterol in adult life are strong and reversible risk factors for CAD.[50] Whether dyslipidemia in childhood contributes to atherosclerotic lesions in coronary and other arteries has been a subject of debate, but accumulating evidence from pathologic and in vivo imaging studies favors a relationship. Atherosclerotic lesions result from deposits of lipid and cholesterol in the intima of the arterial wall.[56] Early lesions, called fatty streaks, are formed from the accumulation of macrophages filled with lipid droplets (foam cells).

Fatty streaks do not disorganize the normal structure of the intima and do not deform or obstruct the artery, and are in themselves not considered harmful.[57] However, some continue to accumulate macrophage foam cells and extracellular lipid and smooth muscle cells—forming raised plaques. From these, more advanced lesions may develop—with further deposition of extracellular lipid, cholesterol crystals, collagen, and potentially calcium.[58] It is these raised lesions that result in a myocardial infarction because of their increasing size and obstruction of the arterial lumen or because of rupture of the fibrous plaque, which results in the release of thrombogenic substances from the necrotic core.[56]

Pathobiologic studies of the coronary arteries of young individuals who died from causes unrelated to heart disease have been useful in documenting the progression of atherosclerosis by age and risk factor determinants. Stary et al. studied more than 500 postmortem samples of coronary arteries from persons younger than 30 years of age and found presence of fatty streaks in the majority of children less than 9 years of age, raised lesions in about half of adolescents, and more advanced lesions in about a third of the young adults studied.[59] In 93 autopsies of young adults for whom childhood risk factor data were available, Berenson and colleagues found that the extent of the surface of arteries covered with fatty streaks and fibrous plaques was positively associated with LDL cholesterol, triglycerides, blood pressure, and body mass index and negatively associated with HDL cholesterol levels in childhood.[60]

The Pathobiological Determinants of Atherosclerosis in Youth (PDAY) study reached similar conclusions from examination of more than 3,000 postmortem samples of coronary arteries of young adults who died from noncardiovascular events and who likewise had a variety of antimortem risk factor measures available.[61] In general, pathology studies have made important contributions to the identification of risk factors for early aspects of the atherosclerotic process. In conjunction with findings from longitudinal studies such as the Framingham Heart Study (in which risk factor assessments of participants preceded the development of cardiovascular disease)[62] a group of risk factors, often referred to as the traditional risk factors for CAD, has been established. A complete list of pediatric risk factors for CAD is found in Table 20-4.

Recent advances in vascular imaging technology have provided a means of measuring early pathologic changes and functional abnormalities against coronary and other arteries in response to adverse changes in cardiovascular disease risk factors. The advantage in using this technology is that walls of superficial arteries can be imaged noninvasively in real time at high resolution, and changes to the arterial wall can be measured as a continuous variable from childhood to adulthood in patients with and without presence of risk factors for CVD.[63] Computed tomography (CT) scanning is considered one of the most sensitive noninvasive tools for imaging the extent and location of coronary artery calcium present in atheroma.[64]

The presence of coronary artery calcium has been associated with adverse cardiovascular disease outcomes in adults.[65] In adolescents, small studies have shown associations among hypercholesterolemia, BMI, and significant coronary artery calcium. In the Muscatine Study (in which participants were assessed for CVD risk factors during their school-age years and later assessed for cardiovascular changes by CT scan), 31% of men and 10% of women aged 29 to 37 years had significant coronary artery calcification.[66] Childhood risk factors associated with calcification were obesity, increased blood pressure, and low HDL cholesterol.

Vascular ultrasound imaging has been utilized to assess alterations in brachial artery flow-mediated dilation, which is a measure of endothelial function, and carotid intima-media thickness (IMT).[64] In adults, both measures have been associated with adverse changes in traditional cardiovascular disease risk factors,[67] respond to normalization of risk factors,[68] and are considered important early markers for the progression of atherosclerotic disease.[67-70] Although few studies have used ultrasound technology to evaluate coronary arteries in the young, children with hypercholesterolemia have been assessed using these measures and have been found to have abnormalities of carotid IMT and brachial artery vasodilation.[71-73]

Further, in young adults aged 33 to 42 years who had comprehensive risk factor assessments performed some 25 years prior Davis et al.[74] found an association between mean carotid IMT and elevations in total cholesterol and triglyceride concentrations during childhood. Lavrencic et al.[75] found that the mean carotid IMT was significantly

TABLE 20-4

Pediatric Risk Factors for Coronary Artery Disease

- Elevated LDL cholesterol (>130 mg/dL)
- Family history of premature (aged <55 years) coronary heart disease, CVD, or peripheral vascular disease
- Smoking
- Hypertension
- Low HDL cholesterol (<35 mg/dL)
- Obesity [>95th percentile weight for height on National Center for Health Statistics (NCH) growth chart]
- Physical inactivity
- Diabetes

greater in youth with FH compared with those in a control group—as well as being significantly greater in all subjects in regard to total cholesterol, LDL cholesterol, and systolic blood pressure. Similar risk factors have been associated with impaired vasodilation, indicating endothelial dysfunction.[76-78]

In summary, these studies confirm the utility of vascular imaging for detecting early pathologic and functional changes to coronary vessels and associations with modifiable CVD risk factors in the young. Clinically, vascular imaging by ultrasound may be a valuable means of estimating the benefit of treating multiple CVD risk factors in children and adolescents. CT scans may be less useful in younger patients because calcium depositions are uncommon before young adulthood.

Screening for Lipid Disorders

ROUTINE SCREENING

Data from pathologic and, more recently, in vivo imaging studies (as discussed previously) support the screening and treatment of children and adolescents with elevated LDL cholesterol levels and other risk factors. For more than a decade, pediatric guidelines established by the NCEP have provided the standard of care with respect to lipid screening and treatment of dyslipidemia in childhood.[79] An algorithm summarizing these diagnostic and therapeutic guidelines is presented in Figure 20-3. In brief, the guidelines recommend targeted blood choles-

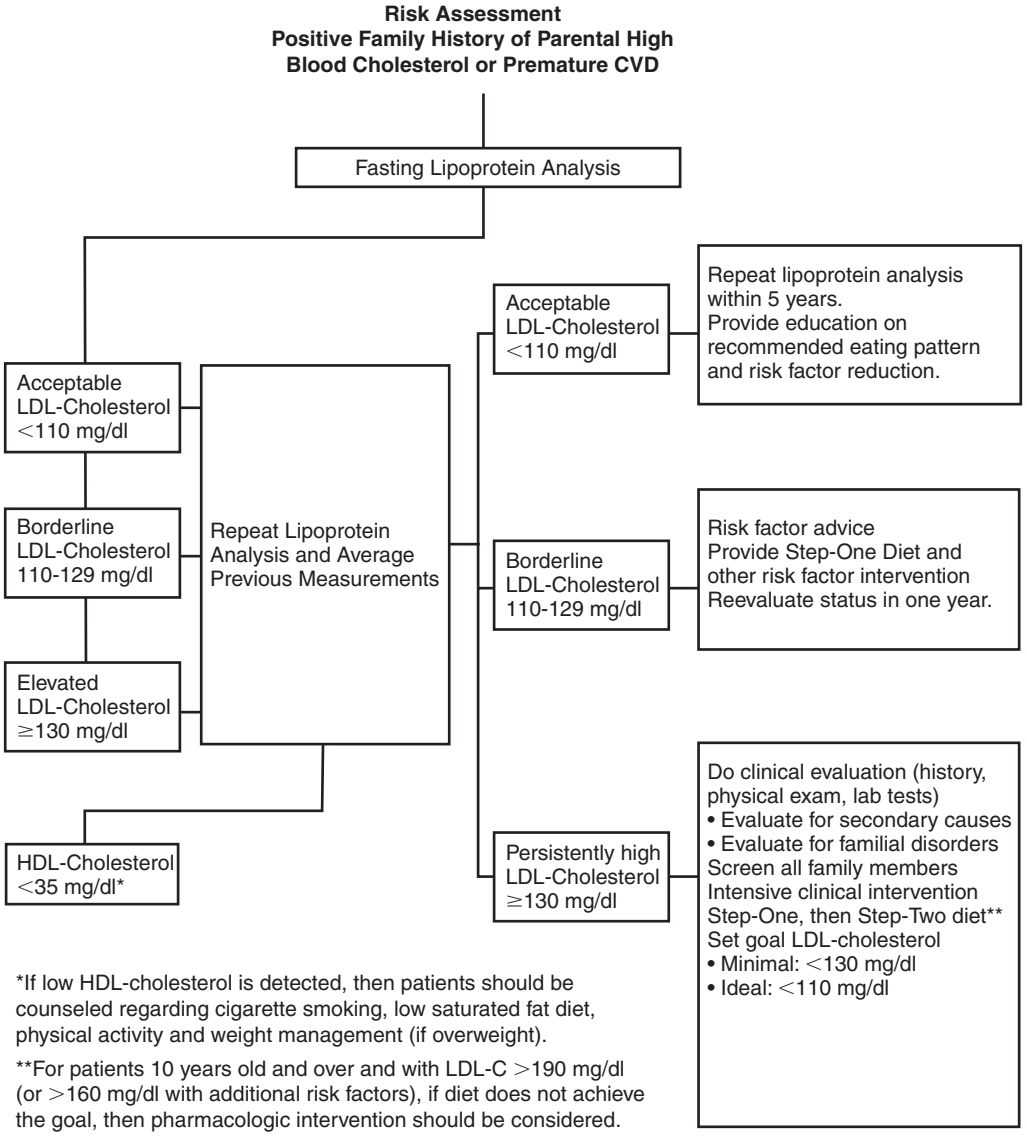

Figure 20-3 Child treatment algorithm based on LDL cholesterol levels. [Reprinted with permission from Williams CL, Hayman LL, Daniles SR, Robinson TN, Steinberger J, Paridon S, et al. (2002). Circulation 106:143-160.]

terol screening if a child or adolescent has a parent with hypercholesterolemia (total cholesterol >240 mg/dL) or if a child has a parent or grandparent <55 years of age who has documented CVD.

CVD is defined as angina pectoris, myocardial infarction, established coronary atherosclerosis, peripheral vascular disease, cerebrovascular disease, or sudden cardiac death. Lipid screening of children with multiple risk factors for future CVD (e.g., smoking, hypertension, obesity, diabetes, poor diet quality, and sedentary lifestyle) is recommended by the NCEP. Screening children whose family histories are unknown is discretionary.

A fasting (12-hour) lipoprotein analysis is recommended for screening a child. A fasting lipoprotein analysis allows quantification of total cholesterol, HDL cholesterol, triglycerides, and calculation of LDL cholesterol. The Friedewald equation [LDL cholesterol = (total cholesterol – HDL cholesterol) – triglycerides/5] can be used to calculate LDL cholesterol as long as the serum triglyceride level is <400 mg/dL.[80] Direct measurement of LDL cholesterol concentration is available through some commercial laboratories and is indicated for individuals whose fasting triglyceride level is >400 mg/dL.

The NCEP defines cut-points for total cholesterol and LDL cholesterol in children based on data from the National Health and Nutrition Examination Survey (NHANES), performed from 1988 to 1994. The 75th and 95th percentiles for lipid values from this survey were used to define "borderline" and "high" risk categories, respectively. Acceptable, borderline, and high risk values for total and LDL cholesterol are outlined in Table 20-5. If a lipoprotein analysis reveals LDL cholesterol to be borderline or high, a repeat test should be performed and the average value of the two tests considered for clinical decision making.[46]

Clinical evaluation of children and adolescents at high risk for CVD based on LDL cholesterol levels should include careful review of the patient's medical and family history and physical examination to identify additional risk factors and secondary causes of dyslipidemia. Assessment should include the following: review of past medical or family history for hypertension, diabetes mellitus, medication use, obesity, poor dietary habits (including excessive intake of saturated fat), sedentary behavior, and tobacco use; measurement of height, weight, and calculation of BMI; Tanner staging to assess pubertal growth; blood pressure measurement; physical inspection of skin, eyes, and tendons for lipid deposition and palpitation of the thyroid gland and liver for signs of enlargement; and laboratory tests (including thyroid, renal, and liver function panels). Glucose and insulin levels should be measured to assess for the presence of metabolic syndrome or diabetes.

Several limitations have been identified regarding the NCEP guidelines for the identification of children and adolescents at high risk for CVD. First, several studies have noted that selectively screening children and adolescents for elevated cholesterol based on parental history may be inadequate to identify a substantial proportion of the population with elevated LDL levels.[81-83] In general, studies have shown that approximately 30% to 60% of pediatric patients with elevated cholesterol would be missed using the NCEP screening approach based on family history.[82,83] A second limitation is that current guidelines give no significant consideration to variation in LDL cholesterol level according to race, gender, age, and level of sexual maturation.

There is considerable variation in LDL cholesterol with age during growth and development. This is especially true during the period of puberty.[84,85] Total and LDL cholesterol levels tend to decline during puberty, meaning that some adolescents will appear normal when in fact they will have elevated levels after puberty. A third limitation is that guidelines were published at a time when the epidemic of overweight and obesity was not yet obvious, and the guidelines do not address screening for low HDL cholesterol and high triglycerides. Recent data from pathobiologic and vascular imaging studies show adverse changes in vascular structure and function in adulthood related to low HDL cholesterol and high triglyceride levels in childhood. These data support pediatric assessment of triglyceride and HDL cholesterol levels. The American Heart Association[86] has recommended that triglyceride levels >130 mg/dL and HDL cholesterol levels <35 mg/dL be considered abnormal for children and adolescents (Table 20-5).

TABLE 20-5

Normal Plasma Lipid and Lipoprotein Concentrations for Children and Adolescents*

Category	Acceptable	Borderline	High
Total cholesterol	<170	170-199	≥200
LDL cholesterol	<110	110-129	≥130
Triglycerides			
0-9 years	<75	75-99	≥100
10-19 years	<90	90-129	≥130
Category	**Acceptable**	**Borderline**	**Low**
HDL cholesterol	>45	35-45	<35

LDL, low-density lipoprotein; and HDL, high-density lipoprotein.

* Values for plasma lipids and lipoproteins are from the National Cholesterol Education Program Expert Panel on Cholesterol Levels in Children.

GENETIC TESTING

Increasingly, DNA-based tests are being used to confirm the diagnosis of FH in patients with a family member who has a mutation or in a young patient with high LDL cholesterol with tendon xanthomas or atherosclerotic disease.[87] Currently, three genes (LDLR, APOB, PCSK9) have been identified in association with mutations that cause this disorder.[88] In addition to LDLR, most laboratories test for the apolipoprotein B gene r500Q mutation. Rapid and relatively inexpensive methods have been developed to test a selected subset of the LDLR mutations. However, more expensive "complete gene scans" are needed for mutation-negative samples.[88] Once a mutation is identified, testing of relatives can be performed rapidly and cheaply.

At present, it is unclear whether knowledge of specific mutations will lead to improved treatment. Several studies have shown that the degree of cholesterol lowering

achieved by statins is influenced by the type of mutation (e.g., individuals with the APOB r3500Q mutation showed a strong positive response to statin therapy).[89,90] In addition, the diagnosis of FH based on genetic testing improved uptake and adherence to treatment in several studies.[91,92] Concerns about long-term benefits and side effects from life-long treatment for identified children remain. As progress in this area continues, current treatment algorithms may need modification to describe the role of genetic testing in clinical practice.

Diet Therapy in Managing Dyslipidemia

The NCEP guidelines outline a two-pronged approach to managing pediatric hypercholesterolemia: one geared to the population in general and the second to individualized treatment of elevated LDL cholesterol levels in high-risk patients. The population-based approach stipulates that all children older than 2 years of age should consume a low-fat diet, referred to as the Step 1 diet.[79] This recommendation is viewed as a primary preventive measure to reduce serum lipids, thereby reducing risk of CAD in the pediatric population at large. The individual patient approach recommends that all children and adolescents with elevated LDL cholesterol first be treated with the Step 1 diet.

If after 3 to 6 months of dietary compliance LDL cholesterol levels remain abnormal further restriction of dietary saturated fat and cholesterol, referred to as the Step 2 diet, is recommended. Repeated studies have shown that this stepwise dietary approach to lowering LDL cholesterol levels is safe and efficacious in children with hypercholesterolemia.[93-95] The nutrient composition of the Step 1 diet is 30% or less of calories from total fat, less than 10% of calories from saturated fat, and less than 300 mg/day of cholesterol—with adequate energy to support growth and development.[79] The dietary restriction on total fat is not intended to be a daily recommendation but rather averaged over several days.[96]

Further, these recommendations are not intended for children younger than 2 years of age because infants and young children are thought to require a higher level of dietary saturated fat and cholesterol to support development of the central nervous system. To prevent overzealous implementation of a very-low-fat diet for children with high cholesterol, which could lead to failure to thrive,[97] the American Academy of Pediatrics (AAP) recently set a lower limit for percentage of energy from fat at 20% of calories.[98] In most cases, with dietary compliance the Step 1 diet should normalize borderline-high LDL cholesterol levels. The reported response to the diet in children with LDL cholesterol levels <130 mg/dL has ranged from 3% to 10%.[46,99]

For children with persistently high LDL cholesterol levels, further reduction of dietary saturated fatty acids and cholesterol is recommended. Specifically, the Step 2 diet calls for restricting saturated fat intake to <7% of calories and cholesterol to <200 mg/day.[79] Based on clinical evidence, these dietary restrictions should achieve an additional LDL cholesterol reduction of 4% to 14%.[100,101] However, the extent to which LDL cholesterol is lowered may depend on previous dietary intake and baseline LDL cholesterol levels.

To achieve the NCEP dietary goals for saturated fat and cholesterol, key sources of these nutrients must be the focus of intervention. Foods high in saturated fat and cholesterol include red meats, poultry with skin, whole-milk dairy products, and egg yolks. The NCEP recommends that red meats be limited to modest amounts of lean cuts (e.g., 5-6 oz per day) and that dairy products be limited to skim or low-fat varieties (24-32 oz/day).[79] Skin should be removed from chicken and turkey, and intake limited to white meat. Processed meats should contain no more than 3 g of fat per serving, and egg yolks should be limited to 4 per week, on the Step 1 diet (2 egg yolks per week on the Step 2 diet). Oils used in cooking should be unsaturated, and soft margarines used in place of butter. Table 20-6 highlights some additional practical dietary strategies for lowering saturated fat and cholesterol in the diets of the young.

To ensure children prescribed low-fat diets consume adequate calories and nutrients to support growth and development, high-fat foods omitted from the diet should be replaced with lower-fat versions of the same. For example, whole-milk dairy products contribute calcium, phosphorus, and protein to the diet—along with substantial amounts of saturated fat and cholesterol. Children should be encouraged to replace whole-milk dairy foods with low-fat or nonfat milk, yogurt, cottage cheese, and frozen desserts to ensure overall nutrient adequacy. Breads, cereals, grains, fruits, and vegetables should comprise the largest proportion of energy in children's diets. Most choices within these food groups are low in fat, cholesterol free, and high in fiber—and will help displace energy sources containing saturated fat. Children should be encouraged to choose 6 to 10 servings of whole-grain cereals, breads, and pasta and to consume at least five servings of fruits and vegetables per day.

TABLE 20-6

Practical Dietary Strategies for Lowering Saturated Fat and Cholesterol

- Eat 5 to 9 servings of fresh, frozen, or canned fruits and vegetables daily.
- Use vegetable oils and soft margarines low in saturated fat and trans fatty acids instead of butter or most other animal fats in the diet.
- Eat whole-grain breads and cereals rather than processed grain products.
- Use nonfat (skim) or low-fat milk and dairy products daily.
- Eat more fish, especially oily fish (broiled or baked).
- Eat lean cuts of meat, and trim any obvious fat from red meat before cooking.
- Take the skin off chicken or turkey and eat only the white meat.
- Avoid processed meats such as hotdogs, sausage, and bologna.
- Avoid creams or sauces made with butter or whole-milk dairy products.
- Choose low-fat snacks such as ginger snaps, graham crackers, pretzels, plain popcorn, animal crackers, and vanilla wafers.
- Use recommended portion sizes on food labels when preparing and serving food.

Although pediatric dietary recommendations do not include specific guidelines for lowering serum triglycerides or raising HDL cholesterol, diets containing high levels of sucrose and excess calories have been associated with adverse changes in these lipids/lipoproteins.[102] For this reason, children should be counseled to reduce intake of simple sugars from processed foods such as cookies and desserts, and limit intake of sugared beverages. Weight management should be a goal of diet therapy for children with a BMI >85th percentile.

Weight reduction approaches should focus on decreasing the child's weight-for-height percentile while maintaining linear growth.[101] Although weight loss may temporarily lower HDL cholesterol, weight stabilization at a new lower level will lead to a gradual increase in HDL cholesterol over time.[103] Moderate caloric restriction can be achieved by following the Step 1 diet. Increased physical activity should be encouraged, and sedentary activities (such as television viewing and playing computer and video games) should be limited to no more than 2 hours per day.

Pharmacologic Management

For many children with moderately or severely elevated LDL cholesterol, diet alone will not lower their cholesterol levels to the acceptable or even borderline range. Long-term drug therapy is associated with decreased incidence of heart disease and overall mortality in adults.[50] However, no studies directly demonstrate the efficacy of administering lipid-lowering drug therapy in children to prevent CAD. In addition, long-term safety studies for some of the newer medications have not been performed.

The pediatric panel of the NCEP recommends using medication only in patients who are at least 10 years of age and whose post-dietary LDL cholesterol level is >190 mg/dL or whose LDL cholesterol level is >160 mg/dL with a family history of early CVD, with two or more risk factors for CVD, or with the metabolic syndrome present (Figure 20-3). A follow-up LDL cholesterol assessment is recommended 6 weeks after starting drug therapy, and every 3 months thereafter until LDL cholesterol goals are met. Thereafter, follow-up can be less frequent.

For children in general, the goal for LDL cholesterol is <130 mg/dL. For children with diabetes, the goal for LDL cholesterol is <100 mg/dL.[104,105] The lower LDL cholesterol goal for children with diabetes reflects a synthesis of pediatric guidelines and treatment recommendations for adults with diabetes that now consider the presence of diabetes a coronary heart disease risk equivalent.[50] Table 20-7 summarizes the recommendations of the American Diabetes Association for lipid screening and management of children and youth with diabetes. Medications used in the treatment of specific lipid abnormalities are summarized in Table 20-8 and are reviewed in the material following.

BILE ACID BINDING AGENTS

Bile acid binding agents lower serum cholesterol indirectly by binding with bile acids in the gastrointestinal tract. This action prevents their reabsorption into the enterohepatic circulation, resulting in their loss from the body and removal from the cholesterol pool.[106] To compensate for this loss, the liver increases endogenous cholesterol synthesis and up-regulates LDL-receptor synthesis—thereby lowering LDL cholesterol levels in the blood. In bile-acid resin trials in children, a dose of 8 g/day while on a cholesterol-lowering diet resulted in a decrease in LDL cholesterol ranging from 10% to 20%.[107,108]

TABLE 20-7

American Diabetes Recommendations for Management of Children and Adolescents with Diabetes*

	Type 1 Diabetes	Type 2 Diabetes
Screening	After glycemic control >2 years at diagnosis if other CVD risk factors; otherwise at 12 years; if normal, rescreen every 5 years	At diagnosis regardless of age; if normal, rescreen every 2 years
Lipid goals	LDL <100 mg/dL HDL >35 mg/dL Triglycerides <150 mg/dL	
Treatment strategies	Glycemic control Diet Physical activity Weight reduction if appropriate Medication indications if initial management fails: • Age >10 years • If LDL >160 mg/dL • If LDL 130–159 mg/dL consider based on CVD risk profile • Statins with or without resins • Fibrates if TG >1,000 mg/dL • Manage other CVD risk factors (Table 20-4) if appropriate	

* Recommendations are from the American Diabetes Association. American Diabetes Association (2005). Standards of medical care in diabetes. Diabetes Care 28(1):S4–S36.

TABLE 20-8

Drugs Used in the Treatment of Pediatric Lipid Disorders

Class of Medication	Common Name	Starting Daily Dose	Change in Lipid Profile	Adverse Effects
Bile acid binding agents	Cholestyramine	80 mg/kg	↓ LDL	Constipation
	Colestipol	5 g	↑ TG	Abdominal cramping
HMG Co-A reductase inhibitors*	Atorvastatin	10 mg	↓ LDL	Dyspepsia
	Simvastatin	5 mg	↓ TG	↑ Liver transaminases
	Pravastatin	10 mg	↑ HDL	↑ CK
	Rosuvastatin	5 mg		Myositis
	Lovastatin	10 mg		
	Fluvastatin	20 mg		
Fibrates*	Bezafibrate	200 mg TID	↓ TG	Constipation
	Clofibrate	500 mg BID	↑ HDL	Myositis
	Fenofibrate	48 mg		Anemia
	Gemfibrozil	600 mg BID		
Niacin*	Niaspan	500 mg @ HS	↓ LDL	Flushing
			↓ TG	Headache
			↑ HDL	↑ Liver transaminases
Cholesterol absorption blocker*	Ezetimibe	10 mg	↓ LDL	Not reported in children or adolescents

* Long-term safety and efficacy has not been established in children and adolescents.
CK = creatine kinase; LDL = low density lipoprotein; TG = triglycerides; and HDL = high-density lipoproteins.

Bile-acid resins come in powder and tablet form. The powder is usually taken twice daily (4-g scoop) mixed with water or juice. Resins in this form tend to be gritty in texture and children complain that they are unpleasant to drink. Tablets are more palatable, but are large and difficult for some children to swallow. Overall, studies report poor to fair compliance with the medication.[106,109] Side effects are few and are mainly gastrointestinal in nature, including constipation and gas. These can be minimized with increased intake of water and fiber. Resins may increase triglyceride levels and may interfere with the absorption of certain medications and fat-soluble vitamins.[110] Supplementation with a multivitamin and folate (1 mg daily) is usually recommended.[106]

HMG-CoA REDUCTASE INHIBITORS

HMG-CoA reductase inhibitors (also known as statins) lower LDL cholesterol in the blood by blocking hepatic HMG Co-A reductase, the rate-limiting enzyme in cholesterol biosynthesis.[111] This action depletes the intracellular cholesterol pool, leading to an up-regulation of LDL receptors and a decrease in serum cholesterol. Doses ranging from 5 to 40 mg/day have resulted in a 20% to 40% lowering of LDL cholesterol, and slight increases in HDL cholesterol levels have been reported in children.[112-114]

In vivo imaging studies have demonstrated improvements in surrogate markers for atherosclerosis with statin therapy. Reversal of endothelial dysfunction and regression of carotid IMT have been reported in children treated with statins over a 2-year period.[115,116] This latter finding suggests that initiation of lipid-lowering statins in childhood may inhibit progression or might even lead to regression of atherosclerosis.

Adverse effects of the medication are few but have included GI complaints, elevated liver transaminase and creatine kinase (CK) levels, and myositits.[106,110,115] For this reason, statins would not be recommended for patients with liver disease. Follow-up of patients treated with statins should include laboratory assessment of liver transaminase and CK levels and identification of adverse physical symptoms such as muscle cramps.

Because statins are potentially teratogenic, it is essential that physicians determine that adolescent girls are not pregnant or likely to become pregnant before initiating therapy.[106] The longest statin trials have been 2 years in length. Thus, whether statins adversely affect long-term growth and development and are safe for lifelong use has not been ascertained. Longer-term safety and efficacy studies are needed, particularly with follow-up of vascular endpoints.

INHIBITORS OF CHOLESTEROL ABSORPTION

Ezetimibe is a new cholesterol-lowering agent that prevents the absorption of cholesterol and plant sterols by inhibiting the passage of sterols across the intestinal wall.[117] The reduction in cholesterol absorption leads to a decrease in hepatic cholesterol uptake and availability. As a result, there is a compensatory increase in hepatic cholesterol biosynthesis, an up-regulation of LDL receptor expression, and an overall decrease in blood LDL cholesterol levels.

In adult trials, a daily intake of 10 mg/day reduced LDL cholesterol by approximately 18%.[117-120] Although Ezetimibe has already been approved for children older than 10 years who have FH, it has not been adequately studied in this group of patients. Such studies are needed to confirm adult findings and to assess the safety and efficacy of this medication for use in children and adolescents.

FIBRIC ACID DERIVATIVES

Fibric acid derivatives (also known as fibrates) lower blood triglyceride levels by reducing the hepatic production of VLDL.[106,117] The drug also increases the production of apoA-I, resulting in higher HDL cholesterol levels. Side effects are similar to those for statins and include GI complaints, elevated liver transaminase activity, and myopathy.[106] For this reason, fibrates are not recommended for used with statins. No cut-points for initiating fibrate therapy in children and adolescents have been established. Because the major risk of elevated triglyceride (pancreatitis) does not increase until triglycerides levels reach 750 to 1,000 mg/dL, many experts recommend withholding fibrate use in children until the triglycerides are persistently >350 mg/dL or a random level is >700 mg/dL.[106]

NIACIN

Niacin decreases hepatic VLDL production, leading to decreased production of LDL cholesterol.[106,117] Children with heterozygous FH treated with 1,000 to 2,250 mg of niacin daily over an average of 8 months showed a 23% to 30% reduction in LDL cholesterol.[120] However, 76% of the children had adverse effects from therapy (e.g., flushing, headache, nausea, glucose intolerance, myopathy, abnormal liver function) and 38% discontinued the drug. Niacin is generally not used to treat children with FH unless LDL cholesterol is persistently elevated or unusual hypertriglyceridemia and low HDL cholesterol are present.[106] Niacin given in combination with statins has been used to treat homozygous FH. Niacin is available in immediate and slow-release forms (Niaspan, Slo-Niacin).

DIETARY ADDITIVES AND SUPPLEMENTS

Plant sterols and stanols consumed at levels of 2 g per day have been shown to reduce LDL cholesterol levels by 9% to 20% in adults.[50] Foods containing these additives (e.g., margarines and salad dressings) lower serum cholesterol by preventing dietary cholesterol absorption in the gastrointestinal tract.[121] In children with familial hypercholesterolemia, use of 2 g/day of plant sterols decreased LDL cholesterol by 14% but did not improve endothelial function.[122] This suggests that LDL cholesterol must be reduced to a certain threshold level before improvement of endothelial function can occur.

More studies examining the long-term effects of plant sterols on the vascular endothelium are warranted. Concern has been raised about the potential for the malabsorption of fat and fat-soluble vitamins in children consuming plant sterols chronically. The AHA recommends reserving the use of foods supplemented with plant sterols/stanols to children with moderate to severe elevation in cholesterol, and monitoring fat-soluble vitamin status.[123]

Dietary supplements containing soluble fiber, garlic, and omega-3 fatty acids have been used to treat pediatric hyperlipidemia with unremarkable findings. In a randomized controlled trial, Dennison et al.[124] studied the effect of psyllium fiber versus placebo on change in blood cholesterol levels of 5- to 17-year-old children. Psyllium fiber (6 g/d) and the placebo were added to a ready-to-eat cereal. Although compliance was excellent, there were no significant effects of the added psyllium on total, LDL, or HDL cholesterol levels over a 5-week period. Garlic extract therapy (300 mg × 3 doses per day) was studied in a randomized controlled trial for effects on serum lipoproteins in 8- to 18-year-old children with FH.[125]

Garlic extract was given in 3 daily doses of 300 mg versus a placebo for 8 weeks. No significant effects of garlic treatment versus placebo were noted on total, LDL, or HDL cholesterol. Omega-3 fatty acids, as found in fish oils, are known to reduce serum triglyceride levels in adults.[50] In a randomized crossover study, children with FH and FCH were supplemented with either 1.2 g/day of docosahexaenoic acid (DHA) or a placebo for 6 weeks.[126] All children were given counseling on the NCEP Step 2 diet. Outcomes studied included triglycerides, LDL and HDL-cholesterol, and endothelial function as measured by flow-mediated dilation (FMD) of the brachial artery.

Findings showed that DHA supplementation was associated with increased levels of total, LDL, and HDL cholesterol but no change in triglycerides compared to the placebo group. FMD improved significantly after DHA supplementation compared to baseline in both groups, and the change was greater in the DHA-treated group versus the controls. This finding suggests that in children DHA may not be effective for positively modifying serum lipids. However, the endothelium may be a therapeutic target for DHA in hyperlipidemic children.

Conclusions and Future Directions

Increasing evidence indicates that extreme elevation in LDL cholesterol is associated with vascular pathology in youth. Fortunately, appropriate therapy can reverse these changes. Pediatric clinical trials of lifestyle and drug therapy to treat lipid abnormalities suggest similar effectiveness and safety to that observed in adults. The majority of studies, however, have been short term in design. Longer-term safety and efficacy studies are needed, particularly with follow-up of vascular endpoints.

Few clinical data are available to document at what age drug therapy should be appropriately and safely started. More work is needed in this regard to support clinical judgments on what age and dosage should be used in children at high risk for CHD. Importantly, current diagnostic and treatment algorithms should be updated to reflect recent advances in the field—including the role of genetic testing in the confirmation and management of genetic hyperlipidemias.

Summary

Introduction

Pediatric endocrinology is a specialty that relies greatly on laboratory testing for evaluating and monitoring children with suspected or known endocrine conditions. It is therefore essential that those involved in the care of children understand all variables involved in proper prescribing, sample collecting, performance, and interpretation of laboratory tests. Appropriate use and application of hormonal assays can improve the health care of children by helping to avoid unnecessary detailed and invasive examinations. We hope this chapter will lend sufficient guidance to help clinicians appropriately select and evaluate endocrine hormone tests. The principles of molecular endocrinology testing are discussed elsewhere in this textbook.

Endocrine hormone assays have evolved from radioimmunoassay (RIA) technology by using monoclonal antibodies, sensitive detection techniques, extensive automation, and most recently tandem mass spectrometry (MS/MS). With extensive automation, the sudden availability of platforms with a menu of commonly demanded hormone tests rapidly broadened access of endocrine testing to more than 1,600 laboratories today.[1]

The distribution of endocrine testing now likely resembles the overall medical testing industry, in which hospitals perform 55% of testing, commercial laboratories perform 24%, physician office laboratories perform 11%, and others (such as nursing homes) perform 10%. As of 2003, laboratory testing at $40 billion accounted for 2.9% of all American health care expenditures. Specialized testing, including endocrinology, consisted of about $3.7 billion.[2] Despite the vast number of testing laboratories, most endocrine testing is concentrated on only a handful of automated analyzers manufactured by a small number of companies.

Recent advances in information technology are also changing the physician, hospital, and laboratory interaction. Similar to computer-computer interfaces, laboratory web-based information systems for ordering testing and receiving results are now increasingly available. These systems may reduce certain types of errors while potentially creating others.[3] How these systems will reliably populate hospital systems, handheld devices, and electronic medical records or practice management systems is an emerging variable.

Changes in the reimbursement environment have influenced the structure of hospital, commercial, and

physician-office laboratories. Today, these laboratories employ only laboratory generalists and depend largely on these simple-to-operate platforms. Although practical, such systems have limited accuracy in certain applications. Their ease of installation and tacit interchangeability are also potential limitations. In most laboratories, appropriate technical knowledge of endocrinology and analytic systems is diminished and is often outsourced to device manufacturers whose continued focus is further integration and consolidation. Although these comments apply primarily to the current situation in the United States, they are likely to reflect trends in all developed countries.

Hormonal Assay Methods

PREANALYTIC VARIABLES

Normal endocrine physiology, nonendocrine illness,[4] sample collection, and handling influence measured hormone levels (Table 21-1). Under normal circumstances in the basal state, many hormones are secreted in an episodic manner. Chronologic age, pubertal stage, emotional and physical stress, nutritional status, and postural effects contribute to the variation. Consequently, some hormones, growth factors, or surrogate markers may have very wide normal basal ranges and large intrasubject variability. Intrasubject variability can be remarkable for 24-hour integrated concentrations[5,6] and for dynamic responses.[7]

Proper collection, documentation, and storage are needed to ensure accurate hormonal determinations.[8,9] Most steroid, thyroid, peptide, and protein hormones (and nearly all measured antibodies) are relatively resistant to collection and handling factors—including freezing and thawing. Generally, a serum sample drawn under normal conditions should be allowed to clot at room temperature for an hour, separated, and frozen until analysis is adequate. See Table 21-2 for patient preparation, sample collection, handling requirements, and relevant information regarding certain hormone assays. For best results, always consult with the specific laboratory to understand its collection and handling requirements.

TABLE 21-1

Preanalytic Variables Affecting Hormonal Measurements

Variable	Hormone
Episodic secretion	Pituitary hormones, cortisol
Exercise (acute)	Adrenocorticotropic hormone (ACTH), anti-diuretic hormone (ADH), aldosterone, cortisol, epinephrine, glucagon, growth hormone (GH), prolactin, norepinephrine, testosterone
Circadian rhythm, diurnal variation	ACTH, cortisol, dehydroepiandrosterone sulfate (DHEAS), epinephrine, estradiol, follicle-stimulating hormone (FSH) , GH, luteinizing hormone (LH), norepinephrine, prolactin, testosterone
Seasonal variation	Estradiol, prolactin, testosterone
Postural change	Aldosterone, epinephrine, norepinephrine, renin
Nutrition	C peptide, estradiol, glucagon, insulin-like growth factor-I (IGF-I), insulin-like growth factor binding protein-1 (IGFBP-1), insulin, proinsulin, thyroxine-binding globulin (TBG)

STANDARDIZATION

Unlike routine chemistries, most quantitative hormone assays can vary widely in absolute terms. To simplify research and clinical findings, standardization of hormone methods has been a long sought after and continuing goal.[10] Standardization of steroid and other small-molecule hormone assays is relatively simple because these hormones are of low molecular weight and are synthesized and highly purified using physical and chemical methods. Such standards are typically available as preparations that can be reliably prepared and stably stored.[11]

By contrast, peptide hormones, protein hormones, and antihormone antibody standards are of high molecular weight and higher complexity (with many circulating isoforms)—making an absolute assignment more difficult. Recombinant technology and the availability of pharmaceutical-grade hormone are enabling improvement.[12] Despite better standards, similarly designed assays often yield different absolute results.[13] Some differences happen for proprietary reasons, but others are reflecting the complexity of the circulating and standard hormone preparations and variances in recognition of these hormones by capture and detection antibody systems. Testing proficiency data from automated systems show that identical systems have not reduced variability substantially for all hormones.

REFERENCE RANGES

For the clinician, basal and dynamic testing reference data appropriate to the method result is more important than the absolute standardization. As outlined in Tables 21-3 through 21-5, ideally reference data should be available for all patient groups commonly making use of the test.[14] These data must be established comprehensively, especially for new analytes, and must account for all factors that partition circulating hormone levels. For existing analytes, a reference method with an extensive normal data set allows for a less costly and more accessible way of establishing reference ranges.

A subset of normal samples can be used to confirm the reference database if the newly implemented method is similar in design and the reference population is the same.[14] Laboratories increasingly rely on device manufacturers to provide this base data set against which the smaller internally derived normal data are statistically evaluated for transference.[15] Current practice may fall short of these requirements because method differences and bias between methods are sometimes unrelated to the differences in reference intervals.[16]

TABLE 21-2

Hormone Assays: Preanalytic and Other Considerations

Hormone	Patient Preparation, Sample Collection, and Hormone Stability	Assay Notes
ACTH	• EDTA • 6-hr RT, 4° C • Ship frozen • Avoid FT	• 1-24 ACTH, used for stimulation studies, and pro-opiomelanocortin (POMC) fragments can lower ACTH levels as measured by two-site methods.
ADH	• EDTA • Avoid FT • Ship frozen	• Solid-phase purification.
Aldosterone	• Patient: posture and sodium • Stability: 1 day at RT, 2 days at 4° C	• Spironolactone and tetrahydroaldosterone 3-glucuronide may cross-react in some assays.
Calcitonin	• 1 day at RT • 1 day at 4° C	• Large calcitonin and others cross-react in some RIA methods. • High dose suppression of values possible with two-site methods. • Heterophile antibodies and human anti-animal antibodies may give falsely elevated results in two-site methods.
Cortisol, urine-free cortisol	• With boric acid 5 days at RT and 14 days at 4° C	• Prednisolone and 6-beta-hydroxycortisol may cross-react.
C peptide	• EDTA: 1 day at RT • RT: 1 day at 4° C • Ship frozen	• C peptide immunoreactivity may be unstable. • Some immunoassays may be affected by anti-insulin antibodies.
Dopamine, epinephrine, norepinephrine	• Patient preparation: posture and activity • Stability: 0 days at 4° C • Must freeze sample ASAP	• Very unstable analytes present in low concentrations.
Estradiol	• 2 days at RT • 6 days at 4° C	• RU-486, Efavirez, and steroid-binding proteins may interfere with some assays.
Free IGF-I	• Avoid FT • Ship frozen	• Direct methods controversial.
GH	• 2 days at RT • 2 days at 4° C	• 20-kD GH react in certain RIA methods. • Human placental lactogen (hPL) may augment or suppress hGH levels. • 44-191 GH in RIA methods. • High hGH concentrations may require sample dilution if accurate results are needed. • After treatment, anti-GH antibodies may suppress GH levels in sandwich assays.
Glucagon	• EDTA • Avoid FT • Ship frozen	• Unstable; keep frozen.
IGF-I	• 2 days at RT • 2 days at 4° C	• IGF binding proteins react in methods that do not exclude or block. • Variable reactivity with therapeutic IGFI and IGFI/IGFBP3 complex with some assays.
Insulin	• 6 hours at RT • 1 day at 4° C • Ship frozen	• Variable reactivity with various recombinant insulins. • On treatment, hook effect possible for two-site assays. • Human anti-insulin antibodies may interfere (use free and total measurements to avoid this issue). • Assays typically most reactive with human insulin, less reactive with porcine insulin, and least reactive with bovine insulin.
IPTH, intact parathyroid hormone	• EDTA • 4 hours at RT • 1 day at 4° C	• Assay terminology: second-generation N-terminal anti-1-24, third-generation N-terminal anti-1-6. • Second and third generations typically use C-terminal anti-39-84. • Midrange PTH RIAs (MPTH) recognize PTH molecules containing amino acid sequences 44-68. • C-terminal (CPTH) assays recognize molecules containing amino acids 39-84. • Circulating PTH fragments are not biologically active unless they have key N-terminal residues (1-24) and can lower or raise results from two-site methods. • Third-generation assays do not detect PTH 7-84 that is not biologically reactive. • Fragments are especially high with renal failure. • Human anti-PTH antibodies may interfere with assays.

TABLE 21-2

Hormone Assays: Preanalytic and Other Considerations—cont'd

Hormone	Patient Preparation, Sample Collection, and Hormone Stability	Assay Notes
LH and FSH	• 2 days at RT • 2 days at 4° C	• HCG for stimulation or due to tumor may augment RIA values and suppress two-site methods.
Osteocalcin	• EDTA • Avoid FT	• Some RIAs more sensitive to degradation.
Proinsulin	• 1 day at RT • 1 day at 4° C	• High insulin levels associated with treatment may suppress proinsulin levels in two-site assays. • Human antibodies specific to insulin or proinsulin.
Prolactin	• 2 days at RT • 2 days at 4° C	• Macroprolactin or big prolactin a complex of prolactin and IgG lacks biologic activity because not freely available to tissues. • Two-site assays may demonstrate suppression (high-dose hook) at extremely high prolactin levels associated with macroprolactinomas.
PTH-rP, parathyroid-hormone-related protein	• Plasma with protease inhibitor • Avoid FT • Ship frozen	• Unstable; collect with inhibitor and keep frozen. • PTHrp N terminal contains key PTH sequences and is biologically active. • Also known as the humoral hypercalcemina of malignancy factor.
Renin	• EDTA • Process at RTsSnap Freeze • Ship frozen • Do not leave cold	• Process ambient and freeze rapidly to avoid plasma renin activity (PRA) increases due to cold-activated proteases. • Activity assays known as PRA. • Also direct renin assays.
Testosterone	• 2 days at RT • 6 days at 4° C	• RU-486, testolactone, and steroid binding proteins may interfere in some assays.
Thyroglobulin	• 2 days at RT • 2 days at 4° C	• Circulating anti-TG antibodies significantly suppress two-site methods. • RIA methods are less likely to be impacted.
TSH, thyroid-stimulating hormone	• 2 days at RT • 2 days at 4° C	• βHCG or alpha subunit with some methods causing falsely lower results. • Heterophile antibodies have been reported as causing falsely high values. • Controversy about TSH reference ranges.
Vitamin D 25 OH	• Avoid FT • Ship frozen	• Assays may or may not efficiently measure D2 form and C-3 epimer.

Notes: Stability: RT = room temperature. FT = freeze/thaw cycle. Stability studies using normal sera have shown that all hormone levels except ACTH, ADH, dopamine, epinephrine, glucagon, insulin, norepinephrine, osteocalcin, IPTH, and renin are relatively stable when kept at ambient temperature (20-25° C) for 1 day. Stability may be worse for patient samples and for samples kept at elevated temperatures, and may vary with the method. For most reliable hormone data, patient samples generally should be separated as soon as possible and kept frozen until measurement. Consult your laboratory for proper handling. Circulating antihormone antibodies will usually suppress two-site assay data. Hormone assay precision, the 95% confidence interval for a hormone level, ranges from ±10-20% to ±15-30%— depending on the absolute hormone concentration and the method used.

Like method-specific normals for basal testing, many dynamic tests can only be interpreted correctly if the method has been validated and normal ranges developed in response to various stimuli.[17,18] If these data are not available, a clinician must rely on information from the literature, from similar assay methods, or from their own clinical experience with the assay method and the provocative stimuli.

METHOD VALIDATION

Underlying our belief in hormone testing is the assumption that the results correlate to biologic action and clinical findings. Such faith is only possible with analytic and clinical validation. Key elements of analytic validation are:

- *Sensitivity:* What is the lowest concentration of hormone detected by the method with less than 20% variation between assay runs?

Note: Selected hormones shown.

- *Specificity:* Does the method measure the intended hormone specifically without interference from other related molecules?
- *Precision:* How variable are data from repeated testing of the same sample?
- *Accuracy:* Does the method yield an absolute value as expected based on adding defined standard to matrix, and does the method render proportional data when the sample is diluted progressively?
- *Carryover:* Is each analysis free from influence by previously measured samples?
- *Reportable range:* Over what range are sensitivity and precision sufficient to allow for validated results?[19,20]

Clinical validation often proves more difficult, and for existing tests is often replaced by testing sets of patient samples having a range of values (for excellent correlation and small, uniform bias).[21] Newly developed analytes especially require careful and detailed assessment of each proposed clinical use prior to widespread acceptance, ideally including calculation of clinical sensitivity, clinical specificity, positive predictive value, negative predictive value, and full receiver-operating characteristic (ROC) analysis.[18,22]

Immunoassay Techniques

Competitive protein binding methods are the basis of some platform methods (Figure 21-1, Table 21-6), but manual RIAs are infrequently used today (yet still have an important role in certain esoteric applications). RIAs use reagents, antibodies, or hormone receptors/binding proteins that bind the analyte in a specific way—commonly called an analyte-specific reagent (ASR).[23] The ASR is added in limited quantity and the endogenous hormone competes with radiolabeled hormone for binding with the ASR. The principle advantage of RIAs in a clinical setting is resistance to autoantibody interference and their relatively broad reactivity with the hormone in its various forms.

The primary limitation of competitive methods is their broader reactivity, often with related molecules that are not biologically relevant. Despite this limitation, for some applications (such as monitoring for residual tumor) broader reactivity may actually be desired. RIAs, but not methods using newer sensitive detection techniques, are also relatively insensitive. RIA technology is still commonly used in select situations, depending on the laboratory. Examples are growth hormone (GH), insulin-like growth factor-I (IGFI), insulin-like growth factor binding protein-3 (IGFBP3), leptin, thyroglobulin, urinary gonadotropins, and numerous steroid hormone methods.

Noncompetitive protein binding methods are widely used as manual and automated platform methods (Figure 21-2, Table 21-6). The methods are commonly known as sandwich methods and are named in part based on the detection method used: IRMA for immunoradiometric (radioisotope detection) assay, ELISA for enzyme-linked immunosorbent assay (enzyme transformation of a colorless substrate to a colored product-spectrophotometric detection), ICMA for immunochemiluminometric assay (chemiluminescent detection), and IFMA for immunofluorimetric assays (time-resolved fluorescent detection). These methods use complementary antibody pairs to capture and detect the analyte of interest.[23]

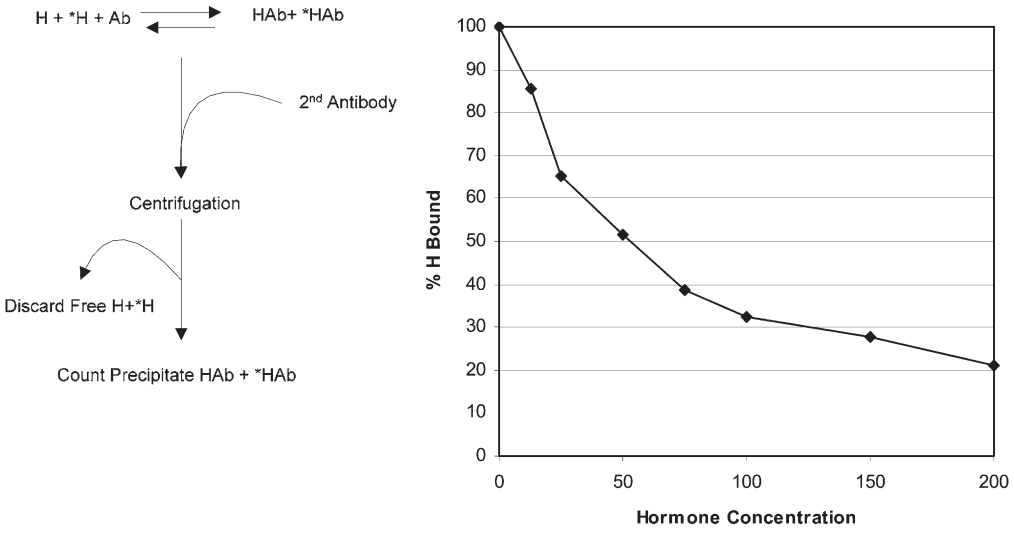

Figure 21-1 Basic hormone radioimmunoassay (RIA). For traditional RIA methods, reagent antibody (Ab) is harvested from the serum of animals. Rabbits or goats are immunized following a prescribed immunization protocol and schedule. Small nonimmunogenic molecules (haptens) such as steroid hormones are first conjugated to irrelevant proteins prior to immunization. Larger human peptide and protein hormones are typically immunogenic in these animals without conjugation. Animals are bled during the schedule, and each lot is evaluated for concentration (titer), affinity, and specificity. The "bleed" with the highest titer, optimal affinity, and specificity is selected for RIA without or with further purification. Hybridoma technology is frequently used to develop monoclonal antibodies (MAbs) from immunized mice. These MAbs are typically used in noncompetitive immunoassay configurations. As shown for RIA (top left), hormone (H) in patient, control, or standard is incubated with purified radiolabeled hormone (*H in this case is ^{125}H) and the reagent antibody (Ab)—shown here in an equilibrium-type reaction. Two key elements for RIA, a competitive immunoassay, is that H and *H are as similar as possible and that they compete for a limiting amount of antihormone antibody (Ab). The antihormone-specific antibody is referred to as the first antibody. For this example, a second antibody (reactive with the animal immunoglobulin of the first antibody) is used along with centrifugation to separate free hormone (H and *H) from hormone bound to the first antibody (HAB and *HAB). The bound fractions (HAB-2nd Ab and *HAB-2nd Ab) precipitate and are then "counted" (counts/min or CPM) in a gamma counter. The bound CPM are converted to % H bound and plotted versus the standard hormone concentration. "Unknown" % H bound from patient samples or controls are converted into hormone concentration. A number of algorithms are used to automatically deduce the most statistically valid standard curve from which unknown responses (% H bound) for patient and control samples are converted into hormone concentration. All hormone assays, including mass spectrometry methods, create some type of dose-response relationship (with standard hormone as a basis for determining hormone levels in patient samples and controls). Most curves are displayed to the operator as a simple linear plot. Shown (top right) is a simple point-to-point plot rarely used today. These data create a linear dose-response curve when plotted as the Logit function versus log of hormone concentration. Based on simple equilibria of binding, the affinity and binding sites (concentration) of an antisera, binding protein, or receptor can also be estimated using Scatchard analysis of data from a set of properly designed experiments.

TABLE 21-6

Immunoassay Techniques

Method and Principle	ASR	Separation of Unbound Label (Effectiveness)	Sensitivity	Specificity	Precision Interassay (% CV)
RIA analyte and tracer competition for ASR	Polyclonal antisera limited	Second antibody (good)	>0.5 ng/mL	Varies. More likely to measure multiple forms related to hormone. Some not biologically reactive.	8-12
ELISA or IRMA two-site capture and detection, noncompetitive	Paired monoclonal or affinity-purified polyclonal antisera	Physical removal of solid phase is manual, gel filtration or magnetic (excellent)	>0.1 ng/mL	Can be excellent. More likely to measure intact biologically active hormone.	7-10
ICMA or IFMA	Paired monoclonal or affinity-purified polyclonal antisera	Physical removal of solid phase is manual, gel filtration or magnetic (excellent)	>1 pg/mL	Can be excellent. More likely to measure intact biologically active hormone.	3-9

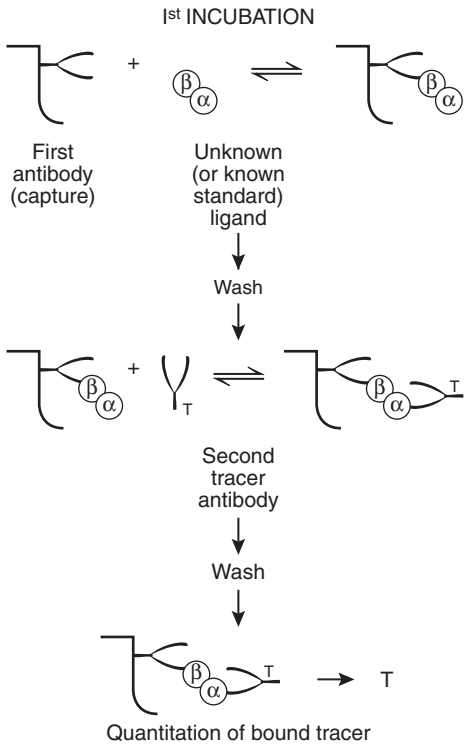

Figure 22-2 Depiction of an assay system with two antibodies in a sandwich system. The first antibody is solid phase (attached to the wall of the vessel) and binds a specific portion of the ligand. After all of the ligand is bound, the reaction vessel is washed. The second antibody is added, which binds to a specific epitope on the other end of the ligand. This antibody contains the tracer, and thus after washing out the excess second antibody the amount of ligand within the sandwich can be quantified as indicated (T, lower right). The tracer can be radioactive, enzymatic, fluorescent, chemiluminescent, or other. Most direct immunoassays add capture and label antibody at the same time, thus eliminating the requirement for an intermediate wash. The format often depends on the characteristics of the antibody pair and the technical requirements of the assay method. Showing the α and β subunits also allows one to see how high levels of the free subunits could actually suppress the apparent hormone levels. Generally, the capture antibody to label antibody stoichiometry is such that the capture is present at a 10:1 ratio or more than the label. High-level cross reactants that bind the label phase can therefore suppress binding.

The antibodies are selected against two noninteracting epitopes, hopefully unique within the hormone of interest. Ideally, both epitopes are essential to the biologic activity of the hormone—giving the assay excellent correlation with hormone bioactivity. The two-site design improves the assay specificity by eliminating smaller partially cross-reactive molecules from detection. Variations of these methods are used on many automated platforms. The primary limitations of these methods are greater interference from nonspecific binding of hormone, autoantibodies, heterophile antibodies (human anti-rabbit or anti-goat antibodies), and reactivity or suppression of reactivity by smaller molecules containing a selected epitope.[24]

Most hormones today are measured by noncompetitive protein binding methods. Examples are adrenocorticotropic hormone (ACTH), follicle-stimulating hormone (FSH), GH, luteinizing hormone (LH), thyroid-stimulating hormone (TSH), and many others. Depending on the analyte, the methods described previously are suitable for direct analyses or may require significant pretreatment (such as solvent extraction and chromatography) prior to immunoassay to remove interfering analytes. Unlike steroid hormones, which are very similar chemically and immunologically, most protein hormones or factors can be measured accurately in relatively direct methods.

CONSOLIDATED ANALYZERS

Today, 10 manufacturers are supporting more than 25 immunoassay analyzers—of which 5 are used widely for performing hormone immunoassays (Table 21-7). Nearly all of the devices perform typical thyroid testing. Many add reproductive hormones, but few offer less frequently ordered hormone tests. All of these methods consolidate more than 20 or 30 hormone or other assays on a single platform that can operate in batch or random access mode with unattended capability, timely turnaround, and cost-effective throughput.

These methods are calibrated automatically and ideally are designed to maintain calibration for long periods and to have procedures that call for as little as one quality control event every 24 hours. The methods are essentially free from user-related bias and require minimal training to operate. Competitive immunoassays and noncompetitive immunoassays combined with sensitive detection techniques are used to maximize analytic sensitivity and specificity to the extent possible with such simple techniques. Limitations vary, depending on the hormone being measured and the sample population being tested. In general, the methods are subject to the same type of interferences associated with other competitive or noncompetitive manual or semiautomated immunoassays.[25]

MASS SPECTROMETRY

Mass spectrometry is a technique that selects and measures the presence and quantity of molecules within a sample. Steroid hormones, for example, are charged in an interface and then accelerated as gas-phase ions into a mass spectrometer operated under vacuum. In tandem mass spectrometry (MS/MS), molecules (gas-phase ions) of interest are selected and fragmented—and products specific to the analyte are again selected for detection. Filter paper blood-spot testing for 17-hydroxyprogesterone (17-OHP) is a new application for LC-MS/MS methods.[26,27] 17-OHP is the marker for 21-hydroxylase deficiency, the most common form of congenital adrenal hyperplasia (CAH).

TABLE 21-7

Commonly Used Analyzers

Analyzer	No. Units	Method(s)	Protein Hormone	Steroid Hormone	Thyroid Hormone
Abbott AxSym Plus	2,400 USA, 10,000 worldwide	Competitive FPIA, noncompetitive MEIA	FSH, hCG, LH, prolactin, TSH, anti-TPO, anti-TG	Cortisol, estradiol, progesterone, testosterone	T3, T4, free T3, free T4, T3 uptake
Bayer Advia Centaur	>1,300 USA, >3,100 worldwide	Competitive chemiluminescent with magnetic particle separation	FSH, hCG, LH, prolactin, TSH, anti-TPO, anti-TG, IPTH, C peptide, insulin	Cortisol, estradiol, progesterone, testosterone	T3, T4, free T3, free T4, T3 uptake
Beckman Coulter Access 2	>1,300 USA	Noncompetitive chemiluminescent assay with magnetic particle separation	FSH, hCG, LH, prolactin, TSH, anti-TG, GH, ostase, TG, insulin	DHEAS, estradiol, unconjugated estriol, cortisol, progesterone, testosterone	T3, T4, T3 uptake
Diagnostic Products Corp. Immunlite 2000	>3,600 worldwide	Noncompetitive chemiluminescent assay with bead separation	Thyroglobulin, TBG, anti-TG, anti-TPO, ACTH, IPTH, hCG, FSH, LH, prolactin, GH, IGFI, IGFBP3, calcitonin, IPTH, gastrin, SHBG	Cortisol, estradiol, unconjugated estriol, progesterone, testosterone, androstenedione	T3, T4, FT3, FT4

Notes: This is a partial listing of platforms and available methods. Check with manufacturer for current configurations. FPIA = fluorescence polarization immunoassay and MEIA = microparticle enzyme immunoassay.

MS sensitivity gains made possible serum testing for CAH follow-up, and for measuring other serum steroids.[28-34] New-generation LC-MS/MS steroid assays have shown improved accuracy, precision, sensitivity, and selectivity (specificity) over simple direct and complex reference immunoassays.[31-34] LC-MS/MS methods using isotope dilution typically use more than five degrees of selectivity to provide quantitative results. Selectivity requirements are greatest when analyzing steroid hormones in pediatric and hormone-deficient samples.

Numerous steroids circulate physiologically that cannot be separated by tandem MS/MS alone—such as cortisol/cortisone,[28] estradiol/estrone,[33] and 17-hydroxyprogesterone/11-deoxycorticosterone.[34] Selectivity in steroid analysis using LC-MS/MS technologies represents the greatest challenge during analysis. For example, estradiol measurement using MS/MS requires resolution of 24 interfering steroids/medications.[35] In Figure 21-3, an isotope dilution LC-MS/MS assay that uses additional preparative steps to remove interfering steroids is compared with an automated direct competitive

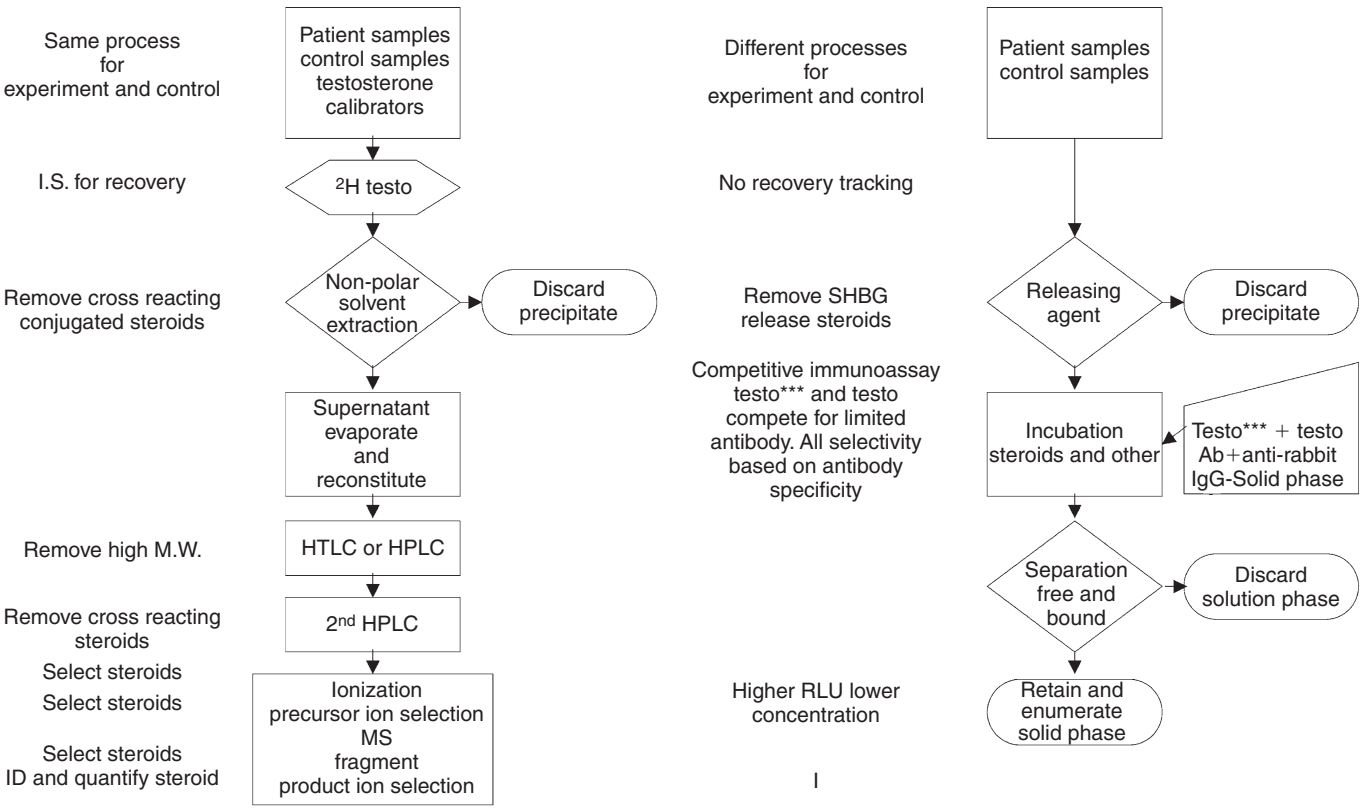

Figure 21-3 Comparison of a direct method of testosterone measurement and an isotope dilution HTC-LC-MS/MS method. *LC/MS/MS:* The isotope dilution protocols follow the general outline shown (top left). First, a stable isotopically labeled mimic [also known as an internal standard (IS)] of the hormone is added to calibrators, quality control samples, and patient samples. Following sample mixing, extraction of the hormone and internal standard are performed off-line using liquid/liquid extraction, solid-phase extraction, or sample dilution/precipitation or on-line using turbulent flow chromatography. This type of sample preparation reduces sample complexity prior to LC-MS/MS detection by removing unwanted sample constituents such as albumin, lipids, salts, and so on. It also enables concentration of analyte. The IS corrects for potential losses of hormone during these processing steps and during MS/MS. Fractionation of the sample is then usually accomplished by liquid chromatography (LC) separation based on hydrophobic differences between potential cross-reacting hormones. This LC fractionation step is critical to the removal of cross-reacting steroids that would otherwise impact the accuracy of steroid measurements by MS/MS. Following LC separation, the effluent flows into an interface—where the hormone solution and IS are converted to gas-phase ions and solvents are removed. The hormone and IS are then detected using MS/MS. MS/MS is depicted in Figure 21-4. See the American Society of Mass Spectrometry (ASMS.org) for more detail and references on this complex technology. Calibration curves based on standards performed in each assay batch are plotted as concentration (X axis) and hormone/IS ratio (Y axis). The concentration of samples is back-calculated against the calibration curve based on the hormone/IS response ratio observed. In comparison with existing immunoassays, calibration curves are linear over 3 to 4 orders (i.e., 3–4 $\log_{10}$). When all components of the isotope dilution LC-MS/MS experiment are considered, it is apparent that in excess of 5 degrees of selectivity are generally used to provide quantitative results. *Direct platform method:* This automated competitive immunoassay follows the outline shown (top right). Samples are treated to release testosterone and other steroids from specific binding proteins, such as SHBG (sex-hormone-binding globulin). Then chemiluminescent-tagged testosterone is added to compete with a limit amount of first antibody directed against testosterone and a solid-phase antibody reactive against the antibody species of the first antibody. After incubation, the solid phase is separated and enumerated. The response information is compared to a stored calibration curve. The instrument requires a two-point calibration every 7 days. Two quality controls are evaluated each day.

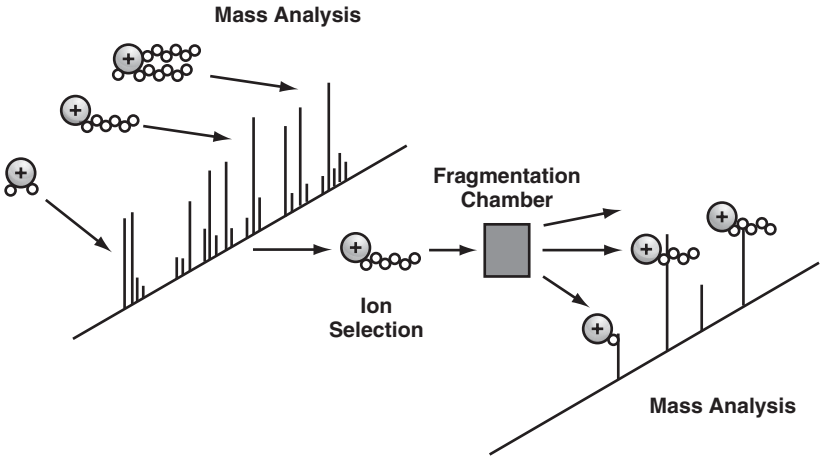

Figure 21-4 Schematic for MS/MS. Two mass analyzers are combined sequentially in the devices known as a tandem mass spectrometry or MS/MS. This method is helpful in identifying and measuring specific hormones within complex mixtures. As shown (top), the first mass analyzer selects ions of a desired mass (more correctly stated, the desired mass/charge ratio) for steroid hormones. Then the selected ions are fragmented into hormone-characteristic ions that are analyzed in the second mass analyzer and enumerated. In this way, the tandem MS device adds analytic specificity to the hormone assay.

immunoassay method for testosterone. A graphical description of MS/MS is provided in Figure 21-4.

Note that development, validation, and operation of MS-based hormone methods require expertise that is in short supply. Facilities suitable for MS and ancillary core competencies are not currently available in many commercial testing laboratories in the private or academic setting. At present, only a handful of laboratories have reported using MS for steroid hormone proficiency testing.[36] To date, LC-MS/MS steroid tests include androstenedione, dehydroepiandrosterone (DHEA), estradiol, estrone, estrone sulfate, progesterone, testosterone, 17-hydroxypregenolone (17-OPN), 17-OHP, pregnenolone, 25-hydroxy-vitamin D_3, and others. Reference methods have been reported for some peptide hormones, such as thyroxine, c peptide, insulin, renin, and others.

Quality Assurance and Quality Control

Laboratory quality assurance (QA) programs include internal and external mechanisms to ensure laboratory quality. The overriding goal of QA and quality control systems is to ensure that results meet or exceed expected operating parameters. Key components of an internal program at the method level are method validation, instrument qualification, assay batch or daily quality control, and data review before reporting. Proficiency testing, laboratory certification, and on-site quality audits are important external systems for laboratory quality. Clinicians are most likely to encounter assay inaccuracy, assay imprecision, or sample errors.

Repeated measurement data typically have a normal distribution, with the difference from the average value being distributed about both sides of the mean without cumulative bias. As such, these data should be reported with a 95% confidence interval [±2 SD or ±2 * (% CV), % CV = Stdev/Average * 100] representing the likely range of true values for a particular sample. For example, the value 10 ng/mL should be reported as 10 ng/mL ± 2 ng/mL if the assay has a variation of 10% in that analytic range. Because data are not reported with an associated variance, it is important to consider such potential variance—especially when reviewing clinically borderline results. Variance for nearly all assay systems is greatest at low levels of detection.

Inaccuracy of a particular assay should always be considered when results are unusual for the clinical presentation, especially when evaluations are being performed on certain patient populations (such as infants and patients with renal impairment) for whom cross reactants are unusually elevated. Although most assay data are reliable, it is estimated that significant medical errors are as frequent as 5%—whereas estimates of laboratory errors, exclusive of blood banking, range from 0.05% to 0.61% (with preanalytic errors accounting for 31%-75%, analytic errors for 13%-32%, and postanalytic errors for 9%-31%).[37] Table 21-8 lists common errors associated with laboratory results.

Case Studies, Common Diagnoses, and Testing

17-OHP

In the United States, most state governments now have mandatory screening for 21-hydroxylase deficiency—by measuring 17 hydroxyprogesterone on filter paper blood spots taken from newborns. By design, these tests have high clinical sensitivity but low clinical specificity. Most positive screens tests will test negative when properly evaluated by a reference method. Reference methods should be completely free of interference from cross-reacting steroids present during the newborn period. A male patient positive on state screening 17-OHP was

TABLE 21-8

Common Errors

Frequency	Type of Error	Error	Example(s)
Very common	Preanalytic	Biological variance	Testosterone, DHEA, prolactin and other pituitary hormones. More consistent results are achieved by pooling multiple draws.
Common	Preanalytic	Wrong patient's samples	Improperly labeled sample, or sample mix-up during draw or in laboratory.
Common	Preanalytic	Incorrect date of birth (DOB) information	With the wrong DOB pediatric samples may not get extraction or other necessary steps and may have incorrect normal data provided with the report.
Common	Preanalytic	Wrong sample type	Serum required for most total calcium determinations, sodium fluoride tubes for glucose and EDTA for ACTH. Most assays are not validated for samples other than serum or plasma.
Common	Preanalytic	Improper patient preparation	Examples; A) Fasting for glucose, cpeptide, insulin, B) Posture for aldosterone, catecholamines and renin.
Common	Preanalytic	Improper sample handling	Examples ACTH, plasma catecholamines, IPTH, renin and PTHrp often problematic. Ambient stability can decline at elevated summer temperatures.
Common	Preanalytic	Systemic illness	Hormone levels may be impacted by systemic illness. Most well recognized is the impact of illness on thyroid hormone levels.
Infrequent	Preanalytic	Drug interference	Many pharmaceuticals directly or indirectly influence hormone levels. Pay attention to time since last dose. Most assays not validated to deal with this type of interference.
Very common	Analytic	Typical assay variance	Tests have inherent variability. Contact the laboratory to discuss borderline results. 95% confidence interval for most hormone immunoassays is at least ±10%-20%.
Common	Analytic	Test used not sufficiently specific for patient in question	Direct measurement of steroids, 17-OHP, and testosterone not appropriate especially for infants, children, and women.
Common	Analytic	Test used not sufficiently sensitive for patient in question	ACTH, calcitonin, GH (acromegaly), estradiol, IGFI, testosterone, and other methods require better analytic sensitivity for certain applications.
Common	Analytic	Patient sample contains cross-reacting substances that raise or lower results for improperly designed or improperly used methods	Stimulation doses of 1-24 ACTH, cortisone, dexamethasone, HCG, antihormone antibodies and others may affect otherwise valid methods. Conjugated steroids and others steroids such as cortisol that circulate at high levels.
Infrequent	Analytic	Assay out of calibration	Method improperly calibrated initially or loses calibration.
Infrequent	Analytic	Assay reporting reference data that are inappropriate for the method	Reference data used not sufficient or insufficiently validated and inappropriate.
Infrequent	Postanalytic	Wrong data	Manual or automated data entry error especially a problem for referred testing.

Notes: Errors that can lead to erroneous hormone reports are included. The errors can be preanalytic, analytic, or postanalytic. Other errors (such as improper test or test method selection) are more difficult to track. An assay designed for use in adults may not be suitable for use with samples from infants and children. Review the laboratory directory of service for proper assay selection, patient preparation, sample collection, and handling.

examined and lacked any hallmarks of CAH. A follow-up serum sample was obtained and referred to a commercial laboratory for 17-OHP measurement.

The laboratory reported a result more than 10 times the upper limit for the reported age. As the data were not congruent with the clinical picture, another serum sample was obtained and referred to an endocrine reference laboratory that reported the value just at the upper limit of normal. Upon further investigation, the first confirmation sample was discovered as being submitted with a transcription or data entry error—changing the patient age from newborn to early childhood. The initial referral laboratory, being aware of cross-reacting steroids present in the newborn, performs extractions prior to 17-OHP determinations on samples from newborns and infants but not from older children.[38]

TESTOSTERONE

An infant with prenatal chromosomes 46XY was born with normal female genitalia. Testosterone by an automated direct immunoassay method was unexpectedly

measured as being four times the upper limit of normal for newborn females in a reference method. Based on the case presentation and laboratory data, a diagnosis of androgen insensitivity was considered. Later, extracted samples were evaluated in an "in-house" RIA and found to be close to what would be an upper limit of normal for female infants. The diagnosis was reconsidered, and at 10 months of age baseline and human chorionic gonadotropin (HCG) stimulation samples had undetectable testosterone levels. Gonadotropins were markedly elevated after luteinizing-hormone-releasing hormone (LHRH) and a repeat ultrasound revealed an infantile uterus. Based on these data, the diagnosis was changed to 46XY complete gonadal dysgenesis.[39]

Summary

Preanalytic patient and sample-related variables must be considered before hormonal sampling is underway. Coexistent illness (including extreme body mass index, emotional well-being, posture, activity level, and recent or current exposure to therapeutic or nutritional products) may affect hormonal concentrations. Studies on normal subjects have also shown that many endocrine hormones exhibit large intrasubject variation, as reflected in broad cross-sectional normal reference ranges. Sample collection errors are important as well but are largely avoidable by following proper collection and handling procedures and by carefully labeling samples and creating accurate and legible requests.

All laboratories must have active and thorough QA programs that include assay validation reports and continuous quality control data. Standard hormone preparations and consolidation of many tests on a few predominant platforms have led to greater comparison of some hormone assays among laboratories. Comparable normal reference data must be confirmed by each laboratory each time they significantly modify or change methods. Pediatric reference data, especially for steroid hormones and insulin-like growth factors, by design must be different for simple methods when compared to complex reference methods.

For these reasons, longitudinal test data are most reliable when all testing is done with a single method—preferably at one laboratory location. When testing is controlled in this way, variation is limited but still typically ranges from 10% to 30%—depending on the method and the hormone concentration being evaluated The other common systematic error relates directly to using simple methodology for complex samples, such as those from infants and children and from patients with kidney disease. Newer automated methods, such as LC-MS/MS coupled with other purification techniques, are beginning to correct a decline in the quality of these complex analyses. However, widespread application of such methods awaits improvements in usability, training, and instrument cost.

The physician and other health care providers as the final line of quality control can influence testing decisions and can intervene when individual patient data seem inappropriate. Ongoing interaction between laboratories and clinicians also contributes to clinical investigation that is integral to the provision of quality care to children with endocrine disorders.

chromosomes in
germ cell defects in, 631–633, 632f
karyotypes of, 611–612
multiple X, 614–615
clinical findings in, 619, 620t
congenital heart disease in, risk of, 635t
cytogenetic findings in, 616t
diagnosis of, 618–619, 619f
edema in, 623
embryology of, 446–447, 446f, 446t
endocrinologic management of, 649–651
environmental factors in, 617–618
estrogen in, 629–630
etiology of, 615–618
eye/ear/skin in, 623–624
facial deformities in, 623f
in fetus, 619f
final height in, 628f–629f, 628t
FSH in, 632t
gastrointestinal disorders in, 641–642
genomic imprinting in, 614
GH in, 626–627
treatment of, 311
gonadal failure in, 631–633, 632t
gonadoblastoma in, 633
growth-promoting therapy for, 625–630
hand radiographs of, 621f
hearing loss in, 630–631, 630t
height velocity in, 624f–626f
history of, 445–446
hypertension in, 638
incidence of, 615–618, 646
karyotype in, 618
kidney deformity in, 638f
lymphatic obstruction of, 622–623, 623f
lymphedema in, 623f
Madelung deformity in, 622, 622f
management of, 646, 646t
mosaicism in, 616
neuropsychological features of, 643–645
Noonan syndrome v., 614
otitis in, 630–631, 630t
pathogenesis of, 612–614, 613f
pelvic ultrasound studies in, 634f
physiologic features of, 620t, 624–625, 624f–625f
prenatal diagnosis of, 618
psychiatric disorders in, 645
ptosis in, 624f
recommendations for, 36–37
renal abnormalities in, 639–640
Turner syndrome *(Continued)*
scoliosis in, 622
skeletal growth disturbances of, 619–622, 620t, 621f
skeletal growth failure in, 624–625, 624f–625f
SRY-gene sequence in, 6f, 283
stigmata in, 621f
therapeutic regimens for, 628–629
transition management of, 651
in women, 651
Type I collagen, 105–106, 105f–106f
Type I cytokine receptors, 27t, 42, 43t
Tyrosine hydroxylase, autoantibodies to, 783

U

Ulrich-Turner syndrome, 610
Ultrasound
abdominal, of adrenal adenoma, 569f
pelvic
in ambiguous genitalia, 149–150
in Turner syndrome, 634f
Urethral folds, 132
Urine
pyridinoline, 107t
steroid excretion in, 461–462
tests, for hypoglycemia, 423t
Urogenital differentiation, 129–130, 130f
Uterus
dysfunctional bleeding of, 584–585, 584t
laboratory studies of, 149–150
symmetric development of, 148f

V

V281L, 13f
VACTERL syndrome, 128t
Vaginal epithelium, 557f
Vaginal septa, transverse, 146
Vagus nerve
afferent, 789–790, 790f
efferent, 794
Van Wyk-Grumbach, 239, 287, 568–569, 677
Vanishing testes, 138, 673
Vascular changes
dyslipidemias and, 845–846, 845t, 846f
in obesity, 801–802
Vasopressin
action of, 341–342, 342f
analogues of, for central diabetes insipidus treatment, 359–360
AVP, 455
biochemistry of, 336–339, 336f–338f
cancer and, 355t
cells, in hypothalamus, 339f
central nervous system and, 355t
CNS and, 355t
dDAVP, 336, 336f
in homeostasis, 336
hyponatremia with
abnormal regulation of, 354–356, 355t
decreased, 356–362, 361f
normal regulation of, 350–353, 352t
in kidney, 342–344, 343f–344f
metabolism of, 341
increased, central diabetes insipidus with, 358
nausea and, 340–341
non-osmotic regulation of, 340–341, 341f
origin of, 337
osmotic regulation of, 339–340, 339f–341f
Vasopressin *(Continued)*
parvocellular neurons role in, 339
peptide products of, 337f
pre-, peptide, structure of, 338f
receptors, 28t, 31, 33, 341–342, 342f
renal cascade of, 342–344, 343f–344f
roles of, 363
SAID, 354–355, 355t, 360–361, 361t
structure of, 336f
Vasopressin V2 receptor (SAID)
causes of, 354, 355t
causing NDI, 360–361, 361f
treatment of, 354–355
VDR. *See* Vitamin D receptor
Very low density lipoproteins (VLDL), disorders of, 843
Viral infections, in diabetes mellitus, 409
Virilizing congenital adrenal hyperplasia, 141–143, 142f
Virilizing tumors, 491–492
Vitamin D, 90–94, 91f, 93f
deficiency of
causing hypocalcemia, 691t
in infants, 725–726, 726f
in gastrointestinal tract, 90f
metabolism of, 91f
repletion of, 93
-resistant rickets, growth abnormalities from, 288
Vitamin D receptor (VDR), 94–96, 94f, 96f
calcitriol involvement with, 94–96
genes regulating, 96f
LBD of, 727, 727f
mRNA, 94f
Vitamin D3 receptor, 52
VLDL. *See* Very low density lipoproteins
Volume sensor, effector pathways and, 344–347, 346f

W

Water
deprivation test, 349, 349f
metabolism disorders
differential diagnosis of, 347–350, 349f
types of, 350–353, 352t, 354f
Weight
of adrenal gland, 447f
body
by age/gender, percentiles, 256f–263f
glucose production v., 172f, 424f
-for-age percentiles
length-for-age and, 256f–258f
stature-for-age and, 260f–261f
-for-length percentiles, head circumference-for-age and, 257f, 259f
loss of
leptin sensitivity and, 795–796
lifestyle modification for, 813–814
low birth, infants, 702–704
at menarche, 576f
Whipple's triad, 171
Whole-body bone mineral content
absorptiometry of, 687f
of neonate, 691f
Williams syndrome, 634
Williams-Beuren syndrome, 700–701
Wilms' tumor gene, 135
Wnt signaling pathway
4, 134t, 135
7A, 134t
in bone mineralization, 98–99

Wolff-Chaikoff blockade, 230
Wolffian duct, 131–132
Wolfram syndrome, 407
Wolman disease, 490
Women. *See also* Female reproductive system
  adolescent, bone deposition in, 109t, 111f
  height velocity chart for, 265f
  mid-follicular phase, blood production rates in, 551t
  Turner syndrome in, 651
  virilized, ambiguous genitalia in, 142f
Workup, of childhood obesity, 812–813, 812t
WT1, 134t

X
X chromosomes
  genes, 612–614
  monosomy, 617
  multiple, 614–615
  showing SHOX, 613, 613f
  small ring, 611–612
X-linked adrenal hypoplasia congenital, 483–484
X-linked congenital diabetes insipidus, 360–361, 361f
Xp22.3, 613, 613f
XX male syndrome, 665–666

Y
Yp11.3, 613, 613f

Z
Zinc-finger DNA binding, 727f
Zona fasciculata, 32
Zona reticularis, 32
